The system might be treated as a regular solution provided that the influence of a particular interaction such as hydrogen bond would be negligible. In the regular solution theory the heat of mixing is proportional to the difference in solubility parameters between solute and solvent as shown by Eq. 10. The solubility parameter of PEG decreases with increase in its molecular weight. Therefore, the solubility of a compound whose solubility parameter is smaller than that of PEG will increase with the molecular weight of PEG, and a compound of larger parameter than PEG will show the opposite tendency. Among the compounds examined here, only ethanol takes a larger value of solubility parameter than PEG. Thus the peculiar behavior of ethanol against the molecular weight of PEG could be explained in terms of solubility parameter. While particular interactions such as hydrogen bond between PEG and organic compound were expected to exist, the influence of such interactions was negligibly small except for dichloromethane and the solution could be treated as a regular solution.

The Crystal and Molecular Structure of Naphthanthrone

Shoji FUJISAWA, Isao OONISHI, Junji AOKI, and Satoshi IWASHIMA*

Department of Chemistry, Faculty of Science, Toho University, Funabashi-shi, Chiba 274

(Received July 5, 1976)

The crystals of naphthanthrone($C_{19}H_{10}O$) are orthorhombic, with the $P2_12_12_1$ space group and these lattice constants: $a=17.345(17)$, $b=3.973(13)$, $c=17.392(14)$ Å, and $Z=4$. The structure was solved by the Patterson method and refined by a block-diagonal least-squares program to give an R-value of 0.085 on the basis of the 897 observed reflections collected by Weissenberg photographs. The molecule is planar within the limits of experimental error and has an approximate symmetry of mm. The molecules are stacked face-to-face by van der Waals forces along the b-axis. The interplanar spacing is 3.50 Å.

The bimolecular condensation of benzanthrone (7*H*-benz[*de*]anthracen-7-one) affords condensation products with nine benzene rings. Similarly, naphthanthrone (6*H*-benzo[*cd*]pyren-6-one) gives products with eleven benzene rings. They are useful and interesting materials in the field of organic semiconductors. It is, therefore, desirable to know the crystal structures of these products and also those of the starting materials in order to study the intrinsic behavior of their electrical conduction. It may be suggested that symmetric naphthanthrone molecules are probably more closely packed in the crystal, since its melting point is 252 °C and far higher than that of benzanthrone (169 °C), in spite of the fact that the former molecule is larger than the latter one by only one additional benzene ring. From these points of view, the present investigation was carried out.

Experimental

The naphthanthrone was prepared by the condensation of pyrene and glycerol in sulfuric acid.[1] The crude product was dissolved in toluene and passed through a column of alumina to obtain the purified crystals. The crystals thus obtained were recrystallized from toluene. After several repetitions of this purification process, crystals suitable for X-ray work were selected.

The unit-cell dimensions were determined from the higher-order reflections on Weissenberg photographs calibrated by reflections from a Cu wire. The systematic absences were: $h00$ for h odd, $0k0$ for k odd and $00l$ for l odd.

Crystal data

$C_{19}H_{10}O$, $M=254.29$, mp 252 °C, Space Group: $P2_12_12_1$, $Z=4$; $a=17.345(17)$, $b=3.973(13)$, $c=17.392(14)$ Å, $U=1199$ Å^3; $D_x=1.409$, $D_m=1.42$ g cm^{-3}, $F(000)=528$, μ(Cu $K\alpha$)$=7.1$ cm^{-1}

The crystal used for X-ray work had dimensions of approximately $0.1\times0.1\times0.8$ mm. Sets of multiple-film equi-inclination Weissenberg photographs were taken about the b-axis (0th to 3rd layers) and about the c-axis (0th to 3rd layers). Cu $K\alpha$ radiation was employed throughout. The intensities were estimated by means of a Rigaku photometer MP3. Weak intensities were visually estimated with standard film strip. They were corrected for Lorentz and polarization factors, but no absorption correction was applied. The range of relative intensities was from 1 to 50000. 897 independent reflections fell within this range, whereas 429 others were too weak to be observed.

Structure Determination and Refinement

The orientation of the molecule was easily deduced from the three-dimensional Patterson maps, but the position of the center of gravity could not be fixed. Therefore, some two-dimensional models were assumed. One of them gave an R_{h0l}-value of 0.45. After two cycles of calculations of the structure factors and the electron densities $\rho(xz)$, the R_{h0l}-value dropped to 0.20. At this stage, the y coordinates of the molecule were calculated, taking the tilt and the packing into account. Structure factor calculations gave the R-value of 0.25.

The structure was refined by a block-diagonal least-squares method with a HBLS4 program written by Dr. Tamaichi Ashida. After six cycles of refinements, the R-value dropped to 0.15. Three more cycles of refinements with anisotropic temperature factors gave the R-value of 0.12. At this stage, the difference synthesis revealed all the hydrogen atoms. Further refinement cycles with isotropic temperature factors for hydrogen atoms reduced R to 0.085. The following weighting scheme was employed: $w=0.4$ if $F_0<F_{min}(=4.0)$, otherwise $w=1.0$. The atomic scattering factors were taken from "*International Table for X-Ray Crystallography*" (1962).[2] The observed and calculated structure factors are listed in Table 1.** The final atomic parameters and their estimated standard deviations are summarized in Table 2.

Description of the Structure and Discussion

Figure 1 illustrates the structure projected along the b-axis. The molecules are stacked face-to-face by van der Waals forces along the b-axis. The interplanar spacing is 3.50 Å. It is slightly greater than the 3.44 and 3.45 Å of violanthrone[3] and the 3.42 Å of isoviolanthrone.[4] Figure 2 shows the superposition of the molecules.

The closest approach between the molecules occurs between O and C(11)$(1-x, 1/2+y, 1/2-z)$, the distance being 3.355 Å. Such short contacts between an oxygen atom and a carbon atom have been found in the crystals of the quinones observed hitherto.[3,5-7]

The bond lengths and angles in the molecule are shown in Figs. 3 and 4, together with estimated standard deviations. The average C–C bond length, 1.408 Å, is comparable to the value, 1.409 Å, of tetrabenzo-[*a*, *cd*, *j*, *lm*]perylene.[8] The bond lengths of C(17)–

A pH and pNa Study of Aqueous Solutions of Sodium Deoxycholate

Gohsuke SUGIHARA and Mitsuru TANAKA

Department of Chemistry, Faculty of Science, Fukuoka University, Nishi-ku, Fukuoka 814

(Received July 7, 1976)

The pH and pNa of aqueous solutions of sodium deoxycholate (SDC) were measured at various temperatures. The critical micelle concentrations (CMC) were determined by means of the crooked points on the plot of pH or pNa *vs.* the SDC concentration. The data obtained were interpreted thermodynamically, and changes in the enthalpy and entropy of micellization were evaluated, from which it was concluded that the hydrogen bond plays a very important role in the micelle formation.

Sodium deoxycholate (SDC), a bile salt, shows unique properties in its physicochemical and biological aspects, and SDC behaves as a surfactant. Although the micellar behavior in an aqueous solution of SDC has been studied in connection with various physicochemical properties,[1-9] the peculiarity with respect to pH and pNa has not been examined sufficiently.

As SDC is a salt of the "weak acid-strong base" type, the solution is basic due to hydrolysis. Though fatty acid soaps are also salts of the "weak acid-strong base" type, they are different from SDC in terms of the architecture of the hydrophobic part of the molecule, the balance of hydrophilicity and lyophilicity, and especially the ability to form intermolecular hydrogen bonding. In this paper the unique behavior of the hydrogen-ion and sodium-ion activity in an aqueous solution of SDC will be examined and discussed.

Experimental

Materials. SDC (Merck Co.) was recrystallized several times from a mixed solution of methanol and ethanol and then dried *in vacuo* at 110 °C. Sodium chloride, of a guaranteed reagent grade, was recrystallized from thrice-distilled water and dried *in vacuo*. The distilled water used for the preparation of solutions was previously freed from CO_2 by passing sufficient CO_2 free air through a soda lime column.

Apparatus and Procedure. a) *pH Measurement*: pH measurements were performed for the determination of the CMC, which was given by the break in the SDC concentration *vs.* pH curve at each temperature. The measurements were carried out using a Hitachi-Horiba pH meter, model F-7. The influence of CO_2 during the measurements was avoided by using an air current freed from CO_2 by means of a soda lime column. The solution to be measured was stirred by means of a magnetic stirrer (Acrobat Stirrer, made by the MS-Kiki Co.) which could be immersed in a water bath. The hydrolysis equilibrium was checked by means of the curve on the recorder for each measurement. The apparatus is shown schematically in Fig. 1.

b) *Activity Measurement of the Sodium Ion*: The measurements were carried out using a Hitachi-Horiba pNa meter, model N-5. The apparatus was almost the same as that of the pH measurements. The calibration curve was made by correlating the observed value with the literature value[10] for the activity of sodium ions in an aqueous solution of NaCl.

Results and Discussion

The pH change with the SDC concentration at various temperatures is shown in Fig. 2, while the relations of the sodium-ion activity *vs.* the SDC concentration are shown in Fig. 3. Every curve in both figures shows a break in its trend at the same concentration at the same temperature. These significant points correspond to the CMC values reported in other papers.[1-7] Accordingly, these methods can be used for the determination of the CMC of SDC. Table 1 lists the values of CMC obtained by both methods at each temperature.

In the concentration range of single dispersion, SDC molecules will dissociate almost perfectly, and

a hydrolysis equilibrium will be established. The concentrations of the undissociated species, sodium deoxycholate (NaDC), and the hydrolyzed species, deoxycholic acid (HDC), will increase with an increase in the SDC concentration. The associations of NaDC and HDC are expected to be easier than that of deoxycholate ions (DC^-) because of the smaller coulombic repulsion among them. Especially, HDC molecules are likely to form stable associates by hydrogen bonding. The micellization will be initiated with the association of HDC, and then accompanied by the participation of NaDC and DC^-. As soon as the micelles are formed, a new reaction of hydrolysis will begin abruptly on the surface of the micelles and a new equilibrium of hydrolysis will be established. Figure 2 shows that the pH increases abruptly from the CMC with an increase in the SDC concentration. This means that the degree of hydrolysis of DC^- in micelles is larger than that in single dispersion.

It can be seen from Fig. 3 that SDC dissociates perfectly in the dilute range of concentration below CMC as a 1-1 electrolyte, and that the degree of dissociation seems to decrease gradually up to the CMC as the concentration increases. Above the CMC the curve shows an abrupt increase in the activity coefficient. This behavior is different from that of sodium dodecylsulfate or sodium tetradecylsulfate.[11] Figures 2 and 3 tell us that the change in the sodium-ion activity in the vicinity of the CMC with an increase in the SDC concentration is contrary to that of the hydrogen-ion activity. This can be interpreted by thermodynamic considerations as follows.

We assume that the composition of the micelles is $DC^-\cdot\alpha H^+\cdot\beta Na^+$, where α and β are the numbers of the H^+ ion and the Na^+ ion respectively, per DC^- ion in the micelle.

Then, the equilibrium of micelle formation is expressed as follows:

$$DC^- + \alpha H^+ + \beta Na^+ \rightleftharpoons DC^-\cdot\alpha H^+\cdot\beta Na^+ \quad (1)$$

The chemical potentials of the components in the solution are, respectively:

$$\mu_{DC^-} = \mu^0_{DC^-} + RT \ln a_{DC^-} \quad (2)$$

$$\mu_{H^+} = \mu^0_{H^+} + RT \ln a_{H^+} \quad (3)$$

$$\mu_{Na^+} = \mu^0_{Na^+} + RT \ln a_{Na^+} \quad (4)$$

The chemical potential of the micelle-forming species ($DC^-\cdot\alpha H^+\cdot\beta Na^+$) in the micelle can be expressed by the following equation, if the micelle is regarded

Table 1. The CMC values determined by pH and pNa measurements

Temperature (°C)	CMC (mol/l) × 10^3	
	by pH measurement	by pNa measurement
10	2.95	
15	3.35	3.24
20	3.55	3.47
25	4.01	4.05
30	4.80	4.57
35	5.35	5.19
40	6.10	

as a pseudo phase:

$$\mu_m = \mu_m^0 (T, P) \tag{5}$$

From Eqs. 2—5 we obtain the free energy change of micelle formation per mole of the micelle-forming species, $\Delta\overline{G}_m$:

$$\Delta\overline{G}_m = \mu_m - \mu_{DC^-} - \alpha\mu_{H^+} - \beta\mu_{Na^+}$$
$$= \Delta\overline{G}_m^0 - RT \ln a_{DC^-} - \alpha RT \ln a_{H^+} - \beta RT \ln a_{Na^+} \tag{6}$$

where

$$\Delta\overline{G}_m^0 = \mu_m^0 - \mu_{DC^-}^0 - \alpha\mu_{H^+}^0 - \beta\mu_{Na^+}^0 = \text{const } (T, P).$$

As $\Delta\overline{G}_m$ is equal to zero at equilibrium, Eqs. 7—9 hold:

$$\ln a_{DC^-} = \text{const}(T, P) - \alpha \ln a_{H^+} - \beta \ln a_{Na^+} \tag{7}$$

Especially, at the CMC

$$\ln \text{CMC} = \text{const}(T, P) - \alpha \ln a_{H^+} - \beta \ln a_{Na^+} \tag{8}$$

and

$$\log a_{Na^+} = \text{const } (T, P) - \frac{1}{\beta} \log a_{DC^-} + \frac{\alpha}{\beta}\text{pH} \tag{9}$$

This equation tells us that $\log a_{Na^+}$ increases with the pH and α, and varies inversely with the β. The rise in $\log a_{Na^+}$ with the concentration above the CMC just corresponds to the rise in pH, and the decreasing tendency of the increase in a_{Na^+} at higher concentrations may be ascribed to the negative sign of the log a_{DC^-} term.

Since $\Delta\overline{G}_m$ can be regarded as a function of T, P a_{DC^-}, a_{Na^+} and a_{H^+}, the following equation holds for the perfect differential of $\Delta\overline{G}_m$:

$$d(\Delta\overline{G}_m) = -\Delta\overline{S}_m dT + \Delta\overline{V}_m dP + \left(\frac{\partial\Delta\overline{G}_m}{\partial \ln a_{DC^-}}\right) d \ln a_{DC^-}$$
$$+ \left(\frac{\partial\Delta\overline{G}_m}{\partial \ln a_{H^+}}\right) d \ln a_{H^+} + \left(\frac{\partial\Delta\overline{G}_m}{\partial \ln a_{Na^+}}\right) d \ln a_{Na^+} \tag{10}$$

The differential coefficients of the third, fourth, and fifth terms in Eq. 10 are obtained from Eq. 6 as $-RT$, $-\alpha RT$, and $-\beta RT$ respectively. Hence, Eq. 11 is derived from Eq. 10;

$$d(\Delta\overline{G}_m) = -\Delta\overline{S}_m dT + \Delta\overline{V}_m dP - RT d\ln a_{DC^-}$$
$$- \alpha RT d \ln a_{H^+} - \beta RT d \ln a_{Na^+} \tag{11}$$

For the reversible micelle formation at a constant pressure, we obtain the following relation:

$$\Delta\overline{S}_m = \frac{\Delta\overline{H}_m}{T} = -RT\left(\frac{\partial \ln a_{DC^-}}{\partial T}\right)_P$$
$$-\alpha RT\left(\frac{\partial \ln a_{H^+}}{\partial T}\right)_p - \beta RT\left(\frac{\partial \ln a_{Na^+}}{\partial T}\right)_P \tag{12}$$

Here, Eq. 12 may be rewritten as follows, assuming the temperature dependency of the activity coefficient of the SDC micelle is negligible:

$$\Delta\overline{S}_m = -2.303\, RT\left\{\left(\frac{\partial \log \text{CMC}}{\partial T}\right)_P - \alpha\left(\frac{\partial \text{pH}}{\partial T}\right)_P - \beta\left(\frac{\partial \text{pNa}}{\partial T}\right)_P\right\} \tag{13}$$

According to the results shown in Figs. 2 and 3, the plot of the pH value at the CMC *vs.* T affords a linear relation with a slope of -5.0×10^{-3}. The plot of the pNa value at the CMC *vs.* T similarly affords a linear relation with a slope of -1.0×10^{-2}. From Table 1, $(\partial \log \text{CMC}/\partial T)_P$ is roughly given as $+1.0\times10^{-2}$ at 20 °C. The α and β are not obtained from our experiment, but the data of Vochten and Joos[12] can be used to determine them approximately. Using Corrin's equation, they estimated β(their notation is K) as 2.0 and 2.5 under the conditions of constant pH values of 7 and 9 respectively at 20 °C. Here, it should be noted that the value of β obtained using Corrin's equation does not account for the contribution of H^+ to the micelle formation, and that β is related only to Na^+. Their data show that the CMC depends strikingly on the pH. The estimation of the α value is possible from the thermodynamic treatment of their data concerning the dependence on pH. Equation 8 is rewritten as follows:

$$\log \text{CMC} = \text{const } (T, P) + \alpha \text{ pH} + \beta \text{ pNa} \tag{14}$$

From Fig. 7 in their paper, α or $\Delta\log \text{CMC}/\Delta\text{pH}$ at a constant sodium-ion concentration is calculated to be about 0.8, independent of the value of the sodium-ion concentration. Using these values, $\Delta\overline{H}_m$ and $\Delta\overline{S}_m$ are evaluated as -6 kcal and -20 e.u. respectively from Eq. 13. On the other hand, the change in the partial molal volume of SDC on micellization, $\Delta\overline{V}_m$, has been obtained as -11 ml/mol at 30 °C from densitometry.[14] $\Delta\overline{H}$, $\Delta\overline{S}$, and $\Delta\overline{V}$ for the gelation of SDC solution all have negative signs which are characteristic of hydrogen-bond formation.[15] It is, then, reasonable to consider from these data that the micelle formation of SDC is mainly caused by hydrogen bonding, such as that between a hydroxyl group of one molecule and a carboxyl group of the other. This is in contrast to the micelle formation of other surfactants, *e.g.*, sodium dodecylsulfate and sodium tetradecylsulfate, which is mainly caused by hydrophobic interaction. It should be noted that $\alpha+\beta$ is nearly equal to unity, which means that micelles of SDC are electrically neutral. As an SDC molecule has two hydroxyl groups, SDC micelles may exist stably in the solution due to their hydrophilicity, which arises from the hydrogen-bond formation between water molecules and the remaining hydroxyl groups that have not been used for the micelle formation and so are able to contribute to the further association of the micelles.

This interpretation supports the helical structure model proposed by Rich and Blow.[8,9]

We would like to acknowledge the valuable discussions and suggestions by Prof. Dr. Ryohei Matuura, Kyushu University, and Prof. Dr. Iwao Satake, Kagoshima University. We are indebted to Miss Noriko Seike, Miss Mariko Ikeda, and Miss Kazuko Matsuo, Fukuoka University, for their technical assistance.

Theoretical Analysis of Optical Rotatory Power of Methylcyclohexanone with Treatment of Conformational Equilibria

Tomoyasu NAKAMURA and Yasumasa J. I'HAYA*

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112

**Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo 182*

(Received July 14, 1976)

Optical rotational strength for the n-π^* transition of (*R*)-3-methylcyclohexanone is calculated by the CNDO/2 and INDO methods and compared with the observed values at 81 and 300 K, taking account of conformational equilibria. The conformer species are chosen so that they have minimal potential energies, the potential energy surface being estimated with a non-bonded interaction approximation. Excited state wave functions are improved by a model potential method. The ratio of the rotational strengths at 81 and 300 K, each of them being calculated as a statistical average of the rotational strengths of four conformers, is in good agreement with the corresponding observed value.

In the course of recent advances in quantum chemical approach for the prediction of optical rotatory power of optically active molecules, there have been brought forward several questions to answer; interpretation of observed circular dichroism spectra which are usually taken in solution, reasonable guess of molecular conformations, accuracy of ground and excited state functions, estimation of two-center (interatomic) matrix elements of the electric and magnetic dipole moment integrals, and so on.

Of all such problems the most important seems to be those about the first two, on which recent measurements[1] of circular dichroism spectra over a wide range of temperature have thrown the ray of hope for the settlement of the matter. That is, the rotational strengths of most optically active ketones increase as temperature goes down. Under the circumstances, one has no choice but to view that there must be several types of conformers mixed in a single solution, distributing according to the Boltzmann law, and giving one a temperature-dependent, statistically averaged rotational strength for a specific electronic transition. This view was first adopted by Moscowitz *et al.*[2] for the interpretation of thermodynamic data of (*R*)-*trans*-2-chloro-5-methylcyclohexanone, though they confined themselves only to a treatment of a two-conformer equilibrium. In the present study, we follow the above viewpoint in a comparison of experimental and theoretical optical rotatory powers of (*R*)-3-methylcyclohexanone, taking account of a multi-conformer equilibrium.

There is no definite way to guess what types of conformers effectively contribute to the mixing and what molecular geometry each conformer has. Among several procedures for conformational analysis of flexible molecules, we turn our attention to a classic model of interatomic interactions, *i.e.*, non-bonded and/or van der Waal's interactions, plus tortional interactions, which has been successfully applied to a number of saturated compounds by many authors.[3,4] Though the model is too simple to predict the precise temperature-dependent rotational strength of (*R*)-3-methylcyclohexanone, we have found after trying several other means that it is the only reliable way to guess the conformational (potential) energy surface of conformers.

As for the absolute magnitudes of rotational strengths of free molecules, there have been reported a good number of molecular orbital calculations, in particular cyclohexanone methyl derivatives have been most carefully investigated.[5] Good excited state wave functions are required in a calculation of rotational strength, and a usual procedure for improving approximate state functions is to invoke a configuration interaction (CI). Since the practical CI procedure for the calculation of matrix elements of the electric and magnetic dipole moments is rather complicated and troublesome, we shall adopt a model potential method in order to improve virtual orbitals to be used in a single-determinantal excited state functions.

Methods of Calculation

As mentioned above, we start from the viewpoint that the proper method for comparison of experimental and theoretical results would be to use a Boltzmann distribution among non-interacting conformers in order to obtain an average value for the rotational strength of the electronic transition under consideration at temperature T:

$$[R^l]^T_{\mathrm{av}} = \frac{\sum_i [\mathrm{R}^l_i]\exp(-E_i/kT)}{\sum_i \exp(-E_i/kT)} \tag{1}$$

where $[R^l_i]$ is the reduced rotational strength in the lth transition of conformer i and has the form

$$[R^l_i] = 1.08 \times 10^{40}\,\mathrm{Im}(\boldsymbol{\mu}^l \cdot \boldsymbol{m}^l), \tag{2}$$

$\boldsymbol{\mu}^l$ and $\boldsymbol{m}^l$ being the electric and magnetic dipole moments associated with transition l, and E_i is the conformational energy of conformer i measured from that of the most stable conformer.

An estimation of the value E_i is most difficult. An *ab initio* calculation of a precise potential curve associated with a conformational change is laborious, whereas a semi-empirical molecular orbital method seems no good to the estimation of such small energy differences as several kcal/mol among conformers. We therefore adopted as a measure of E_i the potential energies due to a non-bonded interaction between atoms and an internal rotation about a single bond. The former is represented by the Lennard-Jones "6—12" potential

$$U_{ij} = \frac{d_{ij}}{r_{ij}^{12}} - \frac{e_{ij}}{r_{ij}^{6}} \tag{3}$$

where d_{ij} and e_{ij} are the constants specific for atoms and assume to take the values given by Scott and Scheraga,[6] r_{ij} being the non-bonded interatomic distance in Å. The potential energy for a single internal rotation is given by

$$U_{\text{rot}} = \frac{1}{2}C(1-\cos 3\phi) \tag{4}$$

where C is the height of the potential peaks above the potential valleys and takes the values determined by Scott and Scheraga. We shall calculate U_{rot} for all the possible internal rotation arising from the change of the dihedral angles $\phi(3)$ and $\phi(5)$ (*vide infra*). An electrostatic (coulomb) interaction is neglected since there is only one polar bond in the molecule under consideration and such an interaction is very small.

The molecular orbitals used for the calculation of $[R_i^i]$ are obtained from the CNDO/2 and INDO methods. All the parameters involved are the same as those proposed by the original authors.[7] In order to obtain better excited state wave functions, we adopted Huzinaga and Arnau's model potential method.[8] The method uses the following Hartree-Fock operator[9] for a "singlet" excitation of one electron from the ith orbital

$$F_i = H + \sum_{j\neq i}(2J_j - K_j) - J_i + 2K_i \tag{5}$$

where J and K are the usual coulomb and exchange operators respectively, and $-J_i+2K_i$ is a pseudopotential which plays a significant part to improve virtual orbitals. The method has been shown to have the advantage of making an excited state calculation easier than the usual CI procedure.

The two-center (interatomic) terms of the electric and magnetic dipole moments are included in calculations of $[R_i^i]$ together with the one-center terms.[10] The dipole velocity formulation is adopted instead of the dipole length formulation. As pointed out by several writers,[11,12] the inclusion of the two-center terms in CNDO and INDO-type calculations is incompatible with the use of the zero differential overlap approximation. Therefore, CNDO and/or INDO basis sets should be transformed into deorthogonalized basis sets under the assumption that the CNDO and INDO basis are represented by Löwdin's orthogonalized atomic orbitals. We follow the recipe for deorthogonalization given by Imamura *et al.*[12]

In short, the molecular orbitals used for the purpose of comparison are divided into the following four:

Method I: CNDO/2 and/or INDO MO's without any modification.

Method II: MO's deorthogonalized.

Method III: MO's improved by the model potential method.

Method IV: MO's improved by the model potential method and deorthogonalized.

Results and Discussion

Figure 1 shows the molecular geometry of (*R*)-3-methylcyclohexanone proposed by Pao and Santry.[13] We first constructed a large number (about 200) of conformers by changing the dihedral angles $\phi(3)$ and $\phi(5)$ shown in Fig. 2, all the CCC angles being fixed

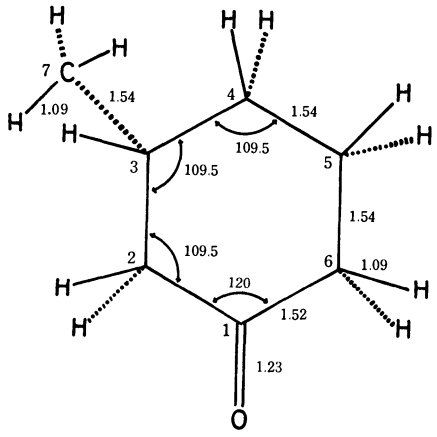

Fig. 1. Molecular geometry of (*R*)-3-methylcyclohexanone; bond lengths are given in Å and angles in degrees.

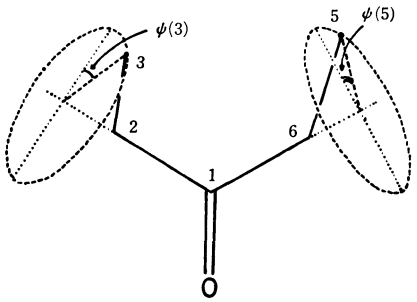

Fig. 2. Dihedral angles $\phi(3)$ and $\phi(5)$ in (*R*)-3-methylcyclohexanone.

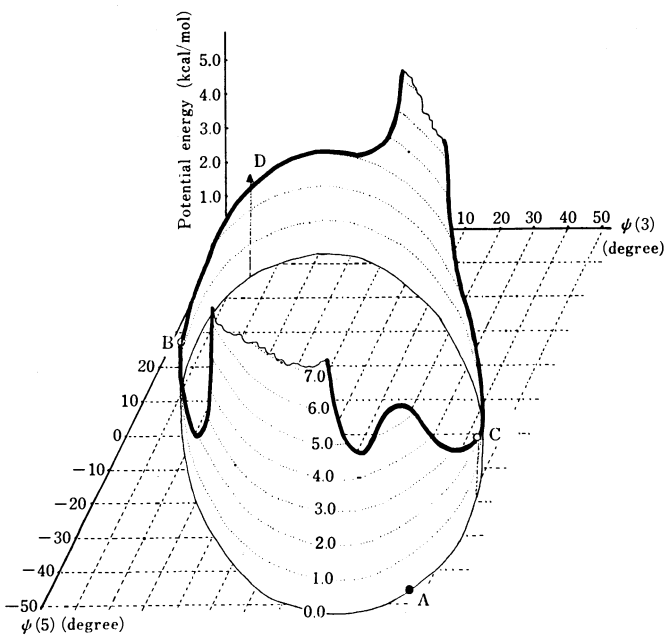

Fig. 3. Bird's-eye view of the potential surface for (*R*)-3-methylcyclohexanone.
A: Chair form with equatrial methyl; D: chair form with axial methyl; B, C: conformers corresponding to two minima of the surface.

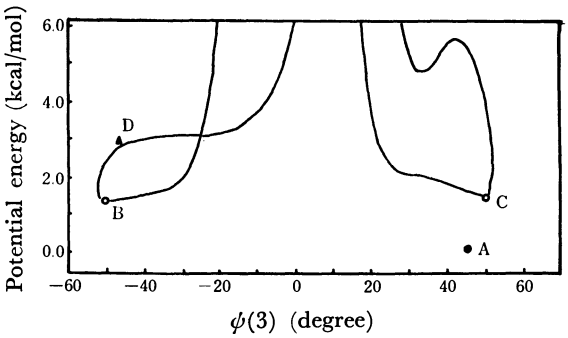

Fig. 4. Projection of the potential surface onto the $\psi(3)$-energy plane. A, B, C, and D are the same as in Fig. 3.

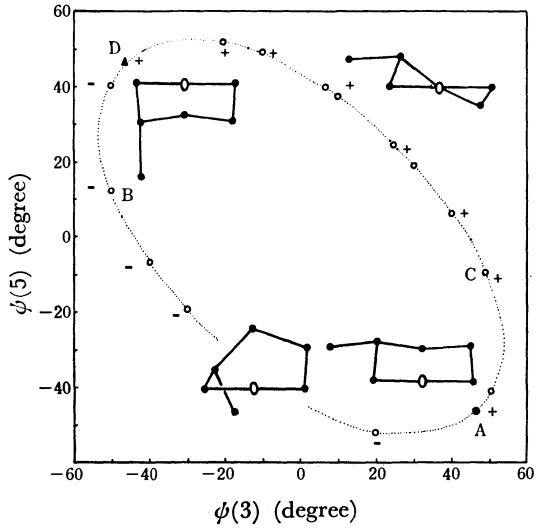

Fig. 5. Projection of the potential surface onto the plane of two dihedral angles, $\psi(3)$ and $\psi(5)$. + and − denote sings of rotational strength and A, B, C, and D are the same as in Fig. 3.

as in Fig. 1, and calculated the total non-bonded potential energies $\Sigma(U_{ij}+U_{rot})$ as a function of $\psi(3)$ and $\psi(5)$. Let the value of $\psi(3)$ be zero when atom C_3 is in the *trans* position with respect to the C=O bond and positive for the counter-clockwise rotation of the C_2–C_3 bond.

The results are illustrated in Fig. 3, where the potential energy is measured from that for the regular chair-form conformer with the equatrial methyl group (A in the figure). No conformer was found to have a lower potential energy than A, which then corresponds to a singular point in the potential energy surface. Thus, the regular chair-form conformer having the equatrial methyl group is computed out to be most stable, as might be expected. On the other hand, the potential energy of the regular chair-form conformer having the axial methyl group, D, comes to the neighborhood of the potential surface of the boat-forms. Figure 4 is a projection of the potential surface onto the $\psi(3)$-energy plane. There are found two potential minima, the corresponding conformers being called B and C.

The projection of the potential surface onto the plane of two dihedral angles $\psi(3)$ and $\psi(5)$ is illustrated in Fig. 5 which shows a correlation between signs of the calculated rotational strengths and the species of conformers. Each open circle corresponds to a selected conformer for which the rotational strength has been calculated and its sign is marked as plus or minus. For reference, some representative conformers are illustrated roughly at their proper positions. These calculated signs of rotational strength agree with those predicted by the octant rule, if it assumes to be applied even for a boat and/or twist boat-form conformer. However, in conflict with the octant rule, the calculated rotational strength for the regular chair-form conformer with the axial methyl group has a positive sign.

In Table 1 is listed a part of the calculated results for rotational strength for the n-π^* transition of (*R*)-3-methylcyclohexanone. Conformers B and C are chosen because they have the potential energies that correspond to minima of the potential surface (*vide supra*). The results for some other conformers of boat-form are also listed for reference.

With these calculated rotational strengths and potential energies of conformers A, B, C, and D, we calculate from Eq. 1 the statistical average of the rotational strength for the n-π^* transition of (*R*)-3-methylcyclohexanone at 300 and 81 K. The results are shown in Tables 2 together with the values Δ defined by

$$\Delta = \frac{[R]_{av}^{81} - [R]_{av}^{300}}{[R]_{av}^{300}} \times 100. \quad (6)$$

There can be seen in Table 2 a quite good agreement between the calculated and observed Δ values, though the absolute values of the predicted rotational strengths

a) Ref. 1. b) Defined by Eq. 6 of the text.

are considerably larger than the observed value (see Table 1 also). Methods III and IV with INDO yield better results, so that an improvement of virtual orbitals such as the present one seems to be prerequisite for calculations of this type. However, we cannot say for certain about the importance of the effect of deorthogonalization which has been demonstrated by other investigators.[12] We shall report elsewhere that a calculation without deorthogonalization leads to incorrect results with respect to a sign of the rotatory strength of (*R*)-3-methylcyclohexylidene-malononitrile.[14] The calculated weights of conformers A, B, C, and D are 82.91, 9.30, 7.11, 0.68%, respectively, at 300 K with Method IV. At 81 K with the same method, the weight of conformer A is 100%.

The above-mentioned calculations are based on the assumption that the potential surface obtained from the consideration of non-bonded interactions can well describe the internal energy profile of the system. What about a situation, if we use as E_i the sum of the electronic energy calculated by the molecular orbital methods and the potential energy due to the non-bonded interactions? As can be seen in Table 3, the results obtained are rather unsatisfactory. This may partly be attributed to the present inconsistent procedure which uses the same conformers as in the previous case (A, B, C, and D). The reason why proper conformers are not used is simply because minima of the energy surface in this case have hardly been found.

Lastly, there still remains a question: Is the sign of the rotational strength of conformer D definitely positive? There has been no calculation reported that conformer D has a negative sign in accordance with the ketone octant rule. We have no mind to challenge the octant rule and simply want to find out a relationship between a sign of rotatory strength and a molecular conformation. We have found that the

20.0	−2.530	−10.430	4.413	2.747	−2038.996
30.0	−10.092	−25.710	0.786	−4.561	−2038.480

a) Clockwise rotation of bond C_3–C_7 in the plane which contains bond C_3–C_7 and is perpendicular to the $C_2C_3C_4$ plane. $\delta\theta$ is taken to the zero at the axial position of bond C_3–C_7 with respect to bond C_1–C_2.

rotational strength gradually decreases as the C_3–C_7 bond rotates in the plane which contains the C_3–C_7 bond and is perpendicular to the $C_2C_3C_4$ plane (Fig. 6). The numerical values obtained are listed in Table 4, where $\delta\theta$ denotes the deviation of the dihedral angle defined above, $\delta\theta=0$ being the axial position of bond C_3–C_7 with respect to bond C_1–C_2 in conformer D. In order to get the sign to be negative, the axial methyl group must rotate by about 20 degrees. This request, on the other hand, inflicts an energy loss of about 0.2 eV (see the last column of Table 4) and is rather unlikely. Thus, in so far as the above estimation is correct, a sign of the rotational strength of conformer D will probably be positive as the present and some other authors predict. It should be noted that the conclusion here is only tentative since we cannot say definitely about the accuracy of the total energies of conformers under consideration. There may be cases that a total energy favors reorientation of axial

methyl groups in some alicyclic ketones. The ketone octant rule will hold properly for such molecules.

In order to see what happens if we start from somewhat different molecular geometry, we have carried out a copy of the above calculation with the geometry of (*R*)-3-methylcyclohexanone proposed by Moffitt *et al.*[15] The overall results however were not very good; *e.g.*, the value of Δ was computed to be about 13.

It is concluded that consideration of the statistical population of conformers is indispensable for accurate understanding of rotational strength data of flexible optically active molecules.

One of us (T. N.) wishes to thank Dr. Yoshiro Nakata of Gumma University for a number of discussions and suggestions concerning the conformational equilibria.

The Approximate Self-Consistent Renormalized RPA: The Electronic Excited States of DNA Bases in the CNDO/S Method

Hirotoshi Ito and Yasumasa J. I'Haya

Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo 182

(Received August 12, 1976)

Comments are given upon the *approximate* self-consistent renormalized RPA(SCrRPA) presented in our previous papar which assumes the correlated ground state wavefunction to be the linear combination of the Hartree-Fock ground state and doubly excited states, in the CI language. The rationalization of the approximate SCrRPA is made from the results computed by the *complete* SCrRPA, whose recipe is simply made. Finally, a numerical comparison of the several RPA methods is made as to the electronic spectra of four DNA bases by using the CNDO/S method.

In the pi-electron semiempirical theories like the Pariser-Parr-Pople model[1] and the valence electron theories such as the CNDO/S[2,3] and the INDO/S[4] methods, the configuration interaction (CI) method has been conventionally used to determine the excitation energies of molecules. On the other side, the random-phase approximation (RPA) has conceptually advantages over the CI method. The latter, when only all the singly excited configurations are included, is actually the same as the Tamm-Dancoff approximation (TDA) which is the lowest order approximation of the equations-of-motion method. For instance, in the CI language, the RPA can include certain *doubly* excited configurations (Z-terms; vide post), in addition to all the *singly* excited configurations (Y-terms). However, the standard RPA often gives the inconsistent solution such as the triplet instability on account of Eq. 3b (vide post). In this respect, the normal RPA (nRPA) is not necessarily superior to the TDA.

This deficiency of the nRPA can be overcome not only by the modification of the HF bases but also by introducing the correlated ground state, instead of the HF ground state, as a reference state.[5] The latter RPA is referred to as a higher RPA. On the basis of the correlated ground state assumed, several modifications to the nRPA have been proposed. The higher RPA derived by Shibuya and McKoy[6] and the self-consistent RPA presented by Ostlund and Karplus[7] are in these streams. The self-consistent polarization propagator approximation (SPPA)[8] is a similar approach. Previously, we also have applied the renormalized higher RPA(rRPA) in Rowe-Simons' formalism[9,10] to the various conjugated molecules.[5]

The rRPA method is based upon the assumption of the correlated ground state which involves the corrections of electron correlation introduced for the Hartree-Fock ground state. Previously, we calculated the non-integral occupation number, *i.e.*, the charge densities from the coefficients of the correlated ground state wavefunction (HF+doubly excited CI's) determined by admixing the Hartree-Fock ground state with various doubly excited configurations using the perturbation theory. In the present paper, we compute the correlated charge densities from the RPA ground state determined by Sanderson and da Providência's recipe.[11,12] As will be mentioned below, the correlated ground state is determined by the self-consistent solution of the rRPA equation (SCrRPA) in an iterative way.

In this case, a trial well correlated ground state may yield approximately a self-consistent solution at several rounds of iterative calculations. In fact, it is demonstrated that the correlated ground state wavefunction in our previous works[5,14] gives an approximate solution of the SCrRPA. The central concern of the present paper is therefore focussed upon the rationalization of the *approximate* SCrRPA in our previous treatment rather than the *complete* SCrRPA. The detailed report of the latter will be presented elsewhere.[13] In the following, we outline the rRPA method, then give some comments upon these two assumptions of the correlated ground state, and finally present some numerical results for DNA bases.

Renormalized Higher RPA

The rRPA equation which was originally given by Rowe[9] and later reformulated by Simons[10] explicitly for the singlet and triplet states is written down for the real basis in the following matrix form

$$\begin{pmatrix} \tilde{A}(S) & \tilde{B}(S) \\ -\tilde{B}^*(S) & -\tilde{A}^*(S) \end{pmatrix} \begin{pmatrix} \tilde{Y}(\lambda S) \\ \tilde{Z}(\lambda S) \end{pmatrix} = \omega_\lambda \begin{pmatrix} \tilde{Y}(\lambda S) \\ \tilde{Z}(\lambda S) \end{pmatrix} \qquad (1)$$

with

$$\tilde{A}_{\mathrm{ph,vf}}(S) = \delta_{\mathrm{pv}}\delta_{\mathrm{hf}}(E_{\mathrm{p}}-E_{\mathrm{h}}) + (2)^{-1}(\rho_{\mathrm{h}}-\rho_{\mathrm{p}})^{1/2}(\rho_{\mathrm{f}}-\rho_{\mathrm{v}})^{1/2} \times (\langle \mathrm{pf}|\mathrm{hv}\rangle + (-)^S\langle \mathrm{pf}|\mathrm{hv}\rangle - \langle \mathrm{pf}|\mathrm{vh}\rangle)$$

$$\tilde{B}_{\mathrm{ph,vf}}(S) = (2)^{-1}(\rho_{\mathrm{h}}-\rho_{\mathrm{p}})^{1/2}(\rho_{\mathrm{f}}-\rho_{\mathrm{v}})^{1/2} \times (\langle \mathrm{pv}|\mathrm{hf}\rangle + (-)^S\langle \mathrm{pv}|\mathrm{hf}\rangle - \langle \mathrm{pv}|\mathrm{fh}\rangle)$$

$$\langle ij|kl\rangle = \langle i(1)j(2)|1/r_{12}|k(1)l(2)\rangle$$

$$\tilde{Y}_{\mathrm{ph}}(\lambda S) = (2)^{-1/2}(\rho_{\mathrm{h}}-\rho_{\mathrm{p}})^{1/2}Y_{\mathrm{ph}}(\lambda S)$$

$$\tilde{Z}_{\mathrm{ph}}(\lambda S) = (2)^{-1/2}(\rho_{\mathrm{h}}-\rho_{\mathrm{p}})^{1/2}Z_{\mathrm{ph}}(\lambda S)$$

from which the TDA and the nRPA are derived as special case. E_i is an orbital energy for the ith Hartree-Fock molecular orbital (MO) ϕ_i. Subscripts ph and vf are used to label the *p*article-*h*ole pair and the *v*acant-*f*illed molecular orbital pair states, respectively. $Y_{\mathrm{ph}}(\lambda S)$ and $Z_{\mathrm{ph}}(\lambda S)$ without tildes are the unrenormalized amplitudes for the singly excited creation operator $0^+_{\lambda SM}$

$$0^+_{\lambda SM} = \sum_{\mathrm{ph}} (Y_{\mathrm{ph}}(\lambda S)C^+_{\mathrm{ph}}(SM) - Z_{\mathrm{ph}}(\lambda S)C_{\mathrm{ph}}(\overline{SM})) \qquad (2)$$

which produces the λth excited state $|\lambda SM>$ when operating on the correlated ground state $|0>$:

$$0^{+}_{\lambda SM}|0> = |\lambda SM> \quad (3a)$$

$$0_{\lambda SM}|0> = 0 \quad (\text{all } \lambda SM) \quad (3b)$$

Here $C^{+}_{\rm ph}(\rm SM)$ and $C_{\rm ph}(\overline{\rm SM})$ are the particle-hole pair creation and annihilation operators, respectively, in the same notation of Ref. 6, S and M being the total spin angular momentum and its z-projection, respectively. ρ_i represents the correlated charge density, *i.e.*, the non-integral occupation number of the ith orbital in the correlated ground state, defined by

$$\rho_i = (2)^{1/2}<0|(2)^{-1/2}(a^{+}_{i\alpha}a_{i\alpha}+a^{+}_{i\alpha}a_{i\beta})|0> = (2)^{1/2}<0|C^{+}_{ii}(00)|0> \quad (4)$$

where $a^{+}_{i\sigma}$ and $a_{i\sigma}$ are the Fermion creation and annihilation operators, respectively, for the ith spin-orbital $\phi_i\sigma_i$.

The correlated RPA ground state is usually assumed to be as follows

$$|0> = N_0 e^{U}|HF> \quad (5)$$

with

$$U = (1/2)\sum_{S=0,1}\sum_{i}\sum_{\rm ph\in\Gamma_i}\sum_{\rm vf\in\Gamma_i} C_{\rm ph,vf}(S)C^{+}_{\rm ph}(\overline{S0})C^{+}_{\rm vf}(S0) \quad (6a)$$

$$\Gamma_i \times \Gamma_i \in \Gamma_{\rm HF}. \quad (6b)$$

Here N_0 is the normalization constant

$$N_0^{-2} = 1 + <HF|U^{\dagger}U|HF> \quad (7)$$

and Γ denotes the irreducible representation of a certain set of excited states under consideration.

Equations 3a and 3b should be a simultaneous solution of Eq. 1, which is therefore iteratively solved in the self-consistent manner. Thus the coefficients $C_{\rm ph,vf}(S)$ can be given by a solution of Eq. 3b. However, it is known that we can safely bypass the problem of solving Eq. 3b by indirectly guessing a good starting ground state.[5,6,14,15] If we know the coefficients $C_{\rm ph,vf}(S)$ of such starting ground state, the charge densities can be calculated. Invoking the identity, Operator $\times e^{U}$, one obtaines

$$\begin{aligned}\rho_{\rm u} &= (2)^{1/2}<0|C^{+}_{\rm uu}(00)|0> \\ &= (2)^{1/2}N_0<0|e^{U}\{C^{+}_{\rm uu}(00) + [C^{+}_{\rm uu}(00),U] \\ &\qquad - (2!)^{-1}[U,[C^{+}_{\rm uu}(00),U]]+\cdots\}|HF> \\ &= (2)^{-1}\sum_{S}\sum_{\rm h}\sum_{\rm vf}|C_{\rm uh,vf}(S)|^2 \quad (\text{for all } \Gamma_i)\end{aligned} \quad (8)$$

where we use the normalization condition of Eq. 7 and assume the orthogonality condition:

$$\ll C^{+}_{\rm uo}(S0)C^{+}_{\rm eg}(\overline{S0})|HF>|C^{+}_{\rm ph}(S0)C^{+}_{\rm vf}(\overline{S0})|HF\gg = <\Psi_{\rm uo,eg}(S)|\Psi_{\rm ph,vf}(S)> = \delta_{\rm uo,ph}\delta_{\rm eg,vf} \quad (9)$$

We have used the notation uo and eg for the *u*noccupied-*o*ccupied and *e*xcited *g*round state molecular orbital pairs. In the braces of the second line of Eq. 8 the terms higher than the second term vanish, formally, under the assumption of Eq. 6.

$$\begin{aligned}\rho_{\rm o} &= 2^{1/2}<0|C^{+}_{\rm oo}(00)|0> \\ &= 2 - (1/2)\sum_{S}\sum_{\rm p}\sum_{\rm vf}|C_{\rm po,vf}(S)|^2 \quad (\text{for all } \Gamma_i)\end{aligned} \quad (10)$$

In the present paper, the starting charge densities ρ_i's are computed by using Eqs. 5, 8, and 10 together with the relationship such as suggested by Shibuya and McKoy:[15]

$$C^{\rm trial}_{\rm ph,vf}(S) \approx (E_{\rm p}+E_{\rm v}-E_{\rm h}-E_{\rm f})^{-1}B^{\rm nRPA}_{\rm ph,vf}(S) \quad (11)$$

As a matter of course, these coefficients are computed for all the particle-hole pair (ph, vf) configurations in the RPA equation. A trial correlated ground state may also be obtained either by solving the CI secular equation constructed by admixing the Hartree-Fock ground state with the doubly excited singlet configurational state, or by the corresponding perturbation treatment.[5,14] From the case when we use Eq. 11 to compute ρ_i, we should not conclude that in the CI method (*cf.* Eq. 16 below) the triplet correlation effect is formally unable to be taken into account because of the spin-orthogonality between the ground and triplet configurational state functions. As will be discussed in the next section, it should be considered that in the CI method the triplet correlation effect is implicitly included as an average of spin-flips through the $\boldsymbol{B}(S)$ matrix of the RPA equation.

If we follow Sanderson and da Providência,[11,12] we can determine a solution of Eq. 3b for the trial rRPA equation, whose matrix elements are computed by the coefficients $C_{\rm ph,vf}(S)$ assumed initially in accordance with Eq. 11. Then, we can newly determine the coefficients as

$$\boldsymbol{C}^{\rm new} = (\tilde{\boldsymbol{Y}}^{-1}\tilde{\boldsymbol{Z}})^{\rm trial} = (\tilde{\boldsymbol{Z}}\tilde{\boldsymbol{Y}}^{-1})^{\rm trial} \quad (12)$$

which gives the new correlated charge densities. Thus, the self-consistent solution of the rRPA equation, that is SCrRPA, may be obtained iteratively. The convergence criterion used is that $|\rho_i(\text{new})-\rho_i(\text{old})| \leqq 10^{-5}$ for all the MO's.

The oscillator strength $f_{\lambda 0}$ for the λth renormalized states is computed by

$$f_{\lambda 0} = (2/3)\omega_\lambda|\boldsymbol{D}_{\lambda 0}|^2 \quad (\omega_\lambda, \boldsymbol{D}_{\lambda 0} \text{ in a.u.}) \quad (13)$$

with

$$\boldsymbol{D}_{\lambda 0} = -\sum(\tilde{Y}^{*}_{\rm ph}(\lambda 0)+\tilde{Z}^{*}_{\rm ph}(\lambda 0))\tilde{\boldsymbol{d}}_{\rm ph} \quad (14)$$

and

$$\tilde{\boldsymbol{d}}_{\rm ph} = (\rho_{\rm h}-\rho_{\rm p})^{1/2}\boldsymbol{d}_{\rm ph} = (\rho_{\rm h}-\rho_{\rm p})^{1/2}<\phi_{\rm p}(1)|\boldsymbol{r}(1)|\phi_{\rm h}(1)> \quad (15)$$

Comments on the Approximately Self-Consistent Ground-State Correlation Amplitude: $C_{\rm ph,vf}(S)$

For the assumption of Eq. 5 together with those of Eq. 11 and/or Eq. 12, we can also assume the following familiar perturbation expansion, Eq. 16, in the CI method. By using the former assumption, we compute the starting correlated charge densities and perform the SCrRPA calculations in order to compare with our previous work based upon the latter assumption.

The criterion for determining the configurational functions to be chosen in Eq. 16 was set up within 10^{-3} in the absolute values of their coefficients. We broke off the CI calculation at the stage that the number of configurations amounted to fifty and computed the

charge densities. We thus truncated the configurations adopted in the RPA equation. In this section, we shall clarify the similarity and the dissimilarity of these two methods for the RPA ground state, and further elucidate the meaning of the CI (TDA) method for the $B(S)$ matrix of the RPA equation.

In the CI language, the correlated ground state may be described by

$$|0\rangle = N_0\Big\{|HF\rangle - \sum_{ij}\sum_{kl}\frac{\langle\Phi_{ij}^{kl}(00)|\mathscr{H}|HF\rangle}{\Delta^1 E_{ij}^{kl}}|\Phi_{ij}^{kl}(00)\rangle + \sum_{mn}\sum_{st}\sum_{ij}\sum_{kl}\frac{\langle\Phi_{mn}^{st}(00)|\mathscr{H}|\Phi_{ij}^{kl}(00)\rangle\langle\Phi_{ij}^{kl}(00)|\mathscr{H}|HF\rangle}{\Delta^1 E_{mn}^{st}\qquad\Delta^1 E_{ij}^{kl}} \times |\Phi_{mn}^{st}(00)\rangle + \cdots\Big\}$$
$$= N_0(|HF\rangle + \sum_{ij}\sum_{kl} C_{ij}^{kl}|\Phi_{ij}^{kl}(00)\rangle + 0(\text{2nd order})) \tag{16}$$

with

$$\Delta^1 E_{ij}^{kl} = \langle\Phi_{ij}^{kl}(00)|\mathscr{H}|\Phi_{ij}^{kl}(00)\rangle - \langle HF|\mathscr{H}|HF\rangle.$$

The HF ground-state and the five types of doubly excited configurational wavefunction $\Phi_{ij}^{kl}(SM)$ are given in terms of the following Slater determinants:[16]

$$|HF\rangle = |1\bar{1}2\bar{2}...f\bar{f}...k\bar{k}...o\bar{o}...g\bar{g}...| \tag{17}$$

$$\Phi_{hh}^{pp}(00) = a_{p\alpha}^{+}a_{p\beta}^{+}a_{h\beta}a_{h\alpha}|HF\rangle = |f\bar{f}p\bar{p}| = C_{ph}^{+}(00)C_{ph}^{+}(00)|HF\rangle \tag{18}$$

$$\Phi_{hh}^{pv}(00) = (2)^{-1/2}(a_{p\alpha}^{+}a_{v\beta}^{+}+a_{v\alpha}^{+}a_{p\beta}^{+})a_{h\beta}a_{h\alpha}|HF\rangle = (2)^{-1/2}(|p\bar{v}|+|v\bar{p}|) = (2)^{1/2}C_{ph}^{+}(00)C_{vh}^{+}(00)|HF\rangle \quad (p\neq v) \tag{19}$$

$$\Phi_{fh}^{pp}(00) = (2)^{-1/2}a_{p\alpha}^{+}a_{p\beta}^{+}(a_{h\beta}a_{f\alpha}+a_{f\beta}a_{h\alpha})|HF\rangle = (2)^{-1/2}(|f\bar{h}p\bar{p}|+|h\bar{f}p\bar{p}|) = (2)^{1/2}C_{pf}^{+}(00)C_{ph}^{+}(00)|HF\rangle \quad (f\neq h) \tag{20}$$

$$\Phi_{fh}^{pv}(I)(00) = (2)^{-1}(a_{p\alpha}^{+}a_{v\beta}^{+}+a_{v\alpha}^{+}a_{p\beta}^{+})(a_{h\beta}a_{f\alpha}+a_{f\beta}a_{h\alpha})|HF\rangle = (2)^{-1}(|f\bar{h}p\bar{v}|+|\bar{f}h\bar{p}v|-|\bar{h}fp\bar{v}|-|h\bar{f}\bar{p}v|) = (2)^{-1}(C_{pf}^{+}(00)C_{vh}^{+}(00) + C_{ph}^{+}(00)C_{vf}^{+}(00))|HF\rangle \quad (p\neq v, f\neq h) \tag{21}$$

$$\Phi_{fh}^{pv}(II)(00) = (2\sqrt{3})^{-1}\{2(a_{p\alpha}^{+}a_{v\alpha}^{+}a_{h\alpha}a_{f\alpha}+a_{p\beta}^{+}a_{v\beta}^{+}a_{h\beta}a_{f\beta}) + (a_{p\alpha}^{+}a_{v\beta}^{+}-a_{v\alpha}^{+}a_{p\beta}^{+})(a_{h\beta}a_{f\alpha}-a_{f\beta}a_{h\alpha})\}|HF\rangle = (2\sqrt{3})^{-1}\{2(|fh\bar{p}\bar{v}|+|\bar{f}\bar{h}pv|) - |fh\bar{p}\bar{v}|-|\bar{f}hp\bar{v}|-|fhp\bar{v}|-|f\bar{h}\bar{p}v|\} = (3)^{-1/2}(C_{pf}^{+}(00)C_{vh}^{+}(00) - C_{ph}^{+}(00)C_{vf}^{+}(00))|HF\rangle \quad (p\neq v, f\neq h) \tag{22}$$

Following Murrell and McEwen,[16] the matrix element between $\Phi_{ij}^{kl}(00)$ and $|HF\rangle$ are easily written down in terms of the matrix elements of $B(S)$ in the RPA equation as

$$\langle\Phi_{hh}^{pp}(00)|\mathscr{H}|HF\rangle = B_{ph,ph}(0) = -B_{ph,ph}(1) \tag{23}$$

$$\langle\Phi_{hh}^{pv}(00)|\mathscr{H}|HF\rangle = (2)^{1/2}B_{ph,vh}(0) = -(2)^{1/2}B_{ph,vh}(1) \tag{24}$$

$$\langle\Phi_{fh}^{pp}(00)|\mathscr{H}|HF\rangle = (2)^{1/2}B_{ph,pf}(1) \tag{25}$$

$$\langle\Phi_{fh}^{pv}(I)(00)|\mathscr{H}|HF\rangle = -\langle pv|fh\rangle - \langle pv|hf\rangle = (2)^{-1}(3B_{ph,vf}(1) - B_{ph,vf}(0)) \tag{26}$$

$$\langle\Phi_{fh}^{pv}(II)(00)|\mathscr{H}|HF\rangle = (3)^{1/2}(\langle pv|hf\rangle - \langle pv|fh\rangle) = (\sqrt{3}/2)(B_{ph,vf}(1)+B_{ph,vf}(0)) \tag{27}$$

which indicate that the ground-state correlation amplitude in this scheme is also determined by the singlet and triplet $B(S)$ matrices just as in Eq. 11.

The derivation of Eqs. 26 and 27 is not straightforward. Nakayama and I'Haya[17] adopted the four-electron spin-functions which are different from Eqs. 21 and 22:

$$\Psi_{fh}^{pv}(I)(00) = (2\sqrt{3})^{-1}\{2(|f\bar{h}\bar{p}v|+|\bar{f}hp\bar{v}|) - |f\bar{h}p\bar{v}|-|\bar{f}hpv|-|\bar{f}\bar{h}pv|-|fhp\bar{v}|\} \tag{28}$$

$$\Psi_{fh}^{pv}(II)(00) = (2)^{-1}\{|f\bar{h}p\bar{v}|+|\bar{f}hpv|-|\bar{f}\bar{h}pv|-|fhp\bar{v}|\}, \tag{29}$$

and obtained the corresponding matrix elements

$$\langle\Psi_{fh}^{pv}(I)(00)|\mathscr{H}|HF\rangle = (3)^{1/2}B_{ph,vf}(1) \tag{30}$$

$$\langle\Psi_{fh}^{pv}(II)(00)|\mathscr{H}|HF\rangle = -B_{ph,vf}(0). \tag{31}$$

It has been pointed out by Anno and Teruya[18] that a set of Eqs. 21 and 22 is transformed into that of Eqs. 28 and 29, and that any unitary transformation of a set of spin-functions given in Eqs. 21 and 22 may be adopted as the configurational basis functions. This implies that an arbitrary degree of freedom of spin-flips is endowed for the four-electron spin-functions. Such an inverse transformation gives

$$\begin{pmatrix}\Phi_{fh}^{pv}(I)\\ \Phi_{fh}^{pv}(II)\end{pmatrix} = \begin{pmatrix}\cos 150^\circ & \sin 150^\circ\\ -\sin 150^\circ & \cos 150^\circ\end{pmatrix}\begin{pmatrix}\Psi_{fh}^{pv}(I)\\ \Psi_{fh}^{pv}(II)\end{pmatrix} \tag{32}$$

from which we can obtain Eqs. 26 and 27 by using Eqs. 30 and 31.

From Eq. 16, the correlated charge densities are written down as (i, j: holes and k, l: particles)

$$\rho_j = 2 - N_0^2\sum_{i}\sum_{kl}|C_{ij}^{kl}|^2(1+\delta_{ij}) \tag{33a}$$

$$\rho_k = N_0^2\sum_{ij}\sum_{l}|C_{ij}^{kl}|^2(1+\delta_{lk}) \tag{34a}$$

which are easily derived in the following way by introducing the one-electron operator in the first quantization, for which we set $e_\nu=1$ after integration:

$$\rho_j = \langle 0|\sum_\nu e_\nu\delta_{\nu j}|0\rangle = N_0^2(1+\sum_{ij'}\sum_{kl}|C_{ij'}^{kl}|^2+\cdots)\langle HF|\sum_\nu e_\nu\delta_{\nu j}|HF\rangle + N_0^2\sum_{ij'}\sum_{kl}|C_{ij'}^{kl}|^2[\langle\Phi_{ij'}^{kl}|\sum_\nu e_\nu\delta_{\nu j}|\Phi_{ij'}^{kl}\rangle - \langle HF|\sum_\nu e_\nu\delta_{\nu j}|HF\rangle]+\cdots = 2 + N_0^2\sum_{ij'}\sum_{kl}|C_{ij'}^{kl}|^2(e_k\delta_{kj}+e_l\delta_{lj} - e_i\delta_{ij}-e_{j'}\delta_{j'j})+\cdots \tag{33b}$$

and similarly

$$\rho_k = \langle 0|\sum_\nu e_\nu\delta_{\nu k}|0\rangle, \tag{34b}$$

δ_{ij} being the Kronecker delta. Note that Eqs. 33a, b and 34a, b correspond to Eqs. 8 and 10 respectively.

a) 40 particle-hole pairs=5(unocc.)×8(occ.) are taken into account. For molecular geometries, see Ref. 21. $n\pi^*$ denotes the σ-π^* and π-σ^* transitions. As for definition of the transition moment directions, θ, see Ref. 22. b) Taken from our previous paper, Ref. 14, with some numerical revision. c) From Refs. 23 and 24. d) K. Imakubo, T. Higashimura, and T. Sidei, *J. Phys. Soc. Jpn.*, **22**, 339 (1967).

It is thus found that the use of Eq. 16 is one of ways to compute the approximately self-consistent charge density ρ_i and is quite similar to the use of Eq. 11. It is also clear that not only the singlet but also the triplet correlation effects are effectively included in Eq. 16 through the $B(S)$ matrix as in Eq. 11.

Numerical Results and Discussion

In the computation, we consider the 40 particle-hole pair configurations obtained by raising an electron from the *eight* highest occupied molecular orbitals to one of the *five* lowest vacant molecular orbitals. The computed results are listed in the first column of Table 1, and compared with the results of our previous work[14] and the experimental values. It is observed that the lowest triplet levels obtained by the SCrRPA are very much refined compared with those calculated with the rRPA. The computed oscillator strengths and the directions of polarizations are almost the same in these RPA's. Table 1 shows that the relationship ω(SCγ-RPA)$>\omega$(rRPA; Eq. 16)$>\omega$(TDA)$>\omega$(nRPA) holds for most cases. More detailedly, the following relationship holds for the four DNA bases:

$$\omega(\text{SCrRPA})>\omega(\text{rRPA; Eq. 16})>\omega(\text{rRPA; Eq. 11})>\omega(\text{TDA})>\omega(\text{nRPA}) \quad (35)$$

After all, the starting correlated RPA ground state obtained with Eq. 11 needs some more iteration steps to attain to a self-consistent renormalized solution, under the constraint of Eq. 12. It can be safely said that the correlated ground state (HF+doubly excited CI's) based upon Eq. 16 in the above treatment yields a satisfactorily approximate SCrRPA solution. The sequence of Eq. 35 indicates that the SCrRPA produces the upper bounds for the energy levels, while the nRPA yields the lower bounds.

The self-consistency was attained after nine iterations for adenine, guanine and cytosine, whereas thymine could not reach self-consistency even after thirteen iterations. We fixed the correlated charge densities as $\rho(\text{new}')=(1/2)\{\rho(\text{new})+\rho(\text{old})\}$ at every iteration step to get a quick convergence. In order to carry out the

Table 2. Pure $\pi\pi^*$ excitation energies (ω, in eV) and oscillator strengths (f) of four DNA bases, for which all the possible $\pi\pi^*$ configurations are taken from the CNDO/S basis MO's

self-consistent calculation of thymine within the limited time (10 min), we therefore had to divide the 80×80 RPA matrix into the two matrices for the $(\pi\pi^*+\sigma\sigma^*)$ elements and the $(\sigma\pi^*+\pi\sigma^*)$ elements. As immediately understood from Eq. 6, such division of the matrix truncates, to some extent, the correlation effect arising from the other symmetry group, but this error seems to be not very large. Perhaps, some other suitable molecular geometries of thymine may give a self-consistent solution for the 40 particle-hole pairs after 9—10 iterations, without dividing the matrix. In fact, for the molecular geometry of thymine given in Ref. 20 we obtain the self-consistency after seven iterations. The results of the SCrRPA are as follows; 3.34 eV ($n\pi^*$, $f=0.018$), 4.36 ($n\pi^*$, $f=0.012$), 5.63 ($\pi\pi^*$, $f=0.019$, $\theta=-2°$), 6.97 ($\pi\pi^*$, $f=0.301$, $\theta=60°$), 7.02 ($n\pi^*$, $f=0.002$)eV for the singlets, and 2.08 ($n\pi^*$), 4.00 ($n\pi^*$)eV for the triplets. These results are somewhat different from those of Table 1.

We also carried out the SCrRPA calculation for all the possible pure $\pi\pi^*$ particle-hole pair configurations taken from the CNDO/S basis molecular orbitals, and found that Eq. 35 holds for the four bases of DNA as shown in Table 2. In particular, it should be noted that the pure $\pi\pi^*$ triplet levels are worse than those of Table 1 obtained from the RPA equations for the 40 particle-hole pair configurations involved the $\pi\pi^*$, $\sigma\sigma^*$, $\sigma\pi^*$, and $\pi\sigma^*$-transitions explicitly. Clearly, comparison of the results in Tables 1 and 2 suggests the great importance of the effect of σ-electron clouds to the refinement of the pure $\pi\pi^*$ triplet levels, which corresponds to the involvement of the dynamical screening by σ-electrons in π-electron transitions as mentioned by Shibuya, I'Haya, and McKoy.[19]

Finally, it should be mentioned that putting aside the problem how to include the electron correlation effect, re-parametrization of CNDO/S method is needed to refine the present results numerically. Especially, the lowest triplet levels of these DNA bases do not agree well with the experimental values. Such disagreement comes from the fact that the Nishimoto-Mataga approximation in the CNDO/S method reproduces the singlet levels well, but makes the triplet levels relatively low. Perhaps, the use of the INDO/S method[4,13] in the SCrRPA may be one of ways for taking steps.

The Crystal and Molecular Structures of Dichloro-1,2-bis(di-*t*-butylphosphino)-ethaneplatinum(II) and its Chlorobenzene Solvate

Masahiro HARADA, Yasushi KAI, Noritake YASUOKA, and Nobutami KASAI

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received July 23, 1976)

X-Ray crystal structure analyses of $[PtCl_2\{(t\text{-}Bu)_2P(CH_2)_2P(t\text{-}Bu)_2\}]$ (I) and $[PtCl_2\{(t\text{-}Bu)_2P(CH_2)_2P(t\text{-}Bu)_2\}, C_6H_5Cl]$ (II) have been carried out. Crystals of I belong to monoclinic system: $a=20.595(3)$, $b=7.917(3)$, $c=14.885(2)$ Å, $\beta=109.03(1)°$, space group $P2_1/c$ with $Z=4$. II forms monoclinic crystals, $P2_1/c$: $a=14.873(2)$, $b=13.193(2)$, $c=15.314(2)$ Å, $\beta=98.75(1)°$, $Z=4$. Both structures, solved by the heavy-atom method, have been refined anisotropically by least-squares procedure to $R=0.067$ and 0.078 for I and II respectively. There is no essential difference between the structures of $[PtCl_2\{(t\text{-}Bu)_2P(CH_2)_2P(t\text{-}Bu)_2\}]$ molecules in I and II. The coordination around the platinum atom is square-planar; Pt–P=2.262(3) and 2.265(3) Å and Pt–Cl=2.374(4) and 2.365(4) Å. The molecule has a pseudo-C_2 symmetry: the platinum atom and the center of the C–C bond in the P–C–C–P lie on this pseudo-C_2 axis.

Recently, Otsuka and his co-workers have made studies of a series of bis(di-substituted phosphino)-alkaneplatinum complexes. In co-operation with them we have carried out the molecular structure determination of these complexes by means of X-ray diffraction. This paper describes the crystal structure analyses of dichloro-1,2-bis(di-*t*-butylphosphino)ethaneplatinum(II) $[PtCl_2\{(t\text{-}Bu)_2P(CH_2)_2P(t\text{-}Bu)_2\}]$ and its chlorobenzene solvate.

Experimental

Crystals of $[PtCl_2\{(t\text{-}Bu)_2P(CH_2)_2P(t\text{-}Bu)_2\}$ (I) were kindly provided by Professor Sei Otsuka and co-workers. Depending upon the recrystallization conditions two kinds of crystals were obtained. Preliminary Weissenberg photographs (Cu-$K\alpha$) showed that both crystals belong to the monoclinic system, and their corresponding space groups are both $P2_1/c$ (No. 14; absent reflections, $h0l$, $l=2n+1$ and $0k0$, $k=2n+1$). Crystals with approximate dimensions of (I) $0.15\times0.17\times0.25$ and (II) $0.27\times0.45\times0.60$ mm were carefully centered on a Rigaku automated, four-circle single-crystal diffractometer. It was necessary to seal the latter crystal in a thin-walled glass capillary tube with a small amount of chlorobenzene in order to prevent decomposition during the experiment.

The unit-cell parameters of both crystals were determined at 20 °C by least-squares fits using 23 and 45 high-angle reflections, respectively. The crystal data are given in Table 1.

Intensity data of both crystals were collected at 20 °C on the Rigaku diffractometer. Graphite-monochromatized Mo$K\alpha$ radiation was used. All data within a 2θ sphere of 54° were measured using the θ-2θ scan technique. The asymmetric scan width $\Delta(2\theta)$ of each reflection was calculated by the equation: $\Delta(2\theta)=(A+B\tan\theta_c)°$, where θ_c is the calculated value of the Bragg angle using $\lambda(MoK\alpha_1)$ (= 0.70926 Å) and $A=2.0$, $B=0.69$ for I and $A=2.4$, $B=0.69$ for II. The starting angle of the scan was $(2\theta_c-A/2)°$, and the scanning speed was 4.0° min^{-1}. The background count was obtained by averaging the two values measured, for 6 and 5 s respectively for I and II, at both ends of a scan. Corrections for background scattering and the usual Lorentz and polarization effects were applied. No absorption correction was employed. For weak reflections of $|F|<3\sigma(F)$ the peak scan was repeated twice. Four standard reflections (10,0,0, 006, 440, 42$\bar{9}$) were measured after every 60 reflections; these remained constant within the error limits, throughout the data collections. Totals of 5035 (4350 non-zero ($|F|\geqq3\sigma(F)$)) and 6504 (5437 non-zero) reflections were collected for I and II, respectively.

a) Flotation in tribromomethane–carbon tetrachloride solution at 20 °C.

Solution and Refinement of Structures

Each of the structures of I and II was solved by the heavy atom method. The platinum atom was located from a three-dimensional Patterson map. All the non-hydrogen atoms were revealed from the subsequent Fourier syntheses. Refinement of the atomic positional and thermal parameters was carried out by the block-diagonal least-squares procedure. The HBLS V program[1] was used.

Final reliability factors are: I, $R=0.088$(0.067 for non-zero reflections); II, $R=0.105$ (0.078). The weighting scheme used was $w=\{\sigma(F)^2+a|F_o|+b|F_o|^2\}^{-1}$ for $|F_o|>0$ and $w=FWT$ for $|F_o|=0$, where $a=0.10071$, $b=0.00007$, and $FWT=0.05613$ for I and $a=0.0365$, $b=0.0039$, and $FWT=0.04715$ for II. A difference synthesis, based on the final atomic parameters, did not reveal the positions of hydrogen atoms nor any other significant features. The final positional and thermal parameters are given in Table 2.*

* The Tables of structure factors are kept as Document No. 7636 and 7637 at the Chemical Society of Japan.

Throughout the calculation the atomic scattering factors used were those of neutral atoms given in International Tables for X-ray Crystallography, Vol. IV.[2] For I, the effects of the anomalous dispersion of Pt, Cl, P, and C atoms were included in the calculation; the values of $\Delta f'$ and $\Delta f''$ were also taken from the International Tables for X-Ray Crystallography.[3]

Results and Discussion

Molecular Structure. Figure 1 gives a stereoscopic drawing of the molecule in I. Bond lengths and bond angles are listed in Table 3. Selected bond lengths and bond angles of the molecule in II are given in Fig. 2 with the numbering scheme of the atoms. Figure 3 shows a comparison of selected bond lengths and bond angles between I and II, in which chemically equivalent bond lengths and bond angles have been averaged. This result clearly shows that there is no essential difference between the molecular structures in I and II, in spite of the different molecular packings. Therefore, from now on we will discuss only the molecular structure of I, the more accurate one of the two, except for the case of crystalline chlorobenzene.

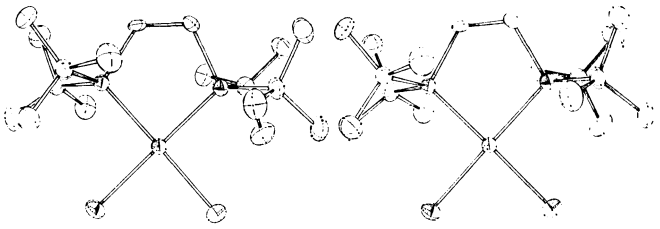

Fig. 1. A stereoscopic drawing of $[PtCl_2\{(t\text{-}Bu)_2P(CH_2)_2P(t\text{-}Bu)_2\}]$ molecule in I. Thermal ellipsoids are drawn at 30% probability level.

The co-ordination around the platinum atom is square-planar: Pt, P, and two Cl atoms are coplanar within 0.004 Å. The molecule has a pseudo C_2 symmetry. The platinum atom lies on the pseudo C_2 axis, which also passes through the center of the C(1)–C(2) bond in $\{(t\text{-}Bu)_2P(CH_2)_2P(t\text{-}Bu)_2\}$ ligand. The P–C–C–P moiety, as a bidentate chelating ligand,

is puckered in a manner similar to that observed in co-ordinated ethylenediamine rings. The methylene carbon atoms are displaced, by 0.30 and 0.28 Å, to the opposite sides of the co-ordination plane.

The Pt–P bond lengths [2.262(3) and 2.265(3) Å] are as much as 0.14 Å shorter than the sum of the covalent radii [2.41 Å].[4] On the other hand, the Pt–Cl bond lengths [2.374(4), 2.365(4) Å] are significantly longer than the sum of the covalent radii [2.30 Å].

The P–C(bridge) bond lengths [both 1.86(2) Å] are close to the sum of the covalent radii [1.87 Å], and are slightly shorter than the P–C(*t*-Bu) bonds [all 1.89(2) Å]. The two *t*-butyl groups attached to the same phosphorus atom are in a staggered position.

Solvated Chlorobenzene Molecule. Crystals of II contain solvated chlorobenzene molecules. The electron-density map calculated on the mean plane of chlorobenzene does not show a normal distribution with respect to magnitude and anisotropy. The rather low peak heights suggest that the occupancy of chlorobenzene is less than unity and/or that their positional fluctuations in the crystal are fairly large. Consequently, the bond lengths and bond angles are not satisfactory ones.

Crystal Structure. A stereoscopic drawing of the molecular packings of I and II are given in Figs. 4 and 5. Figure 6 illustrates the crystal structure of II projected along the c axis. The $[PtCl_2\{(t\text{-}Bu)_2P(CH_2)_2P(t\text{-}Bu)_2\}]$ molecules are piled up in columns along the c axis, and the chlorobenzene molecules are packed in voids between these columns with rather loose molecular contacts.

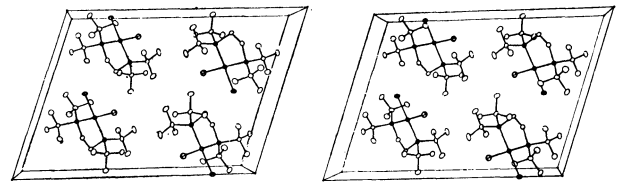

Fig. 4. A stereoscopic drawing of the molecular packing in I.

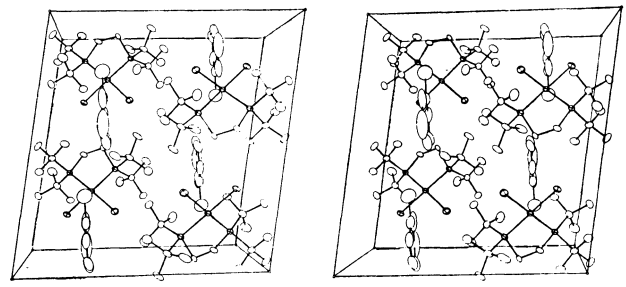

Fig. 5. A stereoscopic drawing of the molecular packing in II.

