Infrared Study of Aniline Adsorbed on Aluminum Halides and on Gallium Chloride

Hiroyasu SATO and Shin-ichi ARASE*

College of Liberal Arts, Kagoshima University, Kagoshima 890

(Received March 4, 1975)

Infrared study was made on aniline adsorbed on aluminum chloride, bromide and iodide. Aniline-d_0 ($C_6H_5NH_2$), aniline-*N,N*-d_2, aniline-d_5 ($C_6D_5NH_2$) and aniline-d_7 were used. Aniline-d_0–gallium chloride system was studied for comparison. Only the bands associated with amino group showed large frequency shifts on complex formation. The structures of adsorbed molecules were discussed in terms of the frequency shift of bands, especially of those assigned to C–N stretching and ND_2 bending modes. The interaction of adsorbed aniline with aluminum chloride is rather weak and predominantly ionic. A strong chemisorption with the formation of an essentially covalent N···Al bond can be deduced for aniline adsorbed on aluminum bromide, iodide and gallium chloride. Such an ionic adsorption on aluminum chloride can be understood by considering the ionic structure of solid aluminum chloride. Some of the observed bands for aniline-d_5 are (cm^{-1}); 3424, 3350, 3312 (NH str.), 1620 (NH_2 bend.) and 1300 (CN str.).

Considering the importance of aluminum halides as catalysts for a large number of organic reactions, the spectroscopic study of organic molecules adsorbed on solid aluminum halides is of much interest. One of the authors (H. S.) studied the UV spectrum (300—150 nm) of aniline adsorbed on aluminum chloride, showing that it has an intermediate feature between free aniline molecule and toluene.[1] This was interpreted by assuming the interaction of the lone pair on the nitrogen atom in aniline molecule with the vacant sp^3-type orbital on the aluminum atom in aluminum chloride.[2] Thus, it is clear that some kind of adsorption complex is formed. Measurement of the IR spectrum is essential for a more detailed discussion on the structures of the adsorption complexes. Such a study, however, has not so far been made.[3] We have measured IR spectra for aniline adsorbed on aluminum chloride, bromide and iodide. The study of aniline adsorbed on aluminum bromide in comparison with that on aluminum chloride is interesting if one considers the difference of these two halides as regards their crystal structures and the physical properties in the solid phase. It is known that the dimeric structure Al_2X_6 (X=Cl, Br) in the gas phase[4] remains on transition to the liquid phase,[5-7] but in the solid phase aluminum chloride has a crystal structure based on an ionic bonding scheme,[8] while solid aluminum bromide retains the dimeric structure.[9] The difference of structure in the solid phase is also reflected in their physical properties. Solid aluminum chloride has a significant electric conductivity; the conductivity increases as the melting point is approached but falls abruptly nearly to zero on melting; the volume increases sharply on melting.[10] Pershina and Raskin[11] showed that the Raman spectrum of solid aluminum chloride differs from that of liquid aluminum chloride, while the Raman spectra of these two phases coincide for aluminum bromide.[12] In the present study, three deuterium-labelled compounds, *i.e.*, aniline-*N,N*-d_2 ($C_6H_5ND_2$), aniline-d_5 ($C_6D_5NH_2$) and aniline-d_7 ($C_6D_5ND_2$) were used together with aniline-d_0 ($C_6H_5NH_2$) to make the assignments of IR bands unambiguously by separating the bands related to the modes in amino group from those related to the modes in phenyl group. Aniline-d_0–gallium chloride system was studied for comparison.

Experimental

Materials. Aluminum chloride was prepared from aluminum and silver chloride *in vacuo*.[1] Aluminum bromide or iodide was prepared in a similar way using the corresponding silver halide. Gallium chloride was prepared from gallium and silver chloride. All the compounds were stored in ampoules with break-off seals. Aniline-d_0 was distilled under reduced pressure, dried over potassium hydroxide and distilled again *in vacuo* before use. Aniline-*N,N*-d_2 was prepared by treating aniline with heavy water. Aniline-d_7 of minimum isotope purity of 99 atom% (J. T. Baker Chemical Co., Philipsburg, N. J., U. S. A.) was distilled under reduced pressure. Aniline-d_5 was prepared by treating aniline-d_7 with water. The three compounds were dried over anhydrous potassium carbonate and distilled *in vacuo* before use.

Procedure. The cell assembly used in IR measurement was similar to the one used previously,[1] but was provided with NaCl or KBr windows. This was degassed thoroughly (more than two hours at 10^{-3} Torr) before use. After aluminum halide or gallium chloride was sublimed onto the NaCl or KBr window plate, aniline vapor was introduced into the cell. After evacuation, IR spectra were recorded on JASCO IRA-1 (for 4000—650 cm^{-1}) or IRA-2 (for 4000—400 cm^{-1}) recording spectrophotometers.[13]

Results

The following symbols are used: aniline-d_0 (**1**) aniline-*N,N*-d_2 (**2**), aniline-d_5 (**3**), aniline-d_7 (**4**), aluminum chloride (A), aluminum bromide (B), aluminum iodide (C), gallium chloride (D). The complexes are also shown by these symbols (*e.g.* **1**A for aniline-d_0–aluminum chloride complex).

Complexes of Aniline-d_0 *and Aniline*-N,N-d_2. IR spectra of **1**, **1**A, **1**B, **1**C and **1**D are shown in Fig. 1, and those of **2**, **2**A and **2**B in Fig. 2. The assignment of IR bands for **1** and **2** was well established by Tsuboi[14] and Evans.[15] The bands of **1** or **2** can be classified into two groups, those associated with (a) the phenyl group, and (b) the amino group (C–N stretching in-

clusive). The full lines show the positions of bands belonging to group (a), dotted lines those of group (b). Some of the bands of complexes fell in the close vicinity of the bands belonging to group (a) of the free molecules, essentially retaining their relative intensities. These bands can be attributed to the modes within the phenyl group of the complex. The complex formation clearly

gave little effect on the vibrations within the phenyl moiety. On the other hand, the bands of group (b) showed a large shift on complex formation. This shows that it is the amino group and C–N bond that are affected by complex formation and that the coordination of the amino group occurs on adsorption. The positions of bands thus attributed to amino group (C–N stretching inclusive) are listed in Table 1.

Complexes of Aniline-d_5 *and Aniline*-d_7. IR spectra of **3**, **3A** and **3B** are shown in Fig. 3, and those of **4**, **4A** and **4B** in Fig. 4. No IR spectrum of **3** seems to have been published. As to **4**, Ostrowska and Tramer[16] published the wave numbers of IR bands in the region above 700 cm^{-1}. They gave assignments for some of the bands. Rai and Maheshwari[17] gave the wave numbers of seven bands without assignments. The positions of bands in our spectrum are in line with theirs.[18] Complete assignments of the bands for **3** and **4** were made. They are given in the Appendix. Since Ostrowska and Tramer[16] did not give assignments

for all the bands, those for **4** are given here for comparison with the assignments of bands in **3**. After these assignments were made, the IR bands of **3** and **4** were classified into groups (a) and (b) as for **1** and **2**. It was found that only the bands of group (b) showed a large shift on complex formation. The positions of bands thus attributed to the amino group (C–N stretching inclusive) are listed in Table 1.

The positions of observed bands for all the systems studied are shown in Fig. 5, with their assignments given by symbols.

(See Text.)

Discussion

Some characteristic bands of complexes are discussed below. Detailed information on the structures of adsorption complexes was obtained by examination of direction and magnitude of the frequency shifts. C–N stretching modes for NH_2 and ND_2 are shown as C–NH_2 and C–ND_2 stretching, respectively.

1) Aluminum Halide Complexes. NH_2 (and ND_2) Stretching Vibration: Substantial reduction was observed in the NH_2 stretching frequencies. The magnitude of the frequency shift for the complexes of **1** and **3** increased in the order: A<B<C. It amounted to about 160 cm^{-1} and more than 200 cm^{-1} for the complex of B and that of C, respectively. The relative order of the frequency shift was the same for ND_2 stretching frequencies (in the complexes of **2** and **4**).

NH_2 Bending Vibration: The band assigned to this mode shifted to lower frequencies in the complexes of **1**. The result is in line with that of aniline adsorbed on alumina.[3] The magnitude of the frequency shift was in the order: **1**A<**1**B<**1**C. In the complexes of **3**, this mode seems to be superimposed on the benzene ring stretching mode and the relative order of magnitude in the frequency shift was the same as above.

C–NH_2 Stretching Vibration: The 1272 cm^{-1} band of **1** has been assigned to the C–NH_2 stretching mode, which is lowered in frequency by the coupling with the NH_2 bending mode.[15] This band is higher in frequency than the corresponding band in aliphatic amines (*e.g.* 1044 cm^{-1} in methylamine[19]) due to the double bond character in the C–N bond.[15,20] The double bond character is given by the partial conjugation of the lone pair on the nitrogen atom with π-electrons in the phenyl group. The band in **1**A, **1**B or **1**C which is to be correlated with this band is at 1140 cm^{-1}, 1201 cm^{-1} or 1164 cm^{-1}, respectively. The relative order of magnitude of the shift was **1**B<**1**C<**1**A. An abnormally large shift for **1**A is to be noted. The 1140 cm^{-1} band in **1**A is peculiar as regards its very high intensity and broadness. The shifts to lower frequencies in the complexes **1**B and **1**C can be explained in terms of the decrease in the double bond character of C–N bond caused by the partial consumption of the lone pair on the nitrogen atom by the formation of N–Al coordination bond. However, the abnormally large shift in

1A can not be explained along this line, because the interaction of the lone pair with aluminum atom in **1**A is weaker than in **1**B, as revealed by their UV spectra.[21] For complexes **3**A, **3**B and **3**C, the band appearing in a position similar to that in the case of **1**A, **1**B and **1**C, respectively, can be assigned as due to this mode (Table 1), and the relative order of magnitude in the frequency shift was the same as above.[22,23]

C–ND_2 Stretching and ND_2 Bending Vibrations: A strong band near 1200 cm^{-1} in each of the complexes of **2** and **4** can be correlated to C–ND_2 stretching vibration.[23,24] The relative order of the magnitude in the frequency shift for the complexes of **2** and **4** is as follows; complex of A< that of B≲ that of C.

A strong band was found in the 900—950 cm^{-1} region in each of the complexes of **2** and **4**. This does not correspond to the bands of phenyl group. When the band around 1200 cm^{-1} was correlated to C–ND_2 stretching vibration, it remains as the only one to be correlated to ND_2 bending vibration. The frequency shift on complex formation is very large, the relative order of magnitude being as follows; complex of B< that of C< that of A. This order is exactly the same as that of the bands attributed to C–NH_2 stretching vibration. An extensive coupling should be assumed between C–ND_2 stretching and ND_2 bending modes in the complexes.

AlX_3 Skeletal Vibration: A strong band was found in the 450—480 cm^{-1} region or near (or lower than) 400 cm^{-1} for the complexes of A or those of B, respectively. The band can be attributed to AlX_3 skeletal vibration, since a band with a similar position and band shape was found in the NH_3–AlX_3 complex (X=Cl or Br).[25]

N···Al Stretching Vibration: No band with considerable intensity was found.

2*)* *Aniline-d_0–Gallium Chloride Complex*: IR spectrum was similar to that of **1**B.

The abnormally low frequency of the band attributed to C–NH_2 stretching vibration in aluminum chloride complexes (**1**A and **3**A) can be explained by assuming a large ionic character and the elongation of C–N bond in these complexes. The presence of such an ionic character in C–N bond can be understood if we consider the "ionic structure" of solid aluminum chloride. The aluminum atom in aluminum chloride carries some positive charge. On the other hand, aniline molecule is rather weakly adsorbed on the surface of aluminum chloride as revealed by its UV spectrum.[21] The IR spectrum shows that the coordination of the amino group occurs on adsorption. The positive charge on the aluminum atom polarizes the C–N bond giving large ionic character in this bond with the bond elongation. The abnormally high intensity of 1140 cm^{-1} band in **1**A would support the assumption of such an ionic C–N bond, since a large change in dipole moment is expected to accompany the C–N stretching vibration.

The abnormally large frequency shift of the bands associated with ND_2 bending vibration in **2**A and **4**A can be explained by considering the coupling of the modes. It is known that C–ND_2 stretching vibration and ND_2 bending vibration have little coupling with each other in the free molecule, though the two belong to the same symmetry species.[14] This situation changes, however, in the complexes we studied. If C–ND_2 stretching frequency is lowered by some ionic character brought into C–N bond and/or by a decrease in the double bond character of C–N bond, the separation between this and ND_2 bending frequencies becomes smaller, and the two modes will be brought into coupling. In the complexes of A, the pronounced reduction of C–ND_2 stretching frequency due to the ionic character of C–N bond brings this mode into an extensive coupling with ND_2 bending mode, the coupling causing two bands widely separated. It is probable that C–ND_2 stretching frequency falls down to nearly equal to or even lower than the ND_2 bending frequency in the free molecule, and these two modes are extensively mixed. As a result the higher wave number member of the coupled modes in the complex has apparently only a small shift toward a lower wave number as compared with the C–ND_2 stretching mode in the free molecule. The lower wave number member in the complex shows an abnormally large shift toward the lower wave number as compared with the ND_2 bending mode in the free molecule. This coupling is shown schematically in

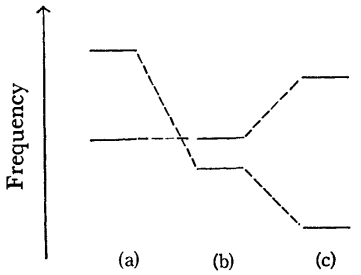

Fig. 6. Diagram showing the coupling of C–ND_2 stretching mode and ND_2 bending mode by complex formation.
(1) in free molecule (**2** or **4**).
(2) hypothetical case in which C–ND_2 stretching mode decreased in frequency and not coupled with ND_2 bending mode.
(3) (2)+coupling, the real case in the complex.

Fig. 6. It can be deduced that the adsorption of aniline on aluminum chloride is rather weak and predomiantly ionic, with a highly polarized C–N bond.

In the complexes of B and C, the interaction of the lone pair on the nitrogen atom in aniline molecule with aluminum halide is larger than in the case of complex of A, as revealed by their UV spectra.[21] The lone pair is partially consumed in the formation of the coordination bond to the aluminum atom, more or less covalent N···Al bond being formed. The hybridization of the nitrogen atom becomes closer to sp^3, and the double bond character of C–N bond decreases. In the complexes of B, the aluminum atom has no large positive charge and the polarization effect on C–N bond is small. If any polarization occurs, the effect will be compensated by the flow of electron from nitrogen atom to aluminum atom. The situation will be similar in the complex of C. In these complexes, the decrease in frequency of C–N stretching mode occurs by the reduction of double bond character of C–N bond.

a) i.p.=in plane, o.p.=out of plane. b) From Ref. 28. All the strong bands (with relative intensity greater than 8 in Table 2 in Ref. 28 except those assigned to CD_3 group vibrations) are listed. c) From Ref. 27. d) Numbering is after Refs. 27 and 28. * Ostrowska and Tramer (Ref. 16) gave assignments for these bands.

This will bring C–ND_2 mode into coupling with ND_2 bending mode to some extent, which will cause the low frequency shift of the bands associated with the ND_2 bending mode in these complexes. Since the reduction of C–ND_2 stretching frequency for these complexes is smaller than for the complex of A, the extent of this coupling should be smaller and hence the frequency shift in ND_2 bending mode also smaller. Thus, the adsorption of aniline on aluminum bromide and iodide can be shown to be a stronger chemisorption (with an essentially covalent N···Al bond) with C–N bond of less polarity than the adsorption on aluminum chloride. Judging from the magnitude of the frequency shifts of bands, the chemisorption on C is stronger than that on B.

In the complex **1D**, the IR spectrum was similar to that of **1B**, and the structure of the adsorbed complex would thus be similar to that of the complex **1B**.

A brief comment will be necessary as to the frequency shifts of NH stretching vibrations. The polarization of C–N bond in the complexes of A accompanies the polarization of N–H bond, reducing the frequencies of N–H stretching vibrations. The frequency shifts of N–H stretching vibrations in these complexes might be larger than in the complexes of B and C owing to this effect, as is the case for the C–N stretching vibrations. However, the observed magnitude of the shifts was in

the order: A<B<C. This can be explained in the following way. There is another factor for reducing the frequencies of N–H stretching vibrations in the complexes of B and C, namely the substantial change in hybridization of the nitrogen atom toward sp^3.

Thus, detailed information on the structures of adsorbed molecules and also on the nature of adsorption (ionic or covalent) was obtained by analyses of the IR spectra.[26]

Our thanks are due to Dr. Taruo Kurokawa, Kogaiboshi Kyokai, Kagoshima Pref., who allowed us the use of their JASCO IRA-2 infrared spectrophotometer.

Appendix

IR Bands of Aniline-d_5 and Aniline-d_7 and Their Assignments. Observed IR bands are listed in Table 2. For aniline-d_7, the positions of bands are in line with the data of Ostrowska and Tramer.[16,18] The assignments of these bands were made as follows. The liquid film of aniline-d_7 was exposed to the air with repeated IR measurement at certain intervals. The content of aniline-d_7 decreased with an increase in aniline-d_5. The bands common to all the spectra were attributed to C_6D_5-group. The assignments were confirmed by comparison with IR bands of benzene-d_6[27] and toluene-d_8.[28] The bands found only in aniline-d_7 or in aniline-d_5 were associated to ND_2- or NH_2-group, respectively. The bands remaining in the intermediate state were assigned to NHD-group. The assignments were compared with those of the corresponding bands in aniline-*N*,*N*-d_2 and aniline-d_0.[14,15] For aniline-d_7, Ostrowska and Tramer[16] gave the assignments of nine bands (shown by asterisks in Table 2). Our assignments for these nine bands agree with theirs except for the band at 741 cm^{-1} which was assigned to CD out-of-plane bending mode.[16] Although this assignment can not be ruled out completely, the band was assigned to ND_2 rocking (or twisting) mode in this paper, since no corresponding band was found in aniline-d_5.

17) J. N. Rai and R. C. Maheshwari, *Indian J. Pure Appl. Phys.*, **9**, 27 (1971).
18) Five bands (711, 1025, 1350, 1580, 2276 cm^{-1}) of the 27 bands were not observed. Three bands (3400, 1066, 928 cm^{-1}) in our spectrum are not reported.[16]
19) A. P. Gray and R. C. Lord, *J. Chem. Phys.*, **26**, 690 (1957).
20) N. B. Colthup, L. H. Daly, and S. Wiberley, "Introduction to Infrared and Raman Spectroscopy," Academic Press, New York, N. Y. (1964), p. 280.
21) The UV spectrum of **1B** was measured on a Shimadzu MPS-50L recording spectrophotometer. The shift of the bands toward shorter wavelength was larger than that in the case of **1A** (Ref. 1). The positions of observed UV bands for **1B** (253, 259, 265 nm, the highest peak being that of 259 nm.) were very close to those of anilinium ion $C_6H_5NH_3^+$ (248, 254, 260 nm in H_2SO_4 aq.; "DMS UV Atlas," Vol. IV, Butterworths, London, D6/4 (1968)). The species giving this UV spectrum, however, was not the anilinium ion, but the aluminum bromide complex, since the IR measurement on the same sample gave the characteristics of the complex. The UV spectrum of **1C** gave a broad band in the 246—274 nm region, with an absorption maximum at 258 nm. The location of this band is similar to that of **1B**.
22) For **3A**, two broad bands (1165 and 1125 cm^{-1}) were found in this region. The latter was assigned to C–NHD stretching mode. However, these two bands might result from two types of adsorbed molecules (adsorbed on two types of sites). If this is the case, the band associated to C–NHD stretching mode may be involved in the 1125 cm^{-1} band. It might be possible that the broad 1140 cm^{-1} band of **1A** is actually composed of two bands, one around 1165 cm^{-1} and the other around 1125 cm^{-1}.
23) The bands appearing in 1100—1120 cm^{-1} region seem to be attributable to NHD species, since they were found at the same positions (within experimental error) in the complexes of **3** and **4**, and at the positions close to these in the complex of **2**. (For the 1125 cm^{-1} band of **3A**, see footnote 22).
24) In the complexes of **2** and **4** with B and C, some of the bands assigned to CN stretching vibration were accompanied by another weak band, the nature of which is not clear. This may result from some chemical reaction occuring on these aluminum halides.
25) H. Sato, unpublished result.
26) The relative order of strength in chemisorption was revealed also in the difference of chemical stability of the complexes **1A** and **1B** when the cell systems were exposed to the air. The complex **1A** decomposed immediately to give the IR spectrum of anilinium ion salt, while the IR spectrum of **1B** did not change appreciably for hours.

(Received April 7, 1975)

For an interpretation of the pH-dependence of the sensitized photocurrent at semiconductor electrodes, measurements have been carried out on n-type TiO_2 and CdS single crystal electrodes. As sensitizing dyes, rhodamine B and 3,3'-diethylthiacarbocyanine iodide which remain stable in a sufficiently wide pH range were used. It has been found that the logarithm of the sensitized photocurrent at TiO_2 electrode depends linearly on the pH of the electrolyte solution, whereas the sensitized photocurrent shows practically no pH-dependence at CdS electrode. These observations have been accounted for on the basis of the different pH-dependence of flatband potentials of these semiconductor electrodes.

Investigations of spectral sensitization by means of electrochemical arrangements have so far been carried out by a number of authors on ZnO,[1-14] TiO_2,[15] CdS,[16,17] GaAs,[4] GaP,[4,18] AgCl,[12,19] AgBr,[12,19] SnO_2,[20] Cu_2O,[12,21] and organic semiconductors[1,22,23] such as perylene, chrysene and anthracene. By addition of a suitable dye to the electrolyte solution and by subsequent illumination of the semiconductor-electrolyte interface with light of the optical absorption band of the dye, an enhancement of the photocurrent (sensitized photocurrent) is observed. For most n-type and p-type semiconductor electrodes, the sensitized photocurrent is produced under anodic and cathodic polarizations, respectively.

The magnitude of the sensitized photocurrent can be influenced by several factors such as light intensity, dye concentration, additives (reducing or oxidizing agents in particular), and the pH value of the electrolyte solution.

As regards the effect of pH on the sensitized photocurrent, three examples have so far been reported uniquely on ZnO electrode. Gerischer *et al.*[1] measured the rose bengale-sensitized photocurrent as a function of the pH of the solution. The sensitized photocurrent exhibited only a slight pH-dependence in the alkaline region and completely disappeared below pH 3.8 (owing presumably to the protonation of the dye). However, their results show a remarkable increase in the sensitized photocurrent as the pH decreases from 5.5 to 4.5.

Hauffe *et al.*[8] measured the fluorescein-sensitized photocurrent with varying pH. The magnitude of the sensitized photocurrent showed a maximum when the solution pH was around 7.0, and decreased both in alkaline and acidic solutions. However, the decrease in the photocurrent in the acidic condition is due to some structural change of the sensitizing dye, as is indicated by a remarkable decrease in the fluorescent intensity when compared with that in neutral and alkaline solutions.

Gerischer and Tributsch,[2] using rhodamine B as a sensitizing dye, found that the logarithm of the sensitized photocurrent increased almost linearly with the pH of the solution as it decreased from 9.0 to 1.5, but they did not give any plausible interpretation.

The examples cited above suggest that in the pH range where the sensitizing dye undergoes no structural change, the sensitized photocurrent increases as the pH of the electrolyte solution decreases.

In order to obtain further information on the pH-dependence of the sensitized photocurrent, we have investigated the pH-dependence of the sensitized photocurrent at two different semiconductor electrodes, using two kinds of sensitizing dyes which remain quite stable in a sufficiently wide pH range.

Experimental

Materials and Measuring Setup. Single crystals of TiO_2 and CdS, supplied from Nakazumi Crystals Co., Ltd. and Teikoku Tsushin Co., Ltd., respectively, were used as the n-type semiconductor electrodes. Both were in the form of platelets with a surface area of 1.0 cm^2 and thickness of 1.0 mm. In the case of TiO_2, the crystal was treated at around 600 °C under high vacuum for three hours, prior to the preparation of the electrode, in order to increase the electrical conductivity. The crystals were then cemented with an epoxy resin so that usually the (001) face and the (0001) face of TiO_2 and CdS, respectively, were in contact with the electrolyte solution. The opposite face was used for a barrier-free electrical contact by means of vacuum evaporated indium. Before measurements, the electrodes were polished with alumina paste. The CdS electrode surface was chemically etched with concentrated HCl for a few seconds.

As the sensitizing dyes, rhodamine B and 3,3'-diethylthiacarbocyanine iodide were used. The electrolyte was 0.2 M Na_2SO_4 aqueous solution, and the pH of the electrolyte solution was varied by adding a small amount of H_2SO_4 or NaOH aqueous solution. All the chemicals used were of reagent grade.

A 500-W xenon lamp was used as the light source. The wavelength of the illuminating light was selected with the use of colored glass filters or a Shimadzu monochromator. Illumination of the electrode-electrolyte interface was carried out either through the electrode attached as the window of the electrochemical cell or through a quartz window and the dye-containing electrolyte solution. The photocurrent was detected by means of a Keithley picoammeter Model 417.

Adsorption Measurements. Since direct measurement of adsorption of dyes with single crystals is difficult, a powdered TiO_2 (Kishida Kagaku Co., Ltd.) was used as an adsorbent. 0.5 g of TiO_2 powder was added to 20 ml of a dye solution of various concentrations containing 0.2 M of Na_2SO_4. The

mixture was put into a glass tube assembled on a stirring machine. The TiO_2 powder was kept in contact with the solution for 30 min at 20 °C, and then separated by centrifuging. The absorbance change of the dye solution was determined by means of a Shimadzu spectrophotometer MPS-5000.

Results and Discussion

Since TiO_2 and CdS are n-type semiconductors with relatively large band gaps (3.0 eV and 2.4 eV, respectively), only a small current flows in darkness under anodic polarization, owing to the formation of a depletion layer for the majority carrier at the surface of the electrode. Figure 1 shows typical current-potential curves for the TiO_2 electrode at two different pH values. In the absence of a sensitizing dye and under illumination with light of longer wavelengths than the intrinsic absorption of TiO_2, a small photocurrent is produced, which is almost independent of the pH of the electrolyte solution. By addition of a sensitizing dye, 3,3′-diethylthiacarbocyanine in the present case, a further photocurrent (sensitized photocurrent) was observed, whose spectral dependence is close to that of the optical absorption of the dye adsorbed to TiO_2. The sensitized photocurrent reaches a saturation value under a slight anodic polarization. As can be seen in Fig. 1, with a decrease in pH from 6.15 to 2.2, the saturation value of the sensitized photocurrent shows a remarkable increase by a factor of more than ten.

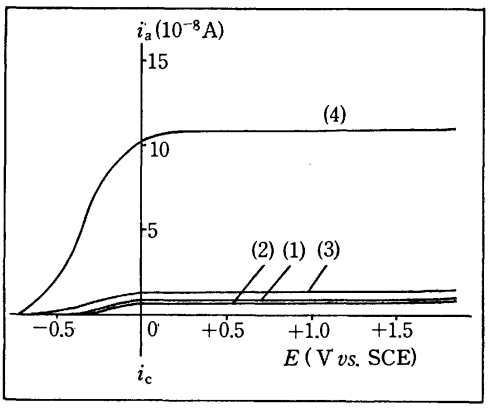

Fig. 1. Current-potential curves for TiO_2 electrode under illumination with $\lambda > 460$ nm.
(1): Blank photocurrent at pH 6.15, (2): same as (1) at pH 2.2, (3): photocurrent by addition of 2×10^{-5} M of 3,3′-diethylthiacarbocyanine at pH 6.15, (4): same as (3) at pH 2.2.

When the sensitized photocurrent is plotted against the dye concentration, in a log-log scale, an almost straight line with a slope of *ca.* 1.0 is obtained in the relatively low concentration region. Figure 2 shows such curves for two different pH values. Decrease in pH enhances the sensitized photocurrent by approximately the same factor, irrespective of the dye concentration.

In the case of the CdS electrode, in contrast to TiO_2 electrode, no pH-dependence of the sensitized photocurrent was observed. Fugure 3 shows the spectra

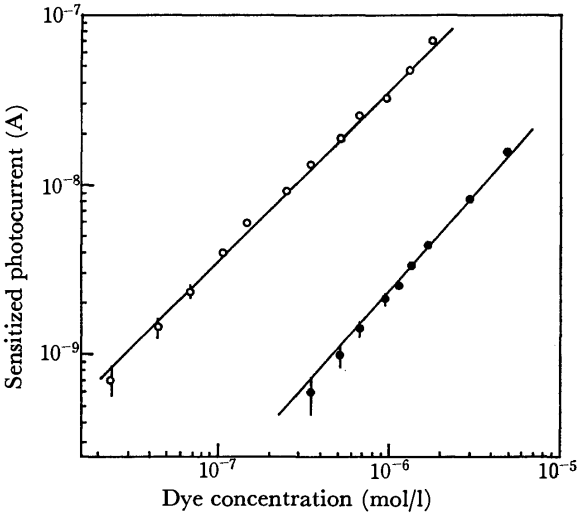

Fig. 2. Dependence of the sensitized photocurrent at TiO_2 electrode upon the concentration of the sentitizing dye (3,3′-diethylthiacarbocyanine iodide) at two different pH values; —○—: pH 2.2, —●—: pH 6.15.

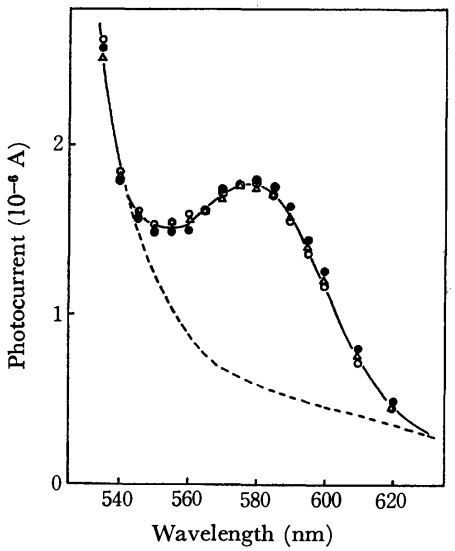

Fig. 3. Spectral dependence of the sensitized photocurrent at CdS electrode with varying pH: ——: pH 5.2, —○—: pH 4.0, —△—: pH 3.0, —●—: pH 2.4, ·····: blank photocurrent.

of the rhodamine B-sensitized photocurrent at CdS electrode for four different pH values.

The experimental results of spectral sensitization measurements at TiO_2 and CdS electrodes are summarized in Fig. 4 as a function of pH of the electrolyte solution, together with the data reported by Gerischer and Tributsch[2] on ZnO electrode. In the cases of TiO_2 and ZnO electrodes, the logarithm of the sensitized photocurrent depends almost linearly upon the pH of the solution containing rhodamine B or 3,3′-diethylthiacarbocyanine iodide as a sensitizing dye, while no detectable dependence being observed for the CdS electrode.

As regards the pH-dependence of the sensitized photocurrent at TiO_2 electrode, it is necessary in the first place to check the possible contributions from any

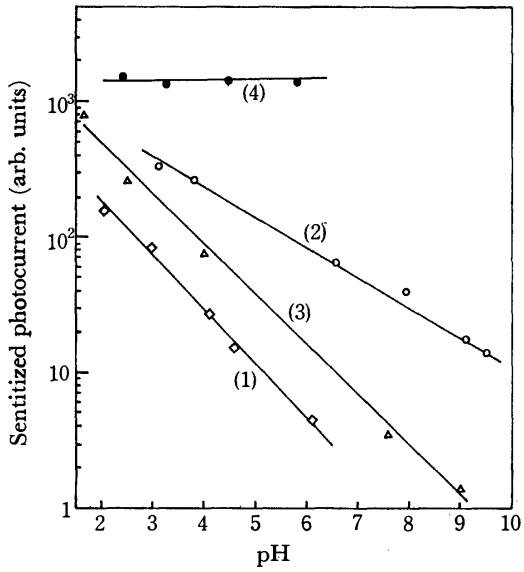

Fig. 4. pH-dependence of the sensitized photocurrents at several semiconductor electrodes;
(1): TiO_2 with 3,3′-diethylthiacarbocyanine, (2) TiO_2 with rhodamine B (3) ZnO with rhodamine B (Gerischer and Tributsch[2]), (4) CdS with rhodamine B.

pH-assisted structural change of the dye molecule and from the pH-dependence of the adsorption characteristics of dyes on TiO_2. The absorption spectra of rhodamine B and 3,3′-diethylthiacarbocyanine iodide were measured in the pH range 2—12, but no detectable change was observed. From this the possibility of the structural change of dye molecules through pH could be ruled out.

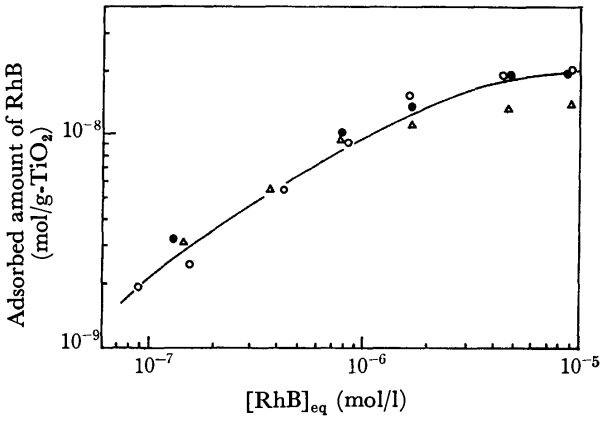

Fig. 5. Adsorption characteristics of rhodamine B on TiO_2 at 20 °C at different pH values; —○—: pH 2.0, —●—: pH 6.15, —△—: pH 10.0.

The adsorption characteristics of the two dyes employed here on TiO_2 have been measured with varying pH of the solution. The results for rhodamine B are shown in Fig. 5. We see that the adsorbability of rhodamine B in the pH range 2—12 falls on the same curve within experimental error. The adsorption of 3,3′-diethylthiacarbocyanine iodide on TiO_2 also is hardly affected by the pH of the solution.

The observations suggest that, in the case of the TiO_2 electrode, a decrease in pH of the electrolyte solution brings about a favorable condition for the occurrence of the spectral sensitization (possibly the electron transfer from the excited dye molecule to the conduction band of the semiconductor).

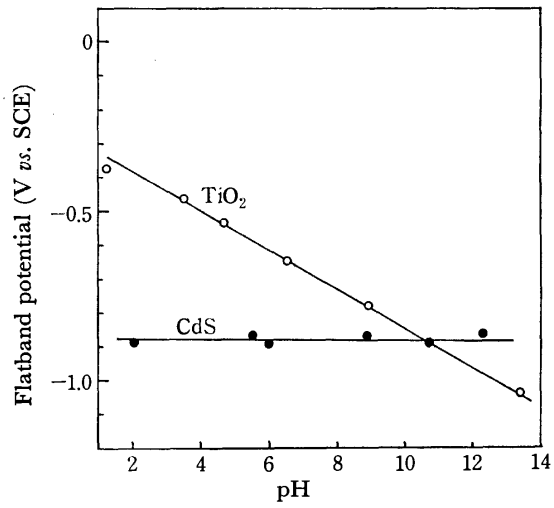

Fig. 6. pH-dependence of flatband potentials of TiO_2 and CdS single crystal electrodes.

In this connection we notice a quite good correlation between the results shown in Fig. 4 and the pH-dependence of the flatband potentials of TiO_2 and CdS electrodes (Fig. 6).[24] The pH-dependence of the flatband potential of the TiO_2 electrode could be elucidated by assuming a dissociation equilibrium[25] at the electrode surface facing the electrolyte solution, such as

$$\text{Ti-O}^{2-} + \text{H}^+ \rightleftarrows \text{Ti-OH}^- \qquad (1)$$

where Ti-O^{2-} denotes a lattice element of the TiO_2 surface, H^+ a proton in the bulk of the electrolyte solution, and Ti-OH^- the lattice element protonized. A thermodynamic consideration on the dissociation equilibrium (1) leads to the following formula:

$$\mu^\circ_{\text{Ti-O}^{2-}} + RT\ln a_{\text{Ti-O}^{2-}} - 2F\Phi_e + \mu^\circ_{H^+} + RT\ln a_{H^+} + F\Phi_s = \mu^\circ_{\text{Ti-OH}^-} + RT\ln a_{\text{Ti-OH}^-} - F\Phi_e \qquad (2)$$

where Φ_e and Φ_s are the potentials of the electrode surface and of the bulk of the solution, respectively. Other symbols have their usual meanings. It follows that the potential difference $\Delta\Phi$ ($=\Phi_e-\Phi_s$) at the phase boundary TiO_2—electrolyte is expressed as

$$\Delta\Phi = \text{const.} + \frac{RT}{F}\ln\frac{a_{\text{Ti-O}^{2-}}}{a_{\text{Ti-OH}^-}} - \frac{2.3RT}{F}\text{pH} \qquad (3)$$

Provided that the second term in Eq. (3) is not significantly affected by the pH change of the electrolyte solution, the electrode potential of TiO_2 shifts by *ca.* 60 mV (at room temperature) per unit decrease in the pH value. This is shown in Fig. 6.

In the ordinary polarization of a semiconductor electrode through the external circuit, most part of the applied voltage operates within the space charge region inside the semiconductor, and the potential difference across the electrical double layer (in the solution-side of the interface) can hardly be changed, owing to much lower carrier concentration in the electrode than

in the bulk of the electrolyte solution. Therefore, the rate of the electron transfer from the excited dye to the semiconductor (sensitized photocurrent) exhibits no detectable dependence on the anodic polarization (practically up to 10 V or more *vs.* S.C.E.) as shown in Fig. 1. The effect of polarization appears only under cathodic polarization where an accumulation layer, which obstructs the electron transfer towards the electrode, is formed at the surface of the semiconductor electrode.

Since the potential difference $\Delta\Phi$ due to pH change of the electrolyte solution is brought about at the electrode surface-electrolyte interface, as is ordinarily the case for the polarization of metal electrodes, the rate of the electron transfer from the excited dye to a semiconductor is expected to depend on the pH of the solution. Postulating an ordinary rate equation for the anodic process and tentatively assuming the one-electron transfer, the anodic sensitized photocurrent i_s can be expressed as

$$i_s \propto \exp\left(\frac{\alpha F}{RT}\eta\right) \tag{4}$$

where α is the transfer coefficient and η the overpotential. In view of the above discussion, the latter can be written as

$$\eta = \text{const.}' + \Delta\Phi \tag{5}$$

Combining Eqs. (3)—(5), one obtains the following formula for the sensitized photocurrent:

$$\log i_s = \text{const.}'' - \alpha\text{pH} \tag{6}$$

This equation seems to hold for the pH-dependence of the sensitized photocurrent at TiO_2 and ZnO electrodes shown in Fig. 4. The value of α falls within 0.26—0.40.

A similar treatment has been reported by Vetter and Gorn[26] concerning the corrosion process taking place at the iron oxide-electrolyte interface. They demonstrated a pH-dependence of the corrosion current, which they accounted for by assuming the potential variation caused by the dissolution equilibrium of oxygen ions at the phase boundary.

In contrast to the sensitized photocurrent, the rate-determining step for the blank photocurrent under long wavelength illumination would be the transport of positively-charged species such as ionized donors from interior to the surface of the electrode, since the latter current originates from light absorption inside the semiconductor. This assumption can be verified by the fact that the magnitude of the blank photocurrent shows practically no pH-dependence (Fig. 1) and that it increases gradually with the increase in the anodic polarization.

The fact that no pH-dependence of the sensitized photocurrent was observed at the CdS electrode would be ascribed to the pH-independence of the potential difference within the double layer, as is indicated by the pH-independence of the flatband potential (Fig. 6). This suggests that no dissociation equilibrium, similar to Eq. (1), could be established at the surface of the CdS electrode.

Studies of MoO_3–Al_2O_3 Catalyst in Ethylene Polymerization. III. The Nature of Mo(V) and Its Relation with Activity

Keizi HASHIMOTO, Shozi WATANABE, and Kimio TARAMA*

The Osaka Municipal Technical Research Institute, Ogimati, Kita-ku, Osaka 530

**Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606*

(Received May 16, 1975)

In order to determine the active center of ethylene polymerization over MoO_3–Al_2O_3, the *g*-tensor and the amount of molybdenum(V) in each chemical state were determined by means of ESR measurement. The anisotropy of the *g*-tensor revealed the strength of the crystal field in the state; the decreasing order of the strengths was as follows: state(S)>state(M)>state(W)>MoO_3–SiO_2≒free MoO_3. In the state(S) molybdenum oxide is insoluble in aq.10M–NH_3, in the state(M) it is soluble in aq. NH_3 but insoluble in water, and in the state(W) it is soluble in water. The amount of molybdenum(V) in the state(W) was studied in connection with the activity, because only the state(W) was suitable for polymerization. The behavior of the activity was in fair agreement with that of the molybdenum(V) content in the state(W) and this content depedned on the amount of supported MoO_3 and on the extent of reduction. The amount of molybdenum(V) in the state (W) corresponded to the amount of chemisorbed hydrogen, which was a polymerization initiator. The chemisorption of oxygen on the catalyst caused a complete disappearance of both the activity and the molybdenum(V) content in the state(W). Therefore, it was concluded that the active center of the polymerization was molybdenum(V) in the state(W).

The polymerization over MoO_3–Al_2O_3 has been studied. In the first paper,[1] we reported about the activity of the catalyst and the kinetics of the polymerization. In the second paper,[2] we reported the relation between the activity and the chemical states of molybdenum oxide on Al_2O_3 and concluded that the oxide on Al_2O_3 might be classified into three chemical states: the state(W) in which molybdenum oxide is soluble in water, the state(M), insoluble in water but soluble in aq.NH_3, and the state(S), insoluble in aq.10M-NH_3.

In general it is known that the activity may be attributed to the low valence of molybdenum on the basis of the fact that an olefin is polymerized in a reducing atmosphere.[3] Emelyanov *et al.*[4] and Voevodskii[5] attempted to relate the polymerization activity to molybdenum(V). However, they did not obtain a clear relation between the activity and the molybdenum(V) content. The explanation for the unfavorable results is that they regarded the molybdenum oxide on Al_2O_3 as a single state without considering the properties of the three chemical states.

The present paper deals with a part of an investigation of the active center, in view of the states. The anisotropy of the *g*-tensor of molybdenum(V) in each chemical states is measured by ESR. The strength of crystal field and the field suitable for polymerization will be discussed on the basis of the ESR data and the activity. In order to show the valence of molybdenum ion as an active center, the molybdenum(V) content in the state(W) is determined by the ESR measurement. The activity is compared with this content, which is due to the amount of supported MoO_3 and the extent of reduction. The amount of polymerization initiator, chemisorbed hydrogen, is determined and compared with the molybdenum(V) content in the state(W). The poisoning effects of oxygen chemisorbed on the catalyst are studied. One interesting conclusion to be drawn from these results in the fact that the polymerization activity in MoO_3–Al_2O_3 is related to the strength of the crystal field and the amount of the molybdenum(V) in the state(W).

Experimental

Preparation of Catalyst. MoO_3–Al_2O_3 and MoO_3–SiO_2 were prepared according to the procedure described previously.[1]

Reactants. Hydrogen and oxygen (more than 99.9%) were used without further purification. Ethylene (99.5%, Seitetu Chemical Co.) was used without further purification. Most of the impurities were methane or ethane.

Treatment of Catalyst. The catalyst were reduced under a hydrogen pressure of 170 Torr at 400 °C before the ESR measurement and the ethylene polymerization. The extent of reduction was determined on the basis of the amount of oxygen completely reoxydating the catalyst. The extent shows the conversion ratio of MoO_3 to MoO_2.

ESR Measurement. The catalysts were placed into a reaction vessel equipped with a pyrex-tube for ESR measurement. The measurement was carried out at room temperature. ESR spectra were obtained with a JES-ME-IX spectrometer (Japan Electron Optics Laboratory Co.) using manganese (II) as an internal standard. The amount of molybdenum (V) in the catalyst was determined by Seshadri's method[6] using copper(II) as an internal standard.

Polymerization. The ethylene was polymerized at 0 °C using the procedure described previously.[1]

Results and Discussion

Crystal Field of Molybdenum Oxide. After reduction in each chemical state, the presence of molybdenum(V) was recognized from ESR studies. The molybdenum(V) in each chemical state showed an anisotropy of the *g*-tensor. The values of the anisotropy are shown in Table 1. The value in MoO_3–SiO_2 is also added in

TABLE 1. *g*-VALUE OF MOLYBDENUM (V)

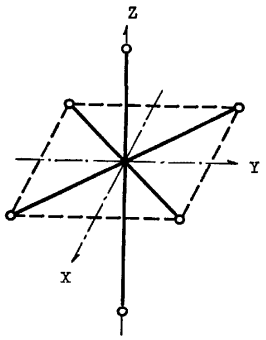

Fig. 1. Model of molybdenum oxide on Al_2O_3.
●: Mo^{6+} ion, ○: O^{2-} ion.

Table 1. As Table 1 shows, the $g_\perp$-value was almost constant in the different states. The $g_{//}$-value varied with the kinds of states and of carriers. The decreasing order of $g_{//}$-values was in agreement with the increase of the interaction between the state and the carrier.[2] The strength of the crystal field in the state was determined on the basis of the anisotropy. According to Andersson's report,[7] the crystal structure of free MoO_3 is a distorted octahedron. Therefore, the structure of molybdenum oxide on Al_2O_3 was supposed to be a distorted octahedron, as shown in Fig. 1. The five-fold degenerate levels of d^1-ion are split into 4-levels in the model and the energy levels decrease in the following order: $a_1(d_{z^2})$, $b_1(d_{x^2-y^2})$, $e(d_{zx}, d_{yz})$, and $b_2(d_{xy})$. Several authors have derived equations for the $g_{//}$ and $g_\perp$ expected in a d^1-model of a distorted octahedron, using a set of molecular orbitals as the basis functions for the calculation. Ballhausen *et al.*[8] placed the unpaired electron in a non-bonding b_2-orbital(d_{xy}), defined the antibonding orbital as $\Phi^*=C_1^*\Phi(\text{metal})+C_2^*\Phi(\text{ligand})$, and derived

$$g_{//}=2\left[1-\frac{4(C_1^*)^2\xi_M}{\Delta E(^2B_2-{}^2B_1)}\right] \quad (1)$$

$$g_\perp=2\left[1-\frac{(C_1^*)^2\xi_M}{\Delta E(^2B_2-{}^2E)}\right] \quad (2)$$

Where ξ_M is the single electron spin-orbit coupling constant for molybdenum. $\Delta E(^2B_2-{}^2B_1)$ is a function of the equatorial Mo–O distance and $\Delta E(^2B_2-{}^2E)$ is a function of both the equatorial and the Mo–O distance along the C_{4v} axis. Since the $g_\perp$-value in Table 1 is almost constant, the quantitative variation of $\Delta E(^2B_2-{}^2E)$ might be small in the different chemical states. The values of $\Delta E(^2B_2-{}^2B_1)$ and $\Delta E(^2B_2-{}^2E)$ were determined as follows. In the previous paper, we reported that state(W) and state(M) occupied most of the alumina surface in 16.7wt%MoO_3–Al_2O_3 and (0—6)wt%MoO_3–Al_2O_3, respectively. The catalysts were prepared in the way that Asmolov *et al.*[9] described. They reported that the adsorption bands in 16.7wt%-MoO_3–Al_2O_3 and (0.2—1.8)wt%MoO_3–Al_2O_3 appeared at 31250 and 33900 cm^{-1}, respectively. In the molybdenyl complexes having a similarly distorted octahedron, the values of $\Delta E(^2B_2-{}^2E)$ and $\Delta E(^2B_2-{}^2B_1)$ were (10000—20000) and (20000—30000) cm^{-1}, respectively.[10,11] Therefore, the values of $\Delta E(^2B_2-{}^2B_1)$ in the state(W) and the state(M) were 31250 and 33900 cm^{-1}. The values of $\Delta E(^2B_2-{}^2E)$ in the state(W) and the state(M) were calculated to be 17300 and 17100 cm^{-1} on the basis of a substitution of these values, the $g_\perp$ and $g_{//}$-values, in Eqs. (1) and (2). Thus, the variation of $\Delta E(^2B_2-{}^2E)$ was small, as expected from the $g_\perp$-values in Table 1. Consequently, the value of $\Delta E(^2B_2-{}^2E)$ was assumed to be 17200 cm^{-1} in both the state(S) and the MoO_3–SiO_2 and those of $\Delta E(^2B_2-{}^2B_1)$ in the state(S) and the MoO_3–SiO_2 were calculated to be 36000 and 24800 cm^{-1}, respectively (Table 2). As Table 2 shows, the value of $\Delta E(^2B_2-{}^2B_1)$ decreased in the following order of states: state(S), state(M), state(W), and MoO_3–SiO_2. Since the value of ΔE-$(^2B_2-{}^2B_1)$ in MoO_3–SiO_2, 24800 cm^{-1}, was nearly equal to that in the single crystal of MoO_3, 24250 cm^{-1},[12] the molybdenum oxide on the SiO_2 had little interaction between the oxide and the SiO_2. The value of ΔE-$(^2B_2-{}^2B_1)$ in the state(S), 36000 cm^{-1}, supported the idea that the state(S) had a strong crystal field. The quantity of $\Delta E(^2B_2-{}^2B_1)$ is a function of the equatorial Mo–O distance as described above and the shortening of the equatorial distance leads to an increase of ΔE-$(^2B_2-{}^2B_1)$. The equatorial Mo–O distance was shortened in the following order of states: MoO_3–SiO_2, state(W), state(M), and state(S). This shortening order was in agreement with the increasing order of the interaction between the molybdenum oxide and the carrier.[2] From the facts presented above, the strengths of the crystal field in each chemical state were not equal and that in the state(W) led the value of $\Delta E(^2B_2-{}^2B_1)$ of molybdenum(V) to *ca.* 31000 cm^{-1}. This strength was suitable for ethylene polymerization and only the state(W) was suitable for it, as described previously.[2]

Table 2. Spectral parameters of molybdenum(V) signals

Sample	$(^2B_2-{}^2B_1)$, (cm^{-1})	$(^2B_2-{}^2E)$, (cm^{-1})
MoO_3–SiO_2	24800	17200[a]

(M)-Al_2O_3	33900[b]	17100
(S)-Al_2O_3	36000	17200[a]

a) Estimated value. b) Ref. 9.

Relation between Activity and Molybdenum(V) content. In order to reveal the valence states of the active molybdenum which was present in the state(W) suitable for polymerization, the catalytic activity was studied in connection with the molybdenum(V) content in the catalysts. The amount of molybdenum(V) in MoO_3–Al_2O_3 is expressed as a sum of the molybdenum(V) contents in three chemical states, that is:

$$(Mo^{5+})_{total}=(Mo^{5+})_W+(Mo^{5+})_M+(Mo^{5+})_S, \quad (3)$$

Where (Mo^{5+}) is the amount of molybdenum(V) and W, M, and S subscripts refer to state(W), state(M), and state(S), respectively. The apparent $g_{//}'$-value of molybdenum(V) in MoO_3–Al_2O_3 varied with the composition of molybdenum(V) in the three states. The apparent $g_{//}'$-values in various comopsitions were determined by the simulation on the basis of the ESR spectra of molybdenum(V) in each state. Figure 2 shows an ESR spectrum simulated in the following composition: $(Mo^{5+})_W$, $(Mo^{5+})_M$, and $(Mo^{5+})_S$ are

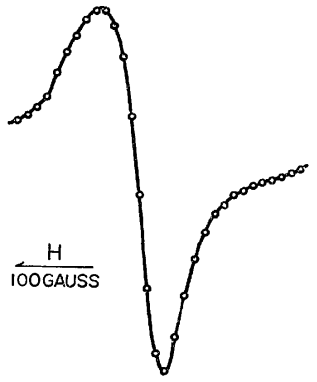

Fig. 2. ESR spectrum of Mo^{5+} in the composition, $(Mo^{5+})_W$, $(Mo^{5+})_M$ and $(Mo^{5+})_S$, respectively, 4.30×10^{18}, 2.14×10^{18} and 3.00×10^{18} spins/g-cat.
○: Points of simulated spectrum, —: measured spectrum.

respectively 4.30×10^{18}, 2.14×10^{18} and 3.00×10^{18} spins/g-cat.. These $g_{//}'$-values of simulated spectra are shown in Table 3. The apparent $g_{//}'$-value was assumed to be approximately expressed as a function of the content, $(Mo^{5+})_W$, $(Mo^{5+})_M$, and $(Mo^{5+})_S$, by the following equation:

$$g_{//}' = \frac{1.8960(Mo^{5+})_W + 1.9086(Mo^{5+})_M + 1.9140(Mo^{5+})_S}{(Mo^{5+})_{total}}, \quad (4)$$

Table 3. Apparent $g_{//}'$-value of molybdenum(V)

Composition (mol%)			$g_{//}'$-Value of simulated spectra	Approximated $g_{//}'$-value
$(Mo^{5+})_W$	$(Mo^{5+})_M$	$(Mo^{5+})_S$		
0	80	20	1.9097	1.9097
20	60	20	1.0973	1.9072
40	40	20	1.9047	1.9046
60	20	20	1.9020	1.9021
0	60	40	1.9107	1.9108
40	30	40	1.9070	1.9070
50	10	40	1.9047	1.9045
60	0	40	1.9030	1.9032
0	40	60	1.9116	1.9118
20	20	60	1.9093	1.9093
30	10	60	1.9080	1.9081

The apparent $g_{//}'$-values calculated from Eq. 4 are shown in Table 3. As Table 3 shows, the apparent $g_{//}'$-value calculated is in fair agreement with the apparent $g_{//}'$-value of the simulated spectrum. Therefore, the apparent $g_{//}'$-value might be approximately expressed by Eq. 4. The substitution of $(Mo^{5+})_{total}$, $(Mo^{5+})_S$, and the apparent $g_{//}'$-value in both Eqs. 3 and 4 determined $(Mo^{5+})_W$, which was present in the crystal field of suitable strength for polymerization.

In order to reveal the relation between $(Mo^{5+})_W$ and the supported molybdite-content, the relations of the molybdite-content to $(Mo^{5+})_{total}$, $(Mo^{5+})_S$, and the apparent $g_{//}'$-value were studied and is shown in Fig. 3. Before the ESR measurement, the catalysts were reduced under a hydrogen pressure of 170 Torr at 400 °C for 15 min. The molybdenum oxide in the state(S) was prepared by the removal of molybdenum oxides in

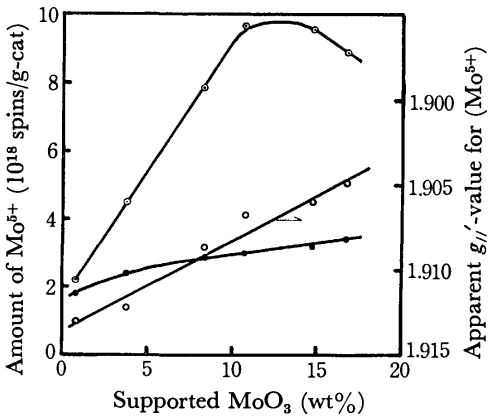

Fig. 3. Relation of the molybdite-content to $(Mo^{5+})_{total}$, $(Mo^{5+})_S$ or the apparent $g_{//}'$-value
○: $(Mo^{5+})_{total}$, ●: $(Mo^{5+})_S$, ○: apparent $g_{//}'$-value for $(Mo^{5+})_{total}$.

both state(W) and state(M) from MoO_3–Al_2O_3 with aq.10 M-NH_3 and reduced under the same conditions before the determination of $(Mo^{5+})_S$. As Fig. 3 shows, $(Mo^{5+})_{total}$ was maximum at a molybdite-content of 10 to 15wt%. The apparent $g_{//}'$-value decreased with an increase of the molybdite-content and $(Mo^{5+})_S$ increased gradually with an increase of the molybdite-content. The behavior of $(Mo^{5+})_{total}$ was in agreement with Voevodskii's result.[5] $(Mo^{5+})_W$ was calculated by substitution of $(Mo^{5+})_S$, $(Mo^{5+})_{total}$, and the apparent $g_{//}'$-value in Fig. 3 into Eqs. 3 and 4. The relation between $(Mo^{5+})_W$ and molybdite-content is shown in Fig. 4. $(Mo^{5+})_W$ was small in the molybdite-content, less than several percents. $(Mo^{5+})_W$ increased with the further molybdite-content. The behavior of $(Mo^{5+})_W$ differed from that of $(Mo^{5+})_{total}$ in Fig. 3.

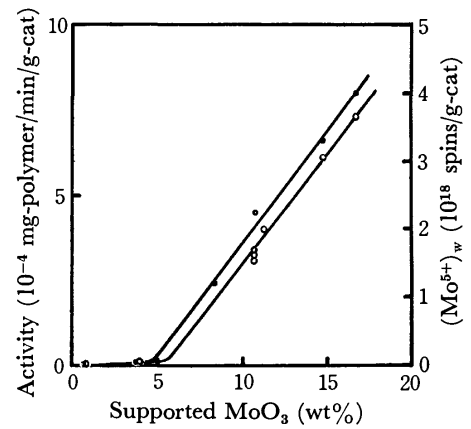

Fig. 4. Relation between the activity and $(Mo^{5+})_W$.
●: $(Mo^{5+})_W$, ○: activity.

Moreover, the relation between the catalytic activity and the molybdite-content is shown in Fig. 4. The catalysts were reduced under a hydrogen pressure of 170 Torr at 400 °C for 15 min before ethylene polymerization. In order to avoid solvent effects and a further reduction of the catalyst with ethylene, ethylene was polymerized under a pressure of 100 to 200 Torr at 0 °C in a gas-solid phase. The activity showed the polymerization rate. As Fig. 4 shows, the behavior

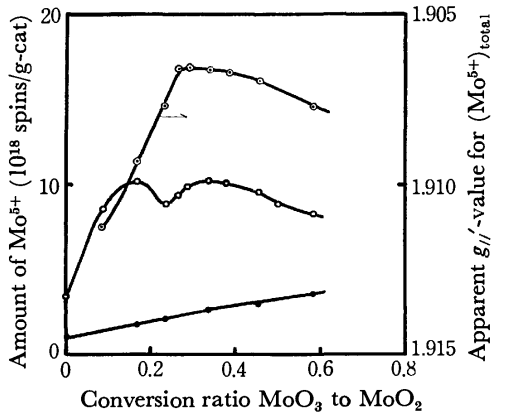

Fig. 5. Relation of the extent of reduction to $(Mo^{5+})_{total}$, $(Mo^{5+})_S$ or the apparent $g_{//}'$-value in 10.7 wt% MoO_3–Al_2O_3.
○: $(Mo^{5+})_{total}$, ●: $(Mo^{5+})_S$, ⊙: apparent $g_{//}'$-value for $(Mo^{5+})_{total}$.

of the activity was in fair agreement with that of $(Mo^{5+})_w$. Therefore, the activity might be attributed to molybdenum(V) in the state(W).

In order to confirm this conclusion, the relation between the conversion ratio of MoO_3 to MoO_2 and either $(Mo^{5+})_w$ or polymerization activity was studied, because $(Mo^{5+})_w$ must vary with the ratio. The relation of the ratio to $(Mo^{5+})_{total}$, the apparent $g_{//}'$-value, and $(Mo^{5+})_S$ were studied in 10.7wt%MoO_3–Al_2O_3 and are shown in Fig. 5. $(Mo^{5+})_S$ was determined by the ESR measurement of the state(S), which was prepared by the same procedure as described above. Before the measurement, the molybdenum oxide in the state(S) and 10.7wt%MoO_3–Al_2O_3 were reduced under a hydrogen pressure of 170 Torr at 400 °C. As Fig. 5 shows, $(Mo^{5+})_{total}$ had two variation points. The apparent $g_{//}'$-value was minimum in the ratio of 0.25 to 0.50. $(Mo^{5+})_S$ increased gradually with an increase of the ratio.

$(Mo^{5+})_S$ was calculated by substitution of $(Mo^{5+})_{total}$, $(Mo^{5+})_S$, and the apparent $g_{//}'$-value in Fig. 5 into Eqs. 3 and 4. The relation between the ratio and $(Mo^{5+})_w$ is shown in Fig. 6. $(Mo^{5+})_w$ was small in the ratio less than 0.20. However, $(Mo^{5+})_w$ increased remarkably in the ratio of 0.20 to 0.24 and showed

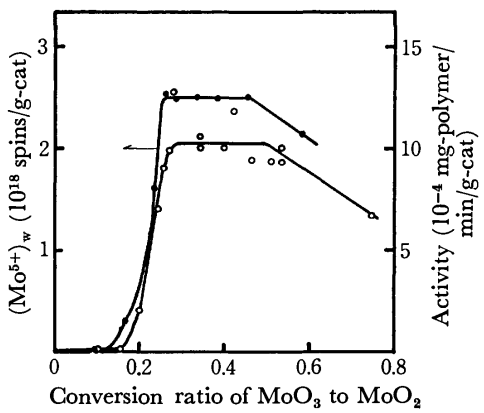

Fig. 6. Relation between the conversion ratio of MoO_3 to MoO_2 and either activity or $(Mo^{5+})_w$.
○: Activity, ●: $(Mo^{5+})_w$.

constant value of *ca.* 2.5×10^{18} spins/g-cat. in the ratio of 0.25 to 0.45. $(Mo^{5+})_w$ decreased gradually for higher ratios.

The relation between the ratio and the catalytic activity is shown in Fig. 6. For the determination of the activity, ethylene was polymerized under the same conditions as described above. As Fig. 6 shows, the behavior of the activity was in fair agreement with that of $(Mo^{5+})_w$.

The polyethylene, which was produced at 50 °C for 5 hr over 10.7wt%MoO_3–Al_2O_3, had an average value of 19000 in polymerization degree. The amount of chemisorbed hydrogen, the polymerization initiator, was calculated on the basis of this polymerization degree and from a consideration of the reaction mechanism.[1] The amount of chemisorbed hydrogen had a value of 1.0×10^{18} site/g-cat. This value corresponded closely to 2.5×10^{18} spin/g-cat. of $(Mo^{5+})_w$.

Exposure to oxygen poisoned completely the active 10.7wt%MoO_3–Al_2O_3 which had been reduced to the ratio of 0.35 and increased the apparent $g_{//}'$-value from 1.907 to 1.910. This increase could be explained by the assumption of the disappearance of $(Mo^{5+})_w$ from the active catalyst in which $(Mo^{5+})_{total}$, $(Mo^{5+})_S$, and $(Mo^{5+})_w$ were 10.2×10^{18}, 2.6×10^{18} and 2.5×10^{18} spin/g-cat, respectively, as Figs. 5 and 6 show. $(Mo^{5+})_w$ was determined to be 5.1×10^{18} spin/g-cat. by the substitution of these values in Eq. 3. The apparent $g_{//}'$-value was determined to be 1.910 by the substitution of $(Mo^{5+})_S$ and $(Mo^{5+})_w$ into Eq. 4. This $g_{//}'$-value was in fair agreement with the experimental one. Exposure to oxygen accompanied the complete disappearance of both catalytic acitivity and $(Mo^{5+})_w$ in 16.7wt%MoO_3–Al_2O_3 as well. Therefore, exposure to oxygen was proved to cause the complete disappearance of both catalytic activity and $(Mo^{5+})_w$.

From the facts described above, it was concluded that the activity should be attributed to molybdenum(V) in the state(W).

Semiempirical Relations in Molecular Liquids. II. Estimation of Thermal Expansivity

Yoshitsugu Oono

Department of Applied Science, Faculty of Engineering, Kyushu University, Higashi-ku, Fukuoka 812

(Received June 2, 1975)

A simple method for the estimation of thermal expansivity of the molecular liquid is proposed. Thermal expansivity α can be calculated by

$$\alpha = T^{-1}\phi(y)/y\phi'(y),$$

where $\phi(y)=p_h/\rho kT$, $y=\pi\rho a^3/6$, p_h is the pressure of a hard sphere fluid, a the effective hard core diameter of the molecule, ρ the number density, and k, T have their usual meanings. For the molecular liquids consisting of compact molecules, the equation gives a fairly accurate estimation of α, which is practically applicable to the estimation of the density of the liquids at 1 atm at desired temperature.

If the effective hard core diameter of the molecule and the density of the liquid are known, then the scaled particle theory (SPT) allows one to calculate surface tension, compressibility, *etc.* of the molecular liquids.[1] From knowledge of the density at room temperature and the approximate value of melting temperature, which are both easily measurable, hard core diameter a at desired temperature can be estimated by the method given in the preceding paper.[2]

If the value of thermal expansivity α calculated by the SPT were accurate, then the density at desired temperature could be estimated from the melting point and the density at room temperature. However, α estimated by the SPT is not sufficiently accurate for practical use.

The purpose of the present paper is to propose a method for the fairly accurate estimation of α from the effective hard core diameter of molecule and density. This method enables one to calculate the density at desired temperature at 1 atm from the melting point and the density at room temperature.

Theory

It is an oversimplified assumption that the volume change at higher densities is mainly due to the repacking of molecular hard cores.[1] Hence the effect of intermolecular attractive forces on the equation of state must be taken into account. The simplest method is to adopt the so-called augmented van der Waals (AVdW) equation of state,[3]

$$p = p_h - \varepsilon\rho^2, \tag{1}$$

where ρ is the number density, p the pressure, p_h the pressure of a hard sphere fluid with hard core diameter a, and ε a constant. Since $p_h/\rho kT$ is the function of $y=\pi\rho a^3/6$ only, we put $p_h=\rho kT\phi(y)$. Thermal expansivity α is given by

$$(\alpha T)^{-1} = (\partial \ln T/\partial \ln V)_p. \tag{2}$$

From Eqs. (1) and (2), taking into account that $p \ll \varepsilon\rho^2$ at higher densities, we obtain

$$(\alpha T)^{-1} = -1 + y\phi'(y)/\phi(y). \tag{3}$$

If $\varepsilon=0$, *i.e.*, $dp=dp_h$, then[1]

$$(\alpha T)^{-1} = 1 + y\phi'(y)/\phi(y). \tag{4}$$

However, the value of αT predicted by Eq. (3) is too large and that by Eq. (4) is too small.

According to the computer experiment by Alder and Hecht,[4] ε strongly depends on y at higher densities. Hence it is suggested that the crudest modification of the AVdW equation of state is to assume ε to be proportional to y^{-1} at higher densities ($y \gtrsim 0.4$). After modification of Eq. (1), we obtain

$$(\alpha T)^{-1} = y\phi'(y)/\phi(y). \tag{5}$$

In deriving Eqs. (3)—(5), the contribution of da/dT is not taken into account, since all the quantities are calculated for the model liquid consisting of hard spheres exerting attractive forces. The diameter of the hard sphere is so chosen after all the calculations are completed to describe the molecular liquid at temperature T. Note that αT does not depend on the details of the intermolecular attractive forces. In the following, we adopt the Carnahan-Stahling equation of state[5] for $\phi(y)$.

Comparison with Observed Data

The observed values of αT at 298 K for organic liquids of nearly spherical molecules and the calculated values of αT given by Eqs. (3)—(5) are plotted *vs.* y which is obtained by means of

$$\sigma T^{-1}\rho^{-2/3} = 4.28\times 10^{-17} y^{1/3}(2+y)/(1-y)^2, \qquad (6)$$

where σ is the surface tension in dyn/cm.[1,2] (Figs. 1—5). The observed data on thermal expansivity at 298 K are calculated by $(\rho_{293\,K}-\rho_{303\,K})/5(\rho_{293\,K}+\rho_{303\,K})$. The data on density and surface tension are obtained from Refs. 6—8. Surface tension scarcely depends on the details of the intermolecular attractive forces,[2] so that use of y estimated from Eq. (6) is suitable. Figures 1—5 show that αT of organic liquids of nearly spherical molecules without strong dipole moments and strongly hydrogen-bonding abilities satisfy Eq. (5), but not Eqs. (3) and (4).

Figure 6 shows that organic liquids of long chain-like molecules deviate considerably from Eq. (5). The deviation is not surprising since the SPT is so constructed as to treat liquids of spherical molecules.

Applications

Estimation of ρ–T *Relation at 1 atm.* As an application of the results of the preceding and the present papers, we show how to estimate ρ at T from the melting point and the density ρ_0 at temperature T_0. The effective hard core diameter a at melting point can be calculated from the melting point and the molecular structure. The effective hard core diameter a_0 at T_0 can be obtained by Eq. (6) from ρ_0 and parachor. Then we can calculate α at T_0 by means of Eq. (5). With the value of α obtained, we can estimate the density at $T_0+\Delta T$ by $\rho=(1-\alpha\Delta T)\rho_0$. The procedure is repeated until the desired temperature is reached. Some examples are given in Tables 1—4, where ΔT is

Liquid Argon at Triple Point. We have proposed the modification of the AVdW equation of state. This equation of state gives good estimation of α and isothermal compressibility β of liquid argon at triple point.

Longuet-Higgins and Widom[3] and Guggenheim[9] estimated α and β of liquid argon at triple point using the AVdW equation of state. The values obtained by Longuet-Higgins and Widom are $\alpha T=0.50$ and $\rho kT\beta=0.058$. Guggenheim estimated y at triple point to be 0.427 from the data of internal pressure, and obtained $\alpha T=0.57$ and $\rho kT\beta=0.0663$. The observed values are $\alpha T=0.37$ and $\rho kT\beta=0.0495$.[3]

Using the modified AVdW equation of state,

$$\frac{p}{\rho kT}=\frac{1+y+y^2-y^3}{(1-y)^3}-\varepsilon' y, \tag{7}$$

where ε' is a constant, and the data of internal pressure used by Guggenheim, we obtain $y=0.422$ at triple point. From this value of y we obtain $\alpha T=0.39$ and $\rho kT\beta=0.050$. These values agree well with the observed data.

Discussion

The effective hard core diameter can be calculated also from the data of isothermal compressibility.[1] The expression of isothermal compressibility in terms of y has been derived from the following considerations.[1] At higher densities the isothermal compression can be regarded as a process of repacking hard spheres. Thus

$$dp = dp_h. \quad (8)$$

The isothermal compressibility can be approximately expressed by

$$\beta = \rho^{-1}(\partial\rho/\partial p_h)_T. \quad (9)$$

If we adopt the equation of state of hard sphere fluid obtained from the original SPT, then we have in cgs unit

$$\rho\beta T = 7.2\times 10^{15} f(y), \quad (10)$$

where

$$f(y) = (1-y)^4/(1+2y)^2. \quad (11)$$

If we adopt the Carnahan-Stahling equation of state, then Eq. (11) is replaced by

$$f_{SC}(y) = (1-y)^4/[(1+2y)^2+y^4-4y^3]. \quad (12)$$

Function $f_{SC}(y)$ is slightly larger than $f(y)$. Using the observed values for ρ, β, and T, we can calculate the effective hard core diameter a_β of the molecule from Eq. (10).

Calculating a_β from Eq. (10) and Eq. (11), and a from Eq. (6), Mayer[10] has shown that a_β and a coincide with each other at room temperature. However, da/dT is about twice as large as da_β/dT. This suggests that the temperature range in which a_β and a are nearly equal is not wide and that there is no universal relation between σ and β. If there is a certain general relation between σ and β (as suggested by the SPT), the observed value of $\rho\beta T$ should be a one-valued function of y obtained from Eq. (6). Some examples of $\rho\beta T$–y relations are shown in Fig. 7 together with those calculated by using Eqs. (11) and (12). Figure 7 shows that, as expected, no universal relation exists between β and σ. At higher densities Eq. (12) is more accurate than Eq. (11). This corresponds to the accuracy of the Carnahan-Stahling equation of state at higher densities.

Since σ scarcely depends on the details of intermolecular forces, it can be concluded that β depends on the details of intermolecular forces in comparison with σ. Thus the assumption (8) is concluded to be oversimplified.

In contrast to this $\rho\beta T$–y relation, the temperature range in which Eq. (5) holds is not very narrow as is shown in Fig. 8.

The internal pressure calculated from the modified

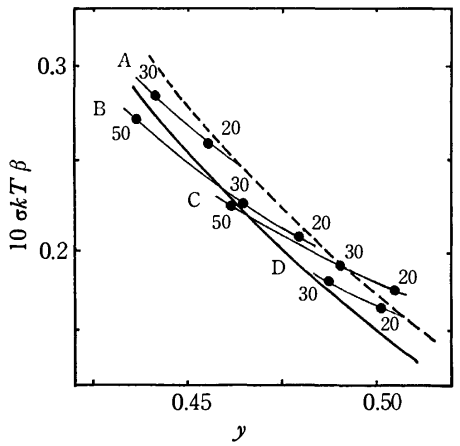

Fig. 7. Relation between compressibility and y. The numbers in the figure denote temperature in °C.

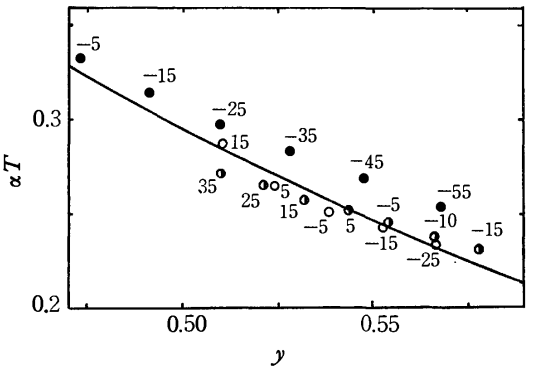

Fig. 8. Relation between thermal expansivity and y. The numbers in the figure denote temperature in °C.
●: Chloroform, ◑: bromobenzene, ○: chlorobenzene.
——: Eq. (5).

AVdW equation of state (7) is proportional not to ρ^2 but to ρ. This contradicts with the observation by Bianchi *et al.*[11] and also with an intuitive picture of the liquid state.[12] However, the modified AVdW equation of state predicts α fairly accurately and thus has a practical value. The original AVdW equation of state, which gives the internal pressure in proportion to ρ^2, gives poor results for α of molecular liquids and for the properties of liquid argon at triple point. As long as we use the van der Waals type equation of state, *i.e.*, $p=p_h-$(effect of intermolecular attractive forces), it is very difficult to work out the equation of state which predicts α accurately and at the same time gives the internal pressure in proportion to ρ^2. Thus there seems to be a limitation to the van der Waals type equation of state even at lower temperatures.

The author wishes to express his appreciation to Professor T. Oyama for a critical reading of the manuscript.

Ionic Adsorption of Lithium Bromide at the Mercury-Dimethyl Sulfoxide Interface

Kohichi YAMAMOTO and Shigeo HAYANO
Institute of Industrial Science, University of Tokyo, Minato-ku, Tokyo 106
(Received June 23, 1975)

The specific adsorption of bromide ions on a mercury electrode from lithium bromide solutions of dimethyl sulfoxide (DMSO) has been studied through the measurement of the differential capacity and the interfacial tension. The capacity data showed the evidence that anions are more weakly, but cations are more strongly, solvated by DMSO molecules than by H_2O. The amounts of specifically adsorbed bromide ions are greater than those values in water at the same electrode charge. The specific adsorption of cations (Li^+) was not found in this study. The inner layer capacity due to the amounts of specific adsorbed anions was calculated, and the ratio of the distances from the metal to the inner Helmholtz plane and to the outer Helmholtz plane were deduced. These values are comparable to those for LiCl in DMSO, but are greater than for water.

Many works on the specific adsorption and the inner layer structure of the electrical double layer have been reported in aqueous system. However, these have been few on non-aqueous systems, especially aprotic solvent systems. It is well known that the role of solvent molecules is very important in the structure of the electrical double layer. An aprotic solvent like dimethyl sulfoxide (DMSO) is very favourable for investigating the electrical double layer, for we can exclude the contribution due to protons. On the other hand, DMSO has been the subject of many recent electrochemical studies[1-4] directed towards the design of new battery systems. The specific adsorption of the supporting electrolyte on the electrode surface has a great influence on these studies. Furthermore, it will be necessary, for a detailed description of electrode kinetics, to analyze the structure of the electrical double layer.

Kolthoff and Reddy[5] obtained an electrocapillary curve of the 0.1M NaCl solution in DMSO. Payne[6] measured the electrocapillary curves and differencial capacities of the double layer for various inorganic salts in DMSO and in mixtures of DMSO and water. However, these studies did not attempt to go into any quantitative discussion of adsorbed ions because of the lack of thermodynamic data. Kim *et al.*[7] discussed the structure of the electrical dorble layer in the presence of LiCl from the measurement of the electrocapillary curves. Hills and Reeves[8] measured the activity coefficients of $LiNO_3$ in DMSO and investigated the degree of ionic adsorption from the measurement of the differential capacities. These two recent detailed studies, however, are different from each other in several points (*e.g.* regarding the solvent effect) in spite of the similar method of data analysis. It is important to investigate systematically halide ions (*e.g.* LiCl, LiB, LiI) in DMSO for the purpose of describing the structure of the electrical double layer and the ionic adsorption in detail. Therefore, a comparison of the above data with the corresponding data for aqueous systems will be useful in discussing the role of solvent molecules.

In the present paper, we will attempt to examine the structure of the electrical double layer in mercury–DMSO containing LiBr. The thermodynamic parameters for the double layer were calculated through measurements of the differential capacity and the interfacial tension.

Experimental

Differential capacity-potential curves were obtained by measuring the in- and out of-phase components of the AC admittance of the mercury electrode–DMSO solution interface by the use of a PAR model 170 electrochemistry system. A 10 mV (peak to peak) amplitude AC voltage with a frequency of 80 Hz was superimposed on the DC voltage applied between the dropping mercuy electrode (DME) and the platinum counter electrode. The scan rate of the DC voltage was 1 mV/s. The drop time of mercury was mechanically controlled at 5 s, and the capillary constant, m, for DME was 0.739 mg/s. The amplitudes of the in- and out of-phase components were recorded as a function of the DME potential. The differential capacity, C, was calculated from:

$$C = \frac{I_1^2 + I_0^2}{2\pi f I_0 V A} \quad (1)$$

where I_1 is the AC current of the in-phase, I_0 is that of the out of-phas,e f is the frequency (Hz), V is its amplitude, and A is the area of the electrode at the end of the drop life, as calculated from the flow rate and the drop time. The precision of the data obtained in this manner was about 0.5%.

The interfacial tension between the mercury electrode and the DMSO solution was measured at the electrocapillary maximum (*i.e.*, point of zero charge) to determine the integral constant in the process of the integration of the capacity-potential curve. This has been done by using a modified Lippmann type capillary electrometer. The capillary electrometer used in this work was constructed by taking several ideas presented by previous workers.[9-11] The tapering capillary was made of a Pyrex capillary tubing with an internal diameter of 1 mm. The tubing was drawn out in a gas flame so as to have the internal diameter of 15—20 μ. Then the capillary was cut at this point. The gas pressure above the mercury reservoir was controlled by a nitrogen gas pressure control system which consists of a series combination of two precision-variable bellows mounted over a screwdriven press. The gas pressure was measured with a Texas Instruments, Inc. Fused-Quartz Precision Pressure Gauge instead of a mercury manometer. A stereomicroscope was employed to observe the capillary tip. The window of the cell was finished to an optically plane to eliminate distortion. The precision of the interfacial tension in this methods is within 0.02%. For the measurements of both the differential capacity and the interfacial tension, the temperature of the cell was controlled at 25.0±0.1 °C. Prior to each measurement the solution was flushed with a high-purity nitrogen which had been deoxygenated, dehydrated in an anhydrous

calcium chloride column, and then presaturated by bubbling it through DMSO. DMSO was refluxed for several hours on calcium hydride and then fractionated through an efficient distillation column at a reduced pressure of about 5 Torr. The water content of the solvent was checked by means of Karl Fisher titration. The analytical reagent grade mercury was used without further purification, while the analytical grade anhydrous LiBr was used after have been dried at 180 °C under a vacuum for 24 hr.

Results and Discussion

Differential capacity *vs.* potential curves for LiBr in DMSO at six concentration levels between 0.753 M and 0.0196 M were obtained in the potential range of −0.35∼−1.65 V (*vs.* aqueous SCE), where no significant DC current and no frequency dispersion of capacity was observed. At more positive potentials, the measurements were not reproducible, this is due to the faradaic admittance. The aqueous SCE was used as a reference electrode, the junction between the reference electrode and the DMSO solution was kept constant in each experiment by employing the 0.200 M LiBr solution in DMSO. The liquid junction between 0.200 M solution and the test solution was made through a fritted glass. The measured potentials, E_m, were converted to the potential scale of the reference electrode reversible to the anion (*i.e.*, to the E^- scale) according to this equation:

$$E^- = E_m + E_{ljp} + \frac{RT}{F} \ln a_\pm \quad (2)$$

Here, E_{ljp} is the liquid junction potential between 0.200 M and x M LiBr in DMSO (test solution); it was calculated using the following equation:

$$E_{ljp} = (2t^+ - 1)\frac{RT}{F} \ln \frac{a_\pm}{a_{\pm 0.200M}} \quad (3)$$

The mean ionic activities, $a_\pm$, were taken form the data of Salomon.[12] The transference number for Li^+ in DMSO, t^+, was estimated to be 0.324 from the mobility data of Dunnett and Gasser.[13] The observed differential capacity *vs.* potential (converted to E^- scale) curves are shown in Fig. 1. The curves are featureless like those of the LiCl[7] and $LiNO_3$[8] solutions in DMSO. The capacity increases rapidly in the anodic branch; this is due to the specific adsorption of the anion. The anodic hump in the capacity curves observed in the cases of $LiClO_4$[6] and KPF_6[6,14] in DMSO were not found anywhere in the concentration range studied. The diffuse layer capacity minimum, which was observed with KPF_6,[6] $LiNO_3$,[8] KNO_3[14] in DMSO, was not detected even in the 0.0196 M LiBr solution. The diffuse layer capacity minimum appears in the vicinity of pzc if there is no significant ionic specific adsorption; *i.e.*, the structure of the double layer can be assumed to be a simple Stern model. Therefore, the differential capacity curves shown in Fig. 1 lead us to the conclusion that Br^- is more specifically adsorbed on the mercury electrode than PF_6^-, ClO_4^- and NO_3^-. In the cathodic branch, the capacity decreases monotonously with the electrode potential to the value of about 7 $\mu F/cm^2$. This limiting value is comparable with that obtained in DMSO containing lithium salt.[6-8] In aqueous systems, in general, at higher cathodic potentials a rise in the capacity curves is observed. This is due to the onset of the faradaic reaction. In the present system, such behaviour was not detectable, so, in the potential region of the invariant capacity (*i.e.*, at extreme cathodic potentials), the structure of the electrical double layer may be determined mainly by the Li^+ cation, which is more firmly solvated in DMSO than in aqueous solutions. This point will be discussed later in detail. The difference in the limiting value in DMSO from those in aqueous solutions (about 16 $\mu F/cm^2$) can be expected from the lower dielectric constant of DMSO, since, in these potential regions, we can assume that there is no ionic specific adsorption.

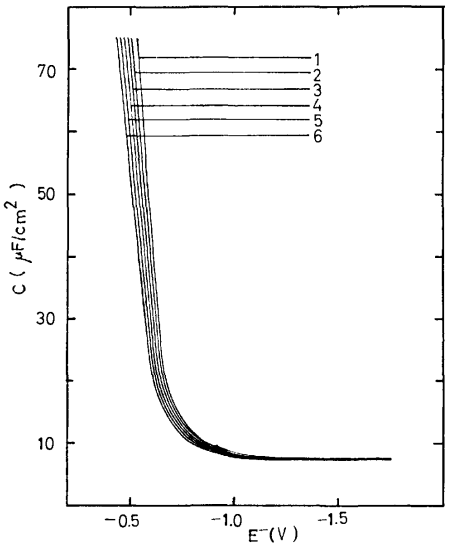

Fig. 1. Differential capacity of electrical double layer at mercury electrode in contact with LiBr solutions in DMSO at 25 °C: (1): 0.753 M, (2): 0.497 M, (3): 0.196 M, (4): 0.0979 M, (5): 0.0497 M, (6): 0.0196 M.

For a detailed discussion, it is a matter of prime importance to establish to what degree bromide ions are specifically adsorbed from DMSO. The capacity *vs.* potential data were integrated to obtain the charge density on the electrode, q_m, and the interfacial tension, γ, over the entire range of concentrations and potentials with the aid of a computer (FACOM 230-55) using a program written in FORTRAN. Then Parsons' auxiliary function, ξ,[15] was evaluated from this equation:

$$\xi_- = \gamma + q_m E^- \quad (4)$$

The surface excess of Li^+ cations, Γ_+, was then calculated from this relationship:

$$\left(\frac{\partial \xi_-}{2RT\partial \ln a_\pm}\right)_{q_m} = -\Gamma_+ = -\frac{q_+}{F} \quad (5)$$

This calculation was carried out first by computer differentiation and then checked manually. The results, expressed as q_+ (*i.e.*, the charge due to the excess of cations), are shown in Fig. 2. This shows that the bromide ion is adsorbed so strongly that the surface excess of lithium ions is positive at all concentrations and all values of q_m. Figure 2 also shows a minimum at all concentrations which is similar to those found with

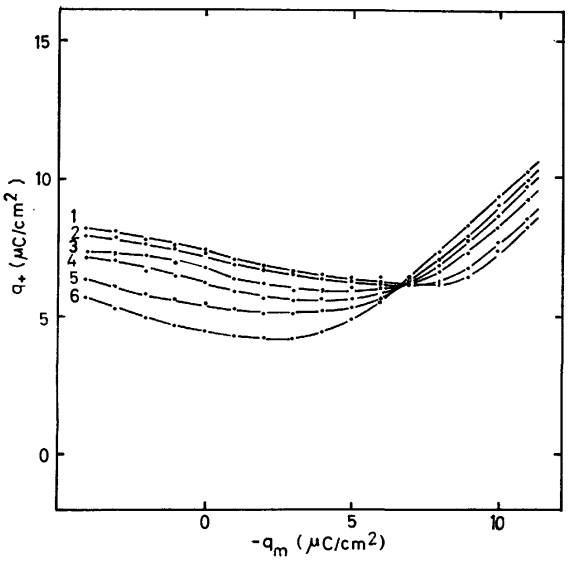

Fig. 2. Charge due to the cations as a function of the electrode charge (q_m) at the corresponding concentration as given in Fig. 1.

LiCl[7] and $LiNO_3$[8] in DMSO and with aqueous solutions of strongly adsorbed species, such as halide ions.[16] The appearence of the invariant point at $q_m = -7\ \mu C/cm^2$ is interesting; such a point is also found in the comparable study of LiCl in DMSO.[7] This invariant point, however, is more negative than those of chloride ions ($q_m = -4\ \mu C/cm^2$).

From the similarity of the surface excess curve with those for aqueous alkali halide solutions[16-17] and the results obtained in the present work, it seems reasonable to assume that lithium ions are present only in the diffuse layer. That is, $q_+ = q_+^{2-s}$, where q_+^{2-s} is the charge in the diffuse layer. On the basis of this assumption, we calculated the potential of the outer Helmholtz plane, ϕ_2, from q_+^{2-s} according to the diffuse layer theory;[18]

$$q_+^{2-s} = \left(\frac{RT\varepsilon C^s}{2\pi}\right)^{1/2}\left[\exp\left(-\frac{F}{2RT}\phi_2\right) - 1\right] \qquad (6)$$

Here, C^s is the electrolyte concentration and ε is the dielectric constant in the diffuse layer, assuming it to be equal to the bulk dielectric constant of DMSO (46.7).[19] Then the charge due to the bromide ions, q_-, and that distributed in the diffuse (q_-^{2-s}) and inner (q_-^1) fouble layer were evaluated according to:

$$-q_m = q_+^{2-s} + q_- \qquad (7)$$

$$q_- = q_-^{2-s} + q_-^1 \qquad (8)$$

$$q_-^{2-s} = -\left(\frac{RT\varepsilon C^s}{2\pi}\right)^{1/2}\left[\exp\left(\frac{F}{2RT}\phi_2\right) - 1\right] \qquad (9)$$

The plots of ϕ_2 *vs.* q_m as a function of the LiBr concentration are shown in Fig. 3. The curves have a striking resemblance to those of the LiCl solution.[7] In the absence of a specific adsorption such as in NaF aqueous solutions,[20-21] the sign of ϕ_2 changes at pzc. However, in the present system, the specific adsorption of bromide ions is so strong that ϕ_2 is negative over the entire range of q_m and the values of ϕ_2 are more negative than those obtained in chloride ions.

The specifically adsorbed charge due to bromide ions

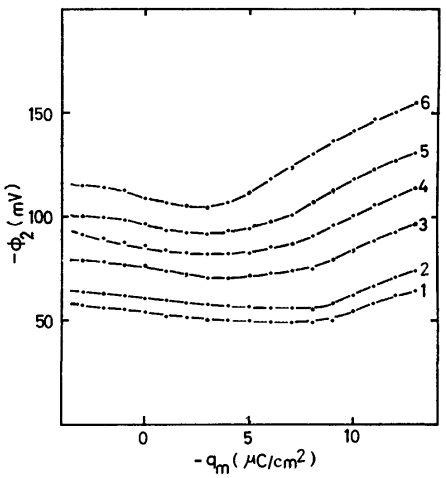

Fig. 3. Potential of outer Helmholtz plane (ϕ_2) as a function of the value of q_m at various LiBr concentrations.

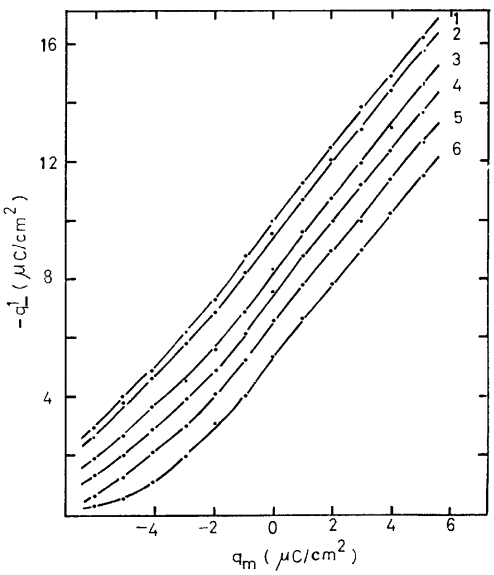

Fig. 4. Charge due to specifically adsorbed bromide ions (q_-^1) as a function of the electrode charge at the corresponding concentration as given in Fig. 1.

(q_-^1) is shown in Fig. 4 as a function of q_m and the LiBr concentration. The figure shows that q_-^1 is a monotonous function of q_m and that the degree of the concentration dependence of q_-^1 changes with q_m, that is, increases with the electrode charge. This behaviour is similar to that found in chloride ions[7] in DMSO and is different from that in nitrate ions[8] in DMSO (*i.e.*, the nitrate-ions system shows a reversed tendency.). At $q_m > 0$ the curves become virtually parallel lines. At the same concentration, say at 0.1 M, some comparisons can be made with the system of other electrolytes in DMSO and with the aqueous potassium bromide solution. The minimum q_m value ($0\ \mu C/cm^2$), the $q_-^1 - q_m$ curves of which in Fig. 4 deviate from a straight line, is more negative than those obtained in chloride ions[7] and nitrate ions[8] in DMSO (*ca.* 2 and 4 $\mu C/cm^2$ respectively), but it is more positive than that with potassium iodide in formamide[22] (*ca.* $-2\ \mu C/cm^2$). The values of the specifically adsorbed charge at pzc are as

follows; −7.5 (in the present system), −5.1 (in KBr aqueous solution),[17] −4.5 (in LiCl solution in DMSO),[7] −3.6 (in $LiNO_3$ solution in DMSO)[8] and −1.2 (in KPF_6 solution in DMSO)[14] (unit is $\mu C/cm^2$). From these results, it may be concluded that the degree of the specific adsorption of anions in DMSO changes in the following order:

$$PF_6^- < NO_3^- < Cl^- < Br^-$$

and the specific adsorption of bromide ions is stronger in DMSO than in H_2O.

The limiting values of the slope at positive q_m values were −1.26~−1.35. These values of the dq_-^1/dq_m will be discussed in the section on Esin and Markov effects below.

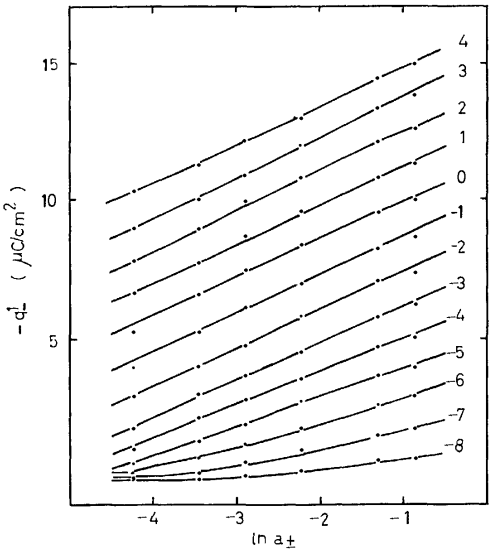

Fig. 5. Charge due to specifically adsorbed bromide ions (q_-^1) as a function of ln $a_\pm$ at the constant value of charge on electrode (q_m). The value of q_m is indicated by each line in $\mu C/cm^2$.

We also show the logarithmic isotherms at a constant q_m in Fig. 5. The figure is similar in character to that obtained for aqueous bromide and iodide solutions.

It is usual to invenstigate the degree of specific adsorption in terms of the Esin and Markov coefficients, defined as:[23-24]

$$\left(\frac{\partial E^+}{\partial \mu}\right)_{q_m} = -\left(\frac{\partial \Gamma_-}{\partial q_m}\right)_\mu \tag{10}$$

or

$$\left(\frac{\partial E^+}{\partial \ln a_\pm}\right)_{q_m} = \frac{2RT}{F}\left[\left(\frac{\partial q_-^1}{\partial q_m}\right)_\mu + \left(\frac{\partial q_-^{2-s}}{\partial q_m}\right)_\mu\right] \tag{11}$$

where E^+ is the potential with respect to the reference electrode reversible to the cation. The right-hand sides of Eq. (10) and (11) can be predicted as follows from the diffiuse double layer theory in the absence of any specific adsorption:

$$\left(\frac{\partial E^+}{\partial \ln a_\pm}\right)_{q_m} = -\frac{1}{2}\exp\left[\sinh^{-1}\left(\frac{q_m}{2A}\right)\right]\left[1+\left(\frac{q_m}{2A}\right)^2\right]^{-1/2}$$

$$A = \left(\frac{RT\varepsilon C^s}{2\pi}\right)^{1/2} \tag{12}$$

The observed results are shown in Fig. 6. According to Eq. (12), if any specific adsorption is absent, two

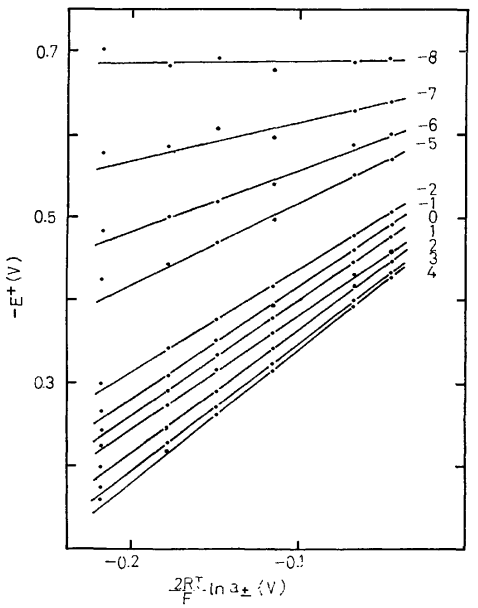

Fig. 6. Esin and Markov plots for LiBr in DMSO at 25 °C. The value of q_m in $\mu C/cm^2$ is incicated by each line.

limiting slopes can be found, *i.e.*, 0 for $q_m \to -\infty$ and −1 for $q_m \to +\infty$ respectively. Furthermore, the value of the slope is −0.5 at pzc (*i.e.*, at $q_m=0$). In this study, however, the values of the slope evidently deviate from those given by Eq. (12); that is because of the significant specific adsorption of bromide ions. The slope becomes steeper with an increase in the electrode charge. At pzc this value is −1.2, and it reaches the limiting value of −1.3 at $q_m=4\,\mu C/cm^2$. This limiting value is compared with those obtained for other electrolytes in DMSO in Table 1. In the second row, the values of $-(\partial q_-^1/\partial q_m)_\mu$ (*i.e.*, the derivatives of the adsorbed anion charge with respect to the electrode charge at a constant chemical potential) are shown. It is well known that the Esin and Markov coefficients are approximately equal to this value[7-8,25] (*cf.* Eq. (11)). In the present work, the two values agree well. This shows the consistency of the experimental data. The values for LiBr in the first row and in the second row in Table 1 are the highest among the electrolytes. The high specific adsorptivity of the bromide ions was confirmed again by these results.

In the discussion of the specific adsorption of ions, we must take into account two important factors. One is the solvation energy of ions, and the other is the interaction between the metal surface and solvent molecules. According to Parker,[26] such dipolar aprotic

solvents as DMSO poorly solvate anion.[12,27] Salomon has reported that the free energy of transfer of LiBr from H_2O to DMSO at 25 °C is 2.515 kcal/mol, and concluded that the order of increasing solvation by DMSO molecules is:

$$Cl^- < Br^- < I^-$$

in spite of the solvation being poorer than the H_2O system. This behaviour is reflected in our study by the rapid rise on the capacity curves in the anodic potential in Fig. 1. Furthermore, as for the ionic solvation, we may infer that the small cations like Li^+ are solvated more steadily in DMSO than in H_2O. This is supported by the evidence that the significant capacity rise found in the case of an aqueous system was not observed in Fig. 1. From these results, the higher specific adsorptivity of bromide ions in the DMSO system seems to be attributable to the difference in the degree of ionic solvation. However, the second factor (*i.e.*, the interction of the mercury electrode surface and the DMSO molecules) is also important, as was pointed out by Hills *et al.*[8] The effect of this factor can be observed on the values of the Esin and Markov coefficients and $-(\partial q_-^1/\partial q_m)_\mu$. These values in Table 1 are higher than those of aqueous solutions for other electrolytes. This may be the influence of the property of the solvent molecules. Hills *et al.*[8] stressed this factor in their study of $LiNO_3$ in DMSO, since the value of $-(\partial q_-^1/\partial q_m)_\mu$ rises with the electrode charge. These values are higher in their system than in the corresponding aqueous system (up to 1.3 for DMSO and 1.22 for water). In our present work, however, we did not observed such a significant difference between these two systems. It is difficult and dangerous to conclude which factor predominantly governs the specific adsorption of ions from only these data. Independent measurements from this point of view are desirable.

For the detailed discussion of the structure of the inner layer, the potential drop across the layer between the electrode surface and the outer Helmholtz plane (oHp), ϕ_{m-2}, was calculated from this relationship:[7,22]

$$\phi_{m-2} = E_m + E_{ljp} - \phi_2 \qquad (13)$$

Here, it should be mentioned that the ϕ_{m-2} potential computed in this way is not equal to the rational potential in the sense of Grahame's definition. ϕ_{m-2} is shown in Fig. 7 as a function of q_-^1 at constant values of q_m. The relationship shown in Fig. 7 indicates a linear function of q_-^1 and the slopes of these straight lines are almost the same except at very negatives of q_m. This slope has the relationship with the standard free energy of adsorption, ΔG:[28-30]

$$\left(\frac{\partial\phi_{m-2}}{\partial q_-^1}\right)_{q_m} = \frac{RT}{F}\left(\frac{\partial(-\Delta G/RT)}{\partial q_m}\right)_{T,P} \qquad (14)$$

Therefore, if we base our discussion on Eq. (14), we may infer that the free energy of adsorption is a linear fuction of q_m and is independent of q_-^1. This behaviour has been shown in the aqueous solution of ions with high specific adsorptivity ions such as I^-[17] and Cl^-[7] in the DMSO solution.[7] However, Eq. (14) is only an approximation because it does not take into account the contribution of the diffuse double layer. This contribution may be very small in the potential range where the specific adsorption of ions is predominant. On the other hand, it becomes effective in other potential ranges. This is supported by the results that the deviation from the constant slope in Fig. 7 increases with the decrease in q_m (*i.e.*, becoming more negative).

The potential of ϕ_{m-2} can be divided into two components according to the following equation:[31]

$$d\phi_{m-2} = \left(\frac{\partial\phi_{m-2}}{\partial q_-^1}\right)_{q_m} dq_-^1 + \left(\frac{\partial\phi_{m-2}}{\partial q_m}\right)_{q_-^1} dq_m. \qquad (15)$$

In Eq. (15), we define the corresponding integral capacities, ${}_{q_-^1}C^i$ and ${}_{q_m}C^i$, according to Grahame and Parsons by:[32]

$$\begin{aligned} {}_{q_-^1}C^i &= 1/(\partial\phi_{m-2}/\partial q_-^1)_{q_m} \\ {}_{q_m}C^i &= 1/(\partial\phi_{m-2}/\partial q_m)_{q_-^1} \end{aligned} \qquad (16)$$

As a first approximation, we assumed that the inner layer can be represented by two condensers in series,

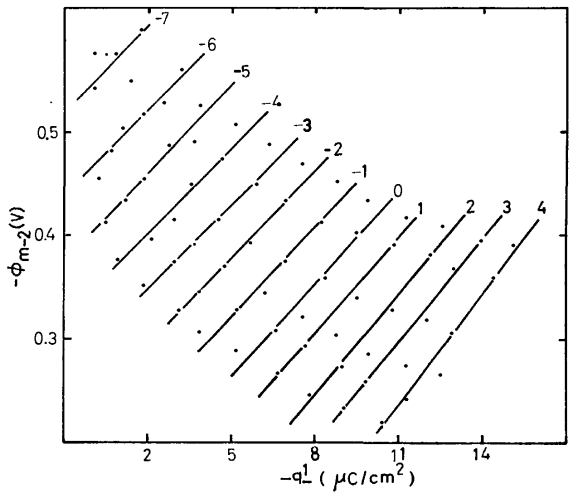

Fig. 7. Potential difference across the inner layer generated by specifically adsorbed anion (ϕ_{m-2}), as a function of the charge due to specifically adsorbed bromide ions (q_-^1) at the constant electrode charge. The value of electrode charge is indicated by each line in μC/cm^2.

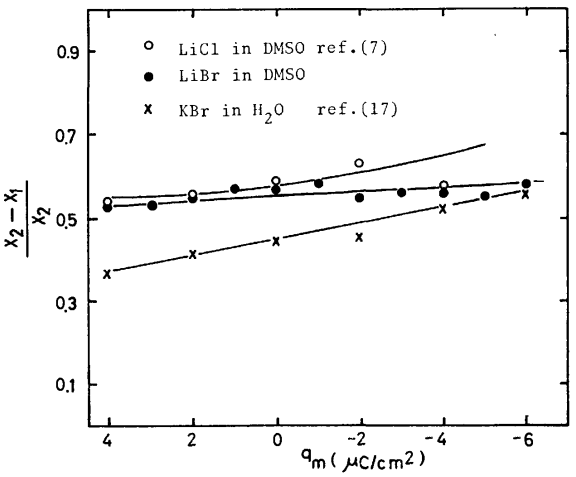

Fig. 8. Variation of distance ratio ($(x_2-x_1)/x_2$) as a function of the electrode charge and comparison it with other data.

the mercuy surface to the inner Helmholtz plane (iHp) and the iHp to the oHp; furthermore, we assumed that the dielectric constants are equal in these two layers. Then we computed the distance ratio $(x_2-x_1)/x_2$ from this relationship:

$$\frac{x_2-x_1}{x_2}=\frac{{}_{q_m}C^i}{{}_{q^-}C^i}, \qquad (17)$$

where x_1 and x_2 are the distances from the metal surface to the iHp and to the oHp respectively. From the results of Fig. 7 we found the integral capacities to be ${}_{q^-}C^i=30\sim36$ μF/cm² and ${}_{q_m}C^i=16\sim21$ μF/cm². These values are comparable to those for LiCl in DMSO. The distance ratios mentioned above found to be 0.52—0.58; the dependence of this ratio on q_m is shown in Fig. 8, where it is also compared with other electrolytes and aqueous system. The plot in the present study seems to be constant over the range of q_m studied and does not show a definite tendency to increase with a decrease in the q_m values. The values of the distance ratio are greater than the corresponding values of bromide ions in an aqueous system[17] (0.35—0.55) in the range of $q_m>0$. However, they are nearly the same at negative values of q_m. If we assume x_2 to be the sum of the thickness of DMSO monolayer (4.8 Å)[33] and the crystallographic radius of the lithium ion of 0.68 Å,[34] the resulting value of x_1 (*i.e.*, the thickness of the iHp) varies from 2.3 Å to 2.6 Å. These are greater than the crystallographic radius of the bromide ion (1.96 Å).[34] If x_1 is assumed to be 1.96 Å, the thickness of the oHp becomes from 4.1 to 4.7 Å. Considering the incompliteness of the solvent monolayer formation, we may say that some of the lithium ions sit inside the DMSO monolayer and that others are present on the outside of the monolayer of solvent molecules. However, this discussion has been based on a simple condenser model; it is only a qualitative discussion. For more detailed discussion, it will be necessary for us to take into consideration the dependence of the dielectric constant on the distance from electrode surface, the influence of the variation in solvent dipoles, and so on.

The authors with to thank Miss Masako Arai and Mr. Masami Iiyama who assisted them extensively in this study.

Theory for Longitudinal Ion Cyclotron Resonance Power Absorption: Application to Line Shape for Nonreactive Ion

Katsuyuki AOYAGI

JEOL Ltd., 1418 Nakagami, Akishima-shi, Tokyo 196

(Received July 2, 1975)

The rf electric field in circular concave electrodes for longitudinal ion cyclotron resonance is investigated. The potential equation of this rf electric field is theoretically derived from Laplace's equation. The equation of the motion of an ion which moves under the simultaneous application of the magnetic field and this rf electric field was solved. The solution of this equation is used to obtain the instantaneous and total power absorptions of the ion from the rf electric field. The power absorption expression is used to derive the line-shape expresssions of the longitudinal ion cyclotron resonance.

Ion cyclotron single- and multiple-resonances have been used extensively in recent years to study a wide field of gas-phase chemistry. The reviews[1] describe the use of ion cyclotron resonance (ICR) in the determination of reaction mechanisms, reaction rates, ion structures, relative acidities and basicities, photodetachment processes, the detection of excited states, thermochemistry, and other properties of ions. Recently, the technique of Fourier transform ion cyclotron resonance (FT-ICR) was developed by Comisarow and Marshall,[2] it improves the ICR spectral resolution by orders of magnitude. By combining the high resolution with the inherent high sensitivity of ICR, FT-ICR makes possible new fields of diamagnetic resonance spectroscopy, such as mass spectrometry with regard to organic chemistry, biology, and medicine.

The principle of ICR is based phenomenologically on the classical motion of charged particles in the magnetic and electric fields. An ion moving in a homogeneous magnetic field describes a helical path which is a combination of a translation along the field line and a circular motion in a plane perpendicular to the direction of the magnetic field. The angular frequency or cyclotron frequency, ω, of the circular motion is given by $\omega=eH/me$, where e/m is the charge-to-mass ratio; H, the magnetic field strength, and c, the speed of light. If an rf electric field with the frequency of ω_1 is applied perpendicular to the magnetic field, and the magnetic field or the rf frequency is swept, the ion resonates at $\omega=\omega_1$ and absorbs energy from the rf electric field; then the ions of a particular e/m ratio are accelerated and the radius of its orbit increases with the time.

ICR is of two types, longitudinal ICR and transverse ICR. In the case of transverse ICR,[1] the guiding center of the circular motion of the ion is migrated at right angles to both the magnetic and electric fields with a uniform drift velocity of v_d. In the other case of longitudinal ICR,[3] the guiding center of the circular motion of the ion is migrated along the magnetic line of force with a uniform traveling velocity of v_z.

In an application of FT-ICR to a wide mass range, a more intence magnetic field than that of the electromagnet used widely is required. Super conducting magnet (SCM)[4] satisfies the requirement mentioned above, and longitudinal ICR is suitable for FT-ICR using SCM.

In this paper, we will propose a potential equation for the longitudinal ICR cell and an exact solution of the equation of the motion of the ion used for driving the power absorption of an ion.

Result and Discussion

RF Electric Field in the ICR Cell. In order to treat the problem, we consider the rf electric field in a vacuum produced by circular concave electrodes arranged cylindrically as is shown in Fig. 1. Let us assume that the frequency of the rf electric field is sufficiently low enough for the displacement current to be neglected, and let us also ignor the axial component of the electric field in the ICR cell. The problem can be reduced to that of solving Laplace's equation:

$$\Delta V = 0, \tag{1}$$

under given conditions, where V is a scalar electric potential. Electric field, $\mathbf{E}$, can be obtained from the potential, V, by using this relation:

$$\mathbf{E} = -grad\, V. \tag{2}$$

Equation (1) is expressed in cylindrical coordinates (r, θ) as:

$$\frac{1}{r}\cdot\frac{\partial}{\partial r}\left(r\frac{\partial V}{\partial r}\right)+\frac{1\partial^2 V}{r^2\partial\theta^2}=0. \tag{3}$$

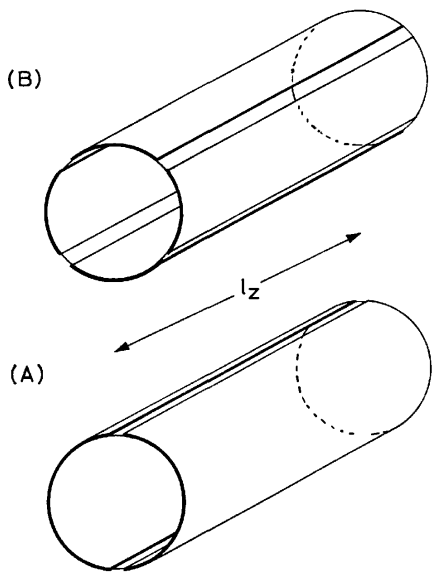

Fig. 1. Electrodes arrangement for theoretical analysis. (A) 2-Split electrodes, (B) 4-split electrodes.

After some analytical treatment, we solve Eq. (3), the result is given by Eq. (A4) (see Appendix). By substituting Eq. (A4) into Eq. (2), we then obtain the expressions of the rf electric field in the case of 2-split electrodes as follows:

$$\mathbf{E}(r)_2 = \left\{ -\frac{2(V_1-V_2)}{\pi} \sum_{k=1}^{k=\infty} \frac{(-1)^{k-1}}{r} \left(\frac{r}{R}\right)^{2k-1} \times \cos(2k-1)\theta \right\} \sin(\omega_1 t+\phi_1) \quad (4a)$$

$$\mathbf{E}(\theta)_2 = \left\{ \frac{2(V_1-V_2)}{\pi} \sum_{k=1}^{k=\infty} \frac{(-1)^{k-1}}{r} \left(\frac{r}{R}\right)^{2k-1} \times \sin(2k-1)\theta \right\} \sin(\omega_1 t+\phi_1), \quad (4b)$$

where V_1 and V_2 are the electric potentials applied to electrodes, and R, the radius of the cylinder indicated in Fig. 1.

Solution of the Equation of Motion. In absence of reactive collisions, the motion of an ion in the ICR cell can be described as follows:

$$\frac{d\mathbf{v}}{dt} = \frac{e}{m}\mathbf{E}(t) + \frac{e}{mc}\mathbf{v}\times\mathbf{H} - \xi\mathbf{v}, \quad (5)$$

where ξ is the reduced collision frequency that specifies the rate of the momentum relaxation of the ion.[5a]

The Cartesian coordinates system is chosen so that the static magnetic field, H, is parallel to the z axis and the rf electric field is perpendicular to the z axis. Therefore, the expressions of the rf electric field in the cylindrical coordinates are transformed to those of the Cartesian coordinates.[6] Equation (4) is transformed as follows:

$$\mathbf{E}(\mathbf{x})_2 = \left\{ -\frac{2(V_1-V_2)}{\pi R}\left[1 - \frac{x^2-y^2}{R^2} + \frac{x^4-6x^2y^2+y^4}{R^4} - \cdots\right]\right\} \sin(\omega_1 t+\phi_1), \quad (6a)$$

$$\mathbf{E}(\mathrm{y})_2 = \left\{ -\frac{2(V_1-V_2)}{\pi R}\left[\frac{2xy}{R^2} - \frac{4x^3y-4xy^3}{R^4} + \frac{6x^5y-20x^3y^3+6xy^5}{R^6} - \cdots\right]\right\} \sin(\omega_1 t+\phi_1). \quad (6b)$$

Equation (5) is now separated into an equation of $\mathbf{v}_z$ only and two coupled equations of $\mathbf{v}_x$ and $\mathbf{v}_y$. The relevant equations of motion are, then:

$$\frac{d\mathbf{v}_x}{dt} = \frac{e}{m}\mathbf{E}_x \sin(\omega_1 t+\phi_1) + \omega\mathbf{v}_y - \xi\mathbf{v}_x, \quad (7a)$$

$$\frac{d\mathbf{v}_y}{dt} = \frac{e}{m}\mathbf{E}_y \sin(\omega_1 t+\phi_1) - \omega\mathbf{v}_x - \xi\mathbf{v}_y, \quad (7b)$$

where $\mathbf{E}_x$ or $\mathbf{E}_y$ only denotes the expression in the brace of Eq. (6).

An ion whose initial velocity, $\mathbf{v}_0$, is due to the thermal velocity leads to a circular motion with the phase angle of ϕ_0; then, $\mathbf{v}_x(0) = -\mathbf{v}_0 \sin\phi_0$ and $\mathbf{v}_y(0) = \mathbf{v}_0 \cos\phi_0$ at $t=0$. The exact solution of Eq. (7) is given by:

$$\mathbf{v}_x = \mathbf{v}_0 \sin(\omega t-\phi_0)\exp(-\xi t) + \frac{e}{m}(\alpha\mathbf{E}_x - \beta\mathbf{E}_y), \quad (8a)$$

$$\mathbf{v}_y = \mathbf{v}_0 \cos(\omega t-\phi_0)\exp(-\xi t) + \frac{e}{m}(\beta\mathbf{E}_x + \alpha\mathbf{E}_y), \quad (8b)$$

where;

$$\alpha = A\sin(\omega_1 t+\phi_1) - B\cos(\omega_1 t+\phi_1) - [(A\cos\omega t + D\sin\omega t)\sin\phi_1 - (B\cos\omega t - C\sin\omega t)\cos\phi_1]\exp(-\xi t),$$

$$\beta = D\sin(\omega_1 t+\phi_1) + C\cos(\omega_1 t+\phi_1) + [(A\sin\omega t - D\cos\omega t)\sin\phi_1 - (B\sin\omega t + C\cos\omega t)\cos\phi_1]\exp(-\xi t),$$

A, B, C, and D are given in the Appendix.

Line-shape Expression for Nonreactive Ion. *a) Power Absorption of an Average Nonreactive Ion*: The power absorption, A, of an ion from the rf electric field is given by:

$$A = \langle e\mathbf{E}(t)\cdot(\mathbf{v}_x+\mathbf{v}_y)\rangle. \quad (9)$$

The initial velocity of an ion with the phase angle of ϕ_0 will not contribute to the actual power absorption. Substituting Eq. (8) into Eq. (9), the power absorption can be obtained by averaging over the ϕ_1 phase angle, since all the values of ϕ_1 are equally probable. With the approximation that:

$$\omega_1 + \omega \approx 2\omega, \qquad \xi \ll \omega_1, \quad (10)$$

the instantaneous power absorption of an average ion is found to be:

$$A(\omega_1 \mp \omega) = \frac{e^2(\mathbf{E}_x^2+\mathbf{E}_y^2)}{4m[(\omega_1-\omega)^2+\xi^2]}\{\xi + [(\omega_1-\omega)\sin(\omega_1-\omega)t - \xi\cos(\omega_1-\omega)t]\exp(-\xi t)\}. \quad (11)$$

b) Total Power Absorption for Nonreactive Ion: Ions are produced in a source region with electron impact at a rate of n_0 ions per second; then they move towards the ion collector through an analyzer region at a constant traveling velocity. It has been assumed that the length of the analyzer region is considerably longer than the diameter of the ICR cell and that the distribution of ions is uniform inside the ICR cell. There are a constant number, $n_0\tau$, of ions in the time τ for an ion move through the analyzer, each absorbing energy at the rate given in Eq. (11). Thus, the total power absorption $A(T)$, is obtained by averaging the integration from 0 to τ, the time required for the ions to absorb energy from the applied rf electric field. The averaged total power absorption is given by:

$$A(T, \omega_1 \mp \omega) = \frac{1}{\tau}\int_0^\tau n_0\tau A(\omega_1 \mp \omega)d\tau = \frac{n_0e^2(\mathbf{E}_x^2+\mathbf{E}_y^2)}{4m[(\omega_1-\omega)^2+\xi^2]}\left\langle \xi\tau + \frac{(\omega_1-\omega)^2-\xi^2}{(\omega_1+\omega)^2+\xi^2} - \left\{\frac{[(\omega_1-\omega)^2-\xi^2]\cos(\omega_1-\omega)\tau + 2\xi(\omega_1-\omega)\sin(\omega_1-\omega)\tau}{(\omega_1-\omega)^2+\xi^2}\right\} \times \exp(-\xi\tau)\right\rangle, \quad (12a)$$

and:

$$A(T, \omega_1=\omega) = \frac{n_0e^2(\mathbf{E}_x^2+\mathbf{E}_y^2)}{4m\xi^2}\left\{1 - \frac{1}{\xi\tau}[1-\exp(-\xi\tau)]\right\}. \quad (12b)$$

If the pressure is sufficiently high for each ion to undergo many nonreactive collisions, Eq. (12a) is reduced to:

$$A(T, \text{high-pressure}) = \frac{n_0 e^2(\mathbf{E}_x^2+\mathbf{E}_y^2)\tau}{4m}\frac{\xi}{(\omega_1-\omega)^2+\xi^2} \quad (13)$$

by the application of the $\xi t \gg 1$ approximation. This high-pressure power absorption represents the Lorentzian line shape. In the collisionless limit, $\xi \to 0$, Eq. (12a) is reduced to:

$$A(T, \text{low-pressure}) = \frac{n_0 e^2(\mathbf{E}_x^2+\mathbf{E}_y^2)}{4m(\omega_1-\omega)^2}[1-\cos(\omega_1-\omega)\tau]. \quad (14)$$

The line shapes of the total power absorption of longitudinal ICR for the ensemble of ions are represented by Eqs. (12)—(14).

Furthermore, the total power absorption and the line-shape expressions for such reactive ions as the primary, secondary, and tertiary ions are formularized theoretically; results similar to those reported previously[5b] have been obtained. A detailed discussion of the longitudinal ICR power absorption for the reactive ions will be published in the near future.

Appendix

a) Solution of Eq. (3).

To solve Eq. (3), we shall assume V in the following form:

$$V(r, \theta) = R(r)G(\theta)\sin(\omega_1 t+\phi_1). \quad (A1)$$

By substituting (A1) into Eq. (3) and by solving the resultant differential equations, we get the general solution of Eq. (3):[7]

$$V(r, \theta) = \sum_{n=0}^{n=\infty}[(r^n(A_n\cos n\theta + B_n \sin n\theta) + r^{-n}(C_n\cos n\theta + D_n \sin n\theta)]\sin(\omega_1 t+\phi_1), \quad (A2)$$

where A_n, B_n, C_n, and D_n are constants which should be determined from the boundary conditions. If we impose these boundary conditions:

$$\mathbf{E} \neq \infty \quad \text{for } r = 0$$
$$V(\theta) = V(-\theta) \quad \text{for } -\pi < \theta < \pi$$

on Eq. (A2), V becomes:

$$V(r, \theta) = \left[a_0+\sum_{n=1}^{n=\infty}\left(\frac{r}{R}\right)^n a_n \cos n\theta\right]\sin(\omega_1 t+\phi_1), \quad (A3)$$

where R is the radius of the cylinder. The potential distribution on the circle at $r=R$ can be expressed by periodic even function of θ as is shown in Fig. 2. Therefore, we can express V by means of a Fourier series. After some algebra, we obtain:

$$a_0 = (V_1+V_2)/2,$$

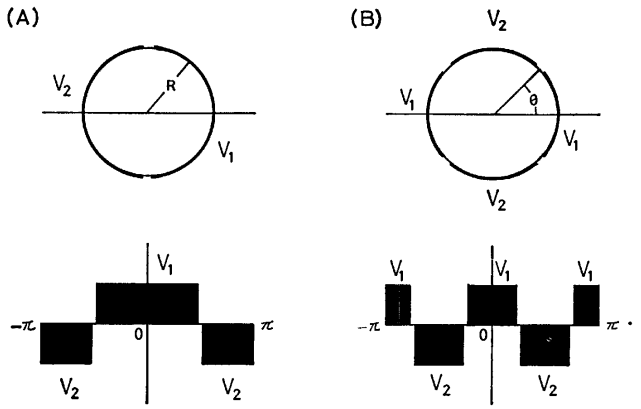

Fig. 2. Potential distribution on circle at $r=R$ of the electrodes (A) and (B), respectively.

$$a_n = [2(V_1-V_2)/n\pi]\sin(n\pi/2)$$

in the case of 2-split electrodes.

When $k=1, 2, 3, \cdots\cdots$, a_n becomes:

$$a_{2k} = 0 \quad \text{for } n=2k$$
$$a_{2k-1} = 2(V_1-V_2)(-1)^{k-1}/\pi(2k-1) \quad \text{for } n=2k-1.$$

Thus, we finally obtain:

$$V(r, \theta)_2 = \left\{\frac{V_1+V_2}{2}+\frac{2(V_1-V_2)}{\pi}\sum_{k=1}^{k=\infty}\frac{(-1)^{k-1}}{2k-1}\left(\frac{r}{R}\right)^{2k-1} \times\cos(2k-1)\theta\right\}\sin(\omega_1 t+\phi_1)$$
for 2 splits. (A4)

In a similar way, Eq. (A4) can be generalized to the potential equation for $2m$-split electrodes as follows:

$$V(r, \theta)_{2m} = \left\{\frac{V_1+V_2}{2}+\frac{2(V_1-V_2)}{\pi}\sum_{k=1}^{k=\infty}\frac{(-1)^{k-1}}{2k-1}\left(\frac{r}{R}\right)^{m(2k-1)} \times\cos[m(2k-1)\theta]\right\}\sin(\omega_1 t+\phi_1)$$
for $2m$ splits, (A5)

where $m=1, 2, 3, \cdots\cdots$.

By substituting Eq. (A5) into Eq. (2), we obtain this expression of the rf electric field for $2m$-split electrodes:

$$\mathbf{E}(r)_{2m} = \left\{-\frac{2(V_1-V_2)}{\pi}\sum_{k=1}^{k=\infty}\frac{m(-1)^{k-1}}{r}\left(\frac{r}{R}\right)^{m(2k-1)} \times\cos[m(2k-1)\theta]\right\}\sin(\omega_1 t+\phi_1), \quad (A6a)$$

$$\mathbf{E}(\theta)_{2m} = \left\{\frac{2(V_1-V_2)}{\pi}\sum_{k=1}^{k=\infty}\frac{m(-1)^{k-1}}{r}\left(\frac{r}{R}\right)^{m(2k-1)} \times\sin[m(2k-1)\theta]\right\}\sin(\omega_1 t+\phi_1)$$
for $2m$ splits. (A6b)

b) List of Notations Used in the Text.

$$A = [\xi(\xi^2+\omega_1^2-\omega^2)+2\xi\omega^2]/F,$$
$$B = \omega_1(\xi^2+\omega_1^2-\omega^2)/F,$$
$$C = 2\xi\omega\omega_1/F,$$
$$D = [\omega(\xi^2+\omega_1^2-\omega^2)-2\xi^2\omega]/F,$$
$$F = [(\omega_1-\omega)^2+\xi^2][(\omega_1+\omega)^2+\xi^2].$$

The Vibrational Spectra and Rotational Isomerism of Chloro(chloromethyl)silanes

Keiichi SERA, Keigo SUEHIRO, Michiro HAYASHI, and Hiromu MURATA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
(Received July 11, 1975)

The infrared spectra of chloro(chloromethyl)methylsilanes $ClCH_2SiCl_{3-n}(CH_3)_n$ (n=0—2) in the liquid and crystalline states and a part of the Raman spectra in the liquid state have been measured. It has become apparent that, for $ClCH_2SiCl_2CH_3$ and $ClCH_2SiCl(CH_3)_2$, two rotational isomers coexist in the liquid state, while only one isomer persists in the crystalline state. The fundamental vibrations for these molecules have been assigned, and the normal vibrations have been calculated on the basis of a modified Urey-Bradley force field. The solvent effects and the calculation of the normal vibrations have indicated that the *gauche* form for $ClCH_2SiCl_2CH_3$ and the *trans* form for $ClCH_2SiCl(CH_3)_2$ persist in the crystalline state. For $ClCH_2SiCl_3$, the barrier height, $V_3(SiCl_3)$, has been estimated to be 4.6 kcal/mol from the torsional force constant.

In our previous papers,[1] we have reported the existence of rotational isomers in the XCH_2SiH_2Y-type (X,Y=Cl or CH_3) molecules. However, with regard to chloro(chloromethyl)dimethylsilane (CCDS) and chloro(ethyl)dimethylsilane, one of the present authors (M. H.) published a paper about fifteen years ago which mentioned that rotational isomers may not exist in these molecules, juaging from the Raman spectra in the liquid and solid states, while the dipole moments of CCDS at various temperatures do indicate the possibility of the existence of the rotational isomers.[2] The Raman spectra of the $ClCH_2SiCl_{3-n}(CH_3)_n$ molecules (n=0—2)[3] and the infrared spectrum of dichloro(chloromethyl)methylsilane (DCMS)[4] have been reported, but no detailed vibrational analyses have been made. The vibrational spectra and assignments of CCDS have been reported by one of the present authors (M. H.),[2] by Goubeau *et al.*,[5] and by Kriegmann *et al.*,[6] but the assignments of the C–Si and C–Cl stretching vibrations have not been consistent with each other.

In the present paper, we will deal anew with the molecular vibrations of the $ClCH_2SiCl_{3-n}(CH_3)_n$ series of molecules (n=0—2) in order to show the existence of the rotational isomers, information about the barrier height around a C–Si bond, and reasonable vibrational assignments for this series of molecules.

Experimental

Trichlorochloromethylsilane (TCS) was prepared by the reaction of tetrachlorosilane with diazomethane.[7] The samples of DCMS and CCDS were commercial products purified by redistillation.

The infrared spectra in the 200—4000 cm^{-1} region were recorded on a Perkin–Elmer instrument (Model 621). For the measurements in the crystalline state, the vapor of the sample was directly condensed on a CsI window cooled with liquid nitrogen in a vacuum and was annealed several times near the melting point. The solution spectra were measured using a sealed KRS-5 cell (0.5 mm thick), with carbon disulfide and acetonitrile as solvents. The Raman spectra in the liquid state were recorded on a JEOL Raman spectrometer (Model JRS-02AS), using an argon-ion laser (488.0 nm) for excitation.

Results and Discussion

Rotational Isomerism and Vibrational Assignments. Figure 1 shows the infrared spectra of TCS, DCMS, and CCDS in the liquid and crystalline states. It has been reported, on the basis of microwave study, that staggered configurations are more stable around a C–Si bond in such molecules as chloromethylsilane[8] and dimethylsilane.[9] For DCMS and CCDS, the two rotational isomers in Fig. 2 are expected. Actually, not for TCS, but for DCMS and CCDS, a few bands observed in the liquid state vanish in the crystalline

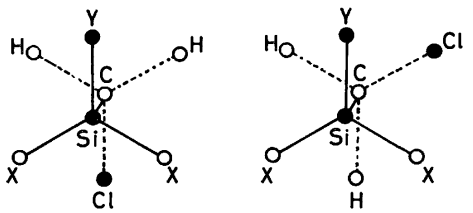

Fig. 2. Possible molecular forms for $ClCH_2SiCl_2CH_3$ and $ClCH_2SiCl(CH_3)_2$.

state. For CCDS, the Raman spectrum in the solid state has previously been reported by one of the present authors (M. H). Unfortunately, the Raman lines which correspond to the disappeared infrared bands in the crystalline state have not vanished completely, though the relative intensities of these lines have remarkably decreased in the solid state.[2] From the above results and the relative intensity changes in the infrared bands in the solution spectra, it may be concluded that, for DCMS and CCDS, two rotational isomers coexist in the liquid state, while only one isomer persists in the crystalline state.

On the other hand, the fundamental vibrations are assigned on the basis of the spectra in the $ClCH_2SiCl_{3-n}(CH_3)_n$ series of molecules (n=0—3) and on the basis of the relative intensities between the infrared bands and Raman lines. Figure 3 shows the correlation of the vibrational assignments of TCS, DCMS, and CCDS, together with that of chloromethyltrimethylsilane.[10] The assignment for CCDS is consistent with that by Goubeua *et al.*[5]

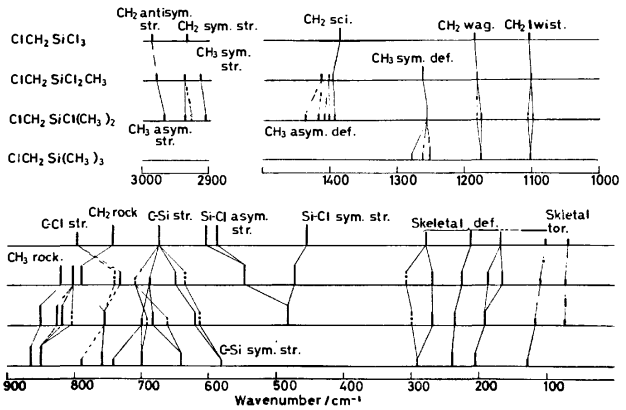

Fig. 3. Correlation of the vibrational assignments of the $ClCH_2SiCl_{3-n}(CH_3)_n$ series of molecules (n=0—3), where the lines in the region below 400 cm^{-1} and above 400 cm^{-1} are the observed Raman lines and the infrared bands respectively.

Solvent Effects. The solvent effects can be used for the determination of the molecular forms for DCMS and CCDS, because the dipole moments are expected to change considerably with an azimuthal angle of internal rotation. The dipole moment calculation based on the bond moments indicates that, for DCMS, the *trans* form is more polar than the *gauche* form, while for CCDS the *gauche* form is more polar than the *trans* form.

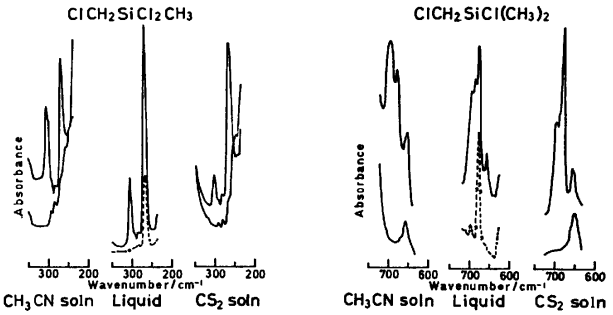

Fig. 4. The solvent effects of the infrared bands for $ClCH_2SiCl_2CH_3$ and $ClCH_2SiCl(CH_3)_2$.
·····: The spectra in the crystalline state.

For DCMS, the solvent effects of the infrared spectra are measured, using the bands at 308 and 269 cm^{-1} assigned to the skeletal deformation vibrations. The band at 308 cm^{-1} vanishes in the crystalline state. Figure 4 shows the solvent effects of the infrared bands. The A_{308}/A_{269} ratio increases when it is mixed with a polar solvent such as acetonitrile, while the reverse is true in a mixture with a non-polar solvent such as carbon disulfide. Therefore, the isomer disappearing in the crystalline state (the *trans* form) is more polar than the other (the *gauche* form).

For CCDS, the solvent effects of the bands at 692 and 683 cm^{-1} assigned to the C–Si stretching vibrations indicate that the isomer disappearing in the crystalline state (the *gauche* form) is more polar than the other

Normal Vibration Calculation. In order to confirm the results of the molecular forms and the vibrational assignments, the normal vibrations of the $ClCH_2SiCl_{3-n}(CH_3)_n$ molecules (n=0—2) were calculated, using Wilson's **GF**-matrix method. The bond lengths used were C–Cl=1.788 Å, CH_2–Si=1.889 Å, CH_3–Si=1.868 Å, Si–Cl=2.021 Å, and C–H=1.095 Å.[8,9,11] All the valence angles were assumed to be tetrahedral, and the internal rotation angles were 180° (*trans*) and 60° (*gauche*). The force constants in the modified Urey-Bradley force field were transferred from those of trichloromethylsilane,[11] chloromethylsilane,[12] and dichloroethylmethylsilane;[13] only the force constants of the skeletal torsions were adjusted to reproduce well the observed torsional frequencies.

The observed and calculated frequencies are summarized in Tables 1—3, together with the predominant potential energy distributions in the internal symmetry coordinates. The force constants are listed in Table 4. The vibrational assignments in Fig. 3 are consistent with the results of the calculations, though the potential energy distributions indicate large mixings between the C–Si and C–Cl stretching vibrations and between the

skeletal deformation vibrations. For the molecular forms of DCMS and CCDS, the conclusion regarding the solvent effects is consistent with that obtained from the comparison of the observed frequencies with the calculated frequencies of the highest-frequency skeletal deformation for each molecular form.

Barriers to Internal Rotation. The barrier height, V_3, assuming the harmonic oscillation ($V=(1/2)V_3(1-\cos 3\alpha)$, $V_3>2.5$ kcal/mol) can be calculated by the use of the torsional frequency or its force constants as

Y(Si–CH_3)	0.051	Y(C–$SiCl_2CH_3$)	0.149
Y(C–$SiCl_3$)	0.143	Y(C–$SiCl(CH_3)_2$)	0.130

a) The units of the force constants are in md/Å for stretching, K; bending, H; repulsion, F; bond interaction, p; and in md.Å for intramolecular tension, κ; torsion, Y.

follows: V_3 (kcal/mol)$=2.858\times10^{-3}\,\nu^2/(9F)$ or $k=(\partial^2V/\partial\alpha^2)_{\alpha=0}=9/2V_3$, that is, k (md. Å)$=0.03126\ V_3$ (kcal/mol), where F is the reduced rotational constant for internal rotation ($F(SiCl_3)=0.3859$ cm^{-1}); ν, the observed torsional frequency in cm^{-1}, and k, the torsional force constant.[14] For TCS, the barrier heights, V_3, calculated from the torsional frequency (68 cm^{-1}) and its force constant (0.143 md. Å) are 3.8 and 4.6 kcal/mol respectively. For the former, the interactions between the torsional vibration and the other vibrations are neglected, while for the latter the kinetic effect of the other vibrations (the **G**-matrix elements between the torsional vibration and the other vibrations) is taken into account. Actually, the potential energy distributions of the skeletal torsion are skeletal tor (79), $SiCl_3$ rock(14), and CH_2 rock(6). The torsional force constants of DCMS and CCDS are 0.149 and 0.130 md.Å, and the barrier heights of $V_3(SiCl_2CH_3)$ and $V_3(SiCl(CH_3)_2)$, assuming a symmetrical-three fold barrier, are 4.8 and 4.2 kcal/mol respectively.

On the other hand, for 1,1,1,2-tetrachloroethane, $V_3(CCl_3)$, has been reported to be 10.2 kcal/mol.[15] Therefore, the barrier height of V_3 for $ClCH_2SiCl_3$ is considerably smaller than that for $ClCH_2CCl_3$, but is higher than that of the free rotation (*ca.* 0.6 kcal/mol).

The authors wish to express their thanks to Dr. Teizo Kitagawa of Osaka University for the use of the Raman spectrophotometer.

The Effect of Organic Additives on the Thermodynamic Parameters of Micellization

Shigeyoshi MIYAGISHI

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa 920

(Received July 12, 1975)

The CMC values of dodecylammonium chloride and iodide and of hexadecylammonium chloride were measured in water upon the addition of acetone, 1-propanol, and urea at several temperatures. The effects of the additives were most remarkable on the CMC of hexadecylammonium chloride at 45.0 °C. Urea was less effective on the disruption of micelles than acetone, while the addition of 1-propanol was most effective. The enthalpy of micellization became more negative, while the entropy of micellization became less positive, as the additive concentration increased. We divided the standard free energy of micellization into the hydrophobic term, ΔG_n°, and the hydrophilic term, ΔG_p°. The value of ΔG_p° became more negative with the additive concentration and contributed to the stabilization of the micelle, while ΔG_n° became less negative. Therefore, it was concluded that the disruption of the micelle in the presence of these organic additives results from an increase in the free energy in the hydrophobic group of the surfactant molecule.

It is well known that the addition of a protein denaturant to a surfactant solution brings about the disruption of a micelle. The two phenomena, *i.e.*, protein denaturation and micelle disruption, are qualitatively similar, and so the effects of the organic additives on the micellar properties have received much attention.

On the other hand, the association of the surfactant molecule itself is a significant problem in physical chemistry, apart from biology. In the investigation of the effect of organic additives, nonionic surfactants have often been used;[1-6] there have been fewer systematic studies of ionic surfactant solutions[7-9] because of the complexity of the electrostatic interaction. However, we could previously obtain some significant results in the alkylammonium halide solutions.[10,11]

In the present investigation, our studies were extended to the effect of the additives on the thermodynamic parameters of micellization. Here we reached the significant conclusion that the increase in the CMC in the presence of the organic additives results from the increase in the free energy of the hydrophobic group in the surfactant molecule.

Experimental

The materials and the experimental procedure were almost the same as those described in previous papers.[10,11] That is, dodecylammonium chloride (DAC), iodide (DAI) and hexadecyammonium chloride (HAC) were used. Their CMC's were measured by the electric conductivity method. The CMC of HAC was not measured in the urea solutions because of the appearance of turbidity.

Results and Discussion

The Effect of the Additives on the CMC. The effect of three organic additives on the micellization of alkylammonium halides was examined. 1-Propanol is a protonic solvent, acetone is aprotic, and urea is well known to be a typical protein denaturant.

The additives affect the micellizations through the breakage of the water structure around the hydrocarbon chain of a surfactant molecule[12] and the modification of the electrostatic interaction.[13] The chloride ion may be a stronger water-structure breaker than the iodide ion, and therefore the water around the hydrocarbon chain may be less ordered and less susceptible to modification by the organic additives in the presence of the chloride ion than in that of the iodide ion. Therefore, the surfactant molecule with a longer hydrocarbon chain or a weaker structure-breaking ion is expected to be more subject to the effect of the additive. The experimental results that the CMC increasing effects of the additives were most remarkable in HAC and less in DAC than in DAI were in accord with these expectations.

CMC$_0$: The CMC in the absence of urea. a) From Ref. 12.

The CMC values in Tables 1—3 are seen to increase with the temperature, irrespective of the presence or absence of the additive, and the increment in HAC is remarkable in the presence of additives. The addition of 1-propanol and acetone affects the micellization to a considerable extent, while urea is least effective.

The CMC values of sodium dodecylsulfate (SDS) in the presence of urea reported by Schick[12] are denoted in Table 3 for comparison with our data. The difference between these two sets of data is relatively small. Therefore, in the absence of a strong structure-breaking ion or a strong structure-making ion, the increments in the CMC values on urea addition seem to be determined mainly by its effect on the hydrophobic group of a surfactant molecule.

Thermodynamic Parameters of Micellization. The standard free energy of micellization can be represented by Eq. (1), and the enthalpy may be calculated from the dependence of the CMC on the temperature by means of Eq. (2):

$$\Delta G^\circ = (1+K_g)RT \ln \text{CMC (mole fraction)} \quad (1)$$

$$\Delta H^\circ = -(1+K_g)RT^2 \frac{d \ln \text{CMC}}{dT} \quad (2)$$

The value of K_g does not change largely with the temperature[14] or with the concentration of the organic additive.[11] The thermodynamic parameters in the present work have been calculated by assuming that $K_g=0.7$.

From the usual relation among thermodynamic functions, the standard entropy of micellization is obtained. In the micellization, the entropy generally has a relatively large positive value, while the enthalpy is small or even negative in an aqueous solution. Shinoda[15] explained these phenomena by taking into account the iceberg formation of the water surrounding a surfactant molecule. Urea is known to denature a protein through the disruption of the iceberg. However, in the present work, acetone, a weaker denaturant, was found to be more effective in the breakage of micelles than urea. Similar phenomena were also suggested by Bruning and Holtzer.[16] A comparison of Fig. 3 with Figs. 1—2 reveals that the effect of urea on the thermodynamic parameters is weaker than those of acetone and 1-propanol and that the enthalpy scarcely changes upon the addition of urea.

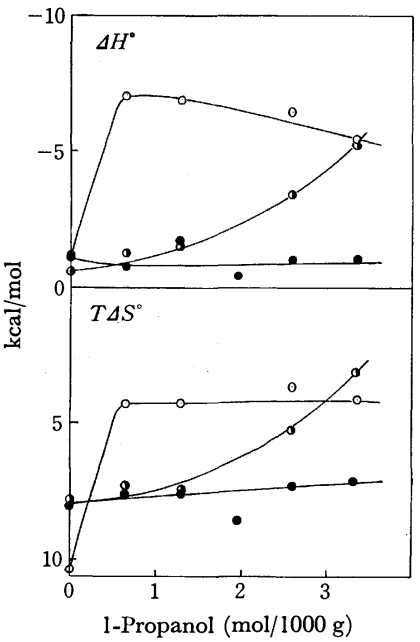

Fig. 1. The effect of 1-propanol on thermodynamic parameters of micellization at 35.0 °C.
—◑—: DAC, —●—: DAI, —○—: HAC.

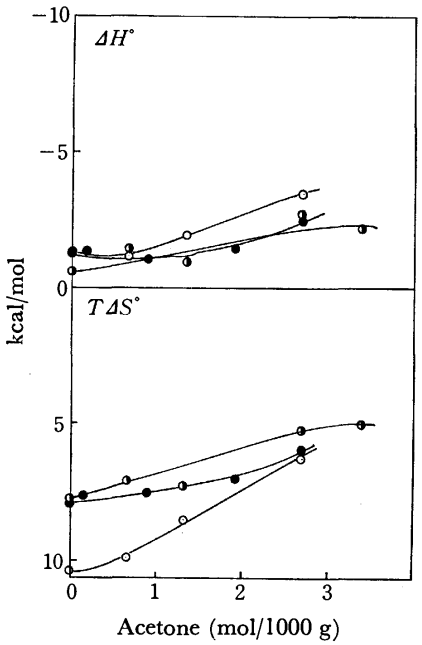

Fig. 2. The effect of acetone on thermodynamic parameters of micellization at 35.0 °C.
Symbols are identical with them in Fig. 1.

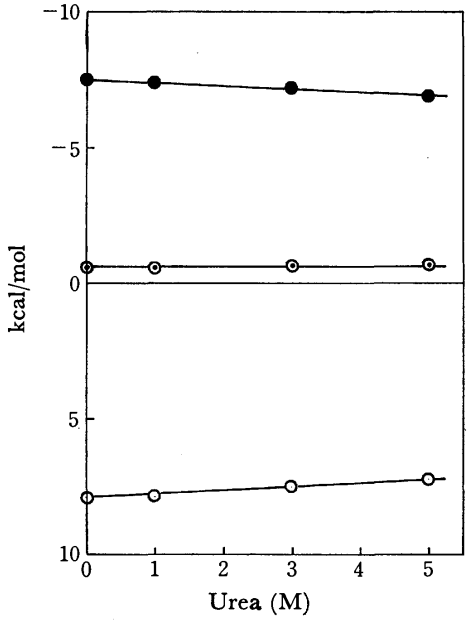

Fig. 3. The effect of urea on thermodynamic parameters of micellization at 35.0 °C.
—●—: $\Delta G°$, —⊙—: $\Delta H°$, —○—: $T\Delta S°$.

Therefore, acetone and 1-propanol seem to affect the micellization through other mechanisms, in addition to the disruption of iceberg; for example, the preferential solvation of the hydrocarbon chain by the additives or the more appropriate solubility parameter of the mixed solvent.

The effects of additives on the enthalpy and the entropy were remarkable in the HAC solution; the difference between their effects in the DAC and DAI solutions was small at low concentrations of the additives. These results suggest that their effects are operative primarily on the hydrophobic group of the surfactant, while only secondarily on the hydrophilic group.

Furthermore, the entalpy is more negative, and the entropy is less positive, in the presence of additives; therefore, the contribution of the enthalpy to the micellization becomes increasingly important with the additive concentrations, in contrast to the predominance of entropy in the aqueous solutions. Such more negative enthalpy in the presence of organic additives has also been observed in other systems.[2-5] We consider these phenomena to result from the decrease in the highly ordered structure through hydrogen bonding in an aqueous solution. Further investigations, however, will be required before a detailed discussion can be done.

The Hydrophobic and the Hydrophilic Terms in the Free Energy. It is possible to divide the standard free energy of micellization in the DAC solution, $\Delta G°_{DAC}$, into two components, one due to the hydrophobic group of the surfactant molecule, $\Delta G°_n$, and the other, due to the hydrophilic group, $\Delta G°_p$. We will represent the standard free energy of micellization in the HAC solutions as $\Delta G°_{HAC}$ and will assume the following equation, similar equations have been used by some other authors:[4,5,9]

$$\Delta G°_n = 3(\Delta G°_{HAC} - \Delta G°_{DAC}) \quad (3)$$

$$\Delta G°_p = \Delta G°_{DAC} - \Delta G°_n \quad (4)$$

Such a division may give further detailed knowledge about the effects of additives. The variations in $\Delta G°_n$ and $\Delta G°_p$ with additive concentrations are represented in Figs. 4—5. The value of $\Delta G°_n$ becomes less negative as the additive concentration increases, while $\Delta G°_p$, surprisingly, becomes more negative. Consequently, we reach the significant conclusion that the increase in $\Delta G°_{DAC}$ in the presence of organic additives should be ascribed to the increase in $\Delta G°_n$. The stabilization of the micelles at the lower concentrations of additives is explained by the more negative $\Delta G°_p$. A similar calculation made with the HAC solutions gave values of $\Delta G°_p$ identical with those in the DAC solution, but the values of $\Delta G°_n$ were more negative.

On the other hand, a comparison between Figs. 4

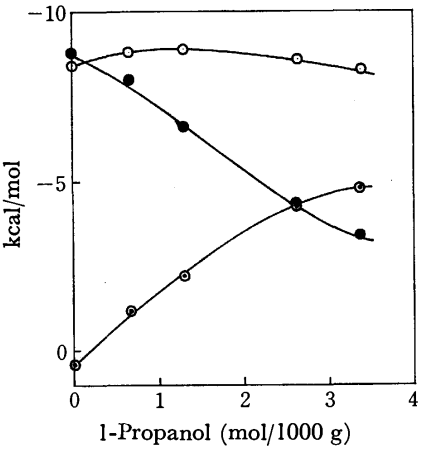

Fig. 4. The effect of 1-propanol on free energy of micellization of DAC at 35.0 °C.
—●—: $\Delta G°_n$, —⊙—: $\Delta G°_p$, —○—: $\Delta G°_{DAC}$.

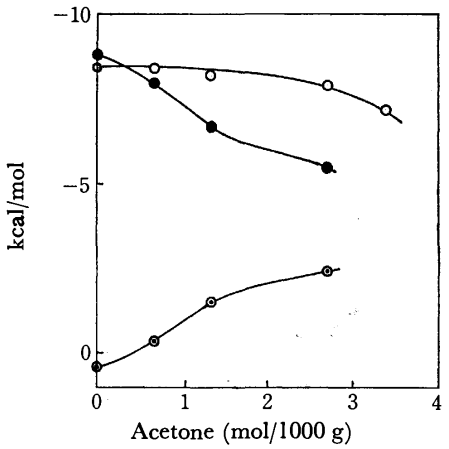

Fig. 5. The effect of acetone on free energy of micellization of DAC at 35.0 °C.
Symbols are identical with them in Fig. 4.

and 5 suggests that 1-propanol increases $-\Delta G_p^\circ$ more than acetone does. According to a previous paper,[10] propanol is more solubilized in the DAC micelle than is acetone. The increase in the solubilizate may produce the decrease in the surface-charge density of the micelle. Therefore, the fact reported above can be explained by the difference in their solubilized amounts.

The author wishes to express his hearty thanks to Professor Ryohei Matuura of Kyushu University and Professor Morie Nishida for their kind discussions throughout this study.

Photoreactions of the Uranyl Ion with Arylaldehydes in Solution

Ryoka MATSUSHIMA,* Kenichi MORI, and Morio SUZUKI

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432

(Received July 23, 1975)

Irradiation of benzaldehyde in a deoxygenated aqueous acetone solution in the presence of the uranyl ion with light of $\lambda \geqq 365$ nm gives the U(IV) species and benzil (**1**) as the main photoredox products, and small amounts of 4-hydroxy-4-phenylbutan-2-one (**2**), *trans*-4-phenyl-3-buten-2-one (**3**), and an unidentified product (**4**). None of them are formed in the absence of the uranyl ion. The products **2** and **3** are assumed to be formed by the uranyl ion-photocatalyzed condensation of benzaldehyde with acetone. Irradiation of acetophenone in the presence of the uranyl ion gives no photoproducts, though the uranyl emission is effectively quenched. *p*-Methoxybenzaldehyde and *p*-chlorobenzaldehyde give the corresponding 4,4′-disubstituted benzils respectively by irradiation under similar conditions. The quantum yield for the formation of the U(IV) species decreases whereas the quenching constant increases with the increase in the electron donating power of the substituent. The physical quenching process appears to compete significantly with the chemical (redox) process. The relative importance of the physical quenching to the chemical quenching process has been estimated. As to the photocatalyzed aldol condensation, the excess vibrational energy, which the quencher and/or the quenchee would possess during or immediately after the quenching interactions, may possibly be converted into the energy of the chemical reaction.

Primary interactions of the excited uranyl ion with organic compounds in solutions may be classified into three types: a) electronic energy transfer,[1,2] b) chemical (redox) interactions such as the abstraction of active hydrogen atoms,[3-5] and c) physical quenching *via* formation and decay of excited state π-complexes[6] (with aromatic molecules). In the previous paper the formation of biacetyl by the photooxidation of acetaldehyde with the uranyl ion has been reported,[5] where the only important interactions is the chemical one.

Arylaldehydes have both physical (π-electron cloud) and chemical (aldehyde hydrogen) quenching centers in one molecule. The present paper is concerned with the photochemistry of the uranyl ion with arylaldehydes, where it may be questioned whether physical and chemical interactions are simply competitive or whether they can be interconverted to some extent.

Experimental

Materials. Benzaldehyde (guaranteed grade) was freshly distilled under reduced nitrogen pressure before use. Other chemicals were of guaranteed reagent grade and were used without further purification. Water was distilled after passing through ion exchange resins.

Quenching Constants. The relative intensities of the uranyl emission near the 510 nm peak were measured with the 436 nm excitation in 60 vol% aqueous acetone solutions containing 0.02 M uranyl nitrate, 0.1 M perchloric acid, and various concentrations of the quenchers, at 25 ± 2 °C. Since the quenching constants were not significantly influenced by the dissolved oxygen, they were measured without deoxygenation. The measurements were carried out by means of a Hitachi 204-type fluorescence spectrophotometer.

Photolysis. 60 vol% aqueous acetone solutions of 0.2 M benzaldehydes in the presence of 0.02 M uranyl nitrate (hexahydrate) and 0.1 M perchloric acid were deoxygenated with oxygen-free nitrogen current, and were sealed in identical 7 ml ampoules. They were irradiated with light of $\lambda \geqq 365$ nm from a 100 or 400 W high pressure mercury lamp. For the quantitative experiments, a merry-go-round irradiation apparatus in a thermostat (10 ± 1 °C) or an optical train with a suitable arrangement for obtaining a parallel light beam perpendicular to the plane of the windows of the photoreaction cells was used. Actinometry was carried out with the ferric oxalate actinometer solution. No correction was made of the quantum yields for formation of the products, though under these conditions some errors might be involved due to the inner filter effects by benzaldehyde or products and the quenching of the excited state uranyl ion by the products.

Analysis of the Photoproducts. After the elimination of acetone from the photolyzed mixture solution, the residual aqueous solution was extracted with chloroform. The chloroform layer was washed with aqueous sodium bisulfate solution to eliminate benzoic acid. The chloroform layer was, after drying and condensation, separated on PLC (silica gel 60 PF-254, Merck) into four portions (**1**, **2**, **3**, and **4**). **2**: IR, 1700 (s), 3400 (broad) cm^{-1}; NMR, δ 2.0 (s, 3H), 2.6 (d, 2H), 4.0 (s, 1H), 5.0 (dd, 1H), 7.2 (m, 5H). **4**: mp, 120.5—122 °C; IR, 1690 cm^{-1}, no OH; NMR, δ 7.1 (s, 1H), 7.5—8.4 (m, 13H). Found: C, 80.32; H, 5.45%. Calcd for $C_{14}H_{10}O_2$: C, 80.00; H, 4.76%.

The amounts of the organic products were determined by densitometry on TLC after conversion into the corresponding 2,4-dinitrophenylhydrazone derivatives. The densitometer was an OZUMOR-82 (Meika KK). The measurements of NMR and IR spectra were carried out by means of a high resolution NMR spectrometer (Hitachi R-24) and an IR spectrometer (Japan Spectroscopic IR-S).

Results and Discussion

Formation of Organic Products. From the photolysis of benzaldehyde–uranyl solution, the products **1** and **3** have been identified respectively as benzil and *trans*-4-

TABLE 1. APPROXIMATE QUANTUM YIELDS OF THE PRODUCTS FROM THE PHOTOLYSIS OF BENZALDEHYDE WITH THE URANYL ION[a]

Product	Quantum yield

1	0.12
2	0.01
3	0.02
4	<0.01

a) Benzaldehyde: 0.2 M; uranyl ion: 0.02 M; perchloric acid: 0.1 M; in 60 vol % aqueous acetone at 10 °C, $\lambda \geqq 365$ nm.

phenyl-3-buten-2-one by comparing their IR and NMR spectra with those of authentic samples, while the product **2** has been assigned to 4-hydroxy-4-phenyl-butan-2-one on the basis of its IR and NMR spectra. The structure of the product **4** has not been clarified, though it may be tentatively assumed to be 2-phenyl-2,3-dihydrobenzofuran-3-one. The approximate quantum yields for the products from the photolysis of uranyl-benzaldehyde solution are listed in Table 1. Benzil (**1**), which was not formed by thermal reaction at 50 °C, is the main organic product, while the products **2**, **3**, and **4** are minor ones. In the absence of the uranyl ion, however, none of them was formed by the photolysis of benzaldehyde under similar conditions. Benzoic acid which is produced by thermal autooxidation of benzaldehyde on oxposure to the air, was unlikely to be an important product of the photoreactions under the present experimental conditions.

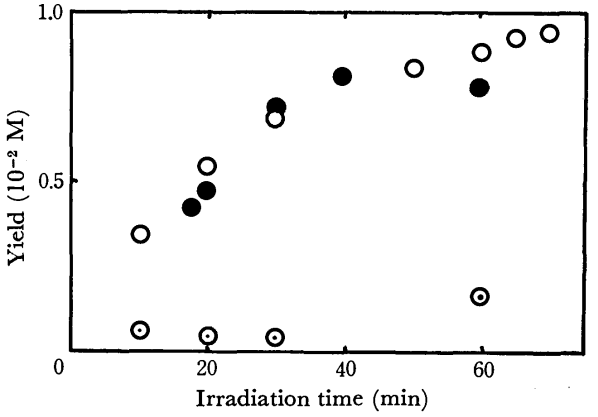

Fig. 1. Product yields at various extents of the photoreaction of benzaldehyde with the uranyl ion. Conditions are similar to those in Table 1. ○: U(IV) species, ●: product **1**, ⊙: product **2**.

Figure 1 shows that the molar ratio of the product **1** to the U(IV) species is close to unity, regardless of the extent of the photoreaction; thus **1** is the main oxidation product and it probably does not undergo any subsequent reactions. *p*-Methoxybenzaldehyde and *p*-chlorobenzaldehyde also gave the corresponding 4,4'-disubstituted benzils as the main organic products by irradiation in the presence of the uranyl ion under similar conditions. The reaction scheme for the formation of the product **1** (and also 4,4'-disubstituted benzils) may be assumed as follows, in analogy to that for the formation of biacetyl by the photooxidation of acetaldehyde with the uranyl ion:[5]

$$*UO_2^{2+} + ArCH{=}O \longrightarrow UO_2^{+} + H^{+} + Ar\dot{C}{=}O$$

$$2Ar\dot{C}{=}O \longrightarrow ArCOCOAr$$

$$2UO_2^{+} \xrightarrow{H^{+}} UO_2^{2+} + U(IV)\ species$$

Unlike the product **1** which is the photoredox product, the products **2** and **3** are formally not the redox products but are aldol condensation products of benzaldehyde with acetone, catalyzed by the excited state uranyl ion. As to the catalyzed aldol condensation by transition metal ions in the ground states, Iwata and Emoto have recently reported the cupric ion-catalyzed condensation of aromatic aldehydes with acetone.[7] Thermal reaction of the uranyl–benzaldehyde mixture for 30 hours at 50 °C also gave the products **2** and **3**, but their amounts were much less compared to those obtained by irradiation of an identical solution for 2 hours at 10 °C with a 100 W high pressure mercury lamp. Direct irradiation (*i.e.*, in the absence of the uranyl ion) with light of 254 nm (from a 160 W low pressure mercury lamp) for 9 hours at 10 °C gave no such condensation products. These facts suggest a photocatalytic action of the uranyl ion, *i.e.*, the condensation of benzaldehyde with acetone is much more accelerated by the excited uranyl ion than by the ground state uranyl ion. In the sense that the uranyl ion is not reduced, the process is a photocatalytic one.

$$ArCH{=}O + CH_3COCH_3 \xrightarrow{*UO_2^{2+}} ArCH(OH)CH_2COCH_3$$

The product **3** is assumed to be formed from the product **2** by dehydration during the analytical procedures, since **2** is easily converted into **3** by similar treatments. Hence the relative yield of the product **2** to **3** is changeable. In order to clarify the possible route for the formation of the product **4**, an investigation was made on the solution conditions of the photoreaction to give **4** (Table 2). The results show that the product **1** is unlikely to be the source of **4**, but that **4** is probably formed only by the photoreaction of benzaldehyde with the uranyl ion. The structure of **4** is, however, uncertain as yet.

Table 2. Conditions of the photoreaction to give the product **4**

Initially added concentrations[a]			Formation of **4**
Uranyl ion, M	Benzaldehyde, M	Benzil, M	
0.00	0.10	0.02	no
0.02	0.00	0.10	no
0.02	0.10	0.00	yes

a) Other conditions were similar to those in Table 1.

Stability of the U(IV) Species. The stabilities of the U(IV) species in solutions exposed to the air were preliminarily examined. Figure 2 shows that the stability of the U(IV) species is significantly solvent-dependent. The stability was higher at low temperature. The amount of the U(IV) species formed was determined either by rapid colorimetric analysis with arsenazo-III[8] immediately after breaking the ampoules or by the direct measurements of the absorbance at its 650 nm peak in the ampoules without exposure to the air.

Formation Quantum Yield of the U(IV) Species. Irradiation with $\lambda \geqq 365$ nm of a deoxygenated 60 vol% aqueous acetone solution of 0.2 M benzaldehyde in the presence of 0.02 M uranyl ion and 0.1 M perchloric acid leads to the reduction of the uranyl ion to give the U(IV) species which is easily identified by its characteristic absorption spectrum (430—700 nm). A series of the substituted benzaldehydes also lead to the formation of the U(IV) species upon irradiation under similar conditions. The formation quantum yields of the

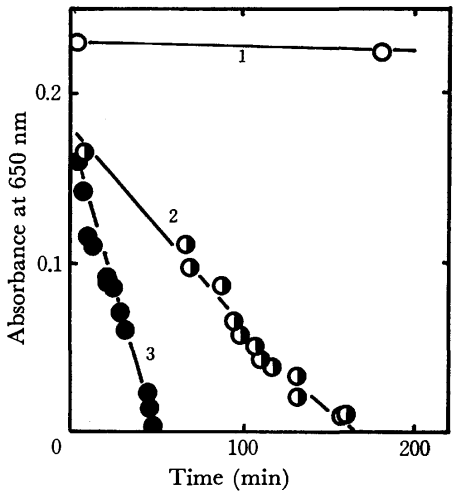

Fig. 2. Stabilities of the U(IV) species in solutions under the air. U(IV) species: 0.02 M, perchloric acid: 0.1 M; (1): in aqueous solution, (2): in 60 vol % aqueous acetone solution, (3): in 60 vol % aqueous acetone solutionin the presence of 0.2 M benzaldehyde.

Table 3. Quenching constants (K) and the quantum yields (ϕ) of the U(IV) formation for substituted benzaldehydes

Substituent	$K\times10^{-2}$. M^{-1}	ϕ	$\sigma^{+a)}$

p-NO_2	2.0	0.6[b)]	0.790

a) Polar substituent constants. b) Because of the low solubility, the initial concentration of *p*-nitrobenzaldehyde was 0.017 M.

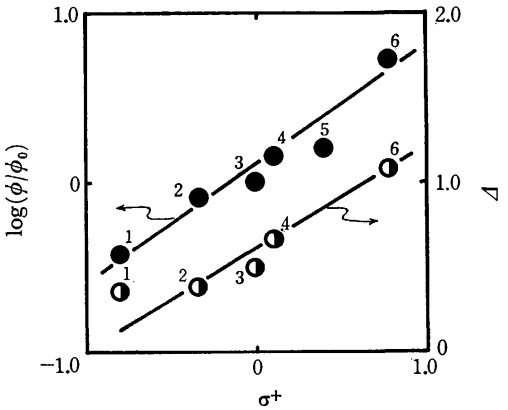

Fig. 3. Plots of $\log(\phi/\phi_0)$ and Δ *vs.* σ^+. Δ is the difference in the ordinates for benzaldehydes (b) and acetophenones (a) in Fig. 4. The numbering is the same as that in Fig. 4.

U(IV) are listed in Table 3. A plot of log (ϕ/ϕ_0) *vs* σ^+ is shown in Fig. 3, where ϕ and ϕ_0 are the formation quantum yields of the U(IV) species for the substituted and parent benzaldehydes respectively.

Unlike the systems of the uranyl–benzaldehydes, neither significant formation of the U(IV) species nor formation of organic photoproducts were detected upon irradiation of the uranyl–acetophenone system under conditions similar to those of the uranyl–benzaldehyde system.

Physical and Chemical Quenching. Quenching constants (K) of substituted benzaldehydes, obtained from the Stern-Volmer plots for the quenching of the uranyl emission in 60% aqueous acetone (containing 0.1 M perchloric acid), are listed in Table 3. The Stern-Volmer plots, $I^\circ/I=1+K[\mathrm{ArCH{=}O}]$, did not always give straight lines; sometimes the lines were concave downward at high concentrations of the quenchers. The quenching constants were obtained at low concentrations of the quenchers (usually, $[\mathrm{ArCH{=}O}]\leqq 2\times10^{-3}$ M).

It may be noted that the photoredox quantum yield inversely proportional to the quenching constant, which indicates that the physical and the chemical quenching processes are competing. The plot of log (K/K_0) *vs* σ^+ shows a straight line with a slope of $\rho=-0.7$ (where K_0 is the quenching constant of benzaldehyde), while similar plot for substituted acetophenones gives a straight line with a slope of $\rho=-1.0$ (Fig. 4). The difference in the slope of the two lines may be noted.

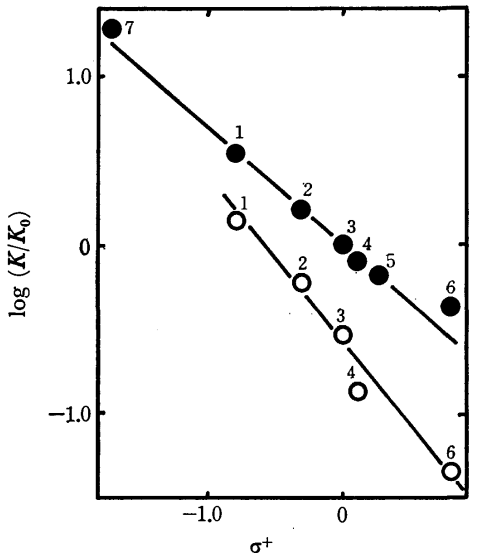

Fig. 4. Plots of $\log(K/K_0)$ *vs.* σ^+ for substituted benzaldehydes (●) and acetophenones (○). The substituents are, 1: *p*-methoxy, 2: *p*-methyl, 3: nonsubstituted, 4: *p*-chloro, 5: *m*-chloro, 6: *p*-nitro, and 7: *p*-dimethylamino, groups.

An electronic excitation energy transfer from the uranyl ion to these substrates will not occur, since it is a highly endothermic process. Quenching of the uranyl emission by acetophenone may be assumed to be essentially a physical quenching process, since it occurs without final chemical changes, while quenching by benzaldehydes involves both chemical and physical processes. From this point of view, the difference in the slope of the two lines in Fig. 4 may be assumed to reflect the chemical quenching of benzaldehydes. Thus the

difference in the ordinate of the two plots in Fig. 4, $\Delta=\log (K/K_0)_b-\log (K/K_0)_a$, which is assumed to be a measure of the chemical part of the quenching interactions, is plotted against σ^+ (open circles in Fig. 3). Here, a and b refer to the series of acetophenones and benzaldehydes, respectively. Figure 3 shows that Δ and $\log (\phi/\phi_0)$ are roughly parallel and suggests that the rate-determining steps are similar (abstration of the aldehyde hydrogen atoms). The apparent positive slope (ρ) in Fig. 3 may indicate that the chemical process is depressed by the competitive physical quenching process as the efficiency of the latter process is increased with the decrease in σ^+.

On the assumption of a simple scheme for the quenching of the uranyl emission by benzaldehydes, an approximate estimation of the relative importance of the physical and chemical (redox) quenching processes may be available. The main scheme may be drawn as follows for the photoredox reaction:

$$*UO_2^{2+} + ArCH{=}O \underset{k_d}{\overset{k_e}{\rightleftharpoons}} *UO_2^{2+} \cdots ArCH{=}O$$

$$\xrightarrow{k_p} UO_2^{2+} + ArCH{=}O + \text{heat} \quad (1)$$

$$\xrightarrow{k_r} UO_2^{+} + Ar\dot{C}{=}O + H^+ \quad (2)$$

$$2UO_2^{+} \xrightarrow[\text{rapid}]{H^+} UO_2^{2+} + \text{U(IV) species} \quad (3)$$

$$2Ar\dot{C}{=}O \xrightarrow[\text{rapid}]{} ArCOCOAr \quad (4)$$

Since the molar ratio of the redox products (benzils and the U(IV) species) is near unity, the following processes are assumed to be less important:

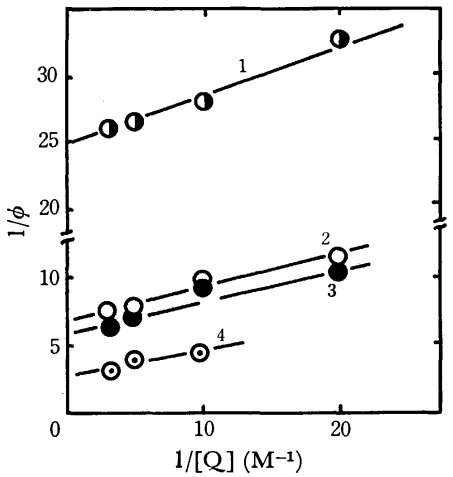

Fig. 5. Plots of $1/\phi$ *vs.* 1/[ArCH=O], for *p*-methoxy (1), *p*-methyl (2), nonsubstituted (3), and *p*-chloro (4), benzaldehydes. Conditions are similar to those in Table 1.

$$Ar\dot{C}{=}O + U(IV) \xrightarrow{H^+} UO_2^{+} + ArCH{=}O$$

$$UO_2^{+} + ArCH{=}O \longrightarrow U(IV) + Ar\dot{C}{=}O + H^+$$

The steady state approximation to $*UO_2^{2+}$, $*UO_2^{2+}\cdots$ ArCH=O, $Ar\dot{C}$=O and UO_2^{+} may eventually yield

$$\frac{1}{\phi} = \left(2+\frac{2k_p}{k_r}\right) + \frac{2(k_d+k_p+k_r)}{\tau_0 k_e k_r[ArCH{=}O]} \quad (5)$$

Here, τ_0 is the emission lifetime of the excited uranyl ion in the absence of benzaldehydes. Equation 5 indicates that the plots of ϕ^{-1} *vs* [benzaldehyde]$^{-1}$ should give a straight line with an intercept not smaller than 2. Figure 5 agrees with Eq. 5. From Eq. 5 the ratio of the physical and the chemical (redox) quenching rate constants, k_p/k_r, is given by $k_p/k_r=$(intercept$-2)/2$. The values obtained from Fig. 5 are listed in Table 4.

Table 4. Rate parameters for the photooxidation of substituted benzaldehydes with the uranyl ion

Substituent	I_s [a]	k_p/k_r [b]
p-OCH_3	25	11.5
p-CH_3	6.8	2.4
H	6.0	2.0
p-Cl	2.5	0.25

a) Intercept of the plot in Fig. 5. b) $k_p/k_r=(I_s-2)/2$.

These results shows that significant physical quenching is competing with the chemical (redox) quenching process, or that the excess vibrational energy (which the quencher and/or the quenchee would possess during or immediately after the physical quenching interactions) is unlikely to be effective for causing the redox reaction. On the other hand, the uranyl ion-photocatalyzed aldol condensation can be assumed to involve the conversion of the excess vibrational energy to that for the chemical process.

Inter- and Intramolecular Exciplexes and EDA Complexes in the 9,10-Dicyanoanthracene and Alkylbenzene Systems

Michiya Itoh,* Yoshiro Kumano, and Toshihiko Okamoto
Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received July 29, 1975)

The exciplex (above ~150 K) and EDA complex (below ~120 K) fluorescence were observed in the 9,10-dicyanoanthracene and several alkylbenzene systems and also in the intramolecular system of (9,10-dicyanoanthracene)-$(CH_2)_3$-(pentamethylbenzene) in the nonpolar solvents. The exciplex fluorescence lifetimes and maxima both in the inter- and intramolecular systems exhibit the continuous change to those of the corresponding EDA complex, which implies the identical fluorescent state of the exciplex and EDA complex. The fluorescence lifetimes and the fluorescence polarization suggest that the fluorescent state of both exciplex and EDA complex may be mostly locally excited state of electron acceptor.

Steady-state and transient spectroscopies, and also theoretical consideration of the electron donor-acceptor (EDA) system in the excited state suggest that the exciplex and the EDA complex may be essentially identical each other. It has been believed, however, that the EDA complex stable in the ground state can not be formed in the EDA system which exhibits the fluorescence of the exciplex stable only in the excited state.[1,2] Itoh and Mimura reported the exciplex and also the EDA complex formation in the nonpolar solution of 9,10-dicyanoanthracene (DCA) and several alkylnaphthalenes, and demonstrated a direct evidence for an identical fluorescent state of the exciplex and EDA complex.[3,4] Recently, Gaweda and Prochorow[5] reported similar evidence for the identical fluorescent state in the tetracyanobenzene and *p*-xylene system from their measurements of the decay times of fluorescence and investigation of the influence of solvent polarity on the fluorescence spectra.

On the other hand, the experimental and theoretical studies in the previous papers revealed that there are two different fluorescent state of the exciplex and EDA complex in the intramolecular system of (9,10-dicyanoanthracene)-$(CH_2)_3$-(naphthalene) (DCAN).[6,7] These two different fluorescent states were attributed to the unsymmetric property of the naphthyl moiety around the trimethylene chain in DCAN. Therefore, an intramolecular system containing an electron donor which has C_2 symmetry around the trimethylene was predicted to show the exciplex and EDA complex fluorescences from the identical fluorescent state. This paper describes further investigation of the exciplex and the EDA complex in the DCA-alkylnaphthalene system and in the intramolecular system of (9,10-dicyanoanthracene)-$(CH_2)_3$-(pentamethylbenzene).

Experimental

Materials and Measurements. Purification of materials and solvents were described in the previous papers. Commercial zone-refined samples of hexamethylbenzene were used after recrystallization (three times) from ethanol. Pentamethylbenzene and durene were recrystallized six or seven times from ethanol.

Determination of the fluorescence and absorption spectra, and the fluorescence polarization were described previously.[4,6] The fluorescence lifetimes and time-resolved fluorescence spectra were determined by analyzing exponential decay curves measured by an oscilloscope (Tektronix 465), and by a coaxial N_2 gas laser excitation (3371 Å, ~20 kW, ~5 ns width).

Synthesis of 1-(9,10-Dicyano-2-anthryl)-3-(pentamethylphenyl)-propane. The sample of *1-(9,10-dicyano-2-anthryl)-3-(pentamethylphenyl)propane* was synthesized by bromination and cyanogenation of 1-(2-anthryl)-3-(pentamethylphenyl)propane, which was prepared by the similar route to that of 1,3-dinaphthylpropane.[8] The unsaturated ketone, *1-(2-anthryl)-3-(pentamethylphenyl)-2-propen-1-one*, was prepared from 2-acetylanthracene and pentamethylbenzaldehyde: mp 214—216 °C.

Found: C, 88.22; H, 6.19%. Calcd for $C_{28}H_{26}O$: C, 88.85; H, 6.92%.

A solution of the unsaturated ketone (400 mg) in tetrahydrofuran (100 ml) was hydrogenated over 5% Pd/C for about 8 hr. The ketone, *1-(2-anthryl)-3-(pentamethylphenyl)-1-propanone* was obtained: mp 190 °C.

Found: C, 87.99; H, 7.49%. Calcd for $C_{28}H_{28}O$: C, 88.38; H, 7.42%.

The ketone (300 mg) was reduced in refluxing (4 hr) diethylene glycol (5 ml) containing hydrazine (1 ml, ~95%) and sodium hydroxide (500 mg). The mixture was diluted with water and extracted with benzene. The yellow product was purified through silica gel with benzene–hexane, and recrystallized from benzene–hexane: mp 181 °C.

Found: C, 91.48; H, 7.49%. Calcd for $C_{28}H_{30}$: C, 91.75; H, 8.25%.

The hydrocarbon was brominated and cyanogenated in the way described in the previous paper.

1-(9,10-Dibromo-2-anthryl)-3-(pentamethylphenyl)propane. Recrystallized from benzene: mp 157 °C.

Found: C, 64.01; H, 5.42%. Calcd for $C_{28}H_{28}Br_2$: C, 64.13; H, 5.38%.

1-(9,10-Dicyano-2-anthryl)-3-(pentamethylphenyl)propane. Purifiedaby preparative thin layer chromatography and recrystallized from hexane: mp 264 °C.

Found: C, 86.43; H, 6.75; N, 6.54%. Calcd for $C_{30}H_{28}N_2$: C, 86.49; H, 6.78; N, 6.73%.

Results and Discussion

The exciplex formation between DCA and aromatic hydrocarbons was reported first by Chandross and Ferguson.[9] The exciplex fluorescence in the 3-methylpentane (MP) solutions of DCA and several alkylbenzenes were observed at room temperature. The exciplex fluorescence was almost quenched below ~150 K, while the fluorescence due to the EDA complex was observed in the nonpolar solution of these

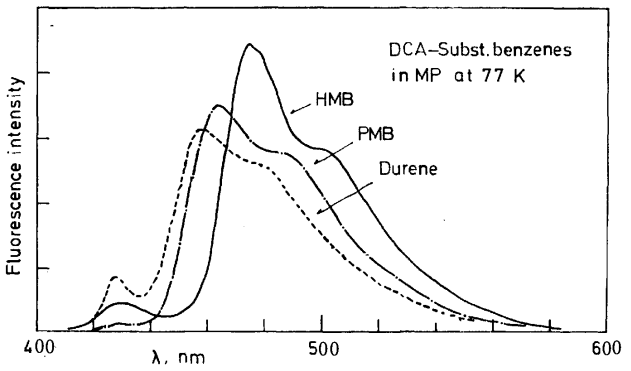

Fig. 1. Fluorescence spectra of MP solutions of DCA and several alkylbenzenes at 77 K (concentrations: DCA, 2×10^{-6} M; HMB, 6×10^{-3} M; pentamethylbenzene, 1×10^{-2} M; durene, 9×10^{-3} M).

EDA systems below ~120 K. The fluorescence spectra of the EDA complexes at 77 K are shown in Fig. 1. These exciplex and EDA complex were characterized by their fluorescence excitation and the absorption spectra at room temperature and at low temperature. The EDA complex fluorescence was observed only in the nonpolar solvents such as MP and methylcyclohexane (MC), but none in the polar solvents.[3,6] The fluorescence behavior in DCA-alkylbenzene is quite similar to the results in DCA-alkylnaphthalene reported previously.[3,4,6] Fluorescence lifetimes of these exciplex and EDA complex are considerably smaller in the DCA–alkylbenzene system (summarized in Table 1) than in the DCA–alkylnaphthalene system (~40—100 ns).

Table 1. Fluorescence maxima and life times of the exciplex (at room temperature) and the EDA complex (at 77 K) in MP solution of DCA and several alkylbenzenes, and of DCAB

DCA–alkylbenzenes and DCAB	Exciplex		EDA complex	
	λ, nm	τ, ns[a]	λ, nm	τ, ns[a]
Hexamethylbenzene	494	19	476	32
Pentamethylbenzene	482	21	465	34
Durene	467	21	~460	34
DCAB	501	72	~507[b]	106

a) Errors are approximately ±1 ns. b) Determined by time-resolved fluorescence spectra.

The fluorescence of the EDA complex in the MP solution of DCA and hexamethylbenzene (HMB) was determined at 77 K to exhibit very small positive polarization with the excitation at 360 nm, as shown in Fig. 2. In the DCA and alkylnaphthalene systems reported previously, the fluorescence polarization of the MP solution of the EDA complex at 77 K with the excitation at 370 nm (LE band in DCA) decreased from negative to more negative value, and the fluorescence lifetimes increased with decreasing ionization potential of alkylnaphthalenes.[4] The results of these fluorescence lifetimes and polarizations in DCA-alkylnaphthalenes were attributed to the considerable charge-transfer

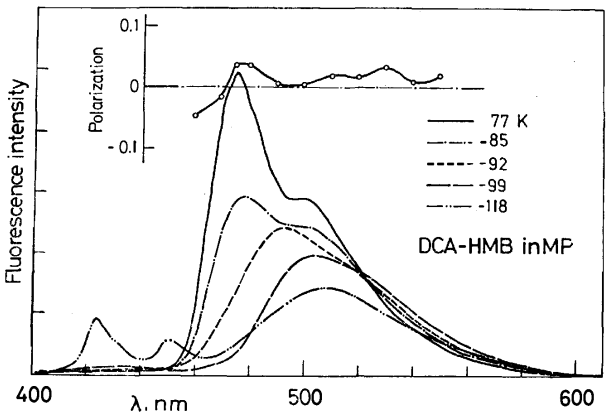

Fig. 2. Fluorescence spectra of an MP solution of DCA and HMB at several temperatures and fluorescence polarization at 77 K excitation at 360 nm). Concentration: DCA, 5×10^{-6} M; HMB, 1×10^{-3} M.

character in the fluorescent state of the EDA complex. From the small fluorescence lifetimes and small positive polarization obtained in DCA–alkylbenzenes, the fluorescent state of the EDA complex in this system seems to consist mostly of the locally excited state of DCA. The fluorescence lifetimes in the MP or MC solution of DCA–HMB exhibit continuous variation from room temperature (exciplex) to 77 K (EDA complex) as shown in Fig. 3, which implies the identical fluorescent state of the exciplex and the EDA complex.

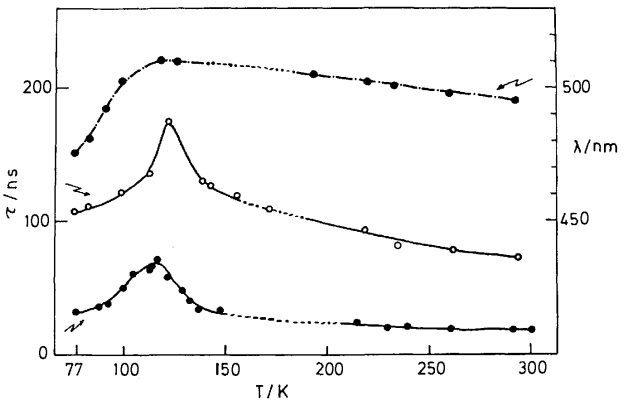

Fig. 3. Temperature dependence of fluorescence maxima and lifetimes of the exciplex and EDA complex in MP (lifetimes monitored at 540 nm); -·-·-●-·-·-and —●— are fluorescence maxima and lifetimes in DCA–HMB, respectively, and —○— is the fluorescence lifetimes in DCAB.

The fluorescences of an MP solution of (9,10-dicyanoanthracene)-$(CH_2)_3$-(pentamethylbenzene) (abbreviated to DCAB) at several temperatures are shown in Fig. 4. The exciplex fluorescence (λ_{max} ~500 nm) was completely quenched below ~150 K, and no fluorescence maximum in this wavelength region was detected at 77 K. However, the time-resolved fluorescence spectra of this solution at 77 K revealed that the fluorescence with a maximum at ~510 nm was hidden by a strong fluorescence of the DCA moiety in DCAB, as shown in Fig. 5. The fluorescence excitation spectrum of this

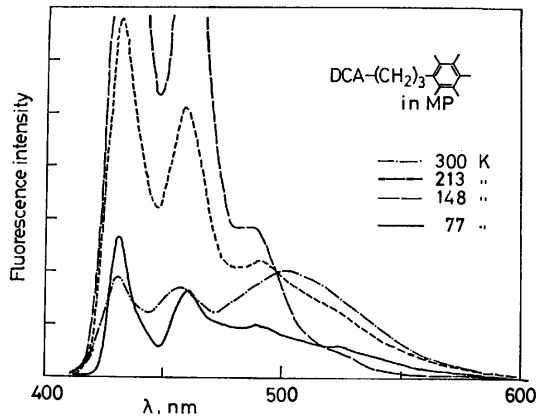

Fig. 4. Fluorescence spectra of an MP solution of DCAB at several temperatures (concentration: ~4×10^{-5} M).

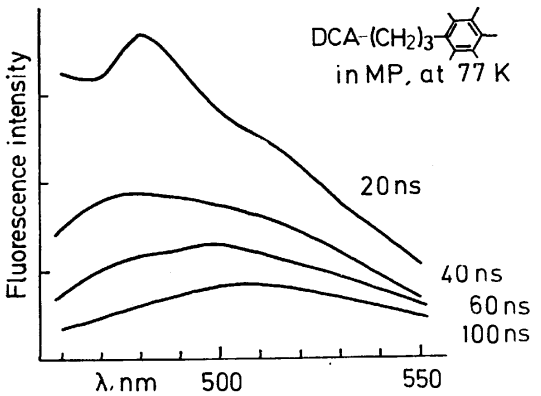

Fig. 5. Time-resolved fluorescence spectra of an MP solution of DCAB at 77 K.

solution (77 K) monitored at 530 nm showed significantly different from the spectrum monitored at 430 nm. Furthermore, the absorption spectrum of DCAB in dilute solution of MP (~10^{-5} M) demonstrated considerable EDA complex formation at 77—140 K. Therefore, the weak fluorescence of an MP solution of DCAB shown in Fig. 5 may be ascribed to the fluorescence of the intramolecular EDA complex.

The rise and decay curves of the exciplex fluorescence were observed in a dioxane solution of DCAB at room temperature by nanosecond laser excitation, while neither rise time of the exciplex fluorescence was detected in less viscous solution such as MP or 2-methyltetrahydrofuran at room temperature, nor rise time was detected in the viscous solution of DCAB in MP at ~100 K where the intramolecular EDA complex was formed. Similar time-development of the exciplex fluorescence was also observed in the intermolecular system of DCA–HMB. They are shown in Fig. 6. These results suggest that the fluorescence in the ~500 nm region at room temperature is ascribed to the exciplex different from the EDA complex at low temperature, though the characterization of the exciplex and the EDA complex was already suggested by the absorption and fluorescence excitation spectra, as mentioned above.

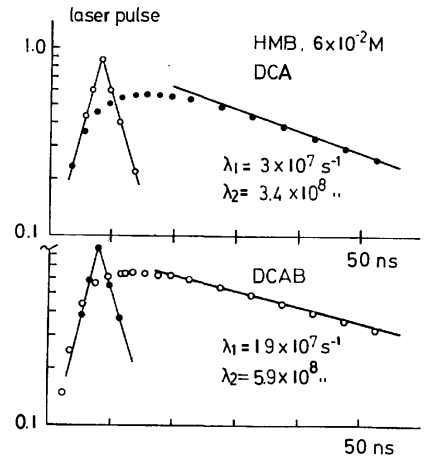

Fig. 6. Time-developments of the exciplex fluorescence (monitored at 560 nm) in the dioxane solutions of DCA–HMB and DCAB at room temperature. Time dependent exciplex concentration is expressed as a following equation; $[(DA)^*]=\frac{C}{\lambda_2-\lambda_1}\{\exp(-\lambda_1 t)-\exp(-\lambda_2 t)\}$. The time constant, λ_1 was obtained from the decay curve, and λ_2 was obtained from λ_1 and the time lag between the maxima of [(DA)*] and the exciting laser pulse; $t_1=\frac{\ln(\lambda_2/\lambda_1)}{\lambda_2-\lambda_1}$.

The fluorescence liferimes of the exciplex (room temperature) in the MP solution of DCAB were observed to vary continuously to that of the EDA complex (77 K). This temperature dependence of the fluorescence lifetimes in DCAB is almost same as that in the DCA–HMB system, as shown in Fig. 3. The continuous change of the fluorescence lifetimes means that there is no different fluorescent state in the exciplex and the EDA complex.[3,4] This fact seems to be attributable to the C_2 symmetry of the pentamethylphenyl moiety around the trimethylene chain in DCAB as metnioned in the introductory section.

As seen in Fig. 3, it is noteworthy that a remarkable temperature dependence of the fluorescence lifetimes of the EDA complex at ~120—77 K. The solvent viscosity increases markedly below ~120 K to make a rigid glass at 77 K.[10] Decrease of fluorescence lifetimes both in the inter- and intramolecular EDA complexes from ~120 K to 77 K are ascribed to the solvent viscosity, and this is consistent with the remarkable temperature dependence of the fluorescence spectra of DCA–HMB shown in Fig. 2. The solvent viscosity reduces the extent which molecular reorientation can occur during the excited state, and as the results the fluorescence lifetime of the EDA complex is reduced. Therefore, the fluorescence emmits from near Franck-Condon excited state of EDA complex at 77 K,[11] which seems to be almost locally excited state of DCA. It is because the fluorescence of the EDA complex of DCA–alkylbenzenes at 77 K has a vibrational progression ($\bar{\nu}$=~1260 cm^{-1}) and positive polarization with the local excitation in the EDA complex, as mentioned above.

The authors wish to acnowledge useful suggestions of Dr. Keitaro Yoshihara and Mr. Minoru Sumitani for making a coaxial nitrogen gas laser.

Vibrational Spectra and Rotational Isomerism of Alkyl Vinyl Ethers

Masaaki SAKAKIBARA, Fuyuhiko INAGAKI, Issei HARADA, and Takehiko SHIMANOUCHI
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received August 1, 1975)

The rotational isomerism of methyl vinyl ether, ethyl vinyl ether, and *n*-butyl vinyl ether has been studied by means of the vibrational spectra and normal frequency calculations. The enthalpy difference between the *skew* and *cis* isomers in the liquid state of methyl vinyl ether has been determined to be 1440 ± 160 cal/mol. Series of C–O torsional transitions in the *cis* well have been observed for methyl vinyl ether and methyl-d_3 vinyl ether in the region near 230 cm^{-1} and analyzed. It has been concluded for ethyl vinyl ether that the *cis-trans* form (CT) is stable in the solid state and that three forms, CT, SG′, and ST, coexist in the liquid and gaseous states. The spectra in the solid state of *n*-butyl vinyl ether are consistent with the calculated frequencies of the CTTT form.

In a preceding paper the analysis of the mid-infrared spectra in the various states with the support by the normal coordinate treatment was successful for the determination of the rotational isomerism about the C–C axis neighboring a C=C double bond.[1] It was concluded that the *cis* and *skew* conformations are stable for the C–C bond neighboring the *trans* C=C bond, and only the *skew* conformation is stable for the C–C bond neighboring the *cis* C=C bond. As an extension of the work, the rotational isomerism about the C–O bond neighboring a C=C double bond has been studied for methyl vinyl ether, ethyl vinyl ether, and *n*-butyl vinyl ether with the additional information of the Raman spectra. The enthalpy differences among the rotational isomers in the liquid state have also been determined.

In the case of methyl vinyl ether and methyl-d_3 vinyl ether, series of the C–O torsional transitions in the *cis* well have been observed and analyzed by the method described in a preceding paper.[2]

The details and the results are reported in the present paper.

Experimental

Methyl vinyl ether, ethyl vinyl ether, and *n*-butyl vinyl ether were obtained commercially. Methyl vinyl ether was used without further purification. Ethyl vinyl ether and *n*-butyl vinyl ether were purified by fractional distillations. Methyl-d_3 vinyl ether was prepared by the interchange reaction,

$$CD_3OD + ROCH{=}CH_2 \rightleftharpoons ROD + CD_3OCH{=}CH_2,$$

with $Hg(OAc)_2$ as the catalyst and *n*-butyl vinyl ether as the starting alkyl vinyl ether. The purity of the sample was checked by means of infrared spectroscopy.

The infrared spectra were recorded on a Hitachi EPI-L double beam grating spectrometer in the region 700—250 cm^{-1} and on a Hitachi FIS-1 vacuum double beam grating spectrometer in the region 300—60 cm^{-1}. The spectra in the gaseous state were obtained by using the 10-cm and 4.9-m cells with white polyethylene windows and those in the liquid state were taken with 0.025—0.01 mm cells of KBr, KRS-5, or polyethylene windows. The spectra in the solid state were observed at the temperature of liquid nitrogen. Sample deposited on a cooled window of KRS-5, silicon, or KBr was repeatedly annealed until no further spectral change was observed. A low-temperature cell and a Hitachi 205 double beam grating spectrometer at the Institute for Protein Research of Osaka University[3] were used for the measurement of the infrared spectra of methyl vinyl ether in the liquid state.

The Raman spectra were obtained on a JEOL JRS-400D spectrophotometer with the 5145 Å line of a Coherent Radiation CR-3 argon ion laser as the exciting line and on a Spex 1401 spectrophotometer equipped with an NEC He-Cd laser and an NEC He–Ne laser. The He–Cd laser line at 4416 Å and the He–Ne laser line at 6328 Å were used as exciting lines. The latter instrument was calibrated with neon gas emission lines and the observed Raman frequencies are believed accurate to 2 cm^{-1}. The Raman spectra at low temperatures were obtained with a simple glass Dewar-type low temperature cell. The temperature of the sample was controlled by the amount of liquid nitrogen or of Dry Ice added to the cell. The temperature was measured with a thermocouple directly inserted into the sample.

The mid-infrared spectra of the three compounds in the gaseous, liquid, and solid states are shown in Figs. 1—3. The far-infrared spectra of methyl vinyl ether and methyl-d_3 vinyl ether are shown in Fig. 4. The Raman spectra of the three compounds are shown in Figs. 5—7. The observed frequencies are listed in Table 1.

Normal Vibration Calculations

For the purpose to correlate the observed vibration bands with the normal modes of the rotational isomers, the normal vibrations have been calculated by Program NCTB, which is a combination of GCCC, BGLZ, and LSMB,[4] and the HITAC 8800/8700 Computer of the

Computer Center of the University of Tokyo. The bond lengths and the bond angles of methyl vinyl ether determined by microwave spectroscopy[5] were used for the CH_2=CH–O–CH_2 part and 1.522 Å, 1.09 Å, and the tetrahedral angle were assumed for the other C–C bonds, C–H bonds, and the rest of the angles. The values of force constants were transferred from those of 1-alkenes,[1] except for those given in Table 2. The

F(C–O–C)	0.40	Y(O–CH_3)	0.11
R(*cis* C=C–O–C)	0.369	WY(=CH_2, C=C)	0.049
		WY(=CH, C=C)	0.145
		YY(=C–O, O–CH_3)	0.064

a) Only the values of modified force constants are listed in the table. Other force constants are transferred from those of olefins (see Table III of Ref. 1).

values given in this table were determined so as to give the best fit with the observed frequencies for the *cis* form of methyl vinyl ether. These values were transferred to ethyl vinyl ether with various conformations and the CTTT form of *n*-butyl vinyl ether. The torsion angles are taken to be 0°, 60°, 120°, and 180° for the *cis*, *gauche*, *skew*, and *trans* forms, respectively.

As in the case of 1-alkene molecules, the *cis* repulsion constant R were taken into account for the two carbon atoms of the =CH_2 and –O–C parts in the *cis* position. The inclusion of this constant explains the C–O–C bending and C=C–O bending vibrations simultaneously.

Results and Discussion

Methyl Vinyl Ether. Since the bands with frequencies less than 750 cm^{-1} are significantly related

a) Overlapped.

to the molecular conformation, the frequencies observed in this region are summarized and compared with the calculated frequencies in Table 3. The infrared and electron diffraction studies by Owen and Sheppard[6] and Owen and Seip[7] show that this molecule has the two rotational isomers, the *cis* form and the *skew* form with the torsion angle 80—110°. This fact is in agreement with the result for the 1-butene molecule which has *cis* and *skew* for the stable conformations.[8] Accordingly, we assigned the observed bands to the vibrations of the *cis* and *skew* forms, by taking into account the possibility of a considerable deviation of the *skew* form torsion angle.

As shown in Table 3, the strong bands observed in the gaseous state at 702 cm^{-1} (*C* type), 585 cm^{-1} (*B* type), and 328 cm^{-1} (*A* and *B* hybrid) are assigned reasonably to the =CH– wagging, C=C–O in-plane, and C–O–C in-plane bending vibrations of the *cis* isomer, respectively. The two low frequency vibrations, methyl torsion and C–O torsion, are predicted to appear at 225±20 cm^{-1} and 219±20 cm^{-1} from the microwave study.[5] The fairly strong band at about 230 cm^{-1} is composed of three distinct equally separated sharp absorptions (Fig. 4). The corresponding band of the methyl deuterated compound is composed of a quartet and is observed lower than that of the undeuterated compound by 4 cm^{-1} (Fig. 4). We assign this band to =C–O– torsion, taking the small isotopic shift in frequency into account. The methyl torsion may be weak and overlapped with this band. The weak and broad band with some structure near 450 cm^{-1} is explained as the progression of =C–O– torsional transitions for $\Delta v=2$. The details about the potential of internal rotation will be discussed in the later part of this paper.

The band observed at about 525 cm^{-1} in the Raman spectra in the gaseous and liquid states is missing in the spectrum in the solid state. This band is the only band assigned to the *skew* form. This fact is justified by the large enthalpy difference to be described below.

The situation about the key band sensitive to the conformation of this molecule is different from that of 1-alkenes. For the latter case the *cis* conformation gives a band near 550 cm^{-1} which is assigned to one of the CH out-of-plane vibrations of the vinyl group and the *skew* conformation gives a band near 640 cm^{-1}, the frequency shift being caused by the coupling between this vibration and the skeletal deformation vibration. In the case of methyl vinyl ether, this vibration has a higher frequency near 700 cm^{-1} and the coupling with the skeletal deformation is small in the *skew* conformation. The C=C–O bending vibration, on the other hand, seems to be the key band to the conformation. The calculated frequency for the C=C–O bending mode varies from 586 cm^{-1} to 504 cm^{-1} as the torsion angle changes from 0° (*cis*) to 180° (*trans*).

The barrier to internal rotation of the C–O axis has been studied in one-dimensional approximation by the use of three $\Delta v=1$ and four $\Delta v=2$ torsional transitions of methyl vinyl ether and four $\Delta v=1$ transitions of methyl-d_3 vinyl ether. The method described in the preceding paper[2] was used for the analysis. $F(\alpha)$'s were calculated numerically by Pitzer's method[9] and expanded in Fourier cosine series. $F(\alpha)_{cis}$ was calculated with the structural parameters determined for the *cis* form by microwave spectroscopy.[5] $F(\alpha)_{skew}$ was calculated with the same structural parameters as those for $F(\alpha)_{cis}$ except the value of the angle C–O–C, 112°, determined by the electron diffraction analysis.[7] Then, $F(\alpha)_{\text{hybrid}}$ was determined so that it may be continuous as going from the *cis* form to the *skew* form. $F(\alpha)$ determined in this way corresponds to the situation that the angle C–O–C varies as the OCH_3 group rotates around the C–O axis. $F(\alpha)_{cis}$ and $F(\alpha)_{\text{hybrid}}$ were used in the calculation. The values of parameters of $F(\alpha)_{cis}$ and $F(\alpha)_{\text{hybrid}}$ are as follows:

$$F(\alpha)_{cis} = \underset{(2.4960)}{2.8807} + \underset{(0.4485)}{0.6620}\cos\alpha + \underset{(0.2191)}{0.2940}\cos 2\alpha + \underset{(0.0545)}{0.0826}\cos 3\alpha + \underset{(0.0167)}{0.0260}\cos 4\alpha + \underset{(0.0047)}{0.0079}\cos 5\alpha + \underset{(0.0014)}{0.0024}\cos 6\alpha$$

$$F(\alpha)_{\text{hybrid}} = \underset{(2.4246)}{2.7724} + \underset{(0.4008)}{0.5905}\cos\alpha + \underset{(0.2187)}{0.2840}\cos 2\alpha + \underset{(0.0533)}{0.0786}\cos 3\alpha + \underset{(0.0172)}{0.0255}\cos 4\alpha + \underset{(0.0048)}{0.0078}\cos 5\alpha + \underset{(0.0015)}{0.0024}\cos 6\alpha$$

where the values in parentheses are for the deuterated species.

At first, several set values of V_1, V_2, and V_3 were estimated from the 1←0 and 2←1 transitions, 234 cm^{-1} and 230 cm^{-1}, and the enthalpy differences, 1150±250 cal/mol (402±87 cm^{-1})[6] and the energy levels were calculated. After preliminary calculations the value of V_2 was fixed at 628.4 cm^{-1}. The least squares adjustment was performed for the following four cases:

Case A: $F(\alpha)_{cis}$ and the data of methyl vinyl ether are used.

Case B: $F(\alpha)_{cis}$ and the data of methyl-d_3 vinyl ether are used.

Case C: $F(\alpha)_{cis}$ and the data of methyl vinyl ether and methyl-d_3 vinyl ether are used.

Case D: $F(\alpha)_{\text{hybrid}}$ and the data of methyl vinyl ether and methyl-d_3 vinyl ether are used.

The results are given in Table 4. The agreement between the observed and the calculated is satisfactory for both Case A and Case B, but the obtained potential parameters are different for these two cases. In Case C, the calculated frequencies of the normal species are higher than the observed and those of the deuterated

a) Potential parameters and dispersions are as follows in the order of Cases A, B, C, and D; V_1, −19.6 (8.1), −27.0(11.7), −3.4(14.8), and −3.8(13.5); V_2, 628.4 fixed; V_3, 1765.8(62.8), 1908.2(119.6), 1775.6(85.2), and 1810.1(83.1); V_6, −119.7(25.8), −91.0(48.6), −90.0(39.9), and −83.8(38.1).

species are lower than the observed. This inconvenience cannot be overcome even in Case D, where different structures are assumed for the different internal rotation angles. All these are explained by the difference of vibrational couplings in the normal and the deuterated species. In the normal species, the C–O torsion may couple with the methyl torsion, which is estimated at about 240 cm^{-1} by microwave study.[5] On the other hand, the methyl torsion shifts to lower frequency region on methyl deuteration and the coupling between C–O torsion and methyl-d_3 torsion becomes small; thus the one dimensional model approximation may work better for the deuterated species. This interpretation is verified by the normal coordinate analysis. The potential energy distribution shows that the methyl torsion and C–O torsion couple in the ratio of one to two in the normal species and in the ratio of one to six in the deuterated species. It is concluded that the set of potential parameters obtained with the data of methyl-d_3 vinyl ether is the most probable of the four cases. The values of the parameters for Case B are as follows: $V_1=-27.0$, $V_2=628.4$, $V_3=1908.0$, and $V_6=-91.0$ cm^{-1} (See also the footnote of Table 4). The *skew* transitions are calculated at about 160 cm^{-1}, but no distinct band has yet been observed.

The observed frequency, 234 cm^{-1}, of C–O torsion of methyl vinyl ether is much higher than that of methyl ethyl ether,[3] 113 cm^{-1}. This may be explained by the conjugation between the vinyl group and the lone pair electron of the oxygen atom.

Ethyl Vinyl Ether. The observed frequencies are compared with the calculated in Table 5. Owen and Sheppard analyzed the rotational fine structure of the band at 813 cm^{-1} and suggested that the stable conformer is the planar "sickle shaped" form (the *cis-trans* form).[10] From the comparison of the infrared spectra of gaseous, liquid, and solid states (Fig. 2), it is clear that

a) Overlapped.

the dominant isomer in the gaseous state is also dominant in the liquid state and remains in the solid state. The weak bands at 523, 500, 425, and 330 cm^{-1} in the spectrum of the gaseous state are also observed in the spectrum of the liquid state and are assigned to the less stable forms. The intensity dependence on temperature was examined for the Raman bands at 600, 533, 500, 436, and 398 cm^{-1} as will be given below. The results indicate that the bands at 600 and 398 cm^{-1} belong to the most stable isomer (the CT form) and the two bands at 500 and 436 cm^{-1} and the band at 533 cm^{-1} are due to the other two less stable isomers. In other words, three rotational isomers coexist in the liquid and gaseous states of ethyl vinyl ether. The obtained enthalpy differences of the two less stable isomers to the CT form are of the same order as the enthalpy difference of the *skew* isomer to the *cis* isomer of methyl vinyl ether. This fact suggests that the two isomers take the *skew* conformation around the C–O axis.

The above discussion is supported by the results of the normal frequency calculations. The key bands to the conformation are the C=C–O bending vibration and the C–O–C bending vibration in the case of ethyl vinyl ether. It is noticed that the *cis* and *skew* forms around the =C–O– axis give frequencies of about 600 and 500 cm^{-1} and the *trans* and *gauche* forms around the –O–C– axis give frequencies of about 400 and 430 cm^{-1}, respectively. The observed frequencies in the solid state correspond well to the calculated frequencies of the CT form. Among the observed frequencies in the liquid state, 500 and 436 cm^{-1} correspond to the calculated frequencies, 510 and 441 cm^{-1}, of the SG′ form (the stretched form). The band at 533 cm^{-1} is assigned to the ST form, the calculated frequency being 526 cm^{-1}. The CG form may be eliminated from the discussion on conformation because of its steric instability.

n-*Butyl Vinyl Ether.* The observed frequencies and the calculated frequencies for the CTTT form are given in Table 6. The complex features of the spectra in the gaseous and liquid states indicate the coexistence of rotational isomers. The situation of the rotational isomerism around the C–C axis next to the O–C axis seems to be rather peculiar. The small repulsive interaction between the oxygen atom and the CH_2

group in the O–CH_2–CH_2–CH_2 part of *n*-butyl vinyl ether makes the *gauche* form more stable than that in the case of the ordinary *n*-hydrocarbons. The complex features of the spectra may partly be due to this situation. The spectra in the solid state, however, are rather simple and have similar patterns to those of methyl vinyl ether and ethyl vinyl ether in the region 600—300 cm^{-1}, with an additional band at 440 cm^{-1}. The bands at 611 and 380 cm^{-1} correspond to those at 591 and 344 cm^{-1} of methyl vinyl ether and those at 603 and 395 cm^{-1} of ethyl vinyl ether, respectively. This fact suggests that the stable isomer in the solid state is the *cis* conformer around the =C–O– axis and the *trans* conformer around the –O–C– axis. An extra band at 440 cm^{-1} may be assigned to the CCC deformation of the extended form of the *n*-butyl group. The corresponding vibration of trans *n*-butane is observed at 425 cm^{-1} in the solid state.[11]

The observed frequencies of the solid state are well

explained by the calculated frequencies of the CTTT form. The calculated frequency at 426 cm^{-1} corresponds to the observed frequency at 440 cm^{-1} in the solid state.

Enthalpy Differences in the Liquid State. The Raman spectra of methyl vinyl ether and ethyl vinyl ether at different temperatures are shown in Fig. 8 and $\ln(I_a/I_b)$ plots *vs* $1/T$ are shown in Fig. 9, where I_a and I_b are the intensities of the Raman bands, a and b, belonging to the two rotational isomers.

For methyl vinyl ether, the enthalpy difference between the two isomers, the *skew* and *cis* forms, is obtained as 1440±160 cal/mol from the intensity dependence of the two bands at 527 and 591 cm^{-1} on temperature (Fig. 8A and plot A of Fig. 9). This value is consistent with the values 1150 and 1200 cal/mol obtained for the gaseous state by infrared[6] and electron diffraction[7] methods within the experimental errors.

In the case of ethyl vinyl ether, the intensity dependence on temperature has been examined for the Raman bands at 600, 533, 500, 436, and 398 cm^{-1} and the enthalpy differences obtained for the band pairs, 533 and 600 cm^{-1}, 436 and 600 cm^{-1}, 500 and 600 cm^{-1}, and 398 and 600 cm^{-1} are 1840±130, 1330±130, 1520±60, and 240±60 cal/mol, respectively (Fig. 8B and plots, B1, B2, B3, and B4 of Fig. 9). The enthalpy difference, 240±60 cal/mol, obtained for the bands at 398 and 600 cm^{-1} does not necessarily indicate that these bands are of different origins. It is possible that the band at 398 cm^{-1} is overlapped by the band due to the ST form (See Table 5).

The authors are indebted to Dr. Teizo Kitagawa of the Institute for Protein Research of Osaka University for the use of the low-temperature cell and the Hitachi 205 spectrometer.

Formation of Diacetylene Ion ($A^2\Pi_u$) by Controlled Electron Impact on Unsaturated Molecules

Masaharu TSUJI,* Teiichiro OGAWA, Totaro IMASAKA, Yukio NISHIMURA,* and Nobuhiko ISHIBASHI

Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812

(Received August 2, 1975)

By the impact of an electron beam (100—450 eV) on aliphatic hydrocarbons (C_2H_2, C_2H_4, C_4H_6), cyclooctadienes, and aromatic molecules (C_6H_6, $C_{10}H_8$, $C_{12}H_{10}$, *etc.*) at about 10^{-3} Torr, the Schüler's T spectrum of diacetylene ion ($A^2\Pi_u$–$X^2\Pi_g$) was observed in the 505—570 nm region, in addition to the well-known systems of H(Balmer), CH(A–X), and C_2(Swan). Three different kinds of mechanisms for the formation of $C_4H_2^+$ (A) were derived from the dependence of the emission intensity on the electron-beam current and the gas pressure: (a) the primary excitation process (C_4H_6), (b) the secondary excitation process (aromatic molecules, cyclooctadienes), and (c) the dimerization excitation process (C_2H_2, C_2H_4). The intensity ratio ($C_4D_2^+/C_4H_2^+$) of the T spectrum from C_6H_6 and C_6D_6 was 0.83 ± 0.04 for the (0,0) sequence at 300 eV excitation.

Schüler and Reinebeck observed a new spectrum in low current discharges through a number of organic vapors (acetylene, benzene, naphthalene, *etc.*), usually in a carrier gas such as helium.[1] This spectrum was labelled "T". Calloman assigned the "T" spectrum to the diacetylene (1,3-butadiyne) ion, $C_4H_2^+(A^2\Pi_u-X^2\Pi_g)$, through isotopic studies and detailed analysis under a high resolution.[2]

Mass-spectrometric measurements have provided information on the mechanism of the formation of $C_4H_2^+$ under electron impact; this ion is produced through a primary collision of an electron with a molecule in the cases of aromatic molecules,[3] and through some ion-molecule reactions at high pressures in the cases of C_2H_2[4] and C_2H_4.[5] In addition, the dimeric ion, $C_4H_2^+$, has been found to be formed by ion-molecule reactions in the α-particle radiolysis of C_2H_2[6] and C_2H_4[7] and in the photoionization of C_2H_2,[8] and by the chemi-ionization reaction between excited- and ground-states of C_2H_2.[9] However, no studies have been carried out on the mechanism of the formation of $C_4H_2^+$ in the excited state.

The photometric measurement on the collision of an electron beam with a molecular jet is of great advantage for the investigation of the excitation, the ionization, and the dissociation processes and of the reactions of the species thus produced.[10–14] We have observed the Schüler's T spectrum by electron impact on aromatic molecules and aliphatic hydrocarbons.[11] It has been found that the excited $C_4H_2^+$ species were formed from naphthalene by a secondary collision of an electron with a primary product.[11] The purpose of this investigation is to elucidate the mechanism for the formation of $C_4H_2^+$ (A) under controlled electron-impact excitation (100—450 eV) on such organic vapors as aromatic molecules, cyclooctadienes, and aliphatic hydrocarbons.

Experimental

The electron-impact apparatus and the experimental procedure are essentially identical with those described previously.[11] An electron beam of a variable energy (100—450 eV) and a variable current (1—3000 μA) passes through the collision chamber so as to collide with the sample gas introduced from a nozzle. The pressure in the collision region was estimated by a penning gauge to be of the order of 10^{-3} Torr when the sample gas was introduced and of the order of 10^{-5} Torr when it was shut off. The pressure in the gas reservoir measured by a mercury manometer was estimated to be proportional to that in the actual collision region.

The photoemission of the excited species was measured in the visible region (400—660 nm) with a JASCO CT-50 monochromator equipped with a 1200 groove/mm grating blazed for 500 nm. The photons were detected by either an EMI 9558QB photomultiplier with a DC amplifier or an HTV R585 photomultiplier with an NF-PC545A photon counter. The isotope effect on the emission intensity of the T spectrum from C_6H_6 and C_6D_6 was measured by exchanging the reagent gases alternatively several times under identical conditions. The intensities were measured in the band area. The wavelength was calibrated by means of a low-pressure mercury lamp; its error was estimated to be within ±2 Å.

The gas samples used were of Research Grade from the Takachiho Trading Co. (C_2H_2 99.6%, C_2H_4 99.8%, 1,3-C_4H_6 99.5%); the other compounds, of the best grade, were obtained from Wako Pure Chemical Ind. or the Kishida Chemical Co., except for C_6D_6, which was obtained from Merck. The samples were subjected to several freeze-pump-thaw cycles before use.

Results

Aromatic Molecules. Most aromatic molecules show the photoemissions of the parent molecule (S_1-S_0) and a few fragment species in the 240—450 nm region under electron-impact excitation.[10–14] The spectra in the visible region (400—660 nm) are found to consist of various bands of fragment species. Typical spectra of C_6H_6 and C_6D_6 are shown in Figs. 1 and 2, in which most features of interest appear.

The sharp lines at 656 (not shown in Figs. 1 and 2), 486, 434, and 410 nm with high peak intensities are identified as the hydrogen Balmer serires ($H_{\alpha,\beta,\gamma,\delta}$ and $D_{\alpha,\beta,\gamma,\delta}$). The 4300 Å system ($A^2\Delta-X^2\Pi$) of the CH or CD radical and the Swan system ($d^3\Pi_g-a^3\Pi_u$) of C_2 are also identified. It should be noticed that, upon deuterium substitution, the intensities of the Balmer

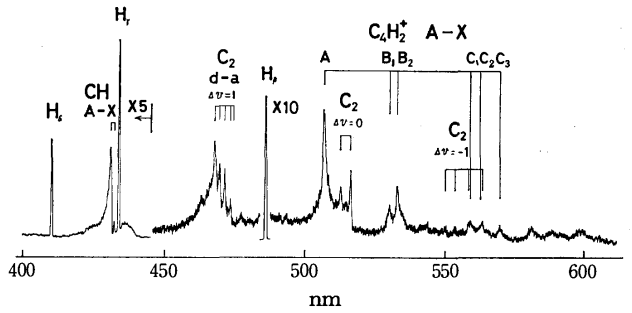

Fig. 1. Emission spectrum of C_6H_6 by controlled electron impact. Electron energy 300 eV, electron-beam current 1 mA, monochromator resolution 4 Å (FWHM).

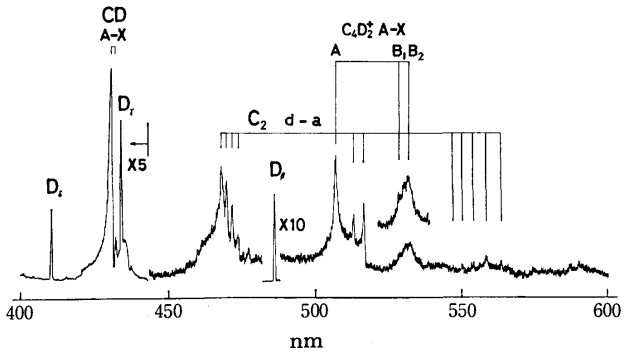

Fig. 2. Emission spectrum of C_6D_6 by controlled electron impact. Electron energy 300 eV, electron-beam current 1 mA, monochromator resolution 4 Å (FWHM). Upper spectrum of group B of $C_4D_2^+$ (A–X); electron energy 300 eV, electron-beam current 2 mA, monochromator resolution 3 Å (FWHM).

lines decrease, while those of the methylidyne radical increase.

The strong band at 5069 Å and the doublet band at 5303 and 5331 Å in the spectrum of C_6H_6 are assigned to the Schüler's T spectrum of $C_4H_2^+$ ($A^2\Pi_u - X^2\Pi_g$).[2] In the spectrum of C_6D_6, the corresponding bands appear at 5064, 5285, and 5318 Å. The doublet band can be resolved more clearly with a higher resolution, because a shoulder at about 530 nm makes the spectrum broad, as is shown in Fig. 2.

The band at around 507 nm, which shows the smallest isotope shift, is assigned to the (0,0) sequence, which is designated as A.[1,2] The bands at 530 and 533 nm, designated as B_1 and B_2, are assigned to the (0, ν_3'') and (0, $2\nu_7''$) sequences. The shoulder at 530 nm in C_6D_6 is ascribed to other strong sequence bands of the group B_2, as was reported by Calloman.[2] The groups C_1 (0, $\nu_3''+2\nu_7''$), C_2 (0, $4\nu_7''$) and C_3 (0, ν_2'') are observed in C_6H_6 at 559, 563, and 570 nm respectively, although the former two bands are partially overlapped on the (1, 2) and (0, 1) bands of the C_2 Swan system. The assignments of the vibrational modes are as follows: ν_2 is symmetric C≡C stretching, ν_3 C–C stretching and ν_7 symmetric bending.

The relative intensity of the T spectrum from C_6D_6 to that from C_6H_6 is measured for group A under 300 eV —1 mA excitation. The $C_4D_2^+/C_4H_2^+$ ratio is found to be 0.83 ± 0.04.

The Schüler's T spectrum is observed for various aromatic molecules, such as benzene, hydrocarbons (toluene, *o*, *m*, *p*-xylenes, cumene, *p*-cymene, phenylacetylene, naphthalene and biphenyl), halides (fluoro-, chloro-, iodo-benzenes, *p*-chlorotoluene and benzyl chloride), and nitrogen derivatives (benzonitrile, aniline and 2-naphthylamine). Schüler and Reinebeck reported that the intensity of the T spectrum was greatly reduced by the substitution of Cl or NH_2.[1] However, no such significant change in intensity can be found in chlorobenzene, aniline, and 2-naphthylamine in the present study. Meanwhile, oxygen derivatives (phenol, anisole, phenetol and benzophenone) and nitrobenzene do not show appreciable bands of $C_4H_2^+$, as in the case of phenol by discharge[1]; this is partly because the intense comet-tail system of CO^+ occupies the wavelength region of the strongest band of $C_4H_2^+$.

All the aromatic molecules described above give the bands of such fragment species as H(Balmer), CH(A-X), and C_2(d-a). Their intensities in C_6H_6 are found to be linear both to the electron-beam current and the gas pressure, as has partly been reported previously.[10] However, the band intensity of $C_4H_2^+$ in C_6H_6 is found to be proportional to the second power of the electron-beam current, although it is also proportional to the gas pressure, as is shown in Fig. 3. Similar results are obtained for H, CH, C_2, and $C_4H_2^+$ in most of the other aromatic molecules described above.

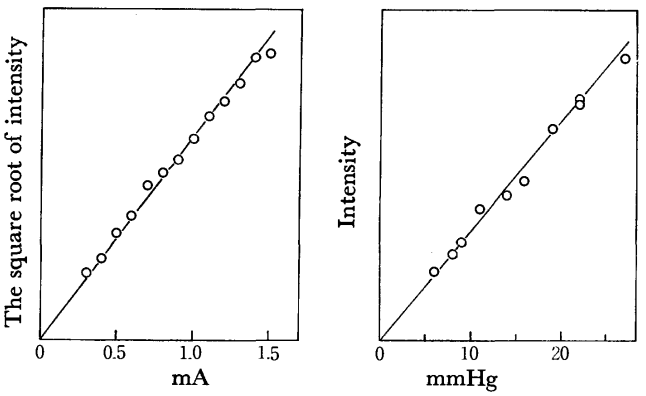

Fig. 3. Dependence of photoemission intensity (arbitrary units) of C_6H_6 on the electron-beam current (mA) and the pressure in the gas reservoir (mmHg).
Left; $C_4H_2^+$ (507 nm), electron energy 300 eV.
Right; $C_4H_2^+$ (507 nm), electron energy 300 eV, electron-beam current 300 μA.

Cyclooctadienes. The emission spectra of such cyclic dienes as 1,3- and 1,5-cyclooctadienes under electron-impact excitation were investigated to see whether these dienes showed the T spectrum, and if, they did, whether the difference in the conjugation of the two double bonds in these isomers affected the mechanism of the formation of $C_4H_2^+$ (A).

Both dienes are found to give the T spectrum with almost the same intensity, in addition to the band systems of H, CH, and C_2. The relationships between their intensities and the electron-beam current are identical with those of C_6H_6 for both isomers; the intensity of the $C_4H_2^+$ band is proportional to the

second power, and that of the other bands to the first power, in the region of 400—1500 μA. However, the pressure dependence of the intensities was difficult to determine because of the low vapor pressures of cyclooctadienes.

Aliphatic Hydrocarbons. Acetylene, ethylene, diacetylene, and butadiene are known to give the strong T spectrum in the positive column of the discharge tube.[1,2] In the present study, this spectrum is observed for acetylene, ethylene, and 1,3-butadiene; besides this spectrum, these molecules show relatively strong bands of H, CH, C_2, and CH^+ (A–X). It should be noticed that the dimeric ion, $C_4H_2^+$, is obtained from C_2H_2 and C_2H_4 at low pressures of about 10^{-3} Torr. However, the intensity is so weak that only the strongest band at 507 nm is appreciable, with a high electron-beam current. Thus, there are significant differences in the intensities of the T spectrum; the order is generally: aromatic molecules>1,3-butadiene≈cyclooctadienes≫acetylene≈ethylene, as compared at 100—450 eV, 1 mA excitation.

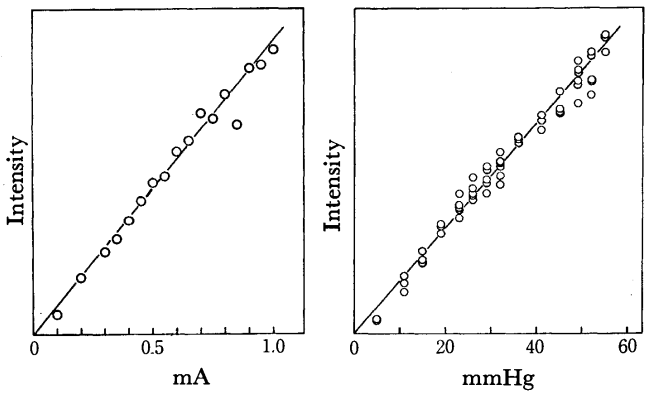

Fig. 4. Dependence of photoemission intensity (arbitrary units) of 1,3-C_4H_6 on the electron-beam current (mA) and the pressure in the gas reservoir (mmHg).
Left; $C_4H_2^+$ (507 nm), electron energy 300 eV.
Right; $C_4H_2^+$ (533 nm), electron energy 300 eV, electron-beam current 100 μA.

The current dependence of the intensity of the $C_4H_2^+$ band from 1,3-butadiene differs from that in the cases of the aromatic molecules; the band intensity of $C_4H_2^+$ as well as those of H, CH, C_2, and CH^+, is proportional to the first power of the electron-beam current and the gas pressure, as is shown in Fig. 4. In the cases of C_2H_2 and C_2H_4, similar quantitative measurements could not be carried out because of the weakness of the T spectrum and because of the band overlap of the group A with the tail band of the C_2 $\Delta v=0$ sequence.

Discussion

The Schüler's T spectrum consists of the (0, 0) and (0, v_i'') sequences and the (0, 0) sequence is the most intense; thus, the Franck-Condon principle indicates that the molecular dimensions of this ion are not very different in the excited- and the ground-states.

The mechanism of the formation of the excited species by electron impact can be discussed in terms of the dependence of the emission intensity on the electron-beam current and the gas pressure. Schüler and Reinebeck reported that they almost exclusively obtained the emissions of C_2, CH, and H_2 with high current densities in a discharge tube through various organic vapors (C_2H_2, C_6H_6, *etc.*).[1] Upon a decrease in the current, the diatomic bands became weak and the T spectrum came out. However, no quantitative measurements have been carried out on the changes in the intensity upon variations in the current density and the gas pressure.

In the present crossed electron-beam and molecular-jet method, most emitting excited species have been confirmed to be produced by a single collision of an electron with a molecule at low pressures;[10–14] such examples are excited fragments as H, CH, and C_2 in the present study, since their emission intensities are proportional both to the electron-beam current and to the gas pressure. Two kinds of exceptions have been pointed out:[13] (1) the excited CN, CO, and CO^+ species produced through the scission of two aromatic bonds (*e.g.*, CO^+ from dimethoxybenzenes[13]), and (2) the excited species produced through the formation of a new chemical bond (*e.g.*, HCl^+ from chlorobenzene[11]). The band intensities in these exceptional cases have often been found to be apparently proportional to the fractional power (1.0—2.0) of the electron-beam current. The deviation from the linearity can be interpreted by the competitive reactions between a one-electron process and a two-electron process, as was reported in the case of CO^+ from dimethoxybenzenes.[13] The formation of $C_4H_2^+$ (A), however, proceeds through either a one-electron process or a two-electron process; the mechanisms can be classified in the following three groups.

(a) The Primary Excitation Process. This process is applicable to 1,3-butadiene. The linear dependence of the emission intensity on the electron-beam current and the gas pressure shows that $C_4H_2^+$ (A) is produced through a unimolecular dissociative excitation induced by a collision with an electron and that the probability of collisional deactivation is negligible within its radiative lifetime:

$$1,3\text{-}C_4H_6 + e \longrightarrow C_4H_2^{+}*$$

where the asterisk denotes the emitting excited state of $A^2\Pi_u$. This result indicates that excited $C_4H_2^+$ (m/e= 50) should be produced in the ionization chamber of a conventional mass spectrometer.

(b) The Secondary Excitation Process. Since the band intensity is proportional to the second power of the electron-beam current and to the first power of the gas pressure, the formation of $C_4H_2^+$ (A) from C_6H_6 proceeds through the two-electron and unimolecular dissociative excitation:

$$M + e \longrightarrow X$$
$$X + e \longrightarrow C_4H_2^{+}*$$

where M represents an incident molecule and where X stands for some kinds of intermediates. The possible intermediates are the ground state of $C_4H_2^+$, C_4H_2, and other larger neutral or ionic species. This process is also applicable to other aromatic molecules.

A number of mass-spectrometric measurements show that $C_4H_2^+$ is produced by the unimolecular decomposition of aromatic molecules.[3] Most of the $C_4H_2^+$ species thus produced in the ionization chamber are expected to be in the ground state.

(c) The Dimerization Excitation Process. One of the most prominent features of C_2H_2 and C_2H_4 in their photolysis and radiolysis is that these olefins are apt to polymerize mainly through consecutive ion-molecule reactions.[4-9] Hence, C_2H_2 and C_2H_4 may dimerize under the present experimental conditions. Meanwhile, since the T spectrum can be observed only at a high electron-beam current, two electrons should participate in the formation of $C_4H_2^+$ (A). These results lead to the conclusion that $C_4H_2^+$ (A) is produced from C_2H_2 and C_2H_4 through collisions of intermediates (neutral or ionic dimerization products) with another electron. The weakness of the intensity of the T spectrum in the present method indicates that the probabilities of such secondary reactions are much smaller than those in the discharge tube.

A number of mass-spectrometric studies of the ion-molecule reactions of C_2H_2 by electron impact[4] and α-particle radiolysis[6] occurring in the ionization chamber at elevated pressures show that the major secondary reactions of the primary ions at about 10^{-3} Torr are the formation of $C_4H_3^+$ and $C_4H_2^+$ as follows:

$$C_2H_2^+ + C_2H_2 \longrightarrow C_4H_2^+ + H_2 \quad (1)$$

$$\searrow C_4H_3^+ + H \quad (2)$$

$$C_2H^+ + C_2H_2 \longrightarrow C_4H_2^+ + H \quad (3)$$

Meanwhile, Koyano *et al.*[9] have reported that $C_4H_3^+$ and $C_4H_2^+$ are formed by the chemi-ionization reaction between excited- and ground-states of C_2H_2 at $5—50 \times 10^{-3}$ Torr. Since the energy-loss spectra of C_2H_2 above 8.0 eV at incident electron energies of 40 and 50 eV have been reported to agree well with the UV spectrum,[15] dimeric ions may be produced *via* chemi-ionization under electron-impact excitation. However, no evidence for chemi-ionization induced by electron impact has been reported in the mass-spectrometric studies.[4] Consequently, the $C_4H_3^+$ and $C_4H_2^+$ formed through the ion-molecule reactions of (1)—(3) would be important intermediates. Besides them, some neutral dimerization products (*e.g.*, C_4H_2 and C_4H_4), as has been shown by VUV photolysis at high pressures,[16] are possible intermediates of $C_4H_2^+$ (A).

The mechanism for the formation of $C_4H_2^+$ (A) from C_2H_4 is probably similar to that from C_2H_2. Possible intermediates are the predominant secondary ions observed in the mass-spectrometric studies[5] (*e.g.*, $C_4H_5^+$ and $C_4H_7^+$) and such neutral species as C_4H_2 and C_4H_4.

The T spectrum can be observed from the non-conjugated cyclic diene as well as from the conjugated one. The formation of $C_4H_2^+$ (A) is confirmed to proceed through a two-electron process, (b) or (c), independent of the conjugation of the two double bonds. Since the intensity of the T spectrum from cyclooctadienes is much stronger than that from C_2H_2 and C_2H_4, and since the possibilities of the secondary reactions are expected to be smaller than those in the cases of C_2H_2 and C_2H_4, the corresponding mechanism for cyclooctadienes is concluded to be (b). The intermediates are probably alike, because no significant difference is found in the intensities of the T spectra of the two isomers.

The reason for the loss of the T spectrum in the oxygen derivatives (PhOH, $PhOCH_3$, $PhOC_2H_5$, and $(Ph)_2CO$) and nitrobenzene, all of which give strong CO^+ emissions, may be partly that another fast dissociative process, probably CO or CO^+ elimination, competes with the $C_4H_2^+$ (A) formation in the first or the second reaction of the (b) mechanism.

The isotope effect on the relative intensity of the T spectrum from C_6H_6 and C_6D_6 should originate from the contributions of the competitive processes of the excitation, the ionization, the dissociation, and the photoemission. The competition between dissociation and preionization in the superexcited states has been pointed out as being responsible for the isotope effect of the hydrogen Balmer emission by electron-impact excitation.[17-21] However, the increase in the intensity of the methylidyne radical upon deuterium substitution established in the present study seems to contradict such an interpretation. It, rather, seems to be caused by the slower rate of the competitive dissociation process, the cleavage of the C-D bond. Thus, the competition of various dissociation channels in the superexcited states plays an important role in determining the isotope effect in such a large molecule as benzene; this effect should also participate in the isotope effect of the diacetylene ion. In addition, differences in various non-radiative decay rates from the excited states of diacetylene ion induced by changes in the vibrational frequencies should be taken into account. Since unidentified secondary processes are involved in the reaction, a detailed interpretation of the isotope effect requires further investigation.

The authors wish to express their thanks to Professor Fumiyuki Nakashio and Dr. Minoru Toyoda for their discussions. Thanks are also due to Professor Tomoo Oyama for the use of his CT-50 monochromator.