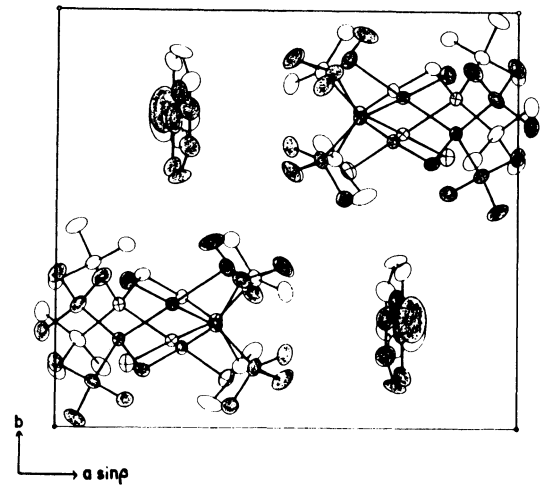

Fig. 6. Crystal structure of II projected along the c axis.

All intermolecular atomic contacts in I and II are considered to be at the usual van der Waals distances.

Computations throughout the present study were carried out on a NEAC 2200-700 computer at Osaka University. Figures 1, 4, and 6 were drawn on the NUMERICON 7000 system at Osaka University with a local version of ORTEP.[5]

The authors wish to express their thanks to Professor Sei Otsuka and his co-workers for the crystals and their helpful discussions.

(Received July 24, 1976)

Proton and carbon-13 nuclear magnetic resonance spectra and Raman spectra of some methylmercury compounds, CH_3HgX, were measured. The spin-spin coupling constants, $^2J(^{199}Hg-H)$ and $^1J(^{13}C-H)$ of methylmercury nitrate in some strong acids were found to increase when the proton resonance of the methyl group attached to the mercury shifts to lower magnetic field. It was also found that the C-H stretching bands of the methyl group shift to higher frequency in the strong acids. The results are explained by an increase of the effective positive charge on the mercury. As has been observed in other alkylmercury compounds, the spin-spin coupling constant between directly bonded mercury and carbon nuclei, $^1J(^{199}Hg-^{13}C)$, of some methylmercury compounds in organic solvents increased with the geminal spin-spin coupling constant, $^2J(^{199}Hg-H)$. The $^1J(^{199}Hg-^{13}C)$ value of methylmercury nitrate in strong acids was found to decrease, whereas the $^2J(^{199}Hg-H)$ values increased in these media. The lowering of the mercury-carbon bond strengths in the strong acids, which was revealed from the mercury-carbon stretching frequency in the Raman spectra, is considered one possible reason for the decrease of the $^1J(^{199}Hg-^{13}C)$ value.

In recent years a great deal of information on heavy atom–proton and –carbon-13 spin-spin couplings has accumulated, particularly for the mercury system. Hatton, Schneider, and Siebrand[1] have shown that in a series of methylmercury compounds, CH_3HgX, the geminal spin-spin coupling constant, $^2J(^{199}Hg-H)$, is approximately accounted for by the Fermi contact mechanism. Henneike[2] has also shown from a semi-empirical molecular orbital study of a number of methylmercury compounds that the orbital contraction for the mercury 6S orbital with increasing electronegativity of the substituent, X, is an important contributing factor to the spin-spin coupling constant. Singh[3] and Ibusuki and Saito[4] have indicated that the Fermi contanct interaction is predominant in the mercury–proton and –carbon-13 spin-spin coupling constants by showing linear relationships between the spin-spin coupling constants $^1J(^{199}Hg-^{13}C)$ and $^2J(^{199}Hg-H)$ which pass almost through the origin for neopentylmercury compounds, $(CH_3)_3CCH_2HgX$, and 2-methoxy-2-methylpropylmercury compounds, $(CH_3)_2C(OCH_3)CH_2HgX$, respectively.

In parallel with these studies, the proton and carbon-13 nuclear magnetic resonance spectra of a variety of organomercury compounds have been used for structural and bonding studies,[5-26] because the $^1J(^{199}Hg-^{13}C)$ and $^2J(^{199}Hg-H)$ values are influenced markedly by substituents at the mercury.

In the present paper, the proton and carbon-13 nuclear magnetic resonance spectra of methylmercury nitrate, CH_3HgNO_3, in some strong acids were studied to find out the effect of the effective positive charge on the mercury on the spin-spin coupling constants, $^1J(^{199}Hg-^{13}C)$, $^2J(^{199}Hg-H)$, and $^1J(^{13}C-H)$. The Raman spectra of methylmercury nitrate were also measured in the strong acids; the results are discussed with the nuclear magnetic resonance spectral date.

Experimental

Preparation of Compounds. Methylmercury bromide was prepared by Grignard reaction of methylmagnesium bromide and mercury dibromide in ether and purified by recrystallization from methanol. Methylmercury cyanide and nitrate were obtained by stirring a mixtures of methylmercury bromide and appropriate silver salts in methanol for 5 h at ambient temperature. After filtering off the silver bromide, concentration of the filtrate at reduced pressure yielded crystalline compounds. The compounds were dried *in vaccuo* and were stored in a desiccator.

NMR Spectra. The Proton magnetic resonance spectra were measured on a JEOL model JNM-PS-100 spectrometer operating at 100 MHz. The chemical shifts were measured relative to internal tetramethylsilane and sodium 2,2-dimethyl-2-silapentane-5-sulfonate, DSS. The spin-spin coupling constants, $^1J(^{13}C-H)$ and $^2J(^{199}Hg-H)$, and the chemical shift of the methyl group, $\delta(Hg-C\underline{H}_3)$, obtained for methylmercury compounds in about 10 wt% solution are shown in Table 1. The values of dimethylmercury[16] and methylmercury ion[21] also appear in Table 1.

The carbon-13 nuclear magnetic resonance spectra were run on a JEOL model JNM-PFT-100 pulse Fourier transform spectrometer operating at 25.14 MHz. Broad band proton noise decoupling was employed to eliminate the spin-spin coupling with the protons and to enhance the signal-to-noise ratio. $(CD_3)_2CO$ was used as a lock signal. Good spectra were obtained generally by scanning 1500—2000 times. The spin-spin coupling constant, $^1J(^{199}Hg-^{13}C)$, for some methylmercury compounds in about 20 wt% solution is shown in Table 1.

Raman Spectra. The Raman spectra were recorded on a JEOL model JRS-02AS spectrometer using laser light of 4880 A. The mercury-carbon and carbon-hydrogen stretching frequencies of methylmercury nitrate in some strong acids are shown in Table 2. The concentration of the compounds was about 20 wt%. The data of some other methylmercury compounds[27-29] are also added for comparison.

Solvents. The organic solvents dried over a desiccant were purified by distillation. Inorganic acids obtained from commercial sources were used without further purification.

Results and Discussion

The proton magnetic resonance data of methylmercury nitrate in Table 1 show that the chemi-

cal shift of the methyl group, $\delta(Hg\text{-}C\underline{H}_3)$, shifts to lower magnetic field and concomitantly the geminal spin-spin coupling constant, $^2J(^{199}Hg\text{-}H)$, increases as the acid strength becomes large or the concentration of the acid increases. The chemical shift of the methyl proton, $\delta(Hg\text{-}C\underline{H}_3)$, of methylmercury nitrate in the strong acids is comparable to that of the methylmercury ion measured by Olah and Clifford[21] in a mixed solvent system, $FSO_3H\text{-}SO_2$, but the geminal spin-spin coupling constant, $^2J(^{199}Hg\text{-}H)$, of methylmercury nitrate is much larger than that of the methylmercury ion. The small $^2J(^{199}Hg\text{-}H)$ value of the naked methylmercury ion was predicted from the semiempirical molecular orbital calculation by Henneike.[2]

A fairly linear relation between the chemical shift of the methyl proton, $\delta(Hg\text{-}C\underline{H}_3)$, and the geminal spin-spin coupling constant, $^2J(^{199}Hg\text{-}H)$, is shown in Fig. 1. The relation is quite similar to that obtained for other series of methylmercury compounds, *i.e.*, increase of the geminal coupling constants, $^2J(^{199}Hg\text{-}H)$, is followed by increase of the electronegativity of

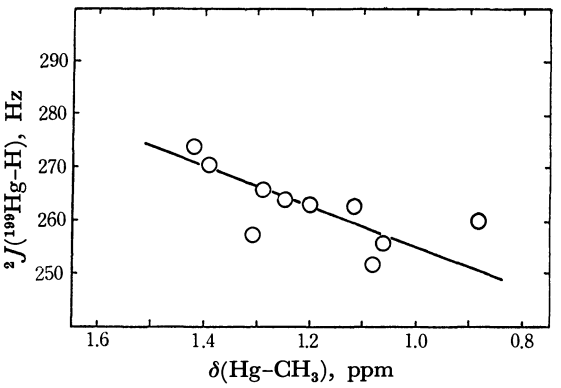

Fig. 1. Correlation between $\delta(Hg\text{-}CH_3)$ and $^2J(^{199}Hg\text{-}H)$ for methylmercury nitrate.

the substituents[10] or by decrease of the pK_a values of carboxylic acids.[15] But the relation is quite different from the relations obtained for dimethyllead dinitrate, dimethyltin oxide, and dimethylthallium nitrate in strong acids,[30] in which the geminal spin-spin coupling constants, $^2J(M\text{-}H)$(M=Sn, Pb, and Tl), decrease as the acid strength or the concentration of the acids increase.

Woodward and co-worker[29,31] have shown that there is the following equilibrium in an aqueous solution of methylmercury nitrate. Since the function of strong acids is to reduce the water activity below that necessary

$$CH_3HgONO_2 + H_2O \rightleftharpoons [CH_3HgOH_2]^+ + NO_3^-$$

to hydrate the cation fully, the equilibrium shown below may shift to the right in strong acids, where

$$[CH_3HgOH_2]^+ + Y^- + H^+ \rightleftharpoons [CH_3Hg^+\cdots Y^-] + H_3O^+$$

Y^- is the acid residue. In the $[CH_3Hg^+\cdots Y^-]$ species, the acid residue may coordinate weakly to mercury from the backside of the C–Hg bond. The effective positive charge, and therefore the orbital contraction of the mercury 6S orbital in the species, $[CH_3Hg^+\cdots Y^-]$, is probably larger than that of the hydrated species, $[CH_3HgOH_2]^+$, because the electron donating ability of the acid residue, Y^-, is considered to be smaller than water. The down field shift of the methyl proton, $\delta(Hg-C\underline{H}_3)$, and increase of the geminal spin-spin coupling constant, $^2J(^{199}Hg-H)$, in strong acids, therefore, may be due to an increase of the species $[CH_3Hg^+\cdots Y^-]$ in these media.

As can be seen from Table 1, the $^1J(^{13}C-H)$ value of the methyl group of the methylmercury nitrate increases when the acid strength or the concentration of the acids increases, although Henneike[2] obtained little variation of the $^1J(^{13}C-H)$ value for methylmercury compounds. Figure 2 gives a linear relation between the $^1J(^{13}C-H)$ and $\delta(Hg-C\underline{H}_3)$ values, which is expressed by the following equation, where the values in parentheses are the errors estimated at the 95% confidence level and the r is the correlation coefficient. The result is quite similar to that obtained for

$$^1J(^{13}C-H) = 9.8(\pm2.7)\delta(Hg-C\underline{H}_3) + 130.4(\pm3.1)\quad r=0.955$$

dimethyltin oxide in strong acids.[30] The dependence

$$^1J(^{13}C-H) = 5.6(\pm1.6)\delta(Sn-C\underline{H}_3) + 130.4(\pm2.1)\quad r=0.933$$

of the $^1J(^{13}C-H)$ value on the chemical shift of the methyl protons is much more acute in the case of methylmercury nitrate. A linear relation is also obtained between the $^1J(^{13}C-H)$ and $^2J(^{199}Hg-H)$ values for methylmercury nitrate in strong acids(see Fig. 2), which is represented by the following equation:

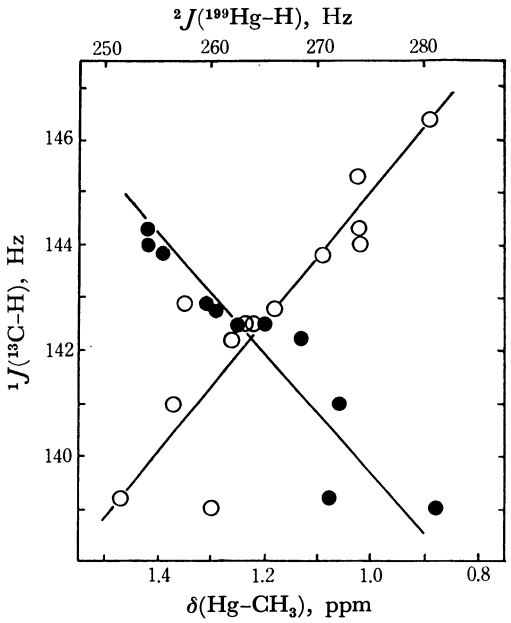

Fig. 2. Correlation between $^1J(^{13}C-H)$ and $\delta(Hg-CH_3)$ (—●—) and $^2J(^{199}Hg-H)$ (—○—) for methylmercury nitrate.

$$^1J(^{13}C-H) = 0.22(\pm0.11)^2J(^{199}Hg-H) + 84(\pm22)\quad r=0.879$$

The C–H symmetric and asymmetric stretching bands shown in Table 2 shift to higher frequencies in strong acids. The values are rather larger than those of dimethylmercury.[27] High C–H stretching freqeuencies of the methyl group of dimethyllead diperchlorate[32] and dimethyltin diperchlorate[33] in aqueous solutions relative to those of tetramethyl-lead and -tin,[34] respectively, have been reported. Brown and Puckett[35] have shown that in a variety of methyl compounds the spin-spin coupling constant, $^1J(^{13}C-H)$, of the methyl group increases linearly with increasing C–H symmetric and asymmetric stretching frequencies and therefore with the C–H stretching force constant. By using the present values for methylmercury nitrate and the reported values of the $^1J(^{13}C-H)$ and ν_{asym}-(C–H) values of 32 methyl compounds, we obtained the following equation relating these quantities:

$$^1J(^{13}C-H) = 0.237(\pm0.034)\nu_{asym}(C-H) - 576(\pm102)\quad r = 0.933$$

They[35] have shown theoretically that the C–H stretching force constant of these methyl compounds should depend on the C–H bond polarity, which will in turn depend on the electronegativity of the group attached to the methyl group. They concluded from these results that changes in the effective nuclear charge of carbon experienced by the electron in the C–H bonds can account for the principal variation in the $^1J(^{13}C-H)$ value of the methyl groups[36] and the assuming of a very large change in the hybridization parameter of carbon to fit the experimental value is not necessary. The increase of the $^1J(^{13}C-H)$ value of methylmercury nitrate in strong acids, therefore, may be accounted for by the same principle. The result is in accordance with the increase of the species $[CH_3Hg^+\cdots Y^-]$ in strong acids, since in this species the effective positive charge on the mercury and therefore the electronegativity of the mercury, is considered to be large.

Table 1 gives the spin-spin coupling constant, $^1J(^{199}Hg-^{13}C)$, of some methylmercury compounds. The value increases when the electron-withdrawing property of the substituent becomes large. A linear relation between the $^1J(^{199}Hg-^{13}C)$ and $^2J(^{199}Hg-H)$ values of these compounds in organic solvents and in water is shown in Fig. 3. The regression analysis for this relation gives the following equation:

$$^1J(^{199}Hg-^{13}C) = 7.65(\pm0.80)^2J(^{199}Hg-H) - 144(\pm173)\quad r = 0.997$$

Similar linear relations have been reported for 2-methoxy-2-methyl-propylmercury derivatives, $(CH_3)_2C(OCH_3)CH_2HgX$,[4] and for neopentylmercury compounds, $(CH_3)_3CCH_2HgX$.[3] The numerical values

$$^1J(^{199}Hg-^{13}C) = 8.47(\pm2.32)^2J(^{199}Hg-H) - 98(\pm140)\quad r=0.981***$$

$$^1J(^{199}Hg-^{13}C) = 7.8^2J(^{199}Hg-H) - 59$$

*** The regression analysis was made by using the reported values.[4]

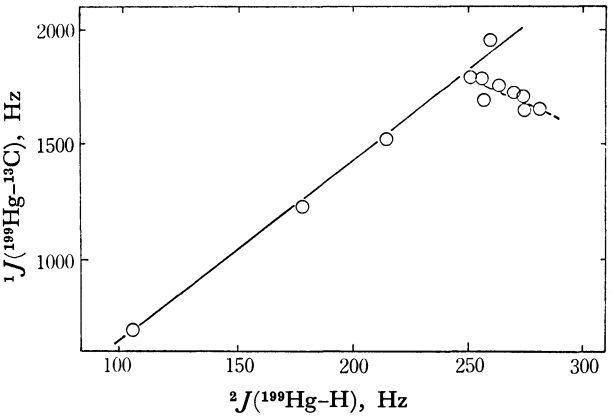

Fig. 3. Correlation between $^1J(^{199}Hg-^{13}C)$ and $^2J(^{199}Hg-H)$ for methylmercury compounds.

of these three equations are very similar. Although the lines do not pass exactly through the origin, the relations indicate that the Fermi contact term is mainly responsible for the spin-spin coupling constants, $^1J(^{199}Hg-^{13}C)$ and $^2J(^{199}Hg-H)$, in these cases. On the other hand, as can be seen from Table 1, the $^1J(^{199}Hg-^{13}C)$ value of methylmercury nitrate decreases when the acid strength increases, whereas the $^2J(^{199}Hg-H)$ value continues to incresae. These results cannot be explained by the simple assumption that the Fermi contact term plays a dominant role in the spin-spin coupling constant, $^1J(^{199}Hg-^{13}C)$.

According to the theory of spin-spin interaction developed by Ramsey,[37] the nuclear spin-spin coupling constant is, in addition to the Fermi contact interaction, affected by the following terms: 1) an orbital-dipole interaction between the magnitic field due to the orbital motion of the electron and the nuclear magnetic dipole (J_{orb}) and 2) a magnetic dipole-dipole interaction between the magnetic dipole of the spinning electron and the nuclear spin(J_{dipole}). Of these three basic interactions, the contact interaction is the main determinant of the nuclear spin-spin coupling constant, especially for H_2.[38] However, the J_{orb} and J_{dipole} terms have been found to be very important when one or both of the nuclei is electronegative, such as in the spin-spin coupling constant, $^1J(^{12}C-^{19}F)$ and $^{2,3}J(^{19}F-^{19}F)$.[39] In the spin-spin coupling constants, $^1J(^{13}C-^{13}C)$, the J_{dipole} term has been found to play a significant role.[39,40] Therefore, the contribution of the J_{orb} and J_{dipole} terms may be one reason for the decrease of the spin-spin coupling constant, $^1J(^{199}Hg-^{13}C)$, of methylmercury nitrate in strong acids. As can be seen from Table 2, the value of the mercury–carbon stretching frequency for methylmercury nitrate has a tendency to decrease in strong acids. The weakening of the mercury–carbon bond, therefore, may also be an another factor leading to a reduction of the $^1J(^{199}Hg-^{13}C)$ value. In an overlap population analysis of the molecular orbitals of the methylmercury compounds,[2] the overlap population between the mercury–carbon bond increases when the electronegativity of the substituent becomes large. The value of the overlap population of the hydrate species $[CH_3HgOH_2]^+$ is the largest among the methylmercury compounds. But the value of the naked methylmercury ion, CH_3Hg^+, is the smallest. Therefore, the bond properties for the mercury–carbon bond of the species $[CH_3Hg^+\cdots Y^-]$, which has been shown to be the predominant species of methylmercury nitrate in strong acids, may be in between those of the ions $[CH_3HgOH_2]^+$ and CH_3Hg^+.

We wish to express our hearty thanks to Professor Rokuro Okawara of Osaka University for his continuous encouragement throughout this study. We are also grateful to Dr. Teizo Kitagawa of the Protein Institute of Osaka University for the measurements of Raman spectra.

Crystal Vibrations and Intermolecular Interactions of CH_3X and CD_3X (X=Cl, Br, and I)

Hideo TAKEUCHI,* Jean-Luc BRIBES,** Issei HARADA, and Takehiko SHIMANOUCHI
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received August 11, 1976)

Normal coordinate treatments of the crystal vibrations of methyl chloride, methyl bromide, methyl iodide, and their perdeuterated analogs have been made. The values of force constants of non-bonded atom interactions have been determined so as to give the best fit to the lattice frequencies and the splitting frequencies of the intramolecular vibrations. It has been found that the dipole-dipole interactions are essential to account for the splittings of some internal modes, but their effects on lattice frequencies are negligible.

Methyl halides are fundamental polar molecules, for which the vibrational spectra in the crystalline state have been investigated extensively. Dows[1] observed the infrared spectra of methyl chloride, methyl bromide, and methyl iodide. He[2] discussed the splittings of intramolecular vibrations of methyl chloride on the basis of the crystal structure[3] and the dipole-dipole and atom-atom interactions. Hexter,[4] Jacox and Hexter,[5] and Kopelman[6] tried to interpret the splittings of the infrared absorptions of methyl halides by considering only the dipole-dipole interaction. Harada[7] also treated the splittings and lattice vibrations of methyl chloride. However, the crystal vibrations of methyl halides have not been fully explored yet, because there has been the lack of the data on the crystal structures of CH_3Br and CH_3I and on most of the lattice vibrations.

Recently, the crystal structures of CH_3Br and CH_3I have been determined.[8] The present authors have measured the Raman spectra of crystalline CH_3X and CD_3X (X=Cl, Br, and I) and interpreted the data on the basis of the crystal structures.[9] It is now possible to investigate the intermolecular interactions in the crystals of methyl halides in detail.

In this paper, we report the results of normal coordinate analysis of the optically active crystal vibrations of methyl halides, and discuss the intermolecular interactions. The observed far-infrared spectra of the crystals are also presented, which adds to the results of an earlier study by Lafferty and Robinson.[10]

Experimental

The far-infrared spectra were measured down to 60 cm^{-1} at liquid nitrogen temperature with a Hitachi FIS-1 far-infrared spectrometer after a similar procedure as described previously.[11] The samples were of the same origins as those used for the measurements of the Raman spectra.[9] The spectra are shown in Fig. 1.

Summary of the Experimental Results

Lattice Vibrations. Assignment to a translational or a rotational lattice mode is made on the basis of the frequency shift on deuteration: The frequency shifts

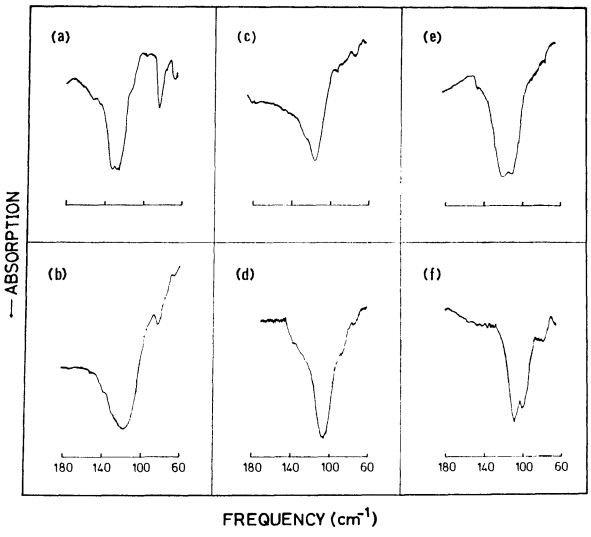

Fig. 1. Far-infrared spectra of methyl halides. (a) CH_3Cl, (b) CD_3Cl, (c) CH_3Br, (d) CD_3Br, (e) CH_3I, (f) CD_3I.

are expected to be about 30% for the rotational modes around the molecular symmetry axis and about 10% for those around the axes perpendicular to it, respectively, whereas the translational modes are expected to show no appreciable shift. Observed lattice frequencies and the assignments are summarized in Table 1.

For methyl chlorides, all the translational lattice vibrations are observed in the Raman spectra. The highest-frequency translational mode is observed also in the far-infrared spectra and therefore is assigned to either A_1 or B_2 species (see Table 2.).

Intramolecular Vibrations. Frequency splittings in the infrared spectra were observed by Dows[1] and Jacox and Hexter.[5] Frequency splittings in the Raman spectra were observed by Ito,[12] Brown and Lippincott,[13] and the present authors.[9]

The following modes are known to be perturbed by the Fermi resonance:[14] ν_1 and ν_4 of CH_3Cl, ν_1 of CH_3Br, ν_1 and ν_5 of CH_3I, and ν_1 of CD_3I.

Anomaly observed in the patterns of splitting and intensity of ν_3 mode for CH_3Cl and CD_3Cl has been ascribed to the coexistence of the chlorine isotopic (^{35}Cl and ^{37}Cl) molecules.[15]

Normal Coordinate Calculations

The calculations of the vibrational frequencies of the crystals have been performed by the use of the

b) Crystal structures are isomorphous; Pnma (D_{2h}^{16}), $Z=4$. A_u mode is infrared and Raman inactive.

Table 3. Computer program CVOA for treating optically active crystal vibrations

Input
- (a) Structure data
  - (1) Unit cell dimension and atomic positions (of one molecule) in the unit-cell coordinate system, or
  - (2) Unit cell dimension and atomic positions (of one molecule) in the Cartesian coordinate system
- (b) Symmetry relationship among molecules in a unit cell
  - Matrices for rotational operations
  - Vectors for translational operations
- (c) Intramolecular coordinates and force field
  - (1) Local symmetry coordinates plus intramolecular force field, or
  - (2) Normal coordinates and normal frequencies of a free molecule
- (d) Intermolecular force field
  - (1) Functional forms of atom-atom interactions, and/or
  - (2) Force constants relating to intermolecular or inter-unit bonding (*e. g.*, hydrogen bond, bond between adjacent units in a polymer chain, *etc.*)

Output
- (a) Frequencies of intramolecular and lattice modes
- (b) Eigenvectors and Cartesian displacements
- (c) Potential energy distributions
- (d) Jacobian

GF matrix method.[16] Computer programs have been developed and the input and output of these programs are outlined in Table 3.

Positions of Atoms. The positions of heavier atoms in the crystals are taken from the data of X-ray analyses[3,8] except for that of the carbon atom of methyl iodide. The structures of methyl groups were assumed to be the same as those in the gaseous state[17] due to the lack of data on the coordinates of hydrogen atoms.

There are two possible orientations of the methyl group. We adopted the one that was preferred in the original X-ray studies[3,8] on consideration of atom-atom contacts. For methyl iodide, after a preliminary calculation the positional parameters of the carbon atom were altered from the original X-ray values (0.3144, 0.25, −0.1039) to (0.3350, 0.25, −0.1003) within the experimental errors of the X-ray analysis. This configuration gives the value (3.29 Å) of the shortest intra-layer H···I distance (in the ac plane, see Fig. 3) nearly equal to that (3.27 Å) of the shortest inter-layer one, which is consistent with the case of methyl bromide (3.02 and 3.00 Å, respectively).

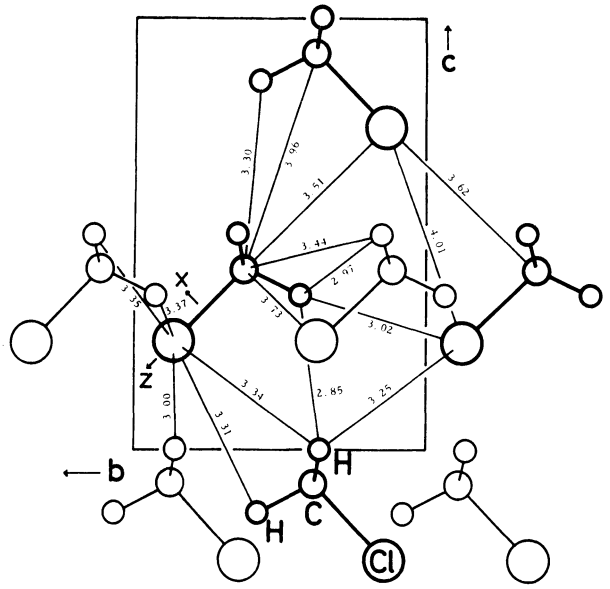

Fig. 2. Crystal structure of methyl chloride.
Interatomic distances (in Å) are indicated.

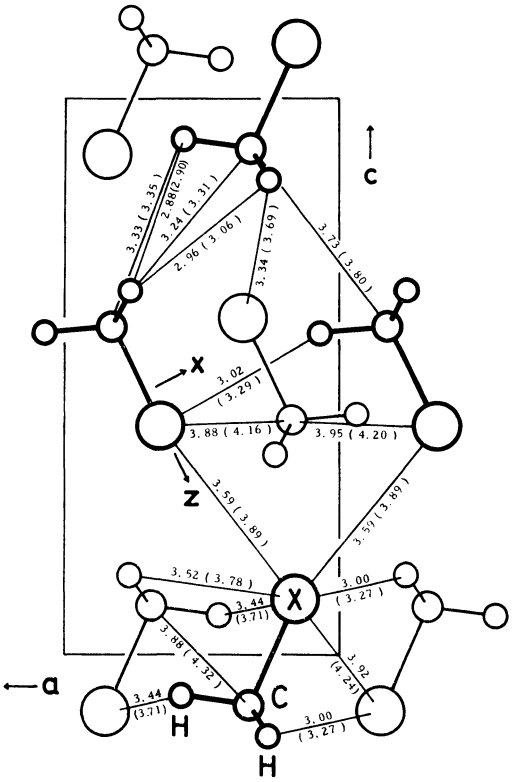

Fig. 3. Crystal structure of methyl bromide or methyl iodide.
Interatomic distances (in Å) are indicated. The values in parentheses are those for methyl iodide.

Figures 2 and 3 show the structures assumed in the calculations.

Intramolecular Potentials. The intramolecular force fields of methyl halides in the free state have been well established.[18,19] In the present calculations, the local symmetry force fields by Shimanouchi[19] are used without modification.

Intermolecular Potentials. Two sets of intermolecular potentials are assumed in the calculations. *Calculation I*: Atom-atom interaction potentials in the form,

$$V(r) = A \exp(-Br) - Cr^{-6}$$

were adopted. As for the constants A, B, and C, the

Table 4. Parameters for the atom-atom potentials

	A (mdyn Å)	B (Å^{-1})	C (mdyn Å^7)	Ref.
H···H	18.45	3.74	0.190	20
C···H	60.93	3.67	0.869	20
C···C	581.3	3.60	3.95	20

Br···C	809.1	3.43	9.44	
Br···Br	1126	3.250	22.6	21
I···H	176.2	3.38	3.14	
I···C	988.9	3.31	14.3	
I···I	1682	3.023	51.9	21

values given by Williams(Set IV)[20] are used for H···H, H···C, and C···C pairs and those given by Dashevsky[21] are used for halogen···halogen pairs. For a pair of hydrogen···halogen or carbon···halogen type the values of potential parameters A and C are taken as the geometric means and the parameter B as the arithmetic mean of the corresponding values for the homonuclear pairs. The values of the parameters are listed in Table 4.

All the atom pairs with a distance shorter than 6.0 Å are taken into account. The second derivatives of $V(r)$'s with respect to the interatomic distances are used as the force constants.

Calculation II: Both the atom-atom interaction potential and the dipole-dipole interaction potential are taken into account.

As for the atom-atom interaction, only the short-distance pairs that are indicated in Figs. 2 and 3 are considered and the corresponding force constants are adjusted to give the best fit to the lattice and the band splitting frequencies.

The method of calculation of the force constants due to the dipole-dipole interaction is described in Appendix. The values of dipole moment derivatives with respect to the internal symmetry coordinates are calculated from the infrared intensities in the gaseous state[22] and are not varied throughout the calculations. The radius of the dipole sum sphere is set equal to 100 Å, which is found to give sufficiently converged values for the force constants.

Results

The resuts of calculations are summarized in Tables

Table 5. Calculated and observed lattice frequencies (in cm^{-1}) of CH_3Cl and CD_3Cl

a) Absolute values are given for ν_1, ν_2, and ν_3. For ν_4, ν_5, and ν_6 maximum values are listed. The ν_1 and ν_5 modes of CH_3I and the ν_1 mode of CD_3I are in Fermi resonance with $2\nu_5$, $\nu_3+\nu_6$, and $2\nu_5$, respectively. b) The infrared data are taken from Ref. 1. c) Contributions of dipole interactions. d) The infrared data are taken from Ref. 5.

5—10. The values of force constants obtained in Calculation II are listed in Table 11. They are compared with the second-derivative curves of the Dashevsky and the Williams potentials in Fig. 4. Observed and calculated splittings for ν_2 and ν_3 of CH_3Br and CH_3I are compared in Fig. 5.

It is seen from the Tables 5—10 that Calculation I gives values in poor agreement with the observed except for the lattice frequencies of CH_3Cl and CD_3Cl. Especially, Calculation I fails to explain the difference in the Raman and infrared frequency splittings of ν_2 and ν_3 of CH_3Br and CH_3I. On the other hand, the lattice frequencies and frequency splittings of symmetric vibrations in Calculation II agree well with the observed except for ν_3 of methyl chlorides. The observed splittings of most of the degenerate vibrations can not be explained by either calculation. This point will be discussed in a later section.

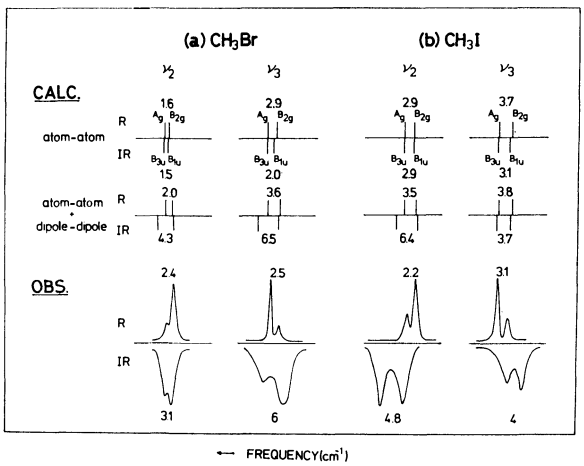

Fig. 5. Comparison of the observed and calculated splittings of ν_2 and ν_3.
(a) CH_3Br, (b)CH_3I. The values in parentheses are the splittings in cm^{-1}.

Some of the results of Calculation II are described below.

Methyl Chlorides. The vibration around 84 cm^{-1} observed in the Raman and far-infrared spectra is assigned to the translational mode along the crystal c axis (T_c) in B_2 symmetry species.

The maximum contribution of the dipole-dipole interaction to the lattice frequencies is evaluated as 5 cm^{-1}.

The splitting of ν_2 and maximum splitting of ν_5 are mainly due to the force between the hydrogen atoms at the shortest distance (2.85 Å, see Fig. 2). Therefore, the value of this force constant can be determined by fitting the calculated to the observed splittings of ν_2 and ν_5. The value thus obtained is 0.012 mdyn/Å, which corresponds to that for a distance of 2.60 Å in the Williams potential.

Although the calculated maximum splitting of ν_6 is about 7 cm^{-1}, only one band appears in each of the infrared and Raman spectra. It may be possible that the factor group components are not resolved because of their comparatively large halfwidths.

The observed splitting pattern of ν_3 is complicated by the coexistence of the chlorine isotopic molecules and simple one-to-one correspondence between the observed and calculated frequencies must be avoided. A quantitative analysis of the ν_3 splitting based on a theory of mixed crystals has shown that the calculated factor group splitting, 6.7 cm^{-1} arising mainly from the dipole-dipole interaction, accounts for the observed splitting in the Raman spectrum.[15]

The dipole-dipole interaction affects the splittings of the other modes only slightly as Dows[2] has already pointed out.

Methyl Bromides and Methyl Iodides. Calculations indicate that the frequencies of T_a mode in B_{1u} species of these molecules are mainly due to the intra-layer Br···Br or I···I interaction force. Accordingly, the values of the force constants for the intra-layer Br···

TABLE 11. INTERATOMIC FORCE CONSTANTS

	I···C	4.16	0.006
		4.20	0.002
	I···I	3.89	0.073
		4.24	0.059

Br and I···I pairs with the distances of 3.59 and 3.89 Å, respectively, are determined definitely to be 0.061 and 0.073 mdyn/Å. These values agree with those expected from the Dashevsky potential. The contributions of the inter-layer Br···Br(3.92 Å) or I···I(4.24 Å) interaction force to the calculated frequencies of T_b modes in B_{1g} and B_{3g} species are about 60% and the interaction force constant is determined to be 0.049 or 0.059 mdyn/Å, respectively. These values correspond to those for distances of 3.68 and 3.97 Å in the Dashevsky potential. The calculated frequencies of the rotational vibrations, R_x and R_y, are dominated by H···H and H···X interaction forces.

The frequency splittings of ν_2 and ν_3 modes in the infrared spectra of these molecules are greater than those in the Raman spectra. The calculated frequency splittings for ν_2 and ν_3 of CH_3Br and CH_3I are in good agreement with the observed (see Fig. 5). This is because Calculation II includes the dipole-dipole interactions and the contributions from the interactions to the infrared splittings are much greater than those to the Raman splittings.

Discussion

The lack of the knowledge on the exact positions of hydrogen atoms and of the vibrational data on single crystals prevents us from discussing the results of calculation in detail. However, it may be of use to clarify the significance of factors which are assumed or disregarded in the present calculations.

First Derivative Terms. In the case of methyl chlorides, Calculation I reproduces the observed lattice frequencies well and we have examined the effects of the first derivative terms $\partial V(r)/\partial r$ of the potentials on the crystal vibration frequencies. It has been found that these terms affect the splittings negligibly as in the case of benzene,[23] while all of the lattice fre-

quencies decrease on inclusion of the terms (8% at maximum). Since the atom-atom interaction force constant is assumed independently for each atom pair in Calculation II, the corresponding linear term may also be included as an independent parameter. The linear terms may be used to lower the lattice frequencies keeping the splittings constant. Evaluation of these terms, however, is only meaningful in the case where the crystal structure and vibrational assingment are solidly established.

Splitting of the Degenerate Modes. As is described above, the agreement between the observed and the calculated splittings of degenerate vibrations in methyl bromide and methyl iodide is poor in either calculation, while the lattice frequencies and splittings of symmetric vibrations are explained by Calculation II. The situation can not be improved by simple modification of the interaction forces. One possible explanation of the large splittings of the degenerate vibrations is that the geometry and the potential of the methyl group are distorted considerably in the crystalline state. In such case, the site group splitting is expected to be far greater than the factor group splitting. In the Raman spectrum of a mixed crystal of CD_3I and CH_3I in the ratio of one to five, ν_4 and ν_5 bands of CD_3I are observed to split into doublets with the separations of 1.5 and 5.0 cm^{-1}, respectively (Fig. 6). These are assigned to the site group splittings, since no splitting is observed at this concentration for ν_3 band for which only the factor group splitting is expected to occur. Hence, it is seen that the site group splitting of ν_5 is mainly responsible for the observed splitting in pure CD_3I and that the splitting of ν_4 observed in pure CD_3I is the site group splitting. On the other hand, the calculated site-group and factor-group splittings are of the same order (2 cm^{-1} each in the case of ν_5). According to a calculation, a change of 1° in the ∠DCD angle causes 1—4 cm^{-1} splittings between $\nu_{\text{in-plane}}$ and $\nu_{\text{out-of-plane}}$ of degenerate vibrations. A slight distortion of the intramolecular potential will give similar effects. It is probable that the cooperative effects of these distortions are observed in the large splittings of the degenerate vibrations. However, these distortions of methyl group give negligible effects to the factor group splittings and lattice frequencies since the accompanying changes in the directions and distances of the atom-atom pairs are not significant.

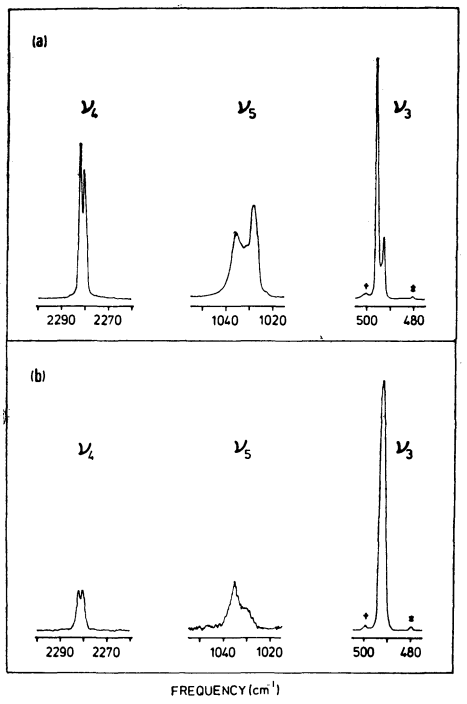

Fig. 6. Parts of the Raman spectra of methyl iodides. (a) CH_3I, (b) mixed crystal of CD_3I and CH_3I in the ratio of one to five. †: ν_3 of $^{12}CHD_2I$, *: ν_3 of $^{13}CD_3I$.

Temperature. The lattice frequencies and frequency splittings have been observed at liquid nitrogen temperature, so that we may observe the lattice vibrational bands and the band splittings as many as possible. On the other hand, the X-ray diffraction measurements have to be made at higher temperatures to avoid cracking of the crystals. The difference in temperature between two observations must also be taken into account. For this reason, Calculation I can not be simply ruled out. However, the difference in the frequency splittings of ν_2 and ν_3 in the infrared and Raman spectra in methyl bromide and methyl iodide may only be explained by taking into account the dipole-dipole interactions.

Appendix

The electrostatic interaction energy between a reference dipole and all the dipoles belonging to a sublattice β of the crystal is expressed in the tensor form

$$V = \boldsymbol{\mu}_\alpha \cdot [\sum_l (\boldsymbol{I}/r_{l\beta}^3 - 3\boldsymbol{r}_{l\beta}\boldsymbol{r}_{l\beta}/r_{l\beta}^5)\exp(-\boldsymbol{k}\cdot\boldsymbol{r}_{l\beta})] \cdot \boldsymbol{\mu}_\beta \quad \text{(A-1)}$$

where $\boldsymbol{r}_{l\beta}$ is the position vector from the reference dipole $\boldsymbol{\mu}_\alpha$ to the dipole $\boldsymbol{\mu}_{l\beta}(=\boldsymbol{\mu}_\beta)$ at the βth site in the lth unit cell and $r_{l\beta}=|\boldsymbol{r}_{l\beta}|$. $\boldsymbol{I}$ represents the identity tensor. The exponential term is the phase factor for a vibrational mode with a wave vector $\boldsymbol{k}$. The summation in the bracket of the above equation is conditionally convergent because of the long-range nature of the dipole-dipole interaction. For a slub-shaped crystal some convergent summation procedures have been developed.[24-28] For crystals of arbitrary shapes, the following approximation after the treatment of static dipole sums by Lorentz[20] will serve to avoid the troublesome convergence problem.

The sum in Eq. A-1 (hereafter signified by $\boldsymbol{T}_{\alpha\beta}$) is divided into three parts:

$$\boldsymbol{T}_{\alpha\beta} = \sum_{r_{l\beta}<R} (\boldsymbol{I}/r_{l\beta}^3 - 3\boldsymbol{r}_{l\beta}\boldsymbol{r}_{l\beta}/r_{l\beta}^5)\exp(-\boldsymbol{k}\cdot\boldsymbol{r}_{l\beta}) + \boldsymbol{T}_L + \boldsymbol{T}_S \quad \text{(A-2)}$$

The first term of this equation expresses the contribution of the dipoles inside the Lorentz sphere of radius R. $\boldsymbol{T}_L$ and $\boldsymbol{T}_S$ arise from the polarization charges on the surface of the Lorentz sphere and on the exterior surface of the crystal, respectively. The latter two influence the frequencies of infrared-active modes.

When $\boldsymbol{k}\approx 0$ (optically active modes), $\boldsymbol{T}_L$ represents the Lorentz field, $\boldsymbol{T}_L = -4\pi\boldsymbol{I}/(3V_c)$ (where V_c is the unit cell volume), and therefore Eq. A-2 leads to

$$\boldsymbol{T}_{\alpha\beta} = \sum_{r_{l\beta}<R} (\boldsymbol{I}/r_{l\beta}{}^3 - 3\boldsymbol{r}_{l\beta}\boldsymbol{r}_{l\beta}/r_{l\beta}{}^5) - 4\pi\boldsymbol{I}/(3V_c) + \boldsymbol{T}_S$$
$$= \boldsymbol{D}_{\alpha\beta} + \boldsymbol{T}_S \qquad \text{(A-3)}$$

This equation defines $\boldsymbol{D}_{\alpha\beta}$ that depends on the crystal structure but not on the shape of the crystal. On the contrary, $\boldsymbol{T}_S$ depends on the shape only.

In the spectrum of polycrystalline sample, $\boldsymbol{T}_S$ affects the band widths, since its contribution depends on the shape and orientation of each crystallite. The widths of most bands of such molecular crystals as are treated in this paper are narrow enough to show up separate band structures even in the polycrystalline state. Consequently, we may neglect the shape-dependent term $\boldsymbol{T}_S$. In this approximation, Eq. A-1 reduces to

$$V = \boldsymbol{\mu}_\alpha \boldsymbol{D}_{\alpha\beta}\boldsymbol{\mu}_\beta \qquad \text{(A-4)}$$

This expression is equivalent to that for the transverse mode in the infinite crystal.[30]

The dipole moment of a unit molecule in the crystal is expanded in powers of displacement coordinates $\boldsymbol{S}$:

$$\boldsymbol{\mu} = \boldsymbol{\mu}^\circ + \sum_i \frac{\partial \boldsymbol{\mu}}{\partial S_i} S_i + \frac{1}{2}\sum_{i,j} \frac{\partial^2 \boldsymbol{\mu}}{\partial S_i \partial S_j} S_i S_j + \cdots \qquad \text{(A-5)}$$

where $\boldsymbol{\mu}^\circ$ is the permanent dipole moment. It may be reasonable to assume that the dipole is located at the center of gravity of the molecule. Substituting Eq. A-5 into Eq. A-4, we obtain the optically-active potential energy matrix element $f_{\alpha\beta}^{ij}$ due to the dipole-dipole interaction:

$$f_{\alpha\beta}^{ij} = \frac{\partial \boldsymbol{\mu}_\alpha}{\partial S_i} \cdot \boldsymbol{D}_{\alpha\beta} \cdot \frac{\partial \boldsymbol{\mu}_\beta}{\partial S_j} \qquad \text{(A-6)}$$

$$f_{\alpha\alpha}^{ij} = \frac{\partial^2 \boldsymbol{\mu}_\alpha}{\partial S_i \partial S_j} \boldsymbol{D}_{\alpha\alpha}\boldsymbol{\mu}_\alpha \qquad \text{(A-7)}$$

The intermode coupling terms $f_{\alpha\beta}^{ij}(i \neq j)$ may be neglected in first order approximation.

For intramolecular modes the value of $\partial\boldsymbol{\mu}/\partial S_i$ is calculated from the infrared absorption intensity in the gaseous state (the oriented gas model), whereas $\partial^2\boldsymbol{\mu}/\partial S_i{}^2$ is not available at the present stage. The force constant $f_{\alpha\alpha}^{ii}$ arising from $\partial^2\boldsymbol{\mu}/\partial S_i{}^2$ contributes to the band shift alone. Therefore we can neglect it in treating only the splittings of internal modes.

For a rotational lattice mode, both of $\partial\boldsymbol{\mu}/\partial S_i$ and $\partial^2\boldsymbol{\mu}/\partial S_i{}^2$ are evaluated analytically by differentiating the permanent dipole with respect to the rotational coordinate. The forces associated with translational motions can be obtained from Eq. A-4 by numerical differentiation.

Complexes between Nucleotide Base and Amino Acid. II. Crystal Structure of 5-Bromocytosine : *N*-Tosyl-L-glutamic Acid

Minoru OHKI, Akio TAKENAKA, Hirotaka SHIMANOUCHI, and Yoshio SASADA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 16, 1976)

The complex crystals of 5-bromocytosine and *N*-tosyl-L-glutamic acid were obtained from their aqueous solution. The space group is P1 with dimensions of $a=10.843(1)$, $b=11.690(2)$, $c=10.879(2)$ Å, $\alpha=122.15(1)$, $\beta=121.38(1)$, $\gamma=69.93(1)°$, and $Z=2$. The structure was solved by the heavy atom method and refined by a block-diagonal least-squares method. The undissociated γ-carboxyl group of glutamic acid is bound with O(2) and N(4) of 5-bromocytosine through hydrogen bonds. This interaction mode is different from those found in some cytosine : glycine complexes and cytidine : *N*-benzyloxycarbonyl-L-glutamic acid complex dihydrate in which the dissociated α-carboxyl group plays a role. This is the first example of interaction between cytosine and the acidic side group of amino acid.

Interactions between nucleic acids and proteins take an important part in several biological processes, though the precise molecular mechanism is still unknown. We have been engaged in preparing complexes of nucleotide base and amino acid followed by X-ray crystallographic studies, which will provide stereochemical basis for the mutual recognition between nucleic acid and protein.

One interaction mode is hydrogen bonds between the dissociated α-carboxyl group of amino acid and protonated N(3) and amino group of cytosine, as found in cytosine : glycine dreivatives[1,2] and in cytidine: *N*-benzyloxycarbonyl-L-glutamic acid complex.[3] We have revealed another type of interaction between γ-carboxyl group of glutamic acid and cytosine in the complex of 5-bromocytosine : *N*-tosyl-L-glutamic acid,[4] and the present paper is a full account of its crystal structure.

Experimental

Prismatic crystals were obtained from an aqueous solution containing equimolar 5-bromocytosine and *N*-tosyl-L-glutamic acid. The complex formation was confirmed by IR spectroscopy and an elementary analysis of these crystals. Found: C, 39.06; H, 3.96; N, 11.15%. Calcd for $C_4H_4N_3OBr \cdot C_{12}H_{15}NO_6S$: C, 39.11; H, 3.91; N, 11.41%. Diffraction pattern of the crystal indicated the crystal system to be triclinic. As the amino acid is L-form, the space group should be P1. The unit-cell dimensions were determined by least-squares calculations with 113 spacings from equator Weissenberg photographs about three different axes, calibration being made with superposed silicon lines ($a=5.43075$ Å). The density measured by flotation in a $CHBr_3$–CCl_4 mixture indicated that there are two 1 : 1 molecular complexes in the unit cell. Crystal data are given in Table 1.

TABLE 1. CRYSTAL DATA

5-Bromocytosine : *N*-tosyl-L-glutamic acid		
$C_4H_4N_3OBr$: $C_{12}H_{15}NO_6S$ F. W.=491.35		
Crystal system: triclinic		
Space group: P1		
$a=10.843(1)$ Å	$b=11.690(2)$ Å	$c=10.879(2)$ Å
$\alpha=122.15(1)°$	$\beta=121.38(1)°$	$\gamma=69.93(1)°$
$U=992.6(2)$ Å^3	$Z=2$	
$D_x=1.644$ g cm^{-3}	$D_m=1.66$ g cm^{-3}	
μ(Cu $K\alpha$) = 45.56 cm^{-1}		

Diffraction data were collected on equi-inclination Weissenberg photographs (0*kl*-8*kl* and *h*0*l*-*h*8*l*) using Ni-filtered Cu $K\alpha$ radiation and the intensities were measured by a TV densitometer.[5] The crystal used for the a- and b-axis rotations were $0.22\times0.20\times0.43$ mm and $0.20\times0.30\times0.40$ mm, respectively. Corrections were made for Lorentz and polarization effects and spot size, but not for absorption. A total of 4259 independent reflexions were obtained, of which zero-reflexions numbered 803. The $N(z)$ test[6] was consistent with non-centrosymmetric space group.

Structure Determination and Refinement

The approximate structure was obtained by the usual heavy atom method. The structure was refined by a block-diagonal least-squares methos; the minimized function was $\sum w\Delta F^2$, where $\Delta F=|F_o|-|F_c|$. In this refinement, the zero-reflexions were assumed to have the value of $|F_o|_{min}(=1.55)$. The zero-reflexions, for which $|F_c|$ values at each cycle were smaller than $|F_o|_{min}$, were omitted from the refinement. The weight function used was as follows: $w=\exp(-as^2-bt^2-cst-ds-et-f)$ for $|F_o|>|F_o|_{min}$, where $s=|F_o|$ and $t=\sin\theta/\lambda$; $w=1/\langle\Delta F^2\rangle$ for $|F_o|=|F_o|_{min}$. The coefficients, *a*, *b*, *c*, *d*, *e*, and *f*, were evaluated by least-squares at each cycle of the structure refinement so that $\langle w\Delta F^2\rangle=1$. The convergence was slow owing to quasi-centrosymmetric structure of the crystal. The refinement was terminated when the maximum shifts of positional and thermal parameters were less than 0.15σ and 0.25σ, respectively. At the final cycle, the coefficients of weight function were −0.0001747, 36.59, 0.03631, 0.05322, −36.13, and 7.320, respectively, and weight for $|F_o|_{min}$ was 0.609. The final value of *R* factor is 0.082 ($R_w=0.080$), and the *R* for reflexions of $|F_o|>3\sigma$ ($\sigma=1/\sqrt{w}$) is 0.065. The comparison between observed and calculated structure factors is given in Table 2.[7] Atomic scattering factors used were taken from "International Tables for X-Ray Crystallography."[8] The positional and thermal parameters are given in Table 3.

Results and Discussion

Bond lengths and angles of the two independent molecules are listed in Table 4. For a few pairs, discrepancy between the lengths of corresponding bonds looks significant; however, this may be attributable to

Table 3. Final positional and thermal parameters

Standard deviations are given in parentheses. The temperature factor has the form, $\exp[-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)]$. All parameters have been multiplied by 10^4.

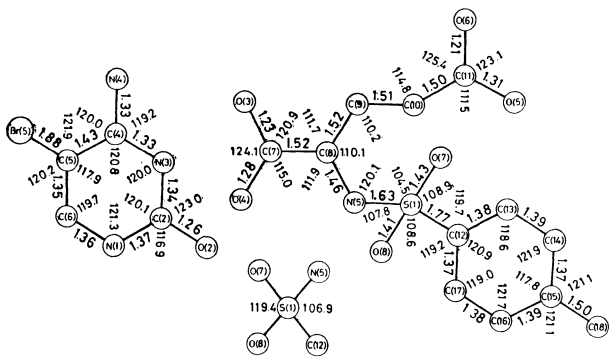

Fig. 1. Average bond lengths and angles of the two independent 5-bromocytosine and *N*-tosyl-L-glutamic acid molecules.

the difficulty in convergence due to pseudo symmetry of the crystal. Their averaged values shown in Fig. 1 are close to authentic ones.

The crystal structure is shown in Fig. 2. The molecules are arranged in layers parallel to the $(1\bar{2}0)$ plane. The complexes are formed by hydrogen bonds in the layer and come in van der Waals contancts with those in adjacent layers. The hydrogen bond scheme in the layer is illustrated in Fig. 3, relevant distances and angles being listed in Table 5. The 5-bromocytosine molecules form a ribbon elongated along [001], by the hydrogen bonds, N(1A)H···O(2B), N(1B)H···O(2A), N(4A)H···N(3B), and N(4B)H···N(3A), the former two and the latter two being related around each of pseudo-center of symmetry. The dihedral angle between the mean planes of cytosines A and B

is 3.5°. On the other hand, the two independent *N*-tosyl-L-glutamic acid molecules are associated by the two hydrogen bonds between the α-carboxyl groups, O(4A)H···O(3B) and O(4B)H···O(3A), related by a pseudo-inversion. These dimers are stacked, by overlapping the tosyl groups, in the same direction as the ribbon. The two independent phenyl planes are almost parallel to each other; the dihedral angle between them is 1.7°, and its spacing is 3.59 Å.

The cytosine ribbons and glutamic acid stacks are linked by the other hydrogen bonds in which the side group of the glutamic acid participates. The O(5) atom is the donor to O(2) of 5-bromocytosine and at the same time the acceptor from N(4) of the neighboring base. In addition, the O(6) atom seems to make a CH···O type interaction with C(6) of the third base. Similar C(6)H···O contact is also observed in crystals of the two forms of cytidylic acid,[9,10] 1-methylcytosine hydrochloride,[11] and 1-(β-D-arabinofuranosyl)cytosine hydrochloride.[12]

The hydrogen bond scheme suggests that the protonation to N(3) of cytosine by the carboxyl group does not occur in the present complex. This is supported by the bond lengths and angles of cytosine molecule (Fig. 3); the C(2)–N(3)–C(4) bond angle 120.0° is close to unprotonated form, and the dimensions of α- and γ- carboxyl groups indicate that their hydrogen atoms are bonded to O(4) atom in α-carboxyl group and O(5) atom in γ-carboxyl group.

In the tosyl groups S(1)–O(8) bonds are *cis* to N(5)–C(8) bonds, and the N(5)–S(1)–O(8) bond angles are larger than N(5)–S(1)–O(7).

The conformations of the two independent glutamic acids are extended ones; the relevant torsion angles are given in Table 6. Atoms in the side group of the amino acid are coplanar; the largest deviation of atoms from the mean plane is 0.14 Å at C(8A) and 0.10 Å at C(9B), and the largest deviation in torsion angle from the *trans* conformation arises around C_β–C_γ bond in both A and B molecules; 15.9° and 6.0°, respectively. The α-carboxyl group makes an angle of 80.9° in A and 84.5° in B with the side group mean plane.

In summary, the present complex formation is due to the undissociated γ-carboxyl group of glutamic acid bound with O(2) and N(4) of 5-bromocytosine through hydrogen bonds. It is quite different from those found in cytosine : *N*-benzoylglycine complex monohydrate,[1] cytosine : *N*-formylglycine complex,[2] and cytidine : *N*-benzyloxycarbonyl-L-glutamic acid complex dihydrate,[3] where the dissociated α-carboxyl group plays a role. The present crystal provides the first example of interaction mode between cytosine and acidic side group of amino acid.

Complex Formation of Crosslinked Poly(4-vinylpyridine) Resins with Copper(II)

Hiroyuki NISHIDE, Jichio DEGUCHI, and Eishun TSUCHIDA

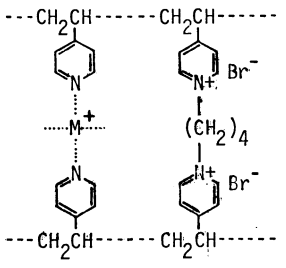
Department of Polymer Chemistry, Waseda University, Tokyo 160

(Received March 12, 1976)

Poly(4-vinylpyridine) was crosslinked with 1,4-dibromobutane. The obtained resin(DBQP) formed a stable complex with Cu^{2+}, and the adsorption capacity of DBQP varied with the degree of crosslinking. The complex formation of DBQP with Cu^{2+} was studied by examining the adsorption equilibrium and the spectroscopic measurement. The resin complex seems to be formed *via* no step-by-step mechanism, and the stability constant was appreciably large in comparison with those of non-crosslinked polymers and of a monomeric analogue. In the highly crosslinked resins, the ligand-field is relatively weak and the stability of the Cu^{2+} complex is decreased.

Poly(4-vinylpyridine) (PVP) forms a stable intrapolymer chelate with copper ions, in which the PVP-chain is markedly contracted.[1-3] Thus, if one makes the PVP-ligand crosslinked and the polymer chain is previously contracted, it is expected that the obtained PVP resin will form the stable complex with Cu^{2+}.

In the present paper, PVP was crosslinked with 1,4-dibromobutane to yield the insoluble PVP resin-(DBQP, I), of which free and unquaternized pyridine groups were utilized to coordinate with a metal ion.



I

The complex formation of this DBQP resin with Cu^{2+} was studied by the adsorption equilibrium and the spectroscopic measurement. The effects of the crosslinking on the stability and structure of the resin complex were discussed.

Experimental

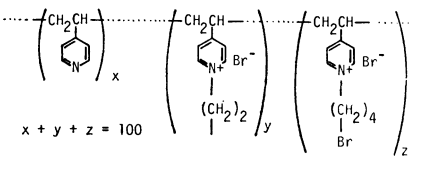
Materials. PVP was prepared by radical polymerization of 4-vinylpyridine, and was purified twice by reprecipitation. The average degree of polymerization of PVP used in this experiment was 122 as measured by vapor pressure osmometry. Analytical grade reagents of 1,4-dibromobutane, pyridine (Py), and copper(II) chloride were used. All solutions were prepared with deionized water.

Preparation of DBQP Resins. The crosslinking reagent, 1,4-dibromobutane, of prescribed concentration [0.025 M (DBQP(1)), 0.1 M (DBQP(2)), 0.3 M(DBQP(3)), or 0.5 M (DBQP (4))] was added to the methanol solution of PVP (1 M). The mixture was vigorously stirred at 65 °C for 5 days. The resin was filtered off, washed with methanol repeatedly, and dried *in vacuo*. The dried resin was ground and the portion of 100—150 mesh size was used in all the experiments presented. The elemental analyses of the resins are shown in Table 1. The total Br content was determined by the Volhard method and the free Br ion in the resin was titrated after the resin was soaked into water. The percentages of crosslinking and of quaternization were calculated by using the C/N ratio, the free Br ion, and the total Br content. The percentage of quaternization was also deduced from the ratio of absorption at 1600 cm^{-1} (due to pyridine group) to the absorption at 1640 cm^{-1} (due to quaternized pyridine group) of IR spectra, and this value was nearly equal to the value which was determined

TABLE 1. ELEMENTAL ANALYSES OF PVP WITH 1,4-DIBROMOBUTANE

Resin	Found(Calcd)				Crosslinking %[a]	Quaternization %[b]	Quaternization %[c]
	C%	N%	Br ion %	Br total %			
DBQP (1)	75.7 (75.5)	12.3 (12.3)	5.77 (5.76)	5.78 (5.76)	4.1	8.2	10
DBQP (2)	68.7 (68.6)	10.6 (10.7)	14.6 (14.7)	14.6 (14.7)	12	24	22
DBQP (3)	60.3 (59.9)	8.65 (8.69)	25.3 (25.3)	26.0 (25.8)	25	51	53
DBQP (4)	57.9 (57.1)	8.02 (8.04)	29.0 (29.0)	29.6 (29.4)	31	63	68

a) Percentage of bridged dibromobutane per pyridine groups of PVP=$y/2$(If all pyridine groups of PVP are crosslinked by dibromobutane, crosslinking % is 50). b) Percentage of quaternized pyridine groups per pyridine groups of PVP=$(y+z)$. c) Percentage of quaternized pyridine groups per pyridine groups of PVP determined by IR spectra.



by the elemental analyses (Table 1). The z term given in the footnote of Table 1 was extremely small, and almost all 1,4-dibromobutane molecules built bridges between two vinylpyridine groups.

Partially-quaternized PVP (QPVP) was prepared by quaternization of PVP with ethylbromide, and the percentage of quaternization was 45.

Adsorption of Cu^{2+} on the DBQP Resin. A batch type equilibration procedure was used to determine the Cu^{2+} uptaken from solution by the resin. The pH value of the system was kept constant by a 0.1 M CH_3COOH-CH_3COONa buffer. The two phases were shaken on a mechanical shaker at room temperature for 5 h. After shaking, the two phases were separated, and the supernatant solution was then analyzed for Cu^{2+} using atomic absorption spectrophotometry (JEOL JAA-7000). The amount of Cu^{2+} in the supernatant subtracted from the amount initially added gave the amount of Cu^{2+} adsorbed on the resin. Cu^{2+} adsorbed on QPVP and PVP were determined by dialysis equilibrium.

Measurements. The visible absorption spectra of the Cu^{2+} complexes of the fine powdered DBQP resin were measured in a Nujol mull or in suspension with a high sensitive spectrophotometer (Union Giken SM-401).

The apparent dissociation rate constant of Cu^{2+} from the Cu^{2+}-resin complex was determined as follows; the Cu^{2+}-resin complex was soaked into 0.1 M EDTA solution, and the increase in the spectra of the Cu^{2+}-EDTA (λ_{max}: 745 nm) formed in the supernatant solution was continuously measured.

Magnetic susceptibility measurements were carried out by Gouy method.

Results and Discussion

When the DBQP resin is added to the Cu^{2+} aqueous solution, the Cu^{2+}–resin complex is easily formed. As seen in Fig. 1, the adsorption equilibrium was attained within 1 h. It was shown in Figs. 1 and 2 that the adsorption of Cu^{2+} on the DBQP resins varied with the degree of crosslinking. Here the concentration of the unquaternized pyridine groups in the resin was kept constant for each resin. The adsorption capacity of Cu^{2+}, *i.e.*, the value of ordinate in Fig. 2 was changed with the degree of crosslinking. The effect of the crosslinking on the Cu^{2+}-resin complexes

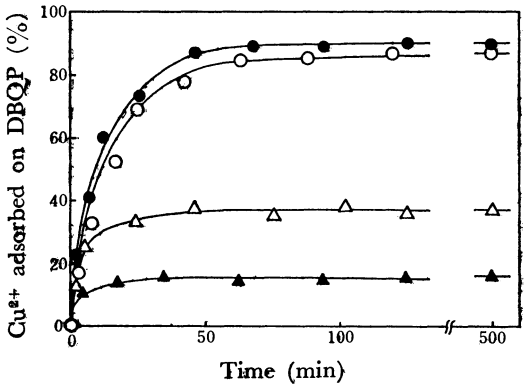


Fig. 1. Complexation between DBQP and Cu^{2+}. [Cu]=0.001 M, $[\bar{N}]/[Cu]=10$, $\mu=0.1$, pH 5.5, ○: DBQP(1), ●: DBQP(2), △: DBQP(3), ▲: DBQP(4), where $\bar{N}$ is the unquaternized and coordinable vinylpyridine group in the resin. DBQP(1)—(4) are shown in Table 1.

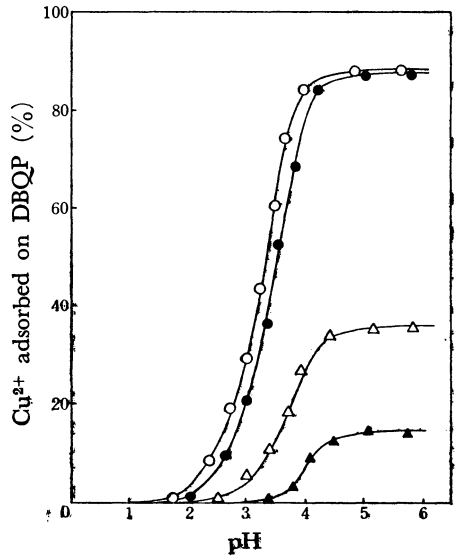

Fig. 2. Effect of crosslinking on Cu^{2+} adsorption. $[\bar{N}]=0.01$ M, $[\bar{N}]/[Cu]=4$, $\mu=0.1$, ○: DBQP(1), ●: DBQP(2), △: DBQP(3), ▲: DBQP(4).

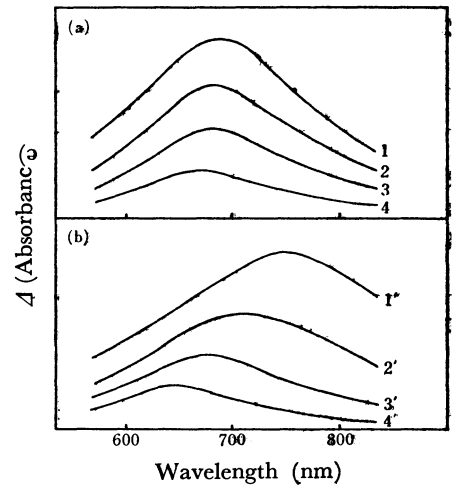

Fig. 3. Visible spectra of Cu^{2+}-DBQP(a) and Cu^{2+}-Py complexes(b). $[\bar{N}]=[Py]=0.05$ M, $\mu=0.1$, pH 5.5, $[\bar{N}]$ or $[Py]/[Cu]=1(1, 1'), 2.5(2, 2'), 5(3, 3'), 20(4), 100(4')$.

were studied from the complex formation equilibrium and the structure of the Cu^{2+} complex.

The visible spectra of the Cu^{2+} complexes with the resin and with Py were measured. As seen in Fig. 3(b), the absorption maximum of the Cu^{2+} complex shifted progressively to shorter wave length as the concentration of Cu^{2+} decreased. This suggests the stepwise formation of Cu^{2+}–Py complexes. On the contrary, the absorption maximum of the Cu^{2+} complex with the resin hardly shifted in Fig. 3 (a). It means that the complex formation between Cu^{2+} and the resin does not proceed *via* step-by-step mechanism and the composition of the Cu^{2+} complex in the resin remains constant throughout the experimental conditions.

The successive stepwise formation constants are represented in Eq. 1 and were calculated by Eq. 2 as follows:

$$\left.\begin{aligned} &Cu + L \overset{\kappa_1}{\rightleftharpoons} CuL_1 \\ &CuL_1 + L \overset{\kappa_2}{\rightleftharpoons} CuL_2 \\ &CuL_2 + L \overset{\kappa_3}{\rightleftharpoons} CuL_3 \\ &CuL_3 + L \overset{\kappa_4}{\rightleftharpoons} CuL_4 \end{aligned}\right\} \quad (1)$$

$$\frac{[Cu]_t}{[Cu]} = 1 + \sum_{n=1}^{4}\left(\prod_{n=1}^{n}\kappa_n\right)[L]^n \quad (2)$$

(L is a pyridine group in the resin and $[Cu]_t$ is the total concentration of Cu)

The concentrations of Cu^{2+} in the supernatant were measured as changing the amount of the resin ($[Cu]_t = 1\times10^{-5}$ M=const, $[L] \gg [Cu]_t$, $[\bar{N}] = 2\times10^{-3}$—$5\times10^{-4}$ M).* As shown in Table 2, the constants increased from κ_1 to κ_4 in the resin system in contrast to the monomeric Py system. This result also supports that the composition of the Cu^{2+} complex is almost CuL_4 where four pyridine groups in the resin coordinate to the Cu^{2+} ion, although the experimental conditions of Table 2 are not the same as the others.

TABLE 2. STEPWISE FORMATION CONSTANTS (κ l/mol) OF Cu^{2+}-DBQP COMPLEXES

Ligand	$\log \kappa_1$	$\log \kappa_2$	$\log \kappa_3$	$\log \kappa_4$
DBQP (1)	2.4	2.8	3.3	3.8
DBQP (2)	2.3	2.7	3.2	3.7
DBQP (3)	2.2	2.4	3.1	3.3
DBQP (4)	1.9	2.3	3.0	3.1
Py[2]	2.5	1.9	1.3	0.8

$[Cu]_t = 1\times10^{-5}$ M, $[\bar{N}] = 2\times10^{-3}$—$5\times10^{-4}$ M, $\mu = 0.10$, pH 5.5.

From the results, the above equations can be also represented by the following.

$$Cu + L' \overset{K}{\rightleftharpoons} CuL' \quad (3)$$

(L' is four pyridine groups in the resin)

The adsorption curves given in Fig. 4 appeared to be a Langmuir type and the stability constant K of the Cu^{2+} complex and the saturated adsorption amount of Cu^{2+} were evaluated by fitting Langmuir's Eq. 4;

$$\frac{c}{a} = \frac{1}{K\cdot A_s} + \frac{1}{A_s}c \quad (4)$$

where A_s is a constant value which corresponds to the saturated adsorption amount, c is the concentration of Cu^{2+}, K is the stability constant, and a is the quantity of adsorption. They are summarized in Table 3 with those of the Cu^{2+} complexes of Py, PVP, and QPVP.

The stability constant K of the Cu^{2+}–PVP complex was about forty times as large as that of the Cu^{2+}–Py complex. Furthermore, the K values in the Cu^{2+}–DBQP system were about one order of magnitude greater than in the non-crosslinked PVP system, which indicates that the DBQP resin uptakes Cu^{2+} from solution in a high efficiency. This phenomenon appears to be general with the polymer complex system,[2,3] and can be explained by the assumption that the concentration of ligand is higher in the polymer domain, especially in the domain for the crosslinked resin system. So that, once the metal ion is attached to one ligand group of the polymer chain, other ligands coordinate more readily.

K and A_s for DBQP decreased largely according to an increase in the number of the crosslinking points. This seems to be caused by the steric hindrance of the crosslinking agent and of the contracted polymer chain, and caused by the electrostatic repulsion among the coordinating Cu^{2+} and the pyridinium ions on the polymer chain as the K value of QPVP is smaller than that of PVP.

Apparent rate constant k_f' of the complex formation given in Eq. 5 was determined. The stability constant of Cu^{2+}–EDTA complex is moderately larger than that of Cu^{2+}–DBQP, and we estimated the apparent

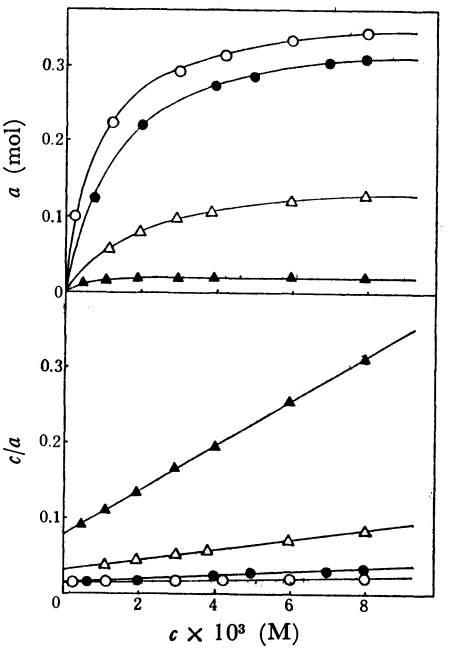

Fig. 4. Adsorption behavior of Cu^{2+} on DBQP resins. $[\bar{N}] = 0.01$ M const., $\mu = 0.1$, pH 5.5, ○: DBQP(1), ●: DBQP(2), △: DBQP(3), ▲: DBQP(4), a is $[Cu^{2+}]$ in solution(M), c is Cu^{2+} adsorbed on DBQP(mol).

TABLE 3. K AND A_s OF Cu^{2+} COMPLEXES

Ligand	K(l/mol)	A_s(mol/unit mol)
DBQP (1)	2810	0.32
DBQP (2)	2370	0.30
DBQP (3)	630	0.12
DBQP (4)	540	0.03
PVP	124	0.45
QPVP	97	0.48
Py[2]	3.2	—

$[\bar{N}]$ in DBQP, QPVP $\doteqdot 0.01$ M, $\mu = 0.10$, pH 5.5.

* Although the κ values in Table 2 are valid under the conditions given in the footnote in Table 2, they may not be adequate under the other conditions (*e. g.* in Fig. 1).

dissociation rate constant k_b' for the reaction in which

$$Cu^{2+} + DBQP \underset{}{\overset{k_f'}{\rightleftharpoons}} Cu^{2+}\text{-}DBQP \quad (5)$$

$$Cu^{2+}\text{-}DBQP + EDTA \underset{}{\overset{k_b'}{\rightleftharpoons}} Cu^{2+}\text{-}EDTA + DBQP \quad (6)$$

EDTA took Cu^{2+} from the stable resin complex, as represented by Eq. 6. In Fig. 5, k_f' and k_b' were plotted against the degree of crosslinking. The k_b' value increased with the stability constant, *i.e.*, Cu^{2+} is more easily dissociated in the highly crosslinked resin, because of the instability of the complex.

The structure of Cu^{2+} complexes involving the resin was deduced from the measurements of visible spectra and magnetic susceptibility of the fine powdered resin complex (Table 4). The effective magnetic moments of the Cu^{2+}–DBQP complexes were about 1.7 B. M. and approximately equal to the value for the mononuclear Cu^{2+} complex. The d-d absorption maxima for the highly crosslinked resins were located at longer wave length and this suggests the relatively weak ligand-field of the highly crosslinked resins.

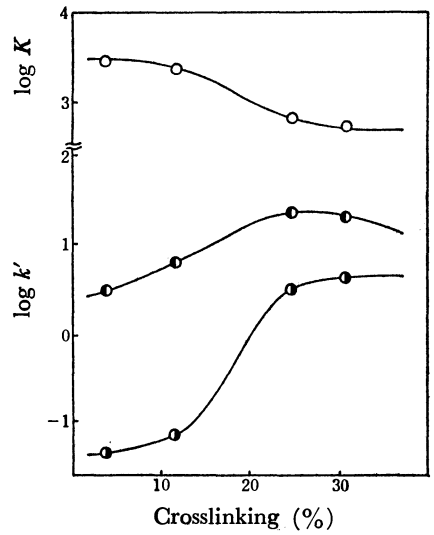

Fig. 5. Effect of crosslinking on k_f' and k_b'.

(Received April 22, 1976)

The crystal structures of two Schiff base complexes, bis[*N*-(3-methoxysalicylidene)isopropylaminato]nickel (II) and -cobalt(II), have been determined. Ni complex: brown, room temperature phase, monoclinic, $P2_1/c$, $a=21.089$, $b=7.254$, $c=14.386$ Å, $\beta=98.40°$, $Z=4$, final $R=0.076$. Co complex: red, triclinic, $P\bar{1}$, $a=22.699$, $b=7.395$, $c=14.099$ Å, $\alpha=107.78$, $\beta=99.03$, $\gamma=93.75°$, $Z=4$, final $R=0.13$. In both crystals the metal ions have distorted tetrahedral coordinations. The two crystals are roughly isostructural, although appreciable differences exist in both of the molecular and crystal structures. The Co complex gives a unique example of the methoxy group which sticks out nearly perpendicularly from the phenyl plane.

Recently Takeuchi and Yamada[1] isolated two stereochemical isomers of bis[*N*-(3-methoxysalicylidene) isopropylaminato]nickel(II). Brown and green crystals were obtained from methanol and ethylether solutions, respectively. In addition to these two crystalline forms, two other new high temperature forms, again brown and green ones, were found by Arai *et al.*[2] in their detailed studies on the thermal and magnetic properties of this complex. The spectroscopic and magnetic studies revealed that in both of the brown forms, room and high temperature ones, the molecular structures are almost the same and the central Ni ions are coordinated tetrahedrally, while in the two green forms the molecules have a square-planar coordination of Ni.[1,2]

The cobalt(II) complex of the same ligand was also prepared, and the Co ion was shown to have a tetrahedral coordination.[3] The unit cell dimension of the crystal is not so far from that of the brown Ni complex in the room temperature form. Thus it may be expected that these two crystals are isostructural with each other, although they are different in symmetry.

In this work, the crystal structures of the brown Ni complex in the room temperature form and of the Co complex were studied.

Experimental

The crystallographic data of the brown room temperature form of bis[*N*-(3-methoxysalicylidene)isopropylaminato]-nickel(II) and those of the red Co complex are listed in Table 1. The data of the red brown crystal of the Cu complex with the same ligand[4] are also listed for comparison.

The X-ray intensity data were obtained on a four-circle diffractometer (Rigaku) with Zr-filtered Mo$K\alpha$ radiation. The 2θ-ω scan method was used, and the background counts were made at both scan limits. The maximum 2θ measured and numbers of non-zero reflections collected and used in the structure determinations are: 55° and 3845 for the Ni complex, and 45° and 3676 for the Co complex, respectively. The intensities were corrected for only Lp factors. The sizes of the crystals used were $0.5\times0.4\times0.2$ mm for the Ni complex, and $0.1\times0.1\times0.3$ mm for the Co complex.

Structure Determination

The structures were determined by the heavy atom Fourier method. The refinements were made by a block-diagonal least-squares calculations.[5] Unit weight was assigned for all the non-zero reflections. All the atomic scattering factors were taken from International Tables for X-Ray Crystallography, Vol. III.[6] For the metal ions the scattering factors of the univalent cations Co^+ and Ni^+ were used in consideration of the electroneutrality principle.[7] The computations were done on a NEAC 2200-700 of Osaka University and a FACOM 230-60 of Nagoya University.

Ni Complex: All the hydrogen atoms were included in the refinement. The final R is 0.076 for non-zero reflections.[8] The final parameters are listed in Tables 2 and 3. The bond distances and angles are shown in Fig. 1. The e.s.d.'s of the distances and angles among the non-hydrogen atoms are 0.004—0.014 Å and 0.2—0.8°, respectively. The ORTEP drawing[9] is shown in Fig. 2.

Co Complex: Two crystallographically independent molecules exist in the crystal. Anisotropic temperature factors were assigned to the Co atoms only, and the C, N and O atoms were refined with isotropic temperature factors. No hydrogen atoms were included in the calculation. The final R is 0.128.[8] No further

Molecular Structure

The molecular stucture of the present Ni complex, except for the methoxy group, is nearly identical with that of bis[*N*-isopropylsalicylaldiminato]nickel(II),[10] and no appreciable difference in the shapes and sizes is found between the two complexes. In the crystal of the Co complex two crystallographically independent molecules, A and B, have almost the same stucture, which bears also close resemblance to those of the two Ni complexes.

The tetrahedral coordination of the Ni(II) and Co(II) ions is thus confirmed. Although the distortions from the ideal tetrahedral form are large owing to the formations of the chelate rings, the distortion in the Co complex is a little smaller than that in the Ni complex. This finding agrees with the expectation of the simple crystal field theory.

Each molecule is characterized by several planar groups, of which details are listed in Tables 5 and 6. In any molecule two salicylideneamine planes intersect nearly at right angle with each other, the dihedral angles being 87, 87, and 79° for the Co(A), Co(B), and Ni complexes, respectively. The angle in bis-[*N*-isopropylsalicylaldiminato]nickel(II) is 82°.[10] The variation in the dihedral angles reflects the magnitudes of the distortions from the ideal tetrahedral coordi-

nation. The metal ions are slightly out of the chelate ring planes by 0.05—0.23 Å. The isopropyl group plane is nearly perpendicular to the chelate ring to which it is attached.

The phenyl groups show a common interesting feature, that is, the three C–C bonds nearest to the metal ion, C(1)–C(2), C(2)–C(3), C(1)–C(6) and their equivalents, are longer than the three farthest C–C bonds, C(3)–C(4), C(4)–C(5), C(5)–C(6) and their equivalents. This feature has been also found in several related compounds,[11] and may be explained by the presences of significant double bond characters in the exocylclic C(2)–O(1), C(1)–C(7) and their equivalents, although the shortenings of the farthest bonds may be partly due to the thermal vibration of the molecules.

The only distinct difference in the molecular structures of the present complexes exist in the methoxy groups. In the Ni complex the methoxy group is coplanar with the phenyl plane to which it is attached. In the Co complexes, one methoxy group is coplanar with the pheny plane, but the other sticks out nearly perpendicularly from the phenyl plane. As shown in Figs. 4 and 6, the orientations of the latter methoxy groups are opposite in the two molecules, A and B.

To our knowledge, the methoxyphenyl group is usually planar, because the planar stucture with a larger conjugate system is usually more stable than the non-planar stucture with a smaller conjugate system. The present Co complex gives a unique example of the non-planar methoxyphenyl group. The bond distances and angles are affected seriously by the orientations of the methoxy groups. The mean values of the bond distances and angles in each of the planar and non-planar structures in the Co complex are shown in Fig. 3, while those for the planar structures reported so far[12] are shown in Fig. 5. In the planar structures the repulsion between the methyl group and the peri-hydrogen atom of C(4) makes the O(2)–C(3)–C(4) angle significantly larger than 120°. The inequality in two bond distances of O(2)–CH_3 and O(2)–C(3) is also characteristic of the planar stucture. The latter bond is shorter than usual O–C single bond. In the non-planar structure the O(2)–C(3)–C(4) angle decreases to the normal value, and the inequality in the two C–O bond distances disappears.

Crystal Structure

The crystal structures viewed along the b axes are compared in Fig. 6. As was expected from the similarity in the unit cell dimensions, two crystals are isostructural in a very rough comparison. The orientations of the Co complexes A and B are not so different from those of the Ni complexes A and B which are related by a c glide plane. The packing schemes in the crystals are also similar to each other. Therefore, the intermolecular potential energies due to the van der Waals forces seem to be almost equal in the two crystals. The difference, however, is singificant, and seems to be in entropy. The crystal of the Ni complex is in a highly ordered state with smaller entropy, while the crystal of the Co complex is in a less ordered state with larger entropy.

The authors express their sincere thanks to Miss Sachiko Bando and Mr. Ken-ichi Sakaguchi for their kind assistance in the experiments.

(Received May 11, 1976)

Two series of new mixed ligand cobalt (III) complexes with the general formulas of [Co(sal_2en)(L-aa)] and [Co(7,7'-Me-sal_2en)(L-aa)] (where L-aa=anion of L-ala, L-val, L-leu, L-isoleu, L-met, L-thr, L-phe, L-tyr, or L-trp) have been prepared and characterized. All are labile for both isomerization and substitution reactions and each exists in an equilibrium mixture of Λ_L- and Δ_L-*cis*-β_1(fac)-isomers ($\Lambda_L > \Delta_L$) in methanol. The isomer's ratios, Λ_L/Δ_L, were estimated from their PMR spectra, and the following facts were found: The increasing order of the ratios is L-ala∼L-met∼L-leu<L-val<L-isoleu<L-thr<L-phe∼L-tyr<L-trp, and the ratios are larger in 7,7'-Me-sal_2en-complexes than in sal_2en-complexes for each amino acid.

Many studies have been undertaken about the steroselectivity in inert cobalt(III) complexes. However, it is often difficult to distinguish between kinetic and thermodynamic stereoselectivities in the inert cobalt(III) complexes.[1-9] On the other hand, it is well known that mixed ligand cobalt(III) complexes containing Schiff-bases are generally substitution labile.[10-15] Since the origin of the stereoselectivity in labile complexes is thought to be thermodynamic, a study of the stereoselectivity of the mixed ligand cobalt(III)–Schiff-base complexes is very interesting. Another interest is from the stereochemical viewpoint. That is, as shown in Fig. 1, the steric stucture of *cis*-β-[Co(sal_2en)(acac)] is extremely distorted as compared with those of the usual cobalt(III) complexes.[16-19] Especially, chelates A and C are so close that an intramolecular steric interaction is expected between them. Therefore, if an optically active bidentate ligand coordinates at the site of the chelate C, such a complex may show high stereoselectivity. In this paper, we report the preparation, the properties and the thremodynamic stereoselectivity of the mixed ligand cobalt(III) complexes containing sal_2en or 7,7'-Me-sal_2en as a Schiff-base ligand and L-amino acid anion.

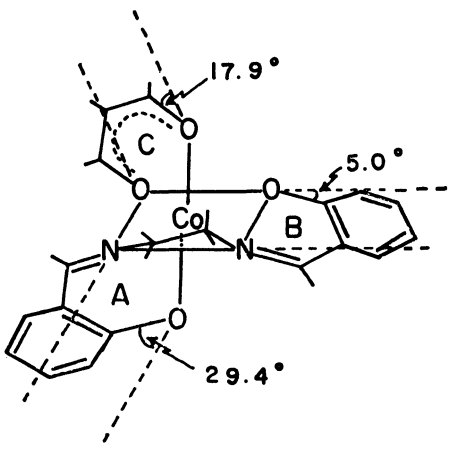

Fig. 1. The distorted chelate skeleton in [Co(sal_2en)(acac)].[17] ---- shows the normal bond direction.

Experimental

Preparation of the Complexes. All the complexes were synthesized from [Co(sal_2en)][20] or [Co(7,7'-Me-sal_2en)][21] and amino acids by air oxidation.

1) Co(III)-sal_2en Series Complexes: Amino acid (0.015 mol) partially dissolved in 25 ml of water was added to a suspension of [Co(sal_2en)] (5.0 g, 0.015 mol) in 130 ml of methanol. In the cases of L-ala, L-val, and L-asp, the amino acid solution was partially neutralized with KOH (0.2 g for L-ala and L-val, 0.5 g for L-asp). The mixture was stirred vigorously in open air at room temperature for the time periods listed in Table 1. The unreacted materials were then removed by filtration, and a brownish green solution was obtained. The methods for isolation and purification of the crude product are as follows.

i) [Co(sal_2en)(gly)], [Co(sal_2en)(L-isoleu)], [Co(sal_2en)(L-met)], [Co(sal_2en)(L-ser)], and [Co(sal_2en)(L-asp)]: The brownish green solution was concentrated to about a half volume at room temperature and to this solution was added water (100 ml). Chloroform (80 ml, twice) was then added and the complex was extracted. Concentrating the solution to a small volume (about 40 ml for gly, L-met, and L-asp) or to dryness (for L-ser and L-isoleu) at room temperature, a green product was obtained. It was recrystallized from methanol–acetone–water (10 : 2 : 1) for gly and L-isoleu or from chloroform for L-met, L-ser, and L-asp. Green crystals were obtained except for L-isoleu (powder).

ii) [Co(sal_2en) (L-ala)], [Co(sal_2en)(L-val)], and [Co(sal_2en)(L-leu)]: Upon concentrating the brownish green solution to about 30 ml under reduced pressure at room temperature, green crystals were deposited. They were recrystallized from methanol–acetone–water (10 : 2 : 1) for L-ala and L-val or from methanol containing 0.1% (gravimetric) KOH for L-leu.

iii) [Co(sal_2en) (L-thr)], [Co(sal_2en)(L-phe)], and [Co(sal_2en)(L-trp)]: Concentrating the brownish green solution to a half or one third volume at room temperature, a green product was obtained. It was recrystallized from methanol for L-thr and L-trp or from methanol–acetone–water (10 : 2 : 1) for L-phe.

iv) [Co(sal_2en) (L-tyr)]: After concentrating the brownish green solution to about a half volume, water (300 ml) and

chloroform (100 ml) were added. The water layer was concentrated to about 100 ml at 50 °C under reduced pressure. The green powder thus obtained was purified by dissolving it in chloroform, followed by filtration and concentration to dryness.

The yields are summarized in Table 1 and the analytical data are listed in Table 2.

2) Co(III)-7,7'-Me-sal$_2$en Series Complexes: Amino acid (0.017 mol) partially dissolved in 50 ml of water was added to a suspension of [Co(7,7'-Me-sal$_2$en)] (5.0 g, 0.014 mol) in 200 ml methanol. The mixture was stirred vigorously in open air for about 3 h at room temperature. In the case of L-tyr, the reaction was continued for a day. After filtration of the solution, the green solution thus obtained was concentrated to a small volume (50—100 ml). Green crystals were obtained and recrystallized from methanol. In the cases of L-leu and L-ser, their complexes were recrystallized from acetone and *N,N*-dimethylformamide, respectively. Yields, 60—90%. The anal. data are listed in Table 2.

In both series of complexes, L-ser- and L-asp-complexes are hardly soluble in methanol. Therefore, we did not measure their AB, CD, and PMR spectra. The IR spectra of all the complexes showed asym. ν(COO) at about 1625—1635 cm^{-1}.

Measurements. The electronic absorption spectra were

measured with a Hitachi EPS-3 Spectrophotometer. The CD spectra were recorded with a JASCO J-20 Automatic Recording Spectropolarimeter. Optical rotations at 435 nm were recorded with a JASCO DIP-180 Automatic Polarimeter. The IR spectra were recorded with a Hitachi EPI-S2 Spectrometer in KBr pellets. The PMR spectra were measured with a Hitachi R-20 Spectrometer (60 MHz) at 35 °C in CD_3OD by using TMS as the internal reference.

Results and Discussion

Properties of the Complexes. All the complexes except for the gly-complexes **1** and **13** exhibit mutarotations in methanol; the data are summarized in Table 3. Some representative mutarotations are shown in Fig. 2. It is seen that there are two patterns of mutarotation; one is for the complexes **2**—**6**, **14**—**16**, **20**, **22**, and **23**, which show quite small rotations soon after dissolution but show large $(-)_{435}$-rotations at equilibrium conditions, The other is for the complexes **8**, **10**, **12**, **17**, **18**, and **24**, which show quite large $(-)_{435}$-rotations soon after dissolution but decrease their magnitudes at equilibrium conditions. As mentioned later, each of the complexes exists as only *cis*-β_1(fac)-geometrical isomer in methanol. Therefore, the mutarotations correspond to the isomerization reaction between $(-)_{435}$- and $(+)_{435}$-isomers. The plots of $\log(\alpha_\infty-\alpha_t)$ *vs.* time give linear relations. Accordingly, the observed isomerization rates, k_{obsd}, can be estimated as listed in Table 3. Since the following equilibrium reaction is thought to occur in solution,

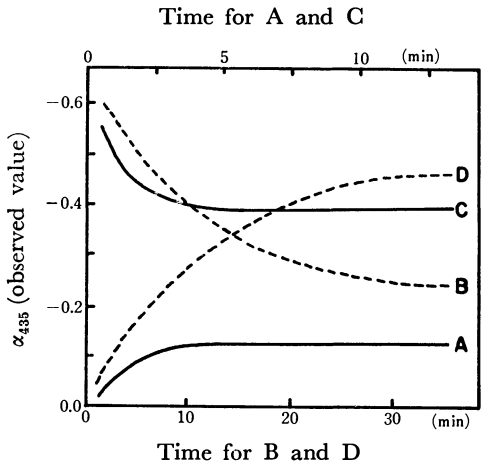

Fig. 2. The representative mutarotations of the complexes in methanol at 25 °C. A: [Co(sal$_2$en)(L-met)], B: [Co(7,7′-Me-sal$_2$en)(L-met)], C: [Co(sal$_2$en)(L-phe)], D: [Co(7,7′-Me-sal$_2$en)(L-phe)].

$(+)_{435}$-isomer $\underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}}$ $(-)_{435}$-isomer, the isomerization rate constants from $(+)_{435}$-isomer to $(-)_{435}$-isomer, k_{+1}, and from $(-)_{435}$-isomer to $(+)_{435}$-isomer, k_{-1}, are written by $k_{+1}=2.303[S/(S+1)]k_{obsd}$ and $k_{-1}=2.303[1/(S+1)]k_{obsd}$ respectively, where S is the stereoselectivity in each complex at the equilibrium condition, $S=(-)_{435}$-isomer/$(+)_{435}$-isomer.[22] The estimated rate constants, k_{+1} and k_{-1}, are also listed in Table 3. It is seen that the isomerization rates are fairly rapid,

a) Estimated value from k_{obs} by extrapolating to time=0; this value contains some error because it takes a few minutes to dissolve the complex in methanol, the + or − rotation is perhaps due to the error and/or the vicinal effect of the coordinated amino acid. b) This complex shows medium $(-)_{435}$-rotation soon after dissolution by exception.

as compared with those of the usual cobalt(III) complexes.[23] As the complexes easily isomerize to establish equilibrium conditions in methanol with $(-)_{435}$-rotations, the stereoselectivity in these complexes at equilibrium conditions is thermodynamic in origin, and $(-)_{435}$-isomers are more stable than $(+)_{435}$-isomers.

It should be noted that the complexes are labile not only for the isomerization reaction mentioned above but also for the substitution reaction of the coordinated amino acid anion. For example, the substitution rate, k_{obsd}, in the following reaction in methanol is observed to be 2.2×10^{-2} s^{-1} mol l^{-1} at 25 °C:

[Co(7,7′-Me-sal$_2$en)(L-phe)] + D-phe$^-$
$\longrightarrow$ [Co(7,7′-Me-sal$_2$en)(D-phe)] + L-phe$^-$

From the above mutarotations and the time dependnt PMR spectra mentioned later, the following facts become clear that the complexes **2**—**6**,**14**—**16**, **20**, **22**, and **23** are isolated each as an 1 : 1 mixture of $(-)_{435}$-and $(+)_{435}$-isomers, but the complexes **8**, **10**, **12**, **17**, **18**, and **24** are isolated each as a pure $(-)_{435}$-isomer. The discrepancy of the composition of the two isomers between the solid state and solution is perhaps due to the solubility of the complexes. That is, when the isomerization is rapid, only the least soluble isomer may be preferentially isolated.

Structure of the Complexes. Figure 3 shows representative AB and CD spectra of the complexes at equilibrium conditions. All the AB and CD spectral data are summarized in Tables 4 and 5.

All the complexes reveal nearly the same AB spectra and very similar CD spectra at equilibrium conditions.

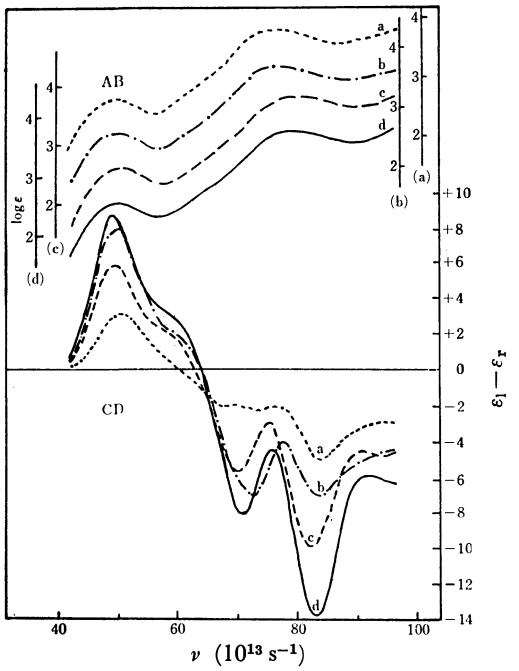

Fig. 3. The representative AB and CD spectra of the complexes in methanol at equilibrium conditions. a: [Co(sal$_2$en) (L-val)], b: [Co(sal$_2$en) (L-phe)], c: [Co(7,7′-Me-sal$_2$en) (L-val)], d: [Co(7,7′-Me-sal$_2$en) (L-phe)]. (a), (b), (c), and (d) are log ε value for the corresponding complexes.

The AB spectra soon after dissolution are also nearly the same as those at the equilibrium conditions in all the complexes. Therefore, these results suggest that 1) $(-)_{435}$- and $(+)_{435}$-isomers in each complex have the same geometrical configuration and 2) the geometrical configuration is the same for all the complexes. It is known that *cis*-α-structure is unstable in cobalt(III)–Schiff-base complexes and the existence of such a complex has not yet been found.[16,19] On the other hand, the *cis*-β-structure is well known.[16-21] Therefore, all the complexes may take either *cis*-β_1(*fac*)- or *cis*-β_2(*mer*)-structure. Another experiment[24] shows that [Co(sal$_2$-(*S*,*S*)-chxn(aa)] complex (where sal$_2$-(*S*,*S*)-chxn indicates the dianion of (1*S*,2*S*) - *N*,*N*′ - 1,2 - cyclohexylenebis (salicylideneamine) and aa, amino acid anion) takes stereoselectively the Λ-*cis*-β-structure with a large $(-)_{435}$-rotation and its AB and CD spectra are quite similar to those of $(-)_{435}$-isomers obtained here. Thus, the Λ-configuration is assigned to the $(-)_{435}$-isomers and Δ to the $(+)_{435}$-isomers. As mentioned later, the results of the stereoselectivity in the complexes show that there exists intramolecular steric repulsion between the alkyl group of the coordinated amino acid anion and H–C=N or CH_3–C=N groups of the Schiff-base ligand, and that the repulsion is stronger in $(+)_{435}$-isomer than in $(-)_{435}$-isomer. The molecular model indicates that such a steric interaction is stronger in Δ_L-configuration than Λ_L, if the complex takes the *cis*-β_1(*fac*)-structure, but is stronger in Λ_L-configuration than in Δ_L, if the complex takes the *cis*-β_2(*mer*)-structure. Therefore, all the complexes are suggested to take the *cis*-β_1(*fac*)-structure. The proposed structures are shown in Fig. 4.

Stereoselectivity. All the PMR specrtal data are summarized in Tables 6 and 7, and the representative PMR spectra are shown in Fig. 5.

In complexes **2**—**6**, **8**, and **14**—**18**, the signal of H-C=N or CH_3–C=N protons of the Schiff-base ligand shows no time dependence; the signal appears only as two peaks with equal intensity, not onoy soon after dissolution but also at the equilibrium condition. However, the signal of the coordinated amino acid anion shows a clear time dependence. For example, as shown in Figs. 5 A and A′, the L-ala-complex **2** shows two kinds of signals with equal intensity for the methyl group of the coordinated L-alanine anion soon after dissolution, but these two signals change in their intensities at the equilibrium condition. Similar behaviors are observed for the complexes **3**—**6**,

4, **5**, **16**, and **17**, due to the complicated overlaps of the alkyl signals, their PMR spectra give no fine information about the isomer's ratios at equilibrium conditions. Therefore, the ratios were estimated from their rotational values at 435 nm or from their CD strengths at 589 nm. That is, the ratio in the complex **17** was estimated by using the $[M]_{435}$-value for its pure $(-)_{435}$-isomer, which was estimated from the kinetic data by extrapolating to time=0, and the $[M]_{435}$-value at the equilibrium condition. The ratio in the complex **16** was obtained by using the $[M]_{435}$-value of pure $(-)_{435}$-isomer of the complex **17** as the $[M]_{435}$-value for a pure $(-)_{435}$-isomer of the complex **16**. In these estimations, we used the following assumptions: that the $[M]_{435}$-values for $(-)_{435}$- and $(+)_{435}$-isomers are the same in each complex, except for the reversed sign, and that the values are quite similar in both L-isoleu- and L-leu-complexes, because the vicinal effect of the coordinated amino acid anion is generally very small as compared with the configurational effect of the chelated ligands.[25-27] However, recently it has been shown for the $[Co(aa)_2(en)]^+$ complex that the vicinal effect is fairly large in some kinds of amino acids.[28] Nearly the same result was also obtained for the [Co(tfac$_2$en)(L-aa)] complex (tfac$_2$en=dianion of *N*,*N*′-ethylenebis(trifluoroacetylacetoneamine)).[29] Thus, the stereoselectivity determined by using CD or ORD strengths may not be so exact as compared with that by PMR intensity. The isomer's ratios in the complexes **4** and **5** were estimated by nearly the same method as those in the complexes **16** and **17**, but by using the $\Delta\varepsilon_{589}$-values at the first absorption region for the complexes **4** and **5** and by using the $\Delta\varepsilon_{589}$-value for pure $(-)_{435}$-isomer of the complex **3**, which was calculated from the $\Delta\varepsilon_{589}$-value of the complex **3** at the equilibrium condition and its isomer's ratio at the same condition.

From the data for the isomer's ratios (Table 8), the

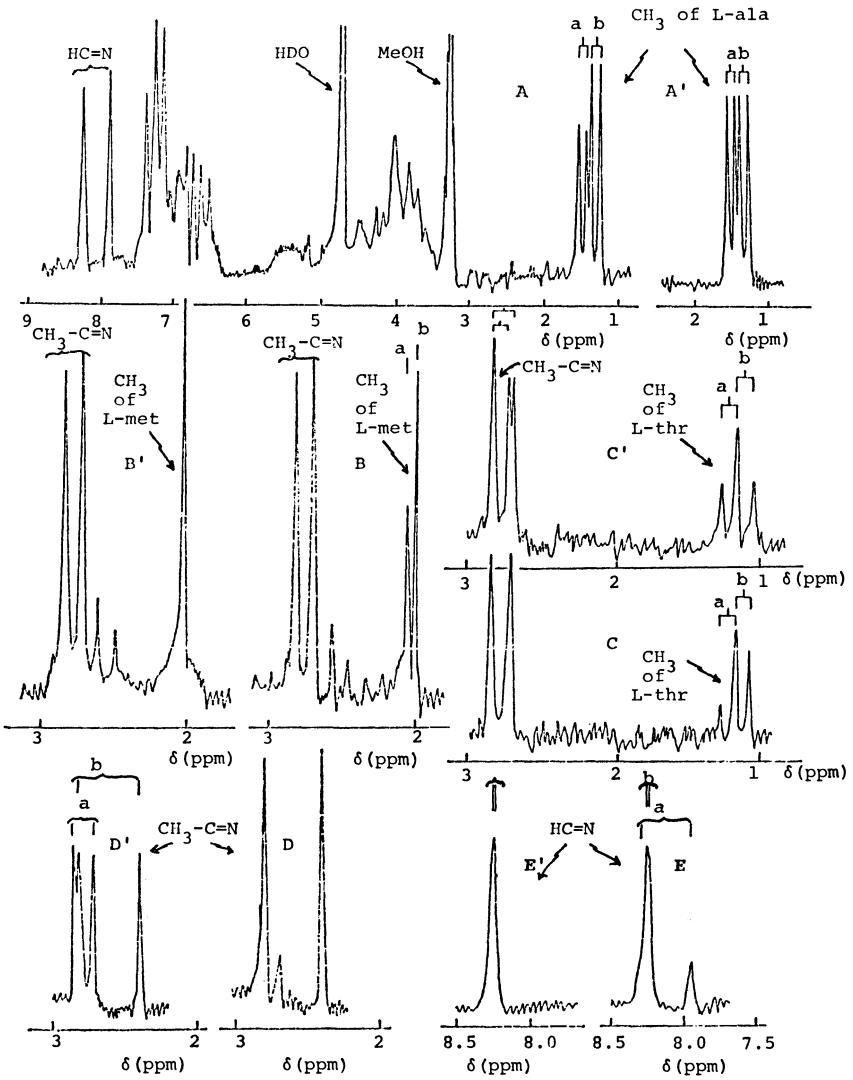

Fig. 5. The representative PMR spectra of the complexes in CD_3OD. A and A′ are PMR spectra of [Co(sal$_2$en)(L-ala)] (1) at the equilibrium condition (A) and soon after dissolution (A′). B and B′ are those of [Co(7,7′-Me-sal$_2$en)(L-met)] (18) at the equilibrium condition (B) and soon after dissolution (B′). C and C, D and D′, and E and E′ are those of [Co(7,7′-Me-sal$_2$en)(L-thr)] (20), [Co(7,7′-Me-sal$_2$en)(L-phe)] (22), and [Co(sal$_2$en)(L-phe)] (10) at the equilibrium conditions (C, D, and E) and soon after dissolution (C′, D′, and E′). The signal of a corresponds to $(+)_{435}$-isomer and that of b to $(-)_{435}$-isomer for all the PMR spectra.

Table 8. Stereoselectivity in the complexes at equilibrium conditions

Amino acid	R-Group	Isomer's ratio, sal$_2$en-complex	$(-)_{435}$-Isomer/$(+)_{435}$-isomer 7,7′-Me-sal$_2$en-complex
L-ala	$-CH_3$	1.4—1.6	1.9—2.1
L-met	$-(CH_2)_2-S-CH_3$	1.4—1.6	1.9—2.1
L-leu	$-CH_2-CH(CH_3)_2$	1.3—1.5[b]	1.9—2.1[a]
L-val	$-CH(CH_3)_2$	1.4—1.6	2.4—2.6
L-isoleu	$-CH(CH_3)(C_2H_5)$	1.2—1.4[b]	2.7—2.9[a]
L-thr	$-CH(CH_3)(OH)$	3.9—4.1	5.2—5.4
L-phe	$-CH_2-C_6H_5$	3.9—4.1	9— 10
L-tyr	$-CH_2-C_6H_4OH$	4.7—4.9	9— 10
L-trp	$-CH_2-C_8H_6N$	7.9—8.3	15— 18

a) Estimated value from α_{435}. b) Estimated value from $\Delta\varepsilon_{589}$.

following facts become clear: that 1) the ratios increase in the order of the amino acid, L-ala∼L-met∼L-leu∼L-val∼L-isoleu<L-thr∼L-phe∼L-tyr<L-trp for sal$_2$en-complexes and L-ala∼L-met∼L-leu<L-val<L-isoleu<L-thr<L-phe∼L-tyr<L-trp for 7,7′-Me-sal$_2$en-complexes; 2) the increasing order coincides with the increasing order of the steric crowding of the alkyl group of the amino acid, especially the steric crowding at the β-carbon atom; and 3) the ratio is larger in 7,7′-Me-sal$_2$en-complexes than in sal$_2$en-complexes for each amino acid. These results show that the stereoselectivity in these complexes at least depends on the intramolecular steric repulsion between the alkyl group of the amino acid anion and the hydrogen atom or methyl group at the C=N bonds of the Schiff-base ligand, and thus the steric interaction is stronger in 7,7′-Me-sal$_2$en-than in the sal$_2$en-complexes. Since the stereoselectivity in these Schiff-base complexes is thermodynamic in origin, as mentioned above, it is also shown that the steric interaction is stronger in $(+)_{435}$-isomer (unstable) than $(-)_{435}$-isomer (stable).

The authors wish to express their deep thanks to Prof. Y. Yoshino of Tokyo University and Prof.K. Sone and Dr. Y. Fukuda of Ochanomizu University for their kind assistance in the CD spectral measurement. The Polarography of the Cadmium(II)–2-Carboxy-1-pyrrolidine-carbodithioate Chelate

Toyokichi KITAGAWA and Kazuo NOMURA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received May 15, 1976)

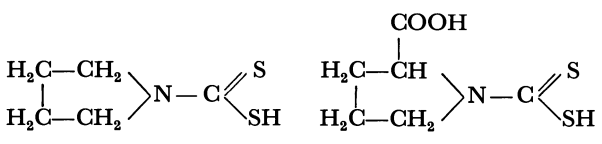
The electrochemical behavior of the cadmium(II) ion in the presence of 2-carboxy-1-pyrrolidinecarbodithioic acid (H_2cpcd) as a chelating agent was investigated in an alkaline medium by d.c. polarography, a.c. polarography, cyclic voltammetry, and chronopotentiometry. The cadmium(II) chelate gave a reversible two-electron reduction wave at −0.86 V *vs.* SCE, with a postwave at −0.95 V. From the dependence of the total wave height on the mercury column height and from the methods of cyclic voltammetry, the electrode reduction of the cadmium(II) chelate was found to be diffusion-controlled. The diffusion current constant was 2.42 $\mu A\ mol^{-1}\ m^3\ mg^{-2/3}\ s^{1/2}$. The postwave was identified as an adsorption wave of the cadmium(II) chelate from the dependence of the postwave height on the mercury column height, the a.c. peak height, the electrocapillary curves, and the results of chronopotentiometry. The surface excess of cadmium(II) chelate adsorbed on the mercury electrode was evaluated by means of three different electrochemical techniques. The composition of the cadmium(II)–cpcd chelate in the presence of excess H_2cpcd was $Cd(cpcd)_2^{2-}$, and the overall stability constant was estimated to be 8.0×10^{12} at 25.0 °C and $\mu=1.5$.

1-Pyrrolidinecarbodithioic acid (Hpcd) [I] is more stable to an acidic solution than 1,1-diethyldithiocarbamic acid, and it forms insoluble complexes with various metal ions. The [I] reagent has been used for the colorimetric determinations and atomic absorption spectrophotometric determinations of metal ions after solvent extraction,[1-3] X-ray analysis of the mercury complex[4] and electrochemical studies of the manganese complex.[5]

The reagent synthesized by the introduction of a carboxyl group at the 2-position of [I], 2-carboxy-1-pyrrolidinecarbdithioic acid (H_2cpcd)[II], has been recently found to form soluble complexes with metal ions in an aqueous solution,[6] and it may be that [II] can be used as an analytical reagent, much like other dithiocarbamic acids.

In a previous paper,[7] the polarographic behavior of [I] and [II], particularly the characteristics of the adsorption prewave, was investigated. Few of polarographic studies of the adsorption postwave has been presented than those of the prewave.[8-10] This paper will deal with the polarographic behavior of the cadmium(II) ion in the presence of H_2cpcd, and particularly with the characteristics of the adsorption postwave.

The structural formulas of [I] and [II] are as follows:



[I] [II]

Experimental

Reagents. Ammonium salt of [II] was prepared by the following procedure. L-Proline (11.5 g) was dissolved in a minimum amount of methanol, and then carbon disulfide (6 ml) was added. The solution was saturated with ammonia gas at 0 °C. The product was filtered off, recrystallized a few times by dissolving it in methanol and precipitating with ethyl ether, and dried under a vacuum for 24 h. Found: C, 32.07; H, 6.64; N, 18.56%. Calcd for $C_6H_{15}O_2N_3S_2$: C, 31.98; H, 6.71; N, 18.65%.

The cadmium(II) sulfate solution was standardized by chelatometric titration, with EDTA as the titrant. All chemicals were of an analytical reagent grade and were used without further purification.

Apparatus. The d.c. and a.c. polarograms were recorded with a Yanagimoto PA-102 polarograph connected to a conventional H-type cell, which was used in conjunction with a saturated calomel electrode (SCE) as a reference electrode and, if necessary, a coiled platinum wire electrode as a counter electrode. The dropping mercury electrode (DME) had the following characteristics: mercury flow-rate $m=0.499$ mg s^{-1} and drop time $t=5.24$ s in a 0.5 mol dm^{-3} sodium sulfate solution at an open circuit and at a mercury column height $h=60$ cm. The AC current was by-passed by the use of a 200 μF capacitor between the coiled platinum wire electrode and SCE. Cyclic voltammograms were recorded with Riken Denshi F-32 or F-43 X-Y recorders in conjunction with the polarograph, using a hanging mercury drop electrode (HMDE). Chronopotentiograms were also recorded with X-Y recorder in conjunction with a Riken Denshi transient time converter TCA-200 using a slow dropping mercury electrode, where $m=0.0349$ mg s^{-1} and $t=208.2$ s. A constant current for the chronopotentiometric measurements was obtained using a dry cell of 200 V and appropriate resistors. The pH of a sample solution was measured with a Toa Denpa HM-5A pH meter.

Procedure. To a freshly prepared sample solution containing 0.5 mol dm^{-3} sodium sulfate as a supporting electrolyte, a 0.02 mol dm^{-3} sodium borate–sodium hydroxide buffer was added to prevent the sample from decomposition because of the poor stability of H_2cpcd in an acidic solution.[11] Solutions were de-aerated with highly purified nitrogen gas for 15 min before recording the polarograms. The cell was immersed in a water thermostat controlled at 25±0.1 °C, and measurements were carried out under a nitrogen atmosphere. Electrocapillary curves were obtained by converting the drop times into the interfacial tension in the potential range from 1.0—1.8 V.

Results and Discussion

D.c. and a.c. Polarography. Figure 1 shows, the d.c. and a.c. polarograms of the cadmium(II) ion in an alkaline solution containing excess H_2cpcd. At the concentrations of 2×10^{-4} mol·dm^{-3} cadmium(II) and 1×10^{-2} mol dm^{-3} H_2cpcd, the d.c. polarogram gives the main wave A at −0.86 V and a postwave, B,

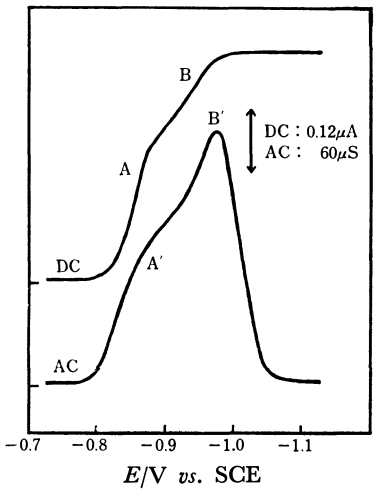


Fig. 1. Polarograms of cadmium(II)-cpcd chelate. [Cd(II)]=2×10^{-4} mol dm^{-3}, [cpcd]=1×10^{-2} mol dm^{-3}, pH 9.4.

at −0.95 V. Two peaks, A′ and B′ of the a.c. polarogram correspond to the d.c. waves. The wave heights are almost constant in the pH range from 4.5 to 11.0 and decrease below pH 4.5. The reversibility of the electrode reactions has been introduced by Senda *et al.* and the reversibility constant is expressed as $K=Y_p\, i_l^{-1}\, n^{-1}\, t^{-1/2}$ where Y_p is the peak admittance of the a.c. wave. The K values for the electrode processes of the two reduction waves are 70.4 and 439.9 S A^{-1} s$^{-1/2}$ respectively. The latter value is much greater than the former, which shows a reversible process. These values suggest that the electrode reaction accompanies a specific adsorption. The adsorption of the reactant and/or product will affect the observed electrochemical behavior. Brdička has shown that, on d.c. polarography, adsorption of the product should manifest itself as an adsorption-controlled prewave, while, the adsorption of the reactant should appear as a postwave.[12]

As Fig. 2 shows, the height of the B postwave is independent of the concentration of the cadmium(II)

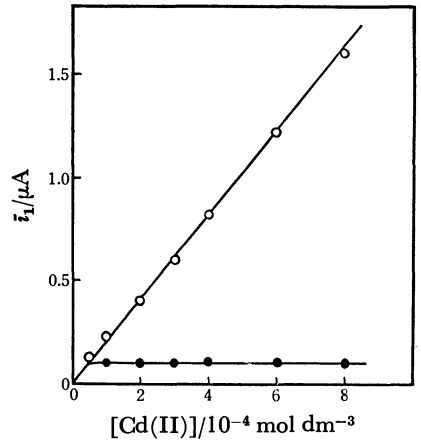

Fig. 2. Dependence of the limiting currents on the concentration of cadmium(II) ion. [cpcd]=1×10^{-2} mol dm^{-3}, pH 9.4, ○: total wasve (A+B), ●: postwave(B).

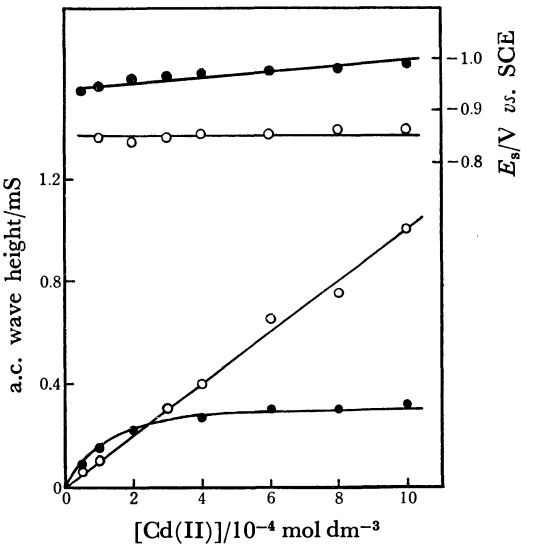

Fig. 3. Dependence of the summit potentials and a.c. wave heights on the concentration of cadmium(II) ion. [cpcd]=1×10^{-2} mol dm^{-3}, pH 9.4, ○: 1st wave(A′), ●: 2nd wave(B′).

ion in the range over 1×10^{-4} mol dm^{-3}, while that of the total wave (A+B) is proportional to the concentration in the range less than 1×10^{-3} mol dm^{-3}. Therefore, the postwave may be considered to be an adsorption wave of the reactant. Figure 3 shows the dependence of the a.c. peak height and the summit potential on the concentration of the cadmium(II) ion. The height of the second peak, B′, increases nonlinearly with an increase in the concentration and approaches a limiting value, while that of the first peak, A′, is approximately proportional to the concentration. The summit potential of B′ shifts to a more negative potential with an increase in the concentration, while that of A′ is independent of the concentration. From these results, the second a.c. wave seems to be a tensammetric desorption wave.[13,14]

The plot of $\log(i/(i_d-i))$ *vs.* E gives a straight line with a reciprocal slope of 30 mV, although the plot displays a downward curvature near the potential corresponding to the postwave. The electrode process of the cadmium(II) chelate is found to be a reversible two-electron reduction.

Electrocapillary Curves. The electrocapillary curves of the cadmium(II) ion in the presence of excess H_2cpcd are shown in Fig. 4. In the presence of H_2cpcd alone a marked depression of the interfacial tension of mercury is observed in the potential range from 0 to −0.85 V. At more negative potentials than about 0.85 V, the interfacial tension of mercury in the presence of H_2cpcd is almost identical to that in its absence. As has been reported previously,[7] cpcd^{2-} itself adsorbs strongly on the surface of the DME in the above potential range. On the addition of the cadmium(II) ion to the H_2cpcd solution, the interfacial tension is depressed much more than in the presence of H_2cpcd only, and the potentials of the desorption shift to more negative values as the concentration of

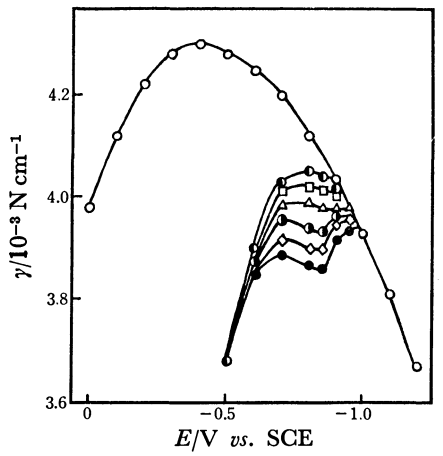

Fig. 4. Electrocapillary curves of cadmium(II)-cpcd chelate.
[cpcd]$=1\times10^{-2}$ mol dm^{-3}, [Cd(II)]=◐: 0, □: 1×10^{-5}, △: 2×10^{-5}, ◑: 4×10^{-5}, ◇: 8×10^{-5}, ●: 2×10^{-4} mol dm^{-3}, ○: base solution.

the cadmium(II) ion increases. At 2×10^{-4} mol dm^{-3} cadmium(II), the interfacial tension is depressed in the potential range from 0 to −0.95 V and reaches its lower limit. This behavior corresponds to the saturation of the adsorbate on the electrode surface. The potential slightly more positive than that of the desorption corresponds to be the potential of the postwave on the d.c. polarogram. Therefore, the postwave is also assigned to the adsorption wave of the cadmium(II) chelate. The minimum of the interfacial tension on the electrocapillary curves for the cadmium(II) chelate appears at the potential of −0.85 V, which corresponds to the initial rise in the polarogram.

Effect of the Mercury Column Height. Table 1 shows the dependence of the wave heights on the mercury column height. The limiting current of the total wave (A+B) is proprotional to $h^{1/2}$; hence, the electrode process is diffusion-controlled. According to the Ilkovič equation, the diffusion current constant, I_d, and the diffusion coefficient, D, of the cadmium chelate can be calculated: $I_d=2.42$ μA mol^{-1} m^3 mg$^{-2/3}$ s$^{1/2}$ and $D=3.97\times10^{-6}$ cm^2 s^{-1} where $n=2$. From the equation of the mean adsorption current, i_a, gives below, i_a should be proportional to h, because m is proportional to h and t to h^{-1}. The limiting current of the B postwave is proportional to h, and the postwave is reassigned to the adsorption wave of cadmium(II) chelate.

Table 1. Dependence of the limiting currents on the mercury column height

h / cm	$\bar{i}_{post}$ / nA	$\bar{i}_{total}$ / nA	$\bar{i}_{post}/h$ / nA·cm^{-1}	$\bar{i}_{total}/h^{1/2}$ / nA·cm$^{-1/2}$

60.0	128	401	2.2	51.8
65.0	140	422	2.2	52.3
70.0	152	432	2.2	51.6
75.0	165	449	2.2	51.8

[Cd(II)]$=2\times10^{-4}$ mol dm^{-3}, [cpcd]$=1\times10^{-2}$ mol dm^{-3}, pH 9.4.

Cyclic Voltammerty. A cyclic voltammogram obtained under the same conditions is shown in Fig. 5. An exceptionally steep rise of the current is observed in the reduction step and is considered to be due to the adsorption of the cadmium(II) chelate. The peak current which is obtained by subtracting the current of the steep rise is proportional to the squareroot of the sweep rate. Consequently, the electrode process is the diffusion-controlled process acompanying the adsorption of the reactant.

Chronopotentiometry, Chronopotentiometry has often been used for the investigation of the adsorption of reactants.[15-17] Figure 6 shows a characteristic potential-time curve of the cadmium(II) chelat. The transition time constant, T, in chronopotentiometry has been revealed by Sand to be as follows; it is constant when the electrode process is diffusion-controlled:

$$T=\frac{i_A\tau^{1/2}}{C}=\frac{1}{2}\pi^{1/2}nFD^{1/2}$$

$[Cd(II)]=2\times10^{-4}$mol dm^{-3}, $[cpcd]=1\times10^{-2}$ mol dm^{-3}, pH 9.4.

where i_A is the applied current density, τ is the transition time, and F is the Faraday constant. The results for the reduction of the cadmium(II) chelate which are summarized in Table 2 show that T tends to increase with an increase in i_A. This behavior is indicative of the adsorption of the electroactive reactant on the surface of the mercury drop electrode.

Surface Excess. Γ_m was calculated by the quantitative treatment of the limiting current caused by the formation of a monolayer of the reactant on the surface of the dropping mercury electrode.[12] Provided the quantity of electricity, Q, is based on the formation of a monolayer until the final time of drop-growth, Q is expressed as Eq. 1:

$$Q = n\,F\,A_t\,\Gamma_m \tag{1}$$

Where Γ_m is the number of moles of a monolayer in a unit area, *i.e.*, the surface excess, A_t is the srea of a mercury drop after t seconds, and n is the number of electrons per mole of a monolayer. Therefore, the net current until the final time of drop-growth is given as:

$$i_a = \frac{\partial Q}{\partial t} = n\,F\,\Gamma_m\left(\frac{\partial A_t}{\partial t}\right) \tag{2}$$

Provided a mercury drop is a complete sphere, the following equation is given:

$$A_t = \left(\frac{3mt}{4\pi d}\right)^{2/3} = 0.848\,m^{2/3}\,t^{2/3} \tag{3}$$

where m is expressed in g s^{-1} and where d is the density of mercury (13.6 g cm^{-3}). The net current introduced from Eq. 2 is:

$$i_a = 5.47\times10^4\,n\,m^{2/3}\,t^{-1/3}\,\Gamma_m \tag{4}$$

and from Eq. 4 the mean adsorption current is:

$$\bar{i}_a = \frac{1}{t_m}\int_0^{t_m} i_a\,dt = 8.17\times10^8\,n\,m^{2/3}\,t_m^{-1/3}\,\Gamma m \tag{5}$$

where m is expressed in mg s^{-1} and $\bar{i}_a$ in μA.

The surface excess of the cadmium(II) chelate can be calculated by the following three methods. The first method[12] is based upon the mean adsorption current of the d.c. polarogram, using Eq. 5. On substituting 0.114 μA for $\bar{i}_a$, Γ_m is 1.93×10^{-10} mol cm^{-2}.

The area occupied by one molecule of an adsorption monolayer can be calculated as follows. The maximum area of a mercury drop, A_m is obtained by the substitution of t for t_m in Eq. 3. $\bar{i}_a t_m/A_m$ is the quantity of electricity per area at the last moment of drop-growth. The quantity of electricity required to form a monolayer according to a two-electron process is:

$$\frac{n\,F}{\text{Avogadro number}} = 3.20\times10^{-19}\text{ C molecule}^{-1}$$

Therefore, the area per molecule of a monolayer, A, is obtained by means of the following equation:

$$\bar{A} = \frac{3.20\times10^{-19}\,A_m}{\bar{i}_a t_m}$$

$\bar{A}$ is 85.8×10^{-16} cm^2 molecule^{-1}.

The second method is a calcualtion from the interfacial tensions at the constant potential, E, using the following equations:[18]

$$\Gamma_s = -\frac{1}{RT}\left(\frac{\partial\gamma}{\partial\ln C}\right)_E \tag{6}$$

where γ is the interfacial tension. Figure 7 shows the variation in the γ of the electrocapillary curves with the concentration of cadmium(II) ion at the potential, E. Γ_s is calculated to be 2.15×10^{-10} mol cm^{-2}.

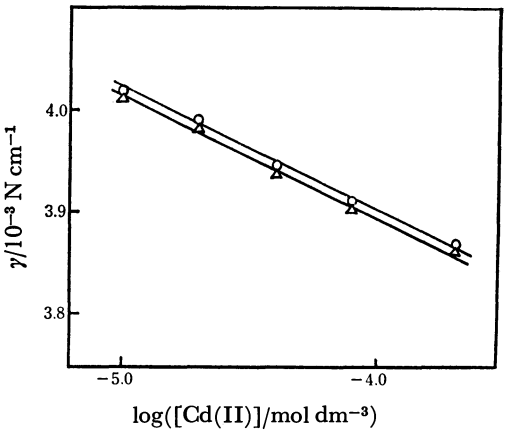

Fig. 7. Dependence of the interfacial tention on the concentration of cadmium(II) ion.
E ○: −0.80 V, △: −0.85 V.

The third methcd is a calculation from the variation in $i_A\tau^{1/2}/C$ with the τ through chronopotentiometry, using various theoretical models of adsorption. Lorenz[19] proposed four theoretical models for chronopotentiomety involving the adsorption of electroactive species. These can be denoted as the ARSR, SAR, SRAR, and equilibrium cases.[17,20] The ARSR model assumes that the adsorbed reactant, AR, is coulometrically depleted prior to the reduction of the solution reactant, SR, and that τ is the sum of the transition times of the AR and SR species. The mathematical relation is:

$$i_A\tau = n\,F\,\Gamma_c + \frac{\pi D(n\,F\,C)^2}{4\,i_A} \tag{7}$$

The SAR model assumes that the SR and AR species react and are depleted simultaneously, that a fixed fraction of the applied current goes to each phase during the entire electrolysis, and that the relation is:

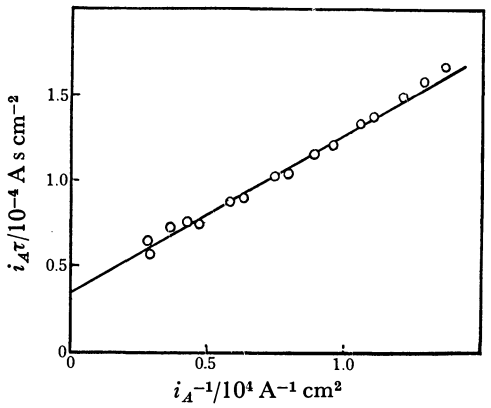

Fig. 8. The plot of $i_A\tau$ *vs.* i_A^{-1}.

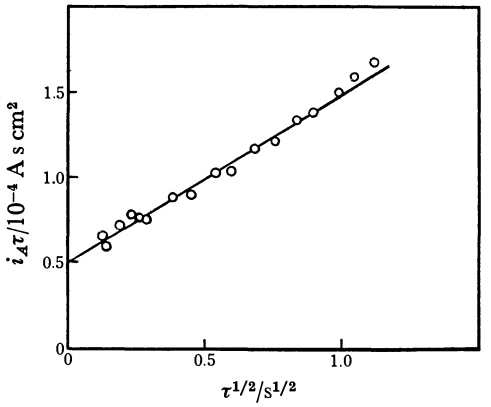

Fig. 9. The plot of $i_A\tau$ *vs.* $\tau^{1/2}$.

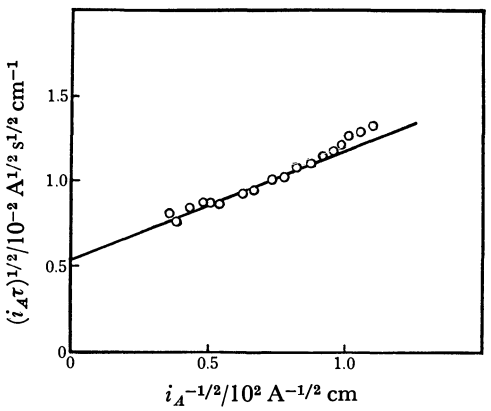

Fig. 10. The plot of $(i_A\tau)^{1/2}$ *vs.* $i_A^{-1/2}$.

$$i_A\tau = n\,F\,\Gamma_c + \frac{n\,F\,C(\pi D\tau)^{1/2}}{2} \tag{8}$$

The SRAR model is the reverse of the ARSR model and assumes that the SR species is coulometrically depleted prior to the reduction of the AR species and that the relation is:

$$(i_A\tau)^{1/2} = (n\,F\,\Gamma_c)^{1/2} + \frac{n\,F\,C(\pi D)^{1/2}}{2\,i_A^{1/2}} \tag{9}$$

The equlibrium model assumes that the species are coupled by a rapid equilibration process accroding to a linear adsorption isotherm, that they are simultaneously depleted at the total transition time, and that the relation is:

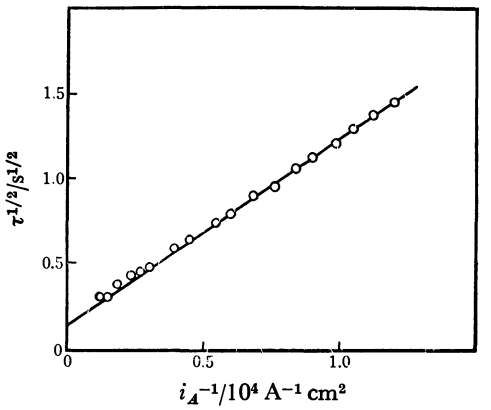

Fig. 11. The plot of $\tau^{1/2}$ *vs.* i_A^{-1}.

$$\tau^{1/2} = \frac{n\,F\,C(\pi D)^{1/2}}{2\,i_A} + \frac{\pi^{1/2}\,\Gamma_c}{2\,D^{1/2}\,C} \tag{10}$$

Figures 8 to 11 show the plots of the four models. Each of them gives a straight line, and the diffusion coefficient, D, can be obtained from the intercept, and Γ_c from the slope; those values are summarized in Table 3. Although it is not possible to make a clear choice between the models on the basis of only these results, the adsorption behavior may be an equilibrium case because of the excellent linearity of the plot according to Eq. 10.

The values of the surface excess obtained from the three methods closely agree with one another. The area per molecule of a monolayer of the complex is about 80×10^{-16} cm^2. The surface excess of $Cd(cpcd)_2^{2-}$ is shown in Table 4, together with $Hg(cpcd)_2^{2-}$ and $Hg(pcd)_2$, which are the oxidationproducts at the DME. On applying either method, the order of the magnitude of the surface excess on the mercury drop is $Hg(pcd)_2 > Hg(cpcd)_2^{2-} > Cd(cpcd)_2^{2-}$. This order may be due to the steric hindrance of the carboxyl group and the spcific interaction between the mercury and the sulfur atoms.

Effect of the Ligand Concentration. By means of the variation in the concentration of H_2cpcd in the presence of the cadmium (II) ion, the stability constants of the

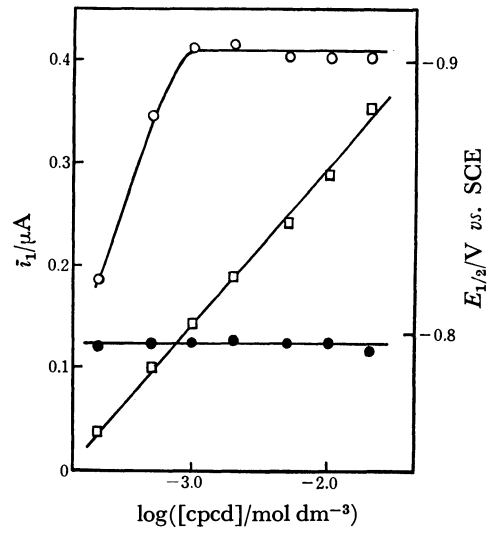

Fig. 12. Dependence of the limiting currents and the halfwave potential on the ligand concetration. [Cd(II)]=2×10^{-4} mol dm^{-3}. ○: total wave(A+B), ●: postwave(B), □: $E_{1/2}$ of the main wave.

cadmium (II)-cpcd chelate can be determined. Figure 12 shows the dependence of these wave heiths and half-wave potentials on the concentartion of H_2cpcd. The limiting current of the total wave (A+B) is nearly constant in concentrations more than 10^{-3} mol dm^{-3}. That of the postwave B is independent of the concentration. The half-wave potential of the main wave, A, shifts linearly to a more negative potential as the concentration of the ligand increases. The slope of the $E_{1/2}$ *vs.* log[cpcd]plot is 57 mV, which corresponds the formation of the 1 : 2 complex. The overall stability costant of the chelate, β_2, is calculated by the Lingane method[21]; it is 5.1×10^{12} at 25 °C and μ= 1.5. The relationship between $E_{1/2}$ and the ligand concentration can slao be analyzed by the method of DeFord and Hume[22]; the value of β_1 and β_2 are 5.5×10^{8} and 8.0×10^{12} respectively.

The electrode reactions for the cadmium(II) chelate are inferred to proceed according to the following four steps:

(1) The $Cd(cpcd)_2^{2-}$ reactant diffuses toward the DME, and then the reactant is completely adsorbed on the surface. The adsorbed molecules are stabilized because of the adsorption energy; hence, the reduction of the adsorbed reactant require a much higher enregy than that of the solute reactant.

$$Cd(cpcd)_2^{2-} \rightleftharpoons Cd(cdcd)_2^{2-}{}_{ads.}$$

(2) The $Cd(cpcd)_2^{2-}$ species, which diffuses from the bulk of the solution, is reduced at first.

$$Cd(cpcd)_2^{2-} + 2e \rightleftharpoons Cd(Hg) + 2\,cpcd^{2-} \text{ (main wave)}$$

(3) The reduction of $Cd(cpcd)_2^{2-}{}_{ads.}$, which was stabilized by adsorption, requires a high energy, and then the wave appears at amore negative potential.

(4) The $Cd(cpcd)_2^{2-}$, which diffuses from the bulk of the solution, is directly reduced.

The authors wish to thank Mr. A. Ichimura for his valuable suggestions and discussions in the course of this work.

Studies of Nitrogen–Phosphorus Compound. XXVII.[1] Synthesis of $N_4P_4(NH_2)_8$ and Its Hydrolysis

Etsuro KOBAYASHI

National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo 151

(Received May 20, 1976)

The method for synthesis of $N_4P_4(NH_2)_8$ by the reaction between $(NPCl_2)_4$ and ammonia and its hydrolysis behavior were investigated. The reaction of $(NPCl_2)_4$ with liquid ammonia took place violently at first, and the resulting product contained more than several percents of an insoluble material. The extract from this product had a rather low yield, about 20—25%. However, such a drastic reaction could be avoided by the addition of a small amount of dioxane to the reaction system; then the insoluble material did not form, and the yield increased to 55—66%. The final product contained P 37—38% and N 50—51%; thus the mole ratio of N to P was exactly 3 : 1 and the composition agreed with that of $N_4P_4(NH_2)_8 \cdot H_2O$. When an aqueous solution of $N_4P_4(NH_2)_8$ was refluxed at 100 °C, the compound was initially hydrolyzed to $PO(NH_2)_3$ and $P_2O_2NH(NH_3)_4$, these being converted into $PO(ONa)(NH_2)_2$. At room temperature, the rate of hydrolysis was quite slow, but the composition of the hydrolysis products was similar to that at 100 °C. In a sodium hydroxide solution, $N_4P_4(NH_2)_8$ was converted directly into $PO(ONa)(NH_2)_2$ at an elevated temperature. The rate of the alkali hydrolysis obeyed a first-order equation, with the rate constants of 1.0×10^{-3}, 2.5×10^{-3}, 1.9×10^{-2}, and 4.2×10^{-2} at 50, 60, 80, and 90 °C, respectively. These values were about 2.7 times that of $N_3P_3(NH_2)_6$. The activation energy of the reaction was 20.8 kcal/mol. The acid hydrolysis behavior resembled that in the neutral hydrolysis, but the reaction was accelerated with acid strength. The formation of tetrametaphosphimate by the hydrolysis of $N_4P_4(NH_2)_8$, that had previously been claimed, could not be reproduced in this study.

The amidated derivatives of the lower polymers of phosphorus dichloride nitride are of interest as fireproof materials[2,3] and fertilizers.[4,5] The completely ammonated products, $N_3P_3(NH_2)_6$ and $N_4P_4(NH_2)_8$, were synthesized by the reactions between $(NPCl_2)_3$ or $(NPCl_2)_4$ and liquid ammonia.[6] The present author previously reported the synthesis of $N_3P_3(NH_2)_6$[7] and the formation of $PO(ONa)(NH_2)_2$ by the alkali hydrolysis of the trimeric variety.[8] In this work, the hydrolysis of $N_4P_4(NH_2)_8$ in neutral, alkali, and acid solutions was investigated. The experimental results partially differ from the previous explanations.[9,10] Thus an improvement in the synthesis of $N_4P_4(NH_2)_8$ and its hydrolysis behaviors will be described.

Experimental

Preparation of $N_4P_4(NH_2)_8$. $(NPCl_2)_4$ (mp 123.0—123.7 °C) used as the raw material was obtained by fractional sublimation under a vacuum from $(NPCl_2)_n$ (n=3—7), which was synthesized by the reaction between phosphorus pentachloride and ammonium chloride. $(NPCl_2)_4$ was treated with liquid ammonia in the presence of a small amount of dioxane. The resulting product was dissolved in water, and the addition of ethanol into the solution gave rise to the precipitate of $N_4P_4(NH_2)_8 \cdot H_2O$, which was separated by filtration from the mother liquor and finally vacuum-dried over over phosphorus pentoxide.

Preparation of Alkali-hydrolysis Product. A 1.00 g portion of $N_4P_4(NH_2)_8 \cdot H_2O$ was refluxed with 100 ml of 0.65 M NaOH in a stainless steel flask for 3 h. The product was precipitated by the addition of excess ethanol into the solution, purified by recrystallization using ethanol, and finally vacuum dried over phosphorus pentoxide for 24 h.

Hydrolysis. For the neutral hydrolysis, a solution of 0.05 M $N_4P_4(NH_2)_8$ (or 0.05 M $N_3P_3(NH_2)_6$) was refluxed at 100 °C. Parts of the solution were taken out at proper time intervals, and these were supplied as the samples for the analysis. Hydrolysis was also carried out at room temperature for 3 weeks. For the alkali hydrolysis, a solution containing 0.05 M $N_4P_4(NH_2)_8$ in 1 M NaOH was prepared, and divided into several test tubes. The tubes were immersed in a bath regulated to a certain temperature. They were then successively withdrawn from the bath at proper time intervals. Both $N_4P_4(NH_2)_8$ and the $PO(ONa)(NH_2)_2$ formed were determined by means of ion-exchange chromatography. The rate of alkali hydrolysis and its activation energy were calculated. For the acid hydrolysis, a solution containing 0.05 M $N_4P_4(NH_2)_8$ in 0.25 M HCl was used. The acid hydrolysis was carried out in the same way as that for the neutral hydrolysis.

Analysis. The phosphorus content was determined gravimetrically as magnesium pyrophosphate. The total nitrogen content was determined by Kjeldahl's method. The sodium content was determined by using a flame photometer. The species of phosphorus amide-compounds were analyzed by ion-exchange chromatography,[8] and distinguished by paper chromatography using an alkalisolvent.[11]

Results and Discussion

Synthesis of $N_4P_4(NH_2)_8$. The synthesizing conditions of tetrameric phosphours diamide nitride and its analytical results are summarized in Table 1.

Formation of Insoluble Material: Generally, the reaction between a low polymer of phosphorus dichloride nitride and liquid ammonia is vigorously carried out, and some partially substituted products represented by $N_nP_nCl_{2n-x}(NH_2)_x$ (n=3,4) form; these are then gradually converted into the completely substituted products. The reactions are as follows:

$$(NPCl_2)_3 + 12NH_3 \rightarrow N_3P_3(NH_2)_6 + 6NH_4Cl \quad (1)$$

$$(NPCl_2)_4 + 16\,NH_3 \rightarrow N_4P_4(NH_2)_8 + 8NH_4Cl \quad (2)$$

The composition of the reaction product in (1) agreed fairly well with the calculated values as the sum of $N_3P_3(NH_2)_6$ and 6 NH_4Cl.[7] However, in the product of Eq. 2, the nitrogen content was less than that of its calculated value, the phosphorus and chlorine contents were conversely greater, and there was a considerable amount of an insoluble material as a by-product. The relations of the content of the insoluble material to the reaction time are shown in Fig. 1.

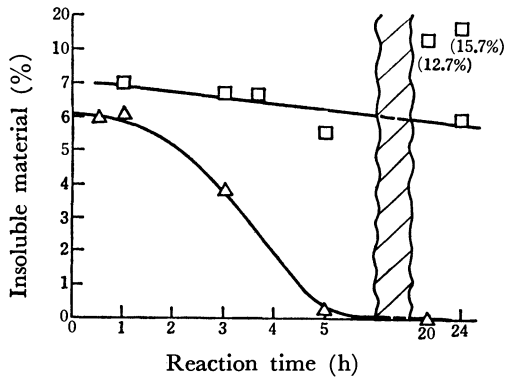

Fig. 1. Weight percent of insoluble material to reaction time.
△ : In the synthesis of $N_3P_3(NH_2)_6$.
□ : In the synthesis of $N_4P_4(NH_2)_8$.

In the formation of $N_3P_3(NH_2)_6$, the insoluble material disappeared in the reaction which lasted for about 5 h. Consequently, all the chloride atoms in $(NPCl_2)_3$ could be completely substituted by the amido groups. In the formation of $N_4P_4(NH_2)_8$, the insoluble material formed did not decrease so much in the course of time. For Nos. 3—6, which use a small amount of chloride, the insoluble material content was 5—6%, while for Nos. 1 and 2, which use a great amount of chloride, it was about 15%. In these cases, no homogeneous reaction between the liquid and solid phases evidently took place. Thus the insoluble material had not disappeared even in a reaction over a long period of time such as 24 h. It was therefore not the partially substituted product designated by $N_4P_4Cl_{8-x}(NH_2)_x$, but possibly a condensed product formed by the deammonation between the amide-phosphorus compounds as the intermediates. In order for the reaction to take place smoothly, the addition of dioxane in the reaction system of $(NPCl_2)_3$ with liquid ammonia has been proposed.[7] Thus in the reaction system of $(NPCl_2)_4$ with liquid ammonia, dioxane was added which resulted in no drastic reaction and very little insoluble material being formed. When no dioxane was added, the reaction product contained more than several% of the insoluble material, and the tetrameric variety extracted from the product showed a lower yield. The yields were remarkably increased by the addition of dioxane as shown in Table 1. The yields of the tetrameric variety were also calculated as 23 (non-addition), 53, 61, 55, and 59% in Nos. 3, 7, 9, and 10, respectively. The effect of dioxane as a medium in this reaction was evident.

Composition of The Product: The tetrameric phosphorus diamide nitride, which separates ammonium chloride as the by product from the reaction product by using liquid ammonia, is an anhydrous product. However, the composition of the material crystallized from an aqueous solution of the reaction product is not yet known. For the products obtained in this work, P content was 37—38%, N content was 50—51%, and the mole ratio of P to N was exactly 1 : 3. From these results, the expected composition was given by the formula $N_4P_4(NH_2)_8 \cdot H_2O$. The X-ray diffraction values of tetrameric phosphorus diamide nitride have not yet been registered on the ASTM X-ray data cards. An X-ray diffraction data of $N_4P_4(NH_2)_8 \cdot H_2O$ is shown in Table 2.

Hydrolysis of $N_4P_4(NH_2)_8$. Neutral Hydrolysis: After refluxing of an aqueous solution of $N_4P_4(NH_2)_8$ at 100 °C, the hydrolysis products were determined by means of ion-exchange chromatography. The results are given in Fig. 2.

Chromatogram I shows the elution for a mixture of various standard materials, while II, III, IV, V, and VI show elutions for some hydrolysis products over the course of time. The hydrolysis of $N_4P_4(NH_2)_8$ (A) was recognized by refluxing for 30 min. A considerable amount of $P_2O_2NH(NH_2)_4$ (C) and $PO(OH)(NH_2)_2$ (D) were formed after 60 min. Form the expected hydrolysis mode shown in Fig. 7, it can be considered that $PO(NH_2)_3$ and $P_2O_2NH(NH_2)_4$ are simultaneously formed. Both $N_4P_4(NH_2)_8$ and $PO(NH_2)_3$ are typical non-electrolytes. They were therefore eluted

at the same position on the ion-exchange chromatogram, as is shown in Fig. 3. However, in paper chromatography, R_f 0.27 $N_4P_4(NH_2)_8$ can be clearly distinguished from R_f 0.67 $PO(NH_2)_3$. In fact, it was seen that both components exist in the solution refluxed for 60 min. The pH of the solution was gradually lowered in the course of the refluxing time. $N_4P_4(NH_2)_8$, $PO(NH_2)_3$, and $P_2O_2NH(NH_2)_4$ then decreased, and $PO(OH)(NH_2)_2$ increased as the main hydrolysis product. A part of the formed diamidophosphate gradually decomposed to monoamidophosphate (H) and some orthophosphate (I). The hydrolysis behavior of $N_3P_3(NH_2)_6$ at 100 °C had also been recognized as analogous to that of $N_4P_4(NH_2)_8$.

Hydrolysis of $N_4P_4(NH_2)_8$ and $(NPCl_2)_8$ at Room Temperature: The elution chromatograms of a mixture of standard materials and hydrolysis products of $N_4P_4(NH_2)_8$ and $(NPCl_2)_4$ are shown in Fig. 3.

In an aqueous solution, $N_4P_4(NH_2)_8$ was stable for about 3 days at room temperature, after which it graudually hydrolyzed. Chromatogram II shows an elution curve for the hydrolysis product of $N_4P_4(NH_2)_8$ after 20 days. The rate of hydrolysis was remarkably slow, the composition of the hydrolysis products being similar to that at 100 °C. Chromatogram III shows the elution for the hydrolysis product of $(NPCl_2)_4$ (0.5 g) in an ether (7.5 ml)–aqueous ammonia (3 M, 8 ml) solution. $(NPCl_2)_4$ was partly converted into $N_4P_4(NH_2)_8$ in spite of the presence of water. The other products were some phosphoryl triamide, tetramidoimdodiphosphate, orthophosphate, and imidodiphosphate. $(NPCl_2)_4$ (0.5 g) was also hydrolyzed in an ether (15 ml)–water (5 ml) solution. The product was neutralized by employing aqueous ammonia, and analyzed by means of ion-exchange chromatography. The result is shown as chromatogram IV. In this hydrolysis, $(NPCl_2)_4$ was converted simultaneously into a cyclic tetrametaphosphimate which gradually hydrolyzed into imidotetraphosphate, imidotriphosphate, imidodiphosphate, and some amidophosphate.

Moureu and Rocquet[9] observed by microscopic examination that the hydrolysis product of $N_4P_4(NH_2)_8$ closely resembles $P_4N_4O_4H_4(ONH_4)_4 \cdot 4H_2O$ which[12] was obtained by the hydrolysis of $(NPCl_2)_4$. It was concluded that the hydrolysis product of $N_4P_4(NH_2)_8$ is the same compound as $P_4N_4O_6H_6(ONH_4)_2$. However, the components were not examined by other analytical techniques. Their result was referred to in a science text.[13] To confirm the validity of their result, the present author has investigated the hydrolysis behavior of $(NPCl_2)_4$ and $N_4P_4(NH_2)_8$. The cyclic tetrametaphosphimate was obviously formed by the hydrolysis of $(NPCl_2)_4$, but the formation of tetrametaphosphimate by the hydrolysis of $N_4P_4(NH_2)_8$ could not be recognized.

Alkali Hydrolysis: The results of alkali and ammoniacal hydrolysis are shown in Fig. 4.