The Crystal and Molecular Structure of Zinc Complex of 2-Chlorobenzoic Acid. I. The Crystal and Molecular Structure of Bis(2-chlorobenzoato)zinc(II)

Yoshifumi NAKACHO, Takeshi MISAWA, Takaji FUJIWARA,* Akio WAKAHARA,* and Ken-ichi TOMITA*

(Received August 22, 1975)

The crystal of bis(2-chlorobenzoato)zinc(II) is monoclinic, space group $P2_1/c$, $a=7.284$, $b=10.480$, $c=19.091$ Å, $\beta=95.59°$, and $Z=4$. The structure was solved by usual heavy atom method and refined to the final R-value of 0.052. In the crystalline state, the complex forms a chain. Each zinc atom is bonded to four oxygen atoms from four different ligands.

Benzoic acid is able to react with metal ion to produce metal complexes in a similar way to aliphatic carboxylic acid, *e.g.*, those in copper(II) formate and copper(II) acetate. We have intended to investigate the influence of chlorine atom at ortho-position on the complex formation between zinc ion and 2-chlorobenzoate ion. Ferguson and Sim determined the crystal structure of 2-chlorobenzoic acid which consists of centrosymmetrically hydrogen-bonded dimers.[1] They found that the steric repulsion between carbonyl group and chlorine atom causes to allow the rotation of carboxyl group about the exocyclic C-C bond, and the chlorine atom and the exocyclic carbon atom are slightly displaced out of the plane of the benzene ring.

In the course of the synthesis of mefenamic acid used as an anti-inflammation drug, a derivative of anthranilic acid, we noticed that zinc complex of 2-chlorobenzoic acid crystallized in two different forms, prismatic and hexagonal pillar-shaped. One of these with a 1:2 ratio of zinc and 2-chlorobenzoic acid, was inactive for the following condensation reaction with 2,3-xylidine and only the other with a 2:3 ratio was reactive.[2] These two complexes could be separated by application of a solvent effect.

The present paper deals with the crystal structure of bis(2-chlorobenzoato)zinc(II), an inactive form of the two different complexes. We will present the structure analysis of the other form of the zinc complex in the following paper.

Experimental

Adding two-molar sodium 2-chlorobenzoate to one-molar zinc chloride in aqueous or methanol solution at room temperature, the white precipitate of zinc complex appeared after a few seconds, which was filtrated, washed several times with water and dissolved in anhydrous acetone. After a few days, transparent prismatic crystals were grown up to a proper size ($0.2\times0.1\times0.1$ mm) for X-ray investigation.

The cell dimensions were first determined from Weissenberg and precession photographs and were refined by remeasurement on a diffractometer. According to the systematic absences of reflection, $h0l$ with $l=2n+1$, and $0k0$ with $k=2n+1$, the crystal belongs to the space group of $P2_1/c$. The density was measured by flotation method in a carbon tetrachloride and ethylene dibromide mixture. The crystallographic data are listed in Table 1. The intensity data were

collected on a Rigaku-Denki four-circle diffractometer with Cu-$K\alpha$ radiation using the ω-2θ scan technique. A total of 1520 independent reflections in the range of $\sin\theta/\lambda \leq 0.53$ Å^{-1} were collected. The observed structure factors were converted into absolute values by Wilson's statistics. No absorption correction was applied.

Structure Determination and Refinement

The structure was solved by the usual heavy atom method. By successive Fourier synthesis, the positional parameters of all non-hydrogen atoms were determined (R-value, $R=\sum||F_o|-|F_c||/\sum|F_o|=0.183$). Further refinements were carried out by the block-diagonal least-squares method with isotropic temperature factors ($R=0.122$) and then anisotropic ones ($R=0.062$). A difference Fourier synthesis calculated at this stage revealed the positions of all eight hydrogen atoms with reasonable peak heights. The final refinement including the hydrogen atoms with isotropic temperature factor ($B=3.9$ Å^2) reduced the R-value to 0.052 (0.046 except $|F_o|=0$). The final atomic coordinats and temperature factors together with their estimated standard deviations are given in Table 2 and 3. The observed and calculated structure factors are listed in Table 4.[3] The atomic scattering factors employed were those listed in the International Tables for X-ray Crystallography.[4] All the numerical calculations were carried out on the NEAC 2200-700 in the Computation Center of Osaka University, using the UNICS programs.[5]

Table 3. The final temperature factors and their standard deviations ($\times 10^4$)

The anisotropic temperature factors are in the form of $\exp[-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)]$.

The bond angles involving the hydrogen atoms were all nearly $120\pm9°$ (E.S.D$\cong$5°)

a) The coordinates of the single and double primed atoms are obtained by the translational operations of $(1-x, -y, 1-z)$ and $(2-x, -y, 1-z)$ from that of original atoms (x,y,z).

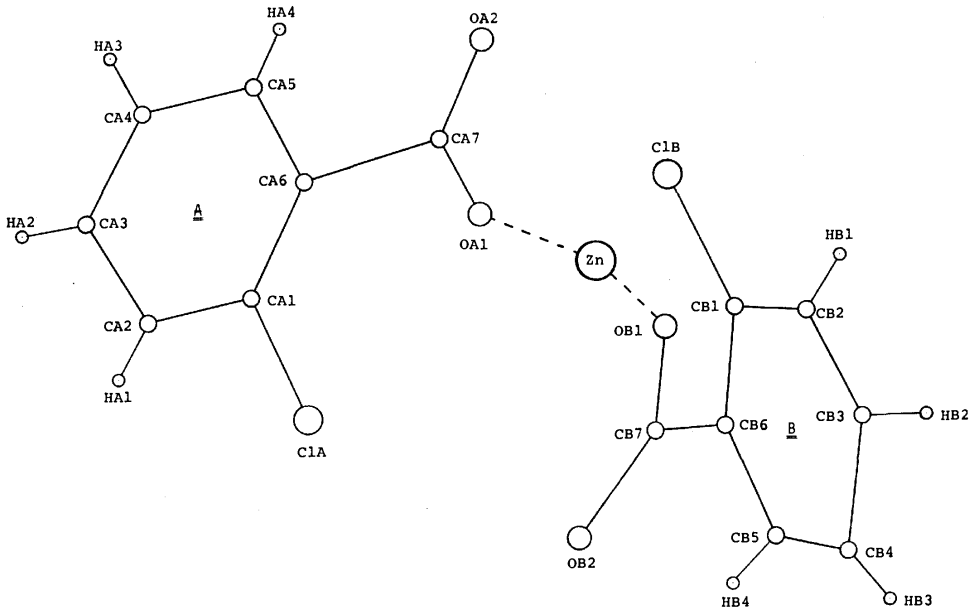

Fig. 1. The atomic numbering scheme of bis(2-chlorobenzoato)zinc(II).

Results and Discussion

The numbering of each atom is represented in Fig. 1. The bond lengths and angles are listed in Table 5, which indicate no significant differences between two independent benzoate ligands. Two C–O bond lengths in carboxyl group range from 1.24 to 1.26 Å which represent the double-bond character, while C_6–C_7 bonds (1.499 and 1.505 Å) are almost pure single-bond which allows the rotation of carboxyl group. The torsion angles between the plane of carboxyl group and that of benzene ring are 9° for ligand A and 41° for ligand B. Such twisting between carboxyl group and the benzene ring plane was also found in the crystal structure of 2-chlorobenzoic acid (14°)[1] and 2-chloro-5-nitrobenzoic acid (23°).[6]

The four carboxyl oxygen atoms coordinate tetrahedrally to each zinc atom as shown in Fig. 2. It is

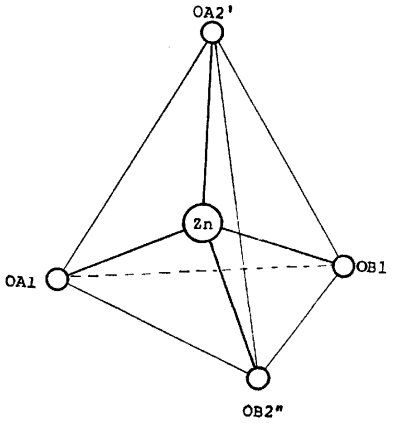

Fig. 2. The coordination of zinc atom.

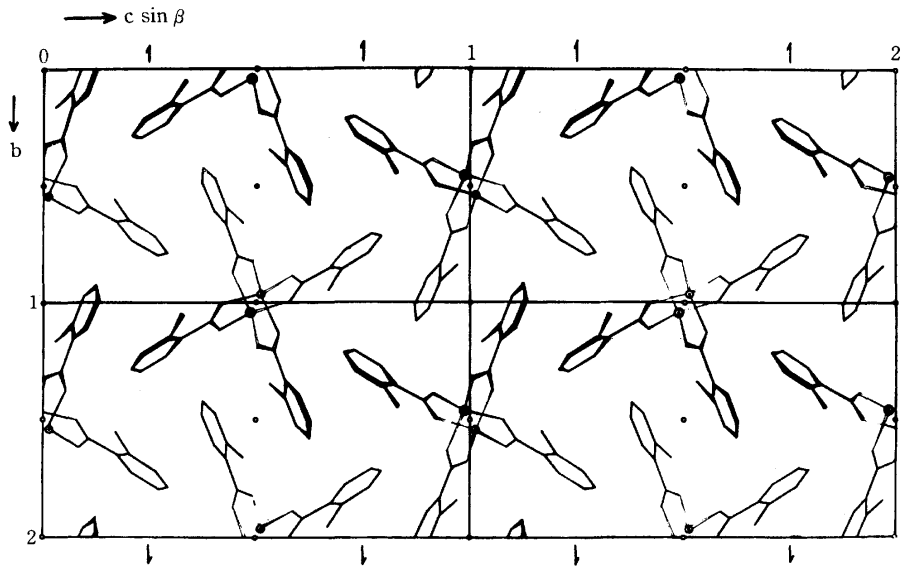

Fig. 3a. The view of the structure looking down the a-axis.

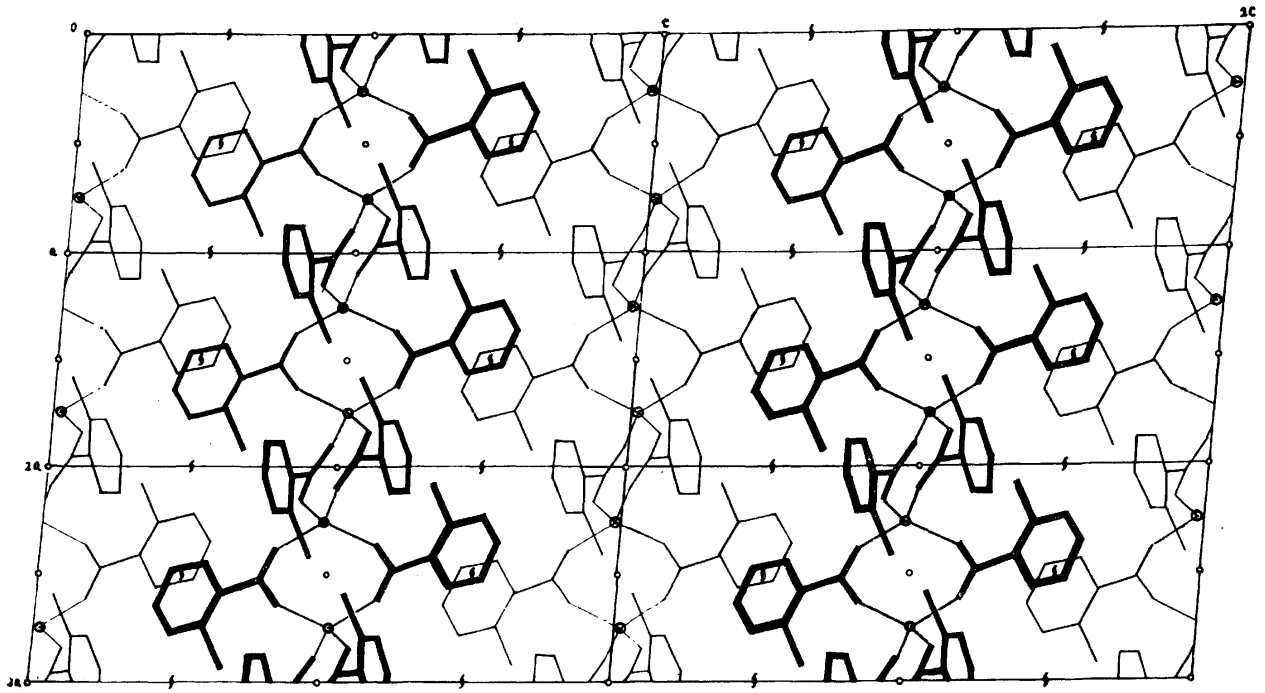

Fig. 3b. The view of the structure looking down the b-axis.

very interesting that four coordinated carboxyl oxygen atoms consist of O_1 of A and B, and O_2 of next neighboring A and B. That is to say, carboxyl oxygen atoms (O_1 and O_2) connect two adjacent zinc atoms to form the infinite chain extending in the direction of the a-axis. The stable coordination number of zinc atom is usually four or six; the former is found in zinc oxyacetate,[7] zinc salicylate dihydrate,[8] di(L-histidino)zinc dihydrate,[9] di(histidino)zinc pentahydrate[10] and the latter in zinc acetate dihydrate,[11] zinc 8-hydroxyquinolate dihydrate.[12] In this crystal, four oxygen atoms coordinate tetrahedrally to the central zinc atom and this sort of coordination may be more stable than that of the pentaligand zinc complex described in the following paper. The arrangements of molecules in the a- and b-axes projections are shown in Fig. 3(a) and 3(b), respectively. Looking down through the a-axis, the plane of each benzene ring sticks out with rotation angle of about 90°. The orientations of the ligands within two chains related by c-glide plane differ by 45° around the a-axis, and therefore, the arrangement of the infinite chains in the [011] direction looks like $+\times+\times+\times\cdots\cdots$ when viewed along the a-axis. Each chain contacts with normal van der Waals distances.

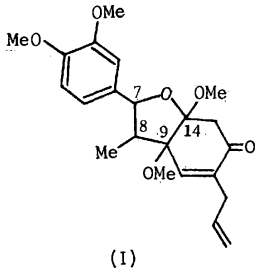
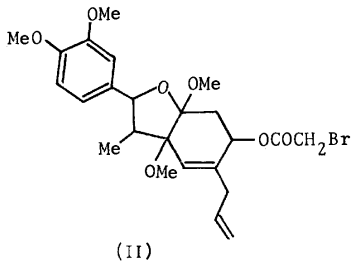
(Received September 5, 1975)

The structure of a bromoacetate of hydroxypiperenone, $C_{24}H_{31}O_7Br$, has been determined by the X-ray diffraction method. The compound crystallized in the space group $P2_1$, with $a=8.296$, $b=13.247$, $c=11.400$ Å, and $\beta=102.8°$. The structure was solved by the heavy-atom method and refined to $R=0.075$ for 1614 reflections. The present analysis has established that the five- and six-membered rings are fused in the *cis* fashion. The absolute configuration of the molecule has been determined by using the anomalous dispersion effect of the bromine atom for Cu $K\alpha$ radiation.

Piperenone isolated from the leaves of *Piper futokadzura* Sieb. et Zucc. shows a distinct antifeeding activity in response to the larvae of *Spodoptera litura* F. The structural formula of piperenone has been shown to be (I),[1] and the configurations at the C(7) and C(8) atoms (refer to Fig. 1) have been presumed to be *S*-form[2] on the basis of chemical and spectroscopic methods. However, the configurations at the C(9) and C(14) atoms could not be determined by these methods. In order to confirm the presumption, and, further, in order to determine the absolute configuration, a bromoacetate of hydroxypiperenone (II) has now been investigated by means of the X-ray diffraction method.



(I)



(II)

Experimental

The bromoacetate of hydroxypiperenone was prepared by the reaction of bromoacetyl bromide and hydroxypiperenone, one of the epimers obtained by the reduction of piperenone with lithium aluminum hydride. The compound crystallized from the hexane–ethyl acetate solution in the form of colorless plates.

A preliminary photographic investigation showed that the crystals were monoclinic with the b axis along the most developed axis, and that the intensities fell off fairly rapidly with an increase in θ. The systematic absence ($0k0$ when k is odd) and optical activity indicated the space group to be $P2_1$. The unit-cell constants were obtained from the Bragg angles measured by a Toshiba four-circle diffractometer using Ni-filtered Cu$K\alpha$ radiation. The crystal data were as follows: $C_{24}H_{31}O_7Br$, mp 153—155 °C, $M=511.4$, monoclinic, $P2_1$, $a=8.296(5)$, $b=13.247(7)$, $c=11.400(6)$ Å, $\beta=102.8(1)°$, $V=1222$ Å^3, $Z=2$, $D_0=1.38$ g/cm^3, $D_x=1.39$ g/cm^3, $\mu=28.6$ cm^{-1} (for Cu$K\alpha$).

A crystal with dimensions of *ca.* $0.12\times0.35\times0.22$ mm^3 was mounted with its b axis parallel to the ϕ axis of the diffractometer. The stationary-crystal stationary-counter technique was applied, with a counting time of 30 s. The intensities of 1616 independent reflections were measured up to $\sin\theta/\lambda=0.53$, with Ni-filtered Cu$K\alpha$ radiation. The background for each reflection was taken from the plots of the background as a function of 2θ. The intensities were corrected for the Lorentz and polarization factors, but not for absorption.

Determination of the Structure

The coordinates of the bromine atom were easily determined from the Patterson map. The locations of the remaining non-hydrogen atoms were determined by successive Fourier syntheses. The coordinates and isotropic temperature factors were initially refined by a block-diagonal least-squares method, using carbon and bromine scattering factors. The atomic species were determined on the bases of the temperature factors and chemical sense. The refinement with anisotropic temperature factors reduced the R value to 0.08. Two

intense reflections, -121 and 013, were rejected from the subsequent calculations.

The absolute configuration of the molecule was determined using the anomalous dispersion effect of the bromine atom ($\Delta f'=-0.9$ and $\Delta f''=1.5$) for Cu$K\alpha$ radiation. The intensities of the Friedel-pair reflections were measured by the ω-2θ scan technique, using Ni-filtered Cu $K\alpha$ radiation with a specimen with dimensions of *ca.* $0.08\times0.20\times0.10$ mm^3. A comparison of the observed and calculated intensities between the Friedel-pair reflections is given in Table 1. Of the 31 hydrogen atoms in the molecule, twelve atoms were located from a difference Fourier map. The final refinement was made by including these hydrogen atoms with fixed parameters and the anomalous dispersion effect of the bromine atom, and by using the following weighting scheme; $w=0.34$ for $F_o=0.0$, $w=1.0$ for $0<F_o\leqq15$, and $w=1.0/(1.0+0.1(F_o-15))$ for $15<F_o$. The final R value was 0.075 for 1614 independent reflections. The final atomic parameters are given in Table 2.***

The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[3] The computations were performed on a TOSBAC-3400 computer at the Tottori University Computing Center, and on a NEAC 2200-N700 computer at the Computation Center of Osaka University.

Results and Discussion

The structural formula and the absolute configuration of the molecule have been established by the present

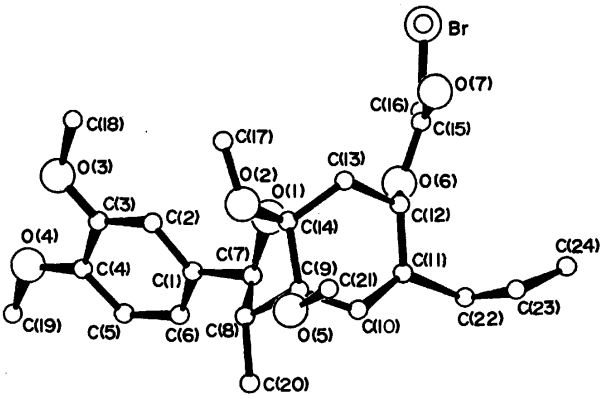

Fig. 1. Perspective view of the molecule and the scheme of atomic numbering.

*** A list of the observed and calculated structure factors is kept by the office of the Chemical Society of Japan (Document No. 7602).

X-ray analysis. The absolute configuration of the molecule is correctly represented by the parameters in Table 2 if the right-handed coordinate system is adopted. A perspective drawing of the molecule and the numbering of atoms are shown in Fig. 1, and a stereoscopic view of the molecule, in Fig. 2. Both figures are drawn with a correct absolute configuration. The least-squares planes and the deviations of atoms from each plane are listed in Table 3. The two methoxy groups bonded to the C(9) and C(14) atoms are in the *cis*-form to each other; the torsion angles† of O(2)–C(14)–C(9)–O(5) and C(8)–C(9)–C(14)–O(1) are −33° and −36° respectively. The torsion angle of H–C(7)–C(8)–

H derived from the X-ray analysis is about −168°. This value can be correlated with the coupling constant (11 Hz) of these hydrogen atoms, derived by an analysis of the NMR spectrum.[4] The five-membered ring comprising the C(7), C(8), C(9), C(14), and O(1) atoms takes a half-chair conformation, and the C_2 axis lies on a line connecting the midpoint of the C(8)–C(9) bond and the O(1) atom. This is one of two conformations of the cyclopentane. As is usually found in the cyclohexene and the heterocyclic rings,[5,6] the six-membered ring comprising the C(9), C(10), C(11), C(12), C(13), and C(14) atoms is also in the form of a half-chair. The ethylenic carbon atoms (C(10) and C(11)) and the two adjacent allylic carbon atoms (C(9) and C(12)) lie approximately on a plane, while the C(13) and C(14) atoms on the other side deviate by 0.26 Å above and 0.32 Å below the plane respectively. The torsion angles in the ring, C(13)–C(14)–C(9)–C(10), C(12)–C(13)–C(14)–C(9), and C(11)–C(12)–C(13)–C(14), are calculated to be −34°, 48°, and −33° respectively. One of the two methoxy groups attached to the benzene ring is approximately coplanar with the benzene ring; the torsion angles of C(5)–C(4)–O(4)–C(19) and C(2)–C(3)–O(3)–C(18) are 2° and 15° respectively. The bond lengths and angles of the molecule are listed in Table 4. They seem to be normal for the respective bond types within the limits of experimental error. The intermolecular distances between the non-hydrogen atoms less than 3.8 Å are listed in Table 5; the table indicates the absence of any abnormally short contact.

The authors wish to thank Mr. Tetsuya Ikeda for his technical assistance in this work, and Professor Tamaichi Ashida of Nagoya University for his permission to use the block-diagonal least-squares program.

Studies of Fragment Ion Distribution and Reaction with a Charge Spectrometer. VIII. Fragmentation Processes of Various Alkyl Halides

Shigeru IKUTA, Kenji YOSHIHARA, and Takanobu SHIOKAWA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received December 13, 1974)

The breakdown curves for C_2H_5X, n-C_3H_7X, and n-C_4H_9X (X=Cl, Br, and I) were obtained by the use of a double mass spectrometer of the perpendicular type. The charge exchange mass spectra for alkyl bromide and alkyl iodide are found to be similar, although those for alkyl chloride are somewhat different from these for bromide and iodide. According to the molecular orbital calculation, the difference of the electronic configuration between chloride and bromide or iodide is found to correspond to the difference of the breakdown curves. The results obtained in this study using larger molecules support our previous analysis on the breakdown processes in smaller molecules: (1) direct scission of the bond which has lost one electron by the charge exchange reaction, (2) electron redistribution, and (3) secondary decomposition (and those of higher order) from the primary fragments. In the case of alkyl chloride, formation of the ion $C_nH_{2n}^+$ is ascribed to the elimination of HX from the molecular ion in its electronically ground but vibrationally excited state.

Fragmentation processes of molecules by electron or photon impact have usually been interpreted by the quasi-equilibrium theory (QET)[1] based on the unimolecular decomposition of the molecular ion in its vibrationally excited state. Contrary to this widely accepted interpretation, some evidence of fragmentation of the molecular ion in its electronically excited state has recently been highlighted.[2-5]

On the other hand Hirota[6] and Lorquet[7] found that the scission probability of the skeletal bond was proportional to the electron density of the corresponding bond in the highest occupied MO. Although this molecular orbital theory applied to fragmentation is interesting, the validity of the theory has been shown to be doubtful.[8] In a word, a theory which is universally applicable has not been available so far.

Therefore, in order to approach the solution of these difficulties, we have proposed some new fragmentation mechanisms on the basis of a MO treatment involving the inner occupied MO's.[9] The fragmentation processes of various CH_3X (X=NH_2, OH, SH, Cl, Br, and I),[5,9] C_2H_5OH, $C_2H_5NH_2$,[10] various alcohols,[11] and various mercaptans[12] have been successfully explained by our interpretation.

In this paper, the breakdown curves of various alkyl halides RX (R=ethyl, propyl, and butyl, and X=Cl, Br, and I) are studied by charge exchange reactions and the effects of the length of the alkyl group (R) and that of the substituent (X) on the fragmentation processes are investigated.

Experimental

Fragmentation processes of various molecular ions produced by charge exchange reactions were studied using a double mass spectrometer of the perpendicular type. Details of the apparatus have already been described.[13] In the work, H_2S^+, $C_2H_2^+$, Xe^+, Kr^+, N_2^+, Ar^+, Xe^{++}, Ne^+, and He^+ ions were used as primary incident ions and admitted into the reaction chamber. The pressure in the reaction chamber was below 6×10^{-6} Torr.

Calculation

Eigenvectors of molecular orbitals of various alkyl halides were calculated according to the Extended Hückel Molecular Orbital method.[14] Details of the calculation were already described in the previous paper.[9] The calculation was performed at the Computer Center of Tohoku University. The models employed for this calculation are shown in Fig. 1.

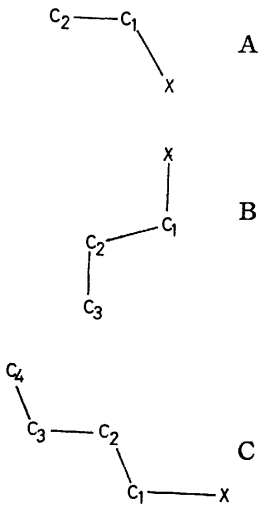

Fig. 1. Models employed for calculation (hydrogens are omitted).
A: Ethyl halide. B: Propyl halide. C: Butyl halide.

Results

(A) Ethyl Halides. The breakdown curves of ethyl chloride and ethyl iodide obtained by charge exchange reactions are shown in Fig. 2 (A) and (B). In the figure the abscissa indicates the recombination energy of the incident positive ions and the ordinate indicates the abundance of the fragment ions. The curves are normalized so that the sum of the abundances of the constituent ions at each energy is equal to 100. The production of the molecular ions must start at

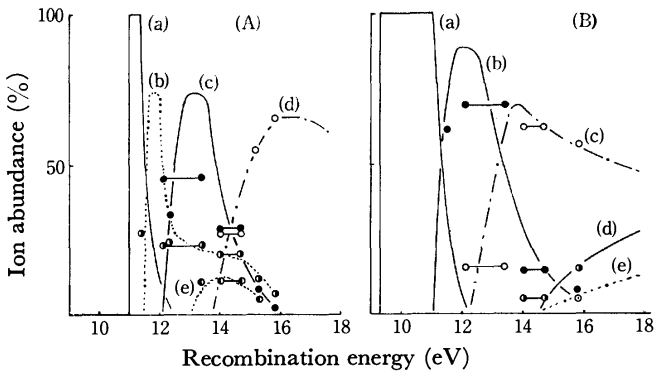

Fig. 2. Breakdown curves of ethyl chloride (A) and ethyl iodide (B).

(B) (a) $C_2H_5I^+$ (b) $C_2H_5^+$ (c) $C_2H_3^+$ (d) I^+ (e) $C_2H_2^+$

the recombination energy equal to the spectroscopic ionization potential.

In ethyl chloride, the $C_2H_4^+$ ion produced by the loss of HCl from the molecular ion in the vibrationally excited state[15] follows the stable molecular ion. Formation of $C_2H_5^+$ ion starts at about 12 eV. The CH_2Cl^+ ion appears at about 13 eV as a result of scission of the C–C bond and its maximum abundance is about 15%. Formation of $C_2H_3^+$ ion produced by unimolecular decomposition of the $C_2H_5^+$ ion starts at 13.5—14.0 eV. The appearance potential of $C_2H_5^+$ ion is equal to that of the second band in the photoelectron spectrum.[16] Therefore, it is thought that the primary fragment ions from the molecular ions are $C_2H_4^+$, $C_2H_5^+$, and CH_2Cl^+, among which the $C_2H_5^+$ and CH_2Cl^+ ions are correlated to the direct fragmentation of the molecular ion in its electronically excited state.

On the other hand, in ethyl iodide the $C_2H_5^+$ ion follows the stable molecular ion. The appearance potential of this ion is equal to that of the second band in the photoelectron spectrum.[16] Formation of the $C_2H_3^+$ ion produced by unimolecular decomposition of the $C_2H_5^+$ ion starts at about 12.5 eV. Formation of the

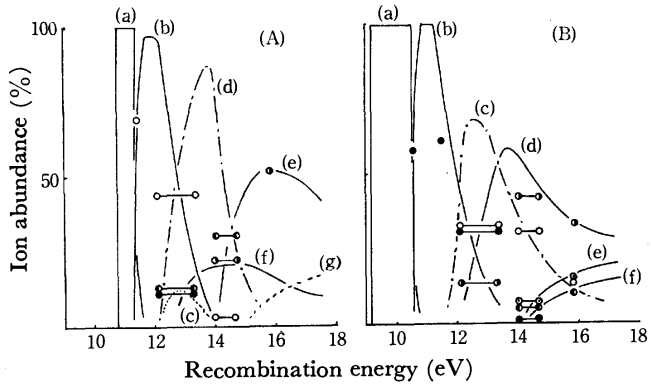

Fig. 3. Breakdown curves of propyl chloride (A) and propyl iodide (B).
(A) (a) $C_3H_7Cl^+$ (b) $C_3H_6^+$ (c) $C_3H_7^+$ (d) $C_2H_5^+$ (e) $C_2H_3^+$ (f) $C_3H_5^+$ (g) $C_3H_3^+$
(B) (a) $C_3H_7I^+$ (b) $C_3H_7^+$ (c) $C_3H_5^+$ (d) $C_2H_3^+$ (e) $C_3H_3^+$ (f) I^+

I^+ and $C_2H_2^+$ ions starts at about 14.5 eV, but the CH_2I^+ ion produced by scission of the C–C bond comprises only a few percent. Therefore, it is concluded that the product of the primary scission of the molecular ions is only the $C_2H_5^+$ ion in the low energy region (<15 eV).

(B) Propyl Halides. The breakdown curves of propyl chloride and propyl iodide obtained by charge exchange reactions are shown in Fig. 3.

In propyl chloride, formation of the $C_3H_6^+$ ion which is produced from the molecular ion in its vibrationally excited state[15] follows that of the stable molecular ion. Formation of the $C_2H_5^+$ ion starts at about 12.0 eV after that of the $C_3H_6^+$ ion and it is thought that this $C_2H_5^+$ ion is produced by the primary scission of the molecular ion. Formation of the $C_3H_7^+$ ion also starts at about 12.0 eV and the maximum abundance of this ion is about 15%. The $C_3H_5^+$ and $C_2H_3^+$ ions are formed as a result of the consecutive decomposition of the $C_3H_6^+$, $C_3H_7^+$, and $C_2H_5^+$ ions. Therefore, these results show that the primary fragment ions of the molecular ion are $C_3H_6^+$, $C_2H_5^+$, and $C_3H_7^+$ ions, among which the $C_2H_5^+$ and $C_3H_7^+$ ions are correlated to the direct fragmentation of the molecular ion in its electronically excited state.

On the other hand, in propyl iodide the formation of $C_3H_7^+$ ion follows that of the stable molecular ion, and this $C_3H_7^+$ ion decomposes further to smaller ions ($C_3H_5^+$, $C_2H_3^+$,……). It is thought that the primary fragment ion is the $C_3H_7^+$ ion alone in the low energy region (<15 eV).

(C) Butyl Halides. The breakdown curves of butyl chloride and butyl iodide obtained by charge exchange reactions are shown in Fig. 4.

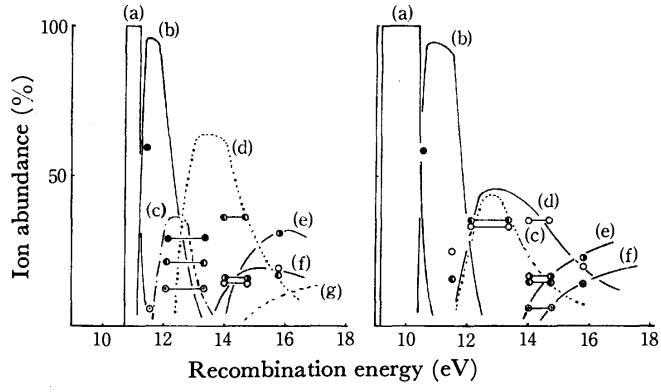

Fig. 4. Breakdown curves of butyl chloride (A) and butyl iodide (B).
(A) (a) $C_4H_9Cl^+$ (b) $C_4H_8^+$ (c) $C_3H_7^+$ (d) $C_3H_5^+$ (e) $C_2H_3^+$ (f) $C_3H_3^+$
(B) (a) $C_4H_9I^+$ (b) $C_4H_9^+$ (c) $C_3H_5^+$ (d) $C_2H_5^+$ (e) $C_2H_3^+$ (f) $C_3H_3^+$

In butyl chloride formation of the $C_4H_8^+$ ion produced by the elimination of hydrogen chloride from the molecular ion in its vibrationally excited state[15] follows that of the stable molecular ion. Formation of the $C_3H_7^+$ ion starts after the appearance of the $C_4H_8^+$ ion and this $C_3H_7^+$ ion is considered to be produced by the primary scission of the molecular ion. Formation of $C_2H_5^+$ starts at about 12.5 eV, after that of the $C_3H_7^+$ ion.

The $C_4H_8^+$, $C_3H_7^+$, and $C_2H_5^+$ ions decompose further to smaller ions. These results and Figure 4 show that the primary fragment ions of the molecular ions are the $C_4H_8^+$, $C_3H_7^+$, and $C_2H_5^+$ ions, among which the $C_3H_7^+$ and $C_2H_5^+$ ions are correlated to the decomposition of the molecular ion in its electronically excited state.

On the other hand, in butyl iodide formation of the $C_4H_9^+$ ion follows that of the stable molecular ion. This $C_4H_9^+$ ion decomposes further to smaller ions ($C_3H_5^+$, $C_2H_5^+$,……). The primary fragment ion of the molecular ion is the $C_4H_9^+$ ion alone in the low energy region (<15 eV).

From these results the dissociation schemes of various molecular ions are shown in Fig. 5.

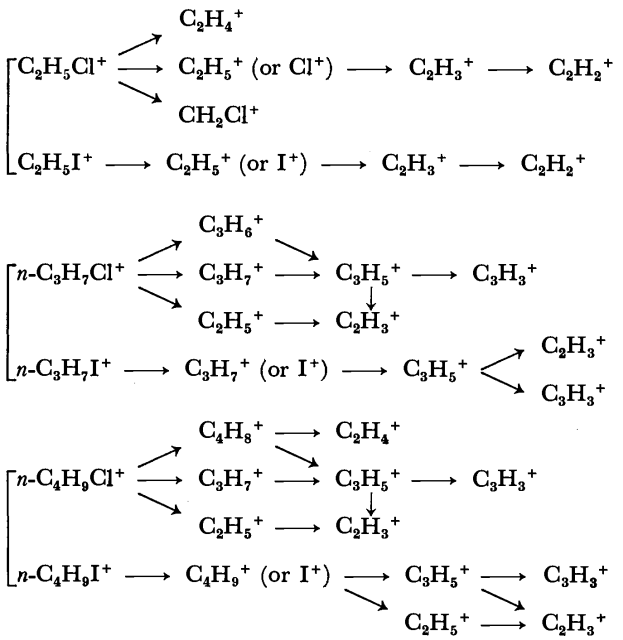

Fig. 5. Dissociation ionization schemes of various alkyl halide-moleular ions.

Discussion

Instead of an interpretation of the mass spectra using the QET[1] and Hirota's theory,[6] we have already set up a new interpretation of fragmentation processes based on the MO treatment.[5,9-12] The scission probabilities of the C–X and C–H bonds in various CH_3X^+ have been well explained by our proposal.[5,9] And the fragmentation processes of various alcohols[11] and mercaptans[12] have been also successfully accounted for. Our interpretation is composed of three basic suppositions, as follows:

(1) The scission first occurs where the electrons are exist densely in the particular occupied MO correlated to the particular ionization.

(2) Process (1) competes with the electron redistribution process after the event of ionization.

(3) In a higher energy region, secondary scission (and those of higher orders) also occurs.

Based on process(1), the primary fragment ions of the molecular ions can be predicted by the main character of the particular MO which correlates to the particular ionization, and the over-all features of the energy dependence of the fragmentation phenomena can be explained by processes (2) and (3) in addition to process (1).

Table 1. Calculated MO energy, observed ionization potential and calculated bonding character in alkyl iodides

		10.48	9.82	
	SOMO	12.36	11.43	C_1–I bonding
	TOMO	13.29	12.22	C–H bonding
	FOMO	13.48	12.78	C_1–C_2 bonding
C_4H_9I	HOMO	10.46	9.24	non-bonding
		10.48	9.79	
	SOMO	12.28	11.22	C_1–I bonding
	TOMO	13.24	11.90	C–H bonding
	FOMO	13.26	12.3	C_1–C_2 bonding

The calculated MO energy, the observed ionization potential, and the general character of the occupied MO for alkyl iodide are shown in Table 1. The highest occupied MO which is degenerated is non-bonding and the second occupied MO is C–I bonding. Therefore, the ionization of the electron in the highest occupied MO results in formation of the stable molecular ion, and the ionization of the electron in the second occupied MO results in formation of the alkyl ion, as shown in the figures. The appearance potential of the alkyl ion is equal to that of the second band in the corresponding photoelectron spectrum.[16] The primary fragment ion of the molecular ion is the alkyl ion alone in the low energy region. No formation of any fragment ions originating from ionization of the electron above the second occupied MO was observed in the present experiments. Therefore, it is considered that the molecular ion in its electronically excited state easily falls into its electronically ground state (or at least into its low-lying electronically excited states) before it decomposes. Similar considerations can be applied to the fragmentation of the molecular ion in alkyl bromide.

The MO energy and the general character of the occupied MO calculated in this work for alkyl chloride are shown in Table 2. The fragment ion produced by the elimination of hydrogen chloride is ascribed to the presence of the molecular ion in its vibrationally excited state.[15] The breakdown curves in ethyl chloride are similar to those of ethyl bromide and ethyl iodide, except for the formation of the $C_2H_4^+$ ion. Therefore, it is assumed that the general character of the various occupied MO's in ethyl chloride is similar to those of ethyl bromide and ethyl iodide.

Table 2. MO energy and bonding character calculated in this work on alkyl chlorides

		MO energy (−eV)	Bonding character
C_2H_5Cl	HOMO	12.88	non-bonding
	SOMO	13.72	C–H bonding
	TOMO	13.90	C–C bonding
	FOMO	14.12	C–Cl bonding
C_3H_7Cl	HOMO	12.84 12.93	non-bonding
	SOMO	13.30	C–H bonding
	TOMO	13.42	C_1–C_2 bonding> C_1–Cl bonding
	FOMO	13.73	C_2–C_3 bonding
C_4H_9Cl	HOMO	12.76 12.91	non-bonding
	SOMO	13.20	C_1–C_2, C_2–C_3,··· bondings
	TOMO	13.25	C–H bonding
	FOMO	13.50	C_2–C_3 bonding

In propyl chloride the highest occupied MO is degenerated n(Cl). The third occupied MO is both C_1–C_2 bonding and C_1–Cl bonding. The calculated partial bond population of C_1–C_2 bonding comprises 75% and that of C_1–Cl bonding comprises 25%. Therefore, ionization of an electron in the third occupied MO results in formation of the $C_2H_5^+$ ion in abundance and a small amount of the $C_3H_7^+$ ion, as shown in Fig. 3. It is thought that the general character of the various occupied MO's in propyl chloride shown in Table 2 is correct.

In butyl chloride the calculated bonding character of the second occupied MO is C_1–C_2, C_2–C_3,·····bondings. From the experimentally obtained breakdown curve, the most dominant one is thought to be C_1–C_2 bonding.

In the molecular ions of alkyl bromide and alkyl iodide, the C–X bond dominantly dissociates and the fragment ions produced by the scission of the other bond can be scarcely observed, in contrast to the fragmentation of molecular ions of alkyl amine, alkyl alcohol, and alkyl mercaptan. This difference is explained by the difference of the general character of the various occupied MO's.

No formation of fragment ions originating from the ionization of an electron above the second occupied MO was observed. Therefore, it is considered that the molecular ion in its electronically excited state easily falls into its electronically ground state or into a less excited electronic one. Although the degree of transition between the electronic states is considered to be large in alkyl bromide and alkyl iodide, as shown in the figures, it seems this is not the case in alkyl chloride. It is likely that this degree decreases in the order of of butyl>propyl>ethyl chloride.

From these results it is shown that the electron redistribution process of our proposal also plays an important role in the higher energy region in the breakdown curve of alkyl halides. Thus, the general trends of fragmentation processes of molecular ions are concluded to be interpreted satisfactorily by our approach, although efforts to make the results more quantitative will be necessary in the future.

The Chemical Behavior of Low Valence Sulfur Compounds. X.[1] Disproportionation of Thiosulfate, Trithionate, Tetrathionate and Sulfite under Acidic Conditions

Tadaaki MIZOGUCHI,* Yoshiaki TAKEI,** and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai 980

(Received February 25, 1975)

The disproportionation of thiosulfate, trithionate, tetrathionate and sulfite in acidic solutions has been studied at relatively high temperatures. Thiosulfate hardly decomposes in the absence of sulfuric acid, even at 150 °C, but decomposes very easily in the presence of sulfuric acid at 70 °C, forming elemental sulfur, tetrathionate and sulfite. Trithionate decomposes to thiosulfate and sulfate at 70 °C, while tetrathionate decomposes only at temperatures above 130 °C after an induction period forming thiosulfate as an intermediate. Sulfite undergoes disproportionation, giving thiosulfate and sulfate at 150 °C, and then elemental sulfur and sulfate accompanied by intermediate formation of tetrathionate. A disproportionation pathway of low valence sulfur oxyacids including thiosulfate, trithionate, tetrathionate and sulfite has been proposed.

Investigations of disproportionation of low valence sulfur compounds such as thiosulfate,[2-4] polythionates[4-8] and sulfite[9-11] have been carried out by a number of workers. It has been shown that some kinds of polythionates play important roles as intermediates in these reactions, but no systematic study seems to have been made, partly because of the lack of a simple and accurate method of analysis. A photometric method for thiosulfate and polythionates[1] described in the previous paper, has been found to be useful.

The disproportionation of thiosulfate, trithionate, tetrathionate and sulfite has been investigated in acidic solutions at relatively high temperatures to obtain the basic data concerning the treatment of waste waters containing low valence sulfur compounds. Sulfuric acid was used as an acidic medium, as this acid is used most widely in industrial fields.

Experimental

Materials. All chemicals except polythionates were of analytical reagent grade. Potassium trithionate and potassium tetrathionate were prepared by Stamm's method[12] and Martin's method,[13] respectively. The concentrations of the stock solution of trithionate and tetrathionate were determined by Procedures C and B, respectively.[1]

Procedure. The reactions were carried out in 25 ml sealed glass tubes. Each tube was sealed soon after the transfer of 15 ml of sample solution together with 0.5 ml of sulfuric acid of different concentration, and placed in a glycerol bath regulated at the desired temperature. The sealed tubes were removed from the bath after a definite period of time, and quickly cooled to room temperature, when necessary, in an ice bath.

Analysis. The seals of the glass tubes were removed and a clear supernatant solution was withdrawn. The sample solution was diluted to a suitable concentration and analyzed for thiosulfate, trithionate, tetrathionate, sulfite and sulfate as follows:

Thiosulfate, Trithionate and Tetrathionate: Since the higher polythionates above tetrathionate were proved by paper chromatography to be absent in the reaction mixtures,[14] the photometric method[1] was used for the determination of the concentrations of thiosulfate, trithionate and tetrathionate. The calibration curves were prepared with a standard thiosulfate solution. The standard addition method was employed to eliminate interferences caused by various chemical compositions of the samples.

Sulfite: The total amount of thiosulfate and sulfite was determined by iodometry. The amount of sulfite was determined by substracting the amount of thiosulfate obtained by photometry from the total amount of thiosulfate and sulfite.

Sulfate: The total amount of sulfite and sulfate was determined gravimetrically as barium sulfate, after oxidizing thiosulfate and sulfite with iodine to tetrathionate and sulfate, respectively. The amount of sulfate formed in the disproportionation was determined by substracting the amount of sulfite and that of sulfuric acid added.

Elemental Sulfur: The elemental sulfur deposited in the glass tubes was dissolved in carbon disulfide. After being washed with water, the carbon disulfide layer was poured into a 200 ml beaker, and then warmed to about 35 °C to evaporate carbon disulfide. The residual elemental sulfur was determined gravimetrically as barium sulfate after oxidation to sulfate with a mixture of potassium chlorate and nitric acid.

Results and Discussion

Disproportionation of Thiosulfate Solution. The effect of reaction time on the decomposition degree of thio-

150	3.6	14.6	0	11.0	4.6	6.1[b]	39.6	13.5	1.98

Initial concn of $Na_2S_2O_3$: 39.7 mg atom-S/l, initial concn of H_2SO_4: 20 mM, time: 2 h. a) Calculated values obtained by assuming that the first stage of thiosulfate decomposition is represented by the reactions shown by Eqs. (1) and (2), and also that the formation of sulfate is attributed to air oxidation of sulfite formed according to the reaction shown by Eq. (2). b) The amount of sulfuric acid added was substracted.

sulfate is shown in Fig. 1. We see that thiosulfate hardly decomposes in the absence of sulfuric acid even at 150 °C, while it decomposes very easily in the presence of sulfuric acid at 70 °C.

The effect of reaction temperature was determined in the range 70—150 °C. The material balance of sulfur atoms can be explained well, taking into consideration elemental sulfur, trithionate, tetrathionate, sulfite and sulfate as reaction products (Table 1). Trithionate can be regarded to be of minor importance as a decomposition product. Thiosulfate decomposes in acidic solution, forming elemental sulfur as a lower oxidation state species, and tetrathionate, sulfite and sulfate as higher oxidation state species. The reactions can be represented by the following equations:

$$5S_2O_3^{2-} + 6H^+ = 2S + 2S_4O_6^{2-} + 3H_2O \quad (1)$$

$$S_2O_3^{2-} + H^+ = S + HSO_3^- \quad (2)$$

$$3S_2O_3^{2-} + 2H^+ = 4S + 2SO_4^{2-} + H_2O \quad (3)$$

When considered thermodynamically,[11,15] hydrogen sulfide besides elemental sulfur is considered to be formed as a lower oxidation state species. However, all the reaction mixtures in the present investigation gave no characteristic odor of hydrogen sulfide.

The amount of tetrathionate formed increases with an increase of reaction temperature in the range 70—130 °C, while that of sulfite decreases with an increase of reaction temperature (Table 1). On the other hand, the amount of sulfate formed is independent of reaction temperature and is as low as about 1 mg atom-S/l. The values of S_{calcd} (Table 1) were calculated by

$$S_{calcd}(\text{mg atom-S/l}) = 0.25(S_4O_6^{2-})\ (\text{mg atom-S/l}) + (HSO_3^-)\ (\text{mg atom-S/l}) + (SO_4^{2-})\ (\text{mg atom-S/l}).$$

The amount of elemental sulfur formed is in good agreement with the calculated values of S_{calcd} in the temperature range 70—130 °C. Therefore, it can be said that tetrathionate and sulfite are formed according to the reactions shown by Eqs. (1) and (2), respectively, and that the formation of sulfate is not attributed to disproportionation of tetrathionate or sulfite but rather to air oxidation of sulfite formed as shown by Eq. (2). On the other hand, it is noted that at the reaction temperature of 150 °C, yields of elemental sulfur and sulfate are higher than those at 130 °C, while the yield of tetrathionate is correspondingly lower. It seems

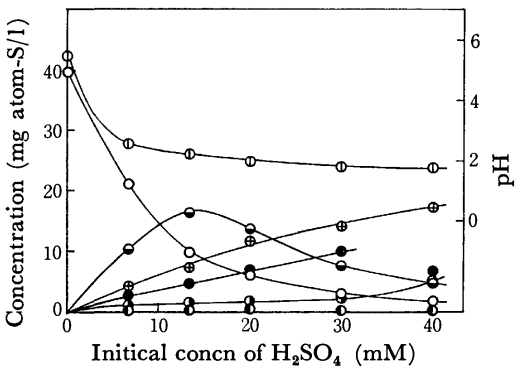

Fig. 2. Effect of sulfuric acid concentration on the disproportionation of thiosulfate solution.

⊕: S, ○: $S_2O_3^{2-}$, ◐: $S_3O_6^{2-}$, ◒: $S_4O_6^{2-}$, ●: HSO_3^-, ◑: SO_4^{2-},[a] ⓘ: pH.
a) The amount of sulfuric acid added was substracted.

that the reaction shown by Eq. (3) proceeds favorably at 150 °C. The successive occurrence of reactions shown by Eqs. (1) and (8) or Eqs. (2) and (11), however, lead to the overall reaction of Eq. (3), which therefore need not necessarily be considered as a separate reaction.

The decomposition of thiosulfate was carried out in sulfuric acid solutions of barious concentrations at 110 °C. From the results (Fig. 2), it is evident that the amount of tetrathionate increases gradually with an increase of sulfuric acid concentration, and after reaching a maximum, finally falls off. On the other hand, the amount of sulfite shows a steady increase with an increase of sulfuric acid concentration. The reason why the amount of sulfite is not so high as to compensate the decrease in the amount of tetrathionate at sulfuric acid concentrations of 30 and 40 mM is that the sulfite formed escapes to the gaseous phase.

Figure 3 shows the tetrathionate concentrations in the final reaction mixtures as functions of temperature and sulfuric acid concentration. At a definite acid concentration, the amount of tetrathionate formed increases with an increase of reaction temperature in the range 70—130 °C. Tetrathionate, however, decomposes above 130 °C, the final concentration decreasing with increasing temperature in the temperature range. The reason why the amount of tetrathionate shows a maximum at a certain concentration of sulfuric acid is not clear.

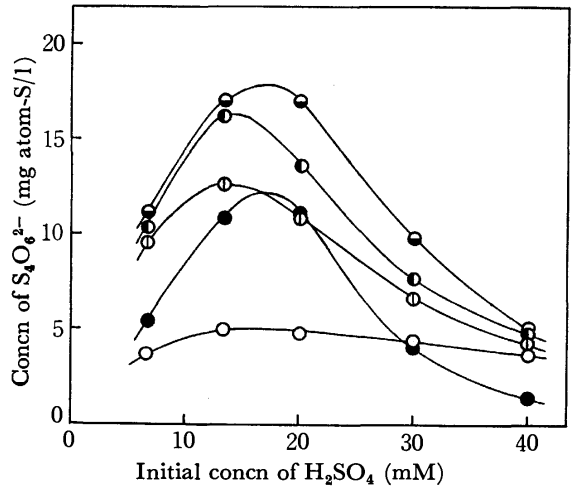

Fig. 3. Effect of reaction temperature and sulfuric acid concentration on the formation of tetrathionate from thiosulfate.
Initial concn of $S_2O_3^{2-}$: 19.9 mM, time: 2 h.
Temp (°C): ○70, ⓘ90, ◐110, ◒130, ●150.

In the experiments shown in Figs. 2 and 3, a fixed reaction time of 2 h was used. However, the decomposition velocity of thiosulfate is very high at even 70 °C, while tetrathionate decomposes hardly below 130 °C. Thus, the amount of tetrathionate formed might not change much even if the reaction time is extended.

It is well known that some kinds of polythionates as well as elemental sulfur and sulfite are formed in the acid decomposition of thiosulfate.[2-4] Many investigators reported that the reaction

$$S_nO_6^{2-} + S_2O_3^{2-} + H^+ \rightleftharpoons S_{n+1}O_6^{2-} + HSO_3^- \quad (n \geqq 3) \qquad (4)$$

played an important role not only in the formation of polythionates[6,7,16,17] but also in their decomposition.[2] The amount of trithionate in the final reaction mixtures was extremely small, compared with that of tetrathionate (Table 1 and Fig. 2). Blasius and Krämer[3] suggested that tetrathionate is formed exclusively in the reaction of thiosulfate with concentrated hydrochloric acid at room temperature. Thus, it may be said that tetrathionate does not always exist in equilibrium with trithionate as shown by Eq. (4), and that the formation reaction of trithionate is represented by

$$4HSO_3^- + S_2O_3^{2-} + 2H^+ = 2S_3O_6^{2-} + 3H_2O \qquad (5).^{18,19}$$

Polythionates except tetrathionate are unstable and decompose readily at high temperature, so the formation reaction of tetrathionate shown by Eq. (1) is the most important in the acid decomposition of thiosulfate solution at relatively high temperature. Janickis[2] reported abnormally higher polythionates, but they might be formed only in highly concentrated acid solutions at a low temperature.

Disproportionation of Trithionate Solution. Trithionate solution undergoes a noticeable decomposition at relatively low temperature.[5,20] The decomposition reaction which takes place in weakly acidic to weakly alkaline solution is represented by

$$S_3O_6^{2-} + H_2O = S_2O_3^{2-} + SO_4^{2-} + 2H^+ \qquad (6)^{5-7}$$

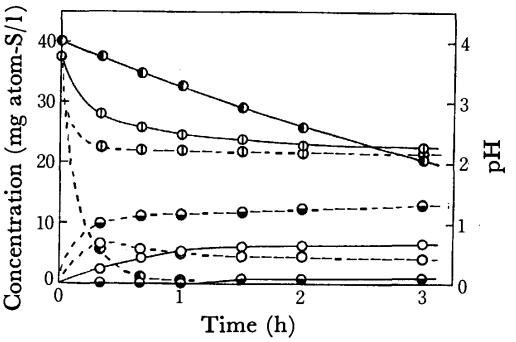

Fig. 4. Disproportionation of potassium trithionate solution.

The numbers in parentheses represent reaction temperatures.
The amounts of elemental sulfur, sulfite and sulfate formed were not determined.

The results of the thermal decomposition of potassium trithionate solution at 70 and 110 °C are shown in Fig. 4. Trithionate solution is very unstable and tends to decompose readily without the addition of acid at as low as 70 °C, as compared with the case of thiosulfate and tetrathionate. The decomposition at 110 °C is characterized by the fact that the velocity is considerably high, and that the amount of tetrathionate formed is large. The phenomena that the amount of tetrathionate formed at 110 °C is larger than that formed at 70 °C is consistent with the results obtained in the present experiments on acid decomposition of thiosulfate solution.

The results of the disproportionation of trithionate solution in the presence of sulfuric acid are shown in Fig. 5. It is seen that elemental sulfur, thiosulfate, tetrathionate, sulfite and sulfate are formed in the decomposition of trithionate solution, and that the composition of reaction mixtures at sulfuric acid concentrations of 0, 10 and 20 mM are almost the same as that of decomposition products of thiosulfate at

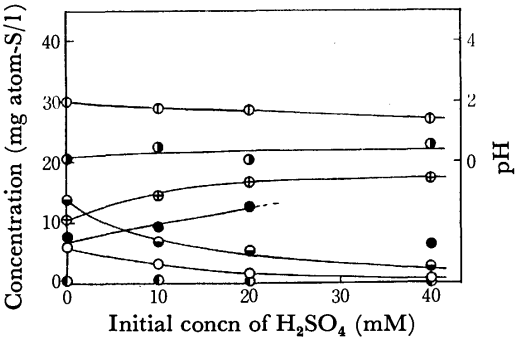

Fig. 5. Effect of sulfuric acid concentration on the disproportionation of trithionate solution.

sulfuric acid concentrations of 20, 30 and 40 mM, respectively (Fig. 2). The only difference is that the amount of sulfate formed is about 20 mM (Fig. 5), which indicates that trithionate decomposes to form equimolar amount of sulfuric acid. Equimolar amounts of thiosulfate and sulfate were exclusively formed from trithionate solution at pH 4.6 (Fig. 6). It seems that trithionate decomposes to thiosulfate, sulfate and hydrogen ions according to Eq. (6), and that the formation of elemental sulfur, tetrathionate and sulfite (Fig. 5) are related to the acid decomposition of thiosulfate thus formed.

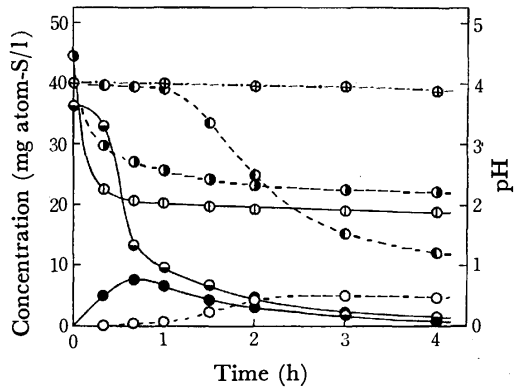

Fig. 7. Disproportionation of potassium tetrathionate solution.
⋯⊕⋯: $S_4O_6^{2-}$ (130 °C), —○—: $S_2O_3^{2-}$ (150 °C), —◐—: $S_4O_6^{2-}$ (150 °C), —◑—: pH (150 °C), —●— $S_2O_3^{2-}$(170 °C), —◒—: $S_4O_6^{2-}$ (170 °C), —ⓟ—: pH (170 °C).

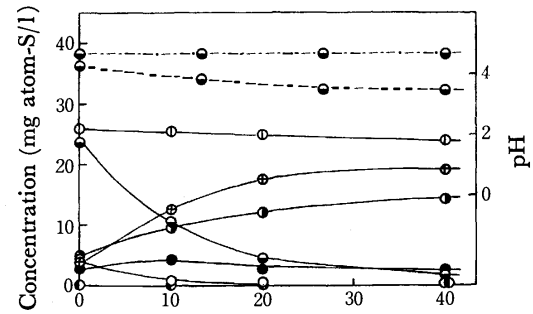
Disproportionation of Tetrathionate Solution. Figure 7 shows the results of the disproportionation of potassium tetrathionate solution at various temperatures. It is seen that tetrathionate scarcely undergoes thermal decomposition at 130 °C, while it decomposes at temperature above 150 °C after an induction period, forming thiosulfate as an intermediate. The reason why the pH of the solution decreases to 3.0 after 20 min of the initiation of experiment is that a small amount of sulfuric acid is formed due to disproportionation of



Figre. 8. Effect of reaction temperature and sulfuric acid concentration on the disproportionation of tetrathionate solution.

tetrathionate.

The results of the disproportionation of tetrathionate solution in the presence of sulfuric acid are shown in Fig. 8. The decomposition degree is fairly high at 150 °C and increases with increasing sulfuric acid concentration. The molar ratio of elemental sulfur to sulfate reaches 1.34 when the initial concentration of sulfuric acid is 40 mM. Accordingly, the decomposition reaction of tetrathionate under the acidic conditions can be represented virtually by

$$3S_4O_6^{2-} + 2H_2O = 7S + 5SO_4^{2-} + 4H^+ \quad (7).$$

However, it is evident from the results shown in Figs. 7 and 8 that thiosulfate is also formed as a decomposition product. Some 80% of sulfur atoms was converted into thiosulfate, the remainder of the sulfur atoms being sulfate under the conditions where thiosulfate was not subjected to acid decomposition (Fig. 9). Thus, the first stage of the disproportionation of tetrathionate could be represented by

$$4S_4O_6^{2-} + 5H_2O = 7S_2O_3^{2-} + 2SO_4^{2-} + 10H^+ \quad (8).$$

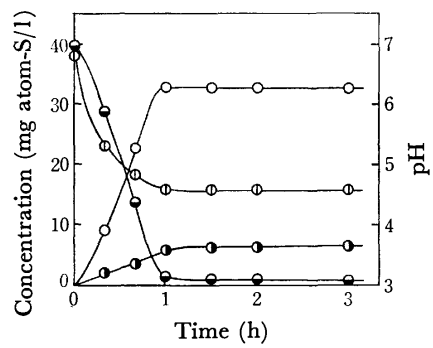

Fig. 9. Disproportionation of tetrathionate in the presence of acetate buffer solution.
Temp: 150 °C, concn of ammonium acetate: 50 mM.
○: $S_2O_3^{2-}$, ◒: $S_4O_6^{2-}$, ◑: SO_4^{2-}, ⓟ: pH.

The formation of elemental sulfur and sulfite (Fig. 8) would be attributed to the acid decomposition of thiosulfate thus formed. Sulfite, however, also decomposes easily under the conditions as seen in Fig. 8,[11] resulting in a small amount of sulfite in the final reaction mixtures. From the results, the relation between decomposition degree of tetrathionate at 150 °C and acidity of solution can be summarized as follows: the decomposition degree of tetrathionate at near pH 5—6 (Fig. 9) is higher than that at near pH 2—3 (Fig. 7), although the decomposition degree increases with increasing sulfuric acid concentration (Fig. 8). Tetrathionate solution at 150 °C seems to be the most stable at near pH 2—3. This tendency is similar to the results obtained by Kurtenacker *et al.*[7] that tetrathionate solution at 50 °C is the most stable at near pH 0—3. Thus, the reactions shown by Eqs. (7) and (8) are important in the decomposition of tetrathionate under the acidic conditions. However, the successive occurrence of reactions shown by Eqs. (8) and (1) or (8), (2) and (11) lead to the overall reaction of (7), and the reaction shown by Eq. (7) is not necessarily considered as a separate reaction.

The equation to represent the decomposition of tetrathionate in acidic solutions has been considered to be as follows:[7,8]

$$2S_4O_6^{2-} = S_3O_6^{2-} + S_5O_6^{2-} \quad (9).$$

The decomposition of potassium pentathionate accompanied by the precipitation of elemental sulfur took place under the same conditions (Fig. 9), whereas no elemental sulfur was formed from tetrathionate. The decomosition of tetrathionate is not represented by Eq. (9). By thermodynamical consideration[11,15] the reactions which reasonably proceed under acidic conditions are restrictedly expressed by Eqs. (7) and (8). Reactions such as those given by Eqs. (9) and (10) which are considered to express the occurrence of decomposition of tetrathionate[7] can be ruled out.

$$4S_4O_6^{2-} + 3H_2O = 5S_2O_3^{2-} + 2S_3O_6^{2-} + 6H^+ \quad (10)$$

Disproportionation of Sulfite Solution. It is well known that sulfurous acid is subjected to disproportionation at 150—200 °C to give elemental sulfur and sulfuric acid.[9,10] Acidic sulfite solution also decomposes to elemental sulfur and acidic sulfate accompanied by intermediate formation of thiosulfate. The reaction is largely accelerated by the presence of thiosulfate.[11] The formation of polythionate, however, has not been verified. Experiments were carried out in order to elucidate the role of polythionates participating in the disproportionation of mixed solutions consisting of sodium sulfite, sodium thiosulfate and sulfuric acid. From the results (Fig. 10) it is evident that thiosulfate does not undergo a remarkable change up to a sulfuric acid concentration of 20 mM. The decrease in sulfite concentration below the acid concentration of 20 mM is caused by air oxidation. The increase in thiosulfate concentration at a sulfuric acid concentration of about 25 mM could be related to the formation of another thiosulfate according to the reaction

$$4HSO_3^- = S_2O_3^{2-} + 2SO_4^{2-} + 2H^+ + H_2O \quad (11).$$

It is seen that the formation of tetrathionate becomes predominant under the conditions where sulfite undergoes disproportionation.

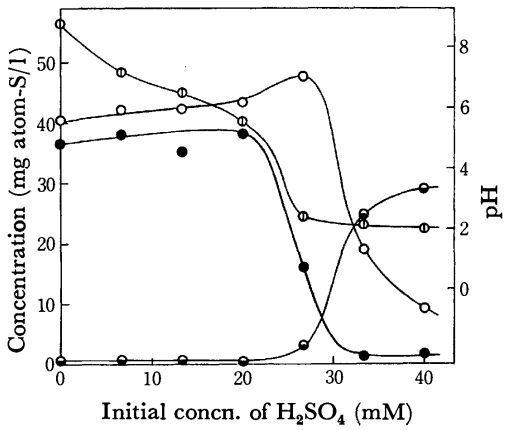

Fig. 10. Disproportionation of mixed solutions of sulfite, thiosulfate and sulfuric acid.
Initial concn of $Na_2S_2O_3$: 21 mM, initial concn of Na_2SO_3: 50 mM, temp: 150 °C, time: 2 h.
○: $S_2O_3^{2-}$, ◒: $S_4O_6^{2-}$, ●: HSO_3^-, ⦶: pH.
The amounts of elemental sulfur and sulfate formed were not determined. When the initial concentration of sulfuric acid is 0, 25, and 40 mM, the initial composition of the solution is given approximately as follows: $Na_2S_2O_3$ (21 mM)—Na_2SO_3 (50 mM), $Na_2S_2O_3$ (21 mM)—$NaHSO_3$ (50 mM), and $Na_2S_2O_3$ (21 mM)—$NaHSO_3$ (20 mM)—H_2SO_3 (30 mM), respectively.

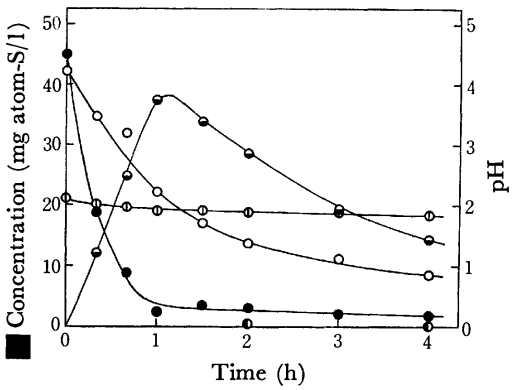

Fig. 11. Time course of the disproportionation of a mixed solution of sulfite, thiosulfate and sulfuric acid.
Initial concn of $Na_2S_2O_3$: 21 mM, initial concn of Na_2SO_3: 45 mM, initial concn of H_2SO_4: 40 mM, temp: 150 °C.
○: $S_2O_3^{2-}$, ◐: $S_3O_6^{2-}$, ◒: $S_4O_6^{2-}$, ●: HSO_3^-, ⦶: pH.
The amounts of elemental sulfur and sulfate formed were not determined.

Figure 11 shows the acid decomposition of a mixed solution of thiosulfate and sulfite with the lapse of time, showing that the decomposition velocity is extremely high, and that the concentration of tetrathionate increases linearly with the lapse of time. The increase in tetrathionate concentration after 1 h from the beginning of experiment is about twice as high as the decrease in thiosulfate concentration, indicating that tetrathionate is formed not only from thiosulfate but also from sulfite. On the other hand, most of the sulfite disappears upon disproportionation within 1 h,

and so tetrathionate is not supplied thereafter, which begins to decrease suddenly. The reason why thiosulfate decomposes at a slower speed than that as seen in Fig. 1 is that, under the conditions shown in Fig. 11, the decomposition of thiosulfate is caused by the proton released in the disproportionation of tetrathionate.

It cannot be made clear from the present experiments what kinds of intermediates are formed in the disproportionation of sulfite. It has been concluded that sulfite firstly decomposes according to Eq. (11) to give thiosulfate and sulfate.[11] Thus, the formation of tetrathionate from sulfite may be explained on the basis of reactions (11) and (1).

Pathway of Disproportionation of Low Valence Sulfur Oxyacids. Tetrathionate undergoes sulfite degradation in faintly acidic to alkaline solution, forming thiosulfate and trithionate as shown by

$$S_4O_6^{2-} + HSO_3^- = S_3O_6^{2-} + S_2O_3^{2-} + H^+ \quad (12).$$

Taking this reaction into consideration, the pathway of disproportionation of low valence sulfur oxyacids including thiosulfate, trithionate, tetrathionate and sulfite is shown to be as follows (Fig. 12). Tetrathionate

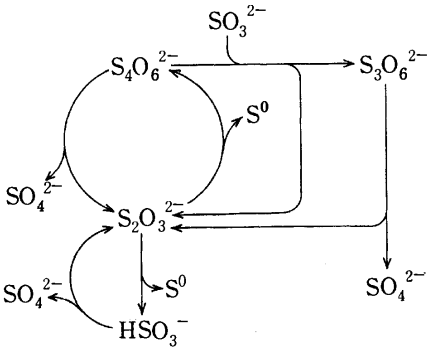

Fig. 12. Pathway of disproportionation of low valence sulfur oxyacids under the acidic conditions.

is decomposed with sulfite to give thiosulfate and trithionate. Trithionate is subjected to hydrolysis to give thiosulfate and sulfate, only if the temperature is high enough. On the other hand, tetrathionate decomposes to thiosulfate and sulfate at the temperature above 130 °C in the absence of sulfite. The thiosulfate thus formed undergoes disproportionation to elemental sulfur and tetrathionate, or elemental sulfur and sulfite. Sulfite undergoes disproportionation to give thiosulfate and sulfate, and then elemental sulfur and sulfate accompanied by intermediate formation of tetrathionate.

The reaction pathway shown in Fig. 12 has been proposed to explain the species detected in the course of the present experiments, such reactions as shown by Eq. (5) thus being excluded. Further study is necessary to clarify the details of the reactions. The reaction pathway (Fig. 12), however, may be useful in understanding the manner in which low valence sulfur oxyacids decompose and the kinds of intermediates formed in acidic solutions at relatively high temperatures.

(Received April 21, 1975)

CNDO- and INDO-type UHF-MO calculations are carried out on MF_6^{n-} (M=V(II), Cr(III), Mn(II), Fe(III), Ni(II)), $NiCl_6^{4-}$, $MnCl_6^{4-}$, $MnCl_4^{2-}$, $MnBr_6^{4-}$, and $CuCl_4^{2-}$. The calculated spin fractions on the ligand orbitals agree well with the experimental values, with a few exceptions. Spin transfers to ligands are mainly attributed to the spin delocalization (SD) mechanism, except those to the 2s and $2p_\sigma$ orbitals of the F ligand in CrF_6^{3-} and VF_6^{4-}, in which spin transfer to those orbitals results from the spin polarization (SP) mechanism. Unpaired electrons are also transferred into the 4s and 4p orbitals of the central metal ion by the SP mechanism. The spin transfers to the ligand due to both the SD and SP mechanisms increase in the order of F<Cl<Br in MnX_6^{4-} and NiX_6^{4-}. The following characterisities of metal-halogen bonds are established; (1) the covalent interaction between the metal d-orbital and the fluorine atom increases in the order Ni(II)<Mn(II)~Fe(III)<Cr(III)~V(II) in MF_6^{n-}, and (2) in metal-halogen covalent interactions, the s-character of halogen decreases in the order F>Cl>Br, while the p-character increases in the same order.

^{19}F NMR studies of open-shell iron-group fluorides have revealed the existence of hyperfine interaction between the fluorine nuclei and the magnetic electrons.[1-7] Similar hyperfine interactions have also been observed in ESR studies of those complexes.[2,8-13] These hyperfine interactions have been explained in terms of the spin fractions on the F ligand.[2-15] It has been accepted that unpaired electrons have been brought into the s and p orbitals of the ligand by metal-fluorine covalency (the spin delocalization (SD) mechanism),[2-16] except in the cases of CrF_6^{3-} and VF_6^{4-}, in which the spin fractions on the 2s orbital of the F ligand are considered to result from the mixing of the excited states (the spin polarization (SP) mechanism).[4,10] However, the spin transfer due to the SP mechanism has not been ascertained theoretically.

Although some theoretical works have been carried out on the electronic structures of these complexes,[14-24] only a few UHF-MO calculations have been presented[19,20,23] which are suitable for studying the spin distribution. Only one INDO-type semi-empirical UHF-MO study of iron-group fluorides has been carried out, by Brown *et al.*[19] In that study, however, the fluorine's 2s orbital was neglected in the basis set, although this orbital is expected to contribute significantly to the metal-fluorine bond. There exists a possibility that this neglect leads to an incorrect conclusion as to the spin distribution.

In this work, semi-empirical UHF-MO calculations, which explicitly included all the valence orbitals, were carried out for iron-group fluorides and some other similar halides, such as $NiCl_6^{4-}$, $MnCl_6^{4-}$, $MnCl_4^{2-}$, $MnBr_6^{4-}$, and $CuCl_4^{2-}$. None of the latter compounds except $CuCl_4^{2-}$ and $MnCl_4^{2-}$ have ever been studied by means of the method, as for as we know. The MO method is a powerful means for studying the electronic structure of transition metal complexes. Especially we need much theoretical support when we attempt to interpret the results of NMR, ESR, *etc.* Thus, the purposes of this work are; (1) to investigate the electronic structures of these complexes, and (2) to ascertain how useful the semi-empirical SCF-MO method is in interpreting the NMR and ESR results of these complexes.

* Present address: Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

Method, Parametrization, and Geometries

Method. A semi-empirical UHF-MO method is used, in which either a CNDO- or INDO-type approximation is included. The approximations used here are the same as our previous ones for the CNDO-type MO method[25] and the same as Konishi's for the INDO-type one[26] respectively. Only the one-electron part of the Fock-matrix elements, H_{rt}, in the INDO-type MO method will be reiterated here:

$$H_{rr} = -I_r - (N_r - 1)\gamma_{rr} - \sum_{t\neq r}^{A} N_r(\gamma_{rt} - 0.5\kappa_{rt}) - \sum_{B\neq A}\sum_{s}^{B} N_s\gamma_{rs} \quad (1)$$

$$H_{rt} = -0.5KS_{rt}(I_r + I_t) \quad (2)$$

where r-AO is on the A atom and where $\sum^A$ means the summation on the A atom. H_{rr} in the CNDO-type MO method is obtained by the use of Eq. (1) by neglecting κ_{rt}. For the Wolfsberg-Helmholz parameter, K,[27] the values of 1.0 and 0.8 are used in the AO pair including the d-orbital and in that including only the s and p orbitals[25b] respectively.

Parametrization. The elements of the first transition series have $d^{n-2}s^2$ configurations in their ground states, except for the Cr atom, which contains the d^5s configuration, where n represents the number of valence electrons. Thus, for metal atoms, the following ionization processes may be considered as valence-state ionizations:

(1) 3d orbital ionization potential (IP); $3d^{n-2}4s^2 \rightarrow 3d^{n-3}4s^2$,

(2) 4s orbital IP; $3d^{n-2}4s^2 \rightarrow 3d^{n-2}4s$,

(3) 4p orbital IP; $3d^{n-2}4s4p \rightarrow 3d^{n-2}4s$.

These values are calculated by using the data of Di Sipio *et al.*[28] The values of the one-center Coulomb repulsion integrals are also taken from the same work.[28] For ligand atoms, the values of the VSIP and one-center Coulomb repulsion integrals are taken from Hinze's work.[29] The values of one-center exchange repulsion intergrals are adopted from Di Sipio's work[30] for metal atoms and from Kato's report[31] for ligand atoms.

In INDO-type MO calculations, the values of the one-center Coulomb repulsion integrals, γ_{ds} and γ_{dp}, are evaluated from Slater-Condon parameters.[30]

The double-ζ type orbitals of Richardson *et al.*[32] are used only for the d-orbitals,[33] while single Slater-type orbitals[34] are used for the s and p orbitals.

Bond Index. The contribution of the AB bond to the total energy, E_{AB}, is used as the bond index.[35,36] This quantity is represented as follows under both approximations, CNDO- and INDO-type used here;

$$E_{AB} = \sum_r^A \sum_t^B [2P_{rt}H_{rt} - \{(P_{rt}^{\alpha})^2 + (P_{rt}^{\beta})^2\}\gamma_{rt}] + \sum_r^A \sum_t^B (P_{rr} - N_r)(P_{tt} - N_t)\gamma_{rt} \quad (3)$$

where $P_{rt} = P_{rt}^{\alpha} + P_{rt}^{\beta}$. The first term on the right-hand side represents approximately the contribution of the covalent bonding interaction, and the second one, approximately that of the electrostatic one. In order to investigate the metal-halogen bonding nature, the first term is divided into individual AO-pair terms, such as $E_{AB(s)}$, $E_{AB(p)}$, and $E_{AB(d)}$;

$$E_{AB(s)} = \sum_r^A [2P_{rs}H_{rs} - \{(P_{rs}^{\alpha})^2 + (P_{rs}^{\beta})^2\}\gamma_{rs}] \quad (4)$$

$$E_{AB(p)} = \sum_r^A \sum_t^{B(p)} [2P_{rt}H_{rt} - \{(P_{rt}^{\alpha})^2 + (P_{rt}^{\beta})^2\}\gamma_{rt}] \quad (5)$$

where $\sum^{B(p)}$ means the summation on the p-orbitals of the B atom. $E_{AB(d)}$ is similarly defined. The quantity, $E_{AB(s)}$, represents the contribution of the B atom's s-orbital to the A-B bond; $E_{AB(p)}$, that of the B atom's p-orbital, and $E_{AB(d)}$, that of the B atom's d-orbital. The second term in Eq. (3) is not divided into individual AO-pair terms, since it approximately represents the electrostatic interaction, and so the division described above is meaningless.

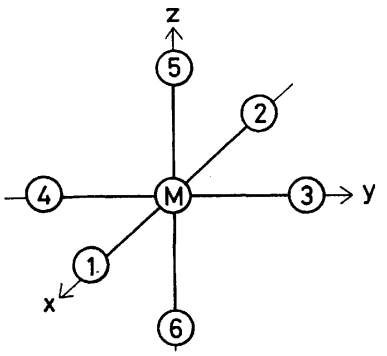

Fig. 1. The coordinate system of MX_6^{n-}.
In $CuCl_4^{2-}$ and $MnCl_4^{2-}$, x, y, and z axis are defined corresponding to their C_4 and C_2 axis respectively.
M–X bond lengths (Å unit): Ni–F=2.00, W. H. Bauer, *Acta Crystallogr.*, **11**, 588 (1958); Mn–F=2.095,[7] and 2.31,[11] see the footnote (f) of Table 3; Fe–F=1.994[11]; Cr–F=1.933;[4] V–F=1.994;[2] Ni–Cl=2.43;[40] Mn–Cl (Oh)=2.63;[13] Mn–Cl (Td)=2.32;[13]; Mn–Br=2.75 (the estimated value); Cu–Cl=2.26.[39]

Geometries. The structure of MX_6^{n-} is assumed for simplicitly to be a rigid octahedron, while its true structure is slightly distorted.[3,4,6] The coordinate system of MX_6^{n-} is shown in Fig. 1. The structures of $CuCl_4^{2-}$ and $MnCl_4^{2-}$ are considered to obey D_{4h}[37] and T_d[13] symmetries respectively.

Results and Discussion

Electron Densities. Table 1 gives the electron distributions calculated by the INDO-type MO method.

The INDO- and CNDO-type MO methods give similar electron densities on the 3d, 4s, and 4p orbitals of the central metal atom; for example, in the CNDO-

Table 1. Electron densities and atomic charges[a]

a) The INDO-type MO method. The single annihilation scarcely affects on these results. b) Ref. 23. c) Ref. 38. d) Mn–F=2.095 Å. e) Ref. 39. g) These values are estimated by assuming that the core AO's are fully occupied.

type MO calculation of NiF_6^{4-}, the electron density on the 3d orbital is 8.201, that on the 4s one is 0.256, and that on the 4p one is 0.502. See also the results of the INDO-type MO calculation of NiF_6^{4-} in Table 1.

In NiF_6^{4-} and $CuCl_4^{2-}$, the electron densities on the 3d orbitals of the central metal atom agree well with those obtained by *ab initio* MO calculations,[23,38] while the electron densities on the 4s and 4p orbitals are remarkably larger than those obtained by the *ab initio* MO calculations. Generally speaking, the *ab initio* MO method gives reasonable electron densities. In transition metal complexes, however, the electron densities on 4s and 4p orbitals depend very much upon the orbital expandings.[39] Thus, the *ab initio* MO method, in which re-optimized AO exponents are not used, does not always give good results for the electron densities in transition metal complexes.

In FeF_6^{3-} and CrF_6^{3-}, the calculated net charges on the central metal ion agree fairly well with the experimental values, as is shown in Table 1. These agreements are better than those of the previous INDO-type method.[19]

In NiX_6^{4-} and MnX_6^{4-} (X=F, Cl, Br), the positive net charge on the central metal ion and the negative net charge on the ligand decrease in this order: F>Cl>Br. This result is reasonable considering the electronegativities of the halogens. While the electron densities on the p_π orbital of the halogen scarcely depend on the kind of halogen, those on the p_σ orbital decrease in this order: F>Cl>Br, and those on the s orbital increase slightly in this order: F<Cl<Br. Since the metal-halogen coordination bond is formed by the electron donation from the halogen anion to metal, and since the stronger interaction should bring about less electron density on the halogen, this result suggests that the contribution of the halogen's p_σ orbital to the metal-halogen bond increases in the order of F<Cl<Br, while that of the s orbital decreases. On this issue, a more detailed discussion will be presented in the following paragraph.

In $MnCl_4^{2-}$, the net charges on the Mn and Cl atoms are smaller than those of $MnCl_6^{4-}$. This suggests that more electrons are donated from ligands to the metal ion in $MnCl_4^{2-}$ than in $MnCl_6^{4-}$. A more precise inspection of the electron densities reveals that the strong electron donation in $MnCl_4^{2-}$ results from the formation of a strong π-bond between the Mn and Cl atoms; in $MnCl_4^{2-}$, the electron densities on the $3p_\pi$ orbitals of the Cl ligand are considerably smaller than those of $MnCl_6^{4-}$, while that on the $3p_\sigma$ orbital in $MnCl_4^{2-}$ is larger than that in $MnCl_6^{4-}$.

Metal-halogen Bonding Nature. In order to investigate the metal-halogen bonding nature, E_{MX} (M= metal atom, X=halogen atom) is divided into $E_{MX(s)}$, $E_{MX(p)}$, $E_{M(d)X}$, and $E_{M(s+p)X}$. The results are given in Table 2.

The absolute values of $E_{M(s+p)X}$ are remarkably large and do not depend very much on the kind of central metal, which suggests the 4s and 4p orbitals participate in the metal-halogen covalent bond to almost the same degree in all complexes. The absolute values of $E_{M(d)X}$ depend largely on the kinds of the metal atoms and increase in this order; Ni(II)<Mn(II)~Fe(III)< Cr(III)~V(II), which suggests that the contribution of the 3d orbitals to the metal-halogen bond increases in this order. This increasing order agrees with the decreasing tendency of the numbers of electrons held in the molecule; *i.e.*, as is shown in Fig. 2, the increasing numbers of electrons result in more electrons in the anti-bonding MO's, e_g^* and t_{2g}^*, and as a consequence

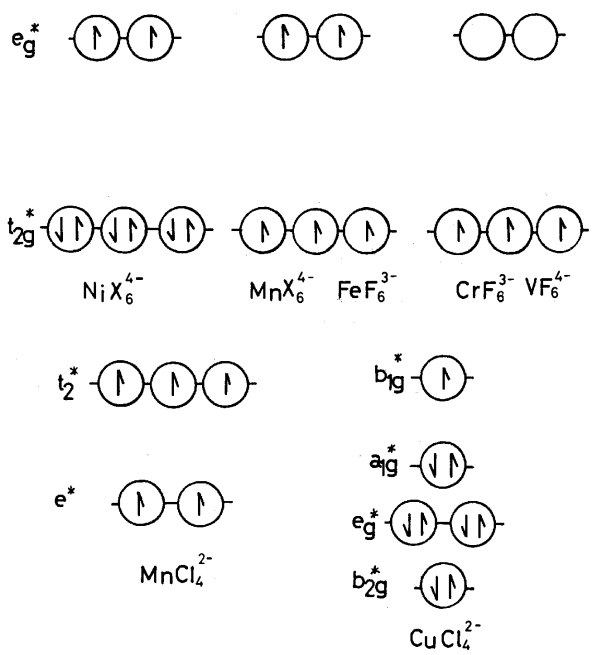

Fig. 2. Schematic MO's mainly contributed from d orbitals of the central metal ion.
These MO's have weak anti-bonding character.

a) "aa" means the results after a single annihilation. b) Ref. 20). c) Ref. 19). d) Ref. 7). e) Ref. 11). f) Mn–F=2.095 Å. Since the ESR data (Mn–F=2.31 Å) is considerably different from NMR one (Mn–F=2.095 Å), two bond lengths of Mn–F are examined. g) Ref. 4). h) Ref. 2).

of this, the metal-halogen bond becomes weak.

The $E_{MX(s)}$ and $E_{MX(p)}$ of MnX_6^{4-} and NiX_6^{4-} are also given in Table 2. The absolute value of $E_{MX(s)}$ decreases in this order; F>Cl>Br, while that of $E_{MX(p)}$ increases in this order; F<Cl<Br. These results suggest that the contribution of the halogen's s orbital to the metal-halogen bond decreases in this order; F>Cl>Br and that the contribution of the halogen's p orbital increases in this order; F<Cl<Br. This bonding nature is consistent with that discussed in the previous paragraph on the basis of electron density.

Spin Fraction on the Ligands. Results are given in Tables 3 and 4, compared with the experimental values[2,4,7,11] and the previously calculated ones.[19,20] In Table 3, "aa" represents the results after a single annihilation.

TABLE 4. SPIN FRACTIONS ON THE Cl⁻ LIGAND[a]

Compounds	f_s (%)		$f_{p_\sigma}-f_{p_\pi}$ (%)	
	Calcd	Obsd	Calcd	Obsd
$NiCl_6^{4-}$	0.33	0.58[b]	2.10	7.3[b]
$MnCl_6^{4-}$	0.37	0.4[c]	1.50	3.9[c]
$MnCl_4^{2-}$	0.25	—	−2.71[d]	—
$CuCl_4^{2-}$	0.27[d]	0.61	5.09	11.9[d]

a) The INDO-type MO method. After a single annihilation. b) Ref. 40). c) Ref. 13). d) This value is the one before annihilation, since our coordinate system cannot give spin fractions on p_σ and p_π orbitals after annihilation.

INDO-type MO calculations give smaller values of f_s and $f_{p_\sigma}-f_{p_\pi}$ than the CNDO-type MO calculations in all complexes.

As is shown in Fig. 2, NiF_6^{4-} has a $t_{2g}^{*6}e_g^{*2}$ configuration, and MnF_6^{4-} and FeF_6^{3-} have $t_{2g}^{*3}e_g^{*2}$ one. Metal-fluorine covalency results in positive spin fractions on the 2s and $2p_\sigma$ orbitals of the F ligand in NiF_6^{4-} and positive ones on the 2s, $2p_\sigma$, and $2p_\pi$ orbitals in MnF_6^{4-} and FeF_6^{3-}. In these complexes, both CNDO- and INDO-type MO methods can give reasonable results on spin fractions, as is shown in Table 3. Our results are in better agreement with the experiments than the previously calculated ones.[19,20] Single annihilations affect the values of f_s and $f_{p_\sigma}-f_{p_\pi}$ hardly at all.

In CrF_6^{3-} and VF_6^{4-}, which contain t_{2g}^{*3} configurations, as is shown in Fig. 2, metal-fluorine covalency brings positive spin fractions into only two $2p_\pi$ orbitals of the F ligand. Negative spin fraction is also observed on the 2s orbital of the F ligand in these complexes; this is thought to be due to the spin polarization.[4,10] While the CNDO-type MO method fails to give this spin fraction, the INDO-type one can give it. The single annihilation, which gives almost complete eigenvalues of $\mathbf{S}^2$ (See Table 5), brings about remarkably large changes in the values of f_s and $f_{p_\sigma}-f_{p_\pi}$. Although, in these complexes, the values of f_s and $f_{p_\sigma}-f_{p_\pi}$ do not fit in with the experimental values except for the f_s value of VF_6^{4-}, these calculated values are better than the results obtained by the previous CNDO/II calculation[20] and seem reasonable considering the relatively large uncertainty in the experimental values.

The results for chloro complexes are given in Table 4; they were calculated by the INDO-type MO method. The calculated values of f_s agree fairly well with the experimental values except for the case of $CuCl_4^{2-}$. The $f_{p_\sigma}-f_{p_\pi}$ value in chloro complexes are larger than those in fluoro complexes, which is reproduced by our calculations. These calculated values, however, are considerably smaller than the experimental values, as is shown in Table 4.

Spin-transfer Mechanism. Spin fractions are divided into two components according to the method of Nakatsuji *et al.*;[42] the components due to the SD mechanism and the others due to the SP mechanism. The results are given in Table 5, together with the expected values of $\mathbf{S}^2$ before and after a single annihilation.

The expectation values of $\mathbf{S}^2$ before annihilation are almost the same to the eigenvalues of $\mathbf{S}^2$ in all complexes, although there is a little difference between the two values in CrF_6^{3-} and VF_6^{4-}. This shows that we can investigate the electronic structures of these complexes with a single Slater determinant. In all the complexes, unpaired electrons are localized in the d orbitals of the central metal ion; this shows that it is reasonable to use the crystal field theory in the qualitative discussion of the electronic structures of these complexes.

a) The INDO-type MO method. These data are spin fraction per an orbital after annihilation. b) "aa" and "ba" mean after and before a single annihilation, respectively. c) Mn–F=2.31 Å. d) In $MnCl_4^{2-}$, t_{2g} and e_g should be replaced by t_2 and e, respectively. e) These values are spin fraction on a p-orbital. In our coordinate system, spin fractions on p-orbital after annihilation can not be divided into those on p_σ and p_π orbitals. f) In $CuCl_4^{2-}$, the other 3d-orbitals and $4p_\pi$-orbital do not have spin fractions.

Spin transfer to the ligands is mainly contributed to by the SD mechanism in NiX_6^{4-}, MnX_6^{4-}, and FeF_6^{3-}. It should be noted, however, that the SP mechanism brings a little negative spin fractions on the P_π orbitals of the ligand in MnX_6^{4-}. In these complexes, spin transfer to the halogen s orbital through the SD mechanism roughly decreases in this order; F≳Cl>Br, while that to the halogen p orbital through the same mechanism increases in the same order; F<Cl<Br. It is interesting that the former decreasing order agrees with decreasing order of the halogen's s orbital contribution to the metal-halogen bond, and that the latter increasing one agrees with the increasing order of the halogen's p-orbital contribution (See Table 2-B). The spin fraction due to the SP mechanism increases in this order; F<Cl<Br. It is also interesting that this order agrees with the reverse order of the spectrochemical series. These interesting features should be investigated in more detail.

In CrF_6^{3-} and VF_6^{4-}, the SD mechanism brings about positive spin fractions on the two $2p_\pi$ orbitals of the F ligand, while the SP mechanism induces negative spin fractions on the 2s and $2p_\sigma$ orbitals of the F ligand. These results support the previous proposal of spin transfer in these complexes.[3,10] In $MnCl_4^{2-}$ and $CuCl_4^{2-}$, the spin fractions on the ligand are mainly due to the SD mechanism, while in $MnCl_4^{2-}$ the SP mechanism contributes considerably to f_s and f_p. In $MnCl_4^{2-}$, spin transfer to the Cl ligand is larger than that in the $MnCl_6^{4-}$.

The SP mechanism also induces spin fractions on the 4s and 4p orbitals of the central metal ion in all the complexes. Furthermore, in CrF_6^{3-} and VF_6^{4-} its mechanism also induces positive spin fractions on the $3d_{e_g}$ orbitals.

Comparison between the CNDO- and INDO-type Methods. The CNDO-type MO method can not give the spin fraction due to the SP mechanism, while the INDO-type one can; in CrF_6^{3-} and VF_6^{4-}, the CNDO-type MO method can not give the spin fraction on the 2s and $2p_\sigma$ orbitals of the F ligand which is induced by the SP mechanism, as has been described in the previous paragraph and shown in Table 5. Thus, the CNDO-type method is inferior to the INDO-type method in treating the spin fraction induced by the SP mechanism. It is worthwhile to compare these two methods in the MO calculation of such complexes as NiF_6^{4-}, where the SD mechanism mainly brings about the spin fraction on the ligand (See Table 5) and where the CNDO-type MO method gives good results for the spin distribution. Table 6 gives the MO energies and MO coefficients of NiF_6^{4-}. The CNDO-type MO method gives quite the same MO energies and the same MO coefficients between α-spin and β-spin MO's, while the INDO-type method gives considerably different values. Thus, the CNDO-type method does not show the polarization effects on the MO energy and MO coefficients sufficiently well and is not satisfactory even in NiF_6^{4-}.

In conclusion, the INDO-type MO method used here can give good results on spin fractions. It is expected that this can be used in studies of the electronic structures of open-shell transition metal complexes and

Table 6. Comparison between the CNDO-type and INDO-type MO methods
$2t_{2g}$* MO of NiF_6^{4-}

Method		ε (eV)[a]	Eigenvector[b]
CNDO	α-spin	7.848	$0.783\,d_{xz} - 0.311[(1z)-(2z)+(5x)-(6x)]$
	β-spin	7.848	$0.783\,d_{xz} - 0.311[(1z)-(2z)+(5x)-(6x)]$
INDO	α-spin	7.621	$0.201\,d_{xz} - 0.201[(1z)-(2z)+(5x)-(6x)]$
	β-sinp	8.818	$0.952\,d_{xz} - 0.153[(1z)-(2z)+(5x)-(6x)]$

a) These positive MO energies would be due to the neglect of effects of cation and/or crystal lattice[19]. The extra potential, such as crystal lattice, do not give so great effect on spin fraction.[19] b) $(1z)$ *etc.* means the p_z orbital of the ligand 1 (See Fig. 1.).

can be of great help in interpreting the results of NMR, ESR, *etc.*

These calculations were carried out using the Facom 230-75 Computer of the Data Processing Center in Kyoto University.

The authors wish to thank Professor Kimio Tarama for his generous support of this work. They also wish to thank Dr. Hideyuki Konishi for his help in the calculation and Dr. Hiroshi Nakatsuji for his help in the single annihilation.

33) When the d-function for the $d^{n-2}s^2$ configuration is used, too small spin fractions are obtained. The use of the d-function for d^n-one gives better results on spin distribution. Thus, although the valence state is taken as the $d^{n-2}s^2$ configuration, the d-function for the d^n configuration is used in this work; this does not seem unreasonable considering that the d-function is used only in calculating the overlap integrals induced in the empirical Wolfsberg-Helmholz approximation.

In the course of our study, this report has been presented, in which spin-polarized multiple scattering X_α calculations are presented on some MF_6^{-n}. Those results fairly agree with experiments to the almost same degree as ours.

A Spectrophotometric Study of Copper(I) Chloro-Complexes in Aqueous 5 M Na(Cl, ClO_4) Solutions

Kazuhiko SUGASAKA and Ayako FUJII

Government Industrial Research Institute, Shikoku, Hananomiya Takamatsu, Kagawa 760

(Received May 6, 1975)

The complex formation of copper(I) ions in aqueous 5 M Na(Cl, ClO_4) solutions was studied by spectrophotometry covering a pH range from acidic to alkaline. Over the range of the chloride concentration of 0.05—5 M in acidic solutions, the complexes $CuCl_2^-$ and $CuCl_3^{2-}$ were found. The molar extinction coefficients of the complexes were determined at various wavelengths from 220 to 320 nm. The equilibrium constant for the reaction $CuCl_2^- + Cl^- = CuCl_3^{2-}$ was determined to be 1.95. Chloro-hydroxo mixed complexes of copper(I), such as $CuClOH^-$, $CuCl_2OH^{2-}$, and $CuCl(OH)_2^{2-}$ were formed in alkaline solutions and the molar extinction coefficients of these species were estimated. The formation constants $\beta_{pq}=[CuCl_{2+p}(OH)^q]/[CuCl_2][Cl]^p[OH]^q$ of the complexes were evaluated to be as follows: $\beta_{-11}=(1.1\pm0.1)\times10^4$, $\beta_{01}=(4.1\pm0.3)\times10^3$, and $\beta_{-12}=(3.8\pm0.7)\times10^6$. No polynuclear complex was formed in the solutions.

It is known that the color of copper(I) oxide changes from yellow to red depending upon the conditions of preparation. Red copper(I) oxide is usually prepared by the electrolysis of a concentrated sodium chloride solution using copper electrodes, while yellow copper(I) oxide is precipitated by the hydrolysis of copper(I) chloride in dilute sodium chloride solutions, the former being used for ship bottom paint for antifouling.

As reported in previous publications[1,2] a search was made for favorable conditions for the preparation of red copper(I) oxide. The present study was undertaken as a continuation of this series of studies.

Since the solubility of copper(I) chloride in water is low, reliable results for the formation of copper(I) chloro-complexes have hitherto scarcely been obtained. The oxidation of copper(I) ions causes another difficulty for the experimental procedures of the study. We first note an investigation by Bodländer and Storbeck[3] who interpreted their results of the solubility measurements of copper(I) chloride in sodium chloride solutions by postulating the formation of the complexes $CuCl_2^-$ and $CuCl_3^{2-}$. More than a quarter century after Bodländer's pioneering work, Fromherz and Menshik[4] showed that the absorption maximum of copper(I) chloro-complexes appeared at 272 nm in a concentrated solution of potassium chloride. Glasner and Avinur[5] found an absorption maximum at 273 nm together with a shoulder at 234 nm in an acidic copper(I) solution containing potassium chloride. The formation of the $CuCl_2^-$ complex in a concentrated hydrochloric acid solution was confirmed by an extraction method and Raman spectrophotometry.[6] The formation constants of copper(I) chloro-complexes have been reported to be $[CuCl_2^-]/[Cu^+][Cl^-]^2=(1.00\pm0.05)\times10^6$, $[CuCl_3^{2-}]/[Cu^+][Cl^-]^3=(0.97\pm0.05)\times10^6$, and hence $[CuCl_3^{2-}]/[CuCl_2^-][Cl^-]=0.97$ by the solubility method.[7]

In all previous studies of copper(I) complexes in chloride solutions, measurements were carried out in acidic solutions.[3-8] It is a well-known fact that an increase in the pH of a copper(I) chloride solution results in precipitates which dissolves with a further increase of pH.[9] Nevertheless, no quantitative investigation has yet been made of alkaline solutions of copper(I) chloride. The aim of the present work is to elucidate the reaction equilibria of copper(I) ions in aqueous chloride solutions over a wide pH range.

Experimental

Reagents. Reagent grade copper(I) chloride was recrystallized from hydrochloric acid and dried at 130 °C in a nitrogen atmosphere after washing the crystals with acetic acid.[10] Copper(I) chloride crystals were dissolved into a 0.5 M sodium chloride solution containing sufficient amounts of sodium perchlorate and perchloric acid in order to maintain the ionic strength and pH at 5 and 1, respectively. Sample solutions were prepared by diluting the stock solution by the addition of sodium chloride and sodium hydroxide solutions. Pure copper wire (99.99% purity) was added to the stock solution for reducing a trace amount of copper(II) ions. The amount of copper(II) ions in the stock solution was calculated not to exceed 4.4×10^{-8} M by using the equilibrium constant of the disproportionation reaction[11] and the formation constants[11] of copper(I) and (II) chloro-complexes reported in the literature. Sodium chloride and sodium perchlorate solutions were prepared from reagent grade chemicals by dissolving them in oxygen free water. All the experimental procedures were carried out in an atmosphere of nitrogen.

Spectrophotometric Measurements were carried out with a Hitachi EPS-3T spectrophotometer. Sample solutions were referred to blank solutions which were identical in composition to the sample solutions except for copper(I) chloride. The influence of copper(II) ions on the measurement of the absorption spectrum was neglected because the amount of copper(II) ions in the sample solution was calculated to not exceed 7.5×10^{-9} M and log ε of the copper(II) chloro-complexes over the wavelength range examined is about 2 to 3.[12] Cells with 1, 2, 10, and 20 mm optical pathlengths were used for the measurements at 25 °C.

Determination of Concentrations of Ions in Solution. The concentration of copper(I) ions in the stock solution was determined by atomic absorption spectrophotometry. The concentration of chloride ions was determined by Mohr's method. Since the concentration of chloride ions was greatly in excess of the copper(I) ions, the concentration of free chloride ions $[Cl^-]$ was equated to the total concentration of sodium chloride in the solution.

pH Measurements. Beckman No. 39013 combination electrodes were used for pH measurements with a Hitachi-Horiba F-5 type expanded-scale pH meter at 25 °C. The electrodes were calibrated against standard solutions of perchloric acid in 5 M Na(Cl, ClO_4) media. In an alkaline region, a series of sodium hydroxide solutions at a constant

ionic medium of 5 M Na(Cl, ClO_4) was used as a series of standard pH buffer solutions. The potentials of the cell obeyed Nernst's equation over the range of the concentration of hydroxide ions from 1×10^{-4} to 3×10^{-2} M to within an uncertainty of ±1 mV.

Results and Discussion

Spectra of Copper(I) Chloride Solutions. Absorption spectra of copper(I) chloride solutions containing various amounts of sodium chloride and sodium hydroxide are shown in Fig. 1. Absorption maxima appeared at 226, 233, and 273 nm depending on the concentrations of chloride and hydroxide ions. In Table 1 are summarized the results of absorption spectra of the solutions. Spectra observed in acidic solutions ($-\log[OH^-]\simeq12$) are similar to those reported by Froherz[4] and Glasner[5] and showed two maxima at wavelengths longer than 200 nm. The absorbance at 273 nm decreased as the concentration of chloride ions decreased.

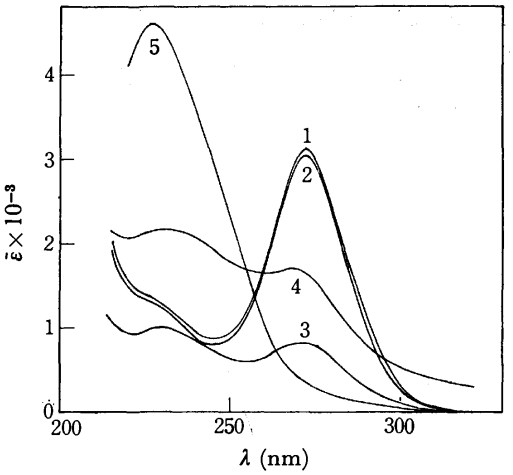

Fig. 1. Spectra of copper(I) chloride aqueous solutions. The compositions of the sample solutions numbered on the curves are shown in Table 1.

The absorption maximum at 226 nm in an alkaline solution has been previously observed.[13] The absorbance at this wavelength increased with the concentration of hydroxide ions, whereas the absorbance at 273 nm decreased.

Table 1. Wavelengths of maximum absorption of copper(I) chloride solutions

No	[Cl⁻] (M)	$-\log[OH^-]$	λ_{max} (nm)
1	5	~12	233(shoulder), 273(sharp)
2	4	~12	233(shoulder), 273(sharp)
3	0.1	~12	233(broad), 270
4	4	2.5[a]	230(broad), 270
5	4	0.25[a]	226(sharp)

a) These values were calculated from the analytical concentrations of hydroxide ions.

Species of Copper(I) Chloro-complexes in Acidic Solutions Containing Sodium Chloride. The apparent molar extinction coefficient $\bar{\varepsilon}=E/[Cu(I)]_{TOT}$ (E denotes the absorbance of a solution for a unit optical length) at 233 and 273 nm varied with the concentration of chloride ions as shown in Fig. 2. $\bar{\varepsilon}$ was independent of the concentration of copper(I) chloride. This result shows that no polynuclear complex of copper(I) was formed in the solution.

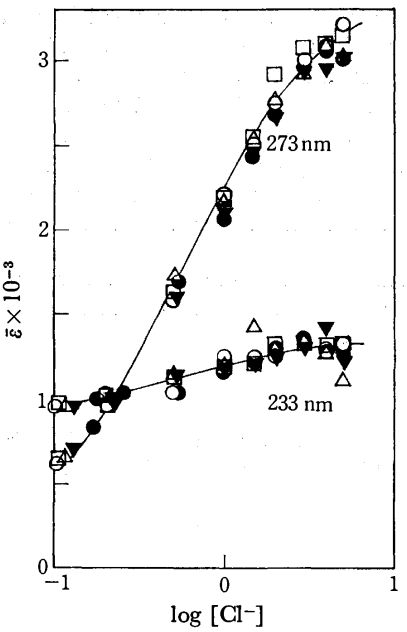

Fig. 2. Plots of $\bar{\varepsilon}$ against log[Cl⁻] ($\mu=5$, $-\log[OH^-]=12$, at 25 °C).
[Cu(I)]=○2.4×10^{-4}, □4.7×10^{-4}, △9.4×10^{-4}, ▼ 1.9×10^{-3}, ●4.7×10^{-3} M.

Copper(I) chloride, which is only slightly soluble in water, becomes soluble in an aqueous solution containing chloride ions to form $CuCl_m^{(m-1)-}$ complexes, where $m\geq2$. Therefore, it may be reasonable to assume that the complex $CuCl_2^-$ is formed at the first stage of complex formation in a chloride solution and formation reactions of higher complexes in solution may be described by the following equation:

$$CuCl_2^- + nCl^- = CuCl_{2+n}^{(n+1)-}. \quad (1)$$

From the material balance of copper(I), the following equation is derived:

$$[Cu(I)]_{TOT} = [CuCl_2^-] + \sum_n \beta_n[CuCl_2^-][Cl^-]^n \quad (2)$$

where $\beta_n=[CuCl_{2+n}^{(n+1)-}]/[CuCl_2^-][Cl^-]^n$. Since the ligand shows no absorption over the entire range studied, the absorbance E per unit path is given by

$$E = \varepsilon_0[CuCl_2^-] + \sum_n \varepsilon_n\beta_n[CuCl_2^-][Cl^-]^n. \quad (3)$$

Then, $\bar{\varepsilon}$ is given by

$$\bar{\varepsilon} = \frac{\varepsilon_0+\sum_n \varepsilon_n\beta_n[Cl^-]^n}{1+\sum_n \beta_n[Cl^-]^n}. \quad (4)$$

The plots of $\bar{\varepsilon}$ *vs.* log[Cl⁻] were fitted to a normalized curve, $y=\log\{a/(1+x)\}$, by choosing a suitable value of a. From this it was found that $n=1$, and thus Eq. (4) is rewritten as

$$\bar{\varepsilon} = \frac{\varepsilon_0+\varepsilon_1\beta_1[Cl^-]}{1+\beta_1[Cl^-]} = \varepsilon_1 + \frac{\varepsilon_0-\varepsilon_1}{1+\beta_1[Cl^-]}. \quad (5)$$

From the best fit to the $\bar{\varepsilon}$ curves at 233 and 273 nm, the following values were obtained: at 273 nm ε_0 (*i.e.*, the molar extinction coefficient of the $CuCl_2^-$ complex) $=0$, $\varepsilon_1=3.5\times10^3$, $\beta_1=1.95$ and at 233 nm $\varepsilon_0=0.9\times10^3$, $\varepsilon_1=1.4\times10^3$ and $\beta_1=1.80$. The formation constant β_1 and the values of ε_0 and ε_1 at 273 and 233 nm were refined with the aid of an electronic computer by means of least squares calculations as shown in Table 2.

Table 2. The molar extinction coefficients and the formation constant of the complexes

λ_{max} (nm)	ε_0	ε_1	β_1
233	$(0.80\pm0.02)\times10^3$	$(1.45\pm0.01)\times10^3$	1.95
273	$(0.00\pm0.08)\times10^3$	$(3.33\pm0.05)\times10^3$	

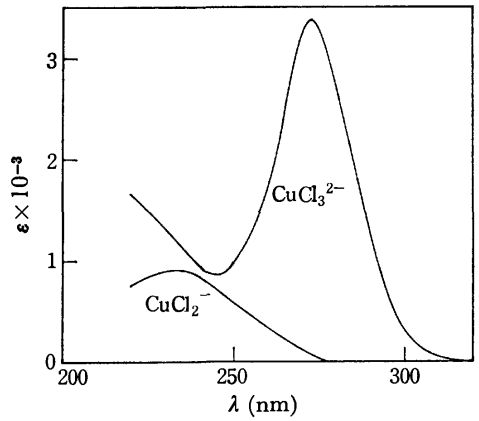

Fig. 3. Calculated spectra for the species of $CuCl_2^-$ and $CuCl_3^{2-}$ in acidic solution.

Figure 3 shows the spectra of the $CuCl_2^-$ and $CuCl_3^{2-}$ complexes calculated from spectrophotometric data at various wavelengths using the constants given in Table 2.

Copper(I) Chloro-complexes in Alkaline Solutions. As shown in Fig. 1, $\bar{\varepsilon}$ at 226 nm increases with the hydroxide ion concentration, whereas $\bar{\varepsilon}$ at 273 nm decreased. Typical examples of the change in $\bar{\varepsilon}$ at 273 and 226 nm with the hydroxide ion concentration are shown in Figs. 4 and 5. $\bar{\varepsilon}$ at 273 and 226 nm also changed with the chloride ion concentration. Therefore, both chloride and hydroxide ions must be taken into consideration in the reaction equilibria of copper(I) chloro-complexes in alkaline solutions. It is obvious that the formation of any polynuclear complex is ruled out because $\bar{\varepsilon}$ was independent of the concentration of copper(I) ions. From the fact that $\bar{\varepsilon}$ at 226 nm at the highest hydroxide ion concentration decreased as the concentration of chloride ions increased, it can be concluded that some $CuCl_{2+p}(OH)_q$ complexes with $p<0$ are formed in the alkaline solution, thus

$$CuCl_2^- + pCl^- + qOH^- = CuCl_{2+p}(OH)_q^{(p+q+1)-}. \quad (6)$$

The material balance for copper(I) ions can be represented by

$$[Cu(I)]_{TOT} = [CuCl_2^-] + \beta_1[CuCl_2][Cl^-] + \sum_p\sum_q \beta_{pq}[CuCl_2^-][Cl^-]^p[OH^-]^q, \quad (7)$$

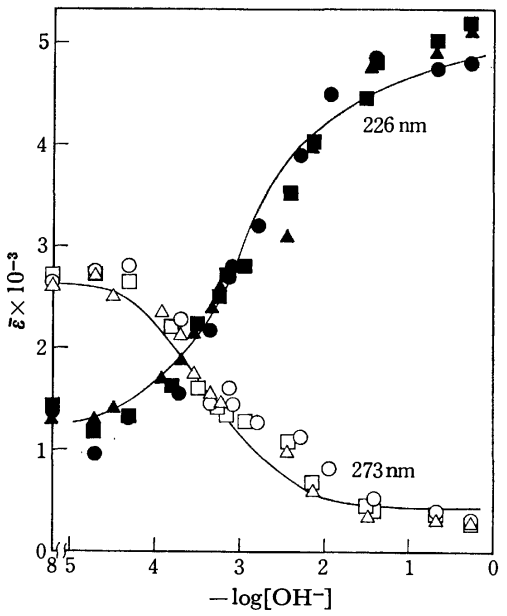

Fig. 4. Plots of $\bar{\varepsilon}$ against the concentration of hydroxide ion.
[Cu(I)]=○2.4×10⁻⁴, □4.6×10⁻⁴, △9.4×10⁻⁴ M, [Cl⁻]=2 M.

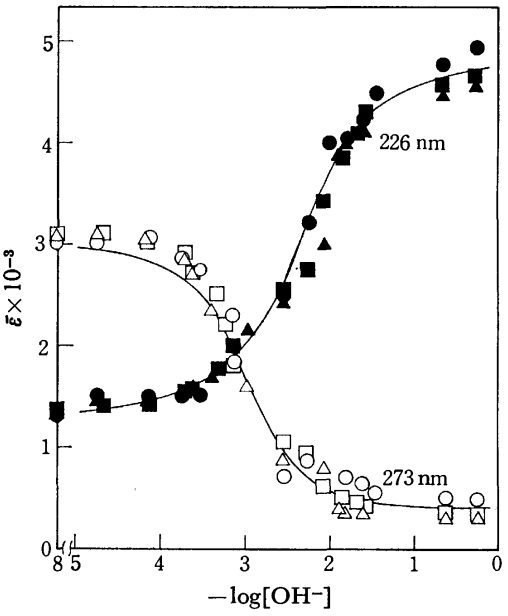

Fig. 5. Plots of $\bar{\varepsilon}$ against the concentration of hydroxide ion.
[Cu(I)]=○2.4×10⁻⁴, □4.6×10⁻⁴, △9.4×10⁻⁴ M [Cl⁻]=4 M.

where p is either positive, zero or negative, and q is zero or a positive integer. The apparent molar extinction coefficient $\bar{\varepsilon}$ may be written as follows:

$$\bar{\varepsilon} = \frac{\varepsilon_0+\varepsilon_1\beta_1[Cl^-]+\sum_p\sum_q\varepsilon_{pq}\beta_{pq}[Cl^-]^p[OH^-]^q}{1+\beta_1[Cl^-]+\sum_p\sum_q\beta_{pq}[Cl^-]^p[OH^-]^q}. \quad (8)$$

By comparing the family of normalized curves, $y=\log\{a/(1+x^b)\}=f(\log x)$, having various values of a and b with the $\bar{\varepsilon}$ *vs.* $\log[OH^-]$ curves at constant $[Cl^-]$, q in the $CuCl_{2+p}(OH)_q^{(p+q+1)-}$ complex can be

roughly estimated. The normalized curve with $b=1$ is less steep and that with $b=2$ is steeper than the experimental ones. These facts suggest that complexes with $q=1$ and 2 are formed in the solution.

In the first approach, the formation of $CuCl_{2+p}OH^{(p+2)-}$ complexes with varying p in the region of relatively low $[OH^-]$ concentration ($-\log[OH^-] \gtrsim 3$) was assumed. With this assumption, Eq. (8) may be rewritten as

$$\bar{\varepsilon} = \frac{\varepsilon_0+\varepsilon_1\beta_1[Cl^-]+\sum_p \varepsilon_{p1}\beta_{p1}[Cl^-]^p[OH^-]}{1+\beta_1[Cl^-]+\sum_p \beta_{p1}[Cl^-]^p[OH^-]}. \quad (9)$$

By rearranging this equation, the following is obtained:

$$F \equiv \{\bar{\varepsilon}(1+\beta_1[Cl^-])-(\varepsilon_0+\varepsilon_1\beta_1[Cl^-])\}[OH^-]^{-1} = \sum_p \varepsilon_{p1}\beta_{p1}[Cl^-]^p - \bar{\varepsilon}\sum_p \beta_{p1}[Cl^-]^p. \quad (10)$$

The plots of F *vs.* $\bar{\varepsilon}$ are shown in Fig. 6 in which three straight lines are seen. The values of $\sum_p \beta_{p1}[Cl^-]^p$ and $\sum_p \varepsilon_{p1}\beta_{p1}[Cl^-]^p$ were obtained from the slopes and intercepts, respectively, of the lines. If it is simply assumed that only one complex is formed, *i.e.*, $p=P$, the values of $\beta_{P1}[Cl^-]^P$ and $\varepsilon_{P1}\beta_{P1}[Cl^-]^P$ are obtained.

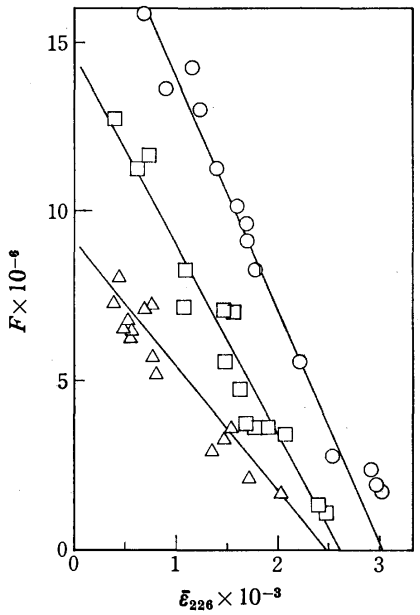

Fig. 6. Plots of F against $\bar{\varepsilon}_{226}$.
$[Cl^-]$=○2, □3, △4 M.

These values are almost inversely proportional to $[Cl^-]$. However, both β_{P1} and $\varepsilon_{P1}\beta_{P1}$ calculated assuming $P=-1$ were not constant but decreased slightly with $[Cl^-]$. Therefore, it is concluded that the $CuCl_2OH^{2-}$ complex must be taken into consideration, in addition to the main product of $CuClOH^-$. On the assumption of the formation of complexes with $P=0$ and -1, β_{-11}, β_{01}, ε_{-11} and ε_{01} were obtained by the simultaneous solution of Eq. (10) at various chloride and hydroxide ion concentrations. At high hydroxide ion concentrations $CuCl_{2+p'}(OH)_2^{(p'+3)-}$ may be formed. Taking into consideration the formation of dihydroxo-complexes, Eq. (8) can be rewritten as

$$\bar{\varepsilon} = \frac{\varepsilon_0+\varepsilon_1\beta_1[Cl^-]+\varepsilon_{-11}\beta_{-11}[Cl^-]^{-1}[OH^-]+\varepsilon_{01}\beta_{01}[OH^-]+\sum_{p'} \varepsilon_{p'2}\beta_{p'2}[Cl^-]^{p'}[OH^-]^2}{1+\beta_1[Cl^-]+\beta_{-11}[Cl^-]^{-1}[OH^-]+\beta_{01}[OH^-]+\sum_{p'} \beta_{p'2}[Cl^-]^{p'}[OH^-]^2}. \quad (11)$$

Rearrangement of Eq. (11) leads to

$$F' \equiv \{\bar{\varepsilon}(1+\beta_1[Cl^-]+(\beta_{-11}[Cl^-]^{-1}+\beta_{01})[OH^-]) -(\varepsilon_0+\varepsilon_1\beta_1[Cl^-]+(\varepsilon_{-11}\beta_{-11}[Cl^-]^{-1} +\varepsilon_{01}\beta_{01})[OH^-])\}[OH^-]^{-2} = \sum_{p'} \varepsilon_{p'2}\beta_{p'2}[Cl^-]^{p'} - \bar{\varepsilon}\sum_{p'} \beta_{p'2}[Cl^-]^{p'}. \quad (12)$$

The left-hand side of Eq. (12), F', can be calculated from the experimental data by the insertion of the values ε_{-11}, ε_{01}, β_{-11} and β_{01} determined in the previous section. The plots of $F'\times[Cl^-]$ *vs.* $\bar{\varepsilon}$ are shown in Fig. 7. The points fall on a single straight line, the

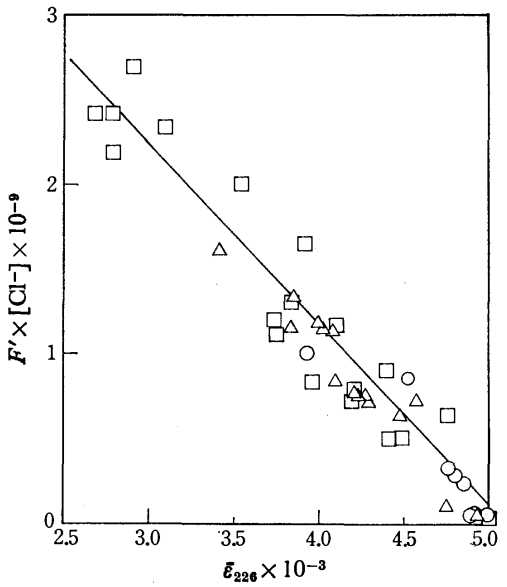

Fig. 7. Plots of $F'\times[Cl^-]$ against $\bar{\varepsilon}_{226}$.
$[Cl^-]$=○2, □3, △4 M.

spread of the points being probably due to experimental uncertainties. From the plot, it can be seen that the values of $F'\times[Cl^-]$ are independent of the chloride ion concentration, and thus $p'=-1$, *i.e.*, $CuCl(OH)_2^{2-}$. From the slope and intercept of the line, the values of β_{-12} and ε_{-12} were obtained.

Finally the formation constants and the molar extinction coefficients of the complexes proposed were refined with the aid of an electronic computer and the results are summarized in Table 3.

Table 3. The molar extinction coefficients and formation constants of copper(I) chloro-hydroxo-complexes

Species	$\varepsilon_{pq}(cm^{-1}\cdot M^{-1})$ 226 nm	273 nm	β_{pq}
$CuClOH^-$	5080	300	$(1.1\pm0.1)\times10^4$
$CuCl_2OH^{2-}$	0	0	$(4.1\pm0.3)\times10^3$
$CuCl(OH)_2^{2-}$	4760	500	$(3.8\pm0.7)\times10^6$

The solid lines in Figs. 4 and 5 show the curves calculated using the constants finally obtained. Although slightly systematic deviations were found in the plots of $\bar{\varepsilon}$ *vs.* $-\log[OH^-]$ at 273 nm, it is expected that better results cannot be obtained assuming additional complexes because of the relatively large uncertainties in the pH measurements and the reproducibility of the data for the alkaline solutions.

The distribution of the complexes in 2 and 4 M chloride solutions at an ionic strength of 5 over the $-\log[OH^-]$ range from 5 to 0 is shown in Fig. 8.

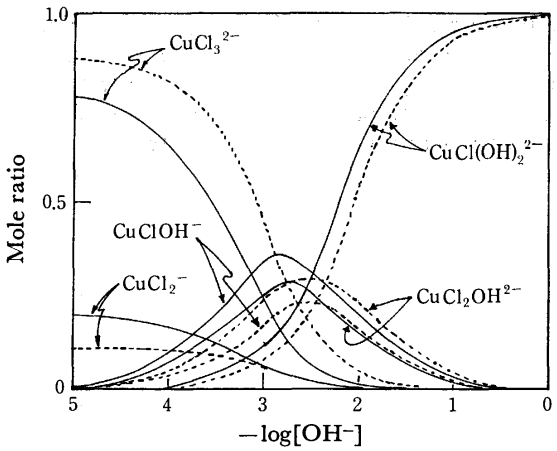

Fig. 8. Distribution of the species of copper(I). $[Cl^-]$=—2, —4 M.

The following equilibrium constants were also obtained from the results in Table 3.

$$CuCl_2^- + OH^- \rightleftharpoons CuClOH^- + Cl^-$$
$$K_{-11} = \beta_{-11} = (1.1\pm0.1)\times10^4 \quad (13)$$
$$CuCl_2^- + OH^- \rightleftharpoons CuCl_2OH^{2-}$$
$$K_{01} = \beta_{01} = (4.1\pm0.3)\times10^3 \quad (14)$$
$$CuCl_3^{2-} + OH^- \rightleftharpoons CuCl_2OH^{2-} + Cl^-$$
$$K_{01}' = \beta_{01}/\beta_1 = (2.1\pm0.2)\times10^3 \quad (15)$$
$$CuClOH^- + OH^- \rightleftharpoons CuCl(OH)_2^{2-}$$
$$K_{-12} = \beta_{-12}/\beta_{-11} = (3.5\pm1.0)\times10^2 \quad (16)$$
$$CuCl_2OH^{2-} + OH^- \rightleftharpoons CuCl(OH)_2^{2-} + Cl^-$$
$$K_{-12}' = \beta_{-12}/\beta_{01} = (0.9\pm0.2)\times10^3 \quad (17)$$

The authors wish to express their grateful thanks to Professor Hitoshi Ohtaki of the Tokyo Institute of Technology for guidance and helpful discussions. We also thank Dr. Shin-ichi Ishiguro for programming the computer calculations.

Heteropolytungstates Containing Cobalt(II) or Cobalt(III)

Akitoshi KOMURA, Mutsuo HAYASHI, and Hiroto IMANAGA
Faculty of Technology, Kanazawa University, Kanazawa 920
(Received May 14, 1975)

The reactions of tungstophosphate with cobalt ion and the properties of heteropolytungstates containing cobalt have been investigated. Unsaturated heteropolyanion $PW_{11}O_{39}^{7-}$ produced by the partial degradation of the parent 12-tungstophosphoric acid reacts with cobalt ion to give 11-tungstocobaltophosphate $PCoW_{11}O_{40}H_2^{5-}$. Discussion is given on the presence of cobalt in the heteropolyanion and on the above reaction. Both 12-tungstocobaltate-(II) and -(III) are very resistant to acid, but 11-tungstocobaltophosphates lose cobalt ion in strongly acidic solutions to give the parent 12-acid. Some aspects of the spectra of the heteropolytungstates, in which cobalt(II) and cobalt(III), respectively, are present in the specific site, are discussed.

The characteristic of molybdenum and tungsten is the formation of numerous isopoly and heteropoly acids and their salts. The heteropolyanions containing two different heteroatoms have been reported.[1-3] Baker and Figgis[4] showed that in heteropolyanions an octahedrally coordinated transition metal atom replaces one of the 12 octahedral tungsten atoms of conventional Keggin structure,[5] being simultaneously coordinated to a water molecule (constitutional water). Malic and Weakley[1,2] prepared many ternary heteropolyanions from the solutions containing unsaturated heteropolyanions which were isolated as solid by Tourné and Tourné,[6] and formulated the ternary heteropolyanions. Weakley[7] reported the replacement of the constitutional water by other ligands mainly in the heteropolyanions containing cobalt. On the other hand, there are some ternary heteropolyanions which can not be interpreted on the basis of the Keggin structure.[8] The anions probably formed through addition reactions appear to have the composition X: Z: W or Mo=1: 1: 12, where both X and Z are heteroatoms. The heteropolyanions containing metal heteroatoms form an important class of coordination compounds, but their chemistry remains unclarified. In order to obtain information on heteropoly complexes, we have investigated the chemical and spectroscopic properties of heteropolytungstates containing cobalt, reported by Weakley.[7] The present paper deals with the formation process of the heteropolyanions and the formulation proposed by Baker and Figgis.[4]

Experimental

Dodeca-tungstophosphoric acid was obtained from Wako Pure Chemical Industries Ltd. (Found: P, 1.0; W, 64.4%). Potassium monohydrogen 12-tungstocobaltate(II) was prepared by Baker's method.[9] The cerimetric titration gave 3550 as its equivalent weight. Found: K, 5.3; Co, 1.7; W, 62.0%. Calcd for $K_5HCoW_{12}O_{40}\cdot 24H_2O$: K, 5.5; Co, 1.7; W, 62.4%, equiv. wt, 3534.

Potassium 11-Tungstophosphate. Preparation was carried out by a modification of Tourné's method.[6] To a solution of 12-tungstophosphoric acid (25 g) in water (300 ml) at 90—100 °C was added 0.5 M-potassium bicarbonate dropwise with stirring until a large portion of the precipitate of the resulting potassium 12-tungstophosphate disappeared (the pH of the solution being then about 5). A small quantity of the residual precipitate was filtered off and the pH of the filtrate was adjusted to 5.25 with potassium acetate buffer solution. The filtrate was concentrated to one third of its original volume and then kept at 5 °C for a few days while white crystals formed. These were filtered off, washed with water, and air-dried at room temperature. Found: K, 8.1; P, 1.0; W, 58.6%. Calcd for $K_7PW_{11}O_{39}\cdot 28H_2O$: K, 7.9; P, 0.9; W, 58.5%.

Potassium 11-Tungstocobalto(II)phosphate. The procedure was based on that for 11-tungstocobalto(II)silicate.[1] A solution of cobalt nitrate (2.2 g) in water (20 ml) was added with stirring to a heated solution (pH 5.3) of 12-tungstophosphoric acid partly degraded in a similar manner to that above. The mixture was concentrated to two thirds of its original volume after being filtered at 60 °C. The solution was kept at 5 °C for a few days while deep red crystals separated. Found: K, 6.8; P, 1.0; Co, 1.6; W, 61.0%. Calcd for $K_5PCoW_{11}O_{40}H_2\cdot 20H_2O$: K, 6.0; P, 0.9; Co, 1.8; W, 61.1%. Weakley[7] gave 15 molecules of water of hydration to the complex.

Pyridinium 11-Tungstocobalto(II)phosphate. This compound was isolated in an attempt to coordinate pyridine to the cobalt atom of potassium 11-tungstocobalto(II)phosphate. Thirty milliliters of 0.1 M-aqueous solution of pyridine was added to a solution of potassium 11-tungstocobalto(II)phosphate (3.34 g) in water (20 ml) with stirring. A pink precipitate which formed immediately was filtered off, washed with an aqueous solution of pyridine and methanol, and air-dried at room temperature. Found: Co, 1.7; W, 64.0%. Calcd for $C_{25}H_{30}N_5PCoW_{11}O_{40}H_2\cdot 5H_2O$: Co, 1.8; W, 62.3%.

Solutions containing cobalt(III) were obtained by constant current electrolysis on a platinum anode placed in a H cell with a fine sintered glass frit separating two compartments. Completion of oxidation was confirmed spectrophotometrically. Electronic and IR spectra were recorded on Hitachi 124 and Nihonbunko DS 301 spectrophotometers, respectively. X-ray powder diffraction data were obtained by use of a Rigaku Denki D-9C X-ray generator with a SG-7 diffractometer. Cu$K\alpha$ radiation and a nickel filter were used in all measurements. Differential thermal analytic (DTA) curves were obtained with a Rigaku Denki 8001 at a heating rate of 15 °C/min. The reference material was α-alumina. Potassium was precipitated and weighed as tetraphenylborate. The remaining elements were determined after alkaline decomposition of the hereropolyanions. Cobalt was precipitated as hydroxide, dissolved in hydrochloric acid, and estimated by EDTA titration. Tungsten was precipitated and weighed as trioxide. Phosphorous was separated as magnesium ammonium phosphate and was weighed as magnesium pyrophosphate after a second precipitation.

Results and Discussion

The DTA curves of heteropolytungstates are given in Fig. 1. All the heteropoly salts showed characteristic

two endothermic peaks which probably correspond to dehydration. The first large endothermic peak was observed at about 130 °C for all the salts. Ignition of the salts at 175 °C gave 60—80% loss of the water of hydration. All the heteropoly salts lost practically all the water above 400 °C with the change in color. The 12-tungstophosphoric acid showed a prominent exothermic peak at 637 °C. Both 11-tungstophosphate and 11-tungstocobalto(II)phosphate showed a complicated feature at high temperature. The X-ray diffraction pattern showed that 11-tungstophosphate and 11-tungstocobalto(II)phosphate belong to the tetragonal series, $a=12.2$, $c=9.08$ Å and $a=12.4$, $c=9.10$ Å, respectively; 12-tungstocobaltate(II) is simple cubic ($a=10.7$ Å). The 12-tungstophosphoric acid was shown to be cubic by Keggin.[5]

Infrared Spectra. The positions and assignments of the main bands are given in Table 1. All the compounds have strong bands at 740—980 cm^{-1} characteristic of polytungstates. The bands at 880—980 cm^{-1} might be assigned to the independent W–O stretching vibration and the broad bands at 740—820 cm^{-1} to the W–O–W bridge vibrations. Such peaks are also observed in the infrared spectra of several heteropolymolybdovanadates.[10] The 12-tungstophosphoric acid having high symmetry Td gives the triply degenerated γ_3 of PO_4 at 1080 cm^{-1}. The band is split into 1085 and 1040 cm^{-1} in 11-tungstophosphate. There is probably a lowering of symmetry from Td in 11-tungstophosphate owing to the lack of one tungsten and the unshared oxygen. The reduction in symmetry of PO_4 should result in the splitting of the degenerate mode γ_3. The complication of the vibration of WO_6 in 11-tungstophosphate can also be attributed to the structural distortion. The splitting of the γ_3 band is also observed in 11-tungstocobaltophosphate where the PO_4 tetrahedron is also distorted because one tungsten atom of 12-tungstophosphate is replaced by cobalt atom. The spectrum of the heteropoly salt with pyridines is similar to that of the potassium 11-tungstocobaltophosphate, except for bands of pyridine at 3060s, 1635m, 1531m, 1482m, 1330w, 1245w, 1200w, and 1165w cm^{-1}. Gill *et al.* distinguished a pyridinium ion from the pyridine coordinated to metals according to infrared spectra.[11] Absorption bands of C=C and C=N bonds in the heteropoly salt with pyridine were shifted to higher wave number than those in pure pyridine in agreement with the observation of Murata and Ikeda.[12] The infrared spectrum shows that the compound is not a pyridine complex but pyridinium salt.

Reactions. The parent 12-heteropolyanions probably

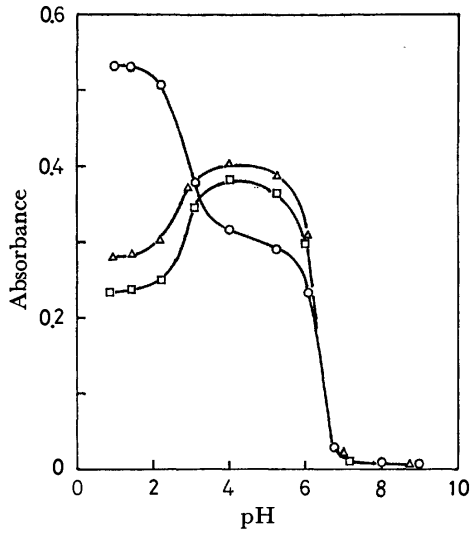

Fig. 2. Relation between the absorbance of 12-tungstophosphate solution and the pH.
The concentration of 12-tungstophosphate is 10^{-5} M.
○: 264 nm, △: 247 nm, □: 235 nm.

undergo gradual degradation on alkalization.[6] The 12-tungstophosphoric acid exihibits a characteristic intense absorption band ($\varepsilon=5.2\times10^4$ 1 $mol^{-1}cm^{-1}$) at 264 nm in acidic solutions. The position of the absorption maximum shifts to shorter wavelength with an increase in pH, no maximum being observed above pH 7. Figure 2 shows the relation between the absorbance of 12-tungstophosphate solution and the pH at different wavelengths. The absorbances show abrupt changes at pH 2.7 and 6.2, a distinct plateau occurring in the 3.5—6 pH region. This suggests that the parent 12-tungstophosphoric acid is transformed into a certain species in this region, and further decomposes into other species above pH 7 (ultimately to WO_4^{2-} and PO_4^{3-}). On the basis of the measurement of pH on rapid neutralization, Schwarzenbach *et al.* presumed the initial process of the degradation as follows.[13]

$$PW_{12}O_{40}^{3-} + 9/2\ OH^- \rightleftharpoons PW_{11}O_{39}^{7-} + 1/12H_2W_{12}O_{40}^{6-} + 13/6H_2O \quad (1)$$

In equilibrium (1) the metatungstate $H_2W_{12}O_{40}^{6-}$ may be some other species. The equilibrium can explain the fact that an aqueous solution of 12-tungstophosphoric acid contains 3–4 titratable H^+ per molecule. Tourné and Tourné isolated solid potassium 11-tungstates by the partial degradation of 12-heteropolyanions.[6] A hydrolysis product which we isolated from the weakly acidic solution of 12-tungstophosphate could also be formulated as potassium 11-tungstophosphate according to the analytical data. The latter compound seems to be further decomposed by base into species such as $P_2W_{19}O_{69}^{14-}$, $(PW_9O_{34}^{9-})_n$, *etc.*[14] On the other hand, 12-tungstocobaltate(II) seems to be considerably resistant to the degradation. Its spectrum showed no change at all on alkalization up to pH 7 though the anion decomposed completely above pH 10.5. The 11-tungstophosphate reacts with cobalt ion under weakly acidic conditions.[6] The stoichiometry of the reaction was examined spectrophotometrically by the molar ratio method (Fig. 3). An inflection in the

absorbance occurred at a heteropolyanion: cobalt ratio of 1 : 1. This indicates the formation of a complex of stoichiometry 1 heteropolyanion: 1 cobalt. As shown in Fig. 4, a similar result was also obtained when the parent 12-acid was allowed to react with cobalt ion at pH 5.2 (whereas no reaction occurred in 0.1 M-hydrochloric acid). This implies that equilibrium (1) lies sufficiently to the right or that the reaction is fairly rapid. We isolated a ternary heteropoly salt from the solution which might contain 11-tungstophosphate and cobalt ion. The analytical data agreed with the values calculated for 11-tungstate rather than for 12-tungstate. The formation of the complex is probably a simple reaction as follows.

$$Co(H_2O)_6^{2+} + PW_{11}O_{39}^{7-} \longrightarrow PCoW_{11}O_{40}H_2^{5-} + 5H_2O \quad (2)$$

Absence of the complex in 0.1 M-HCl can be inter-

preted in terms of equilibria (1) and (2). If we suppose that 11-tungstophosphate remains unchanged when it is dissolved in water, we can estimate the stability constant of the complex, using the molar absorption coefficient (ε) of the species participating in the formation of the complex. The ε values at 540 nm were 75 for 11-tungstocabalto(II)phosphate, 0 for 11-tungstophosphate, and 3.0 l mol^{-1}cm^{-1} for cobalt ion. The stability constant of 11-tungstocobalto(II)phosphate was estimated to be log K=5 at 25 °C.

If 11-tungstocobalto(II)phosphate has the structure of the type proposed by Baker and Figgis,[4] an oxygen atom, probably of a water molecule (or hydroxide ion[15]), should occupy a coordination position of cobalt pointing to the exterior of the heteropoly part. It was difficult to determine from the analytical data whether a water or hydroxide ion occupied the sixth coordination position of the cobalt atom (the charge of anion is different in the two cases). If the above formulation is correct, the water or hydroxide ion coordinated to cobalt should be replaceable by other ligands in aqueous solution. Weakley reported spectrophotometrical indications of the replacement of the constitutional water by other ligands, with the isolation of pyridine complexes.[7] We attempted to replace the water or hydroxide ion with monodentate ligands such as thiocyanate, chloride, ammonia, and pyridine, but could not confirm the formation of any new complex. In the presence of pyridine, an increase in the intensity of the d-d band of 11-tungstocobalto(II)phosphate was observed, but the molar ratio plot at pH 5 was linear until about 5 molar ratio of pyridine to the heteropolytungstate. In larger excess of pyridine, the solid probably corresponding to the pyridinium salt of 11-tungstocobalto(II)phosphate was obtained in disagreement with the results of Weakley.[7] With the other ligands, there were no spectral changes, molar ratio plots at pH 5 being straight lines parallel to the abscissa (molar ratio). Since the replacement at only one of 6 coordination positions of cobalt causes no significant change in the spectrum, it might be difficult to examine spectrophotometrically the replacement of the constitutional water.

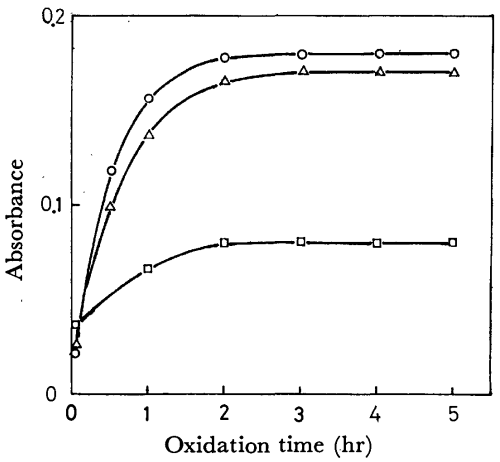

Fig. 5. Variations of the absorbance of the heteropolytungstates containing cobalt with oxidation time.
△: 5×10^{-4} M 11-tungstocobalto(II)phosphate in borate buffer (pH 5), 457 nm. □: the same as above, 540 nm. ○: 7.5×10^{-4} M 12-tungstocobaltate(II) in 0.1 M-sulfuric acid, 390 nm, absorbance (1/5).

It is known that the transition elements in heteropolyanions can be oxidized to higher oxidation states, with only the change in oxidation number of the elements apart from the charge of anions. We carried out the electrolytic oxidation of 11-tungstocobalto(II)-phosphate and 12-tungstocobaltate(II). The complete oxidation of the cobalt(II)-anions could be confirmed spectrophotometrically (Fig. 5). When the oxidized solutions were left to stand, 11-tungstocobalto(III)-phosphate was slowly reduced to 11-tungstocobalto-(II)phosphate, whereas 12-tungstocobaltate(III) was stable and isolated as pure crystals by Baker and McCutcheon.[9] The electrolysis of 11-tungstocobalto-(II)phosphate with phosphate as a buffer solution gave solutions with higher absorbance than those in the case of borate buffer solution, and gave variable molar absorption coefficients depending upon the concentration of the original 11-tungstocobalto(II)phosphate. Other heteropolyanions besides 11-tungstocobalto(III)-phosphate might be formed by the electrolysis of 11-tungstocobalto(II)phosphate in the presence of excess phosphate.

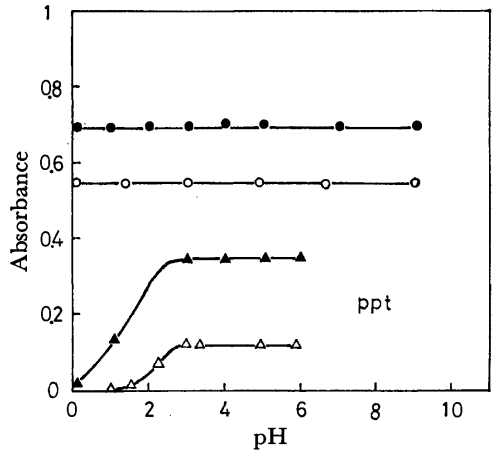

Fig. 6. Variations of the absorbance of the heteropolytungstates with pH.
▲: 10^{-3} M 11-tungstocobalto(III)phosphate, 457 nm. △: 2×10^{-3} M 11-tungstocobalto(II)phosphate, 540 nm. ●: 5×10^{-4} M 12-tungstocobaltate(III), 390 nm. ○: 3×10^{-3} M 12-tungstocobaltate(II), 624 nm.

Figure 6 shows the stability of the heteropolyanions towards acid and base. Both 12-tungstocobaltates are stable in wide pH range below 9 regardless of the oxidation state of cobalt. This does not mean that the anions remain actually unchanged. The anions probably undergo partial degradation at higher pH, but cobalt ions are still present in approximately tetrahedral environment. The 11-tungstocobalto(III)phosphate is slightly more stable towards acid than 11-tungstocobalto-(II)phosphate, but both lose cobalt ion in strongly acidic solutions to give the parent 12-acid. On the other hand, all heteropolyanions are decomposed by strong alkali.

Electronic Spectra. The positions, intensities, and assignments of the absorption maxima are given in

Table 2. The spectra assignments for 11-tungstocobaltophosphates are made on the basis of O_h symmetry, though the true site symmetry around cobalt is probably lower.[1,16)] The spectrum of 11-tungstocobalto-(II)phosphate differs distinctly from that of 12-tungstocobaltate(II) having Td symmetry, resembling that of the well-known cobalt(II) aqua-ion, except in intensity.[1)] This is also the case for the corresponding cobalt(III) complex. When metal heteroatoms are present in octahedral sites, the spectra should resemble those of the corresponding aqua-ions, the ligand-field parameters being of similar magnitude.[1)] Thus, a comparison of the spectra presents evidence supporting the view that cobalt atom in 11-tungstocobaltophosphates is present in essentially octahedral site. In the 12-heteropolyanions, tungsten or molybdenum atoms are effectively in tetragonal oxide environments.[17)] When cobalt replaces a single tungsten, it is to be expected that the CoO_6 group will also be distorted. The splitting of the second band in the 11-tungstocobalto(II)phosphate spectrum might be attributed to the lower site symmetry around cobalt atom. Thus the ε value for 11-tungstocobalto(II)phosphate is 15 times as great as that for the cobalt(II) aqua-ion. The remarkable band in the spectrum of 11-tungstocobalto(III)phosphate is also 5—15 times as intense as the corresponding bands for the cobalt(III) aqua-ion and centrosymmetric 6-molybdocobaltate(III).[1,18,19)] The spectrum of 11-tungstocobalto(III)phosphate indicates that the cobalt(III) is certainly of low-spin and the ligand-field stabilization energy is less even than in the cobalt(III) aqua-ion.[16)] The latter is also the case for the corresponding cobalt-(II) complex. The 12-tungstocobaltate(III) seems to be the first compound containing cobalt(III) in any tetrahedral site.[20)] The band of 25700 cm^{-1} was assigned tentatively to the transition $^5E \rightarrow {}^5T_2$. The ε value is *ca.* 50 times as great as that for 6-molybdocobaltate(III) with cobalt(III) in octahedral site. The heteropolyanions all show an intense absorption in the ultraviolet (Fig. 7). This is characteristic of polytungstates, and is to be ascribed to charge transfer from oxygen to tungsten.[16)] The ultraviolet absorption band for 12-tungstophosphate is shifted 2—3 kK to higher energies in 11-tungstophosphate and 11-tungstocobalto(II)-phosphate, with decreasing ε value. In heteropolyanions containing cobalt, a broad, relatively weak band ($\varepsilon \sim 220$) is superimposed on the ultraviolet absorption edge (spectra 5 and 6 in Fig. 7). This has been ascribed

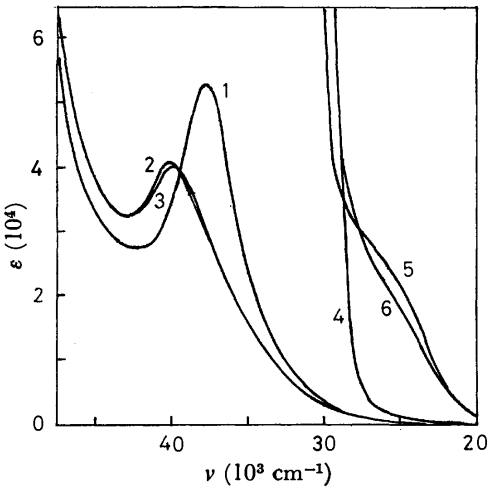

Fig. 7. Ultraviolet absorption spectra of the heteropolyanions. 1,4: 12-tungstophosphoric acid. 2: 11-tungstophosphate. 3,5: 11-tungstocobalto(II)phosphate. 6: 12-tungstocobaltate(II). Ordinate: 4,5,6 (100ε).

by Malik and Weakley[16)] to the charge transfer between cobalt and polytungstate, either from cobalt(II) to tungsten or from oxygen to cobalt(III). The charge transfer from oxygen to cobalt(III) should result in a stabilization of the (III) oxidation state of cobalt.

Effect of Water on Crystallization Process of Coesite

Tetsuya KAMEYAMA and Shigeharu NAKA

Synthetic Crystal Research Laboratory, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received May 19, 1975)

The effect of water on crystallization process of coesite was studied at 450 to 700 °C under 30 kbars by using different starting materials. The presence of water under compression and heating was found to have remarkable effects not only on the kinetics of crystallization of coesite also on the morphology of metastable quartz, consequently of coesite crystals. Under anhydrous condition, from amorphous silica and silica glass, the spherulitic aggregates of metastable quartz appeared. The coesite crystals were developed in the spherulites of quartz as elongated crystals with different sizes and appeared to be defective. When synthetic quartz was used as a starting material, however, no formation of spherulitic aggregates of quartz was observed and granular coesite crystals were obtained. Under hydrous condition, granular coesite crystals with homogeneous size were developed rapidly at 450 °C from both amorphous silica and silica glass through the discrete particles of metastable quartz.

Water plays a very important role in the crystallization and phase transformation of silica.[1-7] Previously,[8] the effect of water on the crystal growth of coesite under 30 kbars at 900 °C has been discussed from crystal morphology and size of coesite formed; in anhydrous condition the coesite grains are sintered and appeared to be defective, whereas in hydrous condition the coesite crystals are euhedral and less defective. It has also been pointed out that the transformation of amorphous silica to coesite is a consecutive process through the metastable phase of quartz and that water accelerates both steps in the consecutive process.[9,10] The formation of spherulitic aggregates of metastable quartz has been briefly reported under anhydrous condition.[11]

In the present paper, the effect of water on the crystallization process of coesite was studied in detail, particularly paying attention to morphology and aggregation state of metastable quartz, by using various starting materials between 450 and 700 °C under 30 kbars.

Experimental

Materials. The starting materials used were noncrystalline silicas, so-called amorphous silica and silica glass, and synthetic quartz. Amorphous silica with particle size of 0.1—10 μm was prepared by hydrolysis of silicon ethoxide and then heating at 1200 °C for 2 h. Silica glass with particle size of 0.5—1.0 μm was prepared by mechanical grinding of the commercial silica glass rods and by means of elutriation. The silica glass was heated at 800 °C for 2 h in order to remove the strain and the adsorbed water. The quartz powder with particle size of 0.5—1.0 μm was prepared by the method similar to the preparation of silica glass. Heating at 800 °C for 48 h was necessary for removing water adsorbed.

High Pressure Treatment. The crystallization of coesite was performed at the temperature range of 450 °C to 700 °C under 30 kbars for various durations up to 96 hr, with a girdle type high pressure apparatus,[10] either with or without water. Amount of water added into the sample was 4, 10, or 16 wt%. The samples were heated with the heating rate of 200 °C/min and after the programmed duration at a desired temperature quenched in the cell under compression.

Characterization of Specimen. The phases formed were identified with the X-ray powder technique and optical microscopy. The proportions of the phases were determined from the relative peak intensities of diffraction lines.[10] The crystallite size of metastable quartz was evaluated from the half widths of X-ray diffraction lines according to Hall's equation. The crystals of metastable quartz and coesite were examined by optical and scanning electron microscopes.

Results and Discussion

Crystallization from Amorphous Silica. In Fig. 1, the variations of proportion of the original amorphous silica, metastable phase of quartz and coesite with heating time are shown in both cases, without water and with 10 wt% water, at 450 °C. The kinetic process of the transformation changes by the addition of water.[9] The effect of water addition was seen not only from kinetics also from morphology of metastable quartz and coesite. Under anhydrous condition, metastable phase of quartz crystallized into spherulitic aggregates with the apparent size up to 50 μm after 4 h heating. These spherulites of quartz were formed in the matrix of unchanged amorphous matrix. The aggregate consisted of fine quartz crystals with the size of 0.5—1.0 μm, of which c-axes oriented radially. The size of the aggragates increased with the increase of heating time. It became up to 300 μm after 48 h. In the center of the spherulitic aggragates, where the radial orientation of crystals of quartz collapsed, needle-like crystals of coesite with the size of 20—50 μm were often found (Fig. 2-A). After 96 h quartz completely transformed to coesite, but the size of coesite crystals did not show any detectable increase. With 10 wt% water, on the other hand,

B: Small quartz aggregates in amorphous silica matrix heated at 450 °C for 1 h in the presence of 10 wt % water (under crossed nicols).

C: Granular coesite crystals formed after heating at 450 °C for 80 min in the presence of 10 wt % water (under open nicol).

D: Quartz aggregates in sintered state after heating for 10 min at 600 °C without water (under crossed nicols).

E: Lath-shaped and needle-like coesite crystals developed in quartz matrix of sintered state after heating for 60 min at 600 °C without water (under open nicol).

F: Penetration twins and lath-shaped coesite crystals grown after heating for 3 h at 600 °C without water (under crossed nicols).

G: Quartz spherulitic aggregates in amorphous silica matrix heated at 600 °C for 3 min in the presence of 4 wt % water (under crossed nicols).

H: Tiny penetration twins and granular crystals of coesite developed in quartz matrix after heating for 10 min at 600 °C in the presence of 4 wt % water (under open nicol).

I: Granular and euhedral coesite crystals grown after heating for 3 h at 600 °C in the presence of 16 wt % water (under open nicol).

most of the original amorphous silica was converted, within a few minutes, to quartz of discrete particles with the size of 0.02—0.03 μm. Many quartz aggregates were also observed in the fine particles of quartz. After 60 minutes, single phase of quartz was obtained and its crystal size increased up to 0.05—0.06 μm (Fig. 2-B). After 80 minutes metastable quartz transformed rapidly to coesite, of which crystal grew to 2—5 μm (Fig. 2-C).

The similar effect of water on crystal morphology was observed during the crystallization process at 600 °C. Some micrographs are shown in Figs. 2-D~I. Under the anhydrous condition (Fig. 2-D~F), amorphous silica completely transformed within 10 minutes to sintered quartz and the size of single crystal region was 1—3 μm (Fig. 2-D). In this case, the crystallization of metastable quartz is rather fast and the crystals sintered each other. This may be why we could not recognize the spherulitic aggregates of quartz crystals. After 60 minutes, the lath-shaped and needle-like crystals of coesite with the size of about 70 μm were developed in

quartz matrix, as shown in Fig. 2-F. The coesite crystals occurred mostly at grain boundaries of quartz crystals, and they grew along the c-axis. After 3 h, single phase of coesite was obtained. Most of the crystals were in lath-shape and 100—300 μm in size. They showed wavy extinction under microscope. The penetration twins of coesite crystals were often observed[12] (Fig. 2-F). With 4 wt% water, amorphous silica crystallized completely to quartz after 3 minutes. In this case, many spherulitic aggregates of quartz crystals were also observed in the matrix of the fine quartz crystals with the size of 0.5—1.0 μm (Fig. 2-G). After 10 minutes, however, the spherulitic aggregates disappeared. The granular crystals and penetration twins of coesite were formed in the matrix of fine quartz crystals (Fig. 2-H). After 60 minutes, the number of twins decreased and the granular coesite crystals with the size of 20—50 μm were formed. In the crystallization with 16 wt% of water, both steps of the consecutive process were so accelerated that only the morphology of coesite crystals could be discussed. The metastable quartz which was formed from amorphous silica in very short time transformed completely to coesite within 10 minutes. The spherulitic aggregates of quartz crystals and also penetration twins of coesite were hardly observed (Fig. 2-I). The granular coesite crystals grew with the increase in heating time. After 3 h, the coesite crystals as large as 100 μm were found, which were transparent and showed clear extinction.

The observation by electron scanning microscope agreed in the sizes and morphology of crystals with the results mentioned above.

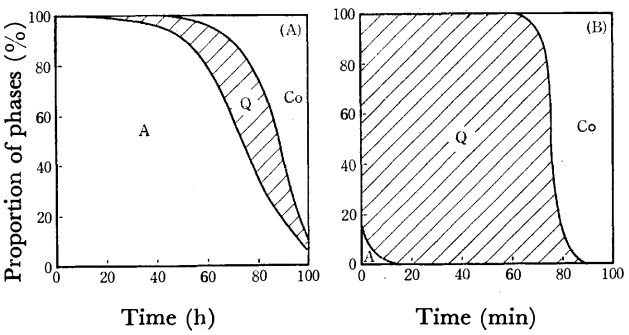

Fig. 3. Variations in proportions of phases obtained from silica glass under 30 kb;
A: without water at 600 °C.
B: with 10 wt % water at 450 °C.

Crystallization from Silica Glass. Under anhydrous condition, silica glass remained in amorphous state even after 96 h at 450 °C. At 600 °C, the crystallization of silica glass to coesite through metastable quartz was observed (Fig. 3-A). This kinetics is rather similar to that from amorphous silica to coesite at 450 °C (Fig. 1-A). The morphological changes during crystallization were found to be also similar to those which were observed at 450 °C on amorphous silica. After 48 h, the spherulitic aggregates of quartz crystals with the size of 20—200 μm were found to be scattered in amosphous matrix (Fig. 4-A). In the spherulite, the c-axes of quartz crystals oriented mostly to the radial direction. The coesite crystals were also developed radially from the center of the quartz spherulites (Fig. 4-B). It seemed likely that before the transformation to coesite the radial arrangement of quartz crystals were destroyed to be random. After 96 h, lath-shaped and needle-like coesite were developed, but the spherulitic texture remained even after the complete transformation to coesite (Fig. 4-C). With 10 wt% water at 450 °C, however, the kinetics and morphological changes to coesite from silica glass was found to be similar to the case from amorphous silica under the same condition, that is, at 450 °C with 10 wt% water (Fig. 3-B).

Crystallization from Quartz. Under anhydrous condition at 450 °C, the starting quartz remained

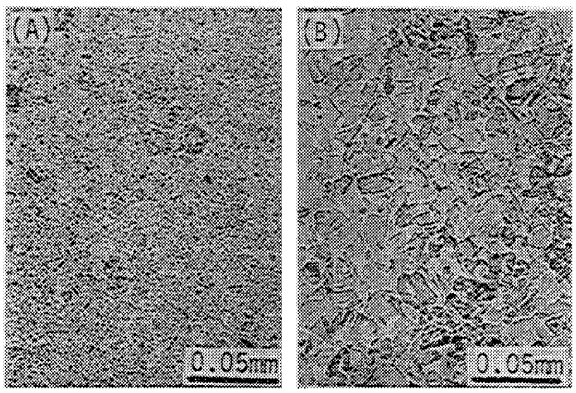

Fig. 5. Microphotographs of coesite prepared from quartz;

C: for 96 h (under crossed nicols).

Table 1. Crystallization of coesite prepared from various starting materials at 450°C under 30 kb with 10 wt% water

Starting materials	Crystallite size of metastable quartz (Å)	Nucleation period (min)	Nucleation rate (s^{-1})	Growth rate (s^{-1})
Amorphous silica, silica glass	200~500	60	2.8×10^{-4}	7.5×10^{-2}
Quartz	5000	80	9.3×10^{-5}	2.8×10^{-2}

unaltered in a powdered state even after 96 h, although the broadening of X-ray diffraction profiles and the undulatory extinction under optical microscope were observed. The single phase of coesite was obtained from the quartz only after 2 h at 700 °C. The coesite crystals formed are in granular shape with the size of 2—5 μm (Fig. 5-A). With 10 wt% water at 450 °C, coesite crystallized after an induction period of about 3 h. After 4 h, 90% of the starting quartz was converted into the granular coesite crystals with the size of 20—40 μm (Fig. 5-B).

Effect of Water on Crystallization of Coesite. Under anhydrous condition, the crystallization rate of coesite is different from the starting materials; amorphous silica changes completely to coesite at 450 °C after 96 hr, but silica glass needs 600 °C and quartz 700 °C for complete transformation to coestite. During the crystallization from amorphous silica and silica glass, the formation of spherulitic aggregates of metastable quartz was observed. The spherulites formed in the silica glass appeared to have better orientation (Fig. 4-A) and are less in number than those in amorphous silica, probably due to the slow rate of transformation of glass to metastable quartz. The formation of spherulitic aggregates may be explained by the surface tension developed in amorphous state, similar to the devitrification of glass.[13] Mostly from the center of the spherulites, the growth of coesite crystals is found to start. Therefore, the formation of spherulites and also orientation of quartz crystals in spherulites restrict the morphology and size of coesite crystals.

Under hydrous condition, no difference in the crystallization rate of coesite is observed between amorphous silica and silica glass. They transform to coesite much faster than quartz. The process of transformation of metastable quartz to coesite seems to be the rate determining step. Since the formation curve of coesite could not be refered to a paraboric law, no long range diffusion process should be involved in the crystallization process of coesite. Thus, the crystallization rate of coesite was analyzed by adopting the linear law,[14] which had been commonly used for the rate determining process of interfacial reaction. The nucleation period of coesite from metastable quartz, the nucleation rate, and the growth rate evaluated from the slope of the formation curve are summarized in Table 1. The crystallite size of metastable quartz is also shown in Table 1. Both the nucleation rate and the growth rate of coesite crystals are found to be larger for amorphous silica and silica glass than for quartz. This difference in the rates may be due to the smaller particle size of metastable quartz formed from amorphous silica and silica glass than that from quartz. It has been well known that the dimension and the microstructure of the starting crystal affect both speed and temperature of its phase transformation.[15]

The coesite crystals prepared from the amorphous phases under anhydrous condition have an elongated form with heterogeneous size and appears to be defective, but well sintered. The crystals prepared under hydrous condition, however, are granular in shape, homogeneous in size and also less defective. With more than 10 wt% of water, the granular crystals of metastable quartz and also of coesite are obtained from any starting materials. Water may prevent the aggragation of metastable quartz. Even in the presence of water the elongated crystals and penetration twins of coesite were often observed at the beginning of crystallization, but they disappeared after prolonged heating. These experimental results may suggest the growth mechanism of coesite as the dissolution and precipitation through a solvent of water. This mechanism may be understood from the fact that water of even 4 wt% is largely enough to cover the surface of quartz and coesite grains by water layer of few tens molecular thickness.

When quartz was used as a starting material, the penetration twins and needle-like crystals of coesite were hardly observed even under anhydrous condition. Random orientation and rigid boundaries of the original quartz particles may prevent the aggregation of quartz and the preferential growth of coesite.

Conclusively, the crystallization process of coesite is found to depend strongly on the morphological characteristics of metastable quartz as well as on the significant roles of water. The granular coesite having homogeneous size could be obtained under hydrous condition through the discrete crystals of metastable quartz. The crystal size of coesite could also be controlled by the selection of heating temperature and time.

The authors wish to thank Dr. M. Inagaki and Dr. Y. Suwa who offered valuable discussion and encouragement on this work.

Studies on the Electrode Processes of Oxovanadium (IV). II. Electrolytic Reduction of Vanadyl Acetylacetonate in Acetonitrile Solution at Mercury Electrode

Mitsutaka KITAMURA, Kazuo YAMASHITA, and Hideo IMAI

Faculty of Integrated Arts and Sciences, Hiroshima University, Hiroshima 730

(Received June 9, 1975)

The electrolytic reduction of vanadyl acetylacetonate in acetonitrile solution was investigated by means of conventional and AC polarography, cyclic voltammetry and controlled-potential electrolysis. A well-defined polarographic cathodic wave was obtained in a solution containing excess acetylacetone. The wave-form was outwardly a single step with two-electron transfer. However, logarithmic analysis revealed that it consists of two steps. The first step is slightly irreversible, being accompanied by V–O bond breaking, and the second one is controlled by the rate of coupled chemical reactions. The reaction mechanism is discussed in detail. The reversible half-wave potentials of the species $[VO(acac)_2]$ and $[V(acac)_3]$ were determined to be -1.93 and -1.78 V *vs.* Ag/0.1 M $AgClO_4$, respectively, from the logarithmic analysis.

Invesigations on the electrolytic reduction of vanadyl ion and its complexes have been made by many authors. Lingane,[1] reporting on the polarographic behavior in aqueous media, found an irreversible cathodic process with two-electron transfer. Later, Lingane and Meites[2] reported that the reduction wave is accompanied by a pre-wave in an unbuffered solution, assumed to be caused by the rate-controlled reduction of $VOOH^+$ formed by the hydrolysis of VO^{2+}. They found that the pre-wave is no longer observed in an oxalate solution, the main-wave being excessively large. They attributed this to a catalytic reduction of hydrogen oxalate ion. Pecsok and Juvet[3] studied the polarographic reduction of vanadyl-versene complex. They attributed the pre-wave to the reduction of +4 to +3 vanadium, and the main-wave to the reduction of +3 to +2 vanadium. The pre-wave in both studies was observed in a limited pH range, and in a strongly acidic or alkaline solution it was completely eradicated. Meites and Moros[4] reported on the electrolytic reduction in an acidic solution, and found that the process consumes a much larger quantity of electricity than expected. This so-called induced current was extensively studied by Israel and Meites,[5] who found that the reduction proceeds in two consecutive steps. They analysed the rate-controlled process and induced current, and pointed out the oligomer formation and deprotonation of the reduced species.

In a previous paper[6] the polarographic cathodic process of vanadyl ion in M potassium oxalate was described. It was pointed out that the irreversible cathodic wave with two-electron transfer shows a trend to split into two waves when the vanadyl ion concentration exceeds 4 mM. The linearity of the wave-height *versus* concentration plot was recognized only up to 2 mM, the dependence of the wave-height on the head of mercury showing a characteristic of diffusion control. In order to clarify the above-mentioned anomalous behavior the present authors investigated the electrolytic reduction of vanadyl acetylacetonate in acetonitrile solution. The results obtained by means of conventional and AC polarography, cyclic voltammetry and controlled-potential electrolysis are presented in this paper.

Experimental

The polarographic current-potential curve was recorded on a Shimadzu Model RP-50 polarograph with an ohmic drop compensator. An AC attachment, Model BF-50 was used for AC polarography. Controlled-potential electrolysis was carried out with a Shimadzu Model PS-2 potentiostat and cyclic voltammetry with a Yanaco Electronic Scanner and Hokuto Denko Model HA-104 potentiostat.

The working electrodes used were a dropping mercury electrode(DME) for the polarography, a hanging mercury drop for the cyclic voltammetry and a mercury pool for the controlled-potential electrolysis. The characteristics of DME are as follows; mercury head=49 cm, rate of mercury flow= 0.71 mg/s, life time=7.2 s in open circuit. A platinum cylinder with a surface area of 1 cm^2 was used as an auxiliary electrode. The reference electrode was $Ag/AgClO_4$ (0.1 M in acetonitrile).

Vanadyl acetylacetonate (bis(2,4-pentanediono)oxovanadium (IV)), $[VO(acac)_2]$, was prepared by the method given by Rowe and Jones,[7] and was recrystallized from a chloroform solution. Acetonitrile (AN) used as a solvent was purified by distillation with phosphorus pentoxide in nitrogen atmosphere.

In order to prevent aerial oxidation, all the solutions of supporting electrolyte and vanadyl acetylacetonate were sufficiently bubbled with purified nitrogen prior to mixing. The prepared solution contained 1 mM vanadyl acetylacetonate, 20 mM acetylacetone (Hacac) and 0.1 M tetraethylammonium perchlorate (TEAP). Purified nitrogen was passed over the solution during the course of electrolysis. The temperature was kept at 20 °C with a water jacket attached to the cell.

Results and Discussion

Polarographic Current-Potential and Current-Time Curves. Vanadyl acetylacetonate usually gives an ill-defined polarographic cathodic wave in an AN solution containing 0.1 M TEAP. When excess Hacac was added to the solution, the wave-form was modified as shown in Fig. 1. A well-defined wave was obtained at least outwardly by adding 20 mM Hacac to 1 mM vanadyl acetylacetonate. Subsequent experiment were carried out under these conditions.

The apparent half-wave potential of the cathodic wave was -2.00 V, the overall electrons transferred per molecule being two. The logarithmic analysis of

the current-potential curve gave a nonlinear plot as shown in Fig. 2. The distorted plot can be divided into three portions, *i.e.*, first and last linear portions and a middle curvilinear portion. The slopes of the first and last portions are 58 and 53 mV, respectively. Both values are approximately equal to the theoretical value of 58 mV for a reversible one-electron transfer process.

The current-time curves during one drop-growth of the DME were recorded at different potentials along the polarographic wave, and the exponent, γ, in $i=kt^{\gamma}$ (i: the current, k: the constant, t: the time) was estimated. In the estimation the rising portion of the i-t curve was omitted because of distortion by the dilution effect. The result is illustrated in Fig. 3.

Vlček[8] classified the varied values of γ as follows:
(a) $\gamma=0.17-0.2$; diffusion-controlled process

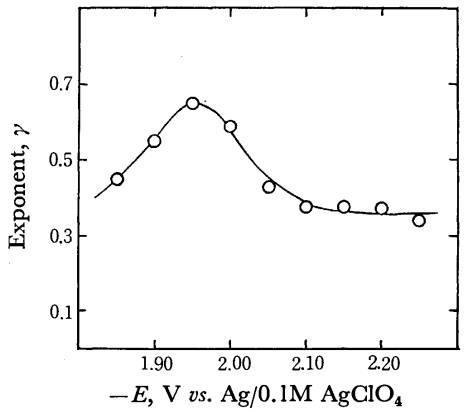

Fig. 3. Variation of exponent, γ, in $i=kt^{\gamma}$ with electrode potential.

(b) $\gamma=0.67$; reaction-rate control
(c) $\gamma=0.2-0.67$; diffusion and reaction-rate in competition
(d) γ changes with t during a drop-growth from 0.67 to 0.2; irreversible process
(e) γ changes with increasing i/i_1 (i_1: the limiting current) or E (E: the applied potential) from $\simeq$0.4 to 0.17 through a maximum; slightly irreversible process

In the present case the value of γ changes with increasing i/i_1 from 0.45 at −1.85 V to 0.34 at −2.25 V through a maximum of 0.65 at −1.95 V. In view of the above-mentioned classification the electrode reaction seems to proceed slightly irreversibly in the first step, proceeding thereafter with diffusion and reaction-rate control in competition.

In relation to the irreversible electrode process of VO^{2+} in M HCl solution, Suchomel and Vlček[8] pointed out that the reaction proceeds inherently in two stages as follows:

$$VO^{2+}\ aq \xrightarrow{+e^-} V(H_2O)_6^{3+} \xrightarrow{+e^-} V(H_2O)_6^{2+}$$

The first step proceeds highly irreversibly and the second one with only a very small overvoltage. No separate waves, corresponding to these two stages, could be observed in the conventional polarogram, but two separate waves appeared (Fig. 1) in the AC polarogram. The first AC peak at −1.85 V is more rounded, showing its irreversible characteristic. The second peak at −2.1 V is rather sharp, reflecting its reversibility. The effect of kinetic currents on an AC polarogram is small compared with the DC polarogram because the reaction time in an AC cycle is small. This supports the fact that the AC polarogram shows distinctly separated peaks.

Controlled-Potential Electrolysis and Cyclic Voltammetry. The controlled-potential electrolysis was carried out in a cell with the anode and cathode compartments separated by a sintered glass disc. By electrolysis at −2.1 V the solution color turned from light-blue (λ_{max} of the optical absorption band=710, 591 and 393 nm) to greenish-yellow. By continuation of electrolysis it turned to dark-green especially in the vicinity of the cathode surface. However, the dark-green color promptly

faded to yellow (λ_{max}=275 nm) on being left to stand in nitrogen atmosphere.

A similar trend was observed in the reduction of VO^{2+} with zinc amalgam. In an acidic aqueous solution vanadyl acetylacetonate was reduced easily by zinc amalgam. The color turned from light-blue to purple, showing the formation of V(II) entities. In AN solution, however, the reduction did not proceed markedly, but it proceeded slowly in the presence of excess Hacac. The reduction product was yellow, giving a polarographic cathodic wave at −1.78 V. On being left to stand in the air, no noticeable change was observed in the yellow coloration after a few hours, but the color faded very slowly in a few days.

The current-potential curve obtained *in situ* in the electrolysis cell is shown in Fig. 4. The greenish-yellow solution gave a cathodic wave at −1.78 V and an anodic wave at about −0.45 V. In addition to these waves the dark-green solution gave an unstable anodic wave at −1.70 V, but it could no longer be observed on being left to stand, the coloration of the solution turning to yellow. The yellow solution obtained finally gave a cathodic wave at −1.78 V and an anodic wave at −0.45 V (A similar anodic wave was observed in 20 mM Hacac solution containing 0.1 M TEAP after controlled-potential electrolysis at −2.3 V. For the cathodic process of Hacac in aqueous solution refer to 9).).

The slope of the logarithmic plot of the cathodic wave developed in the yellow solution was about 65 mV, the initial value being 55 mV (Fig. 6). The exponent, γ, of the current-time relationship varies with increase of i/i_1 from 0.32 at −1.80 V to 0.34 at −1.85 V, 0.35 at −1.90 V and 0.34 at −2.00 and −2.10 V. These results indicate that the cathodic process is a slightly irreversible one-electron transfer one, coupled with a reaction-rate controlled process.

The cyclic voltammogram of vanadyl acetylacetonate in AN solution is shown in Fig. 5. A sharp cathodic peak and a rounded anodic peak appear in the first

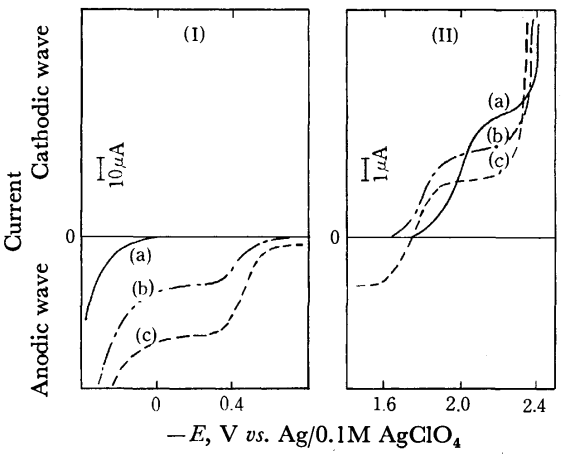

Fig. 4. Polarograms recorded *in situ* in course of controlled-potential electrolysis of [VO(acac)$_2$] in AN solution containing 0.1 M TEAP and 20 mM Hacac at −2.1 V.

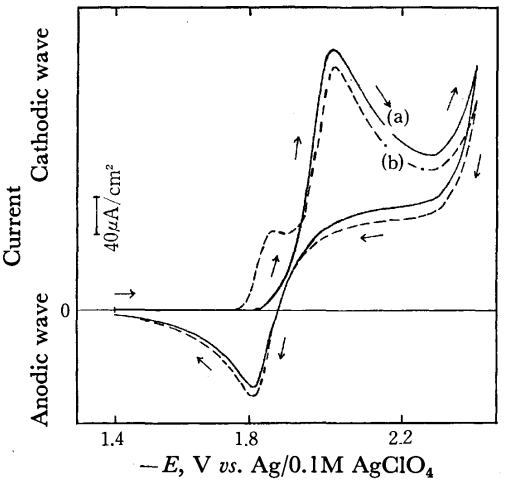

Fig. 5. Cyclic voltammograms of 1 mM [VO(acac)$_2$] in AN solution containing 0.1 M TEAP and 20 mM Hacac.
(a) First cycle of triangular sweep, (b) Second cycle of triangular sweep; scan-rate=50 mV/s.

cycle of the applied triangular voltage. The cathodic peak potential, E_p^c, was −2.02 V, and the anodic peak potential, E_p^a, was −1.80 V. The difference between E_p^a and E_p^c is noticeable as compared with the theoretical value of $E_p^a - E_p^c = 0.058/n$ V[10,11] for a reversible process at 20 °C. However, in the second and the following cycles a new cathodic peak appeared at −1.85 V, its peak-height gradually increasing in the consecutive cycles of the applied sweep. The new peak corresponds to the anodic peak at −1.80 V. When the scan-rate of the triangular voltage decreased from 50 mV/s to 20 and 10 mV/s, the ratio of the anodic and cathodic peak-heights decreased noticeably, the anodic peak disappearing completely under the scan-rate of 5 mV/s. It seems that the entity, which gives an anodic peak at −1.80 V, is unstable in solution, corresponding to the unstable anodic wave developed by the dark-green solution at −1.70 V. It is concluded that the cathodic peaks at −2.02 and −1.85 V and anodic peak at −1.80 V can be assigned to the cathodic waves at −2.00 and −1.78 V and the anodic wave at −1.70 V, respectively, in the conventional polarography.

Reaction Mechanism of Electrode Processes. Vanadyl acetylacetonate is stable and soluble in a large number of solvents without exchange of ligands. Dodge, Templeton and Zalkin[12] reported the composition and structure of anhydrous vanadyl acetylacetonates as five-coordinated complex with VO^{2+} perpendicular to the oxygen base of a square pyramid. The complex presumably retains its VO^{2+} identity in solution forming a distorted octahedral array. The vanadyl oxygen is expected to dominate the electrostatic interactions between the central ion and the ligand by virtue of its close approach to vanadium. The sixth ligand, *trans* to the vanadyl oxygen, is open and can be coordinated by solvent molecules as pointed out by Bernal and Rieger.[13] Ballhausen and Gray[14] investigated the complex by the MO theory, and pointed out the significance of the π-bonding in VO^{2+}. It seems that

at least two factors have to be considered in relation to the irreversible electrode process. The predominant factor is the extreme stability of the V–O bond. Since all the orbitals are occupied and the lowest vacant orbitals in a σ-antibonding orbital are of relatively high energy, the strong V–O bond has to be broken and the low-lying orbital must be vacated for the electron transfer. The second minor factor is a structural change of ligands, *i.e.*, a breaking of the V–O bond accompanies the rearrangement of bidentate ligands, ($acac^-$).

Since the kinetic current is reduced to minimum at the plateau potential of the cathodic wave, the diffusion-controlled current for the first electron transfer can be approximated by one half of the overall limiting current. By using this value a logarithmic plot for the first electron transfer process is obtained as shown in Fig. 6. The reversible half-wave potential of the first electron transfer is estimated to be −1.93 V. The reductant by the first electron transfer would necessitate a ligand rearrangement. Accordingly, the middle portion of the cathodic wave is affected by this rearrangement reaction. Once the reaction is over, the following electron transfer would proceed with a close resemblance to the atomic configuration in the environment. However, the internuclear distance should change due to the ionic valency change of the central atom. The cathodic process developed by the yellow solution seems to correspond to this case. The reversible half-wave potential is estimated to be −1.78 V by logarithmic analysis (Fig. 6). It is noteworthy that this process proceeds at a less negative potential by 0.15 V than the first electron transfer. The discrepancy seems to be attributed mainly to the V–O bond strength. Newton and Baker[15] studied the second-order rate law of the reduction of V(IV) species by V(II) species in an aqueous solution. This reaction seems to play the role of the kinetic current in the present case, causing deformation in the middle portion of the cathodic wave. At the plateau of the polarogram the formation of V(II) species dominates, and the V(IV) entity diffusing toward the electrode from the solution bulk will be depleted in the reaction layer by the reaction of V(II) with V(IV). Thus, the last portion of the polarogram is hardly affected at all by the rate-controlled process. Another possible coupled chemical reaction is the oligomer formation of the reduced species as pointed out by Israel and Meites.[5] No convincing evidence for this process, however, was found in the present investigation.

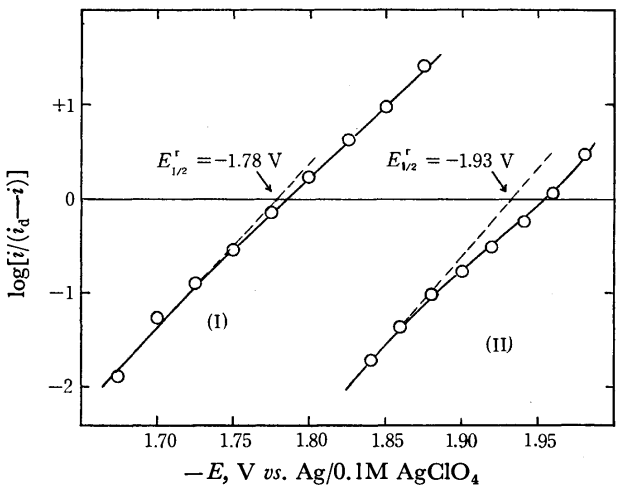

Fig. 6. Logarithmic plots of cathodic processes of (I) $[V(acac)_3]$ and (II) $[VO(acac)_2]$ as assumed to be one-electron transfer process.

The reaction mechanism can be summarized as follows:

(1) The first electron transfer to $[VO(acac)_2]$:

$$[VO(acac)_2] + Hacac + e^- \longrightarrow (V(acac)_2 \cdot O \cdot Hacac^-)^*$$

where * denotes the activated state.

(2) The successive electron transfer to the activated state:

$$(V(acac)_2 \cdot O \cdot Hacac^-)^* + e^- \longrightarrow [V(acac)_3]^- + OH^-$$

(3) The second electron transfer after the ligands rearrangement:

$$[V(acac)_3] + e^- \longrightarrow [V(acac)_3]^-$$

(4) The coupled chemical reactions:
(4-1) the ligands rearrangement:

$$(V(acac)_2 \cdot O \cdot Hacac^-)^* \longrightarrow [V(acac)_3] + OH^-$$

(4-2) A possible following reaction of (4-1):

$$OH^- + Hacac \longrightarrow acac^- + H_2O$$

(4-3) the reduction of V(IV) by V(II):

$$[VO(acac)_2] + [V(acac)_3]^- + Hacac \longrightarrow 2[V(acac)_3] + OH^-$$

(Received June 12, 1975)

The circular dichroism (CD) spectra of *trans*-dichlorobis(diamine)cobalt(III) complexes were measured in methanol solution in the 700—200 nm region, where the diamines have the general formula of $NH_2CH(R)CH_2NH_2$ (R=isopropyl, isobutyl, *sec*-butyl, benzyl and phenyl) and belong to the *S* configuration except the phenyl-substituted one. The spectra are essentially the same as the spectrum of the (*S*)-propylenediamine ((*S*)-pn; R=methyl) complex, except for the (*R*)-*C*-phenylethylenediamine ((*R*)-phenen) complex. The variation of the *C*-substituted alkyl groups has hardly any influence on the CD of the *trans*-$[CoCl_2(diamine)_2]^+$ type complexes, demonstrating that the vicinal contribution from the *C*-substituents can be disregarded in these compounds. The *trans*-$[CoCl_2((R)\text{-phenen})_2]^+$ ion shows a CD pattern differing significantly from that of the *trans*-$[CoCl_2((R)\text{-pn})_2]^+$ ion in the first absorption band region, suggesting the significance of the vicinal effect due to the *C*-substituted phenyl group. The CD curve of *trans*-$[CoCl_2((-)_D\text{-stien})_2]^+$ ion (stien=stilbenediamine) was found to be antimeric to that of the (*R*)-phenen complex. Taking into account the anomalous vicinal effect of the phenyl groups, the absolute configuration of the $(-)_D$-stien was assigned to the (*S,S*) configuration.

Stereochemical features which can contribute to the circular dichroism (CD) of a dissymmetric metal complex have been classified as follows: (1) a distribution of chelate rings about the metal ion (configurational effect), (2) the puckered dissymmetric conformation of individual chelate rings (conformational effect) and (3) the presence of asymmetric groups on the ligands (vicinal effect).[1,2] Some papers indicate that ligand field CD spectra of Co(III) complexes can be differentiated between the configurational and the other two effects in such systems as tris(diamine)Co(III) ion,[3] (*S*)-aminoacidatobis(ethylenediamine)Co(III) ion[4] and tris(aminoacidato)Co(III) complexes.[5] However, it has been pointed out that differentiation between the conformational and vicinal effect is rather difficult, though the latter effect is considered to have minor contributions with respect to the 1,2-diamine chelate rings.[1-2] This may be due to the fact that restriction of the conformation is usually caused by the substitution at the C atom(s) of diamine chelates such as (*R*)-propylenediamine, 2(*R*),3(*R*)-butanediamine and 1(*R*),-2(*R*)-cyclohexanediamine.

Bosnich and Harrowfield reported that the CD spectra of *trans*-$[CoCl_2((R)\text{-pn})_2]^+$ ion ((*R*)-pn=(*R*)-propylenediamine) and *trans*-$[CoCl_2((R)\text{-bn})_2]^+$ ion ((*R*)-bn=2(*R*),3(*R*)-butanediamine) are nearly the same, and the contribution of vicinal effect to optical activity is small.[2] This implies that the introduction of an alkyl group larger than the methyl group into a diamine chelate ring would result in minor changes in the shape and magnitude of CD. In order to confirm the assumption, we have prepared chiral 1,2-diamines with the general formula, $NH_2CH(R)CH_2NH_2$ (*R*=isopyl, isobutyl, *sec*-butyl and benzyl),[6] from the corresponding (*S*)-amino acids, *i.e.*, (*S*)-valine, (*S*)-leucine, (*S*)-isoleucine and (*S*)-phenylalanine, respectively, and obtained *trans*-dichlorocobalt(III) complexes with these diamines. We have also prepared (*R*)-*C*-phenylethylenediamine ((*R*)-phenen)[6] from the corresponding amino acid, (*R*)-*C*-phenylglycine, the absolute configuration of which has been established.[7] The CD spectra of the (*R*)-phenen complex and of the closely related $(-)_D$-stien (stien=stilbenediamine) complex will also be discussed in this report.

Experimental

Preparation of 1,2-Diamines. (*S*)-Valine, (*S*)-leucine and (*S*)-phenylalanine were converted into the amides according to the procedure described by Yang and Rising.[8] (*S*)-Isoleucine amide hydrochloride was obtained by the method of Smith *et al.*[9] (*R*)-phenylglycine amide was also prepared by the known method.[10] All the amino acid amides and their hydrochloride were treated with $LiAlH_4$ in dry tetrahydrofuran according to the procedure of Schnell and Karrer[11] with slight modifications as follows.

To a suspension of $LiAlH_4$ (11.4 g, 0.3 mol) in dry tetrahydrofuran (250 ml) was added 0.1 mol of amino acid amide in small portions. The mixture was stirred and heated under reflux for 24 hr, and then cooled to room temperature. Water (22 ml) was added dropwise with vigorous stirring, and the resulting slurry was stirred for further 1 hr at room temperature. The slurry was filtered by suction; the residue was extracted with tetrahydrofuran (100 ml) under reflux for 1 hr, and filtered again. The extraction was repeated once more, and the filtrate and extracts of tetrahydrofuran were combined. Excess concentrated hydrochloric acid was added, and the mixture was evaporated under reduced pressure almost to dryness. The residue was dissolved in a small volume of water, and then a concentrated sodium hydroxide solution was added in order to make the solution strongly alkaline. The separated amine layer was extracted with ether (total 300 ml). The ether extracts were dried over potassium hydroxide pellets overnight, and ether was removed by distillation under atmospheric pressure. The remaining oily liquid was distilled over potassium hydroxide pellets under atmospheric or reduced pressure. The crude diamines thus obtained were used for preparing cobalt (III) complexes without further purification.

$(-)_D$-Stilbenediamine was prepared and resolved by the known method.[12]

Preparation of Complexes. The *trans*-$[CoCl_2(diamine)_2]$-ClO_4 type complexes of (*S*)-ipren, (*S*)-*i*-buen and (*S*)-*sec*-buen were obtained in aqueous solution by the usual air-oxidation

procedure. To an aqueous solution of $CoCl_2 \cdot 6H_2O$ were added twice the molar amounts of 1,2-diamine, and the resulting solution was aerated for 5 hr at room temperature. Concentrated hydrochloric acid (about 5 ml for 0.01 mol scale) was added, and mixture was evaporated on a water bath until a small amount of green crystals began to separate. To the mixture was added excess perchloric acid (60%), and the green crystals separated were collected and washed with ethanol and ether, and air-dried. The crude products were recrystallized from methanol by adding ether. Found: C, 27.77; H, 6.46; N, 12.71%. Calcd for *trans*-$[CoCl_2((S)\text{-ipren})_2]ClO_4$: C, 27.70; H, 6.51; N, 12.92%. Found:C, 30.93; H, 7.03; N, 11.71%. Calcd for *trans*-$[CoCl_2((S)\text{-}i\text{-buen})_2]ClO_4$: C, 31.22; H, 6.99; N, 12.14%. Found: C, 31.81; H, 7.06; N, 12.24%. Calcd for *trans*-$[CoCl_2((S)\text{-buen})_2]ClO_4$: C, 31.22; H, 6.99; N, 12.14%.

The air-oxidation process was carried out in aqueous methanol and methanol solution for obtaining the (*S*)-benen, (*R*)-phenen complex and $(-)_D$-stien. The subsequent procedures were the same as those mentioned above. Found: C, 39.14; H, 5.66; N, 10.03%. Calcd for *trans*-$[CoCl_2((S)\text{-benen})_2]ClO_4 \cdot H_2O$: C, 39.47; H, 5.52; N, 10.23%. Found: C, 38.54; H, 5.02; N, 11.19%. Calcd for *trans*-$[CoCl_2((R)\text{-phenen})_2]ClO_4$: C, 38.31; H, 4.82; N, 11.17%. Found: C, 53.64; H, 5.46; N, 9.02%. Calcd for *trans*-$[CoCl_2((-)_D\text{-stien})_2]Cl \cdot 2H_2O$: C, 53.73; H, 5.80; N, 8.95%.

Measurements. Visible and ultraviolet absorption spectra were obtained with a Shimadzu MPS 50L recording spectrophotometer. CD spectra were obtained with a JASCO J-20 automatic spectropolarimeter. All the spectra were measured in methanol solution.

Results and Discussion

It has been acknowledged that substituting groups on carbon atoms of puckered 1,2-diamine chelate rings always tend to take the equatorial orientation both in the solid state[13-14] and in solution.[15] Thus, the (*R*)- and (*S*)-pn chelates adopt the *δ*- and *λ-gauche* conformation, respectively, (Fig. 1), according to the nomenclature of the conformation of a diamine chelate ring based on the proposal in the reference.[16]

The alkyl-substituted 1,2-diamine prepared from (*S*)-amino acid should have the *S* configuration with respect to the asymmetric C atoms of the diamine moiety.. Sor far as the alkyl substituents adopts preferably the equatorial orientation upon coordination, the chelate ring of substituted diamine should have the *δ* conformation as well as the (*S*)-pn chelate. Since most investigations on the CD of *trans*-dichloro complexes have dealt with the (*R*)-pn or (*S*)-pn complex, we will discuss the CD spectra of our complexes by comparing them with those of the *trans*-$[CoCl_2((R)\text{-pn})_2]^+$ ion or *trans*-$[CoCl_2((S)\text{-pn})_2]^+$ ion.

(—) *trans*-$[CoCl_2((-)_D\text{-stien})_2]^+$ and (···) *trans*-$[CoCl_2$-$((R)\text{-phenen})_2]^+$.

CD of C-Alkylsubstituted 1,2-Diamine Complexes. The absorption spectra and circular dichroism spectra are given in Figs. 2—4 and Table 1. The first ligand field transition in the absorption spectrum of cobalt(III) in an octahedral field is $^1A_{1g}\rightarrow{}^1T_{1g}(O_h)$ which splits in a tetragonal field (*e.g.* *trans*-$[CoCl_2(NH_3)_4]^+$) into $^1A_{1g}\rightarrow{}^1E_g(D_{4h})$ and $^1A_{2g}(D_{4h})$ component, respectively.[17] The band of *trans*-$[CoCl_2(en)_2]^+$ ion at 16000 cm^{-1} was assigned to the $^1A_{1g}\rightarrow{}^1E_g(D_{4h})$ transition (I_a), and that at 22000 cm^{-1} to the $^1A_{1g}\rightarrow{}^1A_{2g}(D_{4h})$ transition (I_b).[17,18] The 1,2-diamine chelate with the λ conformation, such as (*R*)-pn or (*R*)-chxn ((*R*)-chxn= 1(*R*),2(*R*)-diaminocyclohexane), gives a positive and a negative CD band for the I_a band and the I_b band respectively.[19]

In the near-ultraviolet and ultraviolet regions, the *trans*-$[CoCl_2(NH_3)_4]^+$ ion gives two strong absorption bands which have been assigned to the charge transfer bands from the halides to the central metal ion, The longer wave length band involving the $p_\pi\rightarrow d_{z^2}$ and the shorter wave length band involving the $p_\sigma\rightarrow d_{z^2}$ transition.[20] It was observed that the *trans*-$[CoCl_2((R)$-chxn$)_2]^+$ ion shows a positive and a negative CD bands for the $p_\pi\rightarrow d_{z^2}$ transition and a positive CD band for the $p_\sigma\rightarrow d_{z^2}$ transition band.[21] The (*R*)-pn complex gives a similar CD pattern to that of the (*R*)-chxn complex in the charge transfer region (Fig. 2).[32]

As shown in Figs. 2 and 3, the CD spectra of the *trans*-$[CoCl_2((S)\text{-ipren})_2]^+$, *trans*-$[CoCl_2((S)$-*i*-buen$)_2]^+$, *trans*-$[CoCl_2((S)$-*sec*-buen$)_2]^+$ and *trans*-$[CoCl_2((S)$-benen$)_2]^+$ ion are very similar to each other and to the spectrum of the (*S*)-pn complex (the enantiomorph of (*R*)-pn complex) both in the ligand field and in the charge transfer region. It is apparent from these results that, so far as the methyl, isopropyl, isobutyl, *sec*-butyl and benzyl groups are concerned, the change of the substituting groups on the asymmetric C atom of the diamine chelate makes little contribution to the CD pattern. This means that the optical activity of *trans*-$[CoCl_2(diamine)_2]^+$ system is affected strongly by the conformational contribution and weakly by the vicinal effect.

The (*S*)-*sec*-buen has two asymmetric C atoms, one on the chelate ring and the other in the substituting *sec*-butyl group ((*S*) configuration). A marked resemblance of the CD curves between the (*S*)-*sec*-buen complex

and the (*S*)-*i*-buen complex (and others) suggests that the additional asymmetric center in the (*S*)-*sec*-buen contributes very little to the CD. This also suggests that the vicinal effect does not contribute much to optical activity.

CD of C-*Phenylsubstituted 1,2-Diamine Complexes.* It has been indicated that the (*R*)-phenen chelate ring has the *λ-gauche* conformation with an equatorially situated phenyl group.[23] The CD pattern of the *trans*-$[CoCl_2((R)\text{-phenen})_2]^+$ ion shown in Fig. 4 obviously differes from that of the (*R*)-pn complex. The (*R*)-phenen complex shows positive maxima both in the I_a and in the I_b region. Both CD peaks have comparable intensities with each other. In the case of the *trans*-$[CoCl_2((R)\text{-pn})_2]^+$ ion, its CD is negative in the I_b and positive in the I_a region. The former CD band is considerably weaker than that of the latter.

Bonich and Harrowfield[2] revealed that the CD sign of the $^1A_{1g}\rightarrow{}^1A_{2g}(D_{4h})$ transition region varies with the change of solvents or the states of the samples (crystal or solution state) in a series of *trans*-$[CoCl_2(1,2\text{-diamine})_2]^+$ complexes, where 1,2-diamines are mono- or disubstituted with alkyl groups. However, a minority of the CD in the A_{2g} transition was still recognized in all cases.[2] The anomalous CD behavior of *trans*-$[CoCl_2((R)\text{-phenen})_2]^+$ ion observed in the first absorption band region would be ascribed to the influence of the phenyl group on the chelate ring.

On the other hand, the CD behavior of the (*R*)-phenen complex resembles closely that of the (*R*)-pn complex in the charge transfer region. This indicates that the phenyl group on the chelate ring has little effect on the CD spectrum in this region. We consider that the CD signs of the charge transfer band region can be regarded as a good indication for determining the conformation of 1,2-diamine chelate rings.

It was found that the CD spectrum of the *trans*-$[CoCl_2((-)_D\text{-stien})_2]^+$ ion, shown in Fig. 4, closely resembles that of the (*R*)-phenen complex, though each corresponding peak has the opposite sign. It is significant that in the charge transfer region, where the phenyl group shows little contribution to determining the CD as described above, both the $(-)_D$-stien and the (*R*)-phenen complexes show the same CD pattern with the opposite signs. This indicates that the $(-)_D$-stein and (*R*)-phenen chelate rings take an antimeric conformation to each other.

The (*R*)-phenen complex should have the λ conformation, in which the phenyl group can adopt the equatorial orientation. Hence, the $(-)_D$-stien chelate should have the δ conformation. It has been shown that the two phenyl groups of $(-)_D$-stien take the equatorial orientation simultaneously.[23] The absolute configuration of stien satisfies the requirements that the diamine has the δ conformation and the equatorial phenyl groups must be of the (*S,S*) configuration.

It has recently been reported that the CD spectra of the Zn(II) complexes of $(-)_D$-stien suggest the (*S,S*) configuration for the ligand in these complexes.[25]

The absolute configuration of $(-)_D$-stien has been assigned to the (*R,R*) configuration,[2,24] based on the examination of the equilibrium between the Δ and Λ isomers of $[Co((-)_D\text{-stien})_3]^{3+}$ ion, or the exciton analysis of the CD of $(-)_D$-isomarine, the precursor of $(-)_D$-stien. Bosnich and Harrowfield, however, raised some questions on their assignments. Our assignment mentioned above is entirely reverse to these assignments.

If the $(-)_D$-stien has the (*R,R*) configuration, it would be difficult to explain the remarkable difference in CD between the *trans*-dichloro complexes of $(-)_D$-stien and of (*R*)-phenen. On the other hand, if the $(-)_D$-stien has the (*S,S*) configuration, a very significant problem would arise with regard to the assignment of the Δ and Λ isomers of tris(diamine) complex. Although the true configuration of $(-)_D$-stien should be clarified by X-ray analysis study, we assign the $(-)_D$-stien to the (*S,S*) configuration, since the visible CD curve of the *trans*-$[CoCl_2((-)_D\text{-stien})_2]^+$ ion can be explained by taking into account the vicinal effect of the phenyl group.

By comparing the CD of (*R*)-phenen complex with that of (*R*)-pn complex, it is apparent that the phenyl group affects especially the CD in the I_b ($^1A_{1g}\rightarrow{}^1A_{2g}(D_{4h})$) transition. A strong CD band with negative sign is observed for the *trans*-$[CoCl_2((-)_D\text{-stien})_2]^+$ ion in the I_b region, demonstrating the vicinal effect of the phenyl groups. The visible CD band of the $(-)_D$-stien complex is considerably stronger than that of the (*R*)-phenen complex. This may be due to the difference in the number of phenyl groups between the ligands. The remarkable vicinal effect observed for the phenen, having only one phenyl group, should appear twice as much in the case of stien with two phenyl groups.

It is interesting to note that the (*S*)-benen complex which also has a phenyl group in the ligand shows no obvious influence of the phenyl group in its CD curve. In this case, the phenyl group is separated by a methylene group from the diamine chelate ring. It is suggested, that only the phenyl group attached directly to the 1,2-diamine moiety gives rise to the anomalous vicinal effect in the first absorption band region.

This research was aided in part by a Scientific Research Grant of the Ministry of Education.

The Crystal Structure of Ammonium Pentamolybdodisulfate(IV) (4-) Trihydrate $(NH_4)_4[S^{IV}_2Mo_5O_{21}]\cdot 3H_2O$

Kazuko Y. MATSUMOTO, Masao KATO, and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 16, 1975)

The crystal of $(NH_4)_4S_2Mo_5O_{21}\cdot 3H_2O$ contains a discrete polyanion, $S_2Mo_5O_{21}^{4-}$, formed by reactions in an aqueous solution:

$$5Mo_7O_{24}^{6-} + 14SO_2 + 2H^+ \rightleftarrows 7S_2Mo_5O_{21}^{4-} + H_2O$$

or

$$5MoO_4^{2-} + 2SO_2 + 6H^+ \rightleftarrows S_2Mo_5O_{21}^{4-} + 3H_2O$$

It is orthorhombic, with the space group Pbcn and with $a=15.096(9)$, $b=13.375(8)$, $c=23.734(7)$ Å, $D_m=2.79$, and $D_x=2.79$ g cm^{-3} for $Z=8$. The crystal consists of $S_2Mo_5O_{21}^{4-}$ anions connected with each other by hydrogen bonds, with intervening water molecules and ammonium cations. In the polyanion, five MoO_6 octahedra are connected by edge sharing, and the two octahedra at the two ends are connected by corner sharing to complete the Mo_5O_{21} ring; the two SO_3 trigonal pyramids are attached to the ring from above and below the ring.

Three polymolybdosulfate(IV)(4—) ions, $S_2Mo_8O_{31}^{6-}$,[1] $S_2Mo_5O_{21}^{4-}$,[2] and $S_3Mo_{10}O_{40}^{8-}$,[3] are found in the literature, but the existence of the last species was once regarded as doubtful.[2] Our preparative work, together with powder X-ray diffraction and IR measurements, confirmed the first two polyanions as ammonium salts, $(NH_4)_6S_2Mo_8O_{31}\cdot 5H_2O$ and $(NH_4)_4S_2Mo_5O_{21}\cdot 3H_2O$.

Both samples were examined by means of the single crystal X-ray diffraction technique; the former was found only as twinned crystals. The present structure work deals with the structure of ammonium pentamolybdodisulfate(IV)(4—); the results show that the material is neither an inclusion nor a clathrate compound of SO_2 gas, but contains a discrete polyanion consisting of two SO_3 trigonal pyramids and five MoO_6 octahedra.

Experimental

Preparation. Crystals of $(NH_4)_4S_2Mo_5O_{21}\cdot 3H_2O$ were prepared according to the method described by Rosenheim:[2] a 9 g portion of ammonium paramolybdate was dissolved in 30 ml of water, and SO_2 gas was dissolved in this solution; during this procedure the color of the solution gradually changed to yellow. After the solution had become saturated with SO_2, it was rapidly cooled in an ice-water bath; pale yellow needles of $(NH_4)_4S_2Mo_5O_{21}\cdot 3H_2O$ were thus obtained. If the solution was kept in a desiccator at room temperature, $(NH_4)_6S_2Mo_8O_{31}\cdot 5H_2O$ was crystallized. The results of the elemental analyses of $(NH_4)_4S_2Mo_5O_{21}\cdot 3H_2O$ were as follows: Found: Mo, 47.3; S, 6.4; N, 5.55; H, 1.91%. Calcd: Mo, 47.6; S, 6.4; N, 5.51; H, 2.18%.

The solid sample is stable in air and on X-ray irradiation at room temperature.

IR Measurement. The IR spectra were measured from 400 to 4000 cm^{-1} using Nujol mull and a KBr disk on a Hitachi EPI-G2 spectrometer.

Crystal Data. Preliminary photographs revealed that the crystal is orthorhombic, with the space group Pbcn. The unit-cell dimensions were refined with 12 θ values measured on a diffractometer with Mo$K\alpha$ radiation ($\lambda=0.7107$ Å). The crystal data are as follows:

$(NH_4)_4S_2Mo_5O_{21}\cdot 3H_2O$
F.W. = 1005.9
orthorhombic Pbcn
a = 15.096(9) Å
b = 13.375(8) Å
c = 23.734(7) Å
V = 4792.1 Å^3
D_m = 2.79 g cm^{-3}
D_x = 2.79 g cm^{-3}
Z = 8
μ = 30.4 cm^{-1} (for Mo$K\alpha$)

Data Collection. The intensity data were collected on a Rigaku four-circle automatic diffractometer with graphite-monochromated Mo$K\alpha$ radiation. The ω-2θ scan tachnique, with a scan rate of 2θ 2° min^{-1}, was employed. The scan range was determined for each reflection according to this formula: $\Delta\omega=1.4+0.6\tan\theta$, while the background was counted at each scan end for ten seconds. As a check on the crystal stability during the data collection, three standard reflections were monitored every 50 measurements, but no significant deterioration of the crystal was observed. After applying Lorentz and polarization corrections, 6698 $|F_o|$'s were obtained; of those, 3295 reflections with $|F_o|\geq 3\sigma(F)$ were used for further computation. The crystal used for the intensity measurement was pillar-shaped, approximately 0.3 mm long and 0.1 mm in diameter. No absorption correction was made because of the relatively low absorption coefficient.

Structure Determination

The structure was solved by the heavy atom method. Refinement with anisotropic temperature factors for the molybdenum in the anion and with isotropics for the sulfur and oxygen reduced R_1 to 0.112. This was followed by a difference Fourier synthesis, which revealed the positions of all the other non-hydrogen atoms. Eight peaks on the Fourier projection map were attributed to oxygen atoms of water and nitrogen atoms of ammonium cations.

In order to discern the nitrogen atoms in ammonium cations from the oxygens in water molecules, reference was made to the empirical effective radius for NH_4^+, which was determined from the NH_4^+–O distances in a number of ammonium salts.[4] In crystals containing ammonium cations with high coordination numbers, such as 7, 8 or 9, as in the present crystal, the ammonium cations may be considered to be approximate spheres with an effective radius of 1.65 Å. Accordingly, interatomic distances shorter than 3.5 Å were assigned to nitrogen-oxygen contacts. The most probable assign-

ment and the proposed model of the ammonium and water arrangement in the crystal are given in Table 1 and in Fig. 3.

After six cycles of refinement with anisotropic temperature factors, all the shifts in the parameters were less than their standard deviations and refinement was terminated. The final value of $R_1(=\sum[|F_o|-|F_c|]/\sum|F_o|)$ was 0.060, and that of $R_2(=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2})$ was 0.084.

In the block-diagonal least-squares refinement, the quantity minimized was $\sum w(|F_o|-k|F_c|)^2$; the weighting scheme adopted was $w=0.2$ for $|F_o|<75$ and $w=1.0$ for all the others.

The atomic scattering factors used were taken from Ref. 5, while corrections of the effect of anomalous dispersion for molybdenum and sulfur were based on Ref. 6.

A difference Fourier synthesis was calculated with the reflections in the range of $0\leq\sin\theta\leq0.45$, but no definitive conclusion was drawn about the positions of hydrogens.

The final coordinates and temperature factors are listed in Table. 1. The observed and calculated structure factors are available at the office of this Bulletin as Document No. 7603.

The calculations were performed on a HITAC 8700/8800 computer at the Computer Centre of the University of Tokyo, using a local version of the UNICS programs.[7]

Description and Discussion of the Structure

Molecular Structure. The $S_2Mo_5O_{21}^{4-}$ anion can be described as an assemblage of five distorted MoO_6 octahedra, which are joined through four sharings of edges and one corner sharing nearly on a plane to form a Mo_5O_{21} pentagon. The two SO_3 trigonal pyramids

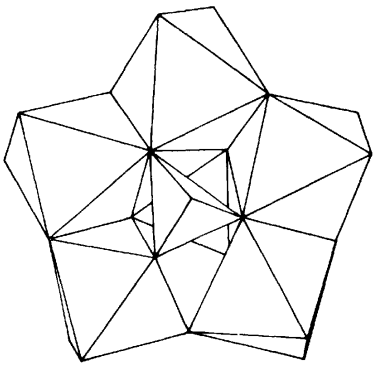

Fig. 1. The structure of $S_2Mo_5O_{21}^{4-}$ anion. Sulfur atoms occupy the apexes of the central trigonal pyramids. Five molybdenum atoms lie nearly on a plane to form a pentagon.

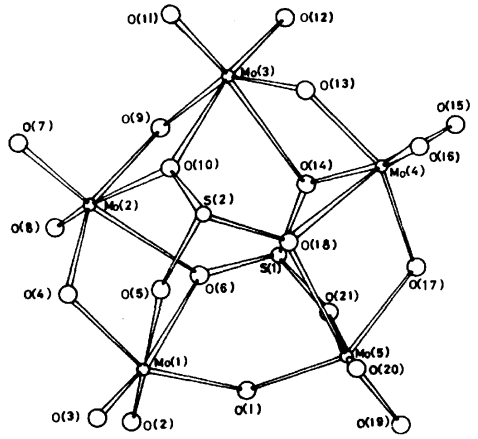

Fig. 2. The structure of $S_2Mo_5O_{21}^{4-}$ anion and its numbering scheme.

are situated so that the Mo_5O_{21} pentagon is capped on both sides by SO_3 pyramids through sharing the oxygens. Figures 1 and 2 show the structure of the anion and numbering scheme adopted for it. The five Mo atoms in the anion are almost co-planar. The equation of the plane through the molybdenum atoms obtained by the least-squares method is:

$$0.03055x - 0.92493y - 0.37892z + 2.82437 = 0.0$$

(x, y, and z are in Å unit)

while the deviations (Å) of each molybdenum from the plane are:

Mo(1) −0.2172, Mo(2) 0.1809, Mo(3) −0.0291
Mo(4) −0.1661, Mo(5) 0.2938

The vector from S(1) to S(2) is almost perpendicular to this plane; the angle between them is 89.25°. The anion has a pseudo twofold axis passing from Mo(3) to O(1).

The structure of the $S_2Mo_5O_{21}^{4-}$ anion is very similar to those of $P_2Mo_5O_{23}^{6-}$,[8] $HP_2Mo_5O_{23}^{5-}$,[9] and $H_2P_2Mo_5O_{23}^{4-}$[10] (Fig. 3). However, the latter anions have hetero atom P's tetrahedrally coordinated by four oxygen atoms; that is, each phosphorus has one unshared atom, while the trigonal pyramidal SO_3 has no such

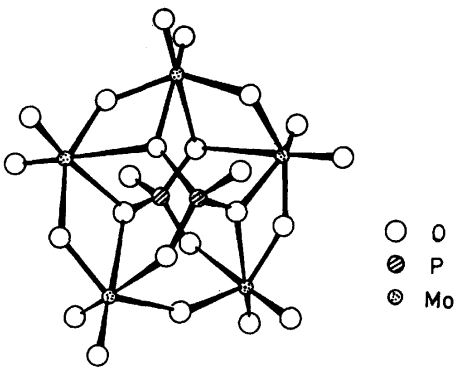

Fig. 3. The structure of $P_2Mo_5O_{23}^{6-}$anion.

terminal oxygen. The bond lengths and angles within the anion are listed in Tables 2 and 3. All the MoO_6 octahedra are disorted, and the Mo–O distances can be grouped into three groups, *i.e.*, Mo–O (unshared, terminal) 1.69—1.74 Å, Mo–O (shared between molybdenums) 1.89—1.95 Å, and Mo–O (shared between molybdenum and sulfur atom) 2.32—2.43 Å. These values are almost equal to the corresponding lengths in the $P_2Mo_5O_{23}^{6-}$ anions.[8-10]

Of the three S–O bondings of the SO_3 trigonal pyramid, two are relatively long; for example, the S(1)–O(6), S(1)–O(4) and S(2)–O(10), S(2)–O(18) distances are comparable to those in the SO_3^{2-} anions, while the other ones, S(1)–O(21) and S(2)–O(5), are as short as the S–O bonds in the SO_4^{2-} ions (1.47—1.49 Å).[11,12] These two types of bonds are different in their bonding schemes as well. O(6), O(14), O(10) and

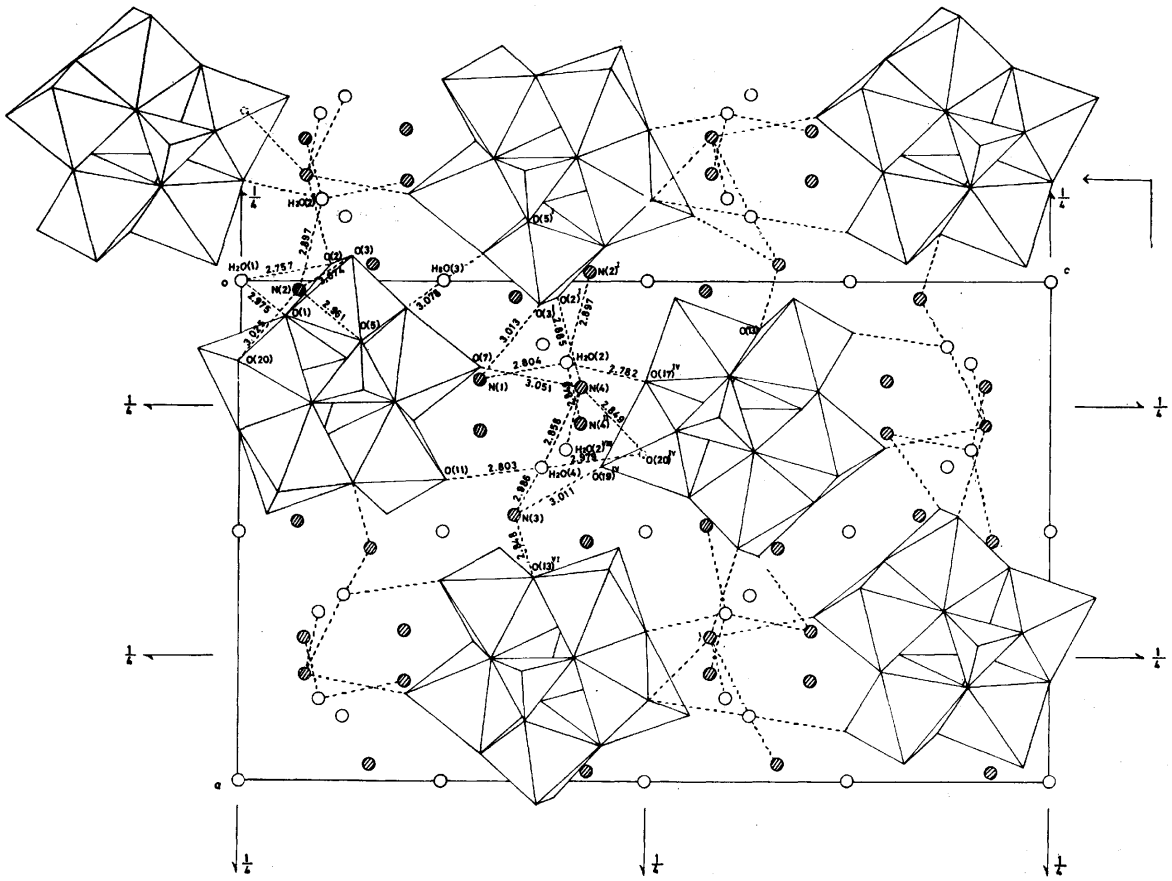

Fig. 4. The crystal structure of $(NH_4)_4S_2Mo_5O_{21}\cdot 3H_2O$. Open circles represent oxygen atoms in the water molecules and shaded circles nitrogen atoms. Only seven anions which lie in the range $y=0.0$—0.5 are depicted for easy viewing.

O(18), all of which make long S–O bonds, are all shared by two Mo atoms, whereas O(21) and O(5) are each bonded to only one Mo atom and make shorter bonds with the sulfur atom. This relation between the S–O lengths and the bonding schemes of the SO_3^{2-} ions corresponds to the general tendency of the elongating effect of a metal atom attached to the oxygen in SO_3^{2-}.[12] The IR spectra of the sample compound show a strong band at *ca.* 1020 cm^{-1} which is assigned to the S–O stretching of the short S–O bonding according to the relationship between the S–O lengths and the stretching frequencies.[11] It does not seem that either of the two lone pairs of S atoms coordinates to any particular atom. The crystal is held by hydrogen bondings between the anions, the cations, and the water of crystallization. Probable hydrogen bondings and van der Waals contacts less than 3.1 Å are given in Fig. 4 and Table 4.

Studies of the Hydrous Titanium Oxide Ion Exchanger. II. The Equivalence of the Exchange Adsorption of Cations and the Dissociation Constant

Yasushi INOUE and Masamichi TSUJI

Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received July 18, 1975)

In order to elucidate the fundamental properties of hydrous titanium oxide as a cation exchanger, the authors examined the stoichiometry of cation exchange and the acid-base property of the exchanger by means of titration curves. The results may be summarized as follows: 1. The equivalent exchange between the hydrogen ion and either the sodium or strontium ion holds over a wide range of conditions, such as the pH, the ionic strength, and the particle size of the exchanger. 2. The method of conditioning for obtaining the exchanger in the pure hydrogen form has been established. 3. The water content in the exchanger depends on the ionic composition. 4. This hydrous titanium oxide is a four-functional, weakly acidic cation exchanger and has the following apparent pK values: pK_1 6.7±0.1, pK_2 10.3±0.2, pK_3 12.3±0.2, and pK_4 13.2±0.2. The corresponding apparent ion exchange capacities are 2.2±0.1, 1.2±0.2, 0.7±0.3, and 0.2±0.3 meq. Na^+/g respectively.

Hydrous titanium oxide ion exchangers were synthesized by various methods, and their composition, ion exchange capacity, stability against various chemicals, and thermal stability were investigated, in the previous paper.[1] The exchangers in the hydrogen form have the composition of $TiO_2 \cdot (2.0—2.2)H_2O$ and a larger exchange capacity (about 3 meq.Cu(II)/g) than the value (1.6 meq.Cu(II)/g) obtained by Heitner-Wirguin *et al.*[2,3] The exchanger is semitransparent, consisting of nearly amorphous particles which are hard enough to be ground into fine particles suitable for column operations. It is stable in both alkaline and dilute acid solutions(<0.1 M).

The release of hydrogen ions by the adsorption of cations on this material strongly suggests that the mechanism of adsorption is ion exchange, but to substantiate the mechanism unambiguously it is necessary to confirm quantitatively the stoichiometric exchange of the ions concerned. This has been undertaken by using the relation that, for the stoichiometric uptake of ions, the plot of the logarithm of the distribution coefficient *vs.* the pH should be a straight line with a slope corresponding to the valency of cations exchanged.[4] However, this relation is valid only if the concentration of exchanging metal ions is very small in comparison with both the hydrogen-ion concentration and the adsorption capacity of the adsorbent; hence, it is limited to a rather narrow range of experimental conditions. Therefore, from papers hitherto published we cannot exclude the possible participation of mechanisms, such as some specific chemical reaction, surface adsorption, or coprecipitation, other than an ion-exchange reaction.

The purpose of the present investigation is to understand the fundamental properties of hydrous titanium oxide as a cation exchanger through examinations of the validity of the equivalent exchange of cations and of the titration curves, which are useful for understanding the acid-base property of the exchanger.

Experimental

Reagents and Apparatus. The strontium and cesium hydroxide solutions were prepared by passing strontium and cesium chloride solutions through a column packed with Dowex-I anion exchange resin in the OH^- form. All the other reagents were the same as have previously been described.[1]

β-Ray counting was undertaken by the use of a Kobe Kogyo Corp. G. M. counter, Model EA-11, coupled with a Kobe Kogyo scaler, Model SA-250. Except for it, all the apparatuses were the same as have previously been described.

Analytical Method. Alkali metal ions were converted to the corresponding pure chloride and indirectly determined by titrating Cl^- ions by means of Fajans' method. Sr^{2+} was determined chelatometrically.[5] OH^- and CO_3^{2-} were determined by a differential titration, using phenolphthalein and methyl orange as indicators. Cl^- was determined by means of Fajans' method, except for cases where the Cl^- ion was not intentionally added, but came from the ^{22}Na tracer solution. In the latter case, it was estimated by means of the electroneutrality relationship.

Synthesis. The synthetic method No. 7′ described in the preceding paper was used throughout this work. The outline was as follows. Into 200 ml of a 2.2 M $TiCl_4$ solution prepared by diluting liquid $TiCl_4$ with water, 800 ml of a 2.8 M NaOH solution was added at an average rate of 25—30 ml/min. Immediately after the addition, the precipitate was filtered through Toyo No. 1 filter paper under suction, removed from the funnel, dispersed into fresh water, and aged. This procedure was repeated until the pH of the filtrate approached a constant value (about 10). Finally, the precipitate was filtered and air-dried. Since the ion exchange capacity of the material thus prepared fluctuated from batch to batch (3.4—3.7 meq./g), samples of the same batch were employed throughout each series of experiments.

Ion-exchange Stoichiometry. The test samples employed were subjected to three kinds of chemical pretreatments by means of the column method to be described below. The columns used for treating 10 g and 5 g portions of the exchanger were 1.0 cmϕ × 15 cm and 0.7 cmϕ × 15 cm respectively. About a 500 ml portion of the conditioning solution per 10 g of the exchanger was passed through at a flow rate of 0.7—1 ml/min.

Sample A: No pretreatment.

Sample B: Sample A was treated with a 0.1 M HCl solution.

Sample C: About 5 g of Sample A was immersed in 100 ml of a 1 M NaOH solution for 2 days and then treated with the 0.1 M HCl solution.

Sample D: Sample B was treated with a 0.1 M NaOH solution and next with the 0.1 M HCl solution.

Following each single treatment, the exchanger was washed until the effluent was neutral. The particle sizes of the material employed were 65—100, 100—200, and 200—350 meshes.

A half-gram portion of each sample was immersed in 50 ml of a suitable solution (NaOH spiked with ^{22}Na, NaOH–NaCl with ^{22}Na, or $Sr(OH)_2$ with ^{89}Sr) in a tightly stoppered vessel for longer than two days at room temperature, with intermittent shaking. This was followed by chemical analysis and by the measurement of the radioactivity of the solution in a suitable aliquot.

Titration Curve. In 50 ml of a MOH or MOH–MCl solution (M=Na, K, Cs) of a suitable concentration (ionic strength: 0.10 or 1.0 M), 0.5 g of the sample was immersed for 2—3 days at room temperature, followed by the pH measurement and by the chemical analysis of the solution. When the ionic strength was 0.10 M, the amount of ion taken up by the exchanger was evaluated from the difference between the initial and the final concentrations of the ions present in the solution. In the case of the ionic strength of 1.0 M, the amount of uptake was estimated either from the decreased amount of the OH^- ion in the solution or from the weight increase in the exchanger. For the latter, the solid phase was weighed after it had been separated from the solution; it was then washed with acetone, air-dried, and humidiated over a desiccator containing a saturated NH_4Cl solution. This method is warranted by the results, to be described later.

Results and Discussion

Weight Change in the Exchanger with the Change in the Ionic Composition. The change in weight of the exchanger with that of the ionic composition was measured by directly weighing the exchanger before and after a suitable treatment which produced a desired ionic composition. The ionic composition was obtained from the difference in the alkali-metal-ion concentrations of the solution before and after treating the exchanger. The weight increment obtained by direct weighing is plotted in Fig. 1 against that calculated from the change in the ionic composition by assuming that only the difference in the weight of the ions exchanged affects the weight of the exchanger. If this assumption is valid, a straight line with a unit slope passing through the point of origin should be obtained (broken line in Fig. 1). For the sodium ion this relation hold except for the large amount of uptake and can be used for the determination of sodium ion in the exchanger, as has been decribed earlier. In the cases of potassium and cesium ions, the curves deviate appreciably from the broken line. This deviation can naturally be considered to be mainly due to the change in the water content in a hydrous oxide such as this. On the basis of this consideration, we can estimate the change in the water content of the exchanger from the data in Fig. 1.

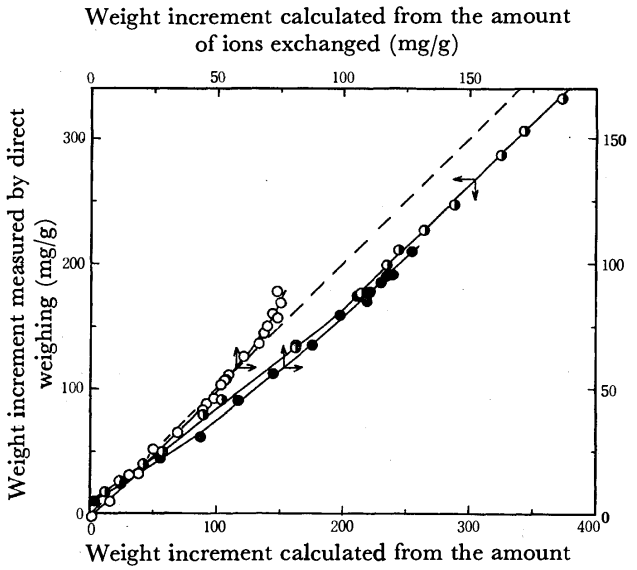

Fig. 1. Weight increase of the exchanger by ion exchange.
○: Na^+ 0.10M; ●: K^+ 0.10M; ◑: Cs^+ 0.10M.

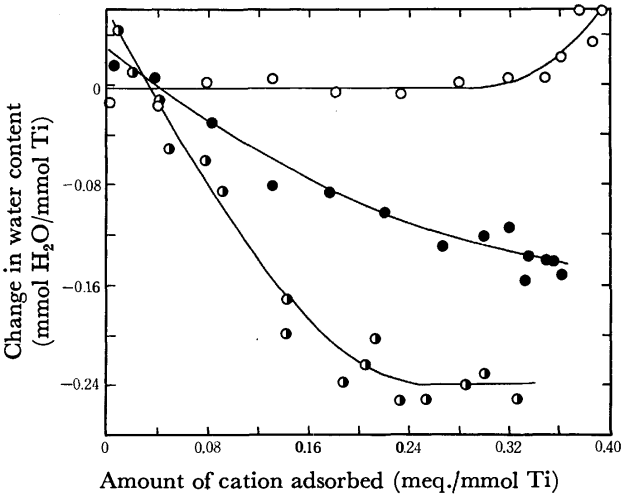

Fig. 2. Change in water content of the exchanger by cation exchange. Marks are the same as used in Fig. 1.

Figure 2 shows the change in the water content of the exchanger in mmol H_2O/mmol Ti against the amount of alkali metal ions taken up in meq./mmol Ti. The horizontal line observed in the case of the sodium ion leads to the conclusion that the exchange between sodium and hydrogen ions causes no change in the water content. The slight deviation from the line in the range of large amounts of sodium-ion uptake is probably due to the reaction with carbon dioxide in the atmosphere during the course of air-drying and humidiating. This explanation is supported by the observations to be described in the next section. Since the same phenomena should also be observed in potassium and cesium exchanges, the curves in Fig. 2 do not show the change in water content quantitatively, especially in the range of higher alkali contents, but the effect is not very large. Therefore, it is evident from Fig. 2 that the ion with the larger ionic radius—that is, with the weaker hydration power, can expel a larger amount of water in the exchanger.

Stoichiometry of the Exchange Reactions. Table 1 represents the experimental results concerning the stoichiometry of the exchange reaction on Samples A

a) γ-Counting. b) Titration. c) Experimental values. d) Corrected values.

and B For Sample A, the ratio of hydrogen ions released to the sodium ions adsorbed was 1.26 (an average of the data on the last column of the table) if we determine the sodium-ion concentration by Fajans' method. This value is somewhat greater than unity, which would be obtained if the ion-exchange stoichiometry holds. The blank Run No. 3 shows that, even in distilled water, some sodium carbonate is released. Assuming that the sodium carbonate comes entirely from the sample, and that the sodium carbonate in the sample completely dissolves in the solution, we may conclude that Sample A contains 0.23 meq. sodium ion/g as a carbonate. This value is also in good agreement with the increase in the carbonate-ion concentration in the sodium hydroxide solution during equilibration with the exchanger. Therefore, the sodium ions originating from the sodium carbonate in the sample can be estimated from the increment in the carbonate ions in solution. When such an amount of sodium ions is subtracted from that in the equilibrium solution, it is revealed that the equivalent exchange holds in each run, as is indicated by the corrected values in the same table.

On the other hand, an average of the ratios of the hydrogen ions released to the sodium ions adsorbed was 0.40, if we calculated the amount of sodium ions adsorbed simply from the difference between the initial and the final activities of the sodium-22 present in solution, assuming a constant specific activity throughout the experiment. This value contradicts the one mentioned above. This discrepancy can be understood by considering that Sample A is not in the pure hydrogen form, but partly in the sodium form.

Assuming that the sodium ion in the exchanger is present as sodium carbonate and fixed ions which are distributed uniformly, and that the specific activity of sodium-22 becomes constant throughout the system after the equilibrium is reached, we obtain the following

equations from the conservations of the sodium ion and radioactivity:

$$\bar{w}_i(m_i - Me/2000) + e + w_i V_i = \bar{w}_f m_f + w_f V_f \quad (1)$$

$$a_i V_i = a_f V_f + S\bar{w}_f m_f \quad (2)$$

$$S = a_i V_i / [\bar{w}_i(m_i - Me/2000) + e + w_i V_i] \quad (3)$$

where w represents the concentration of sodium ions in the liquid phase in meq.Na^+/ml; $\bar{w}$, the concentration of sodium ions fixed in the exchange site in meq.Na^+/g; V, the volume of the liquid phase in ml; m, the weight of the exchanger in g; a, the activity concentration in the solution in cpm/ml; e, the amount of sodium carbonate in the sample in meq.; M, the molecular weight of the sodium carbonate, and S, the specific activity of sodium-22 in cpm/meq.Na^+ after the equilibrium was reached. Furthermore, the i and f suffixes refer to the initial and the final states respectively.

TABLE 2. THE COMPARISON BETWEEN CALCULATED AND EXPERIMENTAL VALUES OF $\bar{w}_i$

Sample	Run	m_i (g)	$\bar{w}_i^{calcd}$ meq./g	$\bar{w}_i^{calcd}$ based on H^+ form	$\bar{w}_i^{exp}$ meq./g
A	1	0.5017	2.71±0.32	2.90±0.35	2.32
	2	0.4979	2.48±0.32	2.64±0.34	
B	1	0.4983	0.15±0.32	0.15±0.32	0.08
	2	0.5016	0.11±0.42	0.11±0.42	

Since the water content of the exchanger does not change in the exchange between sodium and hydrogen ions, as is shown in Fig. 1, $V_i = V_f = V$. Combining Eqs. (1)—(3), we obtain:

$$\bar{w}_i = 2000[(a_i w_f/a_f - w_i)V - e]/(2000 m_i - Me) \quad (4)$$

We can calculate $\bar{w}_i$ by substituting the data in Table 1 into Eq. (4). Table 2 shows the results, together with the values determined directly by chemical analysis. The average of these results, 2.60±0.32 meq.Na^+/g of Sample A, agrees with the analytical value, 2.32 meq.Na^+/g of Sample A, within the limits of experimental error. Accordingly, the isotopic-exchange equilibrium is reached in the exchanger. Furthermore, the average of $\bar{w}_i^{calcd}$ in terms of meq./g of the hydrogen form is 2.77±0.35, as is indicated in the next to the last column of the same table. It is nearly equal to the apparent capacity, 2.6 meq./g (Fig. 4), at pH 10.4, which corresponds to that of the filtrate in the final stage of synthesis. The amount of sodium ions adsorbed by Sample A is 1.18±0.06 meq./g, which corresponds to 1.23±0.06 meq./g of the hydrogen form. This value plus $\bar{w}_i^{calcd}$ is 4.00±0.41 meq./g, which agrees, within the limits of experimental error, with the ion-exchange capacity obtained with the 0.10 M sodium hydroxide solution. From these results, one can conclude that about 75% of the exchange sites are occupied by sodium ion in the stage of synthesis and that some sodium carbonate is also present. The sodium carbonate may be admixed in the stage of aging and/or during storage, when the sodium ions in the exchanger are expelled to form carbonate by means of the action of atmospheric carbon dioxide.

In Sample B, the ratio of hydrogen ions released to sodium ions adsorbed is 1.02±0.04, as is shown in the last column of Table 1. Therefore, the equivalent exchange is also valid for this sample. The one obtained by the radiometric method is also nearly unity, but it seems a little lower. The results of the blank Run No. 3 show that this sample does not contain carbonate. The sodium content, calculated from the data in Table 1 by means of Eq. (4), is 0.13±0.37 meq./g (Table 2), which agrees with the analytical value, 0.08 meq./g, within the limits of experimental error. The conclusion can be derived directly from these results that the treatment with the 0.1 M hydrochloric acid solution can remove carbonate and most of the sodium ions.

The amount of sodium ions adsorbed plus the $\bar{w}_i^{calcd}$ value obtained by the radiometric method, 2.43±0.42 meq./g of the hydrogen form, is smaller than the value on Samples C and D, about 3.5 meq./g. The reason for this discrepancy is not clear, but the treatment with 0.1 M hydrochloric acid solution alone is not sufficient to activate all the exchange sites and so is incomplete.