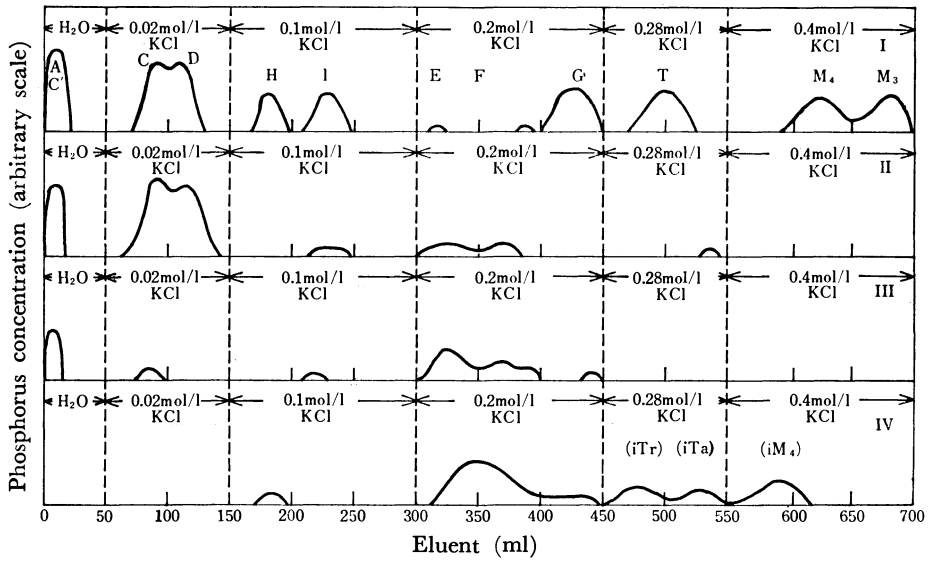

Fig. 3. Chromatographic analysis of hydrolysis products of $N_4P_4(NH_2)_8$ and $(NPCl_2)_4$ at room temperature.
I: Mixture of standard materials [A: $N_4P_4(NH_2)_8$, C: $P_2O_2(NH)(NH_2)_4$, C': $PO(NH_2)_3$, D: $PO(ONa)(NH_2)_2$, G: $Na_4P_2O_7$, H: $PO(ONa)_2NH_2$, I: Na_2HPO_4, T: $Na_5P_3O_{10}$, M_3: $(NaPO_3)_3$, M_4: $(NaPO_3)_4$]
II: Hydrolysis product of $N_4P_4(NH_2)_8$ for 20 day.
III: Hydrolysis product of $(NPCl_2)_4$ in ether-aqueous ammonia solution for 1 h.
IV: Hydrolysis product of $(NPCl_2)_4$ in ether-water solution for 2 h.
Estimated compounds: [E: $P_2O_2(NH)(NH_2)_2$, F: $P_2O_2(NH)(OH)_4$, iTr: $P_3O_3(NH)_2(OH)_5$, iTa: $P_4O_4(NH)_3(OH)_6$, iM_4: $P_4N_4O_4H_4(OH)_4$].

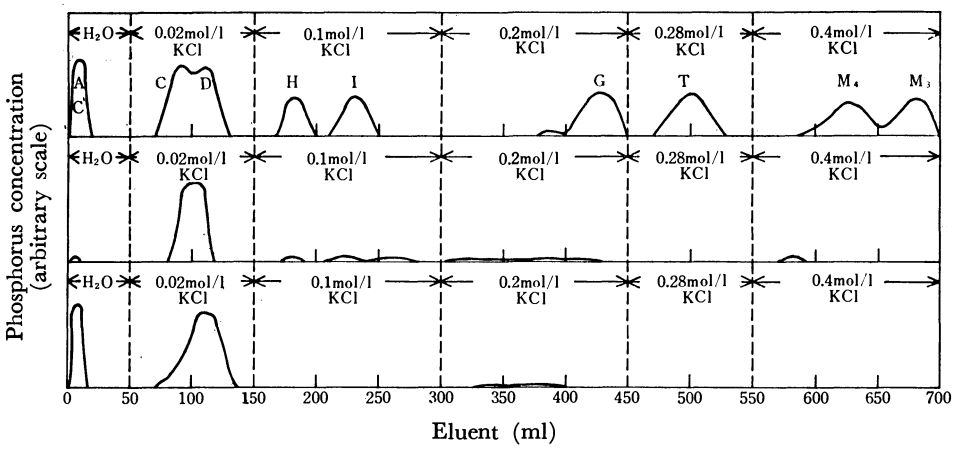

Fig. 4. Chromatographic analysis of various phosphorus compounds and hydrolysis products of $N_4P_4(NH_2)_8$ in alkali solution.
I: Mixture of standard materials [A: $N_4P_4(NH_2)_8$, C: $P_2O_2(NH)(NH_2)_4$, C': $PO(NH_2)_3$, D: $PO(ONa)(NH_2)_2$, G: $Na_4P_2O_7$, H: $PO(ONa)_2NH_2$, I: Na_2HPO_4, T: $Na_5P_3O_{10}$, M_3: $(NaPO_3)_3$, M_4: $(NaPO_3)_4$].
II: Hydrolysis product of $N_4P_4(NH_2)_8$ in 0.65 M NaOH for 3 h at 100 °C.
III: Hydrolysis product of $N_4P_4(NH_2)_8$ in 3 M NH_4OH for 3 h at 100 °C.

Chromatogram I shows the elution for a mixture of the standard materials. Chromatogram II, shows that $N_4P_4(NH_2)_8$ was converted directly into diamidophosphate. On the paper chromatogram for a certain sample of the alkali hydrolysis, only the spots of R_f 0.27 $N_4P_4(NH_2)_8$ and R_f 0.52 $PO(ONa)(NH_2)_2$ appeared. Thus the alkali hydrolysis behavior of $N_4P_4(NH_2)_8$ is much the same as that of $N_3P_3(NH_2)_6$[8]. Chromatogram III shows the elution for an ammoniacal hydrolysis product. The rate of ammoniacal hydrolysis was slower than that of alkali hydrolysis even using the highly concentrated aqueous ammonia; even then $N_4P_4(NH_2)_8$ could not be completely converted into diamidophosphate.

Composition of the Alkali Hydrolysis Product: The formation of the alkali hydrolysis products and diamidophosphate and their analyses are summarized in Table 3.

The phosphorus and nitrogen contents of the hydrolysis products were less than that of $PO(ONa)(NH_2)_2$ obtained by Stokes' method,[14] but the mole ratio of N to P was close to 2 : 1, while the sodium content was greater than the expected value. The previous report[8] gave details of this reasoning. Its

TABLE 3. FORMATION AND ANALYSIS OF DIAMIDOPHOSPHATES

No.	Method	Reaction conditions: Sample (g)	NaOH (g)	Time (min)	Recrystallization	Dry agent	Reaction products: Yield (g)	P (%)	N (%)	Na (%)	P : N : Na (Atomic ratio)
1	Hydrolysis of $N_3P_3(NH_2)_6$ with NaOH solution	2.00	3.2	120	3	Phosphorus pentoxide	2.27	16.4	14.2	23.4	1 : 1.92 : 1.92
2	Hydrolysis of $N_4P_4(NH_2)_8$ with NaOH solution	1.00	2.5	150	3	Phosphorus pentoxide	1.30	15.7	13.6	24.9	1 : 1.92 : 2.14
3	Saponification of $PO(OC_6H_5)(NH_2)_2$ with NaOH solution (Stokes' method)	3.40	0.85	5	4	Phosphorus pentoxide	1.02	25.6	23.3	19.6	1 : 2.01 : 1.03

outline is explained as follows. When an oily diamidophosphate is deposited from its aqueous solution by the addition of ethanol, the salt has a character including an excess of sodium hydroxide. However, the X-ray diffraction of the alkali hydrolysis product of N_4P_4 $(NH_2)_8$ roughly agreed with that of $PO(ONa)(NH_2)_2$ as shown in Table 2, and these values also agreed with those of ASTM X-ray powder data cards. Thus the alkali hydrolysis product is obviously identical with diamidophsphate.

Rate Constants and Activation Energy of the Reaction: Both $N_4P_4(NH_2)_8$ and $PO(ONa)(NH_2)_2$ contained in an aqueous solution of the alkali hydrolysis were studied by means of ion-exchange chromatography. The percentages of $N_4P_4(NH_2)_8$ which remained in the hydrolysis are shown in Fig. 5.

The rate of the hydrolysis increased with the increase of the reaction temperature, obeying a first-order equation, with the rate constants (k) 1.0×10^{-3}, 2.5×10^{-3}, 1.9×10^{-2}, and 4.2×10^{-2} at 50, 60, 80, and 90 °C, respectively. These values are about 2.7 times the value of the alkali hydrolysis of $N_3P_3(NH_2)_6$. The activation energy, obtained from the relation of log k with the reciprocal of the reaction temperature, was 20.8 kcal/mol. This value agrees nearly with 20 kcal/mol for $N_3P_2(NH_2)_6$.[8]

Acid Hydrolysis: The results of the acid hydrolysis are shown in Fig. 6.

The acid hydrolysis behavior resembles that of neutral hydrolysis. However, when the reaction was

I: Mixture of amide phosphorus compounds and phosphates [A: $N_4P_4(NH_2)_8$, C: $P_2O_2(NH)(NH_2)_4$, C': $PO(NH_2)_3$, D: $PO(ONa)(NH_2)_2$, H: $PO(ONa)_2NH_2$, I: Na_2HPO_4, G: $Na_4P_2O_7$].
II—IV: Hydroysis products of $N_4P_4(NH_2)_8$.

accelerated with an acid strength such as pH 1.0, the existence of $PO(NH_2)_3$ and $P_2O_2NH(NH_2)_4$ which are unstable in an acid solution could not be recognized. In this case, $N_4P_4(NH_2)_8$ was hydrolyzed up to the formation of orthophosphates and diphosphates.

Process of Hydrolysis: The process of the neutral or acid hydrolysis is shown in Fig. 7.

A proton from water coordinates to an N atom on the ring of $N_4P_4(NH_2)_8$, one in a double bond between the N and P atoms is cut off, and then the P atom has a positive charge. This coordinates to an OH group, and then the ring is opened. An intermediate (B), which has an asymmetrical structure and is unstable, is formed. It immediately decomposes into unknown compounds (B' and B''), tetramidoimidodiphosphate (C), and phosphoryl triamide (C'). The arrows shown in Fig. 7 denote the course of the hydrolysis. The hy-

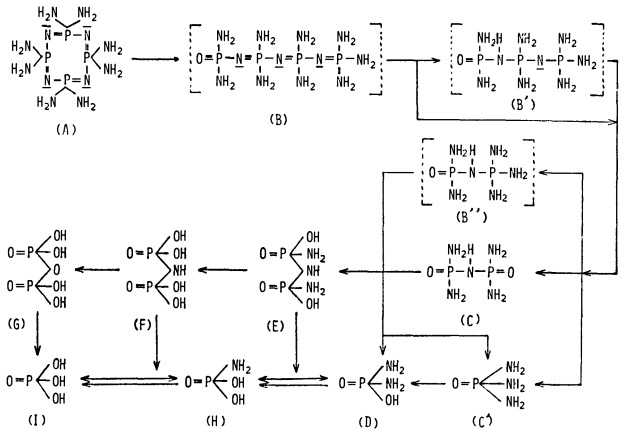

Fig. 7. Hydrolysis of $N_4P_4(NH_2)_8$ in neutral or acid solution.

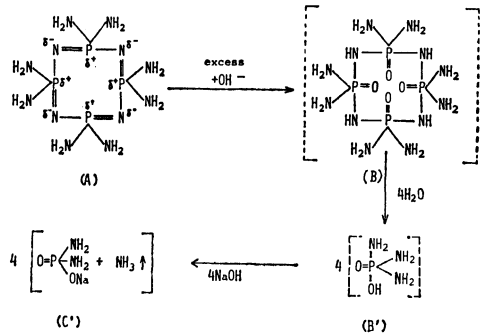

Fig. 8. Hydrolysis of $N_4P_4(NH_2)_8$ in alkali solution.

drolysis of $N_4P_4(NH_2)_8$ roughly progresses up to the formation of diamidophosphate in the neutral solution.

The alkali hydrolysis of $N_4P_4(NH_2)_8$ can be expressed as follows:

$$N_4P_4(NH_2) + 4H_2O + 4NaOH \rightarrow 4PO(ONa)(NH_2) + 4NH_3 \quad (3)$$

The process of the reaction is shown in Fig. 8.

In the P–N ring of $N_4P_4(NH_2)_8$, the electronegativity of phosphorus (2.1) is less than that of nitrogen (3.0). Thus there is the possibility of a polarization such as $N^{\delta-}$–$P^{\delta+}$. In an alkali aqueous solution, the ionic strength of OH^- is large, and this OH group coordinates to the $P^{\delta+}$ atom. Consequently, the double bond between the P and N atoms is cut off and a single bond forms simultaneuously, since the N atom has an electron. At the same time, the P atom is combined by a co-coordinate bond to the O atom in the previously coordinated OH group, and the H in the OH group is separated as an ion; it reacts with the N atom in the P–N ring and then an imido group is formed. This state can be represented as an unknown compound (B). Further, (B) is immediately hydrolyzed into an unknown compound (B'). (B') separates ammonia by the reaction with sodium hydroxide, and is converted directly into diamido phosphate, which is of a stable structure of the sp^3 hybridization.

Structure of Ziegler-Natta Catalysts for the Polymerization of Isoprene

Masao UETSUKI and Yuzuru FUJIWARA

Central Research Laboratories, Kuraray Co, Ltd., Sakazu 2045, *Kurashiki 710*

(Received June 17, 1976)

Structural investigation was carried out by means of ^{1}H-NMR, ESR, and chemical ionization mass spectrometry on the complexes formed by the reaction of alkylaluminum with titanium(IV) *t*-butoxide or vanadium(IV) *t*-butoxide as a catalyst for polymerization of isoprene. The *t*-butoxide was monomeric in benzene, and reduced to form a bivalent complex *via* trivalent ones on addition of the alkylaluminum to the solution followed by the formation of two kinds of binuclear aluminum complexes. In the trivalent state the complexes caused polymerization of isoprene to form five kinds of polymers, 1,4-polymerization of isoprene being likely caused by tris[di-μ-t-butoxo-dialkyltitanium(III)]aluminum, or the corresponding vanadium(III) complex. The final product of the reduction of vanadium(IV) *t*-butoxide was bis(di-μ-alkyl-dialkylaluminum)vanadium(II), which exhibits no catalytic activity.

It is well-known that polymerization of isoprene is caused either by Ziegler-Natta catalysts or by organolithiums. Significant characteristics of the Ziegler-Natta catalysts lie in their ability to form stereoregular polymers, the chemical nature of the catalysts being ascribed to structure and electronic state of the complex composed of aluminum and one of transition elements. Since the pioneer work of Natta *et al.*[1] a number of investigations have been made in this field, but the stucture of the catalysts is not clear so that the mechanism of the catalytic reaction is still ambiguous. The original Ziegler-Natta catalysts, prepared by the reaction of alkylalumium with chloride of titanium or other transition elements, formed a heterogeneous system, which resulted in difficulty in structural study of the catalysts. The polymerization mechanism of isoprene with the catalyst of organolithiums, however, was studied in detail by Morton *et al.*,[2] who examined the propagating chain end of polyisoprene by means of ^{1}H NMR.

Alkylaluminums react with alkoxides of titanium(IV) or vanadium(IV) to form a homogeneous system.[3-6] Natta *et al.*[3] examined polymerization of butadiene and isoprene with the catalysts prepared by the reaction of the alkylaluminums with the titanium(IV) alkoxides by measuring the infranred absorption and X-ray diffraction of the reaction products, and by determining the structures of the 1,2- and the 3,4-polymers. Angelscu *et al.*[4] measured the ESR spectra of the reaction mixture of triethylaluminum and titanium(IV) *t*-butoxide to detect a titanium(III) complex containing two aluminum nuclei. Hirai *et al.*[5,6] also studied the ESR spectra of the reaction mixture of triethylalumium and titanium(IV) butoxide as a catalyst for the polymerization of butadiene, penta-1,3-diene and isoprene to determine the molar ratio of aluminum and titanium in the resulting polynuclear complexes. However, they could not throughly correlate the structure of the Ziegler-Natta catalyst to the reaction mechanism.

We have tried to determine the structure and electronic state of the Ziegler-Natta catalysts prepared by the reaction of trimethyl-, triethyl- or triisobutylaluminum with titanium(IV)- or vanadium(IV) *t*-butoxide as a catalyst for the polymerization of isoprene. The paramagnetic and the diamagnetic species were examined by means of ESR and ^{1}H-NMR, respectively. The evaluation of the *g* factor was performed on the basis of the ligand field theory. Chemical ionization mass spectrometry was utilized in dtermination of the molecular weight of the catalytic complexes.

Experimental

Reagents. Trimethyl-, triethyl-, and triisobutylaluminum were obtained from Ethyl Co. Titanium(IV) chloride was manufactured by Kishida Chemical Co., vanadium(IV) chloride by Wako Pure Chemical Industries, Ltd., and butyllithium by Mitsuwa Chemical Co. These reagents were used without further purification. Aluminum chloride (Kanto Chemical Co.) was ground into powder, and dried *in vacuo* at 25 °C for 20 h. Organic reagents were purified by using dehydration reagents as the occasion demanded. Aluminum-, titanium(IV)- and vanadium(IV) *t*-butoxides were synthesized in diisopropyl ether according to the following reactions,[7,8] and purified by distillation under reduced pressure.

$$\mathrm{LiBu} + \mathrm{HNEt_2} \rightarrow \mathrm{LiNEt_2} + \mathrm{BuH}$$

$$\mathrm{MCl}_n + n\mathrm{LiNEt_2} \rightarrow \mathrm{M(NEt_2)}_n + n\mathrm{LiCl}$$

$$\mathrm{M(NEt_2)}_n + n\textit{t}\text{-BuOH} \rightarrow \mathrm{M}(\textit{t}\text{-BuO})_n + n\mathrm{HNEt_2}$$

where M denotes aluminum, titanium or vanadium.

Preparation of Samples. Samples were prepared under nitrogen atmosphere. The alkylaluminum and the metal alkoxide were separately dissolved in benzene or toluene, and the solutions were mixed to form the catalyst. Aging of the catalyst and polymerization of isoprene were carried out in a reaction tube made of stainless steel for 0.5 and 20 h, respectively. Molar ratios of the transition elements, isoprene and the solvent were fixed at 1.00 : 100 : 300.

Spectral Measurements. ^{1}H-NMR spectra were measured with a Varian Associates HA-100 high resolution spectrometer operating at 100 MHz. ESR spectra were taken on a Japan Electron Optics Laboratory JES-ME3 spectrometer operating in the X-band with 100 KHz modulation. *g*-Values and hyperfine coupling constants were determined by using the ESR signal of manganese dioxide as a standard. Liquid nitrogen was used to measure the ESR spectra at −196 °C. Mass spectra were recorded on a Finnigan 3300F quadrupole spectrometer equipped with a chemical ionization system. Isobutane was used as a reactant gas for the chemical ionization.

Results and Discussion

Polymerization of Isoprene. Experiments of isoprene polymerization were performed in benzene at

80—140 °C with the catalysts prepared by the reaction of trimethyl-, triethyl- or triisobutylaluminum with titanium(IV)- or vanadium(IV) *t*-butoxide. Structure of the reaction products was studied by ^{1}H-NMR spectra. It was found that five types of reactions take place to form 1,4-polyisoprene, 3,4-polyisoprene, 2,6-dimethyl-1,3,6-octatriene, 1-methyl-4-isopropenyl-1-cyclohexene, or 2-methyl-4-isopropenyl-1-cyclohexene. The molar ratio of *cis*- and *trans*-1,4 bonds in 1,4-polyisoprene was *ca.* 1 : 2 showing dependence neither upon the species of the transition element nor upon the present reaction conditions. Three kinds of isoprene dimers, 2,6-dimethyl-1,3,6-octatriene, and 1- and 2-methyl-4-isopropenyl-1-cyclohexenes, could be distilled out from the reaction mixture under reduced pressure, but it was difficuot to separate the two high polymers, 1,4- and 3,4-polyisoprenes, from each other. For convenience, the symbol A is used to show the added molar ratio of the alkylaluminum and titanium-(IV)- or vanadium(IV) *t*-butoxide.

Aging of the catalytic system at 100—140 °C for 20—30 min was required to reproduce the reactions. Yield of the reaction products varied in accordance with the value of A, and the catalytic reaction system containing vanadium was higher in conversion of isoprene as well as in selectivity of the reactions than the system containing titanium. Experimental data with the catalysts composed of trimethylaluminum and titanium(IV)- or vanadium(IV) *t*-butoxide are shown in Figs. 1 and 2, respectively. All the reactions took place mainly in the region $A=1$—7. This suggests that the transition element of the catalytic complex is active at the trivalent state, but not at the tetra- or the bivalent state. Titanium and vanadium are supposed to produce the active complexes with a similar stucture, though their amounts are not equal to each other depending upon the relative stability of the trivalent state.

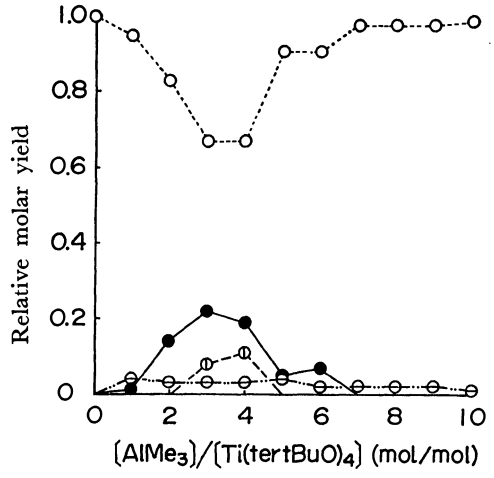

Fig. 1. Yield of the reaction products of isoprene in the catalytic system prepared by trimethylaluminum and titanium(IV) *t*-butoxide. Reaction was performed in benzene at 100 °C for 20 h after aging the catalyst at 140 °C for 30 min. ○, ⦶, ⊖, and ● show isoprene, 2,6-dimethyl-1,3,6,-octatriene, 1-methyl-4-isopropenyl-1-cyclohexene, and 1,4-polyisoprene, respectively.

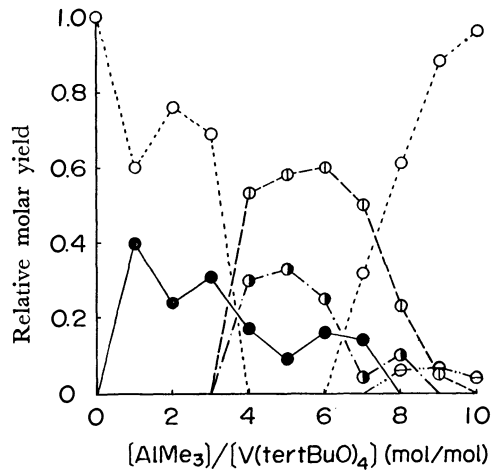

Fig. 2. Yield of the reaction products of isoprene in the catalytic system prepared by trimethylaluminum and vanadium(IV) *t*-butoxide. Reaction was performed in benzene at 100 °C for 20 h after aging the catalyst at 100 °C for 30 min. ◑ show 3,4-polyisoprene, and other circles are the same as in Fig. 1.

When the reaction of isoprene was performed at 100 °C, 1,4-polyisoprene showed the maximum yield at $A=2$—4 and 1—3 with the catalysts containing titanium and vanadium, respectively, and the highest selectivity at $A=1$—2. Both 3,4-polyisoprene and 2,6-dimethyl-1,3,6-octatriene were produced at $A=$ 3—5 and 4—7 with the catalysts containing titanium and vanadium, respectively. 1-Methyl-4-isopropenyl-1-cyclohexene was observed in the whole region of A, and its yield decreased when the catalytic system was aged at relatively low temperature. A similar result was obtained by using triethyl- or triisobutyl-aluminum instead of trimethylaluminum. However, the catalytic system prepared from triisobutylaluminum caused formation of 2-methyl-4-isopropenyl-1-cyclohexene, the yield of which increased with increase in the A value. Thermal reactions of isoprene[9] took place above 140 °C to produce 1- and 2-methyl-4-isopropenyl-1-cyclohexenes.

^{1}H-NMR Spectra. Trivalent aluminum complexes are diamagnetic, their valence state being stable. Trimethylaluminum reacts with aluminum isopropoxide to form three kinds of tetranuclear and two kinds of binuclear complexes, structures of which were determined by means of ^{1}H-NMR in benzene.[10] Similar complexes were observed with the ^{1}H-NMR spectra when aluminum *t*-butoxide was used instead of isopropoxide. Titanium(IV) is also diamagnetic, while the complexes of titanium(III) or vanadium(IV) are paramagnetic because of the electronic configuration of $3d^1$. The diamagnetic complexes showed ^{1}H-NMR signals with high resolution even when a considerable amount of paramagnetic complexes coexisted, though the latter displayed either broad or no signals.

^{1}H-NMR spectra (Fig. 3) were measured with a mixture of trimethylaluminum and titanium(IV) *t*-butoxide at 30 °C after being heated in benzene at 140 °C for 30 min. Bradley *et al.*[11] measured volatility

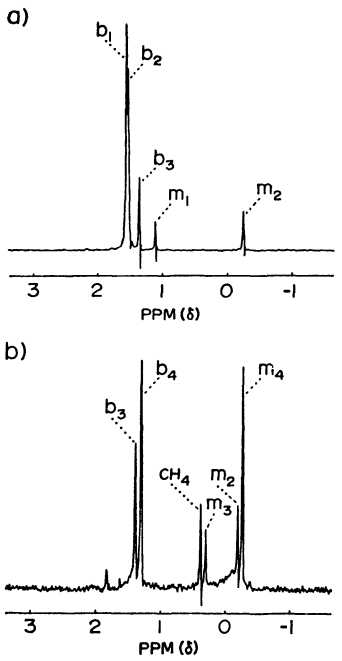

Fig. 3. ^{1}H NMR spectra of the mixture of trimethylaluminum and titanium(IV) *t*-butoxide in benzene at 30 °C after heating at 140 °C for 30 min. The prepared molar ratio of trimethylaluminum and titanium(IV) *t*-butoxide is a) 0.40 : 0.60, and b) 0.90 : 0.10.

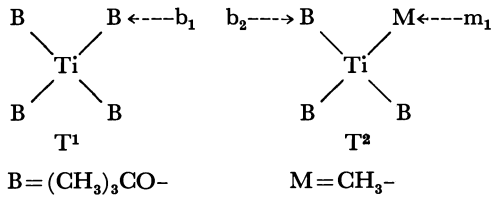
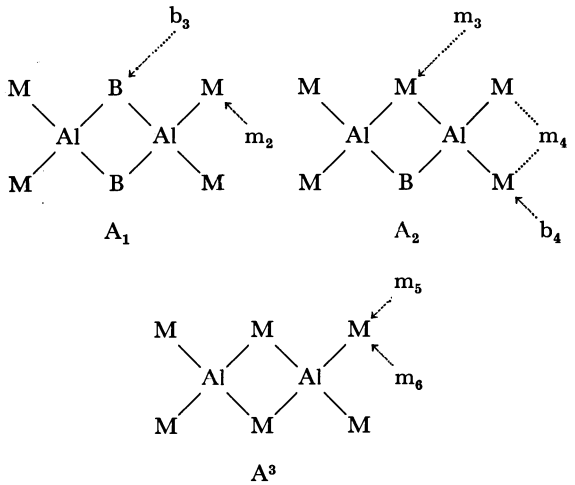


of titanium(IV) *t*-butoxide in order to determine a monomeric stucture of T^1. The monomeric structure was reconfirmed by the fact that titanium(IV) *t*-butoxide shows a ^{1}H-NMR signal, b_1, alone, which represents no splitting attributable to two or more kinds of coordination states of the ligands in toluene even below −50 °C. A pair of signals, b_2 and m_1, with a molar ratio of 3 : 1 are assigned to the *t*-butoxyl and the methyl groups, respectively, of methyl-tri-*t*-butoxotitanium(IV), T^2. Signals of b_3, b_4, m_2, m_3, and m_4, which increased in intensity with increase in the amount of added trimethylaluminum, are assigned to the ligands of binuclear aluminum complexes, A^1 and A^2, from the result of the ^{1}H-NMR measurements of the reaction mixture of trimethylaluminum and aluminum *t*-butoxide.



Hoffmann,[12] and Haaland *et al.*[13] determined the structure of A^1 by use of ^{1}H-NMR and electron diffraction, respectively. A dimeric stucture of trimethylaluminum, A^3, is well-known. The NMR assignment was performed by Muller *et al.*[14]

Vanadium(IV) *t*-butoxide displayed a ^{1}H-NMR signal with a half-height width of 147 Hz at τ=6.82 in benzene at 30 °C, though the line broadening caused by the paramagnetic effect of vanadium(IV) prevented structural examination. On addition of trimethylaluminum to the solution, NMR signals of the binuclear aluminum complexes appeared but none of vanadium(III) and vanadium(II) complexes.

ESR Spectra of Vanadium Complexes. On the basis of volatility measurements, Bradley *et al.*[8] found that vanadium(IV) *t*-butoxide as well as other tertiary alkoxides are monomeric so that the question is the coordination symmetry of the complex. If vanadium(IV) *t*-butoxide takes Td symmetry, the 3d orbitals split into two levels, lower and upper ones of which are degenerate 2-fold with E symmetry and 3-fold with T_2 symmetry, respectively. Taking the spin-orbit interaction as a first-order perturbation to the ligand field splitting, principal values of the *g*-tensor of the tetrahedral complex are represented by

$$\begin{aligned} g_x &= g_e - 2\rho^2\zeta\varepsilon[\sin(\theta/2) - 3\cos(\theta/2)]^2 \\ g_y &= g_e - 2\rho^2\zeta\varepsilon[\sin(\theta/2) + 3\cos(\theta/2)]^2 \\ g_z &= g_e - 2\rho^2\zeta\varepsilon[2\sin(\theta/2)]^2 \end{aligned} \quad (1)$$

where g_e, ρ, and ζ are the *g*-factor for a free electron, an orbital reduction factor, and a spin-orbit coupling constant, respectively. θ is a tortion angle of the ligand about a coordination bond caused by the Jahn-Teller effect.[15] ε denotes the reciprocal of the energy difference between the orbitals with E and T_2 symmetries.

As shown in Fig. 4 the ESR spectrum of vanadium(IV) *t*-butoxide, which was measured in toluene at −196 °C, represents a double octet pattern with an axial symmetry. Anisotropic *g*-values obtained are $g_{//}=1.9395\pm0.0005$ and $g_\perp=1.9870\pm0.0005$, and anisotropic hyperfine coupling constants $A_{//}=1.46\times10^{-2}$ cm^{-1} and $A_\perp=2.13\times10^{-3}$ cm^{-1}. When θ is π in Eq. 1, g_x and g_y become equivalent resulting in the axial symmetry of the complex, *i.e.* $g_{//}=g_z$ and $g_\perp=g_x=g_y$. Thus the axial symmetry of the experimental *g*-values can be interpreted to support the view that vanadium(IV) *t*-butoxide takes the tetrahedral structure. The condition, $\theta=\pi$, indicates that the tetrahedral structure is compressed along one of the 3-fold improper axes.[15]

The magnitude of the spin-orbit coupling constant is estimated from the atomic spectrum as ζ=248 cm^{-1} for the vanadium(IV) ion.[16] The ligand field splitting of the 3d orbitals of vanadium(IV) *t*-butoxide was determined from the near-infrared absorption

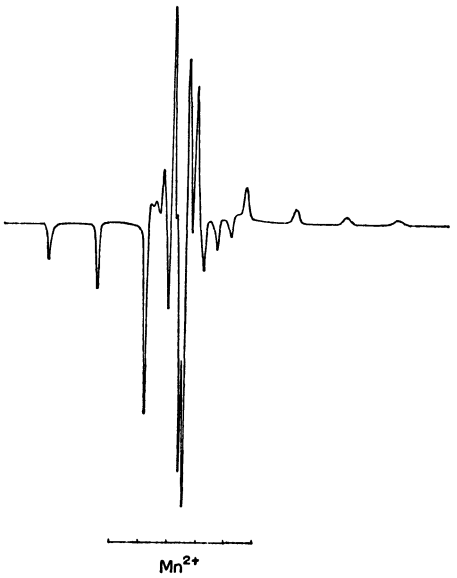


Fig. 4. ESR spectrum of vanadium(IV) *t*-butoxide in toluene at −196 °C.

spectrum in benzene as $\varepsilon^{-1}=1.45\times10^{4}\,cm^{-1}$, a little larger than that obtained by Kokoszka *et al.*[17] The orbital reduction factor of the complex was determined to be $\rho=0.67$ by comparing the calculated values of $g_{//}$ and $g_{\perp}$ with observed values. The anisortopic *g*-values are averaged to be $\bar{g}=1.9712$, which agrees closely with the observed value at 25 °C.

A mixture of trimethylaluminum and vanadium(IV) *t*-butoxide exhibited ESR signals from two kinds of vanadium(IV) complexes besides the signal of vanadium(IV) *t*-butoxide at −196 °C immediately after mixing in toluene at 25 °C. However, partial overlapping of the signals made it difficult to determine both the values of the *g*-factor and the hyperfine coupling constant of the complexes. After the mixture of trimethylaluminum and vanadium(IV) *t*-butoxide was allowed to stand for 1 h at 25 °C ,the signal of vanadium-(IV) *t*-butoxide vanished, and the remaining signals varied with the *A* value as follows: signals of the two kinds of vanadium(IV) complexes were observed at $A<6$, a singlet signal with a maximum slope width of 280—300 Gauss at $6\leq A<8$, an octet signal with a super hyperfine structure, which displayed a coupling with two aluminum nuclei, at $A\geq9$, and the latter two signals at $8\leq A<9$. Since the broad signal observed at $6\leq A<9$ become wider and disappeared with increasing *A* value, it is suggested that the 3d electron of the complex moves between the nuclei of vanadium(IV) and vanadium(III) in the stationary state.

After the disappearance of the signals of vanadium-(IV) complexes at $A=9$ (Fig. 5), the octet signal (Fig. 6) became large in intensity, attaining maximum intensity in 3 h. The signal is, therefore, attributed to a vanadium(II) complex, which takes an electron configuration of $3d^3$. Each peak of the octet signal is composed of eleven consitituent lines to represent the super hyperfine coupling with the spins of a pair of aluminum nuclei. ESR measurements were carried

a) The complex was obtained by the reaction of alkylaluminum with vanadium(IV) alkoxide in toluene at 25 °C, and the ESR spectrum was measured at −196 °C. b) Alkyl group of alkylaluminum. c) Alkoxyl group of vanadium(IV) alkoxide.

$(8.21\pm0.05)\times10^{-3}$ and $(3.7\pm0.1)\times10^{-4}$ cm^{-1}, respectively, as listed in Table 1.

It is difficult to determine the structure of the vanadium(II) complexes from the g-value and the hyperfine and the super hyperfine coupling constants. However, the dependence of the signal intensity upon the A value indicates that they are possibly bis(di-μ-alkyldialkylaluminum)vanadium(II), which is regarded as the final product of a series of reductions of the vanadium(IV) alkoxides with the alkylaluminums as follows. The reactions are summarized as

$$(A/2)(AlR_3)_2 + V(R'O)_4 \rightarrow V(R_2AlR_2)_2 + (A-6)R_2Al(R'O)_2AlR_2 + (1/2)(10-A)R_2AlR(R'O)AlR_2 + R_2 \quad (2)$$

where R and R'O denote the alkyl and the alkoxyl groups, respectively. The condition $6\leq A\leq10$, which is required in Eq. 2, agrees with the result of ESR measurements. The vanadium(II) complexes and the vanadium(IV) alkoxides caused none of the reactions of isoprene.

ESR Spectra of Titanium Complexes. The catalytic reactions of isoprene took place in the region of A in which the transition element assumed a trivalent state. The structures of the catalytic complexes were studied from the ESR spectra of titanium(III) complexes. The ESR spectra of the catalytic system prepared from trimethylaluminum and titanium(IV) t-butoxide are shown in Fig. 7. They were measured in benzene at 25 °C after aging at 140 °C for 30 min, and showed little change through the reactions of isoprene at 100 °C for 20 h.

The ESR signal with $\bar{g}=1.963$ observed at $A=2$—4

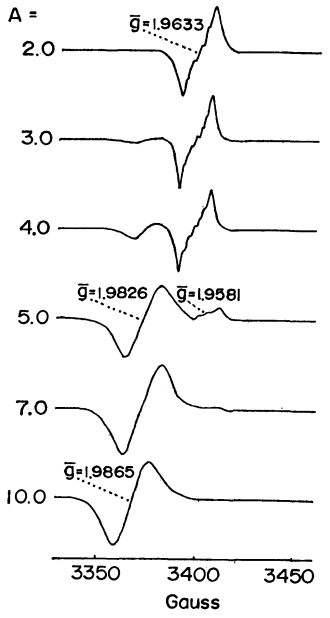

Fig. 7. ESR spectra of titanium(III) complexes of the catalytic system at 25 °C after aging at 140 °C for 30 min. Trimethylaluminum and titanium(IV) t-butoxide were mixed in benzene at the molar ratio, A.

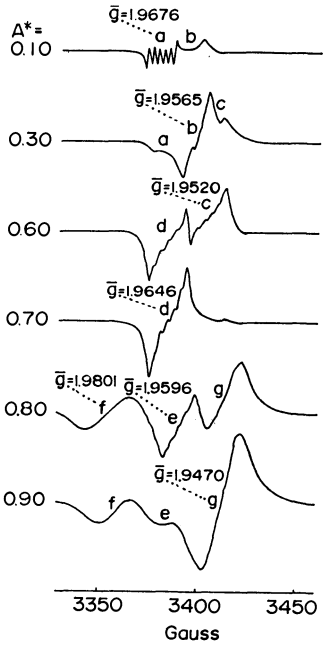

Fig. 8. ESR spectra of titanium(III) complexes at 25 °C immediately after mixing trimethylaluminum and titanium(IV) *t*-butoxide in benzene.
A* designates the prepared molar fraction of trimethylaluminum.

is attributed to the catalyst which caused 1,4-polymerization of isoprene. The signal exhibited a super hyperfine structure bearing six constituent lines to show coupling with an aluminum nucleus, and was affected little by the reactions of isoprene. Some of the other signals might correspond to the titanium(III) complexes, which caused reactions of isoprene other than 1,4-polymerization. Similar results were obtained by using triethylaluminum instead of trimethylaluminum. However, when triisobutylaluminum was used, the signal with $\bar{g}=1.963$ virtually disappeared during the course of reaction of isoprene and turned into signals of other titanium(III) complexes. Before aging the catalyst, seven kinds of signals, denoted by a, b, c, d, e, f, and g in order of appearance with increase in the amount of trimeth ylaluminum, were observed in the mixed solution of trimethylaluminum and titanium(IV) *t*-butoxide at 25 °C as shown in Fig. 8. The signals a, b, c, d, and g displayed a super hyperfine structure owing to coupling with an aluminum nucleus, and the signal e showed coupling with two aluminum nuclei. When trimethylaluminum was added at the molar fraction of 0.10—0.70 in the solution, only the signal d with $\bar{g}=1.965$ remained after aging at 140 °C for 30 min. The signal is attributed to the catalyst for 1,4-polymerization of isoprene.

The molecular structures of the titanium(III) complexes were determined by caluclating the *g*-values with use of models of the coordination structures. The model structures are shown in Fig. 9, where the titanium(III) nucleus is situated in the origin of the Cartesian coordinates. The dashed line designates chelation formed by a pair of ligands between titanium-

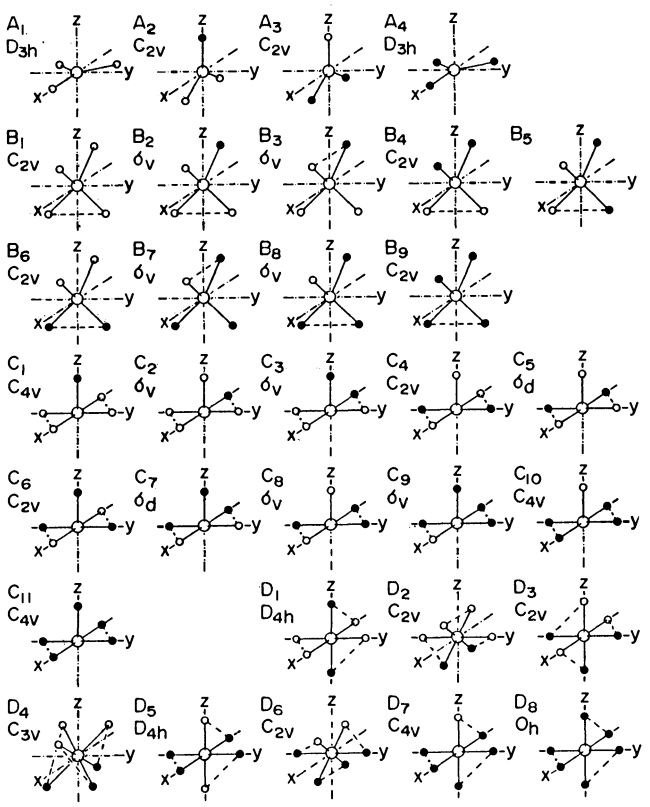

Fig. 9. Model structures of titanium(III) complexes. The titanium(III) nucleus is located at the origin. Dashed line shows chelation formed by a pair of ligands between aluminum and titanium(III) nuclei. The alkoxy and the alkyl groups are shown by ○ and ●, respectively.

(III) and aluminum nuclei. The structures are classified into four groups, A, B, C, and D, in accordance with the number of aluminum nuclei combined with a titanium(III) nucleus, zero, unity, two and three, respectively, which have four, nine, eleven an eight kinds of stuctures, respectively. The structural symmetry of each is designated by the ordinary symbols except the structure, B_5, which has no center of symmetry.

The wave function of the 3d orbital of the titanium(III) complexes, φ_i, is given by a linear combination of d functions, d_0, $d_{\pm1}$ and $d_{\pm2}$, which are classified into six groups (Table 2). In groups 1, 2, 3, and 4 the Jahn-Teller distortion resolves orbital degeneracy of the ground level changing φ_i to φ_i' or φ_i'', while the ground level takes none of the degenerate orbitals in groups 5 and 6. On the basis of the ligand field theory, energy of the orbital, φ_i, is expressed as

$$E_i = Ze^2 \sum_j (\alpha \bar{r^2} \gamma_j R_j^{-3} + \beta \bar{r^4} \delta_j R_j^{-5}) \qquad (3)$$

where the subscript j denotes the coordination electron of the ligand, e the charge of an electron, and *Ze* the effective nuclear charge of the transition element. The charge of a coordination electron is estimated to be *e* and *e*/2 at the terminal and the bridging ligands, respectively, and *r* and *R* designate the radius of the 3d electron and the distance between the coordination

a) Wave function is designated by φ_i when the ground level is not degenerate, and by φ_i' or φ_i'' when the ground level is degenerate. b) θ shows magnitude of the Jahn-Teller distortion. c) C_{ij} is a constant characteristic of the coordination structure.

electron and the center of the transition elements, respectively. α, β, γ_j, and δ_j are variables characteristic of the symmetry of the coordination stucture about the transition element.

If we assume that the 3d electron is distributed spherically around the transition element, $\bar{r}^2$ and $\bar{r}^4$ are substituted by r^2 and r^4, respectively, and r is supposed to be equivalent to the ionic radius, the magnitude of which is known to be 0.76 and 0.60 Å for titanium(III) and vanadium(IV), respectively.[18] Crystallographic data suggest that the length of the coordination bond, L_j, is little affected by the species of the metal atom as well as the saturated alkyl group of the ligand as far as the present compounds are concerned.[19-23] Magnitude of L_j is 1.78 and 2.01 Å for the terminal and the bridging alkoxyl groups, respectively which were determined from the results of studies on titamium(IV) methoxide,[19] titanium(IV) ethoxide,[20] bis[2-methylpentane-2,4-dioxydimethyltitanium(IV)],[21] and oxyvanadium(V) methoxide,[22] and 2.15 and 2.34 Å for

the terminal and the bridging methyl groups, respectively, from the data of trimethylaluminum.[23] A symbol, f_j, is employed to define an attraction rate of the coordination electron toward the transition element on the coordination bond. Then R_j is replaced by $L_j(1-f_j)$. For the sake of simplicity f_j's of the alkyl and the alkoxyl groups are denoted by f_R and f_{RO}, respectively. The value of $G=Ze^2(\rho^2\zeta)^{-1}(g_e-g)$ is then calculated by means of the model structures except B_5 of the titanium(III) complexes, as a function of f_R and f_{RO}.

Numerical calculation was performed with the model structures of group B to obtain a set of values of f_R and f_{RO} so that a linear relation holds between the value of $\bar{G}=(1/3)(G_x+G_y+G_z)$ and the observed value of $g_e-\bar{g}$. The condition $f_R>f_{RO}$ was assumed based on the empirical fact that the alkyl group is stronger in reducing power than the alkoxyl group. The molar ratio of the methyl and the *t*-butoxyl groups of the titanium(III) complexes was assumed to increase with increase in the amount of trimethylalumiunm. Under the conditions that $f_R/f_{RO}=1.4$ and $f_{RO}=0.14$, a linear relation was ontained by choosing pairs of the model structures and the ESR signals as B_1 and a, B_2 and b, B_3 and c, B_4 and d, and B_7 and g as shown in Fig. 10. No other values of f_R and f_{RO} gave such a linear relation. The numerical calculation was also carried out with groups A, C and D to find the linear relation for the pairs of C_6 and e, and D_5 and f. The values of $\bar{G}$ and $g_e-\bar{g}$ are plotted in Fig. 11, where the slope of the straight line yields $\rho^2\zeta(Ze^2)^{-1}=5.0\times10^{-3}$. The $\bar{g}$-values of the model structures thus calculated are given in Table 3. The structures having the degenerate ground level would not exhibit the ESR signal because of molecular vibration.

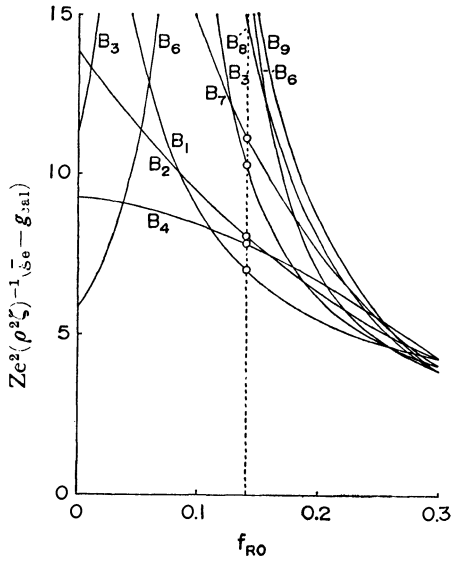

Fig. 10. Variation of calculated $\bar{g}$-value with attraction rate of the coordination electron toward the titanium(III) nucleus at $f_R/f_{RO}=1.4$.

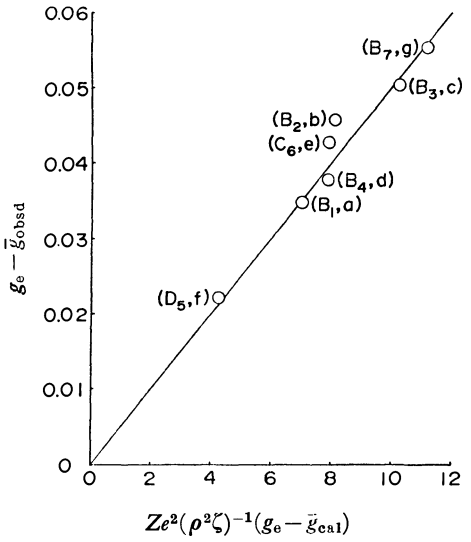

Fig. 11. Calculated and observed $\bar{g}$-values of titanium(III) complexes prepared by trimethylaluminum and titanium(IV) *t*-butoxide.

It is known that the magnitude of ζ of the titanium(III) ion is 154 cm^{-1},[16] and that the ratio of the effective nuclear charge of titanium(III) and that of vanadium(IV) is 3 : 4.[24] Hence the orbital reduction factor of the titanium(III) complex is estimated to be $\rho=0.59$ by using the experimental value of the orbital splitting energy of vanadium(IV) *t*-butoxide. The ρ value suggests that the titanium(III) complexes are larger in covalency of the coordination bond than vanadium(IV) *t*-butoxide. It can be seen from the coordination structure and the electronic state of the titanium(III) complex of B_4 that one of three molecular structures designated by AT^1, AT^2, and AT^3 is

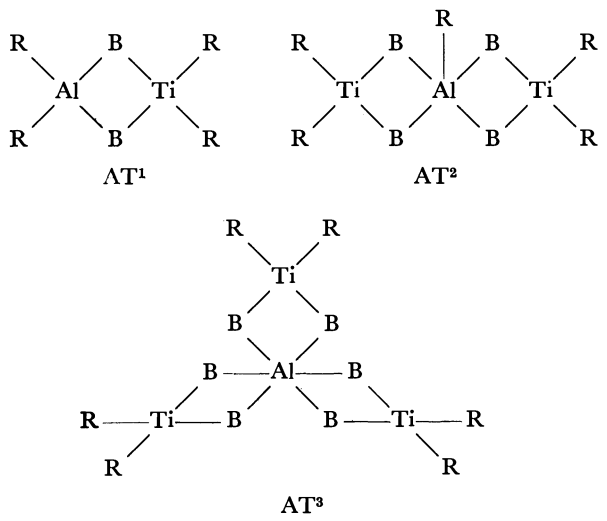
a) $\bar{g}$-values given in parentheses indicate that the complex will not show the ESR signal as a result of degeneracy of the ground level. b) The complex was obtained by the reaction of trimethylaluminum with titanium(IV) *t*-butoxide in toluene, and ESR spectrum was measured at 25 °C.

possible as the catalyst for 1,4-polymerization of isoprene.



R=CH_3-, CH_3CH_2-, or $(CH_3)_2CHCH_2$-

Chemical Ionization Mass Spectra. Measurement of molecular weight is useful for determination of the molecular structure of the catalyst for 1,4-polymerization of isoprene. However, the titanium(III) complex is unstable in the air and its isolation is very difficult, so that ordinary techniques for molecular weight measurements are not available. Chemical ionization mass spectrometry is a useful means for the determination of the molecular weight of such a compound since ions are produced under mild conditions as compared with electron impact mass spectrometry.

The chemical ionization mass spectrum of the reaction mixture of trimethylaluminum and titanium(IV) *t*-butoxide at the molar ratio of 0.60 : 0.40, prepared in benzene followed by aging at 140 °C for 30 min to exhibit the ESR signal of d alone, is shown in Fig. 12. M and B denote the methyl and the *t*-butoxyl groups, respectively. None of the mass peaks observed are from a tetranuclear ion bearing an aluminum nucleus and three titanium nuclei. Peaks at *m/e* 550, 506 and 477 are assigned to ions containing an aluminum nucleus and two tiatnium(III) nuclei, $[AlTi_2M_4B_5H]^+$, $[AlTi_2M_6B_4]^+$ and $[AlTi_2M_4B_4H_2]^+$, respectively, and peaks at *m/e* 492 and 434 to ions having the nuclei of an aluminum, a titanium(III) and a titanium(IV), $[AlTi_2M_5B_4H_2]^+$ and $[AlTi_2M_6B_3H_2]^+$, respectively. On the other hand, the ESR spectrum of this sample showed a single species of the titanium(III) complex, and therefore AT^1 can not exist. If the catalyst is AT^2, the peak at *m/e* 506 should not be observed. An adequate explanation of the mass pattern is that fragments from a tatranuclear complex displayed the mass peaks of the trinuclear ions. Hence AT^3 is the molecular structure of the catalyst for 1,4-polymerization of isoprene.

The catalytic complex, AT^3, is named tris[di-μ-*t*-butoxo-dialkyltitanium(III)]aluminum. The aluminum nucleus is located at the center of the tetranuclear complex with the coordination number of six, while the titanium(III) nuclei occupy the outer three positions at a distance suitable for bidentate coordination of isoprene. Three pairs of the *t*-butoxyl groups combine three titanium(III) nuclei with an aluminum nucleus to support the tetranuclear structure. The alkyl group takes the terminal positions of the titanium(III) nuclei, and may participate directly in the reaction of isoprene.

A proposal is made to interpret the mechanism of 1,4-polymerization of isoprene as follows. Three molecules of isoprene can form bidentate coordi-

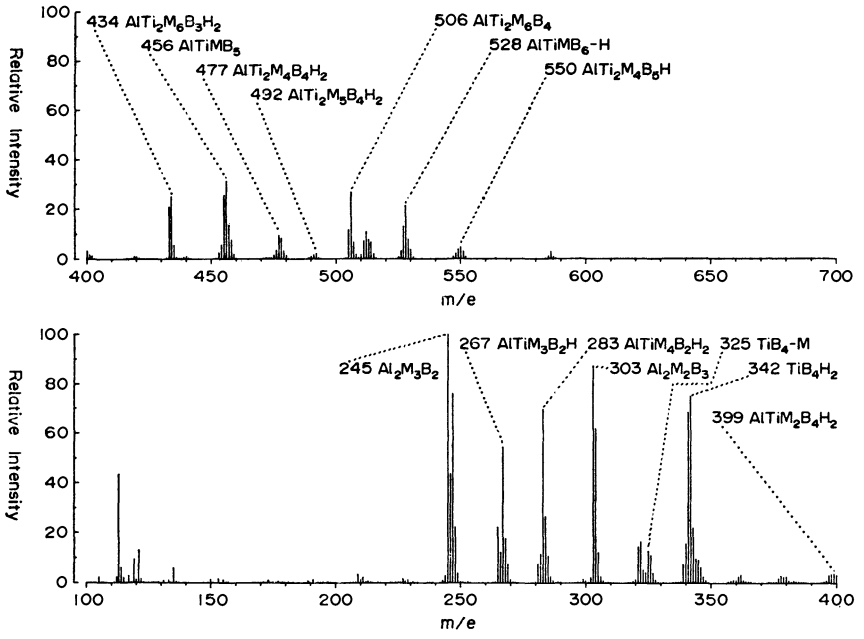


Fig. 12. Chemical ionization mass spectrum of the mixture of trimethylaluminum and titanium(IV) *t*-butoxide at the molar ratio of 0.60 : 0.40 after heating in benzene 140 °C for 30 min.

nation to a catalyst molecule at the same time. As soon as an alkyl group of the catalyst activates one of the terminal carbons of isoprene on the catalyst, another terminal carbon attacks the end of the neighboring isoprene releasing the coordination bond. A new isoprene molecule then takes the unoccupied sites of the catalyst. Thus, 1,4-polyisoprene is produced through the successive coordination of isoprene followed by formation of new carbon-carbon bonds, although the mechanism can not explain regular head to tail polymerization of isoprene and its *cis-trans* selectivity.

Conclusion

Structures of the Ziegler-Natta catalysts for the polymerization of isoprene were studied by means of ^{1}H-NMR, ESR and chemical ionization mass spectrometry. The catalyst was prepared in benzene or toluene by the reaction of alkylaluminum with titanium(IV)- or vanadium(IV) *t*-butoxide. The experiment of polymerization was carried out at 80—140 °C for 20 h after heating the catalyst.

The alkoxide was monomeric in the solution, and reduced by the alkylaluminum to produce a bivalant complex *via* trivalent complexes. The final product of the reduction of vanadium(IV) *t*-butoxide was bis(di-μ-alkyl-dialkylaluminum)vanadium(II). When the transition element took the trivalent state, the catalytic system caused five kinds of polymerization of isoprene.

Coordination structure of seven kinds of titanium(III) complexes was determined by comparing the observed *g*-values with the calculated ones, three kinds of molecular structures remaining as the catalyst for 1,4-polymerization of isoprene. As a result of molecular weight determination it was found that the catalytic complex was tris[di-μ-*t*-butoxo-dialkyltitanium(III)]aluminum.

The catalyst has a tetranuclear stucture suitable for bidentate coordination of isoprene. A proposal was made to interpret the reaction mechanism: the 1,4-polymerization takes place through succssive coordination of isoprene to the catalyst followed by bond formation between a terminal carbon of isoprene and a propagating chain end of polyisoprene, both of which occupy adjacent positions on the catalyst.

The Preparation and Characterization of Isomers of (Amino acidato)-(iminodiacetato)nitrocobaltate(III)(1−) Complexes

Yukihiro YAMAMOTO, Sumio KAIZAKI, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received July 1, 1976)

Three geometrical isomers of *fac(ida)*-$[Co(NO_2)(gly)(ida)]^-$ have been prepared and optically resolved (gly=glycinato(1−) and ida=iminodiacetato(2−) ligand), and their configurations were determined from the visible and ultraviolet absorption, and circular dichroism spectra. A diastereomeric pair was obtained for the corresponding L-alaninato, L-serinato, or L-prolinato complex.

There have been studied several types of cobalt(III) complexes with each one of uni-, bi-, and linear terdentate ligand. Those prepared previously include $[CoX(N-N)(N-N-N)]$,[1] $[CoX(N-N)(O-N-O)]$,[2] $[CoX(N-O)(N-N-N)]$,[3] $[CoX(O-O)(N-N-N)]$,[2,4] and $[CoX(O-O)(O-N-O)]$[4] types: X=unidentate ligand, N-N and N-O=bidentate ligands, N-N-N and O-N-O=linear terdentate ligands, where N and O denote the coordinating atoms. In the present paper, the $[Co(NO_2)(am)(ida)]^-$ complexes belonging to a new type, $[CoX(N-O)(O-N-O)]$, will be reported, where am stands for an amino acidato(1−) ligand such as gly (glycinato), L-ala (L-alaninato), L-ser (L-serinato), or L-pro (L-prolinato), and ida an iminodiacetato(2−) ligand.

Experimental

Preparation and Resolution. 1) Isomers of Na[Co(NO$_2$)(gly)(ida)]: Three grams (0.04 mol) of glycine and 6.80 g of potassium nitrite were dissolved in an aqueous solution (60 cm^3) containing 4.48 g (0.08 mol) of potassium hydroxide and 5.32 g (0.04 mol) of H_2ida. To this mixture was added 9.52 g (0.04 mol) of cobalt(II) chloride hexahydrate in 20 cm^3 of water at 45 °C. The dark red solution resulted was oxidized by adding 5.0 g of 30% hydrogen peroxide and stirring mechanically for about two hours. The deep red reaction mixture was poured into a column (45×750 mm) of a strong base anion-exchange resin (Dowex 1-X8, 200—400 mesh, chloride form). A reddish violet solution was swept out with water. The adsorbed band was eluted with a 0.07 M aqueous solution of sodium chloride. Five colored bands, a red one (i), a violet one (ii), a pinkish red one (iii), and two yellow ones (iv), (v) were eluted in this order. The amounts of the eluates (i) and (iii) were much larger than those of the (ii), (iv) and (v) eluates. The eluate (i) was condensed to a small volume with a vacuum rotary evaporator below 40 °C and the sodium chloride deposited was removed. To the filtrate a small amount of methanol was added and the sodium chloride deposited was removed again. After repeating this procedure, the filtrate was allowed to stand overnight in a refrigerator. Deep red prismatic crystals (isomer A) were obtained. They were filtered and washed with methanol-water(1:1), methanol and ether and then air-dried. Recrystallization was carried out from warm water.

The isolation of crystals from the eluate(iii) was performed by the same method; then violet prismatic fine crystals (isomer B) were obtained and recrystallized from warm water.

To the filtrate from the isomer B were added a mixture of water, methanol, ethanol and acetone (1:1:1:1). After allowing to stand for a long period at room temperature, a mixture of the violet and pinkish red crystals was obtained. The two kinds of crystals were separated by hand. The violet crystals were confirmed to be isomer B, while the pinkish red ones were found to be a new isomer (isomer C).

The eluate (ii) was confirmed to be *cis(N)*-$[Co(ida)_2]^-$ by the measurement of visible to near ultraviolet absorption spectra and elemental analysis. The absorption spectra of the eluate (iv) showed peaks at 21050 and 30030 cm^{-1} and that of the eluate (v) at 21370 and 30030 cm^{-1}. By comparing the absorption data with those reported by Ćelap *et al.*[5], these two complexes seem to correspond to the isomers of $[Co(NO_2)_2(gly)_2]^-$. The elemental analysis of crystals from the eluate (iv) showed the chemical composition of $Na[Co(NO_2)_2(gly)_2]\cdot 1.5H_2O$, but pure crystals were not obtained from the eluate (v).

2) Optical Resolution of the Isomers A, B and C: A suspension of 0.3 g of $(+)_{589}$-$[Co(ox)(en)_2]I$ and 0.13 g of silver acetate in 5 cm^3 of water was ground in a mortar for about 5 minutes. The silver iodide precipitated was filtered off and washed with a small amount of water. To the combined filtrate and washings was added 0.56 g of isomer A. The solution was kept in a refrigerator for a week; then the deep red diastereomer deposited was filtered. The less soluble diastereomer was recrystallized several times to show constant rotation ($[\alpha]_{589}=775°$) from warm water. The diastereomer was converted to the sodium salt by using a cation exchange resin of sodium form (Dowex 50W-X8, 200—400 mesh): $[\alpha]_{589}=-791°$.

The optical resolution of the isomers B and C was carried out by the same method as that of the isomer A: $[\alpha]_{589}=611°$ and 397° for the less soluble diastereomers of the isomers B and C, respectively; $[\alpha]_{589}=194°$ and $-142°$ for the sodium salts, respectively.

3) L-Amino Acidato Complexes: The complex with an L-alaninato, L-serinato, or L-prolinato ligand was prepared by the same method as that of the glycinato complex. In these cases, only one diastereomeric pair (corresponding to the isomer A) was isolated. On the column chromatography (Dowex 1-X8, 200—400 mesh, chloride form, eluting by 0.07 M KCl aqueous solution) of the L-alaninato or L-prolinato complex, two earlier eluted red bands showed the similar absorption bands to the isomer A of glycinato complex. The major CD bands of the two eluates had the opposite signs in the first d-d absorption band region, *i, e.*, (−) for the first eluate (A-1) and (+) for the second eluate (A-2). In the case of L-serinato complex, the separation of isomers on the column chromatography was poor, and these were separated into two parts with opposite rotations at 589 nm by using a fraction collector. The major CD band of the faster eluting part (A-1) had (−) sign and that of the later one (A-2) (+) sign. The crystallizations of these red isomers were made by the same method as that for glycinato isomers. The faster eluted isomer of the L-alaninato complex was not obtained in pure solid. Thus, the absorption and CD measurements of this isomer (A-1) were made in an aqueous

eluate purified on a QAE-sephadex column chromatography; the molar absorptivity is assumed to be the same as that of the isomer A-2.

4) Other Complexes: The complex $Na_2[Co(NO_2)(edta)]\cdot 3H_2O$ was prepared and resolved following the directions of Dwyer and Garvan[6] (edta=ethylenediaminetetraacetato (4−)). The complex $Na[Co(NO_2)(ed3a)]\cdot H_2O$ was prepared by the method of Blackmer *et al.*[7] and resolved by the method of Maricondi and Maricondi[8] (ed3a=ethylenediaminetriacetato(3−)).

Measurements. The visible and ultraviolet absorption spectra were obtained with a Shimadzu UV-200 spectrophotometer. The CD spectra were recorded on a Jasco MOE-1 spectropolarimeter. A Jasco DIP-4 digital polarimeter was used to check optical rotations. Proton magnetic resonance spectra were recorded on a Varian XL-100 spectrometer at about 36 °C, the internal temperature of the probe. A granule of DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) was added to serve as an internal reference. Two drops of 1M-DCl was added to the solvent, D_2O.

Results and Discussion

The analytical data of the complexes obtained are presented in Table 1. For the complex $[Co(NO_2)(gly)(ida)]^-$ five geometrical isomers are possible as is shown in Fig. 1. Three of them (I, II, and III) have a facially coordinating ida ligand and are optically resolvable, while the other two (IV and V) have a meridionally coordinating ida ligand and are optically unresolvable. In the glycinato complex, three optically resolvable geometrical isomers were obtained; thus they should take *fac(ida)* structures, I, II, and III. The fact that the remaining two *mer(ida)* isomers were not obtained is compatible with the previous recognition that the ida ligand can take a *meridional* coordination only with much difficulty.[9] The visible and ultraviolet absorption spectra of the three isomers are shown in Fig. 2. The absorption spectra resemble each other in the charge transfer region, while they are distinguished in the first d-d absorption band region. The three

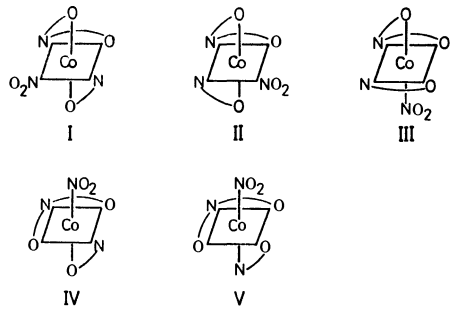

Fig. 1. Five possible geometrical isomers of $[Co(NO_2)(gly)(ida)]^-$. Upper three: *fac(ida)* type; (I) *mer(O)trans(N)*, (II) *mer(O)cis(N)*, and (III) *fac(O)*. Lower two: *mer(ida)* type; (IV) *mer(O)trans(N)* and (V) *mer(O)cis(N)*.

The signs of the optical rotation, (+) or (−), at 589 nm are shown.

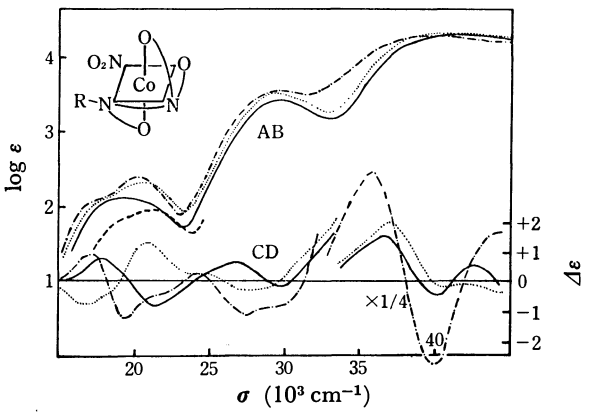

Fig. 3. Absorption (AB) and CD curves of (——), $(+)_{589}$-B; (-·-·-), $(-)_{546}$-$[Co(NO_2)(edta)]^{2-}$; (····), $(+)_{546}$-$[Co(NO_2)(ed3a)]^-$; and absorption curve of (----) the isomer A. The absolute configuration of $(-)_{546}$-$[Co(NO_2)(edta)]^{2-}$ (R=CH_2COO^-) and $(+)_{546}$-$[Co(NO_2)(ed3a)]^-$ (R=H), is shown in the left upper corner.

fac(O) (III) types. The first d-d absorption bands of isomers A and B are broad and that of isomer C sharp as in Fig. 2. According to a semi-empirical rule,[10,11] the former two are assigned to the *mer(O)* configuration and the latter to the *fac(O)*. The geometrical configuration II of the *mer(O)* is similar to that of the $[Co(NO_2)(edta)]^{2-}$ [12] and $[Co(NO_2)(ed3a)]^-$ [7] complexes, except for the chelate ring connecting two donor nitrogens in the latter two complexes. As is shown in Fig. 3, the first absorption band of the isomer B is closer to those of the $[Co(NO_2)(edta)]^{2-}$ and $[Co(NO_2)(ed3a)]^-$ complexes. Moreover, Yamatera's rule[11] predicts, by taking a zero point at the first band position of $[Co(en)_3]^{3+}$ and using parameter values, $\delta(N)=0$, $\delta(O)=-4730\ cm^{-1}$ (estimated from $[Co(ox)_3]^{3-}$), and $\delta(NO_2)=4000\ cm^{-1}$ (estimated from *mer*-$[Co(NH_3)_3(NO_2)_3]$ and *cis*-$[Co(NH_3)_4(NO_2)_2]^{+}$[13]), that the first band splitting components locate at 18700, 18900, and 21100 cm^{-1} for the structure I, 17760, 19920, and 21100 cm^{-1} for II, and 18900, 19920, and 19920 cm^{-1} for III. The lowest energy component of the structure II is expected to lie at lower energy side than that of the structure I, and this is in accord with the observation that the first absorption band of the isomer B extends to the lower energy side. Thus the isomers A, B, and C are assigned to the structure I (*mer(O)trans(N)*), II (*mer(O)cis(N)*), and III (*fac(O)*), respectively.

The CD curves of $(+)_{589}$-B isomer, $(+)_{546}$-$[Co(NO_2)(ed3a)]^-$ and $(-)_{546}$-$[Co(NO_2)(edta)]^{2-}$ are shown in Fig. 3. It has been determined that the latter two complexes take the absolute configuration shown in Fig. 3 on the comparison of their CD spectra with those of the stereospecifically formed $(+)_{546}$-$[Co(NO_2)((R)\text{-pdta})]^{2-}$ [14] and $(-)_{546}$-$[Co(NO_2)((R)\text{-pd3a})]^-$,[15] respectively. Three complexes in Fig. 3 give the resembling CD pattern in the charge transfer band region; *i.e.*, (+) at about 36000 cm^{-1} and (−) at about 40000 cm^{-1}. Therefore, it may be concluded that the $(+)_{589}$-B isomer has the same absolute configuration of the arrangement of donor atoms as the $(+)_{546}$-$[Co(NO_2)(ed3a)]^-$ and $(-)_{546}$-$[Co(NO_2)(edta)]^{2-}$ complexes. The fact that the CD curves of the $(+)_{589}$-B isomer and $(+)_{546}$-$[Co(NO_2)(ed3a)]^-$ are enantiomeric to each other in the first d-d absorption band region suggests that the vicinal effect due to the asymmetric nitrogen atom of $(+)_{546}$-$[Co(NO_2)(ed3a)]^-$ is large enough to invert the CD sign as pointed out by Maricondi and Maricondi.[8] It seems that the CD in the charge transfer region is ascribed mainly to the configurational chirality due to the arrangement of donor atoms. The absolute configuration of the isomer B cannot be named by the current IUPAC rule,[16] because two chiralities due to the arrangement of chelate rings are cancelled by each other such as *ΔΔ*. On the other hand, the IUPAC rule is applicable to the other two isomers, A and C.

The $(-)_{589}$-A and $(-)_{589}$-C isomers give a negative major CD band in the first d-d absorption band region. Thus, the $(-)_{589}$-A and $(-)_{589}$-C isomers may be assigned tentatively to the *Δ* configurations. These two complexes show the similar CD pattern in the charge transfer region also as in Fig. 2.

By applying the additivity rule[17] of the configurational and vicinal effects to the CD curves of A-1 and A-2 diastereomeric isomers with L-ala, L-ser or L-pro, the configurational and vicinal CD contributions can be separated. All the calculated configurational CD curves of the A-1 isomers agree with the observed CD curve of the $(-)_{589}$-A isomer of glycinato complex as in Fig. 4. It was concluded, therefore, that the first eluted A-1 diastereomers with L-amino acidato ligand take the absolute configuration *Δ* same as the $(-)_{589}$-A glycinato complex. The vicinal CD curves of these isomers are different from each other as in Fig. 4.

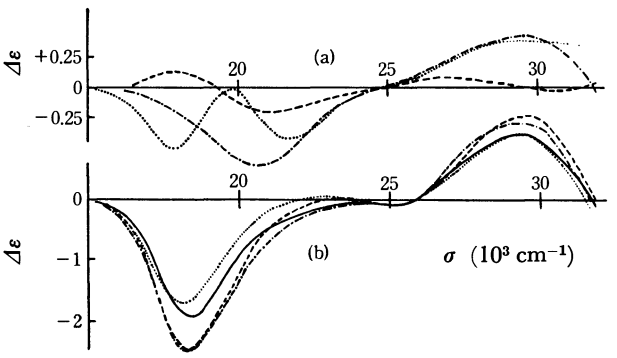

Fig. 4. Calculated vicinal effect (2L) curves (a) and caluculated configurational effect curves (b) of (----), L-alaninato; (-·-·-), L-serinato; and (····), L-prolinato complexes (A-1 series). Observed CD curve of $(-)_{589}$-A glycinato isomer (——) is also shown in (b).

In the pmr spectra of the L-prolinato diastereomers, it is predicted that the magnetic anisotropy of two carbon-oxygen single bonds[18] of the ida ligand plays the most influensive part for the NH proton chemical shift of the coordinated prolinato ligand, and that the NH proton of the *Δ* isomer resonates at the higher magnetic field than that of the *Λ* isomer. In fact, the isomer A-1 resonated at 7.19 ppm and the A-2 at 7.41

ppm. Thus it is confirmed that the A-1 series has the *Δ* absolute configuration and the A-2 *Λ*, and hence that the $(-)_{589}$-A isomer of glycinato complex has the *Δ* absolute configuration.

XPS Study on the Charge Distribution in Chromium(0) Complexes

Fumio KINOMURA, Tadashi TAMURA, Iwao WATANABE, Yu YOKOYAMA, and Shigero IKEDA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received July 5, 1976)

Binding energies of core electrons in $Cr(C_6H_6)_2$, $Cr(C_6H_6)(CO)_3$, and $Cr(CO)_6$ were measured by means of X-ray photoelectron spectroscopic method in solid phase. By comparison with their UPS spectra observed in gasous phase, binding energies referred to vacuum level can be obtained. On the basis of this result, charge distribution in these complexes are estimated. The intramolecular relaxation energy of $Cr(C_6H_6)_2$ is also discussed.

The study of X-ray photoelectron spectroscopic, (XPS), spectra of solid material reveals that the observed binding energy of a core electron is a function of not only the charge density on an atom but also the matrix effects such as Madelung energy, polarization energy, and work function.[1] Therefore, the evalutaion of the matrix effects is required so as to elucidate the charge density on atom from the observed binding energy by XPS method.

In this paper, results of XPS measurements of bis-(benzene) chromiun, chromium benzene tricarbonyl, and chromium hexacarbonyl in solid phase are reported. The matrix effects on observed binding energy were calibrated by comparing the observed valence bands of these compounds to their UPS spectra in gasous phase. This correction made it possible to estimate the effective charge on each atom except for hydrogen atom. Finally, these resullts were examined by comparison of the predicted chemical shift in binding energy of Cr 3p electrons with that of the observed energy. Estimation of the difference of relaxation energies of C ls electrons between benzene and bis-benzene chromium was also attempted.

Exprimental

Bisbenzene chromium[2] and chromium benzene tricarbonyl[3] were prepared, and identified by the elemental analysis and mass spectrometric analysis. Those were stored in sealed samples. Chromium hexacarbonyl was of commercial source (Sterm Chemicals Inc.) and used without any further purification. Thin film of samples was prepared by condensing the sublimated compounds under a vacuum of 10^{-2} Pa on the sample-holder. The surface of the sample-holder was covered with vacuum deposited gold and kept at a temperature of 200 K during XPS measurement.

All of the XPS spectra were recorded by means of an AEI ES 200 type photoelectron spectrometer with aluminium target as an X-ray source. During measurements of XPS spectra the spectrometer was kept at the pressure lower than 10^{-5} Pa. An Au $4f_{7/2}$ peak (83.8 eV), which came from the surface of the sample-holder, was measured simultaneously with XPS spectra of sample and used as a reference of bending energy.

Results and Discussion

The compounds investigated have sufficient vapor pressure to measure XPS spectra in gaseous phase at the moderately elevated temperature. However, the partial decomposition of the sample by heat and/or X-ray irradiation and deposition of thin layer of metallic chromium of non-volatile compounds on aluminum X-ray window was observed. This not only gave the unreliable XPS data but also caused serious damage to XPS spectrometer preventing a prolonged XPS measurement. The XPS measurement in solid phase at low temperature did not cause any trouble and the surface of samples was continuously renewed by the slight evaporation of samples.

The valence region of XPS spectra of these compounds are shown in Fig. 1. The energy level diagrams thus obtained are illustrated in Fig. 2, together with results of UPS spectra in gaseous phase.[4,5] In UPS spectra, chromium benzenene tricarbonyl and hexacarbonyl give the well difined first band separating from the succeeding bands, but the first and second bands in UPS spectrum of bis-benzene chromium close to each other and are observed as a single peak in its XPS spectrum.

When compounds form molecular crystals and the interaction beween molecules in crystal is very weak, their MO's would not encounter with serious perturbation and ionization potentials or binding energies in both solid and gaseous phase would be coincident with each other. Then, the difference of binding energies between gaseous and solid phase should be brought solely by the matrix effects. Of these effects, Madelung energy must be so small that it might be disregarded. Seki *et al.*[6] show that the polarization energy in molecular crystals of some aromatic compounds lies around 1.1 eV within the range of 0.2 eV. Very similar results were obtained by Lyons and Mackie.[7] Therefore the main part of the observed difference of binding energies between gaseous and solid phase is considered to come from the work function.

When the weighted mean values of binding energies of the very closed orbitals observed by He(II) or He(I) UPS were compared with the binding energies of the corresponding bands in XPS spectra, the shifts are paralled and the difference falled within ± 0.2 eV. In Fig. 2, the calibrated binding energies of XPS data were given by broken lines. In the case of bis-benzene chromium, the binding energy of the first band in XPS spectra was set equal to the weighted average of those of the first and second bands in He(II) UPS spectrum. The calibrated binding energies agree well with the binding energies of the corresponding bands in UPS spectra. According to Guest *et al.*[4] the first band of $Cr(C_6H_6)_2$ should be assigned to t_{2g} orbital mainly localized on a chromium atom and the bands below the third bands come from MO's on ligands. A similar assignments were made for $Cr(C_6H_6)(CO)_3$[4] and $Cr(CO)_6$.[5]

C 1s bind eningergies could be given by the sum of group shifts.[13] This reflects that the σ-bond is strongly localized, and leads to the conclusion that most of Δq come from the substituent X, and that the charge distribution on both the substituent and residual groups remains almost constant. Most of the second row elements attach to a carbon atom with the bond length ranging from 1.1 Å to 1.5 Å. Then, in the case where molecules have a similar skeletal structure and do not have polar bonds, it might be expected that the change in V of Eq. 1 can be given as a linear function of the charge density on the carbon atom concerned. Under such circumstances, Eq. 1 can be rewritten as follows:

$$BE = k' \cdot q_C + l' \qquad (2)$$

as has been given by K. Siehgbahn *et al.* in the XPS study of free molecules.[14] For the present purposes, we selected the observed C 1s binding energies for the sp^2 carbon taken from the reliable data and reproduced in the plots of *BE vs.* q_C (Fig. 4.), (the same plot for O 1s binding energies was also given in Fig. 5).

Equation 2 may be used to get the charge distribution in the present compounds from binding energies given in Table 1. Some objection may exist to the utility of Eq. 2 for those compounds owing to 1) the difference of the skeletal structure of bisbenzene chromium from that of the compounds used to induce Eq. 2, and 2) smaller relaxation energy for a C 1s electron in free CO. Bis-benzene chromium forms a π-complex with the separation of 2.19 Å between carbon and chromium atoms. However, in the case of bis-benzene chromium, positive potential at ionized carbon caused by a chromium atom is reduced by negative potential caused by other eleven carbon atoms. This makes the situation simply as the substitution by the twelfth part of chromium with a bond length of 0.8 Å.

The binding energy of a C 1s electron in free CO lies significantly far from the relation given by Eq. 2 as clearly seen from Fig. 4. Davis and Shirley[11] have shown that the relaxation energy of a C 1s electron in CO is the smallest of the compounds of all they studied. According to their results, the relaxation energy of a C 1s electron in CO is smaller than the average of relaxation energies calculated for C 1s electrons in various compounds by amounts of 4.8 eV.

On the other hand, Baerends and Ros[15] showed in the study of metal carbonyls by DVM Xα-SCF MO calculation that the relaxation energy for a C 1s electron in $Cr(CO)_6$ is larger than that in free CO by amounts of 4.0 eV. Therefore, it might be said that the relaxation energy for C 1s electron in $Cr(CO)_6$ is comparable to that found in molecules used to decide Eq. 2.

The Estimation of Chemical Shifts in Cr 3p Binding Energies. The charge distribution in $Cr(CO)_6$, $Cr(C_6H_6)(CO)_3$, and $Cr(C_6H_6)_2$ are given in Table 2. It is presumed that the charge density on a hydrogen atom in benzene remains constant before and after the formation of a complex because a benzene molecule attached to a chromium atom through its π-orbital. Standing on this assumption we determined the charge density on a chromium atom. Assuming that the relaxation energy of 3p electron in these compounds is constant, chemical shifts in Cr 3p binding energy relative to bis-benzene chromium may be obtained to substitute the above obtained charge densities into the equation similar to the Eq. 1. The *k*-value for Cr 3p electron is decided to be 22 eV/unit charge calculating the Coulomb integral between Cr 3p and 3d electrons with Slater orbitals. The calculated chemical shifts are given in Table 3. It should be noted that the binding energy of Cr 3p electron in $Cr(CO)_6$ is larger than that in $Cr(C_6H_6)(CO)_3$, whereas the charge density on chromium atom in $Cr(CO)_6$ is smaller than in $Cr(C_6H_6)(CO)_3$, that is, the later is more positive than the former. The observed chemical shifts agreed well with the calculated chemical shifts. In other words, the relation given by Eq. 2 is no longer applied to the chemical shift in Cr 3p electrons. Evidently, this is due to the difference in molecular structure. CO coordinated through the carbon atom which is more positive than that in benzene. Furthermore, the distance between Cr and C for benzene is larger than that between Cr and C for CO. Therefore, electrostatic potential felt by a chromium atom in $Cr(CO)_6$ is more positive than that in $Cr(C_6H_6)(CO)_3$.

The Relaxation Energy for C 1s Electron in $Cr(C_6H_6)_2$. The difference between the relaxation energies in free and coordinated benzenes, ΔE_R, was obtained to be 0.4 eV to substitute above obtained charge distribution in bis-benzene chromium into Eq. 1. The relaxation energy is given by the equation[11]

$$E_R = \frac{1}{2}(V^* - V)$$

where V^* and V are respectively, the electrostatic potential at ionized carbon in the relaxed hole state and in the ground state. The hole state was expressed by equivalent core model. V^* and V caused by surrounding atoms were calculated on the basis of the potential model. For the atom which has a 1s hole, $1/2(V^* - V)$ was calculated by using the equation given by Basch.[16] The results of these calculation predict that $\Delta E_R = -0.9$ eV. ΔE_R can be estimated also from Fig. 3, which gives $\Delta E_R = -0.1$ eV. The values of ΔE_R obtained by each method may be considered to show a rather agreement with each other.

Table 2. The charge density on atoms estimated from XPS data, (in unit of |e|)

Compound	q_C	q_O	q_{Cr}

$Cr(C_6H_6)(CO)_3$	0.15	−0.29	0.54
	−0.02[a]		
$Cr(C_6H_6)_2$	−0.05	—	0.60

a) The charge density on carbon atom in benzene.

Table 3. Comparison of the estimated chemical shift in Cr 3p electron with that of observed, (in unit of eV).

Compound	Calcd	Obsd
$Cr(C_6H_6)_2$	0.0	0.0
$Cr(C_6H_6)(CO_3)$	1.1	1.9
$Cr(CO)_6$	2.7	2.9

Conclusion

We could obtain the binding energy of a core electron referred to vacuum level by calibrating the binding energy of a valence band observed in solid phase with that in gaseous phase. Within certain selected molecules, the change in binding energy can be directly correlated to the change in charge density. This relation could be applied to the results of XPS measurements of the present compounds for the estimation of charge distribution in these compounds.

Hydrothermal Synthesis of Some Varieties of Zircon

Izumi NAKAI, Tetsuo SHIMA, Mihoko IZAWA, and Kozo NAGASHIMA

Department of Chemistry, Faculty of Science, Tokyo University of Education, Otsuka, Bunkyo-ku, Tokyo 112

(Received July 10, 1976)

Some varieties of zircon which contain yttrium, niobium, and phosphorus in solid solution have been synthesized at temperatures 500—550 °C and under pressures 700—1000 kg/cm². In zircon containing yttrium, the unit cell constants *a* and *c* increase with increase in yttrium content up to 70 mol%. From IR and TGA studies, a valence compensation accompanying the substitution of yttrium is assumed to be effected by a concomitant substitution of OH for O sites, and the variety is represented by a formula $(Zr,Y)Si(O,OH)_4$. On the other hand, the substitution of Nb^{5+} for Zr^{4+} is followed by a decrease in the cell constants. Zircon phase did not form from starting materials with more than 20 mol% of niobium content. From the syntheses of zircon containing both yttrium and niobium, the formula $(Zr,Y,Nb)\ Si(O,OH)_4$ is found to be appropriate for naegite. An attempt was made to synthesize some solid solutions between zircon and xenotime. The unit cell constant *c* of the products is found to decrease with the substitution of PO_4 for SiO_4.

Zircon, $ZrSiO_4$, a widely distributed accessory mineral in igneous rocks, is known to have many varieties such as cyrtolite (water, yttrium rich zircon), naegite (yttrium, niobium rich zircon) and yamaguchilite (yttrium, phosphorus rich zircon).[1] Since the varieties of zircon usually occur in metamict state due to radioactive elements such as uranium and thorium, the properties of the varieties and the mechanisms of the substitutions are not well-known.

In zircon, each silicon atom is surrounded by a tetrahedral group of four oxygen atoms at a distance of 1.61 Å, while each zirconium atom lies between four oxygen atoms at 2.15 Å and a further four at 2.29 Å. These Zr–O distances lie between the limits of 8- and 6-fold coordination.[2] We have studied the isomorphous substitutions of Y^{3+}, Nb^{5+}, and P^{5+} for Zr^{4+} and Si^{4+} sites in zircon. From the relative sizes of the ions involved, it is expected that Zr^{4+} is substituted by Y^{3+} and Nb^{5+}, and Si^{4+} by P^{5+}. This is found to be true in the present work.

Frondel and Collette carried out the hydrothermal synthesis of zircon over the range 150 °C and 4.8 bars to 700 °C and 3100 bars by heating admixed ZrO_2 and SiO_2 gels with water in steel bombs.[3] Single crystal of zircon was also obtained by hydrothermal method.[4,5] In our study, the syntheses of some varieties were carried out by the hydrothermal crystallization of precipitated gels of stoichiometric composition, and the mechanisms of the substitutions and the variations of cell constants were studied.

Experimental

The reagents employed were dilute HNO_3 solutions of $ZrO(NO_3)_2 \cdot 2H_2O$ (EP-grade) and Y_2O_3 (99.99% pure), dilute H_2SO_4 solution of Nb_2O_5(99.9% pure) and aqueous solutions of Na_2SiO_3 (CP-grade, standardized by gravimetric analysis) and $(NH_4)_2HPO_4$ (EP-grade). The starting gels were prepared by mixing each solution to the desired composition. The mixed solutions were adjusted to pH 10 with dilute ammonia. The resulting precipitates were centrifuged, washed with dilute ammonia, dried at 130 °C in an oven and finely ground. The gels were sealed with 0.05 ml water in Ag capsules, inner diameter 3 mm and length 35 mm. The hydrothermal synthesis was carried out in a 150 ml cold seal rene bomb.

All the products were examined by the X-ray powder diffraction method using CuK_α radiation and internal silicon standard. The composition of synthesized zircon is assumed to have a composition corresponding to the initial gel when it appears in a single phase in the product. Unit cell constants were calculated according to the known space group. Some of the products were examined by infrared spectroscopy by the KBr disk method and TGA.

Results and Discussion

Isomorphous Substitution of Yttrium in Zircon. Syntheses of zircon which contains various amounts of yttrium were carried out with gels which have the composition $ZrO_2 : Y_2O_3 : SiO_2 = 1-x : x/2 : 1$, where x varied from 0 to 1. The runs were made under the conditions 530 °C, and 700 kg/cm² for 55 h. The products were white and microcrystalline. The calculated unit cell constants plotted against the initial gel composition are given in Fig. 1. The cell constants *a* and *c* increase linearly as a function of the composition up to about 70 mol% of yttrium content. The significant increase in the cell constants seems to indicate the continuous substitution of large Y^{3+} ion for Zr^{4+} ion. The limit of the substitution is about 70 mol% under our experimental conditions. The product is no longer present in a single phase beyond 70 mol% of yttrium content, and β-yttrialite $Y_2Si_2O_7$ phase and a small amount of an unidentified phase appear besides the zircon phase. Therefore, zircon with high yttrium content (more than 70 mol%) is presumed to be unstable and stabilized by forming

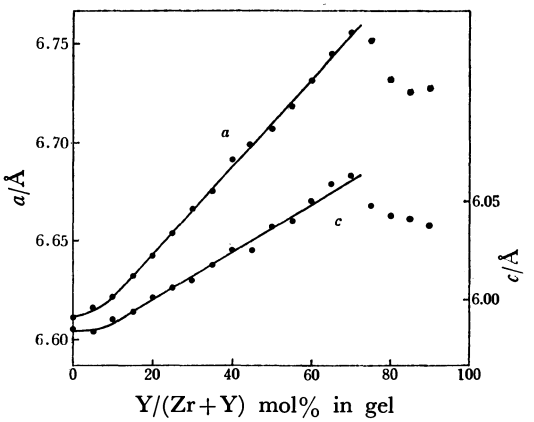

Fig. 1. Unit cell constants *a* and *c* of zircon containing Y.

β-yttrialite and zircon with low yttrium content.

The substitution of trivalent yttrium for quadrivalent zirconium requires some valence compensations in the zircon structure. From an EPR study of natural zircon, Bershov found that when two Y^{3+} ions enter simultaneously into two neighboring zirconium sites the structure is stabilized by the formation of O^- center.[6] The valence compensation of this type, however, seems to be possible only when yttrium is present in zircon in a low concentration less than a few per cent. It should be noted that some varieties of zircon often contain significant amount of water up to 10%. Frondel postulated that some of the water characteristically present in metamict zircon should be regarded as essential and required for the valence compensation in the structure.[7] He suggested a substitution of OH for O in SiO_4 tetrahedra as the valence compensation on the basis of the chemical analysis and thermal study of a natural sample by Kostyleva.[8] This mechanism is adopted here to explain the valence compensation in synthesized zircon. In order to determine the presence of OH, infrared measurements were made on a number of the products which had been dried at 130 °C before measurements. Figure 2 shows IR spectra of pure zircon and zircons containing niobium (16 mol%), yttrium (34 mol%) and yttrium (32 mol%) which was heated at 350 °C for 40 min in advance. Figure 3 shows IR spectra in the 2500—4000 cm^{-1} region of zircon with 5, 25, 45, and 65 mol% yttrium content and zircon with 60 mol% yttrium content which was heated at 1100 °C for 2 h in advance. Zircon containing yttrium gives weak infrared OH absorptions at about 3400, 3200, and 1600 cm^{-1}. Since the absorption at about 3200 cm^{-1} remained after the sample had been dried at 350 °C but disappeared when it had been heated to 1100 °C, the absorption

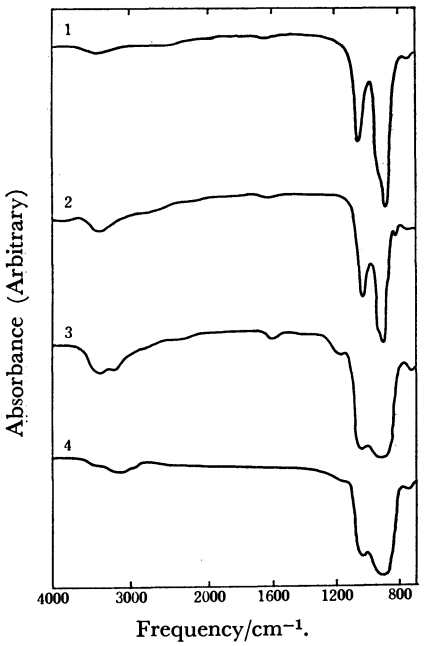

Fig. 2. IR spectra of zircon.
1: Pure, 2: containing 16 mol% Nb, 3: containing 34 mol% Y, 4: containing 32 mol% Y, heated at 350 °C for 40 min.

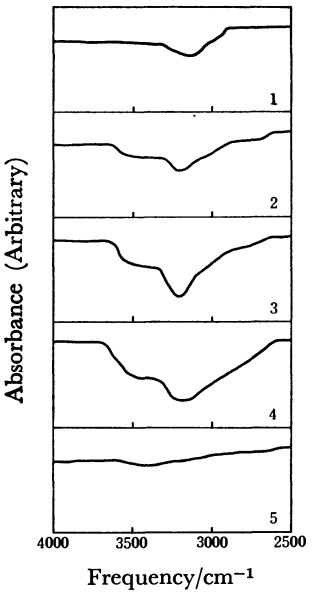

Fig. 3. IR spectra of zircon with Y content of 1 : 5 mol%, 2 : 25 mol%, 3 : 45 mol%, 4 : 65 mol%, 5 : 60 mol%, heated at 1100 °C for 2 h.

is assumed to be due to OH substituting for O in the SiO_4 tetrahedra. The absorptions at about 3400 and 1600 cm^{-1} disappeared when the sample had been dried at 350 °C. These absorptions are assigned to molecular water and OH in the hydrogen bond. The relative intensity of the peak at about 3200 cm^{-1} increases with an increase in yttrium content (Fig. 3). The result seems to support the view that the absorption is due to OH substituting for O in the SiO_4 tetrahedra. The doublet absorption band centered at about 1000 cm^{-1} has been assigned to the Si–O bonds. We see from Fig. 2 that the doublet structure of the absorption band is very indistinct in zircon containing yttrium as compared with that of the band in pure zircon and zircon containing niobium. The indistinctness for the former is probably due to the non-uniformity of the strength of the Si–O bonds in zircon containing yttrium because it has two kinds of Si–O bond, *viz.* Si–O and Si–OH.

TGA study was carried out for the sample containing 40 mol% of yttrium. The result is given in Fig. 4. The TGA curve shows a gradual loss of H_2O up to 0.85% at 350 °C, and a gradual loss of 2.0% H_2O

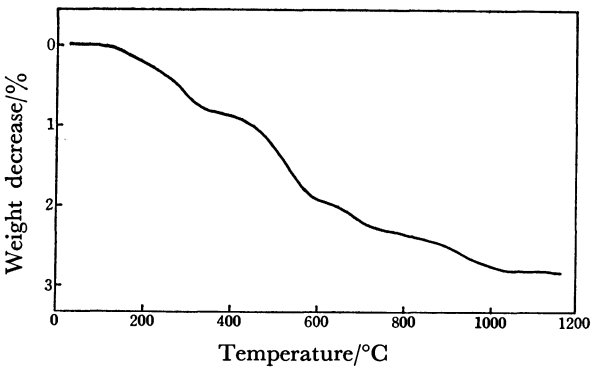

Fig. 4. TGA curve for zircon containing 40 mol% Y.

from 350 to 1000 °C. The former seems to be caused by the dehydration of molecular water and the latter by that of OH substituting for the O sites. The latter 2.0% loss agrees with the calculated value 1.97% evaluated by assuming that the concentration of OH substituting for the O sites in zircon is equal to that of yttrium. The above observations suggest that the following formula is appropriate for the synthesized zircon : $(Zr,Y)Si(O,OH)_4$.

X-Ray diffraction powder pattern for the product heated at 1100 °C for 2 h shows the presence of β-yttrialite as well as zircon. This indicates that $(Zr,Y)Si(O,OH)_4$ decomposes to $ZrSiO_4$, $Y_2Si_2O_7$, and H_2O.

Study on Naegite by Means of Synthesis. One variety of zircon which mainly contains yttrium and niobium is called naegite* and usually written as $(Zr,Y)(Si,Nb)O_4$. The site occupancy of niobium in zircon is of interest. In order to confirm the assumption that Nb^{5+} does not substitute for Si^{4+}, attempts were made to obtain zircon containing niobium from gels having the composition $ZrO_2 : Nb_2O_5 : SiO_2 = 1-x : x/2 : 1$, where x varies from 0 to 1. The syntheses were carried out under the conditions 530 °C and 700 kg/cm² for 55 h. Attempts to prepare zircon containing over 20 mol% niobium were not successful, resulting in mixed phases of ZrO_2, SiO_2 and unknown substances which gave very diffuse X-ray powder patterns. The zircon phase is found to form only when niobium is less than about 15 mol% in the gel composition. A plot of the unit cell constants of the synthesized zircon *versus* the composition is given in Fig. 5. The cell constants decrease slightly with increase in niobium content up to 10 mol% but remain nearly constant above 10 mol%. In view of the relative size of ions, it seems reasonable to consider that the observed decrease in the cell constants results from the substitution of Nb^{5+} for Zr^{4+} and not for Si^{4+}. The substitution of Nb^{5+} for Zr^{4+} requires valence compensation. There are two explanations: (1) It is achieved by cation deficiency. When the concentration of the deficiency is high, cation deficient zircon becomes unstable. This

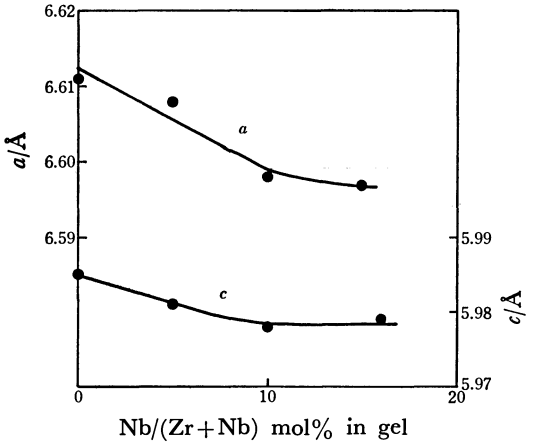

Fig. 5. Unit cell constants a and c of zircon containing Nb.

* A name proposed by T. Wada (1904).

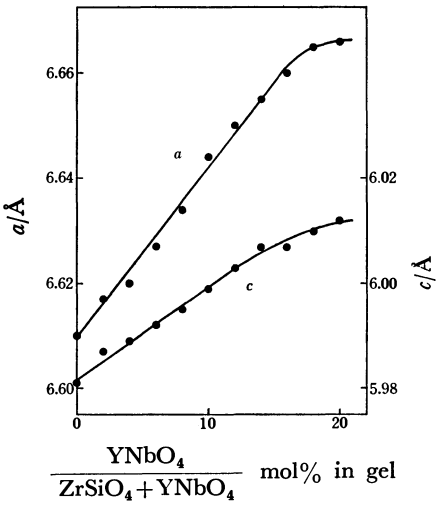

Fig. 6. Unit cell constants a and c of zircon containing Y and Nb.

corresponds to the fact that zircon with high niobium content is not obtained in our syntheses. (2) Niobium exists in zircon in the quadrivalent state but not in the quinquevalent state. The possibility of its presence was reported by Matkovich and Corbett.[9] They heated equimolar amounts of ZrO_2 and SiO_2 in the presence of Nb_2O_5 at 1000 °C in an electric furnace and obtained zircon with cell constants slightly smaller than that of pure zircon. They also heated equimolar amounts of ZrO_2 and SiO_2 in the presence of V_2O_5 and obtained light blue zircon. The color implies the presence of quadrivalent vanadium in zircon. By analogy with vanadium in zircon, they inferred the presence of quadrivalent niobium in zircon. There is, however, no direct evidence of quadrivalent niobium and its presence remains to be clarified.

The syntheses of naegite were carried out under the conditions 530 °C, and 1000 kg/cm² for 81 h. The initial gels had the composition $(Zr_{1-x},Y_x)(Si_{1-x},Nb_x)O_4$, x varying from 0 to 0.2. A plot of the cell constants of the products against the composition is shown in Fig. 6. If we compare the curves in Fig. 1

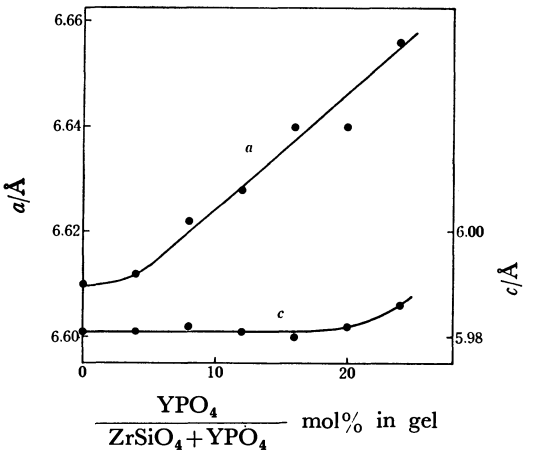

Fig. 7. Unit cell constants a and c of zircon containing Y and P.

and Fig. 6, we see that their shapes resemble each other. Since zircon does not contain niobium in high concentration, the variation in the cell constants seems to be mainly due to the yttrium concentration in synthesized naegite. This corresponds to the fact that yttrium is present in much higher concentration than niobium in natural naegite. Substitution of OH for O sites seems to occur in naegite for valence compensation. Thus the formula $(Zr, Y, Nb)Si(O, OH)_4$ might be appropriate for naegite. The phase $(Zr, Y, Nb)Si(O, OH)_4$ was no longer present in a single phase under the hydrothermal conditions 700 °C and 1000 kg/cm^2, decomposing into fergusonite $YNbO_4$ and zircon phases.

An Attempt to Synthesize Yamaguchilite $(Zr,Y)(Si,P)O_4$. The syntheses of yamaguchilite,* solid solutions of zircon and xenotime (YPO_4), were carried out under the conditions 530 °C and 1000 kg/cm^2 for 81 h. The cell constants of synthesized $(Zr,Y)(Si,P)O_4$ *versus* initial gel composition are plotted in Fig. 7. Although there is no direct evidence of the $ZrSiO_4 : YPO_4$ ratio in the products, there is a significant difference in the variation of the cell constant c between the curves in Figs. 1 and 7: in $(Zr,Y)(Si,P)O_4$, c remains nearly constant up to 20 mol% of the yttrium content. Therefore the substitution of PO_4 for SiO_4 is found to cause a relative decrease in c dimension, not a dimension.

* A name proposed by K. Kimura and Y. Hironaka[1] (1936).

The authors wish to express their thanks to Dr. Yoshinori Fujiki, Mr. Isamu Shindo, Dr. Mamoru Watanabe and Mr. Fujio Izumi of National Institute for Researches in Inorganic Materials for their technical assistance. The authors also wish to thank Dr. Yoshinori Sugitani, Tokyo University of Education, for critical reading of the manuscript. The present work was partially supported by a Grant-in Aid for Scientific Research from the Ministry of Education.

Chart 3

benzoyl)-D-*erythro*-pentofuranoside[8] by acetolysis. The fusion reaction of **17** with **2** gave a mixture of blocked nucleosides, which was subjected to the chromatographic separation on silica gel to give the α- and β-anomers of 1-glycosylpyrazole-3-carboxylate (**18**α, **18**β) and 1-glycosylpyrazole-5-carboxylate (**19**α, **19**β) in yield of 27.4, 20.0, 3.3, and 4.9%, respectively, as crystalline products except for **19**α. It may be noted, in this reaction, that the 3-substituted 1-glycosylpyrazoles (**18**α, **18**β) were formed as major products in accord with the cases of the ribonucleosides[1] and the arabinonucleosides (**5**α, **5**β) syntheses under similar conditions.

Treatment of **18**α, **18**β, **19**α, and **19**β with methanolic ammonia gave 1-(2-deoxy-α-D-*erythro*-pentofuranosyl)-pyrazole-3-carboxamide (**22**α), its β-anomer (**22**β), 1-(2-deoxy-α-D-*erythro*-pentofuranosyl)pyrazole-5-carboxamide (**23**α), and its β-anomer (**23**β), respectively. The chemical shifts for the *H*-5 proton signals of **22**α and **22**β are in agreement with those of the arabinonucleosides **13**α and **13**β, and the chemical shifts for the *H*-3 protons of **23**α and **23**β are comparable with those for **14**α and 1-(β-D-ribofuranosyl)pyrazole-5-carboxamide.[1] Thus, **22**α and **22**β were established as 1-glycosylpyrazole-3-carboxamides, and **23**α and **23**β were as the corresponding 5-carboxamides, respectively. Inspection of the PMR spectra of **22**β and **23**β also revealed that the β-anomers are characterized by each triplet of their anomeric proton signals with a peak width of 12 Hz which is consistent with the β-configuration, and, a quartet with a peak width of 10.7 Hz was observed for the anomeric proton of **23**α. These data were consistent with those reported for 2'-deoxyribonucleosides by Robins and Robins[9], and Witkowski *et al.*[10]

The ultraviolet spectra of the 3-carboxamides (**13**α, **13**β, **22**α, and **22**β) and 5-carboxamides (**14**α, **23**α, and **23**β) showed a characteristic difference each other similar to that reported with respect to the corresponding D-ribofuranosyl derivatives.[1]

Similar fusion of **17** with diethyl pyrazole-3,5-dicarboxylate (**3**) afforded blocked nucleosides (**20**),

which, by treatment with methanolic ammonia, led to an anomeric mixture of 1-(2-deoxy-D-*erythro*-pentofuranosyl)pyrazole-3,5-dicarboxamides (**24**).

Further we similarly synthesized its 2'-deoxy analogue (**25**) as an anomeric mixture since 1-(β-D-ribofuranosyl)-4-nitropyrazole-3,5-dicarboxamide[1] was found cytotoxic.[11]

The downfield shifts of the anomeric proton signals of **24** and **25** were also observed.

Preliminary accounts for structure-activity relationships of the above nucleosides as antiviral agents have already been reported.[11]

Experimental

Melting points were determined on a micro hot stage and were uncorrected. Thin layer chromatography (TLC) was conducted by the use of Wakogel B-5. Silica gel column chromatography was performed by using Wakogel G-200. UV-spectra were taken with a Hitachi Perkin-Elmer UV-VIS spectrometer 139. The PMR spectra were recorded with a Varian A-60D spectrometer (TMS as an internal standard).

*1-O-Acetyl-2,3,5-tri-O-benzyl-D-arabinofuranose (**1**).* 2,3,5-Tri-O-benzyl-D-arabinofuranose (10.0 g, 23.8 mmol) was dissolved in anhydrous pyridine (50 ml), to which was added acetic anhydride (50 ml) under ice-cooling. The mixture was stirred at room temperature for 12 h. After removal of the solvent by evaporation, the resulting syrup was dissolved in ethyl acetate (10 ml) and chromatographed on a silica gel column (400 g, 5×100 cm, packed with benzene). Elution with 20 : 1 benzene–ethyl acetate afforded a syrup of **1**, 9.48 g (86.4%); PMR ($CDCl_3$) : δ 7.40 (s, 15H, Ar), 6.40 (br s, 1H, H-1'), 4.75—3.95 (m, 9H, CH_2–Ar, H-2', H-3', H-4'), 3.65 (d, 2H, H-5', 5''), 2.00 (s, 2.1H, CH_3), 1.95 (s, 0.9H, CH_3), *ca.* 21 : 9 mixture of α and β. Found: C, 72.49; H, 6.36%. Calcd for $C_{28}H_{30}O_6$: C, 72.71; H, 6.54%.

*Ethyl 1-(2,3,5-Tri-O-benzyl-β-D-arabinofuranosyl)pyrazole-3-carboxylate (**5β**), Its α-Anomer (**5α**), and Ethyl 1-(2,3,5-Tri-O-benzyl-α-D-arabinofuranosyl)pyrazole-5-carboxylate (**6α**).* A mixture of ethyl pyrazole-3-carboxylate[5] (**2**, 550 mg, 3.93 mmol) and 1-*O*-acetyl-2,3,5-tri-*O*-benzyl-D-arabinose **1**, 1.70 g, 3.68 mmol) was heated at 140 °C to a melt, to which bis(*p*-nitrophenyl) hydrogenphosphate (3 mg) was added, and the mixture was heated at 140 °C under reduced pressure for 8 min until the evolution of acetic acid ceased. The resulting gum was dissolved in ethyl acetate (5 ml), silica gel (2.5 g) was added, and the resulting suspension was evaporated to dryness. The residue was placed on a column of silica gel (110 g, 2.8×45 cm, packed with 1 : 1 hexane–diisopropyl ether) and eluted with the same solvent system. The effluent was fractionated into 11 mls.

Fraction Nos. 31—38 gave **6α**, a colorless syrup, 165 mg (8.3%). $[\alpha]_D^{25}$+55.3° (*c* 0.77, chloroform). PMR ($CDCl_3$): δ 7.79 (d, 1H, H-3), 7.40 (d, 15H, Ar), 7.10 (d, 1H, $J_{1',2'}$= 3.8 Hz, H-1'), 7.04 (d, 1H, H-4), 5.23 (dq, 1H, H-2'), 4.80—4.20 (m, 10H, CH_2–Ar, H-3', H-4', CH_2–ester), 3.72 (d, 2H, H-5',5''), 1.40 (t, 3H, CH_3–ester). Found: C, 70.85; H, 6.52; N, 4.88%. Calcd for $C_{32}H_{34}O_6N_2$: C, 70.83; H, 6.32; N, 5.16%. Fraction Nos. 63—79 gave **5α**, a colorless syrup, 605 mg (30.4%); $[\alpha]_D^{25}$+35.0° (*c* 1.0, chloroform). PMR ($CDCl_3$): δ 7.80 (d, 1H, H-5), 7.40 (s, 15H, Ar), 6.90 (d, 1H, H-4), 6.18 (d, 1H, $J_{2',1'}$=2.2 Hz, H-1'), 4.80—4.18 (m, 11H, CH_2–Ar, H-2', H-3', N-4', CH_2–ester), 3.70 (d, 2H, H-5', 5''), 1.42 (t, 3H, CH_3–ester). Found: C, 70.53; H, 6.19; N, 4.83%. Calcd for $C_{32}H_{34}O_6N_2$: C, 70.83; H, 6.32; N, 5.16%.

Fraction Nos. 87—102 gave **5β**, a colorless syrup, 957 mg (48.2%); $[\alpha]_D^{25}$+15.0° (*c* 0.50, chloroform). PMR ($CDCl_3$): δ 7.95 (d, 1H, H-5), 7.40 (s, 15H, Ar), 6.88 (d, 1H, H-4), 6.40 (d, 1H, $J_{1',2'}$=4.5 Hz, H-1'), 4.65—4.20 (m, 11H, CH_2–Ar, H-2', H-3', H-4', CH_2–ester), 3.75 (d, 2H, H-5', 5''), 1.38 (t, 3H, CH_3–ester). Found: C, 71.01; H, 6.33; N, 5.07%. Calcd for $C_{32}H_{34}O_6N_2$: C, 70.83; H, 6.32; N, 5.16%.

*Diethyl 1-(2,3,5-Tri-O-benzyl-D-arabinofuranosyl)pyrazole-3,5-dicarboxylate (**7**).* By a method similar to that described above, diethyl pyrazole-3,5-dicarboxylate (**3**) (152 mg, 0.715 mmol) was allowed to react with **1** (330 mg, 0.715 mmol) to afford a gum, which was dissolved in ethyl acetate and chromatographed on a column of silica gel (20 g, 1×20 cm, packed with 20 : 1 benzene–ethyl acetate). Elution with the same solvent afforded **7** as a syrup of an anomeric mixture, 334 mg (76%); PMR ($CDCl_3$) : δ 7.38 (d, 16H, Ar, H-4), 7.10 (d, 0.2H, $J_{1',2'}$=5.0 Hz, H-1') 7.08 (d, 0.8H, $J_{1',2'}$=3.7 Hz, H-1'), 5.25 (dq, 1H, H-2'), 4.75—4.17 (m, 12H, CH_2–Ar, CH_2–ester, H-3', N-4'), 3.68 (d, 2H, H-5', 5''), 1.34 (tt, 6H, CH_3–ester). Found: C, 68.10; H, 6.12; N, 4.27%. Calcd for $C_{35}H_{38}O_8N_2$: C, 68.39; H, 6.23; N, 4.56%.

*Diethyl 1-(2,3,5-Tri-O-benzyl-α-D-arabinofuranosyl)-4-nitropyrazole-3,5-dicarboxylate (**8α**) and Its β-Amoner (**8β**).* By a method similar to that described above, diethyl 4-nitropyrazole 3,5-dicarboxylate[1] (**4**) (355 mg, 1.30 mmol) was allowed to react with **1** (600 mg, 1.30 mmol) to give a gum, which was dissolved in ethyl acetate (1 ml), placed on a column of silica gel (70 g, 2.5×40 cm, packed with 2 : 1 hexane–diisopropyl ether) and eluted successively with 2 : 1 (80 ml) and 1 : 1 hexane–diisopropyl ether. The effluent was fractionated into 7.5 mls.

Fraction Nos. 17—26 gave **8α**, a colorless oil, 464 mg (54.2%); $[\alpha]_D^{25}$+129.5° (*c* 1.0, chloroform). PMR ($CDCl_3$): δ 7.41 (d, 15H, Ar), 6.69 (d, 1H, $J_{1',2'}$=3.4 Hz, H-1'), 5.19 (dt, 1H, H-2'), 4.72—4.25 (m, 12H, CH_2–Ar, CH_2–ester, H-3', H-4'), 3.70 (d, 2H, H-5',5''), 1.33 (tt, 6H, CH_3–ester). Found: C, 64.01; H, 5.81; N, 6.11%. Calcd for $C_{35}H_{37}O_{10}N_3$: C, 63.72; H, 5.65; N, 6.37%.

Fraction Nos. 32—41 gave **8β**, a colorless oil, 124mg (14.5%); $[\alpha]_D^{25}$−75.0° (*c* 1.0, chloroform). PMR ($CDCl_3$): δ 7.40 (d, 15H, Ar), 7.31 (d, 1H, $J_{1',2'}$=5.8 Hz, H-1'), 4.7—3.85 (m, 15H, CH_2–Ar, CH_2–ester, H-2', H-3', H-4', H-5',5''), 1.39 (tt, 6H, CH_3–ester). Found: C, 63.92; H, 5.62; N, 6.19%. Calcd for $C_{35}H_{37}O_{10}N_3$: C, 63.72; H, 5.65; N, 6.37%.

*1-(2,3,5-Tri-O-benzyl-α-D-arabinofuranosyl)pyrazole-3-carboxamide (**9α**).* A solution of **5α** (550 mg, 1.01 mmol) in absolute methanol (15 ml) saturated with ammonia at 0 °C was kept at room temperature for 24 h and evaporated. The residual syrup was washed with hexane and dried at 80 °C *in vacuo* for 10 h to give a colorless syrup of **9α**, 415 mg (80%); $[\alpha]_D^{25}$+39.6° (*c* 1.70, chloroform). PMR ($CDCl_3$): δ 7.71 (d, 1H, H-5), 7.38 (d, 15H, Ar), 7.20 (d, 1H, $J_{1',2'}$= 4.0 Hz, H-1'), 6.97 (d, 1H, H-4), 5.13 (dq, 1H, H-2'), 4.8—4.16 (m, 8H, CH_2–Ar, H-3', H-4'), 3.63 (m, 2H, H-5, 5''). Found: C, 70.14; H, 6.15; N, 8.11%. Calcd for $C_{30}H_{31}O_5N_3$: C, 70.16; H, 6.08; N, 8.18%.

*1-(2,3,5-Tri-O-benzyl-β-D-arabinofuranosyl)pyrazole-3-carboxamide (**9β**).* By the same procedure as that for **9α**, **5β** (800 mg, 1.47 mmol) gave **9β**, 635 mg (84%), as a colorless syrup; $[\alpha]_D^{25}$+19.4° (*c* 1.0 chloroform). PMR ($CDCl_3$): δ 7.89 (d, 1H, H-5), 7.42 (m, 15H, Ar), 6.91 (d, 1H, H-4), 6.50 (br d, 2H, $CONH_2$), 6.22 (d, 1H, $J_{1',2'}$=4.5 Hz, H-1'), 4.7—4.2 (m, 9H, CH_2–Ar, H-2', H-3', H-4'), 3.77 (d, 2H, H-5',5''). Found: C, 70.14; H, 6.15; N, 8.07%. Calcd for

pressure gave a syrup, which was dissolved in 20 : 1 benzene–ethyl acetate and chromatographed on a silica gel column (80 g, 2.5×50 cm, packed with the same solvent system). Elution with the same solvent system afforded a pale-yellow glass of **17**, 4.2 g (88%); PMR ($CDCl_3$): δ 8.32 (s, 8H, Ar), 6.60 (m, 1H, H-1), 5.70 (m, 1H, H-3), 4.70 (br s, 3H H-4, H-5,5′), 2.52 (m, 2H, H-2,2′), 2.13 (d, 3H, CH_3). Found: C, 52.89; H, 3.70; N, 5.68%. Calcd for $C_{21}H_{18}O_{11}N_2$: C, 53.17; H, 3.82; N, 5.91%.

*Ethyl 1-(2-Deoxy-3,5-di-*O*-p-nitrobenzoyl-β-*D*-*erythro*-pentofuranosyl)pyrazole-3-carboxylate (**18β**), Its α-Amoner (**18α**), Ethyl 1-(2-Deoxy-3,5-di-*O*-p-nitrobenzoyl-β-*D*-erythro-pentofuranosyl)pyrazole-5-carboxylate (**19β**) and Its α-Anomer (**19α**).* To a mixture of ethyl pyrazole-3-carboxylate (**2**, 539 mg, 4.24 mmol) and 1-*O*-acetyl-2-deoxy-3,5-di-*O*-*p*-nitorobenzoyl-D-*erythro*-pentofuranose (**17**, 1.6 g, 3.38 mmol) heated at 136 °C to a melt, a catalytic amount of bis(*p*-nitrophenyl) hydrogenphosphate (1 mg) was added and the mixture was kept at 136 °C for 3 min under reduced pressure until the evolution of acetic acid ceased. The resulting mixture was triturated with ethyl acetate (5 ml) and chloroform (20 ml). The chloroform solution was evaporated to dryness and the solid was recrystallized from ethyl acetate to give **18α**, 420 mg (22.6%). The mother liquor and the above ethyl acetate layer were combined, and concetrated to about 2 ml. This was chromatographed on a silica gel column (90 g, 2.5×50 cm, packed with 20 : 1 benzene–ethyl acetate) with the same solvent system. The effluent was fractionated into 9 mls.

Fraction Nos. 34—38 gave colorless crystals of **19β**. Recrystallization from benzene and hexane, 94 mg (4.9%); mp 145.5—146.5 °C. $[\alpha]_D^{25}$ −48.0° (*c* 1.0, chloroform). PMR ($CDCl_3$): δ 8.34 (d, 8H, Ar), 7.68 (d, 1H, H-3), 7.41 (q, 1H, H-1′), 6.98 (d, 1H, H-4), 6.00 (br t, 1H, H-3′), 4.86 (br s, 3H, H-4′, H-5′,5″), 4.42 (q, 2H, CH_2-ester), 3.75—2.40 (m, 2H, H-2′,2″), 1.40 (t, 3H, CH_3-ester). Found: C, 54.00; H, 4.20; N, 10.16%. Calcd for $C_{25}H_{22}O_{11}N_4$: C, 54.15; H, 4.00; N, 10.10%.

Fraction Nos. 39—42 gave a mixture of **19β** and **19α**, 25.9 mg (1.4%), *ca.* 5 : 8 mixture of **19β** and **19α**, by PMR.

Fraction Nos. 41—44 gave **19α**, a colorless syrup, 62 mg (3.3%); $[\alpha]_D^{25}$ +29.5° (*c* 1.0, chloroform). PMR ($CDCl_3$): δ 8.35 (s, 8H, Ar), 7.69 (d, 1H, H-3), 7.32 (q, 1H, H-1′), 7.00 (d, 1H, H-4), 5.70 (q, 1H, H-3′), 5.04—4.60 (m, 3H, H-4′, H-5′,5″), 4.43 (q, 2H, CH_2-ester), 3.11 (t, 2H, H-2′,2″), 1.40 (t, 3H, CH_3-ester). Found: C, 54.73; H, 4.01; N, 9.90%. Calcd for $C_{25}H_{22}O_{11}N_4$: C, 54.15; H, 4.00; N, 10.00%.

Fraction Nos. 64—73 gave colorless crystals of **18β**. Recrystallization of **18β** from ethyl acetate gave a pure sample, 372 mg (20.0%); mp 138—140 °C. $[\alpha]_D^{25}$ −22.5° (*c* 1.0, chloroform). PMR ($CDCl_3$): δ 8.38 (s, 8H, Ar), 7.82 (d, 1H, H-5), 6.90 (d, 1H, H-4), 6.43 (t, 1H, H-1′), 5.98 (br t, 1H, H-3′), 4.72 (br s, 3H, H-4′, H-5′,5″), 4.45 (q, 2H, CH_2-ester), 3.72—2.65 (m, 2H, H-2′,2″), 1.39 (t, 3H, CH_3-ester). Found: C, 54.39; H, 4.22; N, 9.95%. Calcd for $C_{25}H_{22}O_{11}N_4$: C, 54.15; H, 4.00; N, 10.10%.

Fraction Nos. 74—77 gave a mixture of **18β** and **18α**, 120 mg (6.7%), *ca.* 1 : 3 mixture of **18β** and **18α**, by PMR.

Fraction Nos. 78—95 gave crystals of **18α**. Recrystallization of **18α** from ethyl acetate gave a pure sample, 90.9 mg (4.8%); mp 183.5—184.5 °C. $[\alpha]_D^{25}$ −6.0° (*c* 1.0, chloroform). PMR ($CDCl_3$): δ 8.25 (m, 8H, Ar), 7.90 (d, 1H, H-5), 6.97 (d, 1H, H-4), 6.45 (q, 1H, H-1′), 5.77 (m, 1H, H-3′), 4.75 (m, 3H, H-4′, H-5′,5″), 4.48 (q, 2H, CH_2-ester), 3.57—2.62 (m, 2H, H-2′,2″), 1.40 (t, 3H, CH_3-ester). Found: C, 54.28; H, 4.03; N, 10.14%. Calcd for $C_{25}H_{22}O_{11}N_4$: C, 54.15; H, 4.00 N, 10.10%.

*Diethyl 1-(2-Deoxy-3,5-di-*O*-p-nitrobenzoyl-*D*-erythro-pentofuranosyl)pyrazole-3,5-dicarboxamide (**20**).* The reaction of diethyl pyrazole-3,5-dicarboxylate (**3**, 630 mg, 2.96 mmol) with **17** (1.4 g, 2.96 mmol) was carried out in a manner similar to that described above. To a solution of the resulting mixture in acetone (5 ml) silica gel (2.2 g) was added and the mixture was evaporated. The residue was chromatographed on a column of silica gel (100 g) packed with 20 : 1 benzene–ethyl acetate. Elution with benzene–ethyl acetate (10 : 1) afforded **20** as an anomeric mixture, 1.18 g (64%); PMR ($CDCl_3$): δ 8.41 (s, 8H, Ar), 7.50 (m, 2H, H-1′, H-4), 6.2—5.5 (m, 1H, H-3′), 4.75 (m, 3H, H-4′, H-5′,5″), 4.50 (q, 4H, CH_2-ester), 3.6—2.1 (m, 2H, H-2′,2″), 1.40 (t, 6H, CH_3-ester). Found: C, 53.39; H, 4.26; N, 9.01%. Calcd for $C_{28}H_{26}O_{13}N_4$: C, 53.67; H, 4.18; N, 8.94%.

*Diethyl 1-(2-Deoxy-3,5-di-*O*-p-nitrobenzoyl-*D*-erythro-pentofuranosyl)-4-nitropyrazole-3,5-dicarboxylate (**21**).* The reaction of diethyl 4-nitropyrazole-3,5-dicarboxylate (**4**) (590 mg, 2.39 mmol) with **17** (1.13 g, 2.39 mmol) was carried out in the similar manner as described above. The resulting mixture was dissolved in ethyl acetate (5 ml), silica gel (1.8 g) was added and the mixture was evaporated to dryness. The residue was placed on a column of silica gel (80 g, 3×60 cm, packed with 1 : 1 hexane–diisopropyl ether) and eluted by the same solvent system. The effluent was fractionated into 8 mls. Fraction Nos. 21—57 gave a colorless syrup of **21**, 664 mg (42%), as an anomeric mixture; PMR ($CDCl_3$): δ 8.40 (s, 8H, Ar), 7.30 (m, 1H, H-1′), 6.2—5.8 (m, 1H, H-3′), 4.75 (m, 3H, H-4′, H-5′,5″), 4.52 (qq, 4H, CH_2-ester), 3.5—2.5 (m, 2H, H-2′, 2″), 1.45 (tt, 6H, CH_3-ester). Found: C, 49.89; H, 3.60; N, 10.18%. Calcd for $C_{28}H_{25}O_{15}N_5$: C, 50.08; H, 3.75; N, 10.43%.

*1-(2-Deoxy-β-*D*-erythro-pentofuranosyl)pyrazole-3-carboxamide (**22β**)* A solution of **18β** (380 mg, 0.686 mmol) in absolute methanol (10 ml) saturated with ammonia at 0 °C was kept at room temperature for 3 days and evaporated. The residual oil was dissolved in water (10 ml) and the solution was extracted with ethyl acetate (3 ml×4). The aqueous layer was evaporated and the residue was chromatographed on a silica gel column (4 g, 0.8×20 cm) packed with 4 : 1 chloroform–methanol. Elution with the same solvent system afforded a glass of **22β**, 129 mg (83%); $[\alpha]_D^{25}$ −17.5° (*c* 1.0, methanol). PMR (CD_3OD): δ 8.09 (d, 1H, H-5), 6.92 (d, 1H, H-4), 6.35 (t, 1H, H-1′), 4.68 (m, 1H, H-3′), 4.11 (m, 1H, H-4′), 3.78 (m, 2H, H-5′,5″), 2.67 (m, 2H, H-2′,2″). UV: λ_{max}^{water} 213 (ε 11900), λ_{max}^{pH1} 198 (ε 12000), λ_{max}^{pH13} 218 nm (ε 11500). Found: C, 47.27; H, 5.90; N, 18.20%. Calcd for $C_9H_{13}O_4N_3$: C, 47.57; H, 5.77; N, 18.49%.

*1-(2-Deoxy-α-*D*-erythro-pentofuranosyl)pyrazole-3-carboxamide (**22α**).* By a procedure similar to that described above, **18α** (580 mg, 1.05 mmol) gave **22α**, 188 mg (79%), as a colorless syrup; $[\alpha]_D^{25}$ +32.5° (*c* 1.0, methanol). PMR (CD_3OD): δ 8.17 (d, 1H, H-5), 6.96 (d, 1H, H-4), 6.32 (q, 1H, H-1′), 4.39 (m, 2H, H-3′, H-4′), 3.72 (m, 2H, H-5′,5″), 3.12—2.34 (m, 2H, H-2′,2″). UV: λ_{max}^{water} 212 nm (ε 12800), λ_{max}^{pH1} 198 nm (ε 12500), λ_{max}^{pH13} 218 nm (ε 11800). Found: 47.26; H, 5.95; N, 18.19%. Calcd for $C_9H_{13}O_4N_3$: C, 47.57; H, 5.77; N, 18.49%.

*1-(2-Deoxy-β-*D*-erythro-pentofuranosyl)pyrazole-5-carboxamide (**23β**).* By a procedure similar to that described above, **19β** (102 mg, 0.546 mmol) gave **23β**, a colorless glass, 36 mg (82%); $[\alpha]_D^{25}$ −69.5° (*c* 1.0, methanol). PMR (CD_3OD): δ 7.82 (d, 1H, H-3) 7.33 (t, 1H, H-1′), 7.03 (d, 1H, H-4), 4.7—4.18 (m, 2H, H-3′, H-4′), 3.90 (m, 2H, H-5′, 5″), 3.23—2.30 (m, 2H, H-2′,2″). UV: λ_{max}^{water} 220 (ε 12800), λ_{max}^{pH1} 198 (ε 13000), λ_{max}^{pH13} 220 nm (ε 11000).

Found: C, 47.45; H, 5.80; N, 18.64%. Calcd for $C_9H_{13}O_4N_3$: C, 47.57; H, 5.77; N, 18.49%.

*1-(2-Deoxy-α-*D*-erythro-pentofuranosyl)pyrazole-5-carboxamide (**23α**).* By a procedure similar to that described above, **19α** (68 mg, 0.123 mmol) gave **23α**, 21.2 mg (76%), as a colorless glass; $[\alpha]_D^{25}$ +18.3° (*c* 1.0, methanol). PMR (CD_3OD): δ 7.80 (d, 1H, H-3), 7.29 (q, 1H, H-1′), 7.00 (d, 1H, H-4), 4.7—4.2 (m, 2H, H-3′, H-4′), 3.85 (m, 2H, H-5′,5″), 3.20—2.25 (m, 2H, H-2′,2″). UV: λ_{max}^{water} 219 (ε 8300), λ_{max}^{pH1} 200 (ε 8100), λ_{max}^{pH13} 220 nm (ε 9000). Found: C, 47.38; H, 5.85; N, 18.60%. Calcd for $C_9H_{13}O_4N_3$: C, 47.57; H, 5.77; N, 18.49%.

*1-(2-Deoxy-*D*-erythro-pentofuranosyl)pyrazole-3,5-dicarboxamide (**24**).* A solution of **20** (800 mg, 1.28 mmol) in absolute methanol (120 ml) saturated with ammonia at 0 °C was kept at room temperatuer for 12 h, and then heated at 90 °C for 30 h in a sealed tube. The solution was evaporated and the resultant syrup was chromatographed on a silica gel column (40 g, 2×30 cm, packed with 4 : 1 chloroform–methanol): Elution by the same solvent system afforded a syrup of **24**, 218 mg (63%); PMR (DMSO-d_6): δ 7.30 (d, 1H, H-4), 7.00 (tq, 1H, H-1′), 4.8—4.2 (m, 2H, H-3′, H-4′), 3.80 (m, 2H, H-5′,5″), 2.80 (m, 2H, H-2′,2″). Found: C, 44.19; H, 5.18; N, 20.61%. Calcd for $C_{10}H_{14}O_5N_4$: C, 44.44; H, 5.22; N, 20.73%.

*1-(2-Deoxy-*D*-erythro-pentofuranosyl)-4-nitropyrazole-3,5-dicarboxamide (**25**).* By a procedure similar to that described above, **21** (600 mg, 0.91 mmol) gave **25** as an anomeric mixture, 179 mg (61%); PMR (CD_3OD): δ 6.40 (tq, 1H, H-1′), 4.40 (m, 2H, H-3′, H-4′), 3.78 (m, 2H, H-5′,5″), 2.80 (m, 2H, H-2′,2″). Found: C, 38.01; H, 4.00; N, 22.09%. Calcd for $C_{10}H_{13}O_7N_5$: C, 38.10; H, 4.16;N, 22.22%.

The authors wish to thank Mr. Saburo Nakada, Department of Chemistry, Keio University, for microanalysis. This research was supported in part by a grant for cancer research, Ministry of Education, Science and Culture.

Steric Control in the Diels-Alder Reaction[1]

Kazuyoshi SEGUCHI,* Akira SERA,** and Kazuhiro MARUYAMA
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received January 24, 1976)

The Diels-Alder reactions of polychlorocyclopentadienes with substituted ethylenes were investigated, and the rates of the reaction and the *endo* : *exo* adduct distributions were determined. The introduction of a chlorine atom at the C_5 position of cyclopentadiene resulted in an enhanced *endo* preference for substituents in the adducts, despite the depressed reactivity of the diene. This is contrary to what is to be expected from the so-called "selectivity-reactivity relationship in the Diels-Alder reaction." The results in this work were explained in terms of steric interaction between the C_5-chlorine atom of the diene and the substituent of dienophiles.

Many investigators have been interested in *endo* selectivity in the Diels-Alder reaction from both experimental and theoretical points of view. Many factors have been considered to be responsible for the stereochemistry of the reaction.[2-7] However, the elucidation of the steric factor seems to remain incomplete. Early, Martin, and Hill[3] ascribed the deviation from the *endo* rule[2a,3] mainly to a repulsive interaction between the methylene group of cyclopentadiene and substituent(s) of dienophile. This concept has also been employed widely in other reactions.[4] Kobuke *et al.*[6] pointed out the importance of the dispersion force rather than the steric factor in the same reaction.

In the course of our investigation of the correlation between the selectivity and the reactivity in the Diels-Alder reaction,[7] we found a significant deviation when hexachlorocyclopentadiene was employed as a diene. The reaction was found to give *endo* adducts preferentially, although low *endo* adduct distributions were predicted from the correlation.[7] This paper will be concerned with the enhanced *endo* epimer preference of the Diels-Alder reaction of polychlorocyclopentadienes. The role of steric interaction will be discussed in connection with the selectivity-reactivity correlation in the Diels-Alder reaction.

Results and Discussion

The rates and the epimer distributions in the Diels-Alder reactions of 1,2,3,4-tetrachloro- (**1a**) and hexachlorocyclopentadiene (**1c**) with methyl acrylate and styrene were examined by means of GLC. The results are tabulated in Table 1. We already pointed out in the previous paper[7] that the more reactive addenda there are, the more selective the Diels-Alder reaction, where secondary orbital interaction plays an important role. However, Reactions 2 and 3 in Table 1 gave rather high *endo* epimer distributions in spite of the lower reactivity of the substrates. This anormalous behavior is shown definitely in Fig. 1 as a significant deviation from the selectivity-reactivity correlation (Points 2 and 3), while no such deviation was observed in the reaction of tetrachlorocyclopentadiene (Point 1). These facts are likely to indicate the relative importance of steric interaction between the chloromethylene group of **1c** and the substituent of a dienophile; the electronic effect or the secondary orbital interaction plays a subordinate role. Accordingly, we examined more systematically the steric control for the *endo*

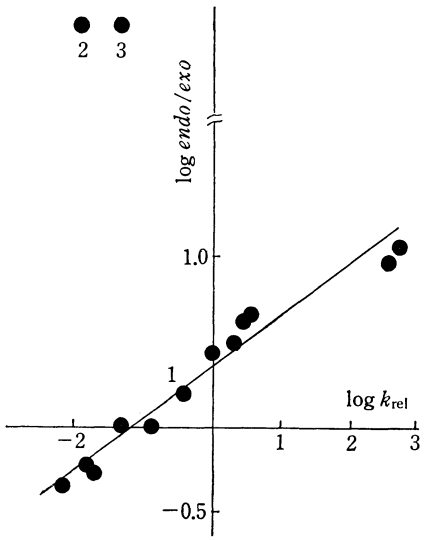

Fig. 1. A correlation of selectivity (log *endo*/*exo*) and reactivity (log k_{rel}) in the Diels-Alder reaction. Numerals denote the reaction numbers cited in Table 1; for the other points (not numbered), see Ref. 7.

selectivity in the Diels-Alder reaction.

The following sets of reactions were carried out in *p*-xylene at 90 °C: diene; **1a** and **1c**: dienophile; monosubstituted ethylenes (methyl acrylate, acrylic acid, acrylonitrile, vinyl acetate, and styrene) and 1,1-disubstituted ethylenes (corresponding alkyl-substituted derivatives). The reactions proceeded smoothly when monosubstituted ethylenes were employed as dienophiles. However, the reactions of **1c** with 1,1-disubstituted ethylenes were not very fast; even after fifteen days at 90 °C the yields of the products were about 30% (the starting materials were recovered). In all the case, the reaction mixtures were readily separated to the *exo* and *endo* isomers by means of GLC. The *endo* isomer distribution was determined by means of GLC or NMR. The *endo* : *exo* isomer ratio was almost independent of the reaction times. The results are tabulated in Table 2, together with the reported data of the reactions of 1,2,3,4,5-pentachlorocyclopentadiene (**1b**).[8] Since the reaction of **1b** gave a mixture of *anti-endo*, *syn-endo*, and *syn-exo* isomers, the 7-*syn*-chloro-*endo*/7-*syn*-chloro-*exo* ratios are also given in Table 2.

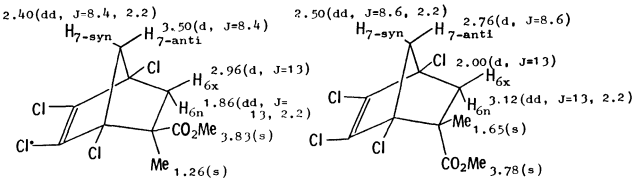
(**1c**) R=Cl OAc, Ph

Scheme 1.

The configuration of the isomeric adducts was deduced by means of NMR analysis, taking into account the following characteristic signals of norbornene derivatives. The shielding effect of the double bond in 5-substituted 2-norbornene leads the proton signals



Scheme 2. Chemical shift in ppm, coupling constant in Hz.

of the 5-*endo* substituents to a higher field than those of the corresponding *exo* substituents. A long-range coupling over the planar W-letter configuration is present between H_{7-syn} and $H_{5n,6n}$. An *exo*-oriented Y makes the difference in the chemical shift between H_{7-syn} and H_{7-anti} larger than an *endo*-oriented Y does. A typical example is shown in Scheme 2 for the adducts of **1a** with methyl methacrylate (**2x** and **2n**).

5-*endo*-Methyl protons in **2x** and *endo*-5-methoxycarbonyl methyl protons in **2n** absorb at a higher field than the corresponding protons of their isomers. The signal of H_{6n} is split into a double doublet by the long-range coupling with H_{7-syn} (J=2.2 Hz) as well as by the coupling with H_{6x}. The configurations of the isomers of the other Diels-Alder adducts were similarly analyzed. The chemical shift and the splitting pattern of these compounds were similar to those of

the reported compounds.[8-11]

On the other hand, in the reactions of **1c** with methyl acrylate, acrylic acid, vinyl acetate, styrene, and isopropenyl acetate, only ones (**3n**—**7n**) of the epimeric adducts were produced (Scheme 3). The configurations of these adducts were determined by zinc–acetic acid reduction.[12] The procedure is known to give the corresponding 1,2,3,4-*syn*-7-pentachloronorbornene derivatives stereoselectively. The reduction products, **9n**—**11n**, were proved to be identical with the respective known compounds by a comparison with their NMR spectra.[8] That is, all of the adducts, **3n**—**6n**, were found to have the *endo* configuration. The configuration of **4n** was determined after it had been converted into **3n** by diazomethane.

The configuration of **12n** was deduced on the basis of the following NMR spectral evidence. The replacement of a 7-*anti*-chlorine atom by a hydrogen atom must affect the chemical shift of 5-*exo*-methyl protons more markedly than that of 5-*endo*-methyl protons. This concept was exemplified by the fact that, of the two epimeric adducts of **1c** with methacrylonitrile, the 5-*endo*-cyano-5-*exo*-methyl epimer (**8n**) revealed its methyl signal at δ 1.98, while the 5-*endo*-methyl-5-*exo*-cyano epimer (**8x**) did so at δ 1.47. Upon the above-cited reduction, **8n** gave **13n**, in which the methyl group resonated at δ 1.71. Similarly, **8x** gave **13x**, with its methyl signal at δ 1.42. That is, the replacement of a 7-*anti*-chlorine atom by a hydrogen atom led the 5-*exo*-methyl signal to a field higher by 0.27 ppm, but had little effect on the 5-*endo*-methyl signal. The chemical-shift difference of the methyl signal of **7n** (δ 2.00) and that of **12n** (δ 1.80) manifested an *exo* configuration for these methyl groups. Accordingly, **7n** was determined to be the 5-*endo*-acetoxy-5-*exo*-methyl epimer.

As is shown in Table 2, the introduction of succesive chlorine atoms at the C_5 position of cyclopentadiene resulted in enhanced *endo* adduct distributions for the reactions of polychlorocyclopentadienes with monosubstituted ethylenes. According to the "Diels-Alder selectivity-reactivity relationship,"[7] the less reactive diene, **1c**, may be anticipated to reveal a lower *endo* selectivity than **1a**. However, this was not the case. The *endo* selectivity for the Diels-Alder reactions of cyclopentadiene has been thought, in general, to be caused by dipole-dipole interaction, attractive force, and other ineractions. However, in the present case, the dienes have chlorine atoms at the C_5 position, so the steric situation should be some what different from the usual Diels-Alder reactions. That is, *exo*-orienting substituent in a transition state should experience rather strong steric crowding. The high *endo* epimer distributions observed for the reactions of **1b** and **1c** suggest that the substituents of the dienophiles are forced to occupy the sterically less hindered *endo* position. In addition, the *endo* : *exo* ratios for **1a** and the 7-*syn*-chloro-*endo* : 7-*syn*-chloro-*exo* ratios for **1b** change almost in parallel with the change in the substituent of dienophiles. Furthermore, no 7-*anti*-chloro-*exo* isomers were found in the adducts of **1b** with monosubstituted ethylenes.[8] These facts clearly indicate the existence of steric repulsion between the *anti* chlorine atom and the *exo* substituent in the transition state. This can be further explained by inspecting the results obtained from the reactions of **1a** and **1c** with 1,1-disubstituted ethylenes. Here, two substituents, X and Y, occupy competitively the *endo* position in the transition state. Table 2 shows that the amounts of the *endo* adducts increase remarkably when the methylene hydrogen atoms of **1a** are replaced by chlorine atoms. Methacrylonitrile reveals a lower *endo*-CN preference in the reaction with **1c**. This is in good accord with Mark's consideration that the sterically least demanding cyano group is forced to the rather unfavored *exo* position when it is in competition with a bulkier group.[13] In addition, such steric crowding in the transition state will be responsible for the lower reactivity of **1c** toward 1,1-disubstituted ethylenes, as is shown in Table 2.

In conclusion, in the Diels-Alder reactions of polychlorocyclopentadienes with substituted ethylenes the steric requirement of bulkier substituents should be considered as one of the predominant factors in determining the *endo* selectivity and should cause the deviation from the selectivity-reactivity relationship.

Experimental

The NMR spectra were recorded on a JEOL PS-100 spectrometer, using TMS as the internal standard. The analytical determination by GLC was performed on a JEOL 20 K gas chromatograph.

Materials. Hexachlorocyclopentadiene (**1c**) was commercially obtained and was distilled; bp 116 °C/17 Torr. The preparation and purification of other diene and dienophiles were reported previously.[7]

The Diels-Alder Reaction and Analytical Procedure. In a typical run, a mixture of 7.3×10^{-3} M of a dienophile, 2.8×10^{-2} M of a diene, and 2 ml of *p*-xylene was sealed in a glass ampoule maintained at 90±0.1 °C. The reaction time was changed from 15 to 72 h for the reactions with 1,2,3,4-tetrachlorocyclopentadiene (**1a**) and from 40 to 300 h for the reactions of hexachlorocyclopentadiene (**1c**) according to the reactivity of the dienophiles. The Diels-Alder adducts were analyzed by means of GLC and NMR, after passage to a bed of silica gel, if neccesary. Stainless steel columns (2 m) packed with 7% Silicon QF-1 (Column A), 5% PEG 20 M (Column B), and 5% Silicon DC550 (Column C) on a Diasolid L were used. For the adducts of **1a**, *endo* isomers showed longer retention times, while for the adducts of **1c** they showed shorter retention times.

Kinetics. Stock solutions of a diene and a dienophile in butyl chloride were prepared and stored in a freezer. Aliquots were taken from the stock solutions and mixed for

each kinetic run. Analysis was done by means of GLC. The initial concentrations of the diene and the dienophile, the column specifications, and the internal standards for quantitative GLC analyses are shown in Table 3. All the reactions studied were clearly second-order and gave a single product or a mixture of *endo* and *exo* isomeric products.

Reaction of **1a** *with Methyl Acrylate.* The Diels-Alder adducts, 1,2,3,4-tetrachloro-5-*endo*-methoxycarbonylbicyclo-[2.2.1]hept-2-ene (**14n**) and its 5-*exo* isomer (**14x**), were separated by the use of Column A at 160 °C (retention times: **14n**, 8.5 min; **14x**, 6.3 min). Mp: **14n**, 86—87 °C; **14x**, 61.5—62.5 °C. NMR (δ): **14n**, 3.78 (3H, s, CO_2CH_3), 3.40 (1H, dd, J=4 and 8 Hz, 5-*exo*-H), 2.52 (2H, bs, 7-*syn*-H and 7-*anti*-H), 2.40—2.50 (2H, m, 6-*endo*-H and 6-*exo*-H); **14x**, 3.83 (3H, s, CO_2CH_3), 2.92 (1H, m, J=2, 4, and 8 Hz, 5-*endo*-H), 3.32 (1H, d, J=8 Hz, 7-*anti*-H), 2.58 (1H, dd, J=4 and 12 Hz, 6-*exo*-H), 2.24—2.32 (2H, m, 6-*endo*-H and 7-*syn*-H). Found: **14n**, C, 36.89; H, 2.79; Cl, 49.05%; **14x**, C, 37.29; H, 2.69; Cl, 48.88%. Calcd for $C_9H_8O_2Cl_4$: C, 37.27; H, 2.78; Cl, 48.99%.

Reaction of **1a** *with Acrylic Acid.* The isomeric distribution was determined by means of the NMR spectra. The Diels-Alder adducts, 1,2,3,4-tetrachloro-5-*endo*-carboxybicyclo-[2.2.1]hept-2-ene (**15n**) and its 5-*exo* isomer (**15x**), were fractionated by recrystallization from benzene–hexane. They were then esterified by diazomethane, and the products were identified by means of GLC with **14n** and **14x** respectively. Mp: **15n**, 161 °C; **15x**, 127—129 °C. NMR (δ): **15n**, 9.30 (1H, s, CO_2H), 3.44 (1H, dd, J=4 and 8 Hz, 5-*exo*-H), 2.41—2.48 (4H, m, other protons); **15x**, 10.45 (1H, s, CO_2H), 3.12 (1H, d, J=8 Hz, 7-*anti*-H), 2.92 (1H, m, J=1, 4, and 8 Hz, 5-*endo*-H), 2.26—2.60 (3H, m, other protons). Found: **15n**, C, 34.57; H, 1.94; Cl, 51.20%; **15x**, C, 35.00; H, 2.18; Cl, 51.22%. Calcd for $C_8H_6O_2Cl_4$: C, 34.82; H, 2.19; Cl, 51.40%.

Reaction of **1a** *with Vinyl Acetate.* The Diels-Alder adducts, 1,2,3,4-tetrachloro-5-*endo*-acetoxybicyclo[2.2.1]hept-2-ene (**16n**) and its 5-*exo* isomer (**16x**), were separated by the use of Column B at 150 °C (retention times: **16n**, 16.3 min; **16x**, 14.1 min). Mp: **16n**, 52—53 °C; **16x**, colorless liquid. NMR (δ): **16n**, 5.54 (1H, dd, J=2 and 8 Hz, 5-*exo*-H), 2.78 (1H, dd, J=8 and 12 Hz, 6-*exo*-H), 2.50—2.58 (2H, bs, 7-*syn*-H and 7-*anti*-H), 2.10 (3H, s, $OCOCH_3$), 1.84 (1H, dd, J=3 and 12 Hz, 6-*endo*-H); **16x**, 5.02 (1H, m, J=1, 3, and 8 Hz, 5-*endo*-H), 2.87 (1H, d, J=8 Hz, 7-*anti*-H), 2.56—2.66 (2H, m, 6-*exo*-H and 7-*syn*-H), 2.17 (3H, s, $OCOCH_3$), 2.02 (1H, dd, J=3 and 12 Hz, 6-*endo*-H). Found: **16n**, C, 37.43; H, 3.05%; **16x**, C, 37.08; H, 2.66%. Calcd for $C_9H_8O_2Cl_4$: C, 37.27; H, 2.78%.

Reaction of **1a** *with Acrylonitrile.* The Diels-Alder adducts, 1,2,3,4-tetrachloro-5-*endo*-cyanobicyclo[2.2.1]hept-2-ene (**17n**) and its 5-*exo* isomer (**17x**), were separated by the use of Column A at 160 °C (retention times: **17n**, 13.5 min; **17x**, 9.7 min). Mp: **17n**, 75—76 °C; **17x**, 92—93 °C. NMR (δ): **17n**, 3.50 (1H, dd, J=4 and 10 Hz, 5-*exo*-H), 2.74 (1H, dd, J=10 and 12 Hz, 6-*exo*-H), 1.50 (2H, bs, 7-*syn*-H and 7-*anti*-H), 1.34 (1H, dd, J=4 and 12 Hz, 6-*endo*-H); **17x**, 3.02 (1H, m, J=2, 5, and 9 Hz, 5-*endo*-H), 2.86 (1H, d, J=8 Hz, 7-*anti*-H), 2.53—2.74 (3H, m, 7-*syn*-H, 6-*endo*-H, and 6-*exo*-H). Found: **17n**, C, 37.58; H, 1.71; Cl, 55.53%; **17x**, C, 37.37; H, 1.71; Cl, 55.18%. Calcd for $C_8H_5NCl_4$: C, 37.44; H, 1.98; Cl, 55.20%.

Reaction of **1a** *with Styrene.* The Diels-Alder adducts, 1,2,3,4-tetrachloro-5-*endo*-phenylbicyclo[2.2.1]hept-2-ene (**18n**) and its 5-*exo* isomer (**18x**), were separated by the use of Column A at 180 °C (retention times: **18n**, 10.2 min; **18x**, 9.1 min). Mp: **18n**, 64—65 °C; **18x**, colorless liquid. NMR (δ): 6.96—7.28 (5H, m, Ph), 3.64 (1H, dd, J=4 and 8 Hz, 5-*exo*-H), 2.32—2.76 (4H, m, other protons); **18x**, 7.30 (5H, s, Ph), 3.10 (1H, m, J=1, 5, and 8 Hz, 5-*endo*-H), 2.80 (1H, d, J=8 Hz, 7-*anti*-H), 2.40—2.76 (3H, m, other protons). Found: **18n**, C, 50.84; H, 3.31%; **18x**, C, 50.85; H, 2.95%. Calcd for $C_{13}H_{10}Cl_4$: C, 50.68; H, 3.27%.

Reaction of **1a** *with Methyl Methacrylate.* The Diels-Alder adducts, 1,2,3,4-tetrachloro-5-*endo*-methoxycarbonyl-5-*exo*-methylbicyclo[2.2.1]hept-2-ene (**2n**) and its 5-*exo*-methoxycarbonyl-5-*endo*-methyl isomer (**2x**), were separated by the use of Column A at 160 °C (retention times: **2n**, 8.7 min; **2x**, 7.0 min) after passage through a bed of silica gel (using benzene–hexane as the eluent). Mp: **2n**, 58.5—59.5 °C; **2x**, 64.5—65.5 °C. The NMR data of these compounds are shown in Scheme 2. Found: **2n**, C, 39.41; H, 3.19%; **2x**, C, 39.23; H, 3.17%. Calcd for $C_{10}H_{10}O_2Cl_4$: C, 39.51; H, 3.32%.

Reaction of **1a** *with Methyl 2-Butylacrylate.* The Diels-Alder adducts, 1,2,3,4-tetrachloro-5-*endo*-methoxycarbonyl-5-*exo*-butylbicyclo[2.2.1]hept-2-ene (**19n**) and its 5-*exo*-methoxycarbonyl-5-*endo*-butyl isomer (**19x**), were separated by the use of Column A at 180 °C (retention times; **19n**; 21.1 min; **19x**, 13.8 min). Mp: **19n**, 77—80 °C; **19x**, colorless liquid. NMR (δ): **19n**, 3.78 (3H, s, CO_2CH_3), 3.02 (1H, dd, J=2 and 12 Hz, 6-*endo*-H), 2.72 (1H, d, J=8 Hz, 7-*anti*-H), 2.46 (1H, dd, J=2 and 8 Hz, 7-*syn*-H), 1.98 (1H, d, J=12 Hz, 6-*exo*-H), 0.96—1.60 (9H, m, Bu); **19x**, 3.87 (3H, s, CO_2CH_3), 3.17 (1H, d, J=8 Hz, 7-*anti*-H), 2.98 (1H, d, J=12 Hz, 6-*exo*-H), 2.34 (1H, dd, J=2 and 12 Hz, 7-*syn*-H), 1.90 (1H, dd, J=2 and 12 Hz, 6-*endo*-H), 0.92—1.55 (9H, m, Bu). Found: **19n**, C, 44.95; H, 4.63%; **19x**, 45.28; H, 4.63%. Calcd for $C_{13}H_{16}O_2Cl_4$: C, 45.11; H, 4.66%.