The results on Samples C and D were obtained by means of the radiometric method. Table 3 shows the equivalent exchange between sodium and hydrogen ions

which takes place in these samples. This relationship holds exactly, irrespective of the particle size, the ionic strength, and the kind of anion.

Table 4 shows that the same is also true when the strontium ion is used as the exchanging cation. Since the carbonate-ion concentration decreased in this run, the amount of hydrogen ions released was estimated from the difference in the sum of carbonate and hydroxide ions before and after the equilibration.

As the results presented above show, the pure-hydrogen-form exchanger can be obtained by treating the air-dried gel first with the 0.1 M hydrochloric acid solution and next with the 0.1 M sodium hydroxide solution, followed by the 0.1 M hydrochloric acid solution. It acts as an ideal cation exchanger, and an equivalent exchange of cations occurs on the exchange sites uniformly distributed in it.

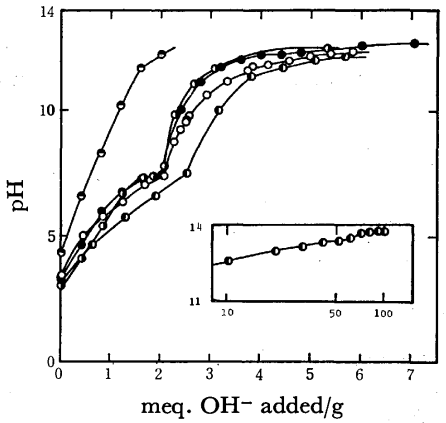

Fig. 3. Titration curves of the exchanger for various alkali metal ions. ◐: Na^+ 1.0M; ◓: K^+ (Ref. 6) 0.1M; ○: Na^+ 0.10M; ●: K^+ 0.10M; ◑: Cs^+ 0.10M.

Acid-base Properties. In order to study the acid-base property of the exchanger, titration curves were constructed by various alkali metal hydroxides, as is shown in Fig. 3. The features are not different from each other except in minor details. The curves obtained with a solution with an ionic strength of 0.10 M present a steep pH jump at pH 7.4. The curve for the potassium ion possesses a small flat portion at pH 12.2, whereas those for the other ions do not.

The titration curve with the sodium hydroxide-sodium chloride mixed solution with an ionic strength of 1.0M also shows a steep pH jump at pH 7.4 and another, less pronounced one at pH 13.5. From these observations, this exchanger can be inferred to possess four kinds of exchange sites.

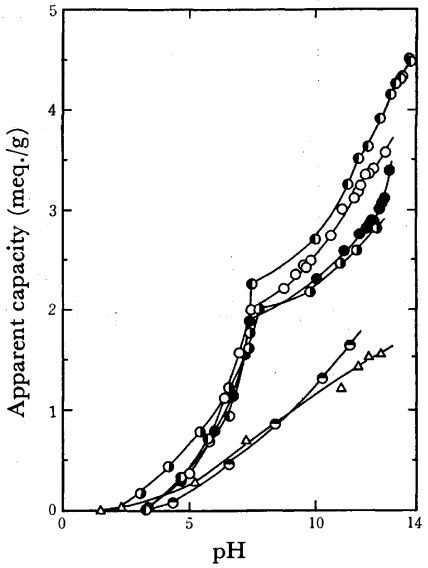

Fig. 4. Apparent capacity of the exchanger as a function of pH. △: Na^+ (Ref. 7); other marks are the same as those in Fig. 3.

The apparent exchange capacity is plotted as a function of the pH in Fig. 4. The curves are consistent with the titration curves, but show some features more clearly. Irrespective of the ionic strength and the kind of ion employed, the first inflecting point appears at pH 7.4, where the first pH jump is observed in the titration curves. While the point indicating the beginning of the participation of the third exchange site is not distinctly observed in the titration curves, it appears more clearly in the cases of the potassium and sodium ions for μ=0.10 at pH 12.2 and 12.0 and in the case of the sodium ion for μ=1.0 at pH 11.7 in Fig. 4. In the latter case, an additional jump in pH is observed at pH 13.5, where a corresponding discontinuity is also observed in Fig. 4.

Another interesting fact may well be noted here. The exchange rate shown in Fig. 5 indicates that the exchange of sodium ions occurs step by step. The amount of sodium ions taken up at the end of each step is nearly the same as the value observed at the inflection point of Fig. 4. This fact not only shows that the rate of exchange is faster in the more acidic site, but also strengthens the observation about the position of the inflection point mentioned above. It can be concluded from these facts that this exchanger possesses four kinds of exchange sites. This conclusion is quite different from the findings by other workers.[6,7] The hydrous titanium oxide prepared by them shows an apparent exchange capacity of about 1.6 meq./g at

pH 12, and up to this pH the inflection point is not observed. This difference is probably attributable to the difference in their synthetic method from the present authors'.

The apparent pK values can be calculated by applying the following equation[8] to the titration curve (Fig. 3) and to the dependency of the apparent capacity on the pH (Fig. 4):

$$pK_i = pH_i + \log (M^+)_i - \log (\bar{X})_i/2$$

where $(M^+)_i$ and pH_i are the alkali-metal-ion concentration and the pH at the half-conversion point of the i-th exchange site respectively. The results are presented in Table 5, together with the results reported by Schiewer.[4] It can be concluded from the table that all the functional groups in the exchanger are weakly acidic. Since the experimental conditions used by Schiewer are appreciably different from ours, we cannot compare the results strictly, but, interestingly enough, the pK_1 value of this exchanger is almost the same as that of Schiewer, 5.7. However, the pK_2 and pK_3 values are completely different from those of Schiewer. This discrepancy may arise from the difference in structure; that is, Schiewer employed a hydrous titanium oxide suspension as an exchanger, whereas the present authors used an exchanger possessing a hard, three-dimensional network.

(Received July 18, 1975)

The structure of the trinuclear complex, formed from *N,N*-diethyl-*N'*-(3-hydroxypropyl)ethylenediamine and copper(II) perchlorate, has been determined from three dimensional X-ray diffraction data. The crystals are monoclinic with the space group $P2_1/c$. The cell dimensions are $a=7.759(6)$, $b=13.21(1)$, $c=15.00(1)$ Å and $\beta=103.95(6)°$. The unit cell contains two molecules and the molecule has a centre of symmetry. The structure has been determined by the heavy atom method and refined by the block diagonal least squares method to give $R=6.83\%$ for 1368 observed reflections. Three copper atoms are arrayed on a straight line, the separations being 2.902 Å. The geometry around the two end copper atoms is best described as a slightly distorted tetragonal pyramid. The central copper atom has a square planar environment.

In the previous paper Nishida and Kida[1] reported the preparation of the binuclear (green) and the trinuclear (blue) copper(II) complexes from *N,N*-dialkyl-*N'*-(3-hydroxypropyl)ethylenediamine, $R_2N(CH_2)_2NH(CH_2)_3OH$ ($R=CH_3$, C_2H_5), copper(II) perchlorate and sodium hydroxide.

When the ligand, copper(II) perchlorate and sodium hydroxide were mixed with the mole ratio 1:1.2:1, green crystals were obtained. This complex was assumed to be binuclear on the bases of the elemental analysis and the magnetic susceptibility measurements over the temperature range 80—300 K. This was verified from the single crystal X-ray diffraction method by Villa *et al.*[2]

On the other hand, when the ligand, copper(II) perchlorate and sodium hydroxide were mixed with the mole ratio 1:2:1, blue crystals were obtained, which were assumed to be of a linear trinuclear structure on the bases of the elemental analysis and the magnetic susceptibility measurements (80—300 K). In the present work a single crystal X-ray diffraction study has been carried out for this compound in order to confirm the above assumption. The detailed structural data are desirable for the elucidation of magnetisms and electronic spectra of the alkoxo-bridged copper(II) complexes.

Experimental

The complex was prepared according to Ref. 1. Single crystals of the complex for the X-ray work were obtained as violet blue needles by slow evaporation of 99% methanol solution at room temperature. For cell parameter determination and intensity measurement an approximately cubic crystal of dimension 0.2 mm was prepared by cutting a larger specimen. The cell parameters were determined from fifteen reflections measured on Syntex $P\bar{1}$ diffractometer by the autoindexing and least squares programs.

The Crystal Data: $Cu_3Cl_2O_{12}N_4C_{18}H_{44}$, formula weight 770.1, monoclinic, space group $P2_1/c$, $a=7.759(6)$, $b=13.21(1)$, $c=15.00(1)$ Å, $\beta=103.95(6)°$, $V=1493.03$ Å^3, $Z=2$, $D_m=1.704$ g·cm^{-3} (by floatation), $D_x=1.712$ g·cm^{-3}, μ(Mo $K\alpha$)$=23.90$ cm^{-1}. Three dimensional intensity data were collected by the θ—2θ scan technique with a variable scan rate from 4.0 to 24.0°/min on a Syntex $P\bar{1}$ four-circle diffractometer using Mo$K\alpha$ radiation monochromated by a graphite plate. Three reflections were monitored after every measurement of 47 reflections, and the monitored data showed good stability. Of the 2650 reflections recorded, 1368 had intensities greater than 2.33 times their estimated standard deviations, and only these unique reflections were used for the structure determination. The data were corrected for Lorentz and polarization effects. Correction for absorption was not applied.

Determination and Refinement of Structure

In the space group $P2_1/c$, the general positions are fourfold. In this crystal, there are only two molecules in a unit cell and each molecule includes three copper atoms. Therefore, each molecule has a center of symmetry, which corresponds to the special position 0, 0, 0 or 0, 1/2, 1/2, and the central copper atom of each molecule is required to be in this special position.

The structure was solved by the heavy atom method. The coordinates of the copper atoms could be easily determined from the three-dimensional Patterson synthesis. The position of the chlorine atom was deduced from the minimum function based on the copper atoms. A three dimensional electron density map was then calculated with all observed reflections phased by the copper and chlorine atoms. The resulting map showed the peaks corresponding to all the remaining non-hydrogen atoms except two oxygen atoms in perchlorate anion. The atomic positions and isotropic temperature factors were refined by the block diagonal least squares method. Further refinement was carried out, introducing anisotropic temperature factors, and the disagreement factor decreased to 11.67%. At this step a difference Fourier synthesis was calculated. The difference Fourier map showed three diffuse peaks, though only two peaks of the two oxygen atoms in perchlorate ion were expected. Accordingly, the occupancy factors of the oxygen atoms were assigned in proportion to the peak values, as shown in Table 1. Six cycles of the block diagonal least squares refinement were applied to the positional and anisotropic thermal parameters of all the non-hydrogen atoms. The disagreement factor was decreased from 8.96 to 7.69% for the observed 1368 reflections. At this stage a difference Fourier synthesis was calculated and the positions of about half of the hydrogen atoms could be determined. The positions of the remaining hydrogen atoms were assigned from the calculation. Introducing these hydrogen atoms, the final set of the least squares calculation was carried out.

The final disagreement factor was 6.83% for the observed 1368 reflections.** Maximum shifts of the positional and thermal parameters in the final cycle did not exceed half their standard deviations. In the least squares procedure, the quantity minimized was $\sum w(k|F_o|-|F_c|)^2$, where k is a scale factor and $w=1$ for $|F_o|\geqq 5.0$ and $w=0$ for $|F_o|<5.0$. The scattering factors for all the atoms were taken from the literature.[3] The final positional and thermal parameters are shown in Tables 1, 2 and 3.

* The observed and calculated structure factors are available at the office of this Bulletin as Document No. 7604.

Description and Discussion of the Structure

A perspective drawing of the complex and the numbering system used in this text are illustrated in Fig. 1. The bond distances and the bond angles within a molecule are listed in Tables 4 and 5.

Three copper atoms are arrayed on a straight line, the separations being 2.902(1) Å. This arrangement has been expected from the magnetic susceptibility measurements over the temperature range 80—300 K.[1] The geometry around the two end copper atoms is best described as a slightly distorted tetragonal pyramid. One of the axial coordination site is occupied by an oxygen atom of perchlorate ion. The bond distance, Cu(2)–O(3), is 2.63(1) Å. The central copper atom has a square planar environment. The Cu–Cu distance (2.902(1) Å), the Cu–O distances (1.904(7)—1.922(7) Å) and the bridging Cu–O–Cu angles(98.6(3), 99.1(3)°) are very close to the corresponding values (2.953(3) Å, 1.915(6)—1.953(6) Å, 99.3(2)° and 99.5(2)°) in the green binuclear complex with the same ligand,[2] and are within the range of ones found in other di-μ-alkoxo copper(II) and di-μ-hydroxo copper(II) complexes.[4-9] The Cu(2)–N(2) distance(2.059(9) Å) is longer than the Cu(2)–N(1) distance(1.977(9) Å), such a tendency was also observed in the green binuclear complex.[2] The C–N, C–O and C–C bond distances of the chelate ring are also similar to those of the green binuclear

x, y, and z denote atomic fractional coordinates.

complex.[2] The ethyl C(8)–C(9) bond length is a little shorter than the normal C–C bond length, and may be explained in terms of heavy thermal motion of C(9) atom. It is noteworthy that a second oxygen atom O(4) of perchlorate ion appears to be in proximity of the axial coordination site of the central copper atom, although the Cu(1)–O(4) separation of 3.13(1) Å is too large for any bonding to be assumed. The positions of oxygens of perchlorate ion were not determined unequivocally and the geometry of the perchlorate ion is different from that of tetrahedron. This may be due to the disorder and the hindered rotation. We attempted to interpret the disorder and the hindered rotation of the perchlorate ion, but no satisfactory interpretation was obtained.

Some least squares planes are given in Table 6, together with the distances of the individual atoms from these planes. The basal plane of pyramidal unit, consisting of Cu(1), O(1), O(2), N(1), N(2), is essentially planar, the deviation of Cu(2) being 0.08 Å in the direction of the axial site. The dihedral angle between the planes passing through Cu(1), O(1), O(2) and Cu(2), O(1), O(2) is 3.5°. The five membered chelate ring has an unsymmetrical skew conformation and C(1) and C(2) are at 0.61 Å and −0.02 Å respectively from the plane through Cu(2), N(1) and N(2). The six membered chelate ring has a chair conformation and Cu(2) and C(4) are at 0.58 Å and −0.68 Å respectively from the plane through N(1), O(2), C(3) and C(5).

Analytical Application of Catalytic Polarographic Current of Nickel(II) in Acidified Thiocyanate Solutions Containing Cobalt(II)

Eiki ITABASHI and Ikuko YUSA
Miyagi University of Education, Aoba, Aramaki, Sendai 980
(Received June 6, 1975)

Simple and sensitive methods have been developed for the determination of nickel(II), based on the catalytic polarographic current in acidic thiocyanate solution in the presence and absence of cobalt(II). The basis of the methods and the effect of variables have been investigated and elucidated. In the absence of cobalt(II), thiocyanate solution containing large amounts of hydrogen ions serves a supporting electrolyte, while an acidic thiocyanate solution containing tetra-*n*-butylammonium salts is suitable for the determination of nickel(II) in the presence of cobalt(II). These methods are applicable to the determination 2×10^{-6} M nickel(II) in the presence and absence of 1×10^{-3} M cobalt(II).

Polarographic as well as anodic stripping methods have been applied for the analysis of nickel(II). It has been found that pyridine is a good supporting electrolyte for the polarographic simultaneous determination of nickel(II) and cobalt(II). Thiocyanate electrolyte serves a good supporting electrolyte when only nickel(II) is to be determined in neutral solution.[1,2] The anodic stripping method has been applied by employing sodium thiocyanate as a supporting electrolyte;[3] however, thiocyanate electrolyte is not suitable for the anodic stripping analysis of nickel, because during the reduction of nickel(II) at both mercury and platinum electrodes the reduction of thiocyanate ions takes place with the formation of sulfides and cyanides.[4-7]

The polarographic reduction of nickel(II) in acidified thiocyanate solution in the presence and absence of tetraalkylammonium salts has previously been reported to exhibit a catalytic wave having the shape of a "maximum".[8] The mechanism of this catalytic wave was thought to involve the cyclic regeneration of the electroactive nickel(II) according to the following reaction sequence:[5,8]

$$NiNCS^{+}_{ads} + 2e \xrightarrow{\text{fast}} Ni(0)NCS^{-}$$

$$Ni(0)NCS^{-} + 3H^{+} \xrightarrow{\text{slow}} Ni^{2+} + HCN + H_2S$$

The cyclic regeneration of nickel(II) accounts for the enhancement of the limiting current. Hydrogen ions act as a neutralizing agent of the reduction products of thiocyanate ion, cyanide and sulfide ions. This catalytic wave is usually sensitive and selective. This immediately suggests the use of the present catalytic wave to determine the concentration of nickel(II). Previously polarographic catalytic current based on the oxidation-reduction,[9,10] dispropotionation,[11] hydrogen reduction wave,[12,13] and pre-wave[14,15] have been employed successfully for the determination of metal ions and nitrogen- or sulfur-containing organic compounds. The present paper reports on some analytical applications utilizing the catalytic current of nickel(II) in the presence and absence of cobalt(II).

Experimental

Chemicals. Nickel(II) perchlorate[16] and cobalt(II) perchlorate[17] were prepared and recrystallized using the procedures given in literatures. Tetra-*n*-butylammonium perchlorate(*n*-Bu_4NClO_4) was prepared by neutralizing a 40% tetra-*n*-butylammonium hydroxide solution with perchloric acid and recrystallized several times from ethyl alcohol, and then dried in a vacuum oven at 80 °C for 20 h. Extra pure grade sodium thiocyanate and perchloric acid were used. All the other chemicals were of chemical grade without further purification. Redistilled water was used and all solutions were deaerated with high-purity nitrogen.

Instrumentation and Electrode Assembly. Direct current (DC) polarographic experiments were carried out with a potentiostat constructed locally with operational amplifiers.[18] Polarograms were recorded with a X-Y recorder.

Two capillaries were used throughout this work. The rate of flow of mercury (m) and the drop time (t) of capillary I were 1.49_6 mg/s and 5.42 s, respectively, measured in deaerated 0.5 M NaCl solution under an applied pressure of 55 cm at −0.65 V *vs.* SCE. Capillary II had the characteristics $m=1.33_1$ mg/s and $t=4.95$ s, in deaerated 0.5 M $NaNO_3$ solution under an applied pressure of 40 cm at −0.56 V *vs.* SCE. Capillaries I and II were employed for the experiments of methods I and II, respectively.

The counter electrode was a platinum spiral electrode which was connected to the electrolytic solution through a glass sinter. The potential of the DME was measured against a saturated calomel electrode (SCE) which was connected to the test solution through a Luggin capillary with a pair of sintered glass discs.

Procedure for the Determination of Nickel(II) in the Presence of Cobalt(II). Because *n*-Bu_4NClO_4 is slightly soluble in water, the electrolytic solutions are usually prepared as follows Into a 25 ml volumetric flask, add 68 mg (8 mM) or 85 mg (10 mM) of *n*-Bu_4NClO_4, and then pour in 10 ml of 2.5 M NaSCN solution. Dissolve *n*-Bu_4NClO_4 in thiocyanate solution by shaking gently. After dissolution of *n*-Bu_4NClO_4 in thiocyanate solution, add perchloric acid and nickel (II) or cobalt(II) solution containing nickel(II), and dilute to 25 ml with distilled water and mix well. Prior separation of the precipitate of $(n\text{-}Bu_4N)_2[Co(NCS)_4]$ is used when the solution contains more than 2×10^{-4} M cobalt(II). Pour the solution into a 100 ml centrifuge tube and then centrifuge for 30 min at 3500 rpm. Transfer the solution into the cell and then analyze the solution by the conventional DC polarographic method.

Treatment of Data. The catalytic wave of nickel(II) in acidic thiocyanate solution appears as a maximum wave. The value of peak current denoted as i_p is measured at the peak potential of the maximum wave. All values are corrected for the residual current or for the limiting current caused to the reduction of metal ions such as iron(III) and copper(II), which are reduced at potentials less negative than nickel(II). The latter way can be done by extrapolation of the linear flat

portion of the limiting current before the maximum wave rises. The concentration of nickel(II) is evaluated with reference to a suitably prepared calibration curve.

Results and Discussion

In the Absence of Cobalt(II) [*Method I*]. Figure 1 shows the DC polarogram obtained in 0.5 M thiocyanate solution containing 2×10^{-5} M nickel(II) and 0.14 M $HClO_4$. Nickel(II) in acidic thiocyanate solution gives a peak current rather a limiting plateau. This peak occurs at about −0.82 V *vs.* SCE. The rise in current at potentials more negative than −1.0 V is attributed to the direct reduction of hydrogen ions. In the absence of nickel(II), hydrogen ions in 0.5 M thiocyanate solution containing 0.14 M $HClO_4$ are reduced at potentials more negative than about −0.87 V.

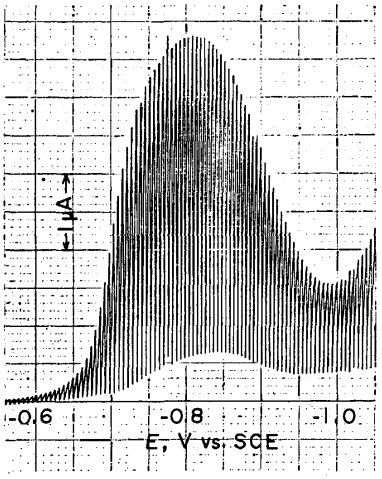

Fig. 1. Reduction wave of 2×10^{-5} M nickel(II) in 0.14 M $HClO_4$ and 0.5 M NaSCN.

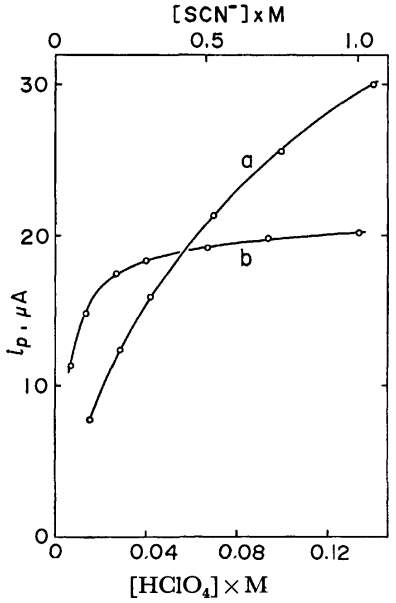

Fig. 2. Effect of concentrations of $HClO_4$ (a) in 0.5 M NaSCN, and NaSCN (b) in 0.056 M $HClO_4$ on the peak current of 1×10^{-4} M nickel(II).

The effect of the concentrations of thiocyanate and hydrogen ions on the peak current was studied to determine its applicability as a method for determing small amounts of nickel(II) polarographically. Figure 2 presents the relationships between the peak current and the concentrations of thiocyanate and hydrogen ions. The peak current increases in height with increase in hydrogen ion concentration. With further addition of $HClO_4$ above 0.2 M, the maximum wave appears as a shoulder on the hydrogen reduction wave. The concentrations 0.14 M in $HClO_4$ and 0.5 M in NaSCN have been selected for further experiments.

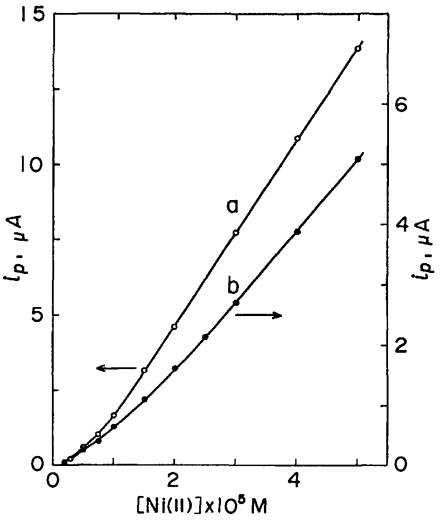

Fig. 3. Plots of i_p *vs.* nickel(II) concentration in 0.5 M NaSCN solution containing 0.14 M $HClO_4$ (a), and in 1.0 M NaSCN solution containing 7×10^{-3} M $HClO_4$ and 8×10^{-3} M *n*-Bu_4NClO_4 (b).

The height of the peak current as a function of the nickel(II) concentration is shown by curve a of Fig. 3. Two distinct portions are present on the curve. The first part at which the rise in the peak current with nickel(II) concentration is greater than linear extends from 2×10^{-6} to 1.5×10^{-5} M. The second portion at which the peak current is proportional to the nickel(II) concentration is observed in the concentration range from 2×10^{-5} to 1×10^{-4} M. This inflection on the calibration curve could indicate that the mechanism of the catalytic wave involves the sequence of reactions and a rate-determing step of the overall process changes over a wide range of nickel(II) concentration. The present method is suited for the determination of 2×10^{-6} to 1×10^{-4} M nickel(II) in the absence of cobalt(II).

In the Presence of Cobalt(II) [*Method II*]. With analysis of mixures, interference is always a possibility with any technique. The effect of cobalt(II) on the catalytic maximum wave of nickel(II) in acidic thiocyanate solution is presented in Fig. 4. These polarograms are drawn as the line through the maximum current observed just before the fall of a mercury drop. The peak height decreases with increase in cobalt(II) concentration. This may be due to the adsorption of

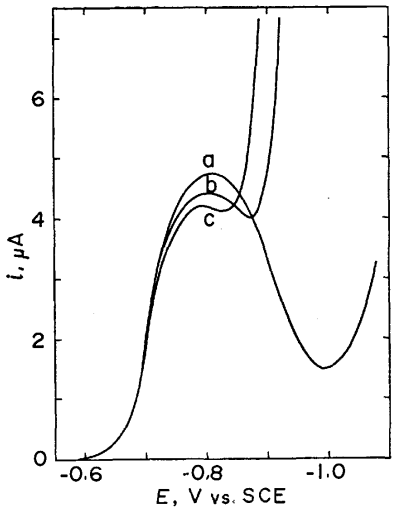

Fig. 4. Effect of cobalt(II) on the reduction waves of 2×10^{-5} M nickel(II) in 0.14 M $HClO_4$ and 0.5 M NaSCN.
[Co(II)]: a) 0, b) 2×10^{-4}, c) 5×10^{-4} M.

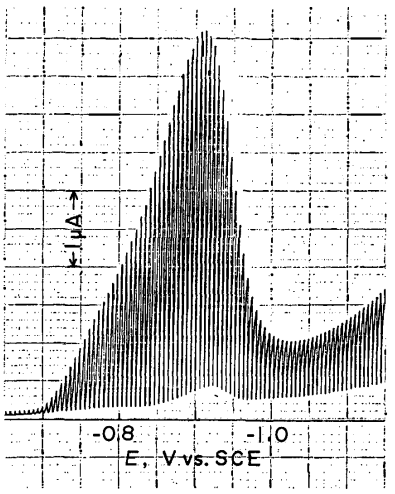

Fig. 5. Reduction wave of 5×10^{-5} M nickel(II) in 7×10^{-3} M $HClO_4$, 8×10^{-3} M n-Bu_4NClO_4 and 1.0 M NaSCN.

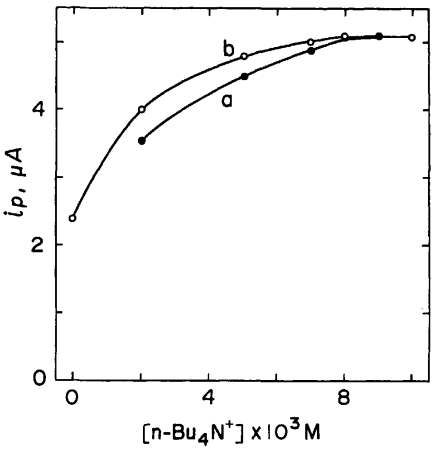

Fig. 6. Effect of concentration of n-Bu_4NClO_4 on the peak current of 5×10^{-5} M nickel(II) in 7×10^{-3} M $HClO_4$ and 1.0 M NaSCN solutions in the presence (a) and absence (b) of 5×10^{-4} M cobalt(II).

cobalt(II)-thiocyanate complexes. Cobalt(II) in thiocyanate solution containing perchloric acid or acetate buffer also exhibits a catalytic maximum wave.[19] This catalytic wave appears in the potential region where cobalt(II) exhibits a pre-wave which arises at less negative potentials than those for the usual hydrated cobalt(II) reduction wave. The catalytic current of cobalt(II) in acidic thiocyanate solution has a mixed adsorption-surface character.[19] If nickel(II)- and cobalt(II)-thiocyanate complexes are coadsorbed at the same potential region, the catalytic current of nickel(II) decreases because of decreasing adsorption of nickel(II)-thiocyanate complexes and hence of decreasing concentration of the active metallic nickel at the electrode surface.

It is therefore necessary to separate cobalt(II) from the solution containing nickel(II). Cobalt(II) in thiocyanate solution containing large cations such as tetraalkylammonium or tetraphenylarsonium ions yields the precipitate having the composition of $(Cat)_2[Co(NCS)_4]$, where Cat^+ is tetra-alkylammonium or -phenylarsonium ion.[20-22]

Of the many tetraalkylammonium salts investigated, n-Bu_4NClO_4 was the most suitable for the separation of cobalt(II) from the thiocyanate solution containing nickel(II).

The catalytic reaction of nickel(II) in acidic thiocyanate solution is also enhanced by the presence of various kinds of tetraalkylammonium ions.[5,8] Figure 5 shows the reduction wave of nickel(II) in acidic thiocyanate solution containing n-Bu_4NClO_4. The values of peak current of 5×10^{-5} M nickel(II) in 7×10^{-3} M $HClO_4$ and 1.0 M NaSCN solutions in the presence and absence of 8×10^{-3} M n-Bu_4NClO_4 are 5.02 and 2.45 μA, respectively.

Acceleration of the catalytic reaction of nickel(II) by the presence of n-Bu_4N^+ ions could be the result of the inhibition of the amalgamation of electrodeposited metallic nickel. The amalgamation of the deposited iron-group metals is known to be inhibited by the presence of some surface-active substances.[23-25]

The effect of concentration of n-Bu_4NClO_4 on the peak height of the catalytic wave of nickel(II) in the presence and absence of cobalt(II) is shown in Fig. 6. The peak current reaches a limiting value as the concentration of n-Bu_4NClO_4 increases. The difference between the peak currents in the presence and absence of cobalt(II) at lower concentrations of n-Bu_4NClO_4 is associated with a decrease in concentration of n-Bu_4N^+ ions in the bulk of solution.

Tetra-n-butylammonium ions in thiocyanate solution containing cobalt(II) are partially consumed for the precipitation of cobalt(II)-thiocyanate complex in the form of $(n\text{-}Bu_4N)_2[Co(NCS)_4]$. The peak current of nickel(II) in thiocyanate solution containing 8×10^{-3} M n-Bu_4NClO_4 remains unchanged with further addition of $HClO_4$ above 5×10^{-3} M, as shown in Fig. 7. Figure 8 presents the dependence of the peak current on the thiocyanate concentration. With further addition of NaSCN above 1.0 M, the peak current reaches a limiting value.

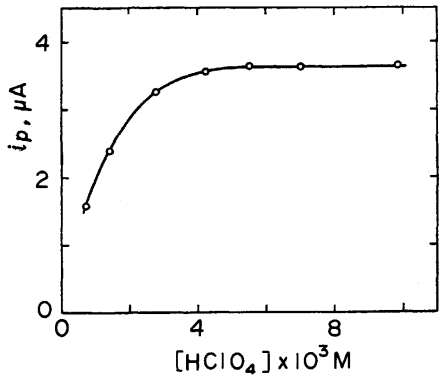

Fig. 7. Effect of concentration of $HClO_4$ on the peak current of 5×10^{-5} M nickel(II) in 8×10^{-3} M n-Bu_4NClO_4 and 0.5 M NaSCN.

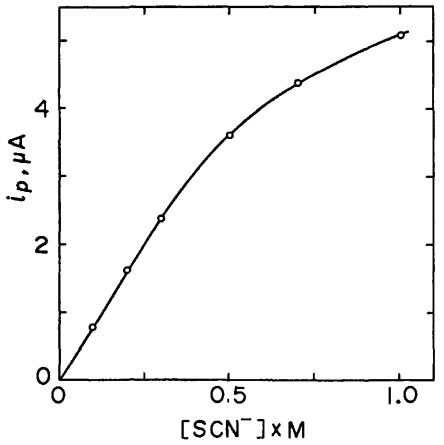

Fig. 8. Effect of thiocyanate concentration on the peak current of 5×10^{-5} M nickel(II) in 7×10^{-3} M $HClO_4$ and 8×10^{-3} M n-Bu_4NClO_4.

As a result of the experiments described above, it is possible to select the conditions and established a procedure for the determination of nickel(II) in the presence of cobalt(II). The experiments were performed with the solutions containing 7×10^{-3} M $HClO_4$, 8×10^{-3} M n-Bu_4NClO_4 and 1.0 M NaSCN. Over the entire range of nickel(II) between 2×10^{-6} and 2×10^{-4} M, the maximum waves were similar to that shown in Fig. 5. The present method has also two distinct portions on the calibration curve, as shown by curve b of Fig. 3. The first part at which the curve is a non-linear extends from 2×10^{-6} to 2×10^{-5} M nickel(II), and the second part at which the curve is a linear is observed in the nickel(II) concentration between 2.5×10^{-5} and 2×10^{-4} M. The quantity of nickel(II) in the presence of cobalt(II) was estimated from the calibration curve. Data compiled in Table 1 verify that in the presence of large excess of cobalt(II) nickel-(II) can be accurately determined within expected polarographic precision. When the solution contains 1×10^{-3} M cobalt(II) and nickel(II) of 2×10^{-5} M or greater, it is desirable to employ 10×10^{-3} M n-Bu_4NClO_4 instead of 8×10^{-3} M. With 1×10^{-3} M cobalt-(II) present, approximately 2×10^{-3} M n-Bu_4N^+ ions are consumed for the precipitation reaction of cobalt(II)-thiocyanate compound in the bulk of solution.

Table 1. Analysis of nickel(II)[a]

[n-Bu_4NClO_4] M×10^3	[Co(II)] M×10^3	[Ni(II)], Taken	M×10^6 Found[b]	Derivation M×10^6

8	0.5	5.0	5.1	−0.3—+0.1
8	1.0	20.0	19.8	−0.5—+0.4
10	1.0	20.0	19.8	−0.3—+0.2
8	0.5	50.0	49.3	−1.2—−0.7
10	0.5	50.0	50.2	−0.4—+0.5

a) Solution contains 7×10^{-3} M $HClO_4$ and 1.0 M NaSCN. b) Average of four replicate determinations on the different solutions.

Effect of Foreign Ions. Methods I and II described in this paper offer higher sensitivity than those being available in the literature.[2] Both methods were applied in a variety of situations to evaluate their effectiveness by employing the solutions containing 2×10^{-5} M nickel(II) and foreign ions.

In method I, the presence of 2×10^{-4} M aluminum-(III), iron(III), zinc(II), and lead(II) is tolerated. An error of 3% or greater occurs with these foreign ions of 5×10^{-4} M present. Chromium(III), copper(II) and cadmium(II) interfere in method I. Chromium(III) reduces the height of the peak current of nickel(II). An acidic thiocyanate solution containing nickel(II) and cadmium(II) gives a single round maximum wave in the potential region between −0.6 and −1.0 V. Copper(II) in acidic thiocyanate solution exhibits an ill-defined reduction wave. Halide, nitrate, sulfate, and oxalate ions are tolerated up to approximately 0.01 M.

In method II, chromium(III) and aluminum(III) are tolerated. Iron(III), copper(II), zinc(II), cadmium-(II), and lead(II) are precipitated in thiocyanate solution containing n-Bu_4N^+ ions. Copper(II), cadmium(II), and zinc(II) are tolerated at low concentration than 2×10^{-4} M. Iron(III) and lead(II) are tolerated up to 5×10^{-5} M. Anions such as bromide, iodide, sulfate, nitrate, and oxalate ions which are in part associated with n-Bu_4N^+ ions are tolerated up to 5×10^{-3} M.

In conclusion, method II is more sensitive than method I. Method II is applicable for the routine analysis of nickel(II) in various cobalt compounds by employing the calibration curve prepared carefully, although the calibration curve is a non-linear.

The authors thank the Ministry of Education for the financial support.

The Crystal Structure of 1-(2-Thiazolylazo)-2-naphtholato-diaquacopper(II) Perchlorate

Masayasu KURAHASHI and Akira KAWASE*

National Research Institute for Metals, 2-3-12, Nakameguro, Meguro-ku, Tokyo 153

(Received July 22, 1975)

The crystal structure of 1-(2-thiazolylazo)-2-naphtholatodiaquacopper(II) perchlorate, $[Cu^{II}(TAN)(H_2O)_2]ClO_4$, has been determined from three-dimensional X-ray data collected by counter methods. The crystals are monoclinic, with the space group $P2_1/c$; $a=13.481(4)$, $b=8.060(4)$, $c=15.307(7)$ Å, $\beta=95.58(4)°$, and $Z=4$. The structure was refined to an R value of 0.086 for 952 non-zero reflections. The copper atom is five-coordinated and has a distorted square-pyramidal environment. The 1-(2-thiazolylazo)-2-naphtholato group (TAN) acts as a terdentate ligand, the phenolic oxygen, the azo nitrogen and the thiazole nitrogen atoms being coordinated to the copper atom to give two five-membered chelate rings. The remaining two positions are occupied by water molecules.

This work is part of a series of studies of the structures of metal chelates of 1-(2-thiazolylazo)-2-naphthol (abbr. as H-TAN). Recently, one of the present authors (M.K.) reported the structures of the Pd(II)-[1] and Ni(II)-chelates[2] and showed that the coordination configurations around the metals are square-planar and octahedral respectively (Fig. 1a and 1b). In both complexes, the 1-(2-thiazolylazo)-2-naphtholato group (abbr. as TAN) is exactly or nearly planar and acts as a terdentate ligand to form two five-membered chelate rings with the metal atom. It can easily be understood that a planar terdentate ligand like TAN can further form a five-coordinated square-pyramidal or trigonal-bipyramidal structure with a metal and two additional unidentate ligands (Fig. 1c and 1d). However, it is impossible for the TAN to give a tetrahedral coordination around the metal (Fig. 1e). In this paper, we will describe the structure of the five-coordinated Cu(II)–TAN complex, in which the copper atom has a square-pyramidal environment. A preliminary account of this work has already been given.[3]

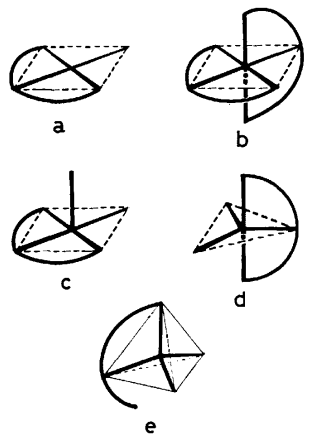

Fig. 1. Coordination of a planar terdentate ligand to the metal. The planar terdentate ligand can coordinate to the metal with (a) square-planar, (b) octahedral, (c) square-pyramidal, and (d) trigonal-bipyramidal environment; however, it is impossible to form a metal-complex with (e) tetrahedral environment.

* Present address: National Chemical Laboratory for Industry, 5-5, 1-Chome, Honmachi, Shibuya-ku, Tokyo, 151

The reaction of Cu(II) with H-TAN gives 1:1 as well as 1:2 Cu(II)–TAN chelates.[4] Furthermore, in view of the structures reported for the Cu(II)–complexes with analogous ligands,[5-7] it was thought that there probably exist various types of 1:1 Cu(II)–TAN complexes with the chemical formulae $[Cu^{II}(TAN)X]$, $[Cu^{II}(TAN)X_2]$, and $[Cu^{II}(TAN)XY]$, where X and Y are unidentate ligands. Accordingly, several attempts were made to produce the complexes using different reactants, different solvents, and different ratios of the reactants. Three crystalline forms (orthorhombic, monoclinic, and triclinic) of 1:1 Cu(II)–TAN complexes were obtained from the different solvents. The present study will deal with the structure of the monoclinic form, the crystallinity of which was comparatively better than the other two. An attempt to crystallize the complex with the composition of $[Cu^{II}Cl(TAN)]$, insoluble either in water or in most organic solvents, has been unsuccessful.

Experimental

An aqueous solution of $Cu^{II}(ClO_4)_2\cdot 6H_2O$ and a dioxane solution of H-TAN were mixed in an approximate molar ratio of 1:1. Blue needle crystals of $[Cu^{II}(TAN)(H_2O)_2]ClO_4$, elongated along the b-axis, were obtained by slow evaporation. The crystal used for the X-ray diffraction study had the dimensions of $0.1\times0.1\times0.25$ mm. The crystal data are listed in Table 1. The unit-cell dimensions were initially determined by Weissenberg photographs taken with Cu$K\alpha$ radiation; they were refined by the least-squares method, using 9 reflections

Table 1. Crystal data

$[Cu(C_{13}H_8N_3OS)(H_2O)_2]ClO_4$

measured by a diffractometer with Mo$K\alpha$ radiation. The density was measured by flotation in an aqueous solution of sodium iodide.

The intensity data were collected on a Rigaku automated four-circle diffractometer, using Mo$K\alpha$ radiation monochromatized with a graphite crystal. The ω-2θ scan technique was employed at a scan rate of 4°/min. The background countings were taken on both sides of each peak for 10 s. If the value of $\sigma(F)/F$ was larger than 0.03, the measurement was repeated and the average value was adopted. All unique reciprocal lattice points with $2\theta \leq 45°$ were examined; 953 reflections with $F > 3\sigma(F)$ were regarded as observed. The measured intensities were corrected for the Lorentz and polarization factors, but no corrections were made for absorption and extinction.

Anisotropic temperature factors ($\times 10^4$)[b)]

Atom	B_{11}	B_{22}	B_{33}	B_{12}	B_{13}	B_{23}
Cu	38(1)	112(6)	25(6)	26(6)	4(2)	9(5)
S	79(5)	227(16)	37(3)	3(16)	28(6)	−34(13)
Cl	59(4)	157(13)	53(3)	19(13)	25(6)	1(11)

a) E.s.d.'s in parentheses are in units of least significant digit. b) The anisotropic temperature factors are of the form:
$\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$

Structure Determination and Refinement

The structure was solved by the heavy-atom method. The positions of the copper and sulfur atoms were deduced from a three-dimensional Patterson map. From the Fourier synthesis phased on the heavy atoms only, the positions of all the non-hydrogen atoms could be found. Block-diagonal least-squares refinement using isotropic temperature factors for all the non-hydrogen atoms reduced R $(=\sum||F_o|-|F_c||/\sum|F_o|)$ to 0.105. A further three cycles of refinement with anisotropic thermal parameters for the copper, sulfur, and chlorine atoms improved R to 0.095. At this stage a difference synthesis was carried out and several hydrogen positions were revealed; however, a few ghost peaks as large as the hydrogen peaks appeared. Accordingly, the hydrogen positions of the ring systems were evaluated by assuming sp^2 hybrid bonds around the relevant carbon atoms and a C–H distance of 1.08 Å; these positions were included but not refined in the final least-squares cycles. The isotropic thermal parameter of 4.0 Å^2 was assigned to the hydrogen atoms. Convergence was reached at $R=0.086$ for all the 952 observed reflections. A unit weight was given to each reflection. The atomic scattering factors were taken from International Tables for X-ray Crystallography, Vol III.[8)] The final atomic parameters and their estimated standard deviations are listed in Table 2. The observed and calculated structure factors are given in Table 3.**

Description of the Structure and Discussion

Perspective drawings of the complex cation and perchlorate anion are shown in Fig. 2, along with the numbering of the atoms. The complex cation is composed of Cu, TAN, and $2H_2O$. The TAN, 1-(2-thiazolylazo)-2-naphtholato group, acts as a terdentate ligand; the phenolic oxygen atom, the azo nitrogen atom adjacent to the naphthol ring, and the thiazole nitrogen atom being coordinated jointly to the copper

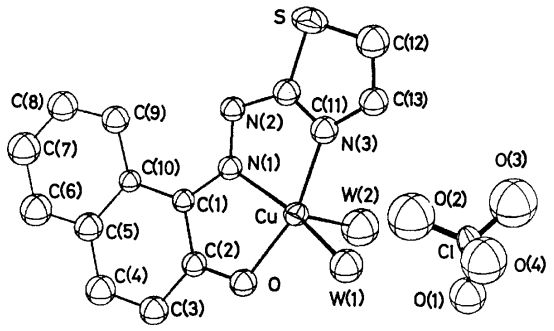

Fig. 2. Perspective drawings of $[Cu(TAN)(H_2O)_2]^+$ and ClO_4^- with numbering of atoms. The Thermal ellipsoids are drawn at 50% probability level (DEAM-4 diagram[11)]). W denotes the water oxygen atom.

** Table 3 is kept as Document No. 7605 at the Chemical Society of Japan, 1-5 Surugadai, Kanda, Chiyoda-ku, Tokyo, 101.

atom, thus giving two five-membered chelate rings. This mode of attachment of the TAN to the metal atom coincides with that observed in the crystals of Fe(II)-,[9] Co(III)-,[10] Ni(II)-,[2] and Pd(II)-chelate.[1] The thiazole sulfur atom does not coordinate to the metal in the present Cu(II)–TAN complex, either.

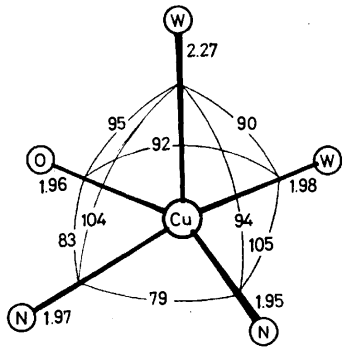

Fig. 3. Coordination geometry about the copper atom.

The coordination geometry about the copper atom is, as is shown in Fig. 3, a distorted square-pyramid whose basal plane consists of three coordinating atoms of TAN and a water-oxygen atom. The copper atom is displaced 0.18 Å from the basal plane toward an apical water oxygen atom.

It has been reported that a copper(II) complex of 1-(2-pyridylazo)-2-naphthol (abbr. as H-PAN), $[Cu^{II}(PAN)H_2O]ClO_4$, has a square-planar environment and that PAN is bonded to the copper atom through the phenolic oxygen atom, the azo nitrogen atom, and the pyridine nitrogen atom, thus giving two five-membered chelate rings.[5] Therefore, the coordination of TAN to the copper atom is similar to that of PAN. However, the coordination number and geometry around the metal are different between the $[Cu^{II}(TAN)(H_2O)_2]^+$ and $[Cu^{II}(PAN)H_2O]^+$ complexes.

The bond lengths and angles in the complex cation are shown in Figs. 4a and 4b respectively. The equatorial bond lengths, Cu–N(1), Cu–N(3), Cu–O, and Cu–W(1) (W refers to an oxygen of the water molecule), are 1.97, 1.95, 1.96, and 1.98 Å respectively, while the axial bond length, Cu–W(2), is 2.27 Å, longer by *ca.* 0.3 Å than any of the equatorial bond lengths. A similar feature has been observed in many copper complexes with a square-pyramidal coordination.[6,7,11] The bond angles around the metal, O–Cu–N(1) and N(1)–Cu–N(3), are compressed to 83 and 79° respectively. In relation to this deformation, Cu–N(3)–C(13), S–C(11)–N(2), N(2)–N(1)–C(1), and N(1)–C(1)–C(10) are enlarged to 134, 123, 127, and 127° respectively. Such deviations from the normal valence angles have been observed in all the metal-TAN complexes reported previously. The W(1)–Cu–W(2) angle is 90°. There is a close intra-ligand contact (2.3 Å) between N(2) and H(9) (hydrogen atom attached to C(9)), as is shown in Fig. 4.

The bond lengths and angles in the perchlorate anion are as follows: Cl–O(1)=1.42(2), Cl–O(2)=1.41(3), Cl–O(3)=1.39(3) and Cl–O(4)=1.41(3) Å, O(1)–Cl–O(2)=105(1), O(1)–Cl–O(3)=109(1), O(1)–Cl–O(4)=111(1), O(2)–Cl–O(3)=114(2), O(2)–Cl–O(4)=108(2),

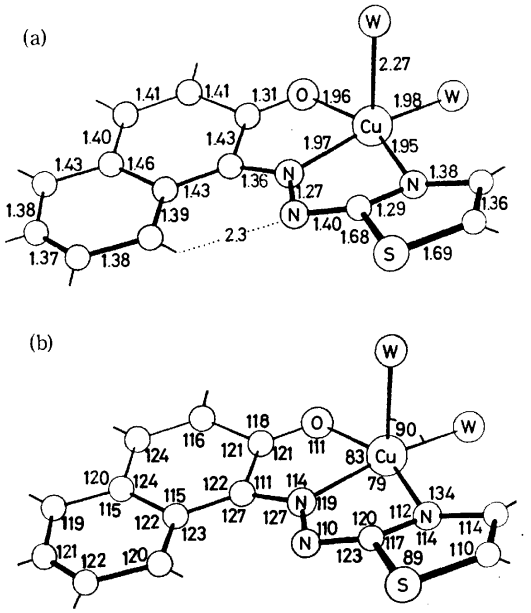

Fig. 4. Bond lengths (a) and bond angles (b) in $[Cu(TAN)(H_2O)_2]^+$. E. s. d.'s are as follows: 0.02Å for Cu–O, Cu–W, and Cu–N. 0.02—0.03 Å for S–C. 0.03 Å for C–O, N–N, and N–C. 0.03—0.04 Å for C–C. 1° for O–Cu–W, O–Cu–N, N–Cu–N, C–S–C, Cu–O–C, and Cu–N–N. 1—2° for N–N–C, C–N–C, and C–C–C.

a) *X*, *Y*, *Z*, are orthogonal coordinate in Å and axes parallel a, b, c*.
b) Only the atoms marked with an asterisk are included in the calculation of each plane.

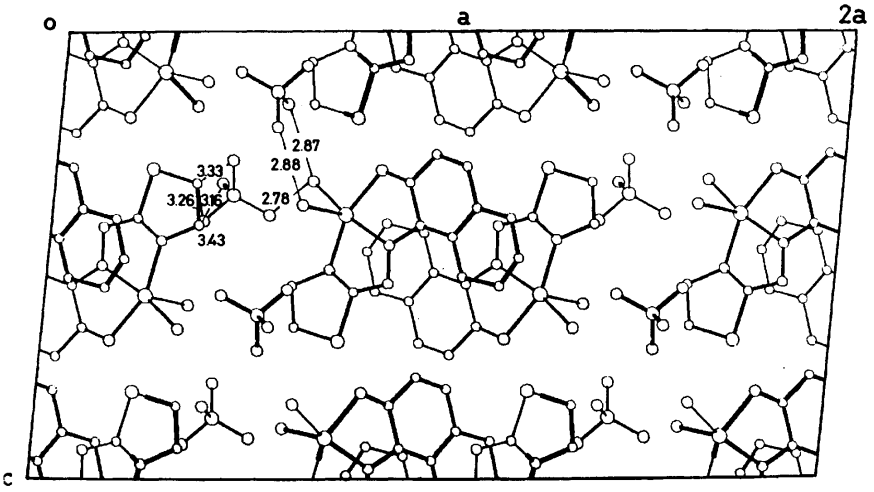

Fig. 5. Crystal structure projected along the b-axis (DEAM-4 diagram[12]).

and O(3)–Cl–O(4)=109(2)°. The perchlorate ion is slightly distorted from a regular tertrahedron. No close contact between Cu and oxygen of the perchlorate anion is observed. The isotropic temperature factors for the oxygen atoms of the perchlorate ion range from 6.0 to 9.9 Å^2, somewhat larger than those for the non-hydrogen atoms of the complex cation.

The deviations of atoms from the various planes are given in Table 4. The mean plane through the Cu and non-hydrogen atoms of the TAN ligand (plane 1) is significantly non-planar, and the S and C(9) atoms are displaced by +0.07 and −0.06 Å respectively. The distances of W(1) and W(2) from this plane are −0.42 and 2.25 Å respectively. On the other hand, the naphthalene ring (plane 2) is planar within a deviation of ±0.02 Å, and all the remaining atoms except oxygens are displaced from the naphthalene plane in the same direction; that is, the TAN ligand is slightly folded along the Cu–N(1) bond at an angle of 2.5°. The non-planarity of the TAN is probably the result of:

(1) the N(2)···H(9) intra-ligand repulsion mentioned above,
(2) the distorted square-pyramidal environment of the Cu atom, or
(3) interionic interactions; relatively short interatomic distances are found between thiazole-ring atoms and perchlorate-oxygen atoms.

The crystal structure projected along the b-axis is shown in Fig. 5. Interatomic distances less than 3.4 Å are listed in Table 5. $[Cu^{II}(TAN)(H_2O)_2]^+$ cations related by the center of symmetry at (0, 0, 0) are stacked alternately along the b-axis to form columns. The columns are held together by van der Waals forces, forming layers parallel to the (001) plane. Perchlorate anions are located around $x=1/2$ between the layers of the complex cations. There are some close approaches between the water-oxygen atoms and the perchlorate-oxygen atoms (Table 5). As can be seen in Fig. 5, the van der Waals forces are predominant around $x=0$, whereas the ionic interactions are predominant around $x=1/2$.

Calculations were carried out on a HITAC 5020F computer at the Computer Center of the National Aerospace Laboratory, using such programs of the UNICS system as PAMI, HBLS-4, and SFR-5. Figures 2 and 5 were produced by the plotter program of DEAM-4.[12]

Reactions of the Di-μ-oxo-bis[aquaoxalatooxomolybdate(V)] Ion

Akitoshi KOMURA, Yasuzi IKEDA, and Hiroto IMANAGA

Faculty of Technology, Kanazawa University, Kanazawa 920

(Received July 23, 1975)

Reactions of the complex ion $[Mo_2O_4(C_2O_4)_2(H_2O)_2]^{2-}$ (I) have been investigated. On acidification with perchloric acid and hydrochloric acid, complex (I) gave molybdenum(V) aqua-dimer ion $[Mo_2O_4(H_2O)_6]^{2+}$, which was converted into the monomeric species $[MoOCl_5]^{2-}$ in concentrated hydrochloric acid. The initial reaction of complex (I) with mercaptoacetic acid, giving a complex of stoichiometry 1 ligand: 1 Mo, was followed by a slower reaction which probably gave higher complexes. In the reactions with *o*-aminophenol and 2,2′-bipyridyl, complexes of stoichiometry 1 ligand: 1 Mo and 1 ligand: 2 Mo, respectively, were formed in solutions. The following complexes have been isolated: $Mo_2O_4(dtc)_2$, $Mo_2O_3(dtc)_4$ (dtc=diethyldithiocarbamate), $MoOCl_3\cdot$phen (phen=1,10-phenanthroline), and $Mo_2O_3Cl_4(bpy)_2$ (bpy=2,2′-bipyridyl). The infrared and electronic spectra of the complexes and their probable structures are given. The relative ease of replacement of ligands from complex (I) has been discussed.

Complexes of molybdenum-(V) and -(VI) with L-cysteine,[1,2] other amino acids[3] and organic sulfur compounds[4] are of interest as models for molybdenum-containing enzymes. It has been established that most of such enzymes contain two molybdenum atoms at the active sites. Molybdenum(V) tends to produce the binuclear oxo complexes bridged with oxide ion. The property of molybdenum(V) complexes and also the variety in both the oxidation number and coordination number of molybdenum might account for the complicated conditions required in the enzymes. The presence of bridging oxygen and terminal oxygen (*i.e.* bonded to only one molybdenum) in binuclear molybdenum(V) complexes might determine the structures and reactivities of the complexes. The oxo-bridged binuclear molybdenum(V) complexes with cysteine,[1,2] dithiocarbamate,[5,6] histidine,[7] oxalate,[8] EDTA,[9] and 8-quinolinol (oxine)[10] have been studied in view of the interest in molybdenum–enzyme systems. Mitchell[11] investigated the substitution reactions of di-μ-oxo-bis-[aquaoxalatooxomolybdate(V)] ion (I), the structure of which was determined by a single-crystal X-ray diffraction study.[12] Further study on the reactions of molybdenum(V) oxalato-complex was undertaken in order to obtain a general picture of the relative ease of replacement of ligands from the binuclear complex.

Experimental

Preparations and reactions were carried out in anaerobic water under an atmosphere of nitrogen, unless otherwise stated. The solution of complex (I) was prepared from the corresponding barium salt and potassium sulfate. The barium salt $Ba[Mo_2O_4(C_2O_4)_2(H_2O)_2]\cdot 3H_2O$ was prepared according to procedures described in the literature.[8,13] Found: Mo, 29.0; C_2O_4, 26.7; Ba, 21.4%. Calcd for $BaMo_2O_{17}C_4H_{10}$: Mo, 29.1; C_2O_4, 26.7; Ba, 20.8%. The oxidation number of the molybdenum is 5.0.

Di-μ-oxo-bis[diethyldithiocarbamatooxomolybdenum(V)], $Mo_2O_4(dtc)_2$. A solution of complex (I) (1.5 mmol) in water (50 ml) was slowly added to a solution of sodium diethyldithiocarbamate (3 mmol) in water (100 ml). A yellow precipitate which formed immediately was collected by filtration, washed with water and ethanol, and dried *in vacuo* over silica gel. The complex was soluble in chloroform and 1,2-dichloroethane. Found: Mo, 35.0; C, 21.8; 5.3; H, 3.5%. Calcd for $Mo_2O_4C_{10}H_{20}N_2S_4$: Mo, 34.8; C, 21.7; N, 5.1; H, 3.6%.

μ-Oxo-bis[bis(diethyldithiocarbamato)oxomolybdenum(V)], $Mo_2O_3(dtc)_4$. A solution of complex (I) (1.25 mmol) in 0.1M-acetate buffer (50 ml, pH 3.0) was added to an ice-cold solution of diethyldithiocarbamate (10 mmol) in water (100 ml). A dark purple precipitate formed immediately and the suspension was stirred for ten minutes. The precipitate was filtered off, washed with water and ethyl ether, and dried *in vacuo* over silica gel. The complex was soluble in chloroform. Found: Mo, 23.3; C, 28.3; N, 7.0; H, 4.8%. Calcd for $Mo_2O_3C_{20}H_{40}N_4S_8$: Mo, 23.1; C, 28.8; N, 6.7; H, 4.8%.

Trichlorooxo(1,10-phenanthroline)molybdenum(V), $MoOCl_3\cdot phen$. We obtained the complex $[Mo_2O_3(C_2O_4)_2(phen)_2]\cdot 2H_2O$ according to the method of Mitchell[11] by the reaction of complex (I) with 1,10-phenanthroline in phthalate buffer solution (pH 4). The former complex (46 mmol) was refluxed in 5M-HCl (50 ml) for twenty minutes. A dark red precipitate which formed was filtered off, washed with 5M-HCl and ethanol, and dried *in vacuo* over silica gel. The complex was insoluble in water. Found: Mo, 24.5; Cl, 26.3; N, 7.4%. Calcd for $MoOCl_3C_{12}H_8N_2$: Mo, 24.1; Cl, 26.7; N, 7.0%.

μ-Oxo-bis[(2,2′-bipyridyl)dichlorooxomolybdenum (V)], $Mo_2O_3Cl_4(bpy)_2$. A phthalate buffer solution (50 ml) containing 2,2′-bipyridyl (7 mmol) and 1M-sulfuric acid (10 ml) was added to a solution of complex (I) (3.5 mmol) in phthalate buffer (50 ml, pH 4). The solution was stirred for fifteen minutes while a buff precipitate formed. The precipitate was filtered off, washed with water and ethanol, and dried *in vacuo* over silica gel. The solid was little soluble in water. The solid contained both oxalate and 2,2′-bipyridyl, whereas it contained neither potassium nor sulfate. Typical analytical values: Mo, 32.6; N, 5.1; C_2O_4, 15.6%. When the solid was refluxed in 5M-HCl, a purple black precipitate was formed. The complex was insoluble in water and common organic solvents. Found: Mo, 27.8; Cl, 19.8; N, 8.0%. Calcd for $Mo_2O_3Cl_4C_{20}H_{16}N_4$: Mo, 27.6; Cl, 20.4; N, 8.1%.

Solutions of the aqua-ion $[Mo_2O_4(H_2O)_6]^{2+}$ were obtained by the following cation-exchange separation. A solution of 2×10^{-2} M-complex (I) in 5M-perchloric acid was aquated for two days under nitrogen. The solution was adsorbed on a cation-exchange column (Dowex 50W-X2) and a yellow band was eluted from the column with 1M-perchloric acid. The analysis of the eluted solution showed that the oxidation state of molybdenum was still 5+, and the solution was free from oxalate ion. UV and visible spectra of solutions were recorded on a Hitachi 124 spectrophotometer with the use of matched silica cells and appropriate reference solutions. IR

spectra of solids in potassium bromide discs were recorded on a Nihonbunko DS 301 spectrophotometer. Molybdenum was determined gravimetrically as molybdenum (VI) oxinate, $MoO_2(C_9H_6ON)_2$, after decomposition of the complexes by heating with a 1: 1 mixture of concentrated nitric and sulfuric acids. The oxidation number of molybdenum was determined by permanganate titration of the complexes, a correction being made for oxalate. Barium was determined gravimetrically as barium sulfate and chlorine as silver chloride. Carbon, hydrogen, and nitrogen were determined by standard microanalytical procedures.

Results and Discussion

Reactions in Solution. The electronic spectrum of complex (I) varied on acidification with perchloric acid. With increasing concentration of perchloric acid, a band at 304 nm in the complex (I) spectrum shifted to shorter wavelength (about 10 nm in 5 M-perchloric acid), whereas a band at 255 nm remained unchanged.

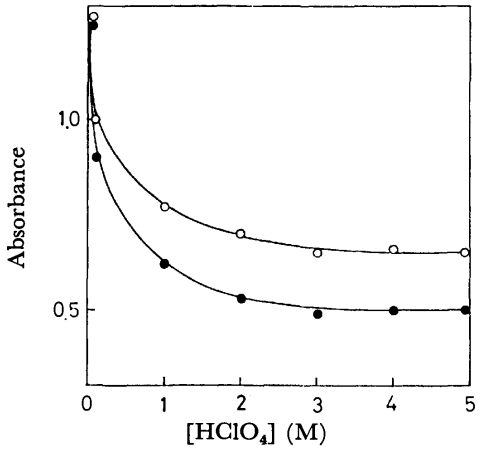

Fig. 1. The variation in absorbances of the complex (I) solution with concentration of perchloric acid. 1.5×10^{-4} M-complex (I). ○: 254 nm. ●: 304 nm.

Figure 1 shows the variation of the absorbances with the concentration of perchloric acid. We attempted to characterize the molybdenum(V) species in aqueous perchloric acid with ion-exchange method. The analytical evidence and the ion-exchange behavior indicate that the molybdenum(V) species is a +2 charged cation to which no oxalate is coordinated. It is well-known[14] that molybdenum(V) salts produce at least three species in aqueous solutions with oxo-molybdenum frameworks MoO^{3+}, $Mo_2O_3^{4+}$, and $Mo_2O_4^{2+}$, which are in an equilibrium dependent on hydrogen ion concentration. Ardon and Pernick[15] have proposed binuclear aqua-ion $[Mo_2O_4(H_2O)_6]^{2+}$ as a molybdenum(V) species in aqueous perchloric acid solutions. Sasaki and Sykes[16] conclude that the molybdenum(V) aqua-ion is stable in the concentration range of 0.5—5 M perchloric acid. Our observations are consistent with this assignment. The conclusion that we also have the molybdenum(V) aqua-dimer is supported by the measurement of the absorption characteristics. The absorption spectrum of the eluted solution has maxima at 294 nm (ε=3400 l mol^{-1} cm^{-1}) and 254 nm (ε=3900). The absorption spectrum is in good agreement with the spectra of Ardon and Pernick; 293 (3454) and 254 nm (3998),[15] and of Sasaki and Sykes; 295 (3546) and 255 nm (4320).[16] On neutralization of the molybdenum(V) aqua-dimer solution in the presence of oxalate, the peak at 294 nm shifted to longer wavelength with a significant increase in absorbance. This is probably consistent with equilibrium (1) in aqueous perchloric acid.

$$[Mo_2O_4(C_2O_4)_2(H_2O)_2]^{2-} + 4H_3O^+ \rightleftarrows [Mo_2O_4(H_2O)_6]^{2+} + 2H_2C_2O_4 \quad (1)$$

On the other hand, a number of studies have been made of the behavior of molybdenum(V) in hydrochloric acid solutions, and monomer-dimer equilibria have been proposed.[14] The electronic spectrum of complex (I) also varied on acidification with hydrochloric acid. With an increase in concentration of hydrochloric acid, the peak at 304 nm in complex (I) initially shifted to shorter wavelength, but the direction of the shift was reversed at [HCl]=1—2 M. Figure 2

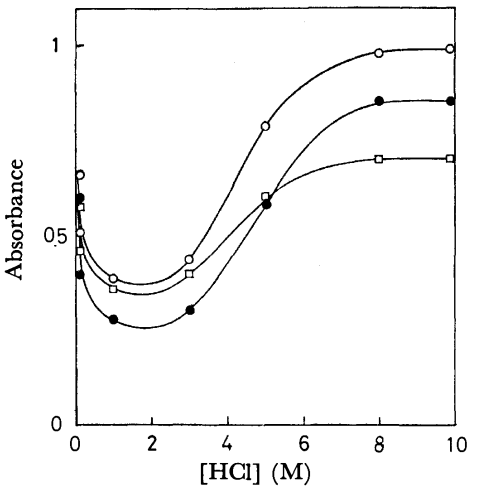

Fig. 2. The variation in absorbances of the complex (I) solution with concentration of hydrochloric acid. 10^{-4} M-complex (I). ○: 240 nm. □: 300 nm. ●: 310 nm.

shows the variation of absorbances with the concentration of hydrochloric acid. The absorbance at each wavelength shows a minimum at [HCl]=1—2 M and approaches a definite value in very high concentration of hydrochloric acid. With concentrated hydrochloric acid, the solution gave the characteristic green color of the pentachlorooxomolybdate(V) ion. Details of the absorption maxima (absorption coefficient per molybdenum), 720 (20), 443 (18), 355 (560), 310 (4700), and 241 nm (5400), are in good agreement with those of $MoOCl_5^{2-}$.[17] The change in the spectrum at [HCl]< 1M might be due to the aquation of complex (I), because the spectral change is identical with that in the aquation with perchloric acid. Ardon and Pernick[15] have shown that the main molybdenum(V) species in dilute hydrochloric acid (<1M) is the aqua-dimer $[Mo_2O_4(H_2O)_6]^{2+}$ as well as in perchloric acid. The change in spectrum of complex (I) at higher concentration of hydrochloric acid might be attributed to the conversion of the molybdenum(V)-dimer into the

monomeric species $[MoOCl_5]^{2-}$ according to the characteristic of the spectral change. When complex (I) was allowed to stand in basic solutions (pH 7—10), the band of 304 nm shifted to longer wavelength with a decrease in absorbance, whereas the band at 255 nm shifted to shorter wavelength with an increase in absorbance. The absorbance of the band at 304 nm remarkably decreased with time in higher pH, probably owing to the oxidation of molybdenum(V). Molybdenum(V) is too easily oxidizable in basic solutions to allow quantitative examination of the reaction.

Reactions of complex (I) with different ligands were carried out in aqueous solutions buffered at pH 4, in which complex (I) persists.[11] Continuous variations plots for 2,2'-bipyridyl are shown in Fig. 3. Maxima in ΔA, deviations of the absorbances of the mixed solutions from the sums of the absorbances of the components, occurred at a 2,2'-bipyridyl: complex (I) ratio of 1: 1 showing the formation of a complex of stoichiometry 1 bpy: 2 Mo. The spectrum of the mixed solution differed from that of complex (I) only in the enhanced absorbance above 350 nm and no new peaks were observed. The plot with *o*-aminophenol is shown

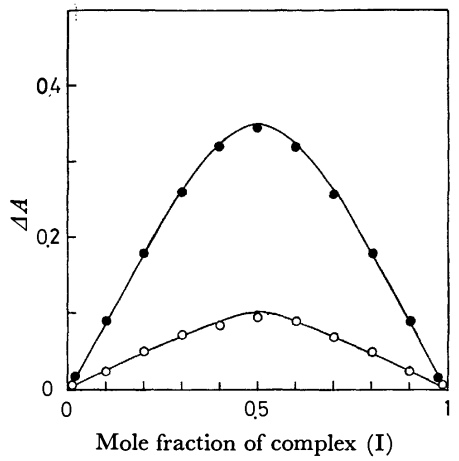

Fig. 3. Continuous variation plots for the reaction of complex (I) with 2,2'-bipyridyl.

●: 400 nm. ○: 450 nm.

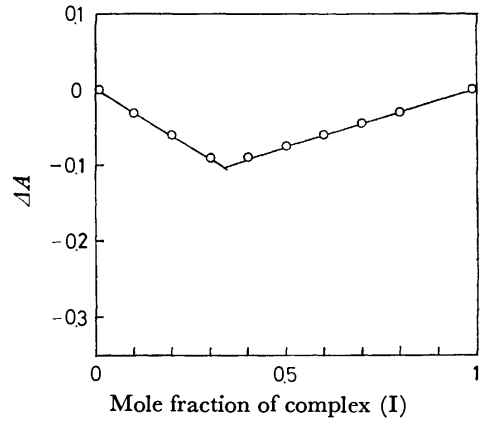

Fig. 4. The continuous variation plot for the reaction of complex (I) with *o*-aminophenol.
The total concentration was 2.5×10^{-4} M. pH 4.0, 435 nm.

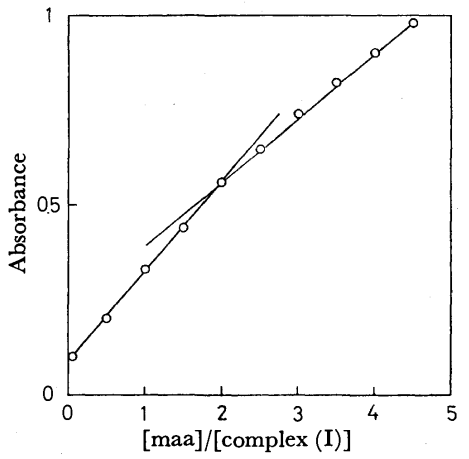

Fig. 5. The molar ratio plot at 30 min after mixing for the reaction of complex (I) with mercaptoacetic acid.
The concentration of complex (I) was 1.25×10^{-4} M. pH 4.0, 430 nm.

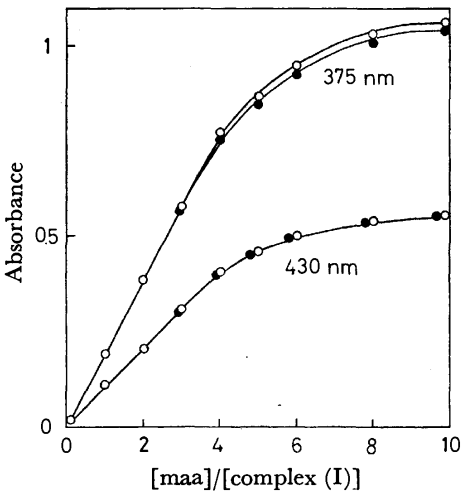

Fig. 6. Molar ratio plots at 15 and 40 hr after mixing for the reaction of complex (I) with mercaptoacetic acid. The concentration of complex (I) was 1.25×10^{-4} M. pH 4.0. ○: 40 hr. ●: 15 hr.

in Fig. 4. Minimum in ΔA occurred at a ligand: complex (I) ratio of 2: 1. This corresponds to the formation of a complex of stoichiometry 1 aminophenol: 1 Mo. Molar ratio plots for mercaptoacetic acid (maa) are shown in Figs. 5 and 6. The plot at 30 minutes after mixing shows the formation of a complex of stoichiometry 1 maa: 1 Mo. The plots after 15 and 40 hours are linear up to 4 molar ratio of mercaptoacetic acid to complex (I), above which ratio both absorbances gradually approach definite values. Thus the initial reaction, giving a 1: 1 complex, is followed by a slower reaction which might give higher complexes. With the following ions and molecules there were no spectral changes, continuous variations plots being straight lines; *O*-ethyl dithiocarbonate, glycine, tartrate, malonate, thiourea, biuret, thiosemicarbazide, and phosphate.

Complexes Isolated. The isolated complexes are listed in Tables 1 and 2. The formulas of the complexes

are based on analyses and physical measurements. For complexes with dithiocarbamate, the oxidation state of molybdenum could not be determined directly because of interference by oxidizable sulfur ligands. The complexes gave the characteristic green color of the $[MoOCl_5]^{2-}$ ion in concentrated hydrochloric acid. Immediate precipitation occurs on mixing complex (I) and dithiocarbamate solutions. Initial preparation gave the products with varying molybdenum percentage and color depending upon the conditions of reaction. A higher mixing-ratio of dithiocarbamate to complex (I) at pH 4 gave smaller molybdenum percentages (dark purple color). Higher pH at a given mixing-ratio gave higher molybdenum percentages (pink color). Visible and infrared spectra suggest that the product (pink) in higher pH and lower mixing-ratio corresponds mainly to complexes of the Mo_2O_4 type, and that (dark purple) in lower pH and higher mixing-ratio to the Mo_2O_3 type. We isolated analytically pure $Mo_2O_4(dtc)_2$ and $Mo_2O_3(dtc)_4$. Our observation is consistent with Kay and Mitchell's comment[2] that molybdenum(V) complexes of the type $Mo_2O_4L_2$ are obtained from aqueous solutions under more alkaline conditions than in the preparation of the complexes $Mo_2O_3L_4$. The complex $Mo_2O_4(dtc)_2$ has recently been prepared by refluxing an aqueous solution of pentachlorooxomolybdate(V) and dithiocarbamate.[6] The complex seems to have structures closely related to the molybdenum(V) complexes with L-cysteine esters, in which unique five-coordinate structures are formed.[18] The complex $Mo_2O_3(dtc)_4$ is considered to be structurally similar to the corresponding dithiocarbonate and phosphorothiolothionate complexes, the structures of which have been determined by single-crystal X-ray crystallography.[19,20] $Mo_2O_4(dtc)_2$ could be easily converted into $Mo_2O_3(dtc)_4$ by stirring with dithiocarbamate in chloroform–methanol (4: 1) solution. Confirming Mitchell's description,[11] we obtained μ-oxo-bis[oxobis(8-quinolinolato)molybdenum(V)]hydrate from a hot solution containing complex (I) and 8-quinolinol. In the reactions of complex (I) with 8-quinolinol one bridging oxo-group of the Mo_2O_4 group was replaced giving complexes of the Mo_2O_3 group. $MoOCl_3$·phen was obtained by refluxing the complex

$[Mo_2O_3(C_2O_4)_2(phen)_2]\cdot 2H_2O$ in 5M-hydrochloric acid. In very prolonged refluxing, a green solution owing to $[MoOCl_5]^{2-}$ formed. The complex $MoOCl_3\cdot$phen was prepared by the reaction of the pentachlorooxomolybdate(V) with 1,10-phenanthroline in dehydrated ethanol.[21] For this complex three different isomeric forms (colored reddish-pink, pale brown, and green) are known to be interconvertible.[21] Judging from the color, our complex seems to be *cis*-isomer. A buff solid obtained by the reaction of complex (I) with 2,2'-bipyridyl at pH 4 seemed to be the Mo_2O_4 type according to the infrared spectrum. The analytical data corresponded to a Mo: oxalate: bpy ratio of 2: 1: 1. The same stoichiometry (2 Mo: 1 bpy) was also observed in the solution studies. However, no reasonable formula could be given. By refluxing the compound in 5M-hydrochloric acid we obtained the monooxo-bridged binuclear complex $Mo_2O_3Cl_4(bpy)_2$.

Infrared Spectra. The positions and assignments of the main bands are given in Table 1. All the complexes have a strong band at 930—980 cm^{-1} assigned to the stretching vibration of the Mo=O group. Bridge vibrations of the molybdenum-oxygen group occur at 700—800 cm^{-1}.[3,5,11] For molybdenum(V) the commonest binuclear oxo-species are the Mo_2O_3 and Mo_2O_4 groups each of which has one terminal oxygen per molybdenum and one or two bridging oxygens respectively. Wing and Callahan[22] showed that the molybdenum-oxygen stretching vibrations are a powerful tool for the characterization of the molybdenum-oxygen bridged complexes, but at present this does not seem to be always the case. Newton *et al.*[6] gave definite assignments for the infrared spectra of two series of molybdenum(V)–dithiocarbamate complexes. In the complexes with dithiocarbamate, the infrared spectra of the Mo_2O_4 groups contain two bands assigned to the terminal Mo=O vibrations and a medium band at *ca.* 740 cm^{-1} assigned to the MoO_2Mo bridge vibration. The higher (*ca.* 980 cm^{-1}) of the absorptions attributed to the terminal Mo=O vibrations is much stronger than the second band (*ca.* 960 cm^{-1}). The infrared spectra of the Mo_2O_3 groups have one band assigned to the terminal Mo=O vibration and a weak band at *ca.* 750 cm^{-1} assigned to the MoOMo bridge vibration. The split band at *ca.* 980 cm^{-1} and the medium absorption at *ca.* 740 cm^{-1} can be used as good indicators of the presence of the Mo_2O_4 moeity in complexes. These correlations are in line with those made in other complexes suggested to have the MoO_2Mo bridge.[23] Each band at about 730 cm^{-1} in complexes (I) and $Mo_2O_4(dtc)_2$ is therefore assigned to vibrations of the MoO_2Mo groups. For complexes with 1,10-phenanthroline and 2,2'-bipyridyl, assignments of bands to the MoOMo bridge vibrations are made uncertain because of ligand vibrations at 700—800 cm^{-1}. The infrared spectra of complexes (I) and $[Mo_2O_3(C_2O_4)_2(phen)_2]\cdot 2H_2O$ have characteristic bands at *ca.* 1630—1710 cm^{-1} assigned to the C=O stretching vibration of coordinated oxalate. As noted by Jowitt and Mitchell,[5] the vibration frequency (1488 cm^{-1}) of $N{=}CS_2$ group for dithiocarbamate increases on coordination because of an increased contribution of the canonical form $Et_2N^+{=}CS_2^{2-}$. In the complex $Mo_2O_3(dtc)_4$ this vibration splits into two bands (as a shoulder) indicating that the two dithiocarbamate groups are not equivalent.[19] The presence of 1,10-phenanthroline in the complexes $[Mo_2O_3(C_2O_4)_2(phen)_2]\cdot 2H_2O$ and $MoOCl_3\cdot$phen is shown by characteristic bands at *ca.* 1625 m, 1516 m, 1426s, 1341m, 1315w, 1147m, 853s, and 725s cm^{-1}. The spectrum of the complex obtained by the reaction of complex (I) with 2,2'-bipyridyl at pH 4 has bands at 955 and 937 cm^{-1} assigned to vibrations of the terminal Mo=O group, showing that the complex probably contains the Mo_2O_4 groups.

Electronic Spectra. The positions, intensities and assignments of the absorption maxima are shown in Table 2. Complex (I) has two peaks assigned to d-d transitions in the visible region, and two intense peaks assigned to charge-transfer transitions ($O^{2-}\rightarrow Mo$) in the UV region.[8] The spectrum of $Mo_2O_3(dtc)_4$ indicated a poorly resolved shoulder at 15600 cm^{-1} assigned to a d-d transition, which is at higher energy

Scheme. Reaction scheme and proposed structures.

Complexes (I)—(VII) have been isolated, others being species postulated in aqueous solutions.

than the first d-d transition for the ion $[MoOCl_5]^{2-}$ (14100 cm^{-1}).[17] A peak or shoulder at less than 18000 cm^{-1} is observed for molybdenum(V) complexes, $Mo_2O_3L_4$ (L=dithiocarbamate, dithiocarbonate, or phosphorothiolothionate), and is assigned to a d-d transition.[5] Strong peaks at 18000—29000 cm^{-1} are characteristic of oxo molybdenum(V) complexes with polarizable ligands,[5] and cover peaks due to d-d transitions expected in this region. In agreement with Jowitt and Mitchell,[5,11] we assigned the peaks in this region in complexes $Mo_2O_3(dtc)_4$ and $[Mo_2O_3(C_2O_4)_2(phen)_2]\cdot 2H_2O$ to ligand-to-molybdenum charge-transfer transitions. The spectrum of $Mo_2O_4(dtc)_2$ was essentially featureless except for a poorly resolved shoulder at 31500 cm^{-1}. We assigned the peak to a charge-transfer transition because of its high absorption coefficient. $MoOCl_3\cdot$phen has only one peak below 20000 cm^{-1}. For the complex $MoOCl_3\cdot$phen (reddish-pink), Saha and Halder[21] observed two peaks at 13700 (ε=179) and 18900 cm^{-1} (ε=282) assigned to d-d transitions. The complex anion $[MoOCl_5]^{2-}$ has also two peaks at 14100 (20) and 22500 cm^{-1} (18) assigned to d-d transitions.[17] The complex $MoOCl_3\cdot$phen we prepared was too insoluble into common organic solvents to observe weak peaks of ε less than 200. Both peaks at 23800 and 27700 cm^{-1} in the complex are assigned to charge-transfer transitions according to the values of the absorption coefficient. A strong peak at 32900 cm^{-1} is assigned to the internal transition ($\pi\rightarrow\pi^*$) of coordinated 1,10-phenanthroline, which is at lower frequency than that of free 1,10-phenanthroline. Peaks at wave numbers greater than 32000 cm^{-1} are assigned to $\pi\rightarrow\pi^*$ transitions of the ligands except for complex (I).

Conclusion

Reactions involved in this paper are summarized in the Scheme. In the initial reaction with mercaptoacetic acid, a complex of stoichiometry 1 ligand: 1 Mo was formed in solution. Similarity of the spectrum of the mixed solution to that of complex (I) except for the enhancement of absorption above 360 nm suggests that no significant structural change occurs in the reaction. We assume that two coordinated waters are replaced by mercaptoacetic acid. With *o*-aminophenol a complex of stoichiometry 1 ligand: 1 Mo was formed in solution. Because of a strong absorption maximum of *o*-aminophenol at 435 nm, we cannot observe the remarkable characteristics in spectrum of the complex. The electrical migration studies showed that the complex was an anion. It is reasonable to assume that coordinated waters and one bridging oxygen were replaced by *o*-aminophenol, because the replacement of oxalate should produce a nonelectrolyte. As the substitution reactions of complex (I), there are four possible stages involving replacement of coordinated water, bridging oxygen, oxalate, and terminal oxygen, respectively. Mitchell[11] discussed the relative ease of replacement of ligands from complex (I) and showed that, qualitatively, the order of the ease was H_2O>one bridging oxygen>oxalate$\gg$terminal oxygen. We agree with Mitchell in concluding that the replacement of coordinated water is easiest. In reactions of complex (I) with 1,10-phenanthroline and *o*-aminophenol, the cleavage of one oxygen bridge of the Mo_2O_4 group occurred keeping oxalate. On the other hand, in the formation of $Mo_2O_4(dtc)_2$ and of $[Mo_2O_4(H_2O)_6]^{2+}$ the

replacement of oxalate occurred without any cleavage of oxygen bridge. The relative ease of replacement of one bridging oxygen and oxalate probably varies with nucleophiles in disagreement with Mitchell's conclusion.[11] Molybdenum(V) has a particular affinity for dithiocarbamate as well as 8-quinolinol. Nevertheless neither ligand can cleave all oxygen bridges of the Mo_2O_4 group and both ultimately give the single-bridged $Mo_2O_3L_4$ species. Strongly acidic conditions are required for the formation of a mononuclear species. Replacement of terminal oxygen whose bond order to molybdenum is approximately two[24] is very unlikely to occur in aqueous solutions (even in concentrated hydrochloric acid). Special stability of monooxo molybdenum(V) moiety MoO^{3+} in aqueous solutions has led to certain interesting investigations of the chemistry of the oxo molybdenum-(V) ions.[21,25]

N-Allylpyrazole as a Ligand. II. The Preparation and Reaction of Some Palladium(II) and Platinum(II) Complexes

Takeshi MIYAMOTO,* Kazuo FUKUSHIMA, Taro SAITO, and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received July 31, 1975)

New complexes of *N*-allylpyrazole(L) with Pd(II) and Pt(II) have been prepared and characterized; they have the general formulae of MX_2L_2 and MX_2L (X=Cl or Br). IR and ^1H NMR studies indicate that the latter complexes are *cis*-planar-chelate and involve both the pyrazolyl nitrogen and the olefinic group in bonding to the metal, while the former are *syn*- and *anti-trans*-planar and contain only uni-dentate pyrazole donor ligands. The treatment of the chelate complex $PtCl_2L$(L= 1-(2-methylallyl)-3,4,5-trimethylpyrazole) with donor ligands (L′) such as phosphines, $AsPh_3$, and py displaces the coordinated olefin,forming *cis*-$PtCl_2LL'$ with a retention of the *cis*-configuration.

Allylpyrazole (Fig. 1), which has both σ-donating nitrogen and π-accepting olefin, can be bound with metal ions in more than one way. We have already reported that the ligand forms bidentate complexes with copper(I) halide and silver nitrate; it also coordinates to metal halides of the first transition series by using only pyrazolyl nitrogen.[1] By analogy with other chelate olefin complexes,[2-9] the coordination chemistry of platinum(II) and palladium(II) has proved to be of interest because they form not only monodentate pyrazolyl-nitrogen complexes, but also stable olefin complexes, with the chelation of allylpyrazole through the nitrogen donor and the olefinic group.

We wish now to report the details of the preparation of palladium(II) and platinum(II) compounds and their properties, especially their spectroscopic characteristics and their substitution reactions.

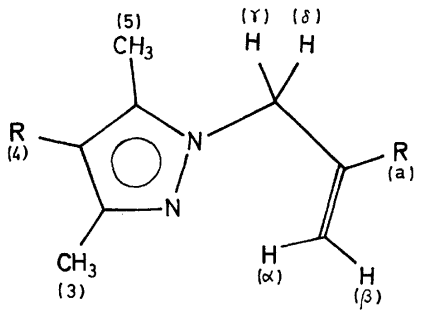

Fig. 1. *N*-Allylpyrazole, R_a, R_4=H or CH_3. Numbers and Greek letters represent the position of the hydrogen atoms.

Experimental

The molecular weight was determined by the Rast method. X-Ray powder diagrams were obtained by means of a Rigaku D-2F apparatus. The other physical measurements were made as has previously been described.[1] The IR and NMR data are collected in Tables 3 and 4 respectively.

Synthesis of Ligands. The four ligands were prepared by the method of Finar and Utting[10] in a *ca.* 40% yield. The names of the ligands are abbreviated thus, based on Fig. 1: admp(R_a=R_4=H); atmp (R_a=H, R_4=Me); amdmp(R_a=Me, R_4=H); amtmp(R_a=R_4=Me).

Preparation of trans-MX_2L_2 (*M=Pd or Pt; X=Cl or Br; L=substituted* N-*allylpyrazoles*). Dipotassium tetrachlorometallate (II) (0.01 M) was dissolved in water, and then an excess of allylpyrazole (0.10 M) was stirred in. Yellow crystals were obtained after stirring at 25 °C for a day and were recrystallized from cold chloroform. The complexes were also prepared by adding allylpyrazole to MCl_2L in cold chloroform. In general, throughout the reaction, the temperature must be maintained below 25 °C. If the temperature is allowed to rise above *ca.* 50 °C, a mixture of MCl_2L and MCl_2L_2 is obtained. The bromo-complex, MBr_2L_2 was prepared by the metathesis of the corresponding chloro-complex with lithium bromide. All the complexes are easily soluble in chloroform or dichloromethane. The analytical data and some properties of the complexes are shown in Table 1. The *trans* structure of $PtCl_2L_2$ was checked by Kurnakov's test.[11]

Preparation of PtX_2L. Dipotassium tetrachloroplatinate (II) (0.01 M) was dissolved in water (20 ml). Into this solution a mixture of allylpyrazole (0.01 M) and concd hydrochloric acid solution (*ca.* 5 ml) was vigorously stirred. Then, the reaction mixture was gently heated on a water bath for about half an hour. After they had been cooled to room temperature, the precipitated crystals were filtered, washed with water, and dried *in vacuo*. Crude products were recrystallized from chloroform(10)–ethanol(90) (yield: 95%). In boiling ethanol, these complexes partly decompose to yield platinum-(0) metal. The purified crystals are stable to light and air. The analytical data and physical properties are summarized in Table 2. The complexes were also obtained by a displacement reaction from bis(benzonitrile)dichloroplatinum(II) (0.01 M) or bis(dimethyl sulfide)dichloroplatinum(II) (0.01 M) with allylpyrazole (0.01 M) in chloroform (yield: *ca.* 80%).

Preparation of $PdCl_2L$. The palladium complexes are prepared by procedures similar to those used for the diolefin complexes.[12] A solution of $PdCl_2$ (0.01 M) in concd hydrochloric acid (5 ml) is diluted with 50 ml ethanol. To this solution, the ligand (0.01 M) is added. Immediately, brown crystals are precipitated. After stirring for 20 min, they are filtered, and washed successively with water, ethanol, and diethyl ether (yield: *ca.* 80%). The analytical data and some properties are given in Table 2. The complexes, except for the case of L=amtmp, are not soluble enough in any solvent to give meaningful structural information in a solution.

Substitution Reaction of 1-(2-Methylallyl)-3,4,5-trimethylpyrazole-dichloroplatinum(II) with Neutral Donor Ligands. The general scheme of the reaction is summarized in Fig. 2. The analytical data and some properties of new complexes are tabulated in Table 5. When tertiary alkylphosphines such as PBu^n_3, PPr^i_3 and PCy_3 were used, all the manipulations were carried out under a nitrogen atmosphere. Some typical reactions will be described:

With PPh_3: In 50 ml of benzene, the yellow complex, $PtCl_2L$ (2.1 g, 0.0051 M), was dispersed. When an equimolar

a) All melting points were uncorrected. b) Molecular Weight: Found, 530; Calcd, 430.

quantity of triphenylphosphine (1.4 g, 0.0053 M) was added to the above mixture, the dispersed complex spontaneously dissolved in the solution. This light-yellow solution was then evacuated to dryness. The residue on crystallization from ethanol (20 ml)–hexane (60 ml) gave *cis*-$PtCl_2LPPh_3$ (yield: 3.2 g, 94% based on $PtCl_2L$). If two equivalents of PPh_3 (2.8 g) were used, snow-white crystals of *cis*-$PtCl_2(PPh_3)_2$ were precipitated from the benzene solution quantitatively.

With PCy_3: A benzene solution (100 ml) containing PCy_3 (7.0 g, 0.025 M) and $PtCl_2L$ (4.3 g, 0.010 M) was concentrated under reduced pressure at room temperature to about half its volume. White, puffy crystals of *cis*-$PtCl_2LPCy_3$ precipitated on the addition of hexane (100 ml). They could be recrystallized from ethanol (10)–hexane (90), even in the presence of excess PCy_3 (2.8 g, 0.01 M) (yield: 5.6 g, 79%).

With $P(OPh)_3$: The addition of $P(OPh)_3$ (3.1 g, 0.010 M) to $PtCl_2L$ (2.1 g, 0.0049 M) in benzene gave a homogeneous solution, from which white crystals of the empirical formula of $Pt_2Cl_4L(P(OPh)_3)_3$ were isolated (yield: 3.0 g, 85%). (Found: C, 39.1; H, 4.4; N, 2.6%, $C_{64}H_{61}N_2O_9P_3Cl_4Pt_2$ requires: C, 38.3; H, 4.5; N, 2.5% which corresponds to a 1: 1 mixture of *cis*-$PtCl_2LP(OPh)_3$ and *cis*-$PtCl_2(P(OPh)_3)_2$).

With Pyridine: A chloroform solution of pyridine (1.8 g, 0.023 M) and $PtCl_2L$ (4.3 g, 0.010 M) was evacuated to give an oily residue. On the addition of ethanol to it, crystals of *cis*-$PtCl_2Lpy$ were formed (yield: 2.5 g, 49%). The *cis* configuration of the product was confirmed by Kurnakov's reaction.[11]

With CO: A benzene solution in which the $PtCl_2L$ complex had been dispersed was bubbled with CO gas. After about 10 min, a homogeneous yellow solution was obtained. The IR spectrum of this solution showed an absorption of a C–O stretching vibration at 2060 cm^{-1}. However, on crystallization, the original comples, $PtCl_2L$, was recovered.

Results and Discussion

The complexing ability of allylpyrazole has been investigated with Ni(II), Pd(II), and Pt(II) ions. As for Pd(II) and Pt(II), two types of complexes, MX_2L and MX_2L_2, have been obtained. The blue nickel complex has been prepared in the presence of a large excess of the ligand, but, unfortunately, its extreme sensitivity to moisture has prevented any accurate analysis or characterization.

Bis-allylpyrazole Complexes, MX_2L_2. The KBr disk or Nujol mull IR spectra of the complexes closely resemble those of the free ligands. Particularly, the C=C vibration of the allyl group found at 1660 or 1640 cm^{-1} does not differ from that of the free ligands (Table 3). This indicates that the olefinic part is free and that only the pyrazolyl nitrogen coordinates to the metal.

The *trans* configuration of PtX_2L_2 has been confirmed by Kurnakov's test. Attempts to isolate *cis*-PtX_2L_2 have been unsuccessful; probably the bulky nature of the ligands hinders the formation of the *cis*-isomer. In the case of palladium complexes, although it has not been

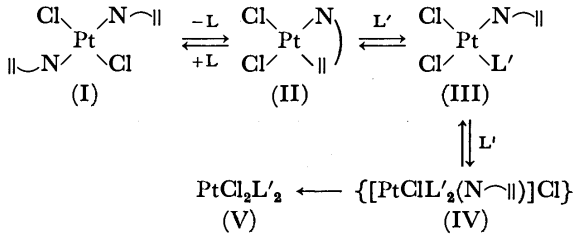

Fig. 2. Scheme.
N⌒|| =amtmp; III, L'=py, $AsPh_3$, PR_3 (R=Ph, Bu^n, Pr^i, Cy, OMe, OPh); IV ionic intermediate (not isolated); V, L'=$AsPh_3$; *trans*, PR_3; *cis* when R=Ph, OMe, OPh; *trans* when R=Bu^n, Pr^i.

definitely determined, the *trans* structure (Fig. 2-I) seems most likely in view of the following NMR results, similar to those for platinum complexes.

The NMR spectra of MX_2L_2 as a whole shift towards a lower magnetic field from the position of the free ligands, also indicating the apparent absence of the coordinated olefin; the coordinated olefin in metal complexes usually shows a remarkable shielding of olefinic protons.[9] Both 3-Me and allyl protons, except for H_β, have two sets of signals as is shown in Table 4. These signals can be assigned to two possible stereoisomers, *syn* and *anti*, which have been assumed in the NMR analysis of tetrazole complexes.[13] It is likely that the low symmetry of the ligand, together with its restricted rotation about M–N bonds, generates these rotational isomers.

Mono-allylpyrazole Complexes, MX_2L. The IR spectra of palladium complexes (Table 3) exhibit a sharp band at 1525 cm^{-1} for L=amdmp and at 1520 cm^{-1} for L=amtmp. No band was observed in the vicinity of 1660 cm^{-1}, the position of the C=C vibration for the free ligand. The above sharp band probably indicates the presence of a palladium-olefin bond (a lowering from the free ligand of $\Delta\nu$=135 or 140 cm^{-1}

a) Coupling constants ($|J_{Pt-H}|$, Hz) in parentheses.

respectively). The sharp bands of medium intensity at 480 cm^{-1} (amdmp) and 490 cm^{-1} (amtmp) may be assigned to ν(Pd–C_2). These bands are present in the region thought to indicate Pd-olefin stretching, as has been found for $PdCl_2$[tri(2-butenyl)arsine][3] (425 cm^{-1}) and $Pd_2Cl_4(C_2H_4)_2$ (427 cm^{-1}). The ^1H NMR spectrum of $PdCl_2L$ (L=amtmp) in $CDCl_3$ shows that the H_γ- and H_δ-protons differ in their chemical shifts ($|J_{H_\gamma-H_\delta}|=16$ Hz), while in the free ligand in $PdCl_2L_2$, the two protons are equivalent (Table 4). This inequality in the chemical shifts suggests that the olefinic group coordinates to palladium.

The platinum(II) complexes, PtX_2L, are generally more soluble than $PdCl_2L$ and can be well characterized by ^1H NMR (Table 4). All the protons of the allyl group in PtX_2L, except for a-Me, are shifted towards higher fields. Changes in the chemical shifts similar to that of the above spectra have been reported for pnicogen-olefin chelate complexes by several workers.[9,14,15] Since a rapid, bonded⇌non-bonded equilibrium of the Pt-olefin bond shows a rather small spin coupling ($|J_{Pt-H_\alpha}|=23$ Hz),[16] the large coupling constants ($|J_{Pt-H}|=60$ Hz) on the present complexes indicate that the allyl group is not liberated from platinum. The IR spectra of platinum complexes also show a characteristic band (*ca.* 1500 cm^{-1}) of the coordinated olefin ($\Delta\nu=140$—160 cm^{-1}). The band in the range of 500—530 cm^{-1} in the PtX_2L series may be assigned to ν(Pt–C_2).

The above IR and NMR results of MX_2L support Fig. 2-II as a possible structure. The molecular weight of $PtCl_2$(amtmp) confirms that the structure of the complex is not that of a chlorine-bridged dimer with monodentate amtmp. The measurement of powder X-ray diagrams has revealed isomorphism in both the palladium and platinum complexes; this also indirectly supports the idea that both Pd(II) and Pt(II) complexes have the same structure (Fig. 2-II).

The observation that the chemical shifts of the allyl protons of MCl_2L, where M=Pd or Pt and L=amtmp, move downfield when platinum is replaced by palladium is consistent with the lower olefin-metal interaction present in the palladium complex, such as in MX_2-(diolefin)[17] and olefinic tertiary phosphine complexes.[9]

Substitution Reaction of $PtCl_2L$ with Donor Molecules. The reaction scheme is outlined in Fig. 2. Only the 1-(2-methylallyl)-3,4,5-trimethylpyrazole complex, $PtCl_2L$, was investigated in detail.

In the reaction of an equivalent donor ligand with $PtCl_2L$ in benzene at room temperature, stable com-

a) All melting points were uncorrected. b) *cis*-Configuration of the complexes is judged from their color.

plexes with the empirical formula of $PtCl_2LL'$ (L'=PR_3, $AsPh_3$ or py) have been isolated and characterized (Table 5). All the new complexes, which are easily soluble in benzene, have a sharp IR absorption at *ca.* 1660 cm^{-1}, indicating the existence of free olefin.

In our system, "mixed" complexes of the *cis*-configuration have been specifically obtained, maintaining the *cis*-configuration of the original chelate complex, whereas the bridge-splitting reaction of Chatt and Venanzi[18] has usually been used in the laboratory to prepare mixed complexes with a *trans*-configuration. This selectivity of the *cis*-configuration can be explained by the relatively higher lability of olefin and the *cis*-directing power of the pyrazolyl nitrogen to the incoming ligand.

With one more equivalent donor (L'=PPh_3, PBu^n_3, PPr^i_3 or $AsPh_3$), the mixed complex, $PtCl_2LL'$, reacted to give a complex of the $PtCl_2L'_2$ type, displacing an equivalent allylpyrazole. The configurations of the isolated complexes depended upon the entering ligand; that is, a configuration favorable to each ligand was observed: *cis* to PPh_3, *trans* to PBu^n_3, PPr^i_3 and $AsPh_3$. These results can be interpreted by means of the consecutive displacement mechanism[19-21] *via* an ionic intermediate, as is shown in Fig. 2.

The equilibrium for the formation of $PtCl_2LL'$ lies too far to the left to permit the isolation of the complexes when L'=CO or $PhNH_2$, and, for steric reasons,[22,23] excess PCy_3 does not displace L from *cis*-$PtCl_2L(PCy_3)$.

When phosphite is used as a donor ligand, a mixture of *cis*-$PtCl_2LP(OR)_3$ and *cis*-$PtCl_2(P(OR)_3)_2$ is obtained. This is attributable to the analogous solubilities of the two compounds.

N-Allylprazole as a Ligand. III.* The Crystal and Molecular Structure of (1-Allyl-3,5-dimethylpyrazole)-copper(I) Chloride

Kazuo FUKUSHIMA, Akiko KOBAYASHI, Takeshi MIYAMOTO, and Yukiyoshi SASAKI
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
(Received July 31, 1975)

The crystal structure of (1-allyl-3,5-dimethylpyrazole)copper(I) chloride, $CuCl(C_8H_{12}N_2)$, has been determined by the three-dimensional X-ray analysis. The crystal is triclinic, space group $P\bar{1}$; $a=8.442(4)$, $b=8.873(6)$, $c=8.112(3)$ Å, $\alpha=103.44(3)$, $\beta=116.42(3)$, $\gamma=63.37(3)°$ and $Z=2$. The structure was refined to an R value of 0.056 for 1196 collected reflections. The complex has a dimeric structure in which the copper(I) ion is surrounded quasi-tetrahedrally by two bridging chlorines, a pyrazole-nitrogen and the olefinic part of the allyl group. The C=C bond distance (1.34 Å) scarcely shows any increase upon coordination to the metal. The olefin plane is almost perpendicular to the Cu-olefin bond axis and shows no significant bendings of the olefinic atoms out of the plane.

We have reported that *N*-allylpyrazole forms complexes with transition metals and in certain metal complexes (M=Cu(I), Ag(I)[1], Pd(II) and Pt(II)[2]) the coordination of the olefin site of the allyl group was indicated. In the Cu(I) and Ag(I) complexes, the coordination of the allyl site was evidenced by the decrease of the C=C vibration frequencies in the solid state. It is well known that Cu(I) ion easily forms complexes with olefins and together with Ag(I) presents the extreme of the transition metal-olefin compounds, in which the σ-donation of the olefinic electrons to the metal might be predominant. Up to present, however, the crystal structures of only a few Cu(I)-olefin complexes have been determined by the X-ray analysis and sufficient structural data are uavailable for the discussion. We now report the crystal structure of CuCl(admp (admp=1-allyl-3,5-dimethylpyrazole), one of the chelate olefin complex of Cu(I).

Experimental

The crystals of CuCl(admp) were grown from an ethanol solution as described in Ref. 1. They were stable in air. Oscillation and Weissenberg photographs were taken to determine the cell dimensions and the space group of the crystals, using the Cu$K\alpha$ radiation ($\lambda=1.5418$ Å).

Crystal data: $CuClC_8H_{12}N_2$, MW=235.1; triclinic, $a=8.442(4)$, $b=8.873(6)$, $c=8.112$ (3) Å, $\alpha=103.44(3)°$, $\beta=116.42(3)°$, $\gamma=63.37(3)°$, $V=486.1$ Å^3; $Z=2$, $D_m=1.67$ g cm^{-3}, $D_x=1.61$ g cm^{-3}; $\mu=0.47$ cm^{-1}; space group $P\bar{1}$.

The intensities of the reflections were measured on a Rigaku automated four-circle diffractometer. The dimensions of the specimen used for the data collection were about $0.1\times0.3\times0.5$ mm. The ω-2θ scan technique was employed. The scan speed was 2°/min in 2θ. The background counts of ten seconds duration were taken at both limits of the scan. The Mo$K\alpha$ radiation ($\lambda=0.71068$ Å) monochromated by a graphite crystal was used. Three standard reflections were measured during the data collection to check any deterioration of the crystal. Independent 1196 reflections ($|F_o|\geq3\sigma(|F_o|)$) were collected up to $2\theta=50°$.

The structure was solved by the conventional heavy atom method. Copper and chlorine atoms were found on a three dimensional Patterson map. All the carbon and nitrogen atoms were located from the successive Fourier and difference syntheses. The parameters of these atoms were refined by a block-diagonal least-squares method to $R=0.091$ with the isotropic temperature factors and to a $R=0.064$ with anisotropic ones. The calculated hydrogen positions were affirmed by the difference syntheses including six methyl hydrogens. Their parameters were refined using isotropic temperature factors. The final R value was 0.056. Atomic scattering factors were taken from International Tables for X-ray Crystallography.[3] Calculations were performed by a HITAC 8800/8700 computer at the Computer Centre of this University, using a local version of the Universal Crystallographic Computation Program System, UNICS.[4]

Description of the Structure

The final atomic parameters are listed in Table 1. The molecular and crystal structures of CuCl(admp) are shown in Figs. 1 and 2. The interatomic distances and bond angles within a molecule are listed in Tables 2 and 3. No unusual intermolecular proximity in the adjacent units is observed.

The complex has a centrosymmetric dimeric structure in which each copper atom is surrounded quasi-tetrahedrally by two bridging chlorines, a nitrogen and an olefinic part of the allyl group (Fig. 1). The olefinic carbons C7 and C8 are 2.13(1) Å and 2.15(1) Å apart

from Cu respectively. The distance between Cu and M, the middle point of C7–C8, is 2.03 Å, which indicates an evident bonding of Cu and olefin (Fig. 3). The dihedral angle between the two planes Cl–Cu–Cl′ and N2–Cu–M is 105.2°, and deviates to some extent from the theoretical 90° of a regular tetrahedron. Chlorine is bonded unequivalently to two copper atoms, 2.525(3) Å apart from one copper and 2.252(4) Å apart from the other. The pyrazole ring and two methyl carbons C4 and C5 make a perfect plane, from which the vectors Cu–N2 and C6–N1 are bent 15.8° and 2.9° respectively to the opposite directions of the plane.

The bond length of the coordinated C=C double bond is 1.34(2) Å. The vector Cu–M is perpendicular

to the C7–C8 bond (88.9(15)°). The deviations of the olefinic atoms from their least-squares plane are less than 0.1 Å and any distinctive features such as a bending out of the plane are not observed. The angle between this plane and Cu–M axis is 87.8°.

Discussion

Preceding studies by Bennett and co-workers have revealed that phosphine-olefin and arsine-olefin type of ligands successfully form stable olefin complexes with a number of transition metals,[5] making much use of the coordination ability of the donor atom. Among them, the structures of Mo(0),[6] Fe(0),[7] Ag(I)[8] and Rh(I)[9,10] complexes have been determined by the single crystal X-ray analysis, whereby a bridging bidentate in the Ag(I) complex and chelating bi- or quadridentate coordination in other complexes were known. Our nitrogen-olefin type ligand, admp, shows an analogous ability of the complex-formation with several transition metals to these chelate olefin type ligands.

As for Cu(I), several N-olefin,[11] P-olefin and As-olefin[12] complexes are known. They were assumed to contain a chelating bidentate coordination but none of them has been devoted to the X-ray analysis. With respect to the simple olefin complexes, up to now, the crystal structures of only three Cu(II)-olefin complexes have been determined by the X-ray analysis. The tetrahedral coordination form is found in CuCl(1,5-cyclooctadiene) dimer,[13] in which Cu is surrounded quasi-tetrahedrally by two bridging chlorines and two C=C moieties. Another coordination form is found in CuCl(1,3,5,7-cyclooctatetraene)[14] and CuCl (2,5-norbornadiene),[15] where two chlorines and one C=C make a trigonal plane around the central copper. The molecular structure of our admp complex, a dimeric tetrahedral coordination, is very analogous to that of the cyclooctadiene complex.

The most remarkable characteristic of the metal-olefin bond present in Cu(I)-admp is that the bond length of the coordinated C=C (1.34(2) Å) is scarcely increased compared with those of the free olefins (1.33—1.35 Å) and the C=C sp^2 plane scarcely shows a distortion upon coordination to Cu. In many metal-olefin complexes, a significant increase of the C=C distance upon complex formation is observed and hence regarded as the most important structural evidence to be explained in the metal-olefin bond nature. For instance, in above cited Fe(0) complex,[7] the bond length of the coordinated C=C is 1.45(2) Å, while that of the uncoordinated C=C is 1.33(2) Å. In Ag(I)[8] and Mo[6] complexes, the coordinated C=C shows a length of 1.41(6) Å and 1.39(2) Å respectively. This indicates that in Cu(I)-admp the metal-olefin interaction may be very weak.

It is known that Cu(I) and Ag(I) are able to form complexes with olefins which mainly consist of the σ-donation of the olefinic electrons to the metal. The IR spectra of Cu(I)- and Ag(I)-admp show the lowering shifts of the ν(C=C) band in the solid states but in solutions, free ν(C=C) and little change of

^{1}H-NMR of the olefinic protons are observed, which may be due to the liberation of the metal-olefin bond. Similar trends of the ^{1}H-NMR were noticed in the P-olefin and As-olefin type complexes of these metals. Such a lability in the Cu(I)-olefin and Ag(I)-olefin bonds is frequently observed.[16,17] It also indicates a weak metal-olefin interaction in these olefin complexes.

The weak metal-olefin interaction of CuCl(admp) is very likely but there remains some curiosity behind. The former X-ray studies on the crystal structures of Cu(I)- and Ag(I)-olefin compounds have reported the small but significant increases of the coordinated C=C bond distances.[18] Hence the metal-olefin interaction in CuCl(admp) should be considered to be particularly weak, although the stretching frequency, ν(C=C), is lowered by 103 cm^{-1}, which is much larger than those of Ag(I)-olefin (50—75 cm^{-1}) and is one of the largest value among the Cu(I)-olefin complexes (80—100 cm^{-1}).[11,12,19] Since the data are too limited and some are old, more investigations of many Cu(I)-olefin complexes will be required, in order to find the reason of this contradiction.

The Preparation, Infrared Spectra, and Thermal Stability in the Solid State of Nickel(II) Complexes with edda-type Polyamino Carboxylic Acids

Ichiro HIRAKO, Tasuku MURAKAMI, and Masahiro HATANO

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, 2-1-1 Katahira, Sendai 980

(Received September 9, 1975)

Some nickel(II) complexes with optically active ethylenediamine-*N,N'*-diacetic acid(edda)-type polyamino carboxylic acids were prepared. Their electronic and infrared spectra and thermogravimetric curves were measured in the solid state. The stretching frequencies of the coordinated carboxylate group and the thermal stability of these complexes in the solid state were quite different from those of bis(amino acidato) complexes.

On the structures and thermal stabilities in the solid state of diaquabis(amino acidato)nickel(II) complexes, extensive works have been reported. The crystal structure of diaquabis(glycinato)nickel(II) is a slightly distorted octahedral, with two glycinate anions of a *trans(N,N)*-configuration in a plane, and with two water molecules occupying its apical positions.[1,2] The diaquabis(amino acidato) complexes are easily dehydrated on heating to form their anhydrous complexes, which are polymeric with bridging through the non-donating oxygen atom in the carboxylate group.[3,4]

On the other hand, not so much has been reported concerning the nickel(II) complexes with edda-type polyamino carboxylic acids, which are expected to form complexes with a *cis(N,N)*-configuration in a plane. In order to obtain information on the differences in structures and thermal stabilities between the edda-type complexes and the bis(amino acidato) complexes, we have now prepared new edda-type complexes and measured their electronic and infrared(IR) spectra and thermogravimetric(TG) curves.

Experimental

Preparation of Ligands. Ethylenediamine-*N,N'*-di-L-α-propionic acid (abbreviated to H_2eddp), ethylenediamine-*N,N'*-di-L-α-isovaleric acid (H_2eddv), ethylenediamine-*N,N'*-di-L-α-hydrocinnamic acid (H_2eddc), ethylenediamine-*N,N'*-di-L-α-(β-hydroxy)propionic acid (H_2eddh), and (*S,S*)-1,1'-ethylenedipyrrolidine-2,2'-dicarboxylic acid (H_2epro) were prepared from L-alanine (L-alaH), L-valine (L-valH), L-phenylalanine (L-phalaH), L-serine (L-serH), and L-proline (L-proH) respectively by a method similar to that described in the literature.[5] These acids were identified by their elementary analyses. The ethylenediamine-*N,N'*-diacetic acid (H_2edda) was obtained commercially. The structural formulas of these polyamino carboxylic acids are shown in Fig. 1.

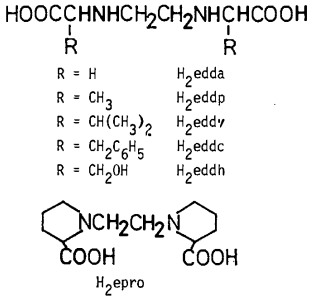

Fig. 1. edda-Type polyamino carboxylic acids. Except for H_2edda these acids are optically active.

Preparation of Nickel(II) Complexes. Hydrated Complexes: The hydrated nickel(II) complexes of these edda-type polyamino carboxylic acids were prepared by the following procedures. Basic nickel(II) carbonate was mixed with an equimolar amount of each polyamino carboxylic acid in an aqueous solution. The solution was concentrated at 70—80 °C on a water bath, and then allowed to stand. Within a few days, blue crystals separated out; they were recrystallized from water. The analytical data of these complexes are summarized in Table 1.

TABLE 1. ANALYTICAL DATA

Complex	C% Obsd (Calcd)	H% Obsd (Calcd)	N% Obsd (Calcd)
$[Ni(edda)(H_2O)_2]\cdot H_2O$	25.26 (25.06)	5.59 (5.57)	9.86 (9.76)
$[Ni(eddp)(H_2O)_2]$	32.41 (32.21)	6.61 (6.06)	9.41 (9.40)
[Ni(eddp)]	36.58 (36.52)	5.59 (5.33)	10.66 (10.63)
$[Ni(eddv)(H_2O)_2]$	42.19 (40.80)	7.55 (7.43)	7.87 (7.94)
[Ni(eddv)]	45.17 (45.40)	6.95 (6.64)	8.61 (8.84)
$[Ni(eddc)(H_2O)_2]\cdot H_2O$	50.80 (51.20)	5.69 (5.55)	6.08 (6.10)
[Ni(eddc)]	56.95 (57.82)	5.66 (5.35)	6.68 (6.67)
$[Ni(eddh)(H_2O)_2]$	29.14 (29.21)	5.47 (5.48)	9.01 (8.54)
$[Ni(epro)(H_2O)_2]$	41.00 (41.30)	5.92 (6.35)	8.10 (8.03)

Anhydrous Complexes: The anhydrous complexes of eddc and eddv were separated out from concentrated hot (70—80 °C) aqueous solutions. The anhydrous eddp complex was obtained on heating its hydrate *in vacuo* at 250 °C. See Table 1 for the results of analyses.

Bis(amino acidato) Complexes: Some bis(L-amino acidato)-nickel(II) complexes were prepared from basic nickel(II) carbonate and L-amino acids according to the method in the literature.[6] These bis(amino acidato) complexes were identified by means of their elementary analyses.

Measurements. The electronic and IR spectra were recorded with Hitachi EPS-3T and EPI-S_2 or EPI-G_2 spectrophotometers respectively, using KBr pellets. The TG curves were obtained with a Perkin-Elmer TGS-1 thermobalance at a heating rate of 8 °C/min in a nitrogen stream. All of the samples used for the TG measurements were ground

and sieved to obtain finely powdered fractions below 100 mesh.

Results and Discussion

The electronic spectra in the solid state of the hydrated nickel(II) complexes of edda, eddp, and eddc exhibited three absorption peaks, at about 10200, 13300 and 16200 cm^{-1}, which are characteristic of the octahedrally coordinated nickel(II) ion. Their anhydrous complexes also showed similar spectra, the peaks of which shifted to slightly lower wave numbers. This spectral profile of the edda-type complexes is identical with that of bis(amino acidato) nickel(II) complexes, suggesting that the anhydrous edda-type complexes are also polymeric, with bridging through the carboxylate groups, like the anhydrous bis(amino acidato) complexes.[4]

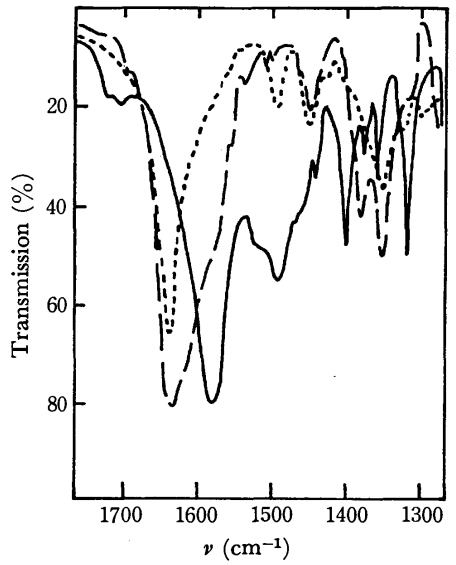

Fig. 2. IR spectra (1700—1300 cm^{-1}) of [Ni(eddp)-$(H_2O)_2$] (—), [Ni(eddp)](—), and [Ni(eddc)] (···).

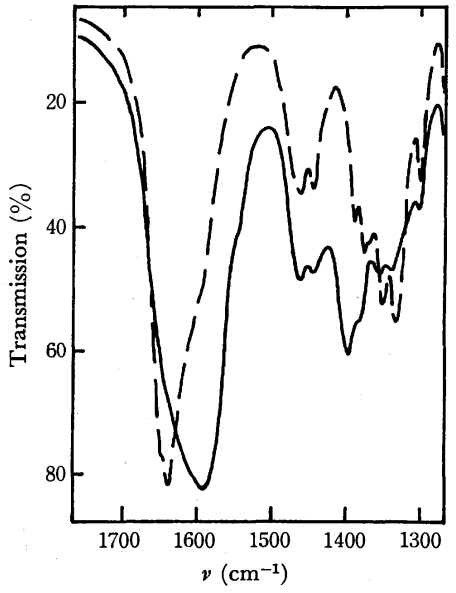

Fig. 3. IR spectra (1700—1300 cm^{-1}) of [Ni(eddv)-$(H_2O)_2$] (—) and [Ni(eddv)] (– –).

Figures 2 and 3 show the IR spectra of the complexes of eddp, eddv, and eddc in the region of 1300—1700 cm^{-1}. The strong band at 1590 cm^{-1} and the medium band at 1400 cm^{-1}, both of which appeared for the hydrated complex of eddp, can be assigned to the antisymmetric and symmetric stretching vibrations of the coordinated COO^- group respectively, as in the case of the bis(amino acidato) complexes.[4,6] When the hydrate was dehydrated on heating, the strong band shifted to 1640 cm^{-1}, with a shoulder at 1580 cm^{-1}. Similarly, the strong band at 1590 cm^{-1} which appeared for the hydrated complex of eddv shifted to 1640 cm^{-1} in its anhydrous complex. Further, the anhydrous eddc complex exhibited the strong band at 1640 cm^{-1}, Therefore, it can be concluded that the antisymmetric COO^- vibration appears at 1640 cm^{-1} for the anhydrous nickel(II) complexes of the edda-type polyamino carboxylic acids. Such a high frequency of the antisymmetric COO^- stretching vibration has also appeared for palladium(II) and platinum(II) complexes of amino acids.[7]

On the other hand, the medium band at 1400 cm^{-1} disappeared in the anhydrous complexes, as may be seen in the figures. Instead of this band, two medium bands appeared at 1380 and 1350 cm^{-1} for the anhydrous eddp complex. Either of these two bands can be expected to correspond to the symmetric COO^- vibration. The anhydrous eddv complexes also exhibited two bands at 1350 and 1330 cm^{-1}. For the anhydrous eddc complex, only one band appeared at 1350 cm^{-1} with a medium strength. From these findings, it seems plausible to assign the band at 1350 cm^{-1} to the symmetric COO^- stretching vibration of the anhydrous complexes.

TABLE 2. THE COO^- STRETCHING FREQUENCIES (cm^{-1})

Complex	ν_{asym}	ν_{sym}	$\Delta\nu$

a) For a residue of nickel oxide.

the antisymmetric and symmetric COO^- vibrations is much greater for the anhydrous edda-type complexes than for their hydrates, while in the bis(amino acidato) complexes the $\Delta\nu$ values of the hydrates are slightly greater than those of their anhydrous complexes.[4] It has been accepted by several authors[6,7] that, as the covalent character of the bond between the metal ion and the coordinated oxygen atom increases, the coordinated carboxylate group becomes more asymmetric, and that, as a result, the increase in the covalent character results in an increase in the frequency separation ($\Delta\nu$) between the two COO^- stretching bands. For example, large $\Delta\nu$ values(about 270 cm^{-1}) have been obtained for the bis(glycinato)palladium(II) and -platinum(II) complexes, in which the covalent character of the metal-oxygen bond is said to be very strong.[7] Therefore, the abnormal large values of $\Delta\nu$ observed for the anhydrous edda-type complexes suggest that the coordinated carboxylate group becomes more asymmetric on dehydration, in spite of the polymerization through the non-donating oxygen atom in the carboxylate group; we might conclude that the covalent character of the metal-oxygen bond in one complex molecule increases also.

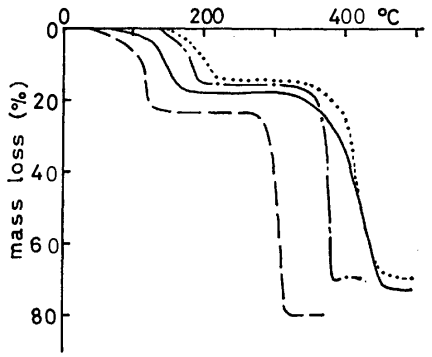

Fig. 4. TG curves of $[Ni(edda)(H_2O)_2]\cdot H_2O$ (—), $[Ni(eddp)(H_2O)_2]$ (···), $[Ni(gly)_2(H_2O)_2]$ (-·-), and $[Ni(L\text{-}ala)_2(H_2O)_2]\cdot 2H_2O$ (—).

Figure 4 shows the TG curves of the hydrated complexes of edda, eddp, glycine and L-alanine. The temperature range and the percentage of mass loss obtained from the TG curves are summarized in Table 3. As may be seen in Fig. 4, the hydrated complexes of edda and L-alanine released three or four moles of water in two steps in the temperature range from 50 to 180 °C. The step in the lower temperature range corresponds to the dehydration of lattice water(s), and the other step, to that of coordinated waters. However, the lattice water was dehydrated over a wider temperature range than the coordinated water. Though the hydrated eddc complex has three moles of water, the two steps corresponding to the dehydrations of lattice and coordinated waters were not distinguished.

The anhydrous edda-type complexes decomposed at a higher temperature than the anhydrous bis(amino acidato) complexes; further, the decomposition of the edda-type complexes was very slow, as may be seen in Fig. 4. These findings show that the edda-type anhydrous complexes are thermally more stable than the bis(amino acidato) complexes in the solid state. This high thermal stability of the edda-type complexes probably results from the increase in the covalent character in the intra-molecular metal-oxygen bond, as is to be expected from the behavior of the COO^- vibrations.

As may be seen in Table 3, bis(L-serinato)nickel(II), which has been established by X-ray analysis to have a *cis*(*N*,*N*)-configuration,[8] decomposed in a lower temperature range than did the edda-type complexes. Similarly, the bis(glycinato) complex, with a *trans*(*N*,*N*)-configuration, also decomposed in the lower temperature range. Further, the bis(L-serinato) complex shows a difference($\Delta\nu$) between the two COO^- vibrations similar to that of the bis(glycinato) complex (Table 2). These findings indicate that the *cis-trans* isomerism is not very significant for the thermal stability and the COO^- vibrations. Therefore, the high stability and the abnormal behavior in the COO^- vibrations observed for the edda-type complexes are expected to result from some structural factors, such as the tetradentate character of the ligands, other than the *cis-trans* isomerism.

The authors wish to thank Professor Takuji Kanno and Dr. Katsuo Itoh of this university for their permission to use the Perkin Elmer thermobalance.

The X-Ray Structure of the $(+)_{589}$-*cis*(O)*trans*(N_α)*cis*(N_δ)-Bis(L-ornithinato)cobalt(III) Complex

Yasuji NAKAYAMA, Shun'ichiro OOI, and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received September 16, 1975)

$(+)_{589}$-Bis(L-ornithinato)cobalt(III) nitrate monohydrate was isolated by ion-exchange chromatography from a reaction mixture of trinitratotriamminecobalt(III) with L-ornithine at pH 9, and was assigned to the *cis*-(O)*trans*(N_α)*cis*(N_δ) isomer on the basis of the absorption and circular dichroism spectra. Then, the geometry of the complex was confirmed by X-ray structure analysis. The red crystal is orthorhombic, with these cell dimensions: $a=14.380$, $b=16.493$, and $c=6.787$ Å. The space group is $P2_12_12_1$, and $Z=4$. The crystal structure was solved by the Patterson and Fourier techniques and was refined by the least-squares method to R 0.099. The Co atom is surrounded by 2 O and 4 N atoms, the former being in *cis* positions. Each of the L-ornithinato ligands assumes the facial coordination, and the complex cation has an approximate two-fold axis by which the ligand are correlated.

The ornithinate ion, H_2N_δ–$(H_2C)_3$–$HC(H_2N_\alpha)$–COO^-, has three donor atoms ($O_{(carboxyl)}$, N_α, N_δ) and is capable of coordinating facially to a metal ion with octahedral stereochemistry,[1] while it acts as a bidentate ligand for the metal ion amenable to a square-planar or an elongated octahedral coordination.[2,3] We have prepared the bis(L-ornithinato)-cobalt(III) complex, $[Co(L\text{-}C_5H_{11}N_2O_2)_2]NO_3\cdot H_2O$, by the reaction of trinitratotriamminecobalt(III) with L-ornithine at pH 9. The complex cation may exist in three geometrical isomers, as is shown in Fig. 1. Actually,

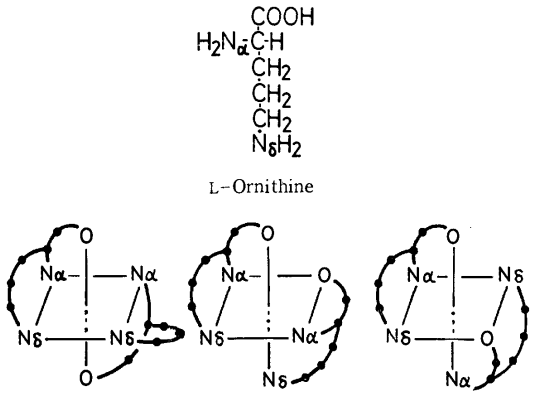

Fig. 1. Possible geometrical isomers of bis(L-ornithinato)-cobalt(III) ion.

the three bands could be separated from the reaction mixture by means of a cation-exchange column. The compound obtained from the most predominant band was inferred to be the *cis*(O)*trans*(N_α)*cis*(N_δ) isomer from its absorption and circular dichroism spectra. In order to confirm the geometry of the complex and in order to examine the conformational details of the chelate rings, the single crystal X-ray structure analysis was performed.

Experimental

Preparation of the Complex. From 1.5 g (0.009 mol) of L-ornithine hydrochloride and 1.5 g (0.009 mol) of silver nitrate, L-ornithine hydrogen nitrate was prepared as an aqueous solution of 40 ml, in which 1.3 g (0.0045 mol) of trinitratotriamminecobalt(III) was suspended. Then, 0.7 g (0.018 mol) of sodium hydroxide in 15 ml of water was added, and the solution was stirred at 50 °C for 5 h in the presence of activated charcoal. After the filtration of the charcoal and dilution to 100 ml, the reaction mixture was sorbed on the cation-exchange column (100—200 mesh Dowex 50W-X8 in the ammonium form). Three main bands developed upon elution with a 0.1 M NH_4NO_3 solution; the fastest band is red-violet in color, while the other two are red, the second band being overwhelmingly most abundant. Red, needle-like crystals were obtained by the slow evaporation of the solution from the second band; they were subsequently recrystallized from water.

Found: C, 29.69; H, 6.16; N, 17.34%; Calcd for $C_{10}H_{24}O_8N_5Co$: C, 29.93; H, 6.04; N, 17.45%.

Spectroscopic Measurements. The AB and CD spectra were recorded at room temperature using a Hitachi EPS-3T Recording Spectrophotometer and a JASCO J-20 Automatic Recording Spectropolarimeter respectively.

X-Ray Data Measurement. Crystal Data: *cis*(O)*trans*-(N_α)*cis*(N_δ)-$[Co(L\text{-}C_5H_{11}O_2N_2)_2]NO_3\cdot H_2O$, $FW=401.32$, orthorhombic, $a=14.380(4)$, $b=16.493(3)$, $c=6.787(2)$ Å, $V=1609.7$ Å^3, $Z=4$, $D_m=1.66$ (flotation), $D_x=1.66$ g cm^{-3}, space group $P2_12_12_1$, $\mu(NiK_\alpha)=25.3$ cm^{-1}. The unit-cell dimensions were determined by the least-squares analysis of the θ values from 45 high-angle reflections on zero-level Weissenberg photographs calibrated with silicon powder.

Multiple-film equi-inclination Weissenberg photographs were taken about a (0—7kl) and c (hk0—6) axes with NiK_α radiation. Crystals with the dimensions of $0.20\times0.15\times0.15$ and $0.15\times0.17\times0.18$ mm were used for the intensity-data collections about the a and c axes respectively. The intensities were measured visually by the use of a calibrated intensity strip and were corrected for Lp factors, spot shape, and absorption. The structure amplitudes were placed on a common arbitrary scale by the least-squares method. A total of 1636 independent reflections was obtained; of those, the intensities of 172 reflections were too weak to be observed.

Determination and Refinement of Crystal Structure

The coordinate of the Co atom was derived from the three-dimensional Patterson synthesis. Approximate coordinates of the other non-hydrogen atoms were obtained from successive Fourier syntheses. The positional and thermal parameters were refined by the block-diagonal-matrix least-squares method, the function minimized being $w(F_o-|F_c|)^2$. Five cycles of refine-

ment ($w=1$ for all reflections) with isotropic temperature factors reduced R and R' ($=[\Sigma w(F_o-|F_c|)^2/\Sigma wF_o^2]^{1/2}$) to 0.116 and 0.152 respectively. In the subsequent refinements, the following weighting scheme was employed:

$$w = 0.3 \quad \text{for } F_o < F_{min}$$
$$w = 1.0 \quad \text{for } F_{min} \leq F_o \leq F_{max}$$
$$w = F_{max}/F_o \quad \text{for } F_{max} < F_o$$

F_{max} and F_{min} were varied as is indicated by F_o and $(\sin\theta/\lambda)$ analysis of $w(F_o-|F_c|)^2$. Moreover, four reflections (020, 080, 120, 200) thought to be suffering from extinction errors were omitted in the least-squares calculation. Anisotropic thermal parameters were introduced in the following step-by-step order: i) first, to the Co atom only; then, ii) to the O atoms of the water molecule and the nitrate ion, and finally, iii) to all the atoms. R' was thus improved in an order of 0.151, 0.143, and 0.133 ($R=0.099$). R'-ratio tests at each stage showed the introduction of thermal anisotropy to be significant at the 0.01 level of significance.[4] In the final cycle of the least-squares refinement, the shifts of the parameters were $<0.3\sigma$, F_{max} and F_{min} being 20.2 and 4.7 respectively. The absolute configuration of the complex cation was derived from the well-established configuration of the L-ornithine.

The atomic scattering factors for C, N, O, and neutral Co atoms were employed from Ref. 5. The real part of the anomalous dispersion was taken into account for the Co atom. The final atomic coordinates and thermal parameters are listed in Table 1. The atomic coordinates correspond exactly to the absolute crystal structure. A complete list of the F_o and $|F_c|$ values is preserved by the Chemical Society of Japan (Document No. 7608). All the computations were carried out by means of the FACOM 270-30 computer at Osaka City University. The computer programs used were RSSFR-4 (Fourier synthesis) and HBLS-IV (least-squares calculation).

Results and Discussion

The AB and CD spectra are shown in Fig. 2, and they are summarized in Table 2. The pattern of the first absorption band (Band I) indicates that the present complex has two O atoms in the *cis* positions. In the figure, the CD curves for the bis(L-2,3-diaminopropionato)cobalt(III) and bis(L-2,4-diaminobutyrato)-cobalt(III) ions are also shown as references.[6,7] In these ions, the amino acidato ligand has the facial coordination *via* 2 N and O atoms and forms a 5-membered ring composed of the carboxyl and α-amino groups as well as a 5- or 6-membered chelate ring involving α- and β- or γ-amino groups. These two complexes have been assigned to the *cis*(O)*trans*(N_α)*cis*(N_β or N_γ) isomers by Liu *et al.*[6,7] The three complexes in Fig. 2 show similar Cotton effects in the Band I region. This

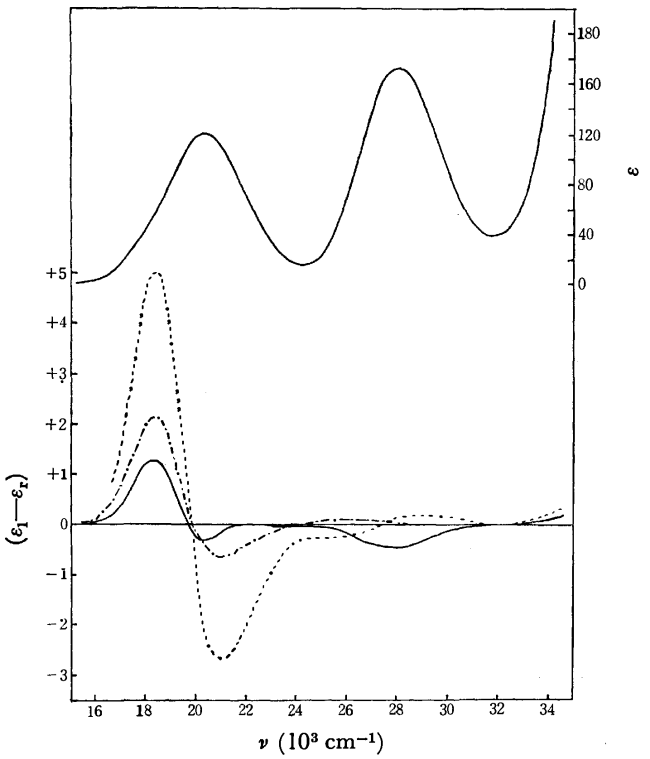

Fig. 2. AB and CD spectra (—) of the present bis(L-ornithinato)cobalt(III) ion, and CD spectra of: (···) *cis*(O)*trans*(N_α)*cis*(N_β) isomer of bis(L-2,3-diaminopropionato)cobalt(III) ion; (-·-) *cis*(O)*trans*(N_α)*cis*(N_γ) isomer of bis(L-2,4-diaminobutyrato)cobalt(III) ion.

implies that the present complex can be assigned to the *cis*(O)*trans*(N_α)*cis*(N_δ) isomer, though the sign of the CD band in the second absorption-band region (Band II) is opposite to the signs of the complexes cited for comparison. However, since the correlation between the CD spectrum and the absolute configuration of the Co(III) chelate of the tridentate α-amino acidato ligand has not yet been established, X-ray structure analysis was undertaken in order to establish the stereochemistry of the present complex.

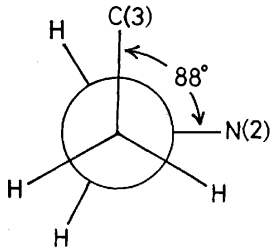
N'(2)–Co–O'(1)	89.5(4)		

Figure 3 shows the absolute configuration of the complex cation. This has a pseudo two-fold axis which passes through the Co atom and bisects N(2)–Co–N'(2) bond angle. This axis correlates the primed and unprimed atoms in Fig. 3. In the bond lengths and angles (Table 3), those related by the two-fold axis are in good agreement within the limits of experimental error.

In the 7-membered chelate ring composed of $N_\alpha(1)$, $C_\alpha(2)$, $C_\beta(3)$, $C_\gamma(4)$, $C_\delta(5)$, $N_\delta(2)$, and Co atoms, the N_α–Co–N_δ bond angle is larger than 90°, the average value being 95.5°; this can be ascribed to the repulsion between two confronting H atoms—H($N_\alpha H_2$) and H($C_\delta H_2$). This value is comparable to that (92°—95°) in the 6-membered ring formed by the trimethylenediamine molecule (tn) and the Co atom.[8,9] The bond angle of Co–N_α–C_α is close to the tetrahedral angle, while that of Co–N_δ–C_δ is much greater than 109.5°, but compares with the corresponding one in the tn ring. The C–C–C and N–C–C angles range from 108° to 116°. They are also similar to those in the tn ring of $[Co(tn)_3]^{3+}$ and the 7-membered ring found in bis(L-ornithinato)palladium(II), but are larger by 2°—5° than those in the L-ornithine hydrochloride[10] and hydrobromide.[11]

The $-CH-CH_2-CH_2-CH_2-$, $-CH_2-CH_2-CH_2-NH_2-$ and $-CH_2-CH_2-NH_2-Co-$ fragments in the 7-membered ring assume a *gauche* conformation. However, the $-H_2C(3)-H_2C(4)-H_2C(5)-H_2N(2)-$ fragment and the corresponding one composed of the primed atoms are somewhat close to the eclipsed conformation; the torsional angles between the two terminal bonds about the central C–C bond are 88° for the unprimed fragment and 87° for the primed one. These values agree well within the limits of experimental error (88° on the average).



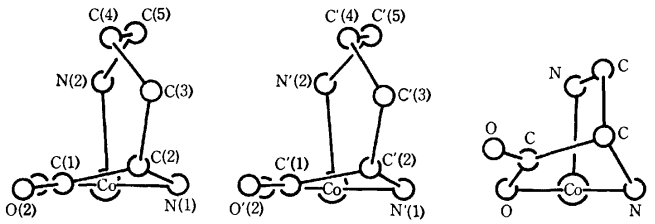


Fig. 4. Elevation of the chelate ring in: (a) and (b), bis(L-ornithinato)cobalt(III) nitrate monohydrate; (c), *cis* (O) *trans* (N_a) *cis* (N_β)-bis (L-2,3-diaminopropionato)-cobalt(III) bromide. Numbers in parentheses indicate the deviation (Å) of the C_α atoms in 5-membered glycinato ring from the (Co, N_α, O) planes.

The elevation of the 5-membered rings (or glycinato rings) formed by the N_α, C_α, $C_{(carboxyl)}$, O, and Co atoms are shown in Fig. 4, where the glycinato ring in bis(L-2,3-diaminopropionato)cobalt(III) bromide is also drawn for comparison.[12] Although the bond lengths and angles in the glycinato ring of the present complex are in good harmony with those in the planar chelate ring made by a glycinate ion and a Co atom,[13] the C(2) and C'(2) atoms are pulled upward from the $Co\langle^{N(1)}_{O(1)}$ and $Co\langle^{N'(1)}_{O'(1)}$ planes by the wing composed of C_α, C_β, C_γ, C_δ, N_δ, and Co atoms. In the glycinato ring of tridentate α-amino acid, the deviation of the C_α atom from the (Co, N_α, O) plane appears to be reduced as the members of the wings are increased.

TABLE 4. PLANES DEFINED BY THE O, Co, AND N_α ATOMS
Deviations(Å) of atoms from the plane are given in square brackets.

TABLE 5. DATA OF THE HYDROGEN BONDS

A–H···B		A···B	H···B	A–H···B	Positions[a] of A	B
N(1)	H_2O	2.92(2)Å	1.91Å	165°	1	1
N(1)	O(4)	2.97(2)	2.01	155	1	3
N(2)	O(2)	2.94(2)	1.98	153	1	4
N(2)	O'(2)	3.05(2)	2.19	139	1	2
N'(1)	O(2)	2.80(2)	2.05	128	1	4
N'(2)	O(3)	2.90(2)	1.99	146	1	1
N'(2)	O(5)	3.01(2)	2.02	161	1	3
H_2O	O(3)	2.94(2)			1	1
H_2O	O'(2)	2.77(2)			1	5

a) Numerals refer to the following equivalent positions:
1 x, y, z 2 $x, y, 1+z$ 3 $x, y, -1+z$
4 $1/2-x, 1-y, 1/2+z$ 5 $1-x, -1/2+y, -1/2-z$

The crystal structure viewed down the c axis is depicted in Fig. 5. There are N–H···O and O–H···O hydrogen bonds in the crystal (Table 5), though they are rather weak in view of the distance between the proton donor and the acceptor. The positions of the H atoms of the amino groups are calculated on the assumption that the N–H distance is 1.03 Å. Both of the H atoms in the $N(1)H_2$ group and in the water molecule, and one of those in the $N(2)H_2$ and $N'(2)H_2$ groups participate in the hydrogen bonding, while none of those in $N'(1)H_2$ groups do.

The authors wish to express their thanks to the Ministry of Education for financial support of this work. They are also grateful to Dr. Ken Hirotsu who adapted the computer programs to FACOM 270-30 computer at Osaka City University.

The Crystal Structure of α-$K_8SiW_{11}O_{39}\cdot 13H_2O$

Kazuko Y. MATSUMOTO and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received September 17, 1975)

α-$K_8SiW_{11}O_{39}\cdot 13H_2O$ is cubic with the space group $P\bar{4}3m$ and $a=10.654(1)$ Å; $D_m=4.40$ g cm^{-3}, $D_x=4.42$ g cm^{-3} for $Z=1$. The crystal contains a discrete $SiW_{11}O_{39}^{8-}$ ion, which is almost identical to α-$SiW_{12}O_{40}^{4-}$ anion in shape and in size but one tungsten atom and the exterior terminal oxygen atom are absent. The position of the vacant hole could not be located because of the seemingly high symmetry of T_d of the polyanion caused by the orientational randomness of the anions. The silicon atom at the center of the polyanion lies on the origin of the cubic lattice and the potassium cations linking α-$SiW_{11}O_{39}^{8-}$ ions are at the middle points of adjacent polyanions.

The 11-tungstosilicate salts were first prepared by Marignac,[1] however he described the compounds as 10-tungstosilicates, $M_8^I SiW_{10}O_{36}$. Most of the 10-tungstosilicates given in the Gmelin's Handbook[2] are now believed to be 11-tungstosilicates.

This heteropoly anion can be regarded as an hydrolytic degradation product of α-$SiW_{12}O_{40}^{4-}$ anion and the reaction is as follows;

$$\alpha\text{-}SiW_{12}O_{40}^{4-} + 6OH^- \rightleftharpoons \alpha\text{-}SiW_{11}O_{39}^{8-} + WO_4^{2-} + 3H_2O$$

This reaction is reversible and addition of acid to a solution of α-$SiW_{11}O_{39}^{8-}$ in the presence of WO_4^{2-} yields α-$SiW_{12}O_{40}^{4-}$ immediately. Even in the absence of WO_4^{2-}, α-$SiW_{12}O_{40}^{4-}$ is formed on acidification from α-$SiW_{11}O_{39}^{8-}$.

Recent investigation by Souchay *et al.*[3] has shown that the α-$SiW_{11}O_{39}^{8-}$ anion is an important intermediate product in the formation of α-$SiW_{12}O_{40}^{4-}$ and the reaction proceeds as follows;

$$SiO(OH)_3^- + 11WO_4^{2-} + 15H^+ \longrightarrow \alpha\text{-}SiW_{11}O_{39}^{8-} + 9H_2O$$

$$\alpha\text{-}SiW_{11}O_{39}^{8-} + WO_4^{2-} + 6H^+ \longrightarrow \alpha\text{-}SiW_{12}O_{40}^{4-} + 3H_2O$$

On the other hand, addition of acidified sodium silicate to a solution of acidified sodium tungstate gives β-$SiW_{11}O_{39}^{8-}$ and β-$SiW_{12}O_{40}^{4-}$ as is shown in Fig. 1. As for the structure of α- and β-$SiW_{12}O_{40}^{4-}$, we have already published the results.[5-7] Recently the formation of three isomers of β-$SiW_{11}O_{39}^{8-}$, β_1, β_2, and β_3, through $SiW_9O_{34}^{10-}$ and $HSiW_9O_{34}^{9-}$ have been reported by Contant *et al.*[4] However these isomers are outscope of the present study. The reaction

$$SiW_{11}O_{39}^{8-} + M^{n+} \longrightarrow SiW_{11}MO_{40}^{(8-n)-}$$

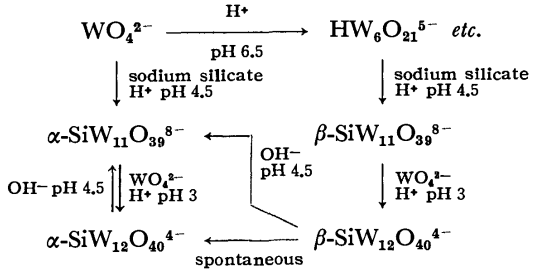

Fig. 1. Formation condition of $SiW_{11}O_{39}^{8-}$ and $SiW_{12}O_{40}^{4-}$ anions at room temperature.

where M is Mn(II), Fe(II), Co(II), Ni(II), Cu(II), Fe(III), Cr(III), V(IV), V(V), and Mo(VI) were reported[8] and the resultant $SiW_{11}MO_{40}^{(8-n)-}$ anions have Keggin structure,[9] in which one of the twelve tungsten atoms is substituted by M. But lanthanide cations (Ln) may be too large to be included in the Keggin structure and form salts of the type $K_{10}Ln(SiW_{11}O_{39})_2\cdot nH_2O$.[10]

Present crystal-structure determination of α-$K_8SiW_{11}O_{39}\cdot 13H_2O$ have revealed that the structure of the α-$SiW_{11}O_{39}^{8-}$ is very similar to that of α-$SiW_{12}O_{40}^{4-}$, which has the Keggin structure, but one tungsten atom and its terminal oxygen atom are missing.

Experimental

Potassium hydroxide was added to a hot concentrated solution of α-$K_4SiW_{12}O_{40}$ with mole-ratio of 6:1; the pH of the solution was increased to 4.5. The crystals of α-$K_8SiW_{11}O_{39}\cdot 13H_2O$ were precipitated on cooling and was recrystallized from water. They are colorless, stable in air and more resistant to reduction that the α-$SiW_{12}O_{40}^{4-}$.

Preliminary oscillation and Weissenberg photographs showed that the crystal is cubic. No systematic absence of the reflections was observed, therefore three space groups, $P\bar{4}3m$, P432, and Pm3m were possible, however further structure analysis determined the space group to be $P\bar{4}3m$. The intensities of the reflections up to $2\theta=60°$ were measured on the Rigaku four-circle diffractometer with graphite-monochromated Mo$K\alpha$ radiation ($\lambda=0.71069$ Å). The ω-2θ scan technique was employed and a total of 312 independent reflections, whose intensities were larger than 3σ, were used for the structure analysis. The data were corrected for Lorentz and polarization factors. No corrections were made for absorption and extinction effects. The crystal used for intensity measurement was of the dimensions $0.1\times0.1\times0.1$ mm and the crystal data are as follows;

α-$K_8SiW_{11}O_{39}\cdot 13H_2O$
F.W. = 3220.7
cubic $P\bar{4}3m$
$a = 10.654(1)$ Å
$V = 1209.3$ Å^3
$Z = 1$
$D_m = 4.40$ g cm^{-1}, $D_x = 4.42$ g cm^{-1}
$\mu = 302.0$ cm^{-1} (for Mo$K\alpha$ radiation)

Structure Determination

The structure was solved by the heavy atom method. The three dimensional Patterson map could not be at

first solved with the three possible space groups assuming eleven tungsten atoms per molecule, but satisfactory solution was obtained assuming that eleven tungsten atoms occupy the twelve tungsten positions of the Keggin structure[9] with equal statistical weight and that the space group is $P\bar{4}3m$. All the other atoms, except five potassium cations and thirteen water molecules, were located from the Fourier synthesis based on the coordinates of tungsten atoms. The structure was refined by the block diagonal least-squares technique with a local version of UNICS[11] program. A weighting scheme, $w=0.2$ for $|F_o|<41$ and $w=1$ otherwise, was employed. At the last stage of the refinement, the temperature factors were assumed to be anisotropic and the last R value, $R=\sum||F_o|-|F_c||/\sum|F_o|$, was 0.069.

The atomic scattering factors used were taken from the International Tables for X-Ray Crystallography.[12] The calculations were performed on a HITAC 8700/8800 computer at the Computer Centre of the University of Tokyo. The atomic coordinates and the temperature factors are listed in Table 1. The final F_o-F_c table is kept at the office of Chemical Society of Japan as Document No. 7607.

Results and Discussion

The structure of the α-$SiW_{11}O_{39}^{8-}$ anion results from removing one WO_6 octahedron from the α-$SiW_{12}O_{40}^{4-}$, which has the Keggin structure, and is illustrated in Fig. 2 as a coordination polyhedra model. The result of the structure determination has shown that α-$SiW_{11}O_{39}^{8-}$ is required to have T_d symmetry and Keggin structure. This apparent high symmetry is effected by orientational randomness of the polyanions in the crystal. The α-$SiW_{11}O_{39}^{8-}$ anion can be regarded as a "deficient Keggin ion," in which one of the twelve equivalent positions of metals and its terminal oxygen, is vacant. This deficient Keggin ion lies in the crystal with its vacant site oriented randomly to one of the twelve positions and with the statistical weight of 11/12. The deformation of the Keggin structure caused by the removal of one tungsten atom could not be studied in detail because of this randomness. The standard deviations of the coordinates of the heavy atoms and the thermal parameters are not so large and accordingly it is inferred that the α-$SiW_{11}O_{39}^{8-}$ is not much deformed from the α-$SiW_{12}O_{40}^{4-}$. The tungsten-oxygen and silicon-oxygen interatomic distances given in Table 2 should be understood as average values for this hypothetical Keggin ion and agree well with those of the α-$SiW_{12}O_{40}^{4-}$ anion.[5]

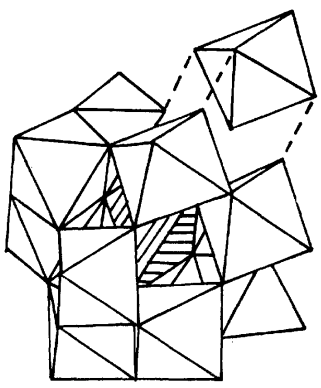

Fig. 2. The structure of the α-$SiW_{11}O_{39}^{8-}$ anion and its structural relation to the α-$SiW_{12}O_{40}^{4-}$ anion.

TABLE 2. INTERATOMIC DISTANCES WITH THEIR ESTIMATED STANDARD DEVIATIONS

W—O(1)	2.422(54)Å	O(2)—O(3)	2.752(85)
O(2)	2.114(70)	O(4)	2.817(101)
O(3)	1.843(50)	O(3)—O(4)	2.684(89)
O(4)	1.662(74)	Si—O(1)	1.617(53)
O(1)—O(2)	2.733(87)	K—O(2)	2.774(70)
O(3)	3.045(72)	K—O(3)	2.795(49)

Three equivalent potassium cations per formula unit were located and are shown in Fig. 3. The potassium ion is octacoordinated by four O(2) and four O(3) in the form of skewed antiprism. The molecular center is at the origin of the cubic cell and the potassium atoms lie at the middle points of the cell edges. There are large straight channels through the center of the unit cell parallel to the three axes and on the Fourier map low electron-density peaks were found in this space, however they could not be interpreted even by assuming random distribution of the unlocated five potassium cations and/or water molecules. Similar situation was encountered when Baker *et al.* solved the crystal structure of ammonium salt of $Co^{III}Co^{II}W_{11}O_{40}^{9-}$, in which he could not locate the ammonium cations and water of crystallization probably because of the disorder in the channels and large pockets formed by the exterior oxygens of the anions.[13] Although this anion is not exactly the same as that of the present compound because the former has the Keggin structure with one

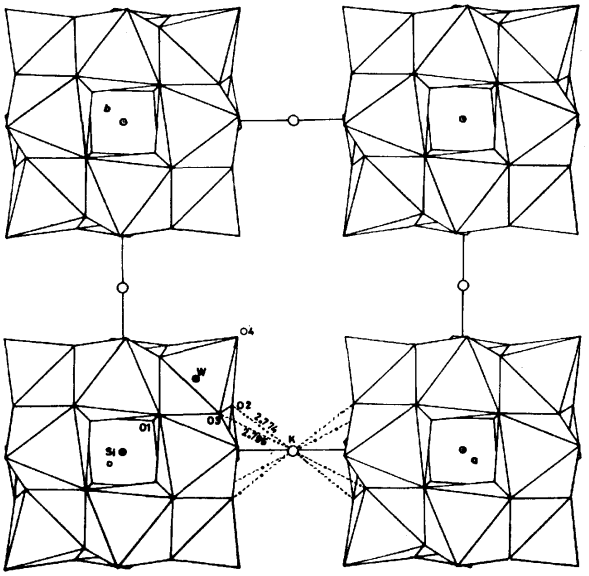

Fig. 3. The crystal structure of α-$K_8SiW_{11}O_{39}\cdot 13H_2O$ showing the coordination around potassium atoms.

of the twelve tungstens replaced by Co^{II}, their crystal structures resemble each other; the ammonium salt of $Co^{III}Co^{II}W_{11}O_{40}^{9-}$ is cubic with the space group Fm3m, the cell constant is just the double of that of the present compound and $Z=8$. The arrangement of anions is an enlarged NaCl type, with the Na^+ ions replaced by a set of Keggin units having one unique orientation and the Cl^- ions replaced by Keggin units with an orientation at right angles to the first set. Therefore if there have not been for the two sets of orientations, the unit-cell dimensions would be the half and the arrangement of the anions would be the same as in the present compound. Single crystal X-ray work of $(NH_4)_7Na_2[GaH_2W_{11}O_{40}]\cdot 15H_2O$, $(NH_4)_{7.3}H_{2.7}[Co^{II}Co^{II}W_{11}O_{40}]\cdot 17H_2O$, $Rb_{6.5}Co_{0.4}H_{2.7}[Co^{II}Co^{II}W_{11}O_{40}]\cdot 15H_2O$, $K_{6.5}H_{2.5}[Co^{II}Co^{II}W_{11}O_{40}]\cdot 13H_2O$, $K_7H[Co^{III}Co^{III}W_{11}O_{40}]\cdot 14H_2O$[13,14] have shown that these compounds are isomorphous with the ammonium salt of $Co^{III}Co^{II}W_{11}O_{40}^{9-}$ in spite of their various number of cations and water of crystallization. The unit-cell edge of $(NH_4)_7Na_2[GaH_2W_{11}O_{40}]\cdot 15H_2O$ shrinks reversibly and continuously with increasing temperature. From these facts, fairly high degree of freedom in the arrangement of cations and water molecules in the channels can be inferred. In the crystal-structure analysis of $K_4SiW_{12}O_{40}\cdot 17H_2O$,[15] some of the potassium atoms could not be located and some works[7,14,16] have reported that crystals of heteropoly acids often contain zeolitic water. These facts suggest that the unlocated potassium atoms and water molecules in the present crystal are a characteristic result of disorder in the cavities between the polyanions.

Isomerism of the Metal Complexes Containing Multidentate Ligands. VII.[1] The Conformational Analysis of the Isomers of [Co(linpen)]$^{3+}$ *

Yuzo Yoshikawa

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received September 22, 1975)

The conformational analysis of the $[Co(dien)_2]^{3+}$ and $[Co(linpen)]^{3+}$ (dien=$H_2N(CH_2CH_2NH)_2H$, linpen=$H_2N(CH_2CH_2NH)_5H$) complexes has been carried out. The former, which can exist in three geometric isomers, was selected as a standard for the determination of several parameters in the strain-energy calculation; they were determined so that the calculated geometries of these isomers were almost the same as those obtained from the crystal structure analysis studies. These results were applied to the strain-energy calculation for the latter, $[Co(linpen)]^{3+}$, which can exist in four geometric isomers. Further, in three of these isomers, some conformational isomers are possible. From the results of the energy-minimized conformational-analysis calculations of these isomers, it has turned out that the assignment of the structures of the configurational and conformational isomers is possible.

A conformational analysis technique has been effectively used to obtain information about the conformational structures of molecules. The strain-energy-minimization technique developed by Boyd[2] has been very frequently applied not only to organic molecules, but also to metal complexes.

Recently Toriumi and Saito[3] modified Boyd's method and reported the results of:

$(+)_{589}$*cis*-β-$[Co(CO_3)(S,S\text{-}3,8\text{-dimetrien})]^+$ [4] calculated by it.

In the present study we have adopted the method of Toriumi and Saito, the main part of which is the same as Boyd's, and calculated the strain energies of the isomers of $[Co(dien)_2]^{3+}$ and $[Co(linpen)]^{3+}$. The force field in this calculation includes contributions from bond stretching, nonbonded interactions, angle bending, and torsional potentials. In the calculations of the nonbonded interactions, only those between nonbonded atoms (except between atoms bonded to the same atom) up to distances of 1.2 times the sum of each van der Waas radius (1.50 Å for N, 1.55 Å for C and 1.20 Å for H atoms) have been treated; the interactions containing a cobalt atom have been omitted. The purpose of this study is to investigate the details of the molecular structures of $[Co(linpen)]^{3+}$ isomers, the isolation and characterization of which have already been reported in this Bulletin.[5] We will first carry out a conformational analysis of the isomers of $[Co(dien)_2]^{3+}$ in order to determine the adequate parameters in the calculation of strain energies by comparing the energy-minimized structures with those determined by X-ray studies.

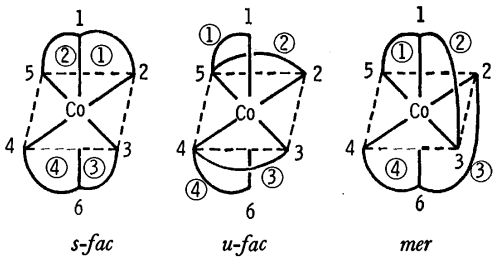

Fig. 1. Three possible geometric isomers of $[Co(dien)_2]^{3+}$. Figures in the circles show the numberings for the chelate rings.

The complex ion, $[Co(dien)_2]^{3+}$, can exist in three geometric isomers, as Fig. 1 shows, and they have all been isolated.[6] Saito *et al.* determined the molecular structures of *s-facial* and *u-facial* isomers of $[Co(dien)_2]^{3+}$ by the X-ray crystal analysis of *s-fac*-$[Co(dien)_2]Br_3$[7] and $\{-\}_{502}$*u-fac*-$[Co(dien)_2][Co(CN)_6]\cdot 2H_2O$**,[8] respectively. According to these results, *s-fac*-$[Co(dien)_2]^{3+}$ has approximately the C_{2h} symmetry and $\{-\}_{502}$*u-fac*-$[Co(dien)_2]^{3+}$ (there are two conformational isomers in the crystals of this complex hexacyanocobaltate(III)), the C_2 symmetry. The conformations of the four

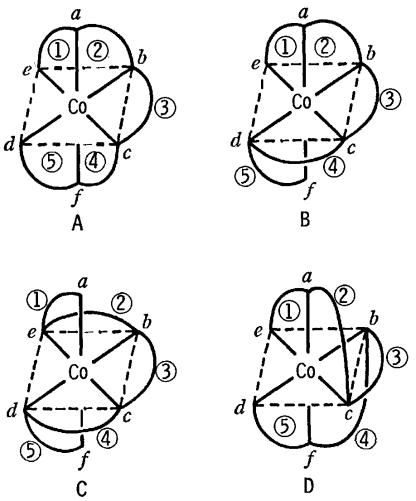

Fig. 2. Four possible geometric isomers of $[Co(linpen)]^{3+}$. Letters, *a*—*f*, are the locant designators according to the nomenclature proposed by IUPAC.[9]

* Presented at the 24th Symposium on Coordination Chemistry, Kanazawa, October, 1974.

** The $\{+\}_\lambda$ or $\{-\}_\lambda$ symbol represents the sign of the CD spectrum at a certain wavelength, λ nm, and $\{-\}_{502}$ corresponds to $(-)_{589}$ in the *u-fac*-$[Co(dien)_2]^{3+}$ complex. This symbol is convenient for characterizing an optically active compound, because there is no need to measure an optical rotation. For the λ, wavelength, it is advisable to adopt that of a maximum CD intensity in a suitable band.

chelate rings in the former are $\lambda\delta\lambda\delta$ (or $\delta\lambda\delta\lambda$), in the order of the numbers of the chelate rings in Fig. 1, while those of the latter are $\lambda\delta\delta\lambda$ and $\lambda\lambda\lambda\lambda$ (denoted as *u-fac*-1 and *u-fac*-2 respectively) for the determined absolute configuration, that is to say, they are skew chelate pairs $\Delta\Lambda\Delta$ (Fig. 1). On the other hand, the structure of *mer*-$[Co(dien)_2]^{3+}$ has not yet been determined. However, it is expected to have a two-fold axis.

The linpen ligand consists of two dien linearly linked by an ethylene group ($-CH_2CH_2-$) between the individual primary amine-N atoms. Therefore, the structures of $[Co(linpen)]^{3+}$, which can exist in four different configurational isomers (Fig. 2), are closely related to those of $[Co(dien)_2]^{3+}$. For example, the A and C isomers are formed by linking N2 to N3 by an ethylene group in the *s-facial* and *u-facial* isomers respectively.

Results and Discussion

The Conformational Analysis of the Isomers of $[Co(dien)_2]^{3+}$. Dwyer *et al.* have attempted the conformational analysis of $[Co(dien)_2]^{3+}$ isomers by using the strain-energy-minimization technique.[10] We analyzed these isomers independently.

The initial molecular structure of each isomer was constructed from the internuclear bond distances; Co–N (primary amine): 1.97 Å, Co–N (secondary amine): 1.95 Å, N–C: 1.49 Å, C–C: 1.51 Å, N–H: 1.03 Å, and C–H: 1.09 Å; the valency angles, ∠NCoN (chelate ring): 86.0°, ∠CoNC: 105—114°, ∠NCC: 105—114°, ∠CNC: 106—118° (*facial*) and 121° (*meridional*), and the angles related to H atoms: 109.5°. Their strain-energy-minimizations were carried out for several sets of equilibrium internuclear bond distances, Co–N, N–C, and C–C, the other parameters[11] being kept constant. Consequently, it was found to be adequate to use the values of 1.935, 1.485, and 1.51 Å for the Co–N, N–C, and C–C equilibrium bond distances respectively, for better fitting the resulting molecular structures to those obtained by X-ray methods. The energy terms obtained from these minimizations, where the root-mean-square coordinate deviations are smaller than 0.005 Å, are shown in Table 1. There are not large differences among these total energies.

Table 1. Final energy terms for the isomers of $[Co(dien)_2]^{3+}$

Isomer	Bond	Nonbond	Angle	Torsion	Total	
s-fac	0.19	1.45	0.55	1.88	4.08	kJ/mol
u-fac-1	0.20	1.46	0.57	1.89	4.12	
u-fac-2	0.26	1.49	0.67	1.70	4.12	
mer	0.26	1.22	1.30	1.29	4.06	

On the other hand, the formation ratios found experimentally in the equilibrium mixture of bromides (25 °C) were *s-fac*: *u-fac*: *mer*=7: 30: 63.

Therefore, the correlation between the minimized strain-energy and the formation percentage of each isomer is not necessarily good. In this case, there may be an inadequate choice for any parameters in the minimization and/or zero level imbalances.[10] The presently calculated molecular geometries (Table 2) are, nevertheless, presumed to be sufficiently accurate by comparison with the experimental structures. Some of these values will be used to construct the molecular structures of $[Co(linpen)]^{3+}$ isomers in the next section.

The Conformational Analysis of the Isomers of $[Co(linpen)]^{3+}$. Figure 2 shows the four geometric isomers of $[Co(linpen)]^{3+}$. The A structure has only secondary amine; the >NH groups of its facial structure are formed in *facial* isomers of $[Co(dien)_2]^{3+}$, but none of the meridional structure. Therefore, this is represented by f_4.*** The B structure contains one >NH group of the meridional structure and is represented by f_2mf (or fmf_2).*** Both the C and D structures have two >NH groups of each structure; they are represented by fm_2f and mf_2m*** respectively.

When the absolute configurations around the secondary amine-N atoms are taken into account for each structure in Fig. 2, the number of isomers is 1 (f_4-*RSSR*= I) for the A, 2 each (f_2mf-*RSRS*, -*RSSS*=II-1, II-2 and fm_2f-*SRRS*, -*SSSS*=III, IV) for B and C respectively, and 3 (mf_2m-*RRRR*, -*RRRS*, -*SRRS*=V, VI, VII) for the D structure, making a total of 8, where *R* and *S*

a) Averages of corresponding values are given. b) Figures in parentheses are the values determined from X-ray crystal structure analysis.[7,8]

*** These designations, f_4, f_2mf, fm_2f, and mf_2m, can be represented by *acbfed*, *acbfde*, *aebcdf*, and *acfbed* respectively by the use of the locant designators according to the nomenclature proposed by IUPAC.[9] The former can also be used as such for optical isomers the absolute configurations of which are not known.

represent the absolute configurations around the secondary amine-N atoms; they are written in the same order as that of *f* and *m*. These eight isomers (I, II-1, II-2, III—VII) have actually been found by means of column chromatography on SP-Sephadex and thus characterized.[5] The II-1 and II-2 isomers, however, were labile and isomerized into a mixture with the formation ratio of about 1 : 1 during the isolation, so they could not be obtained in pure states. All the isomers have the corresponding catoptric forms. In the calculation, the catoptromers shown in Fig. 2 were used. The averages of the individual geometrical values based upon the minimum strain energies of the $[Co(dien)_2]^{3+}$ isomers were mainly used to construct the initial molecular structures of $[Co(linpen)]^{3+}$ isomers with the corresponding ones. In this case, the valency angles, ∠CNC, were 110—114° for the facial and 115—122° for the meridional structures. The force constants and the other parameters in the minimization were the same as for the isomers of $[Co(dien)_2]^{3+}$.

The highest symmetries for *f_4-RSSR*, *fm_2f-SRRS*, *-SSSS*, *mf_2m-RRRR*, and *-SRRS* are C_2, so the calculations for these isomers were initiated from the structures with C_2 symmetry, whereas the *f_2mf-RSRS*, *-RSSS*, and *mf_2m-RRRS* isomers possess only the C_1 symmetry. In the course of the minimization, the symmetry of each isomer was not considered, but all the isomers possessing C_2 symmetry except for *f_4-RSSR* were energy-minimized retaining this symmetry, within the limits of error. The symmetry of the energy-minimized structure of the *f_4-RSSR* isomer was C_1, and its energy was smaller than that of the structure the C_2 symmetry of which was retained in the course of the minimization. The final energy terms are presented in Table 3. All the terms coordinate deviations were smaller than 0.005 Å. The formation percentages in Table 3 are those in the equilibrium mixture of chlorides (25 °C). The III and IV isomers were assigned to *fm_2f-SRRS* and *-SSSS* for the first time on the basis of these results. As a whole, there is a rough tendency for the isomer of a large percentage to have a low minimized energy. When the data in Table 3 are plotted, with the minimized energy as the ordinate and the logarithm of the formation percentage as the abscissa, a very rough linear relationship is obtained (Fig. 3).

If the conformational structure (δ, λ) of each chelate ring is not taken into consideration, only the *f_2mf* II-1 and II-2 isomers have the C_1 symmetry, while all the others have the C_2 symmetry. Therefore, the former are favored by a statistical factor of two over the latter; those formation percentages were divided by two when their data were plotted in Fig. 3. The relatively high abundances of the VI and VII isomers, when considered with their energies, may account for the conformational equilibria being almost independent of those among the configurational isomers; that is to say, the very high stability of the V isomer may make the VI and VII isomers form more abundantly. These results show that conformational analysis may be a technique for the assignment of the structures of the configurational isomers.

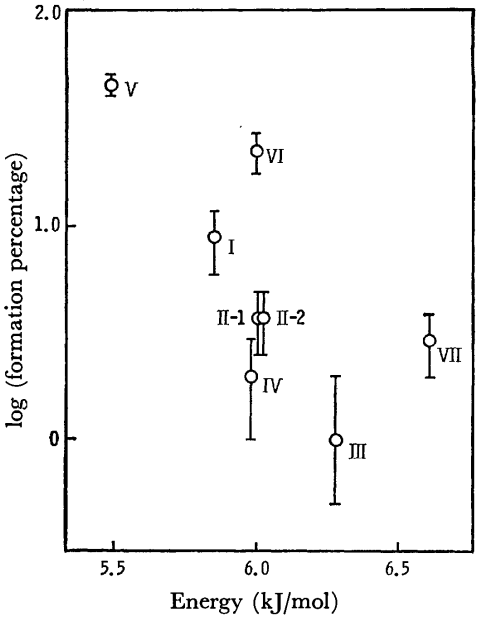

Fig. 3. Plot of log(formation percentage) *vs.* minimized energy for the isomers of $[Co(linpen)]^{3+}$. The formation percentages of both the II-1 and II-2 isomers were divided by two because of the statistical preference for these structures.

In all the calculations described here, the complexes are dealt with as free molecules. In practice, however, they have some mutual interactions with their surroundings. Therefore, it is an important problem awaiting solution to take into account these effects in order to obtain more accurate energies.

All the molecular geometries obtained by the method of the conformational analysis are presented in Table 4.

Table 3. Final energy terms for the isomers of $[Co(linpen)]^{3+}$ (Fig. 2)

Isomer	Sign of CD	Absolute configuration	Proposed[a] prefix	Bond	Nonbond	Angle	Torsion	Total		Formation percentage

a) Positive and negative signs represent δ and λ conformations of chelate rings, respectively.

* As the initial molecular coordinates, those from the X-ray analysis[12] were used.

Generally, the Co–N bond lengths are 1.97—1.98 Å for primary amines, and 1.96—1.97 and 1.94—1.95 Å for secondary amines, with facial and meridional structures respectively, except for a part of the II-2, VI, and VII isomers. The valency angles, ∠NCoN (chelate ring), in the meridional structure are smaller than those in the facial structure.

As the I isomer contains only the facial structure, it can be predicted that the strain for the valency angles in this isomer is smaller than those in all the others which contain the meridional structures; this is in accord with the result shown in Table 3. On the other hand, the III—VII isomers, which contain two meridional structures, have appreciably large strains for all the valency angles except for the V isomer. The strain of the V isomer may be moderately released at the sacrifice of that for the torsion.

During the course of the present study, Sato and Saito have determined the molecular structure of the {+}$_{502}$I isomer from an X-ray analysis of {+}$_{502}$[Co(linpen)][Co(CN)$_6$]·3H$_2$O.[12] The structure which we predicted and energy-minimized agreed completely in its conformations and configurations with that determined by them.

We also carried out the minimization for the I isomer by using the molecular coordinates obtained from the X-ray analysis[12] as the initial ones. These results are also included in Table 4. The agreement between this structure and that obtained previously is excellent.

Thus, we can obtain accurate information on the molecular structures of cobalt(III) complexes from the energy-minimized conformational analysis calculation.

We wish to thank Mr. Koshiro Toriumi and Professor Yoshihiko Saito of the Institute for Solid State Physics, the University of Tokyo, for the permission to use their computer programs and for their valuable discussions. Mr. Koshiro Toriumi also provided helpful advice. We are also indebted to Professors Shoichi Sato and Yoshihiko Saito for obtaining the X-ray crystal analysis data on the {+}$_{502}$I isomer of [Co(linpen)]$^{3+}$. Thanks are also due to the Nagoya University Computer Center for the use of the FACOM 230-60 computer. This research was supported in part by the Matsunaga Science Foundation.

The Effect of Steric Condition in Cobalt(II), Nickel(II) and Copper(II) Complexes with Schiff Bases Obtained from Salicylaldehyde Derivatives and Diphenylmethylamine

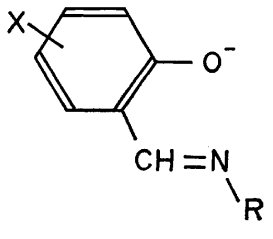
Kuniko YAMANOUCHI and Shoichiro YAMADA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received September 26, 1975)

Cobalt(II), nickel(II) and copper(II) complexes with *N*-diphenylmethyl-ring-substituted salicylideneiminates (abbreviated as X-Sal-Dpm) have been synthesized, in order to examine the steric and electronic effect of a substituent diphenylmethyl group on the structure of the metal complexes. Compounds of the type $M(X\text{-}Sal\text{-}Dpm)_2$ and their adducts of the type $M(X\text{-}Sal\text{-}Dpm)_2 \cdot nL$ have been isolated in crystals, n being 2 or 4 and L being benzene, acetone or pyridine. Both in the solid state and in non-donor solvents, the complexes $Co(X\text{-}Sal\text{-}Dpm)_2$ have a tetrahedral configuration, and $Ni(X\text{-}Sal\text{-}Dpm)_2$ and $Cu(X\text{-}Sal\text{-}Dpm)_2$ have a square-planar configuration, irrespectively of substituents X. The results so far available seem to indicate that the steric hindrance caused by the substituent diphenylmethyl group against the square-planar configuration of the metal complexes may be smaller than that by isopropyl group.

Numerous studies have so far been carried out on 3d transition metal complexes with *N*-substituted salicylideneiminates, which are abbreviated as X-Sal-R (I) in the present paper. These studies have shown that metal complexes of the type $M(X\text{-}Sal\text{-}R)_2$ vary widely in the structure, depending upon the steric condition arising from R and also upon the electronic effect caused by R on the nitrogen atom.[1-3] For instance, the structure of $M(X\text{-}Sal\text{-}n\text{-}alkyl)_2$ often differs from that of the complexes with α-branched alkyl for R, mainly because the steric hindrance arising from the α-branched alkyl is remarkably larger than that from *n*-alkyl. The 3d transition metal complexes with *N*-isopropylsalicylideneiminate and its derivatives have been studied, in comparison with the corresponding *n*-alkyl complexes.[4-6] Since diphenylmethyl, abbreviated as Dpm, is related to isopropyl, bearing two phenyl groups instead of two methyl groups in isopropyl, it is thought to be interesting to investigate metal complexes with Schiff bases having diphenylmethyl for R and compare the steric and electronic effects of the substituent Dpm upon the structure of their metal complexes with those of α-branched alkyls.



I

In the present work, cobalt(II), nickel(II) and copper(II) complexes with *N*-diphenylmethyl-ring-substituted salicylideneiminates have been synthesized and their structures examined mainly on the basis of their electronic absorption spectra and magnetic data.

Experimental

Materials. Analytical data of new complexes prepared in the present work are shown in Tables 1 and 2.

Bis(N-diphenylmethylsalicylideneiminato)copper(II), Cu(H-Sal-Dpm)₂. Diphenylmethylamine (0.01 mol) was added to a suspension of bis(salicylaldehydato)copper(II) (0.01 mol) in ethanol (50 ml) at about 60 °C and heated with stirring at this temperature for about 30 min. A brown precipitate was recrystallized from chloroform to yield olive-green crystals.

Bis(N-diphenylmethyl-5-chlorosalicylideneiminato)copper(II), Bis(N-diphenylmethyl-5-bromosalicylideneiminato)copper(II) and *Bis(N-diphenylmethyl-3-methoxysalicylideneiminato)copper(II)* were prepared as crystals by a method similar to that described above. These copper(II) complexes are olive-green (X=5-Cl, 5-Br) or brown ($X=3\text{-}CH_3O$). They are highly soluble in chloroform and benzene, moderately soluble in acetone and pyridine, and sparingly soluble in methanol and ethanol.

Bis(N-diphenylmethyl-5-chlorosalicylideneiminato)copper(II) Bis(pyridine)-adduct, Cu(5-Cl-Sal-Dpm)₂·2py. The parent complex was dissolved in pyridine at 50—60 °C, filtered while the solution was hot, and allowed to stand overnight in a refrigerator. Green crystals of the bis(pyridine)-adduct were collected by filtration.

Bis(N-diphenylmethyl-5-bromosalicylideneiminato)copper(II) Tetrakis(pyridine)-adduct, Cu(5-Br-Sal-Dpm)₂·4py. A similar procedure to that described above yielded green crystals of the tetrakis(pyridine)-adduct.

Bis(pyridine)-adduct of the same parent complex was isolated, when recrystallization was carried out from pyridine–ethanol (2:1) or pyridine–chloroform (2:1) mixture instead of pyridine itself.

Both these adducts readily lose pyridine molecules, when left in the atmosphere.

Bis(N-diphenylmethyl-ring-substituted salicylideneiminato)nickel(II), Ni(X-Sal-Dpm)₂ (X=H, 5-Cl, 5-Br, 3-CH₃O). Complexes of this type were prepared by a method similar to that for the copper(II) complexes. They are olive-green (X=H, 5-Cl, 5-Br) or greenish brown ($X=3\text{-}CH_3O$). They are highly soluble in chloroform and benzene, moderately soluble in acetone and hot pyridine, and sparingly soluble in methanol, ethanol and cold pyridine.

Bis(N-diphenylmethyl-3-methoxysalicylideneiminato)nickel(II) Tetrakis(pyridine)-adduct, Ni(3-CH₃O-Sal-Dpm)₂·4py. was obtained in green crystals, when the parent complex was recrystallized from pyridine. Bis(pyridine)-adduct could not be isolated by procedures similar to those described above.

All these pyridine adducts of the nickel(II) complexes are much more stable in the atmosphere than the corresponding adducts of the copper(II) and cobalt(II) complexes. They are soluble in benzene, chloroform and acetone, but only

slightly soluble in methanol, ethanol and cold pyridine.

Bis(N-*diphenylmethylsalicylideneiminato*)*cobalt*(*II*), *Co*(*H-Sal-Dpm*)$_2$. This complex was synthesized in the same way as the corresponding copper(II) complex. Recrystallization of the crude product from benzene or chloroform yielded red-orange crystals of the pure complex.

Bis(N-*diphenylmethyl-5-halogenosalicylideneiminato*)*cobalt* (*II*), *Co*(*X-Sal-Dpm*)$_2$ (*X=5-Cl, 5-Br*). The crude products of these complexes were prepared in the same way as described above for Co(H-Sal-Dpm)$_2$. It was not possible to find a suitable solvent for recrystallization. Attempts to recrystallize them yielded either products of insignificant composition or adducts with solvents used in the recrystallization, instead of the pure parent complex.

The pure complexes of the type Co(X-Sal-Dpm)$_2$ were obtained by heating bis(benzene)- or bis(acetone)-adduct (*vide infra*) for about 4 hr at about 80 °C under reduced pressure.

These cobalt(II) complexes are soluble in chloroform, benzene and acetone, but sparingly soluble in methanol, ethanol and cold pyridine.

Bis(N-*diphenylmethyl-5-halogenosalicylideneiminato*)*cobalt*(*II*) *Bis*-(*benzene*)- *and Bis*(*acetone*)-*adducts*, *Co*(*X-Sal-Dpm*)$_2$·2*L* (*X=5-Cl, 5-Br*; *L=benzene, acetone*). Crude products of the parent complexes, which were prepared as described above, were recrystallized from benzene or acetone to yield red-orange crystals of the bis(benzene)- or bis(acetone)-adducts.

Bis(N-*diphenylmethyl-ring-substituted salicylideneiminato*)*cobalt*-(*II*) *Bis*(*pyridine*)-*adducts*, *Co*(*X-Sal-Dpm*)$_2$·2*py* (*X=H, 5-Cl*). Compounds of this type were isolated in yellow-orange crystals by a method similar to that for the corresponding nickel(II) compounds.

Bis(N-*diphenylmethyl-5-bromosalicylideneiminato*)*cobalt*(*II*) *Tetra-kis*(*pyridine*)- *and Bis*(*pyridine*)-*adducts*, *Co*(*5-Br-Sal-Dpm*)$_2$·n*py* (*n*=2,4) were isolated in yellow-orange crystals by a method similar to that for the corresponding nickel(II) compounds.

Bis(N-*diphenylmethyl-3-methoxysalicylideneiminato*)*cobalt*(*II*)

Tetrakis(pyridine)-adduct, Co(3-CH_3O-Sal-Dpm)$_2$·4py, was obtained in yellow-orange crystals in the same way as described above for the corresponding nickel(II) complex. It has not been possible so far to isolate crystals of the parent complex, Co(3-CH_3O-Sal-Dpm)$_2$.

All these pyridine adducts of the cobalt(II) complexes lose pyridine molecules comparatively slowly, when left in the atmosphere. They are considerably soluble in benzene, chloroform and acetone, but only slightly soluble in methanol, ethanol and cold pyridine.

With the cobalt(II), nickel(II) and copper(II) complexes, only bis- and/or tetrakis(pyridine)-adducts were obtained, and adducts of another type, such as mono- and tris-(pyridine)-adducts, have not been isolated.

Bis(N-isopropyl-ring-substituted salicylideneiminato)cobalt(II) Bis-(pyridine)-adducts, Co(X-Sal-i-C_3H_7)$_2$·2py (X=5-Br, 5-NO_2), were obtained in yellow-orange crystals by recrystallizing the parent complex from pyridine or by adding *n*-hexane into a hot solution of the parent complex in pyridine.

Bis(N-cyclohexyl-ring-substituted salicylideneiminato)cobalt(II), Co(X-Sal-Ch)$_2$ (X=5-Cl, 5-Br, 5-NO_2, 3-CH_3O), were prepared, as previously reported, Ch being cyclohexyl.[6]

Bis(N-cyclohexyl-ring-substituted salicylideneiminato)cobalt(II)bis-(pyridine)-adducts, Co(X-Sal-Ch)$_2$·2py (X=5-NO_2, 3-CH_3O) were obtained in yellow-orange crystals by recrystallizing the parent complexes from pyridine or by adding hexane into a hot solution of the parent complexes in pyridine.

Measurements. Electronic absorption spectra of the complexes were measured on a Shimadzu MPS-50L spectrophotometer. Infrared spectra were obtained from Nujol mulls using a Hitachi EPI-S2 infrared spectrophotometer.

Magnetic measurements were carried out by the Gouy method at room temperature using $CoHg(SCN)_4$ as a calibrant.

Since many of the adducts underwent decomposition during the measurements, only those data which may be regarded as accurate and reliable enough for discussion are shown in the tables. Solubility of complexes Co(X-Sal-Dpm)$_2$ and Ni-(X-Sal-Dpm)$_2$ in appropriate solvents including pyridine is not high enough for spectral measurements.

Results and Discussion

Cobalt(II) Complexes. When cobalt(II) acetate, salicylaldehyde and diphenylmethylamine are refluxed in the atmosphere in the presence of alkali, such as sodium carbonate, bis(*N*-diphenylmethylsalicylideneiminato)cobalt(II) is readily obtained, oxidation to the cobalt(III) complex hardly being observed. Any attempt to isolate the tris(Schiff base)cobalt(III) complex has not so far been successful even with hydrogen peroxide.

Previous studies have shown that a similar procedure in the atmosphere readily yields the cobalt(III) complexes of the corresponding Schiff bases, when *n*-alkylamines are employed instead of diphenylmethylamine.[2a] A similar procedure using isopropylamine, *t*-butylamine or arylamines yields only bis(Schiff base)-cobalt(II) complex.[6] Tris(*N*-isopropyl-ring-substituted salicylideneiminato)cobalt(III) complexes,[7] as well as tris(*N*-arylsalicylideneiminato)cobalt(III),[8] are obtained by more effective oxidation using hydrogen peroxide.

Comparison seems to indicate that greater difficulty is encountered in obtaining Co(X-Sal-Dpm)$_3$ than Co(X-Sal-*i*-C_3H_7)$_3$, although it may not be plausible to say definitely that Co(X-Sal-Dpm)$_3$ cannot be isolated at all. The difference in this respect between Dpm and isopropyl may be discussed in terms of the two factors: (a) ligand field strength and (b) steric condition.

It is known that the higher stability of the sexa-coordinated cobalt(III) complex is attained with ligands producing a stronger ligand field. It is expected and has also been confirmed by some experimental results[1,2] that the ligand field of X-Sal-R depends upon the nature of substituents R and decreases in the following order: aryl<CH(ph)$_2$<CH_2ph<*n*-alkyl<*i*-C_3H_7, where ph denotes phenyl group. Thus X-Sal-Dpm would produce a slightly weaker ligand field than X-Sal-*i*-C_3H_7. Therefore, so far as the factor of the ligand field strength is concerned, X-Sal-Dpm would form the tris(Schiff base)-cobalt(III) less readily than X-Sal-*i*-C_3H_7, in agreement with the experimental results.

Alternatively, in order to explain the observed results, one might argue that larger steric hindrance against formation of the tris(Schiff base)cobalt(III) complex would be created by X-Sal-Dpm than by X-Sal-*i*-C_3H_7. This explanation, however, may not be adequate, since in fact, the reverse seems to be the case. The truth is that larger steric hindrance may be exercised by X-Sal-*i*-C_3H_7 than by X-Sal-Dpm in formation of both th square-planar bis(Schiff base)-nickel(II) complexes and the sexa-coordinated bis(pyridine)-adducts of the cobalt(II) complexes, as will be discussed later in this paper. Nevertheless, the steric factor, besides the electronic factor, is also considered to play at least a minor role in preventing the tris-complex formation.

It should be noted that benzene or acetone adducts are obtained, when recrystallization of Co(X-Sal-Dpm)$_2$ is carried out from benzene or acetone, X being Cl and Br. As shown in Table 3, spectra of the benzene adducts are typical of the tetrahedral cobalt(II) complexes. It is presumed that the benzene adducts consist of tetrahedral cobalt(II) complexes and non-coordinated benzene molecules, which presumably occupy interstice in the crystal lattices. The benzene adducts, when dissolved in benzene, show nearly the same electronic spectra as those of the parent complexes, which are typical of the tetrahearal cobalt(II) complexes, as shown in Table 3.

The acetone adducts also show electronic spectra, which are essentially the same as those of the parent complexes. Moreover, the adducts show a strong infrared band at 1700 cm^{-1}, which is assigned to a C=O stretching frequency of a free acetone molecule. It is, therefore, reasonable to consider that they consist of the tetrahedral cobalt(II) complexes and non-coordinated acetone molecules. This conclusion is also supported by the finding that the spectrum of Co(5-Cl-Sal-Dpm)$_2$ in acetone is almost identical with that of the same complex in benzene, showing that the acetone molecule is not bound with the cobalt(II) ion.

It is interesting to note that both bis(pyridine)- and tetrakis(pyridine)-adducts of the cobalt(II) complexes are isolated for X=H, 5-Cl, 5-Br and 3-CH_3O. Although they lose pyridine molecules slowly, they are

crystalline and their analytical data agree only with either the bis- or tetrakis(pyridine)-adduct. The reason why another type of adduct, for example, mono- or tris-(pyridine)-adduct does not occur is not clear. Both the bis- and tetrakis-(pyridine)-adducts show electronic spectra typical of sexa-coordinated bis-(pyridine)bis(*N*-substituted salicylideneiminato)cobalt-(II) complexes, as shown in Table 4. The d-d band at about 10 kK may be assigned to a transition $^4T_{2g} \leftarrow {}^4T_{1g}$ in the scheme of the O_h ligand field symmetry. It is, therefore, presumed that they contain sexa-coordinated bis(pyridine)-cobalt(II) complexes, which probably have a *cis*-structure, judging from the steric condition.

Now we may compare the data in the present work with those for complexes of the type Co(X-Sal-*i*-C_3H_7)$_2$. In previous papers,[2] Co(H-Sal-*i*-C_3H_7)$_2$ was reported to have very low capacity to form a sexa-coordinated bis(pyridine)-adduct, which has not been isolated in crystals so far. Even in pyridine, at least 90% of it exists as the original tetrahedral cobalt(II) complex.[6,9] This is in contrast to the behavior of Co(H-Sal-Dpm)$_2$, which readily forms a bis(pyridine)-adduct. The difference in this respect between these two series of cobalt(II) complexes may be ascribed mainly to the steric factor. The steric factor, however, seems to be rather delicate and not the only dominant factor in this case. The effect of the substituent X on the electronic state of the nitrogen atom in the Schiff base may also play a significant part. As shown in Table 4, when dissolved in pyridine, the complexes Co(X-Sal-*i*-C_3H_7)$_2$, X being 5-Cl, 5-Br and 5-NO_2, consist almost entirely of sexa-coordinated bis(pyridine)-adducts, some of which can be isolated in crystals from their pyridine solutions. The bis(pyridine)-adducts have magnetic moments of 4.8 to 5.1 BM and show electronic spectra typical of the sexacoordinated cobalt(II) complex with a d-d band maximum at about 10 kK. The remarkable difference between Co(H-Sal-*i*-C_3H_7)$_2$ and Co(X-Sal-*i*-C_3H_7)$_2$, X being 5-Cl, 5-Br and 5-NO_2, seems to be noteworthy. The effect of the substituent X is found to be significant.

ν: kK pr: propyl Ch: cyclohexyl

Comparison of Co(X-Sal-Dpm)$_2$ with Co(X-Sal-Ch)$_2$, Ch being cyclohexyl group, may also be interesting. Previous studies have shown that in pyridine, nearly 50% of Co(H-Sal-Ch)$_2$ exists as the original tetrahedral cobalt(II) complex.[6,9] However, it has not so far been possible to isolate bis(pyridine)-adduct. Instead, mono-pyridine-adduct was isolated as red crystals.[10] The effect of the substituent X is again found to be remarkable in the cyclohexyl complexes. As shown in Table 4, electronic spectra indicate that the complexes Co(X-Sal-Ch)$_2$ in pyridine, X being 5-Cl, 5-Br, 5-NO_2 and 5-CH_3O, exist totally as sexa-coordinated bis(pyridine)-adducts. Some of them can also be isolated in crystals from their pyridine solutions, as shown in Table 2. Electronic spectra of these bis(pyridine)-adducts have a d-d band with a maximum at about 10 kK, which is typical of the sexa-coordinated cobalt(II) complex.

Inspection of the data so far available indicates that the relative tendency of Co(X-Sal-R)$_2$ to form sexa-coordinated bis(pyridine)-adducts increases according to the substituent R in the following order: $CH(ph)_2 < Ch < CH(CH_3)_2 < C(CH_3)_3$. This order seems to be in agreement with the order for the steric hindrance arising from the substituent.

Nickel(II) and Copper(II) Complexes. As shown in Tables 1 and 3, complexes of the type Ni(X-Sal-Dpm)$_2$ are diamagnetic in the solid state and show electronic absorption spectra typical of the square-planar nickel(II) complex in non-donor solvents. No absorption band is observed at about 10—11 kK or lower frequencies, where the octahedral or tetrahedral nickel(II) complex is expected to absorb. So far, any tetrahedral species has been neither isolated in crystals, nor detected in the solutions at room temperature for nickel(II) complexes of the type Ni(X-Sal-Dpm)$_2$. This result is in contrast to the result previously reported for complexes of the type Ni(X-Sal-*i*-C_3H_7)$_2$, which exist in non-donor solvents at room temperature in a conformational equilibrium of the planar diamagnetic and pseudo-tetrahedral paramagnetic forms.[4] The equilibrium depends upon the nature of the substituents R; Ni(H-Sal-*i*-C_3H_7)$_2$ in non-donor solvents at room temperature exists almost totally as the tetrahedral species. Moreover, both tetrahedral and squre-planar species of Ni(X-Sal-*i*-C_3H_7)$_2$ were previously isolated.[2b,4,5,11] Comparison indicates that the steric hindrance against the square-planar configuration in the complexes Ni(X-Sal-Dpm)$_2$ is smaller than in Ni(X-Sal-*i*-C_3H_7)$_2$.

Just like the corresponding cobalt(II) complexes, both bis- and tetrakis-(pyridine)-adducts of the nickel(II) complexes are readily isolated. They are of a high spin type and show electronic absorption spectra typical of sexa-coordinated nickel(II) complexes, having a d-d band at about 11 kK, as shown in Table 4. The band at about 11 kK may be assigned to a $^3T_{2g} \leftarrow {}^3A_{2g}$ transition in the scheme of O_h field symmetry. It is presumed, therefore, that they all contain sexa-coordinated bis(pyridine)nickel(II) complexes. A similar trend was previously reported for complexes of the type Ni(X-Sal-*i*-C_3H_7)$_2$, which form sexa-coordinated bis-(pyridine)-adducts, when dissolved in pyridine.[12]

Electronic absorption spectra of copper(II) complexes of the type Cu(X-Sal-Dpm)$_2$ in non-donor solvents are similar to each other and nearly identical with the spectra of complexes Cu(X-Sal-*n*-alkyl)$_2$, having the first d-d band with a maximum at about 17 kK (log ε 2—2.2) and a shoulder at about 22 kK (log ε 2.8—3.0). It may, therefore, be reasonable to presume that these complexes in non-donor solvents have an essentially square-planar configuration.

It should be noted that the spectra of Cu(H-Sal-Dpm)$_2$ in non-donor solvents are remarkably different from those of Cu(H-Sal-*i*-C_3H_7)$_2$,[4,5] which was concluded to contain pseudo-tetrahedral species. The latter complex shows the first d-d band with a maximum at about 15.7 kK, which is found to be shifted toward a considerably lower frequency than that of the former (17 kK). The difference between these two complexes also seems to be in agreement with the assumption that the steric hindrance against the square-planar configuration is smaller in the complexes Cu(X-Sal-Dpm)$_2$ than in Cu(X-Sal-*i*-C_3H_7)$_2$.

Spectra of Cu(X-Sal-Dpm)$_2$ in pyridine differ significantly from their spectra in non-donor solvents; the latter have more broad d-d bands at about 15.5 kK, which is found to be shifted toward lower frequencies, as compared with the corresponding band of the solutions in non-donor solvents. The spectral change in the d-d band region of these copper(II) complexes on going from a non-donor solvent to pyridine is similar to the change observed previously when the quadri-coordinated complex of copper(II) takes up one or two additional pyridine molecules to form a penta- or sexa-coordinated complex.[13]

The pyridine adducts, Cu(X-Sal-Dpm)$_2 \cdot n$py, n being 2 and 4, are isolated in crystals. However, they lose pyridine molecules so readily that it has not been possible to obtain reliable data of electronic absorption spectra and magnetic susceptibilities in most cases. Judging from their behavior in the pyridine solutions, it is most likely that some number of pyridine molecules may be bound with the copper(II) ion. From the experimental data so far available, however, it is difficult to know the exact number of pyridine molecules bound with the copper(II) ion.

Mixed Ligand Copper(II) Complexes of α-Amino Acids with Ligand-Ligand Interactions

Takeshi SAKURAI, Osamu YAMAUCHI, and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received October 6, 1975)

Synthetic and spectroscopic studies have been made on the ternary copper(II) complexes containing two optically active α-amino acids with charged groups in their side chains. Thus, for all combinations of ligands A and B, where A refers to aspartic or glutamic acid and B to arginine, lysine, or ornithine, the mixed ligand complexes, [Cu(L-A)(L-B)] and [Cu(D-A)(L-B)] except [Cu(L-aspartate)(L-ornithine)], were isolated as crystals. Infrared spectra of the isolated complexes suggested the presence of the geometrical isomers. By comparing the observed circular dichroism spectra of the ternary systems with the spectra estimated from those of the corresponding binary systems, the magnitude enhancements were detected for all the Cu(L-A)(L-B) systems, whereas no such enhancement was observed when one of the ligands was L-alanine or L-valine. The spectral behaviors as well as the solid complexes isolated have been interpreted as indicative of the existence of the intramolecular electrostatic bonding between the oppositely charged groups in the side chains of the ligands and their significance as an effective driving force leading to the ternary complex formation.

A mixed ligand metal complex is regarded as a simplified chemical model for the enzyme-metal-substrate complex formed in the course of the enzymatic reaction with a metal ion at the active center. As has been shown for the carboxypeptidase A–peptide complex by the X-ray studies,[1] the electrostatic bonding between the coordinated ligands is certainly one of the important driving forces leading to the formation of mixed ligand complexes. We reported in a previous paper[2] the synthetic and spectroscopic evidence, which suggests that such electrostatic or hydrogen bondings exist between the oppositely charged groups in the side chains of the two ligands in several copper(II)-containing ternary systems and that they affect the formation of mixed ligand complexes. Brookes and Pettit[3] recently showed by potentiometric studies that the ternary systems composed of copper(II), L- or D-histidine, and an amino acid with a positively charged side chain, such as L-arginine, L-lysine, and L-ornithine, exhibit appreciable stereoselectivity, which they ascribed to the electrostatic interaction between the positive group and the carboxylate oxygen of histidine in the systems with two L-ligands.

With a view to obtaining further information about the factors governing the mixed ligand complex formation and finding clues to the mechanism of the enzymatic reactions, we now extended the previous study to the copper(II) complexes of optically active α-amino acids and carried out synthetic and spectroscopic investigations on the possibilities of the electrostatic ligand-ligand interactions within the complex molecules. For the present purpose, we employed L- and D-glutamic acid (L- and D-Glu) and L- and D-aspartic acid (L- and D-Asp) as ligands with negatively charged side chains (referred to as A ligands hereinafter), and L-arginine (L-Arg), L-lysine (L-Lys), and L-ornithine (L-Orn) as ligands with positively charged side chains (referred to as B ligands). Based on the expected chelate structures **1** and **2**, which impose the steric and the mentioned electrostatic requirements on the formation of the ternary complex, Cu(A)(B), we attempted the isolation of the complexes with all combinations of A and B. The present paper deals with the synthesis of the chelates and the discussions of their structures and the intramolecular bondings.

Experimental

Materials. L-Arginine, L-lysine dihydrochloride, L-ornithine monohydrochloride, L- and D-glutamic acid, L- and D-aspartic acid, L-valine, and L-alanine were purchased from Nakarai Chemicals, Ltd. The optical purities of the enantiomers of glutamic and aspartic acids were checked by their specific rotations, $[\alpha]_{20}^{589}$, which were +11.2 and −10.9 (in H_2O) for L- and D-glutamic acid, respectively, and +25.1 and −22.1 (in 3M HCl) for L- and D-aspartic acid, respectively, indicating that the optical purity of D-aspartic acid was slightly lower.

All the chemicals used were of reagent grade or of highest grade available.

Preparation of Mixed Ligand Copper(II) Complexes. The complexes were prepared by essentially the same procedure as typically described below for [Cu(L-Glu)(L-Arg)]. Copper(II) perchlorate hexahydrate (1.85 g, 5 mmol), L-arginine (0.85 g, 5 mmol), and L-glutamic acid (0.74 g, 5 mmol) were dissolved in 30 ml of water, and the pH of the resulting solution was adjusted to *ca.* 9 with aqueous sodium hydroxide. The reaction mixture was stirred for 1 h at room temperature and concentrated *in vacuo* to a small volume at temperatures below 50 °C. Addition of methanol to the residue gave blue crystals, which were recrystallized from aqueous methanol–ethanol.

The pH values of the reaction mixtures containing L-ornithine or L-lysine as B ligands were adjusted to *ca.* 7.

The analytical data for the isolated complexes are shown in Table 1.

Measurements of Absorption and Circular Dichroism (CD) Spectra. The spectroscopic measurements were performed in water at room temperature for the systems with the Cu(II):

A: B ratios of 1: 1: 1 (ternary systems) and 1: 2: 0 and 1: 0: 2 (binary systems) at pH 5—11 at a constant Cu(II) concentration of 5×10^{-3} M. The spectral samples were prepared from 0.1 M stock solutions of copper (II) perchlorate and the amino acids. The pH values, which were roughly adjusted with aqueous sodium hydroxide and dilute perchloric acid, were finally determined after the spectroscopic measurements. The ionic strength (μ) of the solutions was not adjusted at a constant value (μ=variable). Absorption spectra were recorded in the range 400—800 nm on a Union Giken SM-401 high sensitivity recording spectrophotometer. CD spectra were measured in a 1-cm path length quartz cell in the range 350—800 nm with a JASCO MOE-1 spectropolarimeter. Infrared spectra were obtained in the range 4000—650 cm^{-1} with a Hitachi EPI-S2 infrared spectrophotometer with the KBr disk method and in the range 700—200 cm^{-1} with a Hitachi EPI-L grating infrared spectrophotometer in the dry air with the Nujol mull method.

Results and Discussion

Preparation of Mixed Ligand Complexes. As shown in Table 1, all the expected ternary complexes except [Cu(L-Asp)(L-Orn)] were isolated as crystals in good yields. Although it was difficult to obtain pure crystals of [Cu(L-Asp)(L-Orn)], we may assume its formation from the analytical data.[4]

The structures of these complexes are expected from the space-filling models to be such as are expressed by **1** and **2**, which suggest that the (L-A)(L-B) pairs of ligands favor the *trans* structure around the central copper(II) ion (**1**), whereas the (D-A)(L-B) pairs prefer the *cis* structure (**2**). Both structures are more puckered and may be sterically less stable as compared with those without ligand-ligand interactions, but the synthetic results seem to indicate the existence of the electrostatic bondings, which supplement the steric disadvantage incurred. Although the complexes with pairs of A and B containing longer side chains, *e.g.* Glu–Arg and Glu–Lys, were isolated easily, the total length of the two side chains may not be the sole factor affecting the isolation, because [Cu(L-Glu)(L-Orn)] was more easily isolated than [Cu(L-Asp)(L-Lys)] which has the same side chain length as the former. The difficulty encountered in isolation of [Cu(L-Asp)(L-Orn)] with the shortest chain length nevertheless suggests that the chain lengths as well as the solubility and the *cis-trans* geometry around the copper(II) ion exert influence over the formation and crystallization of the complexes.

IR Spectra and cis-trans *Isomerism.* Figure 1 shows the IR spectra of the mixed ligand complexes in the range 4000—650 cm^{-1}. The spectral patterns in the fingerprint region are different from those of the corresponding binary complexes. Subtle spectral differences in this region are also detected between the Cu(L-A)-(L-B) and Cu(D-A)(L-B) series with all combinations

of A and B except the Asp-Orn pair, which may reflect the structural differences as illustrated by **1** and **2**.

Geometrical isomerism has been known to give rise to characteristic bands due to metal-ligand bonds in the range below 700 cm^{-1}.[5] Thus, the spectral patterns of *cis*- and *trans*-[Cu(glycine)$_2$] in this region[6] are considerably different from each other. We see from Fig. 2 that at 700—500 cm^{-1} and 400—330 cm^{-1} the complexes with (L-A)(L-B) pairs give the spectra, which are typical of the A ligands and differ from those exhibited by the complexes [Cu(D-A)(L-B)]. This suggests the presence of the *cis-trans* isomers expressed by **1** and **2**, and since the side chains in these systems are comparable, the isomerism in turn points to the intramolecular ligand-ligand bonding. The stereoselectivity as observed for the histidine-containing ternary copper(II) complexes[3] would implicate the preference of one geometrical isomer over the other in the present ternary systems.

Absorption and CD Spectra and Interpretation of the CD Magnitudes. The CD spectra obtained for each of the systems at various pH values between 5 and 11 were satisfactorily reproducible. The spectral data are summarized in Table 2 and some examples of the curves are depicted in Figs. 3 and 4 (solid lines). The CD magnitudes of the ternary systems increase with pH, indicating that the mixed ligand complexes are the major species present at pH 9—10. The systems with L-Orn show marked spectral changes at pH>8 owing to the apical coordination by the δ-amino group,[2,7,8] while the other systems including those with Asp show

moderate changes.

On the assumption that the CD magnitude is an additive function under the present conditions, we estimated the theoretical CD curves for the ternary systems (broken lines in Figs. 3 and 4) by summing up half the magnitude ($1/2\Delta\varepsilon$) of CuA_2 and of CuB_2 at every wavelength. As is apparent from Fig. 3, the L-Val- or L-Ala-containing ternary systems, where no intramolecular ligand-ligand interaction is expected, exhibit excellent fits of the calculated curves to the experimental ones. On the other hand, serious deviations of the curves are observed most remarkably for the systems with two L-ligands each of which have an oppositely charged side chain that can form intramolecular electrostatic bonds (Fig. 4). Since the spectra were obtained for 5×10^{-3} M solutions, these observations may imply that such discrepancies arise from the intramolecular bonds, which cause fixation of the complex structures and reduce the freedom of motion of the side chains. Regarding the Cu(D-A)(L-B) systems, the experimental curves do not deviate greatly from the expected ones. Because the absolute values of $\Delta\varepsilon$ for these systems are much smaller than those for the Cu(L-A)(L-B) systems and the deviations are roughly in the range of experimental errors, it is difficult to find any significant difference between them.

Inspection of the curve fit of the L-Orn-containing systems was made at pH 7—8, because, as mentioned earlier, they exhibit spectral changes at pH>8 due to apical coordination. These systems give anomalous CD curves which are difficult to interpret, and further investigations will be necessary.

The observed CD magnitudes may be explained by the hexadecant (D_{4h}) rule,[9,10] according to which the side chains of the L-ligands in [Cu(L-A)(L-B)] with the *trans* geometry (**1**) are located in the sectors with negative sign, and this configuration may contribute to the observed magnitude enhancement. Although the complex formation in the binary systems are supposed to be nearly complete at pH 9—10[11] from the pH dependence of the CD magnitude, the above argument is contingent on the species distributions in the ternary systems at equilibrium and a more quantitative comparison of the CD magnitudes should be made from the study of the solution equilibria.

The absorption spectral data in the visible region are

listed in Table 3, which indicates that the peaks of the ternary systems are between those of the corresponding binary systems. The maximum wavelengths and the ε values do not explicitly reflect the effects of the ligand-ligand interactions and the differences due to L- and D-enantiomers, although there are observed slight disagreements in the shapes of the curves. This may not be unexpected, because all the chelate rings of the systems in consideration have the same structures around the copper(II) ion and the ε values of the absorption spectra are more than a hundred times greater than the $\Delta\varepsilon$ values of the CD spectra.

As regards α-amino acids as ligands, only a small number of mixed ligand copper(II) complexes have so far been reported,[12] and we may take this as an indication that isolation of such labile complexes is not always feasible under normal conditions but requires additional factors favoring or stabilizing ternary systems. The present results of the synthesis and the relevant CD spectral information strongly suggest the existence of the ligand-ligand bonding and lead us to the conclusion that such intramolecular bondings serve as an effective driving force for the mixed ligand complex formation.

We thank Miss Tazuko Ikebata for technical assistance and to Miss Teruko Kuroe for elemental analysis. This work was supported by a grant from the Ministry of Education.

The Estimation of the *G*-Values for Ionization and Excitation of Ten-Electron Molecules: Methane, Ammonia, and Water Irradiated by 100 keV Electrons

Kiyoshi OKAZAKI, Shin SATO, and Shin-ichi OHNO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
**Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11*

(Received May 31, 1975)

The binary-encounter collision theory is applied to calculate the *G*-values for the ionization and excitation of methane, ammonia, and water irradiated by 100 keV electrons. Double collision of the incident electron in a molecule is also taken into account. On the assumption of the occurrence of certain reactions in the systems, the *G*-values for electrons, various radicals, and several final products were estimated. Some of the results are as follows: the *G*-values for electrons were 3.60 for methane, 3.56 for ammonia, and 3.00 for water. These values are in fair agreement with the experimental values: 3.6 for methane, 3.8 for ammonia, and 3.3 for water. The calculated *G*-value for hot hydrogen atoms was about 1.0 for all three compounds. The ratios of the *G*-value for excitation to that for electrons are 1.1 for methane, 1.5 for ammonia, and 1.7 for water. An estimation was also made of the *G*-value for the emission of highly-excited hydrogen atoms using reported cross sections. The *G*-values are 0.1 for methane and ammonia, and 0.2 for water.

Methane, ammonia, and water are iso-electronic with neon. The radiolyses of these compounds have been extensively investigated by many radiation chemists.[1-9] They measured the *G*-values of the final products both in the pure state and in systems containing electrons or radical scavengers. On the basis of these results, they constructed reaction sequences consisting of ion-molecule reactions and radical reactions, and estimated the *G*-values for the primary products such as electrons, radicals, and singlet- and triplet-excited states of the parent molecules. On the other hand, radiation physicists are concerned with the *W*-values of these gases (the *W*-value is equal to $100/G$(electrons)) and have measured them accurately.[10-13] They also reported various physical processes occuring during irradiation, such as the emissions of intermediate species and the lifetimes of the highly-excited atoms produced.[14] At present, therefore, we are in a good position to view generally the entire sequence of the radiolyses of methane, ammonia, and water.

Previously, the authors calculated the degradation spectra of electrons in noble gases from He to Xe, and estimated the *G*-values of electrons and singlet- and triplet-excited states.[15,16] Although the method was a classical one, the calculations are in fair agreement with the experimental results. After the calculation on noble gases, they extended the calculation to water irradiated by 10 keV electrons.[17] Since the method of calculation was established, the estimation of the *G*-values for electrons and excited states was straightforward. The main concern in Ref. 17, therefore, was the estimation of the *G*-values of the various products which are of interest to radiation chemists. In order to estimate these values, all of the available spectroscopic, photochemical, and radiation chemical data were considered.

The present paper is an extension of Ref. 17, and treats the radiolyses of methane, ammonia, and water. The water molecule was again chosen as one of the objects of research, since the above three compounds are iso-electronic and it is thought worthwhile to compare them on the same basis.

Method of Calculation

The differential cross section, $\sigma_E(T)$, and the total cross sections for ionization and excitation, $Q_s(T)$, at an electron energy T were estimated using the classical binary-encounter theory, the details of which have been described in previous papers.[15-17] Only the parameters, the binding energy (I_i), the average kinetic energy (E_i), the energy of the first excited singlet state (E_s) and that of the lowest triplet state (E_t) have to be replaced by the values corresponding to those for the molecular orbitals.

The formulation of the stopping power, $S(T)$, is the same as that given in Ref. 17. Once $\sigma_E(T)$ and $S(T)$ are obtained, we can calculate the degradation spectra for electrons, $y(T)$, in the three compounds on the assumption of continuous slowing down. The procedure for the calculation of $y(T)$ is the same as that given in Ref. 15. Since we know that the contribution from double collisions to the *G*-values for electrons cannot be ignored, they were calculated for the three compounds. The cross sections for different types of double collisions have been formulated in Ref. 16. Then, as stated in Ref. 15, we can estimate the *G*-value of any process by integrating $Ty(T)\,Q_s(T)$ over $\ln T$.

Constants Used for Calculation

Tables 1 and 2 summarize all the constants used for the calculations for methane, ammonia, and water. Each value was determined as follows.

$CH_4(1a_1)^2(2a_1)^2(1t_2)^6$: The binding energies ($I_i$) were taken from ESCA data.[18,19] The average kinetic energies (E_i) were calculated from the SCF functions proposed by Palke and Lipscomb.[20] Since the absorption spectrum of methane begins at 1455 Å,[21] the energy of the first excited singlet state, $E_{s,1t_2}$, was assumed to be 8.5 eV. No experimental data on the energies of the inner-shell excited states (E_s and E_t) are available. Therefore, these values were tentatively estimated as shown in Table 1. The equations used

Table 1. Binding energies (I_i), average kinetic energies (E_i), and energies to the first excited singlet state (E_s) and to the lowest triplet state (E_t)

Orbital		No. of electrons	I_i (eV)[a]	E_i (eV)	E_s (eV)	E_t (eV)

$\bar{r}$ (Å)	0.86	0.79	0.75	0.45

for the estimations are summarized in the footnotes of Table 1.

$NH_3(1a_1')^2(2a_1')^2(1e')^4(1a_2'')^2$: The values of I_i were taken from ESCA data, and the E_i values were calculated from the SCF functions proposed by Duncan.[23] The energy of the first excited singlet state, $E_{s,1a_2''}$, was estimated from the electron-impact spectrum data reported by Lassettre *et al.*[24] Other values of E_s and E_t were estimated in a manner similar to those of methane.

$H_2O(1a_1)^2(2a_1)^2(1b_2)^2(3a_1)^2(1b_1)^2$: The values of I_i, $E_{s,1b_1}$ and $E_{t,1b_1}$ are the same as those used in Ref. 17, except for the E_t of the inner shells, which were estimated in a manner similar to that for the values of E_t for methane. The E_i values were calculated from the SCF functions proposed by Ellison and Shull.[26]

Table 2 shows the constants used for the calculations for double collisions. The values for $\bar{I}_i$, $\bar{E}_s$, $\bar{E}_t$, and $\bar{E}_i$ are the averages of the I_i, E_s, E_t, and E_i for the corresponding molecular orbitals.[16,17] The second ionization potential, I_{ii}, of neon is 1.9 times the first ionization potential, I_i.[16] It is assumed that the values of I_{ii} for methane, ammonia, and water are 1.9 times the average first ionization potentials ($\bar{I}_i$). The I_{ii} value calculated for methane is in good agreement with those obtained experimentally[27] and theoretically.[28] The energy of the doubly-excited state (E^{**}) and that of the excited ion (E^{+*}) were determined in a manner similar to those for the rare gases.[16] The mean distance between valence electrons ($\bar{r}$) was calculated by placing them uniformly on a sphere whose radius is the bond length. The bond lengths of C–H, N–H, and O–H are reported to be 1.1, 1.0, and 0.96 Å, respectively.[29]

Results

Figure 1 shows the degradation spectra, $y(T)$, for methane, ammonia, water, and neon. The results for neon were reproduced from a previous paper.[15] At low electron energies (<100 eV), the $y(T)$ for neon is different from those for the iso-electronic molecules. Figure 2 shows the $Ty(T)$ $Q_s(T)$ for the ionization and

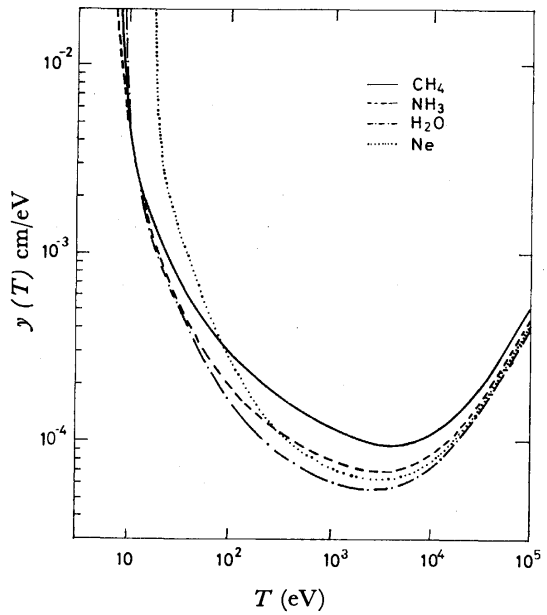

Fig. 1. Degradation spectra in methane, ammonia, water, and neon.

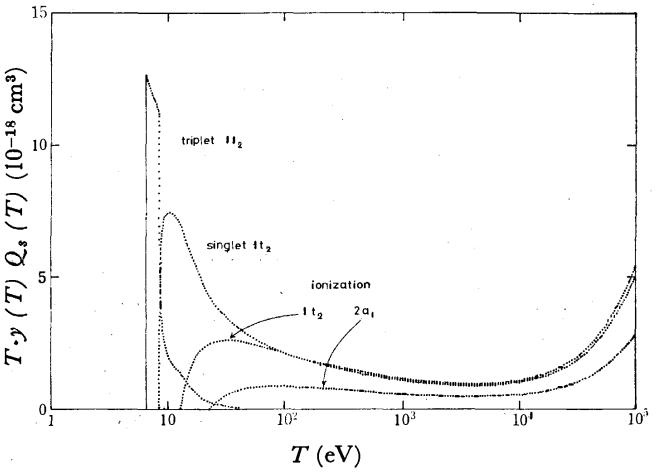

Fig. 2. Contribution of different portions of the electron degradation spectrum to the ionization and excitation in methane.

Table 3. The G-values for ionizations and singlet and triplet excitation. The values in parentheses are those obtained in Ref. 17.

	Orbital	G_i	$G_{ex,s}$	$G_{ex,t}$
CH_4	$1t_2$	2.59	3.45	0.78
	$2a_1$	0.36	0.15	0.0070
	$1a_1$	0.018	0.0005	0.000009
NH_3	$1a_2''$	1.55	3.48	1.12
	$1e'$	1.06	0.89	0.052
	$2a_1'$	0.38	0.19	0.0079
	$1a_1'$	0.0098	0.0002	0.000003
H_2O	$1b_1$	1.17 (1.26)	2.67 (2.80)	0.93 (1.00)
	$3a_1$	0.83 (0.68)	1.22 (0.96)	0.081 (0.029)
	$1b_2$	0.34 (0.44)	0.31 (0.39)	0.015 (0.011)
	$2a_1$	0.21 (0.21)	0.076 (0.076)	0.002 (0.0016)
	$1a_1$	0.0062 (0.005)	0.0001 (0.000079)	1×10^{-6} (1.5×10^{-6})

excitation of methane as a function of ln T. Similar figures can be obtained for ammonia and water. Table 3 summarizes the G-values for the ionization and excitation from each molecular orbital. The values for water in parentheses are those reported previously.[17] Although the values (E_t and E_i) used in the present calculation are slightly different from those in Ref. 17, the G-values obtained are in fair agreement with each other. The difference in the energies of the incident electrons, 10 and 100 keV, produces no noticeable change in the calculated G-values. Table 4 shows the G-values for the double collisions. The yields for double collision for the three compounds are approximately the same.

Table 4. The G-values for doubly-charged ions, doubly-excited molecules, and excited ions

	CH_4	NH_3	H_2O	Ne
M^{++}	0.11	0.10	0.10	0.15
M^{**}	0.16	0.11	0.13	0.11
M^{+*}	0.54	0.43	0.49	0.26

Reaction Sequences and the Product Yields

The calculated G-values which are shown in Tables 3 and 4 cannot be compared directly with the observed values, because most of the ions and excited states initially produced are too short-lived to be measured experimentally. We, therefore, have to consider the reaction sequences for each compound. Since fragmental reports on these reaction mechanisms are abundant,[1-9,17,21,30-57] they were collected and the reaction sequences were reconstructed. The most perplexing problem arises when the branching ratios have to be taken into consideration. Such a case is often encountered in reconstructing the reaction sequence of methane. Therefore, the relative abundances based on the branching ratios are somewhat tentative.

CH_4: The fragmentation modes assumed for the ions and excited states produced are summarized as follows:

	orbital		relative abundance[3,30-34]
Ionization from $(1t_2)$	$\longrightarrow$	$CH_4^+ + e^-$	0.6
	$\searrow$	$CH_3^+ + H + e^-$	0.4
$(2a_1)$	$\longrightarrow$	$CH_4^+ + e^-$	0.6
	$\searrow$	$CH_3^+ + H' + e^-$	0.4
$(1a_1)$	$\longrightarrow$	$CH_4^{6+} + 6e^-$	

where H′ denotes a hot hydrogen atom. When an electron in the $(1a_1)$ orbital is ejected, the Auger effect is expected to occur and fragmentation of the ion will take place, however, since there is no available information for the mode of this fragmentation and the G-value of this process is very small, it was assumed that only ionization occurs and the ions produced react as follows:

$$CH_4^{6+} + 11CH_4 \longrightarrow 6CH_5^+ + 6CH_3$$

The number of electrons ejected in the Auger effect was estimated by the method described in Ref. 15.

Excitation from $(1t_2)$ triplet	$\longrightarrow$	$CH_3 + H$		
singlet	$\longrightarrow$	$CH_3 + H$	0.4	[1,21,35-44]
	$\longrightarrow$	$CH_2 + H_2$	0.4	
	$\longrightarrow$	$CH + H_2 + H$	0.15	
	$\longrightarrow$	$C + 2H_2$	0.05	
$(2a_1)$	$\longrightarrow$	$CH_4^+ + e^-$	0.6	[3,32-34]
	$\searrow$	$CH_3^+ + H' + e^-$	0.4	
$(1a_1)$	$\longrightarrow$	$CH_4^{6+} + 6e^-$	(Auger effect)	

Double collisions:

CH_4^{2+}	$\longrightarrow$	$CH_3^+ + H^+$	0.5	[16,32-34]
	$\searrow$	$CH_2^+ + H^+ + H'$	0.5	
CH_4^{**}	$\longrightarrow$	$CH_4^+ + e^-$	0.6	
	$\searrow$	$CH_3^+ + H' + e^-$	0.4	
CH_4^{+*}	$\longrightarrow$	$CH_3^+ + H'$	0.5	
	$\searrow$	$CH_2^+ + H_2$	0.5	

The successive reactions of these fragment ions have been investigated by many researchers.

Ion-molecule reactions: [3,45]

$CH_4^+ + CH_4$	$\longrightarrow$	$CH_5^+ + CH_3$	
$CH_3^+ + CH_4$	$\longrightarrow$	$C_2H_5^+ + H_2$	
$CH_2^+ + CH_4$	$\nearrow$	$C_2H_5^+ + H$	1/3
	$\longrightarrow$	$C_2H_4^+ + H_2$	1/3
	$\searrow$	$C_2H_3^+ + H_2 + H$	1/3
$C_2H_3^+ + CH_4$	$\longrightarrow$	$C_3H_5^+ + H_2$	
$C_3H_5^+ + CH_4$	$\xrightarrow{+M}$	$C_4H_9^+$	
$H^+ + CH_4$	$\xrightarrow{+M}$	CH_5^+	

Neutralization reaction: [1-3]

$$CH_5^+ + e^- \longrightarrow CH_4 + H$$
$$C_2H_5^+ + e^- \longrightarrow C_2H_4^* + H$$

$$C_2H_4^+ + e^- \xrightarrow{+M} C_2H_4^*$$
$$C_4H_9^+ + e^- \longrightarrow C_3H_6 + CH_3$$

A part of the excited ethylene produced will decompose into acetylene and a hydrogen molecule.[1)]

$$C_2H_4^* \longrightarrow C_2H_4 \quad 2/3$$
$$C_2H_4^* \longrightarrow C_2H_2 + H_2 \quad 1/3$$

Radical reactions: The hot hydrogen atoms produced will react with the substrate, methane.[46)]

$$H' + CH_4 \longrightarrow H_2 + CH_3$$

The radicals, CH_2, CH, and C will undergo the following reactions.[1,2)] Here, it is assumed that the ratio of the amount of singlet methylene ($^1CH_2$) to that of the triplet methylene ($^3CH_2$) is unity and C is in ^1S or ^1D state.

$$^1CH_2 + CH_4 \longrightarrow C_2H_6^*$$
$$C_2H_6^* \longrightarrow C_2H_6$$
$$^3CH_2 + CH_3 \longrightarrow C_2H_5^*$$
$$C_2H_5^* \longrightarrow C_2H_4 + H$$
$$CH + CH_4 \longrightarrow C_2H_4 + H$$
$$C + CH_4 \longrightarrow C_2H_2 + H_2$$

Since hydrogen atoms are not reactive with methane at room temperature, they will remain as one of the most abundant radicals in the system together with methyl radicals.

$$2CH_3 \longrightarrow C_2H_6 \quad k_1$$[9)]
$$CH_3 + H \longrightarrow CH_4 \quad k_2$$
$$2H \longrightarrow H_2 \quad k_3$$

The relative rate constants were assumed to be in the ratio 5: 57: 1 for k_1: k_2: k_3. This ratio is for the reactions of OH radicals and H atoms.[9)] Thus, we can calculate the *G*-values of the intermediate species and final products using the *G*-values of the initial processes shown in Tables 3 and 4. The results are summarized in Table 5 together with the reactions that produced them.

NH_3: A reaction sequence similar to that for methane was constructed as is shown below. This mechanism is much simpler than that for methane because branching is much less common in the case of ammonia.

Ionization from $(1a_2'') \longrightarrow NH_3^+ + e^-$ [47-50)]
$(1e') \longrightarrow NH_2^+ + H + e^-$
$(2a_1') \longrightarrow NH_2^+ + H' + e^-$
$(1a_1') \longrightarrow NH_3^{8+} + 8e^-$ (Auger effect)

Excitation from $(1a_2'') \longrightarrow NH_2 + H$ [51-54)]
$(1e') \longrightarrow NH + 2H \quad 0.85$
$(1e') \longrightarrow NH + H' + H \quad 0.15$
$(2a_1') \longrightarrow NH_3^+ + e^-$ (Autoionization)
$(1a_1') \longrightarrow NH_3^{8+} + 8e^-$ (Auger effect)

Double collisions:

$$NH_3^{2+} \longrightarrow NH_2^+ + H^+$$ [16,49)]
$$NH_3^{**} \longrightarrow NH_3^+ + e^- \text{ (Autoionization)}$$
$$NH_3^{+*} \longrightarrow NH_2^+ + H'$$

Ion-molecule reactions:[47,55)]

$$NH_3^+ + NH_3 \longrightarrow NH_4^+ + NH_2$$
$$NH_2^+ + NH_3 \longrightarrow NH_3^+ + NH_2$$
$$H^+ + NH_3 \longrightarrow NH_4^+$$

TABLE 5. THE *G*-VALUES FOR INTERMEDIATE AND FINAL PRODUCTS FROM METHANE

	Ionization	Excitation	Ion-molecule reaction	Neutralization	Hot-atom reaction	Total intermediate	Radical reaction		Final products

$$NH_3^{8+} + 15NH_3 \longrightarrow 8NH_4^+ + 8NH_2$$

Neutralization reactions:[5,6,56]

$$e^- + NH_4^+ \longrightarrow NH_3 + H$$

Hot-atom reaction:[46]

$$H' + NH_3 \longrightarrow H_2 + NH_2$$

Radical reactions:[6]

$$2NH_2 \longrightarrow N_2H_4$$
$$\searrow\ NH + NH_3$$
$$NH_2 + H \longrightarrow NH_3$$
$$\searrow\ NH + H_2$$
$$2H \longrightarrow H_2$$
$$2NH \longrightarrow N_2 + H_2$$

The rate constants of these radical reactions have been summarized by Willis *et al.*[6] The *G*-values thus estimated are listed in Table 6.

H_2O: The reaction mechanism for water has already been discussed in detail in a previous paper.[17] Here, it is summarized.

Ionization from $(1b_1) \longrightarrow H_2O^+ + e^-$

$(3a_1) \longrightarrow H_2O^+ + e^-$

$(1b_2) \longrightarrow H^+ + OH + e^-$ 0.5

$(2a_1) \longrightarrow H' + OH^+ + e^-$ 0.5

$(1a_1) \longrightarrow H_2O^{8+} + 8e^-$ (Auger effect)

Excitation from $(1b_1) \longrightarrow H + OH$

$(3a_1) \longrightarrow H + OH$ 0.75

$\searrow\ H_2 + O$ 0.25

$(1b_2) \longrightarrow H' + OH$ 0.75

$\searrow\ H_2 + O$ 0.25

$(2a_1) \longrightarrow H^+ + OH + e^-$ 0.5

$\searrow\ H' + OH^+ + e^-$ 0.5

$(1a_1) \longrightarrow H_2O^{8+} + 8e^-$ (Auger effect)

It has been assumed in Ref. 17 that the Auger effect accompanied with the ejection of an electron from the $(1a_1)$ orbital results in the formation of only one H_2O^+ ion. Energetically the reaction assumed above is more probable.

Double collisions:

$$H_2O^{2+} \longrightarrow H^+ + OH^+$$
$$H_2O^{**} \longrightarrow H_2O^+ + e^-$$
$$H_2O^{+*} \longrightarrow H^+ + OH \quad 0.5$$
$$\searrow\ H' + OH^+ \quad 0.5$$

Ion-molecule reactions:

$$H_2O^+ + H_2O \longrightarrow H_3O^+ + OH$$
$$OH^+ + H_2O \longrightarrow H_3O^+ + O$$
$$H^+ + H_2O \longrightarrow H_3O^+$$
$$H_2O^{8+} + 15H_2O \longrightarrow 8H_3O^+ + 8OH$$

Neutralization reaction:

$$H_3O^+ + e^- \longrightarrow H_2O + H$$

Hot-atom reaction:

$$H' + H_2O \longrightarrow H_2 + OH$$

The radicals accumulated in the present system through the foregoing reactions are H, OH, and O atoms. The rate constants of the reactions involving these radicals are not all available, so that we cannot write explicitly the reactions of these radicals.

Table 7 summarizes the *G*-values of several intermediate species calculated on the basis of the reactions assumed above.

Discussion

Comparison of Calculation with Experiment. Table 8 summarizes the *G*-values of the final products from methane. Since methane is one of the most stable hydrocarbons, the results obtained at low dose rates cannot be used for comparison, because the secondary reactions of the products play an important role. The experimental results quoted in Table 8 were obtained using a Febetron at a high dose rate[2,4] and a mass spectrometer.[3] The *G*-values estimated in the present calculation agree fairly well with the experimental values. The calculated *G*-values for hydrogen, ethylene,

and propylene, however, are a little larger than those obtained experimentally. This may be due to the secondary reactions of olefins with hydrogen atoms. Even at the high dose rates obtained using the Febetron, the occurrence of some of the fast secondary reactions cannot be avoided.

Tables 9 and 10 compare the G-values of various products obtained in the radiolysis of ammonia.[5,7,8,56,57] The agreement between calculation and experiment is again good. The calculated G-values of the intermediate products from water are listed in Table 7. These values may be compared with those reported in Ref. 17. Most of the G-values are in good agreement with each other. The G-value for hydrogen atoms listed here should be compared with the $G(H)+G(H_3O^+)-G(H')$ in Table 5 of Ref. 17.

H_2O	33.3	30.2[d]	29.9[b]	
Ne	38.9[f]	36.3[e]		

a) Ref. 10. b) Ref. 11. c) Ref. 13. d) Ref. 12. e) Ref. 58. f) This value is slightly smaller than that reported in Ref. 16 ($W=39.5$). In the present calculation, inner-shell excitation has been included in the estimation of the stopping power.

Table 12. The ratio between the G-value for excitation and that for electrons, and the G-value for total loss of the substrate

	Present estimation		Santar and Bednar[59]	
	G_{ex}/G_e	$G(-M)$	G_{ex}/G_e	$G(-M)$
CH_4	1.10	7.36	0.8—0.9	6.4— 6.9
NH_3	1.50	8.74	1.2—1.6	7.4—10.0
H_2O	1.67	7.86	0.7—1.3	5.5— 7.6
Ne	0.57	3.77	0.4	3.7

ing the number of rough approximations involved in the present calculation, the agreement is surprisingly good.