Reaction of **1a** *with Isopropenyl Acetate.* The isomer distribution was determined by means of GLC using Column A (retention times: 1,2,3,4-tetrachloro-5-*endo*-acetoxy-5-*exo*-methylbicyclo[2.2.1]hept-2-ene (**20n**), 8.2 min; and its 5-*exo*-acetoxy-5-*endo*-methyl isomer (**20x**), 7.2 min). However, the pure isomers could not be obtained because their retention times were too close to each other. NMR (δ, characteristic signals): **20n**, 1.76 (s, 5-CH_3), 1.92 (s, $OCOCH_3$); **20x**, 1.44 (s, 5-CH_3), 2.04 (s, $OCOCH_3$). For the isomer mixture, Found: C, 39.57; H, 3.26%. Calcd for $C_9H_8O_2Cl_4$: C, 39.51; H, 3.32%.

Reaction of **1a** *with Methacrylonitrile.* The Diels-Alder adducts, 1,2,3,4-tetrachloro-5-*endo*-cyano-5-*exo*-methylbicyclo-[2.2.1]hept-2-ene (**21n**) and its 5-*exo*-cyano-5-*endo*-methyl isomer (**21x**), were separated by the use of Column A at 155 °C (retention times: **21n**, 12.0 min; **21x**, 7.7 min). Mp: **21n**, 99—100 °C; **21x**, colorless liquid. NMR (δ): **21n**, 2.70 (1H, dd, J=2 and 12 Hz, 6-*endo*-H), 2.60 (2H, m, 7-*syn*-H and 7-*anti*-H), 2.27 (1H, d, J=12 Hz, 6-*exo*-H), 1.75 (3H, s, CH_3); **21x**, 3.01 (1H, d, J=10 Hz, 7-*anti*-H), 2.86 (1H, d, J=13 Hz, 6-*exo*-H), 2.64 (1H, dd, J=3 and 10 Hz, 7-*syn*-H), 2.10 (1H, dd, J=3 and 13 Hz, 6-*endo*-H), 1.42 (3H, s, CH_3). Found: **21n**, C, 39.89; H, 2.55%; **21x**, C, 39.76; H, 2.49%. Calcd for $C_9H_7NCl_4$: C, 39.89; H, 2.60%.

Reaction of **1a** *with* α*-Methylstyrene.* The isomeric distribution was determined by means of GLC using Column A at 180 °C (retention times: 1,2,3,4-tetrachloro-5-*endo*-phenyl-5-*exo*-methylbicyclo[2.2.1]hept-2-ene (**22n**), 8.8 min and its 5-*exo*-phenyl-5-*endo*-methyl isomer (**22x**), 7.8 min). However, the pure isomers could not be obtained because their retention times were too close to each other. NMR (δ, characteristic signals): **22n**, 1.76 (s, CH_3); **22x**, 1.45

(s, CH_3). For the isomer mixture, Found: C, 52.75; H, 3.81%. Calcd for $C_{14}H_{10}Cl_4$: C, 52.21; H, 3.76%.

Reaction of ***1c*** *with Methyl Acrylate.* The GLC, TLC, and NMR all indicated the presence of a single product, 1,2,3,4,7,7-hexachloro-5-*endo*-methoxycarbonylbicyclo[2.2.1]-hept-2-ene (**3n**); bp 140—145 °C/7 Torr. NMR (δ): 3.65 (1H, dd, J=4 and 7 Hz, 5-*exo*-H), 2.60—2.76 (2H, m, 6-*endo*-H and 6-*exo*-H), 3.82 (3H, s, CO_2CH_3). Found: C, 30.13; H, 1.91; Cl, 59.55%. Calcd for $C_9H_6O_2Cl_6$: C, 30.12; H, 1.69; Cl, 59.28%.

Reaction of ***1c*** *with Acrylic Acid.* The NMR indicated the presence of a single product, 1,2,3,4,7,7-hexachloro-5-*endo*-carboxybicyclo[2.2.1]hept-2-ene (**4n**); mp 142—145 °C. This product was esterified to **3n** by diazomethane. NMR (δ): 11.36 (1H, s, CO_2H), 3.70 (1H, dd, J=4 and 8 Hz, 5-*exo*-H), 2.78 (1H, dd, J=8 and 12 Hz, 6-*exo*-H), 2.62 (1H, dd, J=4 and 12 Hz, 6-*endo*-H). Found: C, 27.84; H, 1.08; Cl, 61.58%. Calcd for $C_8H_4O_2Cl_6$: C, 27.86; H, 1.17; Cl, 61.69%.

Reaction of ***1c*** *with Vinyl Acetate.* The GLC, TLC, and NMR all indicated the presence of a single product, 1,2,3,4,7,7-hexachloro-5-*endo*-acetoxybicyclo[2.2.1]hept-2-ene (**5n**); mp 42.5—43.0 °C. NMR (δ): 5.64 (1H, dd, J=3 and 8 Hz, 5-*exo*-H), 3.10 (1H, dd, J=8 and 13 Hz, 6-*exo*-H), 2.05 (3H, s, $OCOCH_3$), 1.95 (1H, dd, J=3 and 13 Hz, 6-*endo*-H). Found: C, 29.89; H, 1.55; Cl, 59.49%. Calcd for $C_9H_6O_2Cl_6$: C, 30.12; H, 1.69; Cl, 59.28%.

Reaction of ***1c*** *with Styrene.* The GLC, TLC, and NMR all indicated the presence of a single product, 1,2,3,4,7,7-hexachloro-5-*endo*-phenylbicyclo[2.2.1]hept-2-ene (**6n**); mp 74—75 °C. NMR (δ): 6.96—7.40 (5H, m, Ph), 3.90 (1H, dd, J=4 and 12 Hz, 5-*exo*-H), 2.84 (1H, dd, J=8 and 12 Hz, 6-*exo*-H), 2.42 (1H, dd, J=4 and 12 Hz, 6-*endo*-H). Found: C, 41.53; H, 1.92; Cl, 56.17%. Calcd for $C_{13}H_8Cl_6$: C, 41.42; H, 2.14; Cl, 56.44%.

Reaction of ***1c*** *with Acrylonitrile.* The Diels-Alder adducts, 1,2,3,4,7,7-hexachloro-5-*endo*-cyanobicyclo[2.2.1]-hept-2-ene (**23n**) and its 5-*exo*-isomer (**23x**), were separated by the use of Column A at 165 °C (retention times: **23n**, 9.8 min; **23x**, 15.7 min). Mp: **23n**, 141—143 °C; **23x**, 72—75 °C. NMR (δ): **23n**, 3.62 (1H, dd, J=4 and 8 Hz, 5-*exo*-H), 2.86 (1H, dd, J=8 and 12 Hz, 6-*exo*-H), 2.32 (1H, dd, J=4 and 12 Hz, 6-*endo*-H); **23x**, 3.06 (1H, dd, J=4 and 8 Hz, 5-*endo*-H), 2.76 (1H, dd, J=4 and 12 Hz, 6-*exo*-H), 2.42 (1H, dd, J=8 and 12 Hz, 6-*endo*-H). Found: **23n**, C, 29.49; H, 0.86; Cl, 64.84%; **23x**, C, 30.35; H, 0.98; Cl, 63.92;. Calcd for $C_9H_3NCl_6$: C, 29.49,; H, 0.93; Cl, 65.29%.

Reaction of ***1c*** *with Methyl Methacrylate.* Since the GLC peaks of the Diels-Alder adducts, 1,2,3,4,7,7-hexachloro-5-*endo*-methoxycarbonyl-5-*exo*-methylbicyclo[2.2.1]hept-2-ene (**24n**) and its 5-*exo*-methoxycarbonyl-5-*endo*-methyl isomer (**24x**), did not resolve satisfactorily, the isomer distribution was determined by the integration of the NMR spectra. A mixture of **24n** and **24x**; mp 68—70 °C. NMR (δ, characteristic signals): **24n**, 3.79 (s, CO_2CH_3), 1.80 (s, 5-CH_3); **24x**, 3.85 (s, CO_2CH_3), 1.38 (s, 5-CH_3). For the same mixture, Found: C, 32.82; H, 2.17%. Calcd for $C_{10}H_8O_2Cl_6$: C, 32.21; H, 2.16%.

Reaction of ***1c*** *with Methyl 2-Butylacrylate.* Since the GLC peaks of the Diels-Alder adducts, 1,2,3,4,7,7-hexachloro-5-*endo*-methoxycarbonyl-5-*exo*-butylbicyclo[2.2.1]hept-2-ene (**25n**) and its 5-*exo*-methoxycarbonyl-5-*endo*-butyl isomer (**25x**), did not resolve satisfactorily, the isomer distribution was determined by the integration of the NMR spectra. NMR (δ, characteristic signals): **25n**, 3.78 (s, CO_2CH_3), 3.18 (d, J=12 Hz, 6-*endo*-H), 2.44 (d, J=12 Hz, 6-*exo*-H); **25x**, 3.96 (s, CO_2CH_3), 3.39 (d, J=12 Hz, 6-*exo*-H), 1.95 (d, J=12 Hz, 6-*endo*-H). Found: C, 37.62; H, 3.11; Cl, 51.53%. Calcd for $C_{13}H_{14}O_2Cl_6$: C, 37.62; H, 3.40; Cl, 51.27%.

Reaction of ***1c*** *with Isopropenyl Acetate.* The GLC and NMR indicated the presence of a single product, 1,2,3,4,7,-7-hexachloro-5-*endo*-acetoxy-5-*exo*-methylbicyclo[2.2.1]hept-2-ene (**7n**); colorless liquid. NMR (δ): 2.85 (2H, s, 6-*endo*-H and 6-*exo*-H), 2.02 (3H, s, $OCOCH_3$), 2.00 (3H, s, CH_3). Found: C, 32.51; H, 2.17; Cl, 57.11%. Calcd for $C_{10}H_8O_2Cl_6$: C, 32.21; H, 2.16; Cl, 57.05%.

Reaction of ***1c*** *with Methacrylonitrile.* The Diels-Alder adducts, 1,2,3,4,7,7-hexachloro-5-*endo*-cyano-5-*exo*-methylbicyclo[2.2.1]hept-2-ene (**8n**) and its 5-*exo*-cyano-5-*endo*-methyl isomer (**8x**), were separated by the use of Column A at 180 °C (retention times: **8n**, 7.0 min; **8x**, 8.7 min). Mp: **8n**, 185—188 °C; **8x**, 144—145 °C. NMR (δ): **8n**, 2.80 (2H, s, 6-*endo*-H and 6-*exo*-H), 1.98 (3H, s, CH_3); **8x**, 3.12 (1H, d, J=12 Hz, 6-*exo*-H), 2.12 (1H, d, J=12 Hz, 6-*endo*-H), 1.47 (3H, s, CH_3). Found: **8n**, C, 31.84; H, 1.36; Cl, 62.49%; **8x**, C, 32.00; H, 1.40; Cl, 62.42%. Calcd for $C_9H_5NCl_6$: C, 31.80; H, 1.48; Cl, 62.59%.

Reaction of ***1c*** *with α-Methylstyrene.* The Diels-Alder adducts, 1,2,3,4,7,7-hexachloro-5-*endo*-phenyl-5-*exo*-methylbicyclo[2.2.1]hept-2-ene (**26n**) and its 5-*exo*-phenyl-5-*endo*-methyl isomer (**26x**), were separated by the use of Column A at 180 °C (retention times: **26n**, 19.0 min; **26x**, 21.5 min). Mp: **26n**, 67—68 °C; **26x**, colorless liquid. NMR (δ): **26n**, 7.22 (5H, s, Ph), 3.12 (1H, d, J=14 Hz, 6-*exo*-H), 2.64 (1H, d, J=14 Hz, 6-*endo*-H), 1.90 (3H, s, CH_3); **26x**, 7.20—7.80 (5H, m, Ph), 3.50 (1H, d, J=13 Hz, 6-*exo*-H), 2.10 (1H, d, J=13 Hz, 6-*endo*-H), 1.38 (3H, s, CH_3). Found: **26n**, C, 42.92; H, 2.46; Cl, 54.11%; **26x**, C, 43.01; H, 2.71; Cl, 54.64%. Calcd for $C_{14}H_{10}Cl_6$: C, 43.21; H, 2.58, Cl, 54.48%.

Zinc-Acetic Acid Reductions of ***3n—8n.*** Williamson's procedure[12] was used, and the main products were collected by preparative gas chromatography (Column C at 170 °C). 1,2,3,4-*syn*-7-Pentachloro-5-*endo*-methoxycarbonylbicyclo-[2.2.1]hept-2-ene (**9n**), mp 58—59 °C (yield, 66%); lit,[8] 59—60 °C. 1,2,3,4-*syn*-7-Pentachloro-5-*endo*-acetoxybicyclo-[2.2.1]hept-2-ene (**10n**), mp 82—84 °C (yield, 57%); lit,[8] 83.5—84 °C. 1,2,3,4-*syn*-7-Pentachloro-5-*endo*-phenylbicyclo[2.2.1]hept-2-ene (**11n**), mp 61—63 °C (yield, 40%); lit,[8] 62—66 °C. 1,2,3,4-*syn*-7-Pentachloro-5-*endo*-cyano-5-*exo*-methylbicyclo[2.2.1]hept-2-ene (**13n**), mp 101—102 °C (yield, 91%). NMR (δ): 4.37 (1H, s, 7-*anti*-H), 2.78 (1H, d, J=13 Hz, 6-*endo*-H), 2.27 (1H, d, J=13 Hz, 6-*exo*-H), 1.71 (3H, s, CH_3). 1,2,3,4-*syn*-7-Pentachloro-5-*exo*-cyano-5-*endo*-methylbicyclo[2.2.1]hept-2-ene (**13x**), mp 112—114 °C (yield, 81%). NMR (δ): 4.66 (1H, s, 7-*anti*-H), 2.90 (1H, d, J=12 Hz, 6-*exo*-H), 2.17 (1H, d, J=12 Hz, 6-*endo*-H), 1.42 (3H, s, CH_3). Found: **13n**, C, 35.67; H, 2.06%; **13x**, C, 35.55; H, 2.11%. Calcd for $C_9H_6NCl_5$: C, 35.39; H, 1.98%. 1,2,3,4-*syn*-7-Pentachloro-5-*endo*-acetoxy-5-*exo*-methylbicyclo[2.2.1]hept-2-ene (**12n**), mp 74—75 °C (yield, 30%). NMR (δ): 4.30 (1H, s, 7-*anti*-H), 2.72 (1H, d, J=13 Hz, 6-*exo*-H), 2.42 (1H, d, J=13 Hz, 6-*endo*-H), 1.98 (3H, s, $OCOCH_3$), 1.80 (3H, s, CH_3). Found: C, 35.74; H, 2.85%. Calcd for $C_{10}H_9O_2Cl_5$: C, 35.48; H, 2.68%.

Studies on Lignoids in *Lauraceae*. II.[1] Studies on Lignans in the Leaves of *Machilus Japonica* Sieb. et Zucc.

Daisuke TAKAOKA, Keiko WATANABE, and Mitsuru HIROI

Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790

(Received February 2, 1976)

From the leaves of *Machilus japonica* Sieb. et Zucc., four lignans were isolated; they have been found to be (+)-galbacin [**1**], (+)-galbelgin [**2**], (−)-licarin-B [**4**], and a new lignan, machilusin, whose structure can be described as [**3a**] or [**3b**].

The leaves of most species of *Lauraceae* are known to contain the characteristic essential oil, but the systematic studies of the non-volatile components have been few. We planned such systematic studies of the lignans of *Lauraceae* and have already reported the isolation and characterization of several lignans from the leaves of *Cinnamomum Camphora* (Camphor tree).[1]

In this paper, we wish to report some lignans contained in the leaves of *Machilus japonica* Sieb. et Zucc.

Results

From an acetone extract of fresh leaves of *Machilus japonica* Sieb. et Zucc. (Japanese name: "Hosobatabu"), four lignans were isolated; they have been found to be enantiomers of (−)-galbacin[2] isolated from *Himantandra baccata* Bail (syn. *Galbulimima baccata*), of (−)-galbelgin[3] isolated from *Himantandra belgraveana* F. V. Mull., (−)-licarin-B[4] isolated from *Licaria aritu* Ducke (*Lauraceae*), and a new lignan, machilusin.

(+)-Galbacin [*1*]. Oxidation with potassium permanganate affords piperonylic acid. NMR and mass spectra show that this compound is a 2,5-diaryl-3,4-dimethyltetrahydrofuran. Furthermore, the chemical shift of the protons of the two methyl groups in the NMR spectrum indicates that each methyl group is located in *trans* relation to the vicinal aryl group.[5] From this fact, along with the optical activity (dextro), we conclude that this compound is (+)-galbacin [**1**]. The almost identical mp, the absolute value of $[\alpha]_D$, and the mass spectrum[6] confirm this conclusion.

(+)-Galbelgin [*2*]. Oxidation with potassium permanganate affords veratric acid. Mass and NMR spectra and optical activity (dextro) show that this lignan must be the enantiomer of (−)-gabelgin, as in the case of (+)-galbacin. This conclusion is confirmed by the NMR[5] and mass spectra,[6] which are almost identical with those of (−)-galbelgin. The reason why the mp is higher and the absolute value of $[\alpha]_D$ is larger than those reported for (−)-galbelgin is obscure, but we think that the latter might be contaminated with the optically inactive mesoisomer, galgravin, since (−)-galbelgin was isolated along with a very large amount of galgravin from *Himantandra belgrbeana* F. V. Mull.,[3] while we could not find any galgravin in *Machilus japonica* Sieb. et Zucc.

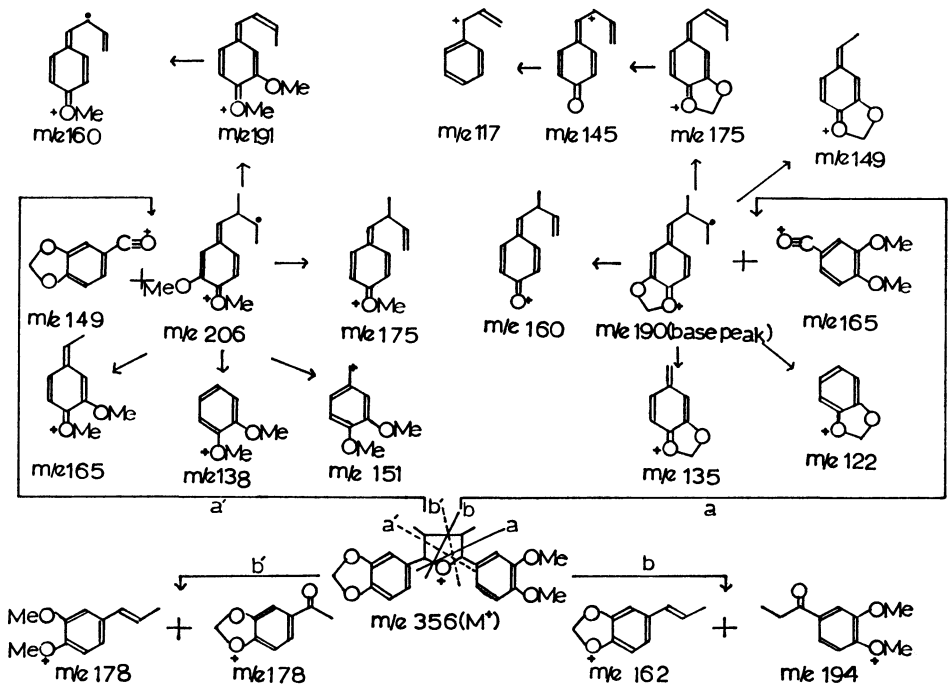
(−)-Machilusin [*3*]. This compound is a new lignan. Oxidation with potassium permanganate affords piperonylic acid and veratric acid (1 : 1). NMR and mass spectra indicate that this compoud is a 2,5-diaryl-3,4-dimethylterahydrofuran.

All of the major peaks of galbacin and galbelgin in the mass spectra have been well established;[6] in the same manner, the fragmentation of machilusin can be explained as represented in Scheme 1.

From the chemical shift of methyl protons in NMR spectrum, it is found that one of the methyl groups is located in *cis* relation and the other in *trans* relation to the vicinal aryl group.[5] Then the relative configuration of this compound can be represented as **3** or **5**.

(+)-Calopeptin[7] and (+)-veraguensin[5] have been reported to have the absolute configurations [**5a**] and [**5b**] respectively. The difference of $[\alpha]_D$ between them is relatively small, and the signals of CH_3CH– in their NMR spectra apear over a relatively wide range, *viz.* from δ 1.5 to 2.5 ppm.[7]

Machilusin is levorotatory and the absolute value of $[\alpha]_D$ differs considerably from the values for calopeptin and veraguensin. The signals of CH_3CH– in the NMR specrum appear in a narrow range, centered at δ 2.4 ppm. These facts indicate that the relative configuration of machilusin must be represented as **3**, *i.e. cis, cis, trans* configuration, not as **5**. In fact, the construction of a molecular model for **3** shows that the two CH_3CH– are so equivalent to each other



Scheme 1.

in the preferential conformation that they would appear in a narrow range in a NMR spectrum.

Then machilusin has either the configuration **3a** or **3b**. **3a** is supposed to be more rational from the viewpoint of the base peak (*m/e* 190) in the mass spectrum, because the bond between C2 and C3 (2,3-bond), bearing two *cis* substituents, may be considered to be cleaved more easily than the 4,5-bond bearing *trans* substituents. A lack of specimen prevented us from performing further studies

Licarin-B [*4*]. The 4th lignan was identified as licarin-B[4] isolated from *Licaria aritu* Ducke, by mp, $[\alpha]_D$ and spectral data.

Experimental

Instruments. $[\alpha]_D$ was measured by the use of Yanako OR-50 (Yanagimoto) and elemental analyses were carried out by CHN Corder MT-2 (Yanagimoto). IR, NMR, and mass spectra were obtained by using IR-400 (Shimadzu), JNM-4H-100 (JEOL), and JMS-01SG-2 (JEOL) respectively.

Isolation of Lignans. Fresh leaves of *Machilus japonica* Sieb. et Zucc., collected at Okitsu, Kochi prefecture, were extracted with acetone; the acetone solution was concentrated and the residue was extracted with hexane. The hexane solution, after concentration, was steam distilled to remove the volatile components and the residue was extracted with hexane. The resulting hexane solution was dried over anhydrous sodium sulfate and, after concentration, was chromatographed on a neutral alumina column (solvent: hexane–ethyl acetate, 95 : 5 to 50 : 50) into 14 fractions.

From the 4th and the 5th fractions, (+)-galbacin, the major lignan, was crystallized in mass, then recrystallized from ethyl acetate (yield: 0.3%).

From the 8th fraction, a white precipitate was filtered and recrystallized from ethyl acetate. The resulting crystals in rod form and the amorphous ones were separated from each other by handpicking. The former were recrystallized from ethyl acetate into pure (+)-gabelgin (yield: 0.005%).

The mother liquid of crude (+)-galbacin, obtained from the 5th fraction, was rechromatographed on a silica gel column (solvent: hexane–ethyl acetate, 95 : 5 to 50 : 50) into 21 fractions. Machilusin was obtained from the 18th fraction by preparative TLC (solvent : hexane–ethyl acetate, 80 : 20) as colorless flat plates (yield: 0.01%).

The 3rd fraction in the first chromatography was rechromatographed on a silica gel column (solvent: hexane–ethyl acetate, 100 : 0 to 60 : 40) into 25 fractions. From the 21st fraction, a pale yellow oil was obtained by means of preparative TLC (solvent: hexane containing 10% ethyl acetate), and this oil was dissolved in a minute amount of hot hexane. On cooling, licarin-B was deposited in white needle-like crystals (a minute amount).

(+)-Galbacin (1). The major lignan, mp 115.5—116 °C, $[\alpha]_D=+117.0°$ (in $CHCl_3$). Found: C, 70.63; H, 5.76%. Calcd for $C_{20}H_{20}O_5$: C, 70.59; H, 5.88%. NMR (δ ppm in $CDCl_3$): 1.03 (6H, d, $J=7$ Hz; CH_3), 1.75 (2H, m; H3, H4), 4.63 (2H, d, $J=9.5$ Hz; H2, H5), 5.97 (4H, s; OCH_2O), 6.75—7.0 (6H; aromatic H).

(+)-Galbelgin (2). Mp 142—142.5 °C, $[\alpha]_D=+129.0°$ (in $CHCl_3$). Found: C, 70.98; H, 7.46%. Calcd for $C_{22}H_{28}O_5$: C, 70.91; H, 7.53%. NMR (δ ppm in $CDCl_3$): 1.07 (6H, d, $J=6$ Hz; CH_3), 1.82 (2H, m; H3, H4), 3.90 (6H, s; CH_3O), 3.94 (6H, s; CH_3O), 4.69 (2H, d, $J=9$ Hz; H2, H5), 6.80—7.05 (6H; aromatic H). MS: *m/e* 372 (M^+), 206 (base peak), 194, 191, 178, 175, 165, 138.

(−)-Machilusin (3). Mp 121—122.0 °C, $[\alpha]_D=-130.6°$ (in $CHCl_3$). Found: C, 70.81; H, 6.68%. Calcd for $C_{21}H_{24}O_5$: C, 70.79; H, 6.74%. NMR (δ ppm in $CDCl_3$): 0.62 (3H, d, $J=7$ Hz; CH_3), 1.01 (3H, d, $J=6.5$ Hz; CH_3), 2.45 (2H, m; H3, H4), 3.90 (6H, s; CH_3O), 4.65 (1H, d, $J=9$ Hz; H2 or H5), 5.47 (1H, d, $J=4$ Hz; H2 or H5), 5.95 (2H, s; OCH_2O), 6.80—7.0 (6H; aromatic H). IR (cm^{-1}, KBr): 1603, 1590, 1510, 1500, 1482, 1463, 1458, 1438, 1418, 1380, 1360, 1344, 1313, 1286, 1262, 1240, 1235, 1220, 1190, 1180, 1152, 1140, 1125, 1090, 1060, 1030, 1020, 1005, 995, 970, 960, 940, 925, 895, 860, 850,

810, 798, 780, 770, 750, 725, 720, 705.

(−)-Licarin-B (4). Mp 86.5—88.0 °C, $[\alpha]_D = -45.4°$ (in $CHCl_3$).

Oxidation of Machilusin (3), Galbacin (1), and Galbelgin (2). To a boiling solution of 50 mg of **3** in 10 ml of acetone, 350 mg of a mixture of potassium permanganate and magnesium sulfate (6 : 5) were added little by little over 30 min and the reaction mixture was refluxed for 6 h. Then it was made alkaline with aq. sodium hydroxide and was filtered. The precipitate was washed with hot water, and the combined washing and filtrate were concentrated *in vacuo* to remove acetone and were washed with ether. The aqueous layer was acidified with dil. sulfuric acid and was extracted with ether. The ether solution was dried over anhydrous sodium sulfate and an excess amount of ether solution of diazomethane was added to this solution. The resulting solution, after being concentrated *in vacuo* to remove unreacted diazomethane, was subjected to gas chromatography (SE 30-golay column, at 150 °C). The product was shown to be a mixture of methyl piperonylate and methyl veratrate (1 : 1) by comparing their R_ts with those of the authentic samples.

In the same manner, galbacin and galbelgin gave methyl piperonylate and methyl veratrate respectively.

The authors wish to express their gratitude to Professor Masahide Kurita, Department of Biology, Ehime University, for his valuable advice in the identification of the species of the material tree, and also to Mr. Muneki Ohuchi, Japan Electon Optics Laboratory Co., LTD., for carrying out some parts of the spin-decoupling experiment.

1,3-Benzodithiolylium Salts. Synthesis and Reactions with Nucleophilic Reagents

Jyuzo NAKAYAMA, Kazuo FUJIWARA, and Masamatsu HOSHINO

Department of Chemistry, Faculty of Science, Saitama University, Urawa, Saitama 338

(Received March 15, 1976)

Various salts of 1,3-benzodithiolylium ion were prepared in excellent yields on treatment of 2-alkoxy- and 2-alkylthio-1,3-benzodithioles with acids in acetic anhydride. The reactions of 1,3-benzodithiolylium tetrafluoroborate (**1a**) with a wide variety of nucleophilic reagents (alcohols, water, thiols, hydrogen sulfide, primary, secondary, and tertiary amines, ammonia, *N,N*-dimethylformamide, electron-rich aromatic compounds, active methylene compounds, tropilidene, and sodium borohydride) were studied. In all cases examined, **1a** reacted with nucleophilic reagents at the 2-position to give the corresponding 1,3-benzodithioles in good yields, excepting the reactions with tertiary amines and *N,N*-dimethylformamide which resulted in the formation of dibenzotetrathiafulvalene. Salt **1a** was also prepared from 1,3-benzodithiole and trityl tetrafluoroborate.

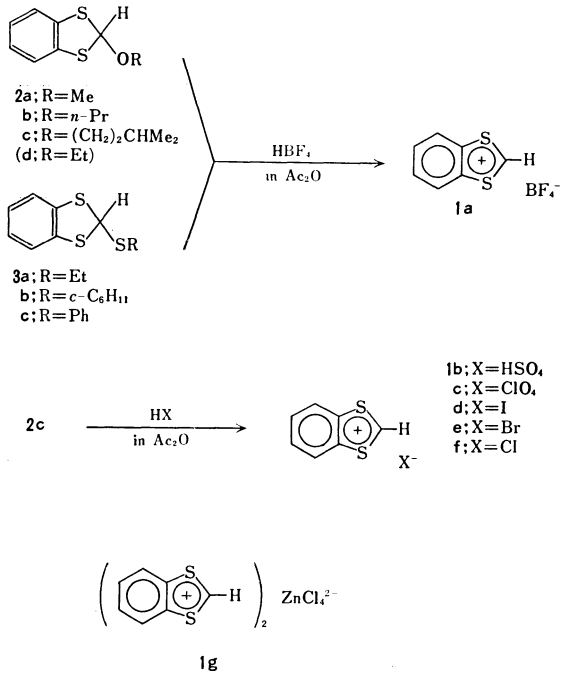
Like 1,2-dithiolylium ion, 1,3-dithiolylium ion possesses a potential aromatic sextet, its aromaticity being the subject of controversy. Recently the synthesis, reactivity, and spectral properties of 1,3-dithiolylium compounds have been intensively studied in efforts to find relationships between their structure and thier chemical and physical properties.[1–3] In a preliminary report we briefly described a convenient synthesis of 1,3-benzodithiolylium tetrafluoroborate (**1a**).[4] We now report the synthesis of various salts of 1,3-benzodithiolylium ion and the reactions of the fluoroborate salt **1a** with a wide variety of nucleophilic reagents.

Results and Discussion

Synthesis of 1,3-Benzodithiolylium Salts. We recently reported a one-step synthesis of 2-alkoxy-1,3-benzodithioles (**2**) on a preparative scale which involves addition of alcohols to the carbene (1,3-benzodithiol-2-ylidene) produced from carbon disulfide and benzyne generated by aprotic diazotization of anthranilic acid.[5] Treatment of a solution of 2-isopentyloxy-1,3-benzodithiole (**2c**) in acetic anhydride with tetrafluoroboric acid at 0 °C gave 1,3-benzodithiolylium tetrafluoroborate (**1a**) in 96% yield. The structure of **1a** was determined on the basis of spectral data and elemental analysis. Benzodithioles **2a** and **2b** gave the fluoroborate salt **1a** in 94 and 88% yields, respectively. Other slats of 1,3-benzodithiolylium ion could also be prepared in a similar way; sulfuric, perchloric, hydriodic, and hydrobromic acids reacted with the benzodithiole **2c** in acetic anhydride to give the hydrogen sulfate **1b** (81%), perchlorate **1c** (94%), iodide **1d** (81%), and bromide **1e** (95%), respectively. The chloride salt **1f**, soluble in the reaction medium when prepared from **2c** and concentrated hydrochloric acid in acetic anhydride, could not be isolated, but its zinc chloride double salt **1g** was obtained in 96% yield by treating the mixture with zinc chloride.

2-Alkylthio-1,3-benzodithioles (**3**) have been easily synthesized in good yields by treatment of the benzodithiole **2c** with thiols in acetic acid.[6] Treatment of compounds **3a**—**c** with tetrafluoroboric acid also yielded the fluoroborate salt **1a** in a respective yield of 86, 90, and 92%.

The only synthetic method for preparing 1,3-benzodithiolylium salts involves the condensation of 1,2-benzenedithiol with formic acid or triethyl orthoformate in the presence of acids.[7] However, the synthesis of 1,2-benzenedithiol is laborious.[8] The present reaction provides the most straightforward synthetic method of salts **1** since the starting material can be obtained on a preparative scale by one-step synthesis. The formation of 1,3-dithiolylium salts from 2-methoxy- and 2-methylthio-1,3-dithioles has been reported.[3b,9]



Scheme 1.

The fluoroborate salt **1a** is stable at room temperature and soluble in polar solvents; it was used to investigate the reactivity of 1,3-benzodithiolylium ion toward a wide variety of nucleophilic reagents.

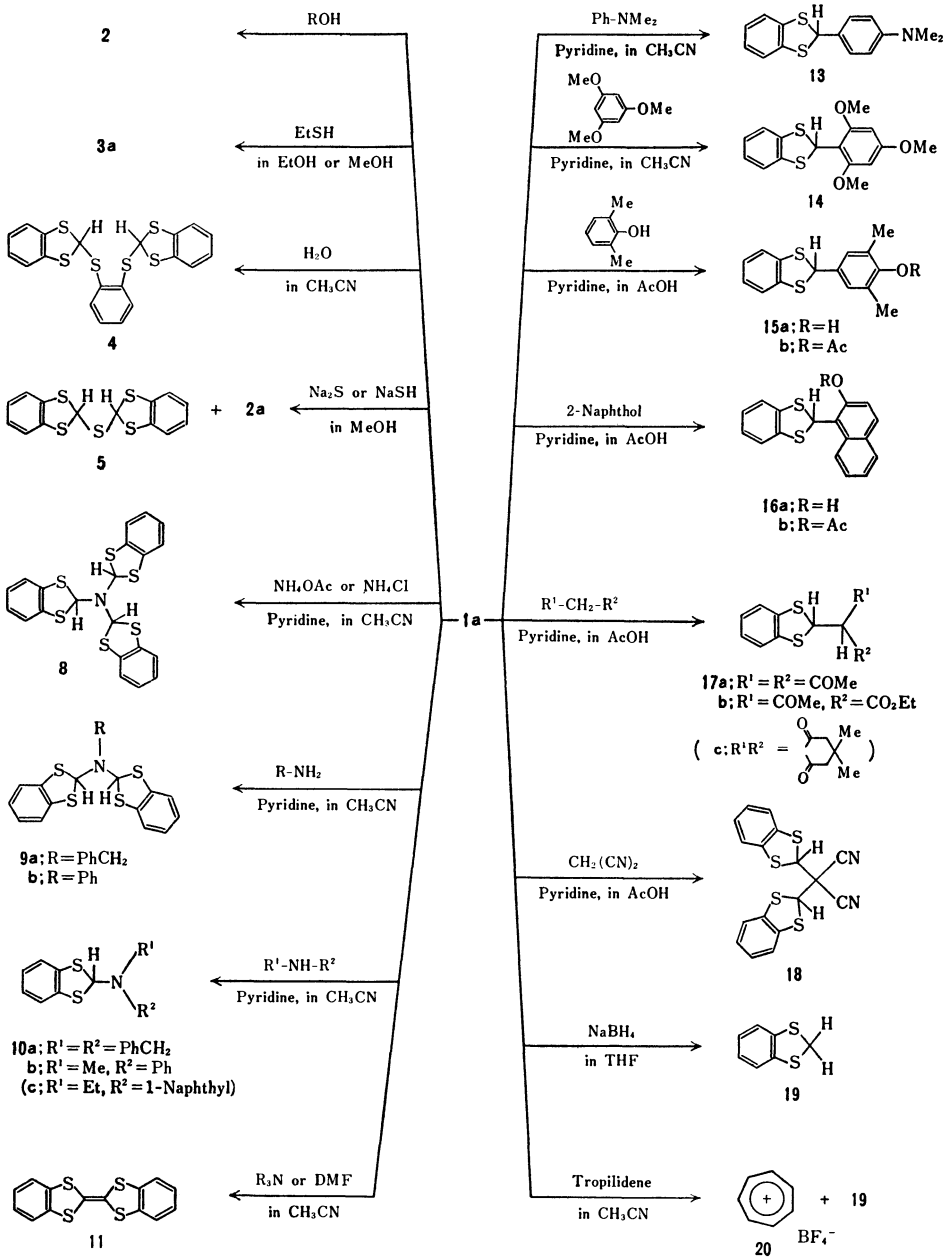
*Reactions of 1,3-Benzodithiolylium Tetrafluoroborate (**1a**) with Nucleophilic Reagents.* Standing the fluoroborate salt **1a** in methanol for 1 h at room temperature gave rise to 2-methoxy-1,3-benzodithiole (**2a**) in 87% yield. Similar treatment of **1a** with ethanol and 1-propanol gave benzodithioles **2d** (75%) and **2b** (94%), respectively. The formation of 2-alkoxy-1,3-dithioles from 1,3-dithiolylium perchlorates and alcohols

in the presence of base has been reported.[3b,7e,10]

Buza *et al.* reported that the perchlorate salt **1c**, on treatment with triethylamine in an aqueous acetonitrile or *N,N*-dimethylformamide, gives compound **4** by partial hydrolysis.[7c] The fluoroborate salt **1a**, when allowed to stand in an aqueous acetonitrile at room temperature for a long period, gave compound **4** in 88% yield. The mechanism of the formation of **4** probably involves the tautomerization of the 2-hydroxy compound **6** to the open chain compound **7** as an initial process as postulated. A similar reaction has been observed with the benzodithiole **2c** in acetic acid.[11]

A solution of the salt **1a** in ethanol was allowed to stand at room temperature for 1 h and then 4 molar amounts of ethanethiol was added. Standing the resulting mixture for another 1 h gave rise to 2-ethylthio-1,3-benzodithiole (**3a**) in 81% yield. This suggests that in ethanol the equilibrium between 1,3-benzodithiolylium ion and 2-ethoxy-1,3-benzodithiole (**2d**), which lies far to **2d**, takes place and that **2d** is converted into the final product **3a** *via* 1,3-benzodithiolylium ion on addition of ethanethiol. Thus, upon standing **1a** in ethanol containing 4 molar amounts of ethanethiol, compound **3a** was obtained in 80% yield; ^{1}H NMR analysis indicated no formation of **2d**. Similarly, **1a** and ethanethiol in methanol gave **3a** in 81% yield.

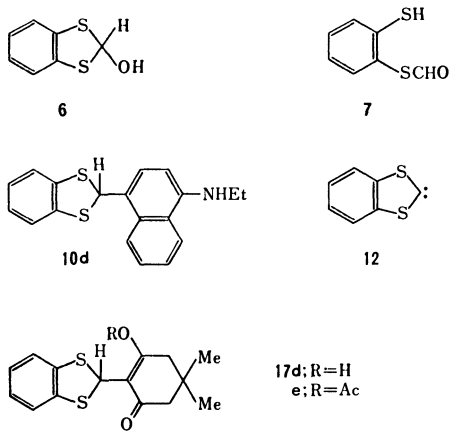
Sodium sulfide reacted with the salt **1a** in methanol to give the sulfide **5** (15%) and the benzodithiole **2a** (69%). The reaction of sodium hydrogensulfide with **1a** in methanol also yielded compounds **5** (33%)



Scheme 2.

and **2a** (54%). The tropylium ion reacts in a similar way with hydrogen sulfide to give ditropyl sulfide.[12] It is of interest that the reaction of 2,4,5-triphenyl-1,3-dithiolylium perchlorate with sodium hydrogensulfide in methanol gives 2,4,5-triphenyl-1,3-dithiole in good yield.[10] In our case no such reduction product was formed.

The reactions of some 1,3-dithiolylium salts with ammonia have been examined,[10,13] a 2-aminodithiole adduct being isolated in one instance.[10] The reaction of ammonium acetate with 3 molar amounts of the salt **1a** in the presence of pyridine in acetonitrile at room temperature gave tris(1,3-benzodithiol-2-yl)amine (**8**) in 86% yield. Neither (1,3-benzodithiol-2-yl)-amine nor bis(1,3-benzodithiol-2-yl)amine was isolated. The strongest support for structure of **8** was provided by ^{1}H NMR spectrum: δ (CS_2) 6.30 (3H, s, methine) and 6.90—7.25 (12H, A_2B_2m, aromatic). Under the same conditions, ammonium chloride and 3 molar amounts of **1a** also gave the amine **8** in 50% yield.



Scheme 3.

Benzylamine reacted with 2 molar amounts of the salt **1a** in the presence of pyridine in acetonitrile at room temperature to give *N*,*N*-bis(1,3-benzodithiol-2-yl)benzylamine (**9a**) in 86% yield. Similarly, aniline and **1a** gave the amine **9b** in 79% yield. Thus, evidently all the amino hydrogens of ammonia and primary amines are replaceable by 1,3-benzodithiol-2-yl groups by **1a**, whereas the reactions of 2-methylthio-1,3-dithiolylium salts with primary amines give either 2-imino-1,3-dithioles or 2-amino-1,3-dithiolylium salts with evolution of methanethiol, depending upon the number of moles of amines employed.[13a,14]

Secondary amines such as dibenzylamine and *N*-methylaniline reacted with the salt **1a** in the presence of pyridine in acetonitrile to give compounds **1a** (90%) and **10b** (92%), products of *N*-alkylation, respectively. With *N*-ethyl-1-naphthylamine, unexpectedly, 4-(1,3-benzodithiol-2-yl)-*N*-ethyl-1-naphthylamine (**10d**) was obtained nearly quantitatively. The formation of **10d** can be explained either by direct electrophilic attack of **1a** on the 4-position of the naphthalene ring of the substrate or by the rearrangement of the primary product **10c** under the conditions employed. In either case, the steric hindrance caused by the *peri*-hydrogen may be responsible for the formation of the product.[15] In this connection it is of interest that the reaction of 2-methylthio-4-phenyl-1,3-dithiolylium perchlorate with *N*-methylaniline gives 2-(*N*-methylanilino)-4-phenyl-1,3-dithiolylium perchlorate with loss of methanethiol, whereas the reaction with diphenylamine yields 2-(*p*-anilinophenyl)-4-phenyl-1,3-dithiolylium perchlorate.[16]

Treatment of the salt **1a** with triethylamine in acetonitrile gave dibenzotetrathiafulvalene **11** in 81% yield in accord with the findings with the perchlorate salt **1c**.[7c-e] Treatment of **1a** with tripropylamine also gave **11** in 84% yield. The formation of **11** can be readily explained by base-catalyzed deprotonation of **1a** and subsequent reaction of the resulting carbene **12** with **1a** followed by deprotonation. Standing **1a** in *N*,*N*-dimethylformamide for 1.5 h at room temperature resulted in the formation of **11** in 80% yield. In connection with the recent discovery of the highly conducting charge transfer salts of tetrathiafulvalenes with 7,7,8,8-tetracyanoquinonedimethane,[17] many derivatives of tetrathiafulvalene have been prepared by treatment of 1,3-dithiolylium salts with base. We believe that *N*,*N*-dimethylformamide serves as a useful base for this conversion, although only tertiary amines have been so far employed.[3b,7c-e,9,18]

Like other 1,3-dithiolylium ions,[16,19] 1,3-benzodithiolylium ion undergoes electrophilic substitution with electron-rich aromatic compounds; *N*,*N*-dimethylaniline and 1,3,5-trimethoxybenzene reacted with the salt **1a** to give compounds **13** (89%) and **14** (98%), respectively. Although the reaction of **1a** with phenol in the presence of pyridine in acetic acid at 60—70 °C for 3 h gave unidentified oils and intractable tars, 2,6-dimethylphenol and 2-naphthol reacted with **1a** to give **15b** (68%) and **16b** (97%), respectively. In these cases, primary products **15a** and **16a** must be acetylated under the conditions employed to give the final products **15b** and **16b**, respectivley.

Reaction of 1,3-dithiolylium salts with active methylene compounds leading to 1,3-dithiol-2-ylidene derivatives have been extensively studied.[3e,14,19c,20] The reaction of **1a** with acetylacetone and ethyl acetoacetate in the presence of pyridine in acetic acid afforded **17a** (92%) and **17b** (89%), respectively. Under the same conditions, dimedone and **1a** gave the acetate **17e** in 76% yield; the primary product **17c**, which exists in the enol form **17d**[21] must be acetylated to give **17e** as observed with 2,6-dimethylphenol and 2-naphthol. The reaction of **1a** with malononitrile, in striking contrast to the foregoing results, gave bis-(1,3-benzodithiol-2-yl)malononitrile (**18**) in 86% yield, although a slight excess of malononitrile was employed. Similar reactions have been observed with benzodithioles **2** and active methylene compounds in acetic acid.[21]

Reduction of the salt **1a** with sodium borohydride in tetrahydrofuran afforded 1,3-benzodithiole (**19**) in 81% yield. The reaction of **1a** with a slight excess of tropilidene in acetonitrile at 0 °C gave tropylium tetrafluoroborate (**20**) and the benzodithiole **19** in a respective yield of 90 and 65%. Hirai has reported

that the reaction of 4-phenyl-1,3-dithiolylium perchlorate with a slight excess of tropilidene in acetic acid at 80 °C gives a mixture of tropylium perchlorate and the starting perchlorate.[3d] These results lead to the conclusion that 1,3-benzodithiolylium ion surpasses 4-phenyl-1,3-dithiolylium ion in ability to accept a hydride, thus suggesting that the positive charge of the former ion is more localized on the 2-position as compared with that of the parent 1,3-dithiolylium ion by the influence of the fused benzene ring.

The benzodithiole **19**, when allowed to react with trityl tetrafluoroborate in acetonitrile, gave rise to the salt **1a** (75%) and triphenylmethane (75%). The reaction provides another new synthetic way to **1a** since **19** can be also synthesized by the literature method.[22]

$$\mathbf{19} + Ph_3C^+BF_4^- \longrightarrow \mathbf{1a} + Ph_3CH$$

Scheme 4.

Finally, it is concluded that 1,3-benzodithiolylium ion reacts exclusively at the 2-position with nucleophilic reagents in agreement with the results by molecular orbital calculations.[23]

Experimental

2-Alkoxy- and 2-alkylthio-1,3-benzodithioles (**2** and **3**) were prepared by the methods described.[5,6] Acetic acid and acetonitrile were distilled over phosphorus pentoxide before use. Other commercial materials were used without further purification, unless otherwise stated. ^1H NMR spectra were determined at 100 MHz with tetramethylsilane as internal reference. IR spectra of solids were taken for Nujol mulls, and those of liquids for films. All melting points are uncorrected.

*1,3-Benzodithiolylium Salts (**1**) from 2-Alkoxy-1,3-benzodithioles (**2**). a) 1,3-Benzodithiolylium Tetrafluoroborate (**1a**)*: To a stirred and ice-cooled solution of 2-isopentyloxy-1,3-benzodithiole (**2c**) (24.0 g, 0.1 mol) in acetic anhydride (300 ml) was added dropwise 42% tetrafluoroboric acid (42 g, 0.2 mol) over a period of 0.5 h. After 0.5 h of stirring at 0 °C, ether (400 ml) was added to precipitate the product completely. Filtration and washing with anhydrous ether (150 ml) gave **1a** as near-white crystals, 23.0 g (96%), mp 149—150 °C (dec). The salt thus obtained gave satisfactory result of elemental analysis and was used for investigation of the reactions with nucleophilic reagents. Recrystallization from anhydrous acetic acid gives a more pure specimen, mp 150—150.5 °C (dec).

ν_{max} 1000—1120 cm^{-1} (BF_4^-); δ (CF_3CO_2D) 8.06—8.26 and 8.66—8.86 (4H, m, aromatic) and 11.50 (1H, s, methine).

Found: C, 35.25; H, 2.11%. Calcd for $C_7H_5BF_4S_2$: C, 35.02; H, 2.10%.

In a similar way, **1a** was prepared from **2a** and **2b** in a respective yield of 94 and 88%.

*b) 1,3-Benzodithiolylium Hydrogen Sulfate (**1b**)*: This salt was prepared from **2c** (0.72 g, 3 mmol) and concentrated sulfuric acid (1.2 g, 12 mmol) in acetic anhydride (15 ml) in 81% yield (0.61 g) as white crystals. It showed no difinite melting point and decomposed gradually from 130 °C. It turned violet even when kept in refrigerator.

Found: C, 33.29; H, 2.46; S, 37.62%. Calcd for $C_7H_6O_4S_3$: C, 33.59; H, 2.42; S, 38.43%.

*c) 1,3-Benzodithiolium Perchlorate (**1c**)*: This salt was prepared from **2c** (0.72 g, 3 mmol) and 60% perchloric acid (1.0 g, 6 mmol) in acetic anhydride (15 ml) in 94% yield (0.71 g) as white crystals. It exploded violetly at 185 °C in agreement with the findings of the previous workers.[7c-e]

*d) 1,3-Benzodithiolylium Iodide (**1d**)*: This salt was prepared from **2c** (0.72 g, 3 mmol) and 57% hydriodic acid (1.35 g, 6 mmol) in acetic anhydride (15 ml) in 81% yield (0.68 g) as orange crystals, mp 101—103 °C (dec).

Found: C, 29.93; H, 1.79; I, 45.25; S, 22.84%. Calcd for $C_7H_5IS_2$: C, 30.00; H, 1.80; I, 45.30; S, 22.89%.

*e) 1,3-Benzodithiolylium Bromide (**1e**)*: This salt was prepared from **2c** (0.72 g, 3 mmol) and 47% hydrobromic acid (1.03 g, 6 mmol) in acetic anhydride (15 ml) in 95% yield (0.66 g) as white crystals, mp 169—170 °C (dec).

Found: C, 36.04; H, 2.14; Br, 34.14; S, 27.51%. Calcd for $C_7H_5BrS_2$: C, 36.06; H, 2.16; Br, 34.28; S, 27.51%.

*f) Bis(1,3-benzodithiolylium) Zinc Tetrachloride (**1g**)*: To a stirred and ice-cooled solution of **2c** (0.72 g, 3 mmol) in acetic anhydride (15 ml) was slowly added concentrated hydrochloric acid (0.61 g, 6 mmol) at 0 °C. After being stirred for 0.5 h, zinc chloride (0.20 g, 1.5 mmol) was added and the mixture was stirred at 0 °C for another 0.5 h. The resulting precipitate was collected and washed with acetonitrile (10 ml) to give 0.74 g (96%) of **1g**. Hurtley and Smiles[7a] reported this salt as orange needles with a red tint of varying depth. However, our product freshly prepared was a white solid, scarcely soluble in organic solvents, darkening from 180 °C and melting at 201—202°C accompanied by decomposition. Its IR spectrum was essentially the same as those of **1a—e.**

Found: C, 32.68; H, 1.96; S, 25.06%. Calcd for $C_{14}H_{10}Cl_4S_4Zn$: C, 32.73; H, 1.96; S, 24.97%.

*Fluoroborate Salt **1a** from 2-Alkylthio-1,3-benzodithioles (**3**).* **1a** was prepared from benzodithioles **3a**, **3b**, and **3c** in a respective yield of 86, 90, and 92% by treatment with tetrafluoroboric acid in the manner described above except that the reaction with **3b** (insoluble in acetic anhydride) was carried out in a mixture of ether and acetic anhydride.

*Reaction of the Salt **1a** with Alcohols.* **1a** (3.60 g, 15 mmol) was dissolved in alcohols (50 ml) and left to stand at room temperature for 1 h. The mixture was poured into water (150 ml) and extracted with ether (150 ml). The ether extract was washed with water, dried over sodium sulfate, and evaporated. The oily residue was purified by distillation.

2-Methoxy-1,3-benzodithiole (**2a**), 87%, colorless oil (solidified in a refrigerator), bp 80 °C/0.5 Torr (lit,[5b] bp 105—106 °C/2 Torr).

2-Ethoxy-1,3-benzodithiole (**2d**), 75%, colorless oil, bp 92—93 °C/1.5 Torr, ν_{max} 1050 cm^{-1} (C–O), δ (CCl_4) 1.12 (3H, t, methyl), 3.43 (2H, q, methylene), 6.80 (1H, s, methine), and 6.9—7.5 (4H, m, aromatic).

Found: C, 54.63; H, 5.14; S, 32.19%. Calcd for $C_9H_{10}OS_2$: C, 54.54; H, 5.09; S, 32.29%.

2-Propoxy-1,3-benzodithiole (**2b**), 94%, colorless oil, bp 86—88 °C/0.5 Torr (lit,[5a] bp 104—105 °C/0.1 Torr).

*Reaction of **1a** with Water.* **1a** (1.20 g, 5 mmol) was dissolved in 4:1 acetonitrile-water (25 ml) and left to stand at room temperature. After several hours colorless needles began to precipitate. The mixture was allowed to stand at room temperature until the needles no longer precipitated (one week). Filtration and wahsing with methanol (10 ml) gave 2,2'-(*o*-phenylenedithio)bis(1,3-benzodithiole), (**4**), 0.66 g (88%), mp 129—131 °C, undepressed on admixture with the authentic specimen.[11]

*Reaction of **1a** with Ethanethiol.* A solution of **1a** (1.20 g, 5 mmol) in ethanol (25 ml) was left at room temperature for 1 h, and then ethanethiol (1.24 g, 20 mmol) was added. After

being left to stand 1 h at room temperature, the mixture was poured into water and extracted with ether. The extract was washed successively with water, 2 M sodium hydroxide, and water, and dried over sodium slfate. The ether was evaporated and the crystalline residue was washed with cold methanol to give 2-ethylthio-1,3-benzodithiole (**3a**), 0.87 g (81%), mp 49—51 °C, undepressed on admixture with the authentic specimen.[6]

When **1a** (1.20 g, 5 mmol) was dissolved in a mixture of ethanethiol (1.24 g, 20 mmol) and ethanol (25 ml) and left to stand at room temperature for 1 h, **3a**, mp 51—51.5 °C, was obtained in 80% yield. ^{1}H NMR analysis of the crude product indicated no formation of **2d**.

*Reaction of **1a** with Sodium Sulfide and Sodium Hydrogensulfide.* **1a** (1.20 g, 5 mmol) was added to a stirred solution of sodium sulfide nonahydrate (1.20 g, 5 mmol) in methanol (15 ml) at room temperature and the mixture was stirred for 0.5 h. The crystalline precipitate was collected and washed with water (30 ml) and then with ethanol (10 ml) to give bis(1,3-benzodithiol-2-yl) sulfide (**5**), 0.13 g (15%), mp 145—147 °C (from $CHCl_3$/hexane), undepressed on admixture with the authentic specimen.[6] The filtrate was poured into water (50 ml) and extracted with ether (100 ml). The ether extract was washed with water, dried over sodium sulfate, and evaporated. The oily residue was distillated to give 2-methoxy-1,3-benzodithiole (**2a**), 0.63 g (69%), bp 130 °C (bath temperature) at 2 Torr.

1a (1.20 g, 5 mmol) was added with stirring to a solution of sodium hydrogensulfide (0.28 g, 5 mmol) in methanol (15 ml) at room temperature. The mixture was stirred for 2 h and worked up as described for the reaction with sodium sulfide to give the sulfide **5**, 0.28 g (33%), mp 145—147 °C and the benzodithiole **2a**, 0.49 g (54%), bp 110 °C (bath temperature) at 0.5 Torr.

*Reaction of **1a** with Ammonium Salts.* To a stirred mixture of ammonium acetate (154 mg, 2 mmol) and pyridine (0.2 ml) in acetonitrile (15 ml) was added in portions **1a** (1.44 g, 6 mmol) and the mixture was stirred at room temperature for 6 h. The crystalline precipitate was collected and washed with ethanol (10 ml) to give tris(1,3-benzodithiol-2-yl)amine (**8**), 0.81 g (86%), mp 247—248 °C (dec) (from benzene, colorless granules).

Found: C, 53.24; H, 3.33; N, 3.19; S, 40.05%. Calcd for $C_{21}H_{15}NS_6$: C, 53.28, H, 3.19; N, 2.96; S, 40.56%.

The reaction of **1a** (1.44 g 6 mmol) with ammonium chloride (105 mg, 2 mmol) in the presence of pyridine (0.2 ml) in acetonitrile (15 ml) at room temperature for 6 h gave compound **8** in 50% yield in addition to a small amount of dibenzotetrathiafulvalene **11**.

*Reaction of **1a** with Primary Amines.* To a stirred mixture of amines (2.5 mmol) and pyridine (0.5 ml) in acetonitrile (10 ml) was added dropwise a solution of **1a** (1.20 g, 5 mmol) in acetonitrile (15 ml) over a period of 5 min. After being stirred for 0.5 h at room temperature, ice water (15 ml) was added to precipitate the products. The precipitate was collected and washed with cold methanol (15 ml).

N,N-Bis(1,3-benzodithiol-2-yl)benzylamine (**9a**), 0.88 g (86%), mp 128—129 °C (from cyclohexane, colorless needles), δ ($CDCl_3$) 3.89 (2H, s, methylene), 6.37 (2H, s, methine), and 6.9—7.4 (13H, m, aromatic).

Found: C, 61.30; H, 4.26; N, 3.36; S, 30.65%. Calcd for $C_{21}H_{17}NS_4$: C, 61.31; H, 4.17; N, 3.41; S, 31.12%.

N,N-Bis(1,3-benzodithiol-2-yl)aniline (**9b**), 0.78 g (79%), mp 134—138 °C (from cyclohexane, colorless granules), δ ($CDCl_3$) 6.71 (2H, s, methine) and 6.8—7.5 (13H, m, aromatic).

Found: C, 60.43; H, 3.96; N, 3.35; S, 32.03%. Calcd for $C_{20}H_{15}NS_4$: C, 60.45; H, 3.81; N, 3.53; S, 32.22%.

*Reaction of **1a** with Secondary Amines.* **1a** (0.48 g, 2 mmol) was added in portions to a stirred mixture of amines (2 mmol) and pyridine (0.2 ml) in acetonitrile (10 ml). After 0.5 h of stirring at room temperature, ice water was added to precipitate the products completely. The precipitate was collected and washed with methanol (10 ml).

N,N-Dibenzyl-1,3-benzodithiol-2-ylamine (**10a**), 0.63 g (90%), mp 94—95 °C (from methanol, colorless needles), δ ($CDCl_3$) 3.63 (4H, methylene), 6.30 (1H, s, methine), and 6.9—7.5 (14H, m, aromatic).

Found: C, 72.14; H, 5.53; N, 4.00; S, 18.20%. Calcd for $C_{21}H_{19}NS_2$: C, 72.19; H, 5.48; N, 4.01; S, 18.32%.

N-Methyl-*N*-(1,3-benzodithiol-2-yl)aniline (**10b**), 0.48 g (92%), mp 120—121 °C (from hexane, colorless needles), δ ($CDCl_3$) 2.71 (3H, s, methyl), 7.13 (1H, s, methine), and 6.95—7.45 (9H, m, aromatic).

Found: C, 64.90; H, 5.10; N, 5.40; S, 24.70%. Calcd for $C_{14}H_{13}NS_2$: C, 64.86; H, 5.05; N, 5.40; S, 24.69%.

4-(1,3-Benzodithiol-2-yl)-*N*-ethyl-1-naphthylamine (**10d**), 0.64 g (99%), mp 97—99 °C (from cyclohexane, needles with a pink tinge), ν_{max} 3350 cm^{-1} (N–H), δ ($CDCl_3$) 1.33 (3H, t, methyl), 3.26 (2H, q, methylene), 4.34 (1H, broad s, N–H), 6.52 (1H, d, aromatic), 7.00 (1H, s, methine), 6.95—7.35 (4H, m, aromatic), *ca.* 7.5 (2H, m, aromatic), *ca.* 7.8 (1H, d/d, aromatic), 7.94 (1H, d, aromatic), and *ca.* 8.1 (1H, d/d, aromatic).

Found: C, 70.51; H, 5.33; N, 4.29; S, 19.81%. Calcd for $C_{19}H_{17}NS_2$: C, 70.57; H, 5.30; N, 4.33; S, 19.79%.

*Reaction of **1a** with Triethylamine.* To a stirred solution of **1a** (2.40 g, 10 mmol) in acetonitrile (10 ml) was added dropwise a solution of triethylamine (3 ml) in acetonitrile (15 ml) over a period of 15 min at room temperature. After being stirred for 0.5 h, the precipitate was collected and washed with benzene (15 ml) to give 1.24 g (81%) of dibenzotetrathiafulvalene **11** as yellow crystals, mp 235—237 °C, undepressed on admixture with the authentic specimen.[24]

*Reaction of **1a** with N,N-Dimethylformamide.* **1a** (2.40 g, 10 mmol) was dissolved in 20 ml of anhydrous *N,N*-dimethylformamide and left at room temperature for 1.5 h. The precipitate was collected and washed with benzene (10 ml) to give 1.21 g (80%) of **11**, mp 235—237 °C.

*Reaction of **1a** with Aromatic Compounds.* *a) With N,N-dimethylaniline and 1,3,5-Trimethoxybenzene*: To a stirred mixture of *N,N*-dimethylaniline (194 mg, 1.6 mmol) and pyridine (0.2 ml) in acetic acid (15 ml) was added **1a** (0.36 g, 1.5 mmol). After 0.5 h, the mixture was diluted with water (10 ml). Filtration of the precipitate and washing with methanol (5 ml) gave 2-[*p*-(dimethylamino)-phenyl]-1,3-benzodithiole (**13**), 0.37 g (89%), mp 119 °C (from ethanol), undepressed on admixture with the authentic specimen.[11]

The reaction of **1a** with 1,3,5-trimethoxybenzen carried out in a similar way gave 0.47 g (98%) of 2-(2,4,6-trimethoxyphenyl)-1,3-benzodithiole (**14**), mp 140—141 °C (from ethanol), undepressed on admixture with the authentic specimen.[11]

b) With 2,6-Dimethylphenol and 2-Naphthol: **1a** (0.36 g, 1.5 mmol) was added in portions to a stirred mixture of 2,6-dimethylphenol (1.6 mmol) and pyridine (0.2 ml) in acetic acid (15 ml). The mixture was heated at 60—70 °C for 3 h and cooled. Ice water (15 ml) was added to precipitate the products. The precipitate was collected and washed with ethanol (10 ml).

2-(4-Acetoxy-3,5-dimethylphenyl)-1,3-benzodithiole (**15b**), 0.32 g (68%), mp 136—137 °C (from ethanol, colorless granules), ν_{max} 1730 cm^{-1} (C=O), δ ($CDCl_3$) 2.10 (6H, s, methyl),

2.30 (3H, s, methyl), 6.18 (1H, s, methine), 6.95—7.30 (4H, m, aromatic), and 7.26 (2H, s, aromatic).

Found: C, 64.24; H, 5.11; S, 20.05%. Calcd for $C_{17}H_{16}O_2S_2$: C, 64.55; H, 5.10; S, 20.23%.

1-(1,3-Benzodithiol-2-yl)-2-acetoxynaphthalene (**16b**), 0.49 g (97%), mp 218—129 °C (from benzene, colorless needles), ν_{max} 1750 cm^{-1} (C=O), δ (DMSO-d_6, at 100 °C) 2.14 (3H, s, methyl), 7.05—7.40 (5H, m, aromatic), 7.48 (1H, s, methine), 7.5—7.6 (2H, m, aromatic), 7.9—8.1 (2H, m, aromatic), and 8.75 (1H, m, aromatic).

Found: C, 67.44; H, 3.88; S, 18.62%. Calcd for $C_{19}H_{14}O_2S_2$: C, 67.45; H, 4.17; S 18.92%.

Reaction of ***1a*** *with Active Methylene Compounds.* To a stirred mixture of active methylene compounds (1.5 mmol) and pyridine (0.2 ml) in acetic acid (10 ml) was added **1a** (0.36 g, 1.5 mmol). After being stirred for 3 h at room temperature, the mixture was diluted with ice water (10 ml). The precipitate was collected and washed with methanol (5 ml). In the reaction with malononitrile, colorless needles separated without addition of water.

3-(1,3-Benzodithiol-2-yl)-2,4-pentanedione (**17a**), 0.35 g (92%), mp 129 °C (from ethanol), undepressed on admixture with the authentic specimen.[21]

Ethyl 2-(1,3-benzodithiol-2-yl)acetoacetate (**17b**), 0.38 g (90%), mp 59—60 °C (from aqueous ethanol), undepressed on admixture with the authentic specimen.[21]

2-(1,3-Benzodithiol-2-yl)-3-acetoxy-5,5-dimethyl-2-cyclohexen-1-one (**17e**), 0.38 g (76%), mp 117—118 °C (from ethanol, colorless needles), ν_{max} 1760, 1658, and 1635 cm^{-1}, δ ($CDCl_3$) 1.07 (6H, s, methyl), 1.54 (3H, s, methyl), 2.34 (2H, s, methylene), 2.55 (2H, s, methylene), 6.38 (1H, s, methine), and 6.9—7.2 (4H, m, aromatic).

Found: C, 60.70; H, 5.20; S, 19.17%. Calcd for $C_{17}H_{18}O_3S_2$: C, 61.07; H, 5.43; S, 19.14%.

Bis(1,3-benzodithiol-2-yl)malononitrile (**18**), 0.24 g (86%), mp 220—221 °C (dec), undepressed on admixture with the authentic specimen.[21]

Reduction of ***1a*** *with Sodium Borohydride.* To a stirred mixture of sodium borohydride (0.40 g, 10 mmol) in anhydrous tetrahydrofuran (30 ml) was added in portions **1a** (2.40 g, 10 mmol) at room temperature. After being stirred for 2 h, the mixture was poured into ice water (200 ml) and extracted with ether (200 ml). The ether extract was washed with water, dried over sodium sulfate, and evaporated. The oily residue was distillated to give 1.24 g (81%) of 1,3-benzodithiole (**19**), bp 103—104 °C/3 Torr (lit,[22] bp 88 °C/0.6 Torr).

Reaction of ***1a*** *with Tropilidene.* To a stirred and ice-cooled solution of tropilidene (1.56 g, 17 mmol) in acetonitrile (10 ml) was added dropwise a solution of **1a** (3.60 g, 15 mmol) in acetonitrile (15 ml) during 20 min. After stirring for 0.5 h at 0 °C, anhydrous ether (40 ml) was added to precipitate the product. Filtration and washing with anhydrous ether (10 ml) gave tropylium tetrafluoroborate (**20**) as white crystals, 2.40 g (90%), mp>210 °C (dec) [lit,[25] mp>210 °C (dec)]. The filtrate and washings combined were washed with water and dried. The ether was evaporated and the residual oil was distillated to give the benzodithiole **19**, 1.50 g (65%), bp 83—85 °C/0.5 Torr.

Fluoroborate Salt ***1a*** *from 1,3-Benzodithiole.* To a stirred and ice-cooled solution of **19** (1.07 g, 7 mmol) in acetonitrile (10 ml) was added dropwise a solution of trityl tetrafluoroborate[25] (2.31 g, 7 mmol) in acetonitrile (15 ml) over a period of 20 min. After stirring for 20 min at 0 °C, anhydrous ether (50 ml) was added to the mixture. The resulting crystalline precipitate was collected and washed with anhydrous ether (10 ml) to give **1a**, 1.26 g (75%), mp 148—150 °C (dec). The filtrate and washings combined were washed with water, dried, and evaporated. The crystalline residue was washed with methanol (10 ml) to give triphenylmethane as white crystals, 1.29 g (75%), mp 93 °C.

Acyl Cyanide. III. Thermal and Base-Catalyzed Reactions of Phenylcarbamoyl Cyanide

Akira Oku,* Takamasa Suzuki, Hajime Koura, and Fujio Mashio
Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received May 6, 1976)

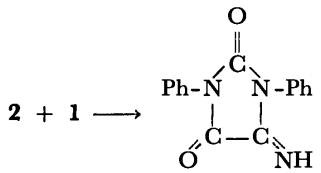
Phenylcarbamoyl cyanide (**1**), under thermal conditions or base-catalysis, behaves as a source of both phenyl isocyanate and hydrogen cyanide in the syntheses of carbamates, cyanohydrins, and iminohydantoins. The reaction mechanism of **1** with methanol in the presence of tertiary amine was investigated. The following observations (i—iii) led us to deduce that phenyl isocyanate was not involved as the intermediate and that the rate-determining step involves nucleophilic displacement of **1** by the alkoxyl group, reinforced by the base: (i) the N–H exchange was too fast to be rate-determining; (ii) *d*-labelling experiments showed $k_H/k_D=1.8$—1.9 in any of the reactions, **1**-d_1+MeOH, **1**-d_0+MeOD, and **1**-d_1+MeOD, and (iii) diphenylcarbamoyl cyanide reacted only 7.2 times slower than did **1**.

Monosubstituted carbamoyl cyanides, RNHCOCN, have been known since 1905, when Dieckmann prepared 1,3-diphenyl-5-iminohydantoin from phenyl isocyanate. However, because of their low thermal stability, relatively few surveys of their chemical properties have appeared in the literature.[1,2] Through the synthesis of a series of thermostable poly(5-iminohydantoin)s from diisocyanates,[3,4] we previously found that the formation of iminohydantoins by the self-condensation of carbamoyl cyanides was facilitated by heating as well as by base catalysis. For this reaction, two mechanisms can be postulated: a) carbamoyl cyanide decomposes thermally or base-catalytically into hydrogen cyanide and isocyanate, after which the latter reacts with another cyanide to give the hydantoin, or b) carbamoyl cyanide self-condenses without forming isocyanate. Much as in the above reaction, carbamoyl cyanide was found to react easily with alcohols to give the corresponding carbamates, and two mechanisms analogous to the above can be postulated: a′) *via* isocyanate, or b′) *via* the nucleophilic displacement of carbamoyl cyanide by alcohol. In view of the paucity of information supporting either mechanism, we have now performed a kinetic study of the reaction of phenylcarbamoyl cyanide with alcohols. Also investigated in the present study is the utilization of phenylcarbamoyl cyanide as a source of isocyanate (masked isocyanate reagent) and hydrogen cyanide as well.

Results and Discussion

Thermal Decomposition of Phenylcarbamoyl Cyanide (1). Cyanide (**1**) gives 1,3-diphenyl-5-iminohydantoin (**4**) when heated in solutions or in molten states. The reaction was interpreted in terms of the thermal decomposition of **1** into hydrogen cyanide and phenyl isocyanate (**2**, not isolated); the latter then reacted further with the undecomposed **1** to give **4**. This assumption prompted the use of bifunctional carbamoyl cyanides as masked reagents of diisocyanates for the synthesis of poly(5-iminohydantoin)s.[3] Thus, we hope that monofunctional carbamoyl cyanides can be utilized as a stable source of isocyanates as well as of hydrogen cyanide in reactions requiring neutral or thermal conditions.

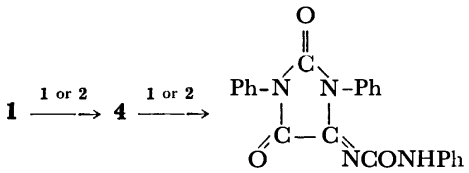
$$\underset{\mathbf{1}}{\mathrm{PhNHCOCN}} \xrightarrow{\text{heat}} \underset{\mathbf{2}}{\mathrm{Ph\text{-}NCO}} + \underset{\mathbf{3}}{\mathrm{HCN}} \qquad (1)$$



$$\mathbf{2} + \mathbf{1} \longrightarrow \mathbf{4} \qquad (2)$$

The mass spectrum of phenylcarbamoyl cyanide (**1**), even when the ionization chamber voltage was varied from 80 to 15 eV and the chamber temperature was lowered from 250 to 160 °C by both direct and indirect in-letting methods, showed no P^+ peak (*m/e* 146 for $C_8H_6N_2O$), but only those peaks ascribable to phenyl isocyanate and hydrogen cyanide. Therefore, either the decomposition of the parent molecule into isocyanate prior to the electron bombardment or the fragmentation of the parent molecular ion after the bombardment must be too fast to allow the detection of the P^+ ion. Coupled with this measurement, the pyrolysis of **1** was carried out by the thermobalance method. Under reduced pressure (20 Torr) **1** started to lose weight appreciably at 85 °C. The decomposition gas trapped in a cold vessel was proved by IR (N=C=O 2270 cm^{-1}) to consist mainly of **2**, while treatment with aniline gave *N,N′*-diphenylurea. Above 110 °C, **1** became a liquid and its decomposition as well as sublimation were considerably accelerated.

The thermal reaction of **1** in solution was then investigated. When **1** alone was heated in boiling dioxane for 60 h, 1,3-diphenyl-5-(phenylcarbamoylimino)-hydantoin (**5**) or **4** was obtained, depending on the reaction conditions (concentration, solvent, and catalyst.)[5] The IR analysis of the solution did not detect



$$\mathbf{1} \xrightarrow{\text{1 or 2}} \mathbf{4} \xrightarrow{\text{1 or 2}} \qquad (3)$$

5

2 throughout the period. Similarly, when **1** was warmed with alcohols in dioxane, the corresponding phenylcarbamates were formed in high yields (Table 1) (as for the mechanism, see below). Consequently, **1** can be adopted as a *phenylcarbamoylating* reagent or, in other words, as a masking reagent of phenyl

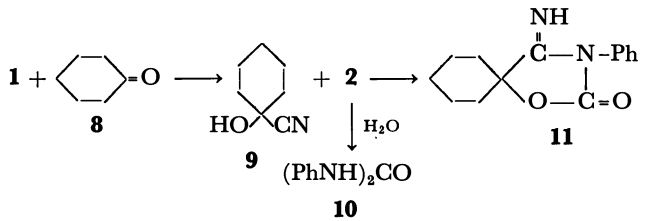
a) A trace amount. b) AcONa was added in Runs 5 and 6. c) Et_3N(0.1 g) was added instead of NaCN. d) The main product was 1,3-diphenyl-5-iminohydantoin.

$$\underset{\mathbf{6}}{\mathbf{1}} + \text{R-OH} \longrightarrow \underset{\mathbf{7}}{\text{PhNHCOOR}} + \text{HCN} \qquad (4)$$

isocyanate in some thermal reactions (or in low-temperature reactions with the aid of bases). Analogously, though less effectively, compound **5** yielded a trace amount of benzyl phenylcarbamate (2%) when treated with benzyl alcohol in boiling dioxane for 30 h, whereas **4** did not.

Generally, investigators are nervous handling hydrogen cyanide in the laboratory. Carbamoyl cyanide, *e.g.*, **1**, can be handled in solid states, being soluble in many organic solvents, and is a safer HCN source. In order to estimate this utilizability, the reaction of **1** with cyclohexanone (**8**) was chosen as the model. The reaction was carried out in the presence of water in order to remove the simultaneously formed isocyanate, **2**, from the reaction system by forming diphenylurea (**10**), because **2** will react further with cyanohydrin,



9, to give cyclic urethane, **11**.[6] The results are shown in Table 2, in which the same salt effect as has been known for the general cyanohydrin synthesis[7] is indicated: *i.e.*, catalysis by a trace amount of the cyanide anion and a buffer effect of sodium acetate in acetic acid.[8] These basic additives also seem to facilitate the decomposition of **1** to generate HCN. Thus, the optimum yield of cyanohydrin **9** was attained almost quantitatively under the conditions of Run 6.

*Base-Catalyzed Reaction of Phenylcarbamoyl Cyanide (**1**) with Methanol.* The formation of carbamates as well as of 5-iminohydantoins from **1** has been known to be facilitated significantly by bases, such as tertiary amines and basic solvents.[3] In order not only to clarify the characteristics of this catalysis, but also to make a rational choice between the two reaction mechanisms, a') and b') (see the Introduction), the rate of the reaction of **1** with methanol was measured under various conditions of base-catalysts, solvents, and isotope-labelling.