Table 12 shows the ratios of the *G*-values for excitation to those for electrons and the *G*-values for the total loss of the substrate. The same values were calculated by Santar and Bednar[59] using the "optical approximation" proposed by Platzman.[58] Both methods seem to be consistent.

Table 13. The calculated *G*-values for emission from excited hydrogen atoms and other species

		CH_4	NH_3	H_2O
H Lyman	α	0.06[a]	0.05[b]	0.04[b]
		0.006[b]		0.16[d]
	β	0.001[a]		0.005[d]
Balmer	α	0.01[a]		0.03[d]
	β	0.003[a]		0.005[d]
	γ	0.001[a]		0.002[d]
	δ	0.0008[a]		0.0008[d]
2s→1s		0.006[a]		
CH		0.008[c]		
C		0.0007[b]		
N			0.008[b]	

The cross section used for the calculation was quoted from Ref. 14 for a), Ref. 39 for b), Ref. 38 for c), and Ref. 60 for d).

The G-value for Emission. Recently, the emission from the excited species produced by electron impact have been measured by several investigators.[14,38,39,60–62] They reported the cross sections for these processes as a function of the energy of incident electrons. Using these cross sections and the degradation spectra obtained here, it is possible to calculate the *G*-values of various emissions for the substrate excited by 100 keV electrons. Table 13 summarizes the calculated results. The total *G*-values for emission from excited hydrogen atoms produced by 100- keV-electron radiolysis are about 0.1 for methane and ammonia, and 0.2 for water.

Solvent Inclusion Effects on the Structure and Electrical Conductivity of Benzidine-TCNQ Complex

Noriaki TAKAHASHI, Kyuya YAKUSHI, Kikujiro ISHII,* and Haruo KURODA
Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Tokyo 113
(Received August 9, 1975)

The solvent-containing modification of benzidine (BD)-tetracyanoquinodimethane (TCNQ) complex is a new type of inclusion compound where solvent molecules are included in the channels of the host lattice formed by hydrogen bonding and charge-transfer interaction between BD and TCNQ. The electrical conductivity at 18 °C is 7×10^{-10} ohm^{-1}·cm^{-1} and the activation energy of semiconduction is 0.54 eV in the solvent-free state, but they change to 10^{-4}—10^{-6} ohm^{-1}·cm^{-1} and 0.1—0.2 eV, respectively, when an aliphatic solvent is included, and to 10^{-6}—10^{-9} ohm^{-1}·cm^{-1} and 0.3—0.5 eV, when benzene or its derivatives is included. By examining the changes of the electrical conductivity and the spin density of BD·TCNQ·[CH_2Cl_2] system with the pressure change of the ambient dichloromethane vapor, it is concluded that the conductivity of BD·TCNQ·[CH_2Cl_2] is strongly controlled by the amount of solvent vacancies in the crystal lattice. The correlations between the electrical properties and crystal structures of solvent-containing modifications are discussed.

In the earlier investigations by Ohmasa *et al.*[1] it was first found that the electronic properties of the solid molecular complex between benzidine (BD) and tetracyano-*p*-quinodimethane (TCNQ) were significantly dependent on the solvent used in the preparation of the crystals, and these phenomena were concluded to be due to the solvent inclusion in the crystal lattice of BD·TCNQ complex. They reported that dichloromethane, 1,2-dichloroethane, dibromomethane, bromoethane, acetonitrile, nitromethane and acetone were able to be included in BD·TCNQ complex, while chloroform and 1,1-dichloroethane were not.

Later, we found that a variety of aromatic solvents such as benzene, chlorobenzene, bromobenzene, toluene, benzonitrile and nitrobenzene can be included in BD·TCNQ complex. By carrying out crystal structure analysis on the solvent-free modification as well as on several solvent-containing modifications, we have concluded that the solvent-containing modifications of BD·TCNQ complex are to be regarded as a new type of inclusion compound where the hydrogen bonding and charge-transfer interaction between donor and acceptor molecules are playing an important role in the formation of the channeled structure of the host lattice.[2-4]

In the present paper, we report the effects of the solvent inclusion on the electrical conductivity of the BD·TCNQ system, and their relations with the crystal structures.

Experimental

The solvent-containing modifications of BD·TCNQ complex were obtained by the following procedures; an appropriate amount of benzidine was dissolved in a hot solution which had been almost saturated with TCNQ, and this solution was gradually cooled and kept at room temperature for about one day yielding the crystals of BD·TCNQ complex from the solution. The solvent-free modification was prepared by the same method using chloroform as the solvent.

Since the included solvent is gradually lost when a crystal of a solvent-containing modification is kept in the ordinary atmosphere at room temperature, we took out the crystals from their mother solutions immediately before each experiment.

The X-ray diffraction patterns of the powder samples were observed with a diffractometer, Geigerflex. The presence of the included solvent was examined by thermogravimetric analysis (TG) combined with differential scanning calorimetry (DSC), which were carried out with a Rigaku TG-DSC apparatus. The infrared absorption spectra were examined by use of Nujol mull method.

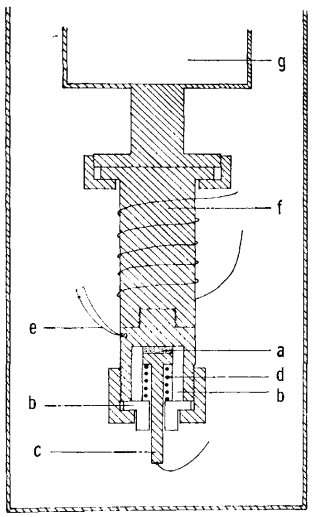

Fig. 1. Apparatus for conductivity measurement: (a) sample, (b) Teflon cylinder, (c) electrode, (d) spring, (e) thermo-couple (Cu-constantan), (f) heat-conductor with a heater, (g) liquid N_2.

The DC conductivity of each modification was measured on a polycrystalline sample by using the apparatus illustrated in Fig. 1. The crystalline powder[5] was packed in the sample cell, and compressed to a polycrystalline disc between the electrodes using a pressure of about 16 kg·cm^{-2}. In this way, the sample was tightly sealed in the cell so as to prevent the evolution of the included solvent during the measurement. To minimize the solvent evolution, we carried out the measurement only at lower temperatures. The size of the polycrystalline disc of the sample was measured after the conductivity experiment. Typically, it was about 8 mm in diameter and about 0.5 mm thick. Applying a DC voltage of 1—20 volt between the electrodes, we measured the current through the sample with an electrometer, Takeda Riken TR-8651.

Results and Discussion

Structural Aspects of Solvent Inclusion. From the examination of the powder X-ray diffraction patterns of various modifications of BD·TCNQ complex, with and without solvent inclusion, we concluded that there are, at least, three different types of crystal lattice for the BD·TCNQ system: The first one (Type I) is the crystal lattice of the solvent-free modification, BD·TCNQ·[n], the second one (Type II) is that of a modification containing an aliphatic solvent, and the third one (Type III) is that of a modification containing an aromatic solvent.

We have carried out the crystal structure analysis on a representative example of each of the above three types; the solvent-free modification, BD·TCNQ·[n], as Type I, the one containing dichloromethane, BD·TCNQ·[CH_2Cl_2], for Type II, and the one containing benzene, BD·TCNQ·[C_6H_6], for Type III. The details of the crystal structure analysis of each modification have been separately reported elsewhere.[2-4] In the crystal of BD·TCNQ·[n],[3] benzidine and TCNQ molecules are alternately stacked on each other to form molecular columns along the c-axis, and those molecular columns are closely packed together without leaving any free space to accommodate solvent molecules.

The crystal structure of BD·TCNQ·[CH_2Cl_2] is reproduced in Fig. 2.[2] Benzidine and TCNQ molecules are alternately stacked on each other to form molecular columns which are almost the same as in BD·TCNQ·[n], but these columns are arranged so as to leave channels running through the crystal along the c-axis, in which solvent molecules are accommodated. There seems to be no specific interaction between the included dichloromethane molecules and the BD·TCNQ host lattice.

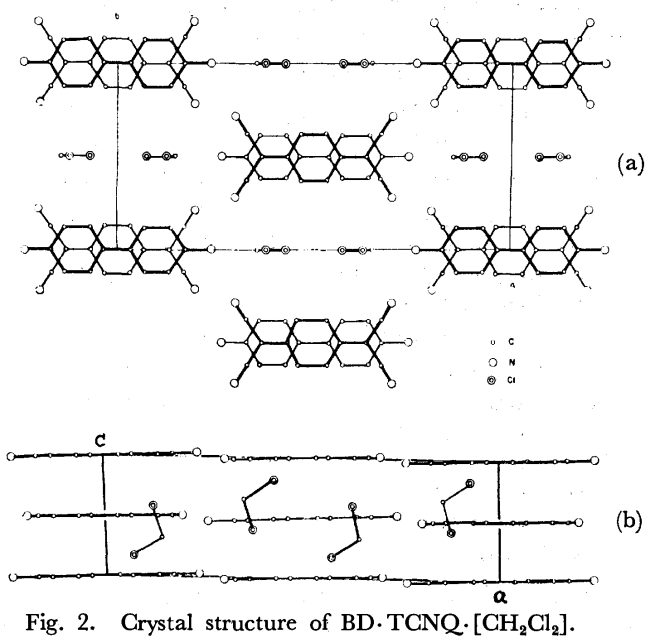

Fig. 2. Crystal structure of BD·TCNQ·[CH_2Cl_2]. (a) projection to the (001) plane, (b) projection to the (010) plane.

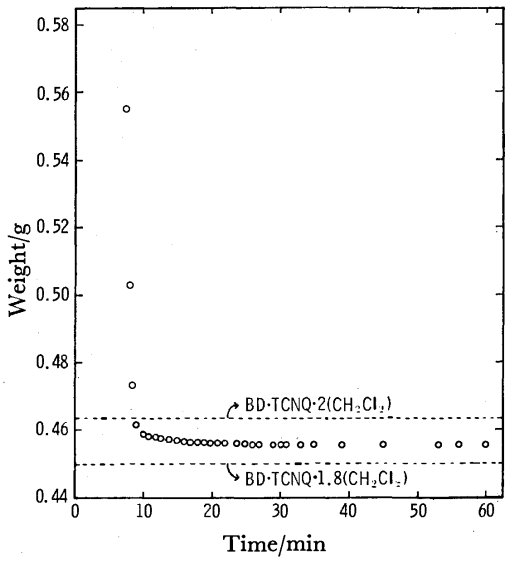

Fig. 3. Weight change of BD·TCNQ·[CH_2Cl_2] powder in the ordinary atmosphere, starting from the state wet with dichloromethane liquid. Note that the weight settles at the value corresponding to BD·TCNQ·1.8 (CH_2Cl_2), and remains the same after that. The mole ratio was calculated from the weight loss of the sample heated in vacuum.

According to the crystal structure, the ideal composition of the BD·TCNQ·[CH_2Cl_2] system is to be BD·TCNQ·2(CH_2Cl_2), but the actual composition was BD·TCNQ·1.8(CH_2Cl_2) under normal conditions. This means that about 10 percent of dichloromethane molecules are missing from the crystal lattice of BD·TCNQ·[CH_2Cl_2] creating the corresponding amount of vacancies at the solvents sites without producing any significant distortion of the host lattice. When the crystalline powder of BD·TCNQ·[CH_2Cl_2], which was wet with an excess dichloromethane, was kept in the ordinary atmosphere, the amount of the included solvent changed with time as shown in Fig. 3. The amount of the included solvent decreased to the value corresponding to BD·TCNQ·1.8(CH_2Cl_2), and thereafter it stayed at the same value for a long period. Further loss of the included solvent took place when the powder was heated to about 60 °C in vacuum, but, in this case, the solvent evolution was accompanied by conversion

Table 1. Crystal data of BD·TCNQ

	Space group	*a*	*b*	*c*	*β*	*Z*
BD·TCNQ·[n]	C2/m	12.231	12.679	6.477	104.84	2
BD·TCNQ·[CH_2Cl_2]	I2/m	20.892	9.950	6.445	91.92	2
BD·TCNQ·[CH_2ClCH_2Cl]	Immm	10.199	20.765	6.529		2
BD·TCNQ·[CH_2BrCH_2Br]	Immm	10.205	20.785	6.525		2
BD·TCNQ·[C_6H_6]	$P2_1/m$	17.184	9.852	7.680	100.3	2

of the crystals to BD·TCNQ·[n]. Seemingly, BD·TCNQ·1.8(CH_2Cl_2) is the limiting composition for keeping the channeled structure of the host lattice.

The crystal data of other two modifications of Type II are compared in Table 1 with those of BD·TCNQ·[CH_2Cl_2]. Above three modifications are almost isomorphous to each other. In effect, preliminary analyses of the crystal structures of BD·TCNQ·[CH_2ClCH_2Cl] and BD·TCNQ·[CH_2BrCH_2Br] have shown that, in these cases, the host lattice is almost the same as in BD·TCNQ·[CH_2Cl_2]. The amount of included solvent was found to be 1.6 mole per one mole of BD·TCNQ in BD·TCNQ·[CH_2ClCH_2Cl] as well as in BD·TCNQ·[CH_2BrCH_2Br], which is approximately equal to the value that is expected to fill up the channels with dichloroethane or dibromoethane. The analyses of the diffraction patterns have led us to conclude the presence of a considerable disorder as regards the arrangement of solvent molecules in the channels. Seemingly, such a disorder has been inevitably introduced to fill up the channels with the solvent molecules. Although a detailed investigation has not yet been carried out on the crystal structure of other modifications of Type II, we believe that all of them commonly possess the same type of host lattice.

The crystal structure of BD·TCNQ·[C_6H_6][4] is different from the structures of the modifications of Type II; The BD·TCNQ column is composed of BD·TCNQ pairs[6] and one benzene molecule is surrounded by four BD·TCNQ pairs. The amount of the included benzene was found to be one mole per one mole of BD·TCNQ as it is expected from the crystal structure. When a crystal of BD·TCNQ·[C_6H_6] is kept in the ordinary atmosphere at room temperature, the included benzene is gradually lost converting the crystal to the solvent-free modification. There seems to be no stable phase which has some fixed amount of solvent vacancies in this case.

As we have already mentioned, the modifications which contain aromatic solvents, exhibit diffraction patterns similar to that of BD·TCNQ·[C_6H_6], and the mole ratio of included solvent is always one mole per one mole of BD·TCNQ as in BD·TCNQ·[C_6H_6]. Thus, the structure of the host lattice is likely to be essentially the same in all of these cases.

Electrical Conductivities of Solvent-containing Modifications. Although some of the solvent-containing modifications were obtainable as a single crystal sufficiently large for performing the measurement of electrical conductivity, we carried out the measurement exclusively on the compressed polycrystalline samples by the method described in the earlier part of this paper because it is more difficult to prevent a loss of the included solvent during the conductivity measurement when we use a small single crystal.

In Fig. 4, we show the experimental results obtained for three representative modifications. For all modifications, the temperature dependence of electrical conductivity was reproducible between the cooling and heating processes, and the relation between the conductivity σ and the temperature was describable with a single exponential function (Eq. (1)).

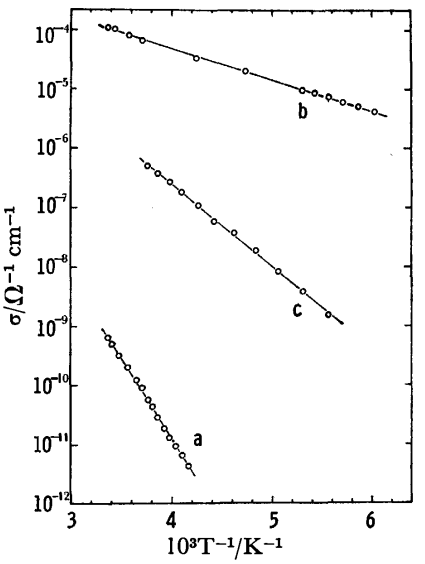

Fig. 4. Temperature dependence of conductivity.
(a) BD·TCNQ·[n], (b) BD·TCNQ·[CH_2Cl_2], and (c) BD·TCNQ·[C_6H_6].

$$\sigma = \sigma_0 \exp(-\Delta E/kT) \quad (1)$$

These facts imply that we were practically able to avoid the solvent loss during the conductivity measurements.

The electrical conductivities at 18 °C and the activation energies of semiconduction are summarized in Table 2, where the results reported by Ohmasa *et al.*[1] are also included for comparison.

TABLE 2. CONDUCTIVITY DATA OF BD·TCNQ

	Included solvent (mole ratio)	Crystal lattice	σ (18°C) [$ohm^{-1}\cdot cm^{-1}$]	ΔE [eV]
(1)	solvent-free	I	7×10^{-10}	0.54
(2)	CH_2Cl_2 (1.8)	II	1×10^{-4}	0.11
(3)	C_2H_5Br (1.8)	II	2×10^{-4}	0.12[a]
(4)	CH_2ClCH_2Cl (1.6)	II	1×10^{-5}	0.14
(5)	CH_3CN (0.8)	II	1×10^{-5}	0.16[a]
(6)	CH_3COCH_3 (0.8)	II	3×10^{-6}	0.21[a]
(7)	C_6H_6 (1.0)	III	1×10^{-6}	0.28
(8)	C_6H_5Cl (1.0)	III	3×10^{-7}	0.38
(9)	C_6H_5Br (1.0)	III	1×10^{-7}	0.40
(10)	$C_6H_5CH_3$ (1.0)	III	3×10^{-8}	0.43
(11)	C_6H_5CN (1.0)	III	2×10^{-9}	0.44
(12)	$C_6H_5NO_2$ (1.1)	III	3×10^{-9}	0.50

a) Ref. 1.

First of all, we note that a large increase of conductivity and a marked lowering of activation energy are caused by the solvent inclusion. These changes are most significant in the modifications which have been classified as Type II. In these cases the conductivities at 18 °C are of the order of 10^{-4}—10^{-6} $ohm^{-1}\cdot cm^{-1}$ and the activation energies are only 0.1—0.2 eV while the former is 10^{-9} $ohm^{-1}\cdot cm^{-1}$ and the latter is 0.54 eV in the case of BD·TCNQ·[n].

According to Eq. (1), the relation between the conductivity at 18 °C, σ (18 °C), and the activation energy of semiconduction, ΔE (in eV units), can be expressed as follows;

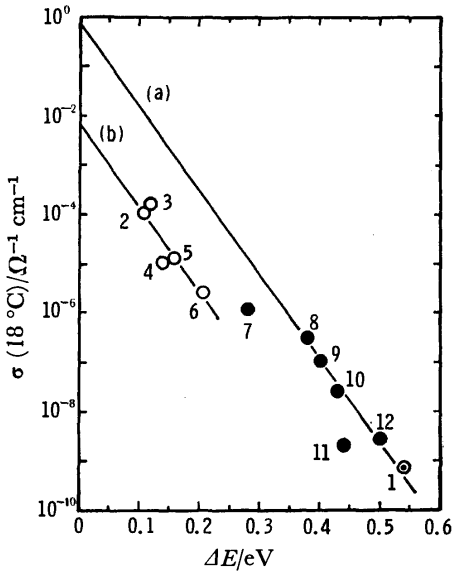

Fig. 5. Plots of the conductivity at 18 °C *versus* the activation energy of semiconduction. (See text for the meanings of lines (a) and (b). Their inclinations corresponds to $-1/kT$ (T=291 K).) Refer Table 2 for the numbering of the systems.

$$\log \sigma\,(18°C) = \log \sigma_0 - 17.32\Delta E \qquad (2)$$

Therefore, if σ_0 is the same for different modifications, we should have a straight line when we plot log σ (18 °C) versus ΔE. We show the log σ (18 °C) *vs.* ΔE plots in Fig. 5. Interestingly, the plots in the ΔE region of 0.4—0.6 eV are on the line (a) which correspond to σ_0=1 ohm^{-1}·cm^{-1}. These plots are concerned with the modifications of Type III and the solvent-free modification. On the other hand, the plots concerned with the modifications of Type II fall on another line (b) which corresponds to σ_0 of about 10^{-2} ohm^{-1}·cm^{-1}. If we assume that the density of states are of the same order of magnitude as the number of BD·TCNQ units per unit volume, and the mobilities of charge carriers are 10^{-2}—10^{-1} cm^2·V^{-1}·s^{-1} as reported for several charge-transfer complexes,[7-9] σ_0 is expected to be 10^{0}—10^{1} ohm^{-1}·cm^{-1} for the intrinsic semiconduction. Naturally, it is difficult to make a quantitative discussion on σ_0 by using the conductivity data obtained of polycrystalline samples, but we could say that the σ_0 value corresponding to the line (a) is not unreasonable for the intrinsic semiconduction while that corresponding to the line (b) is too small.

The value of activation energy provides another criterion. In the case of a charge-transfer complex, the energy gap (*i.e.*, the energy required for the intrinsic carrier formation) can be estimated by the following relation;

$$\varepsilon = I(\mathrm{D}) - A(\mathrm{A}) - \{P(\mathrm{D}^+) + P(\mathrm{A}^-)\} \qquad (3)$$

where I(D) and A(A) are the ionization potential of the donor (D) and the electron affinity of the acceptor (A), respectively, and P(D$^+$) and P(A$^-$) are the polarization energies associated with the formations of D$^+$ and A$^-$ ions in the crystal, respectively. Ionization potential of benzidine is estimated as 7.15 eV from the charge-transfer band of the benzidine-chloranil complex in solution,[10] and the electron affinity of TCNQ has been reported to be 2.8 eV.[11,12] According to Batley and Lyons,[13] the photoionization threshold of BD·TCNQ complex is at 5.03 eV. Since the ionization potential of TCNQ, 9.6 eV,[14] is more than 2 eV higher than that of benzidine, the photoionization threshold corresponds to the energy for the ionization of a benzidine molecule in the crystal of the complex. This energy can be related to I(D) and P(D$^+$) as follows;

$$I(\mathrm{D};\ \text{solid DA}) = I(\mathrm{D}) - P(\mathrm{D}^+) \qquad (4)$$

By substituting I(D; solid DA)=5.03 eV and I(D)=7.15 eV into Eq. (4), we obtain P(D$^+$)=2.12 eV. At present, P(A$^-$) can not be experimentally estimated, but one could reasonably assume it as 1.5—2 eV. If we put these figures into Eq. (3), the energy gap is estimated to be less than 1 eV, which is rather smaller than the twice of the activation energy actually observed of the solvent-free modification. Thus it is not unreasonable to consider that the observed conductivity is due to the intrinsic carrier formation in this case.

We may expect two kinds of effects of solvent inclusion on the activation energy of semiconduction in the BD·TCNQ system. The first is the one associated with the formation of hydrogen bonds between benzidine and TCNQ. We have found that the crystal of the molecular complex which has an infinite hydrogen-bonded chain of donor and acceptor as in quinhydrone, generally exhibits a charge-transfer band at an energy lower by 0.4—0.6 eV than the value that is expected simply from the ionization potential of donor and the electron affinity of acceptor.[16] Seemingly, the value of I(D)$-A$(A) is reduced when a hydrogen-bonded chain or network is formed between donor and acceptor. From this point of view, we can expect that the solvent inclusion of BD·TCNQ complex will cause a decrease of the activation energy of semiconduction, since benzidine and TCNQ molecules are forming hydrogen-bonded networks when solvent molecules are included, while not in the solvent-free state.[17]

The second effect of solvent inclusion is the one associated with a change in the polarization energy term. The values of P(D$^+$) and P(A$^-$) will naturally be affected by the solvent inclusion. Although it is not easy to quantify this effect we can qualitatively predict that the polarization energy term will be a little smaller in the solvent-containing modifications than in the solvent-free modification. Therefore, this effect of solvent inclusion is likely to cause an increase of activation energy.

Since the above two effects are giving mutually opposite contributions, the solvent inclusion will cause a relatively small change in the intrinsic energy gap. In this sense, the activation energies observed of the modification of Type III are quite understandable, but those observed of the modifications of Type II seem to be too small for the intrinsic carrier formation.

Solvent Vacancies and Electrical Conductivity. As we have already mentioned, the amount of the included solvent can vary within a certain range without changing the structure of the host lattice in the case of the modifications of Type II. This is typically the case in BD·TCNQ·[CH_2Cl_2]. Thus we examined the correlation

between the electrical conductivity and the amount of solvent vacancies by varying the pressure of the ambient dichloromethane vapor. For this purpose the crystalline powder of BD·TCNQ·[CH_2Cl_2], still wet with dichloromethane, was packed between two gold-mesh electrodes so as to keep a good contact with the ambient vapor, and put in a glass cell for the conductivity measurement. This cell was connected to the system for controlling the pressure of the dichloromethane vapor. When the vapor pressure was stepwisely varied after the removal of excess dichloromethane, the current changed rather rapidly settling to a new stationary state within 5—10 minutes at each vapor

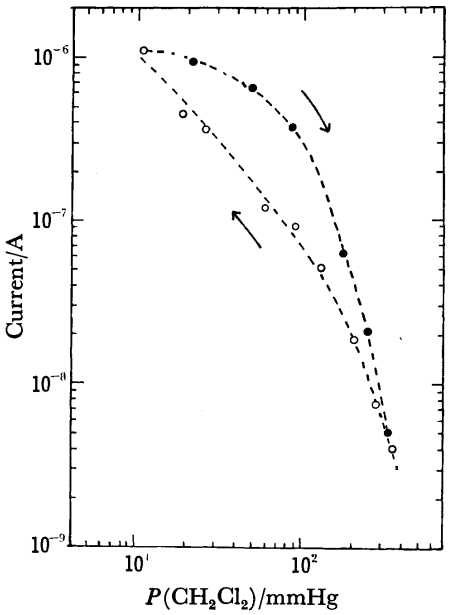

Fig. 6. Dependence of the conductivity of BD·TCNQ·[CH_2Cl_2] on the vapor pressure of dichloromethane in the ambient atmosphere. The current observed at a constant applied field is directly plotted instead of the conductivity.

pressure. In Fig. 6, we plotted the observed steady-state current against the vapor pressure of dichloromethane. In the pressure region above 6 mmHg, the steady-state current significantly increased on decreasing the vapor pressure, and conversely, decreased on increasing the vapor pressure, but there appeared an appreciable hysteresis in the current *vs* pressure curve. The current reached a maximum value at about 6 mmHg, and remained at almost the same value at lower vapor pressures. Examining the amounts of included solvent in the powders which have been subjected to the conditions similar to those in the above experiments, we concluded that the results shown in Fig. 6, are giving the conductivity change due to the variation of the composition, BD·TCNQ·$x(CH_2Cl_2)$ in the range of $1.8 \leq x \leq 2$. The experimental results described above, most clearly demonstrate that the electrical conductivity of the BD·TCNQ·[CH_2Cl_2] system is strongly controlled by the amount of solvent vacancies, and the conductivity data obtained under the ordinary condition, where the composition of the sample is BD·TCNQ·$1.8(CH_2Cl_2)$, should be regarded as primarily associated with an extrinsic semiconduction caused by the presence of solvent vacancies.

In this connection, it is interesting to see that the BD·TCNQ·[CH_2Cl_2] system exhibits a strong ESR absorption in the presence of solvent vacancies. It was reported by Ohmasa *et al.*[1] that BD·TCNQ·[CH_2Cl_2] did not exhibit ESR signal when measured with its well-grown crystals immediately after preparation, but gave strong ESR signals when ground to a fine powder. They observed also that a strong ESR signal appeared when a pulverized sample of BD·TCNQ·[n] was exposed to the vapor of dichloromethane.

In order to elucidate the relation between spin centers and solvent vacancies, we examined the ESR signal of BD·TCNQ·[CH_2Cl_2] powder in the dichloromethane vapor. The powder sample, still wet with an excess dichloromethane, was put into the ESR sample tube which had a stopcock and a joint so that it could be connected to the vacuum system for controlling the vapor pressure of dichloromethane. The ESR signal was first observed in the presence an excess dichloromethane, then its change was observed by stepwisely reducing the vapor pressure of the dichloromethane in the sample tube. At each vapor pressure, we waited for about 45 min before the ESR measurement so that the sample had settled in an equilibrium state with the ambient dichloromethane vapor. The results are shown in Fig. 7, in which we have plotted the spin density against the vapor pressure, both in logarithmic scale.

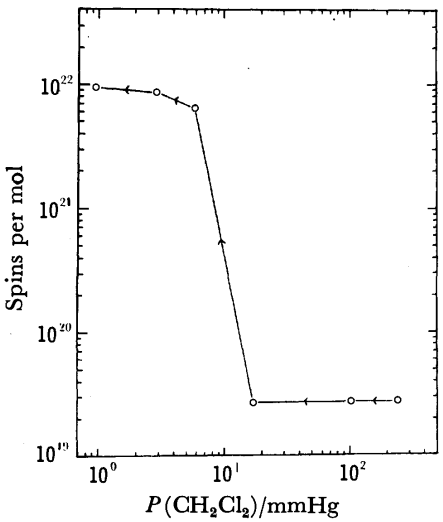

Fig. 7. Dependence of the spin concentration of BD·TCNQ·[CH_2Cl_2] on the vapor pressure of dichloromethane.

Since we had pulverized the crystals, the sample exhibited a weak ESR signal even in the presence of an excess dichloromethane. On driving off the excess dichloromethane, the spin density increased slightly, but after a small initial change it remained almost at a constant magnitude down to 20 mmHg. A steep rise of spin density was observed on decreasing the vapor pressure from 20 mmHg to about 6 mmHg,[15] then the change was leveled off in the lower pressure region. The above data clearly demonstrate that the spin density is closely related to the amount of solvent

vacancies. Although benzidine and TCNQ molecules are essentially in non-ionic states when they are at their regular sites, radical ions could be easily formed through electron transfer from benzidine to TCNQ at the crystal sites which possess features favouring ion-formation, since benzidine has a low ionization potential and TCNQ has a very high electron affinity. Seemingly the solvent vacancies are contributing somehow to the creation of such sites in the crystal. If a radical ion of benzidine and/or that of TCNQ are formed in the crystal, they could also contribute as the origins of extrinsic charge carriers. However, it is not possible to find out a direct correlation between the vapor pressure dependence of spin density (Fig. 7) and that of electrical conductivity (Fig. 6). Possibly, this is because the latter is, to some extent, reflecting the properties of the surface regions of crystals, while the former is more related to the bulk properties.

We examined the temperature dependence of magnetic susceptibility on the powder of BD·TCNQ·1.8(CH_2Cl_2) by means of Faraday method. The observed results are shown in Fig. 8. We found that the

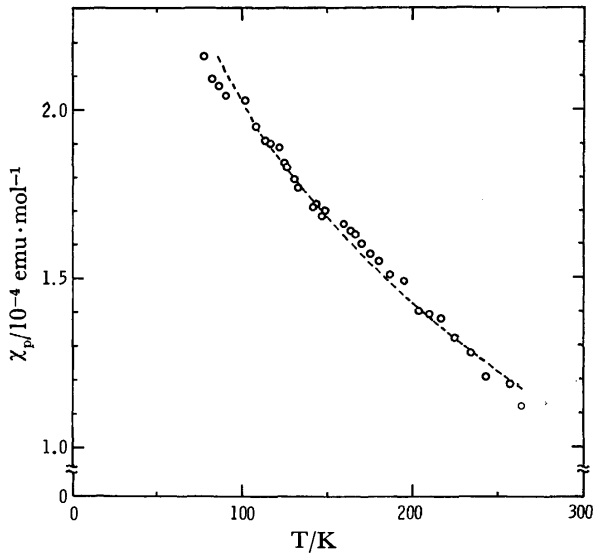

Fig. 8. Temperature dependence of the paramagnetic susceptibility of BD·TCNQ·1.8(CH_2Cl_2).

paramagnetic susceptibility, which was obtained by subtracting the diamagnetic term, $\chi_d=-336\times10^{-6}$ emu·mol^{-1}, from the observed molar susceptibility, followed the Curie-Weiss law with the Weiss temperature of about −130K and the Curie constant $C=0.047$ emu·K. This seems to suggest that the spin centers are not entirely isolated from each other, but are distributed in the state that allows a weak interaction between them.

Mass Spectrometric Study of the Primary Processes in Photochemical Reactions. III. Primary Steps in Simple Ketone Photolysis and Mass Spectrum of Acetyl Radical

Shigeru YAMASHITA

Department of Chemistry, Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received August 20, 1975)

The primary processes of the photolyses of acetone, methyl ethyl ketone, and methyl vinyl ketone have been studied using a high intensity UV light beam and collision-free photochemical reactor incorporated in the ion-source of a mass spectrometer. Photofragment radicals are directly detected from the mass spectrum of the photolyte flow and the primary processes are determined. Mass spectrum of acetyl radical has been obtained in addition to the mass spectra of hydrocarbon free radicals reported in previous papers. As for the ketones investigated, C–C bond rupture between acetyl and the remainder of the molecule is found predominant in the primary process of the photolysis in the region 290—320 nm.

The photolyses of simple ketones have been reported by many workers and the primary processes of these photochemical reactions have been studied on many compounds.[1] Most of the mechanisms, however, were proposed by the analyses of reaction products after the light-off of the experiments. Direct identification of the photofragments produced in the primary processes has been attempted and successful detections of free radicals from photolyses have been reported since the pioneering works in mass spectrometry[2] and in flash photolysis.[3] In most of the mass spectrometric studies for identification of free radicals in photochemical reactions, only the parent-ion peaks of free radicals have been detected.[4-6]

In the previous paper[7] photolysis of methyl and ethyl iodide was carried out using a light source incorporated in the ion-source of a mass spectrometer and the photofragments recorded in the mass spectrum were assigned to CH_3, C_2H_5, and I. The mass spectra of methyl and ethyl radicals thus obtained were in good agreement with the results of previous workers[8] and with theoretical estimation recently reported.[9]

In the present paper, the primary processes of the photolyses of acetone, methyl ethyl ketone and methyl vinyl ketone have been studied by direct identification of the primary photofragments from the mass spectra of photolyte mixtures.

In the case of these simple ketones, possible primary steps are as following since "Norrish Type II" process can be excluded because of the absence of γ-hydrogen atom:

$$CH_3COR + h\nu \longrightarrow CH_3CO + R \quad (1)$$
$$\longrightarrow CH_3 + COR \quad (2)$$
$$\longrightarrow CH_3 + R + CO \quad (3)$$

here, R denotes CH_3, C_2H_5, or C_2H_3 appropriately.

The purpose of the present paper is to detect directly the photofragments expected from processes (1)—(3) and thereby estimate the contribution from each process although the estimation has been reported by the previous workers[1] from the results of conventional analysis of final products.

Experimental

Acetone and methyl ethyl ketone obtained from Wako Pure Chemical Industry Ltd. and methyl vinyl ketone from Aldrich Chemical Co. were purified by vacuum distillation.

The apparatus and procedure were reported elsewhere.[7,10] The molecular flow of the reactant gas was supplied from a 5 l reservoir kept in the dark into the reactor installed in the ion-source of a Hitachi RMU-5 mass spectrometer through an orifice and a Pyrex glass gas-lead.

The light source was a USH-500D 500W high-pressure mercury lamp (Ushio Electric Co.) and the light flux was focused on the molecular flow of the reactant in the reactor through a quartz window of the ion-source.

Considering the absorption spectra of the reactant ketones[1,11] and the transmission of the Pyrex glass of the reactor, the effective wavelength for photolyses was estimated to be in the range 290—320 nm of the mercury lamp output.

The mass spectrum obtained at 50 eV for each run was a superposition of the cracking patterns of the photofragments and that of the unchanged reactant. The mass spectrum of the photofragment mixture was obtained by subtracting the contribution from unreacted reactant ketones.

Results and Discussion

Photolysis of Acetone. Table 1 shows an example of the mass spectrum of photolyte flow of acetone photolysis. By subtracting the contribution from unreacted acetone from the recorded peak height in the second column at each mass number, the residue Δ is obtained

Table 1. Recorded mass spectrum of the photolyte flow of acetone at 50 eV (in arbitrary units)

m/e	Peak height	Acetone contribution	Δ
13	0.2	0.1	0.1
14	1.3	0.9	0.4
15	7.1	5.8	1.3
26	1.1	1.0	0.1
27	1.9	1.7	0.2
28	1.9	1.5	0.4
29	1.3	1.2	0.1
39	1.0	0.9	0.1
41	1.3	1.1	0.2
42	1.7	1.6	0.1
43	27.4	25.0	2.4
58	7.1	7.1	—

as the superposition of the mass spectrum of each photofragment.

The averaged value of Δ obtained from fifteen runs is shown in Table 2 where abundance is normalized at *m/e* 43. The peak height ratio at mass number 15, 14, and 13 is 55: 12: 6, which is equal to 100: 22: 11. This ratio is almost the same as the cracking pattern of methyl radical previously reported.[7] This means that the primary process of acetone photolysis at $\lambda > 290$ nm is almost exclusively the following one:

$$CH_3COCH_3 + h\nu \longrightarrow CH_3CO + CH_3 \quad (4)$$

The above-mentioned observation is consistent with the results of previous works where the formation of acetyl radical was deduced by the static studies.[12]

Table 2. Mass spectrum of photofragment mixture of acetone photolysis

m/e	Abundance	Assignment
13	6±2	CH_3
14	12±4	
15	55±10	
26	7±3	CH_3CO
27	9±3	
28	12±3	
29	8±4	
39	7±3	
41	12±4	
42	9±3	
43	100	

In Table 2, the peaks at *m/e* 26, 27, 28, 29, 39, 41, 42, and 43 are assigned to acetyl radical. That is, peak *m/e* 43 is the base peak in the mass spectrum of acetyl radical and the cracking pattern coefficients of other peaks are shown.

Photolysis of Methyl Ethyl Ketone. Mass spectrum of the photofragment mixture of methyl ethyl ketone photolysis, which was obtained by subtracting the contribution of unreacted ketone from recorded mass spectrum in similar way to the case of acetone photolysis in Table 1, is shown in the second column of Table 3 in the form of relative abundance normalized at *m/e* 43. This abundance ratio is an average obtained from fifteen runs. The peaks *m/e* 43, 42, 41, and 39 are completely due to CH_3CO since the peak height ratio of these peaks is nearly the same as the cracking pattern of acetyl radical mentioned before. In the peaks *m/e* 29, 28, 27, and 26, there are partial contribution from acetyl radical. Since the cracking pattern of CH_3CO is known in Table 2, the residue Δ_1 is obtained by subtracting the contribution of CH_3CO.

In the residue Δ_1, the peaks *m/e* 26—29 may entirely be attributed to ethyl radical C_2H_5 since the peak height ratio in these mass numbers is close to the cracking pattern of C_2H_5 previously reported.[7] By subtracting the contribution of C_2H_5 from Δ_1, small residue Δ_2 is obtained. The peaks *m/e* 15 and 14 are due to CH_3, and *m/e* 57 peak may be assigned to photofragment C_2H_5CO.

Then, besides the major process (5)

$$CH_3COC_2H_5 + h\nu \longrightarrow CH_3CO + C_2H_5 \quad (5)$$

Table 3. Mass spectrum of photofragment mixture of methyl ethyl ketone photolysis

m/e	Abundance	CH_3CO contribution	Δ_1	C_2H_5 contribution	Δ_2
14	4±2		4		4 (CH_3)
15	11±3		11		11
26	8±3	7	1	1	—
27	20±6	9	11	11	—
28	16±6	12	4	4	—
29	21±4	8	13	13	—
39	6±2	6	—		—
41	12±2	12	—		—
42	10±3	10	—		—
43	100	100	—		—
57	8±4		8		8 (C_2H_5CO)

the following process (6) is taken into account as a minor process in the primary step of methyl ethyl ketone photolysis in the wavelength range of this work:

$$CH_3COC_2H_5 + h\nu \longrightarrow CH_3 + C_2H_5CO \quad (6)$$

The quantum yield ratio Φ_5/Φ_6 may be estimated to be 8.4 considering the total ion current ratio $[\sum I(CH_3CO) + \sum I(C_2H_5)]/[\sum I(C_2H_5CO) + \sum I(CH_3)]$ from Table 3 under the assumption of equal ionization cross section of each photofragment radical. Here, $\sum I(R)$ denotes the sum of all of the ion intensities originated from photofragment R.

Pitts and Blacet reported[13] that $\Phi_5/\Phi_6 = 40$ at 313 nm and $\Phi_5/\Phi_6 = 5.5$ at 265 nm by analyzing the final products in the photolysis of methyl ethyl ketone. Considering the effective wavelength range of 290—320 nm in the present work, the estimated Φ_5/Φ_6 value in this work is consistent with their results.

Photolysis of Methyl Vinyl Ketone. Primary process of the photochemical reaction of methyl vinyl ketone in gas phase seems to have not been explored although a number of works have been reported on the polymerization reaction.

An example of the mass spectrum of the photolyte flow of methyl vinyl ketone photolysis is shown in the second column of Table 4. By subtracting the contribution from unreacted methyl vinyl ketone, the residue Δ_1 is obtained as a superposition of the ion current from each photofragment. The residue Δ_2 is obtained by subtracting the CH_3CO contribution from Δ_1. Since the most intense peak in Δ_2 is found at *m/e* 27, the mass number of the base peak in the mass spectrum of vinyl radical recently reported,[14] the contribution from C_2H_3 is subtracted from Δ_2 resulting in the small residue Δ_3.

Because of the small peaks in Δ_3, the minor process (8) is considered although major process is evidently process (7) in the primary step of methyl vinyl ketone photolysis:

$$CH_3COC_2H_3 + h\nu \longrightarrow CH_3CO + C_2H_3 \quad (7)$$

$$CH_3COC_2H_3 + h\nu \longrightarrow C_2H_3CO + CH_3 \quad (8)$$

In the residue Δ_3, the peak *m/e* 15 suggests the formation of CH_3 and the peak *m/e* 55 may be due to C_2H_3CO. Small peaks at *m/e* 39 and 42 are presumably the frag-

TABLE 4. MASS SPECTRUM OF PHOTOFRAGMENT MIXTURE OF METHYL VINYL KETONE PHOTOLYSIS

70	6.2	6.2	—		—		—

ment ions from C_2H_3CO. As for the mass spectra of free radicals previously studied,[7,8,14] the parent-ion peak is always the most intense base peak.

The reproducibility in the mass spectrum of the photolyte flow is poor in the photolysis of methyl vinyl ketone compared with the case of acetone and methyl ethyl ketone under the present experimental conditions probably because of some deposit on the reactor wall, although the predominance of process (7) over process (8) is always found in every run of methyl vinyl ketone photolysis. The contribution ratio (7)/(8) may roughly be estimated about 10.

Summary. As for the simple ketones studied in this work, the following process (I) producing acetyl radical is always found predominant in the primary step of the photolysis of these ketones by mass spectrometric detection of photofragment radicals:

$$CH_3COR + h\nu \longrightarrow CH_3CO + R \qquad (I)$$

($R = CH_3$, C_2H_5 and C_2H_3)

In the case of methyl ethyl ketone and methyl vinyl ketone, the minor process (II) is found by the detection of CH_3 and RCO:

$$CH_3COR + h\nu \longrightarrow CH_3 + RCO \qquad (II)$$

The predominance of process (I) over (II) might be due to the high stability of acetyl radical whose heat of formation is known to be -11 kcal/mol.[15]

The author is grateful to Professor Teruo Hayakawa for encouragement and discussion. This work was supported by research grant from the Ministry of Education.

Study of Organo(2,2'-bipyridine)nickel Complexes. III. NMR Studies on the Interaction of Dialkyl(2,2'-bipyridine)nickel with Solvents and Olefins[1]

Takakazu YAMAMOTO, Yoshiyuki NAKAMURA, and Akio YAMAMOTO
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro, Tokyo 152
(Received August 23, 1975)

The ^{1}H-NMR spectra of $NiR_2(bpy)$ (bpy=2,2'-bipyridine; R=CH_3, C_2H_5, and C_3H_7) and $Ni(C_2H_5)_2(bpy)$–olefin systems (olefin=acrylonitrile and acrylaldehyde) have been studied in a temperature range from −70 °C to 80 °C. The temperature dependence of the chemical shifts of ethyl and 2,2'-bipyridine protons of $Ni(C_2H_5)_2$-(bpy) in non-aromatic solvents (acetonitrile, *N,N*-dimethylformamide, acetone and tetrahydrofuran) is analyzed on the basis of the formation of 1 : 1 solvent-solute complex. The formation constant of the 1 : 1 comples, K_1, and the thermodynamic parameters $\Delta F_1°$, $\Delta H_1°$, and $\Delta S_1°$ are given. The NMR spectra of $NiR_2(bpy)$ in aromatic solvents show the aromatic induced solvent shifts, and the chemical shifts of CH_2 and CH_3 of $Ni(C_2H_5)_2(bpy)$ coincide at 76 °C in benzene to give a sharp singlet peak. The ^{13}C-NMR spectrum of $Ni(C_2H_5)_2(bpy)$ in benzene shows a triplet at 10.63 ppm (CH_2, $J(^{13}C–H)=132$ Hz) and a quartet at 15.97 ppm (CH_3, $J(^{13}C–H)=128$ Hz). The formation constant of $Ni(C_2H_5)_2(bpy)$(olefin), K_2, and the thermodynamic parameters, $\Delta F_2°$, $\Delta H_2°$, and $\Delta S_2°$ have been obtained from the temperature dependence of the NMR spectra of the $Ni(C_2H_5)(bpy)$–olefin systems. The values of the chemical shift differences between CH_2 and CH_3 ($\Delta=\delta_{CH_2}-\delta_{CH_3}$) for $Ni(C_2H_5)_2(bpy)$, $Ni(C_2H_5)_2$-(bpy)(acrylaldehyde), and $Ni(C_2H_5)_2(bpy)$(acrylonitrile) are −0.30, 0.94 and 0.83, respectively. The increase of the values of Δ by the coordination of the electronegative olefins with nickel is regarded as indicating the increase of the electronegativity of nickel due to the back-donation from nickel to the olefin.

Variable temperature NMR study provides a powerful means for clarifying the behavior of various important compounds in solution and extensive NMR studies have been made on the behavior of non-transition metal alkyls.[2] Alkyltransition metal compounds, on the other hand, have received much less attention, and very few systematic NMR studies have been made[3] despite their significance as models for active species in various catalytic reactions such as olefin hydrogenation, isomerization, hydroformylation and polymerization.[4,5] This is mainly due to the lack of suitable diamagnetic alkyltransition metal compounds which are stable enough to allow the NMR study. Dialkyl(2,2'-bipyridine)nickel(II)[6] is suitable for detailed NMR study because of the following advantages. (1) It is thermally stable in the range from −80 to 80 °C, having sufficient solubilities in various organic solvents. (2) A series of alkyl homologs can be readily prepared which allow the study of the effect of chemical environment on each nickel alkyl. (3) It interacts with olefins to form olefin-coordinated complexes, and the effect of olefin coordination on the nature of the alkylnickel complex can be investigated. The study of the interaction of an alkyltransition metal complex with olefins is particularly important in understanding the mechanism of activation of transition metal-to-carbon bond by coordination of olefin since it constitutes a key elementary step in catalytic reactions involving olefins.[5]

Experimental

$NiR_2(bpy)$ was prepared as reported in previous papers.[6] Deuterated solvents were used as purchased from Merck and Co., Inc. Acrylonitrile and acrylaldehyde were dehydrated and purified by distillation. The solvent, olefin, and tetramethylsilane were added to an NMR tube containing NiR_2-(bpy) by a trap-to-trap distillation in a vacuum, and the NMR tube was sealed. The ^{1}H-NMR spectra were obtained with a Japan Electron Optics Laboratory PS-100 spectrometer or a Varian HR-220 spectrometer. The ^{13}C-NMR spectra were obtained with the Japan Electron Optics Laboratory PS-100 spectrometer in the pulsed Fourier transform mode at 25.15 MHz. Chemical shifts are referred to internal TMS both in ^{1}H-NMR and ^{13}C-NMR.

Results and Discussion

NMR Spectra of $NiR_2(bpy)$ in Various Solvents. NMR Spectra of $Ni(C_2H_5)_2(bpy)$ 1 at Various Temperatures: The NMR spectrum of $Ni(C_2H_5)_2(bpy)$ **1** shows a triplet (at lower field) and a quartet (at higher field) of an

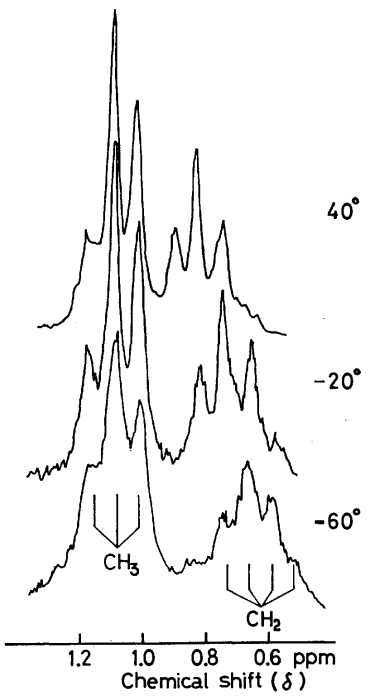

Fig. 1. 100 MHz ^{1}H-NMR spectra of C_2H_5 of $Ni(C_2H_5)_2(bpy)$ in acetone-d_6 at various temperatures.

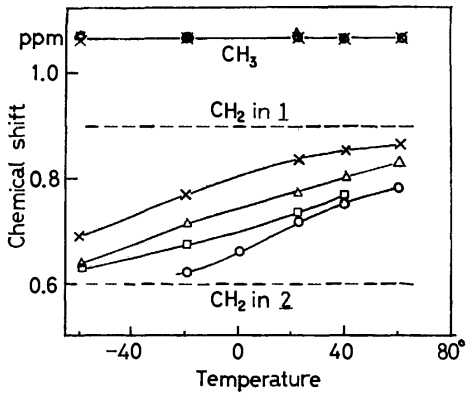

Fig. 2. Temperature dependence of the chemical shifts of CH_2 and CH_3 signals in tetrahydrofuran-d_8 (×), in acetone-d_6(△), in dimethylformamide-d_7(□), and in acetonitrile-d_3(○). Broken lines show the chemical shifts of CH_2 in **1** and **2** (see the text).

area ratio of 3: 2, which were assigned to methyl and methylene protons.[6b]

When a non-aromatic solvent is employed, only the chemical shifts of the methylene protons of the ethyl group varies with temperature in the ethyl region, the chemical shift of methyl protons being essentially temperature independent (Fig. 1). The change of the chemical shifts of CH_3 and CH_2 signals with temperature is shown in Fig. 2.

It is seen that the chemical shift of CH_2 approaches limiting values on cooling and heating. The temperature dependence of the chemical shift of the methylene protons may be accounted for on the basis of the formation of a 1: 1 solvent-solute complex (Eq. 1).[6c,7]

$$\underset{\mathbf{1}}{Ni(C_2H_5)_2(bpy)} + \text{solvent} \overset{K_1}{\rightleftarrows} \underset{\mathbf{2}}{Ni(C_2H_5)_2(bpy)(solvent)} \quad (1)$$

$$K_1 = \frac{[\mathbf{2}]}{[\mathbf{1}][\text{solvent}]} \quad (2)$$

The coordination of solvent with the four coordinate nickel to form a five coordinate nickel compound **2** will cause a change of magnetic character of nickel, which affects the chemical shift of the CH_2 protons. Since the chemical shift of the CH_2 protons in three different solvents (acetonitrile, *N,N*-dimethylformamide, and acetone) approaches the same value (0.60 ppm from TMS) on cooling, we assume that the chemical shift of the CH_2 protons in the solvated species is virtually independent of the solvent coordinated. On heating, **1** becomes predominant and the chemical shift of CH_2 protons approaches 0.90 ppm.

When one assumes a rapid exchange between **1** and **2** in solutions, the ratio [**2**]/[**1**] can be calculated from the chemical shift of $CH_2(\delta)$, which is a weighted mean of the chemical shifts of CH_2 of **1** and **2**, as $(0.90-\delta)/(\delta-0.60)$.

Table 1. Values of $[Ni(C_2H_5)_2(bpy)(solvent)]/[Ni(C_2H_5)_2(bpy)]$

(°C)	Acetonitrile	*N,N*-Dimethylformamide	Acetone	Tetrahydrofuran
−60				3.0
−20		3.0	1.60	0.82
0	4.0			
22	1.5	1.2	0.77	0.28
40	1.0	0.82	0.50	0.20
60	0.67			0.14

Table 1 gives the values of [**2**]/[**1**] at various temperatures.

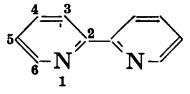
The value of [**2**]/[**1**] at certain temperatures decreases in the order acetonitrile>*N,N*-dimethylformamide>acetone>tetrahydrofuran. The order agrees with the decreasing order of coordination ability of solvent to **1** estimated with visible spectra.[6c]

The plot of the value of [**2**]/[**1**] against $1/T$ gives a straight line. The equilibrium constant K_1 for the solvation of **1** and thermodynamic data are summarized in Table 2. The reproducibility of the curves in Fig. 2 is good.

Table 2 indicates that the enthalpy changes favor the formation of the solvent coordinated species but are compensated by the large negative entropy changes.

The signals of 2,2'-bipyridine protons of diethyl(2,2'-bipyridine)nickel appear in the range 7.5—9.0 ppm in the non-aromatic solvents. On cooling and heating diethyl(2,2'-bipyridine)nickel in the solutions, the chemical shift of each 2,2'-bipyridine proton also approaches a limiting value as in the case of the chemical shift of the methylene protons.

The chemical shifts of the 2,2'-bipyridine protons of **1** and **2**, as numbered below, were estimated from the limiting values and are listed in Table 3.



The ethyl signals of the ethyl nickel complex in aromatic solvents (benzene and toluene) show a large downfield shift presumably due to the aromatic induced solvent shift (AISS).[7,9] In contrast to the temperature

Table 2. Equilibrium constant K_1 at 22°C and thermodynamic data for the coordination of solvent with $Ni(C_2H_5)_2(bpy)$

Solvent[a]	K_1[b] (l/mol)	$\Delta F_1°$ (kcal/mol)	$\Delta H_1°$ (kcal/mol)	$\Delta S_1°$ (e.u.)
Acetonitrile	8.0×10^{-2}	1.5	−4.3	−20
N,N-Dimethylformamide	9.1×10^{-2}	1.4	−3.7	−17
Acetone	5.9×10^{-2}	1.7	−3.1	−16
Tetrahydrofuran	2.3×10^{-2}	2.2	−3.7	−20

a) Protons of solvents are deuterated. b) The value of [**2**]/[**1**] is divided by the molarity of the neat solvent.

Table 3. Chemical shifts of 2,2′-bipyridine protons of **1** and **2** in non-aromatic solvents (acetonitrile, *N,N*-dimethylformamide, acetone, and tetrahydrofuran)[a)]

Compound	3-H and 4-H[b)]	5-H	6-H
1	8.0±0.1m	7.5t	9.0d
2	8.4±0.1m	7.8t	8.9d

a) In ppm from TMS (downfield positive). The assignment of the 2,2′-bipyridine protons in 1,2-dimethoxyethane has been given elsewhere;[8)] d: double, t: triplet, m: multiplet.
b) Signals of 3-H and 4-H were not separated from each other at 100 MHz.

independence of the chemical shift of CH_3 protons in non-aromatic solvents, both chemical shifts of CH_2 and CH_3 protons are temperature dependent in aromatic solvents. The chemical shifts of CH_2 and CH_3 in toluene at various temperatures are given in Table 4.

Table 4. Chemical shift of CH_2 and CH_3 signals in toluene[a)]

Temp. (°C)	CH_2	CH_3
−60	1.66	1.94
−20	1.60	1.87
20	1.57	1.65
40	1.60[b)]	
60	1.52[b)]	

a) In ppm from TMS (downfield positive).
b) CH_2 and CH_3 signals overlap with each other.

In benzene-d_6 the CH_2 and CH_3 signals are resolved at 20 °C or below (Fig. 3), although at 40 °C or above they overlap each other even at 220 MHz. At 40 °C and 59 °C the ^{1}H-NMR spectra of the ethyl region show an A_2B_3 pattern where the chemical shift difference between A and B is comparable to the coupling constant between A and B (Figs. 3b, 3c).[10,11)] At 76 °C in benzene the chemical shifts of CH_2 and CH_3 coincide to give a sharp singlet peak (Fig. 3d). Further increase

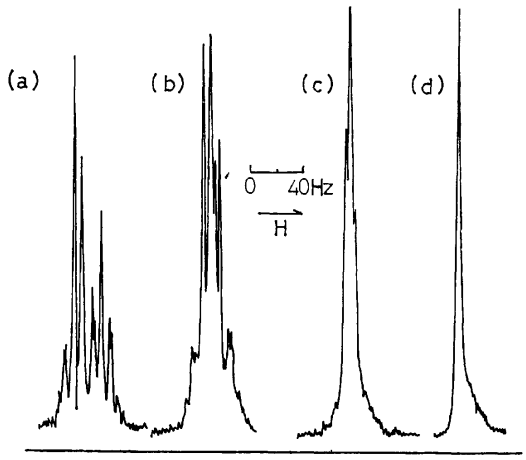


Fig. 3. NMR spectra of the ethyl protons of Ni-$(C_2H_5)_2$(bpy) in benzene-d_6 at 220 MHz. (a) 20 °C, (b) 40 °C, (c) 59 °C, and (d) 76 °C.

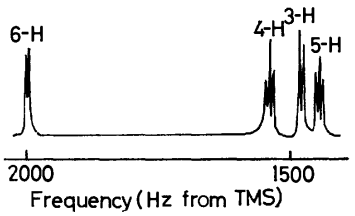

Fig. 4. NMR spectrum of bipyridine protons of Ni-$(C_2H_5)_2$(bpy) in benzene-d_6 at 220 MHz (at 20 °C).

in the temperature led to the decomposition of the ethyl nickel complex.

Signals of 3-H and 4-H of 2,2′-bipyridine, which overlap each other in the non-aromatic solvent, separate in the aromatic solvents (Fig. 4). The enhancements of higher field portions of the 6-H doublet and 4-H triplet and lower field portion of the 3-H doublet and 5-H triplet are consistent with the coupling between 5-H and 6-H, 3-H and 4-H, and 4-H and 5-H.

The ^{1}H-NMR spectrum of $Ni(C_2H_5)_2$(bpy) in pyridine or styrene is essentially the same as that in benzene or toluene, suggesting a coordination of pyridine and styrene with nickel through the aromatic π-ring. However, in contrast to the considerable stability of **1** even in boiling benzene,[6a)] standing of the pyridine or styrene solution at room temperature for some time (30 min or more) caused a scission of Ni–C_2H_5 bonds to form butane.[6c)]

Table 5. ^{13}C-NMR spectrum of $Ni(C_2H_5)_2$(bpy) in benzene at 68 °C (25.15 MHz)

Chemical shift (ppm from TMS)	$J(^{13}C-H)$ (Hz)	Assignment
10.63	132	CH_2
15.97	128	CH_3
120.3∼147.6		2,2′-bipyridine carbons

Although CH_2 and CH_3 signals of **1** in aromatic solvents overlap each other in ^{1}H-NMR at 40 °C or above, the ^{13}C-NMR at 68 °C in benzene gave well separated CH_2 and CH_3 signals at 10.63 and 15.97 ppm from TMS, respectively. The good separation of CH_2 and CH_3 signals in ^{13}C-NMR is considered to be due to a difference of anisotropic character between CH_2 and CH_3 positions to which the ^{13}C-NMR is more sensitive than ^{1}H-NMR.[12)] The ^{13}C-NMR spectroscopic data are listed in Table 5. The magnitude of $J(^{13}C-H)$ indicates that the electronic configuration of carbon is essentially sp^3 both in CH_2 and CH_3 groups of the ethyl nickel complex suggesting a covalent bond between Ni and C_2H_5 rather than an ionic bond.

$Ni(CH_3)_2$(bpy) and $Ni(C_3H_7)_2$(bpy). The ^{1}H-NMR spectrum of $Ni(CH_3)_2$(bpy) in non-aromatic solvent at 100 MHz showed a singlet at δ 0.10 ppm for CH_3, a multiplet at 8.18 ppm for 3-H and 4-H protons of 2,2′-bipyridine, a triplet at 7.62 ppm for 5-H, and a doublet at 8.96 ppm for 6-H. The ^{1}H-NMR spectrum of $Ni(CH_3)_2$(bpy) in aromatic solvents showed the aromatic induced solvent shifts. The NMR spectroscopic data for $Ni(CH_3)_2$(bpy) both in non-aromatic and aromatic solvents are listed in Table 6 together with those for $Ni(C_3H_7)_2$(bpy).

TABLE 6. ^{1}H-NMR SPECTRA OF $Ni(CH_3)_2(bpy)$ AND $Ni(C_3H_7)_2(bpy)$ AT 24 °C (100 MHz, ppm from TMS)[a]

$Ni(CH_3)_2(bpy)$	CH_3	2,2'-bipyridine			
		3-H	4-H	5-H	6-H
In acetone-d_6	−0.10 s	8.18m[b]		7.62t	8.96 d
In toluene-d_8	0.74 s	6.81 d	8.52t	6.60t	9.00 d

$Ni(C_3H_7)_2(bpy)$	α-CH_2	CH_3	β-CH_2	2,2'-bipyridine			
				3-H	4-H	5-H	6-H
In *N,N*-dimethylformamide-d_7	0.8t	1.05t	1.52m	8.27m[b]		7.71t	8.99 d
In benzene-d_6	1.7∼1.8m[b]		2.23m	6.78 d	7.07t	6.65t	9.16 d

a) s=singlet, d=doublet, t=triplet, m=multiplet. b) Unresolved.

^{1}H-NMR spectrum of $Ni(C_3H_7)_2(bpy)$ showed signals of β-methylene at the lowest field amongst the signals of the propyl group similar to the NMR spectrum of $Al(C_3H_7)_3$. No signals assignable to $Ni(i\text{-}C_3H_7)_2(bpy)$, which might be formed through a thermal isomerization of $Ni(C_3H_7)_2(bpy)$, were observed in the NMR spectrum. Chemical shift of each signal of $Ni(CH_3)_2$-(bpy) and $Ni(C_3H_7)_2(bpy)$ showed temperature dependence which may be accounted for on the basis of the solvation of the methyl and propyl nickel complexes as in the case of the ethyl nickel complex.

$Ni(C_2H_5)_2(bpy)$–Olefin System. On addition of olefins (acrylonitrile and acrylaldehyde) to the deep green tetrahydrofuran solution of $Ni(C_2H_5)_2(bpy)$ at

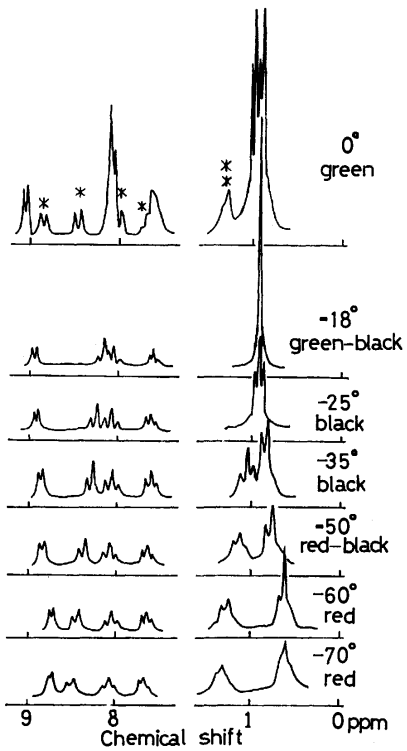

Fig. 5. Temperature dependence of the NMR spectrum of the **1**–acrylonitrile system in tetrahydrofuran-d_8. [acrylonitrile]=1.4 mol/l. [**1**]+[**3**]=0.2 mol/l. At 0 °C the partial scission of the Ni–C_2H_5 bonds takes place to give Ni(bpy)(acrylonitrile) and C_4H_{10}. The signals with * and ‡ show bpy signals of Ni(bpy)(acrylonitrile) and CH_2 signals of butane evolved, respectively.

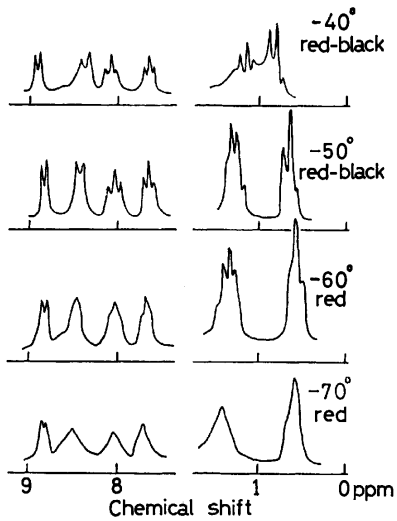

Fig. 6. Temperature dependence of the NMR spectrum of the **1**–acrylaldehyde system in tetrahydrofuran-d_8. [acrylaldehyde]=2.3 mol/l. [**1**]+[**3**]=0.2 mol/l.

−70 °C the color of the solution turned deep red, the NMR spectrum of the **1**–olefin system showing the CH_3 signals of C_2H_5 at higher field than CH_2 signals in contrast to the NMR spectrum of **1** in tetrahydrofuran without olefin. On warming the solution, the coloration turned from deep red to deep green *via* black, the chemical shift of CH_2 and CH_3 signals changing with the coloration (Figs. 5 and 6).

Dialkyl(2,2'-bipyridine)nickel (deep green) forms complexes of the type $NiR_2(bpy)(olefin)$ (deep red) with acrylonitrile and acrylaldehyde at low temperatures.[1,6c] By a visual method based on the change of the color from deep red to deep green on warming the NiR_2-(bpy)–olefin system, the equilibrium constant expressed by Eq. (4) was estimated.[1]

$$\underset{\mathbf{1}}{NiR_2(bpy)} + \text{olefin} \rightleftarrows \underset{\mathbf{3}}{NiR_2(bpy)(olefin)} \qquad (3)$$

$$K_2 = \frac{[NiR_2(bpy)(olefin)]}{[NiR_2(bpy)][olefin]} \qquad (4)$$

From the change of the NMR spectrum of the **1**–olefin system at various temperatures we can estimate the equilibrium constants more accurately than with the visual method. Corresponding to the color change, the NMR spectrum of the **1**–olefin system varies with temperature and the variation of the chemical shifts can

Table 7. Values of [3]/[1] and K_2 calculated from the data in Fig. 7[a)]

[Acryonitrile]=6.5 mol/l				[Acrylonitrile]=1.4 mol/l			
Temp. (°C)	(ppm)	[3]/[1]	K_2 (l/mol)	Temp. (°C)	(ppm)	[3]/[1]	K_2 (l/mol)
−50	0.51	14	2.2	−70	0.52	11	7.9
−40	0.53	9.0	1.4	−60	0.54	7.6	5.4
−30	0.57	5.0	0.77	−50	0.60	3.6	2.6
−20	0.63	2.8	0.43	−42	0.72	1.4	1.0
−10	0.69	1.7	0.26	−35	0.77	1.0	0.72
				−18	0.50	0.4	0.29

a) Solvent=tetrahydrofuran-d_8

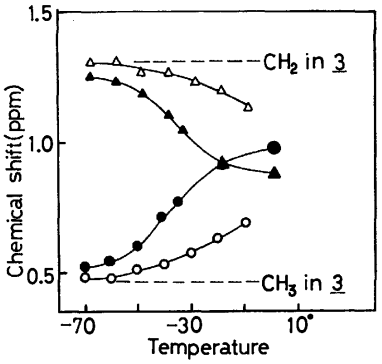

Fig. 7. Chemical shifts of CH_2 and CH_3 protons of the **1**–acrylonitrile systems in tetrahydrofuran-d_8 at various temperatures. ○CH_3 and △CH_2 for [acrylonitrile]=6.5 mol/l, ●CH_3 and ▲CH_2 for [acrylonitrile]=1.4 mol/l.

be explained in terms of a 1 : 1 adduct (**3**) formation and its rapid exchange with the uncoordinated ethylnickel complex **1**. At lower temperatures the olefin-coordinated complex **3** is predominant and the chemical shifts of the CH_3 and CH_2 protons approach the limiting values 0.47 and 1.3 ppm, respectively, corresponding to $Ni(C_2H_5)_2(bpy)$(acrylonitrile) as shown in Fig. 7. On warming the solution, the CH_3 signals shift to lower field and the CH_2 signals to higher field. The extent of the shifts depends on the concentration of acrylonitrile in the solution. In a system containing a lower concentration of acrylonitrile (1.4 mol/l in Fig. 7), the crossing of two signals was observed and the CH_3 and CH_2 protons appeared as a sharp singlet at −18 °C with identical chemical shift values for the CH_3 and CH_2 protons. The CH_3 and CH_2 signals separate again with the CH_3 signals at a lower field than the CH_2 signals by raising the temperature to 0 °C. Further increase of the temperature caused the decomposition of the ethylnickel complex. The decomposition set in at a lower temperature when a higher concentration of acrylonitrile was employed.

From the temperature dependence of the chemical shifts of CH_2 and CH_3 one can calculate the ratio of the concentration of **3** to that of **1**. The ratio [3]/[1] is calculated from the chemical shift of $CH_3(\delta_{CH_3})$ of the **1**–olefin system at the temperature as

$$\frac{[3]}{[1]} = \frac{\delta_{CH_3}(\text{in } 1) - \delta_{CH_3}}{\delta_{CH_3} - \delta_{CH_3}(\text{in } 3)} = \frac{1.07 - \delta_{CH_3}}{\delta_{CH_3} - 0.47} \quad (5)$$

In the equation 1.07 and 0.47 are the limiting chemical shifts of the CH_3 protons in the uncoordinated and fully coordinated ethylnickel complexes **1** and **3**.

The values of [3]/[1] for **1**–acrylonitrile system at various temperatures as well as the equilibrium constant expressed by Eq. (4) are given in Table 7.

The plot of log K_2 against $1/T$ gives a straight line (Fig. 8).

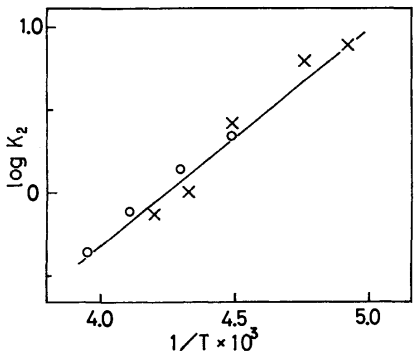

Fig. 8. log K_2 *vs.* $1/T$ for the coordination of acrylonitrile with **1**. ○ for [acrylonitrile]=6.5 mol/l, ● for [acrylonitrile]=1.4 mol/l.

The temperature dependence of the 2,2'-bipyridine signals of the **1**–acrylonitrile system is also accounted for by assuming the equilibrium expressed by Eq. (3).

The 2,2'-bipyridine signals observed at −70 °C can be assigned to those of **3**. On warming, the chemical shift of each 2,2'-bipyridine signal approaches that of **1** (Table 3).

A similar temperature variation of ^{1}H-NMR spectrum to that for the **1**–acrylonitrile system was observed for **1**–acrylaldehyde system. The stability constants of the complexes of the type $Ni(C_2H_5)_2(bpy)$(olefin) and the thermodynamic data for the coordination of olefin with **1** are given in Table 8.

Table 8. Stability constant of $Ni(C_2H_5)_2$-(bpy)(olefin) K_2 at −50 °C and thermodynamic data

Olefin	log K_2	$\Delta F_2°$ kcal/mol	$\Delta H_2°$ kcal/mol	$\Delta S_2°$ e.u.
Acrylonitrile	0.38	−0.4	−6.4	−27
Acrylaldehyde	0.080	−0.1	−7.4	−31

The enthalpy changes for the coordination of olefin are fairly large as compared with those of solvents (*cf.* Table 2).

In the case of **1**–acrylaldehyde system both ethyl and

2,2'-bipyridine signals showed a broadening at low temperatures (−50——70 °C).

Since the signals of solvent impurities (tetrahydrofuran-d_7's) and TMS did not show any broadening at low temperatures, the broadening of the ethyl and 2,2'-bipyridine signals is not considered to be due to the increase of viscosity of the solution but to the decrease of the exchange rate between **1** and **3** at the low temperatures. At −40 °C or above, both the ethyl and 2,2'-bipyridine signals are sharp and the half widths of the signals are constant.

Approximate rates of the coordination and dissociation of olefin and, consequently, the rate constants k_1 and k_{-1} in the following equation have been calculated from the half widths of C_2H_5 and 2,2'-bipyridine signals.[13]

$$\underset{\mathbf{1}}{Ni(C_2H_5)_2(bpy)} + \text{acrylaldehyde} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{\mathbf{3}}{Ni(C_2H_5)_2(bpy)(\text{acrylaldehyde})} \quad (6)$$

The values of k_1 and k_{-1} are *ca.* 1×10^3 l/mol·s and 1×10^3 s^{-1} at −60 °C respectively.

Electronegativities of Nickel in 1 and 3. As for the NMR spectrum of an ethyl group bonded with various atoms Narasimhan and Rogers[14] proposed the straight-line correlation

$$\chi = 0.62\Delta + 2.07 \quad (7)$$

where χ is the electronegativity of M for M–C_2H_5 compounds and Δ is the chemical shift difference between the CH_2 and CH_3 singals ($\Delta = \delta_{CH_2} - \delta_{CH_3}$).

When Eq. (7) is applied to the present nickel complexes, the electronegativities of the nickel in **1**, $Ni(C_2H_5)_2$(bpy)(acrylonitrile), $Ni(C_2H_5)_2$(bpy)(acrylaldehyde) are 1.89, 2.58, and 2.65, respectively (Table 9).

Table 9. Electronegativity of nickel in complexes calculated according to Eq. (7)

Complex	Δ	χ
$Ni(C_2H_5)_2$(bpy)	−0.30	1.89
$Ni(C_2H_5)_2$(bpy)(acrylonitrile)	0.83	2.58
$Ni(C_2H_5)_2$(bpy)(acrylaldehyde)	0.94	2.65

The electronegativity of nickel in **1** is close to Pauling's electronegativity of nickel ($\chi = 1.7$).[6b] When an olefin is coordinated with **1**, the electronegativity of nickel markedly increases almost to the value of carbon ($\chi =$ 2.5—2.6); the chemical shifts of CH_3 and CH_2 of **3** are close to those of butane. The increase of the electronegativity of nickel by the coordination of olefin can be interpreted as due to the back-donation of electron from nickel to the olefin. The result is consistent with the lowering of the highest occupied energy level of nickel by coordination of olefin with **1** as observed in the strong blue shift of a charge-transfer band (Ni→bpy).[1,6c]

The coordination of olefin with **1** makes a homolytic scission of Ni–C_2H_5 bond much easier by a factor of 10^{11} at room temperature than without the coordination of olefin.[15] Since the nickel-carbon bond of **1** is considered to be polarized as $Ni^{\delta+}$—$C^{\delta-}$, the homolytic scission of the nickel-carbon bond in **1**, leading to liberation of an electrically neutral molecule butane, seems to require the migration of electron from carbon to nickel.[16] The scission of the Ni–C bond in **3**, however, may require only a minor migration of electron because of minor polarization of the Ni–C bond as judged from the small difference in electronegativity between Ni and C in **3**. This may account for the easier scission of Ni–C bond by the coordination of olefin.

The authors are grateful to Prof. I. Morishima, Kyoto University, and Mr. K. Kosaka, Japan Electron Optics Laboratory Co. Ltd. for measurements of the 220 MHz ^{1}H- and ^{13}C-NMR spectra, respectively. The authors express appreciation to Professor R. Chujo of our Institute for his helpful discussion on the ^{1}H-NMR spectra of **1** in solutions.

15) The first-order rate constant k for the thermolysis of **1** obtained at high temperature (97—113 °C), $\mathbf{1} \xrightarrow{k} Ni(bpy) + C_4H_{10}$, is extrapolated to 20 °C to give a value of *ca.* 1×10^{-11} s^{-1}.[6c] The stability constant K_2 at 20 °C for $Ni(C_2H_5)_2(bpy)$-(acrylaldehyde) is estimated from the thermodynamic data (Table 8) to be *ca.* 1×10^{-2} l/mol, while the rate constant k_2K_2 for the reaction, $\mathbf{1}$ + acrolein $\overset{K_2}{\rightleftharpoons} \mathbf{3} \overset{k_2}{\rightarrow}$ Ni(bpy)(acrylaldehyde) + butane, is *ca.* 1×10^{-2} l/mol·s at 20 °C,[6c] which gives the value of k_2, the rate constant for the splitting of $Ni-C_2H_5$ bond in $Ni(C_2H_5)_2(bpy)$(acrylaldehyde), 1×10^0 s^{-1}. Therefore we obtain the value of 1×10^{11} for the ratio of k_2 to k.

16) The migration of electron was represented as a promotion of electron from σ_{Ni-C} orbital to the lowest vacant orbital of nickel.[6c]

The Electronic Spectra of α,ω-Di-1-anthrylpolyenes in Solution and in Solid State

Krishnagopal MANDAL and T. N. MISRA

Department of Physics, North Bengal University, Darjeeling, Pin-734430, India

(Received January 6, 1975)

The electronic absorption spectra of a number of α,ω-Di-1-anthrylpolyenes have been studied in solution and in crystals. Three intense and two weak band systems have been observed. The plots of λ^2-n and $\varepsilon-n$ result in a good straight line in lower members. These results suggest that long anthrylpolyenes are not in *all-trans* form. Highest energy emission and lowest energy absorption bands show good overlap and identical solvent behavior. It has been concluded that in anthrylpolyenes the lowest excited state is an allowed ^1B_u type. The terminal anthryl-group interaction effect is such that ^1A_g is not lowered relative to ^1B_u in these polyenes. The absorption bands of anthrylpolyenes in the crystalline state could be explained in terms of factor group split components.

A systematic investigation of spectroscopic properties of conjugated polyenes in different states has been undertaken in this laboratory. It has already been established[1-4] in many linear polyenes with the general structure $R_1-(CH=CH)_n-R_2$ that there exists a low energy excited state below the strongly allowed electronic transition previously observed and that fluorescence of polyenes originates from this state. Here R_1 and R_2 are the end groups. The ground electronic state of these polyenes is ^1A_g and the excited states in increasing energy order are ^1B_u, ^1A_g, ^1A_g, ^1B_u according to the Pariser-Parr-Pople (PPP) method.[5] The ordering of the excited electronic states is altered when double-excited configuration interaction is included.[2] One of the two excited states (^1A_g) is significantly lowered in energy and the ordering of the excited electronic states changes to ^1A_g, ^1B_u, ^1A_g, ^1B_u in butadiene.[2] The high energy ^1B_u and ^1A_g state energies are altered less by inclusion of double-excited configuration, although in hexatriene and octatetraene the higher ^1B_u appears below the highest ^1A_g state.[2] The effect of the end groups on the electronic states of these molecules is well known.[6-9] The first intense transition $^1A_g \rightarrow {}^1B_u$ is at longer wavelength for the end group C_6H_5 than for the end group H or CH_3 when the polyene has the same number (n) of double bonds. In order to study the effect of the terminal groups on the electronic excitation of polyacetylene chromophore, it was thought worthwhile to extend the investigation to other polyenes terminated with aromatic groups. The present paper deals with the results of our investigation on the electronic absorption spectra of a number of anthrylpolyenes in solution and also in the solid state.

Experimental

Highly pure, synthetic α,ω-di-1-anthrylpolyene was obtained from Prof. Nakagawa, Osaka University, Japan as a gift. It was used without further purification. Solvent tetrahydrofuran (THF) used was of spectrograde quality. The electronic absorption spectra were measured at room temperature using a well-matched pair of 1-cm cells with a Spektromom-202 spectrophotometer of Hungarian Optical Works. The electronic spectra in the solid state were obtained in the same spectrophotometer by making a thin crystal film on the quartz plate by gently rubbing the polyene powder. The thickness of the film has been estimated from the absorption spectrum of the solid film. An absorption band unsplit in the crystalline state and its molar extinction coefficient in the solution spectrum have been taken to estimate the thickness. Six α,ω-di-1-anthrylpolyenes of type $R-(CH=CH)_n-R$, which is abbreviated as I_n, have been studied. Here R stands for the anthryl group and $n=1$—6.

spectra of di-1-anthrylpolyene in THF are shown in Fig. 1. Results are summarized in Table 1. The electronic absorption spectrum seems to be composed of three distinct intense electronic band systems. Two more bands are also observed for higher members. The first band system observed in the region 4000—5000 Å is very intense and structureless: its intensity increases with the increase of the number of double bonds. This band is designated as A in the diagram. The band system in the region 3200—3800 Å designated as B is of moderate intensity and shows some structures in the spectra of lower polyenes. The vibronic band represents the upper state fundamental frequency of about 1400 cm^{-1} in I_1, 1310 cm^{-1} in I_2 and 1061 cm^{-1} in I_3. The band system in the high energy region (2500 Å) is also very intense in all the polyenes. This system consists of two bands with a separation of about 200 cm^{-1} between them. These two bands (D and E) seem to belong to two different systems. Finally a weak broad band (C) in the region 2900 Å is observed in the higher members of the group. These results are in complete agreement with that reported by Takeuchi *et al.*[10]

As can be seem from Fig. 1 and Table 1, the longest wavelength maxima and second-longest wavelength maxima both undergo redshift with the increase in length of polyene chain. For linear polyenes, it has generally been accepted[11] that for the longest wavelength band

$$\lambda^2_{max} = A + Bn$$

where n is the number of conjugated double bonds, A and B are constants. This relation has been seen to hold well also for phenylpolyenes, diphenylpolyenes and triphenylpolyenes.[9] We have attempted such a plot for these anthrylpolyenes. For the longest wavelength band a reasonably good straight line is obtained for the lower polyenes only. Owing to broadness of the band, exact estimation of λ_{max} is, however, difficult. For the second band the plot of λ^2_{max} against n-values results in a straight line. These plots are shown in Fig. 2. Shift of other bands with the increase of n is negligible.

For long polyenes the transition moment for the first $^1A_g \rightarrow {}^1B_u$ transition is along the long axis of the molecule and is proportional to the length of the molecule.[12] Molecular orbital theory predicts the same.[12] The

6	1.225	0.103	0.304	1.47

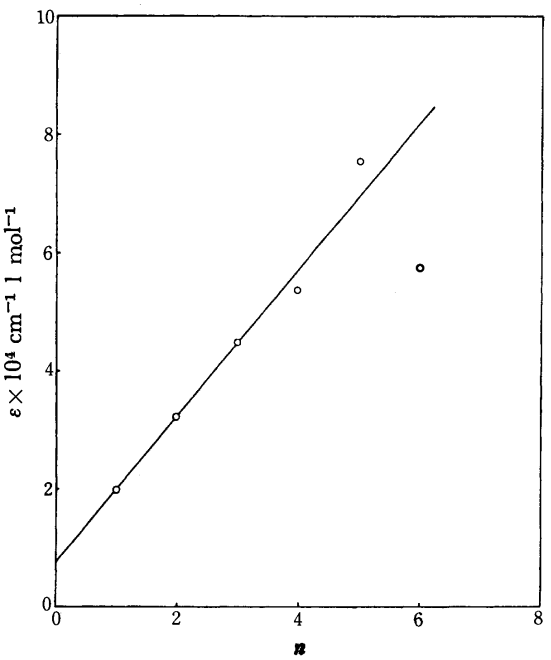

Fig. 3. Plot of ε against n for the longest wavelength maxima.

experimentally obtained oscillator strength values, as presented in Table 2, agree satisfactorily with the prediction. A plot of ε, molar extinction coefficient, *vs.* n, the number of double bonds, gives a good straight line for the first three polyenes. This linear plot (shown in Fig. 3) is also taken as a proof[9] of *all-trans* configuration of the polyene. That I_4—I_6 do not fall in the straight line proves that the higher anthrylpolyenes are not purely *trans*. Both in λ^2–n and ε–n plots, I_6 deviates significantly from the straight line and the molecule is definitely not in *trans* form. Small deviation is also observed in I_4 and I_5 and these two polyenes also do not seem to be in purely *all-trans* form. The high energy symmetry allowed band $^1A_g \rightarrow {}^1B_u$ (^{1}D in Platt's notation) is intense in *all-trans* polyenes. It has, however, generally been observed that the low energy $^1A_g \rightarrow {}^1B_u$ (^{1}B in Platt's notation) is more intense than the high energy $^1A_g \rightarrow {}^1B_u$ transition. In *all-trans* lycopene[13] the molar extinction coefficient have values 186×10^3 and 52×10^3 respectively for the two transitions. As can be seen from Table 2, in anthrylpolyenes the low energy allowed transition is less intense than the high energy allowed transition. This possibly is due to intensity "stealing" from the adjacent intense band E on the high energy side. Of the two bands D and E the lower energy one at about 2620 Å is intense in lower polyenes. As the number of double bonds increases, this band becomes weaker whereas the other at higher energy at about 2430 Å gains in intensity. This high energy band possibly arises from the interaction between ^1B_u state of *all-trans* polyene and the $^1B_{3u}$ state of the anthryl group.

The plots of λ^2 against n, ε against n and the enhancement in intensity of 2430 Å band in I_5 and I_6 perhaps indicates that the long polyenes are not in *all-trans* form. The long polyene chromophore with the large anthryl terminal group may bend the $(CH{=}CH)_n$ chain. In such *cis* form, the transition moment of the $^1A_{1g} \rightarrow {}^1B_{3u}$ transition along the long axis of the anthracene molecule makes a smaller angle with the direction of the transition moment of $^1A_g \rightarrow {}^1B_u$ of the polyene chromophore and the intensity of 2430 Å band may be enhanced in higher members. This *cis* configuration of long anthrylpolyenes is further supported by increased intensity of the *cis* peak at 3640 Å and 3740 Å at I_5 and I_6 respectively and also by the appearance of another symmetry forbidden band (as evidenced from its low intensity) at about 3100 Å and 3140 Å in I_5 and I_6 respectively.

II. Solvent Behavior. In some linear conjugated polyenes there exists a low-lying π-electronic state, transition to which is normally forbidden in *all-trans* form. Emission is observed from this low-lying state and as a result no overlap is usually observed between the intense lowest energy absorption band and the emission band of this *trans* polyene.[14] In the anthrylpolyenes we have observed two weak bands around 3500 Å (B) and 3000 Å (C). These are of forbidden nature and possibly belong to the ^1A_g states of polyene. In addition, three allowed type strong bands A, D, and E have been observed. A and D most likely are transitions to the ^1B_u state of polyene. The E band seems to be related to the $^1B_{3u}$ band of anthracene nucleus. It, therefore, appears that in these polyenes the first excited ^1A_g state is not below the ^1B_u state of polyene. Significant overlap has been observed between the absorption and emission bands in I_1. Solvent effect is a good clue as to the identity of the absorbing and emitting states. The major contribution to the solvent shift of the strong transition can be written in the form[3,15]

$$\bar{\nu} - \bar{\nu}_{gas} = Kf_{eg}\frac{n^2-1}{n^2+2}$$

where $\bar{\nu}$ is the transition energy in cm^{-1}, K is a parameter which is constant for a given molecule, f_{eg} is the oscillator strength for a particular transition of the molecule, n is the solvent refractive index and $(n^2-1)/(n^2+2)$ is the solvent polarizability. A plot of $\bar{\nu}$ for the first absorption and the emission bands of I_1 *versus* $(n^2-1)/(n^2+2)$ is shown in Fig. 4. The slopes of the lines are the same indicating similar value for the absorption and emission oscillator strengths. This result is different from that usually observed[1,16] in linear conjugated polyenes where ^1A_g state has been established to be the lowest excited electronic state. State ordering may as well be different for polyenes with different substituents. We conclude that in α,ω-di-1-anthrylpolyenes the lowest excited state is an allowed ^1B_u type. The terminal anthryl group

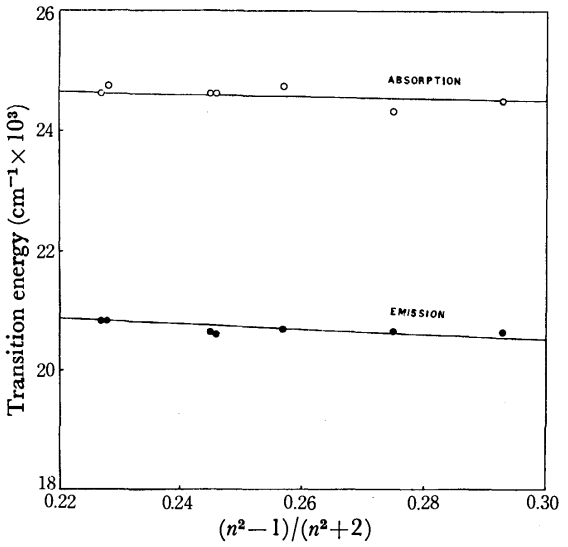

Fig. 4. The positions of the highest energy emission band and lowest energy strong absorption band of I_1 as a function of $(n^2-1)/(n^2+2)$.

interaction effect is such that the electronic state of the acetylene chromophore is lowered in energy with ^1A_g as the ground state and with ^1B_u, ^1A_g, ^1A_g, ^1B_u as the excited states in increasing energy order, the same as when only single-excitation configuration interaction is considered in PPP calculation.

III. Solid Film Spectra. The electronic absorption spectra of anthrylpolyenes in crystalline state are shown in Fig. 5. The bands are broad and there is overlapping between bands. The ordinate shows the intensity of a band relative to others in the same spectrum.

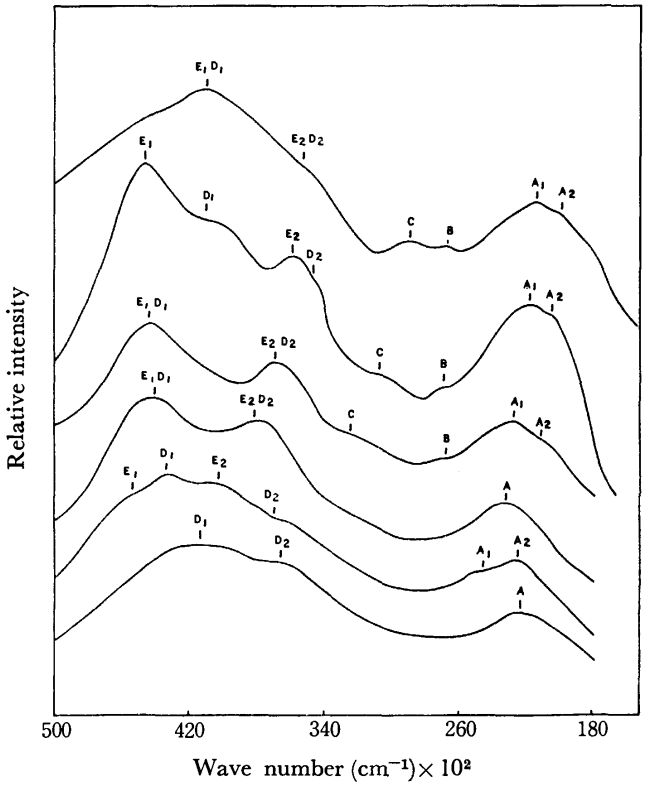

Fig. 5. Absorption spectra of di-1-anthrylpolyenes (I_n) in the solid state. The curves ($n=1-6$) have been displaced upward successively on the ordinate axis from the curve immediately below for clarity.

The band B in the region 3200—3800 Å, which is of moderate intensity in solution, seems to be absent in the lower member in the crystalline state. In the higher members, this band appears with moderate intensity. Further, the other weak band at about 3140 Å appears with moderate intensity in higher polyene crystal spectra but is absent in lower polyenes. These observations indicate that in the crystalline state also lower anthrylpolyenes remain in *all-trans* form but the higher members are in *cis* form: this is likely in view of the longer chain between the two anthryl terminal groups.

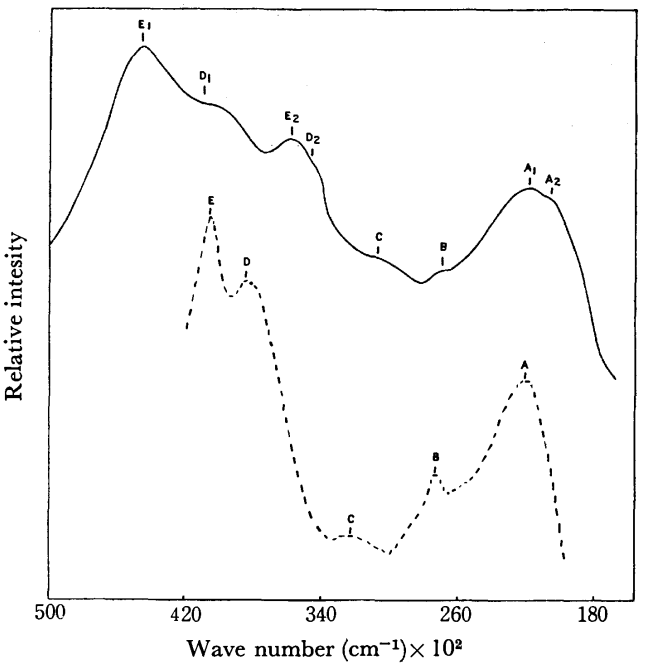

Fig. 6. Absorption spectrum of I_5.
---: Spectrum in THF solution, —: Solid film spectrum.

The crystal spectra differ from the spectra of free molecules in that in the solid state there are more number of bands than in solution and these bands are on both high and low energy sides of the intense solution bands. Some of these bands seem to be the factor group split components of the intense free molecular bands. This is better observed in the solid film spectrum of I_5 which shows structures and better resolution (Fig. 6). Solid state bands A_1 and A_2 on high and low energy sides of solution band A respectively seem to be the split components of A. Identification of weak B and C solution bands in solid film is obvious and no additional structure is observed in this region. In the region of solution bands D and E there are four distinct resolved bands in the crystal spectra. From the structures of the bands it seems that the band D is split into D_1 and D_2 and E is split into E_1 and E_2 in the solid state. Assignments of the bands in the crystal spectra of other anthrylpolyenes are less straightforward. We have, however, attempted a tentative identification of these bands in terms of solu-

tion band in other anthrylpolyenes (Fig. 5). The assignment of the factor group split components in Table 1 is only tentative and numerical values of splitting are of no significance. Study of single crystal polarized spectra at liquid N_2 or liquid He temperature is required for any inequivocal identification of factor group split components.

The authors are thankful to Prof. Nakagawa for his generous gift of anthrylpolyenes. One of the authors (K.G.M.) expressess his thanks to the University Grants Commission, India for a fellowship.

Effect of Water on the Conductance of Hydrogen Halides in Diethylene Glycol

V. SRINIVAS RAO and C. KALIDAS*

Department of Chemistry, Indian Institute of Technology, Madras, 600036, India

(Received May 2, 1975)

The effect of addition of small amounts of water on the conductance of hydrogen chloride and hydrogen bromide in diethylene glycol at 25 °C was investigated. The Λ_0 of both acids sharply decreases with the addition of water, passes through a minimum at about 1.23 wt% of water and then increases. This was explained on the basis of the changes in the proton jump mechanism due to shift of the proton transfer equilibrium, $ROH_2^+ + H_2O \rightleftarrows ROH + H_3O^+$. The role of water in this equilibrium was shown to be similar to the protonation of a Hammett indicator base in acid solutions.

Conductance studies on hydrogen halides in amphiprotic solvents, especially the monohydric alcohols and their aqueous mixtures have received[1–4] some attention in recent years. Such studies are useful[5] in elucidating the effect of solvent structure on the proton migration mechanism in these solvents. Despite this, practically no conductance measurements have been reported[6] in glycols or their aqueous mixtures. The present work, which is in continuation of our earlier work on the subject,[7,8] therefore, deals with the effect of addition of small amounts of water on the conductance of hydrogen chloride and bromide in diethylene glycol in order to elucidate the nature of solute-solvent interactions in these systems.

Experimental

BDH (LR) grade sample of diethylene glycol, purified according to the method described earlier[9] was used. The distilled sample had a bp 120 °C at 10 mmHg, $d^{25\,°C} = 1.115$ g ml^{-1}, and the specific conductivity 9.5×10^{-9} ohm^{-1} cm^{-1} at 25 °C. Conductivity water, obtained by repeatedly distilling double distilled water to which a pinch of permanganate and a trace of sodium hydroxide were added, was used. *p*-Nitroaniline, recrystallised twice from alcohol (mp = 147 °C) was employed as the indicator in H_0 measurements, details of which are given elsewhere.[10] The preparation, purification and standardization of stock HCl and HBr solutions in diethylene glycol are similar to that described[8,9] earlier. The conductance measurements were carried out with a precision conductivity bridge (Model WBR/TAV, WTW, West Germany). A logarithmic indicator amplifier with built-in 1000 Hz generator served as the balance indicator. Further details of the conductance measurements are given[6] elsewhere. All measurements were made at 25.00±0.01 °C employing high boiling liquid paraffin as bath liquid. All solutions were prepared by weight and converted to volume concentrations by appropriate density data. The physical constants of the various solvent mixtures used were identified with the pure solvent in all calculations.

Results and Discussion

The conductance data of the acids are given in Tables 1 and 2. Computer analysis of these data with the Fuoss-Onsager 1965 three parameter equation[11] revealed no significant association of the halides either in the pure solvents[8] or the mixtures. The data were hence analyzed by the Fuoss-Onsager 1965 two parameter equation[11] given by

$$\Lambda = \Lambda_0 - SC^{1/2} + 2EC\log(\tau) + LC \qquad (1)$$

where the various terms have their usual significance. The Λ_0 obtained for the acids in the various solvent mixtures are presented in Table 3. It is seen from this Table that the Λ_0 of the acids decreases continuously as the amount of water added to a solution of HCl or HBr in diethylene glycol increases gradually, passes through a minimum at about 1.23 wt% of water and then increases again with further additions of water. This variation can be qualitatively accounted for in terms of the changes in the proton jump mechanism arising due to the shift of the equilibrium

$$ROH_2^+ + H_2O \rightleftharpoons ROH + H_3O^+ \qquad (2)$$

in which the initial decrease of Λ_0 is caused by the replacement of protons of abnormal conductance (ROH_2^+) by protons of normal conductance (H_3O^+) at low concentrations of water. At higher concentrations of water, the H_3O^+ ions are increasingly surrounded by water molecules and their proton jump mechanism is restored resulting in abnormal conductance of these ions. Similar observations have been made by Goffredi *et al.* in propanol-water mixtures and Selvarajan and Kalidas[7] in ethylene glycol-water and propylene glycol-water mixtures. The equilibrium constant K, of Reaction (2) was evaluated[12] according to

$$\frac{1}{\Lambda_0^\circ-\Lambda_0} = \frac{1}{\Lambda_0^\circ-\Lambda_0^w} + \frac{1-x}{xK(\Lambda_0^\circ-\Lambda_0^w)} \qquad (3)$$

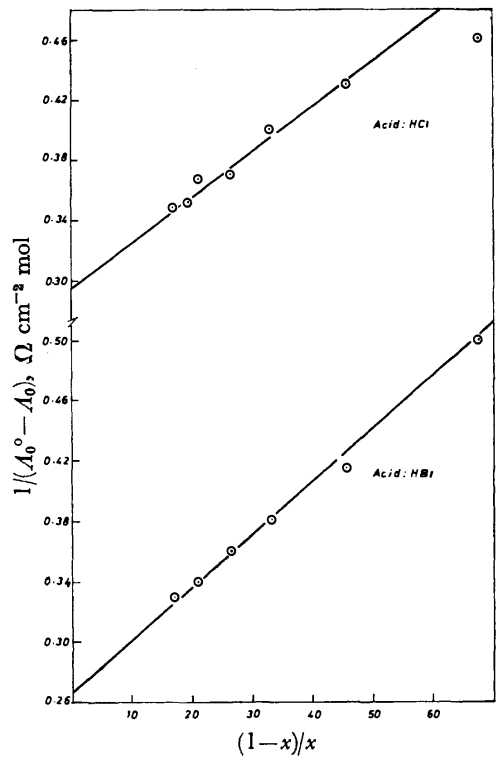

Fig. 1. Plot of $1/(\Lambda_0^\circ-\Lambda_0)$ *vs.* $(1-x)/x$ at 25 °C in diethylene glycol for HCl and HBr.

where Λ_0° represents the conductance of the hydrogen halide in diethylene glycol with the protons in the form of ROH_2^+, Λ_0^w is the (hypothetical) conductance of the same acid in the solvent with the protons in the form of H_3O^+ and Λ_0 is the conductance at a mole fraction x of water. A plot of $1/(\Lambda_0^\circ-\Lambda_0)$ *vs.* $(1-x)/x$ for the two acids is shown in Fig. 1. The average value of K obtained (from the slopes of these plots) corresponding to the least squares fitting of the best straight lines (for the two acids) is 88±12. Although it might be expected that the equilibrium constant of Reaction (2) in different alcohols is related to the basic strengths of these molecules, a comparison of the values in different alcohols shows that this is not true. This is most probably due to the structural influence of the solvent on the proton migration mechanism in amphiprotic solvents, *viz.*, through the free solvent molecules and through hydrogen bonded net works in the solvents as proposed by Goffredi *et al.*[5] It is, however, significant that the role of water in Reaction (2) can be likened to that of a Hammett indicator base in protonation equilibria according to

$$SH^+ + B \rightleftharpoons S + BH^+ \qquad (4)$$

and hence the H_0 difference between two solvents S_1 and S_2 can be related to

$$H_{0(S_2)} - H_{0(S_1)} = \log \frac{K_{(S_2)}}{K_{(S_1)}} \qquad (5)$$

where $K_{(S_2)}$ and $K_{(S_1)}$ are the equilibrium constants of Reaction (2) in the two solvents. Considering S_1 and S_2 to be diethylene glycol and propylene glycol respectively, the H_0 difference was found to be 0.22 (at 0.1 mol/kg concn) while the log ratio of equilibrium constants is 0.31 ($K_{P,G}$=43)[7] which shows the approximate

validity of Equation(5) and hence of the assumption made above.

Our thanks are due to C.S.I.R. for the award of a senior research fellowship to one of us (V.S.R.). We also express our sincere thanks to Prof. M. Goffredi, of the University of Palermo, Italy for providing us with the computer program for the analysis of the conductance data presented in this paper.

Electric Dipole Moment of 4-Chloro-2,3-tetra-, penta-, and hexamethylene Quinoline

Miss DIPTI and Pushti Prakash RASTOGI*
Department of Chemistry, University of Lucknow, Lucknow, India
(Received June 6, 1975)

Electric dipole moments of 4-chloro-2,3-tetra-, penta-, and hexamethylene quinolines[1-3] have been determined in benzene solution at a frequency of 1 MHz by Guggenheim method.[4] The reported results indicate that these compounds are non-planar and the dipole moment increases with the increase in the size of substituted methylene ring.

Recently a series of useful antidepressant and biologically active compounds like, 4-chloro-2,3-tetra-, penta- and hexamethylene quinolines have been prepared and their physical properties have been reported.[1-3] It has been found[6-8] that the dipole moment measurements of substituted quinolines and naphthalenes provide valuable information regarding the mode of interaction and the distribution of π-electrons to assign the structural configuration of these compounds. From this point of view the present series of organic compounds has been selected for the measurement of electric dipole moment and thereby to examine the influence of the size of the substituted methylene ring on the π-electron distribution of 4-chloroquinoline.

Experimental

The dielectric constant measurements were carried out at 25 °C at a radio frequency of 1 MHz with the help of a "Toshniwal" Dipole Meter type RLO9 supplied by Scientific and Industrial Instrument Co., India. The instrument works on a well known principle of heterodyne beat method. The resulting beat frequency is projected on the screen of a cathode ray tube with a 50 cycles per second. A Lissajous figure is obtained on the screen. The readings were recorded at the resonance point indicated on the CRT screen by the formation of a single loop pattern, *i.e.*, an ellipse or a circle.

Refractive indices of the solvent and solutions were determined at 25 °C with the help of "ASCO" Abbe-Refractometer (made in India). The range of this instrument is 1.3000 to 1.7000, the maximum precision attainable being 0.0002. Sodium D-line was used as a source of light and the refractometer was standardized with the help of a glass slab of known refractive index. The instrument directly gives the value of refractive index which is measured with the reading telescope.

The compounds 4-chloro-2,3-tetra-, penta-, and hexamethylene quinolines obtained from Central Drug Research Institute, Lucknow, India were recrystallized from benzene, dried and kept in a vacuum desiccator.

The dipole moment has been calculated by Guggenheim method,[4] *i.e.* by plotting** a quantity Δ against the concentration C, in moles of polar solute per cm^3 given by the relation:

$$\Delta = (\varepsilon_{12}-n_{12}^2) - (\varepsilon_1-n_1^2) \qquad (1)$$

where ε_1, n_1 and ε_{12}, n_{12} represent the dielectric constant and refractive index of pure solvent and solution respectively.

The slope $(\Delta/C)_0$ of the curve at $C=0$ is then used to calculate the dipole moment by means of the equation[9] given below:

$$\mu^2 = \frac{9kT}{4\pi N}\frac{3}{(\varepsilon_1+2)(n_1^2+2)}\left(\frac{\Delta}{C}\right)_0 \qquad (2)$$

The dipole moment, μ, has also been calculated from Eq. (2) by determining the slope (Δ/C), using the mathematical relation based on least squares method,[5] namely

$$\left(\frac{\Delta}{C}\right) = \frac{\sum\Delta\sum C - n\sum(\Delta C)}{(\sum C)^2 - n\sum(C^2)} \qquad (3)$$

where Δ and C represent their usual meaning and that n is the number of observations recorded.

In order to make an estimate of the precision of equipments (Dipole Meter & Refractometer), the dipole moments of some of the liquids like, methanol, pyridine, acetone, and nitrobenzene are determined in benzene solution and are given in Table 1 along with their reported values for the sake of comparison. The experimental and literature values are found to be within the maximum deviation of $\pm 3\%$.

TABLE 1. DIPOLE MOMENT (μ) OF METHANOL, PYRIDINE, ACETONE, AND NITROBENZENE IN BENZENE SOLUTION AT 25 °C

Results

The refractive index, n_{12}, and dielectric constant, ε_{12}, of 4-chloro-2,3-tetra-, penta-, and hexamethylene quinolines are determined in benzene solution at different concentrations at 25 °C and are recorded in Table 2. The Δ values calculated from Eq. (1) are also given in Table 2. These Δ values are plotted against C as shown in Fig. 1. The slopes (Δ/C), evaluated from these linear plots as well as from least-squares relation[5] have been used to determine dipole moment μ, by Guggenheim method.[4] The obtained (Δ/C) and μ values are summarized in Table 3.

* Visiting Scientist, Chemistry Department, University of Leicester, Leicester, England, U. K.

** The slope is directly obtained from the plot of $(\varepsilon_{12}-n_{12}^2)$ against C as the second term on the right hand side in Eq. (1) is constant.

Discussion

It may be observed from Table 3 that the dipole moments of 4-chloro-2,3-tetra-, penta-, and hexamethylene quinolines in benzene solution determined by using (Δ/C) values obtained from graphical and least squares[5] methods are found to be in an excellent agreement and are within the maximum deviation of 2%. It may also be noted that the dipole moment of these compounds increases in the increasing order of the size of substituted methylene ring, *i.e.*, μ tetra$<\mu$ penta$<\mu$ hexa as 4-chloroquinoline being the common constituent to all the above investigated polar compounds.

The geometrical structures and dipole moments[6-8] of 1-chloronaphthalene, quinoline, 4-chloroquinoline, and 4-chloro-2,3-tetra-, penta-, and hexamethylene quinolines are represented in Fig. 2 (see I, II, III, IV, V, and VI respectively).

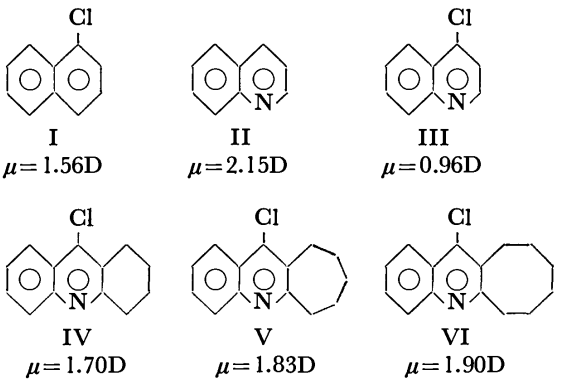

Fig. 2.

It is clear from Fig. 2 (see III) that the 4-chloroquinoline has two dipoles of similar magnitudes that of quinoline itself (2.15D) and the other associated with the C–Cl bond (1.56D). The Cl-substituent increases the electronegativity of the carbon atom to which it is attached and this consequently modifies the π-electron distribution of the quinoline ring. The p-electrons of chlorine atom interacts with the π-electrons of quinoline ring which reduced the net dipole moment of the 4-chloroquinoline (0.96D).

The dipole moments of 4-chloro-2,3-tetra-, penta-, and hexamethylene quinoline are not only in the regular increasing order but are almost twice that of 4-chloroquinoline, which establishes that the substitution of methylene ring is definitely on the different plane to that of the quinoline ring. The dipole moment of these compounds can be considered as the sum of the moments of 4-chloroquinoline and substituent methylene ring, which interact with one another thereby resulting in an increase of the net magnitude of dipole moment.

The authors are grateful to the State C. S. I. R. Lucknow for their valuable financial assistance and to Direcfor, Central Drug Research Institute, Lucknow for providing organic compounds. The thanks are also due to the Indian National Science Academy, New Delhi for their constant encouragement and appreciation.

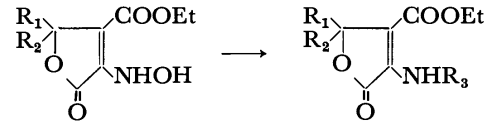
Lactone Carboxylic Acids. VIII.[1] A Synthesis of γ-Substituted α-Amino-butyrolactones from Ethyl γ-Substituted α-Hydroxyaminoaconates

Sigeru TORII,* Masasi UKIDA, Hiromichi KANO, Takuya FURUTA, and Hideo TANAKA
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700
(Received November 2, 1974)

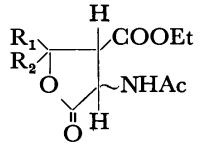
The conversion of α-hydroxyaminoaconates **1a** and **1b** to α-aminoaconates **2a** and **2c** was described, involving a novel reduction of the α-hydroxyamines on treatment with *p*-toluenesulfonyl chloridep–yridine in 62.1—89.5% yields. In the case of the reduction of **1b** *N*-tosyloxy derivative **11b** was isolated. α-Amino-γ-butyrolactones **3** and **4** could be obtained by hydrogenation of *N*-acetates of **2a** and **2c**. Ammonolysis of 2-hydroxy-2-butenolides **5a** and **7a** prepared from acid-hydrolysis of **1b** also gave α-aminobutyrolactones **6**, **8a**, **8b**, **9**, and **10**.

α-Amino-γ-butyrolactones have been used extensively for a variety of synthetic purposes,[2-8] above all in the field of antibiotics synthesis.[9] In this connection, neccessity of the α-aminobutyrolactones as a synthetic intermediate is increasing in recent years. Thus, many attempts have been made to obtain appropriate aminolactones starting from α-halogenobutyrolactone,[2] 2-hydroxy-2-butenolide,[3] α-azidobutyrolactone,[4] 2-carboxy-2-butenolide,[5] α-cyanobutyrolactone,[6] β,γ-dihydroxy-α-amino acid,[7] and others.[8] We wish to report here a convenient synthetic method of γ-substituted α-amino-γ-butyrolactones and its derivatives. The procedure involves initial reduction of ethyl γ-substituted α-hydroxyaminoaconates **1a** and **1b** on treatment with *p*-toluenesulfonyl chloride–pyridine to form the corresponding α-aminoaconates **2a** and **2c** and the subsequent hydrogenation to form α-acetylamino-γ-butyrolactones **3** and **4**.



1a $R_1=R_2=Me$
1b R_1, $R_2=-(CH_2)_5-$

2a $R_1=R_2=Me$, $R_3=H$
2b $R_1=R_2=Me$, $R_3=Ac$
2c R_1, $R_2=-(CH_2)_5-$, $R_3=H$
2d R_1, $R_2=-(CH_2)_5-$, $R_3=Ac$



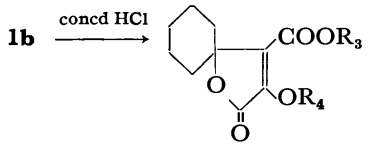
3a $R_1=R_2=Me$ (*trans*)
3b $R_1=R_2=Me$ (*cis*)
4a R_1, $R_2=-(CH_2)_5-$ (*trans*)
4b R_1, $R_2=-(CH_2)_5-$ (*cis*)

Nitrosation of β-ethoxycarbonyl-α-carboxy-γ-butyrolactones with an equimolar amount of sodium nitrite in acetic acid at −5—0 °C gave ethyl α-hydroxyaminoaconates **1a** and **1b** in excellent yields.[10] The infrared spectrum of **1b** showed characteristic bands at 3520 and 3460 cm^{-1} corresponding to NH and OH functions and a broad band at 1744 due to lactone and ester carbonyls. Reduction of **1a** and **1b** to the corresponding primary amines **2a** and **2c** were carried out on treatment with *p*-toluenesulfonyl chloride–pyridine at room temperature for 2 days to afford ethyl γ-substituted α-aminoaconates **2a** and **2c** in 62.1—89.5% yields. The infrared spectrum of **2c** exhibited two sharp bands at 3410 and 3320 cm^{-1} due to primary amine and bands at 1762 and 1692 corresponding to lactone and conjugated ester carbonyls.

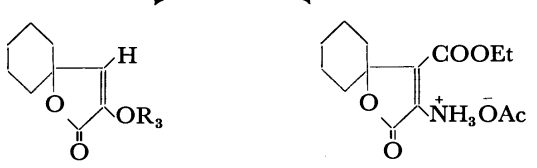
Acetylation of **2c** giving α-acetylaminoaconate **2d** and the subsequent hydrogenation in ethanol containing a small amount of acetic acid over platinum oxide at room temperature gave a mixture of the corresponding α-acetylamino-γ-butyrolactones **4a** and **4b** in quantitative yield. Separation of *cis* and *trans* isomers was accomplished by column chromatography over silica gel to afford 22.2% of **4a** and 77.5% of **4b**, respectively. In the similar manner, conversion of **2a** into the corresponding **3a** and **3b** *via* **2b** was achieved in quantitative yield.

The α-hydroxyaminoaconate **1b** underwent hydrolysis on treatment with concentrated hydrochloric acid at room temperature for 7 days to give ethyl α-hydroxyaconate **5a** as a major product together with **5c** (3.6%). Spectral evidences and the formation of **5b** from **5a** support assignment of the structure of **5a**.

The α-hydroxybutenolides **5a** and **7a** are considered to be a good precursor for α-aminolactone synthesis.[3] Thus, treatment of **5a** with ammonium acetate at 110—120 °C for 6 h afforded **6** in 81.1% yield.



5a $R_3=Et$, $R_4=H$
5b $R_3=Et$, $R_4=Me$
5c $R_3=H$, $R_4=H$
5d $R_3=Me$, $R_4=Me$

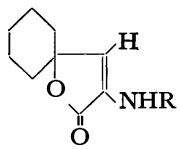


7a $R_3=H$
7b $R_3=Me$

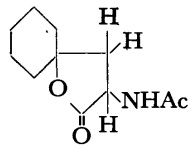
6

Acid-hydrolysis of **5a** under refluxing for 20 h afforded 2-hydroxy-2-butenolide **7a** in 79.6% yield. Ammonolysis of **7a** with 11.3 equivalents of ammonium

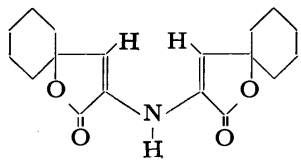
acetate at 104 °C for 30 min gave the α-aminobutenolide **8a** in 92.1% yield. However, in the ammonolysis reaction decrease of the amount of ammonium acetate to 7.6 equivalents provided the dimeric compound **10** as a minor product, whose structure was confirmed by spectral data and elemental analysis.



8a R=H
8b R=Ac



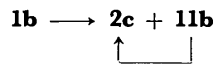
9

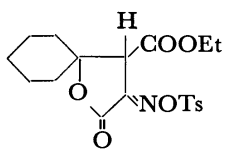


10

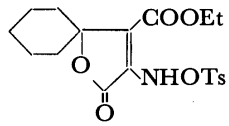
The conversion of **8a** into the α-aminobutyrolactone **9** *via* **8b** was carried out successfully. Treatment of **8a** with acetic anhydride in the presence of a catalytic amount of *p*-toluenesulfonic acid resulted in the acetate **8b** in 95.9% yield. The subsequent hydrogenation of **8b** in ethanol containing a trace of acetic acid over platinum oxide gave **9** in 95% yield.

From the reaction products of **1b** with *p*-tolenesulfonyl chloride–pyridine 7.1% of (tosyloxyamino)aconate **11b** was isolated. Similarly, when **1b** was treated with equimolar amount of butyllithium followed by treatment with *p*-toluenesulfonyl chloride, the reaction produced 26.4% of **11b** in addition to the formation of **2c** (68.7%). The conversion of the tosylate **11b** into **2c** could be carried out by stirring in pyridine at room temperature.



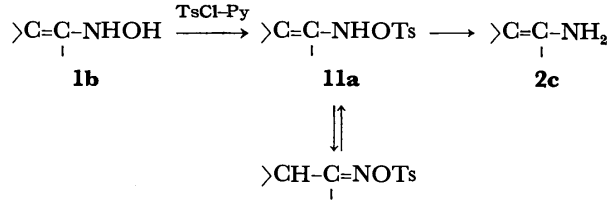


11b



11a

One possible pathway for the formation of **2c** and **11b** from **1b** may involve an unstable intermediate **11a**, a tautomer of **11b**. In the conversion of **11b** into **2c** the



1b **11a** **2c**

11b

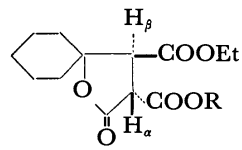
reaction may also proceed *via* the intermediate **11a**, which would provide **2c** promptly in contrast to the slow change of **11b** into **11a**.

Discrimination of *cis* and *trans* isomers of α-amino-β-ethoxycarbonylbutyrolactones **3** and **4** was accomplished by comparison with related compounds **12**,[11] **13**,[12] and **14**.[13] Aminobutyrolactones **3a** and **4a**, which were separated from hydrogenation products of **2b** and **2d** by column chromatography, have PMR coupling constants ($J_{\alpha,\beta}$) of 10.5 and 11.1 Hz respectively, indicating that structure of **3a** and **4a** should be assigned to the *trans* isomers. The butyrolactones **12** and **13**, which are considered to be thermodynamically favorable *trans* isomers, have coupling constants in the range of 10.0—13.0 Hz (Table 1).

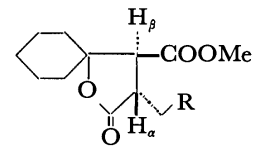
Table 1. Coupling constants between H_α and H_β of α,β-substituted butyrolactones

Compound	H_α (δ)		H_β (δ)	$J_{\alpha,\beta}$ (Hz)	
	cis	*trans*		*cis*	*trans*
3a	—	4.73	3.65	—	11.1
3b	5.29	—	3.43	7.5	—
4a	—	4.76	3.50	—	10.5
4b	5.25	—	3.46	7.5	—
12a	—	4.17	3.54	—	11.0
12b	—	3.96	3.39	—	11.5
12c	—	4.15	3.55	—	11.0
13a	—	3.47	3.04	—	12.8
13b	—	3.30	2.82	—	11.5
14	2.80	2.60[a]	3.07	7.0	11.0

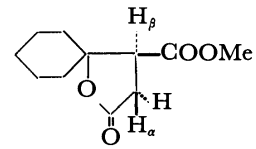
a) The coupling constant of geminal hydrogen atoms at the α position was 18.0 Hz.



12a R=H; **12b** R=Me
12c R=Et



13a R=CHO
13b R=HC=CH$_2$



14

On the other hand, the isomers **3b** and **4b** have identical coupling constant ($J_{\alpha,\beta}$: 7.5 Hz), being assigned to the *cis* isomer based on the result observed in the resemble *cis* substituted cyclopentane system[14] and on the calculation from the Karplus equation.[15]

Experimental

Melting points and boiling points are uncorrected. NMR spectra were recorded on Hitachi R-24 and/or R-20 instruments. IR spectra were determined with a Hitachi EPI-S2, with only major absorptions being cited. Wako gel C-200 silica gel was used for elution chromatography. Elemental analysis was performed by Mr. Tsutomu Okamoto of our Laboratory.

γ,γ-Pentamethylene-β-ethoxycarbonyl-α-carboxy-γ-butyrolactone (12a). Hydrolysis of γ,γ-pentamethylene-α,β-diethoxycarbonyl-γ-butyrolactone (**12c**)[11] (8.9 g, 0.03 mol) with NaOH (3.42 g, 0.09 mol) in aqueous 20% EtOH (18 ml) afforded 7.1 g (87.5%) of **12a** as a white solid: mp 130.0—131.0 °C (from water); IR (neat) 3600—2200 (COOH),

1785, 1740 cm^{-1}; NMR (CCl_4) δ 1.32 (t, J=6.8 Hz, 3H, CH_3), 1.00—2.10 (m, 10H), 3.54 (d, J=11.0 Hz, 1H, H_β), 4.17 (d, J=11.0 Hz, 1H, H_α), 4.27 (q, J=7.0 Hz, 2H, CH_2O). Treatment of the acid with diazomethane gave the corresponding methyl ester **12b**: bp 82.0—86.0 °C/1 mmHg; IR (neat) 1790, 1742 cm^{-1}; NMR ($CDCl_3$) δ 1.29 (t, J=7.0 Hz, 3H, CH_3), 1.00—2.20 (m, 10H), 3.39 (d, J=11.5 Hz, 1H, H_β), 3.76 (s, 3H, CH_3O), 3.96 (d, J=11.5 Hz, 1H, H_α), 4.16 (q, J=7.0 Hz, CH_2O). Found: C, 59.26; H, 7.18%. Calcd for $C_{14}H_{20}O_6$: C, 59.14; H, 7.09%.

*Ethyl γ,γ-Pentamethylene-α-hydroxyaminoaconate (**1b**).* To a stirred solution of **12a** (5.0 g, 18.5 mmol) in AcOH (15 ml) a solution of $NaNO_2$ (1.28 g, 18.5 mmol) in water (3.0 ml) was added dropwise for 10 min at −5—0 °C. The mixture was stirred for 40 min at 5 °C and then diluted with water. After stirring for additional 40 min at 10 °C the organic phase was extracted with ether. The extracts were washed with water, with aqueous $NaHCO_3$, and with water and dried (Na_2SO_4). Evaporation of the solvent under reduced pressure afforded a light yellow oil which was triturated with a small amount of hexane–$CHCl_3$ (3: 1) to give 4.5 g (92%) of **1b** as white crystals: mp 61.5—62.0 °C (from hexane–$CHCl_3$); IR (Nujol) 3520, 3460, 1744, 1660, 1529 cm^{-1}; NMR ($CDCl_3$) δ 1.27 (t, J=7.0 Hz, 3H, CH_3), 1.69 (s, 10H), 2.50—3.10 (broad, 2H, HO–N, 1/2H_2O), 3.81 (s, 1H, NH), 4.19 (q, J=7.0 Hz, 2H, CH_2O).

Found: C, 54.62; H, 6.89%. Calcd for $C_{12}H_{17}NO_5 \cdot 1/2H_2O$: C, 54.54; H, 6.86%.

*Ethyl γ,γ-Pentamethylene-α-aminoaconate (**2c**).* To a stirred solution of **1b** (96.0 mg, 0.36 mmol) in anhydrous pyridine (0.5 ml) *p*-toluenesulfonyl chloride (140 mg, 0.73 mmol) was added portionwise for 30 min. The mixture was stirred for additional 1 h at 0—5 °C under nitrogen and for 2 days at room temperature. After cooling in an ice bath the mixture was poured into 10% HCl and adjusted to pH 7 and extracted with ether. The extracts were washed with aqueous $NaHCO_3$ and with water, dried (Na_2SO_4), and concentrated. The residual oil was chromatographed over silica gel. The first comming elution from the column with CH_2Cl_2(*ca.* 5 ml) gave 10.5 mg (7.1%) of an oil. Upon standing for several days, the oily material bigan to crystallize to give white crystals **11b**, mp 115.0—116.0 °C (from hexane–benzene); IR (Nujol) 1792 (lactone C=O), 1759, 1635, 1596 cm^{-1}; NMR ($CDCl_3$) δ 1.36 (t, J=7.0 Hz, 3H, CH_3), 0.70—2.20 (m, 11H), 2.46 (s, 3H, CH_3C=C), 4.35 (q, J=7.0 Hz, 2H, CH_2O), 7.34 (d, J=8.0 Hz, 2H, HC=C), 7.89 (d, J=8.0 Hz, 2H, HC=C). Found: C, 55.58; H, 5.49%. Calcd for $C_{19}H_{23}NO_7S$: C, 55.74; H, 5.66%.

The second elution with CH_2Cl_2 (*ca.* 20 ml) gave 54.0 mg (62.1%) of **2c**: mp 139.0—139.5 °C (from hexane–CH_2Cl_2); IR (Nujol) 3410, 3320, 1762, 1692, 1661 cm^{-1}; NMR ($CDCl_3$) δ 1.35 (t, J=7.0 Hz, 3H, CH_3), 1.52—2.52 (m, 10H), 4.28 (q, J=7.0 Hz, 2H, CH_2O), 5.59 (broad s, 2H, NH_2). Found: C, 60.45; H, 6.99%. Calcd for $C_{12}H_{17}NO_4$: C, 60.24; H, 7.16%.

The following elution with CH_2Cl_2–AcOEt (10: 1, *ca.* 10 ml) gave 3.0 mg (1.6%) of an amorphous, glassy solid: IR (neat) 3450—2700, 1775, 1731, 1650, 1590, 1563, 1497 cm^{-1}; NMR ($CDCl_3$) δ 1.26 (t, J=7.0 Hz, 3H, CH_3), 1.00—2.50 (m, 10H), 2.40 (s, 3H, CH_3C=C), 4.30 (q, J=7.0 Hz, 2H, CH_2O), 5.50 (broad, 1H, NH), 7.00—7.46 (m, 5H, HC=C), 7.95 (d, J=8.0 Hz, 2H), 8.46 (d, J=6.0 Hz, 2H). Difficulty was encountered in obtaining a pure sample for elemental analysis by recrystallization.

In the similar manner, ethyl γ,γ-dimethyl-α-aminoaconate (**2a**) was obtained in 89.5% yield, mp 120.0 °C (lit,[10] mp 120.0 °C).

*Ethyl γ,γ-Pentamethylene-α-acetylaminoaconate (**2d**).* A mixture of **2c** (126 mg, 0.527 mmol), Ac_2O(1.0 ml) and anhydrous *p*-toluenesulfonic acid (9.0 mg, 0.05 mmol) was stirred for 18 h under nitrogen at room temperature. Upon cooling with an ice-bath the mixture was poured into water and the aqueous solution was adjusted to weak alkaline solution by addition of solid $NaHCO_3$ (1.0 g) and then extracted with ether. The extracts were washed with water, dried (Na_2SO_4) and concentrated. The residue was chromatographed over silica gel using CH_2Cl_2, giving 147.0 mg (99.2%) of **2d**: mp 118.0—119.0 °C (from hexane–CH_2Cl_2), IR (Nujol) 3310 (NH), 1746, 1725, 1668 cm^{-1}; NMR ($CDCl_3$) δ 1.33 (t, J=7.0 Hz, 3H, CH_3), 1.49—2.01 (m, 10H), 2.19 (s, 3H, CH_3CO), 4.33 (q, J=7.0 Hz, 2H, CH_2O), 8.04 (broad, 1H, NH). Found: C, 59.85; H, 6.88%. Calcd for $C_{14}H_{19}NO_5$: C, 59.78; H, 6.81%.

In the similar manner, ethyl γ,γ-dimethyl-α-acetylaminoaconate (**2b**) was obtained in 93.5% yield: mp 115.5—116.5 °C (from hexane–benzene); IR (Nujol) 3320 (NH), 1755, 1724, 1678 cm^{-1}; NMR ($CDCl_3$) δ 1.34 (t, J=7.2 Hz, 3H, CH_3), 1.65 (s, 6H, *gem* CH_3), 2.22 (s, 3H, CH_3CO), 4.37 (q, J=7.2 Hz, CH_2O), 8.18 (broad, 1H, NH). Found: C, 54.90; H, 6.30%. Calcd for $C_{11}H_{15}NO_5$: C, 54.77; H, 6.27%.

*γ,γ-Pentamethylene-β-ethoxycarbonyl-α-acetylamino-γ-butyrolactones (**4a** and **4b**).* Hydrogenation of **2d** (102 mg, 0.36 mmol) was carried out in ethanol (1 ml) containing one drop of AcOH in the presence of platinum oxide (25 mg) for 43 h until 8 ml of hydrogen gas was absorbed. The catalyst was filtered off and washed with ethanol. The filtrate was concentrated under reduced pressure to give 106 mg of a light yellow oil, which was chromatographed over silica gel. Elution of the column with 10—30 ml of benzene–AcOEt (3: 2) gave 79.6 mg (77.5%) of **4b** (*cis*); mp 116.5—117.0 °C (from hexane–CH_2Cl_2): IR (Nujol) 3250 (NH), 3050, 1780, 1736, 1643 cm^{-1}; NMR ($CDCl_3$) δ 1.28 (t, J=7.5 Hz, 3H, CH_3), 1.40—1.95 (m, 10H), 2.03 (s, 3H, CH_3CO), 3.46 (d, J=7.5 Hz, 1H, H_β), 4.23 (q, J=7.0 Hz, 2H, CH_2O), 5.25 (q, J=7.5 Hz, J=7.0 Hz, 1H, H_α), 6.65 (d, J=7.0 Hz, 1H, NH). Found: C, 59.31; H, 7.38%. Calcd for $C_{14}H_{21}NO_5$: C, 59.35; H, 7.47%.

Following elution of the column with 30—40 ml of benzene–AcOEt (3: 2) gave 22.8 mg (22.2%) of **4a** (*trans*): mp 147.5—148.0 °C (from hexane–CH_2Cl_2); IR (Nujol) 3280 (NH), 3080, 1783, 1732, 1658 cm^{-1}; NMR ($CDCl_3$) δ 1.31 (t, J=7.0 Hz, 3H, CH_3), 1.40—1.95 (m, 10H), 2.01 (s, 3H, CH_3CO), 3.50 (d, J=10.5 Hz, 1H, H_β), 4.22 (q, J=7.0 Hz, 2H, CH_2-O); 4.76 (q, J=10.5 Hz, J=7.0 Hz, 1H, H_α), 6.86 (d, J=7.0 Hz, 1H, NH). Found: C, 59.07; H, 7.50%. Calcd for $C_{14}H_{21}NO_5$: C, 59.35; H, 7.47%.

In the similar manner, γ,γ-dimethyl-β-ethoxycarbonyl-α-acetylamino-γ-butyrolactones (**3a** and **3b**) were obtained in quantitative yield. Analytical samples of **3a** and **3b** were obtained by preparative glpc (3a/3b: 1/1.1; Column SE-30, 3 m×4 mm, carrier gas H_2 27 ml/min at 160 °C). **3a** (*trans*, glpc retention time 3.2 min): IR (neat) 3290 (NH), 1790, 1738, 1661 cm^{-1}; NMR ($CDCl_3$) δ 1.32 (t, J=7.1 Hz, 3H, CH_3), 1.33 (s, 6H, *gem* CH_3), 2.05 (s, CH_3CO), 3.65 (d, J=11.1 Hz, 1H, H_β), 4.25 (q, J=7.1 Hz, 2H, CH_2O), 4.73 (q, J=11.1 Hz, 1H, H_α), 6.74 (d, J=6.8 Hz, 1H, NH). Found: C, 54.33; H, 6.98%. Calcd for $C_{11}H_{17}NO_5$: C, 54.31; H, 7.04%.

The compound **3b** (*cis*, glpc retention time 9.0 min): IR (neat) 3310 (NH), 1797, 1736, 1668 cm^{-1}; NMR ($CDCl_3$) δ 1.32 (t, J=7.1 Hz, 3H, CH_3), 1.49, 1.59 (each s, 6H, *gem* CH_3), 3.43 (d, J=7.5 Hz, 1H, H_β), 4.22 (q, J=7.1 Hz, 2H, CH_2O), 5.29 (t, J=7.5 Hz, 1H, H_α), 6.33 (d, J=7.5 Hz, 1H, NH). Found: C, 54.34; H, 7.14%. Calcd for $C_{11}H_{17}NO_5$: C, 54.31; H, 7.04%.

Ethyl γ,γ-Pentamethylene-α-hydroxyaconate (5a). A mixture of **1b** (1.0 g, 3.78 mmol) in concd HCl (25 ml) was allowed to stand for 7 days at room temperature. The precipitate was collected by filtration. The precipitate was taken up in CH_2Cl_2 and the solution was washed with water, dried (Na_2SO_4), and concentrated to give 607 mg (66.8%) of **5a**: mp 118.0—119.0 °C (from hexane–CH_2Cl_2) (lit.[16] mp 119.0—119.5 °C); IR (Nujol) 3235 (OH), 1753, 1713, 1660 cm^{-1}; NMR ($CDCl_3$) δ 1.39 (t, J=7.0 Hz, 3H, CH_3), 1.52—2.36 (m, 10H), 4.35 (q, J=7.0 Hz, 2H, CH_2O), 8.84 (broad s, 1H, OH).

The filtrate was concentrated and extracted with ether. The extracts were washed with water, dried (Na_2SO_4), and concentrated to give 188 mg of an oily material, which was triturated with hexane–CH_2Cl_2 (3: 1) to give 29 mg (3.6%) of **5c**: mp 119.0—119.5 °C (decomp.); IR (Nujol) 3450—2100 (COOH), 1762, 1705, 1680, 1630 cm^{-1}. During recrystallization partial decarboxylation of **5c** was encountered. Thus, the crude acid **5c** (10.0 mg, 0.047 mmol) was treated with excess amount of diazomethane in ether for 30 min at 0—5 °C and then the solvent was evaporated. The residue was chromatographed over silica gel using CH_2Cl_2, which eluted 10.8 mg (95.4%) of **5d**: mp 64.5—65.0 °C (from hexane–CH_2Cl_2); IR (Nujol) 1755, 1698, 1642 cm^{-1}; NMR (CCl_4) δ 1.00—2.70 (m, 10H), 3.79 (s, 3H, CH_3O), 4.19 (s, 3H, CH_3O). Found: C, 60.08; H, 6.66%. Calcd for $C_{12}H_{16}O_5$: C, 59.99; H, 6.71%.

From the residual filtrate 60 mg (6.6%) of **5a** was recovered along with 74 mg (7.4%) of **1b**.

Ethyl γ,γ-Pentamethylene-α-methoxyaconate (5b). The α-hydroxyaconate **5a** (100 mg, 0.42 mmol) was treated with an excess amount of diazomethane in ether for 30 min at 0—5 °C and then the solvent was evaporated. The residue was chromatographed over silica gel using hexane–CH_2Cl_2 (1: 1), which eluted 100 mg (94.5%) of **5b**: mp 84.5—85.0 °C (from hexane–CH_2Cl_2); IR (Nujol) 1763, 1700, 1646 cm^{-1}; NMR (CCl_4) δ 1.32 (t, J=7.0 Hz, 3H, CH_3), 1.48—2.40 (m, 10H), 4.12 (s, 3H, CH_3O), 4.18 (q, J=7.0 Hz, 2H, CH_2O). Found: C, 61.38; H, 7.08%. Calcd for $C_{13}H_{18}O_5$: C, 61.41; H, 7.14%.

4,4-Pentemethylene-3-ethoxycarbonyl-2-ammonio-2-butenolide Acetate (6). A mixture of **5a** (100 mg, 0.416 mmol) and $AcONH_4$ (32.0 mg, 0.416 mmol) was allowed to stand at 110—120 °C under nitrogen for 6 h, and then the resulting white solid was sublimed at 110—120 °C to afford 101 mg (81.1%) of **6**: IR (Nujol) 3220 (NH), 1756, 1682, 1568 (COO^-) cm^{-1}; NMR ($CDCl_3$) δ 1.40 (t, J=7.0 Hz, 3H, CH_3), 1.56—2.10 (m, 10H). 2.15 (s, 3H, CH_3CO), 4.40 (q, J=7.0 Hz, 2H, CH_2O), 6.30—8.00 (broad, 3H, NH_3^+). Found: C, 56.21; H, 7.13%. Calcd for $C_{14}H_{21}NO_6$: C, 56.18; H, 7.07%.

Hydrolysis of 5a. A solution of **5a** (510 mg, 2.12 mmol) in EtOH (4 ml) and concd HCl (12 ml) was stirred for 20 h at 90 °C. The mixture was cooled and filtered with suction. The filtrate was concentrated and extracted with ether. The extracts were washed with aqueous $NaHCO_3$ and water and dried (Na_2SO_4). Removal of the solvent gave 284 mg (79.6%) of **7a**: mp 132.5—133.5 °C (from hexane–CH_2Cl_2)(lit.[16] 136—137 °C); IR (Nujol) 3185 (OH), 1748, 1644 cm^{-1}; NMR ($CDCl_3$) δ 1.64 (broad s, 10H), 5.51—6.81 (broad s, 1H, OH), 6.24 (s, 1H, H_β).

The alkaline solution was acidified to pH 3 with 10% HCl and extracted with ether. After usual work-up, there was obtained 38.0 mg (8.4%) of **5c**: mp 119.0—119.5 °C.

γ,γ-Pentamethylene-α-methoxybutenolide (7b). The α-hydroxybutenolide **7a** (20.0 mg, 0.119 mmol) was treated with an excess amount of diazomethane in ether at 0—5 °C for 30 min. After work-up as an usual manner, there was obtained 21.0 mg (96.8%) of **7b**: mp 73.0—73.5 °C (from hexane–CH_2Cl_2); IR (Nujol) 1770, 1690, 1655 cm^{-1}; NMR (CCl_4) δ 1.64 (s, 10H), 3.29 (s, 3H, CH_3O), 6.15 (s, 1H, H_β). Found: C, 65.73; H, 7.83%. Calcd for $C_{10}H_{14}O_3$: C, 65.92; H, 7.74%.

4,4-Pentamethylene-2-amino-2-butenolide (8a) and its dimer (10). *Procedure A*: A mixture of **7a** (84.1 mg, 0.50 mmol) and $AcONH_4$ (436 mg, 5.65 mmol) was heated for 30 min at 104 °C under nitrogen. The mixture was taken up in $CHCl_3$ and the $CHCl_3$ solution was washed with aqueous $NaHCO_3$, and with water, and dried (Na_2SO_4). Removal of the solvent gave 80 mg of **8a** as a solid. Purification was achieved by chromatography over silica gel using hexane–CH_2Cl_2 to give 77.0 mg (92.1%) of **8a**: mp 139.0—139.5 °C (from hexane–CH_2Cl_2); IR (Nujol) 3420, 3320 (NH), 1740, 1670, 1608 cm^{-1}; NMR ($CDCl_3$) δ 1.62 (s, 10H), 3.75 (broad, 2H, NH), 6.01 (s, 1H, H_β). Found: C, 64.54; H, 7.95%. Calcd for $C_9H_{13}NO_2$: C, 64.65; H, 7.84%.

Procedure B: A mixture of **7a** (172 mg, 1.02 mmol) and $AcONH_4$ (598 mg, 7.76 mmol) was heated to 100 °C for 30 min under nitrogen. After work-up as described above, there was obtained 126 mg (73.7%) of **8a**; mp 139.0—139.5 °C, 12 mg (7.4%) of **10**; mp 187.5—188.5 °C (from hexane–CH_2Cl_2), and 12 mg (7.0%) of the starting material **7a**.

The spectral data together with the result of elemental analysis of **10** are as follows: IR (Nujol) 3380 (NH), 3100, 1770, 1745, 1665 cm^{-1}; NMR ($CDCl_3$) δ 1.70 (s, 20H), 6.19 (s, 2H, H_β), 6.63 (broad s, 1H, NH). Found: C, 68.21; H, 7.30%. Calcd for $C_{18}H_{23}NO_4$: C, 68.12; H, 7.30%.

4,4-Pentamethylene-2-acetylamino-2-butenolide (8b). A mixture of **8a** (25.0 mg, 0.15 mmol), Ac_2O (0.5 ml), and *p*-toluenesulfonic acid (2.5 mg, 0.015 mmol) was stirred under nitrogen for 13 h at room temperature. After work-up as an usual manner, there was obtained 30 mg (95.9%) of **8b**: mp 136.0—137.0 °C (from hexane–CH_2Cl_2); IR (Nujol) 3310 (NH), 1770, 1740, 1693, 1655 cm^{-1}; NMR ($CDCl_3$) δ 1.69 (s, 10H), 2.21 (s, 3H, CH_3CO), 7.53 (s, 1H, H_β), 8.09 (broad s, 1H, NH). Found: C, 63.32; H, 7.19%. Calcd for $C_{11}H_{15}NO_3$: C, 63.14; H, 7.23%.

γ,γ-Pentamethylene-α-acetylamino-γ-butyrolactone (9). Hydrogenation of **8b** (25.0 mg, 0.12 mmol) was carried out in EtOH (0.5 ml) containing AcOH (0.01 ml) in the presence of platinum oxide (5.0 mg) for 38 h at room temperature until 3 ml of hydrogen gas was absorbed. The catalyst was filtered off and washed with EtOH. The combined filtrates were concentrated. The residual oil (31 mg) was cooled at 0—5 °C and triturated with ether to give 24.0 mg (95.0%) of **9** as a white crystal: mp 134.5—135.0 °C (from hexane–CH_2Cl_2); IR (Nujol) 3280 (NH), 3090, 1775, 1655 cm^{-1}; NMR ($CDCl_3$) δ 1.30—1.90 (broad s, 10H), 2.03 (s, 3H, CH_3CO), 2.24 (m, 2H, H_β), 4.80 (m, 1H, H_α), 6.89 (d, J=7.0 Hz, 1H, NH). Found: C, 62.60; H, 8.11%. Calcd. for $C_{11}H_{17}NO_3$: C, 62.54; H, 8.11%.

Reaction of 1b with p-Toluenesulfonyl Chloride–Butyllithium. To a THF solution (1.0 ml) of **1b** (66.2 mg, 0.25 mmol) 1.1 M butyllithium in ether (0.25 ml, 0.275 mmol) was added at −78 °C under nitrogen. After stirring for 30 min at −78 °C *p*-toluenesulfonyl chloride (50.0 mg, 0.26 mmol) was added. The mixture was allowed to warm slowly to room temperature during 2 h and stirring was continued for additional 3 h. The mixture was poured into 1.0 ml of ice-cooled diluted HCl and extracted with $CHCl_3$. The extracts were washed with water, dried (Na_2SO_4), and concentrated. The residue was chromatographed over silica gel. Elution of the column with benzene (2—3 ml) gave 27.1 mg (26.4%) of **11b**. Following elution with benzene–AcOEt (30: 1, 10 ml) gave 41.2 mg (68.7%) of **2c**. The structure of both **11b** and **2c** were identified spectroscopically in comparison with authentic samples.

Reaction of 11b with Pyridine. A solution of **11b** (10.0 mg, 0.024 mmol) in pyridine (0.5 ml) was heated to 110 °C in

a sealed tube for 15 h. The mixture was concentrated *in vacuo* and the residue was chromatographed over silica gel using benzene to give 4.7 mg (80%) of **2c**. IR and NMR spectra were identical with those of authentic sample.

Alternative Procedure: A solution of **11b** (13.5 mg, 0.033 mmol) in pyridine (0.5 ml) was stirred at room temperature under nitrogen for 2 days. The mixture was worked up in the same manner as described above to give 3.3 mg (41.9%) of **2c** and 6.3 mg (46.7%) of **11b** (recovered).

Equilibria and Substrate Specificity Studies with Alcohol Dehydrogenases

Charles C. PRICE and Mitsuhiro IWASA*

Department of Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania 19174, U.S.A.

(Received February 10, 1975)

While secondary alcohols and NAD^+, and ketones and NADH react much slowly than the ethanol–acetaldehyde system in the presence of yeast and liver alcohol dehydrogenases, by starting near equilibrium concentrations, it has been shown that expected thermodynamic equilibria are obtained. With liver ADH, cycloalkanols are remarkably reactive, while with yeast ADH those with six or more carbon atoms in the ring are unreactive. Horse liver ADH shows stereospecificity for 2-octanol, but no stereospecificity for 2-butanol. On the other hand, yeast ADH shows the same stereoselectivity for both alcohols. In the presence of yeast ADH, R(−)-isomers of 2-butanol, 2-octanol and 1-methoxy-2-propanol are not reactive, comparing to the big reactivity of $S(+)$-isomers of these alcohols, but $R(-)$-isomer of propylene glycol is also slightly reactive as $S(+)$-isomer. Further, the reactivity of secondary alcohols with NAD^+ in the presence of liver ADH is following, 2-octanol>2-butanol>2-propanol. These results suggest that horse liver ADH is much less sterically hindered at its active site than yeast ADH and that not only the steric factor but also hydrophobic bonding between the end alkyl group of alcohol and the hydrophobic region of enzyme might be another important factor to determine stereospecificity and reactivity of enzyme.

The stereoselective reduction of acetol to $R(-)$-propylene glycol by fermenting yeast was reported many years ago by Levene and Walti.[1] To improve the convenience of workup, we studied the fermenting yeast reduction of acetol benzoate; to our surprise, the product was the benzoate of $S(+)$-propylene glycol.[2]

The pure enzyme, yeast alcohol dehydrogenase (yeast ADH), has been shown to be stereoselective in the interconversion of ethanol and acetaldehyde.[3] It was the purpose of this investigation to determine whether the enzyme was also stereoselective for ketone reduction and, especially, whether this could explain the reversal of the steric sense of reduction for acetol and acetol benzoate. Kaplan and Van Eys[4] have shown that yeast ADH is indeed stereoselective in oxidizing only the $S(+)$-isomers of 2-butanol and 2-octanol. In this case, the isolated enzyme result accords with the observation that fermenting yeast reduced 2-octanone to the $S(+)$-enantiomer.[5] The absolute optical specificity of the yeast enzyme towards 2-alkanols and its unreactivity towards 3-pentanol, 3-hexanol and 3-heptanol were explained by its inability to accept alkyl groups larger than methyl in the unbound positions in a viable ternary complex.[6] Liver ADH, however, has been reported to lack such stereoselectivity.[7]

While Burton and Wilson[8] have established the equilibrium for 2-propanol–acetone ($K_{eq}=7.19\times10^{-9}$) by starting with mixtures containing three of the four

$$NAD^+ + R_2CHOH \overset{YADH}{\rightleftharpoons} NADH + R_2C{=}O + H^+$$

$$K_{eq} = \frac{[NADH][R_2C{=}O][H^+]}{[NAD^+][R_2CHOH]}$$

organic components, there are reports that cyclic ketones and higher homologs of 2-butanone are not reduced by either yeast or liver alcohol dehydrogenases.[9-11]

Preliminary investigations of the propylene glycol–acetol system were therefore initiated from the alcohol oxidation side.[12] In this early work, 2-hydroxypropyl benzoate was found inactive to enzymic oxidation. 1-Methoxy-2-propanol was, however, reactive. Furthermore, it was shown that methoxyacetone was stereoselectively reduced by fermenting yeast to $S(+)$-1-methoxy-2-propanol. The methoxy group thus provides the same reversal sense as does the benzoate group.

While these preliminary studies[12] showed that oxidation of 1,2-propanediol with yeast ADH did proceed, the reactions were much slower than for ethanol oxidation. Furthermore, the reactions stopped in several hours far short of true equilibrium. It has now been shown that this was due to inactivation of the enzyme during the time required for the slow oxidation of glycol derivatives.

By starting with reaction mixture near equilibrium, it has been possible to show that thermodynamic equilibrium is reached. Based on equilibrium constants and optical density changes at 340 nm, the factors determining stereospecificity of enzymes are discussed.

Experimental

Twice-crystallized yeast ADH and β-NAD⁺ were purchased from Sigma Chemical Co. and further purified. Once-crystallized horse liver ADH was purchased from Worthington Biochemicals and purified in the same way as yeast ADH.

Commercial NAD⁺ (grade III) was further purified by DEAE cellulose column chromatography.[13]

S(+)-1,2-Propanediol was prepared either through yeast reduction of acetol benzoate[α]$_D^{30}$=+26.2 °C (C=1, $CHCl_3$), or from $S(+)$-lactic acid by lithium alminum hydride reduction,[14], [α]$_D^{25}$=+29.10 (C=1, $CHCl_3$).

Acetol[15] was converted to $R(-)$-1,2-propanediol, [α]$_D^{25}$=−27.7 (C=1, $CHCl_3$) by yeast fermentation.

S(+)-and R(−)-Octanol, [α]$_D^{25}$=+8.37 and −8.66, respectively (C=5, 95% ethanol), were prepared by Ingersoll's procedure.[16] $S(+)$-2-Butanol was similarly prepared.[16]

Measurement of Equilibrium Constant. Solutions of different composition were prepared by mixing 1.0 ml of variable mol ratio of alcohol to ketone solutions and 1.90 ml of mixed coenzyme solution (NAD^+ and NaDH in tris buffer) in test tubes. A blank was also made up from 1.0 ml of water and

* Present Address: Mitsui Toatsu Chemicals, Inc. 2—5, Kasumigaseki 3-Chome, Chiyoda-Ku, Tokyo 100, Japan.

1.9 ml of the same coenzyme solution.

These solutions were kept standing for an hour in the 25.0 °C constant temperature bath. Preserved horse liver ADH in the frozen state was diluted with phosphate buffer (near 0 °C). This diluted ADH solution (0.1 ml each) was added to each solution at 25 °C.

Just after adding ADH, the optical density of the blank solution was measured at 340 nm. All the solutions were kept standing at 25.0 °C, usually for 4 h, and then the optical density of each solution was measured at 340 nm. At the same time, the pH of the solution was measured. The amount and direction of shift from the initial concentrations was calculated from the difference of optical density of each solutions from that of the blank.

Results and discussion

Equilibrium Constants. A typical example of the experimental data used to calculate equilibrium constant K_{eq} is summarized in Table 1. Values thus obtained are listed in Table 2.

From the equilibrium constants in Table 2, the standard free energy change for the reaction is readily estimated ($\Delta G = -RT \ln K_{eq}$). With the known $\Delta G^0 = 5.22$ kcal/mol for the NAD$^+$–NADH couple,[8] this leads to values for the ketone–alcohol couples listed in Table 2.

In these experiments we measured the amount of alcohol oxidized by NAD$^+$ through increase in absorbance at 340 nm, a λ_{max} for NADH. It has, however, been shown that ketones, especially acetol and methoxyacetone, undergo a base catalyzed reaction with NAD$^+$ producing compounds with a λ_{max} near 340 nm.[17] In Fig. 1, data on the reaction of several ketones with

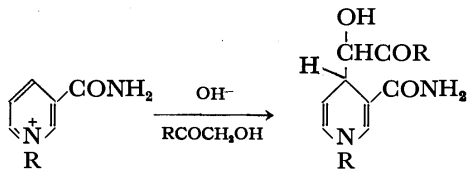
dl-1,2-Propanediol–acetol[a]	7.5×10^{-11}	1.1×10^{-10}	9.3×10^{-11}
(−)-1,2-Propanediol–acetol[b]	7.9×10^{-11}	7.7×10^{-11}	7.8×10^{-11}

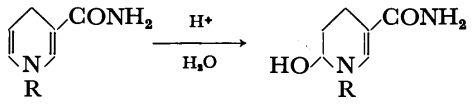
a) K_{ap} using total ROH; since only one enantiomer reacts, the values in parentheses are not proper K_{eq}.
b) To obtain the equilibrium data, acetol was used, although the real system may involve lactaldehyde as well.

NAD^+ at pH 9.1 are summarized.



The ΔOD for acetol and methoxyacetone are so great that the values for K_{eq} would be seriously in error at this pH. At pH 7, there was no increase in OD, even for acetol.

NADH is also known to react with acids[18] to lose optical density at 340 nm.



We found that NADH was rapidly destroyed at pH 6 (*ca.* 20—25% in 19 h, 25°C) and even at pH 7, about 6% reacts in 19 h. The presence of either yeast or liver ADH markedly enhances NADH stability, less than 1% disappearing in 19 h at 25°C. We therefore chose pH 7 as the most suitable pH, both for NADH stability to acid and NAD^+ stability to ketone.

Table 3. The standard free energy changes for various alcohol–ketone systems

Alcohol–ketone system	$\Delta G°$ (kcal mol^{-1})	$\Delta G°$ (lit)
2-Propanol–acetone	5.8	5.89(8), 6.0(19)(20)

Cyclohexanol–cyclohexanone	7.7	7.5(19)
1-Methoxy-2-propanol–methoxyacetone	8.7	8.8(19)
1,2-Propanediol–acetol	8.6	not available

a) K_{eq} for $S(+)$-isomers were used to calculate ΔG, since these are reactive isomers.

The equilibrium data in Table 2 and 3 are in reasonably satisfactory agreement with earlier data obtained by chemical equilibration[19,20] and with the YADH equilibration for 2-propanol–acetone.[8] The fact that yeast and liver ADH give values essentially the same is support for the conclusion that the procedure used has given true equilibrium. The catalyst should, of course, contribute only to the rate and, at the low relative concentrations used, should not influence the equilibrium position.

Stereospecificity of Liver and Yeast ADH for 2-Butanol and 2-Octanol. The data in Table 2 support the earlier proposal[4] that yeast ADH is stereoselective for the $S(+)$-isomers of 2-butanol and 2-octanol, since the "apparent" K_{eq} for the racemates is nearly half of K_{eq} for the $S(+)$-isomers. We found, however, that liver ADH shows optical specificity for 2-octanol and even for 2-butanol it seems to show small optical specificity. Stereospecificity of horse liver ADH for 2-octanol was confirmed by the initial rate of oxidation of secondary alcohols, but that for 2-butanol was not clear as shown in Table 4.

Table 4. Initial rate of oxidation reaction of various alcohols with NAD^+ in the presence of horse liver ADH.

Alcohol	ΔOD at 340/min
2-Propanol	0.012
(+)-2-Butanol	0.016
dl-2-Butanol	0.016
(+)-2-Octanol	0.048
dl-2-Octanol	0.024
(−)-2-Octanol	0.004
(+)-1,2-Propanediol	0.024
dl-1,2-Propanediol	0.018
(−)-1,2-Propanediol	0.016
1-Methoxy-2-propanol	0.024

Initial conc.: NAD^+, 6×10^{-3} M; horse liver ADH, 1.5×10^{-7} N; Tris chloride buffer, 0.02 M; 25.0 °C; pH, 7.1—7.3.

Stereospecificity of ADHs for 1-Methoxy-2-propanol and 1,2-Propanediol. Yeast ADH is probably stereoselective for 1-methoxy-2-propanol, because the "apparent" K_{eq} of yeast ADH is just half of that of horse liver ADH.

As for the motivating reason for this investigation, there appears to be no stereoselection between the $S(+)$- and $R(-)$-1,2-propanediol enantiomers in the presence of ADHs and NAD^+.

There is one complication with propylene glycol oxidation in that it can oxidize at either the primary alcohol group to give lactaldehyde or the secondary to give acetol. Huff[21] reports that liver ADH oxidizes 1,2-propanediol preferentially to lactaldehyde while Tjioe[12] detected acetol (as the 2,4-dinitrophenylhydrazone) using yeast ADH. If the two equilibria for the glycol are established independently, then the overall observed K_{eq} should be $K_{10}+K_{20}$. If we assume that the K_{10} is approximately the same as for ethanol (1.2×10^{-11}) and for K_{20} approximately the same as for 1-methoxy-2-propanol (1.0×10^{-10}), the sum (1.1×10^{-10}) is close to the experimental values for propylene glycol.

Propylene glycol shows different character comparing to other examined secondary alcohols on the points that $R(-)$-isomer shows the same low reactivity as the $S(+)$-isomer even in the presence of yeast ADH. This result is surprising in view of the fact that whole yeast cell catalyze the reduction of acetol to only $R(-)$-1,2-propanediol and the reduction of methoxy acetone and acetol benzoate to $S(+)$-isomer of 1-methoxy-2-propanol and 2-hydroxypropyl benzoate, respectively.[2,12,15]

Effect of Ring Size on Substrate Specificity of ADHs for Cyclic Secondary Alcohols. The reactivity of various cyclic alcohols was examined from optical density changes with horse liver ADH and yeast ADH. Table 5 shows the optical density change of cycloalkanols after 3 hours of oxidation reaction. With horse liver ADH, all the cyclic alkanols show big reactivities which is almost independent of ring size. In the presence of yeast ADH, reactivity of cycloalkanol decreases with

Table 5. Effect of ring size of cyclic alcohols on substrate specificity of alcohol dehydrogenase[a)]

Cycloalkanol	Yeast ADH		Horse liver ADH	
	pH 9.0	pH 7.2	pH 9.0	pH 7.2
C_4	2.0	1.5	1.9	1.5
C_5	0.55	0.4	1.9	1.2
C_6	0	0	1.8	0.8
C_8	0	0	1.9	1.8
C_{12}	0	0	0.2	0.1

a) Initial concentration: NAD^+, 2.0×10^{-4} M; Cyclic alcohols 6.0×10^{-3} except cyclododecanol, about 10^{-3} M; Yeast ADH, 8.4×10^{-7} N; Horse liver ADH, 5.2×10^{-7} N; Tris chloride buffer, 0.02 M, 25.0°C; Unit, ΔOD (340 nm) at 3 h.

increasing ring size and when the number of ring carbon becomes more than 6, it becomes completely non-reactive.

These results indicate that the active site of yeast ADH is much more sterically hindered than horse liver ADH.[6)]

Factors to Determine an Optical Specificity of ADHs for Secondary Alcohols. Dalziel and Dickinson[6,7)] explained the lack of stereospecificity of liver ADH for secondary alcohols with the absence of steric hindrance of the binding site of enzyme.

However, we noted that liver ADH also exhibits optical specificity for higher secondary alcohols even though steric hindrance at the active site of liver ADH is estimated to be small. Therefore, another factor should be considered to explain stereospecificity of enzymes in addition to steric hindrance.

Sigman[22)] determined the dissociation constants $K_{e,s}$(=[E][S]/[ES]) for complexes of liver ADH with various primary alcohols by measuring the diminution that complexes cause in the intensity of enzyme-bipyridine spectrum and showed that bigger alkyl groups interact more strongly with lipophilic site of enzyme.

A plot of initial rate (ΔOD/min) of oxidation reaction of various secondary alcohols shown in Table 4 *vs.* $1/K_{e,s}$ of primary alcohols obtained by Sigman shows that initial rate of oxidation reaction increases with the increases of $1/K_{e,s}$ as shown in Fig. 2. Thus, the reactivity of the alcohols is much influenced by the hydrophobic interaction of end-alkyl group of alcohols with enzyme.

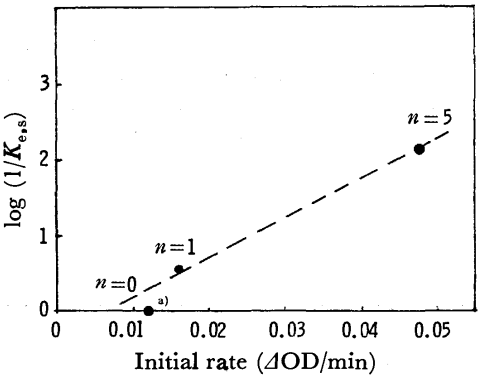

Fig. 2. Plots of the reciprocal of the dissociation constants log ($1/K_{e,s}$) of primary alcohol, $CH_3(CH_2)_n$-OH *vs.* initial rate of oxidation (ΔOD/min) of secondary alcohol, $CH_3(CH_2)_n\rangle CHOH$ (CH_3)

a) $K_{e,s}$ of CH_3OH was estimated to be 1.0 from Sigman's data.[22)]

Stereospecificities of alcohol dehydrogenases for secondary alcohols are summarized in Table 6, which shows a common tendency to three enzymes; $S(+)$-isomers are more reactive in secondary alcohols whose end groups are both normal alkyl or aromatic and $R(-)$-isomers are more reactive or reactive as $S(+)$-isomer in secondary alcohols where one of the end groups is hydroxyl.

If we apply the idea of hydrophobic bonding between substrate and lipophilic site of the enzyme in addition to steric hindrance, we can explain well the optical specificity of the enzymes; thus for 2-butanol, 2-octanol, 1-methoxy-2-propanol and 2-hydroxypropyl benzoate, the C_2H_5–, C_6H_{13}–, CH_3– of $-CH_2OCH_3$ and C_6H_5– of $-CH_2OCOC_6H_5$ group, respectively, binds more strongly with the lipophilic site of the enzyme than does the CH_3-group attached to α-carbon. Hexyl group binds more strongly with lipophilic site of enzyme than ethyl group and this might be a reason why liver ADH shows clear stereospecificity to 2-octanol, in spite it shows small stereospecificity to 2-butanol.

For 1,2-propanediol, the CH_2OH group binds more weakly with the enzyme than CH_3– group attached to α-carbon. As Tsai[23)] observed that the introduction of polar groups such as amino, carbonyl or halogen to primary alcohols renders substrates inactive or inhibitory, generally the introduction of polar groups such as –OH, $-NH_2$, –COOH, $-NO_2$ or halogen to the

Studies of the Isomerization of Unsaturated Carboxylic Acids. II.[1] The Thermal Rearrangement of Citraconic Acid to Itaconic Acid in Aqueous Solutions

Mutsuji SAKAI

Department of Textile Chemistry, Faculty of Textile Science, Kyoto University of Industrial Arts and Textile Fibers, Matsugasaki, Sakyo-ku, Kyoto 606

(Received March 22, 1975)

The thermal reaction of citraconic acid (**2**) in water gives a mixture of products similar to that obtained from itaconic acid (**1**) in water. After 22 h at 170 °C, the equilibrium composition about 74%, 18%, and 8% **1**, **2**, and mesaconic acid respectively. At the optimum conditions (170 °C for 3 h), the yield of **1** is 65%. The mechanism of the reaction is discussed.

Itaconic acid (**1**) is a relatively innocuous vinyl monomer and has been used extensively in industry.[2] This important acid has been conveniently prepared from citraconic anhydride.[3] It is interesting that, in this preparative method, terminal olefin **1** is obtained from citraconic acid (**2**) by thermal rearrangement in water;[4] this is in contrast to the general concept that internal olefins are thermodynamically more stable than the corresponding terminal ones. In spite of extensive studies of base-catalyzed rearrangements[5] and isomerizations[5] of unsaturated acids[6-8] and other compounds,[9,10] similar reactions[5] under neutral to acidic conditions have not received much attention.

The present report will describe the results of studies of the factors that govern equilibration between **1** and **2** under neutral to acidic conditions, and a plausible mechanism of the reaction will be proposed. Under the present conditions, **1** is the most abundant component of the three acids, whereas, under basic conditions, mesaconic acid (**3**) predominates over the others. Thus, the equilibrium between **1** and **2** is practically more important than that between **2** and **3**.

Experimental

All the melting and boiling points are uncorrected.

Materials. Commercial-grade itaconic acid (methylenesuccinic acid) (**1**) was purified by recrystallization from water. The following compounds were prepared by the methods described in the literature: citraconic acid (methylmaleic acid)[11] (**2**), mp 90 °C; mesaconic acid (methylfumalic acid)[11] (**3**), mp 204 °C; citramalic acid (2-hydroxy-2-methylbutanedioic acid)[12] (**4**), mp 116 °C, and paraconic acid (3-carboxy-4-butanolide)[13] (**5**), mp 54 °C.

The methyl ester of **5** was isolated by distillation from the reaction mixture obtained under the conditions that give **5** in the highest yield (170 °C, 22 h) and was identified by the aid of NMR and elemental analyses.

The water was distilled prior to use, and the deuterium oxide was 99.8% pure. The organic solvents were purified by ordinary methods. The other reagents were of a reagent grade.

Procedure. *Reactions in Aqueous Solutions*: A mixture of 1.0 g (7.7 mmol) of **2** and 2.0 g (0.11 mol) of water was sealed into a glass tube, which was then heated to an appropriate temperature in an autoclave filled with water. For the analysis, all the acids were converted into the corresponding methyl esters by the following treatment. From the reaction mixture, the water was removed as benzene azeotrope, and the acids in the residue, together with the glutaric acid added as an internal standard of gas chromatography, were esterified with methanol by refluxing for 5 h in the presence of sulfuric acid. After the removal of the methanol, the mixture was neutralized with an aqueous sodium carbonate and the esters were extracted with benzene. For runs under basic conditions, the reaction mixture was neutralized with sulfuric acid before the water was removed from the mixture. The organic acids were extracted from the residue with hot methanol and worked up similarly. The reactions of the other acids in water were carried out similarly.

Reactions in Deuterium Oxide: A mixture of 1.0 g of **1** and 2.2 g of deuterium oxide was heated at 170 °C for 3 h. The compositions of the products were determined from glc, as will be described below. The deuterium content in α-methylene of **1** was calculated from the relative intensities at δ 6.3 ($=CH_2$), 5.8 ($=CH_2$), and 3.3 ($-CH_2-$) in the NMR spectrum (in D_2O).

Analysis. The benzene extracts were analyzed by gas chromatography using a BDS 90m capillary column with Hitachi Perkin-Elmer F6-D at 150 °C. It was confirmed that no rearrangement took place in the course of the esterification and the gas-chromatographic analysis. The NMR spectra were recorded on a Varian T-60A spectrometer.

Results and Discussion

Thermal Reaction of 2 in an Aqueous Solution. Reactions were carried out in the temperature range from 140 °C to 200 °C. No reaction occurred at 100 °C. The gas chromatogram of the reaction mixture revealed that the mixture consisted of five components (**1**—**5**). The main product of the reaction

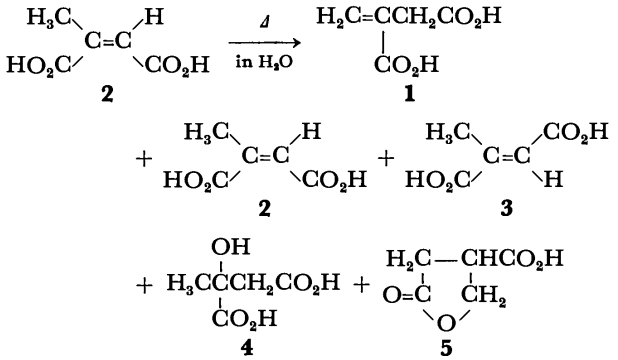
●; **1**, ○; **2**, ⊖; **3**.

was **1**, and the yield was 65%, as is shown in Figs. 1 and 2. Figure 2 also reveals that the maximum yield of **1** can be achieved when the reaction mixture contains at least twice as much water as **2** in weight. Small amounts of other products (**3**, **4**, and **5**) besides **1** and **2** were formed at higher temperatures or by prolonged heating.



An Equilibrium between the Reaction Products. Reactions starting from **1** and **2** gave mixtures with the same equilibrium composition, whereas those from **3**, **4**, and **5** took place with difficulty and large portions of the starting acids were recovered (Table 1). Table 1 and Fig. 3 show the presence of an equilibrium between **1** and **2**, from which the equilibrium composition at

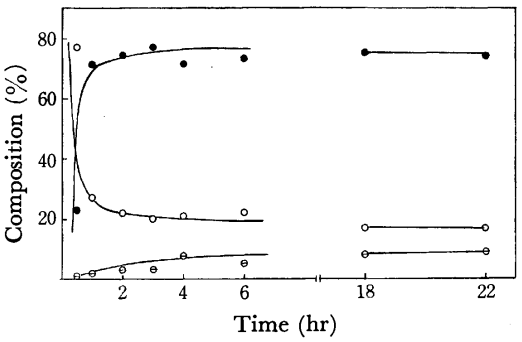


Fig. 3. An equilibrium between **1** and **2**.

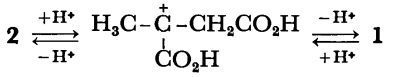
●; **1**, ○; **2**, ⊖; **3**.

170 °C was calculated to be 74% **1**, 18% **2**, and 8% **3**. Neither aprotic (acetonitrile, acetone, and diglyme) nor protic (isovaleric acid and methanol) organic solvents were effective for the reaction at 170 °C, which implies that water is acting not only as a solvent but also as a reagent.

Since both the formation of **3** from **2** and reactions starting from **3**, **4**, or **5** are too slow to account for the rapid rearrangement between **1** and **2**, the possibility of these acids being intermediates of the reaction can be discarded.

It is quite plausible that the reaction proceeds *via* a protonation-deprotonation process, because the reaction mixture is slightly acidic under the present conditions.



However, this mechanism cannot explain the rapid hydrogen-deuterium exchange that accompanies the rearrangement. The NMR analyses of the recovered **1** showed that 65% of the α-methylene protons were exchanged by deuterium when **1** was heated in deuterium oxide for 3 h at 170 °C, whereas practically no exchange was observed at the terminal methylene group. The exchange did not take place when the mixture was heated at 110 °C for 3 h. When **2** was heated in deuterium oxide at 170 °C for 3 h, no exchange was observed at the methyl protons of the

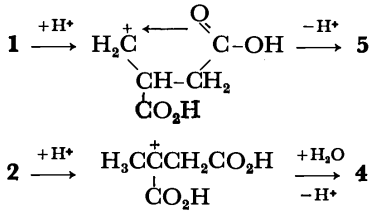
recovered **2**, whereas 85% of the α-methylene protons in **1** produced were exchanged by deuterium. If the intermediate carbonium ion is responsible for the reaction, the terminal methylene-protons must be exchanged by deuterium faster than those in the α-methylene group.

The above observation as well as the effect of additives (*vide infra*) establishes that the reaction involves a carbanion as an intermediate, or that water acts as a general base, in spite of acidic reaction conditions.

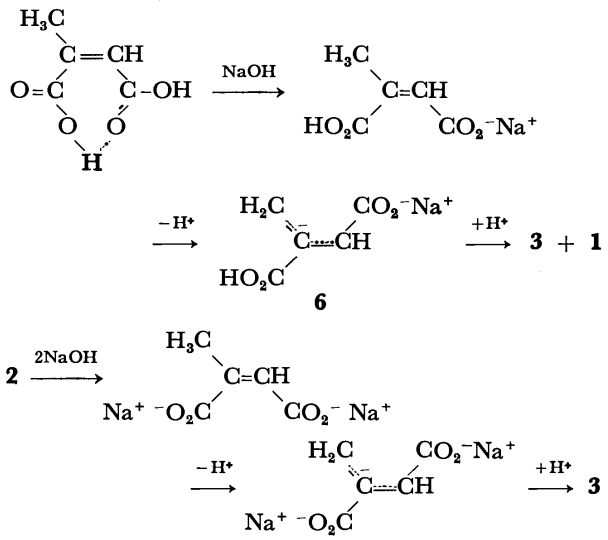
The Effect of Additives on the Reaction. The addition of sulfuric acid not only dramatically retards the rearrangement between **1** and **2**, but also changes the product distribution completely (namely, the distribution of **4** and **5**). This fact again disproves the protonation-deprotonation mechanism for the equilibration. On the other hand, the increase in the yields of **4** and **5** (from **2** and **1** respectively) indicates that these products might be produced *via* carbonium ion intermediates. It should be noted that even *cis-trans* interconversion (**2**⇌**3**) does not proceed in the presence of sulfuric acid.



Sodium hydroxide also retards the rearrangement, but increases the yield of the isomerized product, **3**. The dependency of the product composition (at 170 °C, after 4 h) on the amount of sodium hydroxide added is exemplified by the reaction of **2**, shown in Fig. 4. That these are not equilibrium compositions (except for the values at the zero sodium hydroxide concentration) was confirmed by the fact that the yield of **3** predominated over those of other acids at longer reaction times.

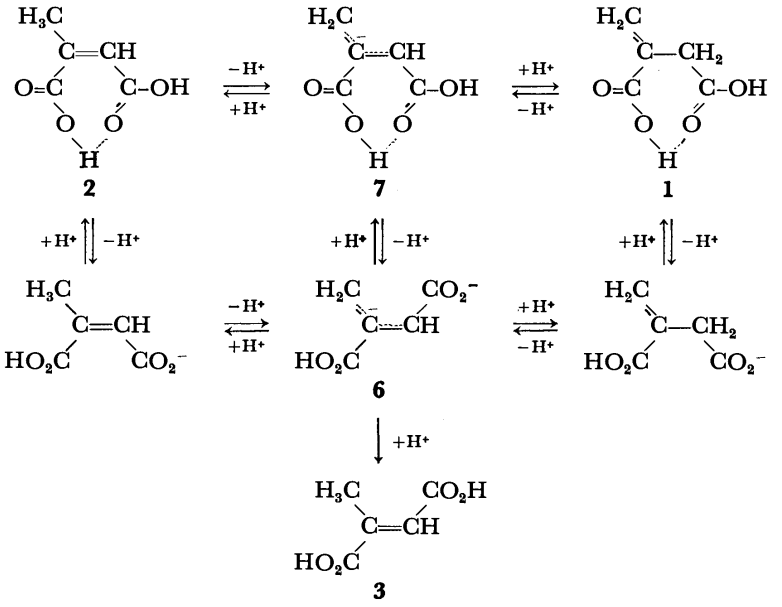
The effect of sodium hydroxide can be interpreted as follows. The added base facilitates the dissociation of carboxylic acids to the corresponding carboxylate anions. Since proton abstraction from a carboxylate anion is a more difficult process than that from an undissociated acid, the rearrangement which proceeds *via* a carbanion intermediate takes place with difficulty from a carboxylate anion. Thus, the species[14)] that undergo the rearrangement are undissociated acids in the range of $0 \leqq [NaOH]/[2] < 1$, whereas a slower rearrangement takes place only from monocarboxylate anions of dicarboxylic acids in the range of $1 \leqq [NaOH]/[2] \leqq 2$. As may be seen from Fig. 4, dicarboxylate anions do not undergo the rearrangement without a specific hydroxide ion catalyst, whereas excess sodium hydroxide ($[NaOH]/[2] > 2$) catalyzes the reaction of dicarboxylate anions.

Undissociated *cis*-acid (**2**) might be stabilized by intramolecular hydrogen bonding,[15)] which is expected to be overcome by ion-pair formation when sodium hydroxide is added to this acid.



Since **6** no more retains the force to hold the *cis*-configuration, it affords a more stable *trans*-acids rather than **2** when reprotonation takes place. The same is true for **1**.

Although the intramolecular hydrogen bonding in **1** and **2** has not been proved directly, its importance in



Scheme 1.

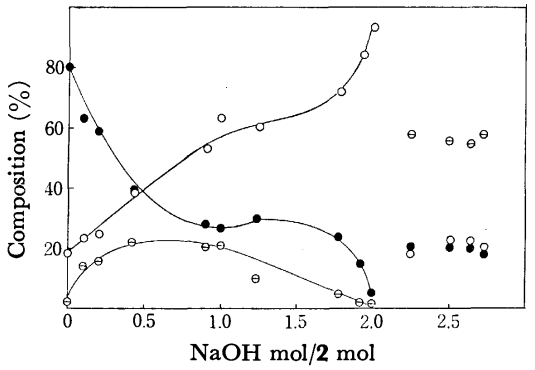


Fig. 4. The effect of sodium hydroxide on the composition.

●; **1**, ○; **2**, ⊖; **3**.

keeping **3** a minor component under acidic conditions and a major one under basic conditions is supported by the following evidence: the dimethyl ester of **2** isomerized to the *trans*-isomer under neutral conditions,[16] and crotonic acid is the main product in the thermal rearrangement of butenoic acids in an aqueous solution.[17] Thus, the *cis*-configuration is more stable than the *trans*-configuration only for dicarboxylic acids.

All of the present results support the idea that the most plausible mechanism for interconversion between **1**, **2**, and **3** in an aqueous solution is that shown in Scheme 1.

Isotope Effect. When the reaction is carried out in deuterium oxide, the rearrangement from **2** to **1** proceeds as quickly as that in water (protium oxide), whereas that from **1** to **2** is dramatically retarded (Table 1). This result is not accounted for by the solvent-isotope effect, because proton abstractions from **1** and **2** should result in inverse isotope effects and protonation to the intermediate carbanion (**7**) is a process which the two reactions have in common. It should be remembered that **1** undergoes hydrogen-deuterium exchange at the α-methylene group faster than it does the rearrangement under the present conditions, and that the reaction of **1** in deuterium oxide is that of the α-deuterated compound. On the other hand, rather small portions of **2** are deuterated under the same conditions; the intermediate carbanion (**7**) formed from **2** prefers to give the rearranged product, **1**, and only small portions of it return to **2** by deuteration. Thus, the present author believes that the isotope effect observed presently indicates that the rate-determining step of the rearrangement is the process of proton abstraction to form **7**; this is in accord with the discussion in the previous section. The energy diagram may be visualized as is illustrated in Fig. 5.

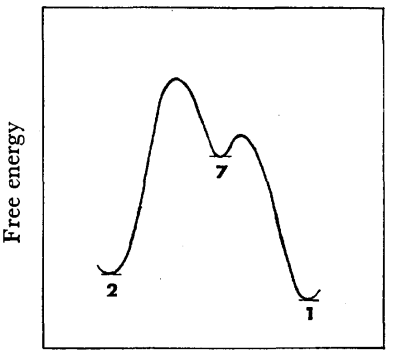

Fig. 5. Schematic energy profile for the rearrangement between **1** and **2**.

Since the reaction is run in a sealed tube at an elevated temperature, the author unfortunately has no device to obtain precise kinetic data to support the mechanism proposed here.

The author wishes to thank Professor Emeritus Sango Kunichika of Kyoto University for his encouragement throughtout this work. He is also grateful to Professors Shinzaburo Oka, Yasumasa Sakakibara, and Atsuyoshi

Ohno for their continuous guidance and helpful discussions.

An External Heavy Atom Effect upon the Photoreaction of *N*-Acetyldiphenylmethyleneamine in Toluene

Shuichiro Asao, Naoki Toshima, and Hidefumi Hirai

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

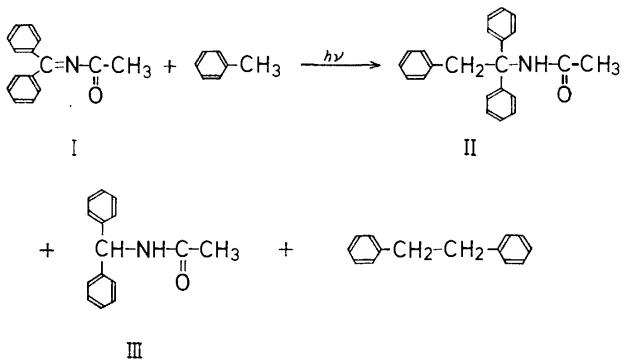
(Received March 28, 1975)

The photochemical conversion of *N*-acetyldiphenylmethyleneamine (I) in toluene to produce an addition product *N*-(1,1,2-triphenylethyl)acetamide and a hydrogenation product *N*-(diphenylmethyl)acetamide has been found to increase remarkably by displacement of *para*-hydrogen of toluene with a halogen (chlorine or bromine). A number of halogenated solvents, especially brominated solvents such as dibromomethane and bromobenzene, also promoted the photoreaction of the imine I with toluene. The extent of the promotion depends on the kind of a halogen atom of the solvent molecule. The reaction rate was accelerated with the number of halogen atoms of the solvent molecule. The conversion rate increased very remarkably when the concentration of bromobenzene increased from 0 to 1 mol/l. The reaction *via* chemical sensitization by benzophenone, a contaminant in imine I, was shown to be insensitive to the heavy atom solvent. The heavy atom effect can be attributed to an increase in the rate of intersystem crossing from the excited singlet state to the triplet state of the imine I. Imine I in the excited state was confirmed to have a hydrogen abstracting character.

The heavy atom effect in the field of molecular photochemistry is known to be a unique phenomenon for spectroscopists.[1-8] It is thought to arise from the increased spin-orbit coupling due to the interaction of the electronic spin with the nucleus of the heavy atom.[9] This effect cannot be observed in the photochemistry of the carbonyl compound. The asymmetry inherent in a carbonyl group was pointed out to produce a sufficient spin-orbit coupling greatly enhancing the rates of T–S transitions involving the n,π^* excited state. Such transitions were predicted to be hardly susceptible to heavy atom effects.[7,9]

Although there are many spectroscopic investigations on the heavy atom effect, little is known of the actual increase of the photoreaction yield due to it.[10-14]

Irradiation of a toluene solution of *N*-acetyldiphenylmethyleneamine (*N*-acetyldiphenylketimine, I), an *N*-analogue of α,β-unsaturated ketone, gave *N*-(1,1,2-triphenylethyl)acetamide (II) and *N*-(diphenylmethyl)-acetamide (III) in 11 and 4.4% yields, respectively.[15]



I II

III

This photoreaction was proposed to proceed not only by the "chemical sensitization" mechanism, but also by the mechanism through the excited state of imine I. In the "chemical sensitization" mechanism, the reaction proceeds *via* an α-acetylamino radical formed by hydrogen atom transfer to imine I from a ketyl radical.[16] The benzophenone ketyl radical is photochemically derived from benzophenone present in the starting imine I as an impurity. Almost all the photoreduction of the imino compounds were proposed to be brought about *via* "chemical sensitization",[17] since the imino compound was easily hydrolyzed to the carbonyl compound which has a hydrogen abstracting character in the excited state.[16] However, we showed that[15] imine I in the excited state has a hydrogen abstracting character, from the fact that the relative reactivity of the substituted toluenes to imine I differs from that to benzophenone,[18] and that the products can be given in the absence of benzophenone based on the investigation of the dependence of the reaction yields on the concentration of benzophenone.

We wish to report the noticeable promotion of the photoreaction rate of imine I with toluene by the heavy atom solvent and the results of research on the heavy atom solvent effects.[19]

Results

Photoreaction of N-*Acetylketimine I with* p-*Halotoluene.* On irradiation of the *p*-halotoluene solution of *N*-acetylketimine I in a Pyrex vessel with a high pressure mercury lamp, the adduct, *N*-[1,1-diphenyl-2-(*p*-halophenyl)ethyl]acetamide (IV) and the hydrogenation product, *N*-(diphenylmethyl)acetamide (III) were obtained. *p*-Fluorotoluene, *p*-chlorotoluene, and *p*-bromotoluene were used as *p*-halotoluenes. The results are shown in Table 1 together with those of toluene as a standard.

The structures of the products were determined from spectroscopic data and elemental analyses (see Experimental).

Table 1. Photoreaction of *N*-acetylketimine I with *p*-halotoluene[a)]

Solvent	Yield (%)[b)]			Relative reactivity	
	Adduct (IV)	Hydrogenation product (III)	Total	I	$^3Ph_2CO$[c)]
Toluene	4.6	1.2	5.8	1.00[d)]	1.00[d)]
p-Fluorotoluene	4.2	1.2	5.4	0.93	1.2
p-Chlorotoluene	11.0	4.0	15.0	2.6	0.97
p-Bromotoluene	20.3	24.5	44.8	7.7	—

a) Irradiation was carried out in benzene (5 ml) solution, of 0.23 mol/l of I with *p*-halotoluene (5 ml) in a Pyrex tube for 50 hr with a high pressure Hg lamp. b) Total yield indicates the conversion of the imine I, in this paper, since the remainder is the starting imine only. See Ref. 20. c) Relative reactivity of alkylbenzenes to the triplet state of benzophenone. See Ref. 18. d) Standard.

The results show that the excited state of I has a quite different photoreactivity from that of benzophenone, *viz.*, in the photoreaction of imine I the total yield increased in the order, *p*-fluoro-<*p*-chloro-<*p*-bromotoluene, *p*-bromotoluene vigorously reacting with I. The extremely high reactivity of *p*-bromotoluene to I suggests the contribution of the so-called heavy atom effect on the photoreaction of I.

Heavy Atom Solvent Effects on the Photoreaction of N-*Acetylketimine I with Toluene.* The effect of the heavy atom solvent was investigated as regards the results of the photoreaction of I with *p*-halotoluene. The results are given in Table 2, with the use of 1 or 5 ml of propyl chloride, chlorobenzene, chloroform, propyl bromide, bromobenzene, or dibromomethane as a halogen-containing solvent in 10 ml of the solution of I (0.23 mol/l). The yields[20)] increased in the presence of halogenated solvents, especially in brominated ones. Propyl chloride and chlorobenzene showed no significant heavy atom effect in a low (1 ml) concentration, but chloroform showed clearly since it contains a larger number of chlorine in the molecule. Increasing the amount of the chlorinated solvent from 1 ml to 5 ml enhanced the effect. The brominated solvents, on the other hand, were remarkably effective. The reaction yields[20)] increased with the bromine content of the solvent molecules in a low (1 ml) concentration, although increasing the amount of the solvent to 5 ml altered the tendency. On irradiation of I in toluene in the presence of ethyl iodide, a deep coloration appeared indicating the depression of the reaction. The yields in the presence of 5 ml of the heavy atom solvent sometimes happened to be lower than those in the presence of 1 ml of the same solvent depending on concentration of toluene (Table 2).

Dependence of the Yield of Photoreaction of N-*Acetylketimine I with Toluene on the Concentration of the Heavy Atom Solvent.* The external heavy atom effect was clarified by the investigation of the relationship between the yield and the concentration of the heavy atom solvent. The photoreaction of I with toluene was carried out using the various concentrations of bromobenzene. The results are shown in Fig. 1. The product yield increased noticeably as the concentration of bromobenzene was increased from 0 to 1.5 mol/l. Further increase in the concentration of the heavy atom solvent, however, resulted in saturation of the increasing yield.

Dependence of the Yield of Photoreaction of N-*Acetylketimine I with Toluene on the Concentration of Benzophenone in the Presence of the Heavy Atom Solvent.* The dependence of the reaction yield upon the concentration of benzophenone was investigated in the presence of bromobenzene. The results are given in Fig. 2 together with those in the absence of bromobenzene.

The amount of benzophenone is the sum of that in the

Table 2. Solvent effect on the yields of the photoreaction of *N*-acetylketimine I with toluene[a)]

Solvent	Volume of solvent added					
	1 ml[b)]			5 ml[c)]		
	Adduct, II (%)	Hydrogenation product, III(%)	Total (%)	Adduct, II (%)	Hydrogenation product, III(%)	Total (%)
Benzene	3.4	0.8	4.2	1.3	0.4	1.7
Acetonitrile	—	—	—	1.4	0.2	1.6
Propyl chloride	3.1	0.7	3.8	2.0	1.4	3.4
Chlorobenzene	3.1	0.7	3.8	3.7	1.9	5.6
Chloroform	5.0	2.0	7.0	6.0	2.2	8.2

Dibromomethane	13.5	4.3	17.8	14.3	5.5	19.8

a) Irradiation was carried out with 0.23 mol/l of I in a Pyrex tube with the merry-go-round type apparatus for 30 hr. b) One milliliter of the solvent listed and 9 ml of toluene were used. c) Five milliliter of the solvent listed and 5 ml of toluene were used.

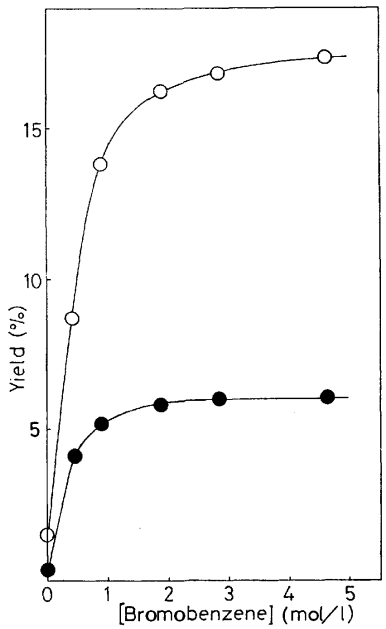

Fig. 1. Dependence of the yields of the photoreaction of *N*-acetylketimine I upon the concentration of bromobenzene in toluene: Adduct (○), hydrogenation product (●); [*N*-Acetylketimine] 0.23 mol/l, [Toluene] 5 ml: Irradiation was carried out above 300 nm for 30 hr at 25 °C.

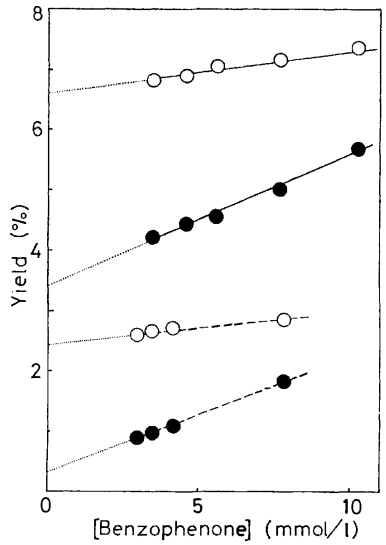

Fig. 2. Dependence of the yields of the photoreaction of *N*-acetylketimine I (0.23 mol/l) with toluene upon the concentration of benzophenone in the presence (—) (Toluene, 9 ml; Bromobenzene, 1 ml), and the absence (---) (Toluene, 10 ml) of bromobenzene: Adduct (○), hydrogenation product (●); irradiation was carried out above 300 nm for 30 hr at 25 °C.

starting imine I as an impurity determined by glpc and that added separately. The yields of both products increased linearly with the concentration of benzophenone, each slope in the presence of bromobenzene being nearly the same as that in its absence, respectively. The full and dashed lines indicate the experimental data and the dotted lines show the extrapolation of the results.

Discussion

The heteroaromatic compound containing a nitrogen atom has been thoroughly investigated both in spectroscopy and in photochemical reactions.[21] The simple acyclic compound containing a C=N bond shows very low photoreactivity,[17,22] and no photoemission.[17] Since the excited state of *N*-acetylketimine I cannot be clarified in spectroscopy, it is difficult to determine its photoreaction mechanism. The sensitization experiment, a procedure for determining the excited triplet state energy indirectly, are not useful for estimating the energy level of the triplet state, since the sensitizers with the hydrogen abstracting character in their excited states can act as the so-called "chemical sensitizer."[17] Sensitization technique is inadequate for determining the triplet state of I, since the sensitizer of a low triplet energy with a hydrogen abstracting character can promote the reaction of I.

Reaction Processes and Heavy Atom Effects. From the results of previous investigation, we proposed a reaction scheme as follows:[15]

Scheme 1.

$$D \xrightarrow{h\nu} {}^3D \quad (1)$$

$${}^3D + RH \xrightarrow{k_a} \cdot DH + \cdot R \quad (2)$$

$$\cdot DH + \cdot R \xrightarrow{k_{cc}} DHR \quad (3)$$

$$2\dot{D}H \xrightarrow{k_D} DH_2 + D \quad (4)$$

$$2\dot{R} \xrightarrow{k_c} R_2 \quad (5)$$

$$B \xrightarrow{h\nu} {}^3B \quad (6)$$

$${}^3B + RH \xrightarrow{k_a'} \cdot BH + \cdot R \quad (7)$$

$$\cdot BH + D \xrightarrow{k_h} \cdot DH + B \quad (8)$$

where D is *N*-acetylketimine I, RH is toluene, B is benzophenone, ·DH is the α-amino radical derived from D by the hydrogen atom abstraction, ·BH is a benzophenone ketyl radical, and DHR and DH_2 are the adduct and the hydrogenation product, respectively.

For a detailed discussion of the external heavy atom effect, the primary processes (Eqs. 1 and 6) should be separated more precisely as shown in Scheme 2.

Scheme 2.

$$D \xrightarrow{h\nu} {}^1D \quad (1a)$$

$${}^1D \xrightarrow{k_{1e}} D \quad (1b)$$

$${}^1D \xrightarrow{k_{1s}} {}^3D \quad (1c)$$

$${}^3D \xrightarrow{k_d} D \quad (1d)$$

$$D \xrightarrow{h\nu'} {}^3D \quad (1e)$$

$$B \xrightarrow{h\nu''} {}^1B \quad (6a)$$

$$ {}^1B \xrightarrow{k_{ic}'} B \quad (6b) $$

$$ {}^1B \xrightarrow{k_{is}'} {}^3B \quad (6c) $$

$$ {}^3B \xrightarrow{k_d'} B \quad (6d) $$

$$ B \xrightarrow{h\nu'''} {}^3B \quad (6e) $$

All possible processes influenced by the heavy atom effect should be considered. They are: (a) an intersystem crossing from the lowest singlet state to the triplet state of the imine I or benzophenone (Eqs. 1c and 6c), (b) a radiative or radiationless decay from the lowest triplet state to the ground state (Eqs. 1d and 6d), (c) light absorption to the triplet state directly from the ground state (Eqs. 1e and 6e), and (d) coupling of two radicals (Eqs. 3 and 5).

A heavy atom promotes the S–T_{π,π^*} transition, but not S–T_{n,π^*} transition.[7,23] In fact, no external heavy atom effect on the yield of the photoreaction of I with toluene was observed on irradiation with light over 390 nm in the presence of benzil. Since light in this region can be absorbed by benzil[24] but not by I or benzophenone, the lowest n,π^* triplet state of benzil not being influenced by the heavy atom effect, the reaction yields were insensitive to the heavy atom solvent. Consequently the processes of Eqs. 6c and 6d (the rate constants of which are k'_{is} and k'_d, respectively) and the transition from the ground singlet state to the excited triplet state of benzophenone (Eq. 6e) should not be susceptible to the heavy atom effect.

The heavy atom effect was negligible for the direct excitation from a ground state to a triplet state of imine I (Eq. 1e), since the toluene solution of imine I under the usual reaction conditions exhibited no S_0–T absorption in the presence of the heavy atom solvent.

A possible process influenced by a heavy atom solvent other than those described above is the hydrogen abstraction step of imine I (Eq. 2). In this process the halo-solvent would act as a polar solvent rather than as a heavy atom solvent. But this is not true since acetonitrile, a polar solvent, exerts no solvent effect (see Table 2). Another possibility is that the halo-solvent decomposes on irradiation to produce radicals which accelerate the photoreaction of I with toluene. In order to exclude this possibility, the heavy atom effect of 1-bromopropane and 2-bromopropane were compared. If the breaking of the C–Br bond occurred on irradiation of bromopropane under the present conditions, the effect of 2-bromopropane would be much larger than that of 1-bromopropane. The experiments indicated a tendency rather contrary to the hypothesis. (Total yield in 1-bromopropane is 5.2% and in 2-bromopropane 3.9% under the same conditions with the use of a merry-go-round type apparatus.)

Consequently, the processes of Eqs. 1c and 1d (k_{is} and k_d, respectively) are noticeably susceptible to the heavy atom solvent.

Comparison of the Two Main Processes Effected by the Heavy Atom Solvent. A heavy atom solvent influences the rate of the processes of Eqs. 1c and 1d. The next problem is whether the rate of the process of Eq. 1c or that of Eq. 1d is much more influenced by a heavy atom solvent. The heavy atom effect on the rate constant k_{is} causes an increase in the product yield, and the effect on the rate constant k_d a decrease in it.

The increasing reactivity of imine I in the heavy atom solvent demonstrates the influence of the heavy atom effect on the increase in the rate of process of Eq. 1c (k_{is}) in the present case. The results of the photoreaction of imine I with toluene in the presence of various amounts of bromobenzene are shown in Fig. 1, which shows a typical saturation curve.[10]

There are two possible mechanisms to explain the saturation in yields when a large amount of bromobenzene is added: One is the balance between the two successive processes, *i.e.*, the intersystem crossing process from the excited singlet state to the triplet state and the deactivation process from the excited triplet state to the ground state. The quantum yield of the intersystem crossing is known to increase greatly in the presence of a small amount of the heavy atom solvent, being effected to a greater extent by the heavy atom solvent than that of the radiative and radiationless decay.[4] However, when a greater amount of a heavy atom solvent is added, the increment of the intersystem crossing quantum yield becomes small, and the rate of the radiative and radiationless deactivation processes begins to increase gradually, the total yield of the photoreaction of imine I with toluene reaching saturation. If an extremely heavy atom solvent is used, the balance would break resulting in a decrease in the product yield.[25] However, this has not yet been reported to occur in the brominated solvent.

As regards the other explanation for the saturation, the total yield of the photoreaction depends only on the quantum yields of the intersystem crossing, which reach the upper limit at a high concentration of a heavy atom solvent, since only a limited number of heavy atoms can exist in the definite surroundings of an imine molecule under these conditions according to the special interaction between imine I and a heavy atom solvent molecule. In this case, it is assumed that the rate of deactivation of the excited triplet to the ground state is not so susceptible to the heavy atom solvent, or the rate of the intersystem crossing is great enough to neglect that of the deactivation process. The assumption is valid since the deactivation process of an imino compound from its excited triplet to the ground state has been proposed to be very rapid.[17] It is impossible in the present stage to determine which of the two views is adequate because of the absence of the means to see the excited state of *N*-acetylketimine I precisely.

Dependence of the Heavy Atom Effect upon the Kind of Halogenated Solvents. A strong evidence for the external heavy atom effect on the present photoreaction is that the photoreaction yield is dependent on the kind of solvent (Table 2). On irradiation of imine I in toluene with 1 ml of a chlorinated solvent, the reaction rate was promoted only by chloroform which contains three chlorine atoms in a molecule, while no promotion of the reaction rate was observed with 1 ml of propyl chloride or chlorobenzene having one chlorine atom in a molecule. However, the presence of 5 ml of each kind of chlorinated solvent in the solution slightly

increased the reaction yield. On the other hand, 1 ml of each kind of brominated solvent in the reaction system drastically promoted the reaction of imine I to the same extent as did 5 ml of the bromo-solvent. The dependence of the yield on the kind of 1 ml of brominated solvent is contrary in the order to that of 5 ml of the solvent. The curious result suggests that the concentration of the bromo-solvent where the saturation of the heavy atom effect occurs is depending on the kind of brominated solvent. Namely, the reaction yield in the presence of 1 ml of dibromomethane could already start to saturated by the same way as shown in Fig. 2 or to decrease from the upper limit by the same way as proposed by Cowan and Koziar.[25]

The effect of a heavy atom solvent on the probability of the transitions in the present photoreaction can be attributed to the indirect mixing mechanism.[8,9,26,27] The singlet state of the solute is mixed electrostatically with the singlet state of the solvent, while the triplet state of the solute is mixed with the triplet state of the solvent. Since the solvent contains a heavy atom, the singlet and triplet states of the solvent are strongly mixed by a spin-orbit interaction. The allowedness of the solvent S–T transition relaxes the spin forbiddenness of the solute S–T transition under consideration.

The probability (P) of the transition has been proposed to be proportional to the square of the spin-orbit coupling parameter (ζ) of the solvent:

$$P \propto \zeta^2$$

Some experimental results were discussed in terms of ζ.[1,4,10] A certain correlation between the photoreaction of N-acetylketimine I and the ζ values of the heavy atom solvent is expected. The total product yields in the presence of 1 ml of the halo-solvent of Table 2 are plotted in Fig. 3 against the square of the ζ value of the various kinds of solvents. The yield and the square of the ζ value roughly show a linear relationship. This clarifies the fact that the solvent in this reaction shows an external heavy atom effect and that the

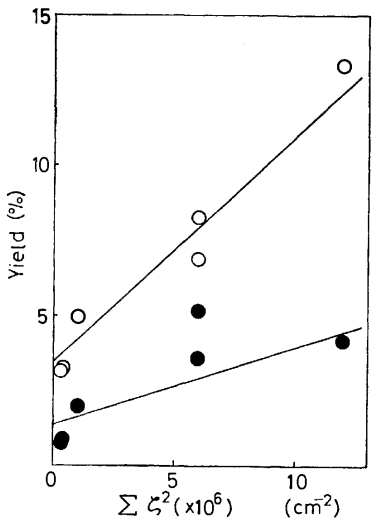

Fig. 3. Dependence of the yields of the photoreaction of N-acetylketimine I with toluene on $\sum$ (ζ^2) values of the heavy atom solvents: Adduct (○), hydrogenation product (●).

mechanism we proposed is in good agreement with the experimental results.

The other explanation proposed for the external heavy atom effect is the charge transfer complexation between the solute and the solvent.[4] The contribution of the charge transfer interaction might be small in our case, since the toluene solution of imine I in dibromomethane showed no absorption in an electronic spectrum. However, the yield in the presence of 1 ml of bromobenzene was larger than in propyl bromide, which result might be due to the acceptor character of the solvents, since no difference is expected in their ζ values. The charge transfer mechanism would be concluded to contribute a little to the photoreaction of imine I.

Relationship between Heavy Atom Effects and Chemical Sensitization. The spectroscopic data from the excited benzophenone was insensitive to the heavy atom solvent.[7] This is in line with the present finding that the effect of benzophenone exhibits no difference in the presence and the absence of a heavy atom solvent in the photoreaction of imine I with toluene. The product yields increase linearly with increasing amount of benzophenone both in benzene and bromobenzene, and the slopes of the line for the adduct and the hydrogenation product yields in the presence of the heavy atom solvent are nearly the same as those without any heavy atom solvent, as shown in Fig. 2. The photoreaction influenced by benzophenone is indifferent to the heavy atom effect. This result is in line with the conclusion that benzophenone can act only as a chemical sensitizer.[15]

The polar effect by the halogenated solvents was not observed in the reaction (Fig. 2), just as the photoreaction of I with toluene in acetonitrile showed no difference from that in benzene (Table 2). This result shows that the reaction *via* chemical sensitization by benzophenone is not influenced by the polar effect. It can be concluded that most parts of the products were produced *via* the excited state of imine I not *via* chemical sensitization in the presence of the heavy atom solvent.

Reaction State of N-*Acetylketimine I.* A point of further interest in connection with the photoreaction of imine I was its reactive state. In the present photoreaction, a high pressure mercury lamp with a Pyrex filter was used for irradiation. Imine I has a π-π^* absorption maximum at 250 nm and tailing with shoulders above 300 nm.[15] It is difficult to say whether the lowest excited singlet state is a π,π^* state or a n,π^*. On the basis of our previous work and the present results of the heavy atom effect,[15] it was confirmed that the reactive state was the excited triplet state of imine I. The observed heavy atom effects on its photochemical behavior support the view that the lowest excited triplet state has a π,π^* character. However, a hydrogen abstracting character may usually belong to the $T_{n,\pi}$ state.[28] Consequently, it could be concluded that $T_{\pi,\pi}$ and $T_{n,\pi}$ states lie closely and are mixed with each other in the case of imine I.

The photoreaction of N-acetylketimine I with toluene was noticeably susceptible to the heavy atom solvent and the yields of the adduct and the hydrogenation product remarkably increases in the presence of the

heavy atom solvent. Though the imino compound has been explained to be not the active hydrogen-abstracting species on irradiation and the photoreduction of the imino compound has been interpreted by a chemical sensitization mechanism, the hydrogen abstracting character of the excited state of imine I is strongly supported by the external heavy atom effect.

Experimental

Materials. Toluene and benzene (Yoneyama Chemical Industry) were dried over sodium by refluxing and distilled. *p*-Fluorotoluene, *p*-chlorotoluene, *p*-bromotoluene, propyl chloride, propyl bromide, and dibromomethane (Tokyo Chemical Industry), and chlorobenzene and bromobenzene (Yoneyama Chemical Inductry) were dried over anhydrous magnesium sulfate and distilled. Benzophenone (Yoneyama Chemical Industry) and benzil (Tokyo Chemical Imdustry) were recrystallized from ethanol. *N*-Acetyldiphenylmethyleneamine (I), bp 168—170 °C/1 mmHg (lit,[29] bp 168—170 °C/1 mmHg), was prepared by the reaction of diphenylmethyleneamine[29] with acetic anhydride and distilled repeatedly.[30]

Instrumentation. Most comparative runs were carried out on a "merry-go-round" type reactor (Riko Kagaku Ltd.) with a turntable device holding ten rotating Pyrex tubes. This turntable also rotates around the irradiation lamp in a water cooled quartz immersion well. The turntable and tubes are held in a constant temperature water bath maintained at 25 °C. Irradiation was carried out with a 500 W high pressure mercury lamp (Eikōsha Ltd.). Glpc analysis was accomplished on an Ohkura Rikagaku gas chromatograph employing a 2 m×3 mmϕ stainless steel column packed with 10% Apiezon Grease L on 60—80 mesh Chromosorb W (HP). High speed liquid chromatography was taken on a Waters ALC-202 high speed liquid chromatograph with a 600 type high pressure pump, a U6K universal injector, and a 660 type solvent programmer. A stainless steel column with Microporasil and chloroform as an eluting solvent were used. Infrared spectra were obtained on a JASCO IR-E spectrometer. NMR spectra were recorded on a JEOL PS-100 or a Hitachi Perkin-Elmer R-20B spectrometer. Mass Spectra were taken on a Hitachi RMS-4 spectrometer. Melting point was determined on a Yanagimoto micro melting point apparatus, and was not corrected.

Photoreaction of N-*Acetylketimine I with* p-*Fluorotoluene.* A *p*-fluorotoluene (30 ml) solution of *N*-acetylketimine I (0.14 mol/l) in a Pyrex tube was degassed in three successive freeze-thaw cycles, and was irradiated under nitrogen with a 500 W high pressure mercury lamp for 100 hr. After irradiation, *p*-fluorotoluene was distilled off at a reduced pressure and the residue were separated by a column chromatography on 100 mesh Marincrodt silica gel. The fraction eluted with benzene contained I. The adduct and the hydrogenation product were eluted separately with chloroform in 4.2 and 1.2% yields, respectively. Yields mean per cent conversion of the starting imine I.[20] The remainder of the imine was recovered in each case. These products were purified by repeated recrystallization from the mixed solvent of cyclohexane and ethanol. The hydrogenation product was identified by comparing the spectral data and by the fact that no melting point depression took place with an authentic sample.[22] The structure of the adduct (mp 197.0—197.7 °C) was inferred from its composition (Found: C, 79.52; H, 6.18; N, 4.49; F, 5.60%; mol wt, 333 by mass spectra. Calcd for $C_{22}H_{20}NOF$: C, 79.23; H, 6.06; N, 4.20; F, 5.70%; mol wt, 333.2.) and the spectral data: The infrared spectra had an amide absorption (ν_{NH}, 3400; ν_{CO}, 1600; δ_{NH} 1530 cm^{-1}) and NMR spectra in $CDCl_3$ showed ten phenyl protons at δ 7.32—6.84, an NH proton at δ 6.15, two methylene protons at δ3.92, and three acetyl protons at δ1.95. The A_2B_2 pattern of four phenyl protons of *p*-fluorobenzyl group splitts into two quartets (δ 6.82, 6.74, 6.60, 6.52; J=8 Hz: δ 6.74, 6.66, 6.54, 6.46; J=8 Hz).

Photoreaction of N-*Acetylketimine I with* p-*Chlorotoluene.* A *p*-chlorotoluene (30 ml) solution of *N*-acetylketimine I (0.14 mol/l) was irradiated under the same conditions as in the photoreaction of imine I with *p*-fluorotoluene, the adduct and the hydrogenation product being obtained in 11.0 and 4.0% yields, respectively. The structure of the adduct was identified as *N*-[1,1-diphenyl-2-(*p*-chlorophenyl)ethyl]acetamide mp 224.0—224.8 °C. Found: C, 75.80; H, 5.57; N, 4.30; Cl, 10.37%; mol wt, 349 by mass spectra. Calcd for $C_{22}H_{20}NOCl$; C, 75.51; H, 5.78; N, 4.00; Cl, 10.14%; mol wt, 349.6. Infrared spectra had an amide absorption (ν_{NH}, 3325; ν_{CO}, 1657; δ_{NH}, 1525 cm^{-1}). NMR spectra showed ten phenyl protons at δ 7.60—6.85, four phenyl protons of A_2B_2 pattern specific for *p*-disubstituted benzene at δ 7.02, 6.96, 6.53, and 6.47 with J=6 Hz, an NH proton at δ 6.10, two methylene protons at δ 3.93, and three methyl protons at δ 1.94.

Photoreaction of N-*Acetylketimine I with* p-*Bromotoluene.* A solution of *N*-acetylketimine I (0.14 mol/l) with *p*-bromotoluene (30 ml) was irradiated under similar conditions to those described before, the adduct and the hydrogenation product being obtained in 20.3 and 24.5% yields, respectively. The adduct was determined as *N*-[1,1-diphenyl-2-(*p*-bromophenyl)ethyl]acetamide: mp 223.0—223.6 °C. Found: C, 67.04; H, 5.12; N, 3.60; Br, 20.24%; mol wt, 394 by mass spectra. Calcd for $C_{22}H_{20}NOBr$: C, 66.99; H, 5.13; N, 3.55; Br, 20.25%; mol wt, 394.1. NMR analysis (in $CDCl_3$) showed ten phenyl protons (δ 7.46—6.78), four phenyl protons of A_2B_2 pattern specific for *p*-disubstituted benzene (δ 7.17, 7.09, 6.52, 6.44; J=8 Hz), an NH proton (δ 6.15), two methylene protons (δ 3.92), and three acetyl protons (δ 1.96), and IR spectra had an amide absorption (ν_{NH}, 3325; ν_{CO}, 1657; δ_{NH}, 1530 cm^{-1}).

Effect of the Solvents and Benzophenone Added. The benzene solution of *N*-acetylketimine I (2.3 mmol) and toluene (5 ml) with or without benzophenone in the presence of a certain amount of heavy atom solvents in a Pyrex tube was degassed in three successive freeze-thaw cycles and irradiated under nitrogen with a 500 W high pressure mercury lamp at 25±1 °C for 30 hr using a merry-go-round type reactor. After irradiation, toluene was distilled off at reduced pressure and the residue was analyzed by a gas chromatography equipped with a 2 m×3 mmϕ column on 10% Apiezon Grease L 60—80 mesh Chromosorb W(HP) or a high speed liquid chromatography on Microporasil using chloroform as an elution solvent. Yields were shown in terms of per cent conversion of the starting imine I. The remainder of the imine was recovered in each case.[20]

Dependence of the Yields of the Photoreaction of N-*Acetylketimine I upon the Concentration of Bromobenzene.* Ten milliliters of benzene solutions containing 0.23 mol/l of *N*-acetylketimine *I*, 5 ml of toluene, and various amounts of bromobenzene (0—4.3 mol/l) were placed in Pyrex tubes, which were then degassed in three freeze-pump-thaw cycles, substituted by nitrogen, and irradiated with 500 W high pressure mercury lamp at 25±1 °C for 30 hr using a merry-go-round type reactor. The reaction mixtures were analyzed by a high speed liquid chromatography employing a stainless steel column with Microporasil using chloroform as an eluting solvent. Results are shown in Fig. 1. Yields are given in terms of per cent conversion of the starting imine I.[20]

Cation, Solvent, and Substituent Effects on the Optical Spectra of Alkali Metal Salts of Arylthiolate Anions

Tokuji MIYASHITA, Takao AOKI, and Minoru MATSUDA

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received May 19, 1975)

The optical spectra of the alkali metal salts of arylthiolate anions have been studied in the two aprotic solvents, tetrahydrofuran (THF) and dimethylformamide (DMF). In the former solvent the position of the absorption maxima depends on the size of the counter cations, even at low temperatures (−72 to −76 °C); nearly linear relationships were observed between the inverse of the alkali metal radius (r_c) and the wave number of the transition ($\bar{\nu}_{max}$) for both room and low temperatures. The intercepts for the extrapolation of both lines for $1/r_c \to 0$ agree with the $\bar{\nu}_{max}$ of the ion pairs observed in DMF at room temperature, and the absorption maxima for this solvent are independent of the size of the counter cations. Thus, the existence of contact ion pairs in THF over the temperature range investigated and that of the solvent-separated ion pairs in DMF at room temperature were revealed. In the latter solvent, however, a hypsochromic shift was observed on lowering the temperature. The substituent effect of arylthiolate anions and the solvent effect of dimethoxyethane and dioxane on the absorption maxima are also discussed. From an inspection of optical spectral data it has been suggested that negative charge of arylthiolate anions is localized mainly on the sulfur atom.

Since the first suggestion by Weinstein that the equilibrium between contact (or intimate) and solvent-separated ion pairs may be established in solutions of low dielectric constant[1] and the further development of this idea by Grunwald,[2] there have been extensive investigations of ion pairs in solutions.[3] Direct evidence for the existence of two distinct types of ion pairs was first demonstrated by optical spectra on cooling a THF solution of alkali metal salts of fluorenyl anions (carbanions)[4] and, though not simultaneously, by ESR studies of alkali metal naphthalenides (radical anions).[5]

In this paper the cation, solvent, and substituent effects on the optical spectra of alkali metal salts of arylthiolate anions is reported. The optical spectra of ion pairs other than carbanions have been studied with the alkali metal salts of phenols and enols[6] and with tetraalkylammonium iodides,[7] but there is no information about the thiolate anions which have a negative charge on the sulfur atom. The phenylthiolate anion is said to be a stronger nucleophile than the corresponding isoelectronic phenoxide ion,[8] and interesting results have been reported in other reactions of thiolate anions to double and triple bonds and also to carbonyl groups.[9,10] Nucleophilic substitutions with these anions are also interesting; the rate increases in dipolar aprotic solvents (*e.g.*, DMF)[11] and electron transfer from the *n*-butylthiolate anion to oxygen in solutions is accelerated in the order methanol<THF< dimethoxyethane (DME)<DMF and is also affected by counter cations ($Na^+ < K^+ < Rb^+ < Cs^+$).[12] These results can be explained by an increase in reactivity caused by changes in the strength of the thiolate anion-counter cation binding.

Thus, it is interesting to investigate the optical spectra of the solutions of alkali metal salts of arylthiolate anions; the effects of the size of the counter cation, solvent, and of the introduction of substituents at the *para*-position on the absorption spectra give some information about the nature of thiolate anions, *i.e.*, the stronger nucleophilic character of thiolate anions can be revealed by an inspection of spectral data.

Experimental

Diphenyl disulfide, acquired commercially, was recrystallized three times from ethanol. Di-*p*-chlorophenyl-, di-*p*-methylphenyl-, di-*p*-methoxyphenyl-, and di-*p*-*t*-butylphenyl disulfide were synthesized from the oxidation of the corresponding thiols and recrystallized three times from ethanol.

Alkali metal salts of arylthiolate anions were prepared from the reduction of the corresponding symmetric aryl disulfides with an appropriate alkali metal in THF,

$$\text{RS–SR} + \text{alkali metal} \xrightarrow{\text{in THF}} \text{RS}^-, \text{M}^+ + \text{RS}\cdot$$

$$\text{RS}\cdot + \text{alkali metal} \longrightarrow \text{RS}^-, \text{M}^+$$

$$\text{RS}\cdot + \text{RS}\cdot \longrightarrow \text{RS–SR}$$

The purification of solvents and the reduction of the disulfides with alkali metals in the solvents were carried out on a high vacuum line using a technique described in Ref. 3b.

Solutions of thiolate anions in solvents other than THF were usually prepared from the corresponding THF solution by removing the THF under vacuum and distilling the appropriate solvent onto the dry salt.

Electronic spectra were recorded with a Cary 14-UV spectrophotometer, using 0.2 cm quartz optical vacuum cells with some measurements made with a 0.18 cm spacer. Concentrations of thiolate anions could be varied by transferring a part of the sample to an adjacent glass ampoule and by distilling the solvent back by cooling the cell. Using this technique, concentrations were adjusted to give optical densities of 0 to 2. A quartz dewar with optical windows was used for the low temperature measurements and precooled methanol with liquid nitrogen was chosen as the cooling liquid. Dry nitrogen gas was blown onto the optical windows to prevent the formation of a frost covering. The temperature of methanol was recorded with a copper-constantan thermocouple located in the vicinity of the cell.

The concentrations of the sodium salt of phenylthiolate anion in THF were determined by the titration of thiolate anions with silver nitrate using a dithizone as an indicator or by electron transfer from thiolate anions to chloranil in THF forming chloranil radical anions having a known molar extinction coefficient,[13] and then, by estimating the molar extinction coefficient of the sodium salt of phenylthiolate anion.

Results

The alkali metal salts of thiolate anions were found to be stable in both THF and DMF over the temperature range investigated (25 to −76 °C) and the optical spectra exhibited sharp absorption bands at 280 nm in THF and at 308 nm in DMF at room temperature. The decimal extinction coefficient of the sodium salt of phenylthiolate anion in THF was found to be about 10^4 l/mol·cm. However, the spectrum of the cesium salt of phenylthiolate anion in THF showed a rather broad band.

Optical Spectra in THF. The position of the absorption maxima (λ_{max}) in THF depended upon the size of the counter cation, temperature, and structure of the thiolate anions. However, it was found that a 100-fold dilution of a *ca.* 10^{-3} mol/l solution did not alter the position; the independence of the position of the absorption maximum on the concentration excludes the possibility of an association of ion pairs under the conditions of the experiment (the concentrations were usually about 10^{-4} mol/l). The position of the absorption maxima of the phenylthiolate anion in THF was shifted toward longer wavelengths when the radius of the counter cations increased and the same phenomenon was observed even at low temperature (−72 to −76 °C); nearly linear relationships were observed between the inverse of the counter cation radius ($1/r_c$) and the wave number of the transition ($\bar{\nu}_{max}$) for both room and low temperatures, as depicted in Fig. 1 (see also Table 1). It is interesting to note that the alkali metal salts of phenylthiolate anions in THF exhibit a single sharp absorption band regardless of the temperature, and at intermediate temperatures the two isolated bands were not observed and no shoulder appeared.

The effect of *para*-substituents of the alkali metal salts of arylthiolate anions on the λ_{max} in THF is shown in

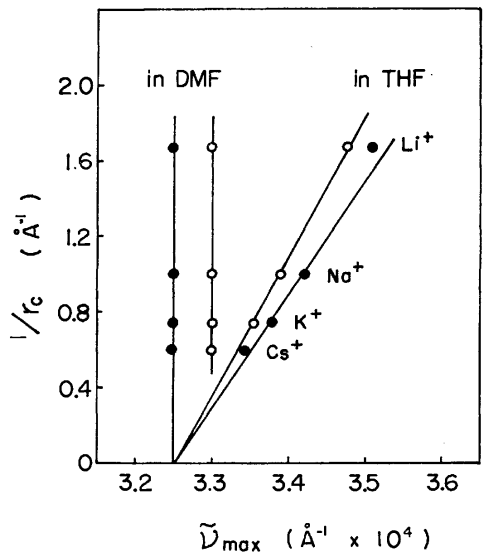

Fig. 1. Relationships between the inverse of the counter cation radius ($1/r_c$) of alkali metal salts of phenylthiolate anions and the wave number of the transition ($\bar{\nu}_{max}$) in THF and DMF. Black and open circles represent the values obtained in room and low temperatures, respectively.

Table 1. Dependence of λ_{max} on the radius of the counter cation (r_c) for alkali thiolate salts in THF and DMF at room and low temperatures

Counter cation	r_c Å	λ_{max}, nm in THF		in DMF	
		20 °C	low temp.(°C)	20 °C	low temp.(°C)
Li^+	0.60	285	287(−72)	308	303(−63)
Na^+	0.96	292	295(−75)	307	303(−43)
K^+	1.33	296	298(−76)	308	303(−62)
Cs^+	1.66	299		308	303(−60)

Table 2, and Fig. 2 shows a plot of the wave number against the Brown-Okamoto substituent constants.

Optical Spectra in DMF. The λ_{max} observed at both room and low temperatures are assembled in Table 1 and depicted in Fig. 1 together with the data in THF. The position of the absorption maximum was not affected by the counter cation (308 nm) and agreed with the extrapolated wave number of both lines obtained in THF for $1/r_c \to 0$. On lowering the temperature to *ca.* −70 °C a hypsochromic shift was observed (303 nm).

Table 2. Substituent effects of sodium arylthiolate anions on λ_{max} in THF at 20 °C

Substituent	CH_3O–	CH_3–	t-C_4H_9–	H–	Cl–
λ_{max}(nm)	279	290	292	292	297

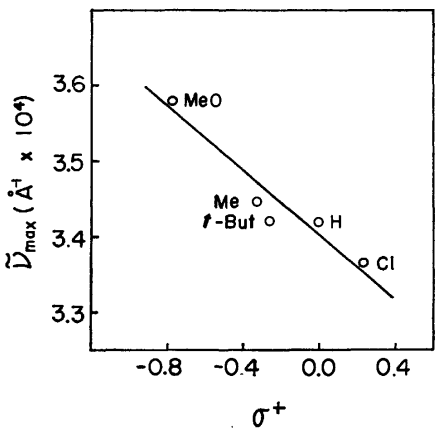

Fig. 2. Relationship between $\bar{\nu}_{max}$ of sodium arylthiolate anions in THF at room temperature and Brown-Okamoto's substituent constant in the Hammett equation (σ^+).

Optical spectra in other solvents, dimethoxyethane (DME) and dioxane, were also measured. These salts were also found to be stable in the solvents. The λ_{max} are given in Table 3.

Table 3. Solvent effects of phenylthiolate salts on λ_{max}(nm) at 20 °C

	Dioxane	THF	DME	DMF
$C_6H_5S^-$, Li^+		285	286	308
$C_6H_5S^-$, Na^+	279	292	292	307

Discussion

The sharp absorption bands observed in THF depended upon both the counter cation and the temperature; even at low temperatures (−72 to −76 °C) the position of the absorption maximum was shifted toward longer wavelengths with increasing size of the counter cation and a nearly linear relationship is observed between the inverse of the counter cation radius r_c and $\bar{\nu}_{max}$ (Fig. 1). A similar bathochromic shift for increasing size of the counter cation has been found for alkali metal salts of fluorenyl anions,[14] phenoxide ions,[6] and ketyl radical anions.[15] The independence of λ_{max} on the concentration has been observed for the sodium salt of phenylthiolate anion in THF. Thus, the shift in THF can be explained as a result of the formation of contact ion pairs, and the cause of the shift has been explained[4] as a perturbation of the molecular energy levels by the positive field of the cation, and a perturbation depends on the electrostatic interaction energy. The excited state is less stable due to the counter cation than the ground state, since in the ground state of an ion pair, the cation is located so as to form the smallest dipole, and a redistribution of charge occurs upon excitation, but as expected from the Franck-Condon principle, the cation has no time to readjust its position. Thus, the smaller the cation the larger the transition energy.[14]

As has been described above the relations for THF depicted in Fig. 1 strongly suggest that the alkali metal salts of phenylthiolate anions in THF exist as contact ion pairs and on lowering the temperature these may interact strongly with the surrounding THF molecules to form on its periphery a slight rigid coordination shell. Such an interaction is expected to be exothermic; the counter cations in contact ion pairs may interact more strongly with THF molecules on lowering the temperature. Although the alkali metal salts of phenylthiolate anions in THF at low temperature may still be classified as tight ion pairs, the strong interaction of THF with counter cations apparently results in a dispersion of positive charge (external solvation) and thus in a slight increase in the average interionic distance between the metal cation and thiolate anion, causing the bathochromic shift.

The process which is responsible for the shift of the position of the absorption maxima is reversible with temperature, but no new isolated band or shoulder appeared at intermediate temperatures, indicating that no discrete types of ion pairs such as contact and solvent-separated ion pairs were present in THF over the temperature range investigated. However, sodium fluorenyl salt in the same solvent exists as discrete types of ion pairs at intermediate temperatures (−30 °C).[14] This is probably attributable to a difference in the nucleophilic characters of carbanions and thiolate anions. The interionic interaction between anions and counter cations may be strengthened by the localization of the negative charge. This appears to be the case for our thiolate anions, since bathochromic shifts with counter cations are observed in THF even on lowering the temperature. Furthermore, this may be supported by the fact that the sodium phenoxide ion and the sodium benzyl carbanion, isoelectronic anions of the thiolate anion, have absorption bands at 303[6] and 355[16] nm, respectively. On the other hand, the λ_{max} of the thiolate anions appears at 285 to 290 nm depending on the counter cation, solvent, and substituent, indicating that the localization of the negative charge on the sulfur atom of thiolate anion could be greater than that on the carbon atom of carbanions.

The intercept $\bar{\nu}^{\circ}_{max}$ obtained on extrapolation of both lines plotted for THF as $1/r_c \rightarrow 0$ agrees with the wave number of the ion pairs observed in DMF at room temperature and no bathochromic shift with counter cation is observed at all in DMF. Thus, it may be safely stated that the entity observed in DMF is solvent-separated ion pairs or solvated free ions, even at room temperature (no difference has been reported in the positions of the absorption maxima of the solvent-separated ion pair and free ion[14]), since the position of the absorption maxima of the ion pairs in DMF at low temperature was not subject to the influence of counter cation (308 nm) (the fraction of free thiolate anions in the investigated solutions should be less than a few percent on the basis of the data reported for solutions containing alkali metal salts of carbanions and radical anions (*e.g.*, Ref. 14). The interionic interaction between a thiolate anion and a counter cation may be weakened by the DMF molecules separating both ions; the anion in the solvent-separated ion pairs is not subject to the influence of the counter cation. A similar observation was made on some alkali metal salts of phenols and enols in DMF.[6] The hypsochromic shift observed on lowering the temperature in DMF (308 to 303 nm) is quite interesting. Two causes could account for such a hypsochromic shift. (1) The negative charge of the thiolate anions may localize on the sulfur atom and hence such anions may exist as a dipolar molecules and be stabilized by an interaction with DMF molecules in the ground state. However, in an excited state, such solvating DMF molecules cannot be rearranged as expected from the Franck-Condon principle giving rise to orientational strain,[17] and thus stablilizing ion pairs. Therefore, thiolate anions in DMF are stabilized on lowering the temperature in the ground state and, on the contrary, the excited state is destabilized, and a hypsochromic shift is expected. (2) It is apparent that thiolate anions in DMF are solvent-separated ion pairs, even at room temperature. On lowering the temperature, however, the strength of the interaction of the DMF separating an ion pair with both the counter cation and the thiolate anion (for more detail, see the discussion of the solvent effect) may increase; *i.e.*, the average interionic distance between the metal cation and the thiolate anion may decrease on lowering the temperature, causing the hypsochromic shift.

As shown in Table 3, the positions of the absorption maxima of the lithium and sodium salts of phenylthiolate anions in the four aprotic solvents shifted toward longer wavelengths; the ease of solvation to the counter cation can be evaluated from the extent of the shift of the position of the absorption maxima, thus, dioxane<

THF<DME<DMF. This order is essentially the same as in the case of the formation of the solvent-separated ion pairs of the alkali metal salts of fluorenyl anions[14] except for DMF (in that study no DMF was used), and is also consistent with the order reported for electron transfer from sodium *n*-butylthiolate anions in solutions to oxygen which was described in the introduction,[12] indicating that the case of electron transfer depends upon the solvation state of the ion pair. Dioxane appears to be a poor solvating agent for alkali cations in view of the reported data on the shift of the absorption spectra of some ion pairs with changing solvents[14] and the position occupied by THF in this order is reasonable. A comparison of the solvating ability of DMF with that of DME can be made for the proton hyperfine coupling constants of alkali metal salts of fluorenone radical anion;[20] DMF yields free ions while DME produces contact ion pairs. Thus, the order obtained here seems, on the whole, plausible. At first sight, the behavior of DME for the lithium salt of phenylthiolate anion may appear strange, since fluorenyl lithium undoubtedly forms a solvent-separated ion pair, even at room temperature. Since the negative charge on thiolate anions is localized mainly on the sulfur atom, arylthiolate anions exist as tight ion pairs even in DME.

It is well known that DMF is a polarizable powerful base like dimethyl sulfoxide and hexamethylphosphoric triamide and the negative charge on the DMF is localized on a bare oxygen atom (the nucleophilicity is centered on this oxygen atom[18]) and DMF possesses a positively-charged nitrogen atom (this is conceivable from NMR data). DMF has a higher dielectric constant (36.7 at 25 °C) than THF (7.4 at 25 °C), but it is obvious that the solvating properties of the solvent rather than its dielectric constant are of prime importance;[19] thus the DMF yields solvent-separated ion pairs by utilizing both sites, one negatively- and the other positively-charged.

As can be seen from Table 2 and Fig. 2, the effects of substituents are reflected on the position of the absorption maxima. As has been described above, the negative charge of the thiolate anions is localized mainly on the sulfur atom, and thus, conjugation between the negative charge located on the sulfur atom and the phenyl ring is not so large. This is also obvious realized from the fact that pK_a of hydrogen sulfide (7.5) roughly equals that of phenylthiol (6.5). In oxide homologues, pK_a of water is 15.8 and that of phenol is 10, thus the oxide anions are stabilized by conjugation with the phenyl ring.[9] Therefore, no substituent effect on the position of the absorption maxima can be expected in the ground state. In general, in $\pi \rightarrow \pi^*$ transitions of odd alternant benzyl-type aromatic hydrocarbons, the excited state is stabilized by conjugation with the substituent, causing a bathochromic shift, *i.e.*, the contribution of the structure  (I) to the excited state produces the stabilization of the excited state (an inductive substituent effect results in only a slight bathochromic shift).[21] This appears to be the case for the substituent effects observed in the optical spectra of sodium metal salts of arylthiolate anions. The greater the localization of the negative charge on the sulfur atom in the ground state, the larger the contribution of structure (I) in the excited state should be, thus a larger bathochromic shift is expected than those caused by the effects of the counter cation and the solvent.

Substituent Effects for the Benzene Ring on Solvolysis of 3,4-Benzotricyclo[4.3.1.0^{1,6}]dec-3-en-2-yl *p*-Nitrobenzoate

Katsuo OHKATA

Chemistry Department, Faculty of Science, Hiroshima University, Higashi-senda-cho, Hiroshima 730

(Received May 23, 1975)

Preparations of *anti*-4′-substituted 3,4-benzotricyclo[4. 3. 1. 0^{1,6}]dec-3-en-2-yl *p*-nitrobenzoates (**1a—d**) are described. The solvolysis of these esters was examined in 80% aqueous acetone. The rates were relatively high but the sensitivity to substituents on the benzene ring was low in comparison with other secondary systems. It is considered that σ-participation rather than π-conjugation might contribute to the rate accelerative effect. In the presence of a base, **1a—d** gave *anti*-alcohol (**12a—d**) (13 to 17%), *syn*-alcohol (**13a—d**) (31 to 78%), and *tert*-alcohol (**14a—d**) (5 to 54%). The product distributions are explained in terms of a nonclassical homonaphthalenium cation (**24**).

There is abundant experimental evidence for selective product formation,[1] rate acceleration,[1a,1b,2] and transmittance of the substituent effect[3] in the solvolysis of various types of substrates in which bent, electron-releasing systems like cyclopropyl groups are situated at the reaction center.[4] The remarkable effect of the cyclopropyl group in stabilizing an adjacent carbocation is well documented for a large number of solvolyses.[1,2,4] Also, a π-electron system such as a phenyl or a vinyl group is similarly capable of conjugation with an adjacent cationic center.[5]

Deno *et al.*[6] and Brown *et al.*[7] reported that a cyclopropyl group contributes to stabilization of the cationic center to a greater extent than does a phenyl group. In contrast, Olah *et al.* reported that the relative effectiveness in delocalizing the positive charge decreases in the following order, Ph>cyclo-C_3H_5>CH_3, on the basis of the ^{13}C chemical shift for the carbocation in various stable species.[8] Then, they suggested that the cyclopropyl group is a more actively participating group in solvolysis than the phenyl group, which delocalizes the charge away from the cationic center better than the cyclopropyl group in the intermediate carbocation.[8] In other words, the effectiveness of charge delocalization (π-conjugation and σ-participation[9,10,17]) by two groups (such π-electron systems as phenyl groups and bent-σ-electron systems as cyclopropyl groups) in the transition state, might be different from that in the intermediate.

These comparisons have been made by studies on the intermolecular competition of different molecules, so that there may be some lack of clarity due to other factors like the steric effect and the solvent effect of the reactivity of the different substrates. The author wishes here to report on the study of the solvolysis of a series of cyclopropylphenylmethyl esters in which the steric environments in the vicinity of the reactive site are essentially identical and a comparison between two substituents can be made intramolecularly.

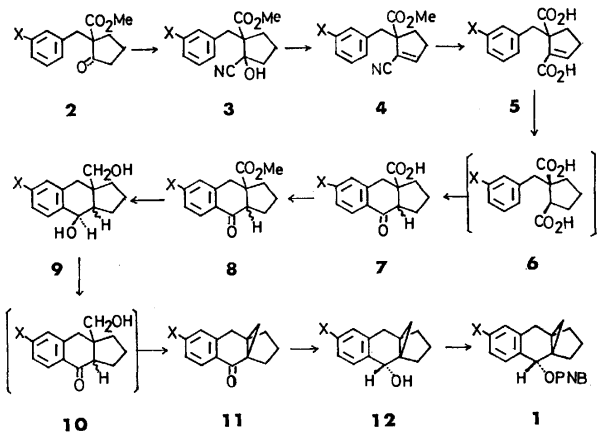
Fig. 1. *p*-Nitrobenzoate (**1**).

From a synthesis and solvolytic study of **1c**, it is regarded as a suitable cyclopropylphenylmethyl derivative for examining the above competitive effects.[10] It is now interesting to investigate the substituent effects at the *para*-position of the reactive center of **1** on both the solvolysis rate and the distribution of the solvolysis products. Much information on σ-participation and π-conjugation may be expected from such studies.

Results

Synthesis. Each *p*-nitrobenzoate (**1a—d**) was prepared by the sequence outlined in Scheme 1, which is the same route as in the case of **1c**.[10] 2-(*m*-Substituted benzyl)-2-methoxycarbonylcyclopentanones (**2a—d**)



Scheme 1.

were prepared by the condensation of 2-methoxycarbonylcyclopentanone with *m*-substituted benzyl chloride. The addition of hydrogen cyanide to **2a—d** gave the cyanohydrins (**3a—d**), which were dehydrated by phosphoryl chloride in dry pyridine to afford the unsaturated cyano esters (**4a—d**), and then the unsaturated dicarboxylic acids (**5a—d**) were obtained by the hydrolysis of these cyano esters. Hydrogenation of **5a—d** with Adams' catalyst in ethyl acetate produced the saturated acids (**6a—d**) in high yields. Intramolecular cyclization of **6a—d** with concentrated sulfuric acid gave rise to the keto acids (**7a—d**). Esterification with diazomethane converted **7a—d** almost completely

into the esters (**8a—d**) which were reduced by lithium aluminum hydride to give a mixture of at least two diols in good yields, the ratio being about 3: 1 in each case. Contrary to the fact that the above minor products were not oxidized with active manganese dioxide, the oxidation of the major diols (**9a—d**) easily afforded the keto alcohols (**10a—d**). These keto alcohols (**10a—d**) were transformed to their tosylates, followed by heating under reflux in dry pyridine to give the ketones (**11a—d**). Spectroscopic and elemental analyses support the structure of the assigned cyclopropyl phenyl ketones. The NMR spectra of **11a—d** show that the aliphatic proton signals are similar to each other and that each substituent on the benzene ring is at a *para*-position to the carbonyl carbon (Table 5).

Reduction of **11a—d** with lithium aluminum hydride in ether gave the alcohols (**12a—d**), in 85—90% yields, concomitant with a traces of other epimers (**13a—d**) (2—5%). The stereochemical assignment of C_2 (reactive center) is based upon a comparison of the NMR spectra of both epimeric alcohols and upon the inference for the direction of the hydride reduction of **11a—d**. Since it has been confirmed by NMR spectroscopy that a proton which is located above the plane of a cyclopropane ring should be shielded in contrast with a proton in the same plane as that of the cyclopropane, a comparison of the chemical shifts of α-carbinyl protons in two epimers was made.[11] The results are shown in Table 1. As is seen, the *anti* geometry of a hydroxyl group relative to a cyclopropane is assigned to **12a—d**, the main reduction product, in which the α-proton was more shielded, and *vice versa*. The expectation for hydride reduction also leads to the same assignment. It may be expected that the reduction of **11a—d** with lithium aluminum hydride predominantly give the *anti* alcohols (**12a—d**), since the hydride attacks from the less hindered side of the carbonyl group.[12]

Kinetic Studies. The rates of solvolysis of *p*-nitrobenzoates (**1a—d**) were determined by titration of *para*-nitrobenzoic acid in 80% aqueous acetone. The results are summarized in Table 2.

Product Studies. Studies of solvolysis products of **1a—d** were carried out in the presence of 2,6-lutidine. After about ten half-lives, the products were extracted

b) Owing to the high reactivity of **1a** (X=MeO), this rate constant at 25 °C may be an upper limit, so that k_{MeO}/k_H is also an upper limit.
c) Ref. 10.

and analyzed using NMR spectroscopy. The product in each series was a mixture of alcohols consisting of **12**, **13**, and **14**, from a comparison of the NMR spectra with those of authentic samples of the **c**-series (X=H).[10] The product distributions were determined from the integral ratio for the characteristic signals in the NMR spectra. The results are summarized in Table 3. The primary alcohols (**15a—d**) could not be detected by way of the extraneous singlet signal due to the hydroxymethyl protons in each case.[10]

The following points may be important in the consideration of the reaction intermediate in the solvolysis of **1a—d**:

1) The ratio, **13a—d**/**12a—d**, was varied with the substituent on the benzene ring.

2) Secondary alcohols (**13a—d** and **12a—d**) increased in the case of the MeO-group, but tertiary alcohols (**14a—d**) increased in the case of the Cl-group.

3) The proportions between (**13a—d**)+(**14a—d**) and (**12a—d**) remained almost unchanged with substituent on the benzene ring.

Discussion

Solvolysis Rate. The rate measurements of S_N1 reactions, *i.e.*, the solvolyses of halides, sulfonates and *p*-nitrobenzoates, have been utilized for the purpose of obtaining information as to the factors influencing the stability or the electronic delocalization in an intermediate carbocation for these reactions.[13] A substituent at the *para*-position of a benzene ring in the benzylic substrate does not affect the steric environment near the reactive center, but does affect the ability of electronic conjugation with the site bearing a positive charge in the reaction intermediate.[14] The reaction constant, ρ, in the Hammett equation, or the effect of a single substituent (for instance, k_{MeO}/k_H) may serve for an approximate measure of the variation between the ground state and the transition state on the benzenoid system. Accordingly, the greater the positive charge on the benzene ring at the trasition state in the rate determining step, the greater the rate enhancement provided by *p*-methoxy substitution.

The rate ratios and the rho values obtained in the present study and in certain related systems are listed in Table 4. The rate ratios, k_{MeO}/k_H, for most of these substrates (**16**, **17**, **18**, **20**, and **21**) are fairly large, 0.7—1.5$\times 10^4$, demonstrating that π-conjugation of the intermediate carbocation with the anisyl group contributes considerably to increasing the solvolysis rate, as is generally observed. On the other hand, the rate ratio, 1.4$\times 10^2$, for **19** is rather smaller than the above examples. Since the substituent effect for a highly reactive system like the *tert*-arylmethyl ester is ordinarily smaller, this may be reasonable taking account of the faster rate of **19** by a factor of 10^2—10^4 compared with the other substrates cited above. This is consistent with the postulation that the more stable the carbocation, the less demand for additional stabilization through neighboring group participation.[18] Compared with these values, the ratio, 44, for **1** is the smallest among that for a number of arylmethyl *p*-nitrobenzoates. The relative reactivity of **1** to **19** under the same conditions is about 0.4, namely the reactivity of **1** is similar to or even less than that of **19**, the tertiary ester, but the ratio k_{MeO}/k_H, for **1** is unexpectedly smaller than one half of the ratio for **19**. This is in contrast with the above discussion. This also shows that the conjugative effect of the *p*-MeO-group in **1** might be quite small at the transition state for solvolysis.

On account of the lower rate ratio, k_{MeO}/k_H, and the lower reactivity of this series of compounds, **1**, compared with *tert*-cyclopropylphenylmethyl systems, it is reasonable to assume that the cyclopropane ring is oriented favorably in the 1-bicyclo[3.1.0]hexyl group of **1** against the reactive center and that its bent σ-bond could participate very well to the ionization process in the transition state (σ-participation). As compared with the π-conjugation which stabilizes the intermediate carbocation and reduces the energy of activation in solvolysis indirectly,[19] σ-participation can immediately contribute to the transition state for ionization in solvolysis and might be more effective for the rate than π-conjugation if the stereochemistry is satisfied. This is a result of the present experiments for the rate determination of **1a—d** at 25 °C, but for more detail it will be necessary to obtain further thermodynamic parameters such as the enthalpy and entropy of activation.

Recently Eaton and Traylor[20] suggested that the

rigid cyclopropyl carbinyl system (**23**) affords at least as much stabilization as in the freely rotating system (**22**). However, the model for comparison cited by them is not necessarily a favorable system for solvolysis. A favorable configuration should also be an important factor for vertical stabilization[22] in an electron transition (vertical process) such as Kosower *et al.* have reported.[23]

Products. It has been established by Olah *et al.* that the charge density of each carbon atom in a stable carbocation is closely related to their ^{13}C chemical shifts.[24] It is also expected that the above charge distribution resembles, to a certain extent, that of the unstable intermediate ions in solvolysis. They suggested that the π-electron system of the phenyl group, when not hindered by steric effects, can conjugatively delocalize charge more effectively than hyperconjugation with bent C–C bonds.[8] Generally, the distribution of substitution products in solvolysis may depend upon a number of effects, for instance, the charge density and steric factors of the carbon atoms which the solvent attacks.

It may be noted from the present result that the distribution of the hydroxylic products varies considerably with the substituent at the *para*-position of the benzene ring in spite of an almost identical steric environment around the reactive site. The proportions between **13** and **12** changed from 2.1 to 4.6 with various substituents on the benzene ring. Therefore, they are dependent upon the properties of intermediate carbocation rather than the steric factor. These discussions result in the proposition that the intermediate carbocation is essentially not the classical carbocation of the benzyl type. The most remarkable feature is the fact that the proportions between **12** and (**13**+**14**) remain almost constant with the substituents on the benzene ring while the yield for **14** increases from the MeO- to the Cl-group.

The result might be explained on the basis of the formation of an intermediate carbocation in which the positive charge would be highly delocalized not only on the aromatic part but also on the cyclopropane ring as in **24**. Since it is usually recognized that the formation of a bridge-head carbocation in relatively small polycyclic systems is an extraordinarily slow process,[25] the localized or classical C-6 carbocation could be excluded in such reactive species as the present substrates. As the primary homo-allylic alcohols (**15a**—**d**) could not be detected in the product analysis, the positive charge might be delocalized even slightly into the primary carbon (C_{10}) in the intermediate ion (**24**).

In the case of a *p*-MeO-derivative, the positive charge may be principally stabilized by the powerful conjugative effect of the *p*-MeO-group, so that the positive charge density at the C_6 carbon is decreased. This results in the formation of **14** in a low yield in comparison with the other cases. Nevertheless, electron delocalization might expand through C_2–C_1–C_6 to a certain extent and cover the side below this planar ionic species. Consequently, a nucleophilic solvent attack would mostly take place from the upper side of the ion to afford **13** rather than **12** which would be produced by a solvent attack from below. A steric effect around the C_2 position, which does not vary with the substituents on the benzene ring, would have to be incorporated in such a nucleophilic substitution at the C_2 position, but a clear distinction between the effects could not be made in the present study.

As the conjugative effect of a substituent decreases, the positive charge density at the C-6 position might increase proportionately and the ratio of the formation of **14** increase also. If it is assumed that the solvent attack at C_6 and C_2 from the upper side depends substantially on the electron delocalization over the aromatic ring and the C_2–C_1–C_6, plane below which the filled orbital rejects the approach of a nucleophilic solvent molecule, the sum of the two products, **13** and **14**, reflects such electronic circumstances of the intermediate ion (**24**). On the other hand, the solvent attack at C_2 from below would occur responding to the degree that the C_1–C_{10} bonding electrons contribute to this intermediate ion when the steric factors offset each other. It has been reported that nucleophilic solvents enter from the *cis* side to a methylene of the cyclopropane in a large number of solvolyses in which a homo-allylic or homo-aromatic carbocation intervenes.[1b,1c,4,26]

In summary, the rates of solvolysis of **1a**—**d** in 80% aqueous acetone were greatly increased and their sensitivity to a substituent on the benzene ring is small in comparison with other cyclopropylphenylmethyl systems. These results indicate that σ-participation rather than π-conjugation might contribute to the rate accelerative effect due to the earlier transition state in which the hybridization of C_2 (reactive carbon) might not be a complete sp^2-hybridization. On the other hand, in the intermediate, the conjugation between the vacant *p*-orbital at C_2 and the aromatic nucleus

would contribute to the stabilization of the intermediate (**24**). The degree of such stabilization by π-conjugation might be varied with the substituent on the benzene ring.

Experimental

All the melting points are uncorrected. The IR spectra were obtained with a Hitachi 215 grating IR spectrophotometer. NMR measurements were carried out on a Varian T-60 spectrometer, using tetramethylsilane as an internal reference.

The details of synthesis of **1c** will be provided in a future publication.[10]

m-*Substituted Benzyl Chloride.* The chlorides were prepared by the reported methods: *m*-methoxy bp 88—89 °C/4 mmHg (lit,[27] bp 124 °C/13 mmHg), *m*-methyl bp 91—92 °C/22 mmHg (lit,[28] 101—102 °C/30 mmHg), and *m*-chloro derivatives bp 103—105 °C/20 mmHg (lit,[29] 104 °C/17 mmHg).

*2-(*m-*Substituted benzyl)-2-methoxycarbonylcyclopentanone (**2a**, **2b**, and **2d**).* *(a) 2-*m-*Methoxybenzyl-2-methoxycarbonylcyclopentanone (**2a**):* To a suspension of 11 g (0.48 mol) of finely dispersed sodium in 150 ml of dry toluene was added a solution of 69 g (0.48 mol) of 2-methoxycarbonylcyclopentanone[30] in 350 ml of dry benzene with stirring in a nitrogen atmosphere for 2 h. After the mixture was heated under reflux for 2.5 h, a solution of 50 g (0.32 mol) of *m*-methoxybenzyl chloride in 100 ml of dry benzene was added in one portion. Then, the reaction mixture was heated under reflux for 25 h. The usual work-up gave 68 g of colorless **2a** in an 80% yield (bp 189—191 °C/5 mmHg).

*(b) 2-*m-*Methylbenzyl-2-methoxycarbonylcyclopentanone (**2b**):* By a similar method to that used in the preparation of **2a**, **2b** (bp 145—150 °C/2 mmHg, 62 g, 83%) was obtained from *m*-methylbenzyl chloride (78 g, 0.56 mol) and 2-methoxycarbonylcyclopentanone (53 g, 0.38 mol).

*(d) 2-*m-*Chlorobenzyl-2-methoxycarbonylcyclopentanone (**2d**):* By a method similar to that used in the preparation of **2a**, **2d** (bp 173—177 °C/5 mmHg, 88 g, 82%) was obtained from *m*-chlorobenzyl chloride (64 g, 0.4 mol) and 2-methoxycarbonylcyclopentanone (71 g, 0.5 mol).

*2-(*m-*Substituted benzyl)-1-hydroxy-2-methoxycarbonylcyclopentanecarbonitrile (**3a**, **3b**, and **3d**).* *(a) 2-*m-*Methoxybenzyl-1-hydroxy-2-methoxycarbonylcyclopentanecarbonitrile (**3a**):* Into an aqueous solution (150 ml) of sodium cyanide (73 g, 1.5 mol) was added an ethereal solution (90 ml of ether) of **2a** (68 g, 0.26 mol) with vigorous stirring and cooling with ice water. Concentrated hydrochloric acid (82 ml) was added to the above mixture at 5—10 °C; vigorous stirring was continued for 30 h. Crude cyanohydrin (**3a**) (64 g) was obtained in an 85% yield by the ordinary extraction procedure, and used for the following dehydration without further purification. Pure sample, mp 90—98 °C (dec), was obtained by recrystallization from carbon tetrachloride. Found: C, 66.17; H, 6.53; N, 4.87%. Calcd for $C_{16}H_{19}NO_4$: C, 66.42; H, 6.62; N, 4.84%.

*(b) 2-*m-*Methylbenzyl-1-hydroxy-2-methoxycarbonylcyclopentanecarbonitrile (**3b**):* By a method similar to that used in the preparation of **3a**, **3b** (mp 105—107 °C (dec), 109 g, 80%) was obtained from **2b** (120 g, 0.49 mol) and sodium cyanide (115 g, 2.4 mol). Found: C, 70.19; H, 6.92; N, 5.15%. Calcd for $C_{16}H_{17}NO_2$: C, 70.31; H, 7.01; N, 5.12%.

*(d) 2-*m-*Chlorobenzyl-1-hydroxy-2-methoxycarbonylcyclopentanecarbonitrile (**3d**):* By a method similar to that used in the preparation of **3a**, **3d** (mp 102—106 °C (dec), 72 g, 73%) was obtained from **2d** (95 g, 0.36 mol) and sodium cyanide (88 g, 1.8 mol). Found: C, 61.52; H, 5.35; N, 4.59; Cl, 12.22%. Calcd for $C_{15}H_{14}NO_2Cl$: C, 61.33; H, 5.49; N, 4.77; Cl, 12.07%.

*5-(*m-*Substituted benzyl)-5-methoxycarbonyl-1-cyclopentenecarbonitrile (**4a**, **4b**, and **4d**).* *(a) 5-*m-*Methoxybenzyl-5-methoxycarbonyl-1-cyclopentenecarbonitrile (**4a**):* To a solution of **3a** (64 g, 0.22 mol) in 220 ml of anhydrous pyridine was added phosphorus oxychloride (100 g, 0.67 mol) with vigorous stirring and cooling below 10 °C. Stirring was continued for 3 h in an ice-water bath, for 12 h at room temperature, and then for 2 h under reflux. After the reaction mixture was poured onto a mixture of crushed ice (100 g) and concd hydrochloric acid (100 ml), 47 g, of **4a** (78% yield) was obtained by the usual work-up; bp 185—190 °C/2 mmHg.

*(b) 5-*m-*Methylbenzyl-5-methoxycarbonyl-1-cyclopentenecarbonitrile (**4b**):* By a method similar to that used in the preparation of **4a**, **4b** (bp 175—184 °C/4 mmHg, 80 g, 89%) was obtained from **3b** (95 g, 0.35 mol) and phosphorus oxychloride (150 g, 1.05 mol).

*(d) 5-*m-*Chlorobenzyl-5-methoxycarbonyl-1-cyclopentenecarbonitrile (**4d**):* The reaction of **3d** (69 g, 0.24 mol) with phosphorus oxychloride (105 g, 0.705 mol) afforded **4d** (bp 192—198 °C/4 mmHg, 55 g, 85%).

*5-(*m-*Substituted benzyl)-1-cyclopentene-1,5-dicarboxylic Acid (**5a**, **5b**, and **5d**).* *(a) 5-*m-*Methoxybenzyl-1-cyclopentene-1,5-dicarboxylic Acid (**5a**).* Hydrolysis of **4a** (38 g, 0.14 mol) was accomplished using 100 ml of concd hydrochloric acid and 50 ml of glacial acetic acid under reflux with stirring for 10 h. The crude **5a** (21 g) was obtained in a 54% yield, and recrystallized from ethyl acetate, mp 196—200 °C. Found: C, 65.09; H, 5.91%. Calcd for $C_{15}H_{16}O_5$: C, 65.21; H, 5.84%.

*(b) 5-*m-*Methylbenzyl-1-cyclopentene-1,5-dicarboxylic Acid (**5b**):* Crude dicarboxylic acid (**5b**) (34 g) obtained from **4b** (40 g, 0.16 mol) in an 82% yield was recrystallized from ethyl acetate to afford pure **5b**, mp 195—198 °C. Found: C, 69.39; H, 6.18%. Calcd for $C_{15}H_{16}O_4$: C, 69.22; H, 6.20%.

*(d) 5-*m-*Chlorobenzyl-1-cyclopentene-1,5-dicarboxylic Acid (**5d**):* Hydrolysis of **4d** (44 g, 0.16 mol) yielded **5d** (33 g, 73%) which was recrystallized from ethyl acetate–petroleum ether to give a pure compound, mp 183—184 °C. Found: C, 59.69; H, 4.54; Cl, 12.71%. Calcd for $C_{14}H_{13}ClO_4$: C, 59.90; H, 4.66; Cl, 12.63%.

*1-(*m-*Substituted benzyl) cyclopentane-1,2-dicarboxylic Acid (**6a**, **6b**, and **6d**).* *(a) 1-*m-*Methoxybenzylcyclopentane-1,2-dicarboxylic Acid (**6a**):* A mixture of 9.0 g (0.033 mol) of **5a** suspended in 500 ml of ethyl acetate and 100 mg of Adams-Pt catalyst was stirred in a hydrogen atmosphere at room temperature; 750 ml (theoretically 728 ml) of hydrogen was absorbed. After the catalyst was filtered out, the solvent was removed under reduced pressure. Saturated dicarboxylic acid (**6a**) was obtained quantitatively and used without further purification for the subsequent dehydration.

*(b) 1-*m-*Methylbenzylcyclopentane-1,2-dicarboxylic Acid (**6b**):* Hydrogenation of **5b** (20 g, 0.077 mol) yielded **6b**.

*(d) 1-*m-*Chlorobenzylcyclopentane-1,2-dicarboxylic Acid (**6d**):* Hydrogenation of **5d** (20 g, 0.071 mol) yielded **6d**.

*3,4-(4'-Substituted benzo)-5-oxo-bicyclo[4.3.0]non-3-ene-1-carboxylic Acid (**7a**, **7b**, and **7d**).* *(a) 3,4-(4'-Methoxybenzo)-5-oxo-bicyclo[4.3.0]non-3-ene-1-carboxylic Acid (**7a**):* A solution of **6a** (9.0 g, 0.033 mol) in a mixture of 80 ml of concd sulfuric acid and 20 ml of water was stirred for 24 h at room temperature. From the reaction mixture, **7a** (5.8 g, mp 146—147 °C) was obtained by the usual work-up in a 67% yield. Found: C, 69.14; H, 6.16%. Calcd for $C_{15}H_{16}O_4$: C, 69.22; H, 6.20%.

*(b) 3,4-(4'-Methylbenzo)-5-oxo-bicyclo[4.3.0]non-3-ene-1-carboxylic Acid (**7b**):* To a solution of **6b** (20 g, 0.076 mol) in 100

ml of benzene was added 100 ml of concentrated sulfuric acid. The mixture was stirred at room temperature for 24 h. By the usual procedure, **7b** (9.0 g, mp 123—124 °C) was obtained in a 48% yield. Found: C, 73.65; H, 6.61%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%.

(d) 3,4-(4'-Chlorobenzo)-5-oxo-bicyclo[4.3.0]non-3-ene-1-carboxylic Acid (7d): By a method similar to that used in the preparation of **7b**, **7d** (mp 182—184 °C, 12.4 g) was obtained from **5d** (20 g, 0.071 mol) in a 66% yield Found: C, 63.52; H, 4.80; Cl, 13.59%. Calcd for $C_{14}H_{13}O_3Cl$: C, 63.52; H, 4.95; Cl, 13.39%.

3,4-(4'-Substituted benzo)-1-hydroxymethyl-5-hydroxybicyclo-[4.3.0]non-3-ene (9a, 9b, and 9d). (a) 3,4-(4'-Methoxybenzo)-1-hydroxymethyl-5-hydrobicyclo [4.3.0] non-3-ene (9a): A solution of 9.8 g (0.038 mol) of **7a** in 50 ml of ether was treated with a distilled solution of diazomethane in 350 ml of ether, prepared from 40 g (*ca.* 0.19 mol) of *p*-toluenesulfonylmethylnitrosoamide. The reaction mixture was kept in an ice bath for 5 h, ether was removed under reduced pressure, and the keto ester (**8a**) (mp 88—89 °C, 8.5 g, 81%) was obtained. Found: C, 69.86; H, 6.64%. Calcd for $C_{16}H_{18}O_4$: C, 70.06; H, 6.61%.

A solution of **8a** (6.27 g, 0.023 mol) in 350 ml of ether was gradually added into a mixture of 5.3 g of $LiAlH_4$ and 100 ml of ether with stirring in an ice bath. After the mixture was stirred at room temperature for 24 h, a minimum amount (12 ml) of water was added to the mixture. Repeated extraction with $CHCl_3$ yielded the crude product, which was recrystallized from $CHCl_3$ to give 3.06 g (54%) (mp 156—157 °C) of **9a** and 2.47 g (43%) (mp 130—135 °C) of a mixture consisting of **9a** and its epimer. The minor diol was not oxidized with active MnO_2 in benzene, while under the same conditions **9a** was smoothly oxidized into keto alcohol (**10a**). Elemental Analysis for **9a**, Found: C, 72.65; H, 8.00%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

(b) 3,4-(4'-Methylbenzo)-1-hydroxymethyl-5-hydroxybicyclo [4.3.0] non-3-ene (9b). Esterification of **7b** (12.2 g) with diazomethane yielded keto ester (**8b**) (mp 66—67 °C, 12.0 g). Found: C, 74.20; H, 7.06%. Calcd for $C_{16}H_{18}O_3$: C, 74.40; H, 7.02%.

Reduction of **8b** (5.3 g, 0.02 mol) with $LiAlH_4$ (3.8 g) yielded **9b** (2.3 g, 47%), a mixture of **9b** and its epimer (1.4 g, mp 114—118 °C, 29%), and an oily product (0.9 g). **9b** was purified by recrystallization from $CHCl_3$, mp 164—165 °C. The epimer of **9b** was not oxidized with active MnO_2 in benzene as above.

(d) 3,4-(4'-Chlorobenzo)-1-hydroxymethyl-5-hydroxybicyclo [4.3.0] non-3-ene (9d): By a method similar to that used in the preparation of **9a**, **9d** (3.0 g, mp 162—163 °C, 56%) and the mixture of **9d** and its epimer (1.5 g, mp 115—125 °C, 28%) were obtained from **8d** (mp 88—89 °C) prepared by esterification of **7d** (5.6 g, 0.021 mol). Elemental analysis for **8d**, Found: C, 64.44; H, 5.22; Cl, 12.81%. Calcd for $C_{15}H_{15}O_3Cl$: C, 64.64; H, 5.43; Cl, 12.71%. **9d**, Found: C, 66.38; H, 6.66; Cl, 13.96%. Calcd for $C_{15}H_{17}O_2Cl$: C, 66.53; H, 6.78; Cl, 14.02%.

3,4-(4'-Substituted benzo)-tricyclo [4.3.1.0^{1,6}] dec-3-en-2-one (11a, 11b, and 11d). (a) 3,4-(4'-Methoxybenzo)-tricyclo [4.3.1.0^{1,6}] dec-3-en-2-one (11a): A mixture of 890 mg (3.58 mmol) of diol (**9a**) (mp 156—157 °C) and 2 g of active MnO_2, crushed immediately before reaction, was suspended in 100 ml of dry benzene. Stirring was continued for 24 hr at room temperature, followed by filtration and then the solvent was removed under reduced pressure. Without further purification 20 ml of dry pyridine and 1.4 g of *p*-toluenesulfonyl chloride were added with cooling in an ice-water bath. Stirring was continued for 15 h at room temperature, then for 3 h under reflux. The reaction mixture was poured onto a mixture of 50 ml of concentrated hydrochloric acid and ice, followed by extraction with ether. The organic layer was washed with 6M-hydrochloric acid and water, and dried over anhydrous sodium sulfate. Removing the solvent, the residue was treated with petroleum ether followed by filtration through neutral alumina. Evaporation of the solvent under reduced pressure gave an oily product. Crystallization and purification gave rise to 602 mg of **11a** (mp 87—88 °C) in a 74% yield based on **9a**. Found: C, 78.75; H, 6.98%. Calcd for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%.

(b) 3,4-(4'-Methylbenzo)-tricyclo [4.3.1.0^{1,6}] dec-3-en-2-one (11b): By a method similar to that used in the preparation of **11a**, **11b** (mp 89—90 °C, 270 mg, 27%) was obtained from **9b** (mp 164—165 °C, 1.1 g, 4.7 mmol). Found: C, 84.81; H, 7.55%. Calcd for $C_{15}H_{16}O$: C, 84.87; H, 7.60%.

(d) 3,4-(4'-Chlorobenzo)-tricyclo [4.3.1.0^{1,6}] dec-3-en-2-one (11d): Similar oxidation and elimination of **9d** (mp 162—163 °C, 1.73 g, 6.8 mmol) gave rise to **11d** (mp 105—106 °C, 780 mg, 49%). Found: C, 72.10; H, 5.62; Cl, 15.05%. Calcd for $C_{14}H_{13}OCl$: C, 72.26; H, 5.63; Cl, 15.23%.

3,4-(4'-Substituted benzo)-tricyclo [4.3.1.0^{1,6}] dec-3-en-2-ol (12a, 12b, and 12d). (a) 3,4-(4'-Methoxybenzo)-tricyclo [4.3.1.0^{1,6}] dec-3-en-2-ol (12a): To a stirred suspension of 130 mg of $LiAlH_4$ in 120 ml of dry ether was added a solution of 560 mg (2.5 mmol) of **11a** in 100 ml of ether. The mixture was stirred for 1 h at 0 °C and for 20 h at room temperature before the excess hydride was carefully decomposed with 0.5 ml of water. The ether layer was decanted and the precipitate was washed several times with ether. The combined organic layer was dried with anhydrous K_2CO_3. The solvent was removed under reduced pressure to yield 550 mg of a colorless solid. Recrystallization from petroleum ether gave a pure product (**12a**) (460 mg, 80%), mp 135—136 °C, and an oily residue (70 mg). It was found from its NMR spectrum that the oily residue consisted of two components **12a** and **13a**. Found: C, 78.44; H, 7.92%. Calcd for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88%.

(b) 3,4-(4'-Methylbenzo)-tricyclo [4.3.1.0^{1,6}] dec-3-en-2-ol (12b): Reduction of **11b** (1.06 g, 4.9 mmol) with $LiAlH_4$ (185 mg) yielded **12b** (940 mg, 89%) which was recrystallized from petroleum ether to give a pure product, mp 68—69 °C and an oily residue (50 mg) which consisted of two components, **12b** and **13b**. Found: C, 83.88; H, 8.68%. Calcd for $C_{15}H_{18}O_2$: C, 84.07; H, 8.47%.

(d) 3,4-(4'-Chlorobenzo)-tricyclo [4.3.1.0^{1,6}] dec-3-en-2-ol (12d): Reduction of **11d** (240 mg, 1.0 mmol) with $LiAlH_4$ (200 mg) yielded **12d** (mp 108—109 °C, 200 mg, 85%) and an oily residue (20 mg) which consisted of two components, **12d** and **13d**. Mass: m^+/e 236 (M^+) and 234 ($C_{14}H_{15}OCl$).

p-*Nitrobenzoate (1a, 1b, and 1d)*. The *p*-nitrobenzoate was prepared by allowing 150 mg (0.065 mmol) of **12a** to react with 240 mg (1.3 mmol) of *p*-nitrobenzoyl chloride in 5 ml of dry pyridine at 5 °C for 24 h. The product was extracted with ether and the organic layer was washed with water, 1M-hydrochloric acid, 5% aqueous sodium hydrogen carbonate, and water. The ether layer was dried over anhydrous sodium sulfate and concentrated under reduced pressure. A light yellow solid was recrystallized from cyclohexane to give **1a** (84 mg, 34%), mp 120—121 °C. Found: C, 69.69; H, 5.43; N, 3.65%. Calcd for $C_{22}H_{21}NO_5$: C, 69.64; H, 5.58; N, 3.69%. By a similar method **1b** (mp 121—122 °C, 58%) and **1d** (mp 144—145 °C, 60%) were obtained. Elemental analysis for **1b**; Found: C, 72.43; H, 5.73; N, 3.80%. Calcd for $C_{22}H_{21}NO_3$: C, 72.71; H, 5.82; N, 3.85%. For **1d**; Found: C, 66.25; H, 4.63; N, 3.50; Calcd for $C_{21}H_{18}NO_4Cl$: C, 65.71; H, 4.73; N, 3.65.

General Kinetic Procedures. For each run approximately 50 mg (*ca.* 0.15 mmol) of *p*-nitrobenzoate (**1a—d**) was weighed into a 50 ml volumetric flask and dissolved in 80% aqueous acetone (*ca.* 3×10^{-3}M). The rate at each temperature (to an accuracy of ±0.03 °C at 25 and 45 °C, and ±0.1 °C at 0 °C) was measured by seven quenching 5.00 ml aliquotes in 20 ml of dry acetone and immediately titrated with a standard aqueous sodium hydroxide solution (*ca.* 0.01M) to a blue end point, using 2 drops of a 1% methanol sodium of Bromothymol Blue as an indicator. The reported values are the average of two runs (Table 2). In all cases infinite titers were measured after *ca.* 10 half-lives and 97 to 102% of the *p*-nitrobenzoic acid was removed. In the case of **1a** (X=MeO), the rate was so fast even at 25 °C that the rate constant was determined by three quenching titers at this temperature.

Preparative Solvolysis of p-*Nitrobenzoate (**1a**, **1b**, **1c**, and **1d**).* *General Method.* A solution of 0.26 mmol of **1c** and 0.5 ml (*ca.* 2.5 mmol) of 2,6-lutidine in 100 ml of 80% acetone–water was heated at 40 °C for *ca.* 40 half-lives. The solution was concentrated under reduced pressure, 50 ml of water was added and the resulting suspension was extracted with ether. The combined ether extracts were washed with water and dried over anhydrous K_2CO_3. Removing the solvent under reduced pressure gave 50 mg of a light yellow oil. Starting from **1c**, the NMR spectrum of the product thus obtained in $CDCl_3$ was essentially identical with the spectrum of a mixture of **12c**, **13c**, and **14c** in the ratio cited previously from five independent experiments.[10] On the basis of this result, the solvolysis product was determined to consist of **12**, **13**, and **14** in each substituent series by comparison of the NMR spectrum with that of the **c**-series (X=H). Then, product distributions were determined by the average ratio of NMR integral values of the vinyl proton signal for **14**, to those of the α-proton signals for **12** and **13** in five runs. The chemical shifts (δ) of the α-proton and vinyl proton signals of the products and the product distributions are

Solvolysis of 2,3-Cyclopenteno-4*H*-homochromen-4-ol Acetate: Comparison with the Corresponding Carbocyclic System

Hiroshi YAMAOKA, Katsuo OHKATA, and Terukiyo HANAFUSA

Chemistry Department, Faculty of Science, Hiroshima University, Higashi-senda-cho, Hiroshima 730

(Received February 26, 1975)

A novel secondary cyclopropylphenylmethyl acetate was prepared from a chromone skeleton *via* homochromone derivatives in order to study solvolytic behavior. Reduction of the cyclopropyl ketone (homochromone) with lithium aluminum hydride in ether to the corresponding secondary alcohol, was found to be highly stereospecific giving only one of the geometrical isomers. The alcohol was converted into its acetate and subjected to solvolysis in 80% acetone–water. The acetate was hydrolyzed at the rate of 3×10^{-5} s^{-1} (25 °C) undergoing alkyl-oxygen fission. This rate constant was as high as the most reactive secondary esters in solvolyses ever reported, and about 20 times as high as the corresponding carbocyclic ester by estimation of the same leaving group. Product studies were undertaken in the presence of sodium hydrogencarbonate, and seven-membered hemiacetal was obtained in good yield. The structural characteristics of the homochromenol ester in the solvolysis are discussed and benzohomopyrylium ion, an extremely delocalized homoaromatic species, is proposed as an intermediate carbocation.

A large number of studies have been made on solvolytic behavior in various cyclopropane derivatives since newer convenient synthetic routes for producing a cyclopropyl group have been reported. Thus, one of the attractive concepts from these studies may be homoconjugation or homoaromaticity in carbocations as the solvolytic intermediate.[1]

Here, a novel secondary cyclopropylphenyl methanol derivative (**1-OAc**) is presented, which is closely related to the corresponding carbocyclic system (**2-OPNB**).[2] The structural characteristics of these systems are: (i) the benzene ring and cyclopropane are connected to each other with both a carbon of the reaction center and an etherial oxygen (or methylene) group, and then a heterocyclic or a carbocyclic six-membered ring is formed, (ii) such a carbon skeleton enables two geometric isomers (*syn*, *anti*) between hydroxyl group and cyclopropane, and (iii) the cyclopropane ring is also fused with a trimethylene group (scissors effect).

	X	Y

	X
5-OH	OH
5-OPNB	OPNB
5-OAc	OAc

* *a* (*anti*) and *s* (*syn*) are referred between hydroxyl and cyclopropane

** -OPNB; paranitrobenzoate

In both systems, the phenyl and cyclopropyl groups are situated in the α-position to the carbon of the reactive center, where both groups can be effective for high reactivity in solvolysis.[3] It is one of the special interests in these substrates that the accelerative effects of each of these two groups seem to compete with each other in the solvolysis. Another interesting point is the difference between **1** and **2** due to the bridged oxygen or the bridged methylene.

Various carbocations may be predicted as solvolytic intermediates of **1-OAc**, and are shown in Fig. 1. From the available data in the literature, we may speculate upon the relative importance of these cations. In the case of a heterocyclic system (**1**), it is interesting that the cation (**e**) is taken for a fully-conjugated homopyrylium ion.[4]

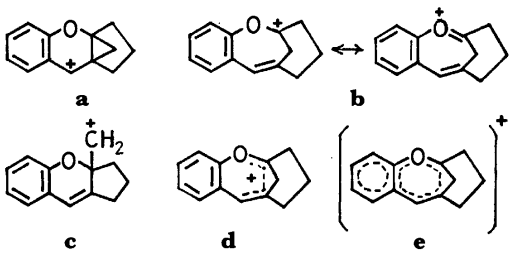

Fig. 1. Cabocations predicted as a solvolytic intermediate of **1-OAc**.

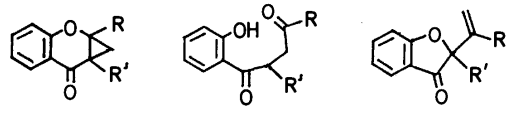
Both **1** and **2** have the cyclopropane fused with a trimethylene bridge which was suggested to be effective in contributing to the anchimeric assistance of the cyclopropane ring in solvolysis.[5] A similar effect of bridged methylene (forming a six-membered ring) in the biscyclopropylmethyl system was reported.[5,6] Regarding the first-order rate constants, the relative rate ratio of **3-OPNB** to **4s-OPNB** to **5s-OPNB** was $1:10^2:3\times10^3$, respectively. The reactivity of **1** is also interesting from another point of view, in which **1** is regarded as a 2-aryloxycyclopropyl methanol derivative. Julia *et al.* reported the isomerization of 2-alkoxy- and 2-aryloxycyclopropyl methanol into an β,γ-unsaturated carbonyl compound and an alcohol or a phenol with sulfuric acid.[7] The solvolytic study of **1-OAc** will be

referred to in the order: (1) synthetic procedure, (2) product study, and (3) kinetic results.

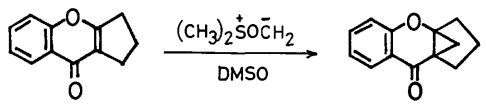
Results and Discussion

Syntheses. Preparation of the Homochromone: It was pointed out by Corey *et al.* that dimethyloxosulfonium methylide is convenient in preparing a cyclopropane ring from corresponding α,β-unsaturated ketones.[8] Chromones, regarded as unsaturated carbonyl compounds, were treated with the above reagent in dimethyl sulfoxide by Ollis *et al.* and three types of additional products were reported:[9] (**i**) 2,3-methanochroman-4-one (homochromone) derivatives, (**ii**) ketophenols obtained from further reaction (hydrolysis) of (**i**), and (**iii**) five-membered ketones including a non-conjugated double bond.



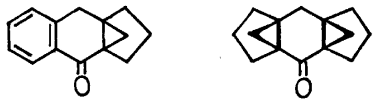
i **ii** **iii**

2,3-Cyclopentenochromone (**6**), an important precursor for producing homochromenol derivatives (**1**), was prepared according to the procedure reported by Boyd *et al.*[10] The reaction of **6** with dimethyloxosulfonium methylide gave homochromone (**7**) (type **i**) in good yield, which was purified using column chromatography on neutral alumina, but the other products (**ii** and **iii**) were not found in this experiment. Though chemical shifts of the protons belonging to the cyclopropane ring in **7** were not obvious owing to the duplication with the signals of a trimethylene group in its NMR spectrum, the wave number of maximum absorption ($\nu_{C=O}$) in the IR spectrum of **7** shifted to higher frequency (20 cm^{-1}) because of the change of the properties of the carbonyl function compared with the corresponding chromone (**6**).



6 **7**

Reduction of the Homochromone (7): Reduction of homochromone (**7**) with lithium aluminum hydride (LAH) in ether gave a secondary alcohol (**1-OH**) in *ca.* 70% yield, which was fairly unstable. Contrary to **7**, **1-OH** showed a typical AB quartet (J=6.5 Hz) due to cyclopropyl methylene protons (δ=1.15, 0.55 ppm) separated from other methylene protons (δ=2.5−1.5 ppm) in its NMR spectrum. Also **1-OH** showed a singlet at δ=4.65 ppm for α-hydrogen, while another singlet was observed at δ=4.92 ppm in the crude minor epimeric alcohol, which was obtained from the mother liquor after repeated recrystallization of the former. An attempt to obtain pure minor alcohol was not successful because of the high stereospecificity of the reduction. Moreover, facile decomposition often occurred (cleavage of the cyclopropane ring) during purification of the mixture of these epimers. Reduction of **7** with sodium borohydride (NBH) in 2-propanol was also stereospecific and gave only one isomer; the spectroscopic data agree well with those of the major product obtained by LAH reduction. The reduction of the closely related ketone (**8**) with both LAH and NBH was also stereospecific, giving only one stereoisomer.[2] It is interesting that the reaction of both **7** and **8** with LAH yielded single alcohols in contrast to **9**, which gave both epimeric alcohols in nearly equal amounts upon reduction with LAH.[5]



8 **9**

Stereochemistry of Homochromenol: It is generally accepted that α-proton *syn* to such a cyclopropane ring as in bicyclo[*m.* 1. 0]- or tricyclo[*m. n.* 1. 0]alkane-2-ol should be more shielded by the cyclopropane than the *anti* proton.[11] Also in the reduction of **7** and **8**, hydride addition with the carbonyl function should predominantly occur from less hindered *syn* to a cyclopropane ring in analogy with the reduction of the related ketone.

On the basis of these prospects, the structure of the main reduction product from **7** is assigned for the *anti* alcohol (between hydroxyl and cyclopropane) at this stage, though this assignment is tentative because of the following equivocal factors: (i) the difference between the carbocyclic and oxacyclic systems, and (ii) the existence of the benzene ring, which may play various roles affecting the magnetic properties of α-hydrogen of **7**.

Recently the stereochemistry of the reduction products from 1,3,5,7-tetramethyltricyclo[5.1.0.$0^{3,5}$]octan-2-one and its derivatives was discussed in another approach to interpreting the NMR spectrum.[12] According to Ref. 12, the reduction took place quite stereospecifically and gave only one isomer assigned to be *syn* alcohol. It is necessary to study from various viewpoints for the stereochemical problem of **1-OH**. This will be discussed by means of the NMR spectra of some substrates including a homochromenol skeleton in a forthcoming paper.

Preparation of the Ester: Attempts to prepare *p*-nitrobenzoate (**1-OPNB**) with *p*-nitrobenzoyl chloride in pyridine were unsuccessful owing to the production of a complex mixture. Then, **1-OH** was transformed into its acetate (**1-OAc**), a colorless liquid, with acetic anhydride in pyridine. The acetate was so unstable that a decomposition occurred in the course of the purification process in column chromatography over neutral alumina. The structure of the acetate was determined by spectroscopic analysis (*cf.* Experimental). This acetate was then subjected to a solvolytic study without further purification.

Product Study in Solvolysis. In the presence of sodium hydrogencarbonate as a suspension in 80% acetone–water at 25 °C for 4 days (*ca.* 10 half-lives), the major solvolysis product of **1-OAc** was a hemiacetal (**10**). Another alcohol (**11**) was contaminated with **10** though the **10**/**11** ratios were somewhat variable from the information of the NMR spectra. The structural determination of these products will now be discussed.

Structural Problem of **10**: On the basis of combustion

analysis, both **10** and **11** are structural isomers of the parent alcohol (**1-OH**). The major product showed a strong absorption at 1640 cm^{-1} in the IR spectrum, and a singlet at $\delta=5.87$ ppm (vinyl) and $\delta=3.55$ ppm (methylene) in the NMR spectrum. Two possible structures are expected from this data: (i) primary alcohol (**12**) produced by b-c bond cleavage of the cyclopropane ring, (ii) tertiary alcohol (hemiacetal) (**10**) produced by a-b bond cleavage of the cyclopropane ring. The signal at $\delta=3.55$ ppm may be assigned to the methylene proton of neopentyl group (i), and not to the allylic (bridged) methylene (ii), according to an estimation from the available data listed in Table 1.

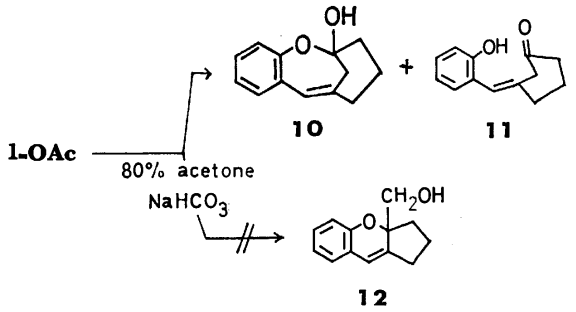


Table 1. Chemical shifts for dual type methylene signals (corresponding to **10** and **12**, respectively)

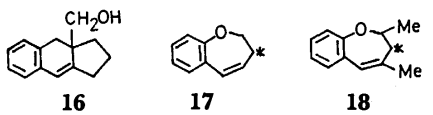
Substrate	Methylene (ppm)	Reference
>C-CH_2-O-	3.36—4.48	13[a,c]
H_3C-CH_2-OH	3.26	14[a,e]
F_3C-CH_2-OH	3.93	14[a,e]
16	3.28	2[a]
>C-CH_2-C=C<	1.86—2.12	13[b,d]
H_3C-CH_2-C=C<	2.02	14[b,e]
F_3C-CH_2-C=C<	2.69	14[b,e]
17	2.6	15[b]
18	2.43	22[b]
10	3.55	f

a) Examples for primary alcohol **12**. b) Examples for hemiacetal **10**. c) Summed for 42 substrates. d) Summed for 11 substrates. e) Calculated value by means of Shoolery's effective shielding constants. f) Observed chemical shift of the major solvolysis product obtained from **1-OAc**.



16 **17** **18**

Acetylation of the alcohol was performed with acetic anhydride in pyridine for the purpose of distinguishing between primary and tertiary alcohols. In contrast to the expectation based on the chemical shift, downfield shift of the signal at $\delta=3.55$ ppm was not observed at all, but a slight upfield shift (0.1 ppm) occurred. Thus, the alcohol was assigned preferably to be tertiary alcohol (ii) from these observations of the NMR spectra.

Europium dipivaloyl methanate, $Eu(dpm)_3$, was utilized in order to obtain further information about the structure. In general, a characteristic downfield shift is expected for methylene adjacent to a hydroxyl group if the substrate is a primary alcohol. On the other hand, such a phenomenon is not expected for tertiary alcohol (hemiacetal). The experimental results for the alcohol obtained in solvolysis are shown in Fig. 2. The extent of the induced downfield shift of both the methylene signal at $\delta=3.55$ ppm and the signals assigned as part of the trimethylene group at $\delta=1.7$—2.6 ppm may be worth noticing in comparison to those of other signals. According to the situation, the structure of this alcohol may be characterized as tertiary alcohol (**10**) rather than primary alcohol (**12**), on the basis of the result from acetylation. The major solvolysis product from **1-OAc** is concluded to be a hemiacetal (**10**). Though the chemical shift of the bridged methylene group of **10** appears at a fairly lower field value ($\delta=3.55$ ppm) than expected, this might be due to steric compression as has been mentioned for cage molecules.[16]

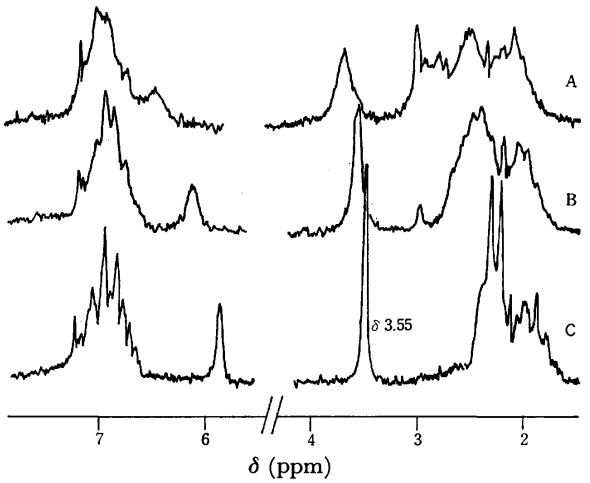


Fig. 2. The NMR spectra of **10** (spectrum C) in $CDCl_3$. After the addition of $Eu(dpm)_3$ into the solution, the spectrum B (10.0 mg) and the spectrum A (18.0 mg) were recorded. Signals for hydroxyl proton were not shown in both spectra A and B owing to enormous downfield shift.

Structural Problem of 11: Characteristics of the minor solvolysis product of **1-OAc** are: (i) positive for $FeCl_3$ in chloroform–phenolic material, (ii) typical IR and UV absorption bands for the aliphatic carbonyl group at 1720 cm^{-1}, and 315 nm ($\varepsilon=350$), respectively, and (iii) the presence of an allylic methylene group adjacent to a carbonyl function ($\delta=3.05$ ppm) based on the NMR spectra. From speculation based on these data, ketophenol (**11**) might be proposed as the structure of this material. Hemiacetal (**10**) was transformed into **11** in the presence of **11** in the medium, *e.g.*, in $CDCl_3$ prepared for the measurement of a NMR spectrum. It is probably due to the phenolic function of **11**. On the basis of this phenomenon, the uncertainty of the ratio **10**/**11** in the solvolysis may be explained satisfactorily.

When the NMR spectrum of **10** in trifluoroacetic acid (TFA) was observed at room temperature, a mixture of **10** and **11** was produced and the former was predominant under the condition. Similarly when the

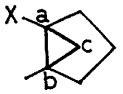
spectrum of **11** was recorded in TFA, the same mixture as above was evidently produced. In both cases, the mixture could be isolated in good yield by quenching the solution. It is interesting that **10** and **11** are converted into each other in TFA. Such a mutual exchange suggests the validity of each structure, since **10** is an intramolecular hemiacetal of a ketophenol (**11**). It was, moreover, found that homochromenol (**1-OH**) was clearly converted into a mixture analogous to the above in TFA at room temperature. Isolation of the mixture was similarly achieved, thus

$$\underset{(\mathbf{1\text{-}OH})}{\text{Parent alcohol}} \xrightarrow[\text{in TFA}]{} \underset{(\mathbf{10})}{\text{Hemiacetal}} \underset{\text{in TFA}}{\overset{\text{in TFA or 11}}{\rightleftharpoons}} \underset{(\mathbf{11})}{\text{Ketophenol}}$$

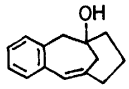
Solvolysis in Another Condition: The hemiacetal (**10**) was also obtained in solvolysis of **1-OAc** in the presence of either pyridine or 2,6-lutidine instead of in the presence of sodium hydrogencarbonate as described above. However, a complex mixture was obtained if any acid was used in order to remove the alkali during a work-up process. It is suggested that the hemiacetal (**10**) may be highly sensitive to acidic substances.

In the absence of any alkali, solvolysis of **1-OAc** gives a yellowish oil whose NMR spectrum suggested the production of complex mixtures, and **10** was not observed at all. Thus, the presence of an alkali is obviously essential to the production of **10** in such reaction conditions.

A Comparison of the Solvolysis Products of 1-OAc with Those from the Corresponding Carbocyclic Ester: According to the product study of a closely related ester (**2-OPNB**), the mixture of **2a-OH**, **2s-OH** and a tertiary alcohol (**13**) was obtained in the ratio of 1.0: 3.3: 3.5 in 80% acetone–water at 25 °C in the presence of the alkali.[2] This is somewhat different from the result for **1-OAc**. A parent alcohol (**2a-OH**) was isomerized into the thermodynamically more stable isomer **13** in the presence of *p*-nitrobenzoic acid, but both parent alcohols (**2a-OH**) and (**2s-OH**) were stable in the presence of the alkali under solvolytic conditions. The alcohol (**13**) is produced in a mode similar to the cleavage of the cyclopropane ring (a-b cleavage), as in the case of hemiacetal (**10**). It is noteworthy that considerably strained bridgehead alcohols, **10** and **13**, were thermodynamically the most stable products in both cases, although a partial ketonization sometimes occurred for **10**. Together with the kinetic results discussed later, these facts might support possible intervention of the homoallylically conjugated or homoaromatically conjugated carbocation in these solvolyses.



Modes of the cleavage of cyclopropane



13

Alkyl-oxygen Fission of Homochromenol Acetate (1-OAc) during Solvolysis: The parent alcohol (**1-OH**) was found to be stable in the presence of sodium hydrogencarbonate under the solvolytic condition. So alkyl-oxygen fission may occur during the solvolysis of **1-OAc** based on the fact that rearranged alcohols **10** and **11** were isolated as solvolysis products of **1-OAc**.

The mode of fission may be confirmed by means of solvolysis in anhydrous methanol (methanolysis). If the solvolysis of **1-OAc** proceeds with an acyl-oxygen fission, the products should be alcohol(s) and methyl acetate. But methyl ether and acetic acid should be obtained in the case of an alkyl-oxygen fission. The reaction scheme is as follows:

$$\mathrm{RO\text{-}\overset{\overset{\mathrm{O}}{\|}}{C}CH_3} \xrightarrow{\text{SO-H}} \mathrm{RO\text{-}H} + \mathrm{SO\text{-}\overset{\overset{\mathrm{O}}{\|}}{C}CH_3}$$

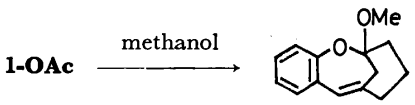
acyl-oxygen fission

$$\mathrm{R\text{-}O\overset{\overset{\mathrm{O}}{\|}}{C}CH_3} \xrightarrow{\text{SO-H}} \mathrm{R\text{-}OS} + \mathrm{H\text{-}O\overset{\overset{\mathrm{O}}{\|}}{C}CH_3}$$

alkyl-oxygen fission

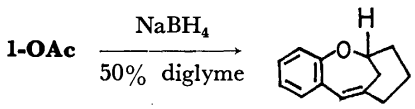
SO- = MeO-, HO-

Methanolysis of **1-OAc** was carried out in the presence of pyridine at 25 °C for 4 days, the methyl ether (**14**) of **10** was obtained as the sole product, and the ether was determined from its spectra. Thus, alkyl-oxygen fission of **1-OAc** during solvolysis may be more plausible.



14

Trapping a Reactive Carbocation with a Hydride Reagent: A high solvolytic reactivity of appropriate esters provides an effective route to the parent (or isomerized) hydrocarbon, which is called *trapping* an intermediate carbocation.[17] The acetate (**1-OAc**), could be converted to a seven-membered unsaturated ether (**15**), as the sole product in 50% aqueous diglyme containing excess NBH. From these product studies in various reactions for **1-OAc** it has been shown that a nucleophile attacks specifically at the bridgehead carbon adjacent to etherial oxygen in the intermediate cation. This is contrary to the fact that the *p*-nitrobenzoate (**2-OPNB**) was converted to a mixture of isomeric alcohols (**2a-OH**, **2s-OH** and **13**) upon solvolysis or to the *parent* hydrocarbon (**2-H**) by the hydride reagent. The difference between the products from the two systems (**1-OAc** and **2-OPNB**) may correspond to the properties of the intermediate carbocation in the reactions, although the leaving groups are different.



15

Kinetic Study of the Solvolysis. The rates of the solvolysis of **1-OAc** were determined in 80% acetone–water solution at 25—40 °C by tracing the increment of the acetic acid produced with 18 aliquots at regular intervals. Each aliquot was quenched by acetone, followed by means of the usual alkaline titration using bromothymol blue as an indicator. All runs showed

Table 2. Solvolysis rates of **1-OAc** and **2-OPNB** in 80% acetone–water[a)]

Substrate	Temperature[b)] °C	k s^{-1}	$\Delta H^{\neq}$ kcal/mol	$\Delta S^{\neq}$ e.u.	Relative rate[c)]	Reference

strictly first-order kinetics up to almost two half-lives (Fig. 3.), despite the fact that the purification of **1-OAc** was difficult. The observed kinetic data are shown in Table 2, and the relative rates of solvolysis for related systems in Table 3.

Thus, **1-OAc** was solvolyzed accompanying alkyl-oxygen fission in 80% acetone–water at the rate of $3.2_4\times10^{-5}$ s^{-1} (25 °C), which is as high as those of the most reactive secondary esters (**5a-OAc**, **5s-OAc**, **19-OAc**, and **20-OPNB**) that have ever been measured in solvolysis.[5,19,20)] The acetate (**1-OAc**) was about 20 times as reactive as the corresponding carbocyclic system (**2a-OPNB**), by estimation of the same leaving group as shown in Table 2, and was solvolyzed *ca.* 10^4 times faster than the secondary cyclopropylphenylmethyl

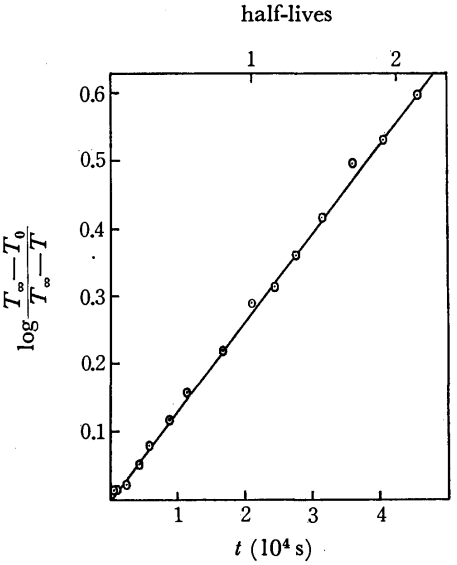

Fig. 3. Plots of the first-order function *vs.* reaction time (or half-lives) for **1-OAc** at 25 °C in 80% acetone–water.

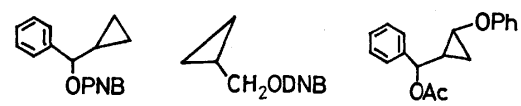
p-nitrobenzoate (**21-OPNB**).[18)] In the following discussion, **21-OPNB** may be chosen as the standard substrate.

Since the benzene ring and the cyclopropane are connected to each other by the bridged oxygen in **1-OAc**, dual types of contributions may be expected for such a high reactivity due to the etherial oxygen: (i) the effect of an *ortho*-alkoxy group on the benzene ring, and (ii) a contribution as β-phenoxy substitution of the cyclopropane. Now the role of the bridged oxygen in the solvolysis will be discussed from such viewpoints.

Substituent Effect of the Benzene Ring: According to the study of Shono *et al.* for the *para* substituent effect of the benzene ring (–OMe, –Me, –H, and –Cl) on **21-OPNB**, the *para*-methoxy ester was 780 times more reactive than the corresponding parent ester (**21-OPNB**): $\rho=-3.61$ *vs.* σ^+.[18)] From these results, an *ortho*-alkoxy substitution in the benzene ring seems to be one of the important factors for the high reactivity of **1-OAc**, though the accelerative effect of the *ortho*-alkoxy group may be usually smaller than that of the *para*-alkoxy group according to available data.[21)]

Effects of Substitution on the Cyclopropane: Rate enhancement due to the substitution was reported for *primary* cyclopropylmethyl 3,5-dinitrobenzoate (**23-ODNB**) such that every methyl substitution at the β-position increased the rate about 10 times that of the corresponding ester, and the substitution of a *trans* β-ethoxy group caused a great acceleration (nearly 10^3 times).[23)] But the substituent effect of the cyclopropane ring for **21-OPNB** has not been reported to date. Therefore, *trans* 2-phenoxycyclopropylphenylmethyl acetate (**24-OAc**) was adopted as an acyclic model system corresponding to its cyclic acetate (**1-OAc**). If a clear rate enhancement in comparison with **21-OPNB** should be observed, the β-aryloxy substitution may be an important cause of the high reactivity of **1-OAc**.

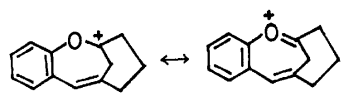


21-OPNB **23-ODNB** **24-OAc**

* -ODNB; 3,5-dinitrobenzoate

In our preliminary experiments, **24-OAc** was not hydrolyzed appreciably under similar solvolytic conditions for **1-OAc.**[22] The effect of the β-aryloxy substitution, therefore, should be explained by means of another contribution, probably due to a *cis* substitution which constitutes a six-membered heterocycle, **1-OAc**. Since it has been pointed out that both the phenyl group and the cyclopropyl group are effective in increasing the reactivity in **21-OPNB,**[18] these are perturbations of such relatively highly reactive systems. The ester (**1-OAc**) involves many complex factors which cause difficulty in determining the origins of the increase in reactivity compared with the standard substrate (**21-OPNB**). Consequently, it appears risky to interpret the observed kinetic data on the basis of the simple additional summation of the effects of *ortho*-alkoxy group of the benzene ring and of the substitution of the cyclopropane in such a sophisticated system as **1-OAc**. The structural characteristics of **1-OAc** may play an important role in solvolysis, since a homochromenol ester is, in general, suitable for creating high reactivity.

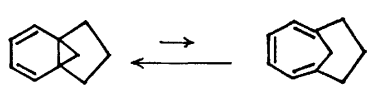
Intermediate Carbocation in the Solvolysis. As shown in the product studies of **1-OAc**, each nucleophile attacks at the carbon adjacent to the etherial oxygen quite specifically in spite of different reaction conditions. According to these product studies, the cation (**b**) appears at first sight to be suitable as a solvolytic intermediate of **1-OAc**.



b

The difficulty in the production of the bridgehead cation is well known, in general. Owing to the assistance of the oxygen adjacent to the carbon of the cationic center, the bridgehead cation (**b**) might be an exception to the above general rule though such a phenomenon has not yet been reported.

Otherwise, the presence of the double bond on the opposite bridge ead carbon diminishes the possibility of **b**. Recently, the relative stability between the norcaradiene form (**f**) and the cycloheptatriene form (**g**) using the NMR spectra was discussed by Vogel *et al.*[24] According to their report, the former (**f**) is much more stable than the latter (**g**) in case of the presence of a trimethylene group. The cation (**b**) is *isoelectronic* to the cycloheptatriene form (**g**), so that **b** may be invalid as a solvolytic intermediate for **1-OAc**.



f **g**

Norcaradiene form Cycloheptatriene form

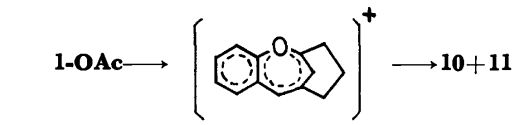
Aromatization sometimes occurs in the solvolysis of highly reactive systems, as shown in Table 3, where the intermediate carbocation may be somewhat stabilized by means of its aromaticity, *e.g.*,

19-OAc ⟶ anthracene[19]

and

20-OPNB ⟶ tetralin[20]

From these prospects, the benzohomopyrylium ion (**e**) might be proposed as the cationic intermediate in the solvolysis of **1-OAc**, and the formation of such extremely delocalized homoaromatic species might greatly contribute to decreasing the activation energy for solvolysis.[1]



e

Benzohomopyrylium ion

Experimental

General. All melting points are uncorrected. The IR spectra were measured using a Hitachi 215 spectrometer, the UV spectra on a Yanaco spectrometer, the mass spectra on a Hitachi RMS-4 spectrometer, and the NMR spectra on a Hitachi R-20 spectrometer. The chemical shifts of the NMR spectra are given in δ, with tetramethylsilane as an internal standard.

Materials. The preparation of 2,3-cyclopentenochromone (**6**) was carried out according to the procedure reported by Boyd *et al.*[10] Mp 127—128 °C (lit,[10] 122—123 °C) (60% yield, colorless prisms, from cyclohexane).

2,3-Cyclopentenohomochromone (2,3-trimethylene-2,3-methanochroman-4-one) (7): To mineral oil-free sodium hydride (NaH), prepared from commercial NaH (3.4 g, 0.071 mol; mineral oil dispersion) by means of triple decantation with light petroleum, was added trimethyloxosulfonium iodide[8] (12.1 g, 0.055 mol) in one portion followed by the addition of anhydrous dimethyl sulfoxide (DMSO) (50 ml) with stirring over a period of 20 min, at first carefully at 20 °C. After the cessation of the violent evolution of hydrogen, the milky-white solution was kept in a nitrogen atmosphere. To the dimethyloxosulfonium methylide produced in DMSO, was added a saturated solution of **6** (9.3 g, 0.05 mol) in DMSO (100 ml) with stirring over a period of 40 min at a temperature of 17—20 °C. The solution turned to grayish green, and then to reddish violet. The mixture was then allowed to stand at room temperature for 2.5 h under nitrogen, warmed to 40° C, maintained for 5 min then cooled in an ice-bath, and anhydrous ether (100 ml) was then added to the solution. The mixture was poured into ice-water, separated, and the aqueous layer was extracted thoroughly with ether. The combined extract was satisfactorily washed with water, and dried on anhydrous sodium sulfate. During the work-up process, separation was sometimes difficult probably due to the poor solubility of unreacted **6**, when the reaction was not complete. The ether was evaporated *in vacuo*, and a yellowish viscous syrup (7.6 g) was obtained, chromatographed on neutral alumina (30 g, activity III, short column) using petroleum ether (boiling range below 40 °C) as an eluent, and the solvent was removed *in vacuo* to give a colorless syrup (7.4 g), which crystallized slowly in a refrigerator. Mp 60—61 °C (6.9 g, 70% yield, colorless prisms, from petroleum ether). IR

(Nujol): 1660, 1610, 1235, 1065 cm^{-1}. NMR (CCl_4): 7.9—6.7 (4H, m, aromatic), 2.6—1.3 (8H, m, trimethylene and cyclopropane). Found: C, 78.15; H, 6.04%. Calcd for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04%.

*2,3-Cyclopenteno-4H-homochromen-4-ol (Homochromenol) (**1-OH**)*: *(a) Reduction of **7** with $LiAlH_4$ in ether.* A solution of **7** (2.00 g) in ether (30 ml) was added portionwise to the well-stirred suspension of lithium aluminum hydride (0.40 g, excess) in ether (10 ml) with ice-cooling. Then the mixture was allowed to sit at room temperature, stirred overnight, and quenched by adding 5 ml of water carefully over 30 min with ice-cooling. The resulting clear solution was decanted and the residue was washed twice with ether. The combined organic solutions were dried over anhydrous potassium carbonate, evaporated *in vacuo* without externel heating to give a colorless oil (2.00 g, quantitative yield), which crystallized in a refrigerator. This material was recrystallized from petroleum ether to yield pure **1-OH** (1.15 g, 57% yield), mp 101—102 °C. IR (nujol): 3350, 1605, 1230, 1070 cm^{-1}. NMR (CCl_4): 7.6—6.5 (4H, m, aromatic), 4.65 (1H, s, α-proton, 2.5—1.5 (7H, m. trimethylene and hydroxyl), 1.15, 0.55 (2H, AB quartet, J=6.5 Hz, cyclopropane). Found: C, 76.95; H, 7.10%. Calcd for $C_{13}H_{14}O_2$: C, 77.20; H, 6.98%.

*(b) Reduction of **7** with $NaBH_4$ in aqueous 2-propanol.* A solution of sodium borohydride (90 mg) in 2-propanol–water (60 ml; 2: 1, by volume) was added to a stirred solution of **7** (1.00 g, 5 mmol) in 2-propanol (40 ml). After being stirred for 2 days at room temperature, 2-propanol was evaporated slowly *in vacuo* without heating and the residue was extracted twice with ether (20 ml). The extracts were combined, washed with water, and dried over anhydrous potassium carbonate. The extract was condensed *in vacuo* to give a colorless oil, whose spectroscopic data agreed well with those of **1-OH** prepared by the above procedure. Pure material (mp 98—100 °C) (0.40 g, 40% yield) was obtained by recrystallization from cyclohexane.

*2,3-Cyclopenteno-4H-homochromen-4-ol Acetate (Homochromenol Acetate) (**1-OAc**)*: To a magnetically-stirred solution of **1-OH** (0.30 g) in pyridine (8 ml), was added a solution of acetic anhydride (0.3 ml) in pyridine (2 ml) over a period of 5 min in an ice–salt bath. After being stirred overnight at room temperature, dry ether (20 ml) was added to the solution, and the mixture was worked up by pouring into ice–water (300 ml). The organic layer was separated, and the aqueous layer was extracted twice with ether (50 ml). The extract was combined, washed with cold water, with ice-cold dilute hydrochloric acid, with water, with 5% sodium hydrogencarbonate and finally with water, and then dried over anhydrous sodium sulfate. The extract was concentrated *in vacuo* without heating to give a colorless oil (0.33 g, 85%). IR (neat): 1730, 1580, 1235, 745 cm^{-1}. MS: (*m/e*) 244 (M^+). NMR (CCl_4): 7.3—6.7 (4H, m, aromatic), 6.05 (1H, s, α-proton), 2.10(3H, s, acetoxy), 2.4—1.2(6H, m, trimethylene), 1.15, 0.75 (2H, AB quartet, J=6.5 Hz, cyclopropane).

For the purpose of purification, the oil was chromatographed on a neutral alumina column. Elution with benzene–petroleum ether (1: 1) produced decomposed substances. When heated for 30 min at 130 °C in a neat condition in a capillary, the oil decomposed.

*Product Studies. Homochromenol Acetate (**1-OAc**) in 80% Acetone–Water*: A solution of the acetate (750 mg) in 80% acetone–water (250 ml) containing sodium hydrogencarbonate (250 mg) was allowed to sit at 25 °C (in a thermostatic bath) for 4 days (*ca.* 12 half-lives). Most of the acetone was evaporated *in vacuo* without heating, and the remaining suspension was extracted with three 50-ml portions of ether. The ether extract was washed with water. After drying over anhydrous sodium sulfate, the ether was removed and the residual partially-crystallized material (602.4 mg, 97% yield) was recrystallyzed from cyclohexane to give pure **10** (310.0 mg, 50% yield). Mp 126—128 °C. IR (Nujol): 3140, 1640, 1270, 1250, 755 cm^{-1}. MS (*m/e*): 202 (M^+). UV λ_{max} (ε) (ethanol): 235 (14000), 277 (2900) nm. NMR ($CDCl_3$): 7.4—6.7 (4H, m, aromatic), 5.87 (1H, s, vinyl), 3.55 (2H, s, allylic bridged methylene), 2.7—1.7 (7H, m, trimethylene and hydroxyl) *cf.* Fig. 2. Found: C, 77.39; H, 6.88%. Calcd for $C_{13}H_{14}O_2$: C, 77.20; H, 6.98%. Acetylation of **10** in a similar manner as described above (from **1-OH** to **1-OAc**) was accomplished to give a colorless oil. IR ($CHCl_3$): 2960, 1770, 1750, 1660 cm^{-1}. NMR ($CDCl_3$): 7.4—6.9 (4H, m, aromatic), 5.87 (1H, s, vinyl), 3.45 (2H, s, allylic bridged methylene), 2.23 (s, acetoxy), 2.6—1.7 (m, others). The above crude product from **1-OAc** in such a solvolytic condition was dissolved in $CDCl_3$, and the NMR measurement was carried out immediately, at which time **10** was found to be almost the sole product, though small amounts of **11** and traces of unidentified materials were present.

When the solvolysis of **1-OAc** was carried out in 80% acetone–water in the presence of pyridine or 2,6-lutidine (a slightly excess amount of the ester), **10** was obtained as a major product. But using any acidic material for removing the alkali during the work-up process, a complex mixture was obtained as a solvolysis product and **10** was not found at all. Similarly, solvolysis of **1-OAc** in 80% acetone–water in the absence of alkali gave a complex mixture. Particular attention should be paid to the treatment of hemiacetal (**10**), since it is highly sensitive to acidic materials.

In addition, parent alcohol (**1-OH**) was stable under the solvolytic condition (in 80% acetone–water at 25 °C for 4 days in the presence of sodium hydrogencarbonate).

*Methanolysis of **1-OAc***: The ester (**1-OAc**) (100 mg) was dissolved in absolute methanol (100 ml) containing pyridine (0.5 ml), and the mixture was allowed to sit at 25 °C for 4 days. After removing the methanol *in vacuo* without heating, CCl_4 (40 ml) was added to the residue and the solvent was removed azeotropically. The residue was dissolved in CCl_4, filtered, and the filtrate was analyzed by NMR spectroscopy. The solvent was removed, ether (50 ml) was added to the residue, the mixture was poured into ice-cold 1M-HCl (70 ml), extracted twice with ether (50 ml), washed with water (50 ml), with 5% sodium hydrogencarbonate (50 ml), and finally with water (50 ml), and then dried over anhydrous sodium sulfate. The colorless oil (96.3 mg) obtained by evaporation of the extract was difficult to crystallize, and produced the same NMR spectrum as the pre-measured NMR spectra made during the work-up process. IR (CCl_4); 3380, 2940, 1480, 1240, 1110, 1050 cm^{-1}. MS (*m/e*): 216 (M^+). NMR (CCl_4); 7.3—6.65 (4H, m, aromatic), 6.08 (1H, s, vinyl), 3.12 (3H, s, methoxy; *cf.* 3.37 for MeO–H), 2.5—1.15 (*ca.* 8H, m, others).

Trapping a Reactive Carbocation with Hydride Reagent: A solution of sodium borohydride (2.0 g) in 50% aqueous diglyme (30 ml) including sodium hydroxide (80 mg) was added to the homochromenol ester (**1-OAc**) (183.2 mg). After being stirred overnight at room temperature, *n*-pentane (50 ml) and water (50 ml) were added to the reaction mixture, separated, and the aqueous layer was extracted twice with *n*-pentane (30 ml). The combined organic layers were washed with water (30 ml), and dried over anhydrous sodium sulfate. The colorless oil (250.4 mg) obtained by evaporation of the extract *in vacuo*, included the remaining diglyme. After distillation, **15** was obtained; bp *ca.* 130 °C/2 mmHg (bath temp) (40 mg). No isomerization (or decomposition) occurred during the distillation as verified by IR, NMR, and GC data. IR (neat): 2900, 1470, 1440, 1180, 1110 cm^{-1}. MS (*m/e*): 186 (M^+). UV (ethanol) λ_{max} 254.5 nm. NMR (CCl_4): 7.4—6.5 (4H,

m, aromatic), 6.10 (1H, s, vinyl), 5.03 (1H, m, bridgehead methine), 3.0—1.7 (8H, m, others).

Kinetic Studies. The rates of solvolysis of homochromenol acetate (**1-OAc**) in 80% acetone–water were determined using solutions in about 0.004 mol concentration and titrating the liberated acetic acid with 0.01 M NaOH in methanol to a bromothymol blue end-point. The base was frequently restandardized against oxalic acid during the course of the work.

Solutions of the acetate in 80% acetone–water (by volume) were prepared in the following manner. The weighed **1-OAc** was dissolved in anhydrous acetone (40 ml). Then, a 75% acetone–water (by volume, 160 ml) solution was prepared, and both solutions were set in a thermostatic bath and maintained at 25 °C (±0.03 °C). About 10 min later, the latter solution poured into the former, and the mixture (**1-OAc** in 80% acetone–water) was well shaken, then dipped in the thermostatic bath. The first aliquot (10 ml) was pipetted after 5—10 min and taken as the zero point. Periodically, each aliquot was taken, quenched by anhydrous acetone (20 ml) and then subjected to titration. Infinity titrations were determined after 10 or more half-lives, and in those cases the liberated acetic acid reached 95—98% of the theoretical amount. Rate constants were calculated to the first-order, and mean values from several runs are shown in Table 2. Typical first-order plots are shown in Fig. 3.

Isomerization of the Parent Alcohol and Interconversion between Hemiacetal and Ketophenol in Trifluoroacetic Acid. A wine red solution of the parent alcohol (**1-OH**) (0.20 g) in trifluoroacetic acid (TFA) (1 ml) was analyzed by NMR spectroscopy. NMR (TFA) 7.5—6.7 (>4H, m, aromatic), 6.0 (<1H, s, vinyl), 3.72, 3.10 (2H, s, s, allylic methylene), 3.1—1.8 (7H, m, others). The ratio **10/11** in TFA was *ca.* 3: 1 in comparison with the characteristic signals of the NMR spectra. The ratio was variable though **10** always predominates in TFA at room temperature even after 3 days. The solution was poured into an ice-cold aqueous sodium hydrogencarbonate solution, extracted three times with ether, next the combined organic layer was washed with cold aqueous sodium hydrogencarbonate and with water, and then dried over anhydrous potassium carbonate. A pale yellow syrup (181.3 mg, 90%) obtained by evaporation of the ether, was pumping *in vacuo* to give **11** (mp 76—78 °C) as the sole product of the NMR spectrum in $CDCl_3$, which was dissolved in benzene and passed through a short column of alumina (activity III). Concentration of the filtrate produced pure **11**, mp 78—80 °C, IR (Nujol): 2950, 1720, 1580, 1240, 750 cm^{-1}. MS (*m/e*): 202 (M^+). UV λ_{max} (ε) (ethanol): 279 (2900), 315 (350) nm. NMR ($CDCl_3$): 7.5—6.6 (5H, m, aromatic and vinyl), 3.05 (2H, s, allylic methylene), 3.0—1.7 (7H, m, trimethylene and hydroxyl). Positive for the $FeCl_3$ test in $CDCl_3$. Found: C, 76.78; H, 6.86%. Calcd for $C_{13}H_{14}O_2$: C, 77.20; H, 6.98%.

When dry ether was added to the above TFA solution before the work-up process, a mixture of **10** and **11** was isolated after similar treatment, and the former was found to be predominant (*ca.* 2: 1) in the NMR spectra in $CDCl_3$. Heating the contents of the $CDCl_3$ solution at 50 °C for 30 min, **11** was obtained as the sole product.

When **11** (40 mg) was dissolved in TFA (0.3 ml) the ratio of **10/11** was *ca.* 9: 4 from the NMR spectrum. NMR (TFA): 7.5, 6.7 (>4H, m, aromatic), 6.02 (<1H, s, vinyl), 3.76, 3.14 (2H, s, s, methylene), 3.0—1.8 (*ca.* 7H, m, others). Ether was added to the solution, then the mixture was treated in the same manner as described above. The yellowish oil (35.8 mg, 90%) obtained was dissolved in $CDCl_3$ for measuring both the IR and NMR spectra. The IR spectrum of this oil was found to be consist of duplicates of **10** and **11**, and the former was at first predominant depending on the relative intensity of each characteristic absorption band (especially 1640 cm^{-1} for **10**, and 1720 cm^{-1} for **11**). However, after several hours the relative intensities were clearly reversed, and the information from NMR spectroscopy agreed well with these results. Similarly, a mixture of **10** and **11** was obtained from **10** in TFA. According to the NMR study, the ratios of **10/11** derivated from **1-OH**, **10**, or **11** in TFA appear to depend on the temperature.

We are indebted to Mr. T. Sugiura for assistance during the experiments, and we also wish to thank to Mrs. S. Kurokawa and Miss S. Eguchi for obtaining the NMR and the mass spectra, respectively. This work was partially supported by a grant in aid from the Ministry of Education, No. 747019 in 1972 and 1973.

Reaction of a Stable Free Nitrogen-centered Radical, 3,4-Dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl, with Grignard Reagents[1)]

Yozo Miura, Yuzo Morimoto, and Masayoshi Kinoshita

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 12, 1975)

The reactions of 3,4-dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl (**1**) with Grignard reagents such as ethyl-, isopropyl-, butyl-, isobutyl-, *s*-butyl-, *t*-butyl-, cyclohexyl-, phenethyl-, phenyl-, and 2-naphthylmagnesium bromides and benzylmagnesium chloride were examined. In the reactions with the alkylmagnesium halides, coupling compounds (**2**) of **1** with alkyl radicals derived from the alkylmagnesium halides were isolated in 41—50% yields. On the other hand, in the reactions with arylmagnesium bromides the corresponding coupling compounds were not isolated, but biphenyl and 2,2′-binaphthyl were isolated in 87 and 86% yields, respectively. From these results, the reactions of **1** with Grignard reagents are concluded to proceed through a homolytic process.

Recently, many reactions of oxygen-centered radicals with organometallic compounds have been investigated,[2)] and these reactions have been demonstrated to proceed through a homolytic process at metal centers, by stereochemical, kinetic, and ESR studies. However, only a few examples of homolytic reactions with nitrogen-centered radicals have been so far reported.[3)]

In the course of preparation of polymers containing stable free radicals,[4)] the reactions of 3,4-dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl (**1**, 1,3,5-triphenylverdazyl),[5)] which is a typical stable free nitrogen-centered radical, with alkylmagnesium halides or alkyllithiums used as an initiator, were examined. It was found that coupling compounds of **1**, 1-alkyl-2,4,6-triphenyl-1,2,3,4-tetrahydro-1,2,4,5-tetrazines (**2**), with radicals derived from these organometallic compounds were formed.[6)] The formation of **2** suggests that the reactions proceed through a homolytic process.

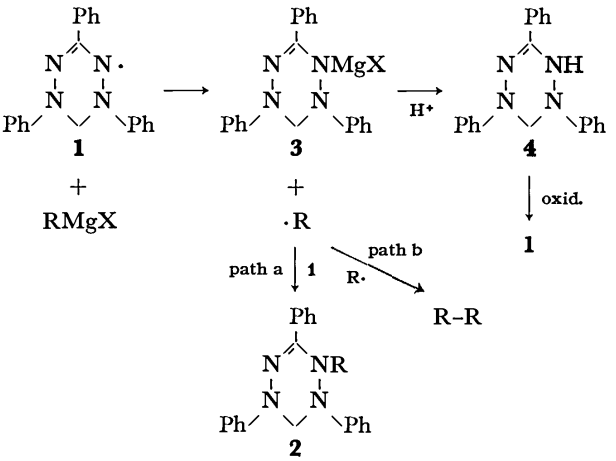
In this paper, the results of the reactions of **1** with various Grignard reagents are described, and the reaction mechanisms will be discussed.

Results and Discussion

Reaction of 1 with Alkylmagnesium Halides. As a Grignard reagent was added gradually to a tetrahydrofuran (THF) solution of **1**, the characteristic dark green color of **1** slowly faded, and turned finally to light yellow within *ca.* 10 min after the Grignard reagent had been added. This yellow solution maintained its color in the absence of moisture. However, when the solution was poured into water, its color retured immediately to green, the coloration indicating that **1** was regenerated. The solution was extracted with benzene, and thin layer chromatography (tlc) revealed the presence of three components in the benzene solution. One of them was easily identified to be **1** on the basis of the green color and the R_f value. One of the other spots disappeared when the benzene solution was allowed to stand for two days under ambient conditions, and the amount of **1** recovered was found to increase gradually from the measurement of absorbance at 720 nm. The spot also disappeared immediatelly upon the addition of catalytic amounts of lead dioxide. A leuco compound (**4**) of **1** is known to be easily oxidized to **1** even by atmospheric oxygen,[5)] and thus, the component was identified to be **4**. This was also ascertained by the R_f value. From these results it is clear that **1** is formed by the oxidation of **4**. The amount of **1** recovered was determined by measuring the absorbance at 720 nm after **4** was oxidized thoroughly to **1**. The results are summarised in Table 1.

Next, the benzene solution was concentrated and subjected to column chromatography. The results indicate the formation of a coupling compound (**2**) of **1** with an alkyl radical derived from the Grignard reagent in 41—50% yields (based on the amount of **1** used).

Reaction of 1 with Arylmagnesium Bromides. The reactions of **1** with arylmagnesium bromides such as phenyl- and 2-naphthylmagnesium bromides were examined. In these cases, the green solution turned to light yellow within *ca.* 2 hr after the addition of the Grignard reagent, and the reaction proceeded much more slowly than that with alkylmagnesium halides. In the extracted benzene solution three components were found. Two of them were identified to be **1** and **4**, respectively. However, the corresponding coupling compound (**2**) was not detected. The amounts of **1** recovered were determined by the same procedure as described above to be 79 and 81% yields (Table 1).



2a : R = C_2H_5 **2f** : R = t-C_4H_9
2b : R = i-C_3H_7 **2g** : R =
2c : R = n-C_4H_9 **2h** : R = CH_2Ph
2d : R = i-C_4H_9 **2i** : R = CH_2CH_2Ph
2e : R = s-C_4H_9

Scheme 1.

These values are much larger than those for alkylmagnesium halides. The benzene solution was then concentrated and subjected to column chromatography to give biphenyl and 2,2'-binaphthyl in almost quantitative yields (Table 1).

Reaction Mechanism. From these results a reasonable reaction mechanism may be illustrated as shown in Scheme. In the reactions of **1** with alkylmagnesium halides, **1** and a Grignard reagent are converted into the corresponding magnesium salt (**3**) and an alkyl radical. The alkyl radical formed is captured exclusively by another **1** to give a coupling compound (**2**, path a). This is also supported by the fact that **1** has been found to be an efficient inhibitor in radical polymerization,[7] and that the amount of octane detected in the reaction of **1** with butylmagnesium bromide was almost the same as found in the course of the preparation of the Grignard reagent. Although **3** is stable under anhydrous conditions, it decomposes immediately in contact with water to give a lueco compound (**4**), which is oxidized gradually by atmospheric oxygen to **1**.

In the reactions with arylmagnesium bromides, aryl radicals formed are not captured by **1**, but are coupled with each other to give the biarlys (path b), and therefore, the amounts of **1** recovered were much larger than those for the alkylmagnesium halides.

In order to confirm whether **1** reacts with a phenyl radical, an attempted reaction of **1** with phenylazotriphenylmethane[8] was examined. A benzene solution containing **1** and two equivalents of the azo-compound was refluxed for a few hours. The resulting reaction mixture was examined by tlc, but the corresponding coupling compoung was not detected.

Experimental

All melting points were uncorrected. Thin layer chromatography was performed on Kieselgel GF_{254} according to Stahl Type 60 (E. Merck, Darmstadt, West Germany), using benzene, and detection was effected by UV irradiation. The NMR spectra were recorded using a Hitachi-Perkin Elmer R-20 Spectrometer in $CDCl_3$, using TMS as an internal standard. The visible spectra were measured with a Hitachi Recording Spectrometer Model EPS-3T.

THF was distilled from KOH, sodium wire, and from $LiAlH_4$ before use. All Grignard reagents were prepared by treating alkyl and aryl halides [2.0 ml except for 2-bromonaphthalene (2.0 g)] with a slight excess of magnesium in THF (50 ml), and the conversions were determined by the method of Gilman *et al.*[9]

3,4-Dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl (**1**) was prepared by treating 1,3,5-triphenylformazan with 37% formalin in the presence of potassium hydrogensulfate according to the procedure of Kuhn and Trischmann,[5] and was recrystallized from methanol, mp 141—142 °C (lit,[5] 139—140 °C).

General Procedure for the Reactions of 1 with Grignard Reagents. **1** (0.50 g, 1.6 mmol) and THF (15 ml) were put in a vessel with a rubber-capped neck. After the dark green THF solution was degassed by freeze-and-thaw cycles, the vessel was sealed. A Grignard reagent was then added gradually to the THF solution at 0 °C through the rubber-cap with a syringe. The green reaction mixture was allowed to stand for *ca.* 10 min (in the reactions with alkylmagnesium halides) and *ca.* 2 hr (for arylmagnesium bromides) at the same temperature, after which, turned to light yellow. After 2 hr, the solution was poured into water, and extracted with benzene. The benzene solution was washed with dilute hydrochloric acid (*ca.* 1 M), and with water, and dried over sodium sulfate. The amount of **1** recovered was determined by the measurement of absorbance at 720 nm (ε 4330 in benzene) in the benzene solution (total volume 3000 ml). Next benzene was evaporated under reduced pressure and the residue obtained was subjected to chromatography on a silica-gel column (Mallinckrodt 100 mesh, 25×400 cm) with benzene, giving a coupling compound (**2**) in the case of reactions with alkylmagnesium halides, and biaryls with arylmagnesium bromides. All results of the reactions are summarized in Tables 1 and 2.

The biphenyl isolated by this method was in the form of pure crystals, 0.12 g (0.78 mmol), mp 70—71 °C (lit,[10] 71 °C). The isolated 2,2'-binaphthyl contained small amounts of naphthalene, which was removed by recrystallization from ethanol, 0.19 g (0.75 mmol), mp 184—185 °C (lit,[11] 185—186 °C). The amounts of biaryls which arise from the preparation procedure of arylmagnesium bromides were determined as follows; the same amounts of arylmagnesium bromides used in the reactions were hydrolyzed, and extracted with benzene. The benzene solution was concentrated, and the residue was analyzed by column chromatography. The amounts of biphenyl and 2,2'-binaphthyl isolated were 0.013 g (0.084 mmol) and 0.015 g (0.059 mmol), respectively.[12] The yields of the

β-Disulfoxides. II. The Preparation of Some Optically Active β-Disulfoxides

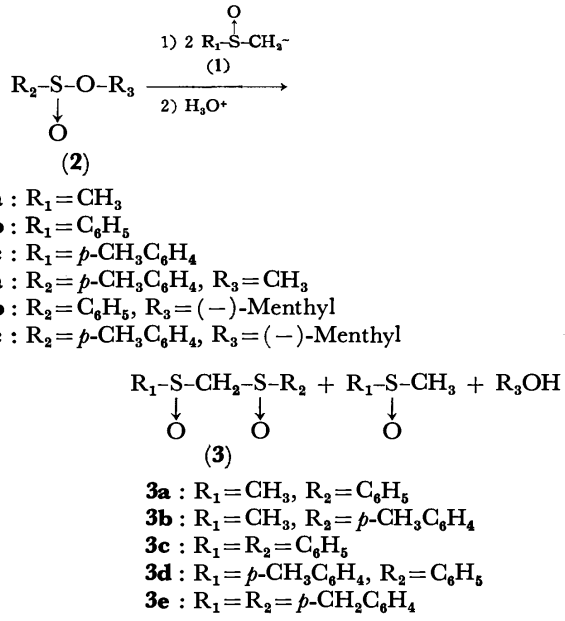
Norio KUNIEDA, Junzo NOKAMI, and Masayoshi KINOSHITA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 16, 1975)

α-Sulfinylcarbanions (**1**) derived from methyl-substituted sulfoxides readily react with arenesulfinic esters (**2**) to give the corresponding β-disulfoxides (**3**) in good yields. The reaction was conducted using (−)-menthyl (−)-(*S*)-benzenesulfinate ((−)-(*S*)-**2b**), (−)-menthyl (−)-(*S*)-*p*-toluenesulfinate ((−)-(*S*)-**2c**), and α-*p*-tolylsulfinylcarbanion derived from (+)-(*R*)- or (−)-(*S*)-methyl *p*-tolyl sulfoxide to produce (*R,S*)- and/or (*S,S*)-diastereoisomers of five β-disulfoxides (**3a—e**). The configurational assignment for the diastereoisomers obtained was accomplished by a combination of NMR and polarimetric analyses.

Recently, we have reported a facile one-step synthesis of β-disulfoxides, starting from arenesulfinic esters and α-sulfinylcarbanions derived from the corresponding methyl-substituted sulfoxides.[1] This reaction is of great advantage in synthesizing optically active β-disulfoxides, because one can readily prepare either optically active methyl-substituted sulfoxides or optically active arenesulfinic esters in a state of high enantiomeric purity.[2] In order to study the stereochemistry of β-disulfoxides,[6] we have now investigated the application of this reaction to the synthesis of some diastereomerically pure β-disulfoxides[(+)-(*S*)-[(*S*)-α-methylsulfinyl]-methyl phenyl sulfoxide((*S,S*)-**3a**), (+)-(*S*)-[(*S*)-α-methylsulfinyl]methyl *p*-tolyl sulfoxide((*S,S*)-**3b**), (+)-(*S*)-[(*R*)-α-methylsulfinyl]methyl *p*-tolyl sulfoxide((*R,S*)-**3b**), (+)-(*S,S*)- and (*R,S*)-bis(phenylsulfinyl)methanes-((*S,S*)- and (*R,S*)-**3c**), (+)-(*S*)-[(*S*)-α-*p*-tolylsulfinyl]-methyl phenyl sulfoxide((*S,S*)-**3d**), and (+)-(*S,S*)- and (*R,S*)-bis(*p*-tolylsulfinyl)methanes((*S,S*)- and (*R,S*)-**3e**)], using (+)-(*R*)- and (−)-(*S*)-methyl *p*-tolyl sulfoxides, (−)-menthyl (−)-(*S*)-benzenesulfinate((−)-(*S*)-**2b**), and (−)-menthyl (−)-(*S*)-*p*-toluenesulfinate((−)-(*S*)-**2c**) as chiral precursors.



Scheme 1.

Results and Discussion

When 2 equivalents of arenesulfinic esters(**2**) were allowed to react with α-sulfinylcarbanions(**1**) in tetrahydrofuran at 0 °C,[8] a diastereomeric mixture of β-disulfoxides(**3**) was produced in a good yield, in a fashion analogous to the case of the reaction of α-methylsulfinylcarbanion with carboxylic esters.[9]

In typical reactions, when (−)-(*S*)-**2c** was treated with 2 equivalents of α-methylsulfinylcarbanion(**1a**) (derived from dimethyl sulfoxide and sodium hydride)[9d] in tetrahydrofuran at 0 °C, dextrorotatory α-methylsulfinylmethyl *p*-tolyl sulfoxides(**3b**) [(*R,S*)-**3b**: (*S,S*)-**3b**=59: 41%][10] was produced in a 85% yield. From the resulting **3b**, diastereomerically pure (*S,S*)-**3b**, $[\alpha]_D^{19}$ +346° (acetone), was isolated by fractional crystallization from benzene. The structural assignment of (*S,S*)-**3b** was supported by the NMR spectrum, which exhibited resonances at 2.76 ppm(s) and 4.00 ppm(s) due to the methyl protons of the methylsulfinyl group and the methylene protons respectively. Though we have not isolated pure (*R,S*)-**3b**, the concentration of the mother liquid, followed by the recrystallization of the residue from hexane–benzene, led to an enrichment in (*R,S*)-**3b**. The NMR spectrum of (*R,S*)-**3b** shows an AB quartet at 4.00 ppm (J_{AB}=7.8 Hz) due to the non-equivalent methylene protons[11] and a singlet at 2.94 ppm due to the methyl protons of the methylsulfinyl group.

When 2 equivalents of α-*p*-tolylsulfinylcarbanion, (*R*)-**1c**, derived from (+)-(*R*)-methyl *p*-tolyl sulfoxide and lithium diethylamide, were allowed to react with racemic methyl *p*-toluenesulfinate(**2a**) in tetrahydrofuran at 0 °C, a diastereomeric mixture of bis(*p*-tolylsulfinyl)methanes(**3e**) [(*R,S*)-**3e**: (*S,S*)-**3e**=62: 38%] was produced. Column chromatography, followed by the fractional crystallization of the resulting **3e**, afforded (*S,S*)-**3e**(*dl*-form) (mp 137.5 °C, $[\alpha]_D^{20}$ +318°(acetone) and optically inactive (*R,S*)-**3e** (*meso*-form) (mp 124.5—125 °C). The NMR spectra (in $CDCl_3$) of each diastereoisomer showed singlets due to methylene protons at 4.05 ppm for (*S,S*)-**3e** and at 4.18 ppm for (*R,S*)-**3e**.[12] In addition, the treatment of (−)-(*S*)-**2c** with 2 equivalents of (*R*)-**1c** afforded a single diastereoisomer (*S,S*)-**3e**; its physical properties as well as specific rotation were found to be identical with those of the (*S,S*)-**3e** mentioned above. Only one diastereoisomer, optically inactive (*R,S*)-**3e**, was also obtained on the treatment of (−)-(*S*)-**2c** with 2 equivalents of (*S*)-**1c**

Table 1. Reaction of α-sulfinylcarbanions (**1**) with arenesulfinic esters (**2**) in tetrahydrofuran at 0 °C

1	2	3 (Yields, %)[a]	Diastereomeric ratio of **3**, (*R*, *S*)/(*S*, *S*)	Isolated diastereoisomers[f]
1a	(−)-(*S*)-**2b**	**3a** (75)[b]	63/37	(*S*, *S*)-**3a**, $[\alpha]_D^{19}$ +403°[e]
1a	(−)-(*S*)-**2c**	**3b** (85)[b]	59/41	(*S*, *S*)-**3b**, $[\alpha]_D^{19}$ +346° (*R*,*S*)-**3b**, $[\alpha]_D^{19}$ +170°[d]
1b	(−)-(*S*)-**2b**	**3c** (78)[b]	57/43	(*S*, *S*)-**3c**, $[\alpha]_D^{15}$ +358° (*R*,*S*)-**3c**, inactive
1b	(−)-(*S*)-**2c**	**3d** (71)[b]	58/42	(*S*, *S*)-**3d**, $[\alpha]_D^{20}$ +334°[e]
1c	(−)-(*S*)-**2c**	**3e** (80)[b]	64/36	(*S*, *S*)-**3e**, $[\alpha]_D^{20}$ +318°[e]
(*R*)-**1c**	**2a**	**3e** (56)[b]	62/38	(*S*, *S*)-**3e**, $[\alpha]_D^{20}$ +318° (*R*,*S*)-**3e**, inactive
(*R*)-**1c**	(−)-(*S*)-**2c**	**3e** (35)[c]	0/100	(*S*, *S*)-**3e**, $[\alpha]_D^{20}$ +318°
(*S*)-**1c**	(−)-(*S*)-**2c**	**3e** (45)[c]	100/0	(*R*,*S*)-**3e**, inactive

a) Yields are based on the starting arenesulfinic esters (**2**). b) Yields of a mixture of diastereoisomers. c) Yields after recrystallization. d) It includes 9.8% (*S*,*S*)-**3b**. e) In this case, no attempt was made to separate (*R*,*S*)-diastereoisomer. f) Specific rotations were determined in acetone.

Table 2. NMR data of β-disulfoxides (**3a**—**e**) in $CDCl_3$

β-Disulfoxides	NMR chemical shift, δ (multiplicity, *J*, Hz), ppm		
	$-CH_2-$	CH_3SO-	$\underline{CH_3}C_6H_4-$
3a (*R*,*S*)	4.03(q, 8.0)	2.96(s)	
(*S*, *S*)	4.02(s)	2.80(s)	
3b (*R*,*S*)	4.00(q, 7.8)	2.94(s)	2.45(s)
(*S*, *S*)	4.00(s)	2.76(s)	2.45(s)
3c (*R*,*S*)	4.12(s)		
(*S*, *S*)	3.92(s)		
3d (*R*,*S*)	4.11(s)		2.39(s)
(*S*, *S*)	3.99(s)		2.39(s)
3e (*R*,*S*)	4.18(s)		2.43(s)
(*S*, *S*)	4.05(s)		2.43(s)

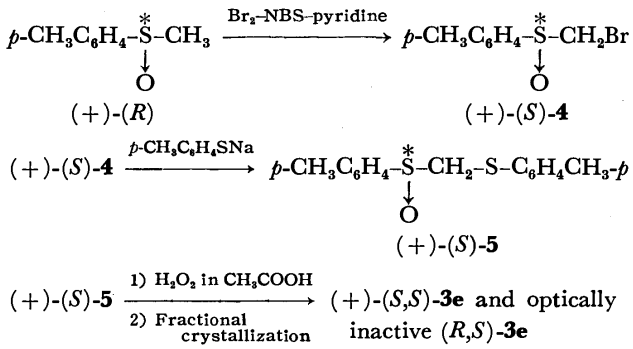
derived from (−)-(*S*)-methyl *p*-tolyl sulfoxide and lithium diethylamide.

By a similar procedure, (+)-(*S*,*S*)-**3a**, (+)-(*S*,*S*)-**3c**, optically inactive (*R*,*S*)-**3c**, and (+)-(*S*,*S*)-**3d** were also prepared, using (−)-(*S*)-**2b** and (−)-(*S*)-**2c** as chiral precursors.

The results of these reactions are summarized in Table 1, while the NMR data of isolated diastereomeric β-disulfoxides are compiled in Table 2.

Incidentally, an attempt was made to confirm that the reaction takes place without any loss of stereochemical integrity in the precursors (see Scheme 2). The treatment of (+)-(*S*)-α-bromomethyl *p*-tolyl sulfoxide(**4**), $[\alpha]_D^{14}$ +208° (acetone), with sodium *p*-tolyl sulfide afforded (+)-(*S*)-*p*-tolyl *p*-tolylthiomethyl sulfoxide(**5**), $[\alpha]_D^{15}$ +76.8° (acetone). The oxidation of **5** with hydrogen peroxide in acetic acid yielded a mixture of diastereoisomers of **3e**[(*R*,*S*)-**3e**: (*S*,*S*)-**3e**= 53: 47%]. The fractional crystallization of the mixture furnished dextrorotatory (*S*,*S*)-**3e** and optically inactive (*R*,*S*)-**3e**; their physical properties were found to be identical with those of the compounds obtained from (*R*)-**1c** and **2a**.

An inspection of these results reveals that the nucleophilic substitution at the sulfur atom of sulfinic esters, the entering α-sulfinylcarbanion and the outgoing alkoxy group, proceeds through an S_N2 process with a complete inversion of configuration, in a fashion



Scheme 2.

similar to the case of normal S_N2-type reactions between sulfinic esters and nucleophiles.[13] Therefore, this reaction is very convenient for obtaining β-disulfoxides in optically and diastereomerically pure states. Moreover, as is revealed in Table 1, in the products of the reaction of **1** with **2** (*R*,*S*)-**3** predominates over (*S*,*S*)-**3**. Though the stereoselectivity may be attributed to the chiralities of both α-sulfinylcarbanions and sulfinic esters, the stereochemical implications of this problem are not yet clear; they will be the subject of our forthcoming paper in this series.

Experimental

General. The optical rotations were measured with a Jasco DPI-4-type polarimeter. The NMR spectra were determined with a Hitachi-Perkin-Elmer R-20 Spectrometer or a Jeol-PS-100 Spectrometer; the chemical shifts are reported in δ units, using tetramethylsilane as the internal reference. The NMR characteristics of β-disulfoxides described here are summarized in Table 2. The IR spectra were obtained with a Jasco IR-G-type spectrometer. All the melting points were taken in a Yanaco MP-type apparatus.

Starting Materials. *(−)-Menthyl (−)-(S)-p-Toluenesulfinate* [(−)-*(S)*-**2c**] was prepared by the reaction of (−)-menthol (Nakarai Chemical Ltd., Kyoto, mp 42—42.5 °C, $[\alpha]_D$ −50 °C (EtOH)) with *p*-toluenesulfinyl chloride according to the method developed by Phillips;[13a] mp 107—107.5 °C, $[\alpha]_D^{25}$ −201° (acetone) [lit,[14] mp 106—107 °C, $[\alpha]_D^{25}$ −199.2° (acetone)]. *(−)-Menthyl (−)-(S)-Benzenesulfinate* [(−)-*(S)*-**2b**] was prepared by the reaction of (−)-menthol

with benzenesulfinyl chloride; mp 50 °C, $[\alpha]_D^{20}$ −200° (acetone) [lit,[15] mp 49—51 °C, $[\alpha]_D$ −205.5° (acetone)]. *(+)-(R)-Methyl p-Tolyl Sulfoxide* was prepared from (−)-(*S*)-**2c** and methylmagnesium iodide according to the method developed by Andersen;[13c] mp 74 °C, $[\alpha]_D^{20}$ +146 °(acetone) [lit,[13f] mp 73—74.5 °C, $[\alpha]_D$ +145.5° (acetone)]. *(−)-(S)-Methyl p-Tolyl Sulfoxide* was prepared by the hydrolysis of the ethoxysulfonium salt of (+)-(*R*)-methyl *p*-tolyl sulfoxide according to the method of Johnson and McCants;[16] mp 74.5 °C, $[\alpha]_D^{20}$ −146 ° (acetone). *Dimethyl Sulfoxide* was freshly distilled from calcium hydride; bp 53 °C/1 mmHg. *Racemic Methyl Phenyl Sulfoxide* was prepared by the periodate oxidation of methyl phenyl sulfide;[17] bp 98—99 °C/1 mmHg(lit,[18] bp 84 °C/0.25 mmHg).

Reaction of **1a** *with (−)-(S)-***2c**. A solution of 2.94 g (0.01 mol) of (−)-(*S*)-**2c** in 10 ml of dry tetrahydrofuran was added, drop by drop to a solution of **1a** (prepared from 12 ml of dimethyl sulfoxide and 0.021 mol of sodium hydride)[9d] in 15 ml of dry tetrahydrofuran at 0 °C under nitrogen. The reaction mixture was then stirred for 1 h at 0 °C under nitrogen. After the addition of water (50 ml), the solution was acidified with 10% hydrochloric acid to a pH of about 3 and extracted with chloroform. The chloroform layer was washed with water and dried over anhydrous sodium sulfate. The column chromatography using a column packed with 100-mesh silica gel and using benzene as the eluent, afforded crude **3b** in an 80% yield; $[\alpha]_D^{19}$ +223° (*c* 0.207, acetone) [(*R,S*)-**3b**: (*S,S*)-**3b**=59: 41%]. (When the residue obtained from the chloroform layer was poured into a large amount of hexane, the hexane-insoluble **3b** was also obtained as a precipitate.) From the resulting **3b**, diastereomerically pure (*S,S*)-**3b** (250 mg) was isolated as colorless needles by fractional crystallization from benzene; mp 147 °C, $[\alpha]_D^{19}$ +346 ° (*c* 0.113, acetone), IR (KBr): 2980, 2900, 1602, 1500, 1430, 1415, 1355, 1300, 1120, 1085, 1055, 1040, 1020, 980, 850, and 715 cm^{-1}. Found: C, 49.85; H, 5.50%. Calcd for $C_9H_{12}O_2S_2$: C, 49.97; H, 5.59%. The concentration of the mother liquid and the crystallization of the residue from hexane–benzene yielded the (*R,S*)-rich diastereoisomer (78 mg) [(*S,S*)-**3b**: (*R,S*)-**3b**=9.8: 90.2%]; $[\alpha]_D^{19}$ +170° (*c* 0.299, acetone). Found: C, 49.88; H, 5.55%. Calcd for $C_9H_{12}O_2S_2$: C, 49.97; H, 5.59%.

Reaction of **1a** *with (−)-(S)-***2b**. A solution of 2.80 g (0.01 mol) of (−)-(*S*)-**2b** in 10 ml of dry tetrahydrofuran was added, drop by drop to a solution of **1a** (0.021 mol) in 15 ml of dry tetrahydrofuran at 0 °C under nitrogen. According to a work-up similar to that described above for **3b**, $[\alpha]_D^{19}$ +280° (*c* 0.180, acetone) [(*R,S*)-**3a**: (*S,S*)-**3a**=63: 37%] was obtained in a 75% yield. From the resulting **3a**, diastereomerically pure (*S,S*)-**3a** (130 mg) was isolated as colorless crystals by fractional crystallization from benzene; mp 138 °C, $[\alpha]_D^{19}$ +403 ° (*c* 0.054, acetone), IR (KBr): 2950, 2900, 1450, 1375, 1080, 1073, 1048, 1023, 993, 955, and 743 cm^{-1}. Found: C, 47.11; H, 4.72%. Calcd for $C_8H_{10}S_2O_2$: C, 47.50; H, 4.98%. No attempt was made to separate (*R,S*)-**3a**.

Reaction of **1b** *with (−)-(S)-***2b**. Methyl phenyl sulfoxide (1.12 g, 0.008 mol) was treated with a solution of lithium diethylamide (prepared from 5.2 ml of a 0.1 g/ml solution of butyllithium in hexane and 585 mg of diethylamine) in 15 ml of dry tetrahydrofuran at 0 °C under nitrogen. After 30 min, a solution of 1.12 g (0.004 mol) of (−)-(*S*)-**2b** in 10 ml of dry tetrahydrofuran was added, and the mixture was stirred for 1 h. The solution was then acidified (*ca.* pH 3) with 10% hydrochloric acid and extracted with chloroform. The chloroform layer was washed with water and dried over anhydrous sodium sulfate. The solvent was evaporated *in vacuo* and washed well with hexane in order to remove the *l*-menthol. Subsequent crystallization from carbon tetrachloride gave (*S,S*)-**3c** (300 mg); mp 136 °C, $[\alpha]_D^{15}$ +358°(*c* 0.190, acetone); IR (KBr): 1480, 1445, 1155, 1075, 1040, 1023, 785, and 738 cm^{-1}. Found: C, 58.55; H, 4.48%. Calcd for $C_{13}H_{12}O_2S_2$: C, 59.06; H, 4.58%. The concentration of the mother liquid and column chromatography on silica gel, using chloroform or benzene as the eluent, followed by recrystallization from hexane–benzene, yielded (*R,S*)-**3c** (250 mg); mp 123 °C. Found: C, 58.71; H, 4.41%. Calcd for $C_{13}H_{12}O_2S_2$: C, 59.06; H, 4.58%.

*Reaction of (R)-***1c** *with* **2a**. A solution of 851 mg (0.005 mol) of **2a** in 10 ml of dry tetrahydrofuran was added, drop by drop to a solution of (*R*)-**1c** (derived from 1.54 g (0.01 mol) of (+)-(*R*)-methyl *p*-tolyl sulfoxide, 6.4 ml of a 0.1 g/ml solution of butyllithium in hexane, and 732 mg of diethylamine in 5 ml of tetrahydrofuran) at 0 °C under nitrogen. A work-up similar to that described for **3c**, a mixture of diastereoisomers of **3e** [(*R,S*)-**3e**: (*S,S*)-**3e**=62: 38%] was produced in an 80% yield. From the mixture, (*S,S*)-**3e** (210 mg) and (*R,S*)-**3e** (135 mg) were obtained by fractional crystallization. (*S,S*)-**3e**: mp 137.5 °C, $[\alpha]_D^{20}$ +318° (*c* 0.110, acetone), IR (KBr): 1500, 1180, 1110, 1080, 1015, and 815 cm^{-1}. Found: C, 61.10; H, 5.38%. Calcd for $C_{15}H_{16}O_2S_2$: C, 61.61; H, 5.51%. Optically inactive (*R,S*)-**3e**: mp 124.5—125 °C.

*Reaction of (R)-***1c** *with (−)-(S)-***2c**. In a manner similar to that used for **3c**, the treatment of 442 mg (0.0015 mol) of (−)-(*S*)-**2c** in 5 ml of dry tetrahydrofuran with (*R*)-**1c** (derived from 463 mg (0.003 mol) of (+)-(*R*)-methyl *p*-tolyl sulfoxide, 0.0031 mol of butyllithium, and 0.0031 mol of diethylamine) afforded crude (*S,S*)-**3e** in an 87% yield. The recrystallization of the crude product from benzene yielded 152 mg of (*S,S*)-**3e** in a diastereomerically pure state; mp 137.5 °C, $[\alpha]_D^{20}$ +318° (*c* 0.190, acetone). Found: C, 61.14; H, 5.28%. Calcd for $C_{15}H_{16}O_2S_2$: C, 61.61; H, 5.51%.

*Reaction of (S)-***1c** *with (−)-(S)-***2c**. Using a procedure similar to that described for **3c**, 99 mg (45% yield) of optically inactive (*R,S*)-**3e** (mp 124.5—125 °C) was obtained from 221 mg (0.00075 mol) of (−)-(*S*)-**2c** and 0.0015 mol of (*S*)-**1c** (derived from 231 mg of (−)-(*S*)-methyl *p*-tolyl sulfoxide and 0.0016 mol of lithium diethylamide).

Reaction of **1b** *with (−)-(S)-***2c**. When a 2.94 g (0.01 mol) of (−)-(*S*)-**2c** was treated with **1b** (derived from 2.81 g of racemic methyl phenyl sulfoxide, 2.8 ml of a 0.1 g/ml solution of butyllithium, and 1.46 g of diethylamine) in dry tetrahydrofuran at 0 °C by a procedure similar to that described for **3c**, a mixture of diastereomeric **3d**[(*R,S*)-**3d**: (*S,S*)-**3d**= 58: 42%] was produced in a 71% yield. From the resulting mixture, (*S,S*)-**3d** was separated as white crystals by fractional crystallization from carbon tetrachloride; mp 100 °C, $[\alpha]_D^{20}$ +334° (*c* 0.205, acetone), IR (KBr): 2950, 2900, 1600, 1450, 1147, 1099, 1080, 1035, 1015, 995, 842, 810, and 740 cm^{-1}. Found: C, 59.10; H, 4.69%. Calcd for $C_{14}H_{14}O_2S_2$: C, 60.40; H, 5.07%. No attempt was made to separate (*R,S*)-**3d**.

*Preparation of (+)-(S)-***4**. (+)-(*R*)-Methyl *p*-tolyl sulfoxide (1.203 g, 0.0078 mol) was brominated with a mixed reagent of bromine (620 mg), *N*-bromosuccinimide (1.388 g), and pyridine (0.7 ml) in methylene chloride (50 ml) according to the published method.[19a] The crude product was recrystallized from hexane–benzene to give (+)-(*S*)-**4** (970 mg, 53% yield); mp 92 °C, $[\alpha]_D^{14}$ +208° (*c* 0.167, acetone). [lit,[19b] $[\alpha]_D^{25}$ +153°(acetone) (optical purity 73%)].

*Preparation of (+)-(S)-***5**. This compound was prepared by the reaction of (+)-(*S*)-**4**(473 mg, 0.00203 mol) with 1 equiv of sodium *p*-tolyl sulfide in acetonitrile–water using a procedure similar to that described by Numata and Oae.[19c] Recrystallization from hexane–benzene gave pure (+)-(*S*)-**5** (360 mg, 64% yield); mp 81.5—82 °C, $[\alpha]_D^{14}$ +76.8° (*c*

0.186, acetone), NMR ($CDCl_3$) δ 2.38 (s, 3H), 2.45 (s, 3H), 4.15 (s, 2H), and 7.45 (m, 8H).

Oxidation of (+)-(S)-5. The oxidation of (+)-(*S*)-**5** (200 mg, 0.000724 mol) was carried out in 5 ml of glacial acetic acid, using 123 mg (0.00108 mol) of 30% hydrogen peroxide, to yield 194 mg of a mixture of diastereoisomers of **3e** [(*R,S*)-**3e**: (*S,S*)-**3e**=53: 47%]. The fractionsl crystallization of the mixture from hexane–benzene afforded 55 mg of (*S,S*)-**3e** (mp 137.5 °C, $[\alpha]_D^{19}$ +318° (*c* 0.132, acetone)) and 45 mg of optically inactive (*R,S*)-**3e** (mp 124.5—125 °C).

Carbonization of Aromatic Hydrocarbons. II. Carbonization of Modified Pyrene in the Presence of Aluminum Chloride

Isao MOCHIDA, Noriyoshi FUKUDA, Keiko MAEDA, and Kenjiro TAKESHITA
Research Institute of Industrial Science, Kyushu University, Fukuoka 812
(Received June 19, 1975)

The carbonization of four hydrogenated and two methylated pyrene derivatives in the presence of aluminum chloride was investigated to elucidate the effects of the slight structural perturbation on the carbonization properties of pyrene. Hexahydropyrene was found to give coke having a needle-like structure *via* similar carbonization steps as naphthalene followed. In contrast, dihydropyrene formed coke of a mosaic structure for the most part. Although 1-methylpyrene produced coke with a needle-like structure, in part, reductively methylated pyrene was converted to a mosaic structure as was pyrene. In the case of needle-coke formation, the carbonization process of hydrogenated and methylated pyrene followed the steps of appearance, growth and coalescence of anisotropic spheres where the reaction started at a lower temperature and proceeded more moderately compared with the case of pyrene. It is thus indicated that a partially lowered aromaticity of pyrene may favor its carbonization into needle coke.

Two kinds of anisotropic graphitizable coke were reported in the carbonization of aromatic hydrocarbons in a previous paper.[1] The first type had a needle-like appearance, which was observed on the coke formed from naphthalene, anthracene, chrysene, *etc.* The second one obtained from pyrene and perylene showed a mosaic structure without any regularity in the arrangement of the anisotropic compounds. The size of orientated domains was found to depend on the rate of carbonization which could be modified by the carbonization conditions such as the holding temperature, time and quantity of the catalyst in the process. The carbonization reactivities should also be controlled by a modification of the aromaticity of the aromatic hydrocarbons. In fact, the carbonization properties of quinoline insoluble of pitches were improved by reductive alkylation and hydrogenation.[2,3]

In the present study, the carbonization of four hydrogenated and two methylated pyrene derivatives was investigated to learn the effect of slight structural changes on the condensation reactivity of the starting material, as well as, on the structures of the resulting coke. By following the carbonization process through microscopic observation, analysis of the evolved gases, and the solubility index, which may indicate the degree of carbonization, the mechanism of needle-like coke formation is discussed.

Experimental

Materials. The materials used in the present study are listed in Table 1. Commercially available materials (from the Wako Co. and the Tokyo Kasei Co.) were carbonized without further purification except for the perhydropyrene and the reductively methylated pyrene (RA-pyrene). Perhydropyrene was synthesized from pyrene by Birch reduction with lithium ethylenediamine.[4] Reductive methylation of pyrene was carried out according to the method reported by Sternberg *et al.*[5] NMR spectra indicated that RA-pyrene had 1.9 methyl groups on the average.

Procedure. Carbonization was carried out in the presence of aluminum chloride ($AlCl_3$/aromatics=0.1 mole ratio). The carbonization was carried out in flowing nitrogen. The rate of the temperature increase and the holding time at a fixed temperature were 150 °C/hr and 2 hr, respectively.

Experimental details in this study have been described in a previous paper.[1]

Analysis of Gases Evolved during Carbonization. Hydrogen and methane evolved during carbonization under a programmed temperature increase (150 °C/hr up to 560 °C) were analyzed by means of a gas chromatograph with a molecular sieve column, the evolved gas being sampled every 15 min.

Results

Carbonization of Hydrogenated Pyrene Derivatives.
Dihydropyrene: Microscopic photographs of coke obtained from dihydropyrene at several holding temperatures are shown in Fig. 1. Slightly warped spheres several microns in diameter were observed in the coke maintained at 380 °C (Fig. 1a). Within a narrow range beyond this temperature, the coke was completely converted into an anisotropic carbon with a disordered mosaic structure such as that observed in the coke from pyrene (Fig. 1b). Before small anisotropic spheres could grow into large oriented domains, the whole coke sample became anisotropic. It should be noted,

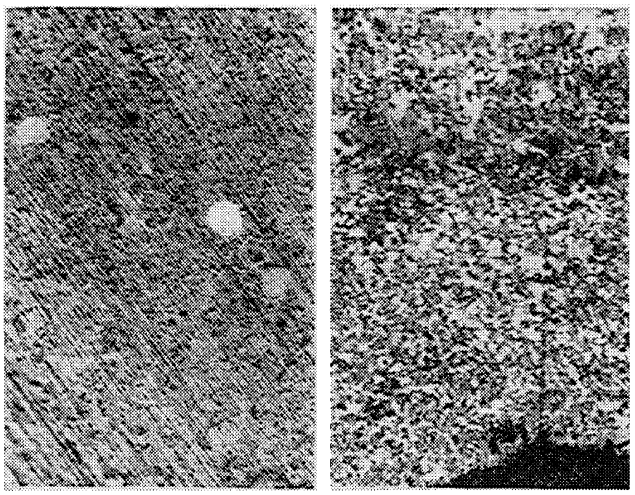

Fig. 1. Microphotographs of carbon obtained from dihydropyrene (under crossed nicols, ×200).
a; carbonization at 380 °C, b; carbonization at 500 °C.

however, that the temperature at which the anisotropy occurred was lower by 20—30 °C than that in the pyrene carbonization.[1)]

Tetrahydropyrene: The coke from tetrahydropyrene remained isotropic up to 380 °C, and then the coke became completely anisotropic at 400 °C, at which temperature the mixed appearance of the oriented and mosaic domains was observed (Fig. 2a). This result may indicate that the hydrogenation of pyrene into tetrahydropyrene produced the structure of a partial-flow pattern, and lowered the temperature for the appearance of anisotropy.

Hexahydropyrene: Hexahydropyrene gave such a sticky carbon below 360 °C that it was impossible to grind it for microscopic observation. As shown in Fig. 2b, the structure of the anisotropic flow pattern was observed for coke maintained at 520°, as well as 380 °C. This flow pattern was quite similar to that of the coke from naphthalene.

Perhydropyrene: In marked contrast, the coke from perhydropyrene remained entirely isotropic up to 500 °C. A photomicrograph of it is shown in Fig. 2c. The yield of carbon was only 5—10%. Because the carbon yield of hexahydropyrene, for example, was 58% at 500 °C, it should be noted that the yield of perhydropyrene was extraordinarily low in comparison with the three other hydropyrenes. Aluminum chloride may not work as a catalyst for the carbonization of non-aromatic hydrocarbons.

Naphthalene	6.737	690	needle
Pyrene	6.744	450	mosaic
Dihydropyrene	6.734	540	mosaic
Tetrahydropyrene	6.747	370	needle and mosaic
Hexahydropyrene	6.734	510	needle

C_0(002); lattice constant (CuK_α). L_c(002); crystal size.

X-Ray Analysis of Coke from Hydrogenated Pyrenes. Table 2 shows the crystallographic parameters of coke obtained from pyrene derivatives at 2500 °C. All carbons showed considerable crystal growth indicating the formation of graphite except for the coke from perhydropyrene. No significant difference in the parameters obtained by X-ray analysis was observable among these types of coke in spite of the different structural features revealed with an optical microscope, as indicated in Table 2.

Carbonization of Methylated Pyrene Derivatives.
1-Methylpyrene: Photomicrographs of the coke obtained

from 1-methylpyrene are shown in Fig. 2d. Anisotropic spheres were observed in the coke maintained at 300 °C, and the coke was converted completely anisotropic having large oriented domains by further heat-treatment. Methylation of pyrene provided the flow pattern structure, and lowered the temperature necessary for the appearance of anisotropic structures.

RA-pyrene: As shown in Fig. 2e, a fine mosaic structure was observed for the coke maintained at 560 °C. It should be noted that reductive methylation of pyrene did not produce the same flow pattern structure as that of 1-methylpyrene, although both derivatives had methyl groups.

The Reactivity of Aromatic Hydrocarbons to Carbonization. The yields of benzene insoluble (BI %) in the cokes obtained from four kinds of aromatic hydrocarbons are plotted against the carbonization temperature in Fig. 3,

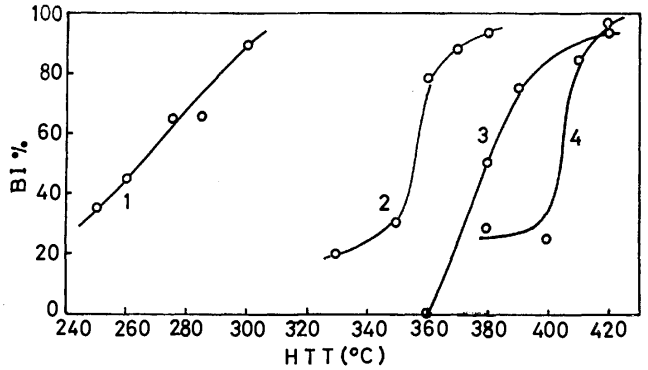

Fig. 3. BI content of carbon from modified pyrenes 1; naphthalene, 2; hexahydropyrene, 3; tetrahydropyrene, 4; pyrene.

because the value of BI% is considered to be one of the criteria for the degree of carbonization. The BI% of the coke from naphthalene increased from 37% at 250 °C to 90% at 300 °C. In contrast, that of the coke from pyrene increased rather rapidly from 25% at 400 °C to 85% at 410 °C. The profiles of the BI% increase in the carbonization of hexahydropyrene and tetrahydropyrene were located in the intermediate between pyrene and naphthalene, as shown in Fig. 3. Furthermore, it is interesting to note that the order of increasing size of the needle-like domains determined by microscopic observation (naphthalene>hexahydropyrene>tetrahydropyrene>pyrene) coincides with the decreasing carbonization temperature necessary for the coke to be insoluble in quinoline.

Hydrogen and methane evolved during the carbonization of dihydropyrene, hexahydropyrene, 1-methylpyrene, and RA-pyrene are shown in Figs. 4 and 5, where the temperature was programmed to rise at the rate of 150 °C/hr up to 560 °C. Analysis of the evolved gases indicated that the modified pyrenes of two pairs (dihydropyrene and hexahydropyrene, and 1-methylpyrene and RA-pyrene) followed different carbonization processes, giving the coke of a needle-like or a mosaic structure, respectively (see Figs. 1 and 2). There are some precautions necessary in the analysis of the present observation of the gases evolved during carbonization. First, the evolution of gases during the heat

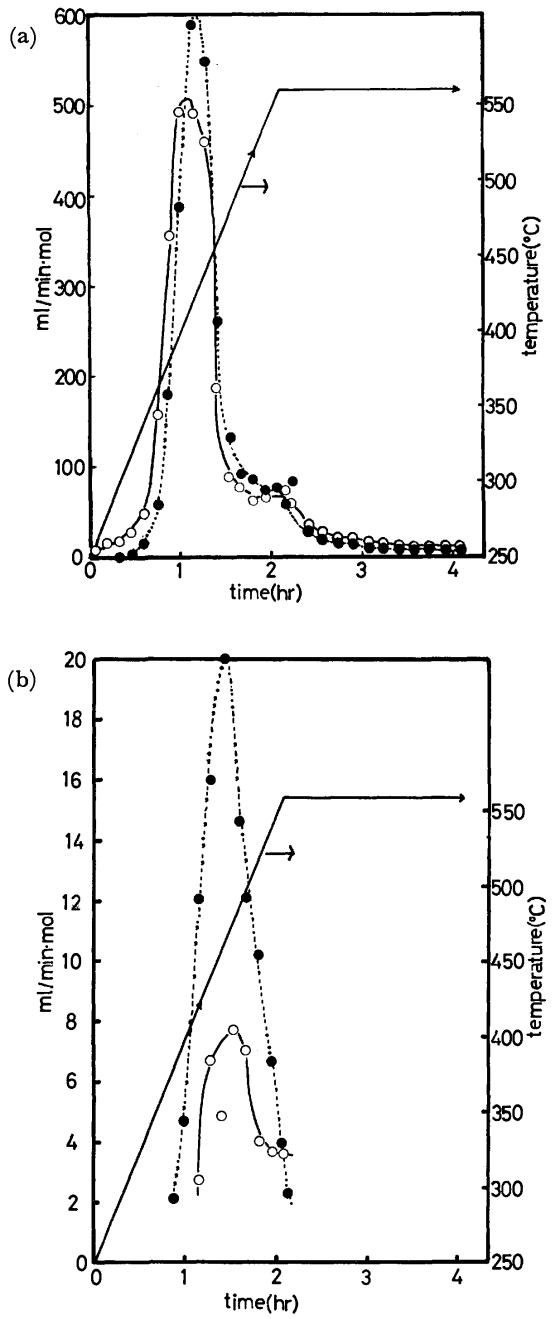

Fig. 4. Evolved gases during the carbonization of dihydropyrene and hexahydropyrene
(a); H_2, (b); CH_4,
—○—; dihydropyrene, —●—, hexahydropyrene.

treatment was ascribed to the elimination reaction, as well as the carbonization reaction, however these two reactions are rather difficult to distinguish clearly. Second, heating conditions for the analysis of the gases and the microscopic observation or BI% analysis were not the same as those described in the experimental section. Thus, a direct comparison of these results is not possible. In general, longer holding times may cause advanced carbonization. Thus, carbonization reactivities of these compounds should be discussed taking into account these conditions.

Three significant differences were noticed in the carbonizations of dihydropyrene and hexahydropyrene.

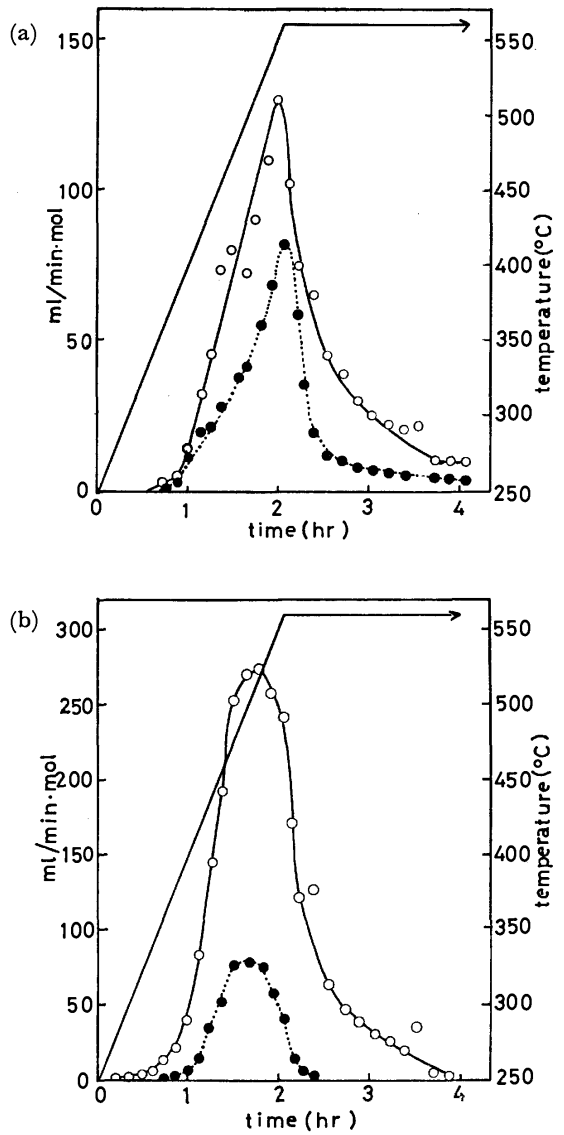

Fig. 5. Evolved gases during the carbonization of 1-methylpyrene and RA-pyrene.
(a); H_2, (b); CH_4,
—○—; RA-pyrene, ---●---; 1-methylpyrene.

First, dehydrogenation of dihydropyrene started at a temperature lower by 50 °C than that for hexahydropyrene perhaps indicating a faster reproduction of pyrene from dihydropyrene, although the total features were quite similar. Second, the amount of evolved methane was much less in the carbonization of dihydropyrene than in that of hexahydropyrene. Such a difference was also observed in the carbonization of pyrene and naphthalene, which resulted in mosaic and needle-like coke structures, respectively. Third, dehydrogenation and demethylation occurred almost simultaneously at 300 °C in the case of hexahydropyrene, indicating that "dehydrogenation" which may convert hexahydropyrene back to pyrene did not take place before carbonization. On the other hand, "dedehydrogenation" of dihyd ropyrene occurred 150 °C below that of demethylation, bringing about a reproduction of pyrene before carbonization.

Methyl groups of RA-pyrene started to evolve at *ca.* 250 °C which was lower by 100 °C and much more methane was evolved compared with 1-methylpyrene, as shown in Fig. 5, although the peaks of the evolution were located at closer temperatures. Methane started to evolve earlier than hydrogen in the case of RA-pyrene. In contrast, both gases started at the same temperature in 1-methylpyrene. Such results may indicate that "demethylation" of RA-pyrene started before the carbonization reaction occurred, converting RA-pyrene to pyrene.

Discussion

The results of X-ray analysis shown in Table 2 show that all carbonization processes of the five kinds of aromatic hydrocarbons may proceed *via* molten phases at the early stage of carbonization and that all of the cokes calcined at 2500 °C show considerable crystal growth, indicating the formation of graphite. However, it is revealed that the types of coke have two different anisotropic structures when examined with an optical microscope, namely, a mosaic structure with small domains and a flow pattern structure with large oriented domains. This fact again indicates that carbonization through the molten phase is not sufficient for the formation of a flow pattern structure, as discussed in a previous study.[1]

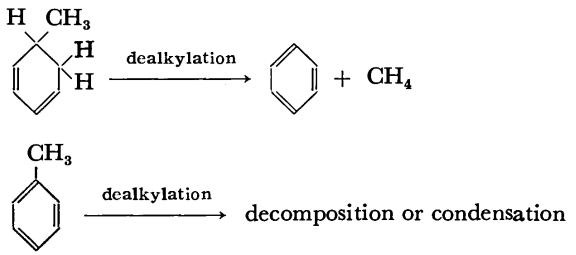
An improvement in the carbonization properties of pyrene into the needle-like coke is clearly achieved by partial hydrogenation and alkylation, as is shown in Figs. 1 and 2. Such an improvement may come from the modified reactivity of the pyrene by a slight structural change. Lowered aromaticity seems to favor the carbonization of pyrene into needle coke. It has been pointed in a previous paper[1] that the steps of appearance, coalescence, and growth of anisotropic spheres may be essential for the formation of the needle cokes as Taylor and Brooks have indicated,[6] and that the starting material should have the appropriate condensation reactivity for the carbonization process to follow these steps because the increase of the molecular weight and of the viscosity of the carbonizing material occurs at the same time during carbonization where molecular arrangement should be completed before solidification.

A change in the reactivity of pyrene by this modification is shown in Figs. 3, 4, and 5. In every case, hydrogenation lowers the temperature at which carbonization begins as indicated by the BI% increase in Fig. 3. If the temperature and the rate of carbonization are decreased enough by hydrogenation or alkylation, the carbon obtained shows a needle-like structure similar to that produced by hexahydropyrene. In such cases, modifying groups introduced should stay on the pyrene nuclei long enough until carbonization has progressed to some extent.

The structures of hexahydropyrene and tetrahydropyrene can be compared to naphthalene and diphenyl, respectively. In a previous paper,[1] the latter two compounds have been found to have quite different reactivities. The different reactivities of the former two compounds due to their structures may bring about the different features of the coke structures.

In contrast, if the introduced groups are eliminated at an early stage of the heat treatment, modification cannot longer be expected to produce a needle-like coke structure which does not occur in the case of pyrene. Dihydropyrene and RA-pyrene are such cases, although warped anisotropic spheres were observed on the coke from dihydropyrene. Dehydrogenation may take place before the anisotropic spheres grow into the flow-pattern structure.

A marked elimination of methyl groups from RA-pyrene should be noted. In reductive alkylation, the introduction of a methyl group should accompany the reduction of the aromatic double bond. Dealkylation of the alkyl-naphthene to form a double bond occurs more easily at elevated temperatures than for the alkyl-aromatic compound, so that the different features of carbonization may be observed as in the cases of 1-methylpyrene and RA-pyrene.



A modification of the carbonization properties of quinoline-insolubles in coal-tar and petroleum pitches has been reported for reductive alkylation and hydrogenation in previous papers,[2,3,7] where both methods could convert some parts of the QI soluble in the solvent (benzene or chloroform). However, hydrogenation produced fusibility at the same time resulting in anisotropic needle coke, whereas reductive alkylation did not. The same situation was observed for the model compounds of pitches in the present study. These results can be explained in terms of elimination reactivity of the groups introduced during the carbonization. The present study indicates that the alkylation may be expected to be effective for a modification of the carbonization properties, and its application to pitches is now in progress.

The Formation of Ethers from *dl*-Citronellol in the Presence of Boron Trifluoride Etherate

Kimiko NAGAI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima, 730

(Received June 23, 1975)

dl-Citronellol reacted with boron trifluoride etherate to give a mixture of a novel cyclic dicitronellyl ether (IX) and an acyclic dicitronellyl ether (X), along with eight minor products. Both major ethers were produced in equilibrium in the presence of the above reagent.

In previous papers it has been reported that a variety of ethers were obtained in reactions of boron trifluoride etherate with monoterpene alcohols, of allylic acyclic geraniol,[1] nerol,[2] and *l*-linalool,[2] of homoallylic cyclic *l*-isopulegol,[3] and of saturated bicyclic *d*-borneol[4] and *dl*-isoborneol.[4] The reactions may be regarded as the acid-catalyzed intermolecular dehydration of these alcohols and/or their isomers. In one case,[2] there was observed further cyclization of the ether, the primary product. In the present work, a study of an analogous acid-catalyzed reaction of *dl*-citronellol (I), in which one double bond is at the ζ-position for the hydroxyl group is reported. Some of the results have previously been reported.[5]

Results and Discussion

The reaction conditions and the product distributions in the present study are summarized in Table 1. In each run, the reaction mixture was roughly divided into two fractions by setting up the boundary at the boiling point of 130 °C in distillation under reduced pressure (3.5 mmHg).

Characterization of Monoterpene Products. Each low-boiling fraction was submitted to column chromatography with silica gel. The hydrocarbon portion thus obtained was small in all runs, and the analysis employing glc comparisons with authentic samples and a combined glc-mass spectrometric technique revealed this part to be a mixture of four compounds, namely, α-terpinene (II), dipentene (III), 2,4(8)-*p*-methadiene (IV), and terpinolene (V). The alcoholic portion was also found to be a mixture of the reactant and three other alcohols, the latter being identified as isopulegol (VI), menthol (VII),[6] and tetrahydrogeraniol (VIII) mainly from spectral data. VIII was the major product. The yields of these alcohols slightly increased with an increase in the amount of boron trifluoride etherate.

Characterization of Dimerized Products. Thin layer and gas chromatography of the high-boiling fractions indicated the production of two dimerized compounds in Experiments 1 and 2, and of three compounds in Experiment 3. Isolation and characterization of these compounds are as follows:

2,2,6,10,10,14-Hexamethyl-1,9-dioxacyclohexadecane (IX): The least polar compound in the column chromatography of the high-boiling fraction was isolated as colorless needles, mp 61—62 °C. Its molecular formula was determined to be $C_{20}H_{40}O_2$ corresponding to a dimerized molecule of the reactant from mass spectra analysis and using the method of Rast. Despite the hydrogen deficient formula, this compound was not hydrogenated over an Adams catalyst in acetic acid. It may be of particular significance that a singlet at δ 1.10 for twelve hydrogens and a doublet at δ 0.85 for six hydrogens with J=6 Hz were observed in the NMR spectrum. The former was assigned to two *gem*-dimethyl groups located on a tertiary carbon and the latter to two secondary methyls. In addition, a triplet at δ 3.28 for four hydrogens with J=6 Hz was assigned to two methylene groups adjacent to the oxygen atoms. In the IR spectrum there was no indication of the presence of a hydroxyl group, but a characteristic absorption band was observed at 1085 cm^{-1} for the ether linkage. These spectroscopic results strongly suggest a highly symmetric structure for this dimeric ether. Thus, the compound was determined to be 2,2,6,10,10,14-hexamethyl-1,9-dioxacyclohexadecane (IX). Additional evidence was obtained from the fact that the reaction of this ether with hydroiodic acid afforded tetra- and di-hydrogeranyl iodides which were prepared independently.

3,7,7,11,15-Pentamethyl-8-oxa-14-hexadecen-1-ol (X): The moderately polar compound eluted by column

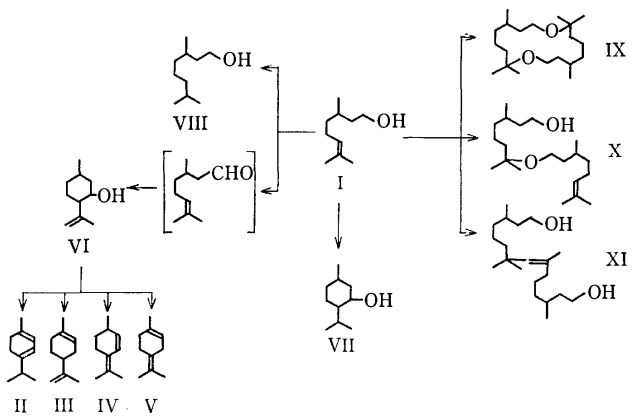
2	10	2	20	24	62.0	0.4				0.7	0.6	3.3	16.0	8.0	—	9.0
3	10	3	20	48	53.7	0.3				1.0	1.0	4.0	10.0	19.0	2.0	9.0

a) Percentages of reaction products were determined by glc on a column of Silicon SE-30 10% on Uniport B (60—80 mesh) at 200 °C.

chromatography of the high-boiling fraction was isolated as a colorless oil in all three runs. Although its molecular weight obtained by mass spectrometry was the same as that of IX, this oil absorbed one equivalent of hydrogen under catalytic reduction. Distinctive bands at 3350 cm^{-1} and 1070 cm^{-1} were present in the IR spectrum due to a primary hydroxyl group and the oil afforded monoacetate upon treatment with acetic anhydride in dry pyridine. Together with the NMR spectrum, this evidence indicates the oil to be 3,7,7,11,-15-pentamethyl-8-oxa-14-hexadecen-1-ol (X). Reaction of the compound with phosphoryl chloride in dry pyridine converted it into an unsaturated ether ($C_{20}H_{38}O$), which was then hydrogenated. Further, the saturated ether was treated with hydroiodic acid giving the tetrahydrogeranyl iodide described above and 2,6-dimethyl-1-octene.[7]

3,7,9,9,13-Pentamethyl-7-pentadecene-1,15-diol (XI): The most polar compound was isolated in a small amount as a colorless oil only from the high-boiling fraction of Experiment 3. This compound was also an isomer of the other two fractions. Taking account of both the spectral data obtained for this product and experiments analogous to those described above, this may be characterized as an unsaturated diol. For determining the position of the double bond, the compound was submitted to osmium tetroxide oxidation followed by silylation with a mixed reagent of hexamethyldisilazane and trimethylchlorosilane to be converted into trimethylsilyl ether. From precise analysis of the mass spectrum of the silyl ether, the unsaturated diol was characterized as 3,7,9,9,13-pentamethyl-7-pentadecene-1,15-diol, as is shown in detail in the Experimental Section.

Reaction Sequence. As given in Table 1, three monoterpene alcohols and four hydrocarbons were found in the low-boiling fraction of the product. Of the monoterpene alcohols, tetrahydrogeraniol (VIII) was the major product in all three runs. Isopulegol (VI) was assumed to be produced by way of citronellal as a possible intermediate, since this cyclization took place with ease under similar conditions. Although citronellal could not be detected in the present study, VIII and citronellal should be produced by disproportionation of citronellol (I). Another alcohol, menthol (VII), was formed probably by cyclization of the reactant (I), in a manner similar to that described in an earlier report.[6] Since the four hydrocarbons were all cyclic diolefins, their precursor should be a cyclic unsaturated alcohol if acid-catalyzed dehydration follows. Isopulegol (VI), mentioned above, may be the most probable precursor in this reaction. These processes are summarized in Scheme 1.



Scheme 1.

TABLE 2. CONVERSION OF CYCLIC (IX) AND ACYCLIC (X) ETHERS IN THE PRESENCE OF BORON TRIFLUORIDE ETHERATE

Composition after the treatment	Starting compound	
	Cyclic diether (IX)	Acyclic ether (X)
IX	86%	42%
X	11	33
XI	1	20
Others	2	5

In the present study, IX and X were the main products. The former, cyclic diether, was predominant when one ml of boron trifluoride etherate was used for ten grams of I, whereas the latter, its isomeric acyclic ether, was preferentially produced when three ml of the reagent was applied. Under the same conditions, IX, could be converted into X in an 11% yield and X was transformed into IX and XI in 42% and 20% yields respectively, as shown in Table 2. Thus, these compounds were in equilibrium under the reaction conditions. The distribution of these dimerized products was estimated by glc analysis where ten grams of citronellol (I) was treated with various amounts of boron trifluoride etherate. The results are given in Fig. 1. It is clearly shown that the distribution is markedly influenced by the molar ratio of the acidic reagent to I.

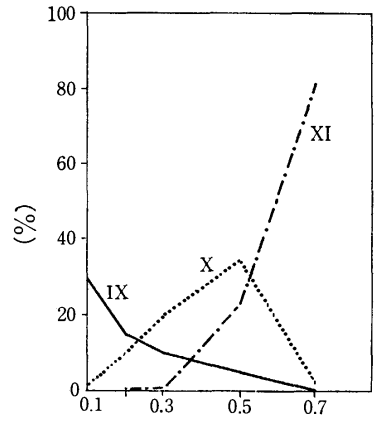


Fig. 1. Dependence of three dimerized species on the concentration of $BF_3 \cdot Et_2O$.
Citronellol each 10 g, no solvent, room temperature, 48 hr.

The formation of the cyclic diether (IX) in the presence of boron trifluoride etherate may be interesting in view of the natural occurrence of large membered cyclic compounds.

Experimental

Apparatus. The glc was carried out using a Hitachi-063, equipped with an FID detector, a stainless-steel separating column (3 mm×3 m) packed with Carbowax 6000 (10%) on Diasolid (60—80 mesh), DEGS (10%) on Shimalite W (60—80 mesh), and Silicon SE-30 (10%) on Uniport B (60—80 mesh); the flow rate of nitrogen, the carrier gas, 20 ml/min. The mass spectra were obtained using a combined apparatus, Shimadzu-LKB 9000 glc and mass spectrometer: a glass separating tube (3 mm×3 m) packed with Carbowax 20 M (10%) on Diasolid (60—80 mesh); temperature program, 5 °C/min from 50 °C to 120 °C; ionization energy, 70 eV; ion accelerating voltage, 3500 V; ionization chamber temperature, 200 °C. The NMR spectra were measured in a $CDCl_3$ solution using a 60 MHz spectrometer, Hitachi R-20, with TMS as an internal reference.

Materials. Commercial citronellol was used, after being purified through repeated fractionations. Bp 109 °C/4 mmHg, d_4^{25} 0.8530, n_D^{25} 1.4539, $[\alpha]_D^{25}$ ±0° ($CHCl_3$). A single peak was observed in glc in each case for separating columns of Carbowax 6000, Silicon SE-30, and DEGS, and the IR and NMR spectra coincided with those of authentic samples.

$BF_3 \cdot Et_2O$ of chemical grade (BF_3 47%) was used without purification.

Reaction of Citronellol with $BF_3 \cdot Et_2O$. To 10 g of citronellol 1, 2, or 3 ml of $BF_3 \cdot Et_2O$ was added drop by drop, the mixture being allowed to stand for 72, 24, and 48 hr at room temperature (*ca.* 20 °C). The mixture, after having been shaken with a saturated aqueous solution of sodium carbonate to decompose the excess of $BF_3 \cdot Et_2O$, was washed with water, dried over anhydrous sodium sulfate, and fractionated into low-boiling (bp 55—130 °C/3.5 mmHg) and high-boiling (bp 130 °C/3.5 mmHg) fractions under reduced pressure.

Characterization of Monoterpene Compounds. Each low-boiling fraction from Experiments 1—3 was eluted over a silica gel column with hexane and then with a mixture of ethyl acetate and hexane (v/v 15:85) for separation into hydrocarbons and alcohols.

Hydrocarbons: Gas chromatographic analysis of each hydrocarbon portion was carried out on a separating column packed with Carbowax 6000 by comparison with authentic samples. The mass spectra of these compounds were obtained using the combined glc-mass spectrometer. Thus, II, III, IV, and V were identified.

Alcohols: The alcohol portions showed three peaks in the glc on a DEGS-packed column in addition to the reactant peak. The gas chromatographic analysis of the portion was carried out using authentic samples, and also each compound was isolated by preparative glc for determining the IR and NMR spectra. The compounds were thus identified as VI, VII, and VIII.

Characterization of Dimerized Compounds. The high-boiling fractions from Experiments 1 and 2 were shown to consist of two compounds (R_f 0.7 and 0.6; t_R 5.3 and 6.3) from tlc with a mixed solvent of ethyl acetate and hexane (v/v 15:85) and from glc on a Silicon SE-30-packed separating column at 200 °C. The high-boiling fraction from Experiment 3 contained three compounds (R_f 0.7, 0.6, and 0.2; t_R 5.3, 6.3, and 10.5). Each fraction was chromatographed over a silica gel column with hexane and then with mixtures of hexane and ethyl acetate increasing in the concentration of ethyl acetate stepwise from 2% to 14%, each compound being isolated.

2,2,6,10,14-Hexamethyl-1,9-dioxacyclohexadecane (IX). The compound with R_f 0.7 and t_R 5.3 was isolated by elution chromatography as white needles, mp 61—62 °C. Mass: *m/e* 41 (36%), 43 (29), 55 (57), 69 (65), 81 (29), 83 (base, C_6H_{11}), 95 (21), 109 (18), 123 (21), 138 (25, $M^+-C_{10}H_{22}O_2$), 140 (50, $M^+-C_{10}H_{20}O_2$), 157 (25, $C_{10}H_{21}O$), 199 (11, $M^+-C_7H_{13}O$), 297 (11, M^+-CH_3), 312 (2, M^+, $C_{20}H_{40}O_2$). IR (CCl_4, cm^{-1}): 1380 and 1362 (CH_3-$\underset{|}{C}$-CH_3), 1085 (C-O-C). NMR ($CDCl_3$, ppm): 0.85 (6H, d, J=6 Hz, $C\underline{H}_3$-CH-), 1.10 (12H, s, $(C\underline{H}_3)_2$-C-O-), 3.28 (4H, t, J=6 Hz, -O-$C\underline{H}_2$-CH_2-).

Found: C, 76.72; H, 13.01%; mol wt (Rast), 317. Calcd for $C_{20}H_{40}O_2$: C, 76.86; H, 12.90%; mol wt, 312.5.

Ether Bond Cleavage of IX: Compound IX (100 mg) was heated with hydroiodic acid (d=1.7, 0.2 ml) under reflux for 10 min. The mixture, after having been poured into water (30 ml), was extracted with ether. After the organic layer was washed with a 10% aqueous solution of sodium bicarbonate and with water and dried over sodium sulfate, evaporation of the solvent gave a colorless oil in a 90% yield, showing two peaks at t_R 9.8 and 10.8 in glc on a Silicon SE-30-packed column. The oil was separated by elution chromatography over a silica gel column with hexane as an eluent.

Identification of Tetrahydrogeranyl Iodide: The compound with t_R 9.8 was a colorless oil, the yield of which was 75% of the ether-cleaved products. n_D^{20} 1.4748. The mass, IR, and NMR spectra were respectively superimposable on those of tetrahydrogeranyl iodide prepared as described below.

Identification of Dihydrogeranyl Iodide: The compound with t_R 10.8 of the ether-cleaved products was also a colorless oil, the yield of which was 25% of the ether-cleaved products. n_D^{20} 1.4978. The mass, IR, and NMR spectra were respectively coincident with those of dihydrogeranyl iodide which was prepared as described below.

Synthesis of Tetrahydrogeranyl Iodide. Tetrahydrogeraniol (2.5 g) was heated with a mixture of red phosphorus (0.15 g) and resublimed iodide (1.3 g) with stirring at 150 °C for 7 hr. The reaction product was taken up into ether. The solution was filtered, and the filtrate was washed successively with water, a 5% aqueous sodium hydroxide solution and water and then dried over anhydrous sodium sulfate. Evaporation of the solvent gave tetrahydrogeranyl iodide as a colorless oil in a 77% yield, which was further purified by elution chromatography over a silica gel column with hexane. n_D^{20} 1.4749. Mass: *m/e* 39 (45%), 41 (70), 43 (base), 55 (14), 57 (85), 71 (53), 85 (14), 99 (13), 127 (5, I^+), 141 (12, $C_{10}H_{21}$), 268 (2, M^+, $C_{10}H_{21}I$). IR (CCl_4, cm^{-1}): 1386, 1381, 1368, 1208, 1178. NMR ($CDCl_3$, ppm): 0.87 (9H, d, J=6 Hz, $C\underline{H}_3$-$\underset{|}{C}$H-$C\underline{H}_3$, $C\underline{H}_3$-$\underset{|}{C}$H-), 1.26 (8H, br.s, -$C\underline{H}_2$-), 3.21 (2H, t, J=6 Hz, -CH_2-$C\underline{H}_2$-I).

Synthesis of Dihydrogeranyl Iodide. A mixture of dihydrogeraniol (2.0 g), red phosphorus (0.1 g) and resublimed iodide (1.0 g) was heated at 150 °C for 3 hr. The mixture was treated similarly as in the case of the preparation of tetrahydrogeranyl iodide to give dihydrogeranyl iodide as a colorless oil in a 58% yield. n_D^{18} 1.4973. Mass: *m/e* 41 (67%), 55 (80), 69 (base), 83 (60), 95 (5), 97 (10), 109 (4), 127 (4, I^+), 139 (5, $C_{10}H_{19}$), 266 (3, M^+, $C_{10}H_{19}I$). IR (CCl_4, cm^{-1}): 1660, 1181, 830. NMR ($CDCl_3$, ppm): 0.87 (3H, d, J=6 Hz, $C\underline{H}_3$-$\underset{|}{C}$H-), 1.60 and 1.67 (each 3H, br.s, $C\underline{H}_3$-$\underset{|}{C}$=CH-), 3.22 (2H, t, J=6 Hz, -CH_2-$C\underline{H}_2$-I), 5.06 (1H, m, -$\underset{|}{C}$=C$\underline{H}$-).

3,7,7,11,15-Pentamethyl-8-oxa-14-hexadecen-1-ol (X). The compound with R_f 0.6 and t_R 6.3 of the high-boiling fraction was isolated as a colorless viscous oil by the above-mentioned elution chromatography. n_D^{27} 1.4601. Mass: *m/e* 41 (28%), 43 (20), 55 (42), 67 (10), 69 (90), 81 (33), 83 (base), 95 (15), 109 (6), 123 (16, C_9H_{15}), 138 (12), 139 (15, $C_{10}H_{19}$), 156 (13, $C_{10}H_{20}O$), 197 (23, $M^+-C_7H_{15}O$), 297 (2, M^+-CH_3), 312

(3, M^+, $C_{20}H_{40}O_2$). IR (CCl_4, cm^{-1}): 3350, 1070 (-OH), 1080 (C-O-C), 1650, 830 (-C=CH-), 1380, 1363 (CH_3-C-CH_3). NMR ($CDCl_3$, ppm): 0.85 (6H, d, J=6 Hz, C$\underline{H}_3$-CH-), 1.10 (6H, s, (C$\underline{H}_3$)$_2$-C-O-), 1.60, 1.68 (each 3H, br.s, C$\underline{H}_3$-C=CH-), 3.30 (2H, t, J=6 Hz, -C-O-C$\underline{H}_2$-CH_2-), 3.64 (2H, t, J=6 Hz, -CH_2-C$\underline{H}_2$-OH), 1.90 (1H, br.s, -O$\underline{H}$), 5.05 (1H, m, -C$\underline{H}$=C-).

Catalytic Hydrogenation of X: Compound X (300 mg) was hydrogenated over platinum oxide (30 mg) in acetic acid (7 ml) to take up one molar equivalent of hydrogen. The mixture was treated according to the usual procedure, dihydro X being obtained as a colorless oil in a good yield. Mass: *m/e* 41 (77%), 43 (base), 55 (77), 57(65), 69 (52), 83 (21), 85 (26), 87 (11), 141 (10), 199 (13), 314 (trace, M^+,$C_{20}H_{42}O$). IR (CCl_4, cm^{-1}): 3370, 1075 (-OH), 1070(C-O-C), 1380, 1368 (CH_3-CH-CH_3 and CH_3-C-CH_3). NMR ($CDCl_3$, ppm): 0.85 (12H, d, J=6 Hz, C$\underline{H}_3$-CH- and C$\underline{H}_3$-C-C$\underline{H}_3$), 1.10 (6H, s, (C$\underline{H}_3$)$_2$C-O-), 2.00 (1H, br.s, -O$\underline{H}$), 3.30 (2H, t, J=6 Hz, -O-C$\underline{H}_2$-CH_2-), 3.65 (2H, t, J=6 Hz, -CH_2-C$\underline{H}_2$-OH).

Acetylation of X: Acetic anhydride (1 ml) was added to a solution of X (500 mg) in dry pyridine (1 ml) and the mixture was allowed to stand overnight at room temperature. The mixture, after having been poured into water, was extracted with ether, and evaporation of the solvent gave monoacetate as an oily substance in a good yield. IR (CCl_4, cm^{-1}): 1745, 1245 (CH_3COO-), 1080 (C-O-C), 1382, 1370 (CH_3-C-CH_3). NMR ($CDCl_3$, ppm): 0.88 (6H, d, J=6 Hz, C$\underline{H}_3$-CH-), 1.10 (6H, s, C$\underline{H}_3$-C-C$\underline{H}_3$), 1.60, 1.68 (each 3H, br.s, C$\underline{H}_3$-C=CH-), 2.02 (3H, s, C$\underline{H}_3$COO-), 4.05 (2H, t, J=6 Hz, CH_3-COO-C$\underline{H}_2$-CH_2-), 5.05 (1H, m, -C$\underline{H}$=C-).

Dehydration of X: A solution of phosphoryl chloride (0.2 ml) in dry pyridine (1 ml) was added to a solution of X (500 mg) in the same solvent under cooling at −5 °C, and the mixture was allowed to stand at the same temperature for 24 hr. The mixture, after having been poured into a 10% ice-cooled aqueous solution of sodium bicarbonate, was taken up into ether. Evaporation of the solvent gave a dehydrated compound (X-A) as an oily substance in a good yield. IR (CCl_4, cm^{-1}): 1650, 890 (CH_2=C-), 1670, 830 (-CH=C-), 1080 (C-O-C), 1385, 1369 (CH_3-C-CH_3). NMR ($CDCl_3$, ppm): 0.88 (6H, d, J=6 Hz, C$\underline{H}_3$-CH-), 1.12 (6H, s, (C$\underline{H}_3$)$_2$=C-O-), 1.60, 1.68 (3H and 6H, each br.s, -C(C$\underline{H}_3$)=C(H)- and -C($\underline{H}_3$C)=C($\underline{H}$)-), 3.30 (2H, t, J=6 Hz, -O-C$\underline{H}_2$-CH_2-), 4.70 (2H, br.s, CH_2=C-), 5.10 (1H, m, -C$\underline{H}$=C-).

Catalytic Hydrogenation of Dehydrated Product X-A: Catalytic hydrogenation of the dehydrated product (X-A, 400 mg) over platinum oxide (40 mg) in acetic acid (6 ml) took up two molar equivalents of hydrogen to give a tetrahydroproduct (X-B) as an oily substance in a good yield. Mass: *m/e* 39 (20%), 41 (85), 43 (95), 55 (91), 57 (base), 69 (98), 81 (72), 83 (44), 85(54), 97 (22), 140 (6), 141 (21), 173 (27), 199 (50, M^+-C_7H_{15}), 265 (3, M^+-CH_3-H_2O), 280 (2, M^+-H_2O), 298 (trace, M^+, $C_{20}H_{42}O$). IR (CCl_4, cm^{-1}): 1382, 1365, 1082. NMR ($CDCl_3$, ppm): 0.85 (12H, d, J=6 Hz, C$\underline{H}_3$-CH-C$\underline{H}_3$ and C$\underline{H}_3$-CH-), 1.08 (6H, s, (C$\underline{H}_3$)$_2$C-O-), 3.25 (2H, t, J=6 Hz, -O-C$\underline{H}_2$-CH_2-).

Ether Bond Cleavage of the Tetrahydro-Compound X-B: X-B (300 mg) was heated with hydroiodic acid (d=1.7, 0.4 ml) under reflux for 10 min, and the reaction product was chromatographed over silica gel with hexane to give two compounds with t_R 7.6 and 9.8 in good yields.

Identification of 2,6-Dimethyl-1-octene: The compound with t_R 7.6 of the ether-cleaved products was obtained as a colorless oil in a relative yield of 30%. Mass: *m/e* 41 (36%), 43 (50), 55 (59), 57 (75), 69 (base), 83 (80), 95 (29), 97 (43), 111 (42), 126 (25), 140 (41, M^+, $C_{10}H_{20}$). The mass spectrum of this compound was in good agreement with that of 2,6-dimethyl-1-octene.[7]

Identification of Tetrahydrogeranyl Iodide: The compound with t_R 9.8 of the ether-cleaved products was obtained as a colorless oil in a relative yield of 70%. The mass, IR, and NMR spectra were respectively superimposable on those of the synthetic samples of tetrahydrogeranyl iodide mentioned above.

3,7,9,9,13-Pentamethyl-7-pentadecene-1,15-diol (XI). The most polar compound (R_f 0.20 and t_R 10.5) of the high-boiling fraction separated in Experiment 3 was isolated in elution chromatography as a colorless oil. n_D^{28} 1.4770. Mass: *m/e* 41 (base), 43 (86%), 55 (68), 57 (56), 59 (10), 67 (25), 69 (71), 70 (40), 71 (41), 81 (22), 83 (20), 95 (18), 112 (11), 123 (8), 138 (4), 156 (3), 269 (2, M^+−C_3H_7), 297 (2, M^+−CH_3), 312 (1, M^+, $C_{20}H_{40}O_2$). IR (CCl_4, cm^{-1}): 3350, 1065, 1020 (-OH), 1388, 1371 (CH_3-C-CH_3), 1650, 860 (-CH=C-). NMR ($CDCl_3$, ppm): 1.63 (3H, br.s, C$\underline{H}_3$-C=CH-), 0.85 (6H, s, C$\underline{H}_3$-C-C$\underline{H}_3$), 0.90 (6H, d, J=6 Hz, C$\underline{H}_3$-CH-), 3.59 (4H, t, J=6 Hz, -CH_2-C$\underline{H}_2$-OH), 3.80 (2H, br.s, -O$\underline{H}$), 5.09 (1H, m, -C$\underline{H}$=C-).

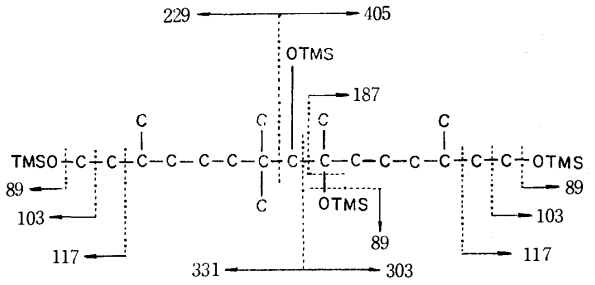
Found: C, 76.67; H, 13.04%; mol wt (Rast), 310. Calcd for $C_{20}H_{40}O_2$: C, 76.86; H, 12.90%; mol wt, 312.5.

Acetylation of XI: XI (100 mg) was treated with acetic anhydride (0.7 ml) in dry pyridine (1.0 ml) at room temperature according to the manner indicated above to give a diacetate as an oily substance in a good yield. IR (CCl_4, cm^{-1}): 1389, 1371 (CH_3-C-CH_3), 1740, 1250 (CH_3COO-), 1650, 855 (-CH=C-). NMR ($CDCl_3$, ppm): 0.82 (6H, s, C$\underline{H}_3$-C-C$\underline{H}_3$), 0.90 (6H, d, J=6 Hz, C$\underline{H}_3$-CH-), 2.02 (6H, s, C$\underline{H}_3$-COO-), 4.09 (4H, t, J=6 Hz, -CH_2-C$\underline{H}_2$-COOCH_3), 5.05 (1H, m, -C=C$\underline{H}$-).

Catalytic Hydrogenation of XI: XI (500 mg) was hydrogenated over platinum oxide (50 mg) in acetic acid (7 ml), and took up one molar equivalent of hydrogen to give a dihydroderivative as a colorless oil in a good yield. Mass: *m/e* 41 (68%), 43 (base), 55 (64), 56 (44), 57 (52), 59 (8), 67 (36), 69 (56), 70 (32), 71 (36), 77 (8), 81 (40), 83 (20), 95 (28), 112 (12), 121 (6), 123 (12), 141 (21), 199 (18), 296 (2, M^+-H_2O), 314 (trace, M^+, $C_{20}H_{42}O_2$). IR (CCl_4, cm^{-1}): 3350, 1065, 1020 (-OH), 1388, 1371 (CH_3-C-CH_3). NMR ($CDCl_3$, ppm): 0.85 (6H, s, C$\underline{H}_3$-C-C$\underline{H}_3$), 0.90 (6H, d, J=6 Hz, C$\underline{H}_3$-CH-), 3.14 (2H, br.s, -O$\underline{H}$), 3.65 (4H, t, J=6 Hz, -CH_2-C$\underline{H}_2$-OH).

Oxidation of XI: A solution of osmium tetroxide (500 mg) in 4 ml of dry benzene was added to a solution of XI (500 mg) in a mixture of dry benzene (5 ml) and dry pyridine (0.5 ml) and the mixture was allowed to stand at room temperature for 6 days. After benzene had been distilled out from the mixture, the residual portion was diluted with ethanol (10 ml), then the solution was refluxed with a 10% aqueous sodium sulfite solution (10 ml) for 2 hr. Brown precipitates thus formed were filtered off, and the filtrate was extracted with chloroform to give a glycol as a colorless oil in a 90% yield. IR (CCl_4, cm^{-1}): 3400, 1160, 1070 (-OH). NMR ($CDCl_3$, ppm): 0.90 (6H, d, J=6 Hz, C$\underline{H}_3$-CH-), 0.99 (6H, s, C$\underline{H}_3$-C-C$\underline{H}_3$), 1.25 (3H, s, C$\underline{H}_3$-C-OH), 2.84 (4H, br.s, -O$\underline{H}$), 3.40 (1H, m, -C-C$\underline{H}$-OH), 3.65 (4H, t, J=6 Hz, -CH_2-C$\underline{H}_2$-OH).

Trimethylsilylation of the Glycol: Hexamethyldisilazane (0.1 ml) and trimethylchlorosilane (0.05 ml) were successively added to a solution of the above glycol (3 mg) in dry pyridine (0.5 ml), and the mixture was heated at 65 °C for 7 min. The mixture was treated according to a usual procedure to give trimethylsilyl ether as an oily substance. Mass: *m/e* 69 (45%), 71 (25), 73 (40), 75 (45), 81 (50), 83 (95), 89 (10), 95 (67), 103 (48), 117 (27), 123 (30), 129 (62), 131 (60), 139 (40), 147 (45), 171 (55), 187 (45), 218 (50), 229 (26), 242 (10), 288 (base), 303 (18), 316 (15), 331 (12), 405 (2), 456 (16), 545 (5). This spectrum was reasonably explained by following fragmentation.



Conversion of Cyclic Diether (IX) and Acyclic Ether (X) by $BF_3 \cdot Et_2O$. A solution of IX (100 mg) in dry ether (1 ml) was mixed with 0.02 ml of $BF_3 \cdot Et_2O$ and the mixture was allowed to stand at room temperature for 48 hr. After the excess catalyst had been decomposed by the addition of a small amount of water, the separated oily layer was analyzed by glc with the Silicon SE-30 separation column. The conversion of acyclic ether was similarly examined. The results are given in Table 2.

The author wishes to express sincere gratitude to Professor Shûichi Hayashi of Hiroshima University for kind and continuous guidance in the course of this work, and also to Assistant Professor Mitsuru Nakayama of Hiroshima University for valuablesuggestions.

Important Role of Fluorescence Reabsorption Mechanism in Sensitized Reaction of Unsaturated Lactones. Evidence against "the Orbital Symmetry Correlations in Sensitization"

Hirochika SAKURAGI, Isao ONO,* Norisuke HATA,* and Katsumi TOKUMARU[1]

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

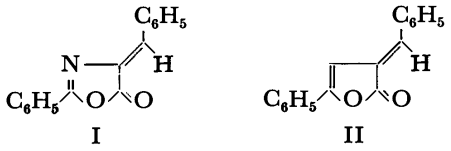
(Received June 26, 1975)

Evidence are presented against Ullman's "the orbital symmetry correlations" between excited aromatic hydrocarbon sensitizers and 4-benzylidene-2-phenyl-5-oxazolone. It is now shown that the oxazolone efficiently quenches the triplet sensitizers regardless of Ullman's classification, and the fluorescence emitted from the sensitizers is reabsorbed by the oxazolone and its wavelength seems to govern the reported reaction course.

Previously Ullman and Baumann reported that under irradiation unsaturated lactones, 4-benzylidene-2-phenyl-5-oxazolone (I) and 2-benzylidene-4-phenyl-3-buten-4-olide (II), depending upon the wavelength of light irradiated or the sensitizers employed, either "selectively" undergo only geometrical isomerization or "unselectively" undergo hydrogen atom abstraction from solvent together with the isomerization.[2] Thus, on direct irradiation of the lactones, 313 nm light caused both reactions, whereas 366 nm light caused only the



I II

isomerization. In sensitized reactions, sensitization with biphenyl, fluorene, and naphthalene led to both reactions, whereas sensitization with phenanthrene, triphenylene, and chrysene resulted in only the isomerization. In order to explain the relation between the selectivity of the reaction course and the structure of the sensitizers, they proposed the "orbital symmetry correlations between the excited sensitizers and the lactones" which implied that the close matching of the orbital symmetry between the lowest unfilled molecular orbital of the lactone and a certain part of the highest occupied orbital of the sensitizer led only to the "selective reaction," the isomerization. They stated that matching of the orbital symmetry between the sensitizer and the lactone molecules would lead to effective excitation of the lactone to its $T_1(\pi,\pi^*)$ state to cause the "selective reaction," whereas no matching of the symmetry would lead to inefficient unselective energy transfer to cause the "unselective reactions."[2]

In a previous communication[3] we presented an aspect against Ullman's postulate by showing that not the triplet but the singlet excited aromatic hydrocarbons played an important role in the sensitized reaction of the lactone II; fluorescence emitted from the hydrocarbon sensitizers was reabsorbed by the lactone and the fluorescence wavelength seemed to govern the course of the reaction.

In this paper we report firm evidence against Ullman and Baumann's postulate on "the orbital symmetry correlations between the excited sensitizer and the substrate." Contrary to their previous proposition, the oxazolone I is now shown to effectively quench the triplet states of the hydrocarbon sensitizers irrespective of "selective" or "unselective" sensitizers on the ground of direct determination of rate constants for the quenching of the triplet hydrocarbons by the oxazolone. Therefore the reported dependence of the reaction course on sensitizers employed does not result from the difference between the sensitizers in rate constants for the quenching of their triplet states by the oxazolone but is shown to be mostly governed by wavelengths of fluorescence emitted from the singlet excited sensitizers which is reabsorbed by the oxazolone.

Results and Discussion

Absorption and Emission Spectra. Figure 1 shows the absorption spectra of the oxazolone in EPA at 77 K and at ambient temperature together with its emission spectrum in EPA at 77 K. The emission was observed only at 77 K and it is attributable to fluorescence, since the emission starts from the end of absorption and shows mirror image relationship with the absorption. Lack of phosphorescence might be due to rapid radiationless deactivation of the triplet state probably resulting in the facile isomerization of the benzylidene group. The singlet excitation energy of the oxazolone is estimated to be 72 kcal/mol from the above result and its triplet excitation energy was reported to be 43 kcal/mol from its singlet-triplet absorption.[2]

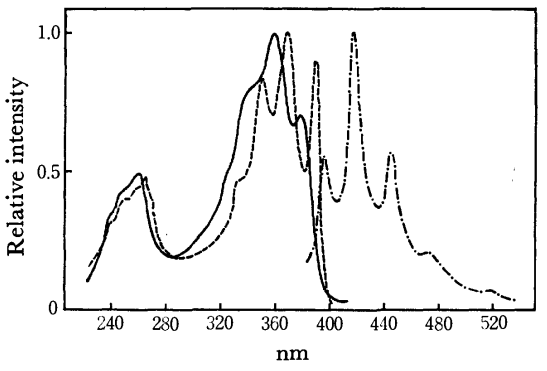


Fig. 1. Absorption and emission spectra of 4-benzylidene-2-phenyl-5-oxazolone in EPA. Absorption at ambient temperature: —, at 77 K: —, emission at 77 K: -·-·-.

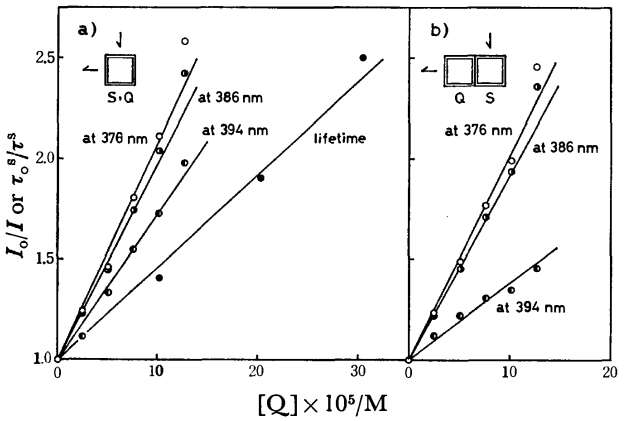

Fig. 2. Stern-Volmer plots. a) Quenching of fluorescence of pyrene (S) by 4-benzylidene-2-phenyl-5-oxazolone (Q) in benzene, b) reabsorption of fluorescence of pyrene (S) by the oxazolone (Q) in benzene.

Quenching of Hydrocarbon Fluorescence by the Oxazolone. Fluorescence of the aromatic hydrocarbons (10^{-5}—10^{-2} mol/l) such as biphenyl, fluorene, naphthalene, triphenylene, chrysene, *p*-terphenyl, phenanthrene, and pyrene was quenched for the intensity and the lifetime by the added oxazolone in benzene solution. Plots of the fluorescence intensity ratio, I_0/I, against the concentration of the oxazolone, [Q], (0—2×10^{-5} mol/l) were, for the most cases, linear only in the lower concentration range of the oxazolone and curved upwards in the higher concentration range as indicated in Fig. 2, where I_0 and I denote the fluorescence intensity of the hydrocarbon in the absence of the oxazolone and that in the presence of the oxazolone in concentration of [Q], respectively. If, in the lower concentration range of the oxazolone, the plots are assumed to obey the Stern-Volmer relationship

$$I_0/I = 1 + k_q^{app}\tau_0^S[Q] \quad (1)$$

(Eq. 1), the apparent quenching rate constants, k_q^{app}, can be obtained from their slopes divided by the lifetimes of the singlet states of the hydrocarbons in the absence of the oxazolone, τ_0^S. The shapes of fluorescence spectra of some hydrocarbons were varied with increase in the concentration of the oxazolone and the fluorescence intensity ratio, I_0/I, was also varied with wavelength at which the emission is observed. These results suggest, as will be discussed later, that the quenching of hydrocarbon fluorescence is mostly due to the reabsorption of fluorescence by the quencher. In Table 1 are listed the apparent quenching rate constants, k_q^{app}, measured at the emission maximum of each hydrocarbon.

For the quenching of the singlet lifetimes of the aromatic hydrocarbons by the oxazolone, plots of τ_0^S/τ^S against the concentration of the oxazolone fitted the

$$\tau_0^S/\tau^S = 1 + k_q^S\tau_0^S[Q] \quad (2)$$

Stern-Volmer relationship (Eq. 2) over the concentration range of the oxazolone employed (0—5×10^{-4} mol/l) (Fig. 2), where τ^S denotes the lifetime of a singlet hydrocarbon in the presence of the oxazolone in concentration [Q]. The bimolecular rate constants, k_q^S, for the quenching process of the excited singlet hydrocarbons by the oxazolone are summarized in Table 1, which shows that k_q^{app} values are several to eighty times larger than k_q^S values. Table 1 also contains I_0/I and τ_0^S/τ^S values obtained at $[Q]=2.0\times10^{-5}$ mol/l, showing that I_0/I values are significantly higher than the corresponding τ_0^S/τ^S values.

a) Conducted under the aerated condition; the concentration of the hydrocarbon: 10^{-5}—10^{-2} M, the concentration of the oxazolone: 0—5×10^{-5} M for the intensity measurement and 0—10^{-4} M for the lifetime measurement. b) Maximum wavelength of fluorescence in nm. c) In $M^{-1}s^{-1}$. d) Values at the oxazolone concentration of 2×10^{-5} M.

The above difference between I_0/I and τ_0^S/τ^S values at the same concentration of the oxazolone is reasonably attributable to reabsorption of the fluorescence from the excited singlet hydrocarbons by the oxazolone by the following reasons. If the added oxazolone acts only to quench the excited singlet hydrocarbon with a rate constant of k_q^S, the fluorescence intensity of the hydrocarbon would be decreased to the same extent as the singlet lifetime, so I_0/I would be equal to τ_0^S/τ^S, but it is not the case. When the fluorescence from the hydrocarbon is reabsorbed by the oxazolone in the surrounding medium, the actually observed fluorescence is to be further reduced in intensity, so, as was actually observed, I_0/I value is to be higher than τ_0^S/τ^S value by an extent corresponding to the reabsorption. A possibility that apparent reduction of the sensitizer fluorescence by the oxazolone would be due to formation of complex between ground states of the sensitizer and the oxazolone is excluded since no new absorption appeared on the mixing of the both compounds in solution.

A fact that the absorption spectrum of the oxazolone effectively overlaps with the emission spectra of the hydrocarbon sensitizers suggests that the singlet hydrocarbons could undergo efficient radiative transfer to the oxazolone, which could cause distortion of the shape of the emission spectra. Actually, as mentioned previously, the emission spectra of some hydrocarbons were changed in the shape with the increase in the concentration of the oxazolone, and slopes of Stern-Volmer plots of I_0/I gave higher values in the region of 340—390 nm where the oxazolone shows higher molecular extinction coefficient. Thus, triphenylene, phenanthrene, and pyrene, which have emission maxima in the region of 360—380 nm, gave higher apparent quenching rate constants $k_q^{app}\tau_0^S$ than biphenyl and fluorene which have emission maxima near 320 nm.

Reabsorption of the fluorescence emitted from the hydrocarbons by the oxazolone was further confirmed

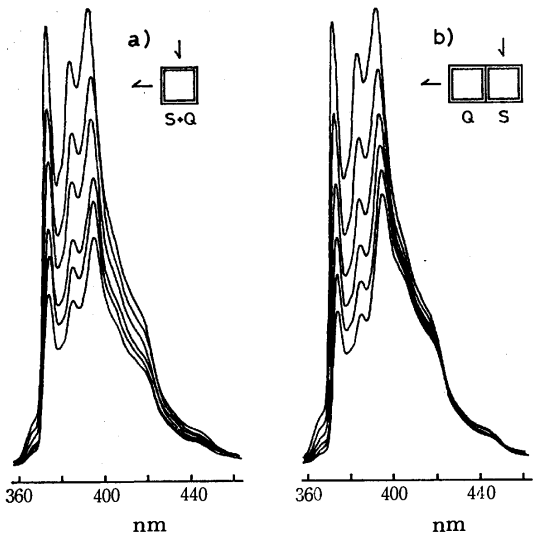

Fig. 3. Changes of fluorescence spectra with the concenration of 4-benzylidene-2-phenyl-5-oxazolone (Q). a) Quenching of fluorescence of pyrene (S) by the oxazolone in benzene, b) reabsorption of fluorescence of pyrene (S) by the oxazolone in benzene.

by the following experiment. A cell containing benzene solution of an emissive hydrocarbon without the oxazolone was placed adjacently to a cell containing benzene solution of the oxazolone in various concentrations, and the fluorescence emitted from the former solution was observed after passing the latter solution. A typical example is shown in Figs. 2 and 3 for pyrene, which has the highest k_q^S value among the sensitizers employed, showing that the spectral change of the fluorescence of the hydrocarbon with added oxazolone in the solution closely resembles that of the fluorescence of the hydrocarbon solution without the oxazolone observed through its reabsorption by the oxazolone solution.

These facts undoubtedly indicate that the fluorescence emitted from the hydrocarbons is effectively reabsorbed by the oxazolone in the surrounding medium, and the reported "selectivity" of the sensitized reaction course seems to depend on the fluorescence wavelength of the sensitizers. In Table 1 are listed $(I_0/I)_{reabs}$ values at $[Q]=2\times10^{-5}$ mol/l which denote estimated values for I_0/I when the decrease of the fluorescence intensity with the oxazolone is assumed to be due only to its reabsorption by the oxazolone, and these values are evaluated from k_q^{app}, k_q^S, and τ_0^S, according to Eq. 3.

$$(I_0/I)_{reabs} = 1 + (k_q^{app} - k_q^S)\tau_0^S[Q] \qquad (3)$$

Quenching of Hydrocarbon Triplet by the Oxazolone. Since the triplet energies of the aromatic hydrocarbons employed are in the range between 56.6 kcal/mol for chrysene and 68.0 kcal/mol for fluorene in a nonpolar solvent,[4] and the first excited triplet energy of the oxazolone has been estimated to be 43.0 kcal/mol[2] in chloroform, triplet energy transfer from the hydrocarbons to the oxazolone is expected to be sufficiently exothermic and to proceed with nearly diffusion-controlled rate constants.

In order to examine whether the quenching of the triplet states of the hydrocarbons by the oxazolone would proceed in different manner between "selective" and "unselective" hydrocarbon sensitizers as was proposed by Ullman, rate constants for the quenching of the triplet hydrocarbons by the oxazolone were measured by flash spectrophotometry. The oxazolone did not show any detectable transient absorption in the region of 380—600 nm on flash excitation. So, the decay of the triplet-triplet absorption of the hydrocarbon was followed in the absence and in the presence of various concentrations of the oxazolone in cyclohexane solution at room temperature.

Figures 4 and 5 show typical oscilloscopic traces of triplet-triplet absorption of naphthalene and triphenylene in the absence (a) and in the presence (b) of the oxazolone obtained by monitoring the absorption at 420 and 430 nm, respectively, and Figs. 6 and 7 contain

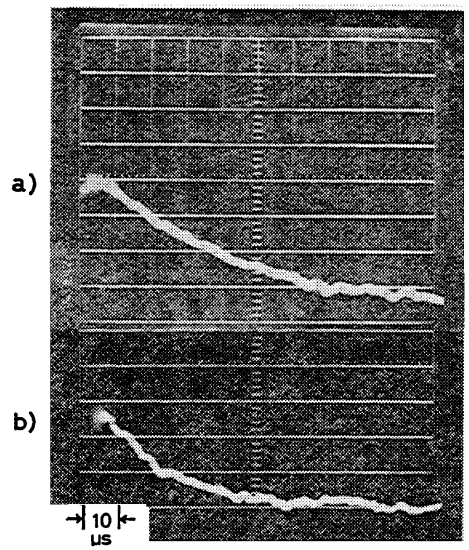

Fig. 4. Oscilloscopic traces of triplet-triplet absorption of naphthalene (7.5×10^{-5} M) in cyclohexane in the absence of 4-benzylidene-2-phenyl-5-oxazolone (a) and in the presence of the oxazolone in 5.5×10^{-6} M (b).

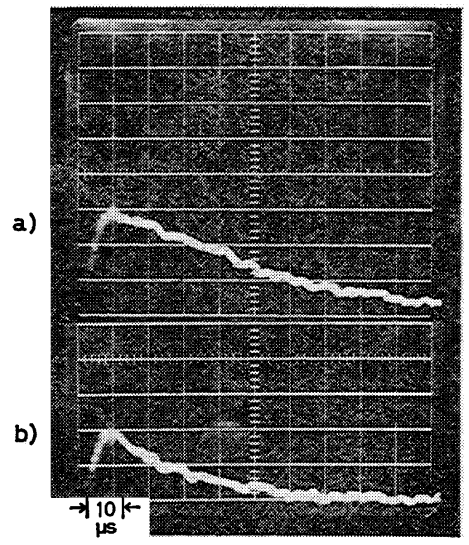

Fig. 5. Oscilloscopic traces of triplet-triplet absorption of triphenylene (3.5×10^{-5} M) in cyclohexane in the absence of 4-benzylidene-2-phenyl-5-oxazolone (a) and in the presence of the oxazolone in 5.5×10^{-6} M (b).

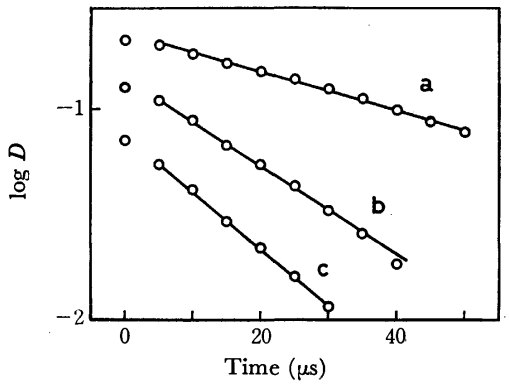

Fig. 6. First-order rate plots for the decay of triplet-triplet absorption (intensity: D) of naphthalene in cyclohexane in the absence of 4-benzylidene-2-phenyl-5-oxazolone (a), in the presence of the oxazolone in 5.5×10^{-6} M (b), and in 1.1×10^{-5} M (c).

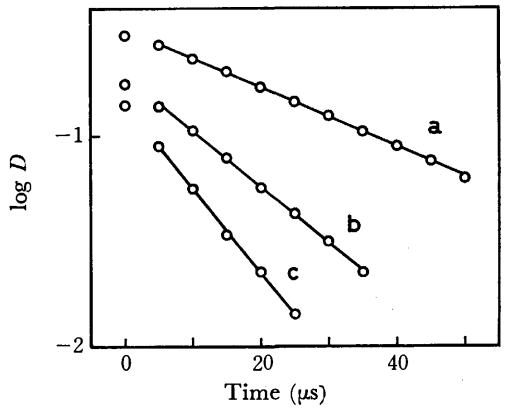

Fig. 7. First-order rate plots for the decay of triplet-triplet absorption (intensity: D) of triphenylene in cyclohexane in the absence of 4-benzylidene-2-phenyl-5-oxazolone (a), in the presence of the oxazolone in 5.5×10^{-6} M (b), and in 1.1×10^{-5} M (c).

first-order plots for the decays of the transients in the presence of different concentrations of the oxazolone. These figures indicate that intensities of triplet-triplet absorptions of the hydrocarbons were reduced and their decay rates were accelerated by the added oxazolone. The slope of the above plots yields the pseudo first-order overall decay coefficient, k', for a particular concentration of the added oxazolone. The coefficient, k', is expressed in the following form:

$$k' = k_d^T + k_q^T[Q] \quad (4)$$

where k_q^T is the second-order rate constant for the triplet quenching and k_d^T represents the first-order coefficient for the unimolecular decay. The observed k' values actually obeyed Eq. 4 to give k_q^T values. The obtained values for k_q^T are summarized in Table 2, together with k_q^{app}, k_q^S, singlet lifetimes, τ_0^S, quantum yields for fluorescence and intersystem crossing, Φ_f and Φ_{IS}, respectively.

Table 2 shows that the triplet states of all sensitizers employed are quenched by the oxazolone with rate constants close to the diffusion-controlled limit regardless of "selective" or "unselective" sensitizers, or of the triplet excitation energy and the structure of the sensitizer. The k_q^T values of fluorene, phenanthrene, and chrysene are larger than those of naphthalene and triphenylene. This result is in contrast with the previous postulate[2] that fluorene and naphthalene classified as "unselective" sensitizers would be more facilely quenched by the oxazolone than the other sensitizers classified as "selective" ones.

New Account for the Effect of the Sensitizers on the Reaction Course. The simplest mechanistic scheme to account for the sensitized reaction is shown in Eqs. 5—15, where S denotes the hydrocarbon sensitizer and Q denotes the oxazolone.

	rate constant	
$S \xrightarrow{h\nu} {}^1S^*$		(5)
${}^1S^* \longrightarrow S_0 + h\nu_f$	k_f	(6)
${}^1S^* \longrightarrow S_0$	k_d^S	(7)
${}^1S^* \longrightarrow {}^3S^*$	k_{IS}	(8)
${}^1S^* + Q \longrightarrow S_0 + {}^1Q^*$	k_q^S	(9)
$Q \xrightarrow{h\nu_f} {}^1Q^*$	k_{reabs}	(10)
${}^3S^* \longrightarrow S_0$	k_d^T	(11)
${}^3S^* + Q \longrightarrow S_0 + {}^3Q^*(\pi,\pi)$	k_q^T	(12)
${}^3Q^*(\pi,\pi) \longrightarrow$ isomerization		(13)
${}^1Q^* \longrightarrow {}^3Q^*(n,\pi)$		(14)
${}^3Q^*(n,\pi) \longrightarrow$ H-abstraction		(15)

Thus, a sensitizer molecule, on absorption of photon, is excited to its singlet state (Eq. 5). The singlet state either undergoes fluorescence emission (Eq. 6), radiationless deactivation to the ground state (Eq. 7), intersystem crossing to the triplet state (Eq. 8), or is quenched by the oxazolone (Eq. 9). The emitted fluorescence

TABLE 3. ESTIMATED QUANTUM YIELDS FOR SENSITIZED REACTIONS OF THE OXAZOLONE IN 2×10^{-5} M THROUGH APPARENT FLUORESCENCE (Φ_f^{app}), INTERSYSTEM CROSSING (Φ_{IS}), QUENCHING OF THE SINGLET SENSITIZERS (Φ_q^S), REABSORPTION OF THE FLUORESCENCE FROM THE SINGLET SENSITIZERS (Φ_{reabs}), AND QUENCHING OF THE TRIPLET SENSITIZERS (Φ_q^T)

	Φ_f^{app}	Φ_{IS}	Φ_q^S	Φ_{reabs}	Φ_q^T
Fluorene	0.46	0.30	0.02	0.21	0.23
Naphthalene	0.19	0.33	0.18	0.05	0.26
Triphenylene	0.05	0.89	0.01	0.05	0.68
Phenanthrene	0.05	0.77	0.06	0.07	0.62
Chrysene	0.07	0.66	0.05	0.06	0.52

can be reabsorbed by the oxazolone and the latter is excited to its singlet state (Eq. 10). The triplet state of the sensitizer either undergoes radiationless deactivation (Eq. 11) or is quenched by the oxazolone to give the lowest triplet state of the latter (Eq. 12). The quantum yields for the singlet quenching (Φ_q^S), for the reabsorption of fluorescence (Φ_{reabs}), for the apparent fluorescence (Φ_f^{app}), and for the triplet quenching (Φ_q^T) by the oxazolone are estimated in the presence of 2×10^{-5} mol/l of the oxazolone according to the following equations 16—20 and summarized in Table 3.

$$\Phi_f^{app} = \frac{k_f\tau_0^S}{1+k_q^{app}\tau_0^S[Q]} \tag{16}$$

$$\Phi_{IS} = \frac{k_{IS}\tau_0^S}{1+k_q^S\tau_0^S[Q]} \tag{17}$$

$$\Phi_q^S = \frac{k_q^S\tau_0^S[Q]}{1+k_q^S\tau_0^S[Q]} \tag{18}$$

$$\Phi_{reabs} = \frac{k_f\tau_0^S}{1+k_q^S\tau_0^S[Q]} - \frac{k_f\tau_0^S}{1+k_q^{app}\tau_0^S[Q]} = \Phi_f - \Phi_f^{app} \tag{19}$$

$$\Phi_q^T = \Phi_{IS}\frac{k_q^T\tau_0^T[Q]}{1+k_q^T\tau_0^T[Q]} \tag{20}$$

Table 3 shows that fluorene and naphthalene, which fluoresce at shorter wavelengths, transfer singlet energy to the oxazolone more efficiently by both bimolecular interaction and reabsorption mechanism, but transfer triplet energy less efficiently than triphenylene, phenanthrene, and chrysene, which fluoresce at longer wavelengths; that is, the "unselective" sensitizers interact with the oxazolone in the singlet state as well as in the triplet state, while the "selective" sensitizers interact more effectively in the triplet state than in the singlet state. These results clearly account for Ullman's observation concerning the dependence of the sensitized reaction course on the structure of the sensitizers employed.

Thus, on taking account of an assumption by Ullman and Baumann that the lowest triplet state of the oxazolone undergoes isomerization and the higher triplet state abstracts hydrogen atom from a solvent, the oxazolone can be easily excited to its $T_1(\pi,\pi^*)$ state by all the sensitizers employed resulting in the isomerization (Eq. 13), but to its higher excited state, for example, T_2 (n, π^*) state, it would be efficiently excited through its singlet state only by sensitization with fluorene and naphthalene (Eqs. 10 and 14) resulting in hydrogen abstraction (Eq. 15).

Finally it should be stressed that reabsorption mechanism can play an important role in some photochemical systems.[5]

Experimental

Materials. 4-Benzylidene-2-phenyl-5-oxazolone was prepared by treating benzaldehyde with *N*-benzoylglycine and recrystallized from benzene.[6] Most sensitizers were purified by column chromatography and recrystallization, and their purities were checked by absorption and fluorescence spectra, and fluorescence lifetimes. Anthracene was prepared by reduction of anthraquinone and recrystallized.[7] Benzene (Wako special grade) was distilled over calcium hydride before use. Cyclohexane (Dotite Spectrosol) was used as received.

Spectra. Absorption spectra were measured with a Hitachi EPS-3 Recording Spectrophotometer. Emission spectra and fluorescence intensities were determined with a Hitachi MPF-2A Fluorescence Spectrophotometer. Reabsorbed emission spectra were measured by observing the emission from hydrocarbon solution in benzene placed in a quartz cell (1 cm in length and 1 cm in width) after passing through an adjacent quartz cell (1 cm in length and 1 cm in width) containing benzene solution of the varying concentration of the oxazolone.

Fluorescence lifetime was measured with a JASCO FL-10 Phase Fluorimeter.

Flash Spectrophotometry. A sample solution contained in a quartz cell (8 cm in length and 2 cm in diameter) was deaerated by bubbling nitrogen. A quartz flash photolysis lamp (10 cm in length and 2 cm in diameter) filled with xenon was operated at 11 kV and 2 μF, dissipating an energy of 120 J; the duration of the flash was 10 μs. The decays of triplet-triplet absorption of hydrocarbons were determined with a xenon lamp (Toshiba 500 W), a plane grating spectrograph (Shimadzu GE-100), a photomultiplier tube (RCA 1P28), and a synchroscope (Toshiba 3054).

The authors' thanks are due to Professor O. Simamura for his discussion, Dr. M. Takakusa, Electrotechnical Laboratory, for the use of a phase fluorimeter in his laboratory, and Professor S. Matsumoto, Aoyama Gakuin University, for the use of a flash spectrophotomeric apparatus.

Studies on 8,9,10,11-Tetrahydro-7*H*-cycloocta[*de*]naphthalenes. I. Conformations of 8,8,10,10-Tetrasubstituted Derivatives of 8,9,10,11-Tetrahydro-7*H*-cycloocta[*de*]naphthalene

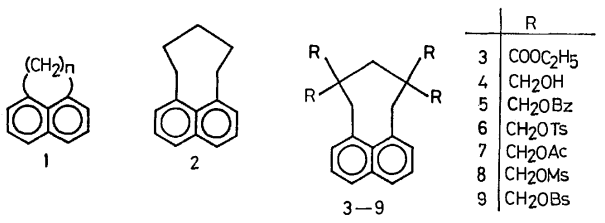
Toshihiro KAMADA, Nobuhide WASADA, and Osamu YAMAMOTO

National Chemical Laboratory for Industry, 1-1-5 Honmachi, Shibuya-ku, Tokyo 151

(Received June 28, 1975)

Several 8,8,10,10-tetrasubstituted 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalenes (**3**—**9**), novel pericyclic compounds of naphthalene, have been prepared through the alkylation reaction of 1,8-bis(bromomethyl)naphthalene and tetraethyl propane-1,1,3,3-tetracarboxylate, and the conformations of the cyclooctene ring in these compounds have been investigated on the basis of the PMR spectra. It is concluded that, at room temperature, the cyclooctene rings of (**3**—**9**) are frozen on the NMR time scale and exist exclusively in the boat form **15**, which is shown to be the most energetically stable conformation for the peri-eight-ring systems from models. Some discussion is also given on the configurations of the substituent groups in (**3**—**9**).

Although alicyclic ring systems, particularly six-membered rings, have been studied extensively by numerous investigators in the last two decades,[1] and although considerable attention has recently been focussed on the peri-interaction in naphthalene derivatives,[2] only a few reports have so far been presented on the pericyclic ring systems, in which methylene chains are fused to a naphthalene ring at the 1,8-positions, **1**. It seems that, in pericyclic naphthalene derivatives, the motions of the methylene chains of the peri-bridged ring are restricted by the naphthalene moiety, and that the rigid peri-bondings cause a large steric crowding in the molecules. This means that the peri-ring in these molecules exists under steric circumstances very different from those in the corresponding saturated cycloalkanes or structurally analogous benzo-derivatives. Among the pericyclic naphthalene derivatives **1**, little information has so far been available on the compounds with ring sizes larger than those of the commonly known acenaphthene (**1**, n=2), 2,3-dihydrophenalene (**1**, n=3) and 7,8,9,10-tetrahydrocyclohepta[*de*]naphthalene (**1**, n=4).[2]



Our interest has been in the stereochemistry of these unknown pericyclic ring systems, particularly the 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene ring **2**, which is the next higher homolog of the cyclohepta[*de*]naphthalene compound. Recently, the unsubstituted hydrocarbon **2** was first synthesized by Nelsen and Gillespie, and some suggestion was given as to its conformation.[3] However, no information has yet been obtained on the substituted derivatives of this compound.

In this paper, some new derivatives of 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene (**3**—**9**) have been prepared, and their stable conformations have been determined on the basis of the PMR spectra.

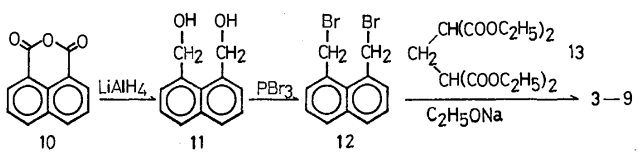
Results

Syntheses. The compounds (**3**—**9**) used in this study were synthesized in the following reaction sequence, outlined in Scheme 1. The starting material was commercially available 1,8-naphthalenedicarboxylic anhydride, **10**, which was reduced with lithium aluminum hydride to 1,8-bis(hydroxymethyl)naphthalene, **11**.[4] Treatment of **11** with phosphorus tribromide and pyridine in ether led to the dibromide, **12**.[5] The next step was the formation of the eight-membered peri-ring. For this purpose, **12** was allowed to react with tetraethyl propane-1,1,3,3-tetracarboxylate, **13**, which had been prepared from diethyl malonate and paraformaldehyde by the condensation reaction in the presence of potassium hydroxide.[6,7] By the reaction between equimolar amounts of **12** and **13** in ethanol-dimethyl sulfoxide at 0 °C, using sodium ethoxide as a condensing agent, tetraethyl 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene-8,8,10,10-tetracarboxylate, **3**, with the desired peri-8 ring, was obtained in 55% yield. Treatment of



Scheme 1.

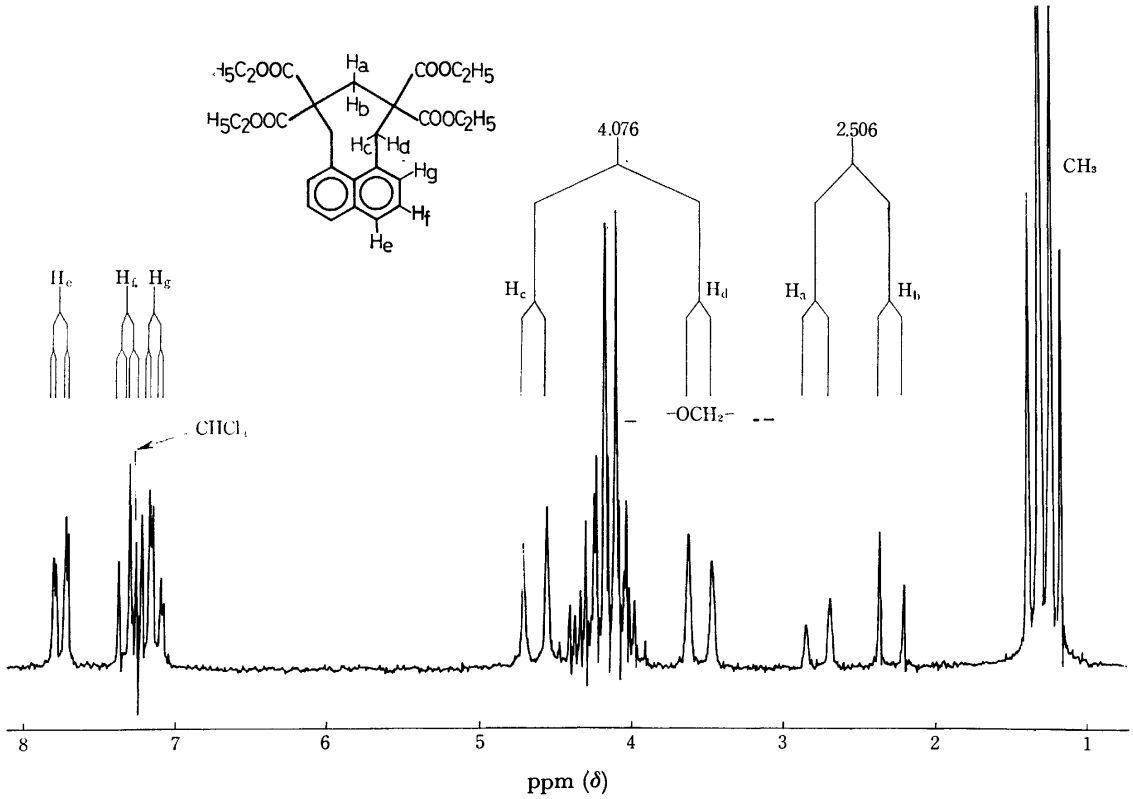


Fig. 1. PMR spectrum of tetraethyl 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene-8,8,10,10-tetracarboxylate (**3**) at 100 MHz in $CDCl_3$ solution.

3 with excess lithium aluminum hydride in ether gave the tetrol **4**, which was then converted to the esters in the usual fashion. Thus, by treating **4** in pyridine with such acylating agents as benzoyl chloride, *p*-toluenesulfonyl chloride, acetic anhydride, methanesulfonyl chloride, and *p*-bromobenzenesulfonyl chloride, the corresponding tetraesters of **4** were obtained- namely, benzoate **5**, tosylate **6**, acetate **7**, mesylate **8**, and brosylate **9** respectively.

After purification, each compound (**3**—**9**) was proved to have the desired structure by elemental analysis as well as by a study of the IR, PMR, and high-resolution mass spectra. The data are summarized in Table 1 except for PMR, which will be given fully later.

PMR Spectra. The room-temperature 100-MHz PMR spectrum of tetraethyl 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene-8,8,10,10-tetracarboxylate, **3**, in *ca.* 10% solution in deuteriochloroform consists of five distinct absorption groups, as is shown in Fig. 1. They are low-field naphthalene absorption bands (6H, e, f, g), a multiplet (8H) in the center of the spectrum due to the methylene protons of ester groups, a high-field methyl signal (12H), and two AB quartets centered at δ 4.076 (4H, c, d) and 2.506 (2H, a, b) respectively. From the positions and relative intensities of each peak, the low-field AB pattern can readily be assigned to the benzylic protons, and the high-field one, to the methylene protons on 9-carbon in the peri-ring. The lower-field portion, H_c, of the benzylic AB pattern can be assigned to hydrogens which point inward to the center of the molecule, since these hydrogens are expected to have a large steric interaction owing to their proximity with each other in the peri-eight ring systems.[8,9]

An important feature observed in the spectrum is that in the C_9-AB pattern, the higher-field methylene proton, H_b, appears as a sharp doublet, while the lower-field H_a affords a considerably broadened peak. The line broadening is also noted in the high-field H_d proton in the benzylic AB pattern, although it is not so remarkable as that for the C_9-methylene proton, H_a. An attempt to resolve these broadened lines by employing a degassed sample was unsuccessful. However, the line broadening in both AB patterns suggests that an appreciable long-range spin-spin interaction exists between one of the C_9-methylene protons, H_a, and an outward-pointing benzylic methylene proton, H_d. Actually, spin-decoupling experiments on **3** demonstrate the presence of this interaction, in which a sharpened doublet results for the C_9-methylene proton, H_a, upon irradiation at the higher-field portion, H_d, of the benzylic AB pattern.

The methyl and naphthalene absorptions are rather simple, as can be seen from the spectrum; thus, by a first-order analysis of the expanded spectra, two methyl groups at δ 1.287 and 1.208 (triplet, J=7.1 Hz, respectively), and three quartets for the aromatic protons at δ 7.730 (e, 2H, J=8.0 and 1.7 Hz), 7.279 (f, 2H, J=8.0 and 7.1 Hz), and 7.116 (g, 2H, J=7.1 and 1.7 Hz) are obtained. This means that two different types of methyl groups and three different types of aromatic protons are present in **3**. From the peak area and the values of the chemical shifts and the coupling constants, the aromatic protons can be assigned most reasonably as is shown in Fig. 1.

The methylene signals of the ester groups, appearing in the center of the spectrum as a complex multiplet rather than the usually observed simple pattern, can

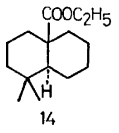
also be completely analyzed, as is shown in Fig. 2. They consist of two distinct methylene groups, one of which resonates at δ 4.131, showing a simple, first-order quartet (j, 4H, J=7.1 Hz), while the other, with two components, resonates at δ 4.301 and 4.070, showing a multiplet of sixteen symmetric lines resulting from AB part of ABX_3 system (h, i, J_{AB}=10.8, $J_{AX}=J_{BX}$=7.1 Hz); *i.e.*, an AB quartet is formed, due to the nonequivalence of the methylene protons, and then each component further splits into a quartet by coupling with the neighboring methyl group. This is a fact of interest in connection with another previously reported compound, **14**, in which *O*-methylene protons of the ethoxycarbonyl group are known to be magnetically nonequivalent to each other.[10]



14

The 100-MHz PMR spectrum of the aliphatic portions of the tosylate **6** at ambient temperature is given in Fig. 3. All the spectra of the oxymethyl derivatives (**4**—**9**) in this region resemble each other well; they all contain four AB quartets, as may be seen in the figure. The high-field AB pattern (a, b, 2H) is readily assigned to the C_9-methylene protons in a manner similar to that described above, while the AB pattern (c, d, 4H) in the low-field region, with a larger coupling constant and a larger chemical-shift difference, can be assigned to the benzylic methylene protons. The remaining two AB patterns (4H), centered at δ 4.080 and 3.326 respectively, are responsible for the protons of oxymethyl groups ($-CH_2O-$) attached to the carbons-8 and -10 of the peri-ring; this means that two different types of methylene groups, belonging to a $\begin{matrix}X\\Y\end{matrix}\!\!\times\!\!CH_2^-$ moiety, are present in (**4**—**9**). The assignments of these methylene signals will be discussed later.

An additional doublet is also observed in the spctra of the tosylate **6** (δ 2.467 and 2.429), the acetate **7** (δ

a) Because of overlapping of the peaks, line-width of this signal cannot be obtained.

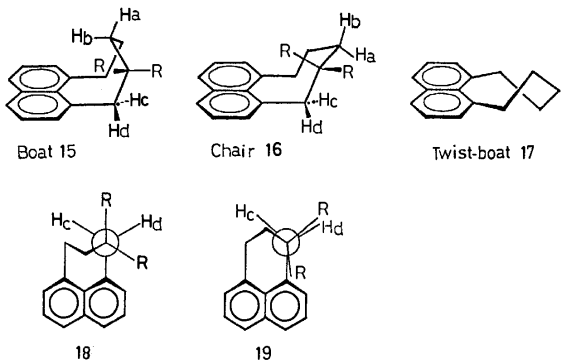
2.096 and 2.072), and the mesylate **8** (δ 3.304 and 3.166); all similarly arise from two different types of methyl protons in the tosyl, acetyl, and mesyl groups respectively.

Again, line broadening is also observed in all the low-field doublets, H_a, of the C_9-methylene AB pattern as in **3**, although to a lesser extent, due to long-range spin-spin interactions with benzylic methylene protons, H_d. This fact suggests that all the molecules of this series (**3**—**9**) have a geometry very similar to one another in solution; this can also be supported by the other analogous spectral features described above. The PMR data for Compounds (**3**—**9**) are summarized in Tables 2,3, and 4.

Discussion

The PMR spectra of Compounds (**3**—**9**) at ambient temperature always give an AB pattern for each of the benzylic and the C_9-methylene protons. This suggests that, in all the compounds, the inversion of the peri-ring has been slow enough at this temperature on the NMR time scale; it also suggests that the molecules always assume only a single energetically stable conformation in solution.

The fact that only a single AB pattern is observed for the benzylic methylene groups in all the spectra indicates the equivalence of the two diastereomeric methylene protons on the benzylic positions in all the compounds, *i.e.*, the equivalence of the positions at carbon-7 and carbon-11. A similar situation can be expected for the positions of C-8 and C-10 in all of this series, since always only two absorption groups are shown for the four substituents at these positions (see spectra). This indicates that the most stable conformation of 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene derivatives (**3**—**9**) has either a mirror plane (C_S) or a two-fold symmetry axis (C_2) passing through the C-9 and angular carbon atoms of the naphthalene nucleus. The simplicity of the naphthalene signals observed in **3** can also be accounted for by the above symmetric conformations. Furthermore, the fact that all the compounds clearly show an AB pattern for the C_9-methylene protons rules out the two-fold axis of symmetry in Compounds (**3**—**9**). If it were not the case, one would expect to find an A_2 singlet for these protons. On the other hand, the models of the 8,8,10,10-tetrasubstituted derivatives of 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene show that the molecules are capable of existing in three conformations: *i.e.*, the boat, **15**, and the chair, **16**, with a C_S symmetry, and the twist-boat, **17**, with a



C_2 symmetry, as was recently suggested by Nelsen and Gillespie for the unsubstituted hydrocarbon **2**.[3] It is understandable, however, that the twist-boat can hardly exist at the ground state in Compounds (**3**—**9**), since the twist-boat is much more strained than the boat or the chair conformation.

Symmetry considerations cannot distinguish between the boat and the chair conformations, but fortunately this distinction can be made by using the values of the chemical shifts and line-widths of the C_9-methylene protons, together with an evaluation of the ring-current effects induced by the naphthalene nucleus. From the data for the 8,8,10,10-tetrasubstituted derivatives of 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene (**3**—**9**) in Table 2, it is apparent that, generally in all the compounds except **3**, the C_9-methylene proton signals, particularly that of the high-field portion, H_b, shift remarkably to the high-field region as compared to the axial protons of cyclohexanes (δ 1.21[11,12] and 1.137[13] ppm); this makes the chemical-shift difference between the protons, H_a and H_b, of the C_9-methylene group in (**4**—**9**) much larger ($\Delta\delta_{obsd}$ 0.85—1.20 ppm) than that between the equatorial and the axial protons in cyclohexane (0.46[12] and 0.479[13] ppm). This comparison is not always accurate, since it is made between compounds with different ring systems and different sub-

stituents. Nevertheless, the above data do indicate the trends of the C_9-methylene protons in the peri-8 ring systems.

The anomalously large chemical-shift difference, $\Delta\delta_{obsd}$, observed for the C_9-geminal protons in the alicyclic ring systems of (**4**—**9**) suggests that these compounds (**4**—**9**) assume a conformation in which either of the methylene protons on C-9 experiences rather large ring-current effects of naphthalene. An examination of the models reveals that the proton, H_a, on C-9 is quite remote from the naphthalene moiety in both the boat and chair conformations; it can be expected to be little affected by the ring-current of naphthalene, while the H_b proton, which is spatially closer to the naphthalene ring in the boat conformation, can be expected to undergo larger ring-current effects; little effect is expected for the H_b proton, in the chair conformation (see diagram). This suggests that there exists a large chemical-shift difference in the C_9-geminal protons in the boat conformation of 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]-naphthalene ring.

Then, the effects of the ring-currents of naphthalene on the chemical shifts of the C_9-protons were evaluated for the boat and chair conformations of the 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene ring. The calculation was done according to the method of Goldstein *et al.*[14] using Eq. (1), where the distances of hydrogens from the naphthalene nucleus necessary for the calculation were obtained from the models:

$$\sigma = \frac{-3434}{R^3}\left[(1-3\cos^2\alpha) + \frac{0.735}{R^2}(35\cos^4\alpha - 30\cos^2\alpha + 3)\right] \quad (1)$$

From the results of the calculation, shown in Table 5, it is clear that, in the boat conformation, the *endo*-orienting C_9-methylene proton, H_b, is shielded to a greater extent (1.50 ppm) than the *exo*-orienting proton, H_a (0.28 ppm), by the effect of the ring-current of naphthalene, while in the chair conformation, the ring-current deshields both the axial (H_a) and the equatorial (H_b) protons of the C_9-methylene group and the effect is very small (0.44 and 0.08 ppm, respectively). Consequently, the chemical-shift difference in the C_9-geminal protons responsible for the ring-current of naphthalene is much larger in the boat conformation (δ_r 1.22 ppm) than in the chair (δ_r 0.36 ppm).

In addition, in order to evaluate the chemical-shift difference in the C_9-geminal protons more accurately, one must also consider the chemical-shift difference in the C_9-geminal protons when the ring-current effects of naphthalene are absent. Since both the boat and chair conformations of the 8,9,10,11-tetrahydro-7*H*-cycloocta-[*de*]naphthalene ring can be considered to have a geometry similar to that of the cyclohexane with respect to the arrangement of the C-8, C-9, and C-10 portions of the peri-ring, the effect of the different configuration on the chemical shifts of the protons in the saturated ring system can be estimated from the experimental values observed in cyclohexane derivatives, in which the signal of the axial protons appears in a field higher than the equatorial protons by 0.1—0.7 ppm (δ_{ae}).[15]

Thus, considering both the effects of the ring-current, δ_r, and the configurational difference, δ_{ae}, the chemical-shift difference in the C_9-geminal protons $\Delta\delta_{calcd}$ for the boat and chair conformations of the 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene ring are calculated as follows. Since, in the boat conformation, the hydrogens, H_a, and H_b, of the C_9-geminal group correspond to the equatorial and the axial protons of the cyclohexane respectively, the chemical-shift difference, $\Delta\delta_{calcd}$, is calculated to be 1.32—1.92 ppm. In the chair conformation, the H_a hydrogen corresponds to the axial, and the H_b hydrogen, to the equatorial; thus, the chemical-shift difference, $\Delta\delta_{calcd}$, is calculated to be −0.34—0.26 ppm (see diagram and Table 5). This result also indicates that the boat conformation has a large chemical-shift difference in the C_9-geminal protons, while the chair has a small one. A comparison of these calculated values $\Delta\delta_{calcd}$, with those observed, $\Delta\delta_{obsd}$, in (**4**—**9**) shows that the experimental values are much closer to that calculated for the boat conformation than that calculated for the chair. This makes it very possible that all the compounds (**4**—**9**) assume a boat form as the most stable conformation in solution at ambient temperature. Therefore, the high-field doublet (b) of the C_9-methylene signals observed in (**4**—**9**) can be assigned to the *endo*-orienting proton, H_b, and the low-field one (a), to the *exo*-orienting proton, H_a, of the boat conformation (see spectra).

The observed values in (**4**—**9**) ($\Delta\delta_{obsd}$ 0.85—1.20 ppm) are somewhat smaller than that calculated for the boat conformation ($\Delta\delta_{calcd}$ 1.32—1.92 ppm). In Compounds (**4**—**9**), however, the value of δ_{ae} is expected to be decreased to some extent by the effect of the axial $-CH_2O-$ groupings attached to the C-8 and C-10 positions.[15] Taking this fact into consideration, the chemical-shift difference calculated for the boat conformation can be expected to be a little smaller than that in Table 5; this results in a better agreement with the experimental values of (**4**—**9**).

It should be noted that there are some differences in the values of $\Delta\delta_{obsd}$ for (**4**—**9**), where **4** with hydroxyl groups exhibits a larger value than the others with more electronegative acyl or sulfonyl groups (**5**—**9**). From

Table 5. Calculation of chemical-shift difference in C_9-methylene protons in 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]-naphthalene ring (ppm unit)

Chair	−0.44	−0.08	0.36	0.1—0.7	−0.34—0.26
Observed in (**4**—**9**)					0.85—1.20 ($\Delta\delta_{obsd}$)

a) Ring-current effect of naphthalene on the chemical shift of the C_9-methylene protons, calculated from Eq. (1). A minus sign indicates a low-field shift. b) Chemical-shift difference in C_9-methylene protons responsible for the ring-current effect of naphthalene. c) Chemical-shift difference in C_9-methylene protons caused by configurational difference between these two protons, estimated from Ref. 15. d) Chemical-shift difference in C_9-methylene protons calculated from the values of δ_r and δ_{ae} (see text).

Tables 2 and 3 it may be seen that the low-field shifts of all the AB absorption-centers (△) including oxymethyl, benzylic, and C_9-protons increase in this order of the compounds: **4**,**6**,**9**,**7**,**8**,**5**. This clearly means that, in all the (**4**—**9**) compounds, not only the oxymethyl groups but also the benzylic and the C_9-methylene groups are substantially affected by the substituents, although they are remote from the benzylic and the C_9-methylene groups in these molecules (**4**—**9**). Table 2 also shows that, in all the (**5**—**9**) compounds, the low-field shift of the absorption-centers (△) is always larger in the C_9-methylene signals than that in the benzylic signals; that is, the C_9-methylene groups are more affected than the benzylic methylene groups by the four substituent groups attached to C-8 and C-10. In the cyclohexane chair conformation, it is known that the equatorial electronegative groups shield both the axial and equatorial protons attached to the adjacent carbon atom, whereas the axial substituents shield the equatorial protons, but cause an appreciable low-field shift of the corresponding axial protons on the contiguous carbon atom.[16] This means that the C_9-methylene proton, H_a, in the tetrasubstituted derivatives of the 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene, with electronegative groupings at the C-8 and C-10 positions, is appreciably deshielded by the effect of the axial electronegative groups attached to the above positions, but the H_b proton is shielded, because the H_a proton in the boat conformation of the 8,9,10,11-tetrahydro-7*H*-cycloocta-[*de*]naphthalene ring corresponds to the equatorial proton of cyclohexane, and the H_b proton, to the axial. It is understandable, therefore, that the differences in chemical shifts between the C_9-methylene proton, H_a, and H_b, in **4** ($\Delta\delta_{obsd}$) are larger by 0.13—0.35 ppm than those in (**5**—**9**), since the signals of the H_b proton in Compounds (**5**—**9**) are expected to shift to a lower-field to a greater extent than in **4** as a result of the effect of acyl- or sulfonyloxymethyl groups on the carbon-8 and 10.

In the case of the benzylic methylene groups, the inward-pointing proton, H_c, is situated at the position *trans* to the equatorial substituents, and the spatial relationship between these two groups is similar to that between the H_b proton and the axial substituents described above. Thus, in contrast to the C_9-methylene protons, a large chemical-shift difference can be expected for the benzylic methylene protons in (**5**—**9**), since the inward-pointing proton, H_c, resonates at an appreciably lower field than the outward-pointing proton, H_d, because of the steric compression, and the H_c proton can be expected to be further deshielded by the acyl- or sulfonyloxymethyl groups in (**5**—**9**). The observed values of $\Delta\delta_{obsd}$ distinctly reveal this trend, where the value for **4** is smaller than those for (**5**—**9**) by 0.05—0.52 ppm (see Table 2). These results further support the predominance of the boat conformation over the chair in all the (**4**—**9**) compounds.

The only exception observed in Table 2 is the ethoxycarbonyl derivative, **3**, which shows a $\Delta\delta_{obsd}$ value of only 0.458 ppm, almost comparable to that of cyclohexane. However, as may be seen in the table, the absorption-centers of both the C_9- and benzylic methylene protons in **3** shift to a considerably lower field than those in other compounds (**4**—**9**); *i.e.*, in **3** both methylene groups are affected by the ethoxycarbonyl groups to a greater extent than in the other compounds, presumably because the electronegative ethoxycarbonyl groups directly attach to the ring carbons, C-8 and C-10, while in the other (**4**—**9**) compounds the acyloxy and sulfonyloxy groups attach to the substituent carbons. The chemical-shift difference in the C_9-methylene group in **3**, therefore, will be appreciably decreased by the effect of the ethoxycarbonyl groups, even if **3** exists in the boat conformation and even if the proton, H_b, in **3** is substantially shielded by the ring-current of naphthalene, as is observed in the other (**4**—**9**) compounds. This suggests a large possibility that the molecule of **3** also assumes the boat form as the most stable conformation at ambient temperature.

In the boat conformation, the four bonds between the C_9-methylene proton, H_a, and the outward-pointing benzylic methylene proton, H_d, lie in one plane in the W-arrangement, while in the chair such an arrangement is absent. Therefore, if the boat is the correct conformation for (**3**—**9**), an appreciably large long-range spin-spin interaction can be expected between these protons in all the (**3**—**9**) compounds.[17,18] Thus, as may be seen in the spectra and in Table 4, the fact that the signal of the C_9-methylene proton, H_a, is always broader than that of the proton, H_b, in (**3**—**9**) undoubtedly indicates the presence of this long-range coupling; hence, this is further evidence in favor of the boat conformation for (**3**—**9**). It may also be noted in Table 4 that the line-widths of both protons, H_a and H_b, are always larger in (**4**—**9**) than in **3**. This means that, in (**4**—**9**), both protons, H_a and H_b, are further coupled with oxymethyl groups attached to the contiguous carbon atoms, C-8 and C-10. It is also apparent from the table that this broadening of the signals is always more remarkable in the signals of H_b than those of H_a. This is presumably because the proton, H_b, in the boat conformation is coupled relatively strongly with the protons of the axial $-CH_2O-$ groups because of their *trans* arrangement.[19-22]

The effect of the substituents is also reflected in the geminal spin couplings of both the C_9- and the benzylic methylene groups in all the (**3**—**9**) compounds. Thus, as can be seen in Table 2, the geminal couplings, J_{gem}, of the C_9-methylene groups in (**3**—**9**) are appreciably larger (14.7—16.0 Hz) than those in the cyclohexanes (12—14 Hz). Moreover, the value of J_{gem} is much larger in the ethoxycarbonyl derivative, **3** (16.0 Hz), than those in the oxymethyl derivatives (**4**—**9**) (15.3—14.7 Hz), in which the value is the smallest in the hydroxy derivative **4**. Similar trends are also found in the geminal couplings of the benzylic methylene protons, in which, again, the value is the largest in **3** (15.6 Hz) and the smallest in **4** (14. 2Hz).

One point not yet discussed is the assignment of the two methylene signals arising from the 8- and 10-substituted groups ($-CH_2O-$ and $-COOC_2H_5$) to the axial and equatorial groups. In the oxymethyl derivatives (**4**—**9**), the axial methylene protons, involving the steric-compression effects, can be responsible for the low-field

AB quartet, and the equatorial ones, for the high-field signals.[16] This assignment is consistent with the results of the evaluation of the ring-current effect of the naphthalene nucleus on the methylene protons belonging to the axial and equatorial $-CH_2O-$ groups in (**4**—**9**), from which it is clear that the equatorial groups resonate at a field higher than the corresponding axials by *ca.* 0.46 ppm in the presence of the free rotations as a result of the ring-current effect.[10]

It is interesting that the nonequivalence of methylene protons is observed in the methylene signals of one of the $-COOC_2H_5$ groups in **3**. A detailed discussion of this point, however, as well as the assignment of methylene signals, must await further studies of the stereochemical properties inherent in these peri-8 ring systems.

All the results presented above provide conclusive evidence that all the (**3**—**9**) compounds exclusively exist in the boat conformation at room temperature in solution. Both the boat and chair conformations of (**3**—**9**) are expected to involve large van der Waals interactions caused by the two inward-pointing benzylic methylene protons, H_c,[8,9] and those caused by the two substituent groups in the 1,3-diaxial relationship to each other.[16] However, the chair conformation is expected to involve additional eclipsing interactions along the bonding between C-7 and C-8, and the bonding between C-10 and C-11 as well. Moreover, in the chair conformation, one can expect steric repulsions to be present between the axial substituents and the naphthalene ring because of their proximity to each other. On the other hand, the boat conformation lacks these additional interactions (see **15**, **16**, and the Newmann projections about the C_7–C_8 bonding, **18** for the boat and **19** for the chair conformation). The boat form, therefore, is the more energetically stable conformation for the 8,8,10,10-tetrasubstituted 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]-naphthalene ring, which well accounts for the predominance of the boat conformation over the chair observed in all the (**3**—**9**) compounds. A model of the boat conformation shows that the distance between the inward-pointing 7,11-hydrogens is *ca.* 0.7 Å, much smaller than the sum of the van der Waals radii of the two hydrogens (2.4 Å). Therefore, the molecules of (**3**—**9**) can be expected to assume a boat conformation which is strained to some extent in such a direction as to avoid the steric repulsions arising from the proximity of the two H_c hydrogens.

Experimental

All melting points were determined on a microscopic hot-stage melting-point apparatus and are reported uncorrected. All the solvents used in the reactions were dried and freshly distilled. Thin-layer chromatography was employed on silica gel to monitor the reactions and to check the purity of the products. After the solvents had been removed from the developed tlc sheets, the spots were detected by iodine vapor. The IR spectra were obtained on a JASCO Model IR-G Grating Infrared Spectrometer, using Uujol mulls. The positions of the absorption maxima are quoted in wave numbers (cm^{-1}), calibrated with polystyrene. The PMR spectra were obtained on a Varian HA-100 D spectrometer (100 MHz) at room temperature, using *ca.* 10% solution of compounds in deuteriochloroform or dimethyl sulfoxide-d_6; the chemical shifts are expressed in ppm (δ) downfield from the internal standard, tetramethylsilane, and the coupling constants (J), in Hz. High-resolution molecular-weight determinations were carried out on a CEC high-resolution mass spectrometer, Model 21-110 B, with a direct-inlet system and an ionization potential of 70 eV.

*1,8-Bis(hydroxymethyl)naphthalene (**11**).* Although Boekelheide and Vick[4] have previously reported the preparation of 1,8-bis(hydroxymethyl)naphthalene by the lithium aluminum hydride reduction of 1,8-naphthalenedicarboxylic anhydride, **11** was obtained in a more excellent yield by the method described below.