Table 3, showing the rate constants as measured by a UV spectroscopic method, indicates that the catalysis of weak bases, such as pyridine or *N,N*-dimethylaniline, is not appreciable, while strong bases such as triethylamine exhibit an apparent rate enhancement even in diluted solutions (10^{-4}—10^{-6} mol/l for base). The

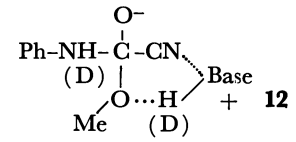
solvent effect is also significant (see Table 4). For example, in dioxane the rate is only 9 times as slow as in methanol, while in cyclohexane it is more than 10^2 times as slow as in dioxane. From these results, we presumed that either of the following two transitions constitutes the rate-determining step: a'') proton abstraction from **1** by a base, or the elimination of cyanide anion from the conjugate base, or b'') the nucleophilic displacement of the cyano group by a base-reinforced methoxyl group.[9]

Mechanism b'') was preferred to a'') by characterizing the deuterium-labelling effect on the rate of the reaction system, Ph–ND (or H)–CO–CN+MeOD(or H) (Table 5). First of all, it was noted that, when **1**-d_1 was prepared by shaking a warm $CDCl_3$ solution of **1**-d_0 with D_2O, the H–D exchange was completed rapidly, without forming either diphenylurea (**10**) or phenyloxamide. This indicates that the N–H abstraction, followed by the rapid elimination of the cyanide anion to give **2**, does not constitute the rate-determining step. In addition, the observed isotope effect, k_H/k_D=1.8—1.95, though not large enough to be the primary kinetic isotope effect, indicates that the elimination of the CN^- group can not be the single step constituting the transition state. The almost equal isotope effects in Runs 3 and 4 (Table 5) may be attributed to the rapid H–D exchange between **1** and methanol prior to the substitution in both runs, and the same equilibrium mixture, in which deuterium incorporates largely into methanol, is formed. This assumption is supported by Run 5, where k_H/k_D is about the same as in Runs 3 and 4.

Consequently, the observed isotope effect can be most rationally interpreted by means of the following tentative model, **12**, for the transition state where the bond fission of MeO–H(D), but not of N–H(D), is involved and where the proton must be almost completely transferred to the base, as is indicated by the small value of the isotope effect. In this mechanism,



+ **12**

the presence of hydrogen on the amide nitrogen must be unimportant in effecting the rate.[10] In fact, the rate of the reaction of diphenylcarbamoyl cyanide (**13**)[11] with methanol, as measured under the same conditions as were set for **1** was only slightly slower than that of **1** ($k_{13}=6.5\times10^{-5}$ s^{-1}, $k_1/k_{13}=7.2$).[12]

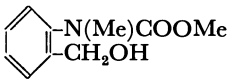
$$(Ph)_2NCOCN + MeOH \longrightarrow (Ph)_2NCOOMe \quad (6)$$

13 **14**

A disproof of Mechanism a'') can also be deduced from the results of Hutchins and his co-workers,[13] who observed a 10^4-fold faster rate of the base-catalyzed intramolecular cyclization of **15** than that of **16**. They elucidated how the reaction of **15** proceeds *via* an isocyanate intermediate, followed by a fast addition of the benzyloxy group, whereas in **16** only a slow displacement by the benzyloxy group is possible. Although this interpretation seems quite similar to Mechanism a''), the k_1/k_{13} ratio of 7.2 seems too small to be accounted for analogously.[14]

In conclusion, though some ambiguity still remains with regard to its details, Mechanism b''), where the RO–H bond fission and the nucleophilic attack of the resulting alkoxyl group are simultaneously involved in the rate-determining transition state, seems most plausible for the reaction of carbamoyl cyanide with alcohols.

15



16

Experimental

Reagents. Phenylcarbamoyl cyanide (**1**) was synthesized from Ph–NCO and HCN according to the method reported for diisocyanates in our previous study.[3] Recrystallization from alcohol-free $CHCl_3$ or Et_2O yielded colorless flakes of **1** (>90%): mp 116—117 °C; $UV_{max}^{cyclohexane}$ 267 nm (ε 10050). Diphenylcarbamoyl cyanide (**13**) was prepared by the reaction of the corresponding chloride with NaCN in MeCN.[11] Recrystallization from a cyclohexane–benzene mixture afforded slightly yellow solids of **13** (65%): mp 130—132 °C; $UV_{max}^{dioxane}$ 262 nm (ε 5000).

Preparation of Phenylcarbamoyl Cyanide-d_1 (*1*-d_1). Deuterated cyanide was prepared by two methods: (i) the reaction of Ph–NCO with DCN, which had been generated from D_2SO_4–D_2O and anhydrous NaCN; (ii) shaking a warm $CDCl_3$ (99.8% d-content) solution of **1** with excess D_2O (99.8% d_2). For recrystallization, $CDCl_3$ was used; otherwise, D–H exchange took place. Also, care was taken not to heat the solution longer than 30 min.

Kinetics. S.P.-Reagent-grade methanol, dioxane, and cyclohexane, available from the Nakarai Chemicals Co., were used in all the measurements. The rates of the reactions of **1** and **13** with methanol were obtained by measuring the change in the absorbance in diluted dioxane solutions (*ca.*

6—8.8×10^{-5} mol/l), where the validity of Beer's rule has preliminarily been confirmed. A Hitachi Model-124 spectrophotometer was used. The analyzing UV bands were: **1** 267 nm (ε 10050), **13** 262 (5000), **7** (R=Me) 236 (15070).

*Pyrolysis of **1**.* A 0.194-g portion of finely pulverized powder of **1** was placed in a platinum basket of a thermobalance (Shimadzu Thermobalance for 2000 mg), whose evacuating outlet was connected to a cold trap cooled at −78 °C. The apparatus was then evacuated to a reduced pressure (20 Torr), and the temperature was raised at a programming rate of 0.7 °C/min from 21 to 74 °C, at a rate of 0.5 °C/min from 74 to 94 °C, and at a rate of 0.2 °C/min from 94 to 103 °C; the weight loss *vs.* time was plotted. The weight loss was observed from 80 °C and was remarkable above 90 °C. Above 110 °C, however, a considerable amount of **1** was sublimed and deposited on the wall of the glass ware; the net loss by the pyrolysis was 46% of the gross loss after 2 h. The trapped liquid (*ca.* 40 mg) showed its ν(NCO) at 2270 cm^{-1} (taken by JASCO IRA-1). An ethereal solution of the trapped liquid gave diphenylurea (65 mg) upon treatment with a few drops of aniline. The remaining solid (88 mg) in the basket was analyzed by TLC (silica gel, $CHCl_3$). Two spots appeared; they were identified with 1,3-diphenyl-5-(phenylcarbamoylimino)hydantoin (**5**, mp 223—225 °C) and unreacted **1** by comparing the R_f values. The mass spectrum of **1** was taken by means of a Hitachi Model RMU-6L by both indirect and direct inletting methods. The spectrum taken at 160 °C and 30 eV showed ion peaks at (*m/e*) 119(Ph-NCO$^+$), 91(PhN$^+$), 64, and 27(HCN$^+$).

*Decomposition of **1** in Cyclohexanone.* To a mixture of **1** (2.6 g, 0.018 mol) and cyclohexanone (9.5 g), we added a solution (2 g) of AcONa saturated in a 1 : 1 mixture of H_2O and AcOH. A catalytic amount of aq NaCN (10 µl of 10% aq solution) was then added, and the total mixture was heated at 67 °C for 17 h. The reaction mixture, without working-up, was directly analyzed by GLC (Apiezon L, 10%, 3 mm×2 m) at 160 °C (below this temperature decomposition of the cyanohydrin was negligible) to find that it consisted of cyclohexanone cyanohydrin (**9**, 98%) and *N,N'*-diphenylurea (**10**). For other runs, see the details in Table 2.

*Thermal Reaction of **1** with Alcohols.* A dioxane solution of **1** and an alcohol were mixed, and the mixture was warmed under the conditions cited in Table 1. After removing the solvent *in vacuo*, the residue was chromatographed (silica gel, $CHCl_3$). The phenylcarbamates thus obtained were all identical with those synthesized independently from Ph-NCO and the corresponding alcohols as for mp and spectroscopic data.

*Reaction of Diphenylcarbamoyl Cyanide (**13**) with Methanol.* Methyl diphenylcarbamate (**14**) was obtained by heating a methanol solution of **13** with a trace amount of triethylamine over 18 h; 100%; mp 84—86 °C.

The authors wish to express their thanks to Mr. Shigeru Fukumori and Mr. Hiroyuki Ueda for their assistance in this study.

14) In other words, if Mechanism a'') is correct, the k_1/k_{13} ratio should have been more than 10^4 because the acidity of the N-H in **1** is greater than in **15** due to the conjugation in the conjugate base, Ph-N=C(-O$^-$)-C≡N.

The Solution Photodimerization of (*E*)-*p*-Nitrocinnamates

Tatsuzo Ishigami, Tomoji Murata, and Tadashi Endo

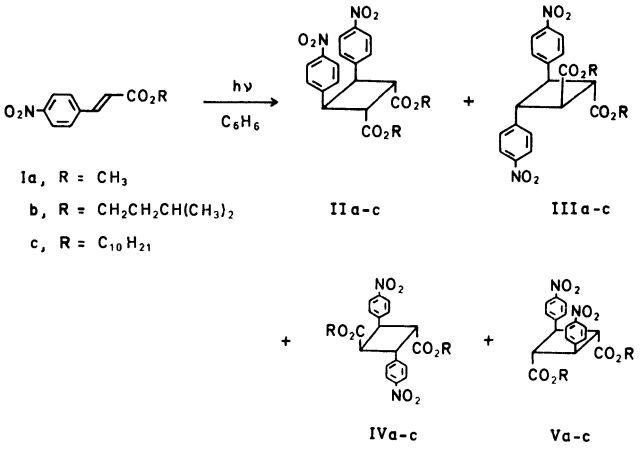
Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received May 12, 1976)

The solution photodimerization of methyl (*E*)-*p*-nitrocinnamate has been studied under various conditions. *Cis* and *trans* dimers of head-to-head configuration were formed predominantly, the ratio of the dimers being highly dependent on the concentration and the solvent. The sensitization, the quenching phenomena, and the external heavy-atom effect were observed in this photodimerization. It appears likely that the excited multiplicity responsible for the formation of the *trans*-dimer is the triplet π,π^* state and that both the singlet and the triplet π,π^* states contribute to the production of the *cis*-dimer.

The formation of four-membered rings through the irradiation of olefins, especially of the α,β-unsaturated carbonyl compounds, is one of the oldest photoreactions in organic chemistry. The photocyclodimerization of the *crystalline* cinnamic acids is a classic illustration of this type of reaction.[1] The crystallographically different α- and β-forms of (*E*)-cinnamic acid exclusively give α-truxillic acid (head-to-tail dimer) and β-truxinic acid (heat-to-head dimer), respectively. The stereospecificity of this cycloaddition is shown to depend mainly upon the packing arrangement of the nearest neighbours in the monomer lattice. Further, cyrstallographic studies have made it clear that, in order for dimerization to occur in either crystal form, the reacting centers must be separated by no more than 4 Å.[1] On the other hand, in *solution* or in the *liquid* state of cinnamic acid, ultraviolet light merely causes an equilibration between the *Z* and *E* isomers.[2] The absence of photodimerization in solution is attributable to the lack of a situation in which the intermolecular carbon-carbon double bonds lie close together, *e.g.*, within 4 Å.

As a fundamental study on the control of photoreactions, this paper deals with the solution photodimerization of (*E*)-*p*-nitrocinnamates giving the two head-to-head photocyclodimers whose ratios vary largely, depending on the irradiation conditions, and also with the mechanistic aspects of this photodimerization.



Results

Photodimerization of Substituted (E)-Cinnamates in Benzene. An argon-saturated benzene solution (0.05 mol dm^{-3}) of methyl (*E*)-*p*-nitrocinnamate (Ia) was externally irradiated with a 450-watt high-pressure mercury arc for 3 h at 10 °C. The resulting solution was subjected to TLC to give the *cis*- (IIa, 14%) and *trans*-head-to-head cyclodimers (IIIa, 29%), together with only a trace amount (1%>) of the *cis*- (IVa) and *trans*-head-to-tail cyclodimers (Va). When the irradiation was effected by the Pyrex-filtered light, the yields of IIa and IIIa were 13 and 36%, respectively. The structures of these cyclobutane derivatives were established by an examination of their NMR and mass spectra.[3] It was also confirmed that both IIa and IIIa are extremely stable under all the irradiation conditions employed.

The *Z*, *E* isomerization of the carbon-carbon double bond generally competes with photodimerization. In the above photoreaction, the rapid equilibration between Ia and its *Z* isomer (VIa) was confirmed by the gas-chromatographic analysis of the reaction mixture; the ratio of Ia to VIa was 0.94 when Ia was irradiated for 10 min and 1.13 under a 3-h irradiation.

In contrast, methyl (*E*)-cinnamate and its derivatives possessing the *p*-chloro, *p*-methoxyl, *p*-methyl, *p*-isopropyl, and *p*-dimethylamino groups underwent only *Z*, *E* isomerization and gave no cyclodimers when irradiated under the conditions described above. However, the prolonged irradiation (65 h) of a more concentrated solution (0.5 mol dm^{-3}) of methyl (*E*)-cinnamate gave the corresponding *cis*- and *trans*-head-to-head cyclodimers in 16 and 37% yields, respectively.

When the bulky isopentyl (Ib) or decyl group (Ic) is the ester moiety, the ratio of the corresponding two cyclodimers (II/III) was found to be 0.26 or 0.20, respectively (Table 1). This can be explained by the greater steric repulsion between the two alkyl groups in II than that in III.

Solvent Effect on the Photodimerization of Ia. The data in Table 2 indicate the dependence of the product distribution on the solvent polarity. The amount of IIa proved to increase with an increase in the dielectric constants[4] or dipole moments[5] of the solvents employed.[6] No relationship existed between the selectivity in this photodimerization and the coefficients of the viscosity[5] of the solvents or the reaction temperature.[7] The use of the polar solvents such as pyridine, acetone, and acetonitrile, raised the yields of the head-to-tail cyclodimers (IVa and Va) considerably in comparison with the use of the nonpolar solvents.

Table 1. Photodimerization of I[a]

Compound	Filter	Conversion (%)	Yield (%)[b]			II/III
			II	III	IV, V	
Ia	Quartz	54	14	29	1	0.48
Ia	Pyrex	62	13	36	2	0.36
Ib	Quartz	55	6	23	1>	0.26
Ic	Quartz	65	8	40	1	0.20

a) Irradiated in a benzene solution (0.05 mol dm^{-3}) under an argon atmosphere with a 450-watt high-pressure mercury lamp for 3 h. b) Based on I employed.

Table 2. Solvent effects on the photodimerization of Ia[a]

Solvent	ε[b]	μ[c]	Conversion (%)	Yield (%)[d]			IIa/IIIa

Solvent[a]	Concn. (mol dm^{-3})	Conversion (%)	Yield (%)[b]		IIa/IIIa
			IIa	IIIa	
Solid-state	—	100	95	0	—
C_6H_6	1×10^{-1}	73	41	16	2.56
C_6H_6	5×10^{-2}	69	15	22	0.68
C_6H_6	5×10^{-3}	69	2	6	0.33

a) Irradiated under an oxygen atmosphere with a 450-watt high-pressure mercury lamp for 3 h. b) Based on Ia employed.

The irradiation of Ia in the halogenated hydrocarbons resulted in the predominant formation of the *trans*-cyclodimer (IIIa) probably by means of the external heavy-atom effect.[8] In the case of dibromomethane, the heavy-atom effect was remarkable, the IIa/IIIa value being 0.03. However, at a lower concentration (5 mol% dibromomethane in benzene) the halogen-containing compounds showed no significant effect.

Effect of Concentration. As is shown in Table 3, the concentration of the reactant (Ia) proved to influence the ratio of the photodimers remarkably. The IIa/IIIa value increased from 0.68 to 2.56 with an increase in the concentration of benzene solution under an oxygen atmosphere. In the case of a dilute solution (5×10^{-3} mol dm^{-3}), polymerization prevailed. These results led us to investigate the solid-state photodimerization. The irradiation of crystalline Ia afforded a single topochemical *cis*-head-to-head cyclodimer (IIa) almost quantitatively. On the other hand, the *trans*-head-to-head cyclodimer was formed as the sole product in only a 7% yield on the irradiation of crystalline methyl (*E*)-*p*-methoxycinnamate. The formation of this "nontopochemical product"[9] might be explained in terms of local melting and the disruption of the lattice control.

Quenching and Sensitization Experiments. The quenching effects of oxygen, azulene, ferrocene, and hydroquinone were also examined (Table 4). In the presence of oxygen, the formation of IIIa was suppressed considerably, the yield of IIa being unaffected. When an argon-saturated 0.05 mol dm^{-3} benzene solution of Ia was irradiated in the presence of azulene (10 mol%, E_T=30.9 kcal/mol[10]), an efficient triplet quencher, the yield of IIIa (10%) turned out to be about one-third that (29%) in the non-quenching solution, the yield of IIa being less affected.

To elucidate the nature of the excited state involved in the formation of IIa and IIIa, the ferrocene quenching[11] was studied in detail. Figures 1 and 2 illustrate the Stern-Volmer plots of the Φ^0/Φ values against the ferrocene concentration for two cyclodimers IIIa and IIa, respectively. With low concentrations of ferrocene ([FcH]$<2.5\times10^{-2}$ mol dm^{-3}) the plot in Fig. 1 is approximately linear, but with higher concentrations ([FcH]$>3.5\times10^{-2}$ mol dm^{-3}) the plot showed an extreme curvature. On the contrary, the relationship between Φ^0_{IIa}/Φ_{IIa} and the ferrocene concentration shown in Fig. 2 is quite different from that of $\Phi^0_{IIIa}/\Phi_{IIIa}$. The quenching plot leveled off once (Φ^0_{IIa}/Φ_{IIa}=1.43) at the concentrations of ferrocene between 5.0×10^{-3} and 3.5×10^{-2} mol dm^{-3}, and again showed a linear increment at higher concentrations.

Table 4. Results of quenching experiments[a]

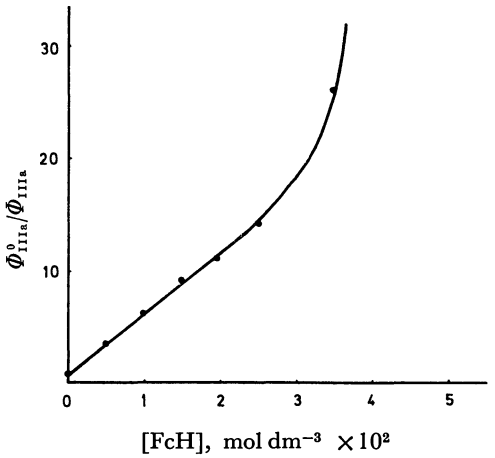

Fig. 1. A Stern-Volmer plot of the IIIa formation as a function of the ferrocene concentration in acetonitrile.

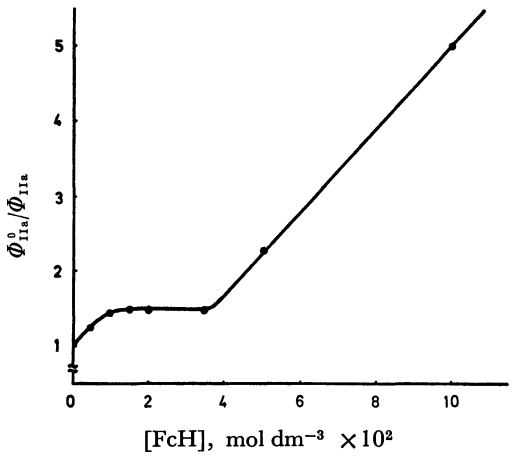

Fig. 2. A Stern-Volmer plot of the IIa formation as a function of the ferrocene concentration in acetonitrile.

The irradiation of Ia in acetonitrile in the presence of an equimolar amount of hydroquinone (an excellent radical scavenger) caused a drastical reduction in the yield of IIIa, along with a slight decline in IIa. It was found that the formation of the head-to-tail cyclodimers (IVa and Va) was suppressed completely by the addition of such a radical scavenger. Further, the rate of the *Z,E* isomerization of Ia was lowered significantly by both the quenchers.

In relation to the possibility of excimer formation in this dimerization, the luminescence of Ia was investigated. No fluorescence from Ia could be observed in benzene at room temperature, probably because of the self-quenching by the methoxycarbonyl or nitro group.[12] The triplet energy of Ia was estimated to be *ca.* 54 kcal/mol based on the phosphorescence measurement of Ia in EPA glass at 77 K. This E_T value suggests that 2,3-butanedione (E_T=56.3 kcal/mol)[13] or 4,4'-bis(dimethylamino)benzophenone (Michler's ketone, E_T=62 kcal/mol)[14] may be an efficient sensitizer. When a benzene solution of Ia (0.05 mol dm^{-3}) and 2,3-butanedione (1.0 mol dm^{-3}) was irradiated (λ>430 nm) for 8 h, the triplet sensitization was observed and the yields of IIa and IIIa were 2 and 17%, respectively. Contrary to our expectations, neither photodimerization nor *Z,E* isomerization of Ia was observed in the Michler's ketone sensitized irradiation (λ>330 nm). This was also the case with the use of dimethylaniline (E_T=76 kcal/mol)[15] in place of Michler's ketone. The quenching by these dimethylamino-containing compounds can be explained by the assumption that the short-lived singlet or triplet exciplex is formed between the nitrophenyl and dimethylaminophenyl moieties and that the excited π-complex consequently undergoes a radiative or radiationless decay to the ground state before the reaction takes place.

Discussion

Increasing solvent polarity favored *cis*-head-to-head cyclodimer formation, while decreasing solvent polarity favored *trans*-head-to-head dimerization. Although neither fluorescence nor triplet excimer[16] phosphorescence from Ia could be observed, it seems probable that this predominant formation of the *cis*-cyclodimer can be interpreted by the hypothesis[17,18] that polar solvents and a concentrated solution generally aid a ground- or excited-state aggregation, leading to a singlet excimer. However, monomer association was not detected in any of the UV spectra at various concentrations (1.0×10^{-5} to 1.0×10^{-1} mol dm^{-3}) in benzene and acetoni-

trile.

Another possible explanation of these observations is the following.[19] Since *cis*-head-to-head dimerization is accompanied by a net increase in the dipole moment, and since *trans* dimerization proceeds with its reduction, solvents of appreciable dipole moments stabilize the transition state[20] (a 1,4-biradical intermediate or weak association between two Ia molecules of the *cis*-head-to-head type orientation), leading to the polar dimer (IIa). This explanation is consistent with the concentration dependence of the *cis* dimerization described before. Concerning the relationship between the concentration and the solvent polarity, Ruhlen and Leermakers have reported that "macroscopic" and "microscopic" polarity decreases as the concentration is reduced.[21] As is shown in Table 2, the effectiveness of *trans* cyclodimerization varied little with the solvents. For *cis* dimerization, however, a change in the solvent from benzene to acetonitrile caused a remarkable two-fold rate acceleration.

The excited-state multiplicities and reaction pathways in this cyclodimerization were studied through sensitization and quenching experiments. The 2,3-butanedione-sensitized irradiation afforded IIIa (IIa/IIIa=0.12) mainly. In the presence of azulene or hydroquinone, the quenching against the IIIa formation is larger than that against the IIa (Table 4). The dissolved oxygen only suppressed the production of IIIa; it had no effect on the yield of IIa.[22] These sensitization and qualitative quenching data suggest that IIIa is formed exclusively from a 1,4-biradical intermediate *via* triplet-excited Ia and IIa mainly from the less-quenchable singlet state with a partial contribution of the triplet-excited state. The linearity of the Stern-Volmer plot for IIIa is a further indication that only one excited state (the triplet state) is involved in the IIIa formation. At the point of $[FcH]=3.5\times10^{-2}$ mol dm^{-3}, the IIIa formation ($\Phi^0_{IIIa}/\Phi_{IIIa}=25.8$) and the *Z*,*E* isomerization of Ia (Ia/VIa=0.188) are quenched almost completely. For IIa, the quenching plot of Φ^0_{IIa}/Φ_{IIa} is once leveled off at the ferrocene concentrations between 5.0×10^{-3} and 3.5×10^{-2} mol dm^{-3}, then it shows a linear increment. The former quenching effect is probably based on the quenching of the triplet state of Ia, and the latter on the singlet quenching (Fig. 2). From the Stern-Volmer plot shown in Fig. 2, the contribution of the triplet state to the IIa formation can be estimated to be 30%; therefore, 70% of the IIa may be formed *via* a singlet state of Ia.

Moreover, the formation of the singlet-derived dimer (IIa) was found to be enormously suppressed in dichloromethane, chloroform, and dibromomethane. This can be ascribed to the heavy-atom solvent, which promotes intersystem crossing, hence providing a higher steady-state concentration of the Ia triplet and resulting in a low efficiency of dimerization from the singlet state (external heavy-atom effect).[23] Considering the heavy-atom effect, which is known to promote the S-$T_{\pi,\pi}$ transition, but not the S-$T_{n,\pi}$ transition,[24] it is likely that the $^3\pi,\pi^*$ state participates in the photodimerization of the aromatic nitro compound Ia to IIa and IIIa. Recent study has shown that the liquid state dimerization of ethyl cinnamate is photosensitized by picramide and *p*-nitroaniline,[25] each of which has a nitro group on its benzene ring. In addition to this fact, our observation described above on the extremely facile photodimerization of Ia should be noted in comparison with methyl (*E*)-cinnamates, which have no nitro group. One possible explanation for these phenomena is that the nitro group in Ia acts as a built-in photosensitizer.

The rapid *Z*,*E* isomerization of Ia competes with its photodimerization, and the photo-stationary value (Ia/VIa) is 1.35 in benzene. Accordingly, there is a very fair possibility that IIa and IIIa might be produced by the turn-over[26] of the VIa-derived intermediate biradicals with the alleviation of the steric intricacy.

In conclusion, we propose the following multipathway mechanism, which is consistent with all of the experimental observations:[27,28] where S=Ia, ^{1}(S···S)=singlet excimer, D=dimers (IIa and IIIa), HA=halo-solvent, Sens=2,3-butanedione, and Q=quencher.

$$S + h\nu \rightarrow {}^1S$$
$${}^1S + S \rightarrow {}^1(S\cdots S)$$
$${}^1(S\cdots S) \rightarrow D\ (IIa)$$
$${}^1S + S \rightarrow D\ (IIa)$$
$${}^1S \rightarrow {}^3S$$
$$S + {}^3Sens \rightarrow {}^3S + Sens$$
$${}^1S + HA \rightarrow {}^3S + HA$$
$${}^3S + S \rightarrow D\ (IIa\ and\ IIIa)$$
$${}^3S + Q \rightarrow S + {}^3Q$$
$${}^3S \rightarrow VIa$$
$$VIa + h\nu \rightarrow {}^1VIa$$
$${}^1VIa \rightarrow S$$

It appears most likely that the IIIa formation proceeds through a biradical intermediate derived from the triplet state (π,π^*) of Ia. In contrast, two different mechanisms are probably concerned with the IIa formation. The major possible pathway is the contribution of a concerted [$_\pi2_s+{}_\pi2_s$] transition state or the geminate reaction of the 1,4-biradical intermediate stabilized in the solvent cage,[29] which is known not to be quenched by a radical scavenger, *via* the singlet excimer of Ia; the minor pathway being the ring closure of the intermediary 1,4-biradical by way of the triplet state (π,π^*) of Ia.

Experimental

General. (*E*)-*p*-Nitrocinnamic acid was prepared from *p*-nitrobenzaldehyde[30] and malonic acid by the method of Wiley and Smith.[31] The following (*E*)-cinnamic acid derivatives were prepared according to the known procedures: *p*-methoxy-,[32] *p*-methyl-,[33] *p*-isopropyl-,[33] *p*-chloro-,[32] and *p*-dimethylamino-(*E*)-cinnamic acid.[34] The esterification of each acid was performed in the presence of sulfuric acid.[35] Acetonitrile was purified in the usual manner.[36] Benzene was purified by two successive distillations. The other reagents were obtained commercially, the liquids were distilled, and the solids were recrystallized, before use. The NMR spectra were taken with a Hitachi R-20 spectrometer in a $CDCl_3$ solution with tetramethylsilane as the internal standard. The mass spectra were made on a Hitachi RMU-

6M mass spectrometer at 70 eV using a heating inlet system. Analytical GLPC chromatography was performed on a Hitachi Model 063 instrument with a flame-ionizaion detector and nitrogen as the carrier gas. The column (3-mm × 1-m) used was 10% silicone SE-30 on Chromosorb W. Analytical and preparative thin layer chromatography (TLC) was carried out on silica gel plates (Merck silica gel 60 F_{254} pre-coated plates).

Irradiation Procedure. All irradiations of solutions were conducted in a 20-ml syrindrical quartz vessel with a neck to accommodate a three-way stopcock. Stirring was effected magnetically. For irradiation with or without a Pyrex filter, a reaction vessel was placed 5 cm away from a light source (Ushio 450 watt UM-452 high-pressure mercury lamp) placed in a water bucket for cooling. In the case of the 313 nm light, the sample solution was irradiated through a Pyrex filter sleeve and a 1-cm path of a 2.0×10^{-3} mol dm^{-3} potassium chromate solution filter.[37] A Toshiba filter V-Y45 was used for the 2,3-butanedione sensitization. The solids were irradiated on Pyrex glass plates at a distance of *ca.* 15 cm at 20 °C.

Irradiation of Ia in Solution. The general execution of the present photodimerization is typically illustrated by the procedure for the conversion of Ia to IIa and IIIa. A benzene solution (20 cm^3) of Ia (207 mg, 1.0 mmol) was saturated with argon after evacuation and then irradiated for 3 h. A quantitative determination by GLPC indicated the recovery of Ia and the yield of VIa to be 23 and 24%, respectively. The reaction mixture was concentrated *in vacuo*, and the residue was subjected to preparative tlc with hexane–ethyl acetate (5:1 v/v) as the eluent to give pure IIa (14%) and IIIa (27%). The identification of IIa and IIIa was made on the basis of the following NMR and mass spectral data by the method given in the literature.[3]

Compound IIa: NMR (60 MHz, $CDCl_3$) δ 3.80 (s, 6H, CH_3), 3.80—4.75 (AA'BB', 4H, cyclobutane ring), 7.24 ($d_{J=9.0\,Hz}$, 2H, aromatic ring), and 8.03 ($d_{J=9.0\,Hz}$, 2H, aromatic ring); mass *m/e* (rel. intensity) 414 (6.8, M^+, $C_{20}H_{18}O_8N_2$), 270 (5.3, $C_{14}H_{10}O_4N_2$), and 207 (100, M/2, $C_{10}H_9O_4N$).

Found: C, 57.88; H, 4.46; N, 6.53%. Calcd for $C_{20}H_{18}O_8N_2$: C, 57.97; H, 4.38; N, 6.76%.

Compound IIIa: NMR (60 MHz, $CDCl_3$) δ 3.82 (s, 6H, CH_3), 3.40—4.10 (AA'BB', 4H, cyclobutane ring), 7.60 ($d_{J=9.0\,Hz}$, 2H, aromatic ring), and 8.20 ($d_{J=9.0\,Hz}$, 2H, aromatic ring); mass *m/e* (rel. intensity) 414 (4.2, M^+, $C_{20}H_{18}O_8N_2$), 270 (12.7, $C_{14}H_{10}O_4N_2$), and 207 (100, M/2, $C_{10}H_9O_4N$).

Found: C, 58.15; H, 4.35; N, 6.88%. Calcd for $C_{20}H_{18}O_8N_2$: C, 57.97; H, 4.38; N, 6.76%.

Despite all our efforts to separate the mixture of IVa and Va, we could not isolate the two isomers in a pure form. Therefore, the structures of IVa and Va were determined by means of the NMR and mass spectra of the mixture. The quantitative analysis of Ia and VIa was performed by the cut-and-weigh integration of GLPC traces using a known amount of benzophenone as the external standard for the correction of the detector response differences.

Actinometry. A conventional method of actinometry was employed; it eliminated errors due to light fluctuations and may inherently give good quantum yield ratios for the Stern-Volmer plot. The actinometer solution, which contained 0.05 mol dm^{-3} Ia in acetonitrile, was photolyzed simultaneously with sample solutions containing 0.05 mol dm^{-3} Ia and varying concentrations of ferrocene. No quantum-yield value was assumed for the actinometer solution. Instead, the ratio (Y^0/Y) of the yields of the dimer in the actinometer and in the sample solutions was used directly. The light absorbed and the time of photolysis were the same for both solutions, so the Y^0/Y value should be equal to the ratio of the quantum yields (Φ^0/Φ).

pH Effects on the Radical Addition of Hydrogensulfite Ion to Olefins

Akihisa SAKUMOTO, Teijiro MIYATA, and Masamitsu WASHINO

Japan Atomic Energy Research Institute, Takasaki, Gunma 370-12

(Received May 20, 1976)

The competitive addition of sodium hydrogensulfite to allyl and 2-methylallyl alcohols was investigated at the pH range from 3 to 5. The relative reactivity of allyl alcohol to 2-methylallyl alcohol decreased with increasing pH. Sulfite radical ion was mainly participating in the addition at pH 5, and hydrogensulfite radical at pH 3. From the kinetic analysis of the pH dependence, the ratio of reactivities of allyl alcohol and 2-methylallyl alcohol toward sulfite radical ion was 0.213, and the same ratio toward hydrogensulfite radical was 0.305. Further, the ratio of reactivities of hydrogensulfite radical and sulfite radical ion toward allyl alcohol was 1.32, and the same ratio toward 2-methylallyl alcohol was 0.927. The dissociation constant of hydrogensulfite radical was the order of 3×10^{-5} ($pK_a=4.5$).

It is well known that the addition reaction of hydrogensulfite ion on α,β-unsaturated bonds conjugated with a functional group such as carbonyl, cyano or nitro group proceeds with an ionic mechanism and produces 1-alkanesulfonates in accord with a simple Michael addition product.[1,2] In the ionic addition, the kinetics and the pH dependence have been extensively investigated.[3,4]

On the other hand, the addition reaction of hydrogensulfite ion to non-conjugated α,β-unsaturated bonds is known to proceed with a radical mechanism and to give products of the anti-Markownikoff character as a main product.[5] Since 1-alkanesulfonates have good surfactant properties and excellent biodegradability,[6] the synthetic reaction initiated by dissolved oxygen,[7] by added free radical agents[8] or by ultraviolet light[9] has been extensively studied, though the kinetics and the adding species are still insufficiently investgated.

In general, sulfite radical ion has been postulated to be the adding species as a chain carrier,[5] but the eleectrically neutral hydrogensulfite radical[10] must be taken into account as the acidity of the solution is increased.

In previous papers, we investigated the kinetics and the hydrogen isotope effect on the radiation-induced addition of sodium hydrogensulfite to allyl alcohol[11,12] and 1-dodecene,[13] in which the sulfite radical ion was postulated as an adding species, but the exact nature of the adding species was not established.

In the present work, allyl and 2-methylallyl alcohols were employed as water soluble olefins for the competitive addition of sodium hydrogensulfite by the photolysis, and the effects of pH and sodium chloride were investigated. From comparison of the ratio of the reactivities of these olefins, some information on the adding species was obtained.

Experimental

Materials. Hydroquinone, sodium hydrogensulfite, and sodium chloride were of GR grade, and no further purification was made. Allyl and 2-methylallyl alcohols of GR grade were refluxed with 2,4-dinitrophenylhydrazine for a few hours and then distilled twice under atmospheric pressure. The purification of water used was performed by distillation.[11]

Preparations of Solutions. Allyl and 2-methylallyl alcohols, and sodium hydrogensulfite were dissolved in the Sörensen solution. Concentrations of allyl and 2-methylallyl alcohols, and sodium hydrogensulfite were 0.439, 0.355, and 0.384—0.480 mol/l, respectively. The ionic strength of the solutions was 1.22 except the case of the solutions including sodium chloride.

pH Range. Figure 1 shows the distribution of ion species of sulfite-hydrogensulfite reagent, which was calculated from the dissociation constant of sulfurous acid.[14] In this work, the pH of the solutions was varied from 3 to 5. The pH value was measured with a TOA HM-18B Digital pH meter.

Irradiation. The reaction vessel was a cylindrical quartz flask fitted with a gas delivery tube which nearly reached to the bottom of the vessel, through which a fairly slow stream of oxygen was supplied during the irradiation. A 30 watt low pressure mercury lamp employed (Rikō-Kagaku UVL-30 LQ) was centered in the reaction vessel. The solution was irradiated at 25 °C for 20 min.

Identification. Allyl and 2-methylallyl alcohols remained in the solution were determined by using a gas chromatograph (Yanagimoto Model G-80) equipped with a flame ionization detector, a thermal conductivity detector, and a 2 m glass column packed with 60—80 mesh Celite 545 coated with 30% Silicone DC 550. 2-Chloroethanol was used as an internal standard.

Conversions of Olefins. The sample solution was irradiated such that from 10 to 40% of 2-methylallyl alcohol was consumed at pH 3.50. In this case, the ratio of conversions of allyl and 2-methylallyl alcohols was independent of the per cent of these olefins consumed. Thus, in this work, about 9% of allyl alcohol and 34% of 2-methylallyl alcohol were consumed.

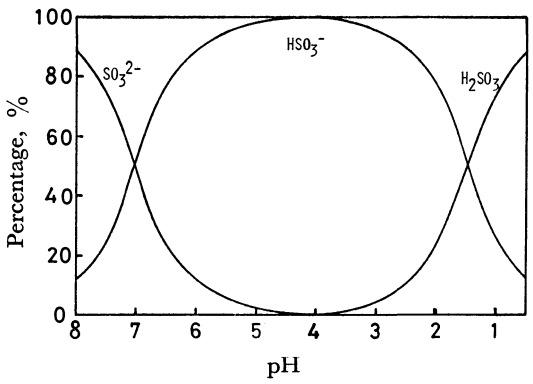

Fig. 1. The ion species distribution of sulfite-hydrogensulfite reagent at 18 °C, which was calculated from the dissociation constant of sulfurous acid.

Results

Competitive additions were performed with runs in duplicate at least. The extent of reaction, that is, the per cent of olefins consumed during a given time of irradiation was not a quite reproducible quantity. It is presumably ascribable to that the chain process by which hydrogensulfite ion adds to olefins is quite susceptible to irradiation time and to trace impurities which can serve as initiators or retardants. However, the ratio of conversions of allyl and 2-methylallyl alcohols was a reproducible quantity at any pH.

The relative reactivity of allyl alcohol (I) to 2-methylallyl alcohol(II) was calculated from the following expression:

$$\text{Relative reactivity} = \frac{(\text{moles of I consumed})/(\text{moles of I initially})}{(\text{moles of II consumed})/(\text{moles of II initially})}$$

The quantity of the relative reactivity was independent of the change from 1.2 to 2.3 in the ratio of the initial concentrations of allyl and 2-methylallyl alcohols.

A plot of the relative reactivity to pH is shown in Fig. 2. As pH was increased, the relative reactivity which remained constant up to about pH 3 decreased gradually and then reached a limiting value above pH 5. The sum of conversions of allyl and 2-methylallyl alcohols at pH 3.07 was 0.162 mol/l and that at pH 4.92 was 0.160 mol/l (Table 1).

Plots of the relative reactivity against the concentration of sodium chloride are shown in Fig. 3. No change of the relative reactivity was observed at pH 2.90. However, the relative reactivity decreased from 0.269 to 0.193 with increasing sodium chloride at pH 4.54. In this case, conversion of 2-methylallyl alcohol increased with increasing sodium chloride; on the other hand, conversion of allyl alcohol remained constant.

Table 1 shows the effect of hydroquinone on conversions of allyl and 2-methylallyl alcohols at pH's 2.90 and 4.54. The solution was added with 2.70×10^{-2} mol/l of hydroquinone and irradiated for 120 min. No consumptions of allyl and 2-methylallyl alcohols were observed in the presence of hydroquinone regardless of the change of pH. Table 1 also shows that the variation of pH in the solution is slight during the irradiation.

Discussion

There is the possibility of the reactions between allyl alcohol and the species $HOCH_2\dot{C}(CH_3)CH_2SO_3^-$ or between 2-methylallyl alcohol and the species $HOCH_2\dot{C}HCH_2SO_3^-$ in the competitive addition because the termination step in the radiation-induced addition of hydrogensulfite ion to allyl alcohol was the reaction between allyl alcohol and the radical $HOCH_2\dot{C}HCH_2SO_3^-$ which was produced by the addition of sulfite radical ion to allyl alcohol.[11]

The kinetic chain length defined as the number of propagation steps per radical of initiator starting chains was 344 in the radiation-induced addition.[11] Since the rate of the termination step is governed by the lability of the hydrogen atom abstracted in olefin, it is assumed that the chain length in the competitive addition is in the same order of magnitude as compared with that in the radiation-induced addition. In other words, the conversions of allyl and 2-methylallyl alcohols by the termination step may be neglected in comparison with the total conversions of these olefins.

In the competitive addition of hydrogensulfite ion to allyl and 2-methylallyl alcohols in the presence of oxygen, it is deduced from the previous paper[11] to produce 3-hydroxypropane-1-sulfonate and 3-hydroxy-2-methylpropane-1-sulfonate with the corresponding 2-hydroxy-1-alkanesulfonates. The formation of these 2-hydroxy-1-alkanesulfonates, however, does not affect conversions of allyl and 2-mehtylallyl alcohols by the reaction of the adding species with these olefins. Therefore, conversions of allyl and 2-methylallyl alcohols in the competitive addition may be regarded as a measure of the reactivities of the corresponding olefins.

Adding Species. The optimum pH for the reaction process was reported to be near 7 by Adams *et al.*[15] or 5—7 by Norton *et al.*[4] This was partly due to a good proportion of hydrogensufite and sulfite ions involved in the propagation during the initial state of the reaction and partly due to decrease in the acidity of the solution causes the undesired side reaction such as the two-electron oxidation of hydrogensulfite ion to hydrogensulfate ion.[4] In this work, the pH range of 3 to 5 was used where nearly 100% of sodium hydrogensulfite dissociated to hydrogensulfite ion.

It is assumed that the species such as SO_2^-, SO_4^- or SO_5^-, produced by the flash photolysis or the pulse radiolysis of sulfite–hydrogensulfite–disulfite ion system,[16] may add to various olefins. Such species, however, should be excluded from the adding species as chain carriers because it is difficult to imagine they can sustain the chain reaction.

Sulfite radical ion, which is proposed as an adding species in the radical addition of hydrogensulfite ion to olefins,[17] possibly exists in equilibrium with hydrogensulfite radical as follows:

$$HSO_3\cdot \rightleftharpoons \cdot SO_3^- + H^+$$

Hydrogensulfite radical, an acidic form of sulfite radical ion, may add to allyl and 2-methylallyl alcohols. Furthermore, this radical in addition to sulfite radical ion had been postulated as one of chain carriers in the autoxidation of sulfite and hydrogensulfite ions, which is one of the most well konwn chain reaction in solution.[18] Therefore, the hydrogensulfite radical is deduced to be one of the adding species in the addition reaction of hydrogensulfite ion.

Addition of hydroquinone suppressed the addition reaction of hydrogensulfite ion as shown in Table 1. Since hydroquinone is an efficient radical scavenger, this observation suggests that the addition reaction proceeds with a radical mechanism over the whole pH range studied.

The effect of hydrogen ion on the relative reactivity was studied. It is well known that when reactions

Table 1. Effect of hydroquinone on conversions of allyl and 2-methylallyl alcohols, and the pH change during the irradiation

Initial concentrations of allyl and 2-methylallyl alcohols are 0.439 and 0.355 mol/l, respectively.

Run	[NaCl][c]	pH		Concentration[d]	
		Initial	Final	Allyl alcohol	2-Methyl-allyl alcohol
1[a]	0.835	4.41		0.434	0.350
2[a]	0.835	2.90		0.436	0.351
3[a]	0	2.95		0.435	0.351
4[b]	0	3.07	3.02	0.395	0.237
5[b]	0	4.92	4.84	0.403	0.231

a) [Hydroquinone] = 2.70×10^{-2} mol/l; irradiation time, 120 min. b) Irradiation time, 20 min. c) mol/l. d) mol/l, after irradiation.

between dipolar molecules or between ions and dipolar molecules occur in solution, there are dipole-dipole interactions between such molecules which promote chemical changes. These interactions are modified by the solvent through its dielectric constant and polar properties.[19] However, the effects of the solvent on such reactions are very small in comparison with the effects on the reactions between ions,[19] as shown in the solvent effects on diazo-coupling reactions.[20,21] Since both allyl and 2-methylallyl alcohols are neutral molecules, the effect of the solvent through the pH change appears to be small. In addition, the extent of the solvent effect tends to cancel in the ratio of the rate constants. Then, if sulfite adical ion is the adding species over the whole pH range studied, the relative reactivity in the competitive addition should be fairly constant, despite change in pH.

The relative reactivity decreased with pH as shown in Fig. 2. Taking account of the equilibrium of sulfite radical ion, it is deduced that hydrogensulfite radical mainly participates in the addition reaction at pH 3 and sulfite radical ion at pH 5. The electronegativity of hydrogensulfite radical is assumed to be different from that of sulfite radical ion. Therefore, decrease of the relative reactivity may be explained by the difference in reactivities of hydrogensulfite radical and sulfite radical ion toward allyl alcohol, and toward 2-methylallyl alcohol.

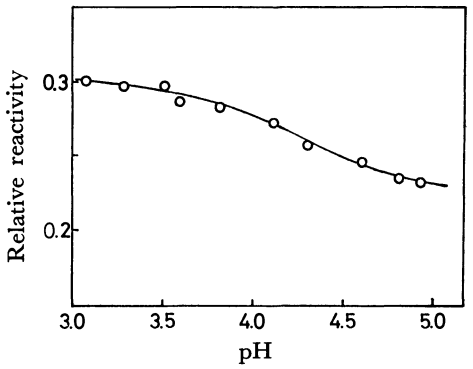

Fig. 2. Variation of the relative reactivity of allyl alcohol to 2-methylallyl alcohol as a function of pH.

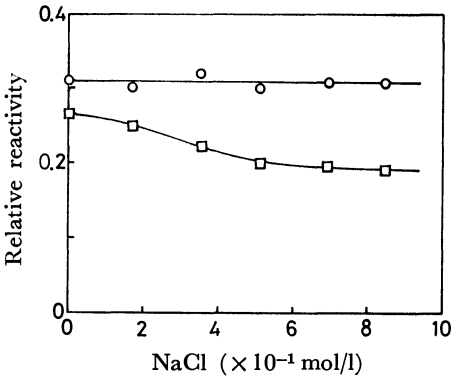

Fig. 3. Effect of sodium chloride on the relative reactivity.
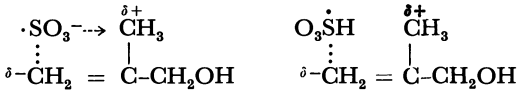
—○— : pH 2.90, —□— : pH 4.54.

In reactions involving neutral molecules or ions and neutral molecules, the influence of the ionic strength on the rate constants is small.[22] The influence of the ionic strength on the relative reactivity in the competitive addition was observed. Namely, the relative reactivity at pH 4.54 decreased with increasing sodium chloride as shown in Fig. 3. In this case, conversion of allyl alcohol remained constant regardless of sodium chloride, while conversion of 2-methylallyl alcohol increased. This observation can also be explained by postulating hydrogensulfite radical and sulfite radical ion as adding species. Hydrogensulfite radical was deduced to be the main adding species at pH 2.90 and sulfite radical ion at pH 4.54. Hence, it is evident that there is the influence of the ionic strength in the reaction between sulfite radical ion and 2-mehtylallyl alcohol.

The methyl group on β-position of 2-methylallyl alcohol is deficient in the electron density because of a electron-donating group. On this basis it is considered that there is the interaction between the negative charge on sulfite radical ion and the methyl group in 2-methylallyl alcohol. Therefore, the influence of the ionic strength is attributable to the difference in the interactions of sulfite radical ion and hydrogensulfite radical toward the methyl group in 2-methylallyl alcohol as follows:



At present, however, no explanation is available to explain the influence of the ionic strength on increase in conversion of 2-methylallyl alcohol.

Dissociation Constant of Hydrogensulfite Radical. The dissociation constant of hydrogensulfite radical, K, was evaluated from the relative reactivity.

Rate constants of reactions between two olefins, allyl and 2-methylallyl alcohols, and the adding species, hydrogensulfite radical and sulfite radical ion, were defined as follows:

$$CH_2{=}CHCH_2OH + \cdot SO_3^- \xrightarrow{k_1} \text{product} \qquad (1)$$

$$CH_2{=}\underset{\underset{CH_3}{|}}{C}CH_2OH + \cdot SO_3^- \xrightarrow{k_2} \text{product} \quad (2)$$

$$CH_2{=}CHCH_2OH + HSO_3\cdot \xrightarrow{k_3} \text{product} \quad (3)$$

$$CH_2{=}\underset{\underset{CH_3}{|}}{C}CH_2OH + HSO_3\cdot \xrightarrow{k_4} \text{product} \quad (4)$$

The ratio of conversion of allyl alcohol, x, to that of 2-methylallyl alcohol, y, at the initial stage of the reaction is expressed by the following equation:

$$\frac{x}{y} = \frac{x_0(k_1[\cdot SO_3^-] + k_3[HSO_3\cdot])}{y_0(k_2[\cdot SO_3^-] + k_4[HSO_3\cdot])} \quad (5)$$

where $[HSO_3\cdot]$ and $[\cdot SO_3^-]$ are concentrations of hydrogensulfite radical and sulfite radical ion, and x_0 and y_0 are initial concentrations of allyl and 2-methylallyl alcohols, respectively.

The K is expressed by the following equation:

$$K = \frac{[\cdot SO_3^-][H^+]}{[HSO_3\cdot]} \times \frac{f(\cdot SO_3^-)f(H^+)}{f(HSO_3\cdot)} \quad (6)$$

where $[H^+]$ is the concentration of hydrogen ion, and $f(HSO_3\cdot)$, $f(\cdot SO_3^-)$, and $f(H^+)$ are activity coefficients of hydrogensulfite radical, sulfite radical ion, and hydrogen ion, respectively.

Substituting Eq. 6 to Eq. 5, the equation required to calculate the K was obtained as follows:

$$\frac{f(\cdot SO_3^-)}{f(HSO_3\cdot)} \times \frac{k_4}{k_2} \times \frac{1}{K} \times [H^+]\times f(H^+) = \frac{\alpha - a}{b - \alpha} \quad (7)$$

where α, a, and b are $(x/y)(y_0/x_0)$, k_1/k_2, and k_3/k_4, respectively.

According to this equation, the term $(\alpha-a)/(b-\alpha)$ should be proportional to the activity of hydrogen ion $[H^+]\times f(H^+)$, because the term $f(\cdot SO_3^-)/f(HSO_3\cdot)\times k_4/k_2\times 1/K$ is constant with a fixed ionic strength. Therefore, the a and b to give this linear relation could be obtained by trial and error. The fitted values of a and b were 0.213 and 0.305, respectively. The solide line in Fig. 4 was drawn by substituting these values into Eq. 7, and the slope was 2.26×10^4.

The term $f(\cdot SO_3^-)/f(HSO_3\cdot)\times k_4/k_2\times 1/K$ in Eq. 7 is equivalent to the slope of the straight line in Fig. 4. Hence, the K can be evaluated by using $f(SO_3^-)$, $f(HSO_3\cdot)$, and k_4/k_2.

The $f(HSO_3\cdot)$ is assumed to be unity because hydrogensulfite radical is a non-charged species.[23] The value of $f(HSO_3^-)$ may be employed to $f(\cdot SO_3^-)$ because the effective diameter of hydrated sulfite radical ion is deduced to be close to that of hydrated hydrogensulfite ion.[24] Now, using the relation between the activity coefficient of ion and the ionic strength in water,[24] the $f(HSO_3^-)$, and hence $f(\cdot SO_3^-)$, was estimated to be 0.70 at the ionic strength 1.2.

The k_4/k_2 was estimated as follows. As shown in Fig. 1, the concentration of hydrogensulfite ion at pH 3.07 is almost equal to that at pH 4.92. Moreover, the pH of the solution hardly changed during the irradiation. Therefore, the sum of rates of hydrogensulfite radical and sulfite radical ion formed by the photolysis at pH 3.07 appears to be equal to that at pH 4.92. In addition, the sum of conversions of allyl and 2-methylallyl alcohols at pH 3.07 was almost equal to that at pH 4.92. In these cases, the irradiation time was fixed for 20 min. On the basis of these results, it is permissible to neglect the difference in the sum of rates of hydrogensulfite radical toward two olefins, allyl and 2-methylallyl alcohols, and sulfite radical ion toward same olefins. Therefore, it may be regarded that allyl and 2-methylallyl alcohols are converted by sulfite radical ion at pH 4.92 and by hydrogensulfite radical at pH 3.07.

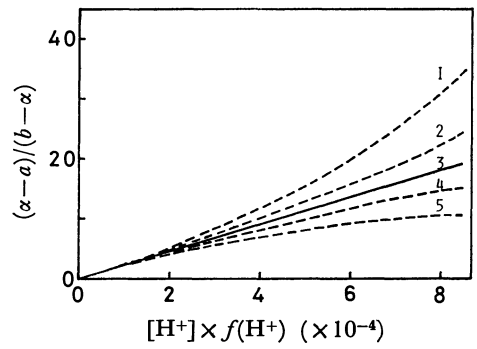


Fig. 4. Variation of $(\alpha-a)/(b-\alpha)$ as a function of the activity of hydrogen ion $[H^+]\times f(H^+)$.
(1) For $a=0.213$ and $b=0.303$, (2) for $a=0.214$ and $b=0.303$, (3) for $a=0.213$ and $b=0.305$, (4) for $a=0.217$ and $b=0.306$, (5) for $a=0.220$ and $b=0.308$.

Now, the ratio of the total amount of allyl and 2-methylallyl alcohols consumed at pH 4.92, S_1, and that at pH 3.07, S_2, at the initial stage of the reaction may be expressed by the following equation.

$$\frac{S_1}{S_2} = \frac{k_2}{k_4} \times \frac{(ax_0+y_0)}{(bx_0+y_0)} \times \frac{[\cdot SO_3^-]}{[HSO_3\cdot]} \quad (8)$$

Taking into account that the rate of the formation of sulfite radical ion at pH 4.92 is deduced to be equal to that of hydrogensulfite radical at pH 3.07 and that the sum of conversions of allyl and 2-methylallyl alcohols at pH 4.92 was almost equal to that at pH 3.07, it may be permitted to postulate $[\cdot SO_3^-]/[HSO_3\cdot]=1$. Now, substituting known values of $a=0.213$, $b=0.305$, $S_1=0.160$, $S_2=0.162$, $x_0=0.439$, and $y_0=0.355$ into Eq. 8, the k_4/k_2 was estimated to be 0.927.

Using the values of k_4/k_2, $f(HSO_3\cdot)$, and $f(\cdot SO_3^-)$, the dissociation constant K was evaluated to be the order of 3×10^{-5} ($pK_a=4.5$). This value is similar to that of $HO_2\cdot$ ($pK_a=4.8$)[25] or simple organic free radical such as $\dot{C}H(OH)CONH_2$ ($pK_a=5.5$)[26] or $CH_3\dot{C}(OH)COOH$ ($pK_a=5.3$).[27]

Apparent Dissociation Constant Obtained Graphically. Since conversion of 2-methylallyl alcohol is more remarkable than that of allyl alcohol, and there is little difference in reactivities of hydrogensulfite redical and sulfite radical ion toward 2-methylally alcohol ($k_4/k_2=0.927$), the relative reactivity-pH curve in Fig. 2 appears to be similar to the dissociation curve of hydrogensulfite radical.

The pH value for the inflection point in Fig. 2 was obtained graphically to be 4.3. Thus, from this pH value, an apparent dissociation constant of hydrogensulfite radical was calculated to be the order of

5×10^{-5} which is compared to the corrected value of 3×10^{-5}.

Reactivities of Olefins and Adding Species. Replacement of one hydrogen atom on β-position of allyl alcohol by a methyl group should donate a negative charge on the terminal methylene carbon. Hence, the electron density on the terminal carbon in 2-methylallyl alcohol is deduced to be higher than that in allyl alcohol.

As already described, k_1/k_2, the ratio of rates in the reactions of allyl and 2-methylallyl alcohols toward sulfite radical ion, was 0.213 and k_3/k_4, the same ratio toward hydrogensulfite radical, was 0.305. These results mean that the reactivity of 2-methylallyl alcohol is larger than that of allyl alcohol regardless of the adding species. This difference in the reactivities is attributed to the difference in the electron densities on the terminal methylene carbon in allyl and 2-methylallyl alcohols.

The k_4/k_2 and k_3/k_1 were used for comparison with the reactivities of hydrogensulfite radical and sulfite radical ion. Since k_4/k_2 was 0.927 as mentioned above, k_3/k_1 was estimated to be 1.32. The former is the ratio of rates in the reactions of hydrogensulfite radical and sulfite radical ion toward 2-methylallyl alcohol, and the latter is the same ratio toward allyl alcohol. Apparently, the reactivity of hydrogensulfite radical toward allyl alcohol is large as compared with that of sulfite radical ion toward same olefin, while the reactivity of hydrogensulfite radical toward 2-methylallyl alcohol is smaller than that of sulfite radical ion toward same olefin. This difference in the trend of reactivities of hydrogensulfite radical and sulfite radical ion is considered, as already described, to be due to the difference in the interactions of hydrogensulfite radical and sulfite radical ion toward the methyl group in 2-methylallyl alcohol.

The addition reaction in this work proceeded with a radical mechanism. Moreover, this addtion was governed by the electronic effect of the methyl group in 2-methylallyl alcohol. This is considered to be due to some degree of electrophilic character of hydrogensulfite radical or sulfite radical ion. No individual rate constant k was determined in this work. Further investigations with different approaches will be necessary.

Synthesis of Protected Peptide Fragments Related to Porcine Motilin[1)]

Shigeru MIHARA, Fumio SHIMIZU, and Seiji MIYAMOTO

The First Research Institute, Tokushima Factory, Otsuka Pharmaceutical Co., Ltd., Kagasuno, Kawauchi-cho, Tokushima 771-01

(Received May 22, 1976)

Syntheses are described of three protected peptide fragments which correspond to positions 1—6, 7—11, and 12—22, respectively, of the entire amino acid sequence of porcine motilin, a gastric motoractivity-promoting polypeptide. Stable tosyl group was used for the protection of ε-amino group of lysine and guanidino group of arginine. These protected peptide fragments were mainly constructed in stepwise manner using benzyloxycarbonyl amino acid by mixed anhydride method in the presence of *N*-hydroxysuccinimide. For preparation of the C-terminal undecapeptide, fragment condensation method was employed using two protected tripeptide azides. The protected peptides and intermediates could be readily purified by simple procedure.

Brown *et al.*[2)] reported the determination of primary structure of porcine motilin, a gastric motoractivity-promoting polypeptide. Synthesis by Wünsch *et al.*[3)] of a norleucine analog based on that structure revealed an incorrect assingment of the amino acid at position 14, and the structure was revised at this position from Glu to Gln.[4)] Yajima *et al.*[5)] have synthesized the docosapeptide corresponding to the revised sequence of porcine motilin.

Limited availability of natural material of this hormone prompted us to prepare it in sufficient amount for further biological and immunological studies. The present paper describes the synthesis of three protected peptide fragments related to porcine motilin which may be employed for the construction of the entire molecule. These protected peptide fragments differ from those used by other investigators for synthesis, of motilin, which correspond to the sequences 1—6 7—11, and 12—22, respectively, as shown in Chart 1.

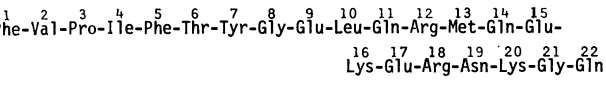

Chart 1. Primary structure of porcine motilin.

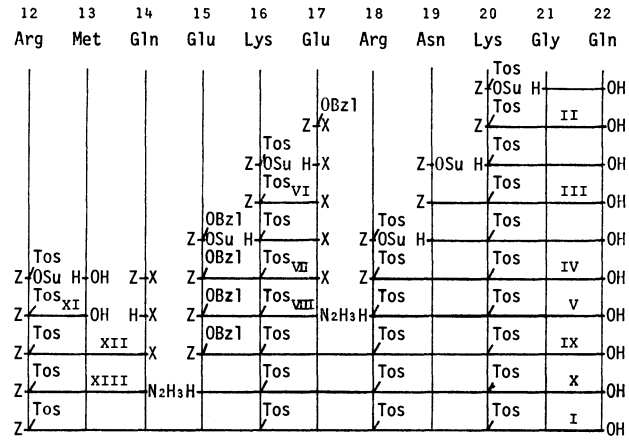
Stable tosyl group was selected for the protection of ε-amino group of lysine and guanidino group of arginine and Z-group was used for protection of α-amino group, since both of the protecting groups can be readily removed by sodium–liquid ammonia or anhydrous HF[6)] treatment at the final step in the synthesis of porcine motilin.

The route for the preparation of C-terminal protected undecapeptide (Fragment 1) (I) is shown in Scheme 1. Protected pentapeptide (IV) was prepared in stepwise manner using Z amino acids by mixed anhydride method in the presence of *N*-hydroxysuccinimide[7)] and then the chain was elongated by acylation with the azides of *N*-benzyloxycarbonyl tripeptides to give protected undecapeptide (I).

Coupling of Z–Lys(Tos)–OSu with triethylammonium salt of H–Gly–Gln–OH[8,9)] produced Z–Lys(Tos)–Gly–Gln–OH (II), which was partially deblocked by hydrogenolysis. Interaction of the resulting product with Z–Asn–OSu[10)] gave Z–Asn–Lys(Tos)–Gly–Gln–OH (III), which was hydrogenated. The partially deblocked tetrapeptide was coupled with Z–Arg(Tos)–OSu and the resulting protected pentapeptide

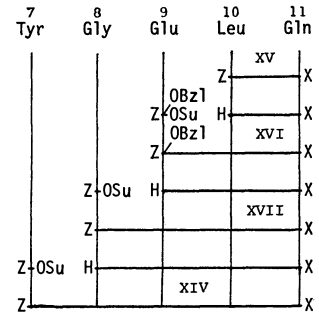


Scheme 1. Synthesis of fragment 1.
X=*t*-butoxycarbonyl hydrazide.

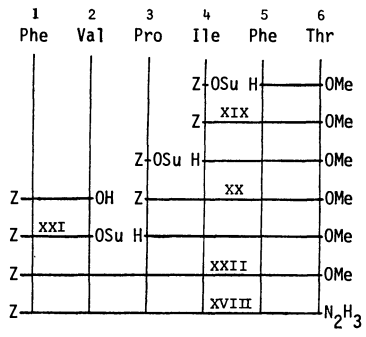
(IV) was subjected to hydrogenolysis to yield H–Arg(Tos)–Asn–Lys(Tos)–Gly–Gln–OH (V). Acylation of V with azide derived from Z–Glu(OBzl)–Lys(Tos)–Glu–NHNH–Boc (VII) gave Z–Glu(OBzl)–Lys(Tos)–Glu–Arg(Tos)–Asn–Lys(Tos)–Gly–Gln–OH (IX). The protected tripeptide hydrazide, VIII, was obtained by the stepwise chain elongation starting from H–Glu–NHNH–Boc derived from Z–Glu(OBzl)–NHNH–Boc.

Hydrogenolysis of IX yielded partially protected octapeptide, H–Glu–Lys(Tos)–Glu–Arg(Tos)–Asn–Lys(Tos)–Gly–Gln–OH (X). This was acylated with azide derived from Z–Arg(Tos)–Met–Gln–NHNH–Boc (XII) to give protected undecapeptide, Z–Arg(Tos)–Met–Gln–Glu–Lys(Tos)–Glu–Arg(Tos)–Asn–Lys(Tos)–Gly–Gln–OH (I). The product was purified by reprecipitation from MeOH with ethyl acetate. Preparation of the protected tripeptide hydrazide XII was accomplished by the interaction of H–Gln–NHNH–Boc[11)] with a mixed anhydride of Z–Arg(Tos)–Met–OH.[12)]

The protected pentapeptide hydrazide (Fragment 2) (XIV) was prepared by the route shown in Scheme 2. Z–Leu–Gln–NHNH–Boc (XV) was obtained by coupling of a mixed anhydride of Z–Leu–OH with H–Gln–NHNH–Boc. This compound was employed as intermediate for preparation of an LH–RH analog.[13)] Hydrogenation of XV gave H–Leu–Gln–NHNH–Boc, which was coupled with Z–Glu(OBzl)–OSu to give protected tripeptide hydrazide (XVI). Subsequent introduction of Gly and Tyr residues was also per-



Scheme 2. Synthesis of fragment 2.



Scheme 3. Synthesis of fragment 3.

formed by active ester procedure.[7] The final product was purified by reprecipitation from MeOH with ethyl acetate to afford the protected pentapeptide hydrazide, Z–Tyr–Gly–Glu–Leu–Gln–NHNH–Boc (XIV).

The route for the preparation of the protected hexapeptide hydrazide (Fragment 3) (XVIII) is shown in Scheme 3.

Z–Phe–Thr–OMe[14] was used as the starting material and hydrogenated to give H–Phe–Thr–OMe, which was coupled with Z–Ile–OSu.[15] The resulting protected tripeptide methyl ester (XIX) was hydrogenated and then the product was acylated with Z–Pro–OSu[7] to give Z–Pro–Ile–Phe–Thr–OMe (XX). Hydrogenation of XX and then acylation with Z–Phe–Val–OSu (XXI) gave Z–Phe–Val–Pro–Ile–Phe–Thr–OMe (XXII), which was converted to the corresponding hydrazide, Z–Phe–Val–Pro–Ile–Phe–Thr–$NHNH_2$ (Fragment 3), by the action of hydrazine.

High purity of the protected peptide fragments, 1, 2, and 3, prepared in this study was proved by elemental analysis, amino acid analysis of their acid hydrolysates and thin-layer chromatography in two solvent systems. The syntheses of these protected peptide fragments proceeded smoothly and homogeneous materials were obtained by simple purification steps. The protected peptide hydrazides, which were prepared mainly by active ester method *via* mixed anhydride or azide procedure, in this study may be suitable intermediates for construction of a large quantity of porcine motilin *via* fragment condensation.[16]

Experimental

The melting points were uncorrected. Optical rotations were measured on a JASCO DIP4 Automatic Polarimeter. Analytical samples were dried *in vacuo* over P_2O_5 at 60—70 °C for 20 h. Amino acid analysis was performed with a HITACHI Model KLA-3B amino acid analyzer. Acid hydrolysis of a sample for amino acid analysis was conducted with 6M HCl at 110 °C for 24 h in a sealed tube. Designations of solvent systems for TLC on silica gel G (Merck) are : R_f^I *n*-BuOH–AcOH–H_2O (4 : 1 : 5) upper layer; R_f^{II} *n*-BuOH–pyridine–AcOH–H_2O (30 : 20 : 6 : 24). All solvents were of reagent grade and were distilled before use. Evaporations were carried out *in vacuo* at 40—45 °C in rotary evaporators.

Z–Lys(Tos)–Gly–Gln–OH (II). Z–Glu–Gln–OH[9] (3.00 g) was hydrogenated over Pd in MeOH (80 ml) containing 10% AcOH (10 ml) in the usual manner. The catalyst was removed by filtration, the filtrate was evaporated and the residue was dried *in vacuo* over P_2O_5 to give H–Gly–Gln–OH[8,9] R_f^I 0.11. To a solution of Z–Lys(Tos)–OH (3.86 g) and *N*-methylmorpholine (0.91 ml) in THF (50 ml) cooled to −15 °C, isobutyl chloroformate (1.11 ml) was added and, after 1 min, an ice-cold solution of *N*-hydroxysuccinimide (1.12 g) in THF (5 ml) was added. The mixture was kept at 0 °C for 5 min and at 20 °C for additional 15 min. The resulting active ester was combined with an ice-cold solution of the above deblocked dipeptide and TEA (1.24 ml) in H_2O (50 ml). The mixture was kept at 20 °C for 20 h, and a bulk of THF was evaporated. The residual aqueous solution was adjusted to pH 8 with TEA and washed with ethyl acetate three times. The solution was acidified with 1 N citric acid and extracted with ethyl acetate. The extracts were dried over Na_2SO_4 and evaporated to give a solid, which was collected by filtration and dried. Reprecipitation from MeOH with ethyl acetate gave II; yield, 3.90 g (70.8%); mp 147—148 °C; $[\alpha]_D^{14}$ −9.6° (*c* 0.52 MeOH); R_f^I 0.64, R_f^{II} 0.72. Found: C, 54.75; H, 6.12; N, 11.09%. Calcd for $C_{28}H_{37}O_9N_5S$: C, 54.27; H, 6.02; N, 11.30%.

Z–Asn–Lys(Tos)–Gly–Gln–OH (III). Hydrogenation of II (1.50 g) was carried out over Pd in MeOH (50 ml) and H_2O (50 ml) in the usual manner. Isolation of the product was performed in the manner as described for the hydrogenation of Z–Gly–Gln–OH, R_f^I 0.33. The hydrogenated material was acylated with the *N*-hydroxysuccinimide ester of Z-Asn-OH (0.96 g) and the product was isolated in the same manner as described for preparation of II. Reprecipitation from MeOH with ethyl acetate gave III; yield, 1.28 g (72.3%); mp 148—150 °C; $[\alpha]_D^{18}$ −27.3° (*c* 0.55 MeOH); R_f^I 0.45, R_f^{II} 0.67. Found: C, 51.76; H, 5.89; N, 13.30%. Calcd for $C_{32}H_{47}O_{11}N_7S \cdot 1/2H_2O$: C, 51.74; H, 5.97; N, 13.19%.

Z–Arg(Tos)–Asn–Lys(Tos)–Gly–Gln–OH (IV). Compound III (1.18 g) was hydrogenated over Pd in MeOH (50 ml) containing 10% AcOH (10 ml) in the usual manner, R_f^I 0.18. The hydrogenated material was acylated with the *N*-hydroxysuccinimide ester of Z–Arg(Tos)–OH (1.11 g) and the product was isolated in the same manner as described for preparation of II. Reprecipitation from MeOH with ethyl acetate gave IV; yield, 1.53 g (91.6%); mp 125—129 °C; $[\alpha]_D^{18}$ −13.0° (*c* 0.54 DMF); R_f^I 0.49, R_f^{II} 0.69. Found: C, 51.17; H, 5.93; N, 14.68%. Calcd for $C_{45}H_{61}O_{14}N_{11}S_2 \cdot H_2O$: C, 50.89; H, 5.98 N, 14.51%.

Z–Lys(Tos)–Glu–NHNH–Boc (VI). Z–Glu(OBzl)–NHNH–Boc (2.60 g) was hydrogenated over Pd in MeOH (50 ml) containing 1 M HCl (5.35 ml) in the usual manner, R_f^I 0.50. The hydrogenated material was coupled with the *N*-hydroxysuccinimide ester of Z–Lys(Tos)–OH (2.55 g) in the same manner as described for preparation of II. The solvents were evaporated. The residue was extracted with ethyl acetate, which was washed with 1 N citric acid and

saturated NaCl and dried over Na_2SO_4. The solvent was evaporated and the residue was solidified by addition of ether. The product was reprecipitated from ethyl acetate with ether; yield, 3.30 g (91.0%); mp 79 °C (dec.); $[\alpha]_D^{25}$ −28.2° (*c* 0.48 MeOH); R_f^I 0.89, R_f^{II} 0.85. Found: C, 55.25; H, 6.77; N, 9.76%. Calcd for $C_{31}H_{43}O_{10}N_5S$: C, 54.93; H, 6.39; N, 10.33%.

Z-Glu(OBzl)-Lys(Tos)-Glu-NHNH-Boc (VII). Compound VI (1.09 g) was hydrogenated over Pd in MeOH (50 ml) in the usual manner, R_f^I 0.60. The hydrogenated material was acylated with the *N*-hydroxysuccinimide ester of Z-Glu(OBzl)-OH (0.71 g) and the product was isolated in the same manner as described for preparation of VI. Reprecipitation from MeOH with ethyl acetate gave VII; yield, 1.03 g (72.0%); mp 81 °C (dec.); $[\alpha]_D^{18}$ −26.8° (*c* 0.50 DMF); R_f^I 0.90, R_f^{II} 0.88. Found: C, 55.56; H, 6.15; N, 8.78%. Calcd for $C_{43}H_{56}O_{13}N_6S\cdot 2H_2O$: C, 55.36; H, 6.48; N, 9.01%.

Z-Arg(Tos)-Met-OH[12] *(XI).* A solution of Z-Arg(Tos)-OH (2.54 g) and *N*-methylmorpholine (0.56 ml) in THF (30 ml) was cooled to −15 °C and isobutyl chloroformate (0.66 ml) was added. After 30 s, *N*-hydroxysuccinimide (0.86 g) dissolved in THF (10 ml) was added. The mixture was combined with an ice-cold solution of H-Met-OH (0.75 g) and TEA (0.70 ml) in H_2O (20 ml). The mixture was kept at 20 °C for 20 h and THF was evaporated. Isolation of the product was carried out in the manner as described for the preparation of II. The residue which was solidified on addition of ether was collected, dried, and reprecipitated from ethyl acetate with ether to give product XI; yield, 2.02 g (66.7%); mp 101—105 °C; $[\alpha]_D^{18}$ −7.4° (*c* 1.01 MeOH); R_f^I 0.83, R_f^{II} 0.80. Found: C, 52.03; H, 5.98; N, 11.54%. Calcd for $C_{26}H_{35}O_7N_5S_2\cdot 1/2H_2O$: C, 51.81; H, 6.02; N, 11.62%.

Z-Arg(Tos)-Met-Gln-NHNH-Boc (XII). Z-Gln-NHNH-Boc[11] (1.00 g) was hydrogenated over Pd in MeOH (50 ml) in the usual manner, R_f^I 0.36. A solution of XI (1.66 g) and *N*-methylmorpholine (0.28 ml) in THF (30 ml) was cooled to −15 °C and isobutyl chloroformate (0.33 ml) was added. After 1 min, the resulting mixed anhydride was combined with an ice-cold solution of the above hydrogenated material in THF (10 ml). The mixture was kept at 0 °C for 5 min and at 20 °C for additional 15 min. The solution was evaporated. The residue was dissolved in ethyl acetate, and the solution was washed successively with 1 N citric acid, saturated NaCl, saturated Na_2HCO_3 and saturated NaCl. The organic layer was dried over Na_2SO_4 and evaporated. The residue which was solidified on addition of ether was collected, dried, and recrystallized from MeOH with ether to give XII; yield, 1.29 g (60.8%); mp 182—183 °C; $[\alpha]_D^{18}$ −16.6° (*c* 0.51 DMF); R_f^I 0.80, R_f^{II} 0.81. Found: C, 51.09; H, 6.38; N, 14.95%. Calcd for $C_{36}H_{53}O_{10}N_9S_2\cdot 1/2H_2O$: C, 51.17; H, 6.44; N, 14.92%.