To a stirred suspension of 50 g of lithium aluminum hydride in a mixture of 1.2 l of absolute ether and 1 l of dry benzene, there was added 125 g of 1,8-naphthalenedicalbyxylic anhydride at a rate sufficient to maintain gentle boiling. After the addition was complete, the mixture was heated under reflux with stirring for an additional 6 days. After the reaction mixture had then been cooled, the excess metal hydride was destroyed by the addition of ethyl acetate and water. The further addition of 2M-aqueous hydrochloric acid to the slurry gave a white solid. This solid was collected, dried, and then heated with benzene containing ether. The benzene solution was separated and evaporated to give a white solid. After washing with dilute acid, the solid was recrystallized from benzene–methanol, giving the diol **11** (99 g; yield, 84%) as colorless needles; mp 156—156.5 °C (lit., mp 157—158 °C[4]) (Found: C, 76.39; H, 6.38%).

*1,8-Bis(bromomethyl)naphthalene (**12**).* 1,8-Bis(bromomethyl)naphthalene, **12**, was prepared in 84% yield by the bromination of 1,8-bis(hydroxymethyl)naphthalene, **11**, with phosphorus tribromide, essentially as has been described by Mitchell and Sondheimer.[5] Mp 131—132 °C (lit., mp 131—132 °C[5]) (Found: C, 46.00; H, 3.20; Br, 51.09%).

*Tetraethyl propane-1,1,3,3-tetracarboxylate (**13**).* Tetraethyl propane-1,1,3,3-tetracarboxylate, **13**, was prepared from diethyl malonate and paraformaldehyde according to the method of Welch.[6] Fractional distillation of the reaction product *in vacuo* using a Vigreux column afforded the tetraester **13**; bp 132—145 °C/0.3 mmHg; mostly distilled at 138 °C (lit., bp 194—198 °C/20 mmHg,[6] bp 190—200 °C/12 mmHg, 210—215 °C/20 mmHg[7]).

*Tetraethyl 8,9,10,11-tetrahydro-7H-cycloocta[de]naphthalene-8,8,10,10-tetracarboxylate (**3**).* A solution of 54 g of tetraethyl propane-1,1,3,3-tetracarboxylate, **13**, in 60 ml of absolute ethanol and 100 ml of dry dimethyl sulfoxide (distilled on calcium hydride) was added quickly to a stirred and cooled (0 °C) solution of sodium ethoxide in ethanol, obtained by dissolving 7.2 g of sodium in 660 ml of absolute ethanol. After 5 min, to this mixture, was added a solution of 54 g of 1,8-bis(bromomethyl)naphthalene, **12**, in 720 ml of dry dimethyl sulfoxide over a period of 12 min. After the addition was complete, stirring and cooling were continued for an additional 1.5 hr. The reaction mixture was then poured into cracked ice and water, and the resulting cloudy solution was extracted with ethyl acetate (500 ml × 5). The ethyl acetate solutions were combined, dried over anhydrous sodium sulfate, and evaporated to leave a yellow oil, which solidified on standing at room temperature. The solid was crushed in cool ethanol, filtered off, and then further purified by recrystallization from ethanol, giving the desired peri-eight-membered ring compound, **3** (43 g; yield, 55%) as colorless prisms.

*8,8,10,10-Tetrakis(hydroxymethyl)-8,9,10,11-tetrahydro-7H-cycloocta[de]naphthalene (**4**).* To a stirred slurry of 10 g of lithium aluminum hydride in 1 l of absolute ether, there was added a suspension of 30 g of the ester **3** in 200 ml of absolute

ether at a rate sufficient to maintain gentle boiling. After the addition was complete, the mixture was boiled under reflux, with vigorous stirring for an additional 120 hr. The excess lithium aluminum hydride was then decomposed by the addition of ethyl acetate, followed by that of 2M-aqueous hydrochloric acid. The resulting white precipitate was collected and extracted with 2 l of boiling ethyl acetate for 3 hr. The extracts and filtrate were then combined, and the solvent was evaporated. The residual solid was washed with 100 ml of diluted hydrochloric acid and recrystallized from methanol, giving the tetrol **4** (16 g; yield, 80%), as fine, colorless needles.

8,8,10,10-Tetrakis(benzoyloxymethyl)-8, 9, 10, 11-tetrahydro-7H-cycloocta[de]*naphthalene (5).* The tetrol **4** (0.1 g), was treated with benzoyl chloride (2 ml) in pyridine (3 ml) at 60 °C for 1 hr, after which the mixture was left at room temperature for 2 days. After the reaction had been completed, the reaction mixture was poured into ice and water and extracted with ethyl acetate. The usual work-up of the ethyl acetate solution gave a brown oil, which crystallized on the addition of cool methanol. After separation, the crystals were further purified by two recrystallizations from benzene–methanol to give the benzoate **5** as colorless needles (0.16 g; yield, 70%).

*8,8,10,10-Tetrakis(*p*-toluenesulfonyloxymethyl)-8, 9, 10, 11-tetrahydro-7H-cycloocta*[de]*naphthalene (6).* To a stirred suspension of 3 g of the tetrol **4** in 19 ml of pyridine, there was added a solution containing 12 g of *p*-toluenesulfonyl chloride and 12 ml of pyridine. The mixture was shaken vigorously for 1 min and then left at room temperature for 7 days. The reaction mixture was poured into 70 ml of ice and water, and the mixture was stirred well for 1 hr at 0 °C. The resulting precipitates were collected and recrystallized from methanol–benzene, yielding 8.6 g (yield, 97%) of the tosylate **6** as colorless needles.

8, 8, 10, 10-Tetrakis(acetoxymethyl)-8, 9, 10, 11-tetrahydro-7H-cycloocta[de]*naphthalene (7).* A mixture of the tetrol **4** (0.1 g), acetic anhydride (5 ml), and pyridine (5 ml) was heated at 60 °C on a water bath, with occasional shaking, for 30 min. The resulting clear solution was then allowed to stand at room temperature for 3 days to complete the reaction. The reaction mixture was poured into 50 ml of ice water; the mixture was stirred at 0 °C for 30 min and then left at room temperature for an additional 3 hr. The solid thus precipitated was collected and recrystallized from ethanol to give the acetate **7** (0.14 g; yield, 92%), as colorless needles.

8, 8, 10, 10-Tetrakis(methanesulfonyloxymethyl)-8, 9, 10, 11-tetrahydro-7H-cycloocta[de]*naphthalene (8).* To a suspension of 0.2 g of the tetrol **4** in 2 ml of pyridine, there was added 1 ml of methanesulfonyl chloride, after which the mixture was shaken vigorously for 10 min. After being left at 0 °C for 1 hr, the reaction mixture was poured into 100 ml of ice water and the mixture was stirred well at 0 °C for 30 min. The solid thus precipitated was filtered off, washed with methanol, and dried *in vacuo*. Recrystallization of this solid from dimethyl sulfoxide–methanol–water yielded the mesylate **8** as a colorless microcrystalline solid (0.3 g; 76%).

*8, 8, 10, 10-Tetrakis(*p*-bromobenzenesulfonyloxymethyl)-8, 9, 10,-11-tetrahydro-7H-cycloocta*[de]*naphthalene (9).* To a stirred suspension of 0.2 g of the tetrol **4** in 2 ml of pyridine, was added a solution of *p*-bromobenzenesulfonyl chloride (1.2 g) in pyridine (2 ml). The mixture was stirred at room temperature for 30 min and then left at room temperature for an additional 2 days. The reaction mixture was poured into 50 ml of ice water, and the mixture was stirred well for 30 min. The white solid thus precipitated was filtered off, washed with methanol, and dried *in vacuo*. Then it was purified by recrystallization from chloroform–methanol–water to give the brosylate **9** (0.56 g; 75%), as microcrystals.

Esters of Phosphorus Oxy Acids as Alkylating Agents. IV. *N*-Alkylation of Imidazole and Its Analogs with Alkyl Esters of Phosphonic and Phosphinic Acids

Masahiro HAYASHI, Kiyoshi YAMAUCHI, and Masayoshi KINOSHITA

Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received August 1, 1975)

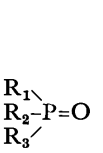
Methyl, ethyl esters of phosphonic and phosphinic acids were found to be efficient alkylating agents for imidazole, benzimidazole, 1,2,4-triazole, 1,2,3-benzotriazole and pyrazole, giving the corresponding *N*-methyl or *N*-ethyl derivatives.

In a previous paper a report was given on the *N*-alkylation reactions of imidazoles with trialkyl phosphates.[1] Since phosphonic and phosphinic acid esters are also considered to be potentially useful as alkylating agents, we investigated the *N*-alkylation of imidazoles with these phosphorus oxy-acid esters, and found simple methods of alkylation for this class of heterocycles.

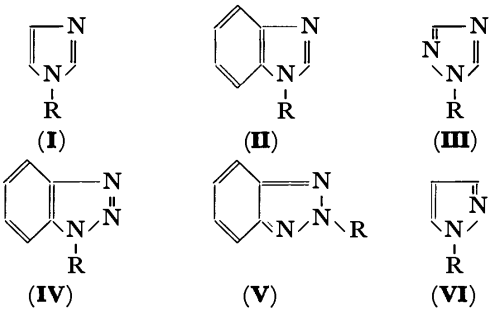
Reactions were carried out by heating a base in an ester, and the products were isolated by distillation or extraction.

Table 1 gives a summary of the alkylation reactions of imidazole (**I**, R=H), benzimidazole (**II**, R=H), 1,2,4-triazole (**III**, R=H), 1,2,3-benzotriazole (**IV**, R=H), and pyrazole (**VI**, R=H).

All the bases underwent *N*-alkylation to give the corresponding products in fairly good yields. Especially, in triazole, reactions brought into substitution at the N-1 position only to afford 1-alkyltriazole (**III**, R=Me, Et). In benzotriazole, the N-1 position was alkylated preferentially to the N-2 position to give 1-alkyl derivatives (**IV**, R=Me, Et) as a main product. High selective alkylation in the present method would be very useful, since other alkylating agents such as alkyl halide, diazomethane and dimethyl sulfate showed much lower selectivity,[2-8] giving a mixture of 1- and 2-alkyl isomers in approximately 5 to 3, 3 to 10, and 2 to 1 mole ratios, respectively.



a: $R_1=R_2=OMe$, $R_3=Me$
Dimethyl methylphosphonate
b: $R_1=R_2=OEt$, $R_3=Et$
Diethyl ethylphosphonate
c: $R_1=OMe$, $R_2=R_3=Me$
Methyl dimethylphosphinate
d: $R_1=OEt$, $R_2=Et$, $R_3=Ph$
Ethyl ethylphenylphosphinate



(**I**) (**II**) (**III**)

(**IV**) (**V**) (**VI**)

Alkyl-imidazoles, benzimidazoles, triazoles and pyrazoles were isolated by direct distillation of the reaction mixtures. Separation of 1-methyl and 2-methylbenzotriazole was carried out easily through fractionating the reaction mixture between a dilute hydrochloric acid and chloroform, since the former is soluble in a dilute acid while the latter goes into the organic layer.

The results suggest that alkyl esters of phosphonic and phosphinic acids could be utilized as convenient alkylating agents for the preparation of *N*-alkyl derivatives of imidazole and its analogs.

TABLE 1. REACTIONS OF IMIDAZOLE AND ITS ANALOGS WITH ESTERS OF PHOSPHONIC AND PHOSPHINIC ACIDS

Base (B)	Ester (E)	Mole ratio (E/B)	React. temp (°C)	React. time (hr)	Product	Yield (%)
Imidazole (**I**)	**a**	0.5	200	1	1-methylimidazole	54
	c	1	200	10.5	1-methylimidazole	50
	b	0.5	200	1	1-ethylimidazole	39
	d	0.5	193	6	1-ethylimidazole	37
Benzimidazole (**II**)	**a**	1	200	5	1-methylbenzimidazole	37
	b	1	200	5	1-ethylbenzimidazole	59
	d	0.5	198	6	1-ethylbenzimidazole	34
1,2,4-Triazole (**III**)	**a**	0.5	200	2	1-methyltriazole	36
	b	0.5	200	1.3	1-ethyltriazole	32
Benzotriazole (**IV**)	**a**	0.5	200	1.5	1-methylbenzotriazole 2-methylbenzotriazole	80 7
	a	0.5	200	3	1-methylbenzotriazole 2-methylbenzotriazole	87 8
	b	0.5	200	2	1-ethylbenzotriazole	71
Pyrazole (**VI**)	**a**	0.5	150	1	1-methylpyrazole	67
	b	0.5	170	1	1-ethyltriazole	62

Experimental

IR were measured with a JASCO IR-G spectrometer. NMR spectra were recorded on a Hitachi-Perkin Elmer R-20 spectrometer with a dilute solution in deuteriochloroform using tetramethylsilane as an internal standard.

Materials. Commercial imidazole, benzimidazole, triazole, benzotriazole and pyrazole were used without further purification. Dimethyl methyl- and diethyl ethylphosphonate were synthesized *via* Arbuzov reaction of the corresponding trialkyl phosphites with alkyl iodides. Methyl dimethyl- and ethyl ethylphenylphosphinates were prepared by the procedure of Reinhardt *et al.*[9]

The following reactions are typical. Reaction conditions are listed in Table 1.

1-Methylimidazole. A mixture of **I** (6.35 g, 0.092 mol) and **a** (5.80 g, 0.047 mol) was heated at 200 °C with stirring for 1 hr. The reaction mixture was treated with aqueous sodium bicarbonate and extracted with chloroform. The organic solution was concentrated and the residue was distilled under diminished pressure to give 1-methylimidazole as a liquid; (4.14 g, 54%), bp 75—76 °C/11 mmHg (lit,[5] 94—95 °C/14 mmHg). The IR spectrum of the product was identical with that of an authentic sample.

1-Ethylbenzimidazole. A mixture of **II** (3.00 g, 0.025 mol) and **d** (2.52 g, 0.014 mol) was heated at 198 °C for 6 hr. The reaction mixture was treated in a manner similar to the alkylation of **I** to give 1.27 g (34%) of 1-ethylbenzimidazole; bp 90—98 °C/1 mmHg (lit,[10] 160—162 °C/12 mmHg); picrate mp 216—217 °C (from ethanol) (lit,[10] 219 °C); IR (neat): 3300 (broad s), 3050 (m), 2970 (s), 2920 (s), 1610 (m), 1500 (s), 1460 (s), 1330 (s), 740 (s), and 700 cm^{-1} (m); NMR: τ 2.43 (complex m, 2H, ring), 2.70 (complex m, 3H, ring), 6.27 (q, J=7 Hz, 2H, $-CH_2-$), and 9.00 (t, J=8 Hz, 3H, $-CH_3$).

1-Methyl-1,2,4-Triazole. *1,2,4*-Triazole (III) (0.95 g, 0.0138 mol) was allowed to react with **a** (0.85 g, 0.0069 mol) to give 0.41 g (46%) of 1-methyl-1,2,4-triazole; bp 60 °C/10 mmHg (lit,[11] 175—176 °C); IR (neat): 3350 (broad s), 3100 (m), 2950 (w), 1520 (s), 1280 (s), 1220 (m), 1140 (s), 1010(m), 990 (m), and 680 cm^{-1} (s); NMR: τ 1.90 (s, 1H, ring) 2.12 (s, 1H, ring), and 6.10 (s, 3H, $-CH_3$).

Methylation of 1,2,3-Benzotriazole. A mixture of **IV** (5.75 g, 0.0482 mol) and **a** (2.99 g, 0.024 mol) was refluxed for 1.5 hr. The reaction mixture was subsequently made alkaline with aqueous sodium bicarbonate and extracted with chloroform (40 ml). The organic layer showed the presence of only two products in thin-layer chromatography (R_f=0.82 and 0.45, $CHCl_3$: CH_3OH=9: 1, Silica-Gel Merck Art-7730). The residue (5.5 g) obtained after evaporation of the solvent was dissolved in deuteriochloroform for study of the NMR spectrum. Only peaks, which are attributed to those of 1-methyl- and 2-methyl-benzotriazoles, were observed. From the area ratio (35: 3) of singlet peaks of CH_3 groups of both isomers (τ 5.74 for 1-methyl- and τ 5.50 for 2-methyl derivative, respectively), the yields of 1-methyl- and 2-methylbenzotriazole were calculated to be 80% and 7%, respectively. The residue (5.5 g) was then dissolved in benzene and fractionated with dilute hydrochloric acid. Neutralization of the acid layer, extraction with chloroform and subsequent recrystallization with hexane gave pure 1-methylbenzotriazole, 3.85 g (60%); mp 64 °C (from hexane) (lit,[12] 65 °C); IR (KBr): 3050 (m), 2950 (m), 1620 (m), 1590 (m), 1500 (s), 1450 (s), 1300 (s), 1270 (s), 1200 (s), 1030 (s), 740 (s), and 660 cm^{-1} (s); NMR: τ 1.95—2.00 (complex m, 1H, ring), 2.50—2.90 (complex m, 3H, ring), and 5.74 (s, 3H, $-CH_3$). Evaporation of benzene gave 2-methylbenzotriazole; 0.32 g (5%): bp 90—95 °C/10 mmHg (lit,[12] 104 °C/15 mmHg); NMR: τ 1.85—2.10 (complex m, 2H, ring), 2.43—2.60 (complex m, 2H, ring), and 5.50 (s, 3H, $-CH_3$).

Ethylation of 1,2,3-Benzotriazole. Benzotriazole (2.97 g, 0.0234 mol) was heated with **b** (2.07 g, 0.0125 mol) at 200 °C for 2 hr. The reaction mixture was neutralized with aqueous sodium bicarbonate and the solution was extracted with chloroform (10 ml×3). The organic layer was concentrated and the residue was distilled to give the product. The NMR spectrum of the distillate showed a set of signals consistent with the expected structure; bp 117 °C/2 mmHg (lit,[11] 150—151 °C/13 mmHg); IR (neat) 3300 (broad s), 3050 (s), 2970 (s), 2920 (s), 1610 (m), 1495 (s), 1469 (s), 1230 (s), 740 (s), and 700 cm^{-1} (m); NMR: τ 1.95—2.30 (complex m, 1H, ring), 2.50—2.90 (complex m, 3H, ring), 5.45 (q, J=8 Hz, 2H, $-CH_2-$), and 8.53 (t, J=8 Hz, 3H, $-CH_3$).

1-Methylpyrazole. 1-Methylpyrazole was distilled at 127 °C during heating of the reaction mixture through a distillating column as a clear liquid; 0.81 g (67%), bp (lit,[13] 127 °C); IR (neat): 3350 (broad s), 3100 (s), 2920 (s), 1515 (s), 1440 (m), 1390 (s), 1275 (s), 1205 (s), 1085 (s), 1065 (m), 1025 (s), 960 (s), 875 (m), 750 (broad s), 675 (s), and 605 cm^{-1} (s); NMR: τ 2.40 —2.80 (complex m, 2H, ring), 3.75—3.85 (complex m, 1H, ring), and 6.22 (s, 3H, $-CH_3$).

(Received August 4, 1975)

Preparations of mono-*N*-protected 2-deoxystreptamines (racemates of **5**, **8**, **9**, **10**, **11**, **12**) from 4(and 6)-*O*-acyl-1,3-di-*N*-benzyloxycarbonyl-2-deoxystreptamines by O→N acyl migration were described. O→N Acyl migration of 2-deoxy-tri-*O*-ethoxycarbonylstreptamine (**15**) led to several protected derivatives (racemates of **16**, **17**, **18**) which also should serve for the preparation of glycosides and other derivatives of 2-deoxystreptamine.

In the course of our synthetic studies of aminoglycoside antibiotics, it was often necessary to protect selectively some of the amino and hydroxyl groups of 2-deoxystreptamine to effect a chemical reaction solely at other sites of the molecule remained intact. In this paper we describe the synthesis of a number of 2-deoxystreptamine derivatives that should serve for the preparation of their glycosides and other derivatives. The syntheses were achieved by way of O→N acyl migration.

The mono-*N*-di-*O*-protected derivatives (**5**,**8**,**9**) were prepared as follows: 1,3-Di-*N*-benzyloxycarbonyl-2-deoxystreptamine[1] was converted to a racemic mixture of 4,5-*O*- and 5,6-*O*-cyclohexylidene derivatives (**1**) by the acetal exchange reaction[2] with 1,1-dimethoxycyclohexane and *p*-toluenesulfonic acid in dimethylformamide. Acetylation or benzoylation or ethoxycarbonylation of **1** gave the corresponding racemic mixture of 6- and 4-*O*-acyl derivatives (**2**,**3**,**4**), respectively.

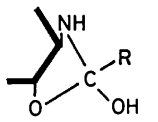
Deblocking of the *N*-protecting groups of the acetyl derivative (**2**) by catalytic hydrogenation with palladium resulted in the formation of 1 (and 3)-*N*-acetyl-4,5(and 5,6)-*O*-cyclohexylidene derivative (**5**, a racemate), which formed a monohydrochloride. This result showed that deblocking was followed by O→N migration.

In the case of similar hydrogenolysis of the benzoyl derivative (**3**), no O→N migration occurred, giving the racemic mixture of 6 (and 4)-*O*-benzoyl-4,5(and 5,6)-*O*-cyclohexylidene-2-deoxystreptamine (**6**), which formed a dihydrochloride. However, when the diacetate of **6** was treated with pyridine[3] at 50 °C for 2 days, migration occurred to give the *N*-benzoyl derivative (**8**), which formed a monohydrochloride.

Similar hydrogenolysis of the ethoxycarbonyl derivative (**4**) also was not followed by O→N migration and gave the racemic mixture of 4,5(and 5,6)-*O*-cyclohexylidene-2-deoxy-6(and 4)-*O*-ethoxycarbonylstreptamine (**7**), whereas similar treatment of **7** with pyridine gave, by way of O→N migration, the *N*-ethoxycarbonyl derivative (**9**), which formed a monohydrochloride.

Removal of the cycloxylidene group from **5**, **8**, and **9** with acid gave mono-*N*-protected 2-deoxystreptamines (**10**, **11**, **12**), respectively.

Next, we investigated the O→N migration of tri-*O*-ethoxycarbonyl derivative (**15**) of 2-deoxystreptamine. Di-*N*-(*p*-methylbenzylidene)-2-deoxystreptamine (**13**) was prepared and made to react with ethyl chloroformate in pyridine to give the tri-*O*-ethoxycarbonyl derivative (**14**), which was treated with 50% acetic acid to give **15**.



I: R=OC_2H_5
II: R=CH_3

Preliminary analysis for the reaction products of **15** with pyridine at various reaction temperatures and periods was made by tlc analysis of the fractions of reaction mixtures, and it was found that the first O→N migration giving mono-*N*-ethoxycarbonyl-di-*O*-ethoxycarbonyl derivative (**16**) was accompanied by the second O→N migration that is much slower to give di-*N*-ethoxycarbonyl-5-*O*-ethoxycarbonyl derivative (**17**). (See Preliminary Experiment on Treatment of **15** with Pyridine in the Experimental Section). However, when **16** was treated with pyridine similarly, it was readily converted to **17**. These results suggested that the migration of ethoxycarbonyl group probably proceeded through an unstable orthoester-amide structure (I) which may retard the second migration for some stereochemical reason. Although the orthoester-amide intermediate could not be isolated in the present work,

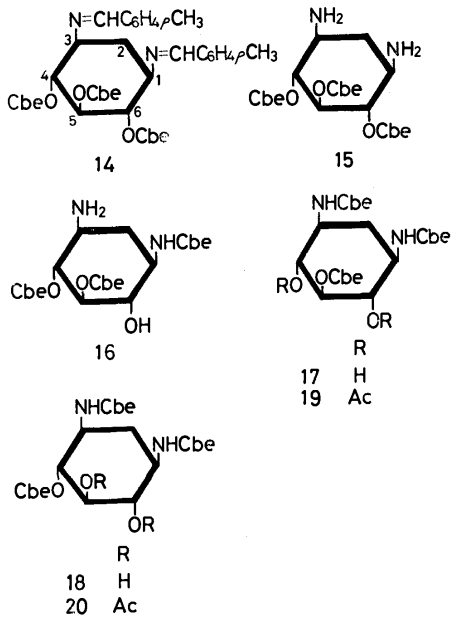
Only one isomer was shown in each compound.



Only one isomer was shown in each compound.

formation of a related structure (II) has been reported by G. Fodor *et al.*,[4] who showed it by IR and PMR spectroscopy.

Furthermore, O→O migration was found to occur at higher temperature (100 °C) and prolonged reaction to give the racemic mixture of 2-deoxy-1,3-di-*N*-ethoxycarbonyl-4(and 6)-*O*-ethoxycarbonylstreptamine (**18**).

Confirmation of the structures of **17** and **18** was carried out by PMR spectral studies of their di-*O*-acetyl derivatives (**19**, **20**). The compound **19** showed a 6-proton singlet of acetyls in each of the $CDCl_3$ and pyridine-d_5, whereas another compound **20** showed two 3-proton singlets of acetyls in each of the above media, indicating that **20** (and also **18**) has an unsymmetrical structure. Periodate oxidation studies of **17** and **18** also afforded the same conclusion.

Experimental

*Racemic Mixture of 1,3-Di-*N*-benzyloxycarbonyl-4,5-*O*-cyclohexylidene-2-deoxystreptamine (1).* To a solution of 1,3-di-*N*-benzyloxycarbonyl-2-deoxystreptamine[1] (14.0 g) in dry DMF (280 ml), *p*-toluenesulfonic acid (0.54 g) and 1,1-dimethoxycyclohexane (9.4 ml) were added and the solution was heated at 50 °C under reduced pressure (~40 Torr). After 5 hr, the same amounts of both reagents were added and the solution was treated similarly. On tlc with benzene–methanol (6: 1), the starting material (R_f 0.33) disappeared and **1** (R_f 0.8) appeared as a single spot. The solution was neutralized with Amberlite IRA 400 (OH form, 25 ml), filtered, and concentrated under reduced pressure to approximately 100 ml, and the concentrate was poured into 0.1% sodium hydrogen carbonate solution (2 l) to deposit an amorphous powder, which was purified by reprecipitation with acetone–water, 15.8 g (95%), mp 149—151 °C.

Found: C, 66.02; H, 6.46; N, 5.39%. Calcd for $C_{28}H_{34}N_2O_7$: C, 65.86; H, 6.71; N, 5.49%.

*Racemic Mixture of 4-O-Acetyl-1,3-di-*N*-benzyloxycarbonyl-5,6-O-cyclohexylidene-2-deoxystreptamine (2).* A sample of **1** was treated in a usual manner with acetic anhydride in pyridine. Reprecipitation from cyclohexane gave **2** in 97% yield, mp 162—163 °C; PMR (in $CDCl_3$) δ: 1.97 (3H, s, OAc).

Found: C, 65.19; H, 6.58; N, 5.07%. Calcd for $C_{30}H_{36}N_2O_8$: C, 65.20; H, 6.57; N, 5.07%.

*Racemic Mixture of 4-O-Benzoyl-1,3-di-*N*-benzyloxycarbonyl-5,6-O-cyclohexylidene-2-deoxystreptamine (3).* A sample of **1** was treated with benzoyl chloride in pyridine in a usual manner to give **3** in 95% yield; Recrystallization from hot ether, mp 182—183 °C; IR (KBr): 1700, 1735 cm^{-1}.

Found: C, 68.49; H, 6.23; N, 4.58%. Calcd for $C_{35}H_{38}N_2O_8$: C, 68.39; H, 6.23; N, 4.56%.

*Racemic Mixture of 1,3-Di-*N*-benzyloxycarbonyl-4,5-O-cyclohexylidene-2-deoxy-6-O-ethoxycarbonylstreptamine (4).* To a solution of **1** (4.99 g) in pyridine (30 ml), ethyl chloroformate (3.1 ml) was added and the solution was allowed to stand at 5 °C overnight. On tlc with benzene–ethanol (20: 1), **1** (R_f 0.43) disappeared and **4** (R_f 0.66) appeared as a single spot. The solution was poured into ice-water and the precipitate was reprecipitated from ether, 5.36 g (94%), mp 150 °C; IR (KBr): 1765 (ν_{CO} of OCbe), 1690 (ν_{CO} of NCbe), 1535 cm^{-1}; PMR (in $CDCl_3$) δ: 1.26 (3H, t, $OCO_2CH_2C\underline{H}_3$).

Found: C, 64.04; H, 6.66; N, 4.83%. Calcd for $C_{31}H_{38}N_2O_9$: C, 63.90; H, 6.57; N, 4.81%.

*Racemic Mixture of 1-*N*-Acetyl-4,5-O-cyclohexylidene-2-deoxystreptamine (5).* A solution of **2** (5.22 g) in aqueous dioxane (1: 5, 25 ml), acetic acid (0.2 ml) was added and the solution was hydrogenated over palladium black at 40 °C overnight. On tlc with benzene–methanol (1: 1), **2** (R_f 1.0) disappeared and **5** (R_f 0.6) appeared as a single spot. The reaction mixture was filtered and the filtrate was evaporated. To the resulting syrup, 0.01 M hydrochloric acid was added until the mixture became weak acidic (pH~4.5) and the solution was evaporated to give a syrup. Addition of acetone gave precipitates, 2.62 g (82%), mp 112—113 °C; IR (KBr): 1635, 1550 cm^{-1}; PMR (in pyridine-d_5+D_2O) δ: 2.13 (3H, s, NAc).

Found: C, 49.67; H, 8.04; N, 7.95; Cl, 10.65%. Calcd for $C_{14}H_{24}N_2O_4 \cdot HCl \cdot H_2O$: C, 49.62; H, 8.03; N, 8.27; Cl, 10.4%.

Racemic Mixture of 4-O-Benzoyl-5,6-O-cyclohexylidene-2-deoxystreptamine (6). A sample of **3** (5.70 g) was hydrogenated in a similar manner as above. On tlc with benzene–methanol (1: 1), **3** (R_f 1.0) disappeared and **6** (R_f 0.3) appeared as a single spot. The reaction mixture was similarly treated as described above, 3.66 g (100%); IR (KBr): 1725 cm^{-1}; no peaks between 1650—1700 cm^{-1}.

Found: C, 54.67; H, 6.98; N, 6.44; Cl, 16.49%. Calcd for $C_{19}H_{26}N_2O_4 \cdot 2HCl$: C, 54.41; H, 6.73; N, 6.68; Cl, 16.91%.

Diacetate of **6** was obtained by using acetic acid instead of hydrochloric acid in the preparation described above, mp 92—93 °C.

Found: C, 59.49; H, 7.39; N, 6.19%. Calcd for $C_{19}H_{26}N_2O_4 \cdot 2CH_3CO_2H$: C, 59.21; H, 7.35; N, 6.01%.

Racemic Mixture of 4,5-O-Cyclohexylidene-2-deoxy-6-O-ethoxycarbonylstreptamine (7). A sample of **4** (5.36 g) was hydrogenated in a similar manner as described in the preparation of **5**. The crude product was recrystallized from acetone containing acetic acid to give **7**, 3.06 g (77%), mp 116—117 °C; tlc: R_f 0.2 (benzene–methanol 2: 1); IR (KBr): 1760 cm^{-1}; PMR (in D_2O) δ: 1.28 (3H, t, $OCO_2CH_2C\underline{H}_3$), 1.90 (6H s, AcOH).

Found: C, 52.72; H, 7.76; N, 6.29%. Calcd for $C_{15}H_{26}N_2O_5 \cdot 2CH_3CO_2H$: C, 52.52; H, 7.89; N, 6.45%.

*Racemic Mixture of 1-*N*-Benzoyl-4,5-O-cyclohexylidene-2-deoxystreptamine (8).* A solution of diacetate (3.66 g) of **6** in pyridine (73 ml) was maintained at 50 °C for 2 days. On tlc with benzene–methanol (3: 1), **6** (R_f 0.16) disappeared and **8** (R_f 0.56) appeared as a single spot. The solution was evaporated and then coevaporated with toluene to leave a residue, which was dissolved in aqueous methanol (1: 1). Addition of

0.01 M hydrochloric acid (pH~4.5) followed by evaporation gave a syrup. The procedure was repeated twice more. The methanol solution of the syrup was treated with charcoal to give the hydrochloride of **8**, 2.49 g (91%), mp 139—140 °C; IR (KBr): 1640, 1535 cm^{-1}.

Found: C, 57.16; H, 6.90; N, 6.47; Cl, 8.95%. Calcd for $C_{19}H_{26}N_2O_4 \cdot HCl \cdot H_2O$: C, 56.92; H, 7.29; N, 6.99; Cl, 8.84%.

Racemic Mixture of 4,5-O-Cyclohexylidene-2-deoxy-1-N-ethoxycarbonylstreptamine (9). The diacetate (3.06 g) of **7** was similarly treated in pyridine as described above. On tlc with benzene–methanol (1: 1), **7** (R_f 0.32) disappeared and **9** (R_f 0.74) appeared as a single spot. The solution was evaporated and then coevaporated with toluene. The residue was dissolved in aqueous methanol (1: 1) containing acetic acid (0.5 ml), treated with charcoal, and the solution was evaporated to give a solid, 2.99 g (82%); IR (KBr): 1690, 1620, 1540 cm^{-1}; PMR (in pyridine-d_5) δ: 1.13 (3H, t, $NCO_2CH_2C\underline{H}_3$), 2.12 (3H, s, AcOH).

Found: C, 54.20; H, 8.41; N, 7.79%. Calcd for $C_{15}H_{26}N_2O_5 \cdot CH_3CO_2H$: C, 54.53; H, 8.08; N, 7.48%.

Removal of Cyclohexylidene Group from 5, 8, and 9. The solution of 0.3 mmol of the starting material in 1M hydrochloric acid (2 ml) was allowed to stand at room temperature overnight. The product was purified by precipitation with acetone.

Racemic Mixture of 1-N-Acetyl-2-deoxystreptamine Hydrochloride (10): yield 82%, mp 171—172 °C. Found: C, 37.63; H, 7.11; N, 10.48, Cl, 13.56%. Calcd for $C_8H_{16}N_2O_4 \cdot HCl \cdot H_2O$: C, 37.14; N, 7.40; N, 10.83; Cl, 13.71%.

Racemic Mixture of 1-N-Benzoyl-2-deoxystreptamine Hydrochloride (11): yield 82%, mp 214—215 °C. Found: C, 50.28; H, 6.18; N, 8.55; Cl, 11.60%. Calcd for $C_{13}H_{18}N_2O_4 \cdot HCl \cdot 1/2H_2O$: C, 50.08; H, 6.47; N, 8.99; Cl, 11.37%.

Racemic Mixture of 2-Deoxy-1-N-ethoxycarbonylstreptamine Hydrochloride (12): yield 89%, mp 207—208 °C. Found: C, 40.06; H, 7.21; N, 10.52; Cl, 13.25%. Calcd for $C_9H_{18}N_2O_5 \cdot HCl$: C, 39.93; H, 7.07; N, 10.35; Cl, 13.10%.

1,3-Di-N-(p-methylbenzylidene)-2-deoxystreptamine (13). To a mixture of 2-deoxystreptamine dihydrochloride (1.02 g) and anhydrous potassium carbonate (6.9 g) in methanol (12 ml), *p*-methylbenzaldehyde (1.3 ml) was added under the atmosphere of nitrogen and the mixture was stirred at room temperature overnight. Evaporation gave a residue, which was extracted with chloroform. The solution was washed with water, dried over sodium sulfate and concentrated to give a syrup. Addition of hexane gave a solid, 1.09 g (63%); IR (KBr): 1630, 1605, 1100, 1030, 815, 500 cm^{-1}; PMR (in $CDCl_3$) δ: 2.31 (6H, s, $C\underline{H}_3C_6H_4$), 8.31 (2H, s, =CH–N).

Found: C, 68.35; H, 7.14; N, 6.96%. Calcd for $C_{22}H_{26}N_2O_3 \cdot H_2O$: C, 68.72; H, 7.34; N, 7.29%.

2-Deoxy-4,5,6-tri-O-ethoxycarbonyl-1,3-di-N-(p-methylbenzylidene)streptamine (14). To a solution of **13** (1.86 g, dried at 80 °C under reduced pressure) in pyridine (19 ml), a small amount of calcium hydride (to remove a trace of moisture) and ethyl chloroformate (2.9 ml) were added and the mixture was stirred at 50 °C overnight. Another ethyl chloroformate (0.8 ml) was added and the mixture was stirred for 1 hr. On tlc with benzene–ethyl acetate–triethylamine (6: 1: 0.01), **13** (R_f 0.2) disappeared and **14** (R_f 0.38) appeared. The mixture was poured into saturated sodium hydrogen carbonate solution (150 ml) and the mixture was stirred for 1 hr. The lower layer separated was extracted with chloroform and the solution was washed with water, dried over sodium sulfate and evaporated to give a syrup. Addition of hexane gave a solid, 2.45 g (85%); IR (KBr): 1750, 1710, 1640, 1610, 1370, 1290—1240 (s), 1010, 880, 820, 790, 510 cm^{-1}; PMR (in $CDCl_3$) δ: 1.08 (6H, t, $OCO_2CH_2C\underline{H}_3$), 1.29 (3H, t, $OCO_2CH_2C\underline{H}_3$), 2.40 (6H, s, $C\underline{H}_3C_6H_4$), 4.08 (4H, q, $OCO_2C\underline{H}_2CH_3$), 4.26 (2H, q, $OCO_2C\underline{H}_2CH_3$), 8.40 (2H, s, =CH–N).

Found: C, 63.50; H, 6.47; N, 4.68%. Calcd for $C_{31}H_{33}N_2O_9$: C, 63.90; H, 6.57; N, 4.81%.

2-Deoxy-4,5,6-tri-O-ethoxycarbonylstreptamine (15) Diacetate. A sample of **14** (3.70 g) was dissolved in 50% acetic acid (60 ml). Monitoring by tlc showed that **14** disappeared immediately, and **15** (R_f 0.5 with the lower layer of chloroform–ethanol–8% aqueous ammonia (2: 1: 1)) appeared. The solution was evaporated to give a syrup. Addition of ether gave a solid, 2.51 g (84%), mp 85—86 °C; IR (KBr): 1760, 1620 (w), 1400, 1280, 1250, 1020, 1000, 880, 780 cm^{-1}.

Found: C, 45.49; H, 6.52; N, 5.25%. Calcd for $C_{15}H_{26}N_2O_9 \cdot 2CH_3CO_2H$: C, 45.78; H, 6.87; N, 5.62%.

Preliminary Experimemt on Treatment of 15 with Pyridine. A solution of **15** (10 mg) in dry pyridine (0.2 ml) was allowed to stand at various temperatures and the change in the reaction was monitored by tlc (Wakogel B5, Wako Pure Chemicals Ind.) with ethyl acetate–ethanol–water (45: 5: 3) (Solvent A) and with chloroform–ethanol–8% aqueous ammonia (6: 1: 1) (lower layer) (Solvent B). Four spots A, B, C, and D appeared: A (R_f 0.1 by Solvent A and 0.1 by Solvent B, **15**), B (R_f 0.35 and 0.38, **16**), C (R_f 0.6 and 0.38, **17**) and D (R_f 0.6 and 0.3, **18**). At 20 °C: after 7 hr: *A* (卅), B(±); 24 hr: A (+), B(卅), C(±); 48 hr; A(±), B(卅), C(+). At 50 °C: 4 hr: A(卄), B(+), C(±); 5.5 hr: A(卄), B(卄), C(±); 7.5 hr: A(±), B(卅), C(+); 10 hr: A(±), B(卄), C(卄); 22 hr: B(卄), C(卄); 46 hr: B(+), C(卅); 50 hr: C(卅), D(+). At 100 °C: 0.5 hr: A(卄), B(+), C(±); 1 hr: A(+), B(卅), C(+); 2 hr: A(±), B(卄), C(卄), D(±); 3 hr: B(+), C(卄), D(卄); 5 hr: C(卄), D(卄).

Racemic Mixture of 2-Deoxy-1-N-ethoxycarbonyl-4,5-di-O-ethoxycarbonylstreptamine (16) and 1,3-Di-N-ethoxycarbonyl-5-O-ethoxycarbonyl-2-deoxystreptamine (17). A solution of **15** (1.18 g) in dry pyridine (21 ml) was allowed to stand at 50 °C for 46 hr. Evaporation of the solution gave a solid, which was charged on a column of silica gel (Wakogel C-200, Wako Pure Chemicals Ind.) and eluted with ethyl acetate–ethanol–water (45: 5: 3). From the earlier fraction, **17** was obtained, 425 mg (47%); Recrystallization from ethyl acetate gave needles, mp 112—113 °C; IR (KBr): 1740 (carbonate), 1700 (carbamate), 1540, 1270 (s), 1040, 880, 780 cm^{-1}; PMR (in $CDCl_3$) δ: 1.25 (6H, t, $NCO_2CH_2C\underline{H}_3$), 1.34 (3H, d, $OCO_2CH_2C\underline{H}_3$), 4.21 (4H, q, $CO_2C\underline{H}_2CH_3$).

Found: C, 47.30; H, 6.70; N, 7.13%. Calcd for $C_{15}H_{26}N_2O_9$: C, 47.61; H, 6.93; N, 7.40%.

From the later fraction, a solid of **16**, 172 mg (free base) (19%) was obtained, IR (KBr): 1750, 1700, 1540, 1270, 1030, 1000, 870, 780 cm^{-1}; PMR (in $CDCl_3$) δ: 1.23 (3H, t, $OCO_2CH_2C\underline{H}_3$), 1.30 (6H, t, $NCO_2CH_2C\underline{H}_3$); no peaks at ~$\delta$ 2 (acetate) was observed.

The hydrochloride of **16**. PMR (in CD_3OD) δ: 1.20 (3H, t, $OCO_2CH_2C\underline{H}_3$), 1.26 and 1.28 (each 3H, t, $NCO_2CH_2C\underline{H}_3$).

Found: C, 43.62; H, 6.44; N, 6.37; Cl, 8.46%. Calcd for $C_{15}H_{26}N_2O_9 \cdot HCl$: C, 43.43; H, 6.56; N, 6.75; Cl, 8.55%.

***17* from *16*.** A solution of **16** (free base, 115 mg) in pyridine (2 ml) was allowed to stand at 35 °C for 12 hr. On tlc, the solution gave a single spot. The solution was evaporated and the residue was similarly purified by chromatography as described above to give **17**, 52 mg (52%).

4,6-Di-O-acetyl-2-deoxy-1,3-di-N-ethoxycarbonyl-5-O-ethoxycarbonylstreptamine (19). A solution of **17** in pyridine was acetylated with acetic anhydride in a usual manner to give **19** almost quantitatively, mp 154—155 °C; IR (KBr): 1760, 1730, 1700, 1530, 1380, 1270, 1230, 1040 cm^{-1}; PMR (in

$CDCl_3$) δ: 1.23 (6H, t, $NCO_2CH_2C\underline{H}_3$), 1.30 (3H, t, $OCO_2CH_2C\underline{H}_3$), 2.07 (6H, s, Ac), 4.15 (6H, q, $CO_2C\underline{H}_2CH_3$).

Found: C, 49.31; H, 6.42; N, 6.01%. Calcd for $C_{19}H_{30}N_2O_{11}$: C, 49.35; H, 6.54; N, 6.05%.

Racemic Mixture of 2-Deoxy-1,3-di-N-ethoxycarbonyl-4-O-ethoxycarbonylstreptamine (18). A solution of the diacetate (1.0 g) of **15** in dry pyridine (20 ml) was heated at 100 °C for 5 hr. Evaporation of the solution gave a solid. The solid was chromatographed on a column of silica gel with ethyl acetate. From the earlier fraction **17** was obtained, 280 mg (37%) and from the later fraction **18**, 258 mg (34%) was obtained; Recrystallization from ethyl acetate gave needles, mp 120—121 °C; IR (KBr): 1740, 1700, 1540, 1270, 1030, 1010, 880, 780 cm^{-1}; PMR (in $CDCl_3$) δ: 1.22 and 1.23 (each 3H, t, $NHCO_2CH_2C\underline{H}_3$), 1.30 (3H, t, $OCO_2CH_2C\underline{H}_3$).

Found: C, 47.66; H, 6.89; N, 7.15%. Calcd for $C_{15}H_{26}N_2O_9$: C, 47.61; H, 6.93; N, 7.40%.

Racemic Mixture of 4,5-Di-O-acetyl-2-deoxy-1,3-di-N-ethoxycarbonyl-6-O-ethoxycarbonylstreptamine (20). A sample of **18** was similarly treated as described in the preparation of **19**, mp 169—170 °C. The IR spectrum was substantially similar to that of **19**. PMR (in $CDCl_3$) δ: 1.21 (6H, t, $NHCO_2CH_2C\underline{H}_3$), 1.27 (3H, t, $OCO_2CH_2C\underline{H}_3$), 2.10 and 2.12 (each 3H, s, Ac), 4.05 (6H, q, $CO_2C\underline{H}_2CH_3$).

Found: C, 49.84; H, 6.51; N, 5.98%. Calcd for $C_{19}H_{30}N_2O_{11}$: C, 49.35; H, 6.54; N, 6.05%.

Periodate Oxidation of the Mixture of 17 and 18. The reaction mixture of **17** and **18** described in the preparation of **18** was evaporated. The residue showed two spots at R_f 0.7 (**17**) and 0.55 (**18**) in almost equal strength on tlc with chloroform–ethanol–8% aqueous ammonia (6: 1: 1). To the solution of the residue (20.1 mg) in aqueous dioxane (1: 1, 0.5 ml), periodic acid (6.1 mg) was added and the solution was allowed to stand at room temperature for 1 hr. The reaction mixture showed a clear spot at R_f 0.7, but the spot at R_f 0.55 disappeared completely.

Racemization Catalyst for Amino Acids. III.* Racemization of Alanine Induced by 4-Nitrosophenol

Kazuhiro HIROTA, Hisanori KOIZUMI,** Yoshio HIRONAKA, and Yoshiharu IZUMI

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Suita, Osaka 565

(Received March 7, 1975)

The racemization of D-alanine was carried out with several derivatives of 4-nitrosophenol in the presence of cupric ion. Their racemization activities have been found to decrease with an increase in the bulk of alkyl group in 4-nitrosophenol. The racemization is accompanied with the decomposition of 4-nitrosophenol, and has been found to be catalyzed by an unidentified product generated in the reaction mixture. The proposed mechanism involves an autoaccelerating reaction.

In the course of studies on the racemization of amino acids, derivatives of 2- or 4-nitrosophenol[1,2] were found to be good catalyst for the racemization of alanine. The catalytic function of these compounds in the reaction was first expected to be the same as that of pyridoxal, since they require similar reaction conditions to those of the pyridoxal-catalyzed racemization.[3] Further they are able to form a Schiff's base with alanine, as pyridoxal does in a step of the racemization reaction. However rate studies of the racemization with 4-nitrosophenol revealed that these compounds are not the actual catalyst but they induce the formation of catalysts for the racemization whose mechanism differs from that of pyridoxal.

In this paper the functions of 4-nitrosophenols in the racemization reaction of D-alanine are explained.

Results and Discussion

Effect of the Substituent on 2,6 or 3,5 Positions in 4-Nitrosophenol on the Racemization. The racemization of D-alanine was performed with several derivatives of 4-nitrosophenol in the presence of cupric ion. The racemization yields and the recoveries of 4-nitrosophenols are shown in Figs. 1 and 2 (Fig. 2 includes some data used in Fig. 1). The time course is sigmoid, consisting of an induced stage and a subsequent steep rise, suggesting an autoaccelerating reaction. The induced period of the racemizations with 2-alkyl substituted 4-nitrosophenols, as seen in Fig. 1, are in the oder: 4-nitrosophenol $<$ 2-methyl-4-nitrosophenol $\simeq$ 2-ethyl-4-nitrosophenol $<$ 2-isopropyl-4-nitrosophenol $<$ 2-*tert*-butyl-4-nitrosophenol. Thus the apparent catalytic activity increases with decreasing steric bulk of the groups in the position *ortho* to the hydroxyl group of the 4-nitrosophenol derivatives. This suggests the contribution of the hydroxyl group of 4-nitrosophenol (**1**) to the initial stage of reaction. With this regard, the Schiff's base formed with alanine and the carbony

group of the quinone form (**2**) of 4-nitrosophenol would play an important role in the initial stage of the reaction.

On the other hand, a function of the nitroso group in the phenol form, **1** in the racemization was suggested by the experiment shown in Fig. 2. The apparent catalytic activity of 3,5-dimethyl-4-nitrosophenol, in which the nitroso group is protected by steric hindrance of the two methyl groups, is lower than that of 3-methyl-4-nitrosophenol. These results indicate that the catalytic activity of the 4-nitrosophenols depends not only on the carbonyl group in **2**, but also on the nitroso group in **1**. Consistent with this is the fact that the lowest activity of racemization among the derivatives of 4-nitrosophenol employed is observed with 2-isopropyl-5-methyl-4-nitrosophenol, in which both of the functional groups are sterically hindered by alkyl groups.

The relative reactivities of the two functional groups, were determined by comparing racemization activities of two structural isomers. The apparent catalytic activities, as seen in Fig. 2, are in the order: 2-methyl-4-nitrosophenol>3-methyl-4-nitrosophenol and 2,6-dimethyl-4-nitrosophenol > 3,5-dimethyl-4-nitrosophenol, respectively. These orders show that the participation of the nitroso group in **1** in the racemization is greater than that of the carbonyl group in **2**.

Relationship between the Racemization of D-*Alanine and the Decomposition of 4-Nitrosophenol.* The racemizations with 4-nitrosophenol, as seen in Figs. 1 and 2, are accompanied by the decomposition of 4-nitrosophenol.

A more detailed rate experiment was performed with 2'-nitro-2-hydroxy-5-nitroso-6,6'-dimethylbiphenyl (**3**). The result, comparing the rates of racemization and the decomposition of **3**, is shown in Fig. 3. The induction period of the racemization corresponds to that of the decomposition of **3** and increases when the concentration of **3** is decreased as seen in comparing A and B of Fig. 3. This indicates that the racemization of D-alanine is actually catalyzed by an unidentified product (X) generated in the reaction mixture, and suggests that the initiation of racemization activity might be a response to the appearance of this product, which is the actual catalyst.

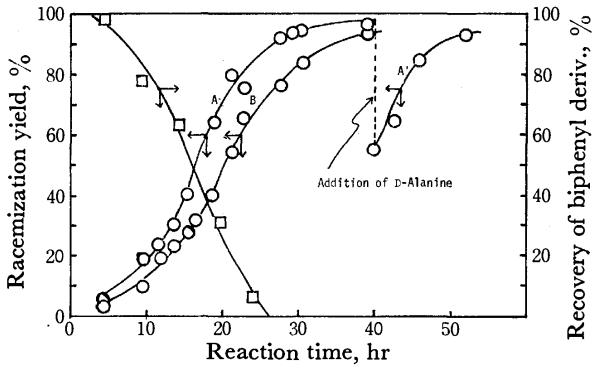

Fig. 3. Time courses of racemization yield and recovery of 2'-nitro-2-hydroxy-5-nitroso-6,6'-dimethylbiphenyl (**3**).
○: Racemization yield of alanine,
A: The reaction mixture of which initial composition consists of D-alanine 445 mg, $CuSO_4 \cdot 5H_2O$ 125 mg, **3** 3.4 mg, and borate buffer (0.05 M, pH 10.4 at 50 °C) was incubated at 50 °C.
A': To the reaction mixture of A at the final stage of racemization, D-alanine 445 mg and $CuSO_4 \cdot 5H_2O$ 125 mg were added. In this manner, the initial racemization yield of the reaction mixture becomes 50%. The mixture was reincuvated another 10 hr at 50 °C.
B: The reaction condition and the initial composition of reaction mixture are same as A, except the amount of **3** (14 mg).
□: Recovery of **3** in the system of A.

The above conclusion is also supported by the experiment shown in A' of Fig. 3; D-alanine and cupric sulfate pentahydrate were added again to the reaction mixture at the final stage of the reaction A in which **3** had already disappeared, and the racemization time course was followed. Additional D-alanine is racemized immediately without the induced period seen in curves A and its initial racemization rate corresponds to the previous maximum observed in curve A. This indicates that the relatively stable compound, X, has accumulated in the reaction mixture and that additional D-alanine can undergo racemization catalyzed by X already present.

Proposed Mechanism of the Racemization. Because the decomposition of 4-nitrosophenol in the reaction condition requires the presence of both D-alanine and cupric ions, the decomposition should proceed *via* a cupric complex DN–Cu containing D-alanine and 4-nitrosophenol. The resulting decomposition product, X, catalyzes both the racemization of D-alanine and the decomposition of DN–Cu in an autoaccelerating reaction. The proposed mechanism of racemization for D-alanine is shown in Eq. 1.

$$\mathrm{D} + \mathrm{N} \overset{Cu^{2+}}{\rightleftharpoons} \mathrm{DN\text{-}Cu} \longrightarrow \mathrm{X} \qquad (1)$$

$$\mathrm{D} \overset{\mathrm{X}}{\rightleftharpoons} \mathrm{L}$$

$$\mathrm{D} + \mathrm{N} \overset{Cu^{2+}}{\rightleftharpoons} \mathrm{DN\text{-}Cu} \rightleftharpoons \mathrm{LN\text{-}Cu} \overset{Cu^{2+}}{\rightleftharpoons} \mathrm{L} + \mathrm{N} \qquad (2)$$

D: D-alanine, L: L-alanine, N: 4-nitrosophenol, X: an unidentified compound.

Since the initial rate of racemization is negligible, the chief role of DN–Cu may be as a promoter to produce X rather than an intermediate in the racemization of D-alanine *via* reaction shown in Eq.(2). The racemization mechanism with 4-nitrosophenol, in this respect, is quite different from that with pyridoxal[3] which forms the metal-amino acid complex to catalyze the racemization.

We have no information about the composition or the structure of X, but we are currently working to confirm them.

Experimental

All melting points are uncorrected. The IR spectra were taken with a Shimadzu 27-G spectrometer. The NMR spectra were recorded by a Hitachi R-24 spectrometer using TMS as the internal standard. Thin layer chromatography was performed on precoated plates of silica gel (E. Merck). The glc analyses were carried on a Shimadzu 4APF apparatus, using neopentylglycolsuccinate (1.5%)-Chromosorb W (300 cm × 0.5 cm).

Materials. 4-Nitrosophenol,[4] 2-methyl-4-nitrosophe-

nol,[5] 3-methyl-4-nitrosophenol,[5] 2,6-dimethyl-4-nitrosophenol,[6] 3,5-dimethyl-4-nitrosophenol,[7] and 2-isopropyl-5-methyl-4-nitrosophenol[8] were prepared from substituted phenols and sodium nitrite according to the methods described previously.

2-Ethyl-4-nitrosophenol. To a solution of sodium nitrite (2.5 g) in water (2000 ml), 2-ethylphenol (6.0 g) was dissolved and 1.5% sulfuric acid (200 ml) was added dropwise while stirring at 0—5 °C for 2 hr. A brown yellow precipitate was collected and recrystallized from benzene with a small amount of charcoal. Yield, 3.0 g (40%); mp 101—102 °C. Found: C, 63.85; H, 6.06; N, 9.13%. Calcd for $C_8H_9N_1O_2$: C, 63.57; H, 6.00; N, 9.27%.

2-Isopropyl-4-nitrosophenol. Concentrated hydrochloric acid (30 ml) was added to a solution of 2-isopropylphenol (13.6 g) dissolved in ethanol (40 ml). The second solution of sodium nitrite (7.0 g) dissolved in water (10 ml) was poured with continuous stirring into the 2-isopropylphenol solution at 0—5 °C. The reaction mixture was allowed to stand for 2 hr at this temperature. After the addition of a solution of urea (0.5 g) in water (2.0 ml), it was evaporated to dryness. The residue was extracted with ether (50 ml). The extract was washed with water and dried over anhydrous sodium sulfate. The ether solution was chromatographed on a column of alumina and eluted with ether to separate an orange yellow fraction from the pitch-like material. Further purification was carried out with this layer chromatography on silica gel in a solvent system of ether–hexane (1 : 1 v/v). A yellow band which gave a positive Liebermann test was scraped off the plate, and extracted with ethyl acetate. After removing the solvent, the residue was recrystallized from 30% ethanol. Yield, 1.0 g (6%); mp 106—107 °C. Found: C, 65.25; H, 6.77; N, 8.61%. Calcd for $C_9H_{11}N_1O_2$: C, 65.44; H, 6.71; N, 8.48%.

2-tert-Butyl-4-nitrosophenol. 2-*tert*-Butylphenol (4.0 g) and sodium nitrite (4.0 g) were dissolved in 0.3% sodium hydroxide (1000 ml). To this solution 6% sulfuric acid (100 ml) was added dropwise with stirring over one hour at 0—3 °C. After standing for 2 hr., a red brown material precipitated. On cooling more of the precipitate formed. The precipitate was recrystallized twice from 25% ethanol to give yellow crystals. Yield, 1.0 g (21%); mp 136—137 °C. Found: C, 67.34; H, 7.35; N, 7.70%. Calcd for $C_{10}H_{13}N_1O_2$: C, 67.02; H, 7.31; N, 7.82%.

2′-Nitro-2-hydroxy-5-nitroso-6,6′-dimethylbiphenyl. 2-Hydroxy-2′-nitro-6,6′-dimethylbiphenyl (243 mg)[9] was dissolved in glacial acetic acid (1.0 ml) and then water (0.2 ml) was added. A solution of sodium nitrite (83 mg) in water (0.2 ml) was added dropwise with stirring at 0—3 °C. The mixture was allowed to stand overnight at the same temperature. The reddish yellow precipitate was collected on a filter and washed twice with 10% ethanol (1.5 ml). The crystals were recrystallized from 30% ethanol with a small amount of charcoal. Yield, 90 mg (33%); mp 200—202 °C. Found: C, 61.10: H, 4.26; N, 10.00%. Calcd for $C_{14}H_{12}N_2O_4$: C, 61.76; H, 4.44; N, 10.29%. IR ($CHCl_3$): 2550 cm^{-1} (OH). NMR (CD_3COCD_3): δ 12.5 (OH), 1.96 and 2.22 (CH_3).

Racemization Reaction. An aqueous solution of D-alanine (0.5 mmol), cupric sulfate pentahydrate (0.05 mmol), and one of the 4-nitrosophenol derivatives (0.0125 mmol) was made. The pH was adjusted to 10.4 (at 50 °C) with 1 M sodium hydroxide and diluted to a total volume of 0.25 ml. After diluting with 0.05 M borate buffer (0.25 ml, pH 10.4 at 50 °C), the mixture was shaken at 50 °C in a sealed tube. At specific time intervals the reaction was stopped by the addition of 0.25 ml of 6 M hydrochloric acid.

Determination of the Racemization Yield. The reaction mixture (0.2 ml) was dried *in vacuo*. The residue was heated with *l*-menthol (1.0 g) 110—120 °C and bubbled with dry hydrogen chloride for 1.5 hr to prepare the *l*-menthyl ester of alanine. Excess *l*-menthol was removed by sublimation at 110—120 °C under reduced pressure. Trifluoroacetic anhydride (0.05 ml) was added and allowed to stand overnight at room temperature to obtain *l*-menthyl L- and D-trifluoroacetylalaninate. After diluting with tetrahydrofuran (0.5 ml), the diastereomers were gas chromatographed at 170 °C. From the ratio of the diastereomers, the racemization yield of D-alanine was calculated.

Determination of the Recovery of 4-Nitrosophenol. The reaction mixture (0.2 ml) was extracted with ethyl acetate (2.0 ml) and the extract (120 μl) was chromatographed on a silica gel with ether–hexane (1 : 1 v/v) as the developing solvent. A yellow band containing 4-nitrosophenols was scraped off the plate and extracted with 0.5 M sodium hydroxide (5.0 ml). The absorption of the extract was measured at 403 nm and the concentration was calculated.

The authors wish to thank Mrs. Kiku Hara and Miss Aiko Yamanouchi for the elemental analyses.

Dehydroannulenes. I. Synthesis and Properties of 1,5,10,14-Tetramethyl-6,8,15,17-tetrakisdehydro[18]annulene[1]

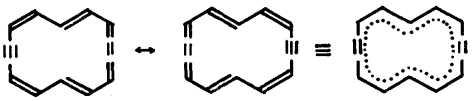
Jūro OJIMA,* Tsutomu KATAKAMI, Gen NAKAMINAMI, and Masazumi NAKAGAWA**

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 18, 1975)

1,6,10,15-Tetramethyl-7,9,15,17-cyclooctadecatetraene-2,4,11,13-tetrayne-1,6-diol (VII), a 18-membered cyclic glycol, was synthesized by a stepwise reaction sequence starting from 3-methyl-2-penten-4-ynal (III). Treatment of the cyclic glycol (VII) with stannous chloride dihydrate in concentrated hydrochloric acid yielded tetramethyltetrakisdehydro[18]annulene (VIII). Examination of the NMR spectra clearly indicates that the tetrakisdehydro[18]annulene (VIII) containing formal diacetylene and hexapentaene units sustains a strong diamagnetic ring current and has a high conformational stability.

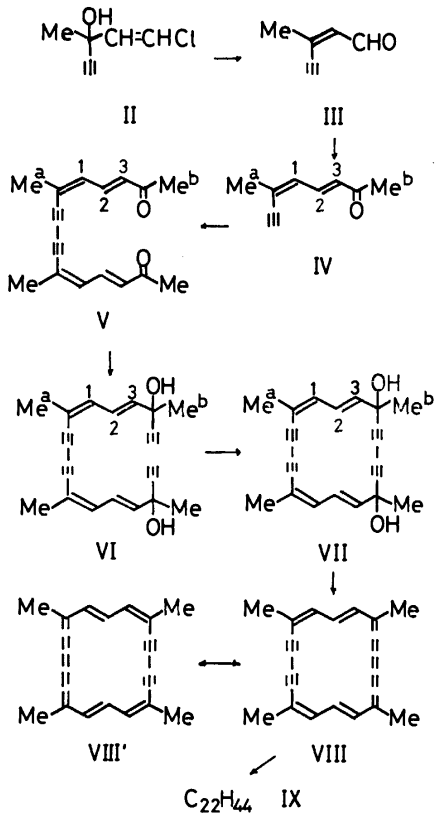
1,8-Bisdehydro[14]annulene (I) obtained by Sondheimer and Gaoni[2] holds an unique position in a wide variety of dehydroannulenes, *i.e.*, the annulene (I) contains formal acetylenic and cumulenic linkages in the



I I'

cyclic system, and equivalent Kekulé structures can be written in contrast to ordinary dehydroannulenes containing one or more acetylenic bonds in which no such type of equivalent resonance structures can be drawn. Bisdehydro[14]annulene (I) can be represented most properly by a symmetrical formula (I'). We have been interested in the synthesis and properties of such symmetrical dehydroannulenes containing linkages of sp-hybridized carbon atoms in the cyclic conjugated system. In this paper, we wish to report the synthesis and properties of tetramethyltetrakisdehydro[18]annulene (VIII) containing formal diacetylene and hexapentaene units in the conjugated ring.[3] The NMR spectrum of VIII provides a clear evidence for the existence of strong diamagnetic ring current in the 18π-electron system.

Ethynyl alcohol (II) prepared by the reaction of ethynylmagnesium bromide with β-chlorovinyl methyl ketone[4] in a high yield was treated with diluted sulfuric acid according to the reported method.[5] Examination of NMR spectrum of the resulting 2-penten-4-ynal reveals that the aldehyde largely consists of the *cis*-isomer (III) (*ca.* 95%) with respect to the ethynyl and the formyl groups consistent with the reported equilibration study of III in acidic conditions[6] being most suitable for the construction of desired 18-membered ring. The aldehyde without separating into pure *cis*-isomer (III) was condensed with acetone by the reported method[5b] with modification to give dieneyne ketone (IV). *trans*-Configuration of the newly formed double bond in IV was confirmed by IR and NMR spectroscopy. Oxidative coupling of IV by cupric acetate in pyridine[7] yielded diketone (V) in an almost quantitative



II III IV V VI VII VIII' VIII $C_{22}H_{44}$ IX

yield. Attempts of bis-ethynylation of the diketone using sodium, lithium or calcium acetylide[8] in liquid ammonia, ethynylmagnesium bromide in tetrahydrofuran and sodium acetylide in *N,N*-dimethylformamide[9] gave fruitless results. Finally, it was found that the diketone (V) can be ethynylated with lithium acetylide-ethylenediamine complex[10] in tetrahydrofuran. The product was chromatographed on alumina. The first substance to be eluted from the column was presumably monoethynylated derivative of V. Desired bis-ethynyl glycol (VI) was obtained from fractions eluted with benzene–ether (4: 6) and ether–ethyl acetate (6: 4) as a yellow viscous liquid in 63% yield. Oxidative coupling of the acyclic glycol (VI) by cupric acetate monohydrate in pyridine–methanol under high dilution conditions using ether as an entraining solvent resulted in a mixture of 18-membered cyclic glycol (VII) in a yield of 69.3%, which, upon chromatography on alumina, yielded a high melting isomer (VIIa) and a low melting isomer (VIIb) in a ratio of *ca.* 1.5: 1. The

** Correspondence should be addressed to this author.

analytical and spectroscopic data, and the molecular weights determined by vapor osmometry were found to be identical. However, mixed melting point determination showed an appreciable depression. The isomerism can be reasonably attributed to *meso*- and *rac*-isomers. Recrystallization of the cyclic glycol (VIIa or VIIb) from acetone, methanol or ethyl acetate gave crystals containing solvent of crystallization in ratio of 1 : 1, 1 : 1 and 1 : 0.5, respectively. Formation of similar adducts has been reported for some 2,4-hexadiyne-1,6-diols and 2-butyne-1,4-diols.[11]

A solution of stannous chloride dihydrate in concentrated hydrochloric acid[12] was added to a vigorously stirred suspension of the cyclic glycol (VIIa or VIIb, or a mixture of them) at room temperature under nitrogen atmosphere. Instantaneous development of deep reddish color was observed. Chromatography of the product in benzene on alumina followed by elution with petroleum ether–benzene yielded a black purple crystalline powder, which gave black purple cubic crystals with metallic lustre upon recrystallization from benzene–petroleum ether (1 : 1) at a low temperature. The crystals gave a reddish purple solution similar to a permanganate solution. Full hydrogenation of the crystals in acetic acid over pre-reduced platinum oxide catalyst gave colorless crystals with low melting point. Absorption of 12.75 moles of hydrogen was observed (theoretical amount for the tetramethyltetrakisdehydro[18]-annulene is 13 moles). The elemental analysis, NMR spectrum and the appearance of molecular ion peak (M^+) at 308 in the mass spectrum provide the support that the low melting hydrocarbon should be tetramethylcycloctadecane (IX, Mol. wt., 308), thus suggesting the black purple crystals is the desired 1,5,10,14-tetramethyl-6,8,15,17-tetradehydro[18]annulene (VIII). The tetrakisdehydro[18]annulene (VIII) was found to be rather unstable compound. Exposure of crystals of VIII to air and diffused daylight at room temperature caused a complete decomposition in a few hours. But a solution of VIII in benzene–petroleum ether could be kept for two weeks without decomposition in a refrigerator.

The measurement of NMR spectrum of the tetrakisdehydro[18]annulene (VIII) was encoutered by some difficulties owing to the poor solubility. As illustrated in Fig. 1, the NMR spectrum in deuteriotetrahydrofuran exhibited signals at τ 0.34 (d, J=16.0 Hz) and τ 7.42 (s), which could be assigned to the outer and the methyl protons, respectively. Although, the presence of high field signal due to the inner protons was expected in view of the appearance of the outer proton signal at a fairly low field, only a weak signal could be scarcely observed at an extremely high field. Therefore, high field portion of spectrum was scanned 10 times and treated with C.A.T. technique clearly revealing the presence of signal of the inner protons at a extremely high field (τ 15.24, t, J=16.0 Hz). The NMR spectrum clearly indicates that the tetrakisdehydro[18]-annulene (VIII) containing formal diacetylene and hexapentaene units sustains a strong diamagnetic ring current. Also, the NMR spectral pattern of VIII suggests the equivalence of the outer protons. The electronic spectrum of VIII in tetrahydrofuran, consisting of three main absorption bands, shows features characteristic of [4n+2]annulenes (Fig. 2). Consequently, the tetrakisdehydro[18]annulene (VIII) can be regarded as an aromatic system with delocalized 18π-electrons being resonance hybrid of two equivalent Kekulé structures (VIII and VIII'). In the other words, the tetrakisdehydro[18]annulene (VIII) can be represented most properly by a symmetrical formula (VIII").

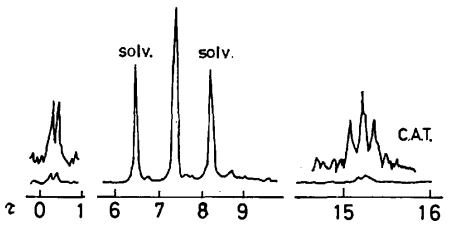

Fig. 1. 100 MHz NMR spectrum of VIII in THF-d_8.

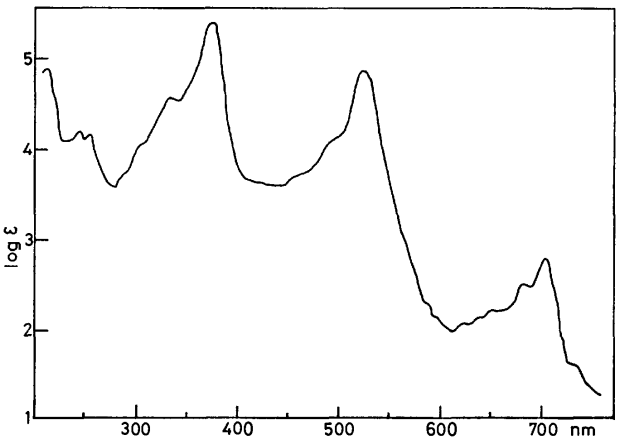

Fig. 2. Electronic spectrum of VIII in THF.

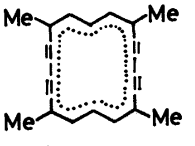
Table 1. NMR spectral parameters of VIII in THF-d_8 (100 MHz, τ-values)

Temperature °C	Outer protons d	Methyl protons s	Inner protons t
−60	0.10	6.65	15.66
−40	0.15	6.81	15.56
−20	0.19	6.98	15.49
0	0.27	7.20	15.38
22.5	0.34	7.42	15.23
40	0.41	7.60	15.09
64	0.44	7.78	14.99

As summarized in Table 1, the NMR spectra of VIII were found to be essentially temperature independent over a range of −60 to +64 °C, reflecting a high conformational stability of the tetrakisdehydro[18]annulene skelton provided by the presence of straight linkages of diacetylene and hexapentaene units. Attempts to



VIII"

measure the spectrum at higher temperatures than 64 °C were failed owing to a rapid decomposition of VIII. Increase of diatropicity along with decrease of temperature can be reasonably attributed to an increase of planarity of the 18-membered ring due to diminishing vibration of ring carbon atoms about their equilibrium positions.

The tetrakisdehydro[18]annulene (VIII) forms 1:1 CT complex with 2,4,7-trinitrofluorenone. Attempt to nitrate VIII with cupric nitrate in acetic anhydride[13,14] or with tetranitromethane in pyridine–methanol[15] or with silver nitrate and benzoyl chloride[16] gave fruitless results. Also, no substituted product could be obtained on treatment of VIII with acetic anhydride in the presence of boron trifluoride etherate under various reaction conditions. Because it has been found that substituent is introduced to the carbon atom adjacent to sp-hydridized carbon atoms in electropholic substitution reactions of dehydroannulenes,[14,17] at least one of the causes of the failure of electrophilic substitution seems to be attributable to the fact that the reactive sites in VIII are blocked by the methyl groups. VIII gave no adduct with maleic anhydride.

In view of the strong diatropicity and high conformational stability found in the tetrakisdehydro[18]annulene (VIII), dehydro-annulenes of this type seems to have the most adequate structure for the study of aromaticity of macrocyclic system.

Experimental

All experiments were performed under nitrogen atmosphere under shielding from light. A high dilution appratus was used for the oxidative cyclization reactions of acyclic glycols. The intermediates were stored usually as diluted solutions in a refigerator to minimize decomposition. All melting and boiling points are uncorrected. Brockmann alumina (Act. II—III) was for chromatography, unless otherwise stated. The IR, UV and mass spectra were obtained on a Hitachi EPI-2, a Hitachi EPS-3 and a Hitachi RMU-7HR spectrometers, respectively. Shoulders in UV spectra are indicated by sh, and strong, medium and weak bands in IR spectra are denoted by S, M, and W, respectively. NMR spectra were measured with a Varian A-60 and JNM-RA-I Spectral Accumlator. The chemical shifts are recorded in τ-values with respect to TMS as an internal standard, and the coupling constants are given in Hz. A Hitachi-Perkin Elmer 115 vapor osmometer was used for the measurements of molecular weights.

1-Chloro-3-methyl-1-penten-4-yn-3-ol (II). To an ice-cooled solution of ethynylmagnesium bromide in tetrahydrofuran (305 ml), prepared from magnesium 12.12 g (0.50 mol) and ethyl bromide 60 g (0.56 mol),[18] was added a solution of β-chlorovinyl methyl ketone (35.2 g, 0.34 mol)[4] in the same solvent (120 ml) over 1.5 hr-period. After the mixture had been stirred overnight at room temperature, saturated ammonium chloride solution was added to the mixture under cooling. The organic layer and ethereal extracts of the aqueous layer were combined, and worked up in the usual way. Dark red liquid thus obtained was distilled under reduced pressure in the presence of a small amount of hydroquinone. Ethynyl alcohol (II) was obtained as a colorless liquid, bp 63—68 °C/1596 Pa, 25—30 g (55—66%). In a run performed under similar conditions, II was obtained in 81% yield.

The reaction of β-chlorovinyl methyl ketone with sodium acetylide in liquid ammonia[5b] gave less satisfactory result.

3-Methyl-2-penten-4-ynal (III). Anionotropic rearrangement of II was carried out with diluted sulfuric acid by the reported method.[5b] The aldehyde (III) was obtained as a pale yellow liquid, bp 45.5—51 °C/1463 Pa, 38.8 g, 86%, NMR (60 MHz, CCl_4): 7.87 (d, J=2, 3H, CH_3), 6.37 (s, 1H, -C≡CH), 3.78 (dd, J=8 and 2, 1H, olefinic H), −0.3 (d, J=8, 1H, -CHO). Weak signals of the *trans*-isomer could be observed at 7.68 (d, J=2, CH_3) and 6.5 (s, -C≡CH). The ratio of *cis*- and *trans*-isomers was estimated to be 95:5 on the basis of the relative intensities of the methyl proton signals.

6-Methyl-3,5-octadien-7-yn-2-one (IV). Diene ketone (IV) was prepared by the reported method[5b] with considerable modification. An ice-cooled mixture of 2.6% aqueous sodium hydroxide (27 ml) and ethanol (27 ml) was added in a portion to a stirred and ice-cooled solution of the aldehyde (III, 11.25 g, 0.119 mol) in acetone (54 ml) under nitrogen atmosphere. After being stirred for 1 hr at the same temperature, the reaction was quenched with 1 M sulfuric acid (11 ml). A dark red liquid obtained from ether extracts was distilled in the presence of hydroquinone under reduced pressure to give dieneyne ketone (IV, bp 42—48 °C/4 Pa, light yellow liquid, 7.39 g, 47%, NMR (60 MHz, CCl_4): 7.79 (d, J=2, 3H, Me^a), 7.78 (s, 3H, Me^b), 6.52 (s, 1H, -C≡CH), 3.97 (d, J=15, 1H, olefinic H^3), 3.62 (dd, J=11 and 2, 1H, olefinic H^1), 2.58 (dd, J=15 and 11, 1H, olefinic H^2).

6,11-Dimethyl-3,5,11,13-hexadecatetraene-7,9-diyne-2,15-dione (V). A solution of the dieneyne ketone (IV, 4.8 g, 0.036 mol) in methanol (51 ml) was added over 40 min-period at room temperature to a homogeneous mixture of cupric acetate monohydrate (14.7 g, 0.074 mol), methanol (149 ml) and pyridine (149 ml). The reaction mixture, after being stirred for 3 hr at the same temperature, was poured into 1 M sulfuric acid (1600 ml) under ice-cooling. The mixture containing fine yellow crystals was extracted with ether, and the extracts were washed with water and dried over sodium sulfate. The most part of the solvent was removed under reduced pressure. Further concentration under ordinary pressure yielded fairly pure diketone (V) as pale yellow crystals (4.734 g, 98.7%). The crystals were recrystallized 4 times from methanol to give an analytical specimen, mp 94—95 °C, IR (KBr-disk): 1650—1690 (triplet, C=O), 1590 (*trans* C=C), 980 (*cis* C=C) cm^{-1}, UV: λ_{max}^{EtOH} 248 sh (12700), 260 (17900), 298 (27500), 346 sh (30600), 364 (30900), 388 (24500), NMR (60 MHz, CCl_4): 7.92 (d, J=2, 6H, Me^a), 7.75 (s, 6H, Me^b), 3.97 (d, J=15, 2H, olefinic H^3), 3.45 (dd, J=11 and 2, 2H, olefinic H^1), 2.64 (dd, J=15 and 11, 2H, olefinic H^2).

Found: C, 81.27; H, 6.83%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%.

3,7,12,16-Tetramethyl-4,6,12,14-octadecatetraene-1,8,10,17-tetrayne-3,16-diol (VI). To a mixture of lithium acetylide-ethylenediamine complex[10] (6.5 g, 0.07 mol) and tetrahydrofuran (100 ml) saturated with acetylene was added at 35 °C a solution of the diketone (V, 3.1 g, 0.012 mol) in the same solvent (35 ml) over a period of 40 min under stirring and bubbling with acetylene. After the mixture had been stirred vigorously for further 3 hr at 30 °C under slow introduction of acetylene, cold water (30 ml) and saturated sodium chloride solution were added successively to the reaction mixture at 10 °C. The organic layer obtained by salting-out the mixture with sodium chloride was combined with ethereal extracts of the aqueous layer, and washed successively with 2 M hydrochloric acid (2 times), water (3 times) and saturated sodium chloride solution (3 times). The solvent was removed, after being dried over sodium sulfate, under reduced pressure to give a dark red liquid. The liquid dissolved in benzene was absorbed on alumina (Woelm, Grade I, 90 g) and eluted with

solvents with increasing polarity. The fractions eluted with benzene–ether–methanol gave bis-ethynyl diol, yellow viscous liquid, 2.32 g (63%). The bis-ethynylation was repeated in nearly the same scale as described above, and total 17 g of the diketone was converted into crude product. The crude product was chromatographed on alumina (Brockmann Act. I, 600 g). A mixture of starting material (V) and mono-ethynylated product was obtained from benzene–ether (19: 1—3: 2) eluates (1.296 g). Following fractions eluted with benzene–ether (3: 2—2: 3) yielded monoethynylated product (1.303 g). Elution with benzene–ether (2: 3) and ether–ethyl acetate (3: 2) gave desired VI (9.503 g). Although all attempts to crystallize VI were failed, the IR (neat): 3370 (broad, OH), 3330 (-C≡CH), 2190, 2050 (-C≡C-), 960 (*trans* C=C) cm^{-1}, NMR (60 MHz, CCl_4): 8.46 (s, 6H, Me^b), 8.05 (d, J=2, 6H, Me^a), 7.46 (s, 2H, -C≡CH), 6.90 (broad, 2H, OH, disappeared on addition of D_2O), 4.20 (d, J=15, 2H, H^3), 3.70 (dd, J=11 and 2, 2H, H^1), 3.07 (dd, J=15 and 11, 2H, H^2) and UV: λ_{max}^{MeOH} 232 sh, 239 sh, 253, 262, 276, 291, 308, 312, 336, 359 were found to be consistent with the assigned structure.

1,6,10,15-Tetramethyl-7,9,15,17-cyclooctadecatetraene-2, 4, 11,13-tetrayne-1,6-diol (VII). A solution of the acyclic glycol (VI, 2.003 g, 0.0063 mol) in ether (70 ml), methanol (70 ml) and pyridine (280 ml) was added over 9.5 hr-period to a stirred and refluxing mixture of cupric acetate monohydrate (5.04 g, 0.025 mol), pyridine (2000 ml) and ether (400 ml). After being refluxed for further 1 hr, the mixture was allowed to stand overnight at room temperature. The reaction mixture was concentrated to 200 ml under pressure on a water-bath kept below 50 °C. The concentrate was chilled and poured into 1M hydrochloric acid (2500 ml) under ice-cooling over 30 min-period. The mixture was extracted 5 times with ether, and the extracts were washed with saturated sodium chloride solution and dried over sodium sulfate. Dark brown oily residue obtained by evaporation of the extracts under reduced pressure below 25 °C was dissolved in benzene and chromatographed on alumina (500 g). Elution with ether–ethyl acetate (9: 1—1: 1) yielded a diastereomeric mixture of the cyclic glycol (VII, 1.376 g, 69.3%). The mixture of VII was chromatographed on alumina and careful elution with solvents with increasing polarity resulted in separation of diastereomers. Fractions eluted with ether–ethyl acetate (9: 1—3: 2) yielded a high melting isomer (VIIa, colorless cubes (from dichloromethane), mp 228—230 °C (dec.), IR (KBr-disk): 3360 (singlet, OH), 2190, 2150 (-C≡C-), 968 (*trans* C=C) cm^{-1}, UV: λ_{max}^{EtOH} 245 sh (28600), 254 (49400), 263.5 (61400), 292 (5120), 308 sh (6570), 327 (11600), 344 (18800), 368 (20100).

Found: C, 83.17; H, 6.22%, Mol. wt., 325 (vapor osmometry). Calcd for $C_{22}H_{20}O_2$: C, 83.51; H, 6.37%, Mol. wt., 316.

When VIIa was recrystallized from methanol, crystals containing 1 mol of methanol were obtained. Removal of the solvent of crystallization was found to be difficult even upon heating to 70 °C *in vacuo* for 39 hr.

Further elution with ether–ethyl acetate (1: 1) and ethyl acetate gave a low melting isomer (VIIb, colorless cubes (from dichloromethane), mp 220—223 °C (dec.), IR (KBr-disk): 3330, 3270 (doublet, OH), 2190, 2150 (-C≡C-), 972 (*trans* (C=C) cm^{-1}, UV: λ_{max}^{EtOH} 246 sh (27700), 254 (49500), 263 (63500), 292 (3330), 307 sh (5110), 326 (10500), 344 (17600), 369 (19300), NMR (60 MHz, DMSO-d_6): 8.53 (s, 6H, Me^b), 8.07 (d, J=2, 6H, Me^a), 6.67 (broad, 2H, disappeared on addition of D_2O), 4.07 (d, J=15, 2H, H^3), 3.34 (dd, J=11 and 2, 2H, H^1), 2.98 (dd, J=15 and 11, 2H, H^2).

Found: C, 83.61; H, 6.38%, Mol. wt., 312 (vapor osmometry). Calcd for $C_{22}H_{20}O_2$: C, 83.51; H, 6.37%, Mol. wt., 316.

VIIb forms crystals containing 1 mol of acetone and 1/2 mol of ethyl acetate. The acetone could be removed upon heating the crystals to 70 °C *in vacuo* for 23 hr.

Melting point of *ca.* 1: 1 mixture of VIIa and VIIb (203—210 °C) showed an appreciable depression.

1,5,10,14-Tetramethyl-6,8,15,17-tetrakisdehydro[18]annulene (VIII). To a vigorously stirred suspension of a diastereomeric mixture of VII (154 mg, 4.87×10^{-4} mol) in pentane (6 ml) and benzene (3 ml) was added at room temperature under nitrogen atmosphere a solution of stannous chloride dihydrate (270 mg, 1.19×10^{-3} mol) in concentrated hydrochloric acid (3 ml). After 10 min, benzene (15 ml) was added in 3 ml portions over 25 min-period. The reddish purple reaction mixture was poured into water (50 ml), and the organic layer was separated. The aqueous layer was extracted 4 times with ether. The combined organic layer and extracts, after being washed successively with water, aqueous sodium hydrogencarbonate and dried over magnesium sulfate for 3 hr, was concentrated to 50 ml under reduced pressure below 18 °C. Benzene was added to the concentrate and again concentrated under reduced pressure to give a benzene solution of the product (30 ml). The benzene solution thus obtained was passed through a column of alumina (50 g). Elution with benzene–petroleum ether gave VIII as a black purple crystalline powder (77 mg, 56%). Cyclic glycol (VII, 20 mg) was recovered from ether–ethyl acetate eluates. A solution of crude VIII in benzene–petroleum ether (1: 1) was kept in a refrigerator (−14 °C) to give pure VIII as black purple cubes with metallic lustre, which showed no melting point, but underwent color change to yellowish brown at *ca.* 180 °C, IR (KBr-disk): 2940 (M), 2910 (S), 2840 (M), 1535 (W), 1495 (W), 1485 (M, broad), 1365 (M), 1350 (M), 1277(M), 1265(W), 1150 (W), 1020(W), 953 (S), 880 (W, broad) cm^{-1}, UV: λ_{max}^{THF} 217.5 (78000), 237 (15200), 248.5 (14700), 259 sh (5150), 266 sh (4120), 272 sh (3670), 290 sh (4810), 306 sh (10400), 334.5 (35100), 371 (228000), 440 sh (2160), 452 (3230), 490 (11400), 520.5 (74200), 582 sh (185), 596 (124), 622 (121), 639 sh (129), 652 (164), 682 (318), 705 (614), 740 sh (37), NMR (60 MHz, CH_3, s): 6.37 (CCl_4), 6.73 (C_6D_6), 6.79 (DMSO-d_6).

Found: C, 93.56; H, 6.40%. Calcd for $C_{22}H_{18}$: C, 93.57; H, 6.43%.

The high and low melting isomers (VIIa and VIIb) gave VIII in almost the same yields as the case of diastereomeric mixture.

A solution of pure VIII could be kept for 2 weeks without any change under shielding from light at −14 °C, but as shown in Table 2, at room temperature, decrease of relative absorption intensity (ε_r) of the maximum at 520.5 nm of a solution of VIII in THF (15 mg/l) along with the elapse of time was observed.

Table 2. Decrease of relative absorption intensity

Time (day)	0	1	16	39	79
ε_r	1.00	0.89	0.83	0.61	0.06

Tetramethylcyclooctadecane (IX). VIII (16.618 mg, 5.885×10^{-3} mol) in acetic acid (10 ml) was reduced over pre-reduced platinum oxide catalyst ($PtO_2\cdot2H_2O$, 69.5 mg). Absorption of hydrogen ceased after 3.5 hr (12.75 mol, theoretical value, 13 mol). A solution of the reduction product in pentane was chromatographed on alumina, and eluted with pentane. The eluates were concentrated under reduced pressure to give colorless liquid, which was dissolved in ethyl

acetate–methanol (15:8). Crystals deposited on strong cooling of the solution were recrystallized from the same solvent to yield tetramethylcyclooctadecane (IX), colorless low melting crystals, IR (neat): 2950 (S), 2925 (S), 1460 (M), 1380 (M), 725 (W) cm^{-1}, NMR (60 MHz, CCl_4): 9.15 (CH_3), 8.73 (CH_2), 8.20 (CH).

Found: C, 85.60; H, 14.02%, M^+ 308. Calcd for $C_{22}H_{44}$: C, 85.63; H, 14.37%, Mol. wt., 308.

CT Complex of VIII with Trinitrofluorenone. A mixture of VIII (53 mg, 0.187 mmol), 2,4,7-trinitrofluorenone (80 mg, 0.253 mmol), benzene (4 ml) and methanol (3 ml) was refluxed for 5 min to give a homogeneous solution. The solution was kept at 0 °C overnight. Black purple needles deposited were collected and washed successively with petroleum ether and benzene to give pure 1: 1 CT complex, which decomposed at 210 °C forming a grey material.

Found: C, 69.46; H, 3.86; N, 7.14%. Calcd for $C_{35}H_{23}N_3O_7$: C, 70.34; H, 3.88; N, 7.03%.

The author wish to thank Dr. K. Hatada and Mr. Y. Terawaki of the Faculty of Scientific Engineering, Osaka University for the measurements of 100 MHz NMR spectra.

Dehydroannulenes. II. Syntheses of Diatropic Dimethyldiphenyl- and Tetraphenyl-tetrakisdehydro[18]annulenes

Tsutomu KATAKAMI, Kunisuke FUKUI, Tetsuhiko OKAMOTO, and Masazumi NAKAGAWA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 18, 1975)

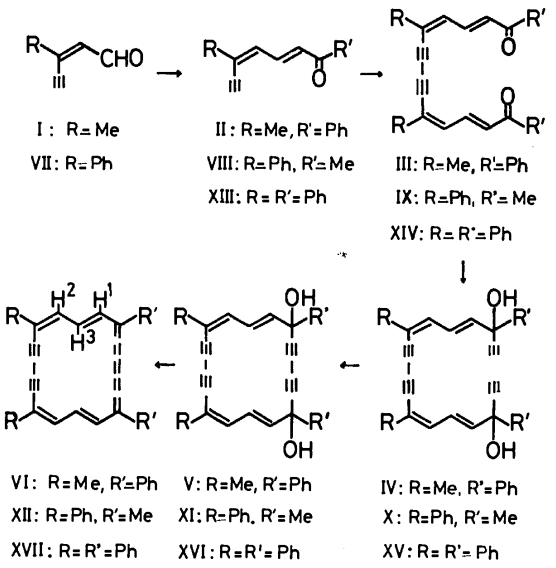
Syntheses of dimethyldiphenyl-(VI and XII) and tetraphenyltetrakisdehydro[18]annulenes (XVII) have been performed. It was found that the reaction sequence used for the synthesis of tetramethyltetrakisdehydro[18]-annulene can be used generally for the preparation of tetrakisdehydro[18]annulenes having various substituents. The annulenes (VI, XII, and XVII) were found to be strongly diatropic having high conformational stability. Remarkable stability is provided by introduction of phenyl groups accompanied with decrease in solubility of the annulene. Dimethyldiphenyl derivative was prepared by two different routes which will lead to isomers (VI and XII) with respect to the relative positions of the diacetylene and hexapentaene linkages to the substituent groups. The isomers (VI and XII) can be regarded as presumably identical, but precise agreement of NMR and UV spectra could not be attained. Bathochromic shift of UV spectra of phenyl substituted annulenes compared with tetramethyl analogue indicated that phenyl groups exert prominent perturbation on the annulene system.

As reported in the previous papers,[1] tetramethyltetrakisdehydro[18]annulene showed a strong diastropicity and a high conformational stability, but was found to be rather unstable. Therefore, the syntheses of tetradehydro[18]annulenes having various substituent groups are considerable interest from various points of view. Firstly, the preparation should offer information on the scope of validity of the reaction sequence used for the synthesis of tetramethyl derivative.[1] Secondly, it can be expected to find out substituent which stabilizes the tetradehydro[18]annulene system making possible further investigation on this type of dehydroannulenes. Finally, information on conjugative effects between the annulene ring and substituent group will be obtained from these studies.

The present paper deals with the synthesis and properties of dimethyldiphenyl- (VI, XII) and tetraphenyltetrakisdehydro[18]annulenes (XVIII).[2]

Synthesis. Synthesis of dimethyldiphenyltetrakisdehydro[18]annulene was performed according to two different route outlined in Scheme.

Dieneyne ketone (II) was obtained by the aldol condensation of 3-methyl-2-penten-4-ynal (I)[1,3] with acetophenone by the reported method[3b] with modification. Oxidative coupling of the ketone (II) by cupric acetate in pyridine–methanol[4] gave sparlingly soluble diketone (III) as yellow crystals. A solution of the diketone (III) in hot benzene was added to a suspension of lithium acetylide–ethylenediamine complex[5] in the same solvent saturated with acetylene to give acyclic glycol (IV). 18-Membered cyclic glycol (V) was obtained as a viscous yellow liquid by the oxidative coupling of IV under high dilution conditions. Treatment of the cyclic glycol (V) with stannous chloride in concentrated hydrochloric acid yielded 5,10-dimethyl-1,14-diphenyl-6,8,-15,17-tetrakisdehydro[18]annulene (VI) as black purple needles in an almost quantitative yield. Full hydrogenation of VI in ethyl acetate over platinum oxide catalyst yielded a liquid hydrocarbon corresponding to dimethyldiphenylcyclooctadecane.



β-Chlorovinyl ketone was prepared by the reported method[6] with modification, which was converted into 1-chloro-3-phenyl-1-penten-4-yn-3-ol in a high yield on treatment with sodium acetylide in liquid ammonia. Anionotropic rearrangement of the alcohol by acid treatment yielded 3-phenyl-2-penten-4-ynal (VII). NMR spectrometry reveals that the aldehyde (VII) is pure *cis*-isomer with respect to the formyl and ethynyl groups. Diene ketone (VIII) obtained by the aldol condensation of VII with acetone was oxidatively coupled by cupric acetate in pyridine[4] to give diketone (IX). Bis-ethynyl alcohol (X) prepared by the reaction of lithium acetylide–ethylenediamine complex[5] with IX yielded cyclic glycol (XI) on treatment with cupric acetate in pyridine–methanol–ether under high dilution conditions. Reduction of the crude cyclic glycol (XI) with stannous chloride dihydrate in concentrated hydrochloric acid gave 9,10-dimethyl-1,14-diphenyl-6,8,15,-17-tetrakisdehydro[18]annulene (XII) as black purple crystals.

The aldol condensation of acetophenone with VII gave diphenyldiene ketone (XIII) in a high yield. The ketone (XIII) was converted into 1,5,10,14-tetraphenyl-6,8,15,17-tetrakisdehydro[18]annulene (XVII, black purple needles) by similar reaction sequence *via* diketone (IXV), acyclic glycol (XV) and cyclic glycol (XVI).

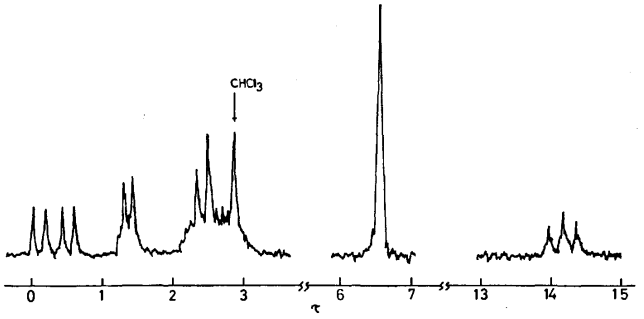

Fig. 1. 60 MHz NMR spectrum of VI in $CDCl_3$.

Properties. The NMR spectrum indicates that 1,14-dimethyl-5,10-diphenyl-6,8,15,17-tetrakisdehydro-[18]annulene (VI) is strongly diatropic exhibiting the inner proton (H^3) signal at extremely high-field (t, τ 14.20) and the outer proton (H^1 and H^2) signals at low-field (H^1, d, τ 0.12; H^2, d, τ 0.54) (Fig. 1). A low-field multiplet (τ 1.36) in the aromatic region could be assigned to *o*-protons of the phenyl groups, which suffer the deshielding effect of diamagnetic ring current of the annulene ring, and the higher-field multiplet at *ca.* τ 2.5 to the *m,p*-protons of the phenyl groups. The signal of methyl protons observed at τ 6.56 as a sharp singlet. As recorded in Table 1, VI showed essentially temperature independent NMR spectra similar to the tetramethyl analogue[1] indicating a high conformational stability of the tetrakisdehydro[18]annulene skelton. The electronic spectrum of VI illustrated in Fig. 2 showed characteristic feature of [4*n*+2]annulenes consisting of three main absorption band.

The dimethyldiphenyltetrakisdehydro[18]annulene (XII) gave an identical IR spectrum with that of VI. However, perfect coincidence of NMR and electronic spectra between VI and XII could not be attained, presumably owing to their instability, and to slight difference in their purity. In spite of the minor difference in physical property, the tetrakisdehydro[18]-annulenes (VI and XII) seemed to be an identical compound.[7]

TABLE 1. NMR PARAMETERS OF VI IN $CDCl_3$
(τ-Values, 100 MHz)

Temperature (°C)	H^1	H^2	*o*-H of phenyl	Methyl-H	H^3
−60	−0.08	0.40	1.18	6.45	14.61
−40	−0.13	0.34	1.17	6.45	14.45
−20	−0.09	0.34	1.20	6.47	14.41
− 6	−0.06	0.40	1.23	6.51	14.35
+25	0.00	0.46	1.26	6.53	14.27
+37	−0.02	0.44	1.29	6.51	14.14
+61	0.01	0.46	1.30	6.53	14.00

Tetraphenyltetrakisdehydro[18]annulene (XVIII) also showed an aromatic NMR spectrum exhibiting the inner proton (H^3) signal at τ 13.19 (t) and the outer proton (H^1 and H^2) signal at τ-0.31 (d). It is to be noted that the replacement of methyl with phenyl groups causes an appreciable down-field shift of all signals (Fig. 3).[8]

The stability of tetrasubstituted tetrakisdehydro[18]-annulenes was found to increase with the increase of phenyl substitution in the sequence of tetramethyl-<dimethyldiphenyl- (VI or XII)<tetraphenyl-derivatives (XVIII). However, as can be seen from Fig. 2, phenyl substitution caused remarkable bathochromic shift of absorption bands and intensification of the longest wavelength band indicating the perturbation of phenyl group on the annulene system. Furthermore, poor solubility of the tetraphenyl derivative (XVIII) in NMR solvents brought about experimental difficulty. In spite of the fairly effectual stabilization effect, phenyl group, aside from its interesting conjugative effect, can not be regarded as the most adequate substituent for the study of aromaticity of annulene system.

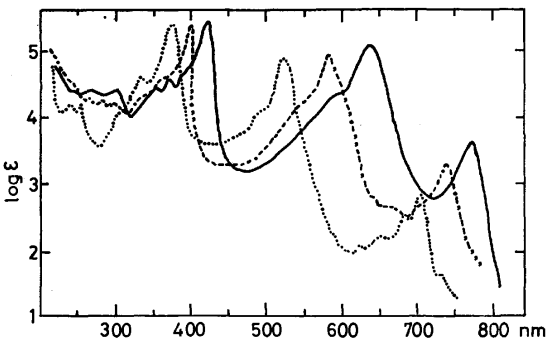

Fig. 2. Electronic spectra of tetrasubstituted tetrakisdehydro[18]annulenes. VI (---), XVII (—) and the tetramethyl analogue (···) in THF.

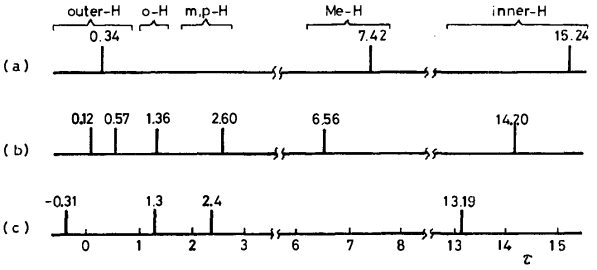

Fig. 3. Chemical shifts of tetrasubstituted tetrakisdehydro [18]annulenes. (a) tetramethyl-, (b) dimethyldiphenyl- (VI), and (c) tetraphenyl- (XVII) derivatives.

Experimental

All melting and boiling points are uncorrected. Brockmann alumina (Act. II—III) was used for chromatography. Evaporation of solvent was performed under reduced pressure in nitrogen atmosphere under shielding from light. A high dilution apparatus was used for the oxidative cyclization reaction of acyclic glycols. The IR, UV and mass spectra were obtained on a Hitachi EPI-2, a Hitachi EPS-3 and a Hitachi RMU-7HR spectrometers, respectively. Shoulder in UV spectrum is denoted by sh, and wavelength of absorption maximum is recorded in nm and ε-value is given in parentheses. NMR spectra were obtained on a Varian A-60 and JNM-4H-100 spectrometers. Chemical shift and coupling constant are given in τ-value with respect to TMS as an internal standard and in Hz, respectively.

1-Benzoyl-4-methyl-1,3-hexadien-5-yne (II). To a water-cooled and stirred mixture of I (2.04 g, 0.0217 mol)[1,3] and acetophenone (2.50 g, 0.0208 mol) was added dropwise a

mixture of 20% aqueous sodium hydroxide (8 ml) and ethanol (4 ml). After being stirred for 15 min, 1M sulfuric acid (30 ml) was added to the reaction mixture, and extracted with ether. The ethereal extracts were worked up in the usual way. The product dissolved in benzene was chromatographed on alumina, and eluted with the same solvent to give II, pale yellow rods, mp 83—87 °C (lit, 86—88 °C),[3b] 1.751 g (40%), IR (Nujol): 3230, 2090, 1655, 1590, 1575, 1360, 1280, 890, 770 cm^{-1}.

1,12-Dibenzoyl-4,9-dimethyl-1,3,9,11-dodecatetraene-5,7-diyne (III). A solution of II (2.23 g, 0.0114 mol) in benzene (50 ml) and methanol (30 ml) was added to a stirred solution of cupric acetate monohydrate (4.5 g) in pyridine (150 ml) and methanol (150 ml). The mixture containing yellow crystals was stirred overnight at room temperature. After the reaction mixture had been concentrated, the insoluble material was collected by filtration and washed throughly with water. The material thus obtained was dried and dissolved in boiling benzene. The hot benzene solution was passed through a short column of alumina. Upon cooling the filtrate, III was obtained as sparingly soluble yellow needles, mp *ca.* 150 °C (dec.), 1.33 g (60%), IR (KBr-disk): 3042, 3002, 1655, 1597, 1585, 1573, 1445, 1432, 1355, 1272, 1220, 1185, 1033, 1020, 980, 903, 853, 840, 774, 688, 658 cm.$^{-1}$

Found: C, 86.29; H, 5.88%. Calcd for $C_{28}H_{22}O_2$: C, 86.12; H, 5.68%.

7,12-Dimethyl-3,16-diphenyl-4,6,12,14-octadecatetraene-1,8,10,17-tetrayne-3,16-diol (IV). A solution of III (1.20 g, 0.00307 mol) in hot benzene (2000 ml) was added over 1.5 hr-period to a stirred suspension of lithium acetylide–ethylenediamine complex (10 g) in the same solvent (200 ml) saturated with acetylene at 35 °C. After acetylene had been introduced for further 3.5 hr at 35—38 °C, the reaction mixture was cooled to 5—7 °C, and water (50 ml) was added. The mixture was worked up in the usual manner. The product dissolved in benzene was chromatographed on alumina (40 g). Fractions obtained by elution with benzene and ethyl acetate, which showed satisfactory IR spectra, were combined and rechromatographed on alumina (10 g). IV was obtained as an amorphous yellow solid, 0.90 g (67%), IR (KBr-disk): 3500, 3350, 3260, 3050, 3020, 2920, 2850, 2190, 2110, 1600, 1580, 1470, 1445, 1370, 1345, 1280, 1170, 1070, 1030, 1015, 1000, 970, 930, 760, 690, 670 cm^{-1}.

Attempts to crystallized this material were failed.

10,15-Dimethyl-1,6-diphenyl-7,9,15,17-cyclooctadecatetraene-2,4,11,13-tetrayne-1,6-diol (V). To a stirred and refluxing solution of cupric acetate monohydrate (1.63 g) in pyridine (2000 ml), methanol (500 ml) and ether (500 ml) was added at 70±3 °C a solution of acyclic glycol (IV, 0.90 g, 2.05mmol) in pyridine (300 ml), methanol (100 ml) and ether (100 ml) over a period of 18 hr. After being stirred for further 1.5 hr at the same temperature, the reaction mixture was concentrated to *ca.* 100 ml at 40±2 °C. The concentrate was poured into 1M hydrochloric acid (3600 ml) under ice-cooling, and extracted with benzene and ethyl acetate. Combined extracts were worked up in the usual way. The product dissolved in benzene was chromatographed on alumina (150 g). Elution with ethyl acetate–benzene gave V as partly crystallized liquid, 242 mg (26.8%), IR (neat): 3300, 2180, 1600, 1580, 1480, 1450, 1035, 970, 760, 695, 670 cm^{-1}.

This material was used directly for the following reaction.

5,10-Dimethyl-1,14-diphenyl-6,8,15,17-tetrakisdehydro[18]annulene (VI). A solution of stannous chloride dihydrate (143.4 mg, 0.0637 mmol) in concentrated hydrochloric acid (3 ml) was added to a stirred suspension of the cyclic glycol (V, 113.7 mg, 0.0258 mmol) in pentane (10 ml) and benzene (5 ml). After being stirred for 10 min, benzene (10 ml) was added to the reaction mixture. After 20 min, ether (30 ml) and water were added to the mixture, and organic layer was treated in the usual fashion. The product dissolved in benzene was chromatographed on alumina (20 g). Elution with the same solvent yielded VI, black purple needles, 102.0 mg (97%), which was recrystallized from petroleum ether–benzene to give analytical specimen of VI, decomposed at 94 °C without fusion, UV: λ_{max}^{THF} 244 (16700), 249.5 (15800), 255.5 (18400), 261 sh (15600), 270 sh (15400), 278 (17600), 298 (13800), 299 (14200), 325 sh (14800), 348 sh (29300), 354 sh (30200), 370 sh (38200), 384 sh (61400), 400 (21800), 544 sh (17900), 584 (88900), 650 sh (738), 670 (443), 715 sh (560), 742 (1930), NMR (60 MHz, $CDCl_3$): 0.12 (d, J=14, H^1), 0.54 (d, J=14, H^2), 1.36 (m, *o*-H of phenyl), 2.3—2.9 (m. *m,p*-H of phenyl), 6.56 (s, CH_3), 14.20 (t, H^3).

Found: C, 94.23; H, 5.61%. Calcd for $C_{32}H_{22}$: C, 94.54; H, 5.46%.

1,6-Dimethyl-10,15-diphenylcyclooctadecane. The annulene (VI, 16.9 mg) in ethyl acetate (15 ml) was reduced over pre-reduced platinum oxide catalyst ($PtO_2 \cdot 2H_2O$, 12.6 mg). The reduction product was chromatographed on alumina and eluted with pentane. Dimethyldiphenylcyclooctadecane was obtained as a colorless liquid, M^+ 432 (Calcd for $C_{32}H_{48}$: 432), IR (neat): 3040, 3010, 2950—2850, 1455, 1375, 1600, 1493, 757, 695 cm^{-1}.

β-Chlorovinyl Phenyl Ketone. To an ice-cooled solution of benzoyl chloride (37 g, 0.264 mol) in chloroform (80 ml) was added crashed anhydrous aluminum chloride (37 g, 0.278 mol) in a rate to keep the temperature below 10 °C. Vinyl chloride was introduced to the mixture below 20 °C until no more absorption could be observed (*ca.* 3 hr). The reaction mixture was poured onto ice (300 g).[6] The organic layer was separated and the aqueous layer was extracted with chloroform. The combined organic layer and extracts were worked up in the usual way. Distillation of the product under reduced pressure yielded β-chlorovinyl phenyl ketone in a high yield under elimination of hydrogen chloride, bp 134—136 °C/2395 Pa, 36.2 g (83%).

1-Chloro-3-phenyl-1-penten-4-yn-3-ol. 1) To a solution of ethynylmagnesium bromide in tetrahydrofuran (120 ml) prepared from ethyl bromide (12 g, 0.11 mol) and magnesium (2.4 g, 0.10 mol)[9] was added over 20 min-period a solution of β-chlorovinyl phenyl ketone (11.0 g, 0.066 mol) in the same solvent (15 ml). After being stirred overnight at room temperature, saturated aqueous ammonium chloride solution was added to the reaction mixture under cooling in an ice-salt bath. The aqueous layer was extracted with ether and combined with the organic layer. The organic solution was worked up in the usual manner, and the crude product was distilled under reduced pressure to give pure ethynyl alcohol, bp 118—119 °C/465.5 Pa, 8.3 g (63%). Explosive decomposition sometimes occurred at the final stage of distillation. 2) A solution of β-chlorovinyl phenyl ketone (87.1 g, 0.523 mol) in tetrahydrofuran (270 ml) was added over 40 min-period at −60 °C to a stirred solution of lithium acetylide (from lithium, 4.1 g, 0.587 mol) in liquid ammonia (600 ml). After the mixture had been stirred overnight at −60∼−30 °C, the ammonia was allowed to evaporate. Saturated ammonium chloride solution was added to the residue under strong cooling with ice-salt bath. The aqueous layer was extracted with ether, and combined with the organic layer. The product, obtained by working up the organic solution in the usual way, was distilled under reduced pressure to give pure alcohol, bp 92—97 °C/66.5 Pa, 77.5 g (77%).

3-Phenyl-2-penten-4-ynal (VII). A mixture of 1-chloro-3-phenyl-1-penten-4-yn-3-ol (77.5 g, 0.403 mol), tetrahydrofuran (300 ml) and 1M sulfuric acid (1800 ml) was stirred

under nitrogen atmosphere for 3 days at room temperature. Sodium chloride was added to the reaction mixture, and the aqueous layer was extracted with ether. The extracts combined with the organic layer was worked up in the usual way. The crude crystals deposited on concentration of the organic solution were recrystallized from carbon tetrachloride–cyclohexane (2: 1) to give pure VII, unstable crystals, mp *ca.* 65 °C, 38.2 g (61%), NMR (60 MHz, CCl_4): 6.25 (s, 1H, ethynyl H), 3.20 (d, J=7, 1H, olefinic H), 2.50 (m, 3H, *m, p*–H of phenyl), 2.15 (m, 2H, *o*–H of phenyl), −0.25 (d, J=7, formyl H). NMR spectrum indicates that VII thus prepared is pure *cis*–isomer with respect to the formyl and ethynyl groups.

Found: C, 84.39; H, 5.23%. Calcd for $C_{11}H_8O$: C, 84.54; H, 5.16%.

2,4-Dinitrophenylhydrazone: orange needles, mp 177—178 °C.

Found: C, 60.71; H, 3.59; N, 16.70%. Calcd for $C_{17}H_{12}N_4O_4$: C, 60.71; H, 3.60; N, 16.66%.

6-Phenyl-3,5-octadien-7-yn-2-one (VIII). A solution of sodium hydroxide (0.70 g, 17.5 mmol) in ethanol (4 ml) and water (4 ml) was added to an ice-cooled solution of VII (2.70 g, 17.3 mmol) in acetone (28 ml). After being stirred for 2 hr at the same temperature, the reaction mixture was neutralized with 1M hydrochloric acid and mixed with water (300 ml). The mixture was extracted with benzene. After working up in the usual way, the product dissolved in carbon tetrachloride was passed through a column of alumina. The crystals obtained from the filtrate (1.16 g, 47%) were dissolved in the same solvent and again passed through a column of alumina. Pure VIII was obtained by recrystallization from ethanol, yellow crystals, mp 70.0—72.0 °C, IR (KBr–disk): 3250, 2080, 1662, 985, 953 $cm.^{-1}$

Found: C, 85.32; H, 6.06%. Calcd for $C_{14}H_{12}O$: C, 85.68 H, 6.10%.

2,4-Dinitrophenylhydrazone: mp 180—190 °C (dec.).

Found: C, 64.13; H, 4.92; N, 14.84%. Calcd for $C_{20}H_{16}N_4O_4$: C, 63.82; H, 4.29; N, 14.89%.

6,11-Diphenyl-3,5,11,13-hexadecatetraen-7,9-diyn-2,15-dione (IX). A mixture of VIII (1.00 g, 5.10 mmol), cupric acetate monohydrate (5.0 g), pyridine (25 ml) and methanol (25 ml) was stirred for 3 hr at room temperature. The reaction mixture was poured into ice-cooled 3M hydrochloric acid (150 ml) and extracted with benzene. After washing and drying, the extracts were concentrated and chromatographed on alumina. Recrystallization of crude crystals from benzene gave pure IX, yellow crystals, mp 130—150 °C (dec.), 0.62 g (63%), IR (KBr–disk): 1663, 1643, 998, 963 cm^{-1}.

Found: C, 86.07; H, 5.70%. Calcd for $C_{28}H_{22}O_2$: C, 86.12; H, 5.68%.

3,16-Dimethyl-7,12-diphenyl-4,6,12,14-octadecatetraene-1,8,10,17-tetrayne-3,16-diol (X). To an ice-cooled and stirred suspension of lithium acetylide–ethylenediamine complex[5] (0.5 g 5.4 mmol) in tetrahydrofuran (50 ml) was added over 10 min-period a solution of IX (300 mg, 0.77 mmol) in the same solvent (30 ml). After being stirred for 3 hr, saturated aqueous solution of ammonium chloride was added to the reaction mixture, and the aqueous layer was extracted with ether. The extracts were combined with the organic layer, and worked up in the usual way. Crude product was chromatographed on alumina, and eluted with benzene–ether. Crude X (208 mg) obtained as light brown liquid on concentrating the eluates was used without further purification for the following reaction.

1,4-Dimethyl-5,10-diphenyl-2,4,10,12-cyclooctadecatetraene-6,8,15,17-tetrayne-1,14-diol (XI). To a stirred and refluxing mixture of cupric acetate monohydrate (3.0 g, 1.5 mmol), pyridine (40 ml), methanol (20 ml) and ether (40 ml) was added over 2 hr-period a solution of crude X (208 mg) in pyridine (25 ml) and ether (25 ml). After being stirred and refluxed for further 2 hr, the reaction mixture was concentrated to *ca.* 80 ml. The concentrate was poured into 3M hydrochloric acid (200 ml) and extracted with benzene. The extracts, after being washed and dried, were concentrated to give crude cyclic glycol (XI), which was chromatographed on alumina, and eluted with benzene–ether. XI (133 mg) obtained from the eluates as light brown liquid was subjected to the further reaction.

1,14-Dimethyl-5,10-diphenyl-6,8,15,17-tetrakisdehydro[18]annulene (XII). The crude cyclic glycol (XI, 133 mg) dissolved in benzene (40 ml) was mixed under nitrogen atmosphere with a solution of stannous chloride dihydrate (0.4 g, 1.8 mmol) in concentrated hydrochloric acid (30 ml). After being stirred for 1 hr at room temperature, the reaction mixture was poured into cold water. The organic layer, after washing and drying, was concentrated, and the residue redissolved in benzene was chromatographed on alumina. Black purple crystals (63 mg, 17% based on IX) obtained from benzene eluates were recrystallized from benzene–cyclohexane, and dried *in vacuo* (0.4 Pa) for 5 hr at room temperature to give pure XII, decomposed at 94 °C without fusion, UV: λ_{max}^{THF} 244 (16600), 256 (19700), 270 sh (15300), 277.5 (17800), 292 sh (13900), 299 (14300), 324 sh (14600), 346 sh (30000), 354 sh (30800), 368 sh (38300), 385 sh (62300), 401 (212000), 542 sh (17400), 582 (85700), 666 sh (371), 715 sh (495), 742 (1790) [A maximum at 249 nm in XII which was also observed in VI disappeared on drying the crystals *in vacuo* for 5 hr.], NMR (60 MHz, $CDCl_3$): 0.05 (d, J=14, H^2), 0.49 (d, J=14, H^1), 1.35 (m, *o*–H of phenyl), 2.4 (m, *m,p*–H of phenyl), 6.54 (s, CH_3), 14.20 (t, H^3). The IR spectrum of XII (KBr–disk) was found to be perfectly identical with that of VI. Found: C, 94.46; H, 5.49%. Calcd for $C_{32}H_{22}$: C, 94.54; H, 5.46%.

CT Complex of XII with Trinitrofluorenone. A solution of XII (28 mg, 0.070 mmol) and 2,4,7-trinitrofluorenone (30 mg, 0.095 mmol) in benzene (15 ml) and methanol (15 ml) was allowed to stand in a refrigerator. Black purple crystals deposited decomposed at *ca.* 180 °C forming colorless solid. Elemental analysis indicates that the 1: 1 CT complex contains 1 mol of benzene as a solvent of crystallization.

Found: C, 76.42; H, 4.20; N, 5.16%. Calcd for $C_{32}H_{22}\cdot C_6H_6\cdot C_{13}H_5N_3O_7$: C, 76.58; H, 4.16; N, 5.25%.

1,5-Diphenyl-2,4-heptadien-6-yn-1-one (XIII). To an ice-cooled and stirred solution of phenylpentynal (VII, 2.70 g, 17.3 mmol) and acetophenone (2.08 g, 17.3 mmol) in ethanol (30 ml) was added a solution of sodium hydroxide (0.8 g, 22 mmol) in ethanol (3 ml) and water (3 ml). After 20 min, crystals deposited were collected by filtration and washed with water and ethanol. The crystals (3.70 g, 83%) were recrystallized from ethanol to give pure XIII, yellow crystals, mp 82.8—83.4 °C, IR (KBr–disk): 3240, 2070, 1653, 1016, 976 cm^{-1}.

Found: C, 88.01; H, 5.44%. Calcd for $C_{19}H_{14}O$: C, 88.34; H, 5.46%.

1,5,10,14-Tetraphenyl-2,4,10,12-tetradecatetraene-6,8-diyne-1,14-dione (XIV). A solution of XIII (3.70 g, 14.3 mmol) in pyridine (25 ml) was added at room temperature to a mixture of cupric acetate monohydrate (7.6 g, 38 mmol), pyridine (25 ml) and methanol (25 ml). After being stirred for 2 hr at the same temperature, the reaction mixture containing crystals was cooled in an ice-bath, and the crystals were collected and washed with methanol and water (3.2 g, 87%). The filtrate and washings were concentrated and poured into 2M hydrochloric acid, and extracted with benzene. The benzene extracts were worked up in the usual way. The residue dissolved

in benzene was passed through a column of alumina. Second crop of XIV (0.1 g) was obtained from the filtrate. Recrystallization of the crystals from benzene gave pure diketone (XIV), orange crystals, mp 159.7—160.2 °C, IR (KBr-disk): 1648, 1015, 971 cm^{-1}.

Found: C, 88.55; H, 5.00%. Calcd for $C_{38}H_{26}O_2$: C, 88.69; H, 5.09%.

3,7,12,16-Tetraphenyl-4,6,12,14-octadecatetraene-1,8,10,17-tetrayne-3,16-diol (XV). A solution of XIV (500 mg, 0.89 mmol) in tetrahydrofuran (44 ml) was added over 20 min-period to a stirred suspension of lithium acetylide-ethylenediamine complex[5] (5.6 g) in benzene (98 ml) saturated with acetylene at 15 °C, and the mixture was stirred for further 3 hr at 30—45 °C. The reaction mixture was poured onto ice-water (20 ml) and mixed with saturated sodium chloride solution (100 ml). The aqueous layer was extracted with benzene, and the extracts were combined with the organic layer. The combined organic layer was concentrated and chromatographed on alumina (8.7 g). Crude XV (352 mg) was obtained as a light brown liquid from the benzene–ether eluates.

1,5,10,14-Tetraphenyl-2,4,9,12-cyclooctadecatetraene-6,8,15,17-tetrayne-1,14-diol (XVI). Oxidative coupling of the crude XV (352 mg) by cupric acetate–pyridine–methanol–ether under similar high dilution conditions used for the preparation of XI gave crude XV (312 mg) as a viscous light brown liquid. The crude material was used for the subsequent reaction.

1,5,10,14-Tetraphenyl-6,8,15,17-tetrakisdehydro[18]annulene (XVII). The crude cyclic glycol (VI, 312 mg) was converted into XVII by the reaction with stannous chloride in concentrated hydrochloric acid under analogous conditions employed for the conversion of XI to XII. Slightly crude XVII, obtained as black purple crystals (159 mg, 31% based on XIV), was recrystallized from benzene to give pure XVII, black purple needles. XVII showed no melting point, but underwent color change at 180—190 °C, UV: λ_{max}^{THF} 245 (23300), 261 (24800), 302 (27000), 351 (26300), 373 (38000), 472 (273000), 635 (108000), 772 (4110), NMR (60 MHz, THF-d_8), −0.31 (d, J=13, H^1, H^2), 1.3 (m, *o*-H of phenyl), 2.4 (m, *m,p*-H of phenyl), 13.19 (t, J=13, H^3). XVII gave, green solutions in organic solvents.

Found: C, 94.83; H, 4.98%. Calcd for $C_{42}H_{26}$: C, 95.06; 95.06; H, 4.94%.

CT Complex of XVII with Trinitrofluorenone. A mixture of XVII (27 mg, 0.051 mmol), 2,4,7-trinitrofluorenone (22 mg, 0.070 mmol), benzene (50 ml) and methanol (25 ml) was refluxed for 3 min. CT complex deposited as black purple needles on standing the homogeneous solution in a refrigerator, which showed color change at *ca.* 240 °C without fusion.

Found: C, 77.26; H, 3.69; N, 4.83%. Calcd for $C_{42}H_{26}\cdot C_{13}H_5N_3O_7$: C, 78.09; H, 3.69; N, 4.99%.

Dehydroannulenes. III. Synthesis and Properties of 1,5,10,14-Tetra-*tert*-butyl-6,8,15,17-tetrakisdehydro[18]annulene

Sachiyo TOMITA and Masazumi NAKAGAWA*

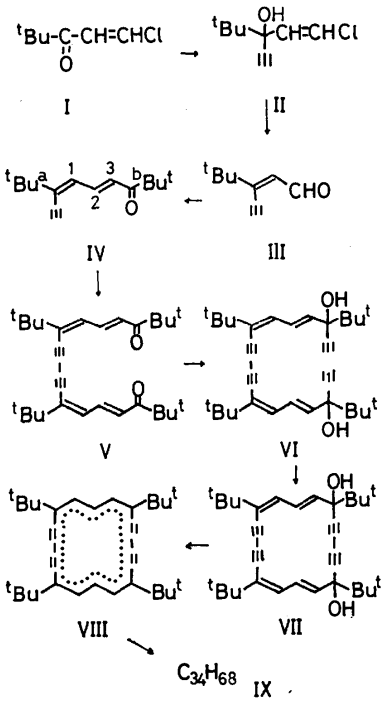
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 18, 1975)

In order to find out substituent groups which provide stability and solubility to tetrakisdehydro[18]annulene system without appreciable electronic interaction with the annulene ring, the synthesis of 1,5,10,14-tetra-*tert*-butyl-6,8,15,17-tetrakisdehydro[18]annulene (VIII) has been catrried out starting from 3-*tert*-butyl-2-penten-4-ynal (III). It was found that the tetra-*tert*-butyl derivative (VIII) is strongly diatropic, and more stable and much more soluble than tetramethyl-, dimethyl-, diphenyl-, and tetraphenyl-analogues. The electronic spectrum of tetra-*tert*-butyl derivative (VIII) was found to be closely related with that of tetramethyltetrakisdehydro[18]annulene indicating a minor electronic perturbation of *tert*-butyl groups on the annulene ring.

As reported in previous papers,[1,2] replacement of methyl groups in 1,5,10,14-tetramethyl-6,8,15,17-tetrakisdehydro[18]annulene with two or four phenyl groups enhances the stability of phenyl substituted annulenes accompanying with marked decrease of their solubility in NMR solvents. Bathochromic shift of electronic spectra of the phenyl substituted annulenes as compared with that of tetramethyl analogue indicates that phenyl group exerts prominent electronic perturbation on the dehydroannulene nucleus. Consequently, it was desired to find out substituent group which provides stability and solubility without appreciable electronic interaction with annulene system. The present paper is concerned with the synthesis and properties of tetra-*tert*-butyltetrakisdehydro[18]annulene (VIII).

tert-Butyl β-chlorovinyl ketone (I), prepared from pinacolone *via* *tert*-butyl β-hydroxyvinyl ketone by the reported method,[3] was ethynylated with lithium acetylide in liquid ammonia. Ethynyl alcohol (II), thus obtained, was converted into 3-*tert*-butyl-2-penten-4-ynal by acid treatment. The aldehyde was found to be pure *cis*-isomer (III) with respect to the formyl and the ethynyl groups on the basis of NMR spectroscopy. The aldol condensation of pinacolone with III yielded dieneyne ketone (IV) as pale yellow crystals. Oxidative coupling of IV by cupric acetate in pyridine[4] gave diketone (V) in a high yield. The reaction of lithium acetylide–ethylenediamine complex[5] in tetrahydrofuran with the diketone (V) gave bis-ethynyl alcohol (VI) in 91.5% yield. Oxidative coupling of VI performed under high dilution conditions by cupric acetate in pyridine–methanol–ether yielded 18-membered cyclic glycol (VII) in an almost quantitative yield. Treatment of a suspension of the cyclic glycol (VII) in benzene with a solution of stannous chloride dihydrate in concentrated hydrochloric acid followed by chromatography on alumina yielded tetra-*tert*-butyltetrakisdehydro[18]annulene (VIII) as deep brown crystals. VIII gave reddish purple solution in organic solvents. Catalytic reduction of VIII in ethyl acetate over platinum catalyst yielded crystalline hydrocarbon (IX) corresponding to tetra-*tert*-butylcyclooctadecane. VIII forms 1 : 1 CT complex with 2,4,7-trinitrofluorenone, which seems to dissociate into components in a tetrahydrofuran solution, because the electronic spectrum was found to be a superposition of the components, and no CT band could be observed.



As illustrated in Fig. 1, 60 MHz NMR spectrum

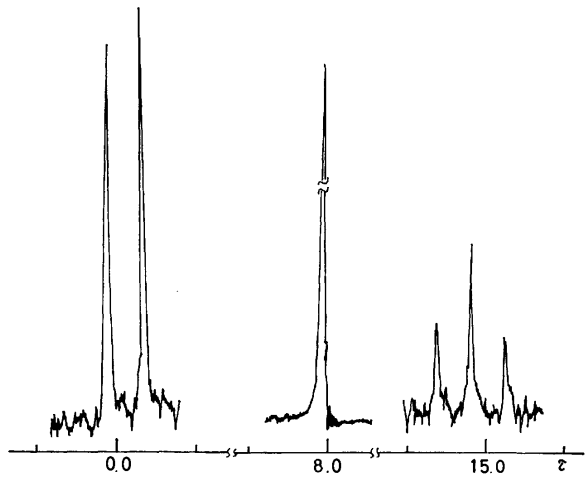


Fig. 1. 60 MHz NMR spectrum of VIII in $CDCl_3$. The signals of inner and outer protons are amplified.

* Author to whom correspondence should be addressed.

clearly indicates that the annulene (VIII) is strongly diatropic exhibiting the inner proton signal at a extremely high field (t, J=13 Hz, τ 14.89 ($CDCl_3$)) and the outer proton signal at a fairly low field (d, J=13 Hz, τ 0.04, ($CDCl_3$)).[6] An appreciable down-field shift of the signal of *tert*-butyl protons (s, τ 7.98 ($CDCl_3$)) can be reasonably ascribed to the deshielding effect of diamagnetic ring current in the 18π-electron system.

Tetra-*tert*-butyltetrakisdehydro[18]annulene (VIII) was found to be more stable and much more soluble than the tetramethyl-,[1] dimethyldiphenyl-[2b,c] and tetraphenyl analogues.[2a,c] The electronic spectrum of VIII shown in Fig. 2 was found to be closely related with that of tetramethyltetrakisdehydro[18]annulene[1] except for a minor bathochromic shift in tetra-*tert*-butyl derivative, thus indicating that the electronic interaction of *tert*-butyl group upon the tetrakisdehydro[18]annulene nucleus is nearly the same as that of methyl group.

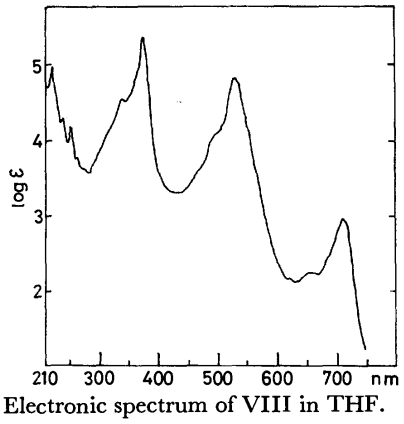

Fig. 2. Electronic spectrum of VIII in THF.

The properties found in tetra-*tert*-butyltetradehydro-[18]annulene (VIII) indicate that the requisite of the substituent, *i.e.*, increase of stability and solubility without enhancement of electronic perturbation, is essentially fulfilled by *tert*-butyl group.

Experimental

All melting and boiling points are not corrected. The IR spectra were measured on a Hitachi EPI-2 or EPI-G3 spectrometer, and the strong, medium and weak bands were indicated by S, M, and W, respectively. The UV spectra, obtained on a Hitachi EPS-3T spectrophotometer, were recorded in nm and the ε-values were given in parentheses. Shoulder was denoted by sh. The mass spectra were measured on a Hitachi RM-50 spectrometer. The NMR spectra were obtained on a Varian A-60 spectrometer. The chemical shifts are given in τ-values with respect to TMS as an internal standard, and the coupling constants are recorded in Hz.

tert-*Butyl β-Chlorovinyl Ketone (I).* The β-chlorovinyl ketone (I) was obtained from *tert*-butyl β-hydroxyvinyl ketone by the reported method[3] in 86% yield as pale yellow liquid, bp 61.5—73 °C/2793 Pa, n_D^{20} 1.4578 (lit, value, bp 65—70 °C/3990 Pa, n_D^{20} 1.4598),[3] NMR (neat): 8.86 (s, 9H, *tert*-butyl-H), 2.62—3.32 (dd, J=13, 2H, olefinic H).

*1-Chloro-3-*tert*-butyl-1-penten-4-yn-3-ol (II).* To a solution of lithium acetylide (from lithium 2.45 g, 0.35 mol) in liquid ammonia (450 ml) was added slowly a solution of the β-chlorovinyl ketone (I, 25.30 g, 0.172 mol) in ether (100 ml). The ammonia was allowed to evaporate under continuous stirring. The residue was mixed with ether (300 ml) and chilled to −30 °C, and then saturated aqueous ammonium chloride solution (150 ml) was slowly added to the mixture. The organic layer was separated and the aqueous layer was extracted with ether. The combined ethereal solution was dried (magnesium sulfate), and the solvent was removed under reduced pressure. The residue on distillation under reduced pressure gave forerun, colorless liquid, bp 50—55 °C/266 Pa, 5.24 g, 17%, and then gave II, colorless liquid, bp 55—59 °C/266 Pa, 20.17 g, 67%, IR (neat): 3600—3360 (OH), 3320 (-C≡CH), 1055 (C-O), 1620 (C=C) cm^{-1}, NMR (CCl_4): 8.98 (s, 9H, *tert*-butyl-H), 7.36 (s, 1H, ethynyl-H), 6.87 (s, 1H, -OH), 3.38—4.08 (dd, J=13, 2H, olefinic-H).

Found: C, 62.29; H, 7.59; Cl, 20.37%. Calcd for $C_9H_{13}OCl$: C, 62.61; H, 7.59; Cl, 20.53%.

The forerun was found to be fairly pure and could be used without purification for the subsequent reaction.

*3-*tert*-Butyl-2-penten-4-ynal (III).* A mixture of the β-chlorovinyl alcohol (III, 10.7 g, 0.062 mol), 2M sulfuric acid (300 ml) and tetrahydrofuran (10 ml) was stirred at 40 °C under nitrogen atmosphere for 46 hr under shielding from light. The reaction mixture was saturated with ammonium sulfate, and the aqueous layer was extracted with ether. The extracts were combined with the organic layer and worked up in the usual way. The residue obtained on evaporating the solvent under reduced pressure was dissolved in carbon tetrachloride and chromatographed on alumina (Brockmann, Act. II—III, 50 g). The carbon tetrachloride eluates were concentrated under reduced pressure, and the residue was distilled *in vacuo*. The pentynal (III) was obtained as an unstable pale yellow liquid, bp 60—62 °C/665 Pa, 5.32 g, 63%, IR (neat): 3270 (-C≡CH), 2750 (-CHO), 1680 (C=O) cm^{-1}, NMR (CCl_4): 8.77 (s, 9H, *tert*-butyl-H), 6.05 (s, ethynyl-H), 3.73 (d, J=8, 1H, olefinic-H), −0.20 (d, J=8, 1H, -CHO).

The aldehyde (III) containing a small amount of II was used in the following reaction, because it was difficult to remove a minor quantity of II in III by distillation and chromatography. Found: C, 78.02; H, 8.82%. Calcd for $C_9H_{12}O$: C, 79.37; H, 8.88%.

*1,5-Di-*tert*-butyl-2,4-pentadien-5-yn-1-one (IV).* An ice-cooled solution of sodium hydroxide (0.622 g, 15.2 mmol) in 99% ethanol (4 ml) and water (4 ml) was added in a portion to a stirred solution of the pentynal (III, 0.833 g, 6.12 mmol) and pinacolone (0.632 g, 6.32 mmol) in 99% ethanol (33 ml) under cooling on an ice-bath. After 24 hr, the reaction was quenched on addition of 1M sulfuric acid (10 ml). The mixture was extracted with ether. The extracts, after being washed and dried, were concentrated under reduced pressure to yield reddish brown liquid. The liquid dissolved in petroleum ether was passed through a column of silica gel (Merck, 10 g). The crystals obtained on concentrating the filtrate were collected and washed with a small amount of cold petroleum ether to give pure IV, pale yellow cubes, mp 52.9—54.9 °C, 0.377 g, IR (neat): 3330 (-C≡CH), 1660 (C=O), 1595 (C=C), 975 (*trans* C=C) cm,$^{-1}$ NMR (CCl_4): 8.87 (s, 9H, *tert*-butyl^a-H), 8.82 (s, 9H, *tert*-butyl^b-H), 6.45 (s, 1H, ethynyl-H), 3.56 (d, J=11, olefinic-H^1), 3.43 (d, J=14, olefinic-H^2). Found: C, 82.52; H, 10.02%. Calcd for $C_{15}H_{22}O$: C, 82.51; H, 10.16%.

The silica gel column was further eluted with ether or benzene. Concentration of the eluates under reduced pressure yielded reddish orange liquid (0.796 g), which showed identical IR and NMR spectra with those of crystalline IV, and could be used without further purification for the subsequent reaction.

*1,5,10,14-Tetra-*tert*-butyl-2,4,10,12-tetradecatetraene-6,8-diyne-1,14-dione (V).* To a stirred solution of cupric acetate monohydrate (6.314 g, 31.8 mmol) in pyridine (19.5 ml) and

methanol (19.5 ml) was added a solution of IV (1.388 g, 6.36 mmol) in methanol (15.7 ml). After being stirred overnight at room temperature, the reaction mixture was poured into ice-cooled 1M sulfuric acid (150 ml). The mixture containing yellow crystals was extracted with ether. The extracts, after washing and drying, were concentrated under reduced pressure. Yellow crystals thus obtained were dissolved in benzene, and the solution was passed through a column of alumina (Brockmann, Act. II—III, 10 g). Crystals obtained from the yellow cubes, mp 202.8—205.0 °C (dec.), 1.198 g, IR (KBr-disk): 1675 (C=O), 1592 (C=C), 1000—990 (doublet, filtrate were recrystallized from benzene to give diketone (V), *trans* C=C) cm^{-1}. Found: C, 82.66; H, 9.63%. Calcd for $C_{30}H_{42}O_2$: C, 82.90; H, 9.74%.

3,7,12,16-Tetra-tert-*butyl-4,6,12,14-octadecatetraene-1, 8, 10, 17-tetrayne-3,16-diol (VI).* To an ice-cooled and stirred suspension of lithium acetylide–ethylenediamine complex[5] (1.288 g) in tetrahydrofuran (90 ml) was added a solution of the diketone (III, 0.410 g, 0.95 mmol) in the same solvent (55 ml). After the cooling bath was removed, the mixture was stirred for further 2 hr at room temperature. Saturated aqueous ammonium chloride solution (100 ml) was added to the reaction mixture under ice-cooling. The aqueous layer was extracted with ether, and the extracts were combined with the organic layer. The combined organic layer was washed 3 times with saturated sodium chloride solution and dried, and evaporated under reduced pressure to give light brown solid. The solid dissolved in ethyl acetate was passed through a short column of alumina (Brockmann, Act. II—III, 3 g). Evaporation of the filtrate under reduced pressure gave faintly orange fine crystals, 0.420 g, 91.5%, which were recrystallized from cyclohexane to give pure VI, colorless crystals, mp 185.8—187.9 °C (dec.), IR (KBr-disk): 3560—3400 (doublet, OH), 3300—3260 (doublet, -C≡CH), 980—965 (doublet, *trans* C=C) cm^{-1}. Found: C, 83.90; H, 9.53%. Calcd for $C_{34}H_{46}O_2$: C, 83.65; H, 9.79%.

3,7,12,16-Tetra-tert-*butyl-4,6,12,14-cyclooctadecatetraene-1,8,10,-17-tetrayne-3,16-diol (VII).* A solution of VI (0.359 g) in pyridine (25 ml) and ether (25 ml) was added over 5 hr-period to a vigorously stirred and refluxing solution of cupric acetate monohydrate (1.16 g) in pyridine (45 ml) and ether (45 ml) using a high dilution apparatus. After the mixture had been stirred for further 2 hr at the same temperature, stirring was continued for 1 hr at room temperature. The ice-cooled reaction mixture, after *ca.* 1/3 volume of the solvents had been removed under reduced pressure, was poured into ice-cooled 2M hydrochloric acid (450 ml). The organic layer was separated, and the aqueous layer was extracted with ether. The extracts combined with the organic layer were worked up in the usual way. Brown solid obtained on evaporating the solvent was dissolved in ethyl acetate, and the solution was passed through a short column of alumina (Brockmann, Act. II—III, 3 g). Slightly crude VI, faintly brown fine crystals, 0.347 g, 96.0%, obtained on evaporating the filtrate, were recrystallized twice from ethanol to give analytical specimen, colorless crystals, mp 239.8—240.3 °C (dec.). The crystals contained 1 mol of ethanol as a solvent of crystallization, which could be removed upon heating to 70 °C *in vacuo* for 48 hr.

Combusion of the cyclic glycol (VI) was found to be difficult, and satisfactory elemental analysis could be obtained on a sample admixed with sucrose. Found: C, 84.74; H, 9.39%. Calcd for $C_{34}H_{44}O_2$: C, 84.25; H, 9.15%.

1,5,10,14-Tetra-tert-*butyl-6, 8,15,17-tetrakisdehydro[18]annulene (VIII).* A solution of stannous chloride dihydrate (0.6 g) in concentrated hydrochloric acid (4 ml) was added in a portion to a vigorously stirred suspension of the cyclic glycol (VII, 0.149 g, 0.308 mmol) in benzene (15 ml) under nitrogen atmosphere. After 30 min, cold water was added to the deep reddish purple reaction mixture. The organic layer was washed with water (3 times), saturated sodium hydrogencarbonate–sodium chloride solution and water, and dried over sodium sulfate in a refrigerator for 3 hr. Residue obtained on concentrating the organic layer under reduced pressure was dissolved in cyclohexane, and passed through a column of alumina (Merck, Act. I, 5 g) and eluted with the same solvent. The filtrate and eluates were combined, and concentrated under reduced pressure. Deep brown fine crystals deposited were collected and washed twice with a small amount of cold petroleum ether to give pure tetra-*tert*-butyltetrakisdehydro-[18]annulene (VIII), mp *ca.* 180 °C (dec.), 0.127 g, 90%, UV: λ_{max}^{THF} 219.5 (97600), 237.8 (19400), 250 (16300), 261 (5740), 275 (4240), 337 (35500), 374 (231000), 407.5 sh (12800), 524.5 (68700), 621 (151), 656 (186), 707 (932), IR (KBr-disk): 2950 (S), 2900 (M), 2870 (S), 1525 (W), 1480 (M), 1460 (S), 1395 (W), 1365 (M), 1285 (M), 1235 (S), 1195 (S), 1065 (M), 1025 (S), 1010 (S), 965 (M), 885(S), 858(S) cm^{-1}, NMR (THF-d_8): 7.98 (s, *tert*-butyl-H), 14.92 (t, J=13, inner-H), 0.02 (d, J=13, outer-H). Found: C, 90.56; H, 9.44%. Calcd for $C_{34}H_{42}$: C, 90.61; H, 9.39%.

VIII was found to be fairly stable even in crystalline state. Crystals of VIII which were placed in a refrigerator (−20 °C) for 3 days still held 70% purity indicating higher stability of VIII than the tetramethyl analogue.[1]

1,5,10,14-Tetra-tert-*butylcyclooctadecane (IX).* VIII (207.3 mg, 0.4277 mmol) in ethyl acetate (90 ml) was hydrogenated over pre-reduced platinum oxide catalyst ($PtO_2 \cdot 2H_2O$, 536.2 mg). After 1.5 hr, 139 ml (27 °C) of hydrogen was absorbed (theoretical volume, 136.9 ml). Yellowish solid obtained was dissolved in petroleum ether, and the solution was passed through a short column of alumina (Merck, Act. I, 2 g). Residue obtained on evaporating the filtrate was recrystallized from ethyl acetate to give tetra-*tert*-butylcyclooctadecane (IX), colorless crystals, mp 189—190 °C. Found: C, 86.08; H, 13.74%, M^+ 476. Calcd for $C_{34}H_{68}$: C, 85.63; H, 14.37%, Mol. wt., 476.9.

CT Complex of VIII with Trinitrofluorenone. A mixture of VIII (30.46 mg, 0.0676 mmol), 2,4,7-trinitrofluorenone (41.05 mg, 0.130 mmol), benzene (3 ml) and methanol (3 ml) was refluxed for a short period, and allowed to stand overnight in a refrigerator. Reddish purple crystals deposited were collected and washed successively with petroleum ether and benzene to give pure complex, reddish purple crystals, which showed no melting point, but underwent color change at *ca.* 215 °C. Found: C, 73.60; H, 6.09; N, 5.46%. Calcd for $C_{34}H_{42} \cdot C_{13}H_5O_7N_3$: C, 73.70; H, 6.19; N, 5.49%.

Dehydroannulenes. IV. Synthesis and Properties of 1,14-Di-*tert*-butyl-5,10-diphenyl-6,8,15,17-tetrakisdehydro[18]annulene. Evidence for the Identity of Diacetylene and Hexapentaene Units in the 18π-Electron System

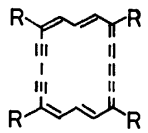
Tateo NOMOTO, Kunisuke FUKUI, and Masazumi NAKAGAWA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 18, 1975)

The synthesis designed to lead to isomeric di-*tert*-butyldiphenyl-tetrakisdehydro[18]annulenes (VII and XIII) have been performed. It was found that the isomeric tetrakisdehydro[18]annulenes (VII and XIII) are identical in all respects, thus providing chemical evidence for the identity of diacetylene and hexapentaene units incorporated in the aromatic 18π-electron system. Argon laster Raman spectra of VII and XIII exhibited single absorption due to stretching vibration of sp-hybridized carbon-carbon bond at 2080 cm^{-1} indicating equalized nature of acetylenic and cumulenic linkages in the aromatic dehydroannulene system.

It has been proved that tetrasubstituted tetrakisdehydro[18]annulene such as I_a, I_b, and I_c[1,2,3] sustain strong diamagnetic ring current suggesting that the acetylenic and cumulenic carbon atoms equally offer their p-electrons in the orbitals perpendicular to the molecular plane for the formation of π-molecular



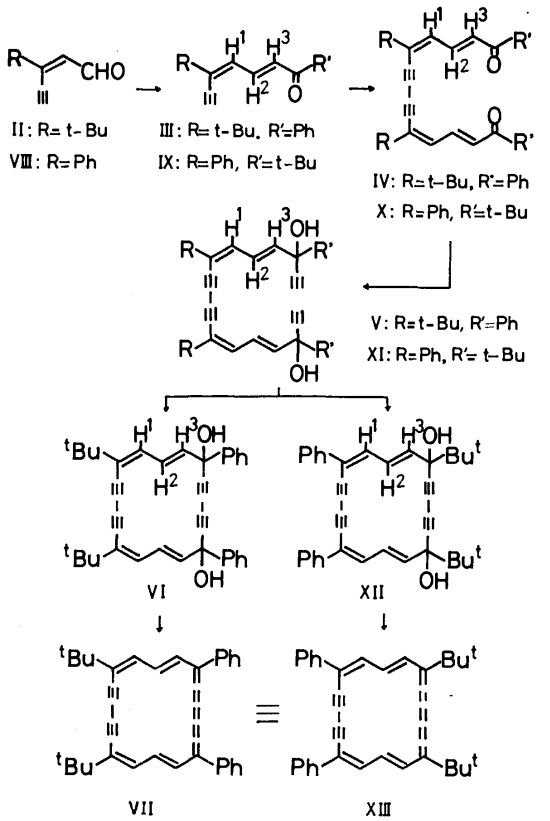
I_a: R=Me

I_b: R=Ph

I_c: R=t-Bu

orbital. Furthermore, the NMR spectral pattern of the symmetrical tetrakisdehydro[18]annulenes (Ia, Ib, and Ic) indicates the equivalence of outer protons. These facts suggest the identity of diacetylene and hexapentaene units in the aromatic system just as formal signle and double bonds in benzene. It is of considerable interest to get further evidence for the identity of diacetylene and cumulene in tetrakisdehydro[18]annulene system. The syntheses of formally isomeric dimethyldiphenyltetrakisdehydro[18]annulenes have been reported in a previous paper.[2b] However, perfect agreement in their physical properties could not be obtained presumably owing to minor difference in purity and to their instability. The present paper is concerned with the syntheses of isomeric di-*tert*-butyldiphenyltetrakisdehydro[18]annulenes (VII and XIII), which can be expected to have higher stability than the dimethyldiphenyl analogue.[3]

Syntheses. The aldol condensation of acetophenone with 3-*tert*-butyl-2-penten-4-ynal (II)[3] yielded dieneyne ketone (III). Oxidative coupling of III by cupric acetate in pyridine[4] gave diketone (IV) in an almost quantitative yield. The diketone (IV) was treated with lithium acetylide-ethylenediamine complex[5] in tetrahydrofuran to give acyclic glycol (V). Oxidation of V by cupric acetate in pyridine-methanol-ether under high dilution conditions resulted in 18-membered cyclic glycol (VI) in 85% yield. A solution



of the cyclic glycol (VI) in ether was mixed with a solution of stannous chloride dihydrate in concentrated hydrochloric acid at a low temperature. Di-*tert*-butyldiphenyltetrakisdehydro[18]annulene (VII) was obtained in 85% yield.

Alternatively, dieneyne ketone (IX) obtained by the aldol condensation of 3-phenyl-2-penten-4-ynal (VIII)[2a] with pinacolone was oxidatively coupled to give diketone (X) in a high yield. Bis-ethynylation of the diketone (X) by lithium acetylide-ethylenediamine comples[5] yielded XI in 97% yield. Oxidative coupling of XI under high dilution conditions gave cyclic glycol (XII), an isomer of VI, in 71% yield. XII could be converted into di-*tert*-butyldiphenyltetrakisdehydro[18]-annulene (XIII) on treatment with stannous chloride in ether saturated with hydrogen chloride.

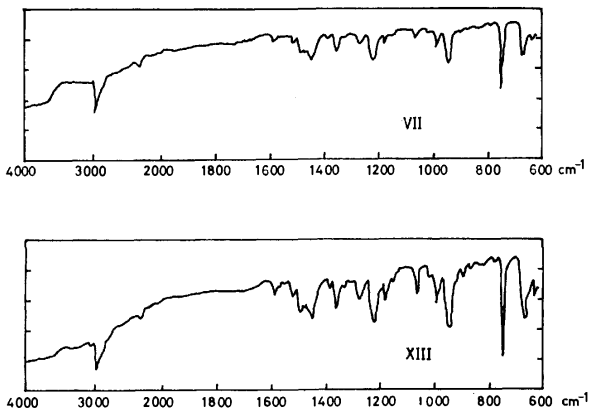

Fig. 1. IR spectra of VII and XIII (KBr-disk).

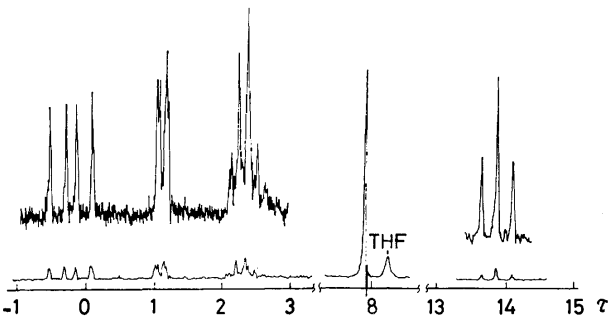

Fig. 2. 60 MHz NMR spectrum of VII in THF-d_8.

Properties. The IR spectra of di-*tert*-butyldiphenyltetrakisdehydro[18]annulenes (VII and XIII) were found to be superimposable as illustrated in Fig. 1. The NMR spectrum of VII shown in Fig. 2 indicates induction of a strong diamagnetic ring current in the tetrakisdehydro[18]annulene ring showing inner proton signal at a fairly high-field and outer proton signals at a low-field. Among two multiplets appeared at medium field, the lower field one could be assigned to *o*-protons of phenyl groups, which suffer deshielding effect of diatropicity of the annulene ring. The higher field multiplet could be reasonably ascribed to *m,p*-protons of phenyl groups, which are disposed in a less deshielding region. Down-field shift of *tert*-butyl proton signal also reflects the diatropicity of the annulene ring. The NMR parameters of VII and XIII are summarized in Table 1. As can be seen from the table, the chemical shifts and coupling constants of all signals of both tetrakisdehydro[18]annulenes (VII and XIII) were found to be identical within the experimental error, the difference of chemical shifts between the corresponding signals being $\tau \pm 0.02$.

Table 1. 60 MHz NMR parameters of VII and XIII in THF-d_8

	VII		XIII	
Outer protons adjacent to phenyl	−0.40 d (14 Hz)	1H	−0.40 d (14 Hz)	1H
Outer protons adjacent to *tert*-butyl	−0.01 d (14 Hz)	1H	0.01 d (14 Hz)	1H
o-Protons of phenyl	1.13m	2H	1.15m	2H
m,p-Protons of phenyl	2.37m	3H	2.39m	3H
Protons of *tert*-butyl	7.93 s	9H	7.93 s	9H
Inner protons	13.90 t (14 Hz)	1H	13.90 t (14 Hz)	1H

The chemical shifts are given in τ-values.

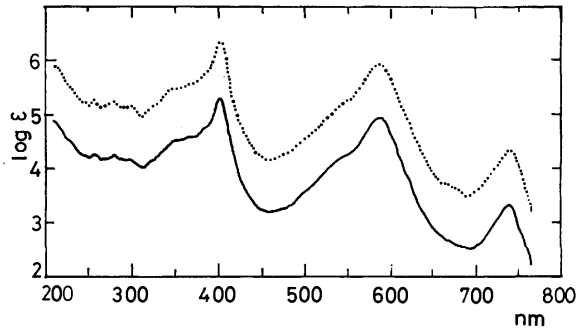

Fig. 3. Electronic spectra of VI (—) and XIII (···) in THF. The curve of XIII has been displaced upward by 1.0 log ε unit increment.

Table 2. Electronic spectra of VII and XIII in THF

λ_{max} in nm ($\varepsilon \times 10^{-2}$)

VII	231 sh (288),	245 sh (160),	256.5 (179),
	270 sh (153),	277.5 (176),	299 (142),
	325 sh (152),	347 sh (303),	368 sh (373),
	386 sh (616),	402 (2200),	544 sh (164),

Shoulder is denoted by sh.

The electronic spectra of VII and XIII are illustrated in Fig. 3, and the numerical data are recorded in Table 2. The wavelength of all absorption maxima were found to be identical in both tetrakisdehydro[18]annulenes (VII and XIII), and the absorption intensities also agreed within the experimental error being the difference between the corresponding maxima *ca.* ±1% at short wavelength region.

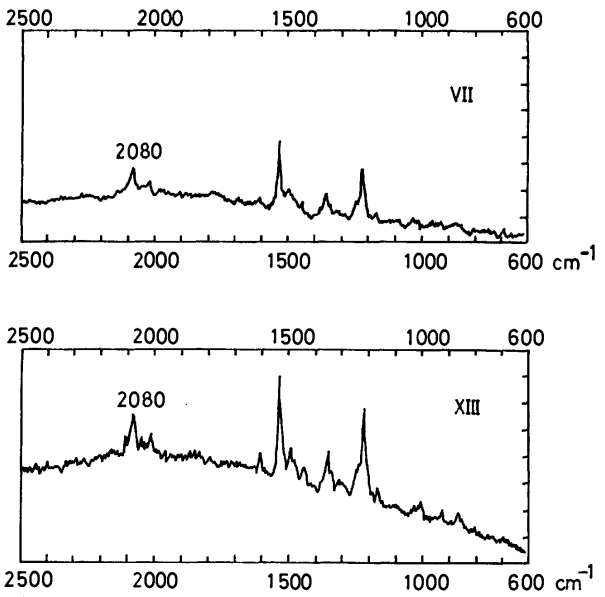

Fig. 4. Argon laser Raman spectra of VII and XIII (KBr-disk).

Argon laser Raman spectra of VII and XIII measured with KBr-disk method at a temperature of liquid nitrogen showed single absorption due to stretching vibration of sp-hybridized carbon-carbon linkage at 2080 cm^{-1} (Fig. 4), thus indicating equalized nature of the diacetylene and hexapentaene linkages incorporated in the aromatic system.

VII and XIII gave identical 1 : 1 CT complexes with 2,4,7-trinitrofluorenone.

The above-stated results provide confirmative evidences for the identity of diacetylenic and cumulenic linkages in the 18π-electron system. Consequently, it can be concluded reasonably that the tetrakisdehydro-[18]annulene ring has a highly delocalized π-electron system consisting of equalized sp-hybridized carbon-carbon linkages and polyene system with minor bond-alternation.

Experimental

All melting points are uncorrected. The IR spectra were obtained on a Hitachi EPI-2 spectrometer, and strong, medium and weak bands are denoted by S, M, and W, respectively. The electronic spectra were measured with a Hitachi EPS-3T spectrophotometer using well-matched pair of quartz cells, and the wavelengths were calibrated with the spectrum of benzene vapor and a didymium glass filter. A Varian A-60 spectrometer was used for the measurements of NMR spectra, and the chemical shifts with respect to TMS as an internal standard and coupling constants are given in τ-values and Hz, respectively. The mass spectra were obtained on a Hitachi RM-50 spectrometer. Laser Raman spectra were measured on a JASCO R750 spectrometer using argon laser (514.5 nm). KBr-disk was prepared under nitrogen atmosphere and measurements were performed in a high vacuum at liquid nitrogen temperature. Merck alumina (Act. II—III) and Merck silica gel (70—325 mesh) were used in chromatography, unless otherwise stated.

Measurements of physical properties of the tetradehydro-[18]annulenes (VII and XIII) were carried out successively using freshly prepared samples.

*1-Phenyl-5-*tert*-butyl-2,4-heptadien-6-yn-1-one (III).* To a stirred solution of II[3] (12.0 g, 0.0881 mol) and acetophenone (10.57 g, 0.0881 mol) in ethanol (55 ml) was added over 15 min-period a solution of sodium hydroxide (4.5 g) in ethanol (12 ml) and water (12 ml) at $-10\sim-5$ °C. The mixture was stirred for further 3—4 hr under ice-cooling (2 °C). Crystals deposited were collected and washed successively with ethanol–water (1: 1) and water to give III, pale yellow crystals, 13.0 g, 62.1%, which were recrystallized from hexane to yield pure III, pale yellow rods, mp 82.1—83.4 °C, IR (KBr-disk): 3280 (M, -C≡CH), 1655 (S, C=O), 1600, 1580 (s, vS, aromatic C=C) cm^{-1}, NMR (CCl_4): 8.75 (s, 9H, *tert*-butyl-H), 6.40 (s, 1H, ethynyl-H), 3.43 (d, $J_{12}=11$, 1H, H^1), 3.03 (d, $J_{23}=15$, 1H, H^3), 2.50 (m, 3.5H, *m*, *p*-H of phenyl and H^2), 2.13 (m, 2.5H, *o*-H of phenyl and H^2).

Found: C, 85.93; H, 7.61%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

The ketone (III) decomposed gradually on stading at room temperature, but could be kept without change in a refrigerator.

*1,14-Diphenyl-5,10-di-*tert*-butyl-2,4, 10, 12-tetradecatetraene-6, 8-diyne-1,14-dione (IV).* A solution of III (1.5 g, 0.0063 mol) in pyridine (6 ml) and methanol (6 ml) was added over 30 min-period to a stirred solution of cupric acetate monohydrate (3.8 g, 0.019 mol) in pyridine (24 ml) and methanol (24 ml) at room temperature. After being stirred for further 9 hr at the same temperature, the reaction mixture was poured into cold 1M sulfuric acid (300 ml), and extracted with benzene. The extracts were worked up in the usual way, and the solvent was removed under reduced pressure. Yellow amorphous solid, thus obtained, could be crystallized from hexane, 1.30 g, 97.7%. Recrystallization of the crystals from hexane containing trace of benzene gave pure IV, yellow leaflets, mp 144—146 °C, IR (KBr-disk): 1655 (S, C=O), 1580 (vS, aromatic C=C) cm^{-1}, NMR (CCl_4): 8.73 (s, 9H, *tert*-butyl-H), 3.34 (d, $J_{12}=11$, 1H, H^1), 3.04 (d, $J_{23}=15$, 1H, H^3), 2.52 (m, 3.5H, *m*,*p*-H of phenyl and H^2), 2.13 (m, 2.5H, *o*-H of phenyl and H^2).

Found: C, 85.97; H, 7.24%. Calcd for $C_{34}H_{34}O_2$: C, 86.04; H, 7.22%.

*3,16-Diphenyl-7,12-di-*tert*-butyl-4,6, 12, 14-octadecatetraene-1,8,-10,17-tetrayne-3,16-diol (V).* To a stirred suspension of lithium acetylide–ethylenediamine complex[5] (4.8 g) in tetrahydrofuran (260 ml) saturated with acetylene was added at room temperature over 1 hr-period a solution of IV (2.0 g, 0.00421 mol) in the same solvent (100 ml) under slow introduction of acetylene. Introduction of acetylene was stopped after 10 min, and the mixture was stirred for further 2.5 hr at the same temperature. Saturated aqueous ammonium chloride solution (30 ml) was added to the reaction mixture under cooling on an ice-bath. The mixture was extracted with ether. Dark colored oily residue obtained on concentrating the extracts *in vacuo* was chromatographed on silica gel (40 g), and eluted with benzene and benzene–ether (95: 5). V (2.2 g, *ca.* 90%) was obtained as a viscous yellow liquid on concentrating the eluates, IR (neat): 3400 (OH), 3280 (-C≡CH) cm^{-1}, NMR (CCl_4): 8.8 (s, 9H, *tert*-butyl-H), 7.5 (broad s, 1H, OH, disappeared on addition of D_2O), 7.25 (s, 1H, ethynyl-H), 4.13 (d, $J_{23}=15$, 1H, H^3), 3.62 (d, $J_{12}=11$, 1H, H^1), 2.83 (m, 4H, *m*, *p*-H of phenyl and H^2), 2.47 (m, 2H, *o*-H of phenyl).

Attempts to crystallize V were failed.

*1,6-Diphenyl-10,15-di-*tert*-butyl-7, 9, 15, 17-cyclooctadecatetraene-2,4,11,13-tetrayne-1,6-diol (VI).* To a stirred and refluxing solution of cupric acetate monohydrate (3.6 g) in pyridine (100 ml), ether (100 ml) and methanol (50 ml) was added over 8.5 hr-period a solution of V (0.7785 g, 0.00148 mol) in pyridine (50 ml), ether (50 ml) and methanol (50 ml) using a high dilution apparatus, and stirring was continued for further 9 hr at the same temperature. The reaction mixture was then stirred at room temperature for 6 hr, and concentrated to 1/3 volume under reduced pressure on a water-bath kept at 40 °C. The concentrate was extracted with ether, and the extracts were washed thoroughly with water, diluted hydrochloric acid, aqueous sodium hydrogencarbonate solution and saturated aqueous sodium chloride solution, successively, and dried over magnesium sulfate. Brown crystalline powder obtained on concentrating the extracts was chromatographed on alumina (25 g). Elution with benzene and benzene–ether (95: 5) yielded pale yellow crystalline powder, which was crystallized from hexane to give pale yellow crystals, 0.661 g, 85.2%. Recrystallization of the crystals from hexane yielded pure cyclic glycol (VI), colorless leaflets, mp *ca.* 160 °C (dec.), IR (KBr-disk): 3390 (broad, OH) cm^{-1}, NMR ($CDCl_3$): 8.82 (s, 9H, *tert*-butyl-H), 7.47 (broad s, 1H, OH, disappeared on addition of D_2O), 4.05 (d, $J_{23}=15$, 1H, H^3), 3.52 (d, $J_{12}=11$, H^1), 2.49 (m, 6H, H^2 and phenyl-H).

Found: C, 86.99; H, 7.18%. Calcd for $C_{38}H_{36}O_2$: C, 86.98; H, 6.91%.

*1,14-Diphenyl-5,10-di-*tert*-butyl-6,8,15,17-tetrakisdehydro[18]-annulene (VII).* A solution of stannous chloride dihydrate (320 mg) in concentrated hydrochloric acid (4 ml) was added

to a stirred solution of VI (150 mg, 0.286 mmol) in ether (35 ml) under nitrogen atmosphere at −12 °C (on an ice–salt-bath). After being stirred for 30 min at the same temperature, ether (30 ml) and ice–water (30 ml) were added to the deep blue violet reaction mixture. The organic layer was washed successively with water, aqueous sodium hydrogencarbonate solution and saturated sodium chloride solution, and passed through a short column of anhydrous potassium carbonate. Reddish purple powder obtained on evaporating the filtrate under reduced pressure was dissolved in hexane–ether (9: 1) and chromatographed on alumina (50 g). Elution with the same solvent yielded reddish purple crystals, 0.112 g, 80.0%. Recrystallization of the crystals from hexane–ether (3: 1) gave pure VII, reddish purple leaflets, mp 189.0—191.0 °C (dec.).

Found: C, 92.77; H, 7.05%, M^+ 490. Calcd for $C_{38}H_{34}$: C, 93.02; H, 6.98%, Mol. wt., 490.7.

CT Complex of VII with Trinitrofluorenone. A solution of 2,4,7-trinitrofluorenone (20 mg) in ether (15 ml) and methanol (15 ml) was added to a solution of VII (30 mg) in ether–methanol (1: 1, 30 ml). After being warmed to 50 °C for 5 min, the mixture was allowed to stand in a refrigerator for 30 min. Fine bluish purple crystals were collected and washed with ether and dried *in vacuo* for 1.5 hr, 34 mg, 69.4%. On attempted melting point determination, the color of the crystals faded at 240—241 °C.

Found: C, 75.87; H, 4.96; N, 5.25%. Calcd for $C_{38}H_{34}\cdot C_{13}H_5N_3O_7$: C, 76.01; H, 4.88; N, 5.21%.

2,2-Dimethyl-7-phenyl-4,6-nonadien-8-yn-3-one (IX). To a stirred solution of 3-phenyl-2-penten-4-ynal[2a] (VIII, 6.0 g, 0.0384 mol) and pinacolone (4.6 g, 0.0461 mol) in ethanol (90 ml) was added under nitrogen atmosphere over 30 min-period at −2 °C a solution of potassium hydroxide (2.16 g, 0.0384 mol) in ethanol (4 ml) and water (4 ml). The mixture was stirred for further 3.5 hr at 2 °C, and then for 15 hr at 14°C. The reaction mixture was mixed with cold diluted hydrochloric acid, and extracted with ether. The extracts, after being worked up in the usual way, were concentrated under reduced pressure. Dark colored oily residue dissolved in carbon tetrachloride–benzene (1: 9) was passed through a column of silica gel (Wakogel, 120 g). Orange yellow liquid obtained on concentrating the filtrate was dissolved in cyclohexane and passed through a column of alumina (60 g). Pale yellow liquid obtained from the filtrate was mixed with a small amount of cyclohexane–hexane (1: 1) to give pale yellow crystals, 3.8 g, 41.6%, which were recrystallized 3 times from the same solvent to give pure IX, pale yellow leaflets, mp 75.5—76.2 °C, IR (KBr-disk): 3250 (S, −C≡CH), 1675 (vS, C=O), 1600, 1575 (sh, vS, aromatic C=C) cm^{-1}, NMR (CCl_4): 8.83 (s, 9H, *tert*-butyl–H), 6.35 (s, 1H, ethynyl–H), 3.33 (d, $J_{23}=15$, 1H, H^3), 3.0 (d, $J_{12}=11$, 1H, H^1), 2.73 (m, 3H, *m,p*-H of phenyl), 2.37 m, 2.71 dd, $J_{23}=15$, $J_{12}=11$ (3H, *o*-H of phenyl and H^2).

Found: C, 85.91; H, 7.64%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

1,14-Di-tert-*butyl-5,10-diphenyl-2,4,10,12-tetradecatetraene-6,8-diyne-1,14-dione (X).* A solution of IX (3.5 g, 0.0147 mol) in pyridine–methanol (1: 1, 30 ml) was added at room temperature over 20 min-period to a stirred solution of cupric acetate monohydrate (8.8 g) in pyridine–methanol (1: 1, 108 ml). After being stirred for further 3 hr at the same temperature, the reaction mixture was poured into cold 1M sulfuric acid (700 ml), and extracted with ether. The extracts, after being worked up in the usual manner, were evaporated under reduced pressure to give yellowish brown powder. The material dissolved in carbon tetrachloride was passed through a column of alumina (30 g). Yellow powder obtained on concentrating the filtrate under reduced pressure was crystallized from hexane, thus yielding X, yellow crystals, 3.4 g, 98.3%, which were recrystallized from hexane–benzene (2: 1) to give analytical specimen, yellow needles, mp 154—156 °C, IR (KBr-disk): 1680 (M, C=O), 1585 (vS, aromatic C=C) cm^{-1}, NMR ($CDCl_3$): 8.8 (s, 9H, *tert*-butyl-H), 3.23 (d, $J_{23}=15$, 1H, H^3), 2.92 (d, $J_{12}=11$, 1H, H^1), 2.7 (m, 3H, *m,p*-H of phenyl), 2.4, m, 2.31, dd, $J_{12}=11$, $J_{23}=15$ (3H, *o*-H of phenyl and H^2).

Found: C, 86.00; H, 7.17%. Calcd for $C_{34}H_{34}O_2$: C, 86.04; H, 7.22%.

3,16-Di-tert-*butyl-7,12-diphenyl-4,6,12,14-octadecatetraene-1,8,-10,17-tetrayne-3,16-diol (XI).* Bis-ethynylation of X (2.0 g, 0.00421 mol) with lithium acetylide–ethylenediamine complex[5] (4.8 g) was carried out under the same reaction conditions as the case of preparation of V. Dark colored oily product was chromatographed on silica gel (40 g). Viscous yellow liquid obtained from benzene and benzene–ether (95: 5) eluates was mixed with hexane, and the solution was allowed to stand overnight in a refrigerator to yield pale yellow crystals, 2.15 g, 97.3%. Recrystallization of the crystals from hexane containing trace of benzene gave pure XI, pale yellow fine crystals, mp 145.5—148.5 °C, IR (KBr-disk): 3560 (M, OH), 3920 (M, −C≡CH), 1600 (W, aromatic (C=C) cm^{-1}, NMR ($CDCl_3$): 8.93 (s, 9H, *tert*-butyl–H), 7.92 (s, 1H, OH, disappeared on addition of D_2O), 7.33 (s, 1H, ethynyl–H), 3.80 (d, $J_{23}=15$, 1H, H^3), 2.77 (m, 5H, *m,p*–H of phenyl and H^2, H^1), 2.38 (m, 2H, *o*–H of phenyl).

Found: C, 86.42; H, 7.31%. Calcd for $C_{38}H_{38}O_2$: C, 86.65; H, 7.27%.

1,6-Di-tert-*butyl-10,15-diphenyl-7,9,15,17-cyclooctadecatetraene-2,4,11,13-tetrayne-1,6-diol (XII).* A solution of XI (1.29 g, 0.00245 mol) in pyridine–ether–methanol (1: 1: 1, 150 ml) was added over 10.5 hr-period to a stirred and refluxing solution of cupric acetate monohydrate (8.8 g) in pyridine (140 ml), ether (100 ml) and methanol (100 ml). After being refluxed under stirring for further 10 hr, a part of solvents was distilled out (bp 40—60 °C, 110 ml), and stirring under reflux was continued for further 4 hr. The reaction mixture was concentrated to 1/3 of its volume under reduced pressure at 40 °C. The concentrate was extracted with ether. The ethereal extracts were worked up in the usual way. Deep brown solid obtained on evaporating the extracts was dissolved in benzene and chromatographed on alumina (25 g). Yellow crystalline powder obtained from benzene and benzene–ether eluates was triturated with a small amount of carbon tetrachloride to give pale yellow crystals, 0.911 g, 70.8%. The crystals were recrystallized from carbon tetrachloride and carbon tetrachloride–hexane (1: 1) to give pure XII, pale yellow needles, mp 156.0—158.0 °C (dec.), IR (KBr-disk): 3400 (OH) cm^{-1}, NMR ($CDCl_3$): 8.89 (s, 9H, *tert*-butyl-H), 8.0 (broad s, 1H, OH, disappeared on addition of D_2O), 3.83 (d, $J_{23}=15$, 1H, H^3), 2.73 (m, 5H, *m,p*-H of phenyl and H^1, H^2), 2.33 (m, 2H, *o*–H of phenyl).

XII recrystallized from carbon tetrachloride or carbon tetrachloride–hexane contained tenaciously a small amount of the chloride and gave unsatisfacotry elemental analysis.

1,14-Diphenyl-5,10-di-tert-*butyl-6,8,15,17-tetrakisdehydro[18]-annulene (XIII).* To a stirred solution of XII (200 mg, 0.381 mmol) in ether (35 ml) cooled to −12 °C was added a mixture of stannous chloride dihydrate (400 mg) in ether (6 ml) saturated with hydrogen chloride. Deep bluish purple solution was stirred for 30 min at the same temperature, and then ether (30 ml) and ice–water (30 ml) were added successively to the reaction mixture. The organic layer was washed thoroughly with cold water, aqueous sodium hydrogencarbonate and sodium chloride solutions, successively. The organic layer, after being passed through a short column of

anhydrous potassium carbonate, was concentrated to give reddish purple powder. The powder dissolved in hexane–ether (9: 1) was chromatographed on alumina (30 g), and eluted with the same solvent. Evaporation of the eluates *in vacuo* yielded reddish purple crystals, 0.126 g, 67.4%, which were recrystallized 3 times from hexane–ether (3: 1) to give analytical specimen of XIII, reddish purple leaflets, mp 189.0—191.0 °C (dec.).

Found: C, 92.60; H, 7.04%, M^+ 490. Calcd for $C_{38}H_{34}$: C, 93.02; H, 6.98%, Mol. wt., 490.7.

CT Complex of XIII with Trinitrofluorenone. A solution of XIII (30 mg) in ether–methanol (1: 1, 30 ml) was mixed with a solution of 2,4,7-trinitrofluorenone (20 mg) in the same solvent (30 ml), and the mixture was kept at 50 °C for 5 min. According to similar procedure as that for the preparation of CT complex of VII, CT complex of XIII was obtained as purple fine crystals, 39 mg, 79.6%. The color of the crystals faded at 240—240.5 °C.

Found: C, 75.82; H, 4.84; N, 5.18%. Calcd for $C_{38}H_{34}\cdot C_{13}H_5N_3O_7$: C, 76.01; H, 4.88; N, 5.21%.

Racemization of Alanine Induced by Copper(I) Oxide

Akira TAI, Kotaro OKADA, Tsutomu MASUDA, and Yoshiharu IZUMI
Division of Organic Chemistry, Institute for Protein Research, Osaka University, Suita, Osaka 565
(Received August 22, 1975)

Copper(I) oxide was found to be an excellent initiator for the racemization of alanine in alkaline aqueous solutions. The rate studies indicate that copper(I) oxide itself is not a catalyst for the racemization but is a pre-catalyst producing real racemization catalysts in the reaction system. The real catalytic system for racemization was found to consist of acetaldehyde and copper(II) ions. Acetaldehyde and copper(II) ions were produced by the oxidation of alanine and copper(I) oxide with oxygen in air, respectively. The function of copper(I) oxide is considered to produce oxidants by reaction with oxygen, which effects the oxidation of alanine.

In the course of studies on the catalytic racemization of alanine with nitrosophenol and copper(II) ions,[1] it was found that the addition of copper(I) oxide to the reaction system accelerates the rate of racemization. Further investigations revealed that even in the absence of nitrosophenol, racemization proceeded at a high rate so long as a catalytic amount of copper(I) oxide was present in the system.

The present paper describes the results of this finding and the function of the copper(I) oxide in this reaction.

Results and Discussion

The experimental systems are listed in Table 1 and the results of experiments 1, 2, and 3 are shown in Fig. 1.

Racemization proceeded at a high rate in the system of experiment 1. Since no detectable racemization was observed in experiment 2 carried out in a nitrogen atmosphere, copper(I) oxide itself was found to be inactive for racemization. From the results of experiment 3, it is also clear that copper(II) ions alone produce no racemization activity. Thus, the presence of copper(I) oxide and air appears to be an essential factor for racemization.

TABLE 1. COMPOSITION OF REACTION SYSTEM[a]

Experiment	Copper compound	Additives	Atmosphere
1	Cu_2O	···	air
2	Cu_2O	···	nitrogen
3	$CuSO_4$	···	air
4	Cu_2O	pyruvic acid[b]	air
5	$CuSO_4$	pyruvic acid	air
6	Cu_2O	pyruvic acid	nitrogen
7	Cu_2O	acetaldehyde[b]	air
8	Cu_2O	acetaldehyde	nitrogen
9	$CuSO_4$	acetaldehyde	air

a) The amounts of alanine, the copper compounds and the buffer solution are given in the experimental section.
b) The amount is adjusted to the maximum amount found in the system of experiment 1; pyruvic acid: 59 mg, acetaldehyde: 20 mg.

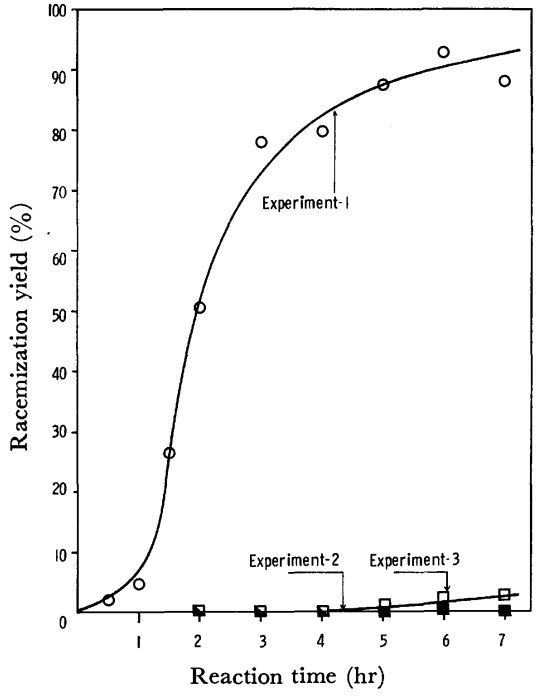

Fig. 1. Time course of racemization of D-alanine. The reaction condition of each experiment is shown in Table 1.

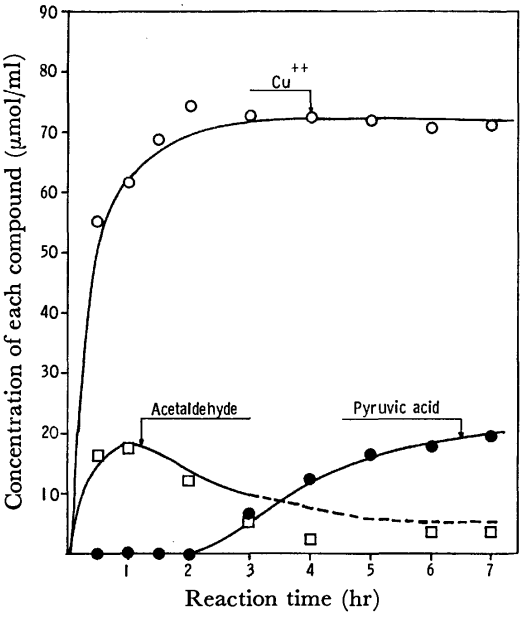

Fig. 2. Concentrations of cupric ion, acetaldehyde and pyruvic acid in the reaction mixture of experiment 1. The concentrations of acetaldehyde shown in a part of broken line are estimated by the average of scatterd analytical resalts caused by the interference of pyruvic acid.

When the presence of the induction period in the course of experiment 1 is taken into account, real racemization catalysts appear to be produced from the reaction mixture in the course of the reaction.

Analysis of the products of experiment 1 during the reaction revealed the presence of small amounts of pyruvic acid and acetaldehyde. The formation of copper(II) ions was suggested by a deep blue coloration of the reaction mixture. Fig. 2 shows the amounts of copper(II) ions, pyruvic acid and acetaldehyde produced during the reaction of experiment 1.

The role of the pyruvic acid in racemization was investigated with systems containing pyruvic acid (experiments 4, 5, and 6 in Table 1). The time courses of racemization in experiments 4, 5, and 6 are shown in Fig. 3.

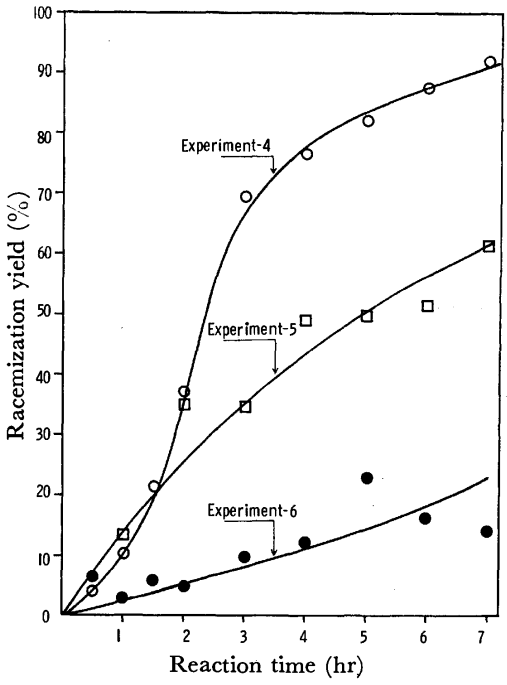

Fig. 3. Time course of racemization of D-alanine. The reaction condition of each experiment is shown in Table 1.

If the racemization of experiment 1 is catalyzed by pyruvic acid or by substances produced from pyruvic acid in the presence of copper(I) oxide or copper(II) ions, these experiments must result in an increase in the racemization rate and a reduction in the induction period. However, experiment 4 almost had the same rate and time course of racemization as did experiment 1 and experiments 5 and 6 resulted in racemization at very low or almost negligible rates.

Although the catalytic action of pyruvic acid is not completely neglected, it is not reasonable to consider pyruvic acid a primary factor governing the racemization in experiment 1.

A major part of the racemization in experiment 5 could be achieved by the transamination between alanine and pyruvic acid.[2]

The action of acetaldehyde in the racemization was also examined with systems containing acetaldehyde

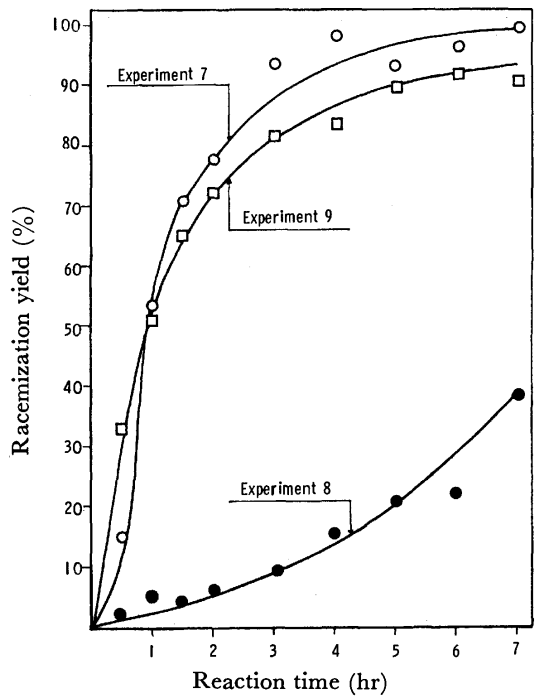

Fig. 4. Time course of racemization of D-alanine. The reaction condition of each experiment is shown in Table 1.

(experiments 7, 8, and 9 in Table 1). The time course of racemization of each experiment is shown in Fig. 4.

The results of experiment 7 reveal that acetaldehyde plays an important role in racemization. However, results of experiment 8 indicate that if there is no oxygen in the system, the rate of racemization becomes negligible even if sufficient amounts of acetaldehyde and copper(I) oxide are present. The fact that experiment 9 resulted in the absence of an induction period and high initial rate of racemization suggests that acetaldehyde is one of the essential components for the catalytic system and requires cupric ions to promote the racemization.

Since negligible effects of substances expected to be produced by the decomposition of alanine such as carbon dioxide, ammonia and ethylamine were confirmed experimentally, the real catalytic system participating in the racemization of experiment 1 was ascertained to consist of acetaldehyde and copper(II) ions.

The mechanism of racemization of alanine in experiment 1 is summarized in two steps: 1) oxidation of copper(I) oxide with oxygen produces copper(II) ions and oxidants, and the reaction of the oxidants with alanine results in the formation of acetaldehyde, and 2) catalytic racemization of alanine with acetaldehyde and copper(II) ions.

The detailed mechanism of catalytic racemization with acetaldehyde and copper(II) ions is not clear at the present time. Work is currently in progress to confirm this. Racemizations catalyzed by nitrosophenol, pyridoxal and their analogues are also being reinvestigated on the basis of this work.

Although the mechanism of the reaction between

copper(I) oxide and oxygen in the present experimental conditions has not been clarified, the formation of oxidants such as superoxide or hydroxy radicals can be expected from the reduction of oxygen with copper-(I) oxide.

The formation of acetaldehyde is considered to proceed by means of the oxidative decarboxylation of alanine because the results of experiments 4 and 5 exclude the possibility of its formation by means of the decarboxylation of pyruvic acid, as does the fact that the formation of acetaldehyde precedes that of pyruvic acid, as is shown in Fig. 2.

The direct formation of acetaldehyde and pyruvic acid from alanine and oxygen in the presence of copper-(I) oxide is interesting as a model reaction of amino acid oxidase. Studies along this line are also under way.

Experimental

All chemicals except those listed below were obtained from commercial sources and used without further purification. Copper(I) oxide was prepared by the reduction of copper(II) sulfate in an aqueous solution with glucose in the presence of potassium sodium tartrate and sodium hydroxide. Acetaldehyde was generated by the decomposition of paraldehyde in the presence of sulfuric acid. Diethyl ether was purified by the method described in Ref. 3).

The infrared spectra were recorded using a Shimadzu IR-27G spectrometer. Colorimetric determination was performed using a Hitachi 124 spectrometer. Gas chromatographic analysis was carried out with a Shimadzu 4APF gas chromatograph using a 300×0.5 cm glass column packed with neopentylglycol succinate (1.5%) on Chromosorb W. Thin-layer chromatography was performed on a precoated plate of Silica-gel HF (E. Merk) with Solvent 1 (hexane/ethyl formate=6/4) or Solvent 2 (butanol/ethanol/12% aqueous ammonia=7/1/2).

Racemization. In a shaker flask, D-alanine (25 m mol), a copper compound (2.5 m mol) and other additives as necessary were dissolved in 23 ml of an alkaline stock solution consisting of a 0.05 M solution of sodium borate and a 1M solution of sodium hydroxide in such a ratio that the pH of the resulting reaction mixture became 10.4 at 50 °C. The mixture was shaken at 50 °C in air or nitrogen. At specific time intervals, a small portion of the reaction mixture was taken out as a sample for analysis. The composition of each experiment is listed in Table 1.

Determination of Racemization Yield. The reaction mixture (0.2 ml) was acidified and dried *in vacuo*. The residue was heated with *l*-menthol (1.0 g). When the temperature of the mixture reached 120 °C, dry hydrogen chloride was passed into the mixture until the esterification of alanine was completed (requiring 1.5 hr). Excess *l*-menthol was removed from the mixture by sublimation at 110 °C at reduced pressure and the residue was allowed to react with trifluoroacetic anhydride (0.4 ml) at room temperature. The resulting *l*-menthyl L- and D-trifluoroacetylalaninate were subjected to gas chromatography at 170 °C. From the ratio of diastereomers, the racemization yield of D-alanine was calculated.

Determination of Copper(II) Ions. Copper(II) ions in the reaction mixture were determined by EDTA titration. The reaction mixture (2 ml) was acidified with 1 M sulfuric acid to pH 4—5, and was then diluted with 20 ml of an acetate buffer (pH 4.5). The solution was titrated with a 1/100 M EDTA solution in the presence of PAN as an indicator.

Characterization of Acetaldehyde and Pyruvic Acid. The reaction mixture of experiment 1 (20 ml) was acidified with hydrochloric acid and mixed with 20 ml of a 0.4% solution of 2,4-dinitrophenylhydrazine in 2 M hydrochloric acid. The reaction products were extracted three times with a 20 ml portion of ether. The combined extracts were extracted twice with a 30 ml portion of a 10% aqueous sodium carbonate solution.

The organic layer was concentrated to 0.5 ml and the reddish-orange crystals that precipitated were collected. The crystals (mp 162.0 °C) were identical with 2,4-dinitrophenylhydrazone of acetaldehyde (**1**) from a mixed melting-point determination, IR spectra and the R_f values (0.65) of tlc (developed with Solvent 1).

The aqueous layer was acidified with 2 M hydrochloric acid and the acid insoluble substance was extracted with a 30 ml portion of ethyl acetate. A yellow precipitate which appeared when the extract was concentrated to 0.3 ml was collected and recrystallized from ethyl acetate to give 2,4-dinitrophenylhydrazone of pyruvic acid (**2**) as yellow crystals (mp 162.5 °C), which was confirmed by a mixed melting-point determination with an authentic sample and by comparison of its IR spectrum and tlc R_f values of tlc (0.57) (developed with Solvent 2) with those of an authentic sample.

Determination of Acetaldehyde and Pyruvic Acid. The amounts of acetaldehyde and pyruvic acid in the reaction mixture were evaluated from those of their 2,4-dinitrophenylhydrazones, which were found in the reaction mixture treated with 2,4-dinitrophenylhydrazine.

The reaction mixture (0.3 ml) was treated with 1 ml of a 0.4% solution of 2,4-dinitrophenylhydrazine in 2 M hydrochloric acid. The products were extracted five times with a 4 ml portion of ether. The combined extracts were made up to 25 ml with ether in a volumetric flask.

a) Isolation and Determination of **1**. A 2 ml portion of the extract was concentrated to 0.1 ml and applied on a tlc plate. The plate was developed with Solvent 1. **1** separated as a yellow band on the plate was recovered by scraping the corresponding part of the silica gel and eluting with 5 ml of methanol. The amount of **1** in the eluate was determined by colorimetry with the absorbance at 355 mμ.

b) Isolation and Determination of **2**. A 0.6 ml portion of the extract was subjected to chromatography on a tlc plate with Solvent 2. **2** separated on the plate was recovered in the same way as in a) except for the use of a 0.1 M sodium bicarbonate solution instead of methanol. The amount of **2** in the eluate was determined by colorimetry with the absorbance at 355 mμ.

(Received September 16, 1975)

2-Amino-2,3-dideoxy-L-glucose (**1**) was synthesized from 2-amino-2-deoxy-L-glucose (**2**). The synthesis was achieved without protection of the anomeric hydroxyl group throughout the reaction sequence. The masked derivative (**9**) of **1** was prepared from **2** by sequential *N*-methoxycarbonylation, benzylidene acetal formation, mesylation, displacement with iodide, and hydrogenolysis. Alkaline hydrolysis of the debenzylidenated product (**10**) led to ring contraction and yielded the 1,2-oxazolidinone derivative (**11**) of a furanose. Acidic hydrolysis of **11** underwent ring expansion and successfully gave **1**.

2-Amino-2,3-dideoxy-L-ribohexose (**1**), an amino L-sugar, is the 3-deoxy derivative of a component of streptomycin. Since the mechanism of resistance of resistant bacteria to streptomycin has been revealed,[1,2,3] and it has been found that the C-3 hydroxyl group of the 2-deoxy-2-methylamino-L-glucose moiety of streptomycin was adenylylated or phosphorylated by ATP and streptomycin adenylyl transferase or streptomycin phosphate transferase, we intended to prepare the unnatural 2-amino-3-deoxy L-sugar (**1**) as an approach to the synthesis of a deoxy variant of streptomycin which does not contain the hydroxyl group masked by the resistant bacteria.

As for the corresponding D-sugar, namely, 2-amino-2,3-dideoxy-D-glucose, Meyer zu Reckendorf and Bonner[4] have reported its synthesis from methyl 2-benzamide-4,6-*O*-benzylidene-2-deoxy-3-*O*-mesyl-β-D-glucopyranoside through 3-thioacetylation followed by catalytic desulfuration, and, subsequently, the amino D-sugar was found in nature as a component of lividomycin.[5] Matsushima and coworkers[6] also prepared 2-acetamido-2,3-dideoxy-D-glucose from benzyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside through 3-chlorination with sulfuryl chloride followed by reduction with tri-*n*-butyltin hydride and α,α′-azobisisobutyronitrile.

In the present paper, we wish to report a novel method for the preparation of the aminodeoxy L-sugar (**1**) from 2-amino-2-deoxy-L-glucose (**2**) that was achieved without protection of the anomeric hydroxyl group throughout the reaction sequence.

The starting L-sugar (**2**) was prepared from L-arabinose by the method of Kuhn and Kirschenlohr.[7] The 4,6-*O*-benzylidene-*N*-methoxycarbonyl derivative (**4**) was prepared through (**3**) similarly to the preparation of *N*-benzyloxycarbonyl-4,6-*O*-benzylidene derivative of 2-amino-2-deoxy-D-glucose by Wesemann and Zilliken.[8] The position of the acetal group (at 4,6-*O*, not at 5,6-*O* of furanose structure) was confirmed by the PMR spectral studies of the mesyl derivatives (**5**,**5**′), the next compounds. Treatment of **4** with mesyl chloride in pyridine containing triethylamine followed by column chromatography gave two crystalline 3-*O*-mesyl derivatives of α-L- (**5**, 47%) and β-L-glucopyranose form (**5**′, 17%). PMR studies of **5** and **5**′ showed the coupling constants, $J_{2,3}$ and $J_{3,4}$=9.5—10 Hz in each of the anomers and $J_{1,2}$=3.5 Hz (in **5**) and 8 Hz (in **5**′). The anomeric proton of **5** or **5**′ also coupled with the anomeric hydroxyl proton, respectively, and, on deuteration, the anomeric proton collapsed to a clear doublet, respectively. These results indicated that the anomeric hydroxyl groups of the both compounds were free and that the both compounds have the glucopyranose structure. It can therefore be assumed that, in the mesylation reaction, an unstable 1-chloride or 1-*O*-mesyl derivative would be formed and hydrolyzed during the subsequent isolation procedure.

The structures of **5** and **5**′ were further confirmed by the PMR spectral studies of their acetyl derivatives. Treatment of the α-anomer (**5**) with acetic anhydride and pyridine followed by chromatographic separation gave 1-*O*-acetyl-α (**6**) and β-derivative (**6**′) in a yield of 72 and 12%, respectively. Acetylation of the β-anomer (**5**′) gave **6** and **6**′ in a yield of 25 and 56%, respectively.

Hydrolysis of **5** or **5**′ with 70% acetic acid readily gave the debenzylidenated compound (**7**).

Next, displacement of the 3-*O*-mesyl group of **5** or **5**′ with iodine was achieved by treatment with sodium iodide in DMF. In general, displacement reaction of 3-sulfonyloxy group by a nucleophile readily proceeds in the case of β-D-glucopyranosides, whereas α-D-glucopyranosides resistant to the displacement owing to 1,3-diaxial type interaction[9,10] in the transition state. We[11] experienced, however, that iodination of 3-sulfonyloxy group in a 2-benzyloxycarbonylamino-α-D-glucoside structure smoothly proceeded in the synthseis of tobramycin from kanamycin B, although the displacement was carried out in high concentration of sodium iodide in DMF. Possibly, the iodination was facilitated by the neighboring group participation of the 2-acylamino group.[12] Also, in the present case, the displacement was carried out with a high concentration of sodium iodide to give almost equal amounts of two iodination products, **8** (35%) and **8**′ (35%), from both of **5** and **5**′. When the concentration of sodium iodide was reduced, the yields of iodinated products became lower. Further details of the structures of **8** and **8**′ were not studied, however, since both of **8** and **8**′ showed $J_{1,2}$=3—3.5 Hz in their PMR spectra, one of them was assumed to have α-L-glucopyranose structure and the other α-L-allopyranose structure.

Catalytic hydrogenation of **8** or **8**′ with Raney nickel gave the 3-deoxy-α-L-pyranose derivative (**9**) in high yield, giving no β-anomer.

Hydrolysis of **9** with 70% acetic acid removed its

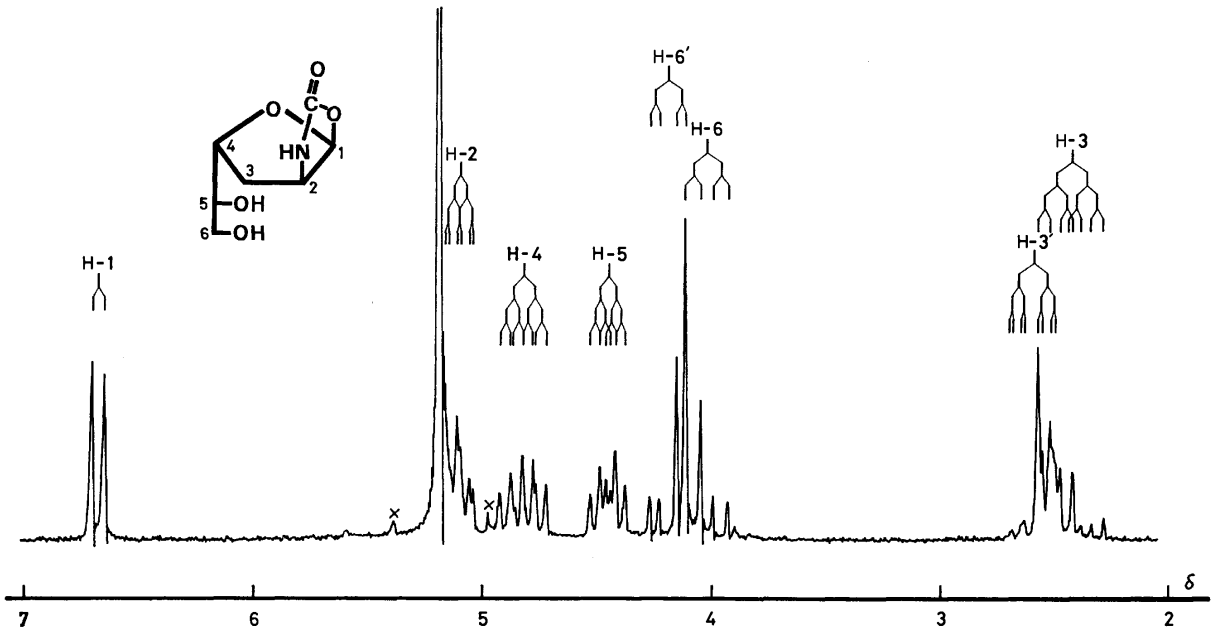

Fig. 1. PMR spectrum of **11**.

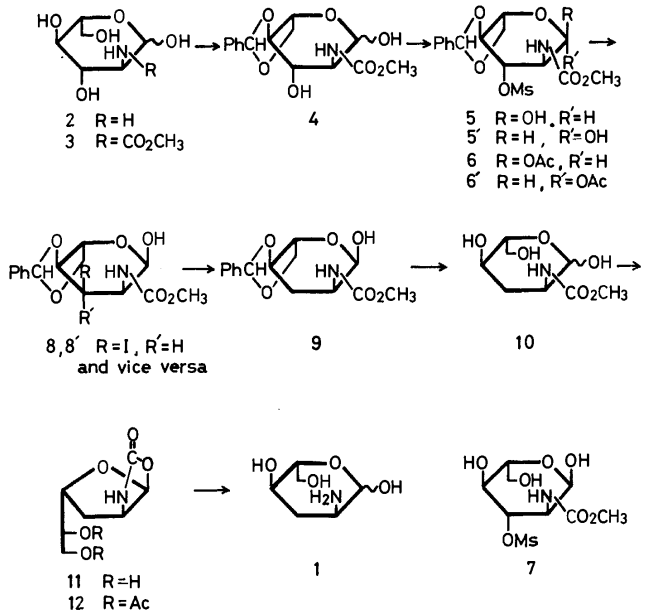
benzylidene group to give 2,3-dideoxy-2-methoxycarbonylamino-L-ribohexose (**10**). The compounds **9** and **10** are useful intermediates for the synthesis of related glycosyl halides and glycosides.

Alkaline hydrolysis of **10** with barium hydroxide to remove its methoxycarbonyl group led exclusively to ring contraction, giving an oxazolidinone derivative of α-L-ribohexofuranose (**11**) in 94% yield. Reactions of **11** with ninhydrin and triphenyltetrazolium chloride (TTC) were negative and, in the IR spectrum, **11** showed an absorption at 1730 cm^{-1}. These facts suggested that **11** was a 1,2-oxazolidinone derivative. The PMR spectrum of **11** (Fig. 1) showed the coupling constants, $J_{1,2}=5.5$, $J_{2,3}=5.5$, $J_{2,3'}=-1.5$, $J_{3,4}=10$, $J_{3',4}=5.5$ Hz and these values indicated that **11** has a furanoside structure and that the oxazolidinone is formed in a *cis* configuration at C-1 and C-2.



For further confirmation of the structure of **11**, it was acetylated to give the di-*O*-acetyl derivative (**12**). The PMR spectrum of **12** showed that only the shift values of H-5, 6, and 6' moved to downfield in comparison with those of the corresponding protons of **11**. This indicated that the hydroxyl groups at C-5 and C-6 of **11** were acetylated.

Naturally, it became of interest to investigate the alkaline hydrolysis of **3**. However, similar treatment of **3** with barium hydroxide failed to give a definite product. It seems therefore that the absence of 3-hydroxyl group in **10** facilitates the formation of oxazolidinone.

Acidic hydrolysis of **11** was found to undergo ring expansion of the furanose to a pyranose. Treatment of **11** with 1 M hydrochloric acid under warming successfully gave, in 78% yield, 2-amino-2,3-dideoxy-L-ribohexose (**1**) which showed a specific rotation numerically compatible with that of D-isomer[5] but opposite in direction.

Experimental

Tlc was carried out on 7.5×2.5 cm slides coated with silica gel (Wakogel B-5, Wako Pure Chemicals Co., Ltd., Osaka) and silica gel column chromatography was performed with Wakogel C-200.

2-Deoxy-2-methoxycarbonylamino-L-glucose (**3**). To an ice-cold suspension of 2-amino-2-deoxy-L-glucose hydrochloride[7] (26.3 g) and anhydrous sodium carbonate (16.9 g) in aqueous acetone (1 : 1, 440 ml), methyl chloroformate (19.7 ml) was added and the mixture was stirred for 1.5 hr in the cold and then for 1.5 hr at room temperature. Evaporation of the reaction mixture gave a residue, which was washed with methanol. The colorless residue was extracted with DMF (200 ml×5) to remove inorganic matter. Evaporation of the extract gave a solid, which was washed with methanol, 21.7 g (75%). Recrystallization from methanol gave crystals of **3**, mp 195—197 °C (decomp.) (*cf.* 2-deoxy-2-methoxycarbonylamino-D-glucose: mp 196—197 °C[13]); $[\alpha]_D^{26}$ −14.4°→−33.4°

(*c* 1, H_2O) (D-isomer: +34°,[13] +27°[14]).

Found: C, 40.49; H, 6.63; N, 5.72%. Calcd for $C_8H_{15}NO_7$: C, 40.50; H, 6.37; N, 5.91%.

4,6-O-Benzylidene-2-deoxy-2-methoxycarbonylamino-L-glucopyranose (4). A mixture of **3** (33.2 g), fuse-dried zinc chloride (33.5 g) and benzaldehyde (96 ml) was stirred at room temperature for 20 hr. The resulting viscous solution was poured into water. The oily precipitate was separated and washed with petroleum ether. The solidified mass was washed further with water and petroleum ether. Recrystallization from methanol gave needles of **4**, 32.5 g (71%), mp 238 °C (decomp.); $[\alpha]_D^{26}$ +55 °→+16.2 ° (*c* 0.5, dioxane); PMR (in $(CD_3)_2SO$) δ: 3.28 (3H s, CO_2CH_3), 5.57 (1H s, PhC<u>H</u>), 7.37 (5H s, Ph).

Found: C, 55.05; H, 5.70; N, 4.09%. Calcd for $C_{15}H_{19}NO_7$: C, 55.38; H, 5.89; N, 4.31%.

4,6-O-Benzylidene-2-deoxy-3-O-mesyl-2-methoxycarbonylamino-α- and β-L-glucopyranose (5 and 5′). To an ice-cold solution of **4** (10.0 g, 30.7 mmols) in pyridine (250 ml), triethylamine (8.6 ml) and mesyl chloride (8.6 ml, 111 mmol) were added and the solution was allowed to stand for 2 hr in the cold. The solution was poured, with stirring, into a mixture of chloroform-1% aqueous sodium carbonate solution. The chloroform layer was washed with water, dried over sodium sulfate and evaporated to give a red-colored solid. The solid was shaken with a mixture of benzene–ethyl acetate (2: 1) and the suspension was filtered to remove the insoluble matter. The filtrate was chromatographed on a column of silica gel with the same solvent system described above. From the eluate, **5** was obtained as a colorless solid, 5.76 g (47%). It was recrystallized from ethanol to give needles, mp 161—161.5 °C (decomp.); $[\alpha]_D^{15}$ −3.3 °→0 ° (*c* 1.5, acetone); R_f 0.25 (benzene–ethyl acetate 2: 1); positive to TTC; PMR (in $(CD_3)_2CO$) δ: 3.04 (3H s, SO_2CH_3), 3.64 (3H s, CO_2CH_3), 4.05—4.3 (2H m), 4.85 (1H q, H-3; $J_{2,3}$=9.5 or 10 Hz, $J_{3,4}$=9.5 or 10 Hz), 5.28 (1H incomplete t, which collapsed to a doublet ($J_{1,2}$=3.5 Hz) on deuteration, H-1), 5.73 (1H, s, PhCH), 6.13 (1H d with small couplings (<0.5 Hz), OH; J=~4 Hz; disappeared on deuteration). Irradiation of the deuterated sample at δ 3.99 collapsed the doublet of H-1 into a singlet and the quartet of H-3 into a broad singlet. Irradiation at δ 3.89 collapsed the quartet of H-3 into a doublet (J=~8 Hz).

Found: C, 47.59; H, 5.21; N, 3.25; S, 7.96%. Calcd for $C_{16}H_{21}NO_9S$: C, 47.64; H, 5.25; N, 3.47; S, 7.95%.

The insoluble matter described above was recrystallized from ethanol to give colorless needles of **5′**, 2.09 g (17%), mp 153.5—154.5 °C (decomp.); $[\alpha]_D^{15}$ +29 °→−3 ° (*c* 1.5, acetone); R_f 0.25 (benzene–ethyl acetate 2: 1); active for TTC; PMR (in $(CD_3)_2CO$) δ: 3.00 (3H s, SO_2CH_3), 3.62 (3H s, CO_2CH_3), 4.32 (1H q, H-6?$_{eq}$; J=4.5 and 10.5 Hz), 4.92 (1H t, H-3; J=9.5 Hz), 5.06 (1H t, H-1; J=~7.5 Hz; collapsed to a doublet ($J_{1,2}$=8 Hz) on deuteration), 5.74 (1H s, PhC<u>H</u>), 6.17 (1H d, OH; J=7.5 Hz;disappeared on deuteration), 7.3—7.6 (5H m, Ph).

Irradiation at δ 6.17 (OH) collapsed the triplet of H-1 to a doublet (J=8 Hz). Irradiation of the deuterated sample at δ 3.70 (H-2 resonated here) collapsed the doublet of H-1 to a singlet and the triplet of H-3 to a doublet (J=~8 Hz).

Found: C, 47.51; H, 5.18; N, 3.22; S, 7.66%.

2-Deoxy-3-O-mesyl-2-methoxycarbonylamino-α-L-glucopyranose (7). A suspension of **5** or **5′** in 70% aqueous acetic acid was heated at 95 °C for 5 min. The resulting clear solution was evaporated to give a solid, which was thoroughly washed with ether and recrystallized from ethanol to give needles of **7**, mp 151.5—153 °C (decomp.); $[\alpha]_D^{22}$ −86 °→−36 ° (*c* 1, methanol); R_f 0.33 (chloroform–methanol 7: 1); PMR (in $CDCl_3$) δ: 3.13 (3H s, SO_2CH_3), 3.67 (3H s, CO_2CH_3), 5.13 (1H d, H-1; $J_{1,2}$=3.5 Hz).

Found: C, 34.45; H, 5.32; N, 4.24; S, 10.10%. Calcd for $C_9H_{17}NO_9S$: C, 34.28; H, 5.44; N, 4.44; S, 10.17%.

1-O-Acetyl-4,6-O-benzylidene-2-deoxy-3-O-mesyl-2-methoxycarbonylamino-α- and β-L-glucopyranose (6 and 6′). *From 5*: A solution of **5** (200 mg) in pyridine (4.6 ml), acetic anhydride (0.05 ml) was added and the solution was allowed to stand at room temperature overnight. After addition of a drop of water, the solution was poured into ice-water. The precipitate was dissolved in chloroform and the solution was washed with water, dried over sodium sulfate and evaporated to give a solid. The solid was shaken with benzene–ethyl acetate (5: 1, 3 ml) and the insoluble product was filtered, washed with the same solvent mixture to give **6**, 60 mg (27%). The filtrate was evaporated and the residue was chromatographed on a column of silica gel with the above solvent mixture. From the earlier fraction, **6′** was obtained, 27 mg (12%), mp 158—159.5 °C (decomp.); $[\alpha]_D^{23}$ −65 ° (*c* 1, $CHCl_3$); R_f 0.48 (benzene–ethyl acetate 2: 1); PMR (in $CDCl_3$) δ: 2.20 (3H s, Ac), 2.98 (3H s, CO_2CH_3), 3.72 (3H s, SO_2CH_3), 3.75—4.0 (3H m, H-4,6$_{ax}$,6$_{eq}$ (or 5)), 4.1—4.45 (2H m, H-2 and 5 (or 6$_{eq}$)), 4.83 (1H t, H-3; J=~10 Hz), 5.19 (1H d, NH; $J_{2,NH}$=9 Hz; disappeared on addition of D_2O and NaOD), 5.59 (1H s, PhC<u>H</u>), 6.24 (1H d, H-1; $J_{1,2}$=3.5 Hz).

Irradiation of H-1 slightly changed the signal bush near 4.3 but not other signals. Irradiation at δ 4.33 (at which H-2 resonated) collapsed the triplet of H-3 (δ 4.83) into a doublet ($J_{2,3}$=~10 Hz), the doublet of N<u>H</u> (δ 5.19) into a singlet and the doublet of H-1 (δ 6.24) into a singlet. Irradiation at δ 3.87 (H-4) collapsed the triplet of H-3 into a doublet (11 Hz=$J_{3,4}$). Irradiation at 5.19 caused the signals at δ 4.1—4.45 to change.

Found: C, 48.64; H, 5.22; N, 2.85; S, 7.39%. Calcd for $C_{18}H_{23}NO_{10}S$: C, 48.54; H, 5.20; N, 3.14; S, 7.20%.

From the later fraction, **6** was obtained, 100 mg (45%). Thus the total yield of **6** is 72%, mp 156.5—158 °C (decomp.); $[\alpha]_D^{23}$ +9 ° (*c* 1, $CHCl_3$); R_f 0.50 (benzene–ethyl acetate 2: 1); PMR (in $CDCl_3$) δ: 2.15 (3H s, Ac), 2.93 (3H s, CO_2CH_3), 3.72 (3H s, SO_2CH_3), 3.6—4.0 (4H m, H-2,4,6$_{ax}$,5(or 6$_{eq}$)), 4.3—4.5 (1H m, H-6$_{eq}$ or 5), 4.98 (1H t, H-3; J=10 Hz), 5.32 (1H d, NH; $J_{2,NH}$=9 Hz; disappeared on addition of D_2O and DCl), 5.55 (1H s, PhC<u>H</u>), 5.95 (1H d, H-1; $J_{1,2}$=8.5 Hz).

Irradiation of H-1 changed the signals at δ 3.75—4.0. Irradiation at δ 3.84 (H-2,4,6$_{ax}$(or 6$_{eq}$)) caused the signals at δ 4.4 (H-6$_{eq}$ or 5), 4.98 (H-3), 5.32 (NH) and 5.95 (H-1) to a singlet, respectively.

Found: C, 48.77; H, 5.22; N, 3.08; S, 7.07%.

From 5′. Prepared in the same way as described above from **5′** (100 mg) giving **6**, 28 mg (25%) and **6′**, 62 mg (56%).

4,6-O-Benzylidene-2-deoxy-3-iodo-2-methoxycarbonylamino-α-L-gluco and α-L-allo(?)-hexopyranose (8 and 8′). A solution of **5** or **5′** (2.5 g) and sodium iodide (25 g) in DMF (30 ml) was heated at 100 °C for 1.5 hr. After addition of chloroform (350 ml), the organic layer was washed with 10% sodium thiosulfate solution (400 ml) and water (400 ml). The solution was dried over sodium sulfate and evaporated to leave a residue, which was shaken with benzene–ethyl acetate (3: 1, 20 ml). The insoluble product was recrystallized from methanol to give needles of **8**, 878 mg (35%), mp 219—221 °C (decomp.); $[\alpha]_D^{22}$ +93.5 °→+29.5 ° (*c* 1, pyridine); R_f 0.36 (benzene–ethyl acetate 2: 1); PMR (in $CDCl_3$+D_2O) δ: 3.69 (1H s, CO_2CH_3), 5.28 (1H d, H-1; $J_{1,2}$=3 Hz), 5.72 (1H s, PhC<u>H</u>).

Found: C, 40.81; H, 4. 08; N, 2.90; I, 28.70%. Calcd for $C_{15}H_{18}NO_6I$: C, 41.40; H, 4.17; N, 3.22; I, 29.16%.

The benzene–ethyl acetate soluble product was purified by

column chromatography with benzene–ethyl acetate (3: 1) to give **8′**, 945 mg (35%), mp 190—192 °C (decomp.); $[\alpha]_D^{23}$ +59.4 ° (*c* 1, $CHCl_3$) (the value kept constant for 20 hr), $[\alpha]_D^{23}$ +59.1 °→+20.1 ° (*c* 0.7, pyridine); R_f 0.36 (benzene–ethyl acetate 2: 1); PMR (in $CDCl_3+D_2O$) δ: 3.73 (3H s, CO_2CH_3), 5.15 (1H d, H-1; $J_{1,2}$=3.5 Hz), 5.70 (1H s, PhCH). Due to its unstable nature, the compound could not be successfully analyzed.

4,6-O-Benzylidene-2, 3-dideoxy-2-methoxycarbonylamino-α-L-ribo-hexopyranose (9). To a solution of **8** (641 mg) in dioxane (25 ml), triethylamine (0.08 ml) and Raney nickel were added and the mixture was shaken under hydrogen (50 lb. in^{-2}) at room temperature. After 5 hr, Raney nickel was replaced with the fresh one and the reaction was continued for further 6 hr. The solution was evaporated and the residue was extracted with ethyl acetate. The solution was washed successively with saturated sodium hydrogen sulfate solution, sodium hydrogen carbonate solution, and water, dried over sodium sulfate and evaporated to give a solid of **9**, 443 mg (97%).

A similar preparation from **8′** (616 mg) gave **9**, 413 mg (94%), mp 201—203 °C; $[\alpha]_D^{22}$ −11.7 ° (*c* 1, dioxane; the value kept constant for 20 hr); R_f 0.32 (benzene–ethyl acetate 2: 1); positive to TTC; PMR (in $CDCl_3$ $+D_2O$) δ: 1.75—2.35 (2H m, H-3,3′), 3.74 (3H s, CO_2CH_3), 5.19 (1H d, H-1; $J_{1,2}$=3.5 Hz), 5.66 (1H s, PhCH).

Found: C, 58.04; H, 6.13; N, 4.50%. Calcd for $C_{15}H_{19}NO_6$: C, 58.24; H, 6.19; N, 4.53%.

2, 3-Dideoxy-2-methoxycarbonylamino-L-ribo-hexose (10). A suspension of **9** (594 mg) in 70% aqueous acetic acid (21 ml) was heated at 95 °C for 5 min. Evaporation *in vacuo* and coevaporation with water gave a syrup. An aqueous solution (40 ml) of the syrup was washed with ether (40 ml ×2) and evaporated to give a solid, 405 mg (95%); $[\alpha]_D^{23}$ −56 °→−38 ° (*c* 1, methanol).

Found: C, 43.21; H, 6.74; N, 6.10%. Calcd for $C_8H_{15}NO_6$: C, 43.43; H, 6.84; N, 6.33%.

3-Deoxy-α-L-ribo-hexofurano[2, 1-d]-2-oxazolidinone (11). An aqueous solution (4.7 ml) of **10** (238 mg) and barium hydroxide octahydrate (470 mg) was heated at 70 °C for 5 min. After cooling, carbon dioxide was introduced and the reaction mixture was centrifuged. The aqueous layer separated was evaporated to give a residue, which was chromatographed on a column of silica gel with chloroform–ethanol–17% aqueous ammonia (10: 4: 0.6). Evaporation of the fraction containing the main product gave a glassy solid. Recrystallization from methanol–ether gave needles of **11**, 184 mg (94%), mp 127—128 °C; $[\alpha]_D^{23}$ +43 ° (*c* 1, methanol); IR (KBr): 1730, 1750 (sh) cm^{-1}; PMR (in D_2O) δ: 1.96 (1H octet, H-3; J=5.5, 10, 13 Hz), 2.07 (1H octet, H-3′; J=1.5, 5.5, 13 Hz), 3.56 (1H q, H-6; J=6.5, 11.5 Hz), 3.67 (1H q, H-6′; J=4, 11.5 Hz), 3.95 (1H d, H-5; J=~4.5, ~4.5, 6.5 Hz), 4.33 (1H m, H-4), 4.60 (1H d, H-2; J=~1.5, ~5.5, ~5.5 Hz), 6.18 (1H d, H-1; J=5.5 Hz); $J_{1,2}$=5.5 Hz, $J_{2,3}$=5.5 Hz, $J_{2,3'}$=−1.5 Hz, $J_{3,3'}$=13 Hz, $J_{3,4}$=10 Hz, $J_{3',4}$=5.5 Hz, $J_{4,5}$=4.5 Hz, $J_{5,6}$=6.5 Hz, $J_{5,6'}$=4 Hz, $J_{6,6'}$=11.5 Hz; mass spectrum: *m/e* 190 (M^+ +1).

Found: C, 44.69; H, 5.75; N, 7.22%. Calcd for $C_7H_{11}NO_5$: C, 44.44; H, 5.86; N, 7.41%.

5,6-Di-O-acetyl-3-deoxy-α-L-ribo-hexofurano[2,1-d]-2-oxazolidinone (12). To a solution of **11** (35 mg) in pyridine (1 ml), acetic anhydride (0.09 ml) was added and the solution was allowed to stand at room temperature overnight. After a drop of water was added, the solution was evaporated and the residue was extracted with chloroform. The solution was washed with water, dried over sodium sulfate and evaporated to give a syrup, 37 mg (74%), which was crystallized from ether to give needles of **12**, mp 89—91 °C; $[\alpha]_D^{23}$ −6 ° (*c* 0.7, methanol); IR (KBr): 1740 cm^{-1}; PMR (in $CDCl_3$–D_2O) δ: 1.75—2.3 (2H m, H-3,3′), 2.07 and 2.09 (each 3H s, Ac), 4.11 (1H q, H-6; J=6, 12 Hz), 4.41 (1H q, H-6′; J=3.5, 12 Hz), 4.3—4.55 (3H m, H-2,4,6), 5.23 (1H d, H-5; J=3.5, 5.5, 5.5 Hz), 6.08 (1H d, H-1; J=5.5 Hz); mass spectrum: *m/e* 274 (M^+ +1).

Found: C, 48.15; H, 5.41; N, 4.83%. Calcd for $C_{11}H_{15}NO_7$: C, 48.35; H, 5.53; N, 5.13%.

2-Amino-2, 3-dideoxy-L-ribo-hexopyranose Hydrochloride (1). A solution of **11** (28 mg) in 1M hydrochloric acid (0.9 ml) was kept at 40 °C for 17 hr. Evaporation *in vacuo* gave a syrup, which was precipitated from methanol–acetone to give a solid of **1**, 23 mg (78%); $[\alpha]_D^{23}$ −48.6 ° (*c* 1.4, water; final value) (D-isomer[5]), $[\alpha]_D^{25}$ +43.9 ° (water)); $R_{f\,2\text{-amino-2-deoxy-L-glucose}}$ 1.26 (ppc with 1-butanol–pyridine–water–acetic acid 6: 4:3: 1 and Toyo-Roshi No. 51 of Toyo-Roshi Co.).

Found: C, 36.45; H, 6.78; N, 6.82; Cl, 17.99%. Calcd for $C_6H_{13}NO_4 \cdot HCl$: C, 36.10; H, 7.07; N, 7.02; Cl, 17.76%.

The authors are grateful to Dr. Hamao Umezawa, Director of Institute of Microbial Chemistry, for his support and encouragement.

Influence of Anhydrous Hydrogen Fluoride on Hen Egg-White Lysozyme. II. Effects on Reduced Hen Egg-White Lysozyme

Saburo AIMOTO and Yasutsugu SHIMONISHI

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received October 8, 1975)

The influences of anhydrous hydrogen fluoride on reduced hen egg-white lysozyme were investigated under standard conditions for peptide synthesis. 1) Enzymatically fully active protein was recovered in poor yield (5%) from reduced hen egg-white lysozyme after treatment with hydrogen fluoride. 2) The yield (29—33%) was improved by addition of 1,4-butanedithiol or L-cysteine during treatment of reduced hen egg-white lysozyme with hydrogen fluoride. 3) Tetragonal crystals which were indistinguishable from those of native hen egg-white lysozyme were recovered after treatment of reduced hen egg-white lysozyme with hydrogen fluoride in the presence of 1,4-butanedithiol, anisole and amino acid derivatives. Thus, the original intact lysozyme could be recovered from an HF-solution of the reduced form.

In studies on the chemical synthesis of the well-characterized protein molecule, native hen egg-white lysozyme (HEL), we examined its recovery after exposure of this enzyme and its derivatives to anhydrous liquid hydrogen fluoride (HF) under usual conditions for peptide synthesis. In the previous paper[1] we reported the effect of HF on the native form of HEL under usual conditions of peptide synthesis and a method for recovering fully active HEL from an HF-solution of native HEL.

This paper reports studies on the influence of HF on the reduced form of HEL. It was found that when reduced HEL was treated with HF under usual conditions for peptide synthesis, its enzymatic activity decreased. In contrast when native HEL was treated with HF, fully active HEL was recovered in good yield (about 50%). Thus there was a difference in the effects of HF on the native and reduced forms of HEL. Next, the effect of thiol compounds during treatment of reduced HEL with HF was examined, because thiol compounds prevent modifications, such as oxidation of proteins. Studies were also made on the effect of treating reduced HEL with HF in the presence of amino acid derivatives, which liberate cations on treatment with HF. Anisole has generally been used as a scavenger of cations liberated from protected amino acids and peptides in acidic medium[2] or on treatment with HF[3]. Therefore, we also examined the effect of the presence of anisole in preliminary experiments on deblocking reactions of protected derivatives[4] of HEL. The results showed that intact, regenerated HEL could be recovered after treating reduced HEL with HF under conditions for peptide synthesis.

Experimental

Materials. Hen egg-white lysozyme (6×crystallized Lot. No. 7103) and spray-dried cells of *Micrococcus lysodeikticus* (Lot. No. 21—88—778) were purchased from Seikagaku Biochemicals (Tokyo). Sephadex was purchased from Pharmacia Co. (Uppsala). Hydrogen fluoride was a product of Daikin Ind. Co. (Osaka). Urea of reagent grade was recrystallized from ethanol before use. All other chemicals used were of analytical grade.

Treatment of Reduced HEL with HF. Reduced HEL was prepared from native HEL by the method of Saxena and Wetlaufer,[5] and after desalting, it was frozen and lyophilized. The freeze-dried powder of reduced HEL (*ca.* 15 mg) was treated with HF (9 ml) under similar conditions to those used with native HEL.[1] The residue of the HF-treated reduced HEL was dissolved in 0.2 M sodium phosphate buffer solution (15 ml) at pH 8.5 containing 1 M mercaptoethanol, 8 M urea and 0.2 mM EDTA·2Na and the solution was stirred overnight at room temperature. Then it was adjusted to below pH 4 by addition of glacial acetic acid and passed through a column of Sephadex G-10 (3.2×60 cm) in 1 M acetic acid. The fractions containing protein were collected and treated under the conditions described below for refolding reduced HEL. Then, the solution containing regenerated HEL was adjusted to pH 4.5—5 with glacial acetic acid. The regenerated HEL was adsorpted on a CM-cellulose column (carboxylic acid cycle), and eluted with 0.3 M sodium phosphate buffer solution at pH 8.0.

Refolding of Reduced HEL to Native HEL. Refolding of reduced HEL (*ca.* 10^{-6} M) to form native HEL was achieved in 0.08 M tris-buffer solution at pH 8.0 containing 5.4×10^{-3}M L-cysteine and 4.8×10^{-4} M L-cystine at 37 °C following the procedure of Saxena and Wetlaufer.[5]

Gel-filtration and Ion-exchange Chromatography of HF-treated Reduced HEL. HF-treated HEL refolded as described above was chromatographed on Sephadex G-50 (2×95 cm) using buffer containing 1M acetic acid and 5 M urea, using the method described in the previous paper.[1] The fractions separated by gel-filtration on Sephadex G-50 were chromatographed on Bio-rex 70 (1×78 cm) using 0.2 M sodium phosphate buffer solution at pH 7.18.

Enzyme Assays. The specific activity of HF-treated HEL was determined by measuring the initial rate of lysis of *Micrococcus lysodeikticus* cells spectrophotometrically at 540 nm following the method described previously,[1] with native HEL, purified on Sephadex G-50, as a standard.

Ultraviolet Spectra. UV-absorption spectra were measured using a Hitachi-spectrophotometer, type-124, equipped with a recording attachment. Spectra were measured at 25 °C.

Crystallization of HF-treated HEL. Crystallization was carried out by the method of Berthou and Jolles[6] with the modifications described in the previous paper.[1]

Results and Discussion

First reduced HEL was treated with HF at 0 °C for 60 min, since it has been found that intact HEL is recovered in good yield (about 50%), when native HEL is treated with HF under these conditions. The HF was completely evaporated off from the HF-solution

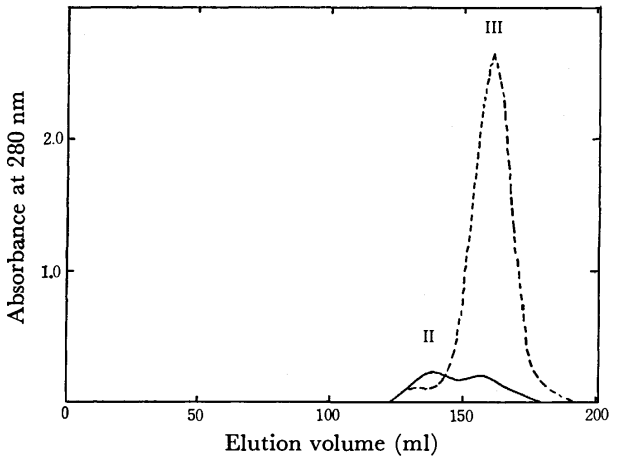

Fig. 1. Sephadex G-50 gel-filtration of reduced HEL after treatment with HF at 0 °C for 60 min and refolding at pH 8.0. The column (2.2×95 cm) was eluted with buffer containing 1M acetic acid and 5M urea. The flow rate was 10 ml per hr.
—: reduced HEL refolded after HF-treatment, — : reduced HEL refolded without HF-treatment.

of reduced HEL *in vacuo*, and the residue was mixed with 0.2 M sodium phosphate buffer solution at pH 8.5 containing 1 M mercaptoethanol, 8 M urea and 0.2 mM EDTA·2Na. This buffer was used because it was thought that reduced HEL might aggregate by forming random disulfide linkages in HF and that this buffer solution might dissociate the aggregates, because it has been used for reducing native enzyme.[5] In fact the residue did aggregate. However, the aggregates did not easily dissolve in this buffer solution. The supernatant was separated from aggregated material and desalted and then treated under the conditions used for refolding reduced HEL. The refolded protein was desalted, lyophilized and chromatographed on Sephadex G–50 in 1 M acetic acid and 5 M urea buffer solution, as shown in Fig. 1. The recovery of a fraction (named fraction III), eluted in the same position as native HEL, corresponded to only 5% of the original native HEL. The recovery of this fraction was low probably because reduced HEL aggregated to sparingly soluble material on treatment with HF.

Next, reduced HEL was treated with HF under the same conditions but in the presence of the thiol compounds listed in Table 1. The residue of HF-treated reduced HEL dissolved in 0.2 M sodium phosphate buffer solution containing 1 M mercaptoethanol, 8 M urea and 0.2 mM EDTA·2Na. This protein fraction was desalted by gel-filtration on Sephadex G-10, treated under the conditions leading to refolding of reduced HEL and then chromatographed on Sephadex G-50. It was found that the recovery of original HEL, eluted in the same position as native HEL, was improved considerably using L-cysteine or 1,4-butanedithiol as the thiol compound and was improved slightly using dithiothreitol. However, scarcely any fraction III was obtained using 2-mercaptoethanol. The chromatogram of regenerated protein on Sephadex G–50 obtained using 1,4-butanedithiol as a thiol compound is shown in Fig. 2. The amount of fraction III in Fig. 2 corresponds to the recovery shown in Table 1.

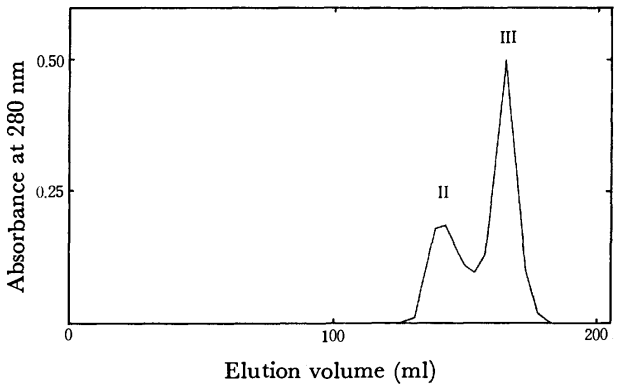

Fig. 2. Sephadex G-50 gel-filtration of reduced HEL after treatment with HF at 0 °C for 60 min in the presence of 1,4-butanedithiol and refolding at pH 8.0. The column (2.0×95 cm) was eluted with buffer containing 1M acetic acid and 5M urea. The flow rate was 10 ml per hr.

TABLE 1. EFFECTS OF THIOL COMPOUNDS ON THE RECOVERY OF FRACTION III FROM HF-TREATED REDUCED HEL

Exp. No.	Thiol compound	HF-treatment	Recovery of fraction III (%)	Specific activity[a] of fraction III (%)
1	—	—[b]	65	98
2	—	0 °C, 60 min	5	95
3	$HSCH_2CH_2OH$[c]	0 °C, 60 min	0—1	43
4	L-Cysteine·HCl ·H_2O[c]	0 °C, 60 min	24	97
5	L-Cysteine[c]	0 °C, 60 min	29	98
6	1,4-Butane-dithiol	0 °C, 60 min	33	99
7	Dithiothreitol[d]	0 °C, 60 min	19	100

a) 6x recrystallized HEL purified on Sephadex G-50 was used as a standard, b) reduced HEL was refolded without HF-treatment, c) 0.8 mmole of thiol compound was added per μmol of protein, d) 0.4 mmole of thiol compound was added per μmol of protein.

Next, we made preliminary experiments on the effect of removal of protecting groups from protected derivatives[4] of HEL. Reduced HEL was first treated with HF in the presence of anisole. 1,4-Butanedithiol was also added to the reaction mixture, because among the thiol compounds tested it caused the greatest improvement in recovery of the original enzyme, as shown in Table 1. When reduced HEL was treated with HF at 0 °C for 60 min with 1,4-butanedithiol, the recovery of the original enzyme was 14% in the presence of anisole and 33% in its absence. The reason for this lower recovery in the presence of anisole seemed to be that the excess anisole could not easily be removed from the HF-reaction mixture, so that the HF could not be removed rapidly. On increase in the time of reaction (120—240 min) of reduced HEL with HF at 0 °C, the amount of fraction III decreased. Furthermore, the yield of fraction III was very low when reduced HEL was treated with HF at a higher temperature (25 °C), even after reaction for only 30 min. These results are summarized in Table 2.

Table 2. Recoveries (%) of fraction III, from reduced HEL (15 mg) treated with HF (9 ml) under various conditions in the presence of 1,4-butanedithiol (0.3 ml) and anisole (1 ml), refolded at pH 8.0 and chromatographed on Sephadex G-50

	30 min	60 min	120 min	240 min
0 °C	17	14	4.1	2.4
25 °C	1.1	0.5	0.6	0.3

Reduced HEL was treated with HF in the presence of anisole, 1,4-butanedithiol and amino acid derivatives, which bind protecting groups and liberate them as cations on treatment with HF. The amino acid derivatives used were N^{ε}-benzyloxycarbonyl-L-lysine, N^{α}-benzyloxycarbonyl-*S*-benzyl-L-cysteine and *S*-*p*-methoxybenzyl-L-cysteine which liberate the benzyl group on treatment with HF, N^{α}-benzyloxycarbonyl-N^{ω}-tosyl-L-arginine which liberates a tosyl group, *t*-butyloxycarbonyl-glycine which liberate a *t*-butyl group and N^{ω}-nitro-L-arginine which liberates a nitro group. The results in Table 3 show that most of these amino acid derivatives did not affect the yield of fraction III but N^{ω}-nitro-L-arginine decreased the yield greatly. The reason for this is unknown.

Table 3. Effects of various amino acid derivatives on the recovery of fraction III from HF-treated reduced HEL

Exp. No.	Amino acid derivative	(mmole)[a]	Recovery of fraction III (%)
1	H-Lys(Z)-OH	1.0	13
2	Z-Cys(Bzl)-OH	0.5	15
3	H-Cys(Bzl(OMe))-OH	1.0	13
4	Z-Arg(Tos)-OH	1.0	16
5	Boc-Gly-OH	1.0	14
6	H-Arg(NO_2)-OH	1.0	3

a) Reduced HEL (15 mg), 1,4-butanedithiol (0.3 ml), anisole (1 ml) and the indicated amino acid derivatives (0.5 mmol or 1.0 mmol) were mixed and treated with HF (9 ml) at 0 °C for 60 min.

Reduced HEL was treated with HF 0 °C for 60 min in the presence of the mixture of amino acid derivatives given in Fig. 3. The regenerated protein fraction was chromatographed on Sephadex G-50 using buffer solution containing 1 M acetic acid and 5 M urea, as shown in Fig. 3. The amount of fraction III obtained was 33% of the initial amount of enzyme. This yield was better than those obtained on treatment of reduced HEL with HF in the presence of any of the amino acid derivatives alone. When fraction III of Fig. 3 was subjected to chromatography on Bio-rex 70 at pH 7.18, the main fraction eluted in the position of native HEL (Fig. 4) was fully active on *Micrococcus lysodeikticus* cells, and it had the same UV-spectrum as native HEL, as shown in Fig. 5. During this chromatography, a fairly large fraction with biological activity was eluted in front of the main fraction, but its properties were not examined. The main fraction in Fig. 4 was desalted on Sephadex G-10 and lyophilized. The lyophilized

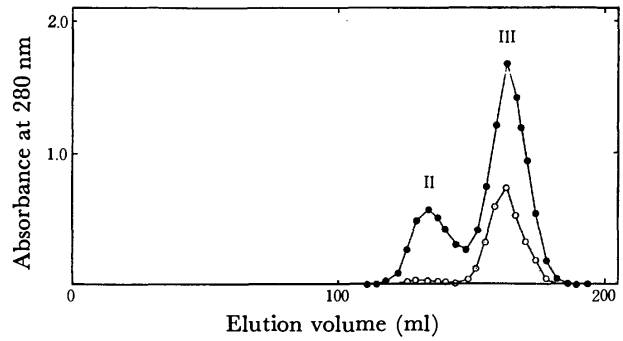

Fig. 3. Sephadex G-50 gel-filtration of reduced HEL treated with HF. The column (2.0×95 cm) was eluted with buffer containing 1M acid acetic and 5M urea. Reduced HEL (38 mg) was mixed with anisole (1.5 ml, 14 mmol), 1,4-butanedithiol (1.0 ml, 8.8 mmol), Z-Arg(Tos)-OH (231 mg, 0.5 mmol), H-Cys (Bzl)-OH (106 mg, 0.5 mmol), H-Cys(Bzl(OMe))-OH·HCl (130 mg, 0.5 mmol) and Boc-Gly-OH (88 mg, 0.5 mmol), treated with HF (15 ml) and refolded at pH 8.0. -●-: HF-treated reduced HEL, -○-: Native HEL.

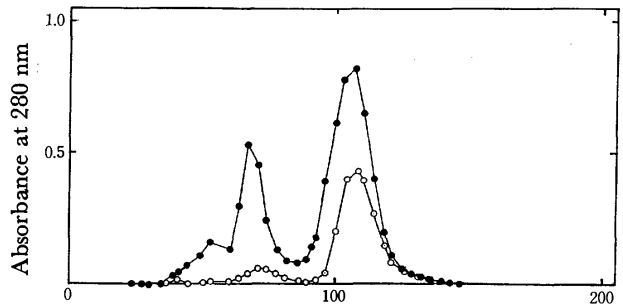

Fig. 4. Ion-exchange chromatogram of HEL on Bio-rex 70. The column (1×78 cm) was eluted with 0.2 M sodium phosphate buffer solution (pH 7.18). The flow rate was 16 ml per hr.
-●-: Fraction III of Fig. 3, -○-: Native HEL.

Table 4. Effects of various compounds on the recovery of fraction III from HF-treated native HEL

Compound	Average recovery of fraction III (%)	Ratio
1) —[a]	65	100
2) None	25	38
3) 1,4-Butanedithiol[b]	36	55
4) L-Cysteine[b]	32	49
5) L-Cysteine·HCl·H_2O[b]	32	49
6) $HSCH_2CH_2OH$[b]	0	0
7) L-Methionine[b]	34	52
8) L-Alanine[c]	26	40
9) L-Tryptophan[d]	18	28
10) L-Tryptophan[e]	3	5
11) L-Tryptophan[f]	0	0

a) Native HEL was reduced and refolded without HF-treatment. The amounts of compounds added per μmole of native HEL were: b) 2.5 mmol, c) 4.0 mmole, d) 0.5 mmol, e) 1.8 mmol and f) 2.4 mmol.

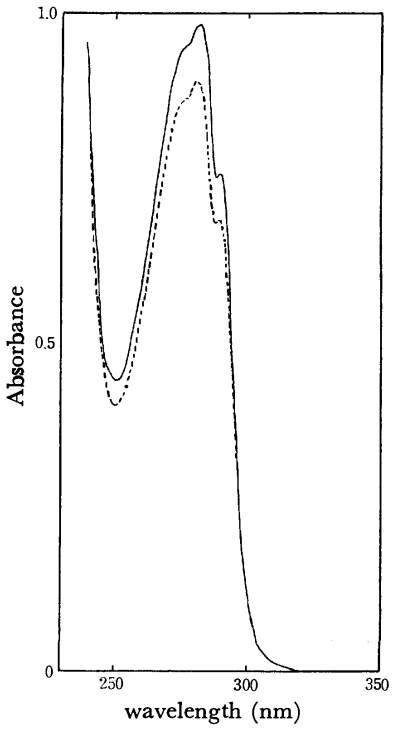

Fig. 5. Ultra-violet absorption spectra of the main fraction of Fig. 4 (—) and native HEL (—). Solvent: 0.2 M sodium phosphate buffer (pH 7.18).

powder was treated under conditions inducing crystallization. The crystals obtained were like those of native HEL, as shown in Fig. 6.

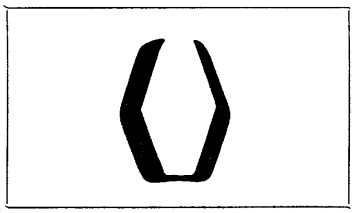

Fig. 6. Microphotograph of crystals of the material from the main fraction of Fig. 4. Crystals were obtained by the method of Berthou and Jolles.[6]

Native HEL was treated with HF under the same conditions as reduced HEL in the presence of various thiol compounds. After treatments similar to those used with reduced HEL the regenerated protein was subjected to chromatography on Sephadex G-50 using buffer solution containing 1 M acetic acid and 5 M urea. The yields of fraction III, eluted at the same position as native HEL, are summarized in Table 4. The recovery of the original enzyme from native HEL treated with in the presence of 1,4-butanedithiol and L-cysteine were 32 and 36%, respectively, while the recovery of original enzyme from native HEL treated with HF in the absence of thiol compounds was 25%. Thus thiol compounds also improved the yield on treatment of native HEL with HF. Since native HEL aggregates slightly in HF,[1] the thiol compounds seemed to prevent both this aggregation and also structural modification of HEL. It was also found that the presence of L-tryptophan during treatment of native HEL with HF greatly decreased the recovery of the original enzyme under the present conditions (Table 4).

The present results show that material with similar properties to original HEL could be recovered in fairly good yield and also in a crystalline state after treatment of reduced HEL with HF in the presence of a thiol compound such as 1,4-butanedithiol under usual conditions for peptide synthesis. In further studies on the chemical synthesis of HEL attempts are in progress to recover HEL with the same properties as native HEL from the *N*-benzyloxycarbonyl derivative of native HEL and the *S*-*p*-methoxybenzyl-derivative of reduced HEL.[4]

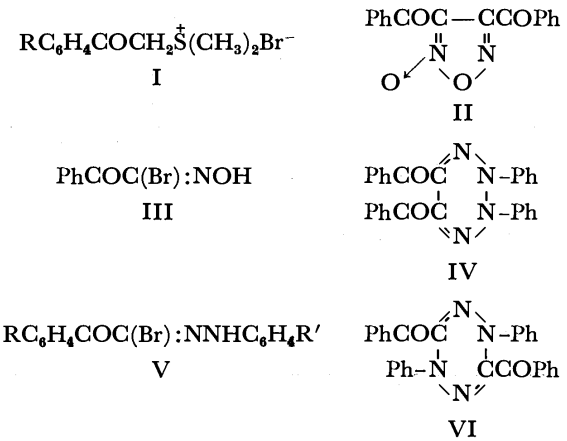
(Received December 7, 1974)

The azo coupling of dimethylphenacylsulfonium bromides (I) with *N*-nitrosoacetanilides in nonaqueous solvents, and with diazotized aniline in aqueous media gave 2-bromophenylglyoxal 2-arylhydrazones (V) and the tetrazine (VI), respectively. V reacted with nucleophiles displacing the bromide. Treatment of V with bases gave VI *via* benzoylphenylnitrilimine (X). 1,3-Dipolar cycloadditions of X onto ethyl acrylate and acrylonitrile afforded the expected cycloadducts. The mechanisms of the reactions are outlined.

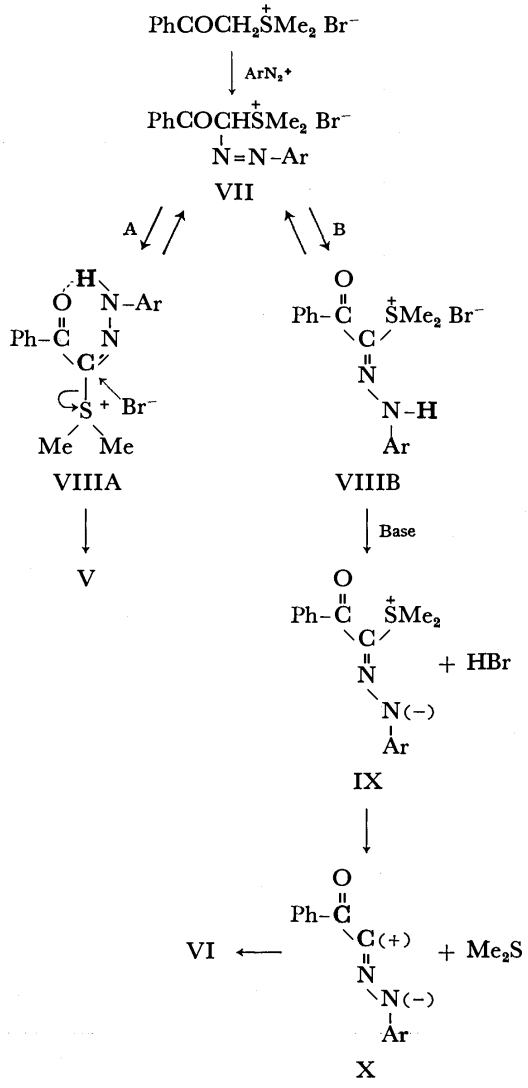
Recently it has been reported that the nitrosation of dimethylphenacylsulfonium bromide (Ia) affords II[1] or III[2] depending on the reaction conditions. In view of the similarity between the azo coupling and nitrosation reaction, it was of interest to investigate the azo coupling of I in aqueous and nonaquous media to see whether or not similar effects would be observed. An earlier report[3] claimed that coupling of benzenediazonium sulfate to Ia gives IV. The structure of the latter cannot be sustained, however. The azo coupling of I in nonaqueous media has not yet been explored. We now report the results of this reaction and some properties of the product formed.



a, R=H; b, R=4-Me; c, R=4-Br; d, R=4-NO_2

Results and Discussion

Treatment of Ia with *N*-nitrosoacetanilide in ether gave 2-bromophenylglyoxal 2-phenylhydrazone (Va, R=R′=H). The latter was also obtained when other organic solvents were used in place of ether. The structure of Va was established by elemental analysis, by molecular weight determination, and by analysis of its spectra (see Experimental). The reactions summarized in Scheme 2 also support structure Va for the reaction product. Similar treatments of Ib—d with *N*-nitrosoacetanilides in EtOH gave the products Vb—g (Table1).



A, in nonaqueous media; B, in aqueous media

Scheme 1.

Reaction of Ia with benzenediazonium chloride in NaOAc buffered solutions gave 1,4-diphenyl-3,6-dibenzoyl-1,4-dihydro-1,2,4,5-tetrazine (VI). The latter was identified by mixed melting point with an authentic sample[4] and by spectral analysis. In addition, the formation of VI from Va upon treatment with bases

* To whom all inquiries should be addressed.

supports its structure. These results indicate that the diazonium coupling product of Ia in aqueous media is VI, and not IV as proposed[3] previously.

The probable mechanism that accounts for the foregoing results is presented in Scheme 1. It is assumed that the configurations of the hydrazone intermediate VIII in the solvents determined the products obtained.[1]

A brief chemical study of the product V is summarized in Scheme 2. The results show that V is highly reactive and reacts with nucleophiles with displacement of its halogen atom, and with bases to form the 1,3-dipolar intermediate X, that readily undergoes dimerization and 1,3-dipolar cycloaddition reactions. The structures of the products XI—XV follow from their method of preparation, the physical data, and their independent syntheses. The orientation of the cycloadditions of X

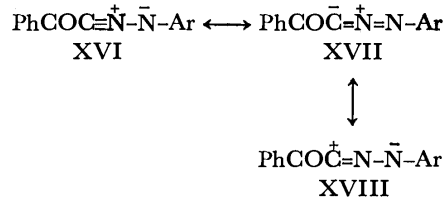
can be interpreted in a manner similar to that proposed for benzoyl cyanide *N*-oxide;[11] *i.e.*, the resonance structures of X would be XVI, XVII, and XVIII, and its principal polarized structure would be XVIII:



Experimental

Mp's are uncorrected. IR and UV spectra were recorded on Unicam SP1000 and Unicam SP8000 spectrophotometers respectively. NMR spectra were recorded on Varian T60-A spectrometer with TMS as an internal standard. Microanalyses were carried out by Alfred Bernhardt, Mikroanalytisches Laboratorium, West Germany.

Reaction of I with N-Nitrosoacetanilides. A mixture of Ia[9] (0.1 mol) and *N*-nitrosoacetanilide[10] (0.12 mol) was stirred in ether for 8 hr at room temperature. Removal of the solvent gave Va (62%), mp 114 °C (EtOH); spectral characteristics: ν_{max} (KBr) 1650 (PhCO), β3240 (NH) cm^{-1}; λ_{max}^{EtOH} (log ε) 372 (4.169), 253 (4.257) nm; δ ($CDCl_3$) 7.5—6.5 (m, 10, ArH), 8.05 (s, 1, NH) ppm. The product Va was also obtained (55—80%) when the reaction was repeated using dioxane, chloroform, acetone, or EtOH in place of ether. The products Vb—g (Table 1) were similarly prepared using EtOH as a solvent.

Reaction of Ia with Benzenediazonium Chloride. To Ia (0.02 mol) in 50 ml EtOH was added NaOAc (8 g, in 30 ml water). The mixture was chilled (0—5 °C), vigorously stirred, treated dropwise (25 min) with PhN_2Cl (0.021 mol), and kept in an ice chest (3 hr). The solid was collected, washed with water, and recrystallized from EtOH to give VI (67%), mp and mixed mp[4] 198 °C; λ_{max}^{EtOH} (log ε): 390 (2.749), 290sh (4.412), 265 (4.542); IR ν_{max} (KBr) 1670 (PhCO) cm^{-1}, NH band was absent; its NMR spectrum ($CDCl_3$) showed only an aromatic proton multiplet.

Reaction of Va with Bases. A mixture of Va (0.01 mol) in EtOH (30 ml) and NaOAc (1 g) in water (5 ml) was refluxed for 30 min and cooled. Working up the reaction mixture gave VI (70%); mp and mixed mp with the sample above 198 °C. VI was similarly obtained by using one equivalent of NaOH or two equivalents of Et_3N in place of NaOAc.

Reactions of V with Nucleophiles, General. Equimolecular quantities of V and the appropriate nucleophile (NaSAr, NaO_2SAr, or NaCN) in EtOH were stirred for 0.5—2 hr and left overnight at room temperature. The product was collected, washed with water and recrystallized from EtOH or AcOH. The compounds XI—XIII prepared are listed in Tables 2—4. The products XIIh and XIIIa proved to be identical with authentic samples.[6,7] Reaction of Va with NaOPh, when carried out in a similar manner, gave VI (68%). IR (KBr) of XII showed bands at 1314 and 1140 cm^{-1} due to $-SO_2-$ asymmetric and symmetric stretchings, and that of XIII exhibited a nitrile band at 2225 cm^{-1}. Both XII and XIII showed common bands at 1650 (PhCO) and 3260—3220 (hydrazone NH) cm^{-1}. UV spectral characteristics of XI—XIII are given in Tables 2—4.

Oxidation of XI. To a solution of XI (2 mmol) in AcOH was added 2 ml of hydrogen peroxide solution (33%); the mixture was left for two days at room temperature, then poured on water. Recrystallization of the product from AcOH gave the corresponding XII (73—78%). Mixed mp with samples prepared above showed no depression.

Formation of XIV and XV, General. A stirred cold solution of equimolecular quantities (5 mmol each) of V and ethyl acrylate (or acrylonitrile) in dry benzene (50 ml) was treated dropwise (30 min) with triethylamine (0.4 ml) in 10 ml of benzene. The mixture was then refluxed for 30 min and left overnight at room temperature, and filtered. The oil residue left after removal of the solvent solidified on trituration with petroleum ether (60/80 °C). Recrystallization from EtOH gave XIV (and XV) (Table 5) in 50—60% yields. The spectral characteristics of XIVa and XVb, taken as typical examples of the series prepared, are as follows: XIVa: ν_{max} (KBr) 1650 (3-PhCO), 1755 (5-EtOCO) cm^{-1}; δ ($CDCl_3$) 7.0—8.5 (m, 10, ArH), 4.95 (t, 1, J=10 Hz, 5-CH), 3.65 (d, 2, J=10 Hz, 4-CH_2), 4.25 (q, 2, J=7 Hz, $-COO\underline{CH_2}-CH_3$), 1.25 (t, 3, J=7 Hz, $-COOCH_2-\underline{CH_3}$) ppm. XVa: ν_{max} (KBr) 1650 (PhCO) cm^{-1}; δ ($CDCl_3$) 7.1—8.5 (m, 10, ArH), 3.77 (d, 2, J=10.5 Hz, 4-CH_2), 5.12 (t, 1, J=10.5 Hz, 5-CH) ppm. The UV maxima of XIV and XV are given in Table 5. The absence of nitrile absorption in the IR spectrum of XVa supports its 5-cyano structure.[8]

Threshold Switching of Violanthrone in a Sandwich-type Cell

Yoshihiko SADAOKA and Yoshiro SAKAI

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received July 9, 1975)

Synopsis. Threshold switching between two impedance states has been observed at room temperature in a sandwich-type cell of violanthrone thin film with the use of silver electrodes. The conductivity of the "on state" is larger than that of the "off state" by a factor of 10^4.

Memory- and threshold-switching phenomena have recently received considerable attention. They were observed in many inorganic compounds,[1,2] memory-switching being observed in evaporated aromatic hydrocarbon thin films[3,4] and in electron-beam-deposited polymer films.[5] In a previous paper[6] we reported the memory switching in a surface-type cell of pyranthrone film.

In the present work threshold switching has been observed in evaporated thin violanthrone film sandwiched between silver electrodes.

Experimental

Violanthrone was purified by sublimation *in vacuo* (10^{-6} Torr). The geometry of the sample was of sandwich type, where violanthrone was deposited over a silver electrode prepared by vacuum evaporation onto the glass substrate through an etched stainless steel mask, the counter silver electrode being plated on top of the film. A schematic illustration of the sample is given in Fig. 1. The lead wires were placed on the electrodes by means of silver paste. The area of the electrode was *ca.* 0.01 cm^2 and the thickness of the violanthrone layer *ca.* 100 nm. Switching behaviour was observed with an AC generator and a synchroscope. Electrical measurements were carried out in the atmosphere.

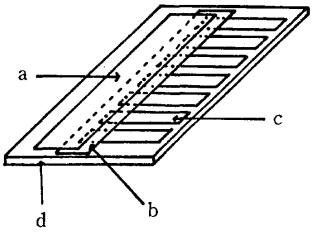

Fig. 1. Sandwich-type cell.
(a) silver electrode, (b) violanthrone film, (c) counter silver electrode, (d) microscope slide.

The microscopic distribution of the temperature on the surface of the sample during the course of switching was recorded with a Nikon 725 thermal plotter having an InSb infrared detector. The detectable spot size with this apparatus is 22 μm and the position of the view can be shifted with the aid of a mobile stage. The state of the film during switching was also observed with an optical microscope. Inspection under the polarizing microscope and the scanning electron microscope showed that the freshly prepared violanthrone films are essentially amorphous.

Results and Discussion

A typical current variation with the applied voltage of 60 Hz for the reversible threshold switching device of violanthrone of the sandwich type is shown in Fig. 2. The film has very low conductance ("off state") as long as the applied voltage is lower than a certain value, so that the current-voltage curve can not be observed in this region. When the voltage exceeded the threshold value, the conductance abruptly increased to the order of 10^{-5} ohm^{-1} and the curve (a) in Fig. 2 appeared. This state is called "on state". The threshold voltage for this device was estimated to be *ca.* 10 V.

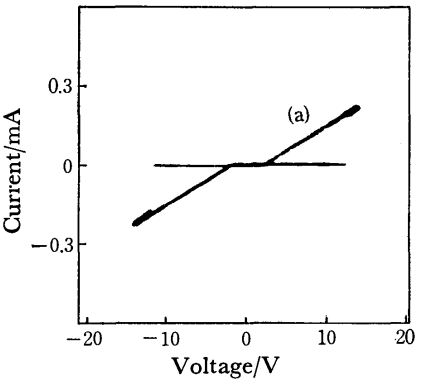

Fig. 2. Response of switching device to 60 Hz voltage.

In general, switching has been interpreted in terms of either a purely electronic effect or a thermal effect. The thermal effect interpretation is based on the premise that the highly localized Joule-heating is occasionally accompanied by structural changes such as crystallization. However, in the present case no difference in temperature was observed on the sample between the switching state and the non-switching state with the aid of a thermal plotter. Inspection of the film under the optical microscope showed no changes after the stable switching had occurred. In some cases unstable switching curves were obtained. In such cases the structural changes were observed during the switching. Observation with the thermal plotter revealed that an electrothermal breakdown had occurred. Thus the electronic effect is distinguishable from the electrothermal effect.

In order to elucidate the switching mechanism, it is desirable to investigate the effect of the film thickness on the switching. However, since it was difficult to prepare a thick and uniform film, surface type cells with various electrode distances were prepared. The minimum distance was 4×10^{-3} cm. In the surface type cell having an electrode distance of 4×10^{-3} cm or more, the

high field conduction in the high resistance state was found to agree with the Richardson-Schottky equation,[7] $\sigma=\sigma_0\exp(\beta_s V^{1/2}/d^{1/2}kT)$. This indicates the existence of the potential barrier at the violanthrone-electrode contact. The thickness of the space-charge-layer was estimated to be 10^{-3} cm.

No reversible threshold switching* occurred in the surface type cell of violanthrone having an electrode distance larger than the thickness of the space-charge-layer and an inspection of the film under the optical microscope showed no change after the threshold switching had occurred in the sandwich type cell of violanthrone. Therefore the threshold switching in the sandwich type cell having an electrode distance smaller than the thickness of the space-charge-layer may be interpreted in terms of the electronic effect such as space-charge-overlap.

* Although the transformation from the "off state" to the "on state" accompanied by structural changes at both interfaces of violanthrone-metal contacts was observed in the surface type cell, the "on state" could not be quenched by lowering the applied voltage in contrast to the case of pyranthrone.[6]

Absorption Spectrum of the Aggregated Radical Anion of Sulfur Dioxide Produced by γ-Irradiation

Osamu Ito, Shigeru Kuwashima, and Minoru Matsuda

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received September 18, 1975)

Synopsis. By γ-irradiation of sulfur dioxide in 2-methyltetrahydrofuran at -196 °C, blue glassy solution was obtained, although the monomer radical anion of sulfur dioxide was colorless. The absorption spectrum of the blue species was identical with that of the stable radical anion produced by the amalgam reduction of sulfur dioxide, which was attributed to the dimer or trimer radical anion.

The dimer radical cations formed by the γ-irradiation of aromatic hydrocarbons have been identified by the absorption bands appearing in the longer wavelength region than those of the monomer radical cations.[1] Recently, the dimer radical anions were studied by means of the absorption and ESR spectra.[2] From these studies, it is revealed that if the dimer or trimer radical anion in which an unpaired electron is delocalized was formed, it would be distinguishable from the monomer one by the characteristic absorption band. In this note, we will report that the γ-irradiation of SO_2 gives a colored radical anion at -196 °C, although a monomer one has been known to be colorless.[3]

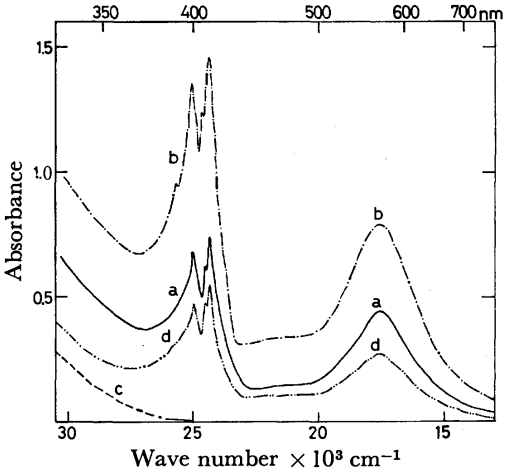

Fig. 1. Absorption spectra of the radical anion formed by γ-irradiation of SO_2 in MTHF at -196 °C (2 mm cell length).
a: $[SO_2]=0.15$ mol/l, b: after thermal annealing of a,
c: $[SO_2]=0.05$ mol/l, d: after thermal annealing of c.

γ-Irradiation of the concentrated SO_2 solution (>0.1 mol/l) in 2-methyltetrahydrofuran (MTHF) at -196 °C gave a blue glassy solution and the absorption bands appeared at 566 nm (band I) and 410 nm (band II) as shown in Fig. 1-a. When the blue glassy solution was warmed slightly, the solution changed to deep blue. By thermal annealing the intensities of the bands I and II, which were observed after recooling to -196 °C, increased with the same proportion without the shift of the positions of the absorption maxima (Fig. 1-b). By the γ-irradiation of the dilute SO_2 solution (<0.05 mol/l), the colorless solution was obtained and only the tail of absorption band appeared at shorter wavelength than 360 nm (Fig. 1-c). By slight melting, this colorless glassy solution turned to a blue solution, whose absorption maxima (Fig. 1-d) were the same as those obtained by the γ-irradiation of the concentrated solution (Fig. 1-a and -b). This suggests that the anionic species, probably monomer radical anion (SO_2^-), exists in the γ-irradiated colorless glass and the blue species, probably aggregated radical anion, may be formed by the collision of SO_2^- and SO_2 by thermal annealing. Although the absorption band due to SO_2^- was observed at 360 nm in aqueous solution by means of flash photolysis[3] and pulse radiolysis,[4] any clear peak was not observed at this region in MTHF glass. However, since SO_2^- may interact strongly with H_2O, this difference can be caused by the solvent effect on the electronic transition and the tail of the absorption band shown in Fig. 1-c may be attributed to SO_2^- in MTHF. Since the blue species was also formed by the γ-irradiation of the crystalline SO_2 at -196 °C, the blue species could not attributed to the reaction products formed by MTHF and SO_2. Furthermore, if SO and SO_3 were formed by γ-irradiation at -196 °C, SO^- and SO_3^- and their aggregates with SO_2 such as $SO^-(SO_2)_n$ and $SO_3^-(SO_2)_n$ must be taken into consideration as blue species. However, SO^-, SO_3^-, and $S_2O_3^-$ were known to be colorless in aqueous solution[3] or in crystalline phase.[5]

The results above indicate the following facts clearly; a) the absorption bands I and II shown in Fig. 1 were attributed to an identical species, since the relative intensities of both bands did not change by the thermal annealing, and b) the blue species increased by thermal annealing was identical with the blue species directly formed by the γ-irradiation of the concentrated solution, since the appreciable shift of the positions of the absorption maxima was not observed by thermal annealing. These results suggest that the blue radical anion can be attributed to the aggregated radical anion of sulfur dioxide, $(SO_2)_n^-$, which may be produced by the following scheme of reactions;

$$n\ SO_2 \rightleftharpoons (SO_2)_n \quad (1)$$

$$MTHF \xrightarrow{\gamma} MTHF^+ + e^- \quad (2)$$

$$(SO_2)_n + e^- \longrightarrow (SO_2)_n^- \quad (3)$$

$$SO_2 + e^- \longrightarrow SO_2^- \quad (4)$$

$$SO_2^- + n-1\ SO_2 \longrightarrow (SO_2)_n^- \quad (5)$$

The formation of the blue species by γ-irradiation of the concentrated solution indicates that the self-association of SO_2 occurred in MTHF at -196 °C before irradiation (reactions (1) and (3)),[6] or SO_2 migrated in MTHF

glass during γ-irradiation (reaction (5)). Increasing of the blue species by the thermal annealing may suggest that the collision of SO_2 and $SO_2^{\cdot-}$ (reaction (5)) occurs before $SO_2^{\cdot-}$ encounters with cationic species in MTHF glass. By the experiments of γ-irradiation, however, any information about a value n in $(SO_2)_n^{\cdot-}$ could not be obtained.

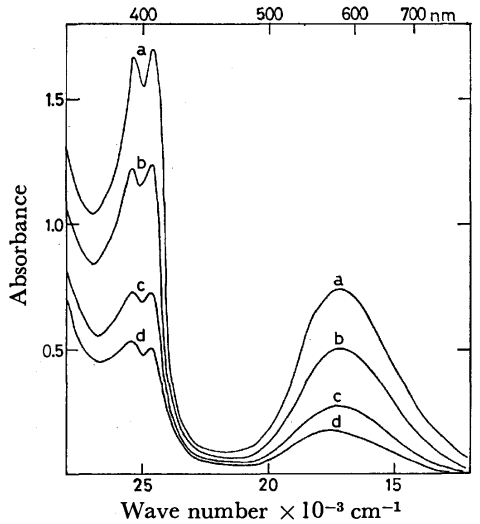

Fig. 2. Absorption spectra of the radical anion formed by sodium amalgam reduction of SO_2 in DMF at various temperatures ($[SO_2]=0.15$ mol/l in 2mm cell). a: 19 °C, b: 0 °C, c: −10 °C, d: −20 °C.

On the other hand, it is reported by Rinker and Lynn that the sodium amalgam reduction of SO_2 gave a stable radical anion having blue color in aprotic solvents.[7] The absorption spectrum of the stable species in dimethylformamide (DMF) was shown in Fig. 2. This absorption spectrum was essentially the same as that of the blue species obtained by γ-irradiation of SO_2. There is no doubt about that both blue species are the identical species. For the stable blue species formed by amalgam reduction or by electrolysis, two different structures have been speculated; bonded dimer radical anion ($O_2\bar{S}$–$\dot{S}O_2 \leftrightarrow O_2\dot{S}$–$\bar{S}O_2$) by Rinker and Lynn[7] and associated trimer ($(SO_2)^{\cdot-}(SO_2)_2$) by Dinse and Möbius.[8]

Before elucidating the structure of the stable blue species, we found that a diamagnetic colorless species coexist with the radical anion in the solution reduced by amalgam. As shown in Fig. 2, with varying temperature the intensities of the two bands at 580 nm (band I) and 400 nm (band II) changed in the same proportion reversibly. Increasing in the intensities of the bands was observed up to 70 °C, and upper limit may exist at higher temperature. With lowering temperature, the intensity of a singlet ESR signal ($g=2.006$) decreased with the same proportion of the intensities of the absorption bands I and II. Thus, it is apparent that the reversible change was caused by the equilibrium between the radical anion and a diamagnetic colorless species, probably a higher aggregate. From this fact it is impossible to elucidate whether the blue species can be attributed to the dimer or trimer radical anion.

It is noteworthy that the absorption spectra of $(SO_2)_n^{\cdot-}$ resemble that of the disulfone radical anion ($(R\text{–}SO_2\text{–}SO_2\text{–}R)^{\cdot-}$).[9] The dialkyl disulfone radical anion showed the absorption bands at 690 nm and 350 nm, although the dialkyl monosulfone radical anion showed a band at 400 nm. In the disulfone radical anion, the absorption band appearing at 690 nm was assigned to the transition having charge-resonance character, which indicates that an unpaired electron is delocalized between two sulfone moieties. Recently Kerr and Williams studied the radical anion of sulfuryl chloride (SO_2Cl_2) by means of the ESR measurements and proposed that $(SO_2Cl_2)^{\cdot-}$ can be thought as a resonance hybrid of ($SO_2^{\cdot-}$, Cl_2) and (SO_2, $Cl_2^{\cdot-}$) or equivalently, as radical anion complex in which the two molecules share an unpaired electron.[10] Supposing that the absorption bands of $(SO_2)_n^{\cdot-}$ appearing at 560—580 nm were assigned to the transition having charge-resonance character, $(SO_2)_n^{\cdot-}$ can be thought as that two or three SO_2 molecules share an unpaired electron in the dimer or trimer radical anion.[11]

11) There are some suggestions that the dimer radical anion is more probable than trimer one, although they are not sufficient. One of them is as follows; estimated value $n=2$ in $(SO_2)^{\cdot-}(SO_2)_n$ by Dinse and Möbius may be slightly larger, since the total intensities of the two ESR signals assigned to the monomer and trimer radical anions decreased with lowering temperature, indicating the formation of the diamagnetic species even by the electrolysis.[8]

Dielectric Behavior of *N*-Methylacetamide

Koichi ITOH, Hiroshi SATO, Hiroaki TAKAHASHI, and Keniti HIGASI
Department of Chemistry, Waseda University, Shinjuku, Tokyo 160

(Received September 27, 1975)

Synopsis. The dielectric constants and losses of liquid *N*-methylacetamide were measured in the frequency range 0.356—2.10 GHz at 31.4 °C. The result provides a definitive evidence for the validity of the simple Debye equation for the dielectric relaxation process of liquid *N*-methylacetamide.

The molecular structure of *N*-methylacetamide has been intensively studied by various physical methods. Infrared and Raman spectra,[1,2] dipole moment,[3] and electron diffraction[4] have been measured and discussed. Bass *et al.*[5] studied dielectric relaxation, but not in a sufficiently wide frequency range. They employed only the VHF range of 1—250 MHz. The present note provides complementary dielectric data for liquid *N*-methylacetamide in view of its great importance as a model compound of biological materials.

Experimental

Commercial *N*-methylacetamide was purified by vacuum distillation prior to use. The purity was examined by measurements of the infrared spectra.

Dielectric constants, ε', and losses, ε'', were measured at 31.4°C at the UHF frequencies of 0.356, 0.516, 0.698, 1.00, 1.50, and 2.10 GHz with an equipment reported in previous papers.[6,10] The errors of the measurement are of the order of a few per cent.

Relaxation time, τ, and the limiting low- and high-frequency dielectric constants, ε_0 and ε_∞, respectively, were calculated by the Debye equation:

$$\varepsilon' - j\varepsilon'' = \varepsilon_\infty + \frac{\varepsilon_0 - \varepsilon_\infty}{1 + j\omega\tau} \qquad (1)$$

where ω is the angular frequency. An iterative method by an electric computer was used for the calculation.

Results and Discussion

The ε' and ε'' values observed at 31.4 °C are summarized in Table 1. Figure 1 shows the Cole-Cole diagram (dashed line) constructed from the UHF data obtained by the present writers and the VHF data provided by Bass *et al.*[5] We see that all the measured points lie in a semi-circle with its center in the ε' axis.

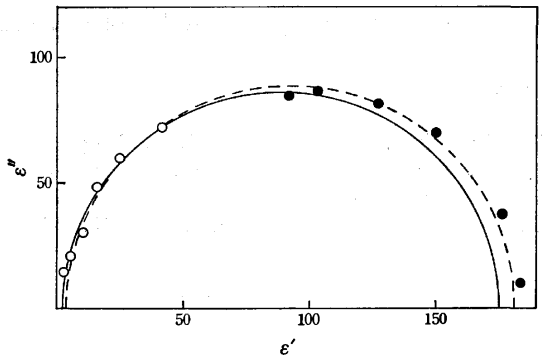

Fig. 1. Cole-Cole plots for liquid *N*-methylacetamide at 31.4 °C: open circles, results of the present investigation; closed circles, literature values from S. J. Bass *et al.*[5] The solid line corresponds to the values of ε_0, ε_∞, and τ of 175.5, 2.37, and 808 ps, respectively, and the dashed line to the values of 181.5, 3.44, and 769 ps, respectively.

Table 1. The observed and calculated ε' and ε'' values of liquid *N*-methylacetamide at 31.4 °C

Frequency (GHz)	ε'		ε''	
	Obsd	Calcd	Obsd	Calcd
2.10	2.43	3.87	14.4	16.0
1.50	5.28	5.31	21.0	22.4
1.00	10.4	8.80	30.3	32.8
0.698	15.7	15.1	48.3	45.3
0.516	25.0	24.4	59.9	57.7
0.356	41.8	42.9	71.9	73.3

The values of the parameters, ε_0, ε_∞ and τ, calculated by Eq. (1) and ε'_{obsd} and ε''_{obsd} in Table 1 are 175.5, 2.37, and 808 ps, respectively. The semi-circle (solid line, Fig. 1) is drawn with the use of this set of parameters. The values of ε'_{calcd} and ε''_{calcd} (Table 1) are those calculated by using the same values of the parameters. If the VHF values of ε' and ε'' reported by Bass *et al.*[5] are included in the calculation, the values of ε_0, ε_∞, and τ become 181.5, 3.44, and 769 ps, respectively—this set of parameters gives the semi-circle (dashed line, Fig. 1).

The experimental values were examined also by the use of the Cole-Cole equation:

$$\varepsilon' - j\varepsilon'' = \varepsilon_\infty + \frac{\varepsilon_0 - \varepsilon_\infty}{1 + (j\omega\tau)^{1-\alpha}} \qquad (2)$$

The distribution parameter, $\alpha=0$, was also obtained, confirming that the dielectric dispersion of liquid *N*-methylacetamide is of the Debye type.

The static dielectric constant of *N*-methylacetamide was reported to be 177.0 at 31.4 °C[5] which lies between 175.5 and 181.5 obtained in this work. The refractive index, n_D, of *N*-methylacetamide is reported to be 1.4185.[5] The fact that ε_∞ is larger than n_D^2 only by 15% suggests that the second and third dielectric relaxations in a higher frequency region, if they exist at all, would have very small values of dielectric absorption.

The results seem to show that all the data for *N*-methylacetamide can be represented by the simple Debye equation. As in the case of the principal dispersion of alcohols, the dielectric relaxation of this substance is governed by the simple exponential decay process. All the existing theories explaining the simple Debye dis-

persion[7,8] assume no interaction between orientating dipoles, which is not suitable for the system of strongly hydrogen-bonded liquids such as alcohols and *N*-substituted amides. The switch-over[9] and cluster[10] mechanisms have been tentatively proposed for the explanation of the dielectric relaxation of alcohols. For liquid *N*-methylacetamide, which is considered to be composed of the linear chains of the hydrogen-bonded molecules, the mechanism might be simpler than that of alcohols.

Note on the Use of Linear Free Energy Relationships in Heterogeneously Catalyzed Reactions

A. P. G. KIEBOOM

Laboratory of Organic Chemistry, Delft University of Technology, Julianalaan 136, Delft 2208, The Netherlands

(Received June 3, 1975)

Synopsis. A critical examination of the use of linear free energy relationships in the study of the mechanism of heterogeneously catalyzed reactions is presented in the case of the ruthenium catalyzed hydrogenation of monoalkylbenzenes reported in the literature.[5] It is concluded that the use of both electronic and steric substituent parameters leads to a quite different mechanistic interpretation as compared to the statements made before in the literature on the basis of just the electronic substituent parameter.

One of the major purposes in the field of heterogeneous catalysis is a better understanding of the reaction mechanism in order to develop somewhat less empiric approximations towards the choice of the catalyst as well as the reaction conditions.[1-3] The study of a particular reaction with the aid of a series of structurally related compounds on a single catalyst has proved a further suitable tool for mechanistic studies. Thus, a systematic variation of the substrate by the introduction of suitable substituents gives a set of experimental data to be correlated by means of a linear free energy relationship (*e.g.* Hammett and Taft relations), from which conclusions about the reaction mechanism involved can be drawn.[4]

On the other hand, one has to be very cautious in correlating experimental data with structural parameters since the substituent itself will give electronic and/or steric (attractive or repulsive) interactions with the catalyst, *i.e.*, substituent effects are often more complicated than in the case of homogeneously catalyzed reactions. In this respect, the recent investigation of Yoshida[5] concerning the mechanism of the hydrogenation of monoalkylbenzenes over ruthenium metal is an illustrative example of ignoring the above-mentioned interactions between the substituents and the catalyst. As will be outlined below, these "secondary" substituent effects may bring about false conclusions concerning the mechanism and the transition state of the reaction studied.

Results and Discussion

Yoshida[5] has studied the hydrogenation of monoalkylbenzenes over ruthenium black at 30 °C and 1 atm with ethanol as the solvent and obtained the following data for the reaction rate constants (k) and adsorption equilibrium constants (K) (Table 1). In addition, both the electronic (σ^*) and steric (E_s) substituent parameters according to Taft[6] have been included in Table 1.

Table 1. Hydrogenation of R-substituted benzenes over ruthenium[a]

Substituent R	log k	log K	σ^*	E_s
H	−1.85	0.30	0.49	1.24
Me	−2.66	0.78	0.00	0.00
Et	−2.88	1.00	−0.10	−0.07
Pr	−3.12	1.18	−0.115	−0.36
i-Pr	−3.34	0.98	−0.19	−0.47

a) log k and log K derived from Fig. 2 of Ref. 5.

Although the size of the substituents at the aromatic nucleus varies considerably, the data of Table 1 were just correlated[5] with the electronic substituent parameter σ^* (Table 2, relations *1* and *4*). On this basis, it was concluded that (i) the initial state of hydrogenation is the adsorption step (in terms of the Horiuti-Polanyi mechanism) and (ii) the rate-determining step involves a nucleophilic attack of a hydride species from the catalyst surface.[5]

However, Table 2 shows that the experimental data may also (and even better) be correlated with the steric substituent parameter E_s (*2* and *5*). Correlation of the experimental data by both σ^* and E_s shows further that *the reaction rate constant is almost completely determined by steric interactions (3)*, whereas *the adsorption equilibrium constant is influenced by electronic as well as steric effects (6)*.

Table 2. Taft relations[a] for the hydrogenation of R-substituted benzenes over ruthenium[5]

No.	Reaction rate (k)	ρ_r^*	δ_r	log k°	R
1	$\log k/k^\circ=\rho_r^*\sigma^*$	2.05	—	−2.80	0.974
2	$\log k/k^\circ=\delta_r E_s$	—	0.82	−2.83	0.983
3	$\log k/k^\circ=\rho_r^*\sigma^*+\delta_r E_s$	0.06	0.81	−2.82	0.983

No.	Adsorption equilibrium (K)	ρ_a^*	δ_a	log K°	R
4	$\log K/K^\circ=\rho_a^*\sigma^*$	−1.16	—	0.87	0.942
5	$\log K/K^\circ=\delta_a E_s$	—	−0.47	0.88	0.944
6	$\log K/K^\circ=\rho_a^*\sigma^*+\delta_a E_s$	−0.40	−0.31	0.88	0.945

a) ρ^* and δ are the polar and steric reaction parameters,[6] respectively, with r=reaction and a=adsorption; k° and K° are the calculated data for toluene (R=Me); R is the correlation coefficient.

This result leads to the following conclusions: (i) *The reaction rate constant is independent of electronic effects, i.e.*, atomic hydrogen has to be considered as the reducing agent. Increase of the size of the substituent decreases the reaction rate, which implies relatively less disturbance in the initial state of hydrogenation as compared to the transition state, and (ii) *The adsorbed state is stabilized by electron-donating substituents, i.e.*, the higher electron density on the aromatic nucleus will result in a stronger

aryl-ruthenium donor bond by π-spd overlap. In addition, increase of the size of the substituent enhances the strength of adsorption, which may point to alkyl-ruthenium bond formation in the initially adsorbed state. This result is in agreement with the steric substituent effect on the rate of hydrogenation and may have some resemblance with the homogeneously ruthenium-catalyzed α-H/D-exchange of aliphatic alcohols.[7] The picture for the adsorbed state, however, remains somewhat uncertain because of the rather low correlation coefficient of the relations *4*—*6*.

Summarizing, it is evident that one has to be very cautious in correlating experimental data with structural parameters in the case of heterogeneously catalyzed reactions.

Some Aspects of the Solid-solid Reaction Products between MgO and V_2O_3

Hirotoshi OSHIMA, Hiroshi YAMAMURA, and Shin-ichi SHIRASAKI

National Institute for Researches in Inorganic Materials, Kurakake, Sakuramura, Niihari-gun, Ibaraki 300-31

(Received April 28, 1975)

Synopsis. This report is concerned with the characterization of the metastably occurring reaction products with the spinel structure of a solid-solid reaction between MgO and V_2O_3 in an H_2 atmosphere. The measurements of the lattice constants and the magnetic properties suggest that the oxygen framework of the product is formed in an early stage of the reaction, followed by the ordering of the magnetic ions in the tetrahedral sites.

The present paper will deal the lattice constants and the magnetic properties of several reaction products obtained by solid-solid reactions between MgO and V_2O_3 in an H_2 atmosphere at different temperatures, the results give an insight into the characteristics of the metastably developed reaction products.

Two series of magnesio-vanadates, $MgO \cdot xV_2O_3$, with the spinel structure were prepared by firing oxide mixtures of MgO and V_2O_3 in different ratios; one of the species was fired at 1100 °C (A specimen series), and the other, at 1200 °C (B specimen series). The V^{3+} ion is stable in the $PO_2 \simeq 10^{-13}$—10^{-23} atm. region at 1100 °C—1200 °C, while the PO_2 in the H_2 atmosphere was measured to be $\sim 10^{-15}$ atm. therefore, only V^{3+} ions are supposed to be present in these materials throughout this investigation. X-Ray diffraction work was carried out in order to make precise lattice-constant measurements of the materials by the conventional method,[1] while the magnetic susceptibility was traced from 180 K to 100 K.

X-Ray diffraction patterns indicated that specimens of $1.0 < x < 1.13$ were monophasic, while specimens of $x > 1.13$ more or less involved vanadium sesquioxide together with the host magnesio-vanadate.

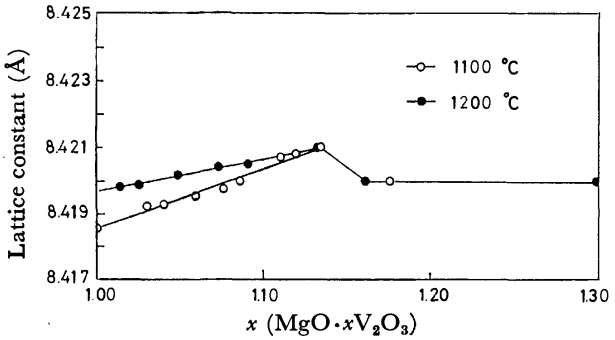

Fig. 1. Lattice constants of magnesio-vanadates with spinel structure.

Figure 1 gives the lattice constants as a function of the x value for the two series of materials. There is the general trend for the lattice constants for the two series to increase linearly with an increase in the x value up to $x = 1.13$. For the materials in this range, excess vanadium ions can occupy the tetrahedral sites of the spinel lattice, and as the result, cation vacancies in these sites may form to maintain the charge neutrality. Therefore, the general trend of present interest may be connected with such configuration change in the tetrahedral sites.

Figure 1 further shows that the respective lattice constants for the two series of materials approach each other with an increase in the x value, finally coinciding at $x = 1.13$. This fact suggests that materials with a larger x value have a larger number of cation vacancies and arrive at an "equilibrium structure" easily by means of the diffusion of oxygen. It is noticeable that at least two different lattice constants are possible for a fixed x value in the range of $1.0 < x < 1.13$. This fact strongly suggests that the A specimen series, with smaller x value, is metastable, in contrast to the B specimen series. The most probable model of the metastable structure is the Schottky-defect pairs of V_{mg}—V_o and V_v—V_o formed on the V_2O_3 side and the MgO side of the reaction product respectively, with their concentration ratio, $V_{mg}/V_v/V_o$, being always kept equal to the ratio of the constituent ions of MgV_2O_4, the number of vacancies decrease with an increase in the temperature. If this idea is correct, the lattice constant of the metastable

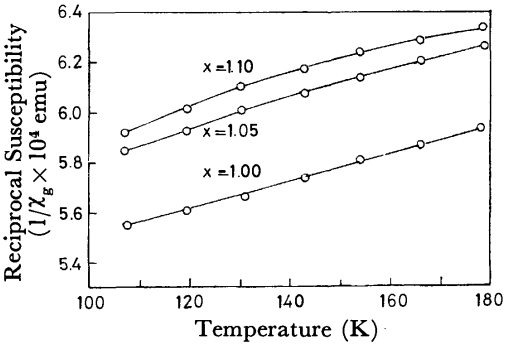

Fig. 2. The reciprocal values of the gram susceptibility ($1/\chi_g$) as a function of temperature for magnesio-vanadates fired at 1100 °C (A specimens).

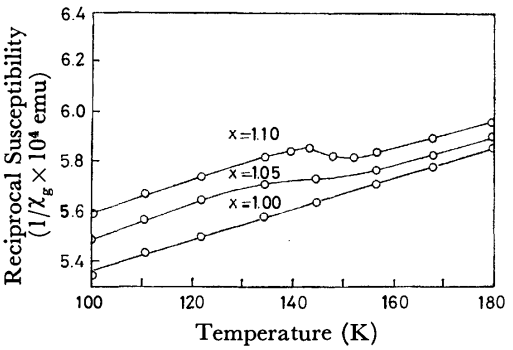

Fig. 3. The reciprocal values of the gram susceptibility ($1/\chi_g$) as a function of temperature for magnesio-vanadates fired at 1200 °C (B specimens).

structure can change by losing the respective vacancies without any change in its overall composition.

Figures 2 and 3 show the reciprocal susceptibility of A and B specimen series as a function of the temperature. The Curie-Weiss law held exactly over the entire range tested for the A specimen series, whereas deviation from the law began from the vicinity of 145 K for the $x=1.05$ and 1.10 materials in the B specimen series. It is unlikely that such anomalous magnetic behavior is associated with V^{3+} ions in the octahedral sites, which are occupied by V^{3+} in all the specimens. The deviation from the Curic-Weiss law may apear as a result of a contribution of an antiferromagnetic-like spin ordering partially occurring over the tetrahedral sites to the major paramagnetic disordering in the sites of the materials. This idea may be supported by the previous magnetic study of V_2O_3.[2] The occurrence of this anomaly, therefore, can be regarded as indirect evidence of cation ordering in the tetrahedral sites. Of the A specimen series and $MgO \cdot V_2O_3$ in the B specimen series, on the other hand, the lack of any cation order-disorder transition suggests cation disordering as well as spin disordering in the tetrahedral sites.

Figure 1 shows that the lattice constants of the two materials of $x=1.13$ fired at 1100 °C and 1200 °C respectively coincide, suggesting that the oxygen framework in the spinel lattice reached the equilibrium state in terms of structure. Nevertheless, the susceptibility versus temperature curves of the two materials are different from each other, thus, the $x=1.13$ material fired at 1200 °C can be regarded as being cation-ordered.

In summary, in the solid-solid reaction products between MgO and V_2O_3, the building of the oxygen framework takes place in an early stage of the reaction, followed by an ordering of the magnetic cations in the tetrahedral sites. A detailed study of this is in progress.

The Stability Constants of Nickel(II) Complexes with Chloride, Thiocyanate, Sulfate, Thiosulfate, and Oxalate Ions, as Determined by a Solvent Extraction Method

Ryokichi MURAI, Kiyoshi KURAKANE, and Tatsuya SEKINE

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received July 23, 1975)

Synopsis. The stability constants of nickel(II) complexes in 1 mol dm^{-3} sodium perchlorate media were determined at 25 °C by means of a solvent extraction method. The values thus obtained for log β_1 and log β_2 are: 0.0 and no second complex (Cl^-), 1.1 and 1.6 (SCN^-), 1.0 and 1.4 (SO_4^{2-}), 0.9 and 1.3 ($S_2O_3^{2-}$), and 3.7 and 6.6 ($C_2O_4^{2-}$), respectively.

Although there have been several reports on the stability constants of nickel(II) complexes with various common anions, most of them have been studied in dilute electrolyte solutions.[1,2] In order to obtain these constants at higher electrolyte concentrations, which are often necessary for various analytical purposes, experiments were made in 1 mol dm^{-3} sodium perchlorate media at 25 °C by means of a solvent extraction method.

Experimental

All the procedures, based on the synergic metal chelate extraction method,[3] were carried out at 25±0.3 °C in a way similar to that described in previous reports.[4,5] The aqueous phase was a 1 mol dm^{-3} $Na(ClO_4)$ medium containing about 10^{-4} mol dm^{-3} of nickel(II), 1×10^{-2} mol dm^{-3} of a sulfanilate buffer, and a certain amount of the ligand anion. This amount of buffer kept the hydrogen-ion concentration about 10^{-3} mol dm^{-3} and has a negligible effect on the extraction. The organic phase was carbon tetrachloride containing 5×10^{-2} mol dm^{-3} of thenoyltrifluoroacetone (TTA) and 3×10^{-2} mol dm^{-3} of trioctylphosphine oxide (TOPO). A 5 ml portion of each solution was placed in a stoppered glass tube and agitated mechanically until the distribution equilibrium was reached; then the whole was centrifuged. The optical absorbance of this organic phase was measured at 410 nm by means of a spectrophotometer. The hydrogen-ion concentration was measured by means of a potentiometer. A correction was made for the dissociation of the hydrogen oxalate ion by using a value of 3.54 for pKa_2 in 1 mol dm^{-3} perchlorate media at 25 °C.[6]

Statistical

The stability constants of complexes with a L_l^- ligand are:

$$\beta_n = [NiL^{2-nl}][Ni^{2+}]^{-1}[L^{l-}]^{-n} \quad (1)$$

The equilibrium constant for the extraction of the Ni^{2+} ion with a chelating extractant, HA, can be written as:

$$Kex = [NiA_2]_{org}[H^+]^2[Ni^{2+}]^{-1}[HA]_{org}^{-2} \quad (2)$$

where "org" denotes a species in the organic phase and where the lack of any subscript denotes a species in the aqueous phase. Even when a synergist which forms adduct chelates with the NiA_2 complex is present, its term can be omitted as long as its concentration is kept constant.[3] When nickel(II) is present in the organic phase as the NiA_2 species and in the aqueous phase as the Ni^{2+}, NiL^{2-l}, and NiL_2^{2-2l} species, the distribution ratio can be written as:

$$D = [NiA_2]_{org}/([Ni^{2+}]+[NiL^{2-l}]+[NiL_2^{2-2l}]) \quad (3)$$

When the distribution ratio in the absence of L^{l-} is denoted by D_0, the following equation can be obtained from Eqs. (1) to (3):

$$D[H^+]^2[HA]_{org}^{-2}Kex^{-1} = (1+\beta_1[L^{l-}]+\beta_2[L^{l-}]^2)^{-1} \quad (4)$$

When the results are plotted in the form of log $D[H^+]^2[HA]_{org}^{-2}Kex^{-1}$ vs. log $[L^{l-}]$, the stability constants can be determined by a curve-fitting method.[6]

Results and Discussion

In the absence of TOPO, the extraction of nickel(II) with TTA in carbon tetrachloride was poor and the

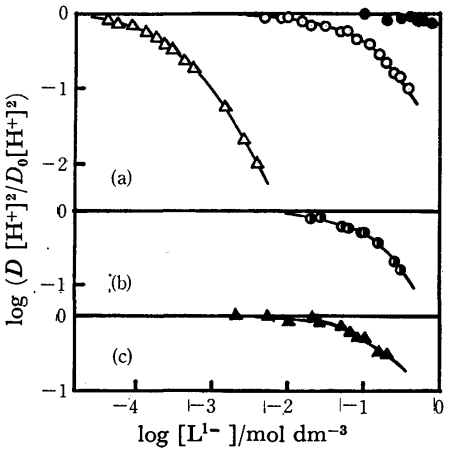

Fig. 1. Decrease in the extraction by complex formation. The ligands are as follows. (a) $C_2O_4^{2-}$ (△), SCN^- (○), and Cl^- (●), (b) SO_4^{2-} (◑), and (c) $S_2O_3^{2-}$ (▲). The curves were obtained by introducing the constants in Table 1 into Eq. (4).

TABLE 1. STABILITY CONSTANTS OF NICKEL(II) AND COBALT(II) COMPLEXES IN 1 mol dm^{-3} SODIUM PERCHLORATE SOLUTION AT 25 °C

Ligand	Ni(II)[a]		Co(II)[b]	
	log β_1	log β_2	log β_1	log β_2

$C_2O_4^{2-}$	3.7	6.6	3.33	6.20

a) Present work. b) From Refs. 4 and 5.

results were not reproducible. In its presence, however, reasonable results, which can be represented by Eq. (4), were obtained in the range of $10^{-2}<D<10$. Figure 1 gives the experimental data. The stability constants obtained are listed in Table 1, together with those of the cobalt(II) complexes previously reported.[4,5] It may be seen from the table that the stability constants of the nickel(II) complexes are, in general, a little higher than those of the corresponding cobalt(II) complexes, as is to be expected from the natural order of stability, although the difference is not large.

The values of the stability constants for these complexes in the literature[1,2] are rather scattered, and, since many of them were obtained at low electrolyte concentrations, a direct comparison with the present results is not possible. However, the previous values for the β_1 of the chloride complex in 1.5 to 2 mol dm^{-3} perchlorate media are somewhat lower than the present values, while those for the β_1 of thiocyanate complexes in 1 to 2 mol dm^{-3} perchlorate media, about $10^{1.2}$, agree well with the present value.

We are grateful to Professor Masaakira Iguchi, who encouraged us to do this work.

Studies on Organic Semiconductors. XVIII. Photoconductivity of Heteroaromatic Compounds and Their Substituted Derivatives

Akira SUGIMOTO, Shinji KATO, Hiroo INOUE, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

(Received February 6, 1975)

Synopsis. The effects of hetero atoms and substituents on the photocurrents of the parent compounds were investigated by comparison of the photocurrents of 52 specimens of the aza-benzenoid and oxa-benzenoid compounds.

Recently, we have reported the photoconductivity of condensed aromatic or heteroaromatic compounds and their substituted derivatives.[1-4] The photoconductivity of the compounds was found to depend strongly on their chemical structures.

The purpose of this paper is to summarize the effects of the substituents and the hetero atoms on the photoconductivity of the parent compounds.

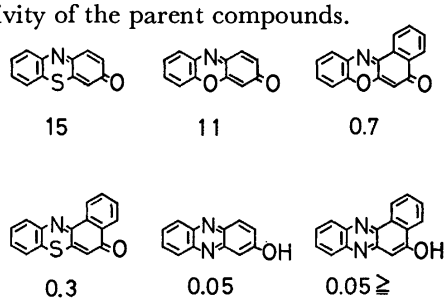

Fig. 1.
The values indicated below the chemical structures are the photocurrents (pico A).

TABLE 1. PHOTOCURRENTS OF OXA- AND AZA-BENZENOIDS, PARENT COMPOUNDS AND THEIR SUBSTITUTED COMPOUNDS

Compound	Hetero atom or substituent	Photocurrent (pico A)[a]

2-OCH_3	0.05
others[a]	<0.05

a) 1-OH, 1-OCH_3, 1-NH_2, 2-Cl, 2,7-$(OCH_3)_2$, 2,7-$(C(CH_3)_3)_2$, 2,7-Cl_2, 1,6-$(CH_3)_2$, 1,6-$(OH)_2$, 1,6-$(NH_2)_2$, 1,4,6-$(OCH_3)_3$, 1,4,6,9-$(OCH_3)_4$

The compounds are of two types; condensed aza-benzenoids containing pyridine-type nitrogen hetero atoms and condensed oxa-benzenoids containing pyran-type oxygen hetero atoms. The former is expressed by Albert[5] as a π-electron deficient system. The compounds belonging to the system are generally oxidized with difficulty by oxygen and apt to behave as an electron acceptor in the formation of a charge-transfer complex. In contrast, oxa-benzenoids are easily oxidized by oxygen and tend to behave as an electron donor in the formation of a charge-transfer complex. Thus, oxa-benzenoids are classified as a π-electron excessive system. The photocurrents of these compounds are summarized in Fig. 1 and Tables 1 and 2.

Effects of Hetero Atoms: Aza-benzenoid compounds show much smaller photocurrents than those of the parent aromatic hydrocarbons.[6] On the other hand, the photocurrent of the oxa-benzenoid compound becomes slightly larger (Table 1). No significant difference of photocurrent between the oxa- and thia-quinonoid compounds was observed. This indicates that the quinonoid structure is a dominant factor governing the photoconductive process (Fig. 1).

Effects of Substituents: (1) The electron-withdrawing substituent, such as a nitro group, gave rise to a decrease in the photocurrent of an oxa-benzenoid compound such as *peri*-xantheno[2,1,9,8-k,l,m,n,a]xanthene, and

an increase in the photocurrent of an aza-benzenoid compound such as phenazine.[2]

(2) The electron-releasing substituent, such as a methoxyl group, has no detectable effect on the photoconductivity of the aza-benzenoid compound. In the case of the oxa-benzenoid compound, the effect of the electron-releasing substituent was uncertain, since the photocurrent could not be measured due to instability in the air.

(3) The substituents at the *peri*-position of the nitrogen atom of phenazine, except for OH or NH_2 group, caused a rise in the photocurrent.[1]

(4) Introduction of the methoxyl, acetyl, ethyl, and cyano groups at 1-, 9-, or 1,5-positions of the anthracene ring resulted in a decrease in the photocurrent of the unsubstituted anthracene (Table 1).[3]

Experimental

Materials. All the samples, except 1,6-dimethyl-, 1,4,6-trimethoxy- and 1,4,6,9-tetramethoxyphenazine, were prepared by the methods described in literature[7] and purified by repeated recrystallization, vacuum sublimation and chromatography.

1,4,6,9-Tetramethoxyphenazine. A mixture of 2,5-dimethoxyaniline (1.5 g, 0.01 mol), 2,5-dimethoxynitrobenzene (5.5 g, 0.03 mol), a powdered KOH (50 g), and benzene (50 ml) was refluxed under stirring for 5 hr, then subjected to steam distillation. After being allowed to stand overnight, a gummy product was filtered off and washed successively with ethanol (100 ml) and benzene (50 ml) until it changed into powder. The powder was subjected to chromatography on alumina with chloroform eluent. From the first reddish fraction, 1,4,6,9-tetramethoxyphenazine was obtained. Recrystallization from benzene gave 300 mg (10%) of reddish vermilion needles: mp >360 °C; NMR (CF_3COOH) δ 7.70 (s, aromatic H, 4H) and 4.34 (s, CH_3, 12H).

Found: C, 63.71; H, 5.30; N, 9.39%. Calcd for $C_{16}H_{16}O_4N_2$: C, 63.99; H, 5.37; N, 9.33%.

1,4,6-Trimethoxyphenazine. This compound was prepared with 6.85 g of *o*-anisidine, 29 g of 2,5-dimethoxynitrobenzene, 80 g of KOH, and 150 ml of benzene according to the method used in the preparation of 1,4,6,9-tetramethoxyphenazine. Recrystallization from benzene gave 1,4,6-trimethoxyphenazine as red crystals (600 mg): mp 254—254.5 °C; NMR (CF_3COOH) δ 8.55—8.12 (m, aromatic H, 2H), 7.81—7.40 (m, aromatic H, 3H), 4.30 (s, CH_3, 6H), and 4.35 (s, CH_3, 3H).

Found: C, 66.42; H, 5.07; N, 10.09%. Calcd for $C_{15}H_{14}O_3N_2$: C, 66.65; H, 5.22; N, 10.37%.

1,6-Dimethylphenazine. A mixture of 3-methyl-2-methoxyaniline (3.5 g), 2-methoxy-3-nitrotoluene (8 g), and KOH (20 g) was added to 150 ml of toluene and refluxed for 5 hr. 1,6-Dimethylphenazine was obtained according to the reported method[8]: mp 218.5—219 °C (lit,[9] 221—222 °C).

Measurements. The surface-type cells of the samples were prepared according to methods given in previous papers and their photocurrents measured under conditions similar to those reported[1-4] (nitrogen atmosphere, 1900 lux, 200 V/cm). The photocurrents of the substituted anthracenes (Table 1) were measured by irradiating the surface-type cell with a monochromatic light, the wavelength of which is shown in parentheses in Table 1. In the case of the other compounds, the cells were irradiated with a white light (320—800 nm).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49(1), 339—340 (1976)

Spectroscopic Study of Alkyl Vinyl Ketones

Ikuo NAITO, Akihiro KINOSHITA, and Tadashi YONEMITSU

Department of Photography, Kyushu Sangyo University, Matsugadai, Higashi-ku, Fukuoka 813

(Received February 10, 1975)

Synopsis. Alkyl vinyl ketones have two conformations, *s-cis* and *s-trans*. The ratios of the two conformers are given by comparing their IR with NMR data. The conformer of *s-cis* is given by the equation, Percentage of *s-cis*=180·($\Delta\delta$ −0.15) (%), where $\Delta\delta$ is the chemical shift difference between *cis* and *trans* protons for carbonyl group. The value of ΔF obtained by means of the equation is related to steric factors Es^c of bearing alkyl groups. The ratio *s-cis*/*s-trans* is determined by the bulkiness of the alkyl group.

Alkyl vinyl ketones (AVK) are in equilibrium between two comparatively stable conformations, *s-cis* and *s-trans*. NMR spectra of AVK were studied and discussed as regards mono substituted ethylene.[1] Kossanyi[2] determined seven kinds of AVK in arbitrary units (δ *cis*+δ*trans*+δ*gem*=0) and reported the effect of the alkyl group. The chemical shift of each vinylic proton can not be compared with other AVK, nor considered to be caused by conformation. The relation between conformations of β,β disubstituted enone and its chemical shift difference, reported by Cottee and Timmons,[3] and Faulk and Fry,[4] seems to be applicable to AVK.

NMR measurement of AVK (CH_2=CH–CO–R, R= Me, *n*-Pr, *i*-Pr, cyclo-Hex, *tert*-Bu and Ph) was carried out in carbon tetrachloride. The chemical shifts of vinylic protons are listed in Table 1. The chemical shift of *cis* proton is shifted to lower magnetic field with the decrease of Taft's σ^* value,[5] contrary to the tendency of *trans* proton. No different effects of alkyl substituent seem to be found for the protons. For 2 methylene cycloalkanones, Klose[6] and Kaiser and Hooper[7] showed a correlation between the chemical shift difference of two geminal olefinic protons and dihedral angle about central C–C bond from the diamagnetic anisotropy of carbonyl group. Similary, the chemical shifts of AVK are greatly affected by its carbonyl group. Since the ketones seem to consist of two comparatively stable conformers, the observed values are the mean values of *s-cis* and *s-trans*, and seem to be proportional to Taft's σ^* values. For the sake of clarification chemical shift differences ($\Delta\delta$=δ*cis*—δ*trans*) are compared with the proportion of $\varepsilon^{a}_{C=O\ s\text{-}cis}$, $(\varepsilon^{a}_{C=O\ s\text{-}cis}/(\varepsilon^{a}_{C=O\ s\text{-}cis}+\varepsilon^{a}_{C=O\ s\text{-}trans}))$ *s-trans* which does not indicate the exact proportion but suggests the part of *s-cis*, as shown Fig. 1. Linearity is found to hold. The conformer of *s-cis* in conjugated enone is given by means of the following equation,

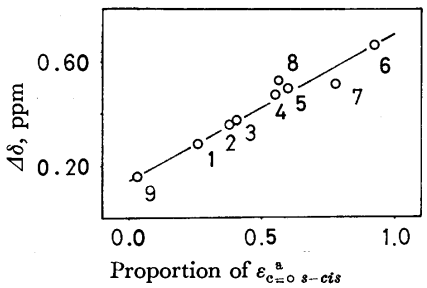

Fig. 1. Relation between the proportion of $\varepsilon_{C=O\ s\text{-}cis}$ and $\Delta\delta$.

10 Methyl propenoate	0.533[c]			1.29[d]	

NMR spectra were measured in carbon tetrachloride (*ca.* 0.5 mol/l) with TMS at 35 °C, using Hitachi R-22 and Japan Electron Optics 4H-100. The chemical shifts were obtained from the spectra which were approximated to ABX type systems.

IR spectra were measured in carbon tetrachloride ($4.0—8.0\times10^{-2}$ mol/l) by the use of Shimadzu IR-27G type and NaCl and 0.2 mm spacer. Each AVK has C=O streching bands near 1700 cm^{-1}.

Higher frequency peak is assigned to *s-cis* the lower frequency peak to *s-trans* conformations.

a) Ref. 8, b) This value was given under the same condition as for the measurements of AVK. c) Ref. 10, d) This value gives the ratio of the C=C *s-cis* to C=C *s-trans* stretching band absorbance.[9]

Percentage of *s-cis*=180 ($\Delta\delta$−0.15) (%). Since propeophenone contains high diamagnetic aromatic group, $\Delta\delta$ of propeophenone deviates from linearity. The value of *s-trans* (0.15 ppm) agrees completely with that of 2-methylene cycloalkanones reported by Kaiser and Hooper,[7] and that proposed for but-3-ene-2-one (R=Me) from carbonyl anisotropy by Barlet *et al.*[11] However, $\Delta\delta$ of *s-cis* (0.72 ppm) appears higher than both the former value[7] (0.64 ppm) and the latter value[11] (0.63 ppm). Since calculated values of AVK by means of Pople's data[12] are 0.79 ppm for *s-cis* and 0.19 ppm for *s-trans* (0.80 ppm and 0.12 ppm for but-3-ene-2-one, respectively),* $\Delta\delta$ of *s-cis* is acceptable. The results support the view that the relation is suitable for CH_2=C–C=O compounds, propenal,[8]** methyl propenoate[9,10] and 3 methyl but-3-ene-2-one, which have stable *s-cis* and *s-trans* but not effective shielding groups.

The *s-cis*/*s-trans* ratio and free energy difference ($\Delta F = F_{s\text{-}cis} - F_{s\text{-}trans}$) are calculated by means of the ratio of *s-cis* (Table 2). Since ΔF seems to be affected by its alkyl groups, it is compared with Hancock's steric factor (Es^c) which does not involve hyperconjugation term (Fig. 2). We see that a linear relation holds and that the *s-cis*/*s-trans* ratio of AVK is determined by the bulkiness of the bearing alkyl group.

TABLE 2. K AND ΔF OF AVK BY EMPLOYING THE EQUATION

Compound R	$\Delta\delta$ (ppm)	*s-cis* (%)	K *s-cis*/*s-trans*	$\Delta F \times 10^{a)}$ (kcal/mol)	E_s^c
Me	0.29	25	0.34	6.63	0.0
Et	0.36	38	0.61	3.03	−0.38
n-Pr	0.38	41	0.71	2.12	−0.67
i-Pr	0.50	63	1.70	−3.23	−1.09

H (Propenal)	0.16	2	0.02	*ca.* 25	
3-Methylbut-3-ene-2-one	0.16	2	0.02	*ca.* 25	

a) $\Delta F = F_{s\text{-}cis} - F_{s\text{-}trans}$.

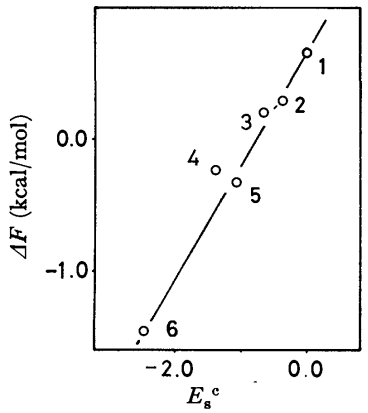

Fig. 2. Relation between ΔF and E_s^c (1=Me, 2=Et, 3=*N*-Pr, 4=cyclo-Hex, 5=*i*-Pr, 6=*t*-Bu)

* The calculation was carried out using ideal molecular coordinates. ($r_{C=C}$=1.34 Å, $r_{=C-H}$=1.08 Å, $r_{=C-C=}$=1.48 Å, $r_{C=O}$=1.21 Å, r_{C-CH_3}=1.54 Å, r_{C-H}=1.10 Å (1.09 Å at position of carbonyl group), $\angle^{C}_{(SP^3)}$=108° 28′ $\angle^{C}_{(SP^2)}$=120°) χ_x^c=10.8, χ_y^c=17.9, χ_z^c=10.8, χ_x^o=18.0, χ_y^o=16.7, χ_z^o=7.2 on carbonyl group, x^{C-C}=5.3 paramagnetic term on C–C single bond. The value of x^{C-H} and x^{C-C} on C–C single bonds which are out of the conjugated plane are neglected.

** Courtieu *et al.*[15] reported that propenal is *s-trans* form above 90% from NMR measurement. As $\nu_{c-o\ s\text{-}cis}$ could not be found, it is possible to consider that propenal is almost of s-*trans* conformation.

Conclusion

The *s-cis*/*s-trans* ratio of AVK is determined by the bulkiness of the alkyl group. Its chemical shift difference of two geminal olefinic protons is determined by the ratio of conformers. ΔH and potential barrier of rotation can be roughly estimated by means of the relation between $\Delta\delta$ and *s-cis* percentage. The ΔH value of but-3-ene-2-one (R=Me) is determined by means of the change of temperature in NMR (0.34 kcal/mol). The result agrees with the value reported by Bowles *et al.*[14] The change of the chemical shifts of vinylic protons are calculated for each conformations by the relation we obtained. Each chemical shift obtained is proportional to Taft's σ^* values of the bearing alkyl group.

Photochemical Reaction of Ethyl 3-Methyl-3-phenylglycidate in Methanol and Ether Solvents

Vo Van CHUNG, Masao TOKUDA,* Akira SUZUKI, and Mitsuomi ITOH
Department of Chemical Process Engineering, Hokkaido University, Sapporo 060

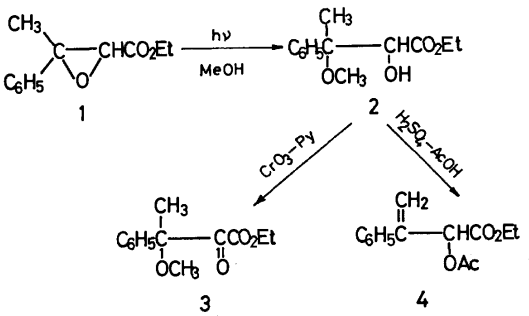
(Received May 26, 1975)

Synopsis. Irradiation of ethyl 3-methyl-3-phenylglycidate (**1**) in methanol gave an ionic addition product of the solvent, whereas in ether solvent different reaction paths leading to β-keto esters and carbene were observed.

It was previously reported that irradiation of aliphatic α,β-epoxy esters in an aprotic solvent gave corresponding β-keto esters,[1] while in a protic solvent completely different types of products were obtained.[2] In this note, we wish to report that the photochemical reaction of α,β-epoxy ester with a β-phenyl substituent in methanol gave an ionic addition product, but in ether solvent the reaction occurred with two competing pathway: a fragmentation to carbene and ketone and a rearrangement to β-keto ester. The photochemical fragmentation of aryl-substituted oxiranes to arylcarbenes has been studied extensively by Griffin and his co-workers.[3] The present work provides an additional example to the few reported ones where fragmentation occurs in the absence of vicinal diaryl substitution on the oxirane ring.[4]

Results and Discussion

Irradiation of ethyl 3-methyl-3-phenylglycidate (**1**) in methanol with 253.7 nm light for 45 hr gave a diastereoisomeric mixture of ethyl 2-hydroxy-3-methoxy-3-phenylbutyrate (**2**). The structure of **2** was determined by spectral data and by the following chemical transformations. Oxidation of **2** with chromium trioxide-pyridine complex gave α-keto ester (**3**), while treatment with warm sulfuric acid–acetic acid solution gave ethyl 2-acetoxy-3-phenyl-3-butenoate (**4**). Furthermore, a thermal reaction of **1** in methanol with a small amount of hydrochloric acid also gave **2** and its methyl ester in 45% and 19% yields, respectively.



Scheme 1.

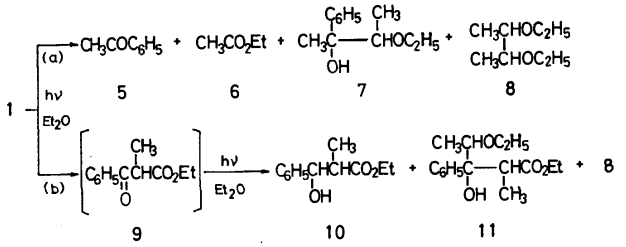
The results obtained under various conditions are summarized in Table 1. When the irradiation was carried out in the presence of hydrochloric acid or under oxygen atmosphere, an increased amount of **2** was obtained. The dark reaction of **1** in methanol did not give a detectable amount of **2**. In addition, it was also established that irradiation of **1** in methanol involving a small amount of alkali did not give **2**. These results demonstrate that this photochemical ionic reaction probably proceeds *via* a protonation of α,β-epoxy ester under irradiation. Photolysis of methanol in the presence of oxygen was reported to produce an acidic substance, which initiated the ionic reaction.[5] However, irradiation of degassed solution of **1** gave a 10% yield of **2**. Moreover, in a similar photochemical reaction of ethyl 1-oxaspiro[2,4]heptane-2-carboxylate, it was reported that the presence or absence of oxygen did not affect the yield of the ionic addition product of methanol.[2] Accordingly, although it is unknown what the nature of the acidic substance is, these results indicate that some acidic substances produced photochemically from the starting epoxy ester or solvent probably play an important role in these reactions.[5c]

Table 1. IRRADIATION OF **1** IN METHANOL UNDER VARIOUS CONDITIONS

Irradiation condition[a]	Yield of **2** (%)	Conversion of **1** (%)
N_2	20	97
N_2[b]	37	100
O_2	36	88
Degassed (1×10^{-4} mmHg)	10	65
Degassed, dark	0	58
Dark, in air	0	67
Dark, in air[b]	7	100

a) Irradiations were carried out with a 15 W low pressure mercury vapor lamp for 45 hr and dark reactions for 45 hr. b) A small amount of HCl was added.

The photochemical reaction of **1** in an aprotic solvent gave the following products mainly *via* two types of reaction paths, namely, a photolytic path leading to acetophenone and carbethoxycarbene (*a*)[3a] and a rearrangement to β-keto ester (*b*).[1] Irradiation of **1** in ether with a high pressure mercury vapor lamp for 90 hr gave acetophenone (**5**, 13%), ethyl acetate (**6**, 3%), 3-ethoxy-2-phenyl-2-butanol (**7**, 7%), 2,3-diethoxybutane (**8**, 40%), ethyl 3-hydroxy-2-methyl-3-phenylpropionate (**10**, 11%), and ethyl 4-ethoxy-3-hydroxy-2-methyl-3-phenylpentanoate (**11**, 32%) in a 95% conversion. Products **7**, **8**, **10**, and **11** involved an almost



Scheme 2

equal amount of diastereoisomers.

The formation of **5**, **7**, and **6** indicates that a photochemical cleavage of **1** occurred mainly at the C_α–O and C_α–C_β bonds. Products **7** and **8** have been shown to be produced by the photochemical reaction of acetophenone in ether,[6] while **6** may result from carbethoxycarbene. Ethyl acetate was shown to be produced by photolysis of ethyl diazoacetate in ether. The photolytic path to **10**, **11**, and **8** through β-keto ester (**9**) was confirmed by the fact that irradiation of **9** under the same conditions gave a mixture of **10**, **11**, and **8**. It was shown that β-methyl substituent migrates to α-carbon in preference to the phenyl group.[1,7]

Experimental

Ethyl 3-methyl-3-phenylglycidate (**1**) was prepared by the procedure of the Darzens synthesis.[8] Ethyl 2-methyl-3-oxo-3-phenylpropionate (**9**) was prepared according to the procedure of Marvel.[9] Quantitative glpc analyses were carried out with the internal standard.

Photochemistry of **1** *in Methanol.* A mixture of **1** and methanol (0.08 M) in a quartz tube was cooled in water and externally irradiated with a 15W low pressure mercury vapor lamp for 45 hr. Nitrogen gas was allowed to pass through the mixture during the irradiation. Distillation and a preparative glpc of the irradiation mixture gave diastereoisomeric ethyl 2-hydroxy-3-methoxy-3-phenylbutyrate (**2**): bp 250 °C; n_D^{23} 1.5050; IR (CCl_4) 3540, 1735 cm^{-1}; NMR (CCl_4) τ 9.02 and 8.92 (t, 3H), 8.42 and 8.40 (s, 3H), 6.85 and 6.90 (s, 3H), 7.42 (s, 1H, OH), 5.98 (s, 1H), 6.10 (q, 2H); *m/e* 238 (M^+), 135, 103. Found: C, 65.32; H, 7.89%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%.

Oxidation of **2** with chromium trioxide and pyridine[10] produced ethyl 3-methoxy-2-oxo-3-phenylbutyrate (**3**): n_D^{20} 1.4980; IR (CCl_4) 1740, 1725 cm^{-1}; NMR (CCl_4) τ 8.82 (t, 3H), 8.37 (s, 3H), 6.80 (s, 3H), 5.87 (q, 2H), 2.7 (s, 5H); *m/e* 135 (M^+–$COCO_2Et$), 104, 73. Found: C, 65.68; H, 7.02%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

Treatment of **2** with freshly prepared warm sulfuric acid–acetic acid solution[11] gave ethyl 2-acetoxy-3-phenyl-3-butenoate (**4**): n_D^{20} 1.5115; IR (CCl_4) 1750, 865 cm^{-1}; NMR (CCl_4) τ 8.90 (t, 3H), 7.90 (s, 3H), 5.92 (q, 2H), 4.56 (s, 1H), 4.46 (s, 1H), 4.25 (s, 1H), 2.72 (m, 5H); *m/e* 248 (M^+), 189, 175, 145. Found: C, 67.87; H, 6.59%. Calcd for $C_{14}H_{16}O_4$: C, 67.73, H, 6.50%.

Thermal reaction of **1** in methanol in the presence of a small amount of HCl for 2 hr gave **2** and diastereoisomeric methyl 2-hydroxy-3-methoxy-3-phenylbutyrate: bp 230 °C, n_D^{23} 1.5160.

Photochemistry of **1** *in Ether.* An etheral solution of **1** (0.08 M) was irradiated with a 500 W high pressure mercury vapor lamp for 90 hr. Distillation and a preparative glpc gave **5**, **6**, **7**, **8**, **10**, and **11**. The identities of **7**, **8**, and **10** were established by comparison of IR, NMR, and mass spectr awith those of authentic samples.[6] β-Hydroxy ester **10** was prepared by a reduction of ethyl 2-methyl-3-oxo-3-phenylpropionate (**9**) with sodium borohydride in ethanol: bp 148—150 °C/11 mmHg (lit,[12] 109—110 °C/0.5 mmHg), n_D^{20} 1.5085 (lit,[12] n_D^{23} 1.5007). The spectral data of **11** were completely identical to those of the product obtained by the irradiation of **9** in ether: IR (CCl_4) 3475, 1735 cm^{-1}; *m/e* 207 (M^+–CH-(OC_2H_5)CH_3), 105, 77. Found: C, 68.53; H, 8.47%. Calcd for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63%.

Photochemistry of **9** *in Ether.* An etheral solution of **9** (0.08 M) was irradiated with a 500 W high pressure mercury vapor lamp for 25 hr. Distillation and a preparative glpc gave **10**, **11**, and **8**. The spectral data of the former two were completely identical to those of **10** and **11** obtained by the irradiation of **1** in ether.

Photochemistry of Ethyl Diazoacetate in Ether. An etheral solution of ethyl diazoacetate (0.3 M) was irradiated with a 500 W high pressure mercury vapor lamp for 15 hr. Distillation and a preparative glpc gave ethyl acetate (**6**), diethyl maleate, diethyl fumarate, ethyl 2-ethoxyacetate, and ethyl 3-ethoxybutanoate. The structure of ethyl 3-ethoxybutanoate was identified by comparison with an authentic sample[13]: n_D^{20} 1.4125 (lit,[13] n_D^{19} 1.4092); IR (CCl_4) 1735, 1200, 1100 cm^{-1}; NMR (CCl_4) τ 8.87 (t, 3H), 8.74 (t, 3H), 8.84 (d, 2H), 7.57 and 7.73 (d, 2H), 6.56 (q, 2H), 5.92 (q, 2H), 6.23 (sex, 1H); *m/e* 160 (M^+), 145, 131, 85, 73.

The Mass Spectra of 3-Aryl-1,2,3-oxathiazolidine 2-Oxides

Fukiko YAMADA, Tomihiro NISHIYAMA, Hiroshi SAMUKAWA, and Yasunari TAKEUCHI

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564

(Received July 7, 1975)

Synopsis. The mass spectra of a series of 3-aryl-1,2,-3-oxathiazolidine 2-oxides were obtained. The fragment ions were chiefly formed by the elimination of SO_2 from the M^+ ion. In this step, both the effects of the ring substituent and the torsion angle of the oxathiazolidine ring on the rate of the elimination were observed.

Recently, the authors reported the mass spectra of a number of 3-aryl-1,2,3-oxathiazolidine 2-oxides and a series of 3-aryl-5-methyl-, or 3-aryl-5-chloromethyl-1,2,3-oxathiazolidine 2-oxides.[1-3] In order to obtain further information about structural influence on the fragmentation pathways, the authors now deal with the correlations of the elimination rates with the substituents of the following 3-aryl-1,2,3-oxathiazolidine 2-oxides (**1**) and with the torsion angles of the oxathiazolidine ring determined from the vicinal coupling constants between the four methylene protons by means of NMR spectroscopy.[4]

Experimental

Compounds. A series of **1** was prepared and purified by a previously reported method.[5] The reaction conditions and the physical properties of **1** were reported in a previous paper by the authors.[4]

Measurements. The mass spectra were obtained with a Japan Electron Optics Co., Ltd., JMS-01SG Mattauch-Herzog double-focusing mass spectrometer at an ionizing energy of 75 eV, an emission current of 200 μA, an accelerating voltage of 6.4 kV, and a vapor pressure of 1.0×10^{-6} mmHg. The ion-source temperature varied between 100 and 150 °C. The accurate masses and elemental compositions were determined by a previously-reported method.[1]

Results and Discussion

The mass spectral data of I—VI are shown in Table 1, while the main fragmentation pathway is shown in Scheme 1. There are three steps of cleavage in the oxathiazolidine ring, the elimination of SO_2 (step 1), of the methyl radical (step 2), and of HCN (step 3).[1] Examination of the data in Table 1 indicates there is a relation between the rate of elimination and the Hammett σ constant of an *m*- or *p*-substituent.[6] Then, the log Z/Z_0 (relative intensities) in step 1 were plotted against σ, except for the data with *o*- and 2,4,6-tri-substituents, as is shown in Fig. 1. In the case of the I,IIb, IIIb, Vb, and Vc, a reasonably good linear correlation is obtained, and the slope is $\rho=+0.81$. On the contrary, the values for IIc, IIIc, and IV deviated from the line. In the cases of steps 2 and 3, no noticeable substituent effect was found.

In a previous paper by the present authors,[4] it was reported that oxathiazolidines tend to form twist-envelope conformations, that their torsion angles vary with both the position and the nature of the ring substituent,

Table 1. Mass spectral data and torsion angles of the compounds

Compd. No.	Rel. Int. (%) M	A	B	C	Torsion[a] angle (θ°)
I	55	16	100	78	15

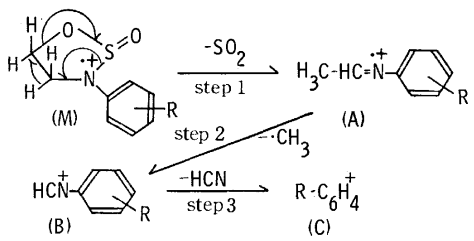
IV	48	27	100	67	14
Va	69	13	100	36	−11
Vb	50	28	100	65	15
Vc	56	27	100	55	12
VI	14	21	100	21	30

a) These values are taken from Ref. 4.



Scheme 1. The main fragmentation pathway of the **1** compounds.

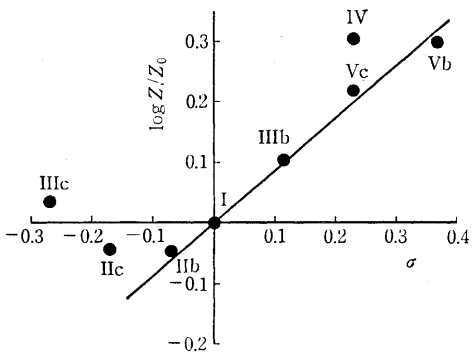


Fig. 1. Correlation of the intensities of the A ion in the 75 eV mass spectra of the **1** compounds. Slope=0.81.

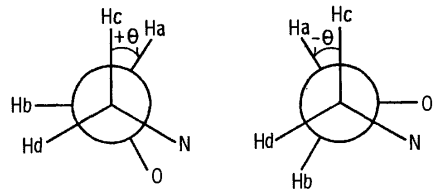
and that the distortions of the oxathiazolidine ring of the compounds with *m*- and *p*-substituents are in the direction of the projection **2**, while those with an *o*-substituent cause a distortion toward the projection **3**, as can be seen in the diagram. The values of the torsion angles are listed in Table 1.



2 **3**

θ; Torsion angle

Regarding the greater deviation from the Hammett correlation in the case of IIIc (Fig. 1), it was considered that there is another energy factor for the elimination of SO_2 because of the small torsion angle for IIIc given in Table 1. The torsion angles of the compounds showed in Fig. 1 are in the range of 11—15 °C except for IIIc.

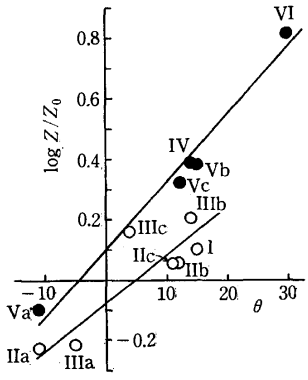


Fig. 2. The plot of the *Z*-values of the initial fragmentation of the **1** compounds against torsion angles (θ).
Z_o-value is obtained from the curve plotted of θ *vs.* *A*/*M* and is 23% at θ=0°.
$Z=[R\text{-}C_6H_4\text{-}\overset{+}{N}\text{-}CHCH_3]/[M^+]$
●: Electron-withdrawing group, ○: electron-donating group.

Therefore, an attempt was made to plot the *z*-values of all the compounds against their torsion angles (Fig. 2). As can be seen in Fig. 2, two kinds of linear correlation are obtained. The upper line due to the data of the compounds with an electron-withdrawing group and the lower line due to those with an electron-donating group.

As is indicated in Scheme 1, the transfer of a hydrogen atom from the C-4 to the C-5 position and the ring cleavage of the molecular ion afford the elimination of the SO_2 group. In the molecular ion, the positive charge is distributed over the nitrogen atom and the aromatic ring. Figure 1 indicates that an electron-withdrawing substituent strongly enhances the formation of the elimination product and the value of approximately +0.81 is relatively large compared with any previously reported values for the rate of an electron-impact collision.[7] Thus, it appears that the reaction is enhanced by an increased positive charge at the reaction site. Figure 2 indicates that, in general, an electron-withdrawing group enhances the rate of elimination, and an electron-donating group supresses it. Moreover, the magnitude of the distortion of the oxathiazolidine ring may markedly affect the rate of elimination. The above two factors, the magnitude of the positive charge at the reaction site and the torsion angle of the oxathiazolidine ring, should make an important contribution to the driving force for an electron-impact collision.

The Chlorination of Norbornadiene by Various Chlorinating Agents

Akira ONOE, Sakae UEMURA,* and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received July 15, 1975)

Synopsis. The chlorination of norbornadiene by $CuCl_2$, $TlCl_3 \cdot 4H_2O$, $SbCl_5$, $SeCl_4$, and VCl_4 in CCl_4 or CH_3CN afforded mainly *trans*-3,5-(**1**) and *exo-cis*-3,5-dichloronortricyclene (**2**). In the reaction with $PbCl_4$, Cl_2, SO_2Cl_2, and PCl_5, appreciable amounts of *exo*-5-*syn*-7-(**3**) and/or *exo-cis*-5,6-dichloronorbornene (**4**) were obtained besides **1** and **2**.

Concerning the chlorination of norbornadiene, the reactions with $CuCl_2$ (gas-phase),[1] Cl_2,[2] $PhICl_2$,[2] $AuCl_3$,[3] and $MoCl_5$[4] have so far been reported. We now give the results of chlorination by various other chlorinating agents. Among the chlorinating agents examined the following were found to be effective: $CuCl_2$, $TlCl_3 \cdot 4H_2O$, $SbCl_5$, $SeCl_4$, VCl_4, $PbCl_4$, SO_2Cl_2, and PCl_5. The products were two isomeric dichloronortricyclenes [*trans*-3,5-(**1**) and *exo-cis*-3,5-(**2**)] and two isomeric dichloronorbornenes [*exo*-5-*syn*-7-(**3**) *exo-cis*-5,6-(**4**)], the distribution of the products depending a great deal on the kind of chlorinating agent and the reaction conditions. The results are shown in the Table together with our previous data on $MoCl_5$.[4]

1 **2** **3** **4**

The product distribution suggests that the chlorinating agents can be classified for convenience into three categories. The first class consists of $CuCl_2$, $TlCl_3 \cdot 4H_2O$, $SbCl_5$, $SeCl_4$, and VCl_4, which gave almost entirely **1** and **2**. Although a radical mechanism has been proposed for the formation of **1** and **2** by $PhICl_2$,[2] it was found that the reactions by these metal chlorides were ionic since no effect was observed by the addition of radical scavengers such as *m*-dinitrobenzene (*m*-DNB) and oxygen, or even when the reactions were carried out under N_2. Furthermore we have observed that the reaction of other olefins such as cyclohexene[5] and norbornene[6] with these metal chlorides proceeds by an ionic mechanism under nearly the same reaction contions. The ability of $SeCl_4$ and VCl_4 to chlorinate olefin, which was firstly found in the reaction with norbornene,[6] was also confirmed in this case (Runs 4 and 5), but no favorable *exo-cis*-addition by VCl_4 as observed in the case of norbornene[6] was found (Run 5).

The second class consists of $PbCl_4$, Cl_2, SO_2Cl_2, and PCl_5, which generally afforded a mixture of **1**, **2**, and **3**. The reactions with SO_2Cl_2 and PCl_5 at higher temperature gave **4** as an additional product (Runs 9 and 11). It is evident that at least **4** is formed by a radical pathway,[7] since the addition of *m*-DNB profoundly decreased the total yield of the products, affording none of **4**. In contrast, in the reactions with chlorine (in the dark) the formation of **4** was only slight (Run 7) and *m*-DNB and bubbling oxygen gave no effect on product distribution, suggesting an ionic process. The ionic nature of $PbCl_4$ was previously reported in the chlorination of norbornene.[6]

The mechanism for the formation of **1**—**3** might be essentially the same as that proposed by Winstein[8] in the bromination of norbornadiene. The attack of anion on C_3 and C_1 of a nonclassical chloronorbornyl cation

TABLE CHLORINATION OF NORBORNADIENE

Run	Norbornadiene (mmol)	Chlorinating agent (mmol)	Solvent (50 ml)	React temp (°C)	React time (hr)	Products Isomer distribution (%) 1	2	3	4	Yield (%)[a]
1	25	$CuCl_2$[b]	25 CH_3CN	80	2	49	50	1	0	82

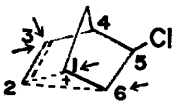
a) Based on the chlorinating agent. Determined by glc. b) LiCl (25 mmol) was added. c) Other products; nortricyclyl chloride (0.2 mmol). d) Other products; nortricyclyl chloride (1.26 mmol) and *exo*-5-chloro-2-norbornene (3.6 mmol). e) Ref. 4.

* To whom all correspondence should be addressed.

(**A**) gives a mixture of **1** and **2**, and **3**, respectively. However, the reason why only the chlorinating agents in this class give **3** is not yet clear. The attack on C_6, which affords **4**, might be sterically unfavorable.



(**A**)

The last class contains only $MoCl_5$ which gave mainly **4** probably by molecular *cis*-addition mechanism.[4]

From a synthetic viewpoint chlorination by $SbCl_5$ is recommended for preparation of **1** and **2** because of its simplicity and high yields of the products. For **3** and **4**, the reactions with PCl_5 (in CH_2Cl_2) and $MoCl_5$, respectively, should be employed, though it is necessary to use preparative glc for isolating each isomer in a pure state.

Experimental

All materials except $PbCl_4$ were commercial products and used without further purification. The reactions were usually carried out by mixing all the reagents at room temperature and then keeping the mixture at reaction temperature under the presence of atmospheric oxygen. In the case of VCl_4, a CCl_4 solution of VCl_4 was added to a CCl_4 solution of norbornadiene in order to avoid the polymerization of diene. In the case of Cl_2, chlorine gas was introduced to a CCl_4 solution of norbornadiene at -20 °C. The identification of each product, **1**—**4**, was described previously.[4] The product mixtures were analyzed by glc by the use of Shimadzu apparatus 5APTF and 4BMPF on both EGSS-X(15%)-Chromosorb-W (3 m) and PEG 6000 (25%)-Chromosorb-W (3 m) columns (carrier gas, N_2; bromobenzene or *trans*-dichlorocyclohexane as internal standard).

Reaction with $PbCl_4$. A solution of CH_2Cl_2 (50 ml) containing $Pb(OAc)_4$ (2.22 g, 5.0 mmol) was kept at -60 °C and was introduced by HCl gas for 10 min.[9] To this solution was slowly added norbornadiene (2.3 g, 25 mmol) at -40 °C and the solution was stirred for 2 hr. After the usual work-up, the organic layer was evaporated to *ca.* 7 ml and analyzed by glc; *exo*-5-chloro-2-norbornene (3.6 mmol), nortricyclyl chloride (1.26 mmol), **1** (1.93 mmol), **2** (0.86 mmol), and **3** (1.13 mmol). The formation of the former two compounds by the reaction of norbornadiene with HCl has been reported.[10]

*Synthesis of **1** and **2**.* A CCl_4 (50 ml) solution of $SbCl_5$ (15 g, 50 mmol) was added to a CCl_4 (150 ml) solution of norbornadiene (9.2 g, 100 mmol) at 25 °C in *ca.* 1 min and the resulting clear solution was stirred for 10 min. To this solution was added water and the precipitated SbOCl was filtered and then CCl_4 layer was distilled to give 6.5 g (80% yield) of a mixture of **1** and **2** (**1**:**2**=58:42); bp 95—96 °C/22 mmHg. The NMR spectrum of both **1** and **2** (separated by preparative glc) was identical with the spectra reported.[2,3]

Extractive Spectrophotometric Determination of Chromium(III) with 1-(2-Pyridylazo)-2-naphthol

B. SUBRAHMANYAM and M. C. ESHWAR
Department of Chemistry, Indian Institute of Technology, Bombay-400076, India
(Received July 9, 1975)

Synopsis. 1-(2-Pyridylazo)-2-naphthol reacts with chromium(III), on heating at 80—90 °C for 35 min, at a pH of 3.2—3.7 in presence of acetate buffer. The reddish-brown chelate, extracted into 1-butanol, has two absorption maxima at 555 and 600 nm of equal intensity. The complex obeys Beer's law in the range 0.3—2.0 μg/ml, has molar absorptivity 1.28×10^4 at 555 nm.

1-(2-Pyridylazo)-2-naphthol, PAN, finds considerable application[1,2] as colorimetric reagent for determination of a number of metal ions. PAN has been found to be selective at lower pH values; hence a detailed investigation of chromium(III) has been carried out. This simple, sensitive and selective method is applied for the determination of chromium content in an alloy steel sample.

Experimental

Apparatus and Reagents. A CΦ4 quartz spectrophotometer with 10 mm quartz cells was used for the absorption measurements. The absorption spectra was recorded on a Perkin-Elmer recording spectrophotometer, Type 402. A cambridge pH meter was used for all pH measurements.

Stock solution of Cr(III) containing 2 mg/ml of chromium was prepared from chromium(III) nitrate (J. T. Baker) and standardized[3] volumetrically. Experimental solutions were obtained by appropriate dilution of stock solution.

1-(2-Pyridylazo)-2-naphthol. 0.1% solution of 1-(2-pyridylazo)-2-naphthol (PAN) was prepared in methyl alcohol.

Buffer solution of pH 3.5 was prepared from 0.2 M sodium acetate and 0.2 M acetic acid.

General Procedure. An aliquot of chromium(III) solution containing <20 μg of chromium was taken, to which were added 5 ml of sodium acetate-acetic acid buffer, pH 3.5, and 1 ml of 0.1% PAN. The contents were shaken thoroughly, made to 15 ml and heated in a boiling water bath for 35 min, allowed to cool, made to 25 ml, and extracted in a separating funnel with 10 ml of butanol for 20 s. After separation of layers, organic phase was collected in a 10 ml volumetric flask containing 1 g of anhydrous sodium sulfate and absorbance of reddish-brown chelate was measured at 555 nm against the reagent blank prepared under similar conditions.

Results and Discussion

Effect of pH. pH was varied from 0.5 to 7, and absorbance was found to be maximum (Fig. 1) in the pH range 3.2—3.7. Hence all studies were carried out at pH 3.5. Sodium acetate-acetic acid buffer was found to be the most suitable one.

Effect of Reagent Concentration. Reagent (0.1% PAN) concentration was varied from 0.1 to 5 ml with 13 μg of Cr(III) per 10 ml. Absorbance was found to be constant with amounts greater than 0.5 ml, hence 1 ml of reagent was used in all studies.

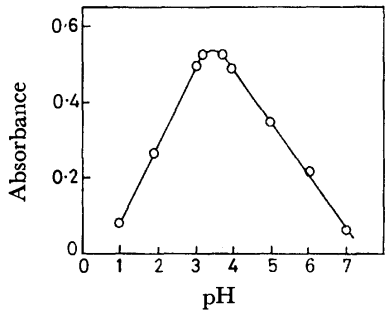

Fig. 1. Effect of pH.
[Chromium]$=3.95\times 10^{-4}$ M.

Effect of Heating and Stability. Reaction of chromium(III) with PAN was too slow at room temperature to be observed, probably due to inertness of $[Cr(H_2O)_6]^{3+}$. However, complexation resulted on heating the reactants to a temperature of 80—90 °C. The time of heating was varied from 5 min to 120 min and stable colour was formed from 30 min onwards. Hence reactants were heated for 35 min in all studies. The complex was found to be stable for more than 48 hr.

Choice of Solvent and Period of Equilibration. Various solvents, such as benzene, xylene, carbon tetrachloride, butanol, chloroform, butyl acetate were tried for extraction of the complex, but the complex was extracted only into chloroform and 1-butanol. As absorbance was found to be greater in 1-butanol than in chloroform, 1-butanol has been selected as suitable solvent.

Period of shaking for extraction of the complex into 1-butanol was varied from 5 s to 180 s, and the absorbance was found to be constant over this period. Hence, a period of 20 s was chosen for extraction.

Absorption Spectra. Absorption spectra of Cr-(III)-PAN chelate, extracted into butanol after heating for 35 min at pH 3.5 was recorded against a reagent blank prepared under similar conditions. The complex showed (Fig. 2) two absorption maxima at 555 and 600 nm, both of equal intensity. Hence, absorbance measurements can be carried out at 555 or 600 nm. The present studies were carried out at 555 nm.

Composition of the Complex. Composition of the complex was determined by Job's continuous variation method which gave a ratio of 1 : 2, metal-to-ligand, and the ratio was verified by mole ratio method.

Beer's Law. Beer's law was obeyed in the concentration range of 0.3 to 2.0 μg/ml of Cr(III). Molar absorptivity was 1.28×10^4 and Sandell's sensitivity was 0.004 μg of Cr(III) per cm^2.

Effect of Diverse Ions. Interference of about 46 ions in determination of 13 μg of Cr(III) per 10 ml was

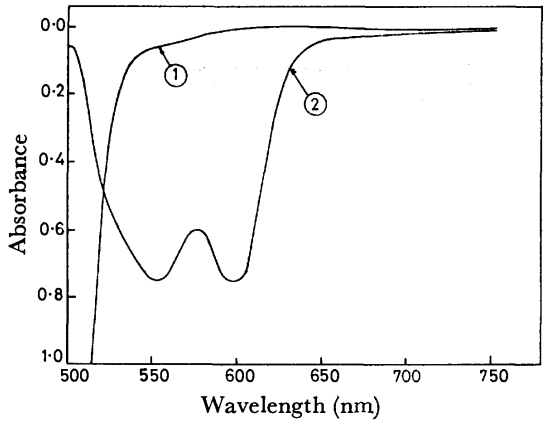

Fig. 2. Absorption spectrum of chromium(III)-PAN complex.
(1): Absorption spectrum of PAN *vs.* solvent,
(2): absorption spectrum of Cr(III)-PAN complex *vs.* reagent blank.
[Cr (III)]$=1.25\times10^{-4}$ M, [PAN]$=2.50\times10^{-4}$ M.

studied, setting the tolerance limit for interfering ions to cause an error of $\pm2\%$ in chromium recovery. Of the interfering ions, Fe(III), Cu(II), Co(II), Ga(III), In(III), and Tl(III) caused positive error, while CN^- and EDTA gave negative error. Interference due to Fe(III), was eliminated by prior extraction with mesityloxide[4] and those of Cu(II), Co(II), Ca(III), In(III), and Tl(III) was overcome by extracting their PAN complexes into chloroform before heating. The tolerance of some of the metal ions was due to decomposition of their chelates with PAN on heating. Most of the cations, associated with chromium, such as manganese, iron, cobalt, nickel, copper, titanium, zirconium, vanadium, niobium, tantalum, molybdenum and tungsten were tolerated, some of them in manyfold concentrations. The effect of foreign ions is shown in Table 1.

Table 1. Effect of diverse ions
Amount of Cr(III) taken: 13 μg/10 ml, pH=3.5

Foreign ion added	Tolerance limit μg
Ag(I), Mn(II), Pb(II), Fe(III)[a], F^-, Cl^-, Br^-, I^-, oxalate	5000
Sr(II), Ba(II), Ca(II), Mg(II), Zr(IV), Nb(V), AsO_4^{3-}, ReO_4^-, TeO_3^{2-}, SeO_3^{2-}, SO_4^{2-}	2000
Ge(IV), Ta(V), PO_4^{3-}, malonate	1000
Be(II), Bi(III)	500
Cd(II), Sb(III), Ti(IV), Zn(II)	200
Ni(II)[b], Cu(II)[c], Ga(III)[c], In(III)[c], Tl(III)[c], VO_3^-, $MO_7O_{24}^{6-}$, WO_4^-	50

a) Extracted with mesityl oxide. b) Masked with DMG.
c) Extracted as PAN complex before heating.

Precision and Accuracy. Relative standard deviation and relative error, calculated from ten repeat determinations with 1.3 μg of Cr(III) per ml, were found to be $\pm1.25\%$ and $\pm0.80\%$ respectively.

Application to the Analysis of Stainless Steel. 0.5 g of austenitic stainless steel (Bureau of Analysed Samples, Newham Hall, U. K., No. 332) was dissolved in 10 ml of 1:4 H_2SO_4 and diluted to 250 ml. Four ml of this solution was acidified with HCl to 3.5 M, transferred to a 100 ml separating funnel and iron was removed by extraction with 10 ml of mesityl oxide.[4] The aqueous layer was evaporated to dryness and made up to 100 ml. An aliquot of this solution was taken, adjusted to pH 3.5, and to it were added 1 ml of PAN, 1 ml of 0.5% DMG and 5 ml of acetate buffer (pH 3.5). The contents were heated for 35 min, transferred after cooling to a separating funnel, and chromium complex extracted with 10 ml of 1-butanol. Absorbance of the organic phase was measured at 555 nm. From duplicate analysis, recovery of chromium was found to be 12.50% and 12.60%, compared to the theoretical value of 12.8%. Other constituents of the alloy are Si–0.44%, S–0.02%, P–0.015%, Mn–0.800%, Ni–12.40% and rest iron.

Authors express their sincere thanks to Council of Scientific and Industrial Research (India) for the award of Junior Research Fellowship to one of them (BS).

Template-Directed Synthesis of Oligonucleotide. Condensation of Nucleotide in the Presence of Polystyrene-Supported Neutral Oligonucleotide Derivative

Takeo SHIMIDZU and Akio IMAI

Department of Hydrocarbon Chemistry, Faculty of Engineering Kyoto University, Kyoto 606

(Received August 7, 1975)

Synopsis. A template-directed synthesis of oligonucleotide in the presence of polystyrene-supported neutral oligonucleotide derivative was studied. The oligonucleotide which has the sequence of the complementary base with the template, the neutral oligonucleotide derivative, yielded with a considerable amount, when the template with degree of oligomerization of 4 was used.

Chemically, we have two ways to synthesize the definite-sequence oligonucleotide: One is the stepwise synthesis of the oligonucleotide and the other is the template-directed synthesis. Several studies relating to the latter, the oligonucleotide syntheses using polynucleotides have been done,[1-8] but they were not necessarily successful.

Observations of those polynucleotide template-directed syntheses indicate a few problem. The complex formation between polynucleotide and condensing nucleotide in aqueous solution is not strong. Generally, that the equilibrium constant of the complex formation between nucleotide bases is remarkable in the aprotic solvent can be seen in IR[9] and NMR[10] studies. In addition, negatively charged phosphate groups both in the polynucleotide and the condensing nucleotide are undesirable for the complex formation. Disadvantage in the chemical reaction of the charged molecules on the polyelectrolyte having the same signed charge has been suggested by Ise.[11]

On the basis of those informations, a novel template-directed synthesis of the oligonucleotide has been tried. The material was synthesized by the method of so-called solid support.[12] In the present study, the cross-linked polystyrene anchored oligonucleotide of which phosphoric acid moiety was esterified by cyanoethyl alcohol was used. This material was synthesized by the method of the preceding paper.[13] The oligonucleotide derivative in the present template was neutral at its phosphate moiety and anchored in the polystyrene matrix. Figure 1 shows an example of the template. The anchored oligonucleotide derivative has a failure in its sequence, in part.

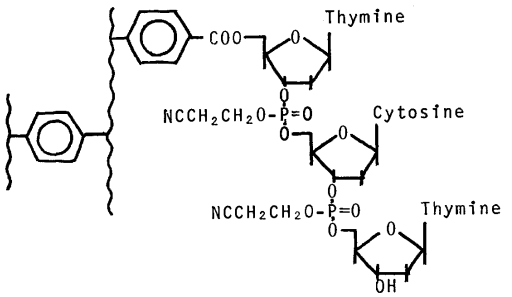

Fig. 1. [PSt]-TCT

Table 1 lists the result of the template-directed condensation of the nucleotide. In this condensation system, it is remarkable that the complementary oligonucleotide whose degree of condensation was more than two was obtained. However, the fully complementary oligonucleotide was scarecely obtained.

TABLE 1. CONDENSATION OF NUCLEOTIDE IN THE PRESENCE OF POLYSTYRENE-SUPPORTED NEUTRAL OLIGONUCLEOTIDE DERIVATIVE

Template	Nucleotide (mol%)	Relative yield of main product (optical density)

a) TTT=96 mg/0.5 g-polymer support, % of the full sequence=79. b) TCT=85 mg/0.5 g-polymer support, % of the full sequence=78. c) TCTC=78 mg/0.5 g-polymer support, % of the full sequence=61. Total nucleotide (pyridinium form)=100 mg (calcd. as free acid). Pyridine=15 ml. Total DCCD=200 mg. Reaction time=24 hr. Room temperature.

In cases of [PSt]-CH_3 and [PSt]-TTT used, the rate of condensation of pdA was relatively high. In the product, the oligonucleotide which was additional product of the template oligonucleotide molecule, TpTpTpdA for example, was found. When four kinds of condensing nucleotides, pT, pdA, pdC, and pdG, were condensed in the presence of [PSt]-TTT or [PSt]-TCT, the maximum yield in the product was pdGpdG. And, in the case of [PSt]-TCT used, the fully complementary product, pdApdGpdA, was not found. On the other hand, when the tetramer template such as [PSt]-TCTC was used, though the fully complementary oligonucleotide, pdApdGpdApdG, was not found in the product, the partly complementary oligonucleotide yielded with a considerable amount. The yield of the partly complementary oligonucleotide appeared to be more prominent in the case that two kinds of condensing nucleotides, pdA and pdG, were used. In addition, the result showed that the yield of the oligonucleotide which was partly complementary with the template sequence close to the polystyrene solid support, *i.e.*, pdApdGpdA, was higher than that which not close to, *i.e.* pdGpdA-pdG. This shows the importance of a matrix constructed by the polymer that gives a hydrophobic enviroment.

Those results could lead the template-directed synthesis of oligonucleotide.

Support in part for this work by the Grant from the Ministry of Education (Grant in aid for Special Project Research 820828 and 911013). Thanks are due to Profeesor Kenichi Fukui for his encouragement. The authors are grateful to Dr. H. Hirai, Nagase Ind. Co., for kindly renting the Peptide Synthetizer Instrument (Schwartz Bioresearch).

The Dye-sensitized Photolysis of Aryl Aryldiazo Sulfone

Toshihiro YAMASE, Hiroshi HISADA, Sadao SUZUKI, and Tsuneo IKAWA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 22, 1975)

Synopsis. The amethyst violet (AV)-sensitized photolysis of *p*-tolyl *p*-anilinobenzenediazo sulfone (TABS) has been investigated in a ethanol–water (9.3: 0.7, v/v) solution. The experimental data on the quantum yield of the sensitized photolysis and the AV fluorescence or phosphorescence intensity were explained in terms of AV-excited singlet sensitization. Studies of both the photoproducts and the heterogeneous photopolymerization of acrylamide supported the mechanism involving the homolytic dissociation of diazosulfone.

Brief reviews of the diazosulfones-imaging system have been published by Dinaburg.[1] When irradiated with actinic light, diazosulfones decompose in the areas illuminated, whereas the non-illuminated parts preserve the ability to undergo coupling reactions with the formation of azo dyes, like usual diazonium compounds. Our purpose was to find a dye-sensitized photolysis for this system, since the dye sensitization will ensure an increase in the overrall photosensitivity. The present note will describe the results of the amethyst violet (AV)-sensitized photolysis of *p*-tolyl *p*-anilinobenzenediazo sulfone (TABS) in an ethanol–water solution. The absorption spectra were recorded on a Hitachi 624 spectrophotometer. The fluorescence and phosphorescence measurements were carried out on a Hitachi MPF-2A spectrofluorimeter. The ESR spectra were recorded on a Varian E-12 X-band spectrometer with 100 kHz magnetic field modulation. Unless specified otherwise, all the experiments were performed at room temperature. Degassing from the solution was carried out by the usual freeze-pump-thaw cycle at 10^{-4} mmHg. The 546 nm irradiation was performed by the use of a 500-W super-high-pressure mercury lamp, equipped with two filters (Toshiba VO-52+KL-54). The light intensities were measured by Reineckate actinometry. The dark reaction of *p*-anilinobenzenediazonium sulfate ($2—4\times10^{-5}$ M) with sodium *p*-toluenesulfinate (STS) ($5\times10^{-4}—3\times10^{-3}$ M) to give TABS in ethanol–water solution was spectrophotometrically studied in order to measure the equilibrium constant (K) for the TABS formation.[2] Its value was determined from the straight line in Benesi-Hildebrand's plot;[3] the resulting value became greater with an increase in the ratio of ethanol in the ethanol–water solvent (Table 1). In the variation in the ethanol–water ratio, the extinction coefficient of TABS at the wavelength (450 nm) of its absorption maximum was unchanged at 2.9×10^{4} M^{-1} cm^{-1}. Some quantitative measurements were made with ethanol–water of 9.3: 0.7, v/v. TABS was stable in the dark during the experimental procedure. The dye-sensitized photolysis of TABS was followed by a change in the absorbance of the solutions at 450 nm. The absorbance of the solution at 546 nm was unchanged during continuous illumination, irrespective of the presence of oxygen.

a) aerobic b) N_2 bubbled c) O_2 bubbled d) deaerated

With $\leq5\times10^{-5}$ M TABS and $\leq4\times10^{-5}$ M AV in an ethanol–water (9.3: 0.7, v/v) solution, the quantum yield (η) for TABS elimination was determined, based on the total absorbed intensity of the 546 nm irradiating light (Table 2). An oxygen effect seemed to be absent in this system at least, since the η value of about 0.04 was unchanged after a thorough degassing of the solution. The η value decreased with a decrease in the TABS concentration and with an increase in the AV concentration or the 546 nm light itensity ($\leq8\times10^{-5}$ E. absorbed/l min).

AV showed a strong fluorescence maximum at 565 nm in ethanol–water (9.3: 0.7, v/v). The steady-state fluorescence intensity decreased with an increase in the AV concentration ($\geq2\times10^{-5}$ M). To check whether or not AV singlets were involved in the sensitization, we examined the effect of added TABS upon the fluorescence intensity of AV (2×10^{-5} M) in degassed solutions. Figure 1 shows the Stern-Volmer plot for the quenching of the fluorescence of AV by TABS. No new emission was detected in the presence of TABS. The fluorescence quenching was scarcely affected by oxygen. STS and water also caused a decrease in the fluorescence intensity, but their quenching constants of 13 and 6.8×10^{-2} M^{-1} were very small in comparison with the value of TABS (3.9×10^{3} M^{-1}). The facts that the oxygen effect seemed to be absent in both the AV fluorescence intensity and the quantum yield of the sensitized TABS photolysis, that the AV fluorescence intensity decreased with an increase in the AV and TABS concentrations, and

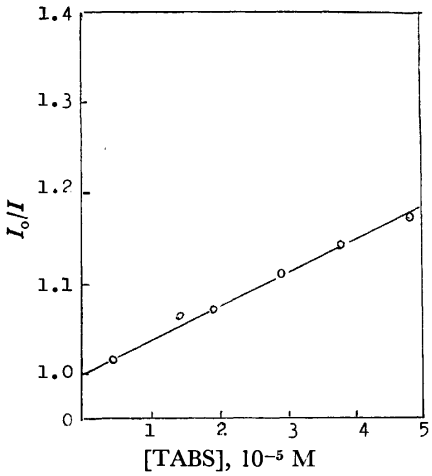

Fig. 1. Quenching of AV fluorescence by TABS, [AV]= 2×10^{-5} μ

that the quantum yield increased with a decrease in the AV concentration and an increase in the TABS concentration support the AV excited singlet sensitization.[4] In addition, AV (10^{-6}—10^{-5} M) emitted a phosphorescence exhibiting its maximum intensity at 730 nm in a deaerated EPA matrix (77 K), and its intensity was significantly reduced by oxygen. Those results may exclude the involvement of excited triplet AV in the sensitization, since the quantum yield of AV-sensitized photolysis should be significantly reduced by oxygen, if the above hypothesis occurs.[5]

The AV-sensitized photolysis of TABS induced the heterogeneous polymerization of acrylamide in a deaerated system without any permanent photobleaching of AV. The molecular weights of the polymers were of the order of thousands. The absence of TABS or the presence of oxygen caused no significant photopolymerization of acrylamide. The ESR spectrum of the polymer obtained showed a broadened single line at $g=2.009$, but the identity of the occluded radicals in the polyacrylamide particles seemed to be uncertain because of the lack of any observable hyperfine structure. The photopolymerization results suggest that the AV-sensitized photolysis of TABS leads to the production of free radical intermediates, which then initiate the polymerization of acrylamide.

Longer periods of the AV-sensitized photolysis of the TABS (~0.4 mmol) formed by a reaction between—0.4 mmol 4DS and ~15 mmol STS in 9.3: 0.7 ethanol-water (100 ml) containing ~0.06 mmol AV under nitrogen gave up to a 90% decomposition of TABS. Sodium *p*-toluenesulfonate readily precipitated out of the solution. The reaction mixture was then poured into 100 ml of a 5% sodium carbonate aqueous solution and filtered off. The filtrate was evaporated under reduced pressure, and the diphenylamine in the residue was separated by thin-layer chromatography on Kieselgel 60 F. Direct photolysis was carried out with the TABS (~0.2 mmol) formed by a reaction between 0.2 mmol 4DS and 5 mmol STS in 50 ml of 9.3: 0.7 ethanol–water. The final products isolated were essentially the same as in the case of AV-sensitized photolysis, sodium *p*-toluenesulfonate and diphenylamine. Photoproduct studies may indicate a similarity in the behabior of TABS decomposition in direct and sensitized photolyses. The direct photolysis of aryl aryldiazosulfone has been considered to undergo homolytic decomposition in neutral media.[6] This situation and the observation of the free radical photopolymerization of acrylamide make it likely that the homolytic dissociation has occurred in the AV-sensitized photolysis of TABS, thus yielding $CH_3C_6H_4SO_2\cdot$ and $C_6H_5NHC_6H_4N_2\cdot$ radicals. The loss of nitrogen from the latter may result in the formation of diphenylamine *via* a hydrogen abstraction from ethanol. The formation of sodium *p*-toluene-sulfonate may be ascribed to the disproportionation of the tosyl radical, as has been noted by da Silva Correa and Waters.[7]

4) The tendency for the quantum yield to decrease with the increase in the incident light intensity may result from the quenching of the excited singlet AV by photoproducts or their precursors (free-radical intermediates) formed *via* the sensitized homolytic dissociation of TABS, although this is not clear from these observations alone.

5) Attempts to detect the TABS phosphorescence and to confirm the absence of any quenching of the AV phosphorescence by TABS failed, probably because of the lower solubility of TABS for EPA.

A Single-step Synthesis of 2-Substituted Benzo-azoles

Nobutaka SUZUKI, Toshiyuki YAMABAYASHI, and Yasuji IZAWA*

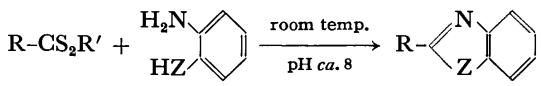
Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu 514

(Received July 28, 1975)

Synopsis. 2-Substituted benzimidazoles (**3a** and **5a**), benzothiazoles (**3b** and **5b**), and benzoxazole (**3c**) are readily synthesized in good yields by treating (thiobenzoylthio)-acetic acid (**1**) or ethyl dithioacetate (**4**) with the corresponding *o*-substituted anilines (**2a**, **2b**, and **2c**) in slightly alkaline media at room temperature.

Numerous methods have been reported for the preparation of 2-substituted benzo-azoles.[1] However, most of them require a procedure with several steps and/or severe reaction conditions.

In our attempt to prepare a series of 2-substituted thiazolines, (thiobenzoylthio)acetic acid[2] (**1**) or ethyl dithioacetate[3] (**4**) was treated with *o*-substituted anilines having a protic group, such as $-NH_2$, $-SH$, or $-OH$ (**2a**, **2b**, and **2c**), in a similar manner to that reported in a previous paper[4] to give the corresponding 2-substituted benzo-azoles (**3a**, **3b**, **3c**, **5a**, and **5b**) in good yields. However, **4** with **2c** gave only an acetanilide (**6c**) instead of 2-methylbenzoxazole (**5c**), in a moderate yield.



1: R=Ph; R'=CH_2CO_2H **2a—c** **3a—c**

4: R=Me; R'=Et **5a—b**

a: Z=NH, **b**: Z=S, **c**: Z=O

In a typical experiment, (thiobenzoylthio)acetic acid[2] (**1**: 2.0 mmol) and *o*-aminothiophenol (**2b**: 2.2 mmol) were dissolved in aqueous MeOH (3: 1) (40 ml), its pH being adjusted to *ca.* 8 with 1M NaOH. The solution was stirred at room temperature[5] under a slightly reduced pressure (aspirator) to remove H_2S generated until the red coloration of **1** disappeared. The progress of reaction was also monitored by tlc [silica gel, PF_{254}-gipshaltig (Merck), hexane–acetone (3: 1)]. The pH of the solution was checked occasionally and adjusted to *ca.* 8 with alkali. After being acidified with 1M HCl (to pH *ca.* 3), the resulting 2-phenylbenzothiazole (**3b**) was isolated from the reaction mixture by extraction with CH_2Cl_2 and $CHCl_3$. Evaporation of solvents followed by crystallization of the residue from aqueous EtOH afforded crystals of **3b**.

Similarly, except for the use of an aqueous EtOH (2: 1) as a solvent, **3a**, **3c**, **5a**, and **5b** were obtained in good yields from the corresponding starting materials (**1** and **4**, with **2a**, **2b**, and **2c**). In the case of **3c**, additional steam distillation of the extracts was necessary to obtain crystals. The reaction conditions and results are summarized in Table 1. The products (**3a**, **3b**, and **3c**) were identified by mp, IR, NMR and mass spectra. Structures of **5a** and **5b** were confirmed by comparison of their mp or bp, IR,[6] and mass spectra with those of the corresponding authentic samples.

An attempted synthesis of 2-methylbenzoxazole (**5c**) (treatment of **4** with **2c**) gave a colorless crystal, mp 204.5—206 °C (lit, bp of **5c**: 200—201 °C) in a moderate yield, which was identified as *N*-acetyl-*o*-aminophenol (**6c**) by its mp, IR,[6] and mass spectra. This seems to be a hydrolysis product of *N*-thioacetyl-*o*-aminophenol (**7**).

Experimental

The mp and bp are uncorrected. The following instruments were used for the spectral measurements: IR: JASCO IR-G; NMR: JEOL JNM-MH-100 (100 MHz) and MS: JEOL D-100.

The authentic 2-methyl-benzimidazole[7] (**5a**) and -benzothiazole[8] (**5b**) were prepared by the methods described in the lit. **5a**: Colorless fine-needles, mp 179—180 °C (64%). **5b**: Colorless liq. bp 121—122.5 °C/20 mmHg (44%). (Thiobenzoylthio)acetic acid[2] (**1**) and ethyl dithioacetate[3] (**4**) were prepared according to the methods described in the lit. **1**: Red fine needles, mp 125 °C (lit,[2] 121—124 °C). **4**: Orange-yellow liq., bp 47—50 °C/12 mmHg (lit,[3] 52 °C/12 mmHg). ν_{max} (neat) 1450, 1190, 1100 cm^{-1}, δ (ppm) (CCl_4) 1.31 (3H, t, J=7.6 Hz), 2.79 (3H, s), and 3.17 (2H, q, 7.6).

General Procedure of the synthesis of the azoles (**3a**, **3b**, **3c**, **5a**, and **5b**) is given in the text and their reaction conditions and results are shown in Table 1.

Attempted Synthesis of **5c** *(formation of* **6c**). Synthetic procedures were similar to the general procedure shown above. The conditions and results are also given in Table 1. **6c**: Colorless leaflets: ν_{max} (KBr) 3400, 1655, 1545 cm^{-1}.

Photoelectrochemical Reactions at $SrTiO_3$ Single Crystal Electrode

Tadashi WATANABE, Akira FUJISHIMA, and Ken-ichi HONDA

Department of Industrial Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 14, 1975)

Electrode characteristics of strontium titanate ($SrTiO_3$) single crystal have been investigated under illumination with light of its intrinsic absorption region. It has been found that the photosensitized electrolytic oxidation of water, known heretofore uniquely on the TiO_2 electrode, can proceed also at the $SrTiO_3$ electrode whose anodic dissolution being negligible. Although the photosensitivity of the $SrTiO_3$ electrode is confined to a little shorter wavelength region than that of the TiO_2 electrode, the formal quantum efficiency of the photosensitized electrolytic oxidation of water is comparable for these two semiconductor electrodes under intrinsic absorption. In contrast to the case of the TiO_2 electrode, the electrochemical photocell consisted of the $SrTiO_3$ anode and platinum cathode can work efficiently even when the pH values of the anodic and cathodic compartments are close to each other. This point is discussed in terms of the flatband potential of these semiconductor electrodes.

We previously reported on the photosensitized electrolytic oxidation of water at the TiO_2 (n-type semiconductor) single crystal electrode,[1,2] and its utilization in an electrochemical photocell[3,4] where water is decomposed to hydrogen and oxygen gases through the light absorption by the electrode. However, no other semiconductor electrodes of this type have ever been reported so far.

Boddy and co-workers[5,6] studied the electrode characteristics of oxide semiconductors such as TiO_2, $KTaO_3$, Ta_2O_5 and $SrTiO_3$ without intended irradiation of the electrode surface. They noted oxygen evolution at the surface of these electrodes under strong anodic polarization, and elucidated this phenomenon on the basis of a tunneling of electrons from the surface oxide ions to the conduction band of the electrode. Since no evidence for the dissolution of the electrode surface was observed, they concluded that the surface oxide ions were supplied by water molecules. Provided that the electrode surface remains stable also at the excited state, the photosensitized electrolytic oxidation is expected to occur on these oxide semiconductor electrodes. However, the photoeffects on these electrodes, excluding TiO_2, have not been investigated in detail.

In the present study we carried out quantitative measurements of electrode characteristics of the $SrTiO_3$ single crystal under illumination with light of its intrinsic absorption range ($\lambda<390$ nm), and verified that the photosensitized electrolytic oxidation of water by surface holes does proceed effectively at the $SrTiO_3$ electrode.

Experimental

Electrode Preparation. Single crystals of $SrTiO_3$ were supplied by Fuji Titanium Industry, Ltd. The crystal was in the form of a platelet of 2.5 cm^2 in surface area and 1.0 mm in thickness. Prior to the preparation of the electrode, the crystal was treated at 600 °C under high vacuum (*ca.* 10^{-3} Torr) for several hours in order to increase the electric conductivity. After this treatment the crystal is colored in blue owing presumably to the formation of oxygen vacancies in the bulk of the crystal and the specific resistivity is found to be around 10^3 ohm·cm. The crystal was cemented with an epoxy resin in such a way that the (001) face of the crystal (perovskite-type) was exposed to the electrolyte solution. The opposite face was used for a barrier-free electrical contact with a conducting wire by means of electroplated indium. Before the measurements, the surface of the electrode thus prepared was polished with an alumina powder, washed with nitric acid and then with de-ionized water. A platinized platinum plate, having the apparent surface area of 10 cm^2, was employed as the counter electrode.

Experimental Setup. Figure 1 schematically shows the apparatus for photocurrent measurements. A 500 watt xenon lamp served as a light source. The wavelength of the illuminating light was selected by means of appropriate colored glass filters (Toshiba Kasei, Ltd.) or a monochromator (Shimadzu, Ltd.). The electrode-electrolyte interface was illuminated through a quartz window attached to the electrolytic cell. Photocurrents were detected by means of a potentiogalvanostat Type HA-101 of Hokuto Denko, Ltd.

The number of photons of the monochromatic light incident to the $SrTiO_3$ electrode surface was determined by the following procedure. (i) First, an exact number of photons at $\lambda=365$ nm was measured by means of chemical actinometry with 0.006 M potassium ferrioxalate aqueous solution, where the light leaving the monochromator was totally absorbed by the actinometer solution. (ii) Second, light energy was measured (in erg/s) at the same geometrical position as (i) in the wavelength range 350—600 nm by means of a JASCO thermopile, where 1 mm^2 of Au black absorbed the incident monochromatic light. Finally, the number of photons calculated from the results of (ii) was corrected on the basis of the results of (i). At the time of photocurrent measurements, the light flux reaching the surface of the $SrTiO_3$ electrode was the same as that incident to the actinometer cell.

Results and Discussion

Static Electrode Characteristics. The flatband potential of the $SrTiO_3$ single crystal electrode has been measured as a function of pH of the electrolyte solution. The determination of the flatband potential of an n-type semiconductor electrode is based on the application of the Mott-Schottky relationship[7]

$$\frac{1}{C_s^2} = \frac{2}{q\kappa\varepsilon_0 N}\left(E - E_{fb} - \frac{kT}{q}\right) \quad (1)$$

where C_s represents the space charge capacitance per unit area (measured by means of an AC bridge described elsewhere[8]), q the electronic charge, κ the dielectric constant of the semiconductor (332 for $SrTiO_3$ at 25 °C[9]), ε_0 the permittivity of vacuum, N the donor concentration, E the electrode potential against an appropriate reference electrode, and E_{fb} the flatband potential.

Figure 2 shows $1/C^2$ *vs.* E plots for the $SrTiO_3$ electrode at various pH values, from the slope of which the magnitude of N is calculated to obtain *ca.* 1.0×10^{19} cm^{-3}. From the intercepts of these curves on the E axis, the flatband potential of the $SrTiO_3$ electrode was determined and the results are shown in Fig. 3, together with those for the TiO_2 electrode reported elsewhere.[10] As is clearly seen, the flatband potential of the $SrTiO_3$ electrode depends almost linearly on pH of the electrolyte solution with the slope of *ca.* −60 mV/ΔpH. Such a dependence supposedly results from a dissociation equilibrium of proton at the oxide electrode surface.[7,8] The value of the flatband potential of the $SrTiO_3$ electrode at a given pH is about 0.30 volts more cathodic than that of the TiO_2 electrode. This point will be discussed later in connection with the electrochemical photocell characteristics of these two semiconductor electrodes.

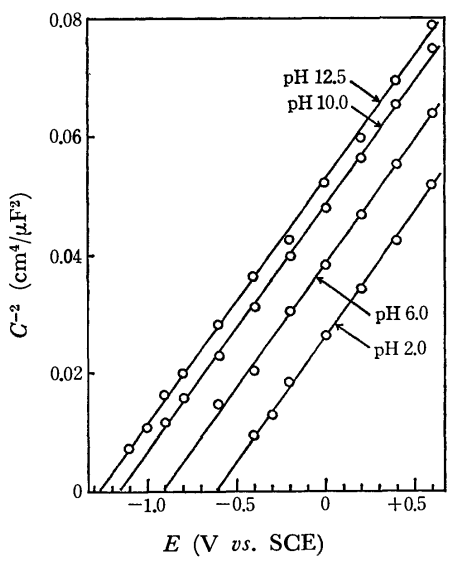

Fig. 2. Mott-Schottky plots for $SrTiO_3$ electrode.

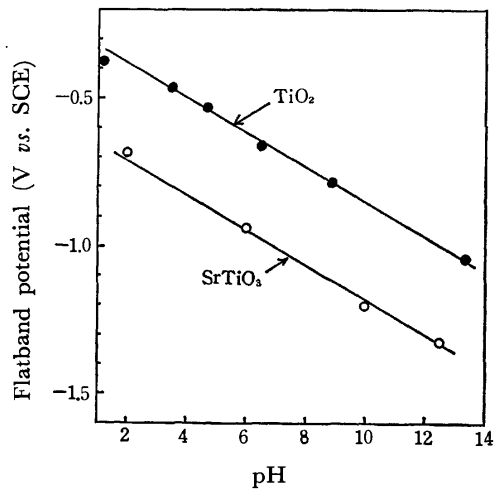

Fig. 3. Dependence of the flatband potentials of $SrTiO_3$ and TiO_2 single crystal electrodes on pH of the electrolyte solution.

Photosensitized Electrolytic Oxidation of Water. The reduced $SrTiO_3$ single crystal electrode behaves like a typical n-type semiconductor electrode. Figure 4 depicts the current-potential characteristics of the $SrTiO_3$ electrode at three different pH values. In darkness, owing to the formation of a depletion layer for the majority carrier (electrons) at the surface of the $SrTiO_3$ electrode, only a small current can be observed under anodic polarization. When the electrode surface is illuminated with light in the wavelength range

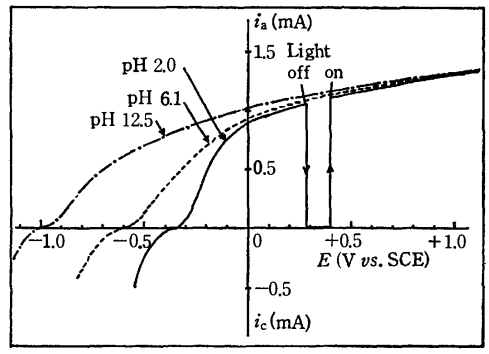

Fig. 4. Current-potential characteristics of $SrTiO_3$ electrode.

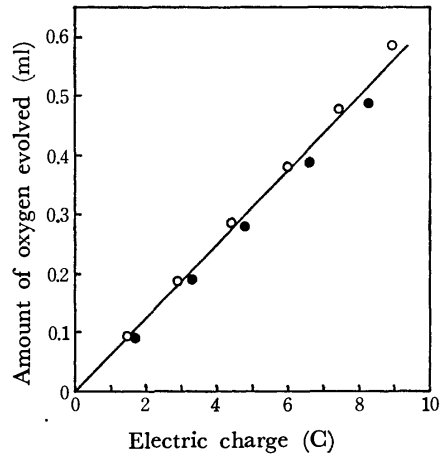

Fig. 5. Dependence of the amount of oxygen (as the standard state) evolved at the $SrTiO_3$ electrode surface on the amount of the electric charge passed through the external circuit. Solid line represents theoretical relationship.

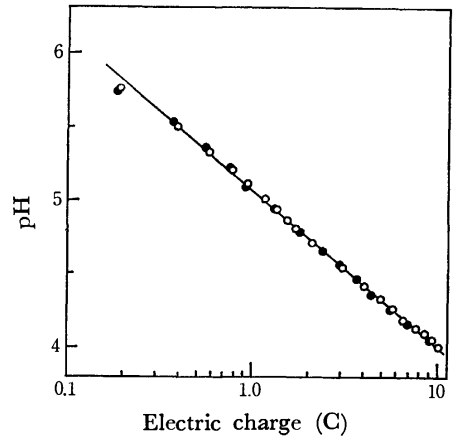

Fig. 6. Variation of pH value of the anodic compartment as a function of the amount of the electric charge passed through the external circuit.
—○—: $SrTiO_3$ (anode)-Pt (cathode) system; —●—: Pt (anode)-Pt (cathode) system under electrolysis.

$\lambda < 390$ nm, a large photocurrent is generated in the anodic polarization, while the cathodic branch remains practically unaffected. The electrode potential at which the anodic photocurrent starts to rise depends on pH of the solution with the slope of *ca.* —60 mV/ΔpH, which conforms to the pH-dependence of the flatband potential.

When the anodic photocurrent is flowing through the $SrTiO_3$ electrode, one can observe gases evolving from the surfaces of the $SrTiO_3$ electrode and of the platinum counter electrode with the apparent volume ratio of *ca.* 1 : 2. Through the examination on a gas chromatograph, these gases were found to be oxygen and hydrogen. The amounts of oxygen and hydrogen evolved have been measured as a function of the electric charge passed through the external circuit. Figure 5 shows the volume (as the standard state) of the oxygen gas evolved at the surface of the $SrTiO_3$ electrode as a function of the electric charge. The open and full circles represent independent measurements. From this figure it is evident that the current efficiency is approximately 100%. We could not notice any evidence for dissolution of the $SrTiO_3$ electrode surface during the electrolysis. The current efficiency for the hydrogen evolution from the platinum counter electrode was found in the range of 97±7%. These observations undoubtedly suggest that the photosensitized oxidation of water proceeds at the illuminated $SrTiO_3$ electrode surface as follows.

$$SrTiO_3 + h\nu \longrightarrow p^+ + e^- \quad (2)$$

$$4p^+ + 2H_2O \longrightarrow 4H^+ + O_2 \quad (3)$$

The residual electrons are transferred to the Pt electrode, where they react with protons to produce hydrogen.

$$2e^- + 2H^+ \longrightarrow H_2 \quad (4)$$

The occurrence of the reaction (3) can be verified by the fact that the value of pH of the anode ($SrTiO_3$) compartment is shifted by unity per decade increase in the amount of the electric charge passed through the electrode-electrolyte interface, as shown in Fig. 6. In this figure is also shown for comparison the variation of pH of the anode compartment for the Pt–Pt system

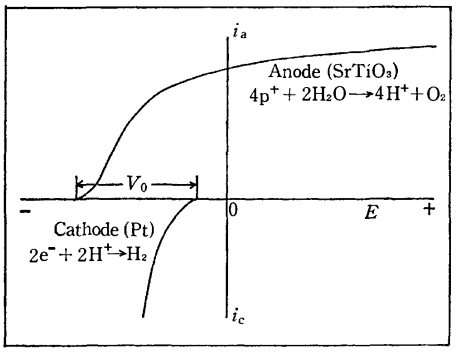

Fig. 7. Electrode reactions at $SrTiO_3$ (anode)-Pt (cathode) system under electrochemical photocell arrangement. V_0 represents the open-circuit cell voltage.

Table 1. Open-circuit cell voltages of $SrTiO_3$-Pt and TiO_2-Pt electrochemical photo-cells

	Common electrolyte solutions	Alkaline (anode)-acid (cathode) solutions
$SrTiO_3$-Pt	0.60 V (0.2 M Na_2SO_4)	1.25 V (1 M NaOH-0.5 M H_2SO_4)
TiO_2-Pt[4]	0.30 V (1 M NaOH)	0.64 V (1 M NaOH-0.5 M H_2SO_4)

during electrolysis.

The electrochemical reactions occurring on the anode ($SrTiO_3$) and cathode (Pt) under the electrochemical photocell arrangement[3,4] are summarized in Fig. 7. The electromotive force (and hence the value of the open-curcuit voltage, V_0) of the $SrTiO_3$ (anode)–Pt (cathode) electrochemical photocell is greater than that of the TiO_2–Pt system, owing to the fact that the flatband potential of the $SrTiO_3$ electrode is situated in the more cathodic region than that of the TiO_2 electrode. The data of V_0's for these semiconductor electrodes under the same illuminating light intensity are summarized in Table 1.

By illuminating the $SrTiO_3$ electrode surface with monochromatic light, the spectral response of the photocurrent has been measured. Since the forbidden gap width of $SrTiO_3$ is *ca.* 3.2 eV, the photosensitivity is confined to the wavelength range below 390 nm. For the estimation of the effectiveness of photocurrent production (and hence of the decomposition of water to hydrogen and oxygen gases), the formal quantum efficiency (*FQE*), defined by

$$FQE = \frac{\text{number of electrons flowing } (s^{-1})}{\text{number of incident photons } (s^{-1})} \quad (5)$$

was employed. The *FQE vs.* wavelength plot for the $SrTiO_3$ anode (0.0 V *vs.* SCE, in 1 M NaOH)–Pt (in 0.5 M H_2SO_4) system is shown in Fig. 8. The value of *FQE* reached 0.2 at 350 nm illumination. By the use of a common electrolyte solution (*e.g.*, 0.2 M Na_2SO_4) for both compartments, the values of *FQE* are lowered by a factor of about 1/2. This factor is much greater than that of the TiO_2–Pt system (*ca.* 1/30[4]), owing presumably to the greater emf of the $SrTiO_3$ anode–

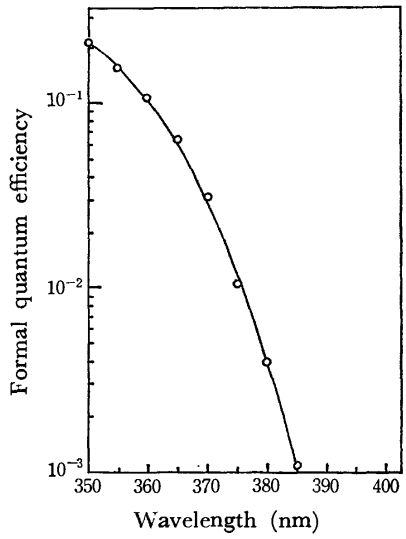

Fig. 8. Formal quantum efficiency of photocurrent production at $SrTiO_3$ anode (0.0 V *vs.* SCE) as a function of the wavelength of the incident light.

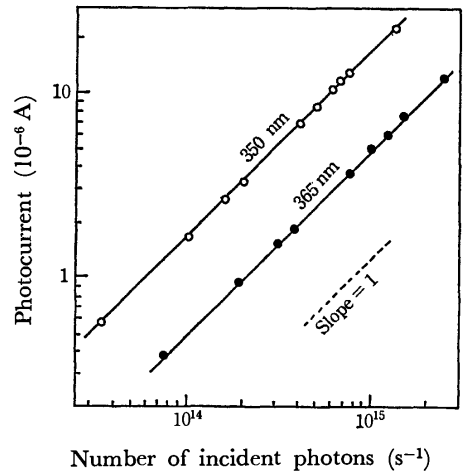

Fig. 9. Dependence of the photocurrent at $SrTiO_3$ electrode (0.0 V *vs.* SCE) on the intensity of the incident light.

Pt cathode electrochemical photocell than that of the TiO_2–Pt cell.

The true quantum efficiency would be much greater than *FQE* because of the high reflectivity of the $SrTiO_3$ crystal surface, whose precise measurement has not been carried out in the present study. For further enhancement of the quantum efficiency, it would be necessary to reduce the processes of electron trapping in the bulk of the semiconductor electrode and of the surface recombination of the charge carriers. These problems, possibly bearing on the thickness of the electrode[11] and/or the condition of the reduction treatment prior to the electrode preparation, are to be examined in the future investigation.

The magnitude of the photocurrent depends linearly on the incident light intensity, as depicted in Fig. 9. Even under the illumination by light with considerably high intensity (*e.g.*, 500 watt xenon lamp with no filters), the photocurrent did not show any saturation tendency.

Based upon the observations described above, it can be concluded that the $SrTiO_3$ single crystal is an excellent semiconductor electrode material for the decomposition of water by means of light energy.

The authors are grateful to Mr. Osamu Tatsuoki for his taking part in the experiments.

The Gas-phase Emission Spectrum of Carbon Disulfide Excited by an N_2 Laser—Magnetic Quenching Effect

Akiyoshi MATSUZAKI and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106

(Received July 8, 1975)

The time-resolved emission spectrum and its temperature dependence were observed with gaseous CS_2 excited by an N_2 laser. The spectrum was found to consist of three band systems, one of them being demonstrated to be emission from the $^1A_2$ state. The collision-free lifetimes and the collisional quenching constants were determined for the three band systems. The emission from the $^1A_2$ state was found to be quenched by a magnetic field because of the enhancement of an intramolecular energy-transfer process. This is the first observation of the magnetic quenching of emission from an excited singlet state.

The absorption spectrum of CS_2 in the region 290—370 nm has been studied by many researchers.[1-10] The longest wavelength absorption (the R system) in the region has been studied by Kleman,[4] by Douglas and Milton,[5] by Hougen,[6] and also by Hochstrasser and Wiersma[7] and has been assigned as the transition to the $^3A_2$ state which correlates with the $\pi\pi^*{}^3\Delta_u$ state of the linear CS_2 molecule. Jungen *et al.*[9,10] studied in detail much stronger absorption (the V system) and assigned it, in accord with Mulliken's prediction,[11] to the transition to the $^1B_2$ state, the upper Renner-Teller component of the $\pi\pi^*{}^1\Delta_u$ state of the linear molecule. Furthermore, they observed absorption due to the transition to the $^1A_2$ state, the corresponding lower component.

According to Jungen *et al.*,[9] there exist two absorption systems in the region of the N_2 laser wavelengths: one of them is due to a transition to a triplet state (the U band system) and the other to the transition to the $^1A_2$ state (the T band system). Brus[12] found that CS_2 emission excited by an N_2 laser shows two separate exponential decays. Mochiji *et al.* studied the emission spectrum of gaseous CS_2 and made a vibrational analysis with the aid of vibrational frequencies in the ground state.[13]

Under these circumstances, we have studied emission spectra of CS_2 excited by an N_2 laser, special attention being paid to the fluorescence from the $^1A_2$ state. We have found that the fluorescence is quenched by the magnetic field because of the enhancement of the intramolecular energy-transfer process. This is the first observation of magnetic quenching of emission from an excited singlet state.[14]

Experimental

An Avco Everett Model C950 N_2 laser was used for the excitation of CS_2. Emission from gaseous CS_2 was monochromatized by a Spex Model 1700 spectrometer and was detected by a combination of an EMI 6256S photomultiplier shielded by μ-metal and a PAR Model 160 boxcar integrator gated by a laser trigger. The signal is smoothed with an *RC* filter with a time constant of 0.2 μs. The N_2 laser intensity detected by this system was not affected by magnetic field. This shows that the shielding of the detecting system is good enough for our purpose. An electromagnet with a 6.5 cm gap was used for the magnetic quenching experiment, its field strength being calibrated by a Rowson-Lush gaussmeter indicator Type 789. A Pyrex glass cell of standard "cross" shaped design was used for the emission measurement which was made in the direction perpendicular to the excitation light. Temperature was controlled by flowing cooled nitrogen gas. Absorption spectra were measured by a Cary recording spectrophotometer model 14.

Wako reagent grade CS_2 was purified by distillation from calcium chloride. The sample pressure was measured by a calibrated Pirani gauge and an oil manometer. The vacuum system is free from Hg and background pressure is 10^{-6} Torr.

Results and Discussion

The Assignment of CS_2 Emission Excited by an N_2 Laser. Time-resolved emission spectra of CS_2 excited by the N_2 laser are shown in Fig. 1. The spectrum measured immediately after excitation ($t=0$) consists of sharp bands and a broad band. The latter decays more slowly than the former, as is clearly seen by a comparison of spectra a and b in Fig. 1.

Let us examine the sharp bands shown in Fig. 2. The most prominent band system labeled A forms a progression originating at the frequency of the N_2 laser, 29656 cm^{-1} and developing to the longer wavelength side with a interval of $2\nu''_2=850$ cm^{-1} [15]. The weaker bands labeled B, C, and D form similar progressions: their displacements from progression A are 210, 435, and 610 cm^{-1}, respectively. Progressions labeled a, b, c, and d appear at frequencies higher by 60 cm^{-1} than progressions A, B, C, and D, respectively. Pro-

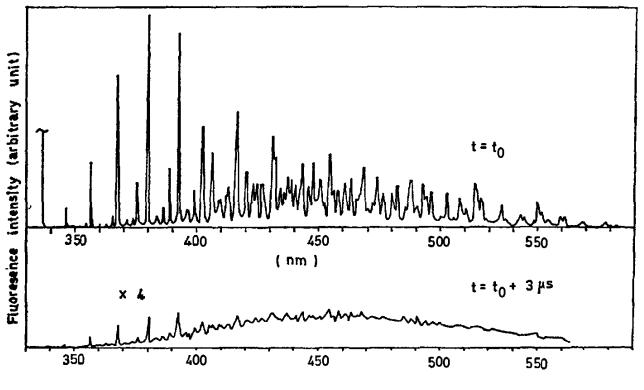

Fig. 1. The time-resolved emission spectra of CS_2 at 25 °C observed 0 μs (spectrum a) and 3 μs (spectrum b) after the fluorescence from the $^1A_2$ state of CS_2 reached the maximum intensity. The CS_2 pressure is 5×10^{-2} Torr.

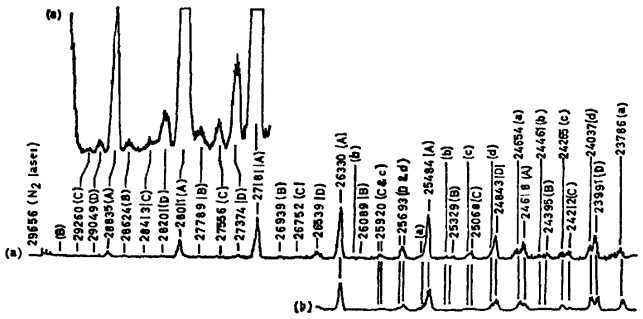

Fig. 2. The emission spectra of CS_2 at (a) 25 °C and (b) −90 °C. The pressure of CS_2 is 5×10^{-2} Torr.

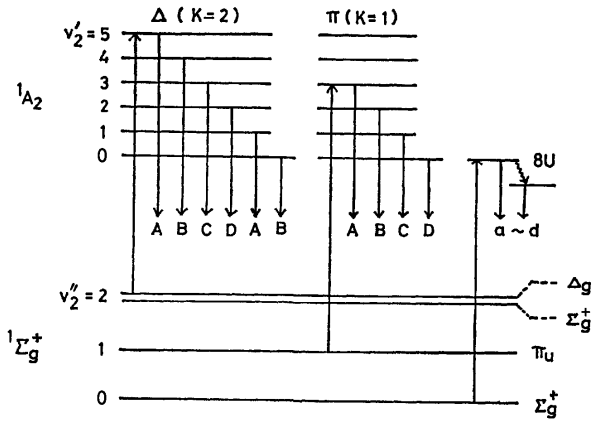

Fig. 3. The energy level diagram of CS_2: The $^1A_2$ and 8U excited states.

gressions a—d are too weak for their assignments to be made clear.

The temperature dependence of the emission spectra was studied at 25, −30, −45, and −90 °C. The spectra measured at 25 and −90 °C are shown in Fig. 2. The emission intensity at 25 °C is much stronger for progressions A—D than for progressions a—d. But progressions A—D rapidly decrease the intensity with lowering temperature and at −90 °C are weaker than progressions a—d. This means that progressions A—D and a—d belong to different electronic states.

According to Jungen *et al.*[9,10] who studied the absorption spectrum of CS_2, the N_2 laser excites the molecule to rovibronic levels of the $^1A_2$ state, say the 050(K=2) and 030(K=1) levels of $^1A_2$, and also to the upper level of the 8U band which corresponds to a transition to a triplet state and is known to display a Zeeman effect.[4] This is shown schematically in Fig. 3.

The transition from the ground state to the $^1A_2$ state is forbidden, but the mixing between the $^1A_2$ and $^1B_2$ components of the $^1\Delta_u$ state by the Renner-Teller effect can cause the hot bands to appear. In this case, the absorption intensity corresponding to the transition to the $^1A_2$ state is approximately proportional to K^2 [10] and also to the Boltzmann distribution in the lower state. This means that the fluorescence intensity from the $^1A_2$ state increases greatly with increasing temperature. Therefore, the A—D progressions sensitive to temperature are assigned to the transitions from the $^1A_2$ state. On the other hand, progressions a—d are regarded as emission from the excited levels of the 8U band system insensitive to temperature. The assignment of progressions A—D is supported by the fact that they shift each other by ~210 cm^{-1}, ν'_2 of the $^1A_2$ state reported by Jungen *et al.*[10] Furthermore, this assignment is consistent with the fact that the bands belonging to progressions A—D show no splitting or broadening under magnetic field of 13.3 kG.[16] Thus progressions A—D are assigned to the fluorescence from the 050(K=2) and 030(K=1) levels, the 040 (K=2) and 020(K=1) levels, the 030(K=2) and 010(K=1) levels, and the 020(K=2) and 000(K=1) levels, respectively. This is shown schematically in Fig. 3. Since their transition intensities are proportional to K^2, progression A is mainly from the 050(K=2) level of the $^1A_2$ state.

Let us turn to the broad band in Fig. 1 (b). This band is similar to emission of gaseous CS_2 excited optically at 290—330 nm,[17] excited by microwave discharge[18] or to that excited by electron impact of 200 eV[19] and also to emission of solid CS_2 or CS_2 in Ar and N_2 matrices excited at 260 nm.[19] The gas-phase emission was tentatively assigned by Douglas[17] and by others[18,19] to the transition from the excited state of the V system, say, the $^1B_2$ state. On the other hand, the solid-phase emission was assigned to the transition from the $^3A_2$ state. The decay times of the gas-phase emission and of the solid-phase emission are 15 μs and 1.8—2.1 ms, respectively. The former is very close to that of the broad band, 17 μs. This indicates that the broad band is tentatively assigned as the transition from the $^1B_2$ state.

Decay Times and Quenching Rates of the Emission. Figure 4 shows the plots of the decay rates, τ^{-1}, observed

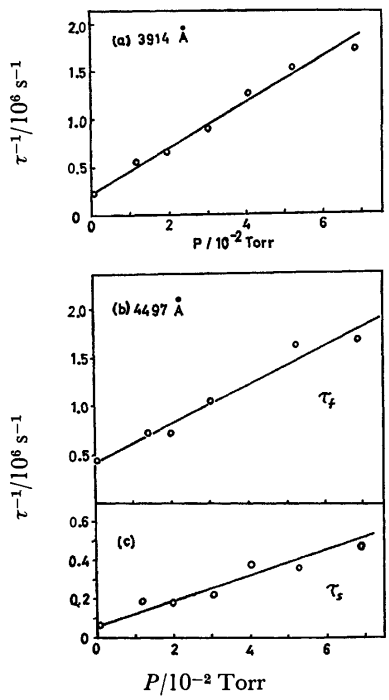

Fig. 4. The plots of decay rates *versus* the CS_2 pressure at 25 °C: (a) for the A band (391.4 nm); (b) for the a band (449.7 nm); (c) for the broad band (449.7 nm).

Table 1. Collision-free lifetimes (τ_0) and collisional quenching rate constants (k)

4475	broad	17.0±0.1	1.7±0.3

Table 2. The effect of the CS_2 pressure (P) on the fluorescence intensities

P (Torr)	$I_{A'}/I_A$[a)]	I_B/I_A[a)]	I_C/I_A[a)]	I_D/I_A[a)]
2×10^{-3}	1.1	0.07	0.12	0.29
2×10^{-2}	1.1	0.08	0.14	0.32
1×10^{-2}	1.1	0.09	0.15	0.35
10	1.1	0.10	0.17	0.36
49	1.1	0.11	0.19	0.38

a) $I_{A'}$, I_A, I_B, I_C, and I_D are the fluorescence intensities of the bands at 3797(band A), 3923(band A), 3832(band B), 3857(band C), 3891 Å(band D), respectively.

with the bands belonging to progressions A and a and with the broad band *versus* CS_2 pressure. We can see that the linear relationship is satisfied for each band. This indicates that a Stern-Volmer mechanism holds for collisional quenching by the ground-state CS_2 molecule. The slope and intercept give a collisional quenching rate constant and a collision-free lifetime, respectively. The result is shown in Table 1.

As pointed out by Kleman,[4] the $^1A_2$ state is perturbed by triplet states, as revealed by the observed perturbation to the vibrational and rotational structures of the corresponding absorption spectrum. However, since we can observe no effect of the magnetic field upon the positions and shapes of fluorescence bands belonging to progressions A, B, C, and D, it is clear that the mixing of triplet states is rather small and the singlet character is predominant for the $^1A_2$ state.

The appearance of the emission bands belonging to progression A suggests the "resonance limit". The effect of increasing collision frequency on the peak intensities of bands A—D is given in Table 2. Even at the CS_2 pressure of 10^{-3} Torr, under almost collision-free circumstances for instance, bands B—D have appreciable intensities.

Brus[12] observed the non-exponential decay of the unresolved emission of CS_2 excited by an N_2 laser and evaluated the collision-free lifetimes (τ_0) and collisional quenching rates (k): $\tau_0=2.9$ μs, $k=(7.9\pm1.2)\times10^{-10}$ cm^3/molecule s for the short-lived component; $\tau_0=17$ μs, $k=(1.2\pm1.0)\times10^{-10}$ cm^3/molecule s for the long-lived component. His results agree quite well with our results. He assigned the short and long-lived emissions to the transitions from the B_2 and degenerate A_1 and B_1 components of the $^3A_2$ state,[5,6] respectively, which has the zero-field splitting of 30—40 cm^{-1}.[7] However, this assignment is very improbable for the following reasons: (1) The N_2 laser wavelengths coincide with no absorption lines of the R system corresponding to the transition to the $^3A_2$ state. (2) The absorption band of the R system is insensitive to temperature, whereas progressions A—D under consideration are very sensitive to temperature. (3) The vibrational frequency, ν'_2 in the upper state of progressions A—D, ~210 cm^{-1}, is not equal to that in the R system, 311 cm^{-1} [4].

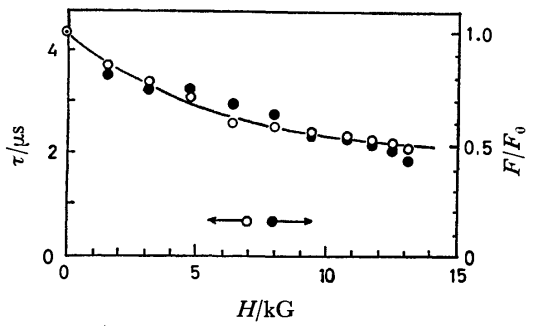

Fig. 5. Plots of F/F_0 and τ *versus* magnetic field(H): the pressure of CS_2 is 10^{-3} Torr.

Magnetic Quenching of Fluorescence. The effect of the magnetic field upon the emission intensity and lifetime of CS_2 was studied with a band at 379.7 nm which was assigned to the transition from the $^1A_2$ (0, 5, 0) state to the ground state. The lifetime, τ, and the integrated emission intensities in the absence and in the presence of the magnetic field, F_0 and F, respectively, were measured at 379.7 nm. The τ and F/F_0 values are plotted against the magnetic field in Fig. 5. As is clearly seen in this figure, the magnetic field effect is parallel for both quantities; they are reduced to about a half in the presence of the magnetic field of ~13 kG. This means that nonradiative energy-transfer (intramolecular or intermolecular) processes are enhanced in the magnetic field.

In order to study further the mechanism of the magnetic quenching observed with CS_2, we measured the pressure dependence of the fluorescence decay rate at 379.7 nm in the presence of the magnetic fields of 0, 4.7, and 12.6 kG. The Stern-Volmer plots of the observed decay rates *versus* the CS_2 pressure are shown in Fig. 6. From the straight lines obtained, the collision-free lifetimes, τ_0, and collisional quenching constants, k, were evaluated as given in Table 3. This table shows that the collision-free lifetime becomes shorter with an increase in the magnetic field, while the collisional quenching constant remains unchanged within the limits of experimental error.

The above-mentioned facts lead to the conclusion that the observed magnetic quenching of the fluorescence is due to an enhancement of an intramolecular nonradiative process. In view of the fact that the $^1A_2$ state is perturbed to some extent by the triplet states densely distributed in the appropriate energy region,[4] it is reasonable to consider that the intersystem crossing to these triplet states occurs as one of the nonradiative processes and is enhanced by the magnetic field.

According to our experimental result shown in

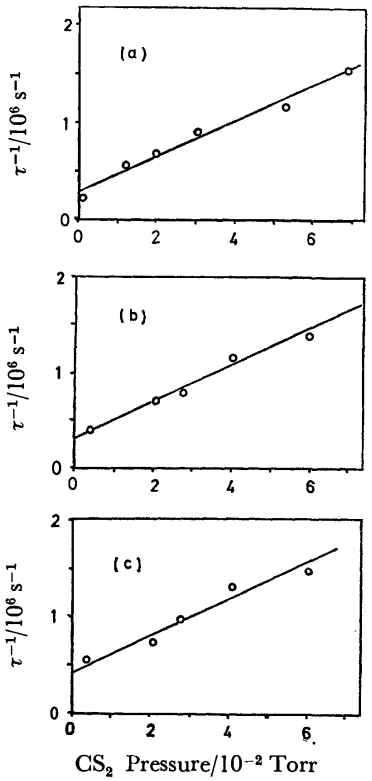

Fig. 6. Plots of τ^{-1} *versus* the CS_2 pressure.
(a) in the absence of magnetic field
(b) in the magnetic field of 4.7 kG
(c) in the magnetic field of 12.6 kG

TABLE 3. COLLISION FREE LIFETIMES (τ_0) AND COLLISIONAL QUENCHING CONSTANTS (k) IN THE PRESENCE OF MAGNETIC FIELD (H)

H (kG)	τ_0 (μs)	$k(10^{-10}$ cm^3/molecule s)
0	4.1±0.2	5.6±0.2
4.7	3.2±0.2	5.6±0.2
12.6	2.2±0.3	5.5±0.2

Fig. 7, the $(F_0/F)-1$ value is proportional to the square of the magnetic field in the range higher than 5 kG and decreases rapidly with decreasing magnetic field below 4 kG. The extrapolation of the straight line representing the relation between $(F_0/F)-1$ and H^2 does not pass the origin. We measured very carefully the magnetic-field effect upon the $(F_0/F)-1$ value in the low-field region. The result is also shown in Fig. 7. It is emphasized that, below 700 G, the $(F_0/F)-1$ value decreases once and thereafter increases steeply with increasing magnetic field. Atkins has made theoretical studies to explain this phenomenon.[20]

Emission from the $B^3\Pi\ 0_u^+$ state of iodine is known to be quenched by a magnetic field.[21,22] This phenomenon was explained by an induced predissociation caused by the magnetic mixing of an unbound 0_u^- state. Solarz *et al.* found that the fluorescence of nitrogen dioxide is quenched by magnetically induced collisional quenching.[23] The quenched states of iodine and nitrogen dioxide are triplet and doublet, respectively, and are paramagnetic. In the present study, we found

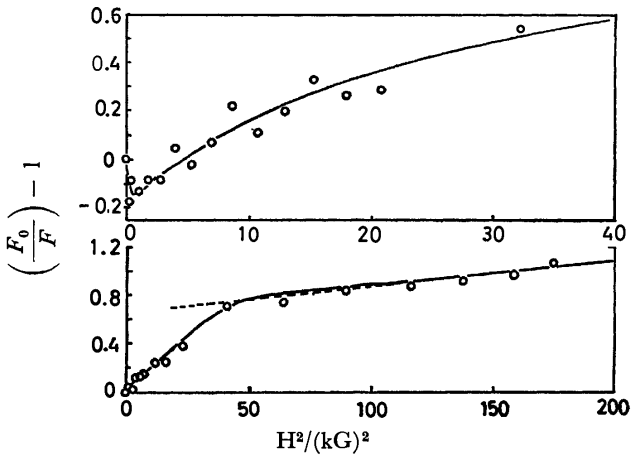

Fig. 7. Plots of $(F_0/F-1)$ *versus* the square of magnetic field: the pressure of CS_2 is 10^{-3} Torr.

that the fluorescence from the $^1A_2$ state of CS_2 was quenched by a magnetic field. This is the first example of the magnetic quenching of emission from a singlet state.

Thermal Separation Column with Vertical Barriers. I. Analytical Studies on the Thermal Separation Column Having Vertical Barriers

Kazuo SASAKI, Tsutomu YOSHITOMI, and Norio MIURA

Department of Applied Chemistry, Hiroshima University, Hiroshima 730

(Received January 30, 1975)

The effect of installing a couple of vertical flow barriers inside a double cylinder-type thermal separation column has been studied analytically. The method of analysis is entirely similar to that developed by Jones and Furry. The only change is that an additional parameter, which specifies the location of the barriers, has been introduced. The results indicated that the installation of barriers retards the convectional velocity and leads to a remarkable increase in the equilibrium separation. With the optimum design, which is achieved by locating barriers at 5/8 parts of the half-width of the wall spacing, the logarithmic equilibrium separation will become 4 times greater than that in the open column.

The use of thermal diffusion phenomena is practical enrichment of one component from a gaseous mixture was established by Clusius and Dickel[1] in 1938. The method is often useful in certain restricted purposes; however, it is still necessary to improve the operational characteristics of the Clusius-Dickel column for a wider application of the method.

Accordingly, various ideas have been introduced for improving the column efficiency. For instance, tilting the column, [9-11] use of column packing[12,13] or spiral wire[14,2] inside the annular space, and columns with moving wall[10,13] have been examined with more or less satisfactory results. It is interesting that almost all of these attempts for improving the thermal separation unit were made with liquid mixtures.

In contrast, most experiments with gaseous mixtures so far reported have been conducted by using the Clusius-Dickel column in its original form. In many papers of gaseous separation, attention was focused on the effectiveness of spacers, which are usually installed in a Clusius-Dickel type column in order to fix the central heating wire at a proper position. The first use of such spacers is seen in the work of Clusius and Dickel themselves in 1939.[3] In the experiment of separating an isotopic mixture of hydrogen chloride, they found that the introduction of spacers resulted in an increase of the separation efficiency. Later, Donaldson and Watson[4] found that simple wire crosses which were welded perpendicularly on the heating wire at given regular distances significantly increased the separation efficiency. According to Corbett and Watson,[5] however, the effect of spacers was insignificant and even disadvantageous when too many spacers were installed. Although discussion on the effectiveness of spacers have continued up to the present,[6,7] no unified theory seems to have been accepted.

In such a situation, the work of Treacy and Rich[15] seems exceptional. They examined the effect of installing several types of flow barriers inside the working space of the separation column. According to them, introduction of barriers usually resulted in the increase of both the magnitude and the rate of separation. Their work seems, however, unsystematic and lacks theoretical support.

In the following part of this paper, we shall examine the possibility of improving a thermal separation column by installing a couple of vertical flow barriers inside the column space.

Basic Idea and Analytical Approach

Basic Idea. As is well known, in a typical Clusius-Dickel apparatus, the velocity profile of vertical current has a maximum at a point having a finite distance from the wall surface. On the other hand, the maximum temperature difference, which is the driving force of the thermal diffusion, is attained undoubtedly at the wall surface. It is apparent that the convectional flow arises in an inefficient way. If we are able to move the position of maximum convectional velocity towards the wall surface, the efficiency will increase. This was our basic idea for the present study. We further thought that a vertical barrier will serve to separate functionally the column space to allow convection and thermal diffusion separately and this will lead to improvement of the column efficiency.

Analytical Approach-Modification of the Theory of Jones and Furry.[8] *Transport Equation by Jones and Furry*: Jones and Furry[8] developed a theory for the thermal separation in a Clusius-Dickel type column. Assuming the separation column to be a plane parallel type, they derived the following fundamental equations for the total transport of the lighter component, τ_1, in the upward direction:

$$\tau_1 = wB\rho\bar{v}(\alpha\Delta T/2\overline{T})c_1c_2 - \{wB\rho\bar{v}(\bar{v}w^2/D) + 2wB\rho D\}\frac{\partial c_1}{\partial z} \quad (1), \text{ (Eq. (52), Ref. 8)}$$

Alternatively,

$$\tau_1 = Hc_1(1-c_1) - (K_c+K_d)\frac{dc_1}{dz} \quad (2), \text{ (Eq. (53), Ref. 8)}$$

with the following abbreviations,

$$H = \frac{\alpha\rho^2 g w^3 B}{96\eta}\left(\frac{\Delta T}{\overline{T}}\right)^2 \quad (3), \text{ (Eq. (54), Ref. 8)}$$

$$K_c = \frac{\rho^3 g^3 w^7 B}{2304\eta^2 D}\left(\frac{\Delta T}{\overline{T}}\right)^2 \quad (4), \text{ (Eq. (55), Ref. 8)}$$

and

$$K_d = 2wB\rho D \quad (5), \text{ (Eq. (56), Ref. 8)}$$

Modification of the Theory: An entirely similar treatment can be applied to the present case, where a couple of plane parallel screens are installed vertically inside the column. We shall describe the procedure shortly. Prior to developing this analysis, we suppose the conditions of column operation to be as follows.

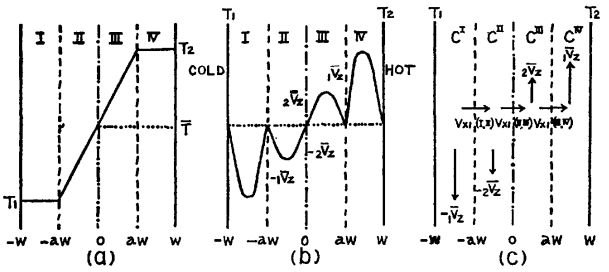

Fig. 1. Assumptions and notations for a column which equipped a couple of screens.
(a): Temperature gradient. (b) Convectional flow velocity as a function of x. (c) Notations.

1. The apparatus is of the plane parallel type having an interwall distance of $2w$.
2. Two screens are placed at positions $\pm aw$ parallel to the column wall.
3. A temperature gradient is set up between the pair of screens and the two gaps produced outside the screens, $|aw|<x<|w|$, are kept isothermal.[17]
4. The velocity of vertical gas flow is zero at $x=\pm aw$ where the two screens are located.

Accordingly, the space in the column are divided vertically into four sub-columns: column I ($-w\leq x\leq -aw$), II ($-aw\leq x\leq 0$), III ($0\leq x\leq aw$), and IV ($aw\leq x\leq w$). The symbols and coordinates necessary for the analytical treatment are given in Fig. 1 and are also listed at the end of this article. Unless otherwise stated, the symbols used by Jones and Furry will be used.

On account of the above assumptions, the basic equation to be solved for the region of $-aw<x<aw$ becomes

$$\eta\frac{\mathrm{d}^2{}_2v_z(x)}{\mathrm{d}x^2}=-\rho g\frac{x\Delta T}{2aw\overline{T}} \tag{6}$$

Under the boundary condition

$$\text{at } x=\pm aw;\ {}_2v_z(x)=0$$

Eq. (6) is solved to give

$${}_2v_z=\frac{\rho g\Delta T}{12\eta aw\overline{T}}\times(a^2w^2-x^2) \tag{7}$$

Denoting the average velocity of convectional flow in columns II and III as ${}_2\bar{v}_z$, we obtain

$${}_2\bar{v}_z=\frac{1}{aw}\int_0^{aw}{}_2v_z(x)\mathrm{d}x=\frac{\rho gw^2}{48\eta}\frac{\Delta T}{\overline{T}}a^2 \tag{8}$$

On the other hand, in column IV, where the region is specified by $aw\leq x\leq w$, the temperature must be the same everywhere, by assumption, and is given by

$$T=T_2=\overline{T}+\Delta T/2 \tag{9}$$

The convectional flow in column IV may be expressed as

$$\eta\frac{\mathrm{d}^2{}_1v_z(x)}{\mathrm{d}x^2}=-\rho g\frac{\Delta T}{2\overline{T}} \tag{10}$$

This equation is solved under the boundary condition

$${}_1v_z=0 \text{ at } x=aw \text{ and } x=w$$

to give the average vertical velocity in column IV (and also in column I)

$${}_1\bar{v}_z=\frac{\rho gw^2}{48\eta}\frac{\Delta T}{\overline{T}}\cdot 2(1-a)^2 \tag{11}$$

Since there will be a transport down the tube because of ordinary diffusion, the total transport of the lighter component up the tube will be

$$\tau_1'=\{(c_1^{IV}-c_1^{I})(1-\alpha){}_1\bar{v}_z+(c_1^{III}-c_1^{II})a\,{}_2\bar{v}_z\}\omega B\rho -2DwB\rho\frac{\partial c_1}{\partial z} \tag{12}$$

where $c_1{}^J$ stands for the average concentration of the lighter component in column J.

For the transverse flow, we have the following set of approximate equations:

$$\rho c_1v_{x1}(\mathrm{I,\ II})=-\rho D\ \mathrm{grad}\ c_1=-\frac{2(c_1^{II}-c_1^{I})\rho D}{w} \tag{13}$$

$$\rho c_1v_{x1}(\mathrm{II,\ III})=\rho D(\alpha c_1c_2\ \mathrm{grad}\ \ln T-\mathrm{grad}\ c_1)=\rho D\left(\alpha c_1c_2\frac{\Delta T}{2aw\overline{T}}-\frac{c_1^{III}-c_1^{II}}{aw}\right) \tag{14}$$

$$\rho c_1v_{x1}(\mathrm{III,\ IV})=-\rho D\ \mathrm{grad}\ c_1=-\frac{2(c_1^{IV}-c_1^{III})\rho D}{w} \tag{15}$$

where $v_{x1}(H,\ J)$ represents the rate of the horizontal transport of the lighter component from column H to J.

If we assume the concentration change from column to column is so small that c_1^{I}, c_1^{II}, c_1^{III}, and c_1^{IV} can be safely replaced by c_1, the terms $(c_1^{IV}-c_1^{I})$ and $(c_1^{III}-c_1^{II})$ appearing in Eq. (12) can be evaluated by the aid of Eqs. (13) through (15) to give

$$c_1^{III}-c_1^{II}=\alpha c_1c_2\frac{\Delta T}{2\overline{T}}+\frac{w^2}{D}\{(a^2-a){}_1\bar{v}_z-a^2{}_2\bar{v}_z\}\frac{\partial c_1}{\partial z} \tag{16}$$

$$c_1^{IV}-c_1^{I}=\alpha c_1c_2\frac{\Delta T}{2\overline{T}}+\frac{w^2}{D}\{(a^2-1){}_1\bar{v}_z-a^2{}_2\bar{v}_z\}\frac{\delta c_1}{\partial z} \tag{17}$$

Accordingly, Eq. (12) is now rewritten in the form of Eq. (2)

$$\tau_1'=H'c_1c_2-(K_c'+K_d')\frac{\mathrm{d}c_1}{\mathrm{d}z}\ . \tag{18}$$

Where the constants are defined as follows:

$$H'=\frac{\alpha\rho gw^3B}{96\eta}\left(\frac{\Delta T}{\overline{T}}\right)^2\{2(1-a)^3+a^3\}=\{2(1-a)^3+a^3\}H \tag{19}$$

$$K_c'=\frac{\rho^3g^2w^7B}{2304\eta^2D}\left(\frac{\Delta T}{\overline{T}}\right)^2\{4(1-a)^6(1+a)+4a^4(1-a)^3+a^7\}=\{4(1-a)^6(1+a)+4a^4(1-a)^3+a^7\}K_c \tag{20}$$

$$K_d'=K_d\ . \tag{21}$$

Operational Characteristics and Remarks

Several parameters which are important for describing the operational characteristics of the separation column have already been given by Jones and Furry.[8] We shall reproduce some of the results necessary in the following discussion.

The equilibrium separation factor, q_e, is given by

$$q_e=e^{2AL} \tag{22}$$

where the parameter A is defined as

$$A=H/2(K_c+K_d) \tag{23}$$

and L is the length of the separation column.

We now examine the separation characteristics of

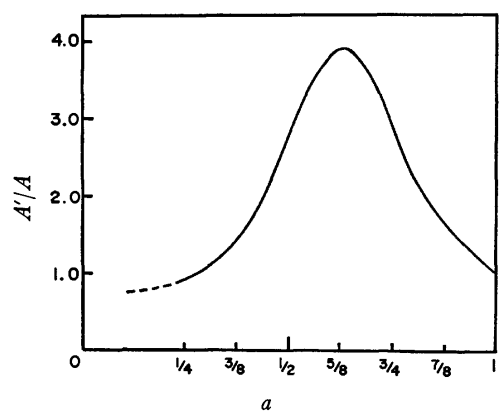

Fig. 2. The relative performance, A'/A, against design parameter a.

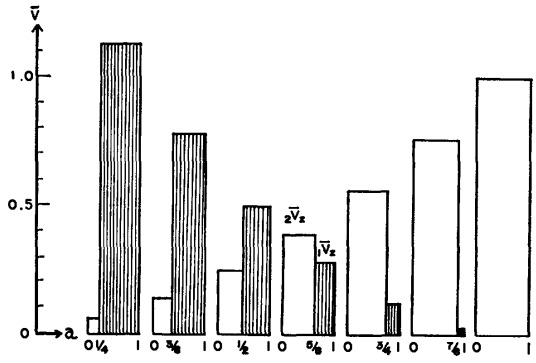

Fig. 3. Change in average convectional velocity in sub-columns I and IV ($_1\bar{v}_2$) and II and III ($_2\bar{v}_2$) with various value of design parameter a. Hatched bar represents $_1\bar{v}_z$ and empty bar $_2v_z$, respectively.

columns with and without screens. For simplicity, we suppose that the value of K_c is sufficiently greater than K_d, so that the contribution of the latter can be ignored in the expression of A in Eq. (23). As has been done already in Eqs. (18) through (21), the symbols corresponding to the column with screens will be primed to distinguish them from the ordinary column symbols. When K_d is ignorable, the change in A' with varying a can be expressed by a simple analytical function

$$\frac{A'}{A}=\frac{H'/2K_c'}{H/2K_c}=\frac{2(1-a)^3+a^3}{4(1-a)^6(1+a)+4a^4(1-a)^3+a^7} \qquad (24)$$

this function is graphicaly represented in Fig. 2. It is seen that the use of screens significantly increases the equilibrium separation factor. In order to see what was the cause of this improvement, we prepared Fig. 3, where the average velocity of convectional flow is indicated as a function of the design parameter a. It is indisputable that the vertical movement of gas is suppressed by the installation of screens and the supression becomes maximum at about $a=5/8$, where the separation becomes also maximum. This is predictable analytically also in the following manner. Eqs. (3) and (4) can be rewritten in terms of $\bar{v}$

$$H=\frac{1}{2}\alpha\bar{\rho}wB\bar{v}\left(\frac{\Delta T}{\bar{T}}\right)$$

$$K_c=\frac{\bar{\rho}w^2B\bar{v}^2}{D}$$

Accordingly, if K_d is ignored,

$$\ln q_e=\frac{HL}{K_c}=\frac{\alpha DL(\Delta T/\bar{T})}{2w^2\bar{v}}$$

The last equation indicates that q_e will increase when $\bar{v}$ decreases. Accordingly, our original idea, which anticipated an improvement by shifting the position of maximum vertical velocity towards the column wall, must be said to have been not wholly correct.

Treacy and Rich[15] studied the effect of barriers introduced in a double-cylinder type separation column. They found that the use of compound barriers made by cutting the vertical into sections of length suitable for insertion between horizontals exhibits a pronounced increase of column efficiency. Although they state that use of single vertical barriers is still effective for increasing efficiency, the data shown in the paper are not convincing. This is quite natural because they ignored the importance of the location of the barriers. In order to prove the result of the foregoing analysis to be acceptable, we need some experimental vertification. This will be reported in a following paper.[16]

Conclusion

It was confirmed analytically that the introduction of a couple of vertical barriers in a thermal separation column should increase the separation significantly. The improvement is rather sensitive to the design parameter a and the maximum improvement is expected at about $a=5/8$, where a four times greater value can be expected in $\ln q_e$ as compared with the ordinary column.

At the end of this article, it should be noted that in the foregoing treatment we have used somewhat particular boundary conditions according to which the temperature gradient exists only over the region specified by $-aw\leq x\leq aw$. This was necessary because of mathematical simplification. In an actual column, however, a finite temperature gradient may be unavoidable over the regions outside the screens. Errors due to this assumption will be larger for smaller values of design parameter a. This point will be examined in a future paper.

Table of Notation

$A=H/2(K_c+K_d)$, [cm^{-1}].
a=design parameter, $0<a<1$.
B=mean circumference, [cm].
c=either c_1 or c_2.
$\bar{c}=1-c$.
c_1=fractional molar concentration of the lighter component.
c_2=fractional molar concentration of the heavier component. $c_1+c_2=1$.
c_1^J=average concentration of the lighter component in column J.
D=coefficient of self-diffusion, [cm^2/s].
g=acceleration of gravity, [cm/s^2].
H, [g/s], K_c, K_d, [g cm/s]=transport coefficient.
L=length of column, $0\leq z\leq L$, [cm].

q=separation factor.
$q_e = e^{2AL}$=equilibrium separation factor.
T=absolute temperature, [K].
T_1=temperature of cold wall [K].
T_2=temperature of hot wall, $T_2 > T_1$, [K].
$\overline{T} = (T_1 + T_2)/2$, [K].
$\Delta T = T_2 - T_1$, [K].
v=velocity of convectional flow, [cm/s].
$\bar{v}$=average velocity of convectional flow, [cm/s].
${}_1\bar{v}_z$=average velocity of convectional flow in columns I and IV, [cm/s].
${}_2\bar{v}_z$=average velocity of convectional flow in columns II and III, [cm/s].
$v_{x1}(H,J)$=rate of the horizontal transport of the lighter component from column H to J, [cm/s].
w=one-half of the distance between the hot and cold walls. [cm].
x=coordinate perpendicular to the walls, $-w \leq x \leq w$, [cm].
z=coordinate along the column, $0 \leq x \leq L$, [cm].
α=thermal diffusion constant.
η=viscosity, [P].
ρ=density, [g/cm^3].
τ_1=transport of species 1 along the column, mass per unit time, [g/s].

17) This assumption is necessary only for mathematical simplicity. In an actual column, however, there may be a finite temperature gradient in the gaps concerned. Because of this assumption, the question may arise whether "The comparison should be made with an open column having width of $2aw$ but not of $2w$". In fact, there may be two different views with regard to the installation of barriers: 1) screens are merely inserted in the column space of width of $2w$ and 2) additional spaces are produced outside the pair of screens. If, for an actual column, a finite temperature gradient is unavoidable over spaces outside the screens, the former view must be accepted. In the following part of this paper and also in the successive paper, the discussion has been developed on this standpoint.

Thermal Separation Column with Vertical Barriers. II. Performance of a Thermal Separation Column with Vertical Barriers

Kazuo SASAKI, Norio MIURA, and Tsutomu YOSHITOMI
Department of Applied Chemistry, Hiroshima University, Hiroshima 730

(Received January 30, 1975)

The performance of a newly designed thermal separation column has been examined. The apparatus was constructed along the line of mathematical analysis developed in the preceding paper. The column was basically composed of two coaxial cylinders inside of which two additional cylinders of fine stainless steel screen were installed to control the gas flows in the column. An equimolar mixture of argon and nitrogen was used as the test gas. A definite improvement in the magnitude of equilibrium separation was demonstrated in accordance with the theory. In addition, the rate of attainment of steady state was found not so much different from that with open column when temperature exceeded 140 °C or more.

As has been described in the preceding paper,[1] mathematical analysis predicted that the additional installation of a couple of wire gauzes or something like that, which effectively control the relative magnitude of convectional and horizontal flow of gas, will increase the performance of thermal separation markedly. Treacy and Rich[5] studied the effect of several sorts of flow barriers in a Clusius column and reported that the simultaneous use of horizontal and vertical barriers resulted in a remarkable increase in the separation. Their data seems to indicate that the single use of vertical barriers is not so much effective.

The design of column used by them, however, seems not suitable to test our theory and the data presented were so restricted. We thus attempted to construct a column which closely satisfies the assumptions made in the mathematical analysis.

The following is the first full report on the performance of thermal separation column having several types of barriers.

Experimental

Description of the Column. An outline of the column used are shown in Fig. 1. The inner tube (1) of the column was made of iron pipe of 21.7 mm o.d., and 970 mm in its effective length. On the outer surface of this tube, eight long iron bars (2) having square form cross section (2 mm in width, 4 mm in height) were welded parallelly along the direction of the length. Thus the horizontal cross section of the inner tube assembly has a form of a gear. Around this cylinder (30 mmϕ) a 100 mesh stainless steel screen (3) was tightly wound with thin wire.

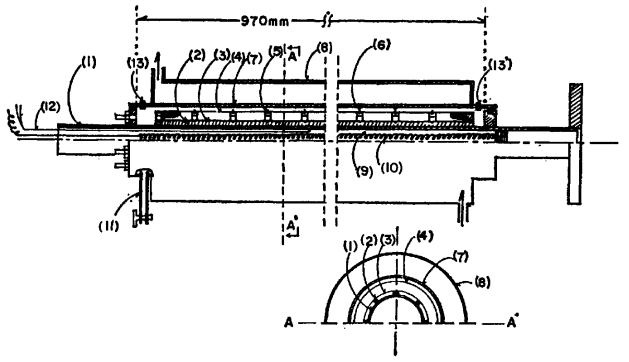

Fig. 1. Apparatus.
1: Inner tube, 2: square bar of iron, 3: inner screen, 4: outer screen, 5: aluminium O-ring, 6: binding wire, 7: outer tube, 8: water jacket, 9: heat mediator, 10: nichrome heater, 11: gas inlet, 12: thermocouple, and 13(13'): sampling port.

Outside the inner tube assembly, another cylindrical stainless steel screen was coaxially suspended (4). In order to keep the shape of cylinder, twenty aluminium O-rings of 38 mm i.d. and 44.8 mm o.d. (5) were placed with a regular distance (4 cm) and the screen was tightly bound onto the aluminium O-rings with steel wire. Each edge of the binding wire (6) was made to contact with the inner surface of the cold wall (52.7 mmϕ) (7) in order to keep, as far as possible, the temperature of the outer screen same as that of the cold wall. This benefited also to hold the suspended outer screen at a proper position. The size of the column and dimensions of each part were determined by purely technical reason except that the value of design parameter a was adjusted to be 1/2. The central hollow cylinder (9) of the inner tube was filled with a mineral oil as the heat mediator in which a 300 W nichrome wire (10) was immersed. The outer cylinder was surrounded by a water jacket (8) of vinyl chloride pipe through which tap water was flown.

The test gas inlet (11) was placed just below the top of the column. No particular gas reservoir was attached.

Operation of the Column. In an actual operation, the whole assembly was evacuated through the inlet tube (11) and the temperature difference was applied. After setting up the steady temperature difference, the test gas, 50% Ar–50% N_2, was introduced until a desired pressure was attained. The temperature of the hot wall was measured at the backside of it by means of a copper-constantan thermocouple (12), while that of cold plate was measured by a thermometer at exit of cooling water. The temperature variation along the direction of column was unable to detect by this method. Since oil was used as the heat mediator the highest temperature available was limited at 200 °C or so. Sample gas was withdrawn by a hypodermic syringe from two sampling ports (13) which were consisted of small silicone rubber stoppers. The progress of the thermal separation was monitored by periodical sampling and analysis with an ordinary gas chromatograph in which a 1 m column of molecular sieve 5 A was installed. By the aid of digital integrater maximum deviation of the readings was able to control within 0.1%.

As the control experiments, several series of data were collected with an open column which was an exact duplicate of the column described above except that no barrier was equipped.

Results

Equilibrium Separation and the Temperature Effect. In Fig. 2, are shown the results of two representative runnings observed with novel and ordinary columns under the same operational condition. In this figure, the scale of the ordinate is expressed by the ratio of direct reading of the gas-chromatographic peak areas of argon and nitrogen. A couple of curves drawn with solid line stand for the measurement with the novel column while another couple with dotted line for the ordinary column. Ascending curves stand for the measurement at the top of the column and descending curves at bottom. The couple of solid curves (novel column) in ascending and descending directions are not exactly symmetrical. The volume of free space at the column top was made slightly bigger than that of the bottom. Accordingly, if this structural assymmetry of the column was the cause, the depression of the curve would be more pronounced in the ascending curves. Local assymmetry of barrier location may be accounted for. On the other hand, the couple of curves observed with the ordinary column (dotted line) are exactly symmetrical. In any case, since the equilibrium was found to attain within five minutes in both columns, q_e data presented in the following were those observed after 20 minutes operation.

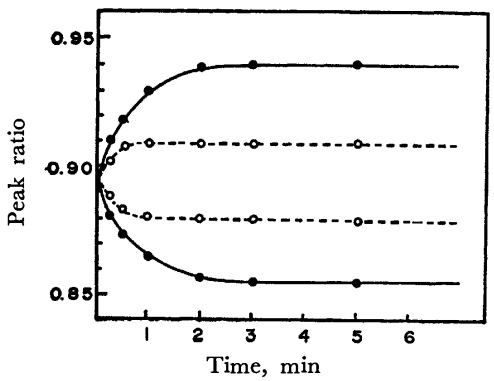

Fig. 2. Progress of separation with time.
Solid line: Column with barriers. Dotted line: Open coulmn. ΔT: 78 °C, pressure: 790 mmHg.

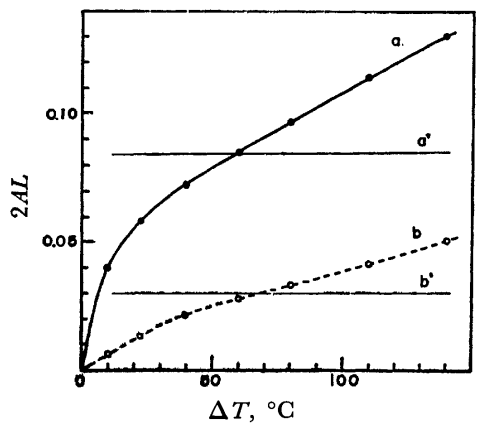

Fig. 3. Logarithm of equilibrium separation against temperature difference. Pressure: 790 mmHg.
Solid line: novel column. Dotted line: open column.

Results of a series of runnings in which the working pressure was kept constant and the temperature difference applied was varied are summarized in Fig. 3. The scale of the ordinate is logarithm of the equilibrium separation factor, ln q_e ($=2AL$).

The curves clearly indicate that, as the theoretical analysis predicted, the magnitude of the equilibrium separation is always greater with novel column (solid line) than with the ordinary one (dotted line). In this figure, the two horizontal lines indicates the theoretical values of the logarithmic equilibrium separation for the novel column (curve a') and ordinary column (b').[6] One thing to be stressed with this figure is not the dissimilarity[7] between the experimental and theoretical curve forms but is that the experimental separations are greater than the theoretical values when the temperature difference exceeds 70 °C or so regardless of the column type. As far as the authors are aware, it is usual that the experimental separation, particularly with hot-wire column, doesn't exceed theoretical value. The present result might be correlated with the shape and sizes of column used.

Pressure Effect. Similarly, the effect of pressure was studied under the condition of constant temperature difference. The results obtained are shown in Fig. 4 in which theoretical curves (a' and b') are drawn using the following relationship.

$$2AL = \frac{1.231 \times 24 \times \eta DL\alpha}{\rho g w^4 P^2} \qquad (1)$$

The numerical factor 1.231 is the correction factor for the cylindricity of the column used (see Eqs. (100) through (111) in Ref. 2). In accordance with the theory (curves a' and b'), the separation factor observed appears to decline with increasing pressure (curves a and b). Curve a, which stands for the observation with the novel column, appears to lie down at the lower pressure region. As has been frequently shown,[2,3] the separation factor makes a maximum at a low pressure. This effect is not seen in curve b which stands for the measurements with ordinary column. In any case, it is apparent that the performance of the novel

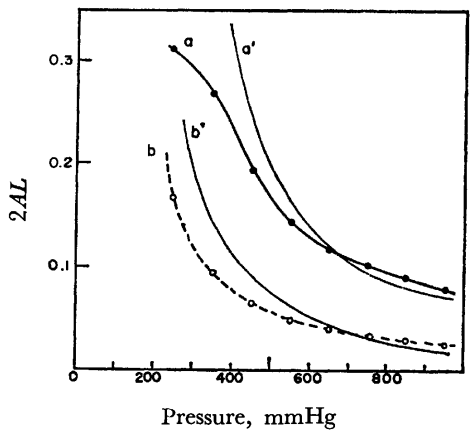

Fig. 4. Pressure effect on the logarithmic equilibrium separation.
a: observed with novel column, b: with ordinary column a' and b' are calculated on the base of Eq. (1). Temperature difference: 78 °C.

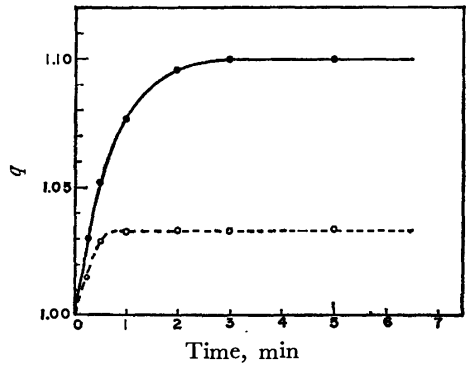

Fig. 5. Progress of thermal separation with time. Temperature difference: 78 °C, Pressure: 790 mmHg. Solid line: novel column, Dotted line: ordinary column.

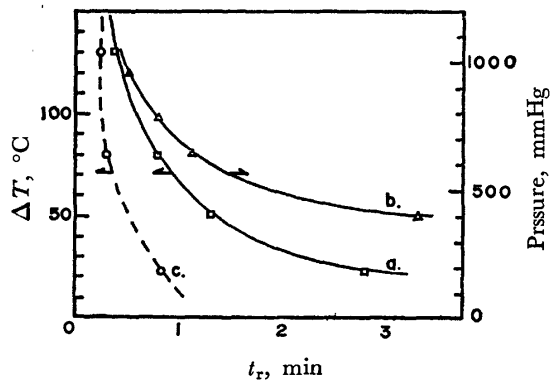

Fig. 6. Change in relaxation time, t_r, against ΔT (curve a) and pressure (curve b). Curve c represents the effect of ΔT observed with open column.

column is always better than that of the ordinary one.

Rate of Attainmnet of Equilibrium Separation. Although it is now undoubted that the magnitude of equilibrium separation is definitely improved, there is another important factor in the practice, *i.e.*, the rate of attainment of the equilibrium separation. This point is answered graphically in Fig. 5, where the scale of the ordinate is expressed by the separation factor q (not to be confused with q_e). It is clearly seen that the separation progresses with higher rate in the novel column than in the ordinary one. Although only two representative curves are shown in this figure, the situation was the same through all measurements in the present study.

The characteristics of the relaxation time was fully studied with the novel column. The effect of temperature difference was studied under a constant pressure of 790 mmHg, while the pressure effect was studied by keeping temperature difference 78 °C. These are shown in Fig. 6 with curves a and b respectively. The behavior of the curves are quite ordinary and the relaxation time decreases with the increase of both temperature difference and pressure.

Discussion

According to the original theory of Jones and Furry, the equilibrium separation does depend neither mean temperature nor the temperature difference, if the coefficient K_d is sufficiently less than K_c (see Eqs. (3), (4) and (23) in the foregoing paper). This was the case for the apparatus presently used (calculated K_c is 3×10^3 times greater than K_d). Accordingly, the experimental variation of the equilibrium separation with the change in applied temperature difference, as is exemplified by Fig. 3, is beyond the theory at present.

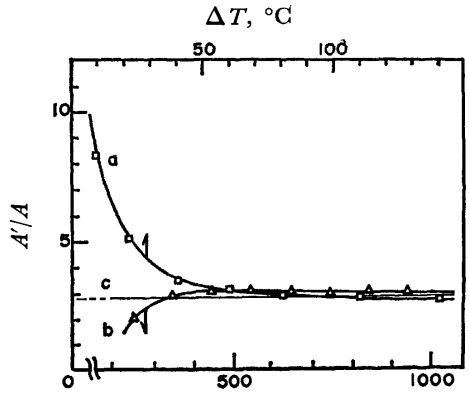

Fig. 7. Quality factor, A'/A, against ΔT (curve a) and pressure (curve b). Curve c represents theoretical value.

On the other hand, results shown in Fig. 4 indicate, regardless of the type of column, that the agreement between theory and experiment is quite good when the pressure effect is concerned.

The equilibrium separation factor is correlated with the theoretical transport coefficients by the equation

$$q_e = \exp(2AL), \text{ where } 2AL = HL/(K_c+K_d).$$

Accordingly, in order to see the relative performance of the two types of column, it will be worth to define the "quality factor" f as follows

$$f = \ln q_e'/\ln q_e = A'/A \qquad (2)$$

in which primed symbols stand for the novel column. On the base of experimental results shown in Figs. 3 and 4 the quality factor was calculated as a function of both the temperature difference and pressure respectively. This is shown in Fig. 7. It is interesting to see that the quality factor at a difference of 10 °C of temperature is 8.3 and reduces rapidly first and gradually later with increasing temperature difference. At the maximum temperature difference applied (140 °C), the quality factor takes a value of 2.6. This indicates that the performance of the novel column is equivalent to that of an ordinary column having 2.6 times longer length. A graphical estimation indicated that the quality factor will be still more than 2.3 at the temperature difference of 500 °C, which is thought as a practical condition in the gas phase operation.

Curve b in Fig. 7 is drawn for a series of experiments show in Fig. 4. In this case also, the quality factor becomes almost constant at higher pressure region but reduces strongly at lower pressure. The straight line c is the theoretical value[8] which is an only function of the design parameter a. It is obvious that at pressure more than 400 mmHg and the temperature difference exceeding 60 °C, the agreement between theory and

experiment is excellent.

According to Jones and Furry,[2] in cases where the equilibrium separation is sufficiently small so that $c(1-c)$ does not change appreciably along the column, the progress of the thermal separation is characterized by

$$\Delta = \Delta_e(1-e^{-t/t_r}) \quad (3)$$

where Δ is the concentration difference at top and bottom of column and suffix e means the value at equilibrium. The relaxation time, tr, is[9]

$$tr = 2mAL/H = mL/(K_c+K_d).$$

In the latter equation, m represents mass of gas in the positive reservoir. Since K_c is sufficiently greater than K_d the ratio of the relaxation times for the two types of column having the same dimension should be the ratio of K_c's.

$$t_r'/t_r = K_c/K_c'$$

According to this equation, the relaxation time of the novel column should be much longer than the ordinary column of the same dimension. Numerical evaluation indicated that the ratio of relaxation time becomes to 11.4 at maximum corresponding to $a=5/8$.

If this prediction was acceptable the benefit of using screens would be worthless because of a long time consumption. This was not the case, however. That the initial rise of curves in Fig. 5 is undoubtedly steeper in the novel column is an indisputable proof. Furthermore, as is seen in curve a in Fig. 6, the relaxation time of the novel column is certainly greater at smaller temperature difference but becomes almost indistinguishable at higher temperature difference. A similar behavior of t_r' is seen in curve b which represents the dependence on pressure. It is readily seen that the temperature difference was even smaller (ΔT was 78 °C in the measurement of curve b), the increase in pressure decreases the relaxation time. Treacy and Rich[5] also stated that the installation of barriers resulted in the increased rate of separation.

The authors are indeed grateful to Professors T. Chiba and M. Ohmori of Mechanical Engineering Department for their collaboration in constructing the separation columns. The authors are also indebted to Dr. Yoshimura of Chemical Engineering Department for his courtesy in giving every facility throughout this work.

Table of Notation

$A=H/2(K_c+K_d)$, [cm^{-1}].
D=self-diffusion coefficient, [cm^2/s].
H=transport coefficient, [g/s].
L=length of column, [cm].
K_c and K_d=transport coefficient, [g·cm/s].
P=dimensionless relative pressure.
g=acceleration of gravity, [cm/s^2].
m=mass of gas in positive reservoir, [g].
q=separation factor at transient state.
q_e=separation factor at steady state.
t_r=relaxation time, [s].
w=half-width of the annular space, [cm].
α=thermal diffusion constant.
ρ=density, [g/cm^3].
η=viscosity, [P].

6) Theoretical values were calculated by means of the following relationships

$$A = \frac{H}{2(K_c+K_d)} \fallingdotseq \frac{12\alpha\eta D}{\rho g w^4}$$

and

$$A' = \frac{H'}{2(K_c'+K_d')} \fallingdotseq 2.82\,A$$

for the ordinary and novel columns, respectively. In the evaluation of these equations, we adapted 0.102[4] as the α value which seems largest among we found.
7) When K_d is extremely less than K_c, theoretical value of equilibrium separation becomes independent of temperature difference as far as temperature dependence of characteristic constants, η, D, and ρ, are ignored. (see Eqs. (3), (4) and (23) in the preceeding paper).
8) See Eq. (24) in the foregoing paper.
9) This expression is applicable when the column has finite size of reservoirs at both ends (see Eq. (194) in Ref. 2) and thus inappropriate for the present case. It seems, however, the tentative use of this equation dosen't result in a serious error. For instance, if Eq. (163) in Ref. 2 was used in place of this equation, the result was unchanged.

Effects of Quinones on the Protonation Reaction of TCNQ Anion Radical; The Role of a Protonated Quinone as a Strong Electron Acceptor

Akihiko YAMAGISHI and Mutsuo YAMADA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March, 13, 1975)

Various kinds of substituted *p*-benzoquinones (Q) have been found to accelerate the rate of the reaction between 7,7,8,8-tetracyanoquinodimethane(TCNQ) anion radical and hydrogen chloride in acetonitrile. The stoichiometry of the reaction is altered by the presence of Q from $2TCNQ^- + 2H^+ = TCNQ + H_2TCNQ$ to $2TCNQ^- + 2H^+ + Q = 2TCNQ + QH_2$. In case of *p*-benzoquinone, the rate of the disappearance of $TCNQ^-$ is expressed by $v = k[TCNQ^-][Q][H^+]$, where $k = 3.0 \times 10^8$ M^{-2} s^{-1} at 8 °C. From these results, it is concluded that a protonated quinone QH^+ is an active species which accepts an electron from $TCNQ^-$.

In the previous paper, the protonation reaction of 7,7,8,8-tetracyanoquinodimethane (TCNQ) anion radical by hydrogen chloride was investigated in various organic solvents.[1] Comparing the protonation rate of $TCNQ^-$ with that of semiquinone ion (Q^-), it was revealed that $TCNQ^-$ reacts with a proton with the rate more than one order slower than Q^- does.

From these results it is expected that the reaction of $TCNQ^-$ with HCl is accelerated by Q, when Q rapidly accepts an electron from $TCNQ^-$ and is protonated to hydroquinone.

$$TCNQ^- + Q \rightleftharpoons TCNQ + Q^- \quad (1)$$

$$2Q^- + 2H^+ \rightarrow QH_2 + Q \quad (2)$$

Reaction paths (1) and (2) may proceed faster than the direct protonation of $TCNQ^-$, as far as a sufficient amount of Q^- is produced rapidly by reaction (1).[2]

Based on the above expectation, the effects of quinone on the protonation reaction of $TCNQ^-$ have been investigated using acetonitrile as a solvent. The present result may provide a new aspect as to the function of quinones in oxidation-reduction reactions especially in the acidic aprotic medium.

Experimental

p-Chloranil, *p*-benzoquinone, 1,4-naphthoquinone and di-*t*-butyl-*p*-benzoquinone were sublimed once. Chloro-*p*-benzoquinone was synthesized according to Levy and Schultz.[3] The product was identified with IR spectra.[4] Other reagents were prepared as described previously.[1]

The visible spectra were measured with a Hitachi EPS-3T spectrophotometer. The rate was measured in acetonitrile with a Union Giken RA-1300 rapid scan stopped-flow spectrophotometer. The rate was obtained by mixing the solution containing Na^+TCNQ^- and quinone with HCl. All measurements were performed at 8 °C. A Union Giken temperature-jump apparatus was used to try to detect a protonated quinone.

Results

As a preliminary experiment, the rate of the disappearance of $TCNQ^-$ is measured by mixing the solution of HCl with the solution containing both Na^+TCNQ^- and a quinone. The kinetic results are summarized in Table 1. All quinones except di-*t*-butyl-*p*-benzoquinone are found to accelerate the rate of the reaction. The accelerating capacity of quinone is expressed by the quantity, $\ln 2/\{t_{1/2}[Q][HCl]\}$, where [Q] is the concentration of quinone, [HCl] the initial concentration of HCl and $t_{1/2}$ the half-life of the reaction, although the decay of $TCNQ^-$ with time is either exponential or non-exponential, depending on the kind of quinone.

The detailed study of the kinetics of the reaction has

TABLE 2. THE STOICHIOMETRY OF THE REACTION OF Na^+TCNQ^- WITH HCl IN PRESENCE OF *p*-BENZOQUINONE

$[Na^+TCNQ^-]_0$/M	[HCl]/M	[Q]/M	[TCNQ]/M
6.58×10^{-6}	1.0×10^{-5}	0	3.43×10^{-6}
6.58×10^{-6}	1.0×10^{-5}	3.36×10^{-2}	6.48×10^{-6}
6.58×10^{-6}	5.0×10^{-5}	3.36×10^{-2}	6.48×10^{-6}

been performed in the case of *p*-benzoquinone. In Table 2, the stoichiometry of the reaction is presented. In the absence of quinone, the overall stoichiometry is expressed by

$$2TCNQ^- + 2H^+ = TCNQ + H_2TCNQ, \quad (3)$$

where H_2TCNQ denotes *p*-phenylenedimalononitrile.[1] On the other hand, when *p*-benzoquinone is present, almost 100% of Na^+TCNQ^- is converted to TCNQ. The same result is obtained for *p*-chloranil where the decrease of *p*-chloranil is found to be equal to 44% of the initial amount of Na^+TCNQ^-. Therefore, the stoichiometry of the reaction in the presence of quinone is expressed as below.

$$2TCNQ^- + Q + 2H^+ = 2TCNQ + H_2Q \quad (4)$$

This stoichiometry suggests that $TCNQ^-$ is oxidized to TCNQ by Q instead of being protonated and that it is Q^- that is protonated.

The decay of $TCNQ^-$ with time is shown in Fig. 1. In the absence of Q, $TCNQ^-$ decreases according to the following equation as established previously.[1]

$$-d[TCNQ^-]/dt = k[TCNQ^-]^2[H^+], \quad (5)$$

in which the initial concentration of $TCNQ^-$ is less than 10^{-5} M. On the other hand, $TCNQ^-$ decreases exponentially in the presence of a large excess of Q. The pseudo first-order rate constant k_{obsd} is linearly dependent on both the concentrations of *p*-benzoquinone and of HCl (Figs. 2 and 3). k_{obsd} is independent of both the concentrations of Na^+TCNQ^- and TCNQ (Figs. 4 and 5). Thus the decay rate is expressed as

$$-d[TCNQ^-]/dt = k_{ap}[TCNQ^-][Q][H^+], \quad (6)$$

and

$$k_{ap} = 3.0\times10^8\ M^{-2}\ s^{-1} \text{ at } 8\ ^\circ C,$$

where HCl is considered to dissociate completely in acetonitrile.

In order to detect a protonated species of quinone, the ultraviolet spectra of *p*-benzoquinone are measured in the acetonitrile containing concentrated $HClO_4$ (Fig. 6). As $HClO_4$ is added, the peak at 243 nm is displaced by several nanometers to the longer wavelength. No new peak at 358 nm is detected contrary to the observation by Eggins and Chambers.[5] Comparing the present result with the red shift of the absorption peak at 245 nm of acetophenone in concentrated sulfuric acid due to the protonation of a carbonyl group,[6] this observation is considered to support the protonation of *p*-benzoquinone. It should be noted, however, that the observed change of electronic spectra may also include the change of medium properties, since the peak at 243 nm in acetonitrile displaces to 245 nm when acetonitrile contains 40 volume % of water. Although the temperature-jump measurements are performed for the solution containing *p*-benzoquinone and concentrated $HClO_4$, no change of the transmittance is detected at the temperature-jump in the wavelength region of 255—280 nm.

Discussion

The most striking feature of the present result is that quinones of low electron affinity like *p*-benzoquinone have an effect to accelerate the protonation rate of $TCNQ^-$.

At first, the accelerating effect by quinones seems to be ascribed to reaction paths (1) and (2). This may be true at least partially with *p*-chloranil and chloro-*p*-benzoquinone. In case of *p*-benzoquinone and other quinones, however, the participation of reaction (1) is negligible, since the forward rate of this reaction is too slow to give any effect on the reaction mechanism. The forward reaction rate constant k_1 is evaluated according to the following equation.[2]

$$k_1 = Z\exp(-\Delta F^\circ/RT) \text{ for } \Delta F^\circ > 0 \quad (7)$$

where Z is 10^{11} M^{-1} s^{-1} and ΔF° the change of the free energy of reaction (1). Assuming ΔF° to be the difference of the half-wave reduction potential between TCNQ and Q, k_1 thus estimated is given in the last column in Table 1.[7] Evidently k_1 except for *p*-chloranil is too small to explain the observed acceleration effect by quinones. To overcome this difficulty, two possible mechanisms are postulated by noticing the [H^+] dependence of the overall rate (Eq. (6)).

As a first possibility, it is assumed that there exists a pre-equilibrium of the protonation of $TCNQ^-$ (8), which is followed by the oxidation reaction by Q either through electron-transfer or through hydrogen atom transfer, (9) or (9)'.

$$TCNQ^- + H^+ \rightleftharpoons HTCNQ\cdot \quad (8)$$

$$HTCNQ\cdot + Q \rightarrow HTCNQ^+ + Q^- \quad (9)$$

or

$$HTCNQ\cdot + Q \rightarrow TCNQ + QH\cdot \quad (9)'$$

The [H^+] dependence of the rate may arise from reaction (8) which constitutes a pre-equilibrium in the overall reaction mechanisms. As K_8 was determined to be about 1.7 ± 0.6 M^{-1},[1] k_9 or $k_{9'}$ becomes about 2×10^8 M^{-1} s^{-1}. It is very unlikely, however, that reaction (9) or (9)' proceeds with such a large rate constant, considering that the oxidation of HTCNQ· is less favoured than that of $TCNQ^-$ itself from an energetic point of view.[1]

As a second possibility, it is assumed that there exists a pre-equilibrium where Q is protonated to QH^+, followed by the oxidation of $TCNQ^-$ by QH^+.

$$Q + H^+ \rightleftharpoons QH^+;\ K_{10} \quad (10)$$

$$TCNQ^- + QH^+ \rightarrow TCNQ + QH\cdot \quad (11)$$

The [H^+] dependence arises from reaction (10) under the condition that reaction (11) is rate-determining. If this is the case, k_{ap} in Eq. (6) is equated to

$$k_{ap} = K_{10}k_{11}, \quad (12)$$

where K_{10} and k_{11} are the equilibrium constant of reaction (10) and the forward rate constant of reaction

(11), respectively. The fact that the rate is independent of the TCNQ concentration is also consistent with this mechanism. Thus at the present stage of the investigation, it is concluded that protonated quinones QH^+ accelerate the protonation rate of $TCNQ^-$ by accepting an electron from $TCNQ^-$.

The validity of this conclusion is supported by the fact that QH^+ is a stronger electron-acceptor than Q itself. This fact is confirmed by evaluating the electron affinity of QH^+ as follows.

$$QH^+ + e \rightleftharpoons QH\cdot \quad (13)$$

$$Q + e \rightleftharpoons Q^- \quad (14)$$

The free energy change of reaction (13), ΔF_{13}, is related to the free energy change of reaction (14), ΔF_{14}, as below.

$$\Delta F_{13} - \Delta F_{14} = RT \ln K_{10} - RT \ln K_{16} \quad (15)$$

in which K_{10} and K_{16} are the equilibrium constants of the protonations of Q and Q^-, respectively.

$$Q + H^+ \rightleftharpoons QH^+ \quad (10)$$

$$Q^- + H^+ \rightleftharpoons QH\cdot \quad (16)$$

Using the values reported in Refs. 8 and 9, $K_{10} = 10^{-1.0}\,M^{-1}$ in water and $K_{16} = 10^{4.1}\,M^{-1}$ in water containing excess acetone and 2-propanol, $\Delta F_{13} - \Delta F_{14}$ is approximately estimated to be -6.6 kcal at 8 °C. If protonated *p*-benzoquinone QH^+ increases its electron affinity by this amount, QH^+ is as strong an electron acceptor as 2,5- or 2,6-dichloro-*p*-benzoquinone.

In the field of electrochemistry, it has been noted that the electrochemical reduction of quinone in the presence of proton donors displays the additional irreversible reduction wave at the less negative potential.[5,10] This additional wave indicates the existence of the more easily reducible species than neutral quinone. This species was suspected to be a protonated quinone.[5] The present conclusion that protonated quinone becomes a stronger electron-acceptor in homogeneous reaction is completely consistent with these electrochemical results, and confirms the above proposal.

Baxendale *et al.* studied the oxidation of Fe(II) by *p*-benzoquinone in aqueous solution.[11] In their study it is observed that the oxidation rate is independent of proton concentration from 0.35 to 0.15 M. This seems to contradict with the present results. However, since a proton in water is more stably solvated than in acetonitrile, K_{10} in aqueous solution is considered to be too small to produce the sufficient concentration of QH^+. Therefore, the present finding as to the high reactivity of QH^+ is important only in aprotic solvents where unstable proton leads to the large value of K_{10}.

The authors wish thanks to Prof. Masatoshi Fujimoto for his encouragement and also to Prof. Yoshio Matsunaga for his kind advices in synthesizing and identifiying chloro-*p*-benzoquinone.

Gel Filtration of Aqueous Sodium Dodecyl Sulfate

Hitoshi SUZUKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received March 31, 1975)

The tail analysis of gel filtration was applied to a sodium dodecyl sulfate (SDS) solution using Sephadex G-50. This method is more simple and useful than the frontal analysis method formerly reported. The relative elution rate of SDS micelle, R_m, increased with an increase in the SDS concentration above CMC, reached a maximum near 16 mmol/l and then decreased up to 100 mmol/l. The application of the Laurent-Killander equation gave a micellar radius of 17.6 Å at CMC and 11.7 Å at the maximum R_m, corresponding to aggregation numbers of 35 and 80, respectively. The apparent decrease of R_m observed above 20 mmol/l was due to an structural change of the Sephadex gel caused by the addition of SDS. The micellar weight was estimated referring to a substance of known molecular weight; it was found to be constant in the region from 15 to 100 mmol/l SDS. The results of gel filtration of the SDS solution using CPG-10 as a gel column were similar to the case of Sephadex G-50; a micellar weight and an aggregation number of 25000 and 88, respectively, in the constant R_m range were obtained.

As for the study of the dissolved state of the solute by gel filtration, zone and band analyses are possible. The former method is used to measure the position of a sharp peak of the elution curve obtained by charging a small amount of the sample, while the latter method is used to determine the positions of the front F and the tails M and S of the elution curve as shown in Fig. 1, obtained by charging a relatively large amount of material in band form. Band analysis enables the detection of species of solutes in rapid equilibrium with each other as has been mentioned previously.[1)]

Using the latter method, the present authors have measured the elution rate (R_m) of micelles, a measure of the micellar size, and the CMC from the elution rate of the front (R_f) for sodium dodecyl sulfate assuming the size of the micelles and the intermicellar concentration to be independent of the total concentration.[1)] Also the R_m have been measured directly using frontal analysis applying the extrapolation method[2)] and the same results as those employing the former method[1,2)] were obtained.

However, the frontal method with extrapolation, requires fairly large amounts of the substance and a troublesome procedure. Compared with this, tail analysis, namely, the analysis of the tail part of elution curve obtained by charging a large amount of the sample, proved to be quite simple and useful. Reliable information concerning the dissolved state of the surfactants, especially the state of the micelles, are directly obtained under some assumptions. The present paper reports the results obtained by applying the tail analysis of gel filtration to aqueous solutions of SDS using Sephadex G-50 and CPG-10 glass gel column.

Experimental

Materials. Sodium dodecyl sulfate was prepared by the same method as reported in a preceding paper.[2)] Sodium chloride of the first reagent grade was used after recrystallization. Distilled water was boiled and degassed before use. Blue Dextran 2000, a product of Pharmacia, Uppsala, was used for the measurement of the void volume of the gel bed used. Poly(vinyl alcohol)s (PVA) and the molecular weight marker kits of non-enzymatic proteins of known molecular weight were used as molecular weight standards. The PVA were kindly supplied by Nippon Gosei Kogyo Co., Ltd. and the proteins were obtained from Mann Research Laboratories Inc., New York.

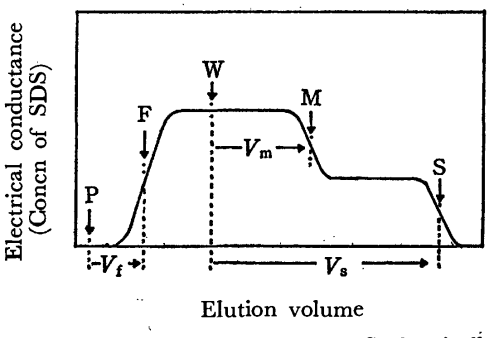

Fig. 1. The elution curve for an SDS micelle (frontal and tail analysis).
P and W: the points of sample and water charge, respectively, F: the front of the solution, M and S: the tails of micelles and single ion, V_f, V_m, and V_s: the elution volumes of front, micelles, and single ions, respectively.

The elution curve obtained is shown in Fig. 1. Elution volumes V_f, V_m, and V_s of the front F, the tails of the micelles M, and single ions S were measured as the volumes between the charge point of the sample P and the point F, between the charge point of water W, and between the points M and S on the elution curve, respectively. Relative elution rates of the front and micelles were respectively calculated from

$$R_f = V_s/V_f,\ R_m = V_s/V_m,\ \text{together with}\ R_s = 1, \quad (1)$$

R_s being the elution rate of the single ions.

Results and Discussion

Gel Filtration Using Sephadex Gel. (A) *SDS Solution*: The elution rate of micelles, R_m, calculated from V_m obtained by tail analysis is plotted against the total concentration of SDS as shown by open circles in Fig. 2. As is seen, R_m increases slightly at first, reaches a maximum near 16 mmol/l, and then decreases with increasing concentration of SDS, in agreement with previous results obtained by frontal analysis.[1,2)] A similar change with a change in the concentration was also observed with the Sephadex G-75 gel column. A linear relation between $(R_m - R_s)R_f/(R_m - R_f)$ and C predicted in a preceding paper[2)] was confirmed to be valid, and the CMC of 8.6 mmol/l

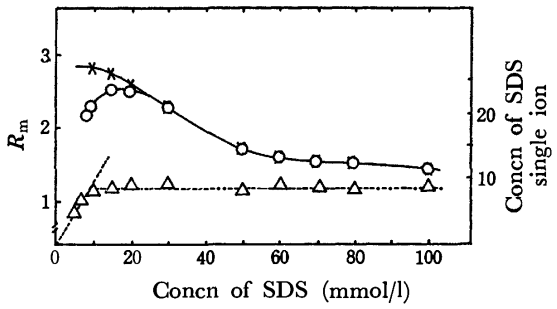

Fig. 2. R_m and the concn of SDS single ion *vs.* SDS concn using tail analysis.
×: Commercial SDS, ○: pure SDS, △: the concn of SDS single ion (CMC).

was obtained from the crossing point of this line with the horizontal straight line passing through unity on the ordinate; this CMC value is in agreement with the previous results.[2] However, the above plot deviates from linearity above 20 mmol/l, probably due to a change in gel matrix as discussed below. The lower plateau of the elution curve of Fig. 1 was also plotted against the concentration shown by the triangles in Fig. 2. As is seen, the value remains constant up to 100 mmol/l. This may indicate that the micelle-monomer equilibrium is relatively simple for SDS up to about 100 mmol/l, excluding the existence of the so-called second CMC.[3] But this does not necessarily mean that the intermicellar SDS concentration is constant. A detailed study will be reported in the near future on this subject.

(B) *Concentration Dependence of* R_m: The increase of R_m with C obtained from the tail analysis for pure SDS (open circles in Fig. 2) reflects the increase of micellar size up to about 16 mmol/l. The following experiment confirms this increase in micellar size.

An SDS solution of concentration C was charged on top of the gel which had been previously equilibrated with the SDS solution of the concentration C' between C and CMC, and was eluted with water. If the elution rate of micelles in the solution of higher concentration C is larger than that in the solution of lower concentration C', the front of the former solution goes ahead of the tail of the latter and a peak of high concentration $C+C'$ is expected to appear at the front. However, the peak was not actually observed and the front of the elution curve exhibited two simple plateaus corresponding to the concentrations C and C'. In addition, the R_f of the apparent front of the solution of concentration C is slightly but distinctly smaller than the R_m of the same solution. Since the elution volumes of NaCl and Blue Dextran confirm the absence of the effect of SDS below 20 mmol/l on the gel structure of Sephadex G-50, the above phenomena may be explained if we assume that the intermicellar concentration of single SDS ions is not equal in the solutions of differing concentrations C and C'. Figure 3 illustrates the phenomena which occurs according to such reasoning, where (a) is the initial and (b) the intermediate states of gel filtration. In this figure, the abscissa denotes the position and direction of the eluting solute, point 0 being the upper end of the gel column, and

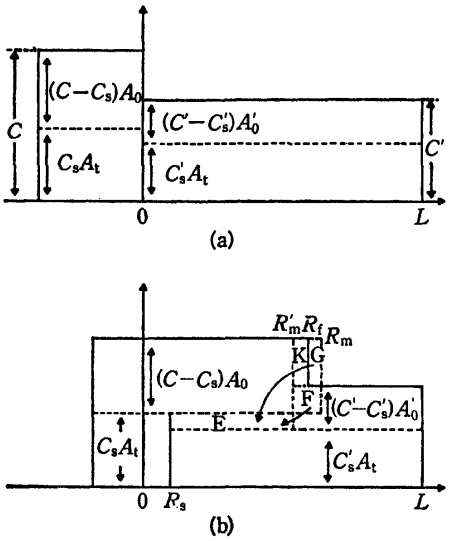

Fig. 3. The schematic representation of gel filtration of an SDS micellar solution near to the CMC.
(a) Initial and (b) intermediate state of gel filtration.

the ordinate shows the quantities of SDS single ions, (C_sA_t), and micelles, $(C-C_s)A_0$, per unit column length for both the solution of concentration C and that of concentration C'. Furthermore, $A_0(A_0')$ and A_t denoted the cross-sectional areas of the gel column through which the micelles and single ions, respectively, can pass. R_s, R_m, R_m', and R_f represent the elution rates of SDS single ions, of micelles in solution of concentrations C and C' and of the front of the solution of concentration C, respectively. In the course of gel filtration, the front of fast flowing micelles of concentration C advances ahead of the tail of the slowly flowing micelles in the solution of concentration C' by an amount $K+G+F$, as is shown in Fig. 3. Material balance gives the amount of SDS of

$$F = [(C'-C_s')A_0' + C_s'A_t - C_sA_t]\ (R_m - R_m') \quad (2)$$

and the amount of SDS of

$$G = [(C-C_s)A_0 + C_sA_t - (C'-C_s)A_0' - C_s'A_t](R_m - R_f) \quad (3)$$

that should fill the concentration gap of the portion

$$E = (C_sA_t - C_s'A_t)(R_m' - 1) \quad (4)$$

as indicated by the curved arrows in Fig. 3. Here, C_s and C_s' denote the intermicellar concentration of the solutions of concentrations C and C', respectively. Then, from Eqs. (1)—(4), the following equation results for CMC$<C'<C$

$$(C-C_s)(1-R_f/R_m) - (C'-C_s')(1-R_f'/R_m') = (C_s-C_s')(R_f-1) \quad (5)$$

From a similar consideration, the following equation is obtained instead of Eq. (5), in the case of

$C' <$ CMC $< C$

$$(1-R_f/R_m)(C-C_s) = (C_s-C')(R_f-1) \quad (6)$$

Gel filtration conducted for the system of $C=10$ mmol/l and $C'=8.5$ mmol/l solutions gave $R_f=2.24$. This value together with $R_m=2.37$ for $C=10$ mmol/l (Fig. 2) when substituted into Eq. (6) gives $C_s=8.55$ mmol/l

for $C=10$ mmol/l. Successive experiments for the system of $C'=10$ mmol/l and $C=14$ mmol/l solutions gave $R_f=2.44$. From this value together with $R_m=2.52$, $R_m'=2.37$, and $C_s'=8.55$ mmol/l, $C_s=8.73$ mmol/l for $C=14$ mmol/l was obtained using Eq. (5).

The data suggest a small but not negligible increase of the intermicellar concentration above CMC in accord with the results obtained by the electromotive force measurement.[4] A detailed gel filtration study of this problem will appear in the near future. A short extrapolation of the C_s *vs.* C relation at a point at which $C_s=C$ gives CMC=8.50 mmol/l, a value close to the value of 8.6 mmol/l obtained in a preceding paper[1,2] under the assumption of a constant intermicellar concentration.

As regards the decrease of R_m for SDS solutions of concentrations greater than 30 mmol/l, the change in gel structure as mentioned in below can be taken into account. However, a similar experiment as that shown in Fig. 3 also offers some information concerning the behavior of micelles flowing through a gel of high SDS concentration, where aqueous SDS solutions of $C=60$, 70, and 80 mmol/l were eluted through a gel column filled with a $C'=50$ mmol/l SDS solution. Figure 4(a) represents the initial and Fig. 4(b) the intermediate states during gel filtration. The notations used are the same as in Fig. 3. In this case, contrary to the dilute system described above, the apparent R_m for the solution of concentration C is considered to be smaller than that for the solution of concentration C'. Therefore, as the filtration proceeds, a gap or a space containing no micelles may form between the tail of foregoing micelles and the front of the micelles which follow, and an elution curve resembling the dotted line in Fig. 4 is expected. However, in this case as in the former case, two simple plateaus corresponding to the concentrations C and C' appeared without any gap. As in Fig. 3, the elution rate R_f

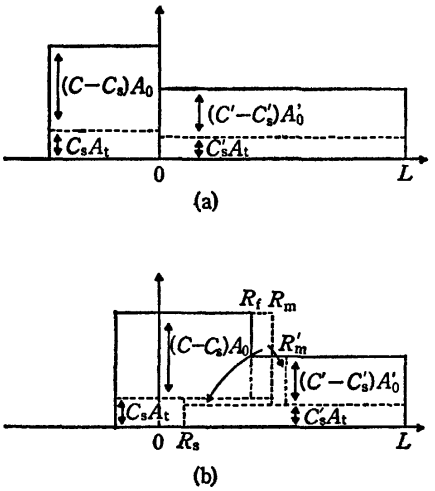

Fig. 4. The schematic representation of the front and the tail during gel filtration in higher concn of SDS. R_m': the tail of micelle in 50 mmol/l solution, R_m and R_f: the imaginary and actual fronts of micelles in C mmol/l solution, R_s: the tail of single ion in 50 mmol/l solutoin. The arrows indicates the eventual shift of solute.

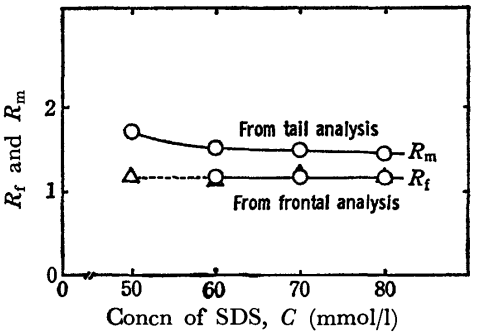

Fig. 5. The relationship between the elution rate for frontal analysis and that from tail analysis.
○: Observed, △: calculated.

observed in Fig. 4 is smaller than R_m, but the difference is fairly large compared with the case of Fig. 3, shown by circles in Fig. 5, and the value of R_f extrapolated to $C=50$ mmol/l does not agree with R_m at the same concentration, as was the case in the lower concentration region.[2]

These phenomena are explained by the higher concentration of micelles filling the above mentioned gap as is shown by the curved arrows in Fig. 4. Eq. (5) applies also in this case although the situation is somewhat different from the case shown in Fig. 3. The rate of the elution front, R_f, is calculated by putting the R_m obtained from the tail analysis into Eq. (5). The results are shown in Fig. 5 as triangles, which are seen to be in good agreement with observed values. By the trial-and-error-method best-fit values are obtained by setting $S_s=C_s'=8.7$ mmol/l. The results indicate the probable mechanism of filling at the elution front mentioned above and may suggest that the intermicellar concentration C_s is approximately constant over the region of SDS concentration from CMC to 80 mmol/l, further study being under way on this point.

(*C*) *Micellar Size*: The size of micelles can be estimated either from the theoretical formula taking account of the gel structure or from the elution volume using the appropriate substances as molecular weight standards. The former method utilizes the Laurent-Killander equation[5]

$$(V_e-V_o)/(V_t-V_o) = \exp[-\pi L(r_r-r_s)^2] \quad (7)$$

where V_t is the total volume of the gel bed, V_0 the void volume, V_e the elution volume of the substance, L and r_r are the concentration and radius of rods considered as an approximation of the structure of gel matrix (the values being 8.2×10^{12} cm/cm^3 and 7×10^{-8} cm, respectively, for Sephadex G-50) and r_s is the

Table 1. Micellar size of SDS

Concn of SDS	V_m	Radius(Å)	n
8.5 mmol/l	14.35 ml	17.6	35
10.0 mmol/l	13.20 ml	19.9	54
15.0 mmol/l	12.20 ml	22.7	80
20.0 mmol/l	12.47 ml	21.0	63

$n=89$ (K. J. Mysels)[9,10]
$n=40-70$ (H. V. Tartar)[8]

radius of the eluted particles. The hydrodynamic radii of the micelles calculated by setting $V_e = V_m$ in Eq. (7) are shown for SDS in Table 1.

The aggregation number of the micelles is calculated by dividing the micelle volume (calculated as a sphere of radius r_s) by 368.6 ml/mol, the molar volume of hydrated SDS molecules considered to be the constituent of hydrated micelles. Here, the amount of hydration was estimated from the conductivity measurement proposed by Nakagaki,[6] the value being in good agreement with that obtained from the intrinsic viscosity measurement.[7]

Calculation were not made for solutions with concentrations higher than 20 mmol/l because of the uncertainty of the V_m value due to the change in Sephadex gel structure. The aggregation numbers given by Tartar[8] and Mysels[9,10] are also listed in Table 1 for comparison. Table 1 suggests the possibility that the wide range of aggregation numbers reported is not due exclusively to experimental error but in part due to an actual increase in size with concentration. It may also be inferred that such a change in micellar size with concentration taking place in the solution near CMC may not be detectable by methods other than gel filtration.

It is noted that the micellar weight shown in Table 1 is in agreement with the value obtained by CPG gel filtration at 15 mmol/l SDS concentration, which is described below.

To confirm the probable change in the gel matrix of Sephadex beyond 20 mmol/l, and to determine the micellar weight of SDS more accurately, molecular weight standards were used. For each concentration of SDS with which the gel column is equilibrated, gel filtration was carried out with such standards of known molecular weight as sodium chloride, Blue Dextran, myoglobin, cytochrome C, and chymotrypsinogen. An calibration curve of the elution volume *vs.* molecular weight was obtained as shown in Fig. 6.

The actual molecular weight of the protein–SDS complex used for this plot was estimated by tail analysis of the elution curve, obtained by gel filtration of the protein–SDS solution in a manner similar to the measure-

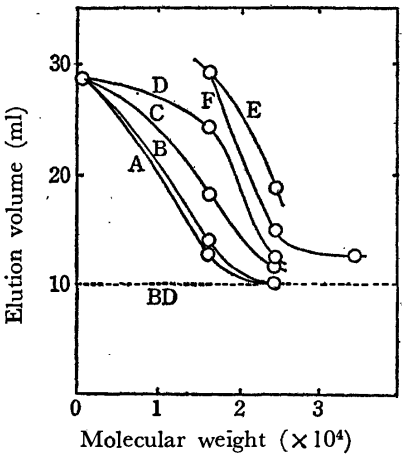

Fig. 6. The calibration curve for SDS solution.
(A): 8.5 mmol/l, (B): 15 mmol/l, (C): 30 mmol/l, (D): 50 mmol/l, (E): 70 mmol/l, (F): 100 mmol/l, BD: Blue Dextran.

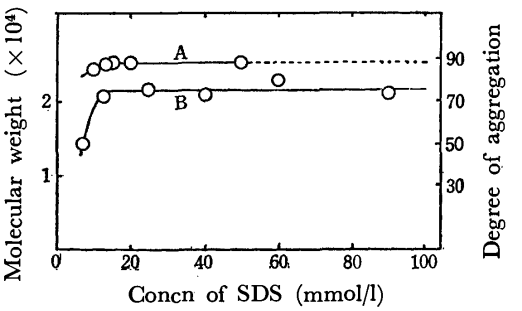

Fig. 7. The dependence of the micellar weight on the concentration of SDS measured using CPG-10 gel.
(A): CPG-10 gel, (B): Sephadex gel.

ment of the poly(vinyl acetate)–SDS system.[11] Further details of the measurement will be reported elsewhere. The results show that the protein–SDS complex contains 0.45 g of SDS per g of protein in the concentration range of SDS studied which is compared with the saturated amount of about 1 g per g of protein obtained after prolonged contact of SDS with the protein[12,13] as compared with about 1 hr contact in the present experiment.

As is seen in Fig. 6, a marked change in the gel structure was found to occur beyond 30 mmol/l. The micellar weights were calculated using these calibration curves and were plotted against the concentration, as is shown in Fig. 7. It is evident that the micellar size increases from CMC to about 15 mmol/l of SDS beyond which it remains constant over a wide range of concentrations contrary to the apparent R_m and the micellar weight decreases with increasing concentration in the case of Sephadex gel. The aggregation number of SDS micelles corresponding to this plateau is about 75. In the above calculation, hydration of the protein is assumed to be nearly equal to that of the SDS which may be permissible when both amounts of hydration[14] are compared.

Gel Filtration of an Aqueous SDS Solution by CPG-10. *(A) Elution Curve for Aqueous SDS Solution*: As mentioned above, the pore distribution of Sephadex gel is affected by a concentrated SDS solution. To avoid such a disturbance, CPG-10, a porous rigid glass gel was used instead of the Sephadex gel and the elution curve was measured for varying concentrations of SDS. A curve similar to that in Fig. 1 was obtained and the conductivity corresponding to the height of each plateau of the curve was plotted against the total concentration of SDS, as is shown in Fig. 8. Three straight lines met at one point giving CMC=8.6 mmol/l as in the case of Sephadex G-50[2]. From the observed values of V_f and V_m, R_f and R_m were calculated using Eq. (1). R_m, plotted against the SDS concentration, shows a slight increase in micellar size with concentration from CMC up to about 15 mmol/l beyond which it remains constant at least up to 50 mmol/l, as is shown in Fig. 9. This confirms the previous results obtained using Sephadex G-50 shown in Fig. 7.

Furthermore, the $(R_m - R_s)R_f/(R_m - T_f)R_s$ *vs.* C plot was made below and above CMC, and two straight lines, one passing through the origin and the other parallel to the c-axis, were obtained as shown in Fig.

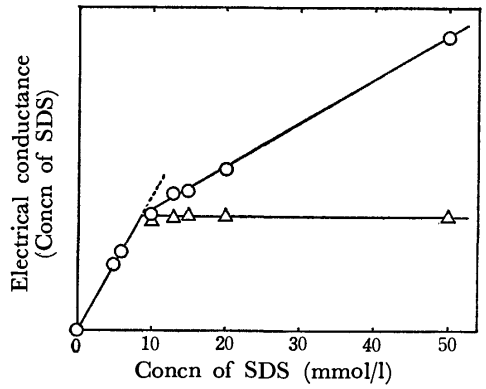

Fig. 8. The conductance of an SDS solution obtained by gel filtration using CPG-10.
○: conductance of the solution, △: conductance of the tail part of the solution (CMC).

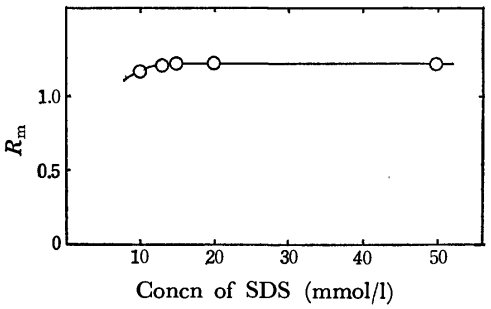

Fig. 9. The dependence of R_m on the concentration of SDS measured using CPG-10 gel.

10. The crossing point of these straight lines gives CMC=8.6 mmol/l in agreement with the value obtained previously. The fact that a straight line passes through the origin indicates the decomposition of micelle being instantaneous as was pointed out in a previous paper[2] using Sephadex G-50. It is emphasized in addition that the linearity shown in Fig. 10 extending up to and the probably beyond 50 mmol/l of SDS, as compared with the deviation from linearity over 20 mmol/l in the case of the Sephadex gel, clearly confirms the inert nature of CPG towards SDS.

(*B*) *Measurement of Micellar Weight*: To obtain the micellar weight of SDS, a calibration curve of the elution volume *vs.* molecular weight of the unhydrated SDS micelles, shown as SDS in Fig. 11, was constructed from the relation of the elution volume *vs.* molecular weight of the hydrated poly(vinyl alcohol) obtained by the conductance method,[6] shown as PVA in Fig. 11. To obtain the calibration curve, the amount of hydration of SDS (0.6 g of H_2O/g of SDS) was taken into account. To avoid disturbances due to the adsorption of poly(vinyl alcohol), the gel was treated with a dilute solution of albumin, then with a sufficient amount of concentrated SDS solution and washed with water. From this curve and the observed V_m, the micellar weight was calculated and plotted against the concentration as shown in Fig. 7. Again, a slight increase in the micellar weight is seen up to about 20 mmol/l, above which a constant micellar weight of approximately 25000 was obtained up to about 50 mmol/l. An aggregation number of about 88 was obtained for the maximum

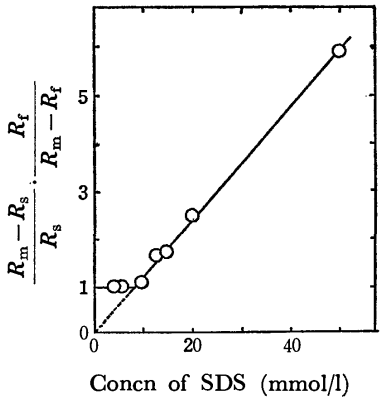

Fig. 10. The relationship between R_f and the concentration of SDS using CPG-10 gel.

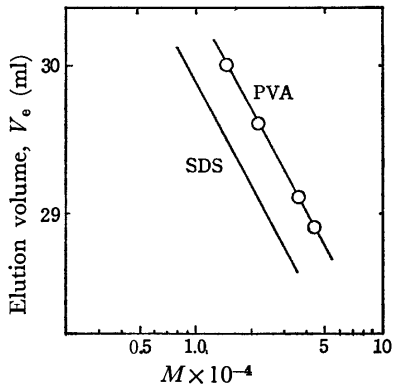

Fig. 11. The CPG-10 system calibration curve, showing the molecular weights of poly(v nyl alcohol)s relative to V_e plotted as a linear log function.

micellar weight. The value is larger than the value obtained using Sephadex G-50 with standards of known molecular weight but is near the maximum aggregation number shown in Table 1 calculated using the Laurent-Killander equation. The results obtained by the CPG gel method are considered to be more reliable considering the stability of the gel matrix.

In conclusion, it is emphasized that the frontal and tail analysis of gel filtration is useful for the study of the state and behavior of micelles in surfactant solutions. It is particularly suited for the study of micellar solutions near CMC, where other methods such as X-ray analysis, osmometry, and the light scattering method are not so effective.

The author wishes to express his deep gratitude to Professor Tsunetaka Sasaki for his kind direction and valuable criticism throughout the work.

Studies of the Effect of 1-Dodecanol on the Micellization of Sodium Dodecyl Sulfate by Gel Filtration

Hitoshi SUZUKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received April 5, 1975)

The tail analysis of gel filtration was applied to an aqueous sodium dodecyl sulfate (SDS) solution containing solubilized 1-dodecanol. Commercial SDS containing 1-dodecanol as an impurity showed a maximum micellar size at CMC. The addition of 1-dodecanol caused an increase in the micellar size due to solubilization. The amount of 1-dodecanol impurity was estimated from the elution rate of the micelle, R_m, the result being in agreement with that obtained by surface tension measurements.

Concerning the property of aqueous solutions of surfactants employed for solubilizing long-chain alcohols which are sparingly soluble in water, studies have been mainly directed towards the effect of solubilization on the critical micelle concentration (CMC) and the determination of the amount solubilized. Studies on the estimation of the effect of the solubilizate on micellar size are rather few.[1]

The addition of solubilizates is known to lower the CMC and to increase the micellar size as measured by the visual dye method,[2] viscosity,[3] light scattering,[1] and others. However, the application of the gel filtration method affords a more simple and direct means of studying the solubilization by micelles especially near CMC. In the present report, the elution behavior of SDS micelles solubilizing 1-dodecanol was studied and the change of the CMC and the micellar size due to solubilization are discussed.

Experimental

Materials. Sodium dodecyl sulfate was prepared by the same method as described in a preceding paper,[4] and a commercial SDS without purification was also used. A solubilized system was prepared by dissolving known amounts of SDS and 1-dodecanol (DOH) or tritium labelled 1-dodecanol (TDOH) in ethanol, evaporating the ethanol and dissolving the residue in water. The labelled 1-dodecanol was kindly supplied by Dr. K. Tajima of our laboratory.

Procedures. The apparatus used for gel filtration was essentially the same as that reported in Ref. 4. The gel filtration experiments were made using two columns of 1.1×30.5 cm and 1.2×10 cm gel beds packed with Sephadex G-50 fine (Pharmacia, Uppsala, Sweden). To the gel column previously equilibrated with water, a known amount of the sample solution was added and was eluted with water. The elution curve was obtained by automatically recording the electrical conductance or the refractive index of solution eluted. All of the gel filtration experiments were carried out in an air thermostat at 30 °C. For the purpose of radioactivity measurement, eluates were taken in 1 ml fractions, and 30 μl of the eluate from each fraction was completely evaporated in a planchet at room temperature. The radioactivity of each eluate was determined by a 2π windowless gas flow counter.

As mentioned in a previous paper,[4] from the measurement of the elution volumes, V_f, V_m, V_s, the relative elution rates of the front and micelles were calculated from

$$R_f = V_s/V_f,\ R_m = V_s/V_m,\ R_s = 1$$

respectively, where, the elution rate of single ions was conventionally taken to be unity.

Surface tension measurements of aqueous solutions of SDS were carried out using a du Noüy tensiometer at room temperature (25 °C).

Results and Discussion

In order to study the solubilization by micelles by the tail analysis[5] of gel filtration, SDS solutions with solubilized TDOH were used. Figure 1 shows the elution curves obtained for SDS solutions with and without DOH, where A and B indicate the tails of the DOH and SDS micelles of the solubilized system measured by radioactivity and the electrical conductance, respectively, and C is the tail of SDS micelles measured by the electrical conductance for the system without any solubilizate. The elution curve A indicates the practical insolubility of 1-dodecanol in the intermicellar solution, and the agreement of elution volumes between A and B indicates the perfect incorporation of 1-dodecanol into micelles. Furthermore, a larger elution volume of C compared with A and B indicates the increase in size of the micelles due to solubilization.

Figure 2 shows the fronts of the elution curve of the solubilized system shown in Fig. 1. The shapes of the fronts for A and B are rather different compared with the similarity in the shapes of A and B tails shown in Fig. 1. Front A shows a sharp peak and is situated in advance of the front B which has a usual slope. This is explained as follows. A part of micelles containing the solubilizate decomposes at the front during gel filtration, resulting in the precipitation of solubilized 1-dodecanol, whereby a part of the precipitate is resolubilized and concentrated in the undecomposed

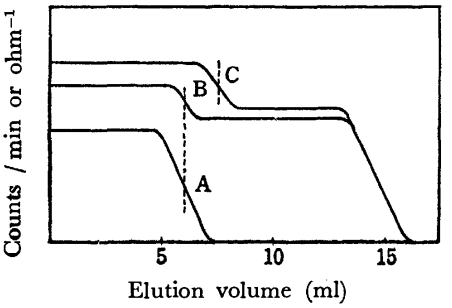

Fig. 1. Elution tail of micellar solution containing solubilized TDOH.
Curve A is from radioactivity measurement, curves B and C are from conductance, respectively (C, 1-dodecanol free).

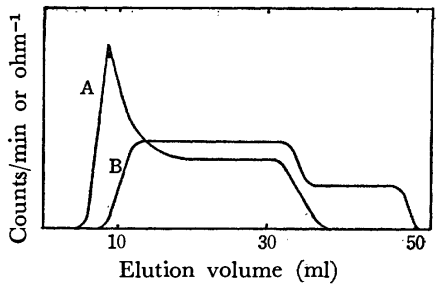

Fig. 2. Front of elution curve for micellar solution of SDS containing solubilized TDOH.

micelles, while the rest of the precipitates being larger in size than the micelles advance faster than the micelles. Thus, 1-dodecanol is gradually concentrated in the micelles and forms a sharp peak in front of the micelles. The peak was also confirmed by detecting the front using a differential refractometer which has been described in detail.[6]

For the study of the change of the micellar size due to the solubilization, the R_m obtained with commercial SDS containing 1-dodecanol as impurities was plotted against the concentration shown by crosses in Fig. 3. As is seen, the commercial SDS shows remarkably larger R_m values than does a pure sample (open circles); R_m is largest at CMC and decreases with an increase in SDS concentration. At sufficiently high concentrations, both the pure and commercial products gave the same value of R_m. The marked increase of R_m for commercial SDS can be explained as follows. Although the total amount of 1-dodecanol contained as impurities in aqueous SDS solutions near CMC is not very large, the amount of 1-dodecanol solubilized per micelle may become fairly large since the number of micelles formed just above CMC is very few. This causes the formation of large micelles for impure SDS just above CMC. At higher concentrations, the number of micelles increases more rapidly than the amount of 1-dodecanol increases, and the effect of 1-dodecanol solubilization on micellar size becomes practically insignificant at sufficiently large concentrations of SDS. Thus, the micelle radius of commercial SDS, which contains 1-dodecanol as an impurity, is considerably larger than that of pure SDS near CMC. At higher concentrations of SDS, this difference tends to disappear. The hydrodynamic radii of the micelle calculated by the Laurent-Killander equation are shown for pure and impure (containing 1-dodecanol) SDS in Table 1. The increase in micellar size with the increase in the solubilized amount of DOH at a constant SDS concentration of 10 mmol/l was measured by the increase of R_m shown by squares in Fig. 3.

From a comparison of these R_m values with those

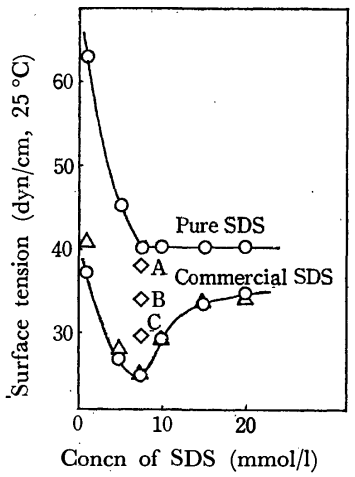

Fig. 4. Dependence of the surface tension on concentration of SDS containing solubilized DOH.
◇ A, ◇ B, ◇ C, △, SDS containing 0.07×10^{-2}, 0.26×10^{-2}, 1.03×10^{-2}, and 2.75×10^{-2} mol DOH per mol SDS, respectively.

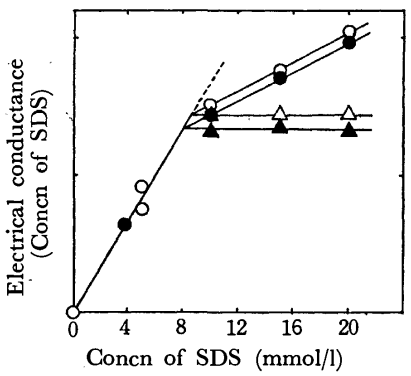

Fig. 5. Conductance of SDS solution obtained by gel filtration.
○, ●, conductance of the solution; △, ▲, conductance at the CMC; ○, △, pure SDS; ●, ▲, commercial SDS.

for commercial SDS used in the present experiment, the impurity (tentatively assumed to be 1-dodecanol) in the commercial SDS is estimated to be about 2.2×10^{-2} mol of DOH per mol of SDS. A similar amount was obtained from the surface tension measurement. Thus, the surface tensions of solutions containing the same amounts of SDS (near CMC) but varying amounts of 1-dodecanol were plotted against the concentrations of 1-dodecanol. Figure 4 shows the results together with the surface tension for commercial SDS. From this figure, about 2.75×10^{-2} mol of DOH/mol of SDS was obtained for the commercial SDS.

It was further confirmed from the plots of the plateau of the elution *vs.* concentration curve shown in Fig. 5[4] that the CMC of impure SDS, 7.8 mmol/l, was lower than that of pure SDS, 8.5 mmol/l, obtained from a similar plot which is in accordance with the general view on the effect of such a solubilizate.[7,8]

The author wishes to express his deep gratitude to Professor Tsunetaka Sasaki for his kind direction and valuable criticism throughout the work.

Formation of Excited Molecules and Atoms by Controlled Electron Impact on Hydrogen Chloride and Chlorinated Methanes

Minoru TOYODA, Teiichiro OGAWA, and Nobuhiko ISHIBASHI
Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812

(Received April 14, 1975)

The dissociation, ionization, and excitation of hydrogen chloride and chlorinated methanes under controlled electron-impact excitation were studied at low pressures. The photoemissions (200—600 nm) were observed and assigned to HCl^+, CH, CH^+, CCl, H, and Cl^+. Such species as H and HCl^+ from HCl, and H and CH from CH_2Cl_2 were concluded to be produced by some one-electron processes. The photoemission of the HCl^+ produced from CH_2Cl_2 increases quadratically with the electron-beam current; in this case HCl^+ is mainly produced by the molecular elimination of HCl and the successive ionization excitation by the second electron. The threshold energies of the photoemissions were found to be 16.8 eV for HCl^{+*} from HCl, 19.8 eV for H* from HCl, and 17.6 eV for CH*(A) from $CHCl_3$. The processes of the excitation of these species near the threshold were discussed.

Information on the primary ionization, dissociation, and excitation of atoms and molecules can be obtained by the measurement of the emission spectrum excited by controlled electron impact at low pressures, since the excited molecule will normally emit radiation before undergoing a collision. This information is pertinent to various aspects of physics and chemistry, such as gaseous electrical discharges, collision phenomena, mass spectroscopy, and radiation chemistry. The emission spectra of aromatic molecules and of H_2S, CS_2, and thiols obtained by this method have been reported, and the processes of excitation have been discussed.[1-3]

The electronic spectrum of HCl^+ ($A^2\Sigma^+ - X^2\Pi$) has been measured by Brice and Jenkins,[4] Norling,[5] and Sheasley and Mathews.[6] The photoelectron spectrum of HCl was obtained by Lempka *et al*[7] and Turner *et al*.[8] Haugh[9,10] studied the collision of HCl with He^+, Ar^+, and Kr^+, and found an unusual vibrational distribution and the quadratic intensity dependence of the vibrational bands on the target-gas pressures.

Spectroscopic studies of the dissociative excitation of chlorinated methanes have been carried out by means of an electron-impact method[11] and by means of an electric discharge method.[12] The photoemission of HCl^+ was observed even though chlorinated methanes have no H-Cl bond. However, the mechanisms of their fragmentation and excitation processes have been left unsolved.

In the present report, the emission spectra of hydrogen chloride, dichloromethane, and chloroform under controlled electron-impact excitation will be presented, and compared with the results of the previous investigations. The mechanism of the excitation and dissociation by electron-impact will be discussed in terms of the intensity of the emission and threshold behavior.

Experimental

The experimental arrangement used in this work has been described elsewhere;[1,13] however, the apparatus has been partly modified in order to improve it. Thermal electrons emitted by a heated tungsten filament are accelerated and are then introduced into a collision chamber through a hole (4 mm in diameter). The energy of the electrons is externally controlled from 10 to 450 eV. The sample gas is jetted through a nozzle (0.1 mm in diameter) and collides with the electron beam. The pressure during the operation, as measured with a Penning gauge, is of the order of 10^{-4} mmHg, though the density of the gas in the middle of the molecular jet may be higher.

The collision cell used in the measurement with the electron energy near the threshold contains a brass cylinder inside the glass cell to remove the effect of space charges and secondary electrons. In order to avoid a space-charge effect, electron-beam currents of less than 5 μA have been used when the electron energy is below 30 eV. The electron energy scale is calibrated by thresholds of the molecular lines of N_2 (3371 Å, 11.1 eV[14]) and N_2^+ (3914 Å, 18.4 eV[14]).

The photoemission is observed perpendicularly to both the electron beam and the molecular beam. A JASCO CT-50 monochromator equipped with an EMI 9558Q B or an HTV R585 photomultiplier is used for the photoelectric detection. The monochromator has a 1200 line/mm grating blazed for 500 nm and has a reciprocal dispersion of 1.65 nm/mm. A Teledyne Philbric 1026-01 OP amplifier is used for the measurement of strong emissions, and an NF PC-545A photon counter, for the measurement of a weak signal near the threshold. The spectral sensitivity of the light detection system is determined by using a rohdamine B cell and by using an Ushio JC 24-150 halogen lamp.[15] The deviation of the two calibration curves is below 10% between 280 and 450 nm. The band intensities were determined by means of the peak height for the measurement of the intensity dependences on the electron-beam current and the gas pressure. However, the peak area was measured for the determination of the relative intensity of vibrational structures; the experimental uncertainty of the intensity measurements is, in this case, estimated to be about 20%.

The hydrogen chloride and deuterium chloride (99%) were obtained from the Takachiho Chemical Ind. and from Stohler. The dichloromethane and chloroform were obtained from Kishida, and the deuterated chloroform (99%) from Merk. Each sample was frozen and pumped repeatedly to remove any dissolved gases.

Results

Hydrogen Chloride and Deuterium Chloride. Typical emission spectra of HCl and DCl by controlled electron impact are shown in Fig. 1. A slit width of 50 μm was used for these measurements. The electron energy was 300 eV, and the electron-beam current was 1 mA. The dominant bands extending from 270 to 460 nm in these spectra are assigned to the $A^2\Sigma^+ - X^2\Pi$ transition of HCl^+. More than 6 vibrational levels of the upper

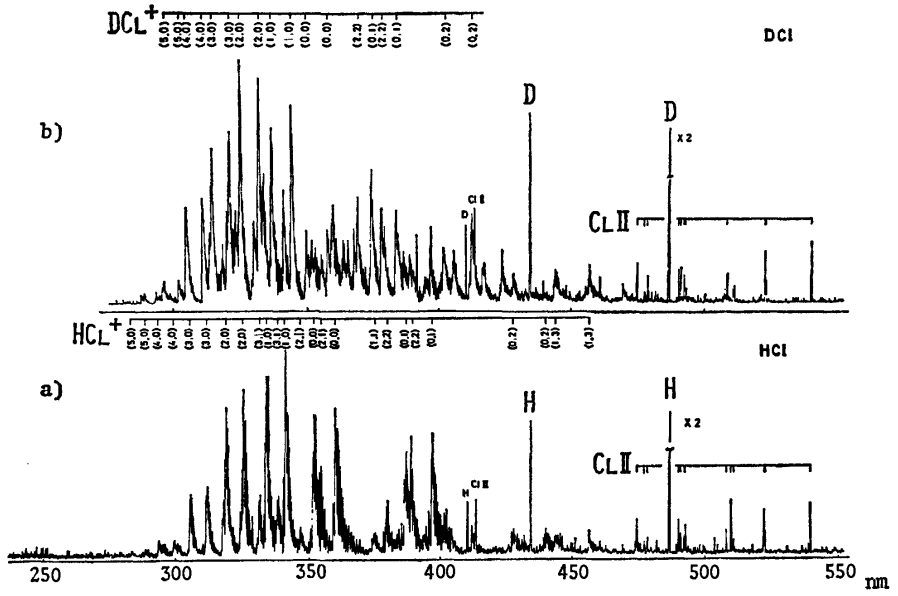

Fig. 1. Emission spectra of HCl (a) and DCl (b) by controlled electron impact. Electron energy 300 eV; electron-beam current 1 mA.

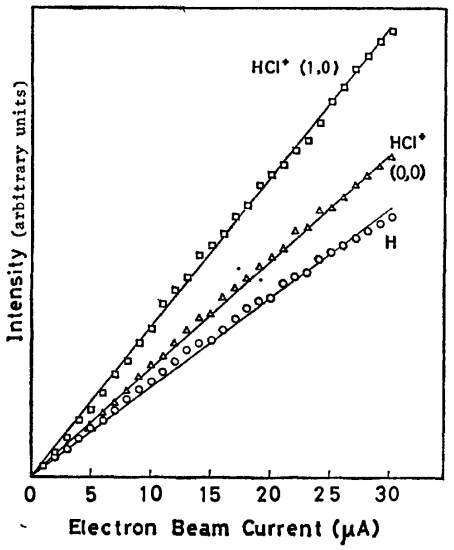

Fig. 2. Dependence of photoemission intensities of H (○) and HCl^+ (△ and □) on the electron-beam current. Electron energy was 300 eV.

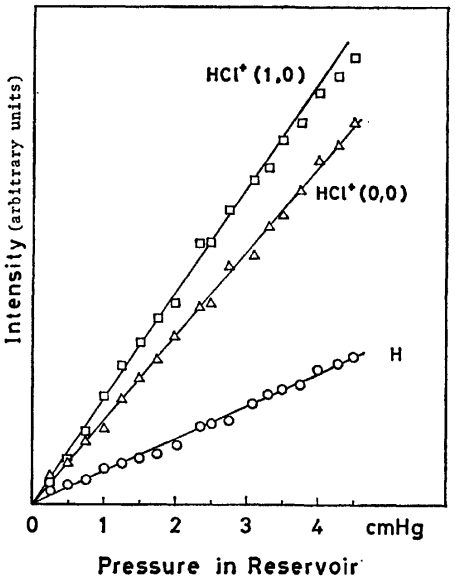

Fig. 3. Dependence of photoemission intensities of H (○) and HCl^+ (△ and □) on the gas pressure in the gas reservoir. Electron energy was 300 eV and the electron-beam current was 50 μA.

electronic state ($A^2\Sigma^+$) of HCl^+ are excited by electron impact. The strong bands of the $A-X$ system of HCl^+ are, in the order of calibrated intensities, (2, 0), (1, 0), (0, 0), and (0, 1). The intensity of the (v′, 0) band in a v″ progression is found to be the strongest; the intensity decreases at higher vibrational levels of v″. The DCl^+ spectrum shows an isotope shift in the vibrational structure. Such fragment species as H or D and Cl^+ are also observed, as is indicated in the figure.

The dependencies of the photoemission intensity of the H_β line and the HCl^+ bands from HCl on the incident electron-beam current and the target-gas pressure are shown in Figs. 2 and 3 respectively. The gas pressure was measured in the gas reservoir, where the pressure was estimated to be proportional to that in the collision chamber. Linear relations hold in all cases, and the intensity of the photoemissions of H and HCl^+ from HCl is given as follows:

$$I = k_1[e][HCl] \quad (1)$$

where I and k_1 stand for the emission intensity and a proportionality constant.

The threshold energies (minimum appearance potential) of the photoemissions of HCl^+ and H were measured; they are shown in Table 1, together with the calculated values. For the ionization excitation of HCl, the threshold energy was calculated by adding up the ionization energy of HCl and the excitation

Table 1. Threshold energy for ionization and dissociation excitation for HCl and $CHCl_3$

Process	Threshold energy (eV) Calcd	Obsd	
$HCl \xrightarrow{e} HCl^+*(0,0)$	16.3	16.8±1.0	(a)
$H^*(n=4)+Cl(3p^{52}P)$	17.2	19.8±1.0	(b)
$H^*(n=4)+Cl(4s^{14}P)$	26.1		(c)
$H^*(n=4)+Cl(4s^{12}P)$	26.4		(d)
$CHCl_3 \xrightarrow{e} CH^*(A)+Cl_2(X)+Cl(3p^{52}P)$	12.0		(e)
$CH^*(A)+Cl_2(A)+Cl(3p^{52}P)$	14.2		(f)
$CH^*(A)+3Cl(3p^{52}P)$	14.4	17.6±1.0	(g)
$CH^*(A)+Cl_2(C)+Cl(3p^{52}P)$	19.1		(h)

$I(HCl) = 12.82$ eV[16], $D(H\text{-}Cl) = 4.48$ eV[14]

$E_{calcd(e)}(CH^*) = D(CCl_3\text{-}H)+D(CCl_2\text{-}Cl)+D(CCl\text{-}Cl)+D(C\text{-}Cl)-D(C\text{-}H)-D(Cl\text{-}Cl)+h\nu$
$= 3.90^{17}+2.36^{18}+3.45^{18}+5.33^{18}-3.47^{14}-2.48^{14}+2.87$
$= 12.0$ eV

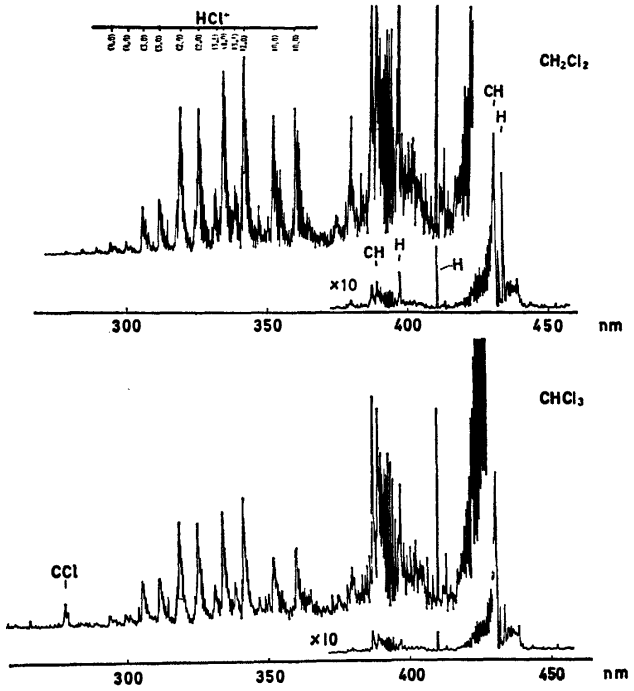

Fig. 4. Emission spectra of dichloromethane and chloroform by controlled electron impact. Electron energy 300 eV.

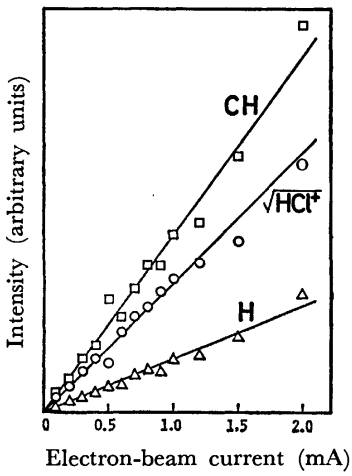

Fig. 5. Dependence of photoemission intensities of H (△), CH (□), and HCl^+ (○) on the electon-beam current. The square root of the intensity of HCl^+ is shown so that the quadratic dependence is clearly indicated. The electron energy was 300 eV.

energy of HCl^+. For the dissociation processes of HCl, the threshold energy was calculated by adding up the dissociation energy into fragments in their ground states and the relevant excitation energies of one or both of fragments, as given in Table 1. The calculated values can be expected to be smaller than the observed values by the amount of the kinetic, vibrational, and rotational energies of the species produced.

Dichloromethane and Chloroform. Typical emission spectra of dichloromethane and chloroform are shown in Fig. 4. The hydrogen Balmer series and HCl^+ doublet bands are obtained as in the case of HCl. The bands at 431 and 432 nm are assigned to the (0, 0) and (2, 2) bands of the $A^2\Delta-X^2\Pi$ transition of the CH radical, and the band at 387 nm, to its $B^2\Sigma^-$—$X^2\Pi$ transition. CCl shows a weak band at 278 nm, which is superimposed on the (6, 0) band of HCl^+. The emission at about 350 nm is assigned to CH^+ (see also Fig. 7). The 2800 Å and 2368 Å systems of CCl and the sharp line of the neutral carbon atom at 248 nm are also observed.

The spectrum of chloroform is identical to that of dichloromethane except for the relative amount of the fragments produced; for example, the ratio of the emission intensity of CH to that of H in $CHCl_3$ is much larger than that in CH_2Cl_2. Deuterated chloroform gives the bands of DCl^+.

The intensity of the photoemissions of H and CH produced from CH_2Cl_2 is proportional to both the electron-beam current and the gas pressure, as in the case of HCl, as is shown in Figs. 5 and 6. On the other hand, the square root of the emission intensity of HCl^+ is proportional to the electron-beam current (Fig. 5), while the pressure dependence of the intensity of HCl^+ is linear, as are H and CH (Fig. 6). The

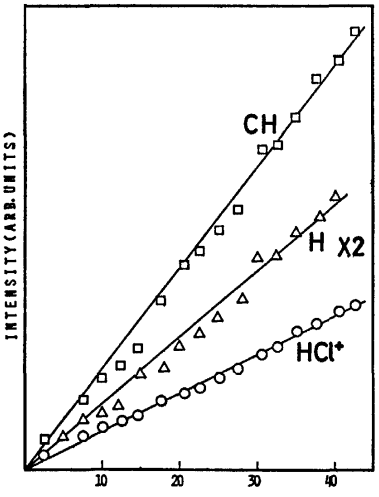

Fig. 6. Dependence of photoemission intensities of H (△), CH (□), and HCl^+ (○) on the gas pressure in the gas reservoir. The electron energy was 300 eV and the electron-beam current was 200 μA.

above findings give the following equations for the emission intensity of HCl^+ from CH_2Cl_2:

$$I = k_2[e]^2[CH_2Cl_2] \quad (2)$$

and for that of H and CH:

$$I = k_2[e][CH_2Cl_2] \quad (3)$$

The threshold energy of the photoemission of CH ($A^2\Delta - X^2\Pi$) was also measured; it is shown in Table 1, together with the calculated values.

Discussion

Hydrogen Chloride and Deuterium Chloride. The first vibrational quanta in the $A^2\Sigma^+$ and $X^2\Pi$ ionic states of HCl^+ and the ground state of the neutral molecule (HCl) are 1527, 2568, and 2886 cm^{-1} [14] respectively. The reduction of the vibrational quantum upon ionization in the $^2\Sigma^+$ state is much greater than that in the $^2\Pi$ state, as a result of the difference in the bonding nature of the orbital from which the electron is ejected for ionization. This is consistent with the difference in the bond length of the three species involved: 1.514 Å for HCl^+ ($^2\Sigma^+$), 1.315 Å for HCl^+ ($^2\Pi$) and 1.275 Å for the ground state of HCl.[14] This difference in the bond length is responsible for the greater population in the higher vibrational levels in the $^2\Sigma^+$ state, as is to be expected from the Franck-Condon factors for the transition between HCl (ground state) and HCl^+ ($A^2\Sigma^+$).

The emission intensity of a diatomic molecule in a transition from the v′ vibrational level of the upper state to the v″ vibrational level of the lower state is given by this expression:[14]

$$I_{v'v''} = KN_{v'}\nu^4 Re^2 q_{v'v''} \quad (4)$$

where K is a constant, $N_{v'}$ is the number of molecules in the upper state, Re is an electronic transition moment, and $q_{v'v''}$ is a Franck-Condon factor. If Re is constant for a series of transitions, the emission intensity of a band depends on the product of ν^4 and the Franck-Condon factor. Haugh[19] pointed out that Re decreases strongly at a large interatomic distance for the $A^2\Sigma^+ - X^2\Pi$ transition of HCl^+. In the present study, the intensities of the bands seem to give a displacement from the calculated Franck-Condon factors; the observed v′ progression with v″=0(v′, 0) is relatively more intense than the expected value. This displacement may be elucidated by Haugh's suggestion that the electronic transition moment decreases with an increase of v″.

The intensities of both H and HCl^+ are proportional to the electron-beam current and the gas pressure, as is shown in Equation (1). Thus, the ionization excitation and the dissociative excitation of HCl are concluded to proceed by one-electron unimolecular processes as follows:

$$HCl + e \rightarrow \begin{cases} HCl^{+*} \rightarrow HCl^+ + h\nu \\ H^*,\ Cl^{+*} \rightarrow H,\ Cl^+ + h\nu \end{cases}$$

where the asterisk stands for an excited state.

In the collision of HCl with He^+,[10] the ratio of the vibrational intensity of the (0, 0) band to the (1, 0) band at various target-gas pressures was not constant. The quadratic intensity dependence of the vibrational bands with the target-gas pressures has been obtained, and a reactive intermediate has been suggested. These are, however, not observed in the present case, and so no intermediate species need be considered in the present study. A difference in the method of the excitation sometimes results in a different distribution of the vibrational populations of the products, as may be seen also in the case of CN.[20]

The calculated and observed threshold values for the ionization excitation of hydrogen chloride agree well, as is shown in Table 1. This result shows that HCl^{+*} is also produced by a direct ionization-excitation of HCl near the threshold. For Balmer β of the hydrogen atom (4861 Å) from HCl, the observed onset potential is 19.8±1.0 eV. This onset is unambiguously due to the dissociation process (b), which is followed by the simultaneous formation of Cl in the ground state. In Reaction (b) the dissociation products carry off an excess energy of about 2.6 eV; the hydrogen atom shares 97% of the total excess energy. Ogawa *et al.*[21] measured the Doppler width of the light emission of H* formed by the 300 eV electron-impact on HCl and determined the kinetic energy to be 7.3 eV. Thus, the H atom produced by electron-impact seems to be hot.[21]

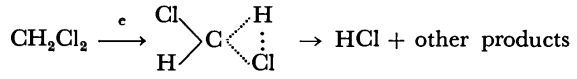
Dichloromethane and Chloroform. Though dichloromethane and chloroform have no direct H–Cl bond, the bands of the hydrogen chloride ion are clearly observed at high electron-beam currents. There are three plausible mechanisms for the formation of HCl^{+*}. The first one is a recombination of two atomic species:

$$H + Cl \rightarrow HCl^{+*}$$

where H and Cl, which may be ionic or excited, are produced in the primary processes. The second is an abstraction mechanism:

$$H(\text{or } Cl) + CH_2Cl_2 \rightarrow HCl^{+*}.$$

The third is a molecular elimination mechanism:



$$HCl \xrightarrow{e} HCl^{+*}.$$

The first and third mechanisms are compatible with the quadratic dependence of the emission intensity on the electron-beam current, while the second one is not. The third mechanism is supported by the linear relation between the photoemission intensity and the target-gas pressure, while the first and the second ones are not. The spectrum of a mixture of D_2O and CCl_4 was investigated; if either a recombination or an abstraction mechanism were correct, the emission from DCl^+ would be observed. No DCl^+ bands could be observed, however, even when the emissions of D and Cl^+ were very strong.

The spectrum of HCl^+ has well-resolved vibrational and rotational structures. The rotation-vibration bands of HCl^+ obtained from HCl were compared with those from CH_2Cl_2, as is shown in part in Fig. 7. The structures not only of the parts shown in Fig. 7, but also of the other parts of rotation-vibration bands were found to coincide completely. The relaxation processes of the electronically excited species can be ignored in the present study. Thus, this result reveals that the HCl^{+*} species obtained from CH_2Cl_2 may be formed *via* HCl in the ground state, since the intensity distribution of a band is related with the wave function of the initial and final states, as is given in Eq. (4). If these species were formed through other processes, the rotation-vibration bands would change clearly.

Dibeler and Bernstein[22] observed the CCl_2^+ ion from $CHCl_3$ and $CDCl_3$ by using a mass spectrometer. The impact voltages used in their study were 50 and 70 eV, smaller than the one used in the present study; however, no significant differences in emission spectra have been observed in this energy region, and their results can be carried over on the present study. They suggested that the CCl_2^+ ion was formed primarily by dissociation of neutral HCl or DCl molecules from $CHCl_3$ or $CDCl_3$, rather than by dissociation into the separated atoms, and that the amount of HCl thus produced was larger than that of HCl^+. These results support the molecular elimination mechanism suggested above.

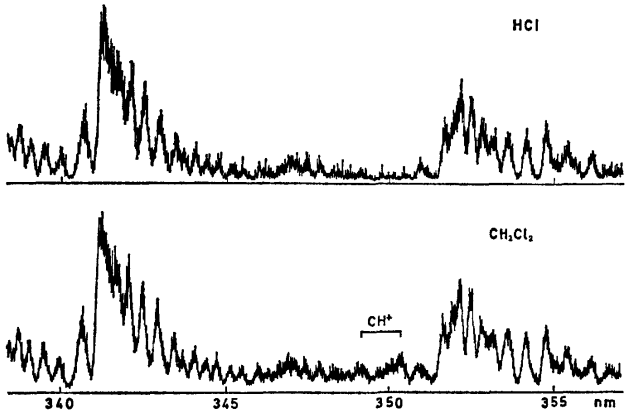


Fig. 7. Comparison of rotation-vibration bands of HCl^+ obtained from HCl with that from CH_2Cl_2. Slit width 50 μm.

Thus, the excited HCl^+ from chlorinated methanes is concluded to be produced mainly by the molecular elimination mechanism.

Since the intensity of the photoemissions of H and CH are expressed in Equation (3), it can be concluded that H and CH are produced in some one-electron unimolecular processes.

The relative intensity of the band of CH to the line of H from chloroform is larger than that in the case of dichloromethane. Since the formation of the CH radical requires the C–H bond rupture in CH_2Cl_2, and since the bond energy of a CH bond is larger than that of a C–Cl bond, the CH radical would be produced more easily from $CHCl_3$. The observation of the 2368 Å system of CCl and the C(I) atomic line in $CHCl_3$ can be explained in the same way.

For the dissociative excitation leading to CH* (4314 Å) from $CHCl_3$, the calculated and the observed threshold are also shown in Table 1. The energy consideration requires that the dissociation process involves Reactions (e)—(g) near the observed threshold. In Reaction (e), however, the excess energy is about 5.6 eV; this energy should be carried away mainly as the translational energy, since CH is not rotationally and vibrationally excited and since the rotational energy of Cl_2 would be small. This value seems to be too large for the total kinetic energy of CH*, Cl, and Cl_2. Even if Cl_2 were vibrationally excited up to the dissociation limit, CH*, Cl, and Cl_2 would still have about 3.2 eV as the kinetic energy. Reaction (e), therefore, makes only a small contribution to the formation of CH* near the threshold region.

The authors wish to thank Professor Tomoo Oyama for the use of his CT-50 monochromator and Mr. Masaharu Tsuji for his discussion. The authors are also indebted to Dr. Mamoru Susuki of the Electrotechnical Laboratory for the determination of spectral irradiance of a standard lamp.

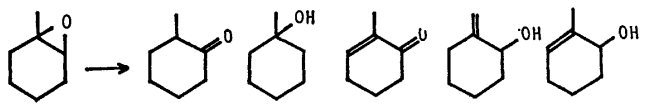
(Received April 24, 1975)

The reaction of 1-methylcyclohexene oxide at 108 °C was found to give predominantly 2-methylcyclohexanone (III) over $FeSO_4$, but predominantly allyl alcohols (VI) over TiO_2–ZrO_2 of various compositions. $NiSO_4$ gave the same amount of both products, III and VI. The selectivities over $FeSO_4$ and $NiSO_4$ were not much varied with calcination temperatures from 150 °C to 700 °C, while the catalytic activities were higher with $NiSO_4$ calcined at low temperature and with $FeSO_4$ calcined at high temperature. $FeSO_4$ and $NiSO_4$ gave the preferential formation of an allyl alcohol with *exo*-double bond, 2-methylene cyclohexanol (VIa), while TiO_2–ZrO_2 formed predominantly an allyl alcohol with *endo*-double bond, 2-methyl-2-cyclohexene-1-ol (VIb). Both the acidity and basicity of TiO_2–ZrO_2 were observed to increase by mixing each oxide and to correlate with the catalytic activity. The allyl alcohol formation was explained by an acid-base bifunctional mechanism.

We have recently reported some works on the isomerization of 1-methylcyclohexene oxide catalyzed by solid acids and bases,[1,2] where ketone (III) or allyl alcohols (VI) of five main products, with a small amount of 1-methylcyclohexene (I) and unidentified compound (II) (supposedly the dehydrated diene-compound of (VI)), was predominantly formed depending on the type of catalysts: $SiO_2 \cdot Al_2O_3$, H_2SO_4/SiO_2, low-temperature calcined solid H_3PO_4 and $LiClO_4$ produced almost 100% ketone, while Al_2O_3 and TiO_2 gave more than 80% of allyl alcohols (VI).[1]



III IV V VIa VIb

In connection with our interests in the strikingly different selectivities, we have examined further the catalytic properties of TiO_2–ZrO_2, $NiSO_4$, and $FeSO_4$ for this isomerization reaction from the following several points of view: 1) TiO_2–ZrO_2 showed much higher catalytic activity with the predominant formation of allyl alcohol than TiO_2,[2] and the existence of basic sites on the surface was suggested from the catalytic action for the partial conversion of ethanol into butadiene;[3] 2) $NiSO_4$ gave the same amount of both ketone and allyl alcohol[2]; and 3) $FeSO_4$ was found to show the significant catalytic activity for a preferential formation of ketone and also exhibited a surprisingly high catalytic activity for the Friedel-Crafts benzylation of toluene with benzyl chloride when calcined at high temperature.[4]

In the present paper, we discuss more in detail the catalytic activity and selectivity of TiO_2–ZrO_2, $NiSO_4$, and $FeSO_4$ for the isomerization of 1-methylcyclohexene oxide, particularly the relationship between the surface property and the selectivity.

Experimental

1-Methylcyclohexene oxide, supplied from Takasago Perfumery Co., was fractionally distilled to purify to more than 98% and toluene, a guaranteed reagent, used as a solvent was redistilled over sodium metal.

$NiSO_4$ and $FeSO_4$ were prepared by calcining their heptahydrates, guaranteed reagents of Wako Pure Chemical Co and Kanto Chemical Co., respectively. TiO_2, ZrO_2 and TiO_2–ZrO_2 of various compositions were prepared by thermal decomposition of H_4TiO_4, $Zr(OH)_4$ and H_4TiO_4–$Zr(OH)_4$, respectively. The procedure for the preparation of these materials was described previously.[3] All the catalysts were calcined in air and stored in sealed ampoules until use.

The procedures of reaction and analysis of the products were followed by those of the previous experiment.[1]

The amounts of base of TiO_2–ZrO_2 catalysts were measured by titrating the 100 mesh powder suspended in benzene with 0.1 M benzoic acid benzene solution, using 2,4,6-trinitroaniline ($pK_{BH}=12.2$) as an indicator.

Results and Discussion

The reaction of 1-methylcyclohexene oxide over TiO_2–ZrO_2, $NiSO_4$ and $FeSO_4$ catalysts gave five main products, 2-methylcyclohexanone (III), 1-methylcyclohexanol (IV), 2-methyl-2-cyclohexene-1-one (V), 2-methylenecyclohexanol (VIa) and 2-methyl-2-cyclohexene-1-ol (VIb), as observed in our previous paper.[1]

Table 1 shows the catalytic activities and selectivities of these catalysts in 2 hr at 108 °C. The over-all reaction followed first order reaction kinetics with respect to the oxide concentration except those with $NiSO_4$ calcined at 250 °C and $FeSO_4$ heat-treated above 400 °C, in which the reaction rate was found to diminish greatly after 30 min, probably owing to the contamination of the catalyst surface with some polymers produced by those high catalytic activities.

The products are mainly divided into two groups, ketone (III) and allyl alcohols (VI). The former was formed predominantly over $FeSO_4$, while the latter was given by TiO_2, TiO_2–ZrO_2 and ZrO_2 with a marked amount of IV and V, obviously formed by hydrogen transfers from V to IV (approximately the same yield found). $NiSO_4$ gave the same amount of both products. It is of interest that the selectivities are almost the same over $NiSO_4$ and $FeSO_4$ heat-treated at any temperatures from 150 to 700 °C, though solid H_3PO_4 formed almost 100% ketone when calcined at 200 to 300 °C, but gave the same amount of both

ketone and allyl alcohols when calcined at higher temperature, 400—900 °C, the formation of allyl alcohols being concluded to be due to the creation of basic sites on the surface at high temperature.[1] This indicates that the active sites of $NiSO_4$ and $FeSO_4$ catalysts for this isomerization are not altered even if these catalysts were prepared at the high temperature such as 500, 600 or 700 °C, though the structural and catalytic changes caused by calcination temperature are known in both cases of $NiSO_4$[5] and $FeSO_4$[6]

The isomerization between ketone and allyl alcohols was not found in every reaction under the present reaction conditions. Heats of formation of allyl alcohols and ketone in gas phase at 25° were calculated by use of Benson *et al.*'s second-order approximation which is the law of additivity of group properties.[7] They were −47.89 kcal/mol for 2-methylenecyclohexanol (VIa), −49.29 for 2-methyl-2-cyclohexene-1-ol (VIb) and −63.26 for 2-methylcyclohexanone (III). The differences in entropies of these materials were also calculated to be −1.94 e.u. for the entropy of ketonization of VIa to III, and +19.38 e.u. for that of VIb to III in gas phase at 25 °C. From these values, equilibrium constants of allyl alcohols to ketone were obtained to be 7.2×10^{10} for VIa to III and 3.6×10^{14} for VIb to III in gas phase at 25 °, indicating that the catalytic action of the present catalysts is quite selective.

An example of the time variation of the conversion to each product is shown in Fig. 1, where the catalyst is TiO_2–ZrO_2 (molar ratio = 1 : 1). The reaction entirely

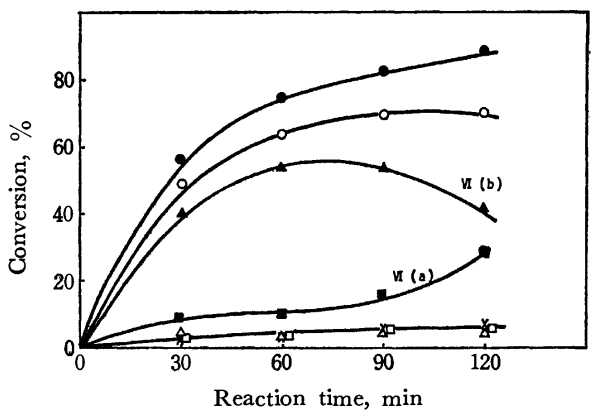

Fig. 1. Isomerization of 1-methylcyclohexene oxide over TiO_2–ZrO (1 : 1). (-●-) Total conversion, Conversion to III (-△-), IV (-×-), V (-□-), VI (-○-).

followed first-order reaction kinetics with respect to the oxide concentration, and the conversions to III, IV, V, and VI increased almost parallel to each other with time. It is also seen that, in the formation of allyl alcohol, VIb exceeded VIa and isomerized gradually to VIa after 60 min. On the contrary, $NiSO_4$ (350 °C) gave much more VIa than VIb (Table 1), and the isomerization between them with reaction time was not observed: 12.0% (VIa) and 1.6% (VIb) at 30 min; 25.0 and 2.0 at 1.0 hr; 35.2 and 3.7 at 1.5 hr; and 35.7 and 7.3 at 2.0 hr. VIa generally exceeds VIb because

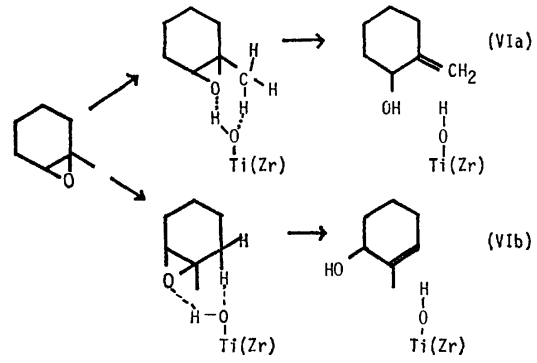
* The sample precipitated by NH_3 following the procedure of Ref. 4.

of the preference of primary proton abstraction over secondary one caused by the more enhanced acidity of primary hydrogen by the electronic effect. Our previous observations followed this rule: 51.1% (VIa) and 23.5% (VIb) over Al_2O_3; 6.7 and 1.9 over zeolite H-F9; and 9.2 and 8.3 over solid H_3PO_4 heat-treated at 400°C.[1] The similar observations, the preferential formations of allyl alcohol with *exo*-double bond in the rearrangement of cycloalkene oxides, are found in literatures: for 1-methylcyclohexene,[8] 1-methylcycloheptene[8] and α-pinene oxides[9] with lithium diethylamide; for menthene and limonene oxides with aluminum isopropoxide[10]; and for limonene [11],α-pinene,[11,12] 1-methylcyclopentene[12] and 3-carene oxides with alumina.[12] The example opposite to the above rule, the favorable formation of allyl alcohol with *endo*-double bond, has not been found except for the case of 1-methylcyclopentene oxide with lithium diethylamide[8] and alumina,[12] probably caused by the stereochemically preferred geometry. As seen in Table 1, the TiO_2–ZrO_2 catalysts gave the preferential formation of VIb, while $NiSO_4$ and $FeSO_4$ formed predominantly VIa. Figure 2 shows the relation between catalytic activity and acidity as well as basicity of TiO_2–ZrO_2 at various compositions, where the total conversion % of the oxide per 0.3 g of the catalyst was taken as activity. TiO_2–ZrO_2 (1 : 1) changed 2,4,6-trinitroaniline ($pK_{BH} = 12.2$) to the basic color, but TiO_2 and ZrO_2 did not change the acidic color of BTB ($pK_a = 7.2$) to its basic color. It should be noted that both acidity and basicity increase by mixing TiO_2 and ZrO_2 up to the equal composition, as seen in the figure.

The catalytic activity correlates well with both the acidity and basicity. It is known that acid sites alone are active for the selective formation of ketone and basic sites alone are almost inactive for the isomerization of 1-methylcyclohexene oxide.[1] Therefore, these facts indicate that allyl alcohol, main product produced by the TiO_2–ZrO_2 catalysts, is formed on both acidic and basic sites on the catalyst. In other words, the allyl alcohol formation is explained by acid-base bifunctional mechanism. Since the acidic sites on the surface of TiO_2 prepared by calcining H_4TiO_4 in air are determined to be the Brönsted type,[15] the reaction is considered to proceed by the following mechanism.



An oxygen atom of the oxide adsorbs on a proton of the catalyst, while a hydrogen atom of the methyl or methylene group on oxygen (basic site) of the catalyst surface, and both the opening of the epoxide ring and the hydrogen abstraction from the methyl or methylene group take place simultaneously to form the allyl alcohol. The breaking of α-bond of oxygen is much more favorable due to the electronic effect of the methyl group, since no compound formed by the breaking of β-bond is found in the products. The choice of the VIa or VIb formation seems to depend on the distance between acidic and basic sites on the catalyst. The distance of TiO_2–ZrO_2 is supposed to be different from those of $NiSO_4$ and $FeSO_4$, judging from the preferential formation of VIb or VIa.

The acidic and basic strength of catalysts must be an important factor which controls the ketone formation. If the acid strength is too strong, the α-bond cleavage prior to the hydrogen abstraction would occur to form the ketone, while, if it is too weak, the hydrogen abstraction would hardly occur.

ZrO_2 calcined at 350 °C showed higher activity than that treated at 500 °C. The similar phenomena were also observed for the dehydration reaction of ethanol over ZrO_2, where the catalytic activity of the catalyst heat-treated at 400 °C was more than two times as high as that calcined at 500 or 600 °C.[4]

It is of interest that TiO_2–ZrO_2 (1 : 1 and 1 : 3) prepared by the coprecipitation method with NH_3 showed higher activity than those with urea, though the acidity was opposite to the activity. This seems to suggest the unusual surface property of TiO_2–ZrO_2.

Figure 3 shows the relation between catalytic activity and acidity of $NiSO_4$ and $FeSO_4$ calcined at various temperatures. The activity of $NiSO_4$ calcined at higher temperature correlates with its acidity measured by the indicator method. However, no correlation was found for $NiSO_4$ calcined at lower temperature. The high activity at low calcination temperature is considered to be due to the relatively weak Brönsted acid, which can not be measured by the indicator method, proposed by Ben-Dor and Margalith.[17]

In the case of $NiSO_4$ calcined at 250 °C, the conversion to VI was low compared to that for other

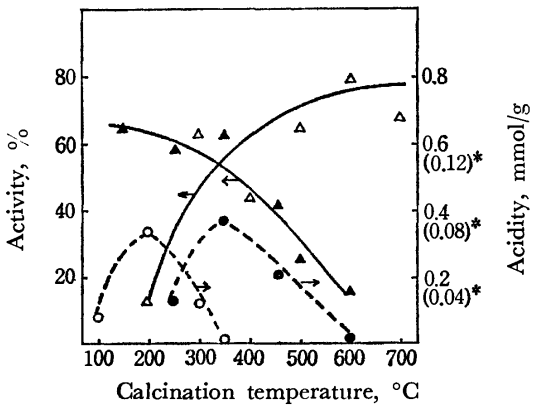


Fig. 3. Catalytic activity and acidity ($pK_a = 1.5$)[6,16] of $NiSO_4$ and $FeSO_4$ calcined at various temperatures.
(▲) $NiSO_4$, (△) and (○) $FeSO_4$.
*Scale in parenthesis correspounds to $NiSO_4$.

$NiSO_4$ catalysts (Table 1). Since both the decrease of VI and the increase of II were observed during the course of reaction, it seems that VI was dehydrated to give II by strong Brönsted acid, because the maximum of Brönsted acidity of $NiSO_4$ appears when calcined at 250 °C.[18] It is inferred from the explanation about the reaction mechanism of the allyl alcohol formation as mentioned already that $NiSO_4$ has also basic sites because of the considerable formation of allyl alcohols.

The activity of $FeSO_4$ is not related to the acidity. Figure 3 shows that the higher the calcination temperature, the higher the catalytic activity. Since the preferential formation of ketone was concluded to be given by strong acid, it is supposed that additional acid sites, which were not observed by the butylamine titration method, were created when calcined at high temperature. However, the possibility that the active sites are different from acid sites can not be excluded in the case of $FeSO_4$.

We thank Mr. Noboru Nishiyama and Mr. Hirotake Mori for their assistance with reaction experiments.

The Formation and Dissociation of the Solvated Ion-pair in the Excited Pyrene–Dicyanobenzene System

Tetsuro HINO, Hiroshi MASUHARA*, and Noboru MATAGA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received June 18, 1975)

Nanosecond laser photolysis has been applied to investigate the photochemical primary processes of the pyrene-*p*-dicyanobenzene system in some solvents. The solvated ion-pair is formed by the excitation and its yield increases as the dielectric constant of the solvent does; this was explained with the empirical equation proposed previously. The dissociation of the solvated ion-pair to free ions was directly observed in moderately polar solvents and the rate constant of the dissociation was determined, which is in agreement with the values calculated by Eigen's equation. The role of the ion-pair formation in the fluorescence quenching was discussed on the basis of the present results, and it was concluded that some unknown quenching processes other than the triplet formation compete with the solvation to ion-pairs.

We have been studying the ionic photodissociation processes of the excited electron donor-acceptor (EDA) systems by using the nanosecond laser photolysis method. The excited singlet and triplet states of EDA complexes, which are stable in the ground state, and exciplexes are all called excited EDA systems in the present paper. These systems are suitable for clarifying the relation between photophysical as well as photochemical primary processes and molecular interactions. Ionic photodissociation to the donor cation and the acceptor anion in polar solvents is one of the important primary processes and has been referred to in many fields of chemistry. The results obtained by laser photolysis are summarized as follows: (1) Several different dissociation patterns have been demonstrated. Dissociations from the excited singlet or triplet states are known in the case of EDA complexes, while the problem in the case of exciplexes is not about the spin state but about the excited state relaxed or nonrelaxed with respect to the solvation.[1] (2) The important role of the nonrelaxed state in the dissociation process was confirmed.[1a,2] The dissociation of pyrene–*N*,*N*-dimethylaniline (DMA) and *s*-tetracyanobenzene–toluene systems occurs from the excited singlet state nonrelaxed with respect to the solvent orientation. (3) A new empirical equation for the relationship between the yield and the solvent dielectric constant was proposed. The solvent effect on the ionic photodissociation seems to be well explained in terms of the dielectric constant.[1a] (4) Ionic dissociation yields of several EDA systems in acetonitrile depend upon the chemical property of the quencher and not on the strength of the EDA interaction.[3]

In the present work we will show another kind of ionic dissociation process: namely, the results for the formation and dissociation processes of the solvated ion-pair will be shown in the case of the pyrene–*p*-dicyanobenzene(DCNB) system.

Experimental

The transient absorption spectral and photocurrent measurements were performed by using the same apparatus as reported previously.[4] The exciting pulse of 347 nm was produced through the ADP frequency doubler with a conversion efficiency of *ca.* 8%. The ADP crystal was set in an air bath to control the temperature. The fluctuation was ±0.6 °C. The temperature matched and phase matched ADP gives a constant output of the exciting pulse.

Pyrene was chromatographically purified. DCNB was recrystallized several times and sublimated. All the solvents were spectrograde (Dotite, Nakarai, or Merck) and used without further purification. Pyridine was dried over potassium hydroxide and distilled. The concentration of pyrene was adjusted to give an appropriate absorbance (0.1—0.4) at 347 nm, which is a suitable condition for the present laser photolysis measurements. The concentration of DCNB was determined so as to quench the pyrene fluorescence more than 90%. The solutions were completely degassed by usual freeze-pump-thaw method.

Results and Discussion

The Formation and Dissociation Processes of the Solvated Ion-Pair in the Pyrene–DCNB System. The transient absorption spectra of the pyrene–DCNB–dichloromethane system shown in Fig. 1 were obtained at 50 ns after the laser excitation. These spectra can be reproduced with the superposition of the bands of the pyrene cation, the DCNB anion, and the triplet pyrene. The ionic species and the triplet pyrene are produced immediately after the excitation with the pulse. The kinetic relation between the transmittance at 445 nm (the pyrene cation) and the photocurrent is given in Fig. 2. The transmittance is almost constant in the course of a few μs, while the peak photocurrent is attained in several hundred nanoseconds. The difference of the time dependence between the transmittance and the current may be ascribed to an ionic transient, which gives no current but shows an absorption similar to that of the pyrene cation. This transient may be an ion-pair of the pyrene cation and the DCNB anion or the pyrene–DCNB exciplex, since the absorption spectra of both species are expected to be reproduced with the superposition of the bands of the pyrene cation and the DCNB anion.[5] Because the lifetime of the exciplex in the dichloromethane solution is ~30 ns, a curve of photocurrent rising more quickly than the observed one should be found if the free ions were formed from the exciplex. Therefore, the present transient seems to be an ion-pair of the pyrene cation and the DCNB anion, which is of course completely solvated. The latter ion-pair is produced rapidly by

laser excitation and dissociates gradually into free ions.

The solvent effect on the dissociation process is shown in Fig. 3. Faster rising curves are obtained in solvents with higher polarity, and the maximum value of the photocurrent in acetonitrile is reached immediately after excitation. These solvent effects are consistent with the following theoretical estimation of reaction rates. The rate constant of the diffusion-controlled dissociation was calculated by Eq. (1).[6,7]

$$k_{diss} = 4\pi N'(D_{A^-} + D_{D^+})a\delta/\Delta V(1-\exp(-\delta)) \quad (1)$$

where $\delta = e^2/\varepsilon kTa$ and $\Delta V = 4\pi N'a^3/3$. The notations are the same as in Ref. 7. The encounter distance a was assumed to be 7 Å. The experimental rate constant (k_{exp}) was determined from the exponential growth curve of the photocurrent. The results obtained are listed in Table 1. The k_{exp} in these solvents is almost identical with k_{diss}, but not with $1/\tau_f$. Thus the present solvent effect is well explained by assuming the diffusion-controlled dissociation mechanism.

As mentioned in the previous paper[1a], the ionic dissociation of the pyrene–DMA system occurs in the excited state nonrelaxed with respect to the solvation. Although the energy levels of the initial encounter complex, the solvated ion-pair, and the free ions of the pyrene–DMA system are almost equal to those of the pyrene–DCNB system, their dissociation processes are not similar. This difference may be characteristic of the "chemical property" of the quencher, although the precise nature of the "chemical property" is still unknown. Recently we have studied the ionic photodissociation of various pyrene-quencher systems in polar solvents and found no general relation between the yield of free ions and the strength of the EDA interaction.[3] It was emphasized that the "chemical property" of the quencher is a key for understanding the ionic photodissociation mechanism.

The Solvent Effect on the Yield of the Ion-pair Formation. The relative yield of ionic species (ion-pair or free ions) in acetonitrile and in dichloromethane was obtained by absorption spectral measurements. The ratio of the yields obtained immediately after the excitation in the former and the latter solvents was 1 : 0.25. On the other hand, the ratio obtained by comparing the maximum value of the transient photocurrent was 1 : 0.22. Since free ions are favored in acetonitrile,[8] the above agreement of the ratios for the spectral and the photocurrent data means that most of the ion-pair dissociate into ions even in dichloromethane. Therefore, the yield of ion-pair formation in some solvents may be estimated by examining the photo-

TABLE 2. QUANTUM YIELDS OF THE ION-PAIR FORMATION

Solvents	ε	ϕ_{pc}[a)]	ϕ_{ab}[b)]
Dichloromethane	8.93	0.08	0.25
1,2-Dichloroethane	10.4	0.11	
Pyridine	12.4	0.14	
Acetone	20.7	0.32	
Acetonitrile	37.5	0.38	1.00

a) ϕ_{pc} are the absolute yields obtained from the photocurrent data. b) ϕ_{ab} are the relative yields obtained from the absorption spectral measurements.

current data. As shown in Table 1, the rate constant of dissociation is larger than 10^7 s^{-1}, while the rate of the recombination of free ions is calculated to be 10^5—10^6 s^{-1}, since the rate constant of the diffusion-controlled process is 10^{10} M^{-1} s^{-1} and the concentration of ions is 10^{-4}—10^{-5} M. Since the decay of free ions due to the recombination is almost negligible at an early stage after the excitation, the dissociation may be approximately completed. Then the values of the current are proportional to the yield of the ion-pairs. The obtained yields are listed in Table 2.

The yield increases as the solvent polarity (dielectric constant) increases. The present results can be well explained with the following empirical equation for the relationship between the yield (ϕ) and the solvent dielectric constant (ε), proposed in the previous work[1a)].

$$\log\left(\frac{1}{\phi}-1\right)=\frac{p}{\varepsilon}+q \qquad (2)$$

where p and q represent constants. It has been pointed out[1a)] that the following two conclusions are given when Eq. (2) is satisfied: (1) The ionic photodissociation depending upon ε competes with the other radiationless processes independent of ε. (2) The identical dissociation mechanism is expected in various solvents. Therefore it may be concluded that the free ions in acetonitrile are also formed through the ion-pair and that some radiationless process independent of the solvent dielectric constant competes with the ion-pair formation.

Discussion on the Fluorescence Quenching Mechanism. The fluorescence quenching process has been studied in detail in various solvents by Mataga *et al.*[2,4b,9)] and by Weller *et al.*[7)] One of the main quenching processes has been pointed out to be the formation of the solvated ion-pair competing with the exciplex formation.[7)] However, there have been no observations concerning the dynamic behavior of the solvated ion-pair up to now, and the formation and dissociation processes of the solvated ion-pair have been made clear in the present work for the first time.

A quantitative analysis of the produced intermediates seems important for understanding the quenching processes. The yield of ions and the triplet molecule are estimated in the usual way.[4)] The yields of ions in acetonitrile and in dichloromethane were 0.38 and 0.08, respectively. On the other hand, the yields of the pyrene triplet in acetonitrile and in dichloromethane were 0.11 and 0.07, respectively. The sum of these yields is smaller than unity in both solvents and the residual radiationless transitions may compete with the above processes. This conclusion is in good agreement with the above result of the solvent effect on the ion-pair yield. Such a degradation process has not always been postulated in the previous papers. However, the former process seems to be important for elucidating the fluorescence quenching process due to the electron transfer in the excited EDA systems. This conclusion is consistent with the results of ionic photodissociation of pyrene–DMA, pyrene–electron acceptors, and tetracycnobenzene–aromatic hydrocarbon systems.[1,3,4a)]

Finally, the intersystem crossing process of the present system should be mentioned. In dichloromethane solution an appreciable amount of triplet molecules is formed at 50 ns (shown in Fig. 1) after the laser oscillation, when the decay of the ion-pair can be neglected. Therefore, a triplet formation through the solvated ion-pair of the present type may be excluded. Recently, similar results have been reported,[10)] although the nature of this particular behavior is not clear.

Proton Magnetic Resonance Spectra of Metal Ammine Complexes. VI.* The *trans*-Effect in Cobalt(III) Amine Compounds as Studied by the Rate of Hydrogen-Deuterium Exchange

Ushio SAKAGUCHI, Koichi MAEDA, and Hayami YONEDA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received June 30, 1975)

The rate of the isotopic deuterium exchange has been measured for several cobalt(III) amine complexes in D_2O. The substituents CN^-, NO_2^-, and possibly SO_3^{2-} decelerate the exchange of the amine protons *trans* to these ligands, leading in some cases to a smaller rate for these protons than for the *cis* ones. On the other hand, the *trans*-proton labilizing ligands include F^-, Cl^-, Br^-, H_2O, CO_3^{2-}, $OCONH_2^-$, N_3^-, CH_3NH_2, CH_3COO^-, and the malonate, fumarate, and oxalate ions. The above observation clearly indicates that the HD exchange rate can be a measure of the *trans*-effect of these ligand molecules.

In previous papers,[1-4] we have reported that the chemical shifts of amine protons of some cobalt(III) complexes are primarily determined by the magnetic anisotropy of the central metal ion. In pentaamine cobalt(III) compounds $[CoX(NH_3)_5]^{n+}$, the ammine proton chemical shifts could be quantitatively explained by using the theory based on the anisotropic magnetic field of the cobaltic ion along with the cobalt-59 chemical shifts. Small but significant discrepancies between the theory and the observations were noted for the *trans* hydrogens of the cyano- and nitro-pentaammine complexes. These hydrogens resonated at a field higher than that expected from the theory. The succeeding paper will deal with the assignment of the amine protons in the NMR spectra of bis(en) type complexes, where en is ethylenediamine. It will be shown that the chemical shifts of these protons can be explained in a manner similar to the pentaammines. The *trans* amine hydrogens of *cis*-$[Co(CN)_2en_2]^+$ appeared at a more shielded position than that the magnetic anisotropy of the metal ion would predict.

All the above phenomena seemed to point to an increase in the electron densities on these *trans* amine hydrogens. In other words, we attribute the discrepancies between the theory of chemical shift and the observed shift values to the inductive effects of the substituents. Thus, we expect that an increase or decrease in the electron density on a particular proton will be reflected in the rate of HD exchange of this proton. Here we report the results of measurements on the rate of hydrogen-deuterium exchange of ammine and amine protons of some cobalt(III) complexes. A part of the present paper has already been reported.[1]

Experimental

Materials. All the complexes investigated in this work are known compounds and were prepared by well-established methods. The identity of the complex was confirmed spectrophotometrically. Deuterium oxide (99.8 atom % D minimum) and dimethyl sulfoxide-d_6 (99.5 atom % D minimum) were purchased from Stohler Isotope Chemicals (Cal., U.S.A.).

Measurements. All the measurements were made on a Varian T-60 NMR spectrometer operating at 60 MHz and at a temperature of 30 °C. All the complexes except $[Co(NO_2)(NH_3)_5](NO_3)_2$ were dissolved in deuterium oxide to almost saturation and the signal intensities corresponding to amine hydrogens were measured at suitable time intervals. *t*-Buthyl alcohol was added as an internal reference for intensity if necessary. Since the solubility of the nitro-pentaammine compound in D_2O was too small, it was decided to use the dimethyl sulfoxide-d_6/D_2O mixed solution (90 : 10 wt%) as the solvent. Amine hydrogen signals of ethylenediamine overlapped, in some instances heavily, with the HDO signal, which tended to hamper an accurate measurement of intensities.

Results and Discussion

The rate of hydrogen exchange in cobalt(III) amine complexes was first reported by Anderson *et al.*[5] and the subsequent works of Block and Gold[6] and Basolo and his coworkers[7-9] established the following points: (i) the rate of HD exchange is specific hydroxide ion catalysed and is proportional to the concentration of OH^- ions, (ii) the observed pseudo-first-order rate constant is independent of the concentration of the metal ion, and (iii) the rate is unaffected by the added salt if the proper correction for the solution pH has been made according to (i). The results of Yamatera and Fujita[10] appeared to put forward an important objection to (iii). All these workers and others[11-16] reported that in a particular compound the amine protons *trans* to a substituent exchange faster than those *cis* to the substituent. However, this statement was necessarily non-definitive since these authors

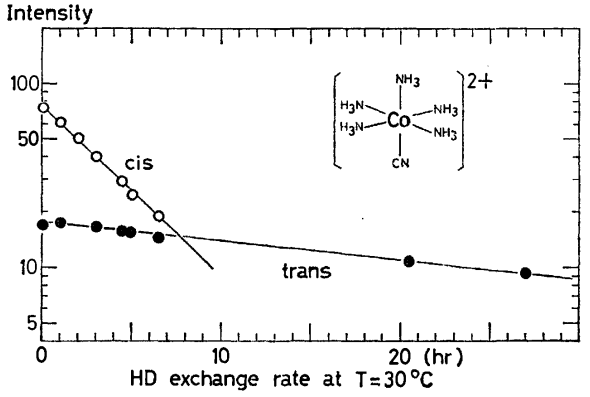

Fig. 1. The changes in ammine proton signal intensities of $[CoCN(NH_3)_5]^{2+}$ in D_2O.

* Part V: H. Yoneda, K. Maeda, and U. Sakaguchi, *Chem. Lett.*, **1975**, 107.

measured the overall rates. Separate rates for *cis* and *trans* hydrogens were first obtained by Clifton and Pratt[11] for fumaratopentaammine cobalt(III) ion, followed by the measurements of Buckingham *et al.*[14] on $[CoCl(NH_3)_5]^{2+}$ and $[CoCl(CH_3NH_2)_5]^{2+}$. Basolo *et al.*[7-9] obtained two rate constants for *cis*-$[Co(NO_2)_2(NH_3)_4]^+$ and *cis*-$[Co(NO_2)_2en_2]^+$ and Basolo and Pearson[17] stated, in their recent review, that it is not known whether the hydrogens exchanging faster are those *trans* to NO_2^- or to NH_3 and en. We solved this problem by obtaining a method for assigning NMR signals of coordinated NH_3 or en.[1-3] Thus, all the data described in the literature can now be considered to have reported that *trans* ammine protons are more labile against deuterium substitution than *cis* ones. Our present data offer another type of example, where the *trans* hydrogens are *less* labile. This is especially noted for compounds containing the cyanide, nitrite, and possibly sulfite ions.

Pentaamines. We have measured the exchange rate for cyano-, nitro-, and fluoro-pentaamine complexes. In this type of compounds, the assignment of the NMR signals follows immediately from their intensities. The result for the cyano compound is illustrated in Fig. 1. The data are summarized in Table 1 in terms of the pseudo-first-order rate constants. As is evident from Fig. 1, the *trans* hydrogens exchange an order of magnitude more slowly than the remaining four *cis* protons: $k_t=6.2\times10^{-6}$ s^{-1} and $k_c=6.0\times10^{-5}$ s^{-1}. k_t and k_c stand for the pseudo-first-order rate constants for *trans* and *cis* hydrogens. The nitropentaammine compound gives only a single absorption when it is dissolved in dimethyl sulfoxide or trifluoroacetic acid. This was shown[4] to be a mere coincidence of the *trans* and *cis* absorptions. For reasons mentioned previously, the rate for this compound was obtained in the dimethyl sulfoxide-d_6/D_2O mixed solvent. Separate rates for the *cis* and *trans* ammonia hydrogens can, however, be obtained by fitting the intensity-time data to an expression $[4\exp(-k_ct)+\exp(-k_tt)]$; see Fig. 2. It can readily be seen that the *trans* hydrogens are less labile than the *cis* ones. Since the rates of this compound were measured in mixed solvent, it may not pertinent to compare this data with those of the other complexes

TABLE 1.

Complex	k_c[a]	k_t[a]	Other rates[a]
$[CoCN(NH_3)_5](ClO_4)_2$	60	6.2	
$[CoNO_2(NH_3)_5](NO_3)_2$	180	17	
$[CoF(NH_3)_5](NO_3)_2$	58	(fast)	
cis-$[Co(CN)_2(NH_3)_4]Cl$	390	62	
$[Co\text{-}(CO_3)(NH_3)_4]_2SO_4$	1300	2200	
cis-$[Co(CH_3COO)_2\text{-}(NH_3)_4]ClO_4$	140	680	
cis-$NH_4[Co(SO_3)_2(NH_3)_4]$	(fast)	490[b]	
$[Co(NH_3)_4en](NO_3)_3$	1500	6500	3200[c]
cis-$[Co(CN)_2en_2]Cl$	680	310

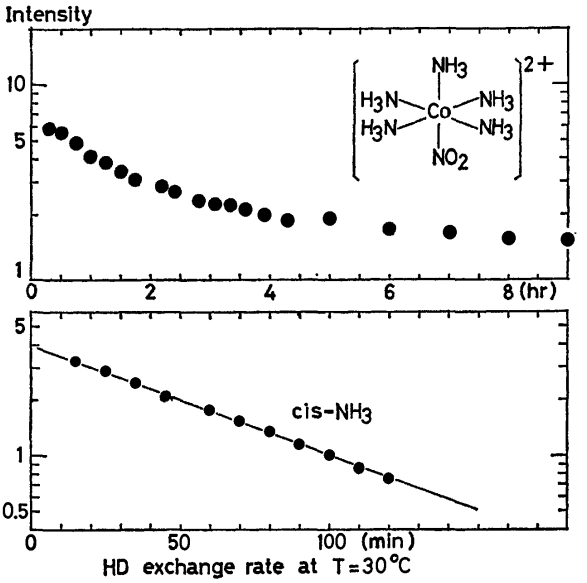

Fig. 2. HD exchange in $[Co(NO_2)(NH_3)_5]^{2+}$; (upper) experimental data, (lower) data analysed for *cis* ammine hydrogens.

for which deuterium oxide was used as the solvent.

Previously, Palmer and Basolo[8] obtained only a single rate constant for HD exchange in fluoro-, chloro-, bromo-, and nitro-pentaammine compounds. Basolo *et al.*[9] reported that all of the hydrogens of $[CoCl(NH_3)_5]^{2+}$ exchange at the same rate. Clifton and Pratt[11] showed that the rate of exchange of the *trans* ammonia protons is two orders of magnitude greater than that of the *cis* protons. Buckingham *et al.*[14] found that the *trans* hydrogens of $[CoCl(NH_3)_5]^{2+}$ and $[CoCl(CH_3NH_2)_5]^{2+}$ exchange with deuterium sixty times faster than the *cis* ones, thus invalidating the statement of Basolo *et al.* on the chloropentaammine complex. Further, for $[CoX(NH_3)_5]$ (X=H_2O, N_3^-, $OCONH_2^-$, Cl^-, and Br^-) they obtained spectra where the *trans* NH_3 was completely deuterated, leaving the four *cis* NH_3 groups substantially unaffected. Therefore, the *trans* ammine protons have been believed to be the more labile in pentaammine complexes containing H_2O, F^-, Cl^-, Br^-, N_3^-, $OCONH_2^-$, NO_2^-, and the fumarate ion.

In summary, the substituents X=CN^- and NO_2^- decelerate the *trans* hydrogens, while F^-, Cl^-, Br^-, H_2O, N_3^-, $OCONH_2^-$, CH_3NH_2, and the fumarate ion labilize the *trans* protons.

cis-*Tetraammine and* cis-*Bis(ethylenediamine) Complexes.* Block and Gold[6] and Basolo *et al.*[9] reported only one rate constant for $[Co(ox)(NH_3)_4]^+$ and *cis*-$[Co(NH_3)_2en_2]^{3+}$, where ox is the oxalate ion. Clifton and Pratt[11] observed that in *cis*-$[CoCl_2en_2]^+$ the *trans* protons are the faster, but their measurements of the rates were complicated by aquation and a subsequent isomerization of the complex. The only examples where separate rates for *trans* and *cis* hydrogens were obtained were *cis*-$[Co(NO_2)_2(NH_3)_4]^+$ and *cis*-$[Co(NO_2)_2en_2]^+$.[8]

The complexes of the types *cis*-$[CoX_2(NH_3)_4]$ and *cis*-$[CoX_2en_2]$ exhibit two singlets with an intensity

ratio 1 : 1 if these compounds are dissolved in D_2O. Thus, the signal assignment to the *trans* and *cis* hydrogens is not so straightforward as in pentaammine complexes. In the previous papers, we outlined the method for the assignment. Qualitatively, the *trans* hydrogens are more deshielded than the *cis* ones if the ligand X is a strong-field ligand, *e.g.*, CN^- or NO_2^-. For a weak ligand X, the *trans* hydrogens resonate at higher magnetic field. In this way we could assign almost all resonances examined in this work.

Figure 3 gives the result for *cis*-$[Co(CN)_2en_2]^+$. As in the case of the cyanopentaammine complex, the cyanide ion can be seen to decelerate the *trans* protons. The result for *cis*-$[Co(CN)_2(NH_3)_4]^+$ is illustrated in Fig. 4, which also shows that the *trans* hydrogens appearing at lower field than the *cis* ones are the less labile against deuterium substitution. The rate of the *trans* protons is about one-sixth of that of the *cis* protons. For *cis*-$[CoX_2(NH_3)_4]$ containing CH_3COO^-, en, and CO_3^{2-}, it was found that the *trans* protons are the more labile: see Fig. 5 and Table 1.

The complex *cis*-$[Co(SO_3)_2(NH_3)_4]^-$ shows two absorptions in water, while in D_2O only one signal can be observed, at a position coincident with that of the high field signal observed in water. This indicates that the low field signal disappears rapidly on dissolving in D_2O. Since no cobalt-59 chemical shift value is available for sulfito-containing compounds, we can make no assignment for these signals. However, it is highly probable that the high field signal which exchanges slowly is due to the *trans* ammonia. Numerous examples suggestive of a large *trans*-ligand labilizing effect of the sulfite ion are well documented.[17-20] Thus, it will be reasonable to assume that the *trans* hydrogens are upfield shifted owing to this *trans*-labilizing effect (see below). This deduction is not inconsistent with the slower rate for these *trans* hydrogens.

Separate rates for the *cis* and *trans* hydrogens of *cis*-$[Co(NO_2)_2en_2]^+$ and *cis*-$[Co(NO_2)_2(NH_3)_4]^+$ have been reported by Palmer and Basolo.[8] They noticed that the slower rates are about the same as the rates for the corresponding *trans* isomers and therefore they assigned the greater lability to the *trans* hydrogens. Their assignments, however, didn't seem to be sound enough and we re-examined both complexes. The complex *cis*-$[Co(NO_2)_2en_2]^+$ shows two NH_2 resonances. The signal situated at lower field exchanges with deuterium and disappears rapidly. The high field line exchanges much more slowly.

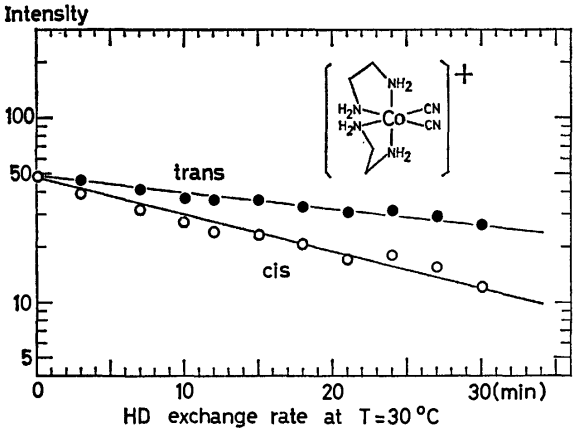

Fig. 3. The rate of hydrogen exchange in *cis*-$[Co(CN)_2en_2]^+$.

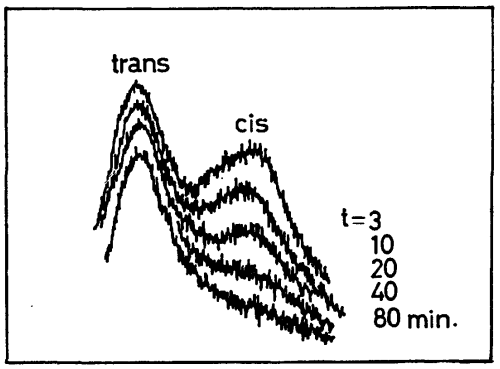

Fig. 4. The spectra of *cis*-$[Co(CN)_2(NH_3)_4]^+$ in D_2O observed at suitable time intervals after dissolution.

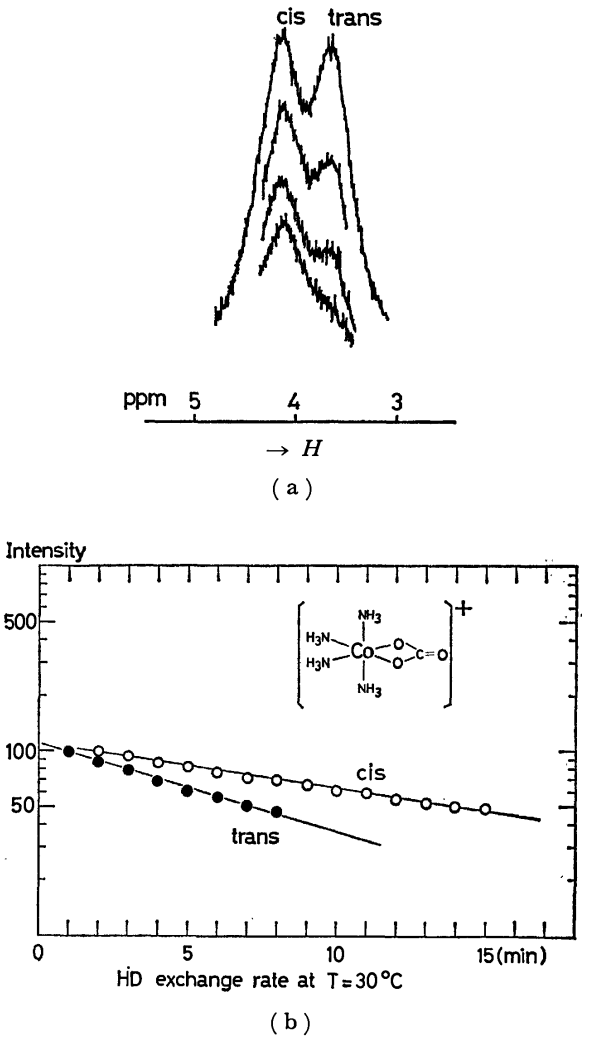

Fig. 5. (a) The spectra of $[CoCO_3(NH_3)_4]^+$ taken at every four minutes. (b) The plot of the signal intensities of ammine hydrogens in $[CoCO_3(NH_3)_4]^+$ against time.

In the preceding papers, we assigned the low field signal to the *trans* amines based on the magnetic anisotropy of the cobalt ion. If our assignment is correct, then it follows that the *trans* hydrogens are the more labile. This is in line with the deduction of Basolo and Palmer. *cis*-$[Co(NO_2)_2(NH_3)_4]^+$ exhibits only a single absorption in D_2O and in acidified D_2O. Therefore, we cannot tell which hydrogens are exchanging faster. It is to be noted that in $[Co(NO_2)(NH_3)_5]^{2+}$ the *trans* hydrogens are the slower, while in *cis*-$[Co(NO_2)_2en_2]^+$ and probably in *cis*-$[Co(NO_2)_2(NH_3)_4]^+$ they are the faster. We cannot at present give any explanation for this observation.

The trans-*Effect.* As is evident from the previous discussions, the exchange rate of amine hydrogens is greatly affected by the substituent *trans* to the protons under consideration. In conjunction with all the literature data, it can be concluded that the effect of the ligand X is primarily the most prominent on the *trans* (to X) hydrogens.

In general, coordinated ligand molecules are under the electron-withdrawing effect of the positively charged metal ions. Therefore, if the Co–NH_3 bond become strengthened for some reason, the electron density on this nitrogen atom will be decreased, with a concomitant labilization of the hydrogen atoms attached to this nitrogen. Conversely, if the Co–N bond is weakened, the electron density on this nitrogen atom will be restored, with the result that the hydrogen atoms bound to this nitrogen atom become less labile. This reasoning explains almost all the foregoing observations. Fujiwara *et al.*[21] have shown from the analysis of their cobalt-59 chemical shift data that the cobalt-cyanide, cobalt-nitro, and cobalt-sulfur bondings are much more covalent than the other Co-oxygen, Co-halogen(pseudohalogen), and Co-nitrogen bondings. Thus, if we presume that the cobalt-nitrogen bonds *trans* to the cyanide, nitrite, and sulfite ions assume the more ionic character, the deceleration of the exchange rates of the hydrogens attached to these nitrogen atoms may be expected.

If we assume that the rate of HD exchange results at least partially from the ground-state weakening of the *trans* Co–N bonds, we can expect the structural *trans*-effect especially for complexes with *trans*-decelerating ligands. It is rather difficult, as pointed out by Pratt and Thorp,[18] to decide whether any bond-length variation is significant and therefore whether this can be ascribed to effects of the lattice and the counter ion(s). With this in mind, we first note that Snow[22] added the carbonato ion to a growing list of anions including NO_2^-, Cl^-, thiosulfate, and thiocyanate (both sulfur ligands are sulfur-bonded) which do not show the structural *trans*-effect in ammine cobalt(III) compounds. The crystal and molecular structures of $[CoCN(NH_3)_5]Cl_2$ and $[CoCN(NH_3)_5](ClO_4)_2 \cdot 0.5H_2O$ have been determined by Ozbirn and Jacobson.[23] Although they did not state so explicitly in their paper, the *trans* Co–N bonds in both complexes are definitely longer than the *cis* ones. The differences of the bond lengths are 0.031 and 0.027 Å for the former and the latter compounds, respectively, which are well beyond the experimental uncertainties of thier work. Elder and Trkula[24] reported that the large *trans*-effect of sulfite ion is evident in the molecular structure of $[Co(SO_3)(NH_3)_5]^+$, where the *trans* Co–N bond length is 2.055(2)Å and the corresponding *cis* ones are 1.962—1.972(average= 1.966(4))Å. In *trans*-$[Co(SO_3)(NCS)en_2] \cdot 2H_2O$, the sulfite ion is reported,[25] however, to cause no significant bond lengthening. As is apparent from the examples of the sulfito- and nitro-containing compounds, the results of the molecular structure determination do not completely parallel the hydrogen exchange rates. In some cases, however, the *trans*-bond lengthening effect has really been observed.

Conclusion

Thr rate of HD exchange can be considered to be a manifestation of the *trans*-effect; the cyanide, nitrite, and possibly sulfite ions decelerate the exchange of *trans* hydrogens while F^-, Cl^-, Br^-, H_2O, N_3^-, CH_3COO^-, CO_3^{2-}, $OCONH_2^-$, ox, CH_3NH_2, and malonate ion tend to labilize the *trans* NH hydrogens. It will be noted that these *trans*-accelerating ligands are all weak-field ligands and are situated at lower positions than NH_3 or en in the spectrochemical series. This correlation of the HD exchange rate with the spectrochemical series has been rationalized qualitatively in terms of the electron donating or withdrawing power of the substituents. Furthermore, the crystal structure data seem to indicate that the effect of substituents, especially that of the *trans*-decelerating ligands, results at least partially from the ground-state weakening of the *trans* Co–N bonds.

Proton Magnetic Resonance Spectra of Metal Ammine Complexes. VII.* Amine Proton Chemical Shifts in Bis(ethylenediamine)cobalt(III) Compounds

Ushio SAKAGUCHI, Shigeo YAMAZAKI, and Hayami YONEDA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received June 30, 1975)

Amine proton chemical shifts have been measured for some *cis*-bis(ethylenediamine)cobalt(III) complexes in trifluoroacetic acid. The shifts can be explained quantitatively by the magnetic anisotropy of the central metal ion and by assuming fast conformational inversion of chelate rings. Discrepancy between the observed and the computed shift values is apparent, however, for the *trans* hydrogens of the *cis*-dicyano compound, which may be due to the ground-state *trans*-effect of the cyanide ion. The chemical shifts of amine protons of *cis*-tetraammine and *cis*-bis(trimethylenediamine)compounds have been briefly discussed.

We have been interested in the proton chemical shifts of cobalt(III) ammine and amine compounds and have succeeded in explaining the ammine chemical shifts in pentaammine complexes $[CoX(NH_3)_5]^{n+}$.[1-5] In previous papers it was shown that the anisotropy of the paramagnetic term of the magnetic susceptibility of the central metal ion is responsible for the shift variation of coordinated ammonia molecules.

We here report the results of the chemical shift measurements on *cis*-bis(ethylenediamine)cobalt(III) compounds, *cis*-$[CoX_2en_2]$, in trifluoroacetic acid and the results are discussed in terms of the magnetic anisotropy of the cobalt ion. This paper makes the first step of our investigations on bis(en) complexes and an interpretation of the ethylenic part of the PMR spectra in relation to the conformation of en rings will be reported in subsequent publications. Although the PMR spectra of cobalt(III) ethylenediamine complexes have been studied by several workers,[6-21] no clear-cut explanation has been given, however, to chemical shifts and/or band shapes. Clifton and Pratt[12] enumerated several effects as probable causes of the different NH absorptions. These include the intramolecular hydrogen bonding between the *cis* amine groups and the ligand, the effects of magnetic anisotropy of the ligand, and a reduced polarity of the *trans* amine group due to polarization of the metal ion by the negative ligand. While it is clear that the substituent X must affect NH chemical shifts the reasons were not immediately apparent. Lantzke and Watts[11] considered similarly. Since they also had no quantitative measure of the extent of shielding or deshielding by each ligand, it was not possible to decide which hydrogens give rise to which resonance. Hendrickson and Jolly[15] may be the first to note the importance of the magnetic anisotropy of the central metal ion. Thus, they could predict that the *trans* protons resonate at higher field than the *cis* ones for weak-field ligand X and the opposite trend is possible for strong-field ligands.

Experimental

All the complexes used in this work are known compounds and were prepared by well-established methods. The complex prepared were identified spectrophotometrically. Trifluoroacetic acid of extra pure grade, purchased from Katayama Chemical Industries Co., Ltd., was used as the solvent. The measurement was made on a Varian A-60 or T-60 spectrometer at ambient probe temperature. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal standard for the chemical shift.

Method of Calculation

Theoretical. In this paper the chemical shift difference between the *cis* and *trans* ammine protons will be considered. If we attribute this difference to the anisotropy of the temperature-independent paramagnetism or the second-order paramagnetism of the cobalt(III) ion, and if the point-dipole approximation is appropriate to the problem, we can derive an equation for the chemical shift of ligand protons under the influence of the magnetic anisotropy of the cobalt(III) ion. Under these conditions Ramsey's expression for chemical shielding is reduced to[1-4]

$$\sigma = \left(\frac{1}{R^3} - \frac{3RR}{R^5}\right)\chi^{\mathrm{p}} \tag{1}$$

All the notations have their usual significances.[1-3] The paramagnetic term of the magnetic susceptibility of a cobalt(III) ion, χ^{p}, can generally be related[2,3] to the shielding constant of the cobalt-59 nucleus, $\sigma^{\mathrm{p}}(^{59}\mathrm{Co})$, as

$$\chi^{\mathrm{p}} = -\sigma^{\mathrm{p}}(^{59}\mathrm{Co})/2\langle r^{-3}\rangle \tag{2}$$

Here $\langle r^{-3}\rangle$ is an average of r^{-3} over a metal 3d orbital. Fujiwara *et al.*[22] discovered that the cobalt-59 chemical shift of the [Co(ABCDEF)] complex is given, to a good approximation, by the sum of contributions from each ligand A to F, see Fig. 1 and Ref. 3.

$$\sigma^{\mathrm{p}}_{\mathrm{iso}}(^{59}\mathrm{Co}) = \sum_{\mathrm{X}} (2/3)\sigma(\mathrm{X}) \tag{3}$$

In this equation $\sigma^{\mathrm{p}}_{\mathrm{iso}}(^{59}\mathrm{Co})$ is the observed shift of the cobalt-59 resonance and $\sigma(\mathrm{X})$ is the contribution from the ligand X. $\sigma(\mathrm{X})$ values for typical ligands are given in Ref. 3. This additivity originates from the relations[3]

$$\sigma^{\mathrm{p}}_{xx}(^{59}\mathrm{Co}) = \sigma(\mathrm{C}) + \sigma(\mathrm{D}) + \sigma(\mathrm{E}) + \sigma(\mathrm{F}) \tag{4}$$

$$\sigma^{\mathrm{p}}_{yy}(^{59}\mathrm{Co}) = \sigma(\mathrm{A}) + \sigma(\mathrm{B}) + \sigma(\mathrm{E}) + \sigma(\mathrm{F}) \tag{5}$$

$$\sigma^{\mathrm{p}}_{zz}(^{59}\mathrm{Co}) = \sigma(\mathrm{A}) + \sigma(\mathrm{B}) + \sigma(\mathrm{C}) + \sigma(\mathrm{D}) \tag{6}$$

Although these equations can predict cobalt-59 chemical shifts with few exceptions and with a good accuracy,[22] it is somewhat open to question, whether they can

* Part VI; U. Sakaguchi, K. Maeda, and H. Yoneda, This Bulletin, **49**, 397 (1976).

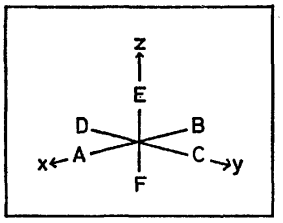

Fig. 1. The definition of the coordinate system for the complex [Co(ABCDEF)].

predict with any accuracy the anisotropy of cobalt-59 chemical shifts, which is relevant to the present investigation. In pentaammine cobalt(III) compounds, evidence has been given to their accuracy with which they predict the anisotropy.[4] If we assume the validity of the above additivity for *cis*-bis(en) complexes also, the proton chemical shift is given by an average of the following principal values of the shielding tensor.

$$\sigma_{xx} = -(1-3\sin^2\theta\cos^2\phi)(\sigma(C)+\sigma(D)+\sigma(E)+\sigma(F))/2R^3\langle r^{-3}\rangle \quad (7)$$

$$\sigma_{yy} = -(1-3\sin^2\theta\sin^2\phi)(\sigma(A)+\sigma(B)+\sigma(E)+\sigma(F))/2R^3\langle r^{-3}\rangle \quad (8)$$

$$\sigma_{zz} = -(1-3\cos^2\theta)(\sigma(A)+\sigma(B)+\sigma(C)+\sigma(D))/2R^3\langle r^{-3}\rangle \quad (9)$$

We will show that these expressions, along with the data of cobalt-59 chemical shifts, can give a good description of the chemical shift variation of amine hydrogens of *cis*-$[CoX_2en_2]$ ions.

Geometry of Complexes and Conformational Inversion of Chelate Rings. We approximate the arrangement of six nitrogen ligands around the cobalt ion to a regular octahedron and assume that all amine protons lie on the coordinate axes defined on this octahedron. The reason for this choice is as follows. First, we started with a more accurate model by using the crystallographically determined positions of amine protons in $(+)_{495}$-$[Coen_2(L\text{-glu})](ClO_4)$,[23] where L-glu represents the L-glutamate ion. In this molecule en rings assume the *gauche* conformation and the distance R between the amine proton(s) and the metal ion was calculated at around $R=2.53$ Å (4.77 a.u.). These geometrical factors coupled with Eqs. (7) to (9) render the chemical shift of eight amine protons of bis(en) compounds. For *cis*-$[CoCl(NO_2)en_2]^+$, the shift values ranging from -0.48 ppm to $+0.75$ ppm (relative to the shift of $[Coen_3]^{3+}$) were obtained. Thus, we should expect eight absorption lines, which is not in accord with the observation.[11] The discrepancies between the observed shift values and the computed ones are readily apparent for other *cis*-bis(en) complexes also. Therefore, we adopted a more realistic model, in which the fast conformational interconversion of the chelate rings are allowed. The shift values were calculated for amine protons situated at their averaged positions. In this model, four amine hydrogens *cis* to X are to appear as a single absorption, which should be the case with the *trans* protons. After taking the effect of fast conformational inversion into account, we obtain the chemical shift of *cis* NH_2 as

$$\sigma_{iso} \simeq -1.625(\sigma(en)/2 - \sigma(X))/6R^3\langle r^{-3}\rangle \quad (10)$$

For *trans* NH_2 we have

$$\sigma_{iso} \simeq 0.8125(\sigma(en)/2 - \sigma(X))/6R^3\langle r^{-3}\rangle \quad (11)$$

Likewise a singlet is expected for *trans*-$[CoXYen_2]$ at a position specified by

$$\sigma_{iso} \simeq 0.8125(\sigma(X) + \sigma(Y) - \sigma(en))/6R^3\langle r^{-3}\rangle \quad (12)$$

This model leads to four absorption lines for *cis*-$[CoXYen_2]$ corresponding to *trans* (to X) NH_2, *trans* (to Y) NH_2, and the two types of NH_2 groups both *cis* to X and Y. This expectation is not in line with the observation.[11] Further, these equations give shift values which are in poorer agreement with the measurement than does the next model. Thus, we are led to the simplest model where all amine hydrogens are on the coordinate axes of a regular octahedron. In this model the *cis* hydrogens of *cis*-bis(en) compounds appear at

$$\sigma_{iso} \simeq -2(\sigma(en)/2 - \sigma(X))/6R^3\langle r^{-3}\rangle \quad (13)$$

and the *trans* protons appear at

$$\sigma_{iso} \simeq (\sigma(en)/2 - \sigma(X))/6R^3\langle r^{-3}\rangle \quad (14)$$

The expected shift pattern may roughly be summarized as follows; (i) the *cis* hydrogens resonate at lower magnetic field than the *trans* ones if the ligand X is lower than en in the spectrochemical series, and (ii) if X is a strong-field ligand, then the opposite behavior is expected, see Fig. 2. In Fig. 2, the angle between the cone and the z-axis is 54°44′ corresponding to $(3\cos^2\theta-1)=0$. It should be noted that Eqs. (7) to (14) give shift values as measured from the chemical shift of $[Coen_3]^{3+}$. The value of $\langle r^{-3}\rangle$ was chosen to be 5.77 a.u.[2] of $[Co(NH_3)_6]^{3+}$ for all the complexes investigated here.

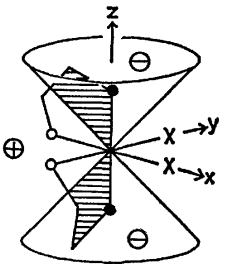

Fig. 2. A schematic presentation of the shift behavior expected for *cis*-$[CoX_2en_2]$, where X is assumed to be a weak-field ligand. Plus and minus refer to up- and down-field shifts, respectively.

Results

Typical examples of PMR spectra of *cis*-$[CoX_2en_2]$ complexes in trifluoroacetic acid are given in Fig. 3. In Fig. 3, the absorptions around $\tau=3$ ppm are due to methylene protons and those ranging from $\tau=4$ to 6 ppm due to amine hydrogens. The results of our measurements on *cis*-bis(en) compounds with substituents X=CN^-, NO_2^-, NCS^-, N_3^-, Cl^-, Br^-, CH_2ClCOO^-, and X_2=oxalate ion are illustrated in Fig. 4,

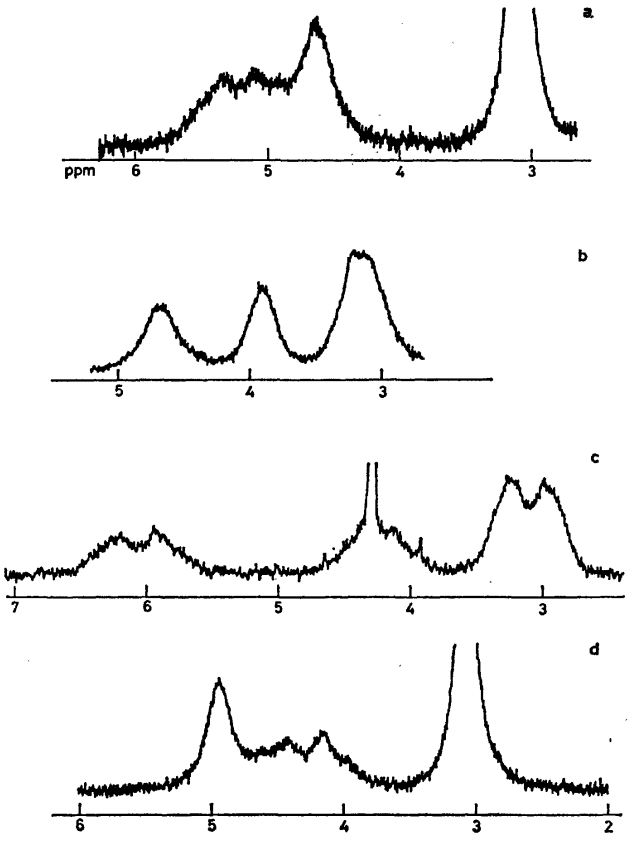

Fig. 3. Typical examples of the PMR spectra of *cis*-bis(en) complexes measured in trifluoroacetic acid. (a) *cis*-$[Co(ox)en_2]^+$, (b) *cis*-$[Co(CN)_2en_2]^+$, (c) *cis*-$[Co(CH_2ClCOO)_2en_2]^+$, and d) *cis*-$[Co(NO_2)_2en_2]^+$.

together with the computed shift values.

Discussion

cis-$[CoX_2en_2]$. We can see at once from Fig. 4 that the theory based on the magnetic anisotropy of the central cobalt(III) ion can explain not only the orders of magnitude of the chemical shifts of amine protons but also their exact values. From this we draw some important conclusions. First, it can be concluded that the chemical shift of these amine hydrogens are primarily determined by the anisotropy of the magnetic susceptibility of the metal ion. We employed several drastic approximations in computing the shielding constants. We approximated the symmetry around the cobalt ion to a regular octahedron and placed all amine protons on the coordinate axes. The same Co–H distances were assumed for all the complexes examined. Further, our model is based on the point-dipole approximation and the additivity of cobalt-59 chemical shifts. Fast conformational inversion was postulated to obtain a better agreement with the observation. The fact that we could obtain an excellent agreement with the observation notwithstanding all these approximations suggests that the magnetic anisotropy of the metal ion has the prime importance in determining the shift values of these compounds.

In our model the effect of covalency between the cobalt and nitrogen or X atoms are taken into consideration implicitly *via* the shielding constants of cobalt-59 nuclei. The abscissa in Fig. 4 is the wavelengths of the first absorption maxima of the corresponding compounds. No simple linear relation exists between the shift values and the wavelengths of the first absorption maxima. This may be a clear indication that we should take the covalency into account. Hendrickson and Jolly[15] argued that the trend of the chemical shifts of $[CoX(NH_3)_5]$ does not exactly match the spectrochemical series since in the shielding expression the exponential factor of the metal radial functions might be expected to vary.[24] With this reservation in mind we can expect the qualitative shift pattern as shown in Fig. 2.

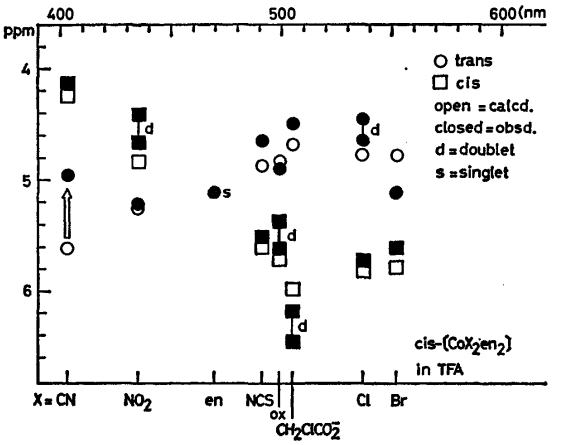

Fig. 4. A plot of the computed shift values of amine hydrogens against the observed shifts. TFA stands for trifluoroacetic acid.

While the agreement between the computed and the measured shifts is surprisingly good for complexes with NO_2^-, NCS^-, Cl^-, Br^-, CH_2ClCOO^-, and oxalate ion, the *trans* hydrogens of the dicyano compound appear at a position much higher than that expected from the theory. The shift of the *cis* hydrogens is fully explained. The discrepancy for the *trans* protons seems to be ascribed to the large inductive effect of the cyanide ion.[25] Fujiwara *et al.*[26] showed from the analysis of cobalt-59 chemical shifts that the Co–CN bond is the most covalent among the Co–O, Co–halogen, or Co–N bonds. Let us consider the CN–Co–NH_2 fragment with NH_2 *trans* to CN^-. The electron density on the NH_2 nitrogen atom will, thus, be restored to a great extent, with a concomitant weakening of the *trans* Co–NH_2 bonding. This will result in an enhanced shielding of the amine hydrogens under consideration, which is just in accord with the observation, see Fig. 4. These inductive effects were not properly taken into account in our model. An increase or decrease in electron density on an amine hydrogen atom will be detected as the rate of hydrogen deuterium exchange or as the pK_a value of the complex. Evidence supporting this deduction has really been obtained for pentaammine and *cis*-bis(en) complexes.[25,27] This result and its implication were discussed in Part VI of this series.

Tetraammines. We here discuss the empirical rule of Jolly *et al.*[14] for tetraammine cobalt(III) com-

plexes. They found that if we assume that the chemical shift of a coordinated ammonia molecule is the sum of five terms characteristic of the other five ligands and their positions, then it is possible, using the data of a series of compounds $[CoX(NH_3)_5]$, to estimate the chemical shift values of ammonia molecules in tetraammine complexes. It seems worthwhile to show that this empirical rule can be accomodated properly in our theory which is based on the magnetic anisotorpy of the cobalt(III) ion. For the pentaammine compound, we take the z-axis as the symmetry axis of the molecule. The chemical shift of the *trans* ammonia protons of this molecule is given by[3]

$$\sigma_{1so} \simeq (3\cos^2\theta-1)(\sigma(NH_3) - \sigma(X))/6R^3\langle r^{-3}\rangle \quad (15)$$

Similarly the shielding constant of the *cis* protons is given, after allowing for the rapid rotation of ammonia molecules around their C_3 axes, by the expression

$$\sigma_{1so} \simeq -(3\cos^2\theta-1)(\sigma(NH_3) - \sigma(X))/12R^3\langle r^{-3}\rangle \quad (16)$$

Here θ is the angle between the Co–N and Co–H axes and is unaffected by the NH_3 rotation. The above equations may be reinterpreted in the following way. If we define the quantity Δ_X, which is characteristic of the ligand X, by

$$\Delta_X \equiv (3\cos^2\theta-1)(\sigma(NH_3) - \sigma(X))/12R^3\langle r^{-3}\rangle \quad (17)$$

Eqs. (15) and (16) indicate that the contribution of the ligand X to the chemical shift of the *trans* protons is $2\Delta_X$ and that to the *cis* protons is $-\Delta_X$. On the other hand, in *cis*-$[CoXY(NH_3)_4]$ the chemical shift of the ammonia protons *cis* to both X and Y is shown, after taking the NH_3 rotation into account, to be given by

$$\sigma_{iso} \simeq (3\cos^2\theta-1)(\sigma(X) + \sigma(Y) - 2\sigma(NH_3))/12R^3\langle r^{-3}\rangle \quad (18)$$

$$\equiv (-\Delta_X) + (-\Delta_Y) \quad (19)$$

Likewise, for the ammonia molecule *trans* to X and *cis* to Y the following expression holds.

$$\sigma_{iso} \simeq (2\Delta_X) + (-\Delta_Y) \quad (20)$$

In view of the fact that Jolly *et al.* chose the chemical shift of $[Co(NH_3)_6]^{3+}$ as the reference and set it equal to zero, the above equations are just the analytical expressions of their empirical rule. More importantly the above results imply that the chemical shifts of coordinated ammonia molecules are dominated by the magnetic anisotropy of the central metal ion.

cis-Bis(trimethylenediamine) Complexes; Here we will briefly examine the chemical shift of amine protons of *cis*-$[CoX_2tn_2]$, where tn is trimethylenediamine. Kawaguchi and Kawaguchi[28] obtained the PMR spectra of *cis*-bis(tn) compounds containing the cyanide, azide, and thiocyanate ions as the ligand X. While the *trans* isomers exhibit a single absorption in the amine proton region, the *cis* compounds show a well-resolved doublet. Since it is highly probable that the chemical shifts of these amine protons are governed by the magnetic anisotropy of the metal ion, we would like to assign the amine signals according to Eqs. (13) and (14). The *trans* NH_2 may be more deshielded than the *cis* one when the substituent X is the cyanide ion. Thus, it follows that in *cis*-$[Co(CN)_2tn_2]^+$ the absorption centered at about 5.7 ppm from DSS is due to the *trans* hydrogens and that at 6.87 ppm is due to the *cis* ones. Similarly in the azido-containing complex the peak resonating at 6.1 ppm can be attributed to the *trans* amine protons.

The Infrared and Raman Spectra of *p*-Azoxyanisole in the Crystalline, Nematic and Isotropic Liquid Phases

Kazuo SHIBATA, Masaki KUTSUKAKE, Hiroaki TAKAHASHI, and Keniti HIGASI
Department of Chemistry, School of Science and Engineering, Waseda University, Tokyo 160
(Received August 1, 1975)

The infrared and Raman spectra of *p*-azoxyanisole were measured in the crystalline, nematic, and isotropic liquid phases. In the internal vibrational region, abrupt changes in intensity were observed at the crystalline-nematic phase transition; however, no appreciable change was detected at the nematic-isotropic liquid phase transition. In the external vibrational region, some of the Raman lattice bands, which eventually vanish in the isotropic liquid phase, persist in the nematic phase, while some of the infrared lattice bands disappear and a new band appears as the crystalline-nematic phase transition point is reached and traversed. The assignments of the infrared and Raman bands which appear or disappear in the nematic phase are discussed.

The study of the infrared and Raman spectra of liquid crystal compounds provides an attractive approach for the elucidation of the forces that determine the order and molecular structure in the various phases exhibited by liquid crystal compounds. In spite of this, the number of investigations of infrared and Raman spectra with relation to this particular subject has been quite small.

The infrared spectra of a nematic liquid crystal compound, *p*-azoxyanisole (PAA), have been measured by Bulkin *et al.*[1,2] and by Gruger and Calvé.[3] Bulkin *et al.* reported the infrared spectra of the crystalline, nematic, and isotropic liquid phases in the 600—450 cm^{-1} and 200—50 cm^{-1} regions. They showed that the band at 509 cm^{-1} disappeared at the crystalline-nematic (c-n) phase transition,[1] and that the lattice bands below 150 cm^{-1} disappeared and a broad band emerged at about 100 cm^{-1} above the c-n phase transition temperature.[2] They also showed that the intensity of the disappearing bands began to decrease well below the transition temperature and suggested that there were pretransition effects.

The Raman spectra of PAA in the three phases have been measured by several investigators.[3-8] Amer *et al.*[4] measured the temperature dependence of the Raman bands in the 1300—1225 cm^{-1} and 100—30 cm^{-1} regions. They reported that the variation in the integrated intensity as well as in the bandwidth with the temperature has a characteristic quasi-discontinuity at the c-n phase transition. They also showed that the band at 75 cm^{-1} vanished completely, while the bands at 52 and 40 cm^{-1} persisted in the nematic phase. This result, however, does not agree with that obtained by Bulkin and Prochaska[5], who showed that the band at 52 cm^{-1} vanished while the bands at 70 and 45 cm^{-1} persisted in the nematic phase.

The purpose of this paper is to clarify the behavior of the Raman-active lattice modes of PAA in relation to the temperature variation and to explain the infrared and Raman bands, which change remarkably in intensity at the c-n phase transition.

Experimental

PAA purchased from Tokyo Kasei Kogyo Co., Ltd., was purified by recrystallization from methanol. The sample exhibited a nematic mesophase in the temperature range from 118 to 136 °C.

The infrared spectra were recorded with a Hitachi EPI-G3 spectrophotometer (4000—400 cm^{-1}) and a Hitachi FIS-3 spectrophotometer (400—30 cm^{-1}). The frequency accuracy is probably within ± 2 cm^{-1}. The spectra of the crystalline, nematic, and isotropic liquid phases were recorded as thin films sandwiched between KBr or silicon plates, depending on the frequency range. An electrically heated cell from Hitachi Co., Ltd., provided with an alumel-chromel thermocouple was used to measure the temperature variation.

The Raman spectra were obtained with a Shimadzu R-2D double monochromator equipped with a cooled photomultiplier (ITT FW 130) and a photon-counting system. The excitation source was an Ar^+ laser (Spectra Physics Model 165) operated at 514.5 nm. The output power at the laser-head was 80 mW for the crystalline phase, while it was 350 mW for the nematic and isotropic liquid phases. The frequencies were calibrated using emission lines from the laser and are believed accurate to ± 5 cm^{-1}. The spectral slitwidth was 1.2 cm^{-1} for the 1700—1000 cm^{-1} region, while it was 4.8 cm^{-1} for the 1000—100 cm^{-1} region. The sample cell was inserted in an electrically heated brass block and placed in a box packed with asbestos. The sample temperature was monitored constantly; the temperature fluctuations were less than 1 °C.

Results

The molecular structure of PAA, $CH_3O\text{-}C_6H_4\text{-}N(O)=N\text{-}C_6H_4\text{-}OCH_3$, has been determined by X-ray diffraction.[9] The –N=N– bond is twisted away from the planar *trans* form by 4.2°, and the angle between the normals of the two benzene rings is 22.6°. Hence, the molecule has no symmetry at all. The PAA crystal belongs to the monoclinic system, and the space group is C_{2h}^5–$P2_1/a$, with four molecules in a Bravais unit cell.

Intramolecular Mode The infrared spectra between 1800 and 400 cm^{-1} of PAA in the crystalline, nematic, and isotropic liquid phases are given in Fig. 1. The Raman spectra for the three phases are shown between 1700 and 100 cm^{-1} in Fig. 2. The Raman bands in the 1700—1000 cm^{-1} region are extremely intense compared with those in the lower-frequency range. The spectra in the 1700—1000 cm^{-1} region were recorded with the slit-width one fourth of that in the 1000—100 cm^{-1} region.

Neither the infrared nor the Raman spectra exhibit any significant change at the nematic-isotropic liquid (n-i) phase transition: the infrared and Raman spectra of the nematic phase are virtually the same as

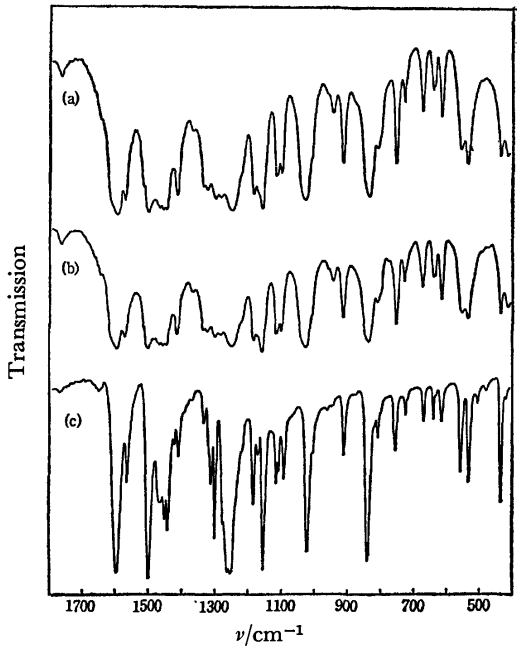

Fig. 1. Infrared spectra between 1800 and 400 cm^{-1} of PAA.
(a): isotropic liquid phase (at 140 °C). (b): nematic phase (at 125 °C). (c): crystalline phase (at 25 °C).

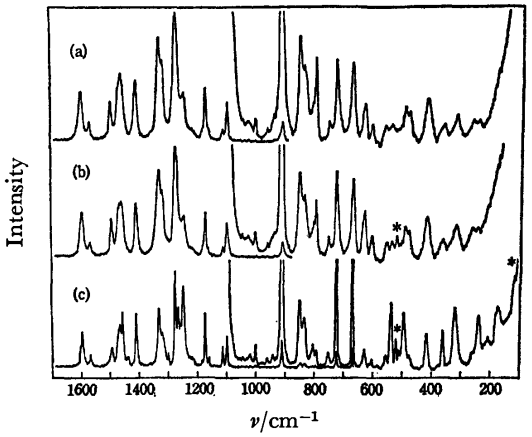

Fig. 2. Raman spectra between 1700 and 100 cm^{-1} of PAA. Spectral slit-width is 1.2 cm^{-1} for the 1700—1000 cm^{-1} region, while it is 4.8 cm^{-1} for the 1000—100 cm^{-1} region.
(a): isotropic liquid phase (at 140 °C). (b): nematic phase (at 125 °C). (c): crystalline phase (at 25 °C).
* denotes the emission lines from the Ar$^+$ laser.

those of the isotropic liquid phase, except for slightly different band-widths due to the different temperatures. In sharp contrast to this, several of the spectral features change almost abruptly at the c-n phase transition: many infrared and Raman bands change in their relative intensities, some increasing while others decrease. Most of the bands become broadened in the nematic phase. Further, some of the infrared and Raman bands exhibit small frequency shifts.

Of particular interest is the fact that the infrared bands at 1311, 509, and 482 cm^{-1} in the crystalline phase disappear above the c-n phase transition temperature (Fig. 3). Bulkin *et al.*[1] noticed that the

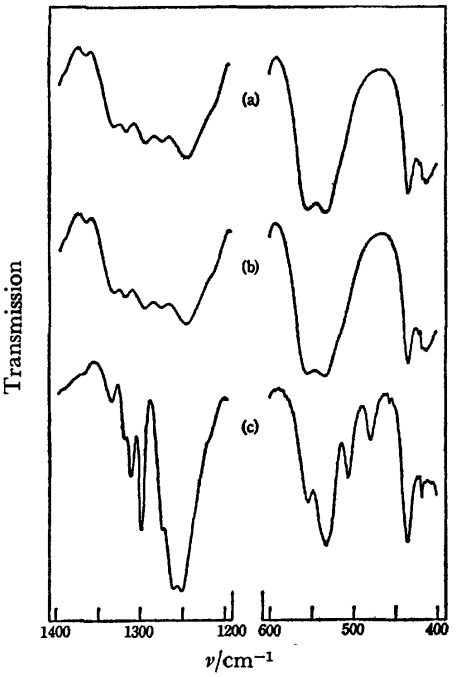

Fig. 3. Temperature dependence of the infrared bands at 1311, 509 and 482 cm^{-1}.
(a): isotropic liquid phase (at 140 °C). (b): nematic phase (at 125 °C). (c): crystalline phase (at 25 °C).

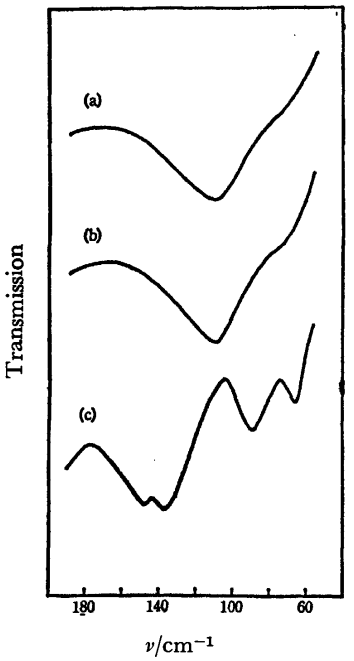

Fig. 4. Infrared spectra of PAA in the external vibrational region.

infrared band at 509 cm^{-1} vanishes at the c-n phase transition; however, they failed to observe the disappearance of the bands at 1311 and 482 cm^{-1}.

Intermolecular Modes The infrared spectra between 180 and 60 cm^{-1} of PAA in the crystalline, nematic, and isotropic liquid phases are reproduced in Fig. 4. In the crystalline phase, four bands are

observed at 150, 137, 89 and 67 cm^{-1}. In the nematic and isotropic liquid phases, some of the bands disappear, and, instead, an intense and broad band appears at about 108 cm^{-1}. This observation is in accord with that reported by Bulkin *et al.*[2]

The Raman spectra below 140 cm^{-1} for the three phases are shown in Fig. 5. Five bands are clearly seen at 94, 75, 56, 42 and 21 cm^{-1} in the crystalline phase. In the nematic phase, the 75 cm^{-1} band disappears and the bands at 56 and 42 cm^{-1} decrease in intensity. In the isotropic liquid phase, only the band at 94 cm^{-1} exists. The behavior of the band at 21 cm^{-1} is not clear because of the overlapping by the Rayleigh wing. This result agrees with that obtained by Amer *et al.*;[4,6] however, it does not agree with those obtained by Bulkin *et al.*[5] and Gruger and Calvé.[3] Bulkin *et al.* claimed that it was the 56 cm^{-1} band that disappeared in the nematic phase. On the other hand, Gruger and Calvé reported that the three bands at 75, 56, and 42 cm^{-1} all existed in the nematic phase at 119 °C, but at 125 °C (still in the nematic phase) only the 42 cm^{-1} band remained. The conclusions differ from one to another because of the extreme difficulty of obtaining high-quality Raman spectra below 100 cm^{-1} of the nematic and isotropic liquid phases as a result of the sudden broadening of the Rayleigh wing at the c-n phase transition. We examined the temperature dependence of these three lattice bands with great care and obtained good reproducible spectra, thus confirming that the band at 75 cm^{-1} vanishes unambiguously, whereas the bands at 56 and 42 cm^{-1}, although they become very much weakened, still exist in the nematic phase.

Discussion

A nematic mesophase may be characterized by the tendency of all molecules to align themselves parallel to a preferred axis in space, although they are not fixed in position. Such a tendency, however, may still be present in the isotropic liquid phase, though among much smaller groups of molecules.[17]

McLoughlin *et al.*[10] concluded, from the volume changes at the c-n and n-i phase transitions, that there is, usually, no room for PAA molecules to rotate freely about their own long axes, in either the nematic or isotropic liquid phase. This suggests that the rotational motion about the long axis of a PAA molecule is hindered by neighboring molecules and becomes a librational oscillation even in the nematic and isotropic liquid phases; the frequency of the oscillation, however, is possibly different from that of the corresponding librational mode in the crystalline phase as a result of the different intermolecular force field.

The appearance of an intense and broad infrared band at 108 cm^{-1} at the c-n phase transition might be well explained if one could assume that this band originates from the librational oscillation about the molecular long axis, and further, that the short-range order is responsible for the librational oscillation appearing in the infrared spectra. It has been known that the polar molecules in the liquid state exhibit a broad and intense absorption in the far-infrared region (mostly below 100 cm^{-1});[11-13] this absorption band can be explained as due to the librational oscillation of each polar molecule within the cage formed by its neighbors.[14,15] Thus, it seems reasonable to assume that the infrared band at 108 cm^{-1} of PAA has the same origin as the absorption of polar molecules. Evans *et al.*[16] explained a strong band centered near 130 cm^{-1} of a liquid crystal compound, *N*-(*p*-methoxybenzylidene)-*p*-*n*-butylaniline (MBBA), in its nematic and isotropic liquid phases as being due to this type of absorption.

On the other hand, the disappearance of the Raman band at 75 cm^{-1} at the c-n phase transition may be interpreted on the assumption that this band is due to the Raman-active librational mode about the long axis, but the long-range order is essential to the appearance of the librational oscillation in the Raman spectra.

We have seen that the Raman bands at 56 cm^{-1} and 42 cm^{-1} persist in the nematic phase, although they vanish in the isotropic liquid phase. Thus, these bands can be assigned either to the librational modes about the molecular short axes or to the translational modes along the axes; along these axes, the long-range order still exists in the nematic phase. The Raman band at 94 cm^{-1} must be an internal mode because this band is seen in the isotropic liquid phase; besides, it does not exhibit any appreciable frequency shift through the phase transitions.

In the internal vibrational region, the infrared bands at 1311, 509, and 482 cm^{-1} vanish above the c-n phase transition point. These bands may be

assigned to combination modes between the librational mode about the molecular long axis and intramolecular modes; in the nematic phase, the librational mode disappears and, hence, its combination modes. It is difficult to explain these bands, except for the band at 1311 cm^{-1}, in terms of the crystal-field splitting, because they are far from any adjacent bands. The following combinations are, though, considered probable; 1247 (R)+67 (IR)=1314, 437 (IR)+75 (R)=512, and 418 (R)+67 (IR)=485.

In a nematic liquid crystal compound, *N*-anisyliden-*p*-aminophenyl acetate (APAPA), the infrared and Raman bands arising from rotational isomers which exist in the nematic and isotropic liquid phases were identified, and the energy difference between the isomers was estimated.[18] Therefore, it seems highly probable that more than one molecular conformation around the C–OCH_3 bonds are present for PAA in the nematic and isotropic liquid phases. The remarkable intensity changes at the c-n phase transition might be caused by the changes not only in the molecular orientation but also in the conformation.

Bulkin *et al.*[1,5] reported that there are pretransition effects at the c-n phase transition. It is true that the peak heights and band-widths of the infrared and Raman bands start to change well below the transition temperature, but this is what one would expect from the temperature variation in the spectra of any compounds, regardless of the phase transition. we found that the appearance or disappearance of the infrared and Raman bands took place almost abruptly at the transition temperature.

Theoretical Calculations of the Infrared Absorption Intensities of Simultaneous Transitions

Hiroyuki SHINODA and Munehisa MITSUYA

Department of Applied Chemistry, Faculty of Science and Engineering, Waseda University, Nishi-Ohkubo, Shinjuku-ku, Tokyo 160

(Received August 13, 1975)

The formula of the infrared absorption intensity of a simultaneous transition has been derived on the basis of the vibronic expansion technique, with two simple assumptions. By the use of the foumula, the theoretical calculations of the intensities for the CO_2–N_2 and CO_2–H_2 systems have been done, the electronic wave functions being calculated by the CNDO/2 method. In both cases, it was found that the main contribution to the absorption intensity arises from the coupling between the electronic state of CO_2 and the nuclear vibration of the homonuclear diatomic molecule. Furthermore, the intensities of the fundamental, first-overtone, and combination bands of CO_2 have been calculated according to the formula corresponding to an intramolecular process, and the intensities of the overtone and combination bands caused by the intermolecular process have been calculated. These calculated results have been discussed in comparison with one another.

In their investigations of the infrared absorption spectra of the compressed gaseous mixture of carbon dioxide and nitrogen, Fahrenfort and Ketelaar[1] found new bands which were not observed in compressed gas of pure carbon dioxide. They attributed the bands to simultaneous transitions in each of the two compounds. The same phenomenon was found in the mixture of CO_2 and H_2 and also in CO_2 and O_2. Fahrenfort and Ketelaar suggested that the phenomena depend on the polarization of the symmetrical diatomic molecule under the influence of the electric field of the rather large quadrupole moment arising from the partial dipoles presented in CO_2. Ketelaar and his co-workers went on to investigate the simultaneous transitions in several liquified mixtures[2] and proposed a theoretical development of the simultaneous transition.[3] Their development is based on the idea that the dipole moment of the system is expanded in a power series of the vibrational normal coordinates. This idea has been used to explain the infrared absorption intensities of the vibrational transitions in a separate molecule;[4] in the expansion, the first derivatives with respect to the normal coordinates are related to the intensities of the fundamental tones, the second derivatives are related to the first overtones, and so on. For the intensity of a Raman scattering, a similar approach has been adopted in the form of the expansion of a molecular polarizability.[5] On the other hand, the formula of the Raman intensity has been derived by the use of the vibronic expansion technique,[6] which is different from that described above.

In this work the formulas of the infrared absorption intensities have been derived by the use of the vibronic expansion technique; the formula of the intensity for the simultaneous transition has also been derived. Moreover, by the use of these formulas, the intensities of the simultaneous transition for the CO_2–N_2 and CO_2–H_2 systems and of the fundamental, overtone, and combination bands of CO_2 have been calculated. The electronic wave functions have been evaluated by the CNDO/2 method.

Theoretical

Intramolecular Transition. The expression of the infrared absorption intensity for the vibrational transition from the ground state, o, to the excited state, m, of a molecule is given as:[7]

$$A_{m\leftarrow o} = \frac{8\pi^3}{3ch}\nu_{mo}(N_o - N_m)|\mu_{m,o}|^2; \quad (1)$$

$$\mu_{m,o} = \langle m|\hat{\mu}|o\rangle, \quad (2)$$

where c is the velocity of light; h, Planck's constant; ν_{mo}, the frequency of the absorbed light; N_o and N_m, the number of molecules per unit volume in the o and m states respectively, and $\hat{\mu}$, the electric dipole moment operator. The wave functions, $|o>$ and $|m>$, are described by the product of an electronic wave function and a vibrational wave function:

$$|o> = |\phi_g>|\varphi_o^g> \quad (3)$$

and:

$$|m> = |\psi_g>|\varphi_m^g>, \quad (4)$$

where $|\phi_g>$ is the wave function of the electronic ground state involving the nuclear coordinates as parameters and where $|\varphi_o^g>$ and $|\varphi_m^g>$ are the wave functions of the vibrational ground and the vibrational m-th states respectively, both of which belong to the electronic ground state. The Hamiltonian for the electronic system could be expanded in a Taylor series with respect to the normal coordinates, Q_a's, around the equilibrium nuclear position:

$$H = H_0 + \sum_a H_a'Q_a + \frac{1}{2}\sum_a\sum_b H_{ab}''Q_aQ_b + \textit{higher-order terms}, \quad (5)$$

where

$$H_a' = (\partial H/\partial Q_a)_0$$

and

$$H_{ab}'' = (\partial^2 H/\partial Q_a \partial Q_b)_0.$$

When H_0 is regarded as the unperturbed Hamiltonian which has the eigenvalues, ε_i^0's, and the corresponding eigenfunctions, $|\psi_i^0>$'s, and when the other terms on the right-hand side in Eq. (5) are regarded as the perturbation on H_0, we can make use of the perturbation method for obtaining the $|\psi_g>$. The expression of $|\psi_g>$ with the zeroth-, the first-, and the second-order terms of normal coordinates can be written as:[8]

$$|\psi_g> = |\psi_g^0> + \sum_a \sum_{i\neq g} \frac{\langle\psi_i^0|H_a'|\psi_g^0\rangle Q_a}{\varepsilon_g^0-\varepsilon_i^0}|\psi_i^0> + \sum_{a,b}\sum_{i\neq g}\left\{\frac{1}{2}\frac{\langle\psi_i^0|H_{ab}''|\psi_g^0\rangle}{\varepsilon_g^0-\varepsilon_i^0} + \sum_{j\neq g}\frac{\langle\psi_g^0|H_a'|\psi_j^0\rangle\langle\psi_j^0|H_b'|\psi_i^0\rangle}{(\varepsilon_g^0-\varepsilon_j^0)(\varepsilon_g^0-\varepsilon_i^0)} - \frac{\langle\psi_g^0|H_a'|\psi_g^0\rangle\langle\psi_g^0|H_b'|\psi_i^0\rangle}{(\varepsilon_g^0-\varepsilon_i^0)^2}\right\}Q_aQ_b|\psi_i^0\rangle. \quad (6)$$

It is convenient for the following development to show that $\hat{\boldsymbol{\mu}}$ can be expressed as follows:[9]

$$\hat{\boldsymbol{\mu}} = \hat{\boldsymbol{\mu}}_e + \hat{\boldsymbol{\mu}}_n = \hat{\boldsymbol{\mu}}_e + \hat{\boldsymbol{\mu}}_n^0 + \sum_a \mathbf{k}_a Q_a = \hat{\boldsymbol{\mu}}_0 + \sum \mathbf{k}_a Q_a, \quad (7)$$

where $\hat{\boldsymbol{\mu}}_e$ and $\hat{\boldsymbol{\mu}}_n$ are the electronic and nuclear parts of $\hat{\boldsymbol{\mu}}$ respectively, where $\hat{\boldsymbol{\mu}}_n^0$ is $\hat{\boldsymbol{\mu}}_n$ with the equilibrium nuclear position, and where $\hat{\boldsymbol{\mu}}_0$ is the sum of $\hat{\boldsymbol{\mu}}_e$ and $\hat{\boldsymbol{\mu}}_n^0$. By applying Eq. (6) to Eqs. (3) and (4), and considering the orthonormality between $|\psi_i^0>$'s, $\boldsymbol{\mu}_{m,o}$ is rewritten as:

$$\boldsymbol{\mu}_{m,o} = \langle\psi_g^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle\langle\varphi_m^g|\varphi_o^g\rangle + \sum_a\left\{\mathbf{k}_a - 2\sum_{i\neq g}\frac{\langle\psi_g^0|H_a'|\psi_i^0\rangle\langle\psi_i^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle}{\varepsilon_i^0-\varepsilon_g^0}\right\}\langle\varphi_m^g|Q_a|\varphi_o^g\rangle + \sum_{a,b}\left[\sum_{i\neq g}\sum_{j\neq g}\left\{\frac{\langle\psi_g^0|H_a'|\psi_i^0\rangle\langle\psi_i^0|\hat{\boldsymbol{\mu}}_0|\psi_j^0\rangle\langle\psi_j^0|H_b'|\psi_g^0\rangle}{(\varepsilon_i^0-\varepsilon_g^0)(\varepsilon_j^0-\varepsilon_g^0)} + 2\frac{\langle\psi_g^0|H_a'|\psi_i^0\rangle\langle\psi_i^0|H_b'|\psi_j^0\rangle\langle\psi_j^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle}{(\varepsilon_i^0-\varepsilon_g^0)(\varepsilon_j^0-\varepsilon_g^0)}\right\} - \sum_{i\neq g}\left\{\frac{\langle\psi_g^0|H_{ab}''|\psi_i^0\rangle\langle\psi_i^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle}{\varepsilon_i^0-\varepsilon_g^0} + 2\frac{\langle\psi_g^0|H_a'|\psi_g^0\rangle\langle\psi_g^0|H_b'|\psi_i^0\rangle\langle\psi_i^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle}{(\varepsilon_i^0-\varepsilon_g^0)^2}\right\}\right]\langle\varphi_m^g|Q_aQ_b|\varphi_o^g\rangle. \quad (8)$$

with the harmonic oscillator approximation, the transition moments for the fundamental tone and the first overtone of the a normal vibration and for the combination tone of the a and b normal vibrations are given as:

Fundamental tone:

$$\boldsymbol{\mu}_{1,0}^a = \left\{\mathbf{k}_a - 2\sum_{i\neq g}\frac{\langle\psi_g^0|H_a'|\psi_i^0\rangle\langle\psi_i^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle}{\varepsilon_i^0-\varepsilon_g^0}\right\}\langle\varphi_1^g|Q_a|\varphi_0^g\rangle: \quad (9)$$

First overtone:

$$\boldsymbol{\mu}_{2,0}^a = \left[\sum_{i\neq g}\sum_{j\neq g}\left\{\frac{\langle\psi_g^0|H_a'|\psi_i^0\rangle\langle\psi_i^0|\hat{\boldsymbol{\mu}}_0|\psi_j^0\rangle\langle\psi_j^0|H_a'|\psi_g^0\rangle}{(\varepsilon_i^0-\varepsilon_g^0)(\varepsilon_j^0-\varepsilon_g^0)} + 2\frac{\langle\psi_g^0|H_a'|\psi_i^0\rangle\langle\psi_i^0|H_a'|\psi_j^0\rangle\langle\psi_j^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle}{(\varepsilon_i^0-\varepsilon_g^0)(\varepsilon_j^0-\varepsilon_g^0)}\right\} - \sum_{i\neq g}\left\{\frac{\langle\psi_g^0|H_{aa}''|\psi_i^0\rangle\langle\psi_i^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle}{\varepsilon_i^0-\varepsilon_g^0} + 2\frac{\langle\psi_g^0|H_a'|\psi_g^0\rangle\langle\psi_g^0|H_a'|\psi_i^0\rangle\langle\psi_i^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle}{(\varepsilon_i^0-\varepsilon_g^0)^2}\right\}\right]\langle\varphi_2^g|Q_a^2|\varphi_0^g\rangle: \quad (10)$$

Combination tone:

$$\boldsymbol{\mu}_{(1,1),0}^{a,b} = \left[2\sum_{i\neq g}\sum_{j\neq g}\left\{\frac{\langle\psi_g^0|H_a'|\psi_i^0\rangle\langle\psi_i^0|\hat{\boldsymbol{\mu}}_0|\psi_j^0|H_b'\rangle\langle\psi_i^0|\psi_g^0\rangle}{(\varepsilon_i^0-\varepsilon_g^0)(\varepsilon_j^0-\varepsilon_g^0)} + \frac{\langle\psi_g^0|H_a'|\psi_i^0\rangle\langle\psi_i^0|H_b'|\psi_j^0\rangle\langle\psi_j^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle}{(\varepsilon_i^0-\varepsilon_g^0)(\varepsilon_j^0-\varepsilon_g^0)} + \frac{\langle\psi_g^0|H_b'|\psi_i^0\rangle\langle\psi_i^0|H_a'|\psi_j^0\rangle\langle\psi_j^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle}{(\varepsilon_i^0-\varepsilon_g^0)(\varepsilon_j^0-\varepsilon_g^0)}\right\} - 2\sum_{i\neq g}\left\{\frac{\langle\psi_g^0|H_{ab}''|\psi_i^0\rangle\langle\psi_i^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle}{\varepsilon_i^0-\varepsilon_g^0} + \frac{\langle\psi_g^0|H_a'|\psi_g^0\rangle\langle\psi_g^0|H_b'|\psi_i^0\rangle\langle\psi_i^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle}{(\varepsilon_i^0-\varepsilon_g^0)^2} + \frac{\langle\psi_g^0|H_b'|\psi_g^0\rangle\langle\psi_g^0|H_a'|\psi_i^0\rangle\langle\psi_i^0|\hat{\boldsymbol{\mu}}_0|\psi_g^0\rangle}{(\varepsilon_i^0-\varepsilon_g^0)^2}\right\}\right]\langle\varphi_{(1,1)}^g|Q_aQ_b|\varphi_0^g\rangle. \quad (11)$$

Simultaneous Transition. In order to derive the expression of the transition moment for a simultaneous transition, we introduce two assumptions:

(i) The normal modes in a separate molecule remain in a two-molecule system.

(ii) The electron-transfer and -exchange between molecules do not appear.

The first assumption is supported by the experimental fact that the wave number of a simultaneous transition is equal to the sum of the wave numbers of the constituent fundamental tones. There is no experimental evidence to support the second assumption. On the basis of their theoretical investigation of intermolecular forces, however, Murrell *et al.*[10] suggested that the effect of the electron-exchange appears in the region of intermolecular distances shorter than 3 Å, as is shown in the figures in their report, and that the electron-transfer is not important when the charge-transfer states are not detected spectroscopically. Therefore, the use of the second assumption will not bring a fatal error into the results of the calculations for a gas phase; also, it has the merit that the expression of the transition moment becomes very simple, as will be shown later.

With the first assumption, the electronic Hamiltonian of two-molecule system is given as:

$$H = H^A + H^B + U^0 + \sum_a U_a'Q_a + \sum_b U_b'Q_b, \quad (12)$$

$$H^A = H_0^A + \sum_a H_a'Q_a \quad [\text{where } H_a' = (\partial H^A/\partial Q_a)_0], \quad (13)$$

$$H^B = H_0^B + \sum_b H_b'Q_b \quad [\text{where } H_b' = (\partial H^B/\partial Q_b)_0], \quad (14)$$

$$U_a' = (\partial U/\partial Q_a)_0, \quad (15)$$

and

$$U_b' = (\partial U/\partial Q_b)_0, \quad (16)$$

where H^A and H^B are the electronic Hamiltonians of the separate molecules, A and B respectively; U, the intermolecular interaction operator including the nuclear coordinates as parameter, and U^0, U with a specified molecular configuration, each molecule keeping the equilibrium geometry. Since the wave number of the simultaneous transition considered in this work is the sum of those of the constituent fundamental tones, it is sufficient to consider the first-order term in each normal coordinate. Hereafter, Q_a in the A

molecule and Q_b in the B molecule will be considered typical. The electronic wave function of the two-molecule system with an infinite separation is consistently given by the product of the wave functions of the separate molecules:

$$|\Psi^0_{ik}> = |\phi^A_i>|\phi^B_k>, \tag{17}$$

$$|\phi^A_i> = |\phi^{A0}_i> + \sum_{j\neq i} \frac{\langle\phi^{A0}_j|H_a'|\phi^{A0}_i\rangle Q_a}{\varepsilon^{A0}_i - \varepsilon^{A0}_j}|\phi^{A0}_j>, \tag{18}$$

and

$$|\phi^B_k> = |\phi^{B0}_k> + \sum_{l\neq k} \frac{\langle\phi^{B0}_l|H_b'|\phi^{B0}_k\rangle Q_b}{\varepsilon^{B0}_k - \varepsilon^{B0}_l}|\phi^{B0}_l>, \tag{19}$$

where the A and B superscripts indicate the separate molecules, A and B respectively, and where the 0 superscript in $|\Psi^0_{ik}>$ indicates the infinite separation. For the simultaneous transition, the initial state, o, and the final state, m, in Eq. (1) are given by the following expressions respectively:

$$|o> = |\Psi_g>|\Phi^g_{00}\rangle \tag{20}$$

and

$$|m> = |\Psi_g>|\Phi^g_{11}\rangle, \tag{21}$$

where $|\Psi_g>$ is the wave function of the electronic ground state of two-molecule system and where $|\Phi^g_{00}>$ and $|\Phi^g_{11}>$ are the wave functions of the vibrational initial and final states respectively. Regarding the last three terms in Eq. (12) as a perturbation caused by an interaction between neighbouring molecules, we can expand the wave function $|\Psi_g>$ by the use of the first-order perturbation method:

$$|\Psi_g> = |\Psi^0_{gg}> + \sum'_{(ik)} \frac{\langle\Psi^0_{ik}|U^0 + U_a'Q_a + U_b'Q_b|\Psi^0_{gg}\rangle}{E^0_{gg} - E^0_{ik}}|\Psi^0_{ik}>, \tag{22}$$

where E^0_{ik} is the energy of the $|\Psi^0_{ik}>$ state and where the prime in $\sum'$ indicates that the sum over (ik) does not include (gg). From the second assumption, the wave functions corresponding to the electron-transfers between molecules are also omitted. By substituting Eq. (22) into Eqs. (20) and (21), the following expression of $\mu_{m,o}$ in Eq. (2) can be obtained:

$$\mu_{m,o} = \langle\Phi^g_{11}|\mu_{m,o}(0) + \mu_{m,o}(1) + \mu_{m,o}(2)|\Phi^g_{00}\rangle, \tag{23}$$

where:

$$\mu_{m,o}(0) = \langle\Psi^0_{gg}|\hat{\mu}|\Psi^0_{gg}\rangle + 2\sum'_{(ik)} \frac{\langle\Psi^0_{gg}|\hat{\mu}|\Psi^0_{ik}\rangle\langle\Psi^0_{ik}|U_a'Q_a + U_b'Q_b|\Psi^0_{gg}\rangle}{E^0_{gg} - E^0_{ik}} + \sum'_{(ik)}\sum'_{(jl)} \frac{\langle\Psi^0_{gg}|U_a'Q_a + U_b'Q_b|\Psi^0_{ik}\rangle\langle\Psi^0_{ik}|\hat{\mu}|\Psi^0_{jl}\rangle\langle\Psi^0_{jl}|U_a'Q_a + U_b'Q_b|\Psi^0_{gg}\rangle}{(E^0_{gg} - E^0_{ik})(E^0_{gg} - E^0_{jl})}, \tag{24}$$

$$\mu_{m,o}(1) = 2\sum'_{(ik)} \frac{\langle\Psi^0_{gg}|\hat{\mu}|\Psi^0_{ik}\rangle\langle\Psi^0_{ik}|U^0|\Psi^0_{gg}\rangle}{E^0_{gg} - E^0_{ik}} + 2\sum'_{(ik)}\sum'_{(jl)} \frac{\langle\Psi^0_{gg}|U^0|\Psi^0_{ik}\rangle\langle\Psi^0_{ik}|\hat{\mu}|\Psi^0_{jl}\rangle\langle\Psi^0_{jl}|U_a'Q_a + U_b'Q_b|\Psi^0_{gg}\rangle}{(E^0_{gg} - E^0_{ik})(E^0_{gg} - E^0_{jl})} \tag{25}$$

and

$$\mu_{m,o}(2) = \sum'_{(ik)}\sum'_{(jl)} \frac{\langle\Psi^0_{gg}|U^0|\Psi^0_{ik}\rangle\langle\Psi^0_{ik}|\hat{\mu}|\Psi^0_{jl}\rangle\langle\Psi^0_{jl}|U^0|\Psi^0_{gg}\rangle}{(E^0_{gg} - E^0_{ik})(E^0_{gg} - E^0_{jl})} \tag{26}$$

In the above expressions, $\mu_{m,o}(0)$, $\mu_{m,o}(1)$, and $\mu_{m,o}(2)$ are the zeroth-, the first-, and the second-order terms of U^0 respectively. If the higher-order perturbations were considered in the expansion of $|\Psi_g>$, some other terms would be added to Eqs. (24)—(26). The terms contributing to the simultaneous transitions must include three kinds of matrix elements, two of them being those of the vibronic coupling operators referring to Q_a and Q_b respectively, and one of them being that of $\hat{\mu}$. Therefore, the lowest-order term contributing to the simultaneous transitions is the third-order one. The terms in $\mu_{m,o}(1)$ and $\mu_{m,o}(2)$ always include the matrix elements of U^0; therefore, their contributions to the simultaneous transitions arise from higher-order terms than the third-order one. In this work, the intensities of the simultaneous transitions have been calculated by considering only $\mu_{m,o}(0)$, which gives the lowest-order contribution. The influences of $\mu_{m,o}(1)$ and $\mu_{m,o}(2)$ will be investigated in the future. When $|\Psi^0_{ik}>$'s in Eq. (24) were rewritten by the use of the expressions in Eqs. (17)—(19), and only the terms including Q_aQ_b were retained, $\mu_{m,o}(0)$ was given as:

$$\begin{aligned}\mu_{m,o}(0) = {} & 2\sum_{i\neq g}\sum_{k\neq g} C^A_{ig}C^B_{kg}\{\langle gg|\hat{\mu}_0|ik\rangle + \langle ig|\hat{\mu}_0|gk\rangle\}Q_aQ_b + 2\sum'_{(ik)} \frac{1}{E^0_{gg} - E^0_{ik}}\Big[\sum_{n\neq i} C^A_{ni}\{\langle gg|U_b'|nk\rangle\langle ik|\hat{\mu}_0|gg\rangle \\ & + \langle gg|U_b'|ik\rangle\langle nk|\hat{\mu}_0|gg\rangle\} + \sum_{m\neq g} C^A_{mg}\{\langle mg|U_b'|ik\rangle\langle ik|\hat{\mu}_0|gg\rangle \\ & + \langle gg|U_b'|ik\rangle\langle ik|\hat{\mu}_0|mg\rangle\} + \sum_{s\neq k} C^B_{sk}\{\langle gg|U_a'|is\rangle\langle ik|\hat{\mu}_0|gg\rangle \\ & + \langle gg|U_a'|ik\rangle\langle is|\hat{\mu}_0|gg\rangle\} + \sum_{r\neq g} C^B_{rg}\{\langle gr|U_a'|ik\rangle\langle ik|\hat{\mu}_0|gg\rangle + \langle gg|U_a'|ik\rangle\langle ik|\hat{\mu}_0|gr\rangle\}\Big]Q_aQ_b \\ & + \sum'_{(ik)}\sum'_{(jl)} \frac{1}{(E^0_{gg} - E^0_{ik})(E^0_{gg} - E^0_{jl})}\{\langle gg|U_a'|ik\rangle\langle ik|\hat{\mu}_0|jl\rangle\langle jl|U_b'|gg\rangle + \langle gg|U_b'|ik\rangle\langle ik|\hat{\mu}_0|jl\rangle\langle jl|U_a'|gg\rangle\}Q_aQ_b,\end{aligned} \tag{27}$$

where $C^A_{ij} = \langle\phi^{A0}_i|H_a'|\phi^{A0}_j\rangle/(\varepsilon^{A0}_j - \varepsilon^{A0}_i)$; $C^B_{kl} = \langle\phi^{B0}_k|H_b'|\phi^{B0}_l\rangle/(\varepsilon^{B0}_l - \varepsilon^{B0}_k)$; and $|ij> = |\phi^{A0}_i>|\phi^{B0}_j>$. From the second assumption and the facts that the operators, U_a', U_b' and $\hat{\mu}_0$, are sums of the one-electron operators and that the electronic wave functions in the separated molecules are orthonormalized, the integrals on the right-hand side of Eq. (27) are reduced to one-molecule integrals as follows:

$$\left.\begin{aligned}\langle ij|U_a'|kl\rangle &= \langle\phi^{B0}_j|U_a'|\phi^{B0}_l\rangle\delta_{ik}, \\ \langle ij|U_b'|kl\rangle &= \langle\phi^{A0}_i|U_b'|\phi^{A0}_k\rangle\delta_{jl}, \\ \langle ij|\hat{\mu}_0|kl\rangle &= \langle\phi^{A0}_i|\hat{\mu}_0|\phi^{A0}_k\rangle\delta_{jl} + \langle\phi^{B0}_j|\hat{\mu}_0|\phi^{B0}_l\rangle\delta_{ik}.\end{aligned}\right\} \tag{28}$$

Considering Eq. (28) and adopting the approximation that $E^0_{ik}=\varepsilon^{A0}_i+\varepsilon^{B0}_k$, we can divide $\mu_{m,o}(0)$ into two parts:

$$\mu_{m,o}(0) = \{\mu^A_{m,o}(0)+\mu^B_{m,o}(0)\}Q_aQ_b, \tag{29}$$

where

$$\mu^A_{m,o}(0) = 2\Bigg[\sum_{i\neq g}\sum_{j\neq g}\left\{\frac{\langle\psi^{A0}_g|\hat{\mu}_0|\psi^{A0}_i\rangle\langle\psi^{A0}_i|U_b'|\psi^{A0}_j\rangle\langle\psi^{A0}_j|H_a'|\psi^{A0}_g\rangle}{(\varepsilon^{A0}_g-\varepsilon^{A0}_i)(\varepsilon^{A0}_g-\varepsilon^{A0}_j)}+\frac{\langle\psi^{A0}_g|U_b'|\psi^{A0}_i\rangle\langle\psi^{A0}_i|\hat{\mu}_0|\psi^{A0}_j\rangle\langle\psi^{A0}_j|H_a'|\psi^{A0}_g\rangle}{(\varepsilon^{A0}_g-\varepsilon^{A0}_i)(\varepsilon^{A0}_g-\varepsilon^{A0}_j)}\right\}$$
$$+\sum_{\substack{i\neq g\\(i\neq j)}}\sum_{j\neq g}\frac{\langle\psi^{A0}_g|U_b'|\psi^{A0}_i\rangle\langle\psi^{A0}_i|H_a'|\psi^{A0}_j\rangle\langle\psi^{A0}_j|\hat{\mu}_0|\psi^{A0}_g\rangle}{(\varepsilon^{A0}_g-\varepsilon^{A0}_i)(\varepsilon^{A0}_g-\varepsilon^{A0}_j)}-\sum_{i\neq g}\left\{\frac{\langle\psi^{A0}_g|U_b'|\psi^{A0}_g\rangle\langle\psi^{A0}_g|H_a'|\psi^{A0}_i\rangle\langle\psi^{A0}_i|\hat{\mu}_0|\psi^{A0}_g\rangle}{(\varepsilon^{A0}_g-\varepsilon^{A0}_i)^2}\right.$$
$$\left.+\frac{\langle\psi^{A0}_g|U_b'|\psi^{A0}_i\rangle\langle\psi^{A0}_i|H_a'|\psi^{A0}_g\rangle\langle\psi^{A0}_g|\hat{\mu}_0|\psi^{A0}_g\rangle}{(\varepsilon^{A0}_g-\varepsilon^{A0}_i)^2}\right\}\Bigg] \tag{30}$$

$$\mu^B_{m,o}(0) = 2\Bigg[\sum_{k\neq g}\sum_{l\neq g}\left\{\frac{\langle\psi^{B0}_g|\hat{\mu}_0|\psi^{B0}_k\rangle\langle\psi^{B0}_k|U_a'|\psi^{B0}_l\rangle\langle\psi^{B0}_l|H_b'|\psi^{B0}_g\rangle}{(\varepsilon^{B0}_g-\varepsilon^{B0}_k)(\varepsilon^{B0}_g-\varepsilon^{B0}_l)}+\frac{\langle\psi^{B0}_g|U_a'|\psi^{B0}_k\rangle\langle\psi^{B0}_k|\hat{\mu}_0|\psi^{B0}_l\rangle\langle\psi^{B0}_l|H_b'|\psi^{B0}_g\rangle}{(\varepsilon^{B0}_g-\varepsilon^{B0}_k)(\varepsilon^{B0}_g-\varepsilon^{B0}_l)}\right\}$$
$$+\sum_{\substack{k\neq g\\(k\neq l)}}\sum_{l\neq g}\frac{\langle\psi^{B0}_g|U_a'|\psi^{B0}_k\rangle\langle\psi^{B0}_k|H_b'|\psi^{B0}_l\rangle\langle\psi^{B0}_l|\hat{\mu}_0|\psi^{B0}_g\rangle}{(\varepsilon^{B0}_g-\varepsilon^{B0}_k)(\varepsilon^{B0}_g-\varepsilon^{B0}_l)}-\sum_{k\neq g}\left\{\frac{\langle\psi^{B0}_g|U_a'|\psi^{B0}_g\rangle\langle\psi^{B0}_g|H_b'|\psi^{B0}_k\rangle\langle\psi^{B0}_k|\hat{\mu}_0|\psi^{B0}_g\rangle}{(\varepsilon^{B0}_g-\varepsilon^{B0}_k)^2}\right.$$
$$\left.+\frac{\langle\psi^{B0}_g|U_a'|\psi^{B0}_k\rangle\langle\psi^{B0}_k|H_b'|\psi^{B0}_g\rangle\langle\psi^{B0}_g|\hat{\mu}_0|\psi^{B0}_g\rangle}{(\varepsilon^{B0}_g-\varepsilon^{B0}_k)^2}\right\}\Bigg]. \tag{31}$$

$\mu^A_{m,o}(0)$ indicates the contribution of the coupling between the electronic state of the A molecule and the nuclear vibration of the B molecule to the intensity of the simultaneous transition, and $\mu^B_{m,o}(0)$, the coupling between the electronic state of the B molecule and the nuclear vibration of the A molecule.

Methods of Calculations

In order to calculate the transition moment according to the expressions derived in the previous section, the electronic wave function, $|\psi^0_g>$, and the energy, ε^0_g, of the separate molecule in the ground state were obtained by the CNDO/2 method, an approximate elf-consistent molecular orbital theory, proposed by Pople *et al.*[11] The excited states, $|\psi^0_i>$'s, were approximated by the singly-excited configurations, χ^m_i's,[12] and their energies, ε^m_i's, were evaluated from the well-known expression:[13]

$$\varepsilon^m_i = \varepsilon^0_g - e_l + e_m - J_{lm} + 2K_{lm}, \tag{32}$$

where e_l and e_m are the orbital energies of the l-th and the m-th molecular orbitals respectively, and where J_{lm} and K_{lm} are the Coulomb- and exchange-integrals respectively. In this work, the terms including the operator, H''_{ab}, were neglected. The integrals in Eqs. (9)—(11), (30), and (31), *i.e.*, $\langle\psi^0_i|\hat{\mu}_0|\psi^0_j\rangle$, *etc.*, were expanded to the integral terms with the one-electron molecular orbitals and were calculated by the methods in Refs. 14 and 15. The calculations of the absorption intensities with reference to the intermolecular interaction were performed for 20 different arrangements, including variations in the intermolecular distance and in the orientation of the two molecules; the distances were fixed at 4.0, 6.0, 8.0, 15.0, and 30.0 Å, and the four kinds of the orientation shown in Fig. 1 were employed.

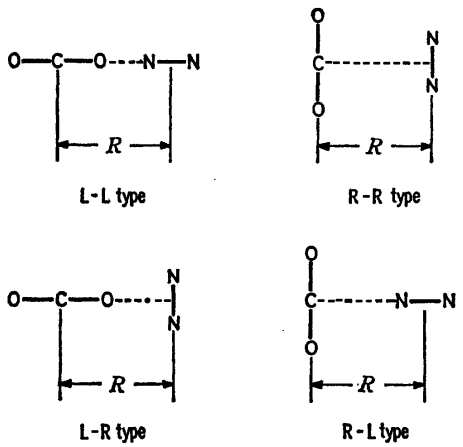

Fig. 1. The orientation of two molecures; R is the intermolecular distance.

Results and Discussion

The results will be discussed for the cases of the simultaneous transitions in the CO_2–N_2 and CO_2–H_2 systems and for the case of the vibrational transition of the CO_2 system, with reference to the intramolecular and intermolecular processes. In the following discussions, the same notations, ν_1, ν_2, and ν_3, for the fundamental bands of CO_2 as those in Ref. 16 are employed, while ν_{N_2} and ν_{H_2} denote the fundamental bands of N_2 and H_2 respectively. The L_x matrices, which are required in calculating the matrix elements of the vibronic coupling operator, were evaluated by the usual **GF** method, the **F** matrix elements in Ref. 16 being employed.

Simultaneous Transition. In the first place, in order to make a brief discussion of the results, the averaged values of the intensities of the simultaneous transition, as calculated for four kinds of orientations at a specified intermolecular distance, were compared with the experimental results. If a certain orientation between molecules should be considered in the compressed system, there will be a problem in the adoption of the averaged values as described above. However, in the level of the approximation used in this work, there was little reason to choose between the four orientations. The variations in the averaged value of the intensities with the intermolecular distance are shown in Figs. 2 and 3 for the CO_2–N_2 and CO_2–H_2 systems respectively. In the experiment with the CO_2–N_2 system,[1] the simultaneous transitions, $\nu_2+\nu_{N_2}$ and $\nu_3+\nu_{N_2}$, are observed, but $\nu_1+\nu_{N_2}$ is not ob-

served. There is difference between the observed and theoretical results with reference to the $\nu_1+\nu_{N_2}$ transition; the calculated intensity of $\nu_1+\nu_{N_2}$ was comparable to that of $\nu_2+\nu_{N_2}$. The difference may be derived from the overestimation in the approximate calculation of the integral which is required in the estimation of the matrix elements of the vibronic coupling operators, and which is connected with the intensities of the $\nu_1+\nu_{N_2}$ and $\nu_3+\nu_{N_2}$ transitions. There is a reason for this. That is, from the comparison between the values of the approximate and rigorous calculations of the integral which contributes to the absorption intensity related to the C–O stretching mode in CO_2, it is found that the difference between those values is remarkably large (see Fig. 4). The

defect in the approximate calculation, however, has no influence on the value of the absorption intensity with reference to the bending mode of a linear molecule, because the scalar product in Eq. (17) in Ref. 15 is always equal to zero.

The theoretical intensities of the simultaneous transitions were calculated from the transition moments, which were divided into two parts, $\mu^A_{m,o}(0)$ and $\mu^B_{m,o}(0)$, as indicated in Eq. (29). In the CO_2–N_2 system, the A part is the transition moment derived from the coupling between the electronic state of CO_2 and the nuclear vibration of N_2, while the B part is that derived from the coupling between the electronic state of N_2 and the nuclear vibration of CO_2. The calculated intensities are listed in Tables 1—3, in which the first line indicates the value from the A part of the transition moment, and the second line, the value from the B part. In the cases of the L-R, R-R, and R-L types of orientation between the molecules, the intensities from the B part were affected by the degenerate bending vibrations, one of which is set on the plane involving the two molecules and the other one of which is set out of the plane; the intensities in the case of the out-of-plane bending vibration were zero. On the other hand, in cases of the other orientations, the intensities from the A and B parts were not affected by the different bending modes. Therefore, the values in Table 2 indicate only the case of the in-plane bending vibration. From the tables, it is found that the contributions of the A and B parts of the transition moment to the absorption intensity caused by the simultaneous transition differ from each other. The A part is effective on the intensities of $\nu_2+\nu_{N_2}$ and $\nu_3+\nu_{N_2}$ at all the orientations. The B part is, however, effective on the intensity of $\nu_2+\nu_{N_2}$ at the L-R and R-L types of orientation and on that of $\nu_3+\nu_{N_2}$ at the L-L and R-R types. The intensity of $\nu_1+\nu_{N_2}$ arises from the restricted parts, the A part at the L-L and L-R types of the orientation, and the

B part at the L-L and R-L types. For the intensities of all the simultaneous transitions, the A part at the L-L type of orientation makes the dominant contribution.

The following general considerations can be derived from these results. On the simultaneous transition of the A–B system, when the vibrational mode of the A molecule is infrared-active, the intermolecular vibronic coupling between the electronic state of the A molecule and the nuclear vibration of the B molecule is always effective. When both the vibrational modes of the molecules, A and B, are infrared-inactive, it does not necessarily follow that a simultaneous transition is not found. Rather, the finding of the phenomenon depends on the orientation of the molecules. Special attention should be paid to the latter conclusion.

These conclusions disagree with those suggested by Hooge and Ketelaar,[3] who discussed the problem on the basis of the expansion of the dipole moment with the normal coordinates. They suggested that the necessary condition for the appearance of a simul-

taneous band is that one of the vibrational modes is infrared-active, while the other mode is Raman-active. The results of the CO_2–H_2 system are analogous to those of the CO_2–N_2 system. Therefore, their discussions are omitted.

Carbon Dioxide: The infrared absorption intensities of CO_2 have been measured by several investigators for the gas[17–19] and solid phases.[20] The calculated values of the intensities, with reference to the intramolecular and intermolecular processes, are shown in Table 4; the experimental results in the gas phase are also included. For the intensities from the intermolecular process, the averaged values are adopted for the same reason as has been presented before. The table shows that the intermolecular interaction contributes slightly to the absorption intensities at the atmospheric pressure and at the intermolecular distance of about 30 Å. Therefore, it is considered that the experimental results at the ordinary pressure correspond to the results caused by the intramolecular process. In the experiment, two fundamental bands, ν_2 and ν_3, with very strong intensities and two combination bands, $\nu_1+\nu_2$ and $\nu_1+\nu_3$, with medium and strong intensities respectively are observed. In the calculated results, the intensity of ν_3 is the strongest, while that of ν_2 is weaker than those of $\nu_1+\nu_2$ and $\nu_1+\nu_3$. From the comparison between the experimental and the calculated results, it is found that the calculated intensity of ν_2 is underestimated and that the theoretical values for the other absorption bands are overestimated. It is considered that these overestimations arise from the defect in the approximate calculation described before. It is noteworthy that the intensity from the intermolecular process increases with a decrease in the intermolecular distance (see Table 4). In any case, it is found that the intermolecular interaction contributes, more or less, to the intensities of the overtone and combination bands, some of which have no intensity from the intramolecular process. These results establish that the intermolecular vibronic coupling is an important factor for the infrared absorption intensity of the compressed gas of a one-component system. Also, the following statement might be made; in discussing the intensity of the vibrational spectra of the liquid phase, it is necessary to include an argument based on the intermolecular vibronic coupling.

Summary

The formulas of the infrared-absorption intensity for the intramolecular and intermolecular processes have been derived by the use of the vibronic expansion technique. The intensities for the simultaneous transitions of the CO_2–N_2 and CO_2–H_2 systems and for CO_2 have been calculated. Since the matrix elements of the vibronic coupling operator were only approximately calculated, quantitative conclusions could not be obtained. The qualitative conclusion is that, for any pair of vibrational modes between molecules, the intensities of the simultaneous transitions are not zero, although their magnitudes depend on the orientation of the molecules and are not always large enough to be observed. One remarkable suggestion is that the intermolecular interaction, like the intramolecular anharmonicities, is an important factor in discussing infrared absorption intensities in liquids and solutions. In that case, the method used in averaging the orientation of molecules will become an essential problem in the treatment of intermolecular interactions.

The authors would like to thank Professor Tomoo Miyazaki for his helpful advice and for his critical reading of the manuscript. In their calculations, they were also helped by "The University Contribution" of UNIVAC Japan, Ltd.

Electronic Spectra of Perylene and Coronene Evaporated Films as a Function of Their Crystallinity

Yusuke KAMURA,* Ichimin SHIROTANI, Koichi OHNO,# Kazuhiko SEKI, and Hiroo INOKUCHI**

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

#College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received August 20, 1975)

The absorption spectra of evaporated thin films of perylene and coronene have been studied as a function of their crystallinity. The amorphous films deposited on a low-temperature substrate *in vacuo* gave rise to "molecular" spectra which are very different from those of the polycrystalline films. The absorption spectra of amorphous films gradually changed with an increase in the substrate temperature to become similar to those of the polycrystalline films.

It has been found that the spectral responses of the evaporated thin films of polycyclic aromatic compounds depend on the temperature of their substrate during vacuum evaporation.[1-6] This behavior has been interpreted as being due to the difference in molecular aggregation in the films; that is, the evaporation of aromatics onto a high-temperature substrate yields oriented polycrystalline films, while evaporation onto a substrate kept at a low temperature gives rise to amorphous ones.

In a previous paper, we have reported[4,5] the absorption spectra and their pressure dependences of naphthacene and pentacene evaporated films. The Davydov splitting of the 0–0 band in their oriented polycrystalline films was found at atmospheric pressure, and the magnitude of this splitting increased with increasing pressure; on the other hand, no Davydov splitting could be observed in amorphous films, and the pressure-induced spectral red shifts were found to be slightly larger than those in the polycrystalline state.

Further, it was found that naphthacene and pentacene in the amorphous state are much more unstable and reactive than in the polycrystalline state under illumination and also under heat treatment in air.[4]

By means of a polarizing microscope, just after the evaporation a very dark image was observed for the naphthacene and pentacene amorphous films with a crossed nicol condition.[3] In a few days, however, several bright microcrystallites appeared in the dark background, their number increasing day by day. The change in the absorption spectrum due to crystallization was not measured because of the interference of a chemical reaction in the film.

In this paper, we will present the results of some studies of the electronic spectra of the perylene and coronene evaporated films as a function of the crystallinity and will also discuss the relation between the electronic states and the structures of the films.

Experimental

Synthesized perylene and synthesized coronene were purified by recrystallization and sublimation. Their thin films were prepared by evaporation onto a quartz substrate kept at room temperature (RT-film) or a low temperature (~170 K) (LT-film) in a vacuum of 10^{-4} Torr. The thickness of the films was monitored by means of a quartz-crystal oscillator and was estimated to be about 6×10^2 Å. The absorption spectra of the films were measured with a Cary 14 spectrophotometer.

The absorption spectra of the RT-film were measured at room temperature. The temperature dependence of the spectra of the LT-film was studied from 170 to 300 K *in vacuo*. The change in the X-ray diffraction patterns and also that in the absorption spectra of LT-films were investigated at room temperature. Further, the structures of these films were studied with a polarizing microscope.

In order to confirm the orientation of molecules in the film, and also in order to assign the absorption spectra, some additional experiments were carried out: the quartz substrate was inclined with respect to the incident light beam so that the transition with their polarization vector perpendicular to the plane of the substrate could be observed in the absorption spectra.

Results and Discussion

Absorption Spectra of Perylene and Coronene LT-films. We have already reported some findings on the absorption spectra of the naphthacene and pentacene evaporated films.[4] The characteristic absorption bands in the RT-film (oriented microcrystalline film) disappear in the LT-film (amorphous film); The absorption spectra in the LT-films resemble those of the corresponding free molecules in solution. Figures 1 and 2 show the absorption spectra of the LT- and RT-films and an ethanol solution for perylene and coronene respectively. The spectra of the LT-films at 170 K were similar to the molecular spectra in solution, but they were very different from those of the RT-films. These findings are similar to those for naphthacene and pentacene.[4]

Figure 3 shows the temperature dependence of the absorption spectra of the coronene LT-film. Its absorption bands gradually changed with an increase in the temperature. The absorption spectrum in the LT-film at room temperature agrees approximately with that of the RT-film. As is shown in Fig. 4, the absorption band of the perylene LT-film at room temperature was not similar to that of the RT-film.

By means of a polarizing microscope, a very dark image was observed for naphthacene and pentacene LT-films at room temperature using crossed nicols. However, in the case of perylene and coronene LT-

films at room temperature, a large number of bright crystallites were found against a dark background, and the number increased with the time.

From these facts we may conclude that the amorphous state in their LT-films undergoes a crystallization process with a change in the temperature and also with time.

Figure 5 shows the X-ray diffraction patterns of the LT- and RT-films of coronene at room temperature. The sharp peaks corresponding to the (00l) plane[7] were found for the RT-film, but no peaks could be observed for the LT-film. Similar results, in Fig. 6, were also found in perylene films.[8] As has been mentioned above, though LT-films at room temperature are partially crystallized, it should be noted that the sharp X-ray diffraction lines could not be found. This may be interpreted as follows: in the annealed films the crystallites are not oriented, and the thickness of the films is not sufficient for diffraction patterns to be observed.

The absorption bands of the naphthacene and pentacene LT-films are gradually changed with the

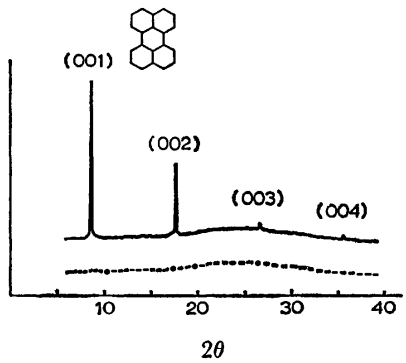

Fig. 6. X-Ray diffraction patterns of perylene evaporated films at room temperature.
——: RT-film, ----: LT-film.

passage of time at room temperature. Although the formation of microcrystals is observed in the LT-films, this spectral change arises mainly from the chemical reaction.[4]

Amorphous films of coronene and perylene, however, were easily annealed. In particular, the rate of the crystallization of amorphous coronene was very rapid. On the other hand, amorphous naphthacene and pentacene crystallized very slowly. These results suggest that the various effects of annealing on the amorphous organic films may be related to the difference in molecular shape.

Molecular Orientation in the Evaporated Films. The absorption spectra of the perylene single crystal has been studied in terms of the Davydov splitting of the exciton states by Tanaka.[9,10] The spectra were observed through the ab plane of the crystal, and the a-axis and b-axis polarization components were resolved. The absorption spectrum was found to be in good agreement with our spectrum of the RT-film when the plane of the substrate was set perpendicular to the incident light beam (Fig. 1). In our oriented microcrystalline film, however, only the bands of the b-axis polarization component could be found at 460 and 440 nm for the first electronic transition band between 400—500 nm. This is reasonable, since the b-axis polarization component in this spectral region is much larger than the a-axis one in the single crystal ab-plane spectra obtained by Tanaka. It has been shown that the first electronic transition band has its polarization vector along the long axis (L-axis) of the molecule.[9,10] As may be seen from Fig. 7,[8] the L-axis is almost perpendicular to the ab plane, whereas the short molecular axis (M-axis) is nearly parallel to the ab plane. Therefore, the L-axis polarized transitions in the crystals can be expected to be of a much reduced intensity in the ab-plane spectra in comparison with those observed for the LT-film and the solution. In fact, this can be seen from Fig. 1, where the 250—260 nm bands have been assigned as an M-axis transition;[9,10] therefore, they are considered to be slightly emphasized in the spectrum of the RT-film. The weakened L-axis transition bands, however, may be expected to appear when the ab planes of the single crystal on the oriented microcrystals are inclined nearly parallel to the direction of the

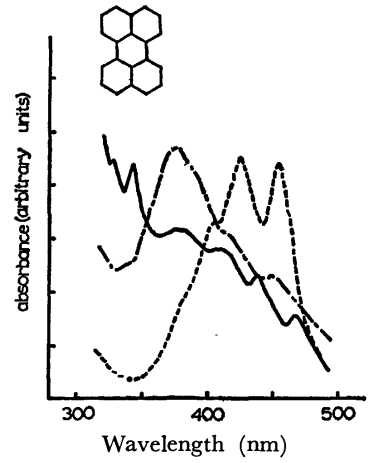

Fig. 8. Absorption spectra of perylene evaporated films.
——: Incident light with respect to the normal of the substrate is perpendicular, ——: incident light with respect to the normal of the substrate is set about 75°, ----: LT-film.

incident-light beam. An additional experiment for the RT-film of perylene, where the angle of the incident light with respect to the normal of the substrate was set at about 75° (Fig. 8), clearly revealed the ac polarization component of the exciton states, which should be much more polarized along the crystal c'-axis normal to the ab plane. The peaks at 405 and 445 nm observed in this spectrum were found to be in good agreement with those observed in the c-axis polarization component of the ab-plane crystal spectra. From the arguments given above, one can conclude that the perylene RT-film should be regarded as oriented microcrystalline films in which the crystallites are oriented with their ab planes parallel to the substrate planes. This is consistent with the orientation of the crystallites determined by X-ray diffraction in the previous subsection.

The spectral behavior of the evaporated films of coronene is very similar to that found for perylene. The absorption spectrum of the LT-film is shown in Fig. 2; it is found to agree well with the solution spectra. The most prominent band at about 300 nm in this spectrum of the LT-film may be assigned to a $^1A_{1g} \rightarrow {}^1E_{1u}$ transition, as in the case of the analogue in the solution spectra.[11] The absorption spectrum of the coronene RT-film, when the incident light beam was

set perpendicular to the substrate, was found to be in good agreement with the ab-plane absorption spectra of the single crystals obtained by Tanaka.[11] His analysis showed that the bands between 280 and 320 nm could be assigned in terms of the Davydov splitting of the exciton states arising from a $^1E_{1u}$ state of the molecule. From our additional experiment, the band at 290 nm in the RT-film spectra increases in intensity on a decrease in the incident light angle with respect to the normal of the substrate: 0°, 45°, and 60° (Fig. 9), in this order. One can therefore assign the band at 290 nm to one of the ac polarization components of the exciton states arising from the $^1E_{1u}$ state, which should be much more polarized along the crystal c'-axis normal to the ab plane. This assignment of the 290 nm band is consistent with that made by Tanaka.[11] From the assignments given above, we can also conclude, for the coronene evaporated films, that the LT-film should be regarded as an amorphous film in which the orientation of the molecules is disordered, and that the RT-film is composed of a large number of crystals oriented with their ab planes parallel to the substrate.

Fluorescence Spectra of Perylene and Coronene Evaporated Films. Figure 10 shows the temperature dependence of the fluorescence spectra of the perylene RT- and LT-films. The fluorescence spectra of RT-film were similar to those of the α-type of perylene single crystal.[9] A broad emission band was observed in both films at room temperature. Judging from the results of the fluorescence of the perylene crystal,[9] the broad emission may arise from the excimer emission. This emission in the RT-film disappeared at the temperature of liquid nitrogen, where a monomer-like emission was observed. On the other hand, the excimer emission appeared in the LT-film at 77 K. This shows that the short-range molecular interaction in the amorphous state is rather stronger than that in the crystalline state. In a previous paper,[5] we have reported the pressure shift of the vibronic band in organic films; the pressure-induced spectral shifts in the amorphous state are slightly larger than those in the crystalline state. On the basis of the results of the emission spectra and the pressure shift, we may conclude that the intermolecular interactions in organic amorphous films are never weak in comparison with those in crystalline films. Figure 11 shows the temperature dependence of the fluorescence spectra of the coronene RT- and LT-films. Both the RT- and the LT-films of coronene showed an excimer-type emission at room temperature. However, at very low temperatures the excimer-type emission band could not be found in the fluorescence spectrum of the RT-film. In contrast, the LT-film showed an excimer-type emission at any temperature between room temperature and 4.2 K. It may, therefore, be suggested that, in the LT-film, the excited dimer state is rather more favorable than in the RT-film, where the emission spectrum may be affected by energy transfer through the exciton states.

Crystallization Processes in the Disordered Aggregates by Annealing. As has been mentioned in the previous subsections, the LT-films of coronene and

perylene undergo some annealing processes at room temperature, while for naphthacene and pentacene the LT-films are considered to be in amorphous states when they are left at room temperature for a few days. The absorption spectrum of the annealed LT-film coronene became very similar to that of the RT-film (Fig. 3). In connection with the results in the previous subsection, this may lead us to conclude that the annealed LT-film of coronene is in a microcrystalline state. Whether the annealed LT-film is oriented or not may be ascertained as follows. Since the absorption peaks in the spectrum of the annealed LT-film agree well with those of the RT-film and also with those of single crystals, the crystallites in the annealed LT-film may be considered as single crystals in which the arrangement and orientation of coronene molecules are almost perfect. Therefore, the diffuse X-ray diffraction pattern observed for the annealed LT-film may not be accounted for a disorder of the molecular orientation and arrangement in the microcrystals. As can be seen from Fig. 3, the 290 nm band for the annealed LT-film is slightly more intense than that for the RT-film. Furthermore, the spectra of the annealed LT-film were found to be independent of the incident-light angle. These facts indicate that the orientation of the crystallites is almost at random in the annealed LT-film. This may be the reason why the X-ray diffraction pattern was found to be still diffuse for the annealed LT-film.

The absorption spectrum of the annealed LT-film of perylene is shown in Fig. 4, together with those of the LT-film and the RT-film. For perylene, the absorption spectrum of the annealed LT-film did not become similar to that of the RT-film, but remained rather similar to that of the LT-film. The spectral peaks found in the L-axis transition bands for the annealed LT-film correspond well to those of the LT-film. The spectral intensities for these bands, however, were weakened in the annealed LT-film. These facts mean that the molecular orientation in the crystallites found through the microscope for the annealed LT-film is disordered to some extent and that the L-axis of the perylene molecules in the annealed LT-film is slightly oriented on average perpendicular to the plane of the substrate. Furthermore, the M-axis transition band at 250 nm for the annealed LT-film is found to be more intense than that observed for the LT-film; the M-axes of the perylene molecules in the annealed LT-film may also be slightly oriented on average parallel to the plane of the substrate. Since, for the annealed LT-film, crystallites were actually observed with a microscope, the molecules in the crystallites may be arranged in a way similar to that of the perfect crystals, especially for such a large disc-like-shaped planar molecule as perylene. One may, therefore, suggest that the annealed LT-film of perylene is composed of imperfect crystallites in which the orientation of the molecules within the molecular plane is disordered to some extent.

The various effects of annealing at room temperature on the LT-films may be related to the difference in their molecular shape. As was seen in the previous subsection, the fluorescence spectra of the LT-films and also of the annealed LT-films of perylene and coronene were found to be of the excimer type. This means that the molecules in the films are stacked in a similar way, with their planes parallel to one another. In the perfect crystals the molecules are regularly stacked. If such a stacking structure is well distributed in the LT-films of coronene and perylene, the rate-determining step lies in the molecular re-orientation within the crystal lattice. On the basis of this assumption the behavior of the annealed LT-films of coronene and perylene can be explained as follows. Since a coronene molecule has an almost disc-like shape, rotational motion along the normal-axis of the molecular plane may proceed in the aggregates without any serious change in the arrangements of the neighboring molecules; it follows that the LT-film of coronene may be almost perfectly annealed into a microcrystalline film. Since the perylene molecule is not so perfect in disc shape as coronene, rotational motion occurs less readily and may result in the imperfect crystal growth found in the annealed LT-film. On the other hand, for long-plate-like molecules, for example, naphthacene and pentacene, such a rotational motion may be inhibited because the re-orientation of the molecular axes should be quite difficult without the exclusion of neighboring molecules. One can, therefore, understand that the properties of the LT-films of naphthacene and pentacene are retained even if the films are left at room temperature for a few days.

The authors wish to thank Professor Satoshi Iwashima for his gift of the chemicals and Mr. Mikio Yagi for the measurements of the fluorescence spectra. Their thanks are also due to Dr. Yusei Maruyama for his helpful discussion.

Kinetic Studies of the Crystallization of Vitreous Beryllium Fluoride

Seiichi TAMURA and Toshio YOKOKAWA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 1, 1975)

The kinetics of the crystallization of vitreous beryllium fluoride were studied using the quantitative X-ray diffraction and calorimetric methods. Analysis of the data using the Johnson-Mehl-Avrami equation shows that the crystallization proceeds through spherulitic growth. The activation energy of 222 kJ mol^{-1} was obtained from the temperature dependence of the crystallization rate using a modified Johnson-Mehl-Avrami equation.

Investigations of the crystallization of beryllium fluoride from various fluoroberyllate glasses have been reported by many workers. However, no quantitative analysis of the crystallization of the pure vitreous beryllium fluoride has been performed. Several years ago, Batsanova *et al.* made a rough estimate of the rate of crystallization of pure vitreous beryllium fluoride at three temperatures.[1] The crystallization data, however, could not be analyzed because the data were very scarce; their main objective was to study the structure of the glasses.

Recently, enthalpy increments of the crystalline, liquid, and vitreous beryllium fluoride were measured between 456 and 1083 K by the normal drop method and by the transposed-temperature drop method in our laboratory.[2,3] In the transposed-temperature drop calorimetry, it was observed that the vitreous phase turned into the crystalline phase between 623 and 800 K. Qualitatively, the rate of crystallization at about 730 K was faster than those below and above that temperature. We measured the rate of crystallization by a calorimetric method using the enthalpy data as well as an X-ray diffraction method, and studied the kinetics of crystallization in detail using the Johnson-Mehl-Avrami equation.

Experimental

Materials. The beryllium fluoride used for this study was prepared from a commercial beryllium fluoride (Mitsuwa Kagaku Co., Ltd.) which was approximately 99.5 moles per cent pure. The sample was further purified by vacuum distillation at about 1070 K. Beryllium fluoride vapor was condensed onto the inner wall of a platinum crucible of about 800 K. Further analysis was not carried out for the purified beryllium fluoride. The vitreous sample was prepared by heating the sample in a sealed platinum container at 903 K and by then dropping it into the silver crucible at room temperature for rapid cooling. These vitreous samples were then submitted to the X-ray diffraction method and the calorimetric measurements.

Calorimetric Method. The calorimeter used for this study was a high-temperature calorimeter of the Calvet type which has been described previously.[4] The assembly of the apparatus is identical to that used previously in the normal drop method. However, the calorimeter was maintained at 730 or 760 K, and coarse silver powder was used instead of liquid mercury to aid heat conduction in the calorimeter cells. Although the electric furnace above the calorimeter had two different constant-temperature zones, only one of them was used for the present study. The vitreous sample (1.5 to 2.5 g) was loaded into a platinum container 8 mm in diameter, 45 mm in height, and 0.2 mm thick (2 to 2.5 g) and the top of the container was sealed by arc-welding in a glove box filled with nitrogen. The method of the quantitative determination of crystallization by the calorimeter is as follows. First, a vitreous sample of n moles is inserted into the furnace and maintained at a certain temperature, T_1, for the time t and then partially crystallized by the mole fraction, X. Then the sample is dropped into the calorimeter at another temperature, T_0, and crystallized completely in it. In this case, the measured heat, Q, contains both enthalpy increments, $\{H(T_1)-H(T_0)\}$, and the heat of crystallization,

$$\{H(\mathrm{gl},\ T_0)-H(\mathrm{c},\ T_0)\};$$

$$Q = nX\{H(\mathrm{c},\ T_1)-H(\mathrm{c},\ T_0)\}+n(1-X)\{H(\mathrm{gl},\ T_1)-H(\mathrm{gl},\ T_0)\}+n(1-X)\{H(\mathrm{gl},\ T_0)-H(\mathrm{c},\ T_0)\} \quad (1)$$

This equation can be rewritten in this form;

$$X = \frac{\{H(\mathrm{gl},\ T_1)-H(\mathrm{gl},\ T_0)\}+\{H(\mathrm{gl},\ T_0)-H(\mathrm{c},\ T_0)\}-Q/n}{\{H(\mathrm{gl},\ T_1)-H(\mathrm{gl},\ T_0)\}+\{H(\mathrm{gl},\ T_0)-H(\mathrm{c},\ T_0)\}-\{H(\mathrm{c},\ T_1)-H(\mathrm{c},\ T_0)\}} \quad (2)$$

Thus, the mole fraction of the crystalline phase, X, can be determined by means of the measured heat, Q, and the enthalpy data obtained previously. The temperatures used for measuring the crystallization rate ranged from 626 to 821 K.

X-Ray Diffraction Method. The further quantitative determination of the crystallization was done by means of X-ray diffraction analysis, using the powder method. Use was made of a Tokyo Shibaura Electric ADG-102 or ADG-301 diffractometer furnished with a fine focus copper tube, a nickel filter, and a SU-021E or SU-321 high-temperature sample holder attached to a goniometer, GD-2 or GD-3. The vitreous sample was grounded to 200 mesh in an agate mortar. Then the powder sample (0.1 g) was pressed on a platinum plate under a pressure of 8 MPa. The platinum plate with the sample was put on the heater in a high-temperature sample holder. Before heating, the sample was evacuated at 373 K for a day to evaporate the adsorbed water. Then the sample was heated at various constant temperatures. It took 5 min for the sample to attain thermal equilibrium in each heating. The integrated intensity of the strongest diffraction peak (101) at 27.5 degrees in 2θ was counted every two minutes. After these measurements, the sample was rapidly cooled to room temperature and then again heated at 730 K (optimum temperature of crystallization) for one hour in order to crystallize it completely. Then the sample was brought to the original temperature, and the intensity of the diffraction peak of this 100-per-cent-crystallized sample was counted in order to confirm the normalization. During these processes, the sample on the platinum plate was left as it had been in the high-temperature sample holder *in vacuo*. Mechanical mix-

tures of vitreous and crystalline powder of various compositions were prepared for the calibration experiment. The intensity of diffraction was proportional to the composition of the crystalline part within ±5 per cent. The temperatures for measurement ranged from 630 to 750 K.

Results and Discussion

The volume fraction of the crystallized part obtained by both the X-ray diffraction and calorimetric methods is shown at various temperatures as functions of the time in Fig. 1. The crystallization starts almost without induction time at each temperature and proceeds rapidly up to the 0.9-volume fraction, after which it proceeds very slowly. Although the temperature range covered is different in each method, the crystallization rate shows a maximum around 720 K and decays both below and above that temperature. The temperature ranges which the two experiments covered were different because (1) the calorimetry mainly covered higher-temperature ranges, since the scatter of the data is large at low temperatures, and so the time consumption for every experimental point became formidable and (2) the X-ray diffraction method covered low-temperature ranges since, because of the temperature inertia of the sample furnace, the crystallization during the heating period (especially around 720 K with a maximum crystallization rate) was too much to be neglected compared with that in time

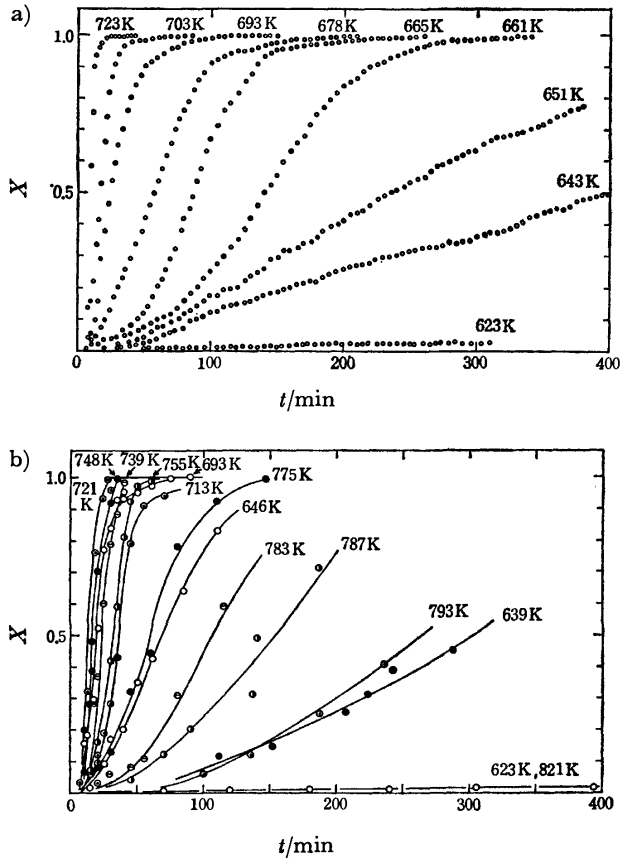

Fig. 1. a) Variation of crystallinity with time by the X-ray diffraction.
b) Variation of crystallinity with time by the calorimetric method.

intervals at the aimed-for temperature higher than 720 K.

The Johnson-Mehl-Avrami (J-M-A) equation has been developed to describe the kinetics of processes where nucleation and growth occur together.[5,6] Application of the J-M-A expression enables one to predict the volume fraction of a new phase that will form as a function of time, if suitable information about the nucleation and growth rates is available or if they can be assumed:

$$X = 1 - \exp\left\{-\int_{t'=0}^{t'=t} gIG^n(t-t')^n \mathrm{d}t'\right\} \quad (3)$$

Eq. (3) is the general form of the J-M-A equation: g is a shape factor; I, the nucleation rate; G, the growth rate; t', the time at which a given particle is nucleated; n, an integer which depends on the dimensionality of the growth mechanism, and X, the volume fraction of the new phase. In deriving this equation, the growth rate was assumed to be independent of the time. Eq. (3) may be integrated only by making specific assumptions about the variation in I with the time. If I is assumed to be independent of the time, Eq. (4) is obtained by integrating Eq. (3):

$$X = 1 - \exp\{-gIG^n t^{n+1}/(n+1)\} \quad (4)$$

If the nucleation rate, I, is assumed to be a rapidly decreasing function of the time—if, that is, the nucleation is completed at an early stage in the reaction, I may be replaced by the number of nuclei, N_0;

$$X = 1 - \exp(-gN_0G^n t^n/n) \quad (5)$$

For the present system, the latter assumption seems to be suitable since it has been found in our laboratory that, even at the same temperature, the crystallization rate of the "quenched glass," which has been quenched to room temperature before it is brought to the growth temperature, is very much greater than that of the "non-quenched glass" prepared by cooling a molten sample directly to the temperature of the growth experiment. This implies that the numbers of nuclei in the unit volumes of both the glasses are quite different at the beginning of the reaction. Thus, the nucleation in the quenched glass seems to have finished in an early stage of the reaction. Leadbetter and Whycherley also observed that the quenched glass of beryllium fluoride contained a number of small bubbles lined with a white powder which was identified with the quartz form of beryllium fluoride by means of X-ray diffraction.[7] When gN_0G^n/n in Eq. (5) is set equal to k_c, defined as a crystallization rate constant, one obtains Eq. (6), which is the same form as the so-called Kolmogorow-Avrami equation:[8]

$$X = 1 - \exp(-k_c t^n) \quad (6)$$

By taking the double logarithm of both sides of Eq. (6), one gets the following equation:

$$\ln\ln\left(\frac{1}{1-X}\right) = n\ln t + \ln k_c \quad (7)$$

If the left-hand side of Eq. (7) is plotted against $\ln t$, one may know the growth morphology of the transforming phase from the slope of the line, n. The curves

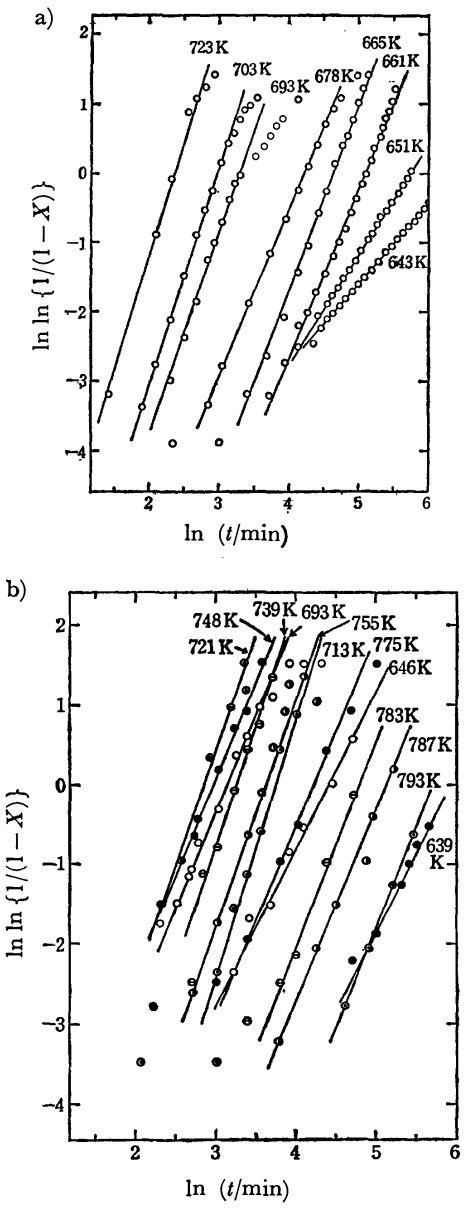

Fig. 2. a) Variation of ln ln $(1/(1-X))$ with ln t by the X-ray diffraction.
b) Variation of ln ln $(1/(1-X))$ with ln t by the calorimetric method.

are shown in Fig. 2. The values of the initial slopes of the curves before impingement occurs are presented in Table 1. Within the limits of experimental error, the values for the sample above 660 K are approximately 3, as is to be expected if the crystal growth during these periods is spherulitic in nature and if all the nuclei have been constituted at the beginning of the transformation. Below 660 K, the values of the slopes of the lines decrease to 2 or 1. Therefore, the growth mechanisms seem to be different from each other above and below this temperature, although much more information will be necessary before any conclusion can be drawn. A phenomenon similar to this was observed in the crystallization study of vitreous selenium.[9] Crystallization study by means of an electron micrograph or a photomicrograph is desirable to determine the more exact growth morphology of vitreous beryllium fluoride.

646	1.9	69
639	2.1	304

The crystallization rate constant was determined from the plots of Eq. (7) using the values of n and $t_{X=0.5}$, which is referred to the time of $X=0.5$. As has been mentioned above, k_c was defined as gN_0G^n/n. Therefore,

$$\ln k_c(T) = \ln (gN_0(T)/n) + n \ln G(T) \tag{8}$$

As Strnad and Douglas noticed, it is implicitly assumed that the nuclei formed during the low-temperature treatment are not redissolved on heating to the growth temperature and, further, that the growth temperature must be chosen so that the nucleation rate at the growth temperature is negligible.[10] Thus,

$$N_0(T) = \text{constant.}$$

Then, as the first term on the right-hand side of Eq. (8) is independent of the temperature, one gets Eq. (9) when the temperature of 693 K is taken as the standard temperature:

$$\ln G'_{exp}(T) \equiv \ln \{G(T)/G(693\text{ K})\} = 1/n \ln\{k_c(T)/k_c(693\text{ K})\} \tag{9}$$

where $G'_{exp}(T)$ is defined as the relative growth rate. The logarithm of $G'_{exp}(T)$ is plotted against $1/T$ in Fig. 3.

On the other hand, Hillig and Turnbull proposed a semi-empirical equation for the growth rate.[11] Further, Ainslie *et al.* reduced this equation to Eq. (10) for vitreous silica using the Stokes-Einstein relation and other simple approximations:[12]

$$G(T) = f\Delta h(T_m - T)/(3\pi a_0^2 \eta T_m) \tag{10}$$

where f is the fraction of crystal surface sites to which

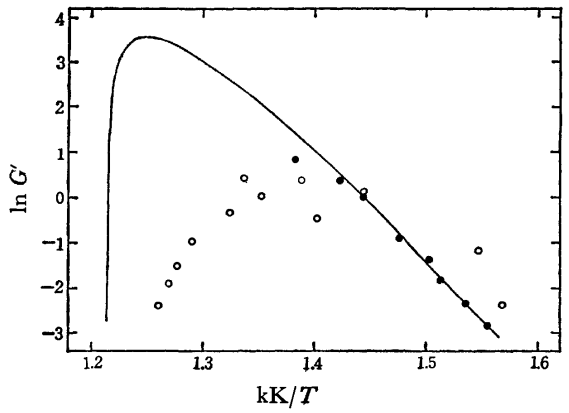

Fig. 3. Temperature dependence of relative growth rate.

molecules can be attached in the growth process, Δh is the heat of fusion per molecule, T_m is the melting temperature, a_0 is the jump distance, and η is the viscosity. As a matter of fact, Wagstaff found from his experimental data for vitreous silica that the crystal-growth rate could be represented by an equation of the same type as Eq. (10).[13] This temperature dependence of the growth rate can be applied to vitreous beryllium fluoride since it is very similar to vitreous silica in structure and in thermodynamic properties, especially the entropy of fusion. The viscosity of beryllium fluoride was measured over 10 orders of magnitude; it was found that it could be represented by an Arrhenius-type equation.[14,15] Using this temperature equation for η in Eq. (10), one obtains the relative growth rate, $G'_{theor}(T)$:

$$\ln G'_{theor}(T) \equiv \ln\{G(T)/G(693\ \mathrm{K})\} = -Q_\eta'/RT + \ln(T_m - T) + 35.074 \qquad (11)$$

where R is the gas constant and where Q_η is the activation energy for the viscous flow, 230±12 kJ mol^{-1}.[15] The logarithm of $G'_{theor}(T)$ is also shown in Fig. 3. The two curves are consistent in the points that both have a maximum and behave similarly at both ends (especially at the lower temperatures). However, the temperature of the maximum is different by about 80 K and the behavior of decreasing after the maximum is dissimilar on the high-temperature side. Considering the consistency of the low-temperature side, it seems reasonable that the discrepancy cited above is attributable to the assumption of a constant N_0. It is interesting to note that the discrepancy can be eliminated if the nuclei partly redissolve on heating above 720 K and that the ratio of the number of the nuclei diminished to 10^{-1}, 10^{-3} and 10^{-6} at 730 K, 760 K, and 795 K respectively compared with that of 693 K.

Further, if the temperature dependence of the growth rate reported by Ainslie *et al.*, Eq. (10), is substituted into Eq. (5), one gets:

$$X = 1 - \exp\{(-gN_0t^n/n)[A(T_m - T)\exp(-Q_\eta/RT)]^n\} \qquad (12)$$

where A is equal to $f\Delta h/(3\pi a_0^2 T_m C)$; here C is a pre-

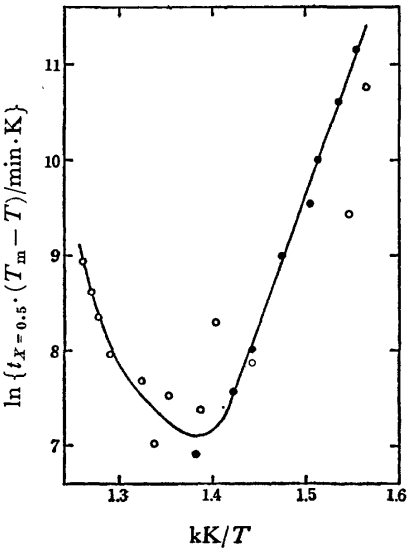

Fig. 4. Temperature dependence of $\ln\{(T_m - T)\cdot t_{X=0.5}\}$.
○: By calorimetric method, ●: by X-ray diffraction.

exponential factor in the viscosity expression. At a constant degree of crystallization, α, one obtains Eq. (13) by rearranging the terms of Eq. (12) and by taking the logarithms of both sides:

$$\ln\{t_{X=\alpha}\cdot(T_m - T)\} = Q_\eta/RT - \frac{\ln(A^n N_0 g/n)/\ln\left(\frac{1}{1-\alpha}\right)}{n} \qquad (13)$$

If the logarithm of the temperature difference, $(T_m - T)$, multiplied by the time needed to form a given volume fraction of the crystalline phase is plotted against $1/T$, when $N_0(T)$ is independent of the temperature, a straight line should be obtained with a slope of Q_η/R. The logarithm, $\ln\{t_{X=0.5}(T_m - T)\}$, is plotted as a function of $1/T$ in Fig. 4. We thus obtained, instead of a straight line, a curve which has a minimum value at about 720 K. However, a linearity holds true below 720 K. The activation energy for the viscous flow is evaluated from the slope of the straight line. The activation energies were obtained also when the temperature dependence of the times of X=0.4 and the 0.6-volume fraction were analyzed. The activation energy was estimated to be 222±4 kJ mol^{-1} as the mean value from the slopes of the lines of X=0.4, 0.5 and 0.6. This value is in excellent agreement with that obtained by the viscosity measurement, 230±12 kJ mol^{-1}. Above 720 K, depending on the crystallization temperature, some of the nuclei seem to redissolve on heating and seem not to contribute to the growth. This will correspond to the "deactivation of the crystallization centers" described in Dzhalilov's paper.[9]

Photoelectron Ejection and Fluorescence from Molecular "Rydberg" States in Polar Solvents

Yoshihiro NAKATO, Akihiro NAKANE,* and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received October 6, 1975)

Absorption and fluorescence spectra and photo-current yield curves of tetraaminoethylenes are studied. The UV absorption of these compounds is mostly attributable to the transitions from the ground state to the "vertical" Rydberg-like and ionized states. Their spectral shapes in ether and in pentane are nearly coincident with each other, showing that these states just after excitation are little affected by the solvent polarity. Based on this result and the results of photo-current measurements, the spontaneous formation of free, solvated electrons from the "vertical" Rydberg-like states in polar solvents has been verified. It is also found that the maximum wave numbers, the lifetimes and the yields of the fluorescence from the lowest "relaxed" Rydberg-like state depend strongly on solvent polarity, temperature and rigidity. These results are explained by taking account of the competition between electron ejection and relaxation processes and of the presence of a non-fluorescent, solvated cation-electron pair. The photo-electron ejection from other organic molecules in polar solvents reported before is shown to be explained by the same scheme as presented here.

So far, several different mechanisms on the electron ejection from organic molecules into polar solvents under illumination in the near ultraviolet region have been proposed, as reviewed previously.[1,2] This rather conflicting situation seems to arise mainly from the change of the ionization threshold with solvent polarity, causing varied degree of solvation for the ejected electron and parent cation.

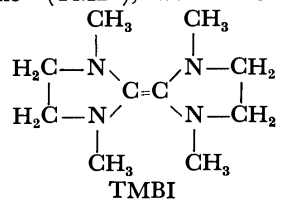
The solvated cation-electron pair was proposed by some authors as a long-lived intermediate state caused by excitation in order to explain the appearance of the absorption spectra assigned to the cation not contributing to the photo-current.[1,3-5] Such a state is of great interest, but more experimental knowledge seems necessary for defining it clearly.

Recently, we reported the absorption spectra of some molecules assigned to transitions to Rydberg-like and ionized states in organic solvents.[2,6,7] From the measurements of photo-currents and absorption spectra, it was suggested that a spontaneous formation of the solvated electron from the Rydberg-like states occurred in polar solvents, competing with the relaxation to the lower excited states.[2] It was also found that the energy and yield of the fluorescence, conceivably originating from the lowest Rydberg-like state, decreased with increasing solvent polarity.[2,8]

In the present paper, we will report the results of our detailed studies on the photo-electron ejection and the Rydberg-like states of tetraaminoethylenes in polar solvents.

Experimental

The preparation and handling of tetrakis(dimethylamino)-ethylene (TMAE), and 1,1',3,3'-tetramethyl-2,2'-bi-imidazolidinylidene (TMBI), were described previously.[6]



TMBI

* Present Address: Toray Industries Inc., Plastic Application Technology Dept., 9-1 Ooe-cho, Minato-ku, Nagoya 455-91, Japan.

Purification of solvents was made in a similar way as described elsewhere.[2,6] These solvents, especially the polar ones, were carefully dried with Na-K alloy in evacuated ampoules.

Absorption spectra were measured with a Cary Model 15 spectrophotometer. Fluorescence and its excitation spectra were measured with an Aminco-Bowman spectrophotofluorimeter, which was calibrated at Prof. Mataga's laboratory to obtain the correct fluorescence quantum spectrum by use of a standard lamp. The spectral distribution of the excitation light intensity of this apparatus was also obtained by the actinometry using the fluorescence of a concentrated Rhodamin B solution. Steady-state photo-currents were measured by using a quartz cell equipped with two parallel electrodes.[2] The temperatures of the sample solutions were controlled by putting the cell in a quartz Dewar containing isopentane cooled with nitrogen gas.

The fluorescence lifetime was measured with a nitrogen gas laser (λ 337.1 nm) as an exciting light source, having the duration of about 5 ns and a repetition frequency of *ca.* 50 Hz. The fluorescence decay was recorded by a photomultiplier, a sampling oscilloscope and an X-Y recorder.

Results

The absorption spectra of TMBI observed in pentane and diethyl ether are shown in Fig. 1. The absorption spectra, the photo-current yield curves and the fluorescence excitation spectra of TMAE in ether and hydrocarbons are shown in Fig. 2. The photo-

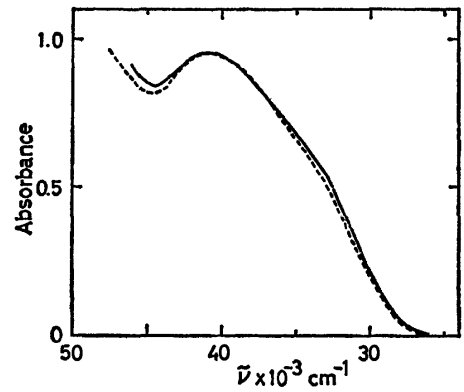


Fig. 1. The absorption spectra of TMBI in ether (----) and in pentane (——).

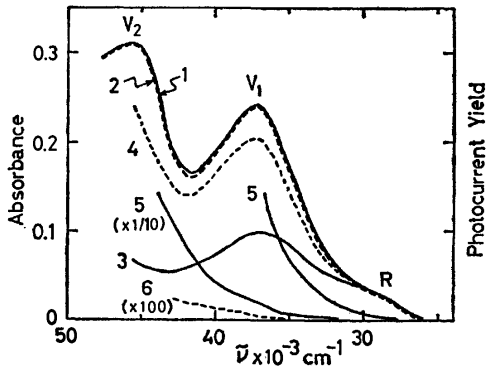

Fig. 2. The absorption spectra, the photo-current yield curves and the fluorescence excitation spectra of TMAE. Curve 1: The absorption spectrum in ether. Curve 2: That in pentane. Curve 3: The fluorescence excitation spectrum in ether. Curve 4: That in 3-methylpentane. Curve 5: The photo-current yield curve in ether. Curve 6: That in pentane. The fluorescence excitation spectra both in ether and in 3-methylpentane are adjusted so as to make their strengths agree with those of the corresponding absorption spectra in the lower energy region.

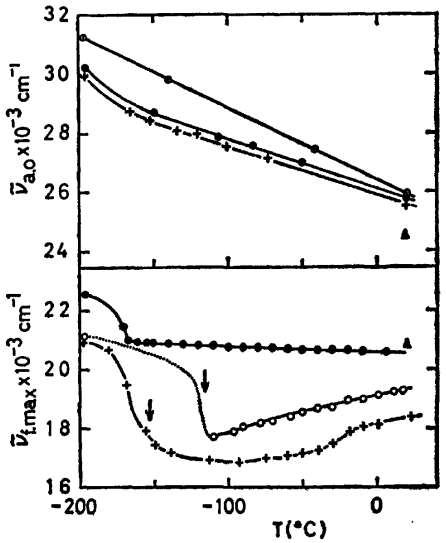

Fig. 3. The temperature dependence of the onset of the absorption band ($\tilde{\nu}_{ao}$) and the fluorescence maximum ($\tilde{\nu}_{f,max}$) of TMAE: (●) in 3-methylpentane, (○) ether, (+) 2-methyltetrahydrofuran (2-MTHF), (▲) the gas phase. The temperature dependence of the wave number of the absorption onset of TMBI in 3-methylpentane (⊙) is also included.[7] Arrows show the solidifying point of the solvent (the melting point in the case of ether and the temperature at which the dielectric constant abruptly changes in the case of 2-MTHF[13b]). Dotted lines are drawn by conjecture so that the temperature dependences of $\tilde{\nu}_{f,max}$, τ_f and ϕ_f^{rel} in Figs. 3 and 4 will be in harmony with each other in each solvent.

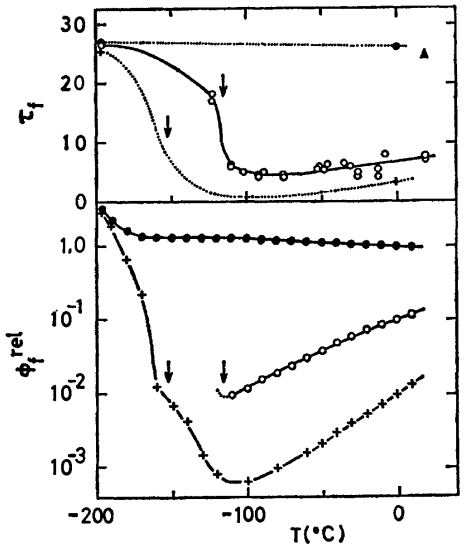

Fig. 4. The temperature dependence of the fluorescence lifetime (τ_f, in ns) and the relative fluorescence yield (ϕ_f^{rel}) of TMAE: (●) in 3-methylpentane, (○) ether, (+) 2-methyltetrahydrofuran, (▲) the gas phase. The wave number of excitation light is 30.3 kK for measurements of ϕ_f^{rel}, and 29.7 kK for τ_f. ϕ_f^{rel} is corrected for the change of the absorption intensity at 30.3 kK with temperature. The meanings of arrows and dotted lines are the same as those in Fig. 3.

current yield in the present work means $(\varepsilon \cdot i)/(I_0-I)$ in a relative scale,[9] where ε, i and (I_0-I) are the molar extinction coefficient, the steady-state photo-current and the light intensity absorbed by the sample solution, respectively.[10] The absolute photo-ionization yield in ether is about 0.9×10^{-5} electrons per absorbed photon at 29.4 kK ($\times10^3$ cm^{-1}) and that in pentane is about 1.6×10^{-7} at 40 kK.

Figure 3 shows the solvent and temperature dependences of the onset of the absorption spectrum and the fluorescence maximum of TMAE, and Fig. 4 shows those of the fluorescence lifetime and the relative yield. The absorption bands in polar solvents do not change much from those in nonpolar solvents. Both are gradually blue-shifted with decreasing temperature, while the fluorescence wave numbers, lifetimes and yields in polar solvents are quite different from those in nonpolar solvents. They show monotone decrease down to about −100 °C and abrupt increase below that due to solidification of these solvents.

The fluorescence of TMAE was quenched by atmospheric oxygen. When air was introduced into evacuated sample cells, the fluorescence intensity decreased instantaneously but the absorption intensity remained nearly the same at least for about ten minutes. The rate constant of the quenching reaction, calculated from the fluorescence lifetime, 7 ns, and an oxygen concentration, 4×10^{-3} M, is 1.9×10^{10} M^{-1} s^{-1}, the same order of magnitude as that for a diffusion-limited reaction.

Discussion

As reported previously,[6,7] the absorption spectrum of TMBI in the wave number region lower than 45 kK is assigned to the transitions to the Rydberg-like and ionized states. The transition to the lowest (π-π^*)-

type excited state of TMBI appears as the steeply rising absorption beginning at 45 kK. The close agreement of the spectra in pentane and ether (Fig. 1) shows that the Rydberg-like and ionized states just after the vertical excitations are little affected by the solvent polarity. This fact can also be regarded as a proof of the existence of "dry" electrons in polar solvents, first proposed by Hamill.[11]

In the absorption spectra of TMAE (Fig. 2), only the transitions to the lower Rydberg-like states appear as a shoulder (denoted by R in Fig. 2) and those to the higher Rydberg-like states and to the ionized state are hidden by the strong (π-π^*)-type absorption bands (denoted by V_1 and V_2).[2,6] However, the overall absorption spectrum in ether is identical with that in pentane.

Quite contrary, the photo-current yield curve and the fluorescence excitation spectrum in ether are much different from those in hydrocarbons (Fig. 2). Based on the above argument, this can be attributed to the relaxation processes from the vertical or Franck-Condon states, leading to different solvation states with solvent polarity.

Various relaxation processes expected for the ether solution are given in Fig. 5, including the ones already proposed and discussed in some detail in a previous paper.[2] Since the "vertical" ionization threshold in ether should be equal to that in pentane (~34 kK) as seen from the close agreement of the absorption spectra, the steeply rising photo-current in the region higher than 34 kK observed in ether (Fig. 2) is assigned to

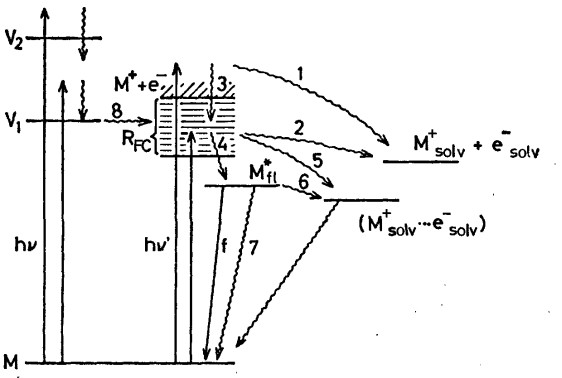

Fig. 5. The levels and processes showing photo-excitation and relaxation of TMAE in polar solvents such as ether. M: The ground state TMAE. V_1 and V_2: The (π-π^*)-type excited states of TMAE, each corresponding to the absorption bands denoted by V_1 and V_2 in Fig. 2. R_{FC}: The vertical (or Franck-Condon), Rydberg-like states. $M^+ + e^-$: The Franck-Condon, ionized state. M^*_{fl}: The fluorescent state (the solvated Rydberg state). $M^+_{solv} + e^-_{solv}$: The solvated cation and electron, free from each other. $(M^+_{solv} \cdots e^-_{solv})$: The non-fluorescent, solvated cation-electron pair. In nonpolar solvents, the state of free cation and electron contributing to photo-currents lies at almost the same energy as the Franck-Condon, ionized state. The solvated states such as $M^+_{solv} + e^-_{solv}$ and $(M^+_{solv} \cdots e^-_{solv})$ as well as the solvation processes (1), (2), (5), and (6) are of course absent in non-polar solvents and the fluorescent state is the Rydberg state situated in the solvent cavity.

the direct photoionization, and the photo-current in the lower energy region is assigned to process (2), the spontaneous formation of the solvated electrons from the "vertical" Rydberg states. The amount of charge carriers observed in ether at −65 °C is found to be twice as large as that at room temperature. This can be explained in view of the increase of the dielectric constant of ether (6.7 at −65 °C and 4.5 at room temperature). It is therefore expected that the ionization process (2) becomes more efficient in more polar solvents.

The shape of the fluorescence excitation spectrum in ether in the lower energy region nearly coincides with that of the Rydberg absorption band (R), while the shape of the photo-current yield curve in ether does not (Fig. 2). These results show that the ionization process *via* the fluorescent state ($R_{FC} \rightsquigarrow M^*_{fl} \rightsquigarrow M^+_{solv} + e^-_{solv}$) is not a main process, or in other words, process (2) competes, as shown in Fig. 5, with other relaxation processes (4) and (5), which will be discussed later.

The fluorescence excitation spectrum in ether extends into the region of the photo-current action spectrum, indicating the presence of processes (3) and (4), the relaxation from the vertical, ionized and Rydberg states to the fluorescent state in ether as well as in nonpolar solvents. Its shape in the higher energy region is rather different from the absorption spectrum, though the fluorescence excitation spectrum in 3-methylpentane is much more similar to the absorption spectrum. These results indicate that processes (2) and (5) exist and process (1) is more probable in ether.

These fluorescence excitation spectra show peaks corresponding to those of the absorption spectra (V_1),[12] suggesting the existence of non-radiative transition from the V_1-state to the Rydberg-like state (process (8)). One might thus expect that an auto-ionization from the V_1-state would occur in ether. The photo-current yield curve, however, shows very slight swelling at about 37 kK (Fig. 2). This fact can be explained by assuming that the molecules excited to the vibrationally excited V_1-state first relax to its lowest vibrational level lying near 30 kK, as shown in Fig. 5, and next pass into the Rydberg-like state, for which the photo-current yield is much smaller than for the case where the molecules are excited directly to the Rydberg-like or ionized states of the same energy as the vibrationally excited V_1-state.

The present results obtained in an extended temperature range (Fig. 3) are in good harmony with the structures of Rydberg states in solution discussed before,[2,8] and confirm them. Namely, the gradual blue-shifts of the lowest Rydberg absorption bands with lowering the temperature are attributed to the elevation of the solvent density surrounding the solute molecules increasing the repulsive interaction between the Rydberg electron and the solvents in the vertical Rydberg state. The relative constancy of the position of the fluorescence maximum with temperature in the case of fluid, 3-methylpentane solutions is ascribed to the presence of the relaxation from the vertical to the fluorescent state, leading to the expansion

of the solvent cavity so as to lower the Rydberg electron-solvent repulsive interaction. The red-shifts of the fluorescence maxima in fluid, polar solvents with decreasing temperature are also ascribed to the relaxation process leading to the solvated Rydberg state, going further by the increasing dielectric polarization at low temperature.[13] The blue-shifts of the fluorescence maxima on solidification of the solvents, both polar and nonpolar, are attributed to the restriction of such relaxations in rigid solutions.

The fluorescence lifetimes (τ_f) decrease greatly with increasing polarity and with decreasing temperature in polar solvents, but are restored to nearly the same level in the rigid solvents at 77 K as that in 3-methylpentane at room temperature, irrespective of whether they are polar or non-polar (Fig. 4). The Rydberg orbital in the fluorescent state in rigid solutions at 77 K must be largely distorted due to the repulsive interaction between the Rydberg electron and the surrounding solvent molecules as seen from the blue-shifts of the fluorescence maxima, while that in hydrocarbons at room temperature must be almost the same as that in the vapor phase, since the molecules in the Rydberg state are situated within the solvent cavity. These considerations lead to the conclusion that the fluorescence lifetime is hardly affected by distortion of the Rydberg orbital due to the surrounding solvent molecules.

We therefore tentatively assume that a non-fluorescent, solvated cation-electron pair, $(M^+_{solv}\cdots e^-_{solv})$, exists as an intermediate state attained by processes (5) and (6) in the case of polar solvents, as shown schematically in Fig. 5. The lifetime in polar solvents is then expressed by $\tau_f=1/(k_f+k_7+k_6)$, where k_f and k_7 are the rate constants of radiative and non-radiative processes from the fluorescent to the ground state, and k_6 is that of process (6). Since k_f and probably k_7 are nearly independent of the distortion of the Rydberg orbital and, therefore, of the solvent polarity, as discussed above, the decrease of τ_f with solvent polarity is mainly attributed to the increase of k_6.