Z-Glu(OBzl)-Lys(Tos)-Glu-Arg(Tos)-Asn-Lys(Tos)-Gly-Gln-OH (IX). Compound IV (1.00 g) was hydrogenated over Pd in MeOH (50 ml) containing 10% AcOH (10 ml) in the usual manner to give V, R_f^I 0.27. A solution of VII (1.64 g) in TFA (5 ml) was kept at 20 °C for 20 min and addition of ether gave precipitate, which was collected by filtration and dried over KOH. This material (VIII) (1.53 g) was dissolved in DMF (20 ml), and the solution cooled at −15 °C, and 6 M HCl in dioxane (0.96 ml) and isopentyl nitrite (0.28 ml) were added. The mixture was left at −10 °C for 5 min and neutralized with TEA (0.81 ml). To the solution was added an ice-cold solution of the above hydrogenated material V and TEA (0.13 ml) in DMF (30 ml). The mixture was stirred at 4 °C for 20 h and the solvent was evaporated. The residue was extracted with five portions of *n*-BuOH which were washed with six portions of 10% AcOH. Evaporation of *n*-BuOH layers gave a viscous oil, which was solidified from MeOH with ethyl acetate, collected and reprecipitated from MeOH with ethyl acetate to give IX; yield, 1.56 g (97.0%); mp 165—166 °C; $[\alpha]_D^{18}$ −13.4° (*c* 0.52 DMF); R_f^I 0.60, R_f^{II} 0.72. Found: C, 53.36; H, 6.00; N, 12.10%. Calcd for $C_{75}H_{99}O_{23}N_{15}S_3$: C, 53.78; H, 5.96; N, 12.54%.

Z-Arg(Tos)-Met-Gln-Glu-Lys(Tos)-Glu-Arg(Tos)-Asn-Lys(Tos)-Gly-Gln-OH (I) (Fragment 1). Compound IX (0.80 g) was hydrogenated over Pd in MeOH (50 ml) and 50% AcOH (50 ml) for 40 h in the usual manner to give X, R_f^I 0.38. A solution of XII (0.80 g) in TFA (3.5 ml) was kept at 20 °C for 30 min and addition of peroxide free ether gave precipitate, which was collected by filtration and dried over KOH. This material (XIII) was dissolved in DMF (20 ml) and the solution cooled at −15 °C and 6 M HCl in dioxane (0.48 ml) and isopentyl nitrite (0.14 ml) were added. The mixture was left at −10 °C for 5 min and neutralized with TEA (0.53 ml). To the solution was added an ice-cold solution of the above hydrogenated material X and TEA (0.06 ml) in DMF (15 ml). The mixture was stirred at 4 °C for 20 h and the solvent was evaporated. The residue was extracted with five portions of *n*-BuOH which were washed with six portions of 15% AcOH. Evaporation of the *n*-BuOH layers gave an oil, which was solidified from MeOH with ethyl acetate, collected and reprecipitated from MeOH with ethyl acetate to give I; yield, 0.61 g (59.3%); mp 164—165 °C; $[\alpha]_D^{18}$ −17.0° (*c* 0.53 DMF); R_f^I 0.38, R_f^{II} 0.61; amino acid ratios in acid hydrolysate: Met, 0.84; Glu, 4.15; Asp, 0.96; Gly, 0.90; Arg(Tos) and Lys(Tos) were not determined. Found: C, 50.12; H, 6.04; N, 13.66%. Calcd for $C_{91}H_{128}O_{29}N_{22}S_5\cdot 2H_2O$: C, 49.90; H, 6.07; N, 14.07%.

Z-Leu-Gln-NHNH-Boc (XV). A solution of Z-Leu-OH (3.82 g) and *N*-methylmorpholine (1.46 ml) in THF (50 ml) was cooled to −15 °C and isobutyl chloroformate (1.74 ml) was added. After 30 s, the resulting mixed anhydride was combined with an ice-cold solution of H-Gln-NHNH-Boc, derived from Z-Gln-NHNH-Boc[11] (4.37 g), and TEA (1.68 ml) in THF (40 ml). The mixture was kept at 4 °C for 5 min and at 20 °C for further 15 min. The solvent was evaporated. Isolation of the product XV was carried out in the manner as described for the preparation of II; yield, 4.02 g (66.0%); mp 139—140 °C; $[\alpha]_D^{20}$ −44.2° (*c* 0.50 MeOH); R_f^I 0.79, R_f^{II} 0.87. Found: C, 56.47; H, 7.43; N, 13.89%. Calcd for $C_{28}H_{37}O_7N_5$: C, 56.79; H, 7.35; N, 13.80%.

Z-Glu(OBzl)-Leu-Gln-NHNH-Boc (XVI). Compound XV (2.00 g) was hydrogenated over Pd in MeOH (50 ml) containing 1 M HCl (3.9 ml) in the usual manner, R_f^I 0.48. The hydrogenated material was coupled with the *N*-hydroxysuccinimide ester of Z-Glu(OBzl)-OH (1.74 g) in the same manner as described for preparation of II. The solvent was evaporated. The residue was solidified by addition of H_2O, which was collected by filtration and dried. Reprecipitation from MeOH with ethyl acetate gave XVI; yield, 2.30 g (81.1%); mp 175—180 °C; $[\alpha]_D^{18}$ −26.6° (*c* 0.53 DMF); R_f^I 0.89, R_f^{II} 0.92. Found: C, 59.73; H, 6.93; N, 11.44%. Calcd for $C_{36}H_{50}O_{10}N_6$: C, 59.49; H, 6.93; N, 11.56%.

Z-Gly-Glu-Leu-Gln-NHNH-Boc (XVII). Compound XVI (2.20 g) was hydrogenated over Pd in MeOH (80 ml) containing 10% AcOH (10 ml) in the usual manner, R_f^I 0.38. The hydrogenated material was coupled with the *N*-hydroxysuccinimide ester of Z-Gly-OH (0.76 g) in

the same manner as described for preparation of II. The solvents were evaporated. The residue was dissolved in ethyl acetate, and the solution was washed with 1 N citric acid and H_2O and dried over Na_2SO_4. The solvent was evaporated to give solid which was collected by filtration and dried. Reprecipitation from MeOH with ethyl acetate gave XVII; yield, 1.44 g (68.6%); mp 163—166 °C; $[\alpha]_D^{20}$ −22.9° (*c* 0.50 DMF); R_f^I 0.75, R_f^{II} 0.76. Found: C, 53.38; H, 6.93; N, 14.46%. Calcd for $C_{31}H_{47}O_{11}N_7$: C, 53.67; H, 6.83; H, 14.13%.

Z–Tyr–Gly–Glu–Leu–Gln–NHNH–Boc (XIV) (Fragment 2). Compound XVII (1.41 g) was hydrogenated over Pd in MeOH (50 ml) containing 10% AcOH (5 ml) in the usual manner, R_f^I 0.35. DCC (0.50 g) was added to a solution of Z–Tyr–OH (0.77 g) and *N*-hydroxysuccinimide (0.28 g) in THF (40 ml) at 4 °C. The mixture was stirred at 4 °C for 20 h. The dicyclohexylurea was removed by filtration, and the solvent was evaporated. The residue, which was solidified on addition of ether–petroleum ether (1 : 2), was collected and dried. The resulting active ester was added to an ice-cold solution of the above hydrogenated material and TEA (0.28 ml) in DMF (20 ml). The mixture was kept at 20 °C for 20 h and DMF was evaporated. The residue was dissolved in ethyl acetate, which was washed with 1 N citric acid and H_2O and dried. The solvent was evaporated and the residue was solidified by addition of MeOH–ethyl acetate, collected, and reprecipitated from MeOH with ethyl acetate to give XIV; yield, 1.46 g (84.0%); mp 164—165 °C; $[\alpha]_D^{16}$ −46.4° (*c* 0.54 DMF); R_f^I 0.79, R_f^{II} 0.77; amino acid ratios in acid hydrolysate: Tyr, 0.89; Gly, 0.99; Glu, 2.10; Leu, 1.03. Found: C, 54.87; H, 6.62; H, 12.86%. Calcd for $C_{40}H_{56}O_{13}N_8 \cdot H_2O$: C, 54.91; H, 6.68; N, 12.81%.

Z–Ile–Phe–Thr–OMe (XIX). *Z–Phe–Thr–OMe*[14] (2.90 g) was hydrogenated over Pd in MeOH (50 ml) containing 1 M HCl (7 ml) in the usual manner, R_f^I 0.55. Z–Ile–OSu[15] (3.80 g) was added to an ice-cold solution of the above hydrogenated material and TEA (0.98 ml) in DMF (50 ml). The mixture was kept at 20 °C for 40 h and the solvent was evaporated. To the residue was added 1 N citric acid. The precipitate thus formed was collected by filtration and then washed with hot MeOH to yield XIX; yield, 3.15 g (85.4%); mp 210—211 °C; $[\alpha]_D^{20}$ −13.1° (*c* 0.50 DMSO); R_f^I 0.87, R_f^{II} 0.85. Found: C, 63.66; H, 7.11; N, 8.19%. Calcd for $C_{28}H_{37}O_7N_3$: C, 63.74; H, 7.07; N, 7.96%.

Z–Pro–Ile–Phe–Thr–OMe (XX). Compound XIX (3.00 g) was hydrogenated over Pd in MeOH (80 ml) containing 10% AcOH (10 ml) in the usual manner, R_f^I 0.52. Z–Pro–OSu[7] (2.95 g) was added to an ice-cold solution of the above hydrogenated material and TEA (0.79 ml) in DMF (50 ml). The mixture was kept at 20 °C for 20 h and the solvent was evaporated. The residue was solidified by addition of 5% AcOH, which was collected by filtration, washed with H_2O and dried. The solid was then washed with hot MeOH to give XX; yield, 3.35 g (94.4%); mp 235—236 °C; $[\alpha]_D^{20}$ −38.2° (*c* 0.50 DMSO); R_f^I 0.86, R_f^{II} 0.85. Found: C, 63.00; H, 7.02; N, 9.27%. Calcd for $C_{33}H_{44}O_8N_4$: C, 63.44; H, 7.10; N, 8.97%.

Z–Phe–Val–OSu (XXI). To an ice-cold solution of Z–Phe–Val–OH[17] (3.05 g) and *N*-hydroxysuccinimide (0.88 g) in THF (40 ml) was added DCC (1.58 g), and the mixture was stirred at 4 °C for 18 h. The suspension was filtered, and the filtrate was evaporated. The solid residue, which was obtained on addition of ether, was collected, dried, and recrystallized from EtOH; 3.25 g (85.2%); mp 156—157 °C; $[\alpha]_D^{20}$ −11.6° (*c* 2.30 dioxane); Found: C, 63.23; H, 6.14; N, 8.46%. Calcd for $C_{26}H_{29}O_7N_3$: C, 63.02; H, 5.90; N, 8.48%.

Z–Phe–Val–Pro–Ile–Phe–Thr–OMe (XXII). Compound XX (1.73 g) was hydrogenated over Pd in a mixture of MeOH (80 ml), 10% AcOH (30 ml) and *n*-BuOH (20 ml) in the usual manner, R_f^I 0.51. Z–Phe–Val–OSu (1.64 g) was added to an ice-cold solution of the above hydrogenated material and TEA (0.38 ml) in DMF (20 ml). The mixture was kept at 20 °C for 20 h and the solvent was evaporated. Isolation of the product was carried out in the manner as described for the preparation of I; yield, 0.99 g (40.3%); mp 172—174 °C; $[\alpha]_D^{16}$ −58.5° (*c* 0.51 DMF); R_f^I 0.86, R_f^{II} 0.90. Found: C, 63.31; H, 7.25; N, 9.89%. Calcd for $C_{47}H_{62}O_9N_6 \cdot H_2O$: C, 63.50; H, 7.26; H, 9.45%.

Z–Phe–Val–Pro–Ile–Phe–Thr–NHNH$_2$ (XVIII) (Fragment 3). Hydrazine hydrate (90%) (0.92 ml) was added to an ice-cold solution of XXII (0.95 g) in DMF (3 ml) and the solution was kept at 20 °C for 20 h. The solvent was evaporated and the residue was extracted with five portions of *n*-BuOH which were washed with six portions of 10% AcOH. Evaporations of the *n*-BuOH layers gave an oil which was solidified by addition of ether. The solid was collected and dried; yield, 0.58 g (60.7%); mp 209—211 °C; $[\alpha]_D^{20}$ −45.9° (*c* 0.51 DMSO); R_f^I 0.75, R_f^{II} 0.80; amino acid ratios in acid hydrolysate: Phe, 2.04; Val, 1.12; Pro, 0.93; Ile, 1.00; Thr, 0.92. Found: C, 62.64; H, 7.06; N, 12.55%. Calcd for $C_{46}H_{62}O_9N_8 \cdot H_2O$: C, 62.14; H, 7.26; N, 12.60%.

The authors are deeply indebted to Prof. Noboru Yanaihara, Shizuoka College of Pharmacy, and Mr. Akihiko Otsuka, vice president of Otsuka Pharmaceutical Co., Ltd., for their kind advice and encouragment during the course of this work.

(Received May 22, 1976)

Synthesis of porcine motilin is described. Construction of the entire molecule of this hormone was carried out by the fragment condensation method in solution employing Rudinger's azide modification, and the resulting protected docosapeptide was deblocked by sodium-liquid ammonia procedure. Purification of the final product was performed by ion exchange chromatography on CM-Sephadex using ammonium acetate as eluent and gel filtration on BiO-Gel P-6. Purity of the synthetic docosapeptide was assessed by TLC in two different solvent systems and amino acid analysis. This polypeptide showed gastric motoractivity stimulating action on 30 min intravenous infusion in dogs in 5 ng/kg/min doses, which is characteristic to porcine motilin.

Porcine motilin is a single chain peptide consisting of 22 amino acid residues.[2,3)] We have described in the preceding paper[4)] synthesis of the three protected peptide fragments 1, 2, and 3 corresponding to the amino acid sequences 1—6, 7—11, and 12—22 of the porcine motilin molecule, respectively (Chart 1). Using these fragments, our continuous synthetic studies on this gastrointestinal hormone have been focussed on its total synthesis by efficient means in regard to yield and purity of the products. The details of the synthesis are described in this communication. Syntheses of porcine motilin[5,6)] and its analogs, [13-Nle, 14-Glu]-motilin,[7)] by different approaches have been reported.

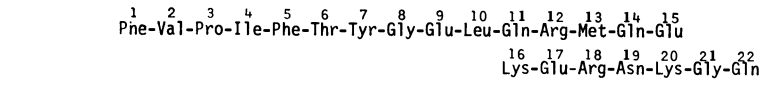

Chart 1. Primary structure of porcine motilin.

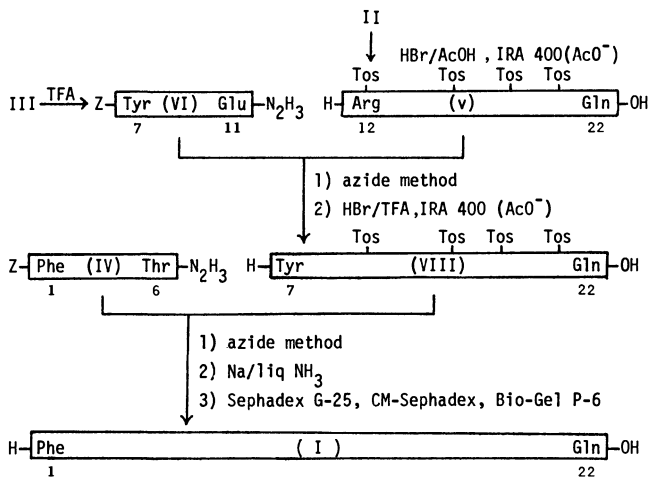
Construction of the entire molecule of porcine motilin was conducted by the fragment condensation method in solution employing Rudinger's azide modification.[8)] Scheme 1 shows the route for our synthesis of porcine motilin using the three protected peptide fragments 1, 2, and 3.

Z–Arg(Tos)–Met–Gln–Glu–Lys(Tos)–Glu–Arg(Tos)–Asn–Lys(Tos)–Gly–Gln–OH[4)] (Fragment 1) (II) was deblocked by HBr in acetic acid in the presence of anisole and ethyl methyl sulfide as scavengers. The resulting partially protected undecapeptide H–Arg(Tos)–Met–Gln–Glu–Lys(Tos)–Glu–Arg(Tos)–Asn–Lys(Tos)–Gly–Gln–OH (V) was coupled with the azide derived from Z–Tyr–Gly–Glu–Leu–Gln–NHNH–Boc[4)] (Fragment 2) (III) to give protected hexadecapeptide, Z–Tyr–Gly–Glu–Leu–Gln–Arg(Tos)–Met–Gln–Glu–Lys(Tos)–Glu–Arg(Tos)–Asn–Lys(Tos)–Gly–Gln–OH (VII). The crude product was distributed into *n*-BuOH and 10% AcOH. The *n*-BuOH layers were evaporated and the desired product was precipitated by addition of 10% AcOH. Removal of the Z-group from the protected hexadecapeptide (VII) was conducted with HBr in trifluoroacetic acid containing anisole and ethyl methyl sulfide as scavengers. The resulting partially protected hexadecapeptide hydrobromide was converted to the acetate (VIII) and coupled with the azide derived from Z–Phe–Val–Pro–Ile–Phe–Thr–$NHNH_2$[4)] (Fragment 3) (IV). The products were distributed into *n*-BuOH and 10% AcOH. Crude protected docosapeptide Z–Phe–Val–Pro–Ile–Phe–Thr–Tyr–Gly–Glu–Leu–Gln–Arg(Tos)–Met–Gln–Glu–Lys(Tos)–Glu–Arg(Tos)–Asn–Lys(Tos)–Gly–Gln–OH (IX) was obtained from the *n*-BuOH layers.



Scheme 1. Synthesis of porcine motilin.

Deblocking of this material was carried out by the treatment of sodium in liquid ammonia. The tosyl groups protecting the side chain amino function of lysine and guanidino function of arginine and the Z-group attached to the N-terminal phenylalanine were simultaneously cleaved by this process. The resulting material was subjected to gel filtration on Sephadex G-25 and then to ion exchange chromatography on CM-Sephadex using as eluate NH_4OAc buffer (pH 4.5) of linear gradient concentration. The desired product was eluated with 0.2—0.3 M NH_4OAc. The purified docosapeptide, after gel filtration on Bio-Gel P-6, gave the expected amino acid analysis with its acid hydrolysate and behaved as a single component on thin-layer chromatography in two solvent systems. Its stereohomogeneity was assessed by AP-M digestion.

This synthetic polypeptide showed gastric motoractivity stimulating action in the stomach and duodenum of dogs on 30 min intravenous infusion in 5 ng/kg/min

doses, which is characteristic to natural porcine motilin.

In the present investigation, our route for synthesis of porcine motilin using three protected peptide fragments was found to be efficient to obtain the hormone of high purity. In particular, use of sodium in liquid ammonia for deprotection of the final coupling product was effective in this synthesis.

Experimental

The melting points were uncorrected. Optical rotations were measured on a JASCO DIP4 Automatic Polarimeter. Analytical samples were dried *in vacuo* over P_2O_5 at 60—70 °C for 20 h. Amino acid analysis was performed with a HITACHI Model KLA-3B amino acid analyzer. Acid hydrolysis of a sample for amino acid analysis was conducted with 6 M HCl at 110 °C for 24 h in a sealed tube. AP-M digestion[9] (400 mU AP-M/mg sample) was carried out in 0.05 M Tris-HCl buffer (pH 7.8) at 37 °C for 24 h. Designations of solvent systems for TLC on silica gel G (Merck) are: R_f^I *n*-BuOH–AcOH–H_2O (4 : 1 : 5) upper layer; R_f^{II} *n*-BuOH–pyridine–AcOH–H_2O (30 : 20 : 6 : 24). All solvents were of reagent grade and were distilled before use. Evaporations were carried out *in vacuo* at 40—45 °C in rotary evaporaters.

Z–Tyr–Gly–Glu–Leu–Gln–Arg(Tos)–Met–Gln–Glu–Lys(Tos)–Glu–Arg(Tos)–Asn–Lys(Tos)–Gly–Gln–OH (VII). To a solution of II (0.517 g) in glacial AcOH (2 ml) was added 25% HBr solution in AcOH (3 ml) containing anisole (0.1 ml) and ethyl methyl sulfide (0.1 ml). The solution was kept at 20 °C for 1 h and peroxide-free anhydrous ether was added. The resulting precipitate was collected, washed with ether and dried over KOH. The material was dissolved in *n*-BuOH–MeOH–H_2O (1 : 1 : 1) (100 ml) and the solution was passed through IRA-400 column (acetate form). The solvents were evaporated and the residue was lyophilized to give V; yield, 0.303 g (67.2%), R_f^I 0.29.

A solution of III (0.257 g) in TFA (1 ml) was kept at 20 °C for 30 min and addition of anhydrous ether gave precipitate, which was collected by filtration and dried over KOH. This material was dissolved in DMF (3 ml), and the solution cooled at −15 °C, and 6 M HCl in dioxane (0.25 ml) and 10% isopentyl nitrite in DMF (0.44 ml) were added. The mixture was left at −10 °C for 5 min and neutralized with 10% TEA in DMF (2.50 ml). To the solution was added an ice-cold solution of V (0.303 g) in DMF (5 ml) containing TEA (0.06 ml). The mixture was stirred at 4 °C for 20 h. An additional azide prepared from III (0.257 g) was added and the reaction mixture was stirred at 4 °C for further 20 h. After evaporation of solvents, the product was distributed into *n*-BuOH and 10% AcOH in 10 separatory funnels, and the *n*-BuOH layers containing the desired material was evaporated. To the residue was added 10% AcOH to give precipitate, which was collected by filtration, washed with MeOH and dried; yield, 0.190 g (46.2%); mp 120 °C (dec); $[\alpha]_D^{18}$ −21.0° (*c* 0.50 DMF); R_f^I 0.40, R_f^{II} 0.62. Found: C, 50.18; H, 6.03; N, 13.43%. Calcd for $C_{118}H_{166}O_{38}N_{28}S_5 \cdot 4H_2O$: C, 50.30; H, 6.22; N, 13.92%.

H–Phe–Val–Pro–Ile–Phe–Thr–Tyr–Gly–Glu–Leu–Gln–Arg–Met–Gln–Glu–Lys–Glu–Arg–Asn–Lys–Gly–Gln–OH (I) (Porcine motilin). Compound VII (0.170 g) was dissolved in TFA (5 ml) containing anisole (0.1 ml) and ethyl methyl sulfide (0.1 ml), which was bubbled with HBr gas at 0 °C for 15 min and then at 20 °C for 15 min. The reaction mixture was allowed to stand at 20 °C for 30 min, and peroxide-free anhydrous ether was added. The resulting precipitate was collected by filtration and dried. The amorphous material was dissolved in *n*-BuOH–MeOH–H_2O (1 : 1 : 1) (50 ml) and the solution was passed through IRA-400 column (acetate form). The solvents were evaporated and the residue was lyophilized to yield VIII as acetate, R_f^I 0.38. A solution of IV (0.160 g) in DMF (3 ml) was cooled to −15 °C and 6 M HCl in dioxane (0.16 ml) and 10% isopentyl nitrite in DMF (0.28 ml) were added. After 1 min, the solution was neutralized with 10% TEA in DMF (1.28 ml) and mixed with an ice-cold solution of the above partially deblocked material VIII in DMF (4 ml) containing TEA (0.04 ml). The mixture was stirred at 4 °C for 20 h. An additional azide prepared from IV (0.120 g) was added and the reaction mixture was stirred at 4 °C for further 20 h. After evaporation of solvents, the product was distributed into *n*-BuOH and 10% AcOH in 5 separated funnels and the *n*-BuOH layers containing the desired material were evaporated. Ethyl acetate was added to the residual solution to give amorphous material, which was reprecipitated from MeOH with ethyl acetate to give IX.

The protected docosapeptide, IX, was dissolved in liquid ammonia (20 ml) and small pieces of Na were added until the blue color of the reaction mixture was maintained for 2 min. Ammonium chloride (1.0 g) was added and ammonia was evaporated off. The residue was dissolved in 50% AcOH and applied to a Sephadex G-25 column (3.1 × 190 cm) which was eluted with the same solvent. Fractions of 15 g each were collected. The desired material was located in the tubes No. 36—46. The solvents of these fractions were evaporated and the residue was dissolved in 0.01 M NH_4OAc (pH 4.5) (5 ml). The solutions were applied to a column of CM-Sephadex C-25 (2.0 × 5 cm) equilibrated with the buffer. The column was washed with 0.01 M NH_4OAc (pH 4.5) (200 ml) and then eluted with linear gradient of NH_4OAc (pH 4.5) from 0.01 M to 0.5 M using 0.01 M (500 ml) and 0.5 M (500 ml) of the buffer. Fractions of 10 g each were collected. Each fraction was examined by TLC in two different solvent systems and UV absorption at 278 nm. The desired material with minor contamination was eluted in the tubes No. 65—85. The eluates were collected and the solvent was evaporated. After repeated lyophilization, the product was dissolved in 50% AcOH and applied on Bio-Gel P-6 column (3.2 × 190 cm), which was eluted with the same solvent. Fractions of 10 ml each were collected. The desired peptide behaving as a single component on TLC was located in tubes No. 64—75. These were pooled and lyophilized; yield, 49 mg. $[\alpha]_D^{20}$ −53.7° (*c* 0.49 H_2O); R_f^I 0.15, R_f^{II} 0.43; amino acid ratios in acid hydrolysate: Phe, 1.87; Val, 0.96; Pro, 0.96; Ile, 1.04; Thr, 0.94; Tyr, 0.97; Gly, 2.00; Glu, 5.60; Leu, 1.07; Arg, 2.00; Met, 0.77; Lys, 2.13; Asp, 1.00 (average recovery 88%); amino acid ratios in AP-M digest[10]: Phe, 2.18; Ile, 1.22; Tyr, 0.97; Gly, 2.08; Glu, 2.90; Leu, 1.01; Arg, 1.69; Met, 0.84; Lys, 2.10 (recovery 81%) (Asn, Gln and Thr were not estimated and Val and Pro were found in trace).[11,12] Found: C, 47.45; H, 7.39: N, 15.38%. Calcd for $C_{120}H_{188}O_{35}N_{34}S \cdot CH_3COOH \cdot 18H_2O$: C, 47.52; H, 7.45; N, 15.44%.

The authors wish to express their sincere thanks to Dr. Zen Itoh, the Department of Surgery of Gunma University, for bioassay. Thanks are also due to Mr. Akihiko Otsuka, vice president of Otsuka Pharmaceutical Co., Ltd., for his support during the course of this work.

The Reaction of Disodium Tetracarbonylferrate(−II) with Aldehydes[1]

Masakazu YAMASHITA, Yoshihisa WATANABE, Take-aki MITSUDO, and Yoshinobu TAKEGAMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received June 1, 1976)

Disodium tetracarbonylferrate (−II) is an efficient catalyst for the dismutation of aromatic aldehydes to esters, $2RCHO \rightarrow RCOOCH_2R$. Aliphatic ones give aldol-condensation products upon treatment with the ferrate. A successive reaction of the ferrate with an aldehyde, RCHO, and then with alkyl iodide, R'I, gives an ester, $R'COOCH_2R$, after protonation. The mechanisms of these reactions are discussed.

Disodium tetracarbonylferrate(−II) (**1**) is known to be a selective reagent for organic syntheses. For example, using this reagent, alkyl halides or carboxylic acid derivatives are selectively converted into aldehydes[2-5] or ketones,[6,7] and enol esters are derived from β-oxoalkyl halides.[8]

Although the reactions of alkyl halides, tosylates, or carboxylic acid derivatives with **1** have been studied hitherto, little attention has been paid to the reaction of **1** with carbonyl compounds. This report will deal with the reaction of **1** with aldehydes.

Results and Discussion

Certain aldehydes react with **1** under mild conditions to give an ester; two aldehyde groups are transformed into the corresponding alkoxyl and carboxyl functions, existing in combination as an ester. These reactions proceed by means of a catalytic amount of

$$2RCHO \xrightarrow{(1)} RCOOCH_2R$$

1. When benzaldehyde (100 mmol) was treated with **1** (3 mmol) in tetrahydrofuran at 25 °C for 40 h under an argon atmosphere, an essentially complete convertion of the aldehyde was observed and benzyl benzoate was obtained in a 95% yield. Under similar conditions, *p*-tolualdehyde, *p*-chlorobenzaldehyde, and α-naphthaldehyde gave the corresponding esters. *p*-Anisaldehyde scarcely reacted with **1** at 25 °C, but gave the *p*-methoxybenzyl *p*-methoxybenzoate ester at 60 °C. The by-products obtained in these reactions were small amounts of alcohols such as benzyl alcohol (less than 3%). Aliphatic aldehydes and furfural also reacted with **1** under identical conditions, but the corresponding esters were not obtained. Furfural gave only tarry materials upon treatment with **1**. The treatment of aliphatic aldehydes such as *n*-butyraldehyde with an equimolar amount of **1** gave aldol condensates and then hydrogenated products, such as 2-ethyl-2-hexenal and 2-ethylhexanal. The formation of these products is due to the basicity of **1**, $[Fe(CO)_4]^{2-}$[9] and the reducing ability of $[FeH(CO)_4]^-$[10] which transforms α,β-unsaturated carbonyl compounds into saturated ones.[11] The results are summarized in Table 1. The conditions were not optimized for these reactions. These reactions are scarcely affected by the atmosphere; no remarkable difference was detected in the reaction rates under a carbon monoxide atmosphere compared with that under an argon atmosphere.

In the reactions of *p*-substituted benzaldehydes with **1**, there is a remarkable influence of the substituents on the relative reaction rates. The yields of esters *vs.* time plots for the reaction of **1** with the substituted benzaldehydes are shown in Fig. 1. The apparent order of their reactivities was as follows: $p\text{-}ClC_6H_4CHO > C_6H_5CHO > p\text{-}CH_3C_6H_4CHO > p\text{-}CH_3OC_6H_4CHO$. The reactivity decreases with an increase in the electron-releasing property of the substituents. This suggests that the reaction is influenced by the electron density on the carbonyl carbon of the aldehydes which the ferrate (**1**) attacks nucleophilically.

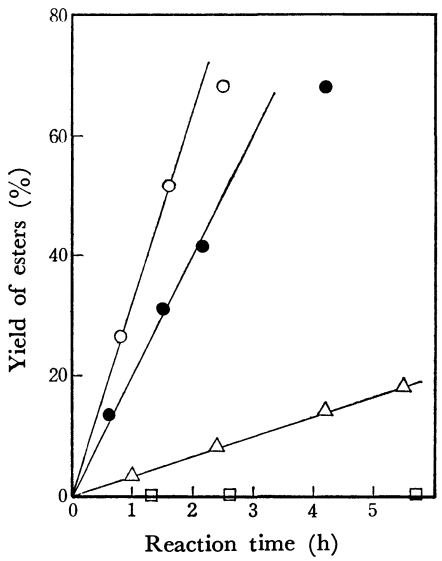

Fig. 1. Yield of ester *vs.* time plots for the reaction of $Na_2Fe(CO)_4$ with aldehydes (in THF, at 25 °C, under argon).
○ : *p*-Chlorobenzaldehyde, ● : benzaldehyde, △ : *p*-tolualdehyde, □ : *p*-anisaldehyde.

When an equimolar mixture of benzaldehyde (50 mmol) and *p*-anisaldehyde (50 mmol) was stirred with **1** (3 mmol) at 25 °C, 17 mmol of benzyl benzoate and 11 mmol of benzyl *p*-methoxybenzoate were obtained, but no *p*-methoxybenzyl *p*-methoxybenzoate and *p*-methoxybenzyl benzoate were produced. This shows that *p*-anisaldehyde can react as only an acid component even at 25 °C, though alone it scarcely reacts with **1** at this temperature (Exp. 5).

As the reaction scheme, the following one is considered (Scheme 1). First, the ferrate (**1**) attacks the carbonyl carbon of the aldehyde nucleophilically to give an adduct (**2**). The addition of the second aldehyde to **2** is followed by the loss of the ferrate

TABLE 1. REACTION OF ALDEHYDES WITH $Na_2Fe(CO)_4$

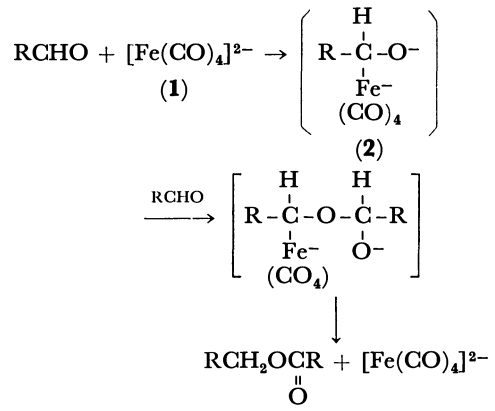

Scheme 1.

to give the esters. This scheme is roughly the same as that of the well-known variations of the base-induced dismutation of aldehydes, *e.g.*, catalyzed by the RO^- alkoxide.[12] In the base-catalysed dismutation of aldehydes, the view that the first step of the reaction proceeds by an initial coordination of the base with the aldehyde carbonyl group is supported by the investigations of the effect of substituents upon the rate of the reaction.[12]

The formation of benzyl *p*-methoxybenzoate (Exp. 10) implies that *p*-anisaldehyde is able to react with the adduct (**2**), as a second aldehyde, though it does not form an adduct (**2**) upon treatment with **1** at 25 °C.

After **1** had been stirred with an equimolar amount of an aldehyde (R^1CHO) in tetrahydrofuran at 25 °C for 5 h, an excess of alkyl iodide (R^2I) was added and the reaction mixture was stirred for an additional 5 h. After the treatment of the mixture with acetic acid and a usual workup, a second ester, $R^2COOCH_2R^1$, was obtained besides the $R^1COOCH_2R^1$ ester. The

results are listed in Table 2. The acetyl and propionyl groups of the esters ($R^2COOCH_2R^1$) appear to be from methyl or ethyl iodide, and the ferrate

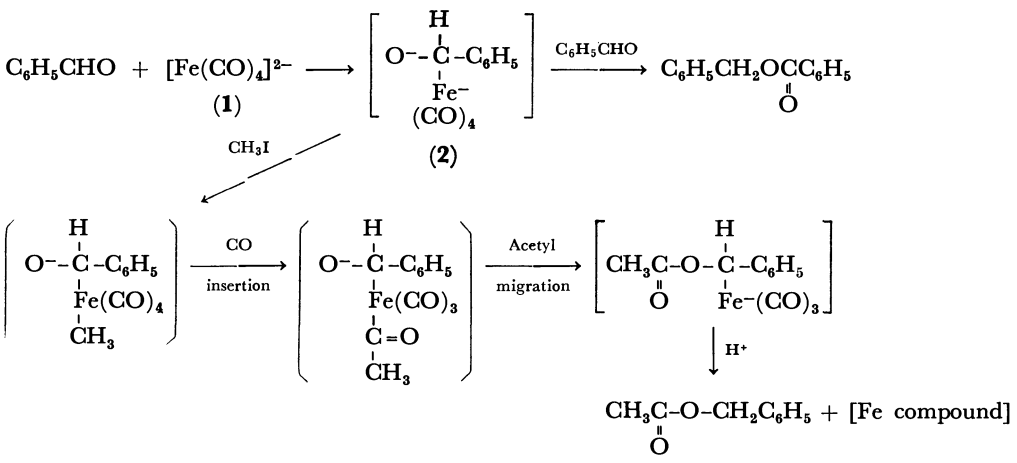

Scheme 2.

(**1**), *via* a carbonyl insertion reaction.

In these reactions, the initial adduct (**2**) (in Scheme 1) is also assumed to be an intermediate. As for the formation of benzyl acetate, the following reaction scheme is considered (Scheme 2). The adduct (**2**) is methylated at first;[13] this is followed by a carbonyl insertion reaction, the intramolecular migration of the acetyl group,[14] and protonation to give benzyl acetate. The fact that the deuteration of the reaction mixture with deuterium oxide instead of protonation gave deuterated benzyl acetate, $CH_3COOCH(D)C_6H_5$, is consistent with the scheme described above.

The effect of disodium tetracarbonylferrate (**1**) as a catalyst of the dismutation of aldehydes to the ester is assumed to be due to its high nucleophilicity. Less nucleophilic alkyl or acyl carbonylferrates(0) did not react with the aldehydes used in this reaction.

Experimental

The aldehydes were all commercial products; they were dehydrated over Drierite and distilled twice before use. The disodium tetracarbonylferrate (**1**) was prepared according to the method described in the literature.[3] The pentacarbonyliron was a commercial product and was used without further purification. The methyl iodide and ethyl iodide were also commercial products and were distilled before use. The solvent, tetrahydrofuran, was purified by distillation after being dried over lithium aluminium hydride.

Reaction of Aldehydes with ***1***. The reaction of benzaldehyde with **1** illustrates a typical procedure. Freshly distilled benzaldehyde (100 mmol) was added to a solution of 3 mmol of **1** in 25 ml of tetrahydrofuran, and the mixture was stirred at 25 °C under an argon atmosphere. After 40 h, the solvent was evaporated and the liquid thus obtained was chromatographed over alumina and then distilled to give pure benzyl benzoate(yield, 95%). The identity was established by a comparison of the spectral data(IR and NMR) and retention time of GLPC with those of an authentic sample. In the case of *p*-chlorobenzaldehyde and α-naphthaldehyde, the products were purified by recrystallization after being chromatographed.

The reaction procedure of butyraldehyde with (**1**) was as follows. To a solution of 11 mmol of (**1**) in tetrahydrofuran (40 ml), we added 0.94 g (13 mmol) of freshly distilled butyraldehyde, after which the reaction mixture was stirred at 25 °C for 3 h under an argon atmosphere. Then the mixture was poured into 50 ml of water and extracted with 50 ml of diethyl ether, after which the organic extracts were submitted to GLPC analysis. The products, 2-ethyl-2-hexenal and 2-ethylhexanal, were identified by a comparison of the retention time of the GLPC with those of authentic samples; the yields were determined using internal standards.

Successive Reaction of ***1*** *with Aldehydes and with Alkyl Iodides.* In a typical procedure, into 11 mmol of **1** in tetrahydrofuran (50 ml) we stirred 11 mmol of aldehyde in tetrahydrofuran (10 ml) at 25 °C under an argon atmosphere. A few hours later, the reaction mixture was treated with an excess of alkyl iodide and stirred for an additional 5 h. After 2 ml of water or acetic acid had then been poured into the reaction mixture, the solvent was evaporated and the residue was fractionally distilled. The esters thus obtained were identified by means of their spectral data (IR and NMR) and by a comparison of the retention time of the GLPC with those of authentic samples; the yields were determined using internal standards.

Formation and Reactions of Alkoxydiaminosulfonium Salts

Hiroshi MINATO,* Kentaro OKUMA, and Michio KOBAYASHI

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

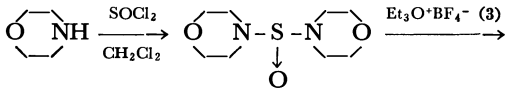
(Received June 7, 1976)

Ethoxydimorpholinosulfonium tetrafluoroborate and tetraphenylborate were prepared by ethylation of dimorpholino sulfoxide. They were readily hydrolyzed with water but did not react with methanol. In the reactions with nucleophiles, they acted as ethylating agent for β-picoline, triethylamine, diethylamine, methoxide ion, and chloride ion. When dimorpholino sulfide, 1-chlorobenzotriazole, and an alcohol were allowed to react at −80 °C, the main products were an alkyl chloride, dimorpholino sulfoxide, and morpholinium chloride. Alkoxydimorpholinosulfonium chloride was presumed to be the intermediate, which decomposed by an S_N2-type nucleophilic attack of chloride ion on the alkyl group. When (+)-2-octanol was used, the 2-chlorooctane formed was of almost completely inverted configuration (enantiomeric excess, 97%). The yield of alkyl chlorides decreased in the order of methyl (80%), isopropyl (51), and *t*-butyl (20).

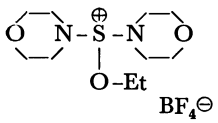
Dialkoxysulfonium ions,[1-3] alkoxyaminosulfonium ions,[3,4] diaminosulfonium ions[5] were reported, but sulfonium ions possessing three hetero-substituents have not been described in the literature except a short communication from our laboratories.[6] Since alkoxydiaminosulfonium ions appear to be interesting species, we have studied their chemistry, and the results are described in this paper.

Results and Discussion

The synthesis of alkoxydiaminosulfonium ions was attempted by alkylation of diamino sulfoxides. Diamino sulfoxides were prepared by the reaction of an amine with thionyl chloride. They are readily decomposed by a trace amount of moisture, and must be handled with great care. Ethoxydimorpholinosulfonium tetrafluoroborate (**1a**) was successfully prepared by ethylation of dimorpholino sulfoxide (**2**) with triethyloxonium tetrafluoroborate (**3**) in well-dried dichloromethane in a dry box. The pale-yellow



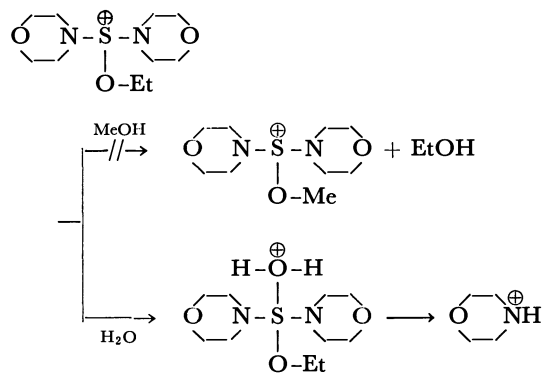
2



1a

crystals obtained are extremely moisture-sensitive, and all the synthetic procedure must be carried out in a dry box. They are easily decomposed by a small amount of water in solvents or in the atmosphere, and morpholinium salts are produced. However, when crude crystals of **1a** were dissolved in anhydrous methanol and recrystallized, purified crystals were obtained without decomposition or alcohol exchange. Thus, alkoxydiaminosulfonium ions are not affected by alcohols, but extremely sensitive towards water. The reaction with water produces HBF_4, which probably catalyzes the decomposition.

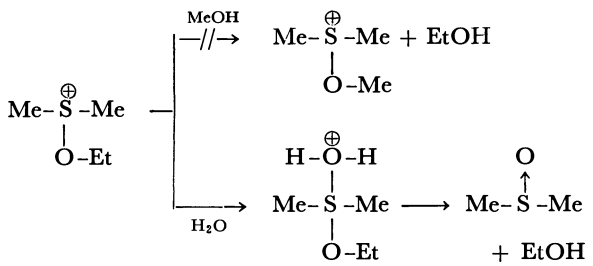
In an attempt to convert **1a** into crystals which can be handled more easily, crystals of **1a** were dissolved in acetone and anion exchange was attempted by addition of an acetone solution of sodium tetraphenylborate. However, such treatment simply hydrolyzed **1a**, and ethoxydimorpholinosulfonium tetraphenylborate (**1b**) was not obtained. After several attempts, crystalline **1b** was successfully prepared when sodium tetraphenylborate was added to the reaction mixture without isolating solid **1a**. In a similar manner, crystalline ethoxybis(diethylamino)sulfonium tetraphenylborate was prepared.



Crystalline **1b** can be handled much more easily than **1a**, and its elemental analyses gave satisfactory results. It was possible to determine its melting point too.

When the reactivity of **1b** with methanol and water was examined, it was found that an equimolar mixture of **1b** and methanol in hexadeuterioacetone did not react at all after 1 day, whereas **1b** was completely hydrolyzed when its hexadeuterioacetone solution was allowed to stand in an uncapped PMR tube for 1 day.

Such remarkable difference in reactivities of **1** with water and methanol appears to be of considerable interest, and we investigated reactions of a simpler alkoxysulfonium salt, dimethylethoxysulfonium tetrafluoroborate. When this alkoxysulfonium salt was



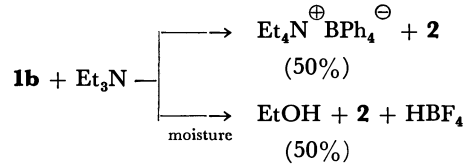
allowed to stand in methanol for 12 h, it did not react at all with methanol, whereas in a hexadeuterioacetone solution containing water (10 equiv.) 65% of the salt was hydrolyzed in 12 h.

Smith and Winstein found that dimethylbenzyloxysulfonium tosylate was not solvolyzed in absolute methanol but yielded benzyl alcohol upon addition of water.[6,7] Thus not only **1** but also dialkylalkoxysulfonium salts are very reactive with water and not reactive with alcohols.

By use of ^{18}O-enriched water[8] and an optically-active alkoxysulfonium salt,[9] Johnson and his coworkers showed that the hydrolysis of alkoxysulfonium salts proceeds by a nucleophilic displacement on sulfur with inversion of configuration of the sulfur atom. It is likely that the hydrolysis of **1** proceeds in a similar manner.

Then the reactions of **1** with nucleophiles were investigated. When **1a** was mixed with an equimolar amount of β-picoline at room temperature, **1a** acted as an ethylating agent but only in a 40% yield. The rest of the **1a** used was hydrolyzed by moisture in solvent and atmosphere, and morpholinium tetrafluoroborate was formed.

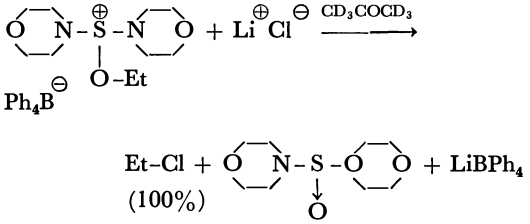
When equimolar amounts of **1b** and triethylamine were allowed to react in hexadeuterioacetone, the products showed that both ethylation of the amine (50%) and hydrolysis with moisture (50%) took place.



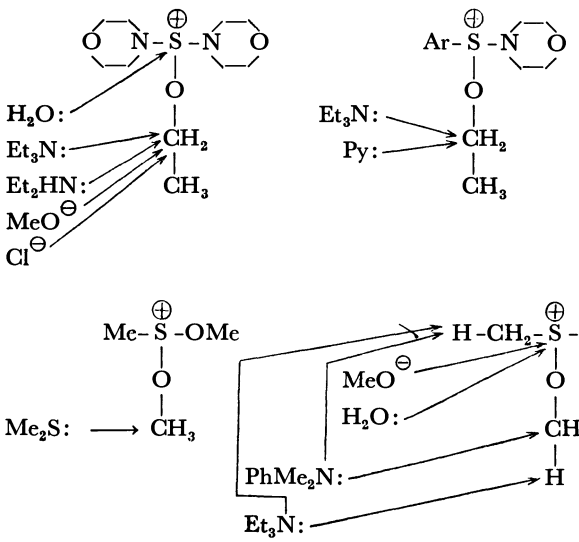
In a similar manner, the treatment of **1b** with diethylamine resulted in ethylation of the amine (40%) and hydrolysis with moisture (60%).

When **1b** was let to react with a slightly excess of potassium methoxide in hexadeuterated DMSO, **1b** ethylated the nucleophile.

When **1b** and lithium chloride were dissolved in hexadeuterioacetone, the PMR spectrum of the solution showed that **1b** was converted to ethyl chloride and **2**.

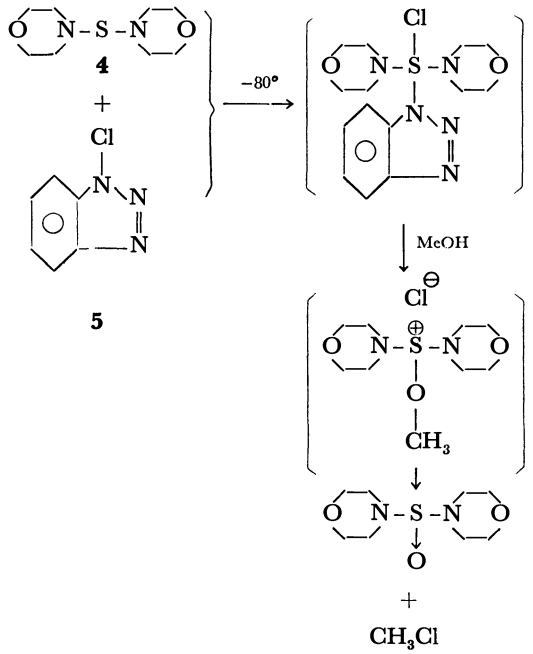


The reactivity of **1** with nucleophiles is summarized below, and compared with those of alkoxyaminosulfonium ions,[3] dialkoxysulfonium ion,[1] and alkoxysulfonium ions.[10,11] The above comparison shows that alkoxysulfonium ions possessing an amino group, two amino groups, or another alkoxy group receive the attack of nucleophiles (except water) on the carbon atom adjacent to the oxygen atom. Thus, the reactions of hetero-atom substituted alkoxysulfonium ions with nucleophiles are simpler than those of alkylaryl-alkoxysulfonium ions.[11]



Since the main reaction of **1** with nucleophiles has been shown to be ethylation of the nucleophiles, it seems desirable to study the reactions of alkoxydiaminosulfonium salts other than **1**. However, it was not possible to prepare such sulfonium salts by the method used for the preparation of **1**, because trimethyloxonium tetrafluoroborate is not soluble in dichloromethane, and neither triisopropyl- nor tri-*t*-butyloxonium salts are available.

Therefore, preparation of alkoxydiaminosulfonium salts was attempted from other routes. Johnson *et al.*[13] prepared alkoxysulfonium salts by treating dialkyl sulfides with 1-chlorobenzotriazole, an alcohol and silver tetrafluoroborate. If diamino sulfides react in a similar manner, formation of alkoxydiaminosulfonium salts is expected. Therefore, equimolar amounts



of dimorpholino sulfide (**4**) and 1-chlorobenzotriazole (**5**) were mixed in dichloromethane at −80 °C, and to the yellow solution formed (a sulfurane[13]) an equimolar amount of methanol was added. When the mixture was warmed up, its PMR spectrum suggested that the reaction shown above occurred. Methoxydimorpholinosulfonium chloride is the product expected from the results of Johnson *et al.*[13] Since we have already shown that **1b** is readily converted by chloride ion to **2** and ethyl chloride, the scheme shown above probably represents the main reactions taking place in a mixture of **4**, **5**, and an alcohol. In order to determine the stereochemistry of this nucleophilic reaction on the carbon atom adjacent to the oxygen atom, (+)-2-octanol was treated in a similar manner. The 2-chlorooctane obtained was found to be of almost completely inverted configuration (enantiomeric excess, 97%). Thus the nucleophilic attack of chloride ion on an alkoxydiaminosulfonium ion is an S_N2-type reaction with inversion of configuration.

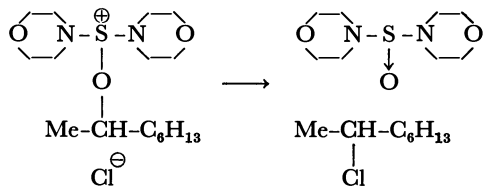


Table 1 summarizes the results of reactions of diamino sulfide (**4** or bis(dimethylamino) sulfide (**6**)) with **5** (or *N*-chlorosuccinimide (**7**)) and an alcohol (MeOH, *i*-Pr-OH, or *t*-BuOH).

As shown in Table 1, the yields of alkylation of chloride by alkoxydiaminosulfonium ions decrease in the order of Me, *i*-Pr, and *t*-Bu. This fact is probably ascribable to greater tendency for S_N1-type reaction of alkoxydiaminosulfonium ions when the alkyl group is secondary or tertiary. When **7** was used in place of **5**, yields were not improved, but when **6** was used in place of **4**, the yields were improved. Even with isopropyl alcohol, S_N2-type alkylation of chloride took place in an 85% yield.

Table 1. Products of the reaction of diamino sulfides with 5 (or 7) and alcohols

Reactants	Products (mol %)
4 + **5** + MeOH	MeCl(80), **2**(80)
4 + **5** + *i*-PrOH	*i*-PrCl(51), *i*-PrOH(21), **2**(60)
4 + **5** + *t*-BuCl(20)	*t*-BuCl(20), *t*-BuOH(10)
4 + **5** + (+)-2-octanol	(−)-octylCl (25)[a]
4 + **7** + MeOH	MeCl(45),
4 + **7** + *i*-PrOH	*i*-PrCl(47), Me_2CO(6)
4 + **7** + *t*-BuOH	*t*-BuCl(18), *t*-BuOH(16)
6 + **7** + MeOH	many products
6 + **7** + *i*-PrOH	*i*-PrCl(51), *i*-PrOH(40), Me_2CO(8.7)
6 + **7** + *t*-BuOH	*t*-BuCl(35)
6 + **5** + MeOH	MeCl(83), $(Me_2N)_2S{\rightarrow}O$ (90)
6 + **5** + *i*-PrOH	*i*-PrCl(85), $(Me_2N)_2S{\rightarrow}O$ (78)
6 + **5** + *t*-BuOH	*t*-BuCl(40)
6 + **5** + 2-octanol	2-octylCl (51),[a,b] $(Me_2N)_2S{\rightarrow}O$ (95)

a) Yield after isolated. b) By PMR, the yield was 70%.

Corey et al. treated succinimidodimethylsulfonium ion with benzyl and allyl alcohols, and obtained the corresponding chloride.[14] However, their reaction works only with benzyl and allyl alcohols, and not with ordinary primary or secondary alcohols. It is of interest that in our system a primary alcohol or a secondary alcohol is transformed into chloride in much better yield than a tertiary alcohol.

Experimental

Dimorpholino sulfide (mp 125—126°; lit,[15] 125—126 °C), and bis(dimethylamino) sulfide (bp 30—32 °C/15 Torr; lit,[15] 33.5—36 °C/14 Torr) were prepared by the methods described in the literature.[15] (+)-2-Octanol was purchased from Fluka AG; $[\alpha]_{546}^{20}=+11°$.

Dimorpholino sulfoxide was prepared from morpholine and thionyl chloride; mp 52 °C.[16] Bis(diethylamino) sulfoxide was prepared in a similar manner.

1-Chlorobenzotriazole was prepared from benzotriazole and a 10% aq NaOCl solution according to the method in the literature.[13]

*Formation of Ethoxydimorpholinosulfonium Tetrafluoroborate (**1a**).* After a dichloromethane solution of **2** (40 mmol) and **3** (42 mmol) was refluxed for 2 h, ether was added. The brown-black oil which precipitated was recrystallized from methanol in a dry box. Pale yellow crystals of **1a** were obtained (24.6%). PMR (CD_3COCD_3), δ 1.52 (t, 3, CH_3), 3.50—3.71 (m, 8, N-CH_2), 3.74—4.00 (m, 8, O-CH_2), 4.61 (q, 2, $C\underline{H}_2CH_3$). Because of its instability, it was not possible to carry out successful elemental analysis.

*Reaction between **1a** and β-Picoline.* An equimolar mixture of the reactants were allowed to stand in CD_3COCD_3 at room temperature for 2 h, and *N*-ethylpicolinium salt was found in a 40% yield (identified by comparison with an authentic sample). PMR(CD_3COCD_3), δ 1.71 (t, $C\underline{H}_3$-CH_2), 2.60 (s, CH_3-Py), 4.80 (q, $C\underline{H}_2CH_3$).

*Formation of Ethoxydimorpholinosulfonium Tetraphenylborate (**1b**).* A dichloromethane solution (30 ml) of **2** (10 mmol) and **3** (10.6 mmol) was refluxed for 2 h, and to this orange-red solution an acetone solution (25 ml) of $NaBPh_4$(9.36 mmol) was added. Addition of some ether and acetone precipitated $NaBF_4$, and further addition of ether precipitated **1b**: 3.85 g (67.7%). Repeated crystallizations from acetone–ether yielded white prisms, mp 113 °C (dec). Found: C, 71.78; H, 7.54; N, 5.02%. Calcd for $C_{34}H_{41}N_2O_3BS$: C, 71.82; H, 7.27; N, 4.93%. PMR(CD_3COCD_3) δ 1.47 (t, 3, J= 7.2 Hz, $C\underline{H}_3CH_2O$), 3.30—3.57 (m, 8, $NC\underline{H}_2$), 3.63—3.90 (m, 8, $NCH_2C\underline{H}_2O$), 4.46 (q, 2, J=7.2 Hz, $OC\underline{H}_2CH_3$), 6.82—7.53 (m, 20, C_6H_5); ^{13}CMR(CD_3COCD_3) δ 15.34 ($\underline{C}H_3CH_2O$), 47.07 ($NCH_2\underline{C}H_2O$), 66.88 ($N\underline{C}H_2$), 72.07 ($O\underline{C}H_2CH_3$).

Ethoxybis(diethylamino)sulfonium Tetraphenylborate was prepared in a similar manner; yield, 60.0%, mp 119 °C (dec). Found: C, 75.39; H, 8.85; N, 4.90%. Calcd for $C_{34}H_{55}N_2OBS$: C, 75.54; H, 8.39; N, 5.18%. PMR(CD_3COCD_3) δ 1.22 (t, 12, J=7.0 Hz, $C\underline{H}_3CH_2N$), 1.45 (t, 3, J=6.5 Hz, $C\underline{H}_3CH_2O$), 3.46 (q, 8, J=7.0 Hz, $CH_3C\underline{H}_2N$), 4.28 (q, 2, J=6.5 Hz, $CH_3C\underline{H}_2O$); ^{13}CMR(CD_3COCD_3) δ 13.72 ($\underline{C}H_3CH_2N$), 15.18 ($\underline{C}H_3CH_2O$), 42.45 ($CH_3\underline{C}H_2N$), 70.29 ($CH_3\underline{C}H_2O$).

*Decomposition of **1b** in CD_3COCD_3.* When a CD_3COCD_3 solution of **1b** was allowed to stand in an uncapped PMR

tube at room temperature for 1 day, **1b** was hydrolyzed and morpholinium tetraphenylborate precipitated, which was identified by determining its PMR spectrum in CD_3SOCD_3.

*Treatment of **1b** with Methanol in CD_3COCD_3.* When equimolar amounts of **1b** and well-dried methanol were dissolved in CD_3COCD_3 and allowed to stand in a capped PMR tube at room temperature for 1 day, no change was observed in its PMR spectrum.

Reaction between Dimethylethoxysulfonium Tetrafluoroborate and D_2O or CD_3OD. When a CD_3COCD_3 solution of the salt (1 equiv.) and D_2O (10 equiv.) was allowed to stand for 12 h at 34 °C, its PMR spectrum showed that 65% of the salt was hydrolyzed, forming CH_3SOCH_3 (δ 2.67) and EtOD (δ 1.10(t) and 3.56(q)). When a CD_3OD solution of the salt was allowed to stand for 12 h at 34 °C, no CD_3O-EtO exchange was observed and about 10% of the salt was hydrolyzed probably by the moisture in CD_3OD, forming CH_3SOCH_3 and EtOD.

*Reaction between **1b** and Triethylamine.* When equimolar amounts of **1b** and triethylamine were mixed in CD_3COCD_3 at room temperature, reaction was complete in 3 h, and tetraethylammonium tetraphenylborate precipitated. It was filtered and identified by determining its PMR spectrum in CD_3SOCD_3; δ 1.22 (t, 3, CH_3), 3.21 (q, 2, CH_2); yield, 50%. In the filtrate, ethanol (50%) and **2**(100%) (PMR-(CD_3COCD_3), δ 2.90—3.12 (NCH_2), 3.60—3.78 (OCH_2)) were found.

*Reaction between **1b** and Diethylamine.* When equimolar amounts of **1b** and diethylamine were mixed in CD_3COCD_3 at room temperature, reaction was complete in 20 min; its PMR spectrum showed complete disappearance of **1b** and formation of **2**. The precipitates formed were filtered, and their PMR spectrum in CD_3SOCD_3 showed the presence of $Et_3NH^+BPh_4^-$ (40%) (δ 1.34(t, 9, CH_3), 3.16 (q, 6, CH_2), and 6.80—7.50 (m, 20, C_6H_5)) and $Et_2NH_2^+BPh_4^-$ (60%) (δ 1.27 (t, 6, CH_3), 3.12 (q, 4, CH_2), and 6.80—7.50 (m, 20, C_6H_5)).

*Reaction between **1b** and Potassium Methoxide.* When CD_3SOCD_3 solutions of **1b** (0.53 mmol) and KOMe (0.93 mmol) were mixed at room temperature the PMR spectrum of the mixture showed that **1b** was quantitatively converted to ethyl methyl ether; δ 1.08 (t, 3, $\underline{CH_3}CH_2$), 3.18 (s, 3, CH_3O), and 3.47 (q, 2, CH_2).

*Reaction between **1b** and Chloride Ion.* When **1b** (1 equiv.) and lithium chloride (4 equiv.) were mixed in CD_3COCD_3 at room temperature, the PMR spectrum of the solution showed that **1b** was quantitatively converted to **2** and ethyl chloride (δ 1.47 (t, 3, J=7.2 Hz, CH_3), and 3.63 (q, 2, J=7.2 Hz, CH_2).

*Reaction of **4** with **5** and MeOH.* A dichloromethane solution (3 ml) of **4** (3.0 mmol) and dichloromethane solution (4 ml) of **5** (3.0 mmol) were cooled to −18 °C, and then mixed. To this yellow solution, a cooled dichloromethane solution (2 ml) of methanol (3.0 mmol) was added at −80 °C. Mixing of these three solutions must be done with exclusion of moisture either in a glass apparatus sealed from the atmosphere or in a dry box. The mixture was warmed up to room temperature. Distillation gave a distillate and a residue. The distillate contained CH_3Cl (δ 3.00; yield, 80%). The residue contained **2** [δ 3.00—3.20 (N-CH_2) and 3.60—3.80 (OCH_2); yield, 80%] and an unidentified methyl compound (δ 3.50; yield, 20%).

Reactions with other alcohols were carried out in a similar manner with equimolar mixtures.

The reaction of **6** with **5** and 2-propanol gave *i*-PrCl (δ 1.46 (d); yield 85%) and acetone (δ 2.13(s); yield 15%) in the distillate, and $(Me_2N)_2S\rightarrow O$ (δ 2.61 (s); yield 78%) and an unidentified compound (δ 2.81(s); yield 22%) in the residue.

*Reaction of **4** with **5** and (+)-2-Octanol.* An equimolar mixture (10 mmol each) of the reactants was treated as described above. 2-Chlorooctane was collected at 51—52°/14 Torr; yield, 25%. $[\alpha]_D^{23}=-34.91°$ (c 7.38, CH_2Cl_2); enantiomeric excess $\%=-34.91/-36.15^{17)}\times 100=96.6\%$.

Substituent Effect on the Dissociation Constants of 5-(Substituted Styryl)-2-aminotropones

Toshio KOBAYASHI, Kimiaki IMAFUKU, and Hisashi MATSUMURA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received June 7, 1976)

The dissociation constants of various 5-styryl-2-aminotropones were determined spectrophotometrically using 50%(v/v) aqueous methanol and correlated by the use of Hammett equation, with $\rho=0.57$.

The quantitative estimation of the transmission of electronic effects through a system of conjugated double bonds is of great theoretical importance and has attracted the attention of many chemists. The most convenient systems are aromatic compounds of the R–C_6H_4–CH=CH–G–Y type, where G is an aromatic ring, such as benzene, pyridine, and tropone. The dissociation constants of various 4-aminostilbenes (G=C_6H_4, Y=NH_2),[1] 4-hydroxystilbenes (G=C_6H_4, Y=OH),[2] and 4-styrylpyridines (G=C_5H_4N)[3] and the chemical shifts of 4-fluorostilbenes (G=C_6H_4, Y=F)[4] have been measured in the past. It has been found that the electronic effect of the substituent in one ring is transmitted through the ethylene linkage to the reaction center in another ring and correlated by the Hammett equation.

Previously, we reported the substituent effects on the dissociation constants of 4-[5] and 5-styryltropolones[6] and 4- and 6-styryl-2-aminotropones.[7] However, the substituent effect in 5-styryl-2-aminotropones has not been investigated. In the present study, the dissociation constants of several 5-styryl-2-aminotropones, shown in Fig. 1, were measured spectrophotometrically, and the electronic effects of the substituents on their dissociation constants were discussed quantitatively.

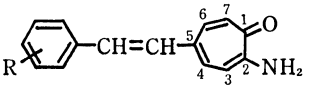

Fig. 1.

Results and Discussion

The dissociation constants of 5-(*p*-methoxystyryl)-, 5-(*p*-methylstyryl)-, 5-(*m*-methylstyryl)-, 5-styryl-, 5-(*m*-methoxystyryl)-, and 5-(*p*-chlorostyryl)-2-aminotropones were determined spectrophotometrically in 50%(v/v) aqueous methanol at 23 °C. Their pK_a values are listed in Table 1, together with their mp's. The pK_a value (2.21) of 5-styryl-2-aminotropone is smaller than those of 4- and 6-styryl-2-aminotropones (pK_a 2.54 for 4-styryl and 2.57 for 6-styryl isomers).[7] This might be mainly due to the conjugate interaction between the amino group and the styryl group in 5-styryl-2-aminotropones. Further, 5-styryl-2-aminotropones show pK_a values between 2.05 (*p*-chloro) and 2.35 (*p*-methoxy) and are less basic than *p*-(substituted styryl)anilines (*i.e.*, 3'- and 4'-substituted 4-aminostilbenes [pK_a 3.67 (*p*-chloro) to 3.86 (*p*-methoxy)]).[1] This may be attributed to the electron-withdrawing effect of the carbonyl group adjacent to the amino group in the tropone nucleus.

TABLE 1. pK_a VALUES OF 2-AMINO-5-STYRYLTROPONES IN 50%(v/v) METHANOL

No.[a]	R	Mp (°C)	$c\times10^5$ (mol/l)	λ (nm)	pK_a
1	*p*-OCH_3	244—245	1.640	290	2.35±0.05
2	*p*-CH_3	232—234	1.881	284	2.28±0.03
3	*m*-CH_3	172	1.991	282	2.24±0.04
4	H	205—206[b]	2.273	280	2.21±0.07
5	*m*-OCH_3	162	1.877	287	2.15±0.05
6	*p*-Cl	231—232	1.585	283	2.05±0.03

a) Numbers correspond to those given in Fig. 2.
b) Mp 205—206 °C (Ref. H. Matsumura, *Nippon Kagaku Zasshi*, **81**, 1763 (1960)).

When the pK_a values of 5-styryl-2-aminotropones are plotted against the Hammett substituent constants, σ,[8] of the substituent in the benzene ring, the plot gives the straight line shown in Fig. 2, and the following equation is obtained by the least-squares method:

$$pK_a = 2.20 - 0.57\,\sigma \quad (r=0.991)$$

In the case of 4- and 6-styryl-2-aminotropones, the effects of the substituents in the benzene ring are mainly transmitted to the amino group in the tropone nucleus by the inductive effect, while the styryl group in 5-styryl-2-aminotropones is located at a position where resonance interaction between the styryl group and the reaction center of tropone nucleus is possible; therefore, the transmission of the electronic effects by the fairly large resonance effect as well as by the inductive effect can be expected. The ρ values of 4-, 5-, and 6-styryl-2-aminotropones are listed in Table 2. When the 4-styryl and 6-styryl derivatives are compared

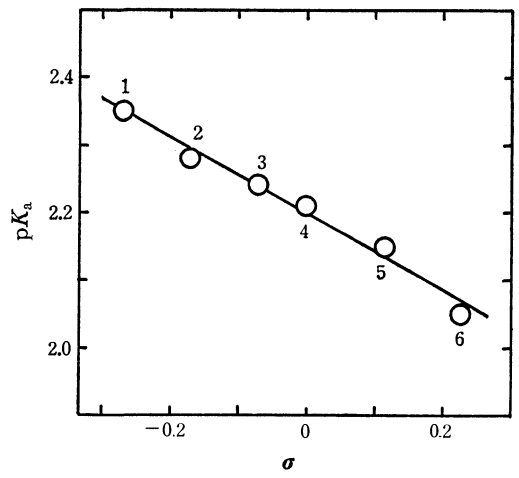

Fig. 2. The Hammett plot of pK_a's of 2-amino-5-styryltropones.

TABLE 2. THE ρ VALUES OF 4-, 5-, AND 6-STYRYL-2-AMINOTROPONES

Styryl-substituted 2-aminotropones	ρ
4-Styryl	0.59
5-Styryl	0.57
6-Styryl	0.40

with each other, the ρ value of the 4-styryl isomers is larger than that of the 6-styryl isomers because of the difference in distance between the styryl group and the amino group. On the other hand, the distance of the 5-styryl group in this work from the amino group is almost equal to that in the case of the 6-styryl derivatives. In other words, it may be assumed that the transmissibility which is caused by the inductive effect is almost equal in the 5- and 6-styryl derivatives. Thus, it is thought that a part of the ρ value of the 5-styryl isomers is due to the resonance effect mentioned above and is comparable to the difference in the ρ values based on the inductive effect, which is caused by the difference in distance from the 4- and 5-styryl groups to the amino group. Our results revealed that transmission through the styryl group varies with the position at which the styryl group is attached, the values being reduced in this order:

$$\text{4-styryl} \simeq \text{5-styryl} > \text{6-styryl}$$

Next, the dissociation constants were determined in 50%(v/v) aqueous ethanol at 25 °C. The Hammett analysis of them gave the following linear regression:

$$pK_a = 2.02 - 0.92\,\sigma \quad (r=0.992)$$

This ρ value is larger than that in 50% aqueous methanol. Such a difference is also observed[8] in the dissociation of benzoic acids, the ρ values being 1.085 in 50% aqueous methanol and 1.601 in 50% aqueous ethanol. It is thought that the difference between the two media is attributable to their polarity. Furthermore, the ρ value of 5-styryl-2-aminotropones is larger than the value for the dissociation of 4-aminostilbenes (0.42 in 50% aqueous ethanol at 20 °C).[1] This might be due to the fact that the tropone nucleus is charged slightly by the polarization of the carbonyl group. It is thought that there is some conjugate interaction between the styryl group and the carbonyl group.

Experimental

Materials. The 5-(substituted styryl)-2-aminotropones were prepared by the abnormal substitution reaction of 2-chloro-4-styryltropones, which has themselves been obtained from 4-styryltropolones in three steps. This method will be described elsewhere. Their melting points are listed in Table 1.

Measurement of Dissociation Constants. The dissociation constants of the 2-amino-5-styryltropones were measured spectrophotometrically in 50% aqueous methanol at 23 °C and in 50% aqueous ethanol at 25 °C, using the method of Albert and Serjeant.[9] The constants were obtained by using this equation:

$$pK_a = pH + \log \frac{A_B - A}{A - A_{BH^+}}$$

where A_B and A_{BH^+} are the absorbance of the base and its conjugate acid respectively. The absorption spectra were taken on a Hitachi EPS-3T spectrophotometer, while the pH values were measured by mean of Hitachi-Horiba F-7 pH meter.

N-Halogen Compounds of Cyanamide Derivatives. VIII.[1] A Convenient Method of Preparing 1,2,4-Oxadiazoles from *N*-Haloamidino Compounds

Toshio FUCHIGAMI and Keijiro ODO

Department of Electronic Chemistry, The Graduate School, Tokyo Institute of Technology
Ookayama, Meguro-ku, Tokyo 152

(Received June 11, 1976)

A new, efficient method for the preparation of 1,2,4-oxadiazoles from *N*-benzoylamidino compounds by treatment with *t*-butyl hypochlorite and sodium hydroxide has been devised. It was supposed that the ring formation proceeds *via* a nitrene intermediate.

1,2,4-Oxadiazoles have usually been prepared by the acylation of amidoximes[2] or by the Beckmann rearrangement of glyoximes.[3] In both cases, the cyclization involves dehydration and needs vigorous reaction conditions, and these procedures have not always given satisfactory results.

In this paper, we will describe a new, convenient method of synthesizing 1,2,4-oxadiazoles from *N*-chloro-*N'*-benzoylamidino compounds (amidines, *O*-alkylisoureas, and guanidine), together with the mechanism of the ring formation.

Results and Discussion

N-Benzoyl Derivatives of Amidino Compounds (I, II, and III). *N*-Benzoylamidines (I) are usually available by the reactions of amidines with benzoic anhydride.[4] We have found that I were prepared in good yields by the reaction of amidine hydrochlorides with benzoyl chloride in the presence of two equivalents of sodium hydroxide. *N*-Benzoyl-*O*-alkylisoureas (II) and *N*-benzoyl-*N',N'*-pentamethyleneguanidine (III) were prepared by a similar method. Isoureas, II, which were solids with low melting points, could be isolated from an aqueous reaction mixture by extraction with ether.

Table 1 summarizes the results of the preparation of I, II, and III.

Preparation of 1,2,4-Oxadiazoles (IV, V, and VI). 1,2,4-Oxadiazoles were easily obtained from I, II, and III in excellent yields under mild conditions. The following procedure is a typical one. An ethanolic suspension of an amidino compound was treated with *t*-butyl hypochlorite to form *N*-chloro compound, which was then warmed with aqueous sodium hydroxide. The structures of these heterocyclic compounds were confirmed by means of elemental analysis and by studies of the IR and mass spectra.

Table 2 shows the results of the preparation of IV, V, and VI.

As is shown in Table 2, *N*-benzoylbenzamidine (Ia) was transformed to 1,2,4-oxadiazole (IVa) in a good yield. However, in the case of *N*-benzoyl-*p*-toluamidine (Ib), the yield of IVb decreased because of the formation of a by-product, *p*-tolylurea, which was due to the migration of the *p*-tolyl group to a nitrogen atom. Thus, the *p*-methyl group was found to cause the rearrangement, but the reason has not yet been clarified. Studies of the relationship between various substituents and the reactivities of *N*-chloro compounds of I are in progress.

In the case of II, 1,2,4-oxadiazoles (Va—d) were prepared in excellent yields without exception.

This new method of synthesizing 1,2,4-oxadiazoles

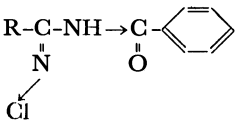
a) The active chlorine contents were iodometrically determined.

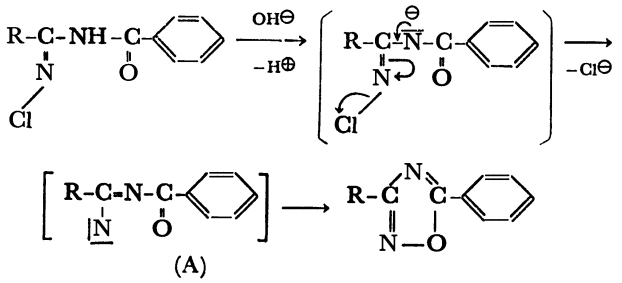
seems to be very convenient, that is, all operations are simple and the products can be obtained directly in an adequate purity.

N-Chloro compounds of I, II, and III are relatively stable; their physical properties are shown in Table 4.

Reaction Mechanism. The hydrogen atom of the NH group of a *N*-chloro compound seems to be acidic as a result of the electron-attracting effect of the chlorine atom and the benzoyl group.



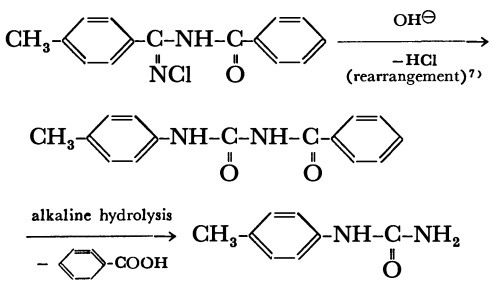
In fact, *N*-chloro compounds of I, II, and III are soluble in an alkaline solution, and the disapearance of the active chlorine takes only a short time. Therefore, this cyclization may be initiated by the removal of a proton from the NH group with a hydroxide ion. The loss of a chloride ion from the resulting anion may form a nitrene intermediate (A). The nitrene thus formed probably attacks the oxygen of the carbonyl group to give 1,2,4-oxadiazole. Such a



Scheme 1.

nitrene intermediate has previously been proposed by us[5] in the thermolysis of acyl derivatives of *N*-benzimidoyl-*S,S*-dimethylsulfilimine, giving 1,2,4-oxadiazoles, and by Miorana[6] in the photolysis of *β*-azidovinyl ketones, giving isoxazoles.

The by-product, *p*-tolylurea, may be formed by a mechanism similar to that mentioned in the rearrangement of *N*-alkyl-*N'*-chloroamidines.[7]



Experimental

The melting points are uncorrected. The NMR spectra were recorded at 60 MHz in $CDCl_3$, with TMS as the internal standard, using a Hitachi R-24A spectrometer. The mass spectra were taken with a JEOL JMS-D100 mass spectrometer. The UV spectra were taken with a Hitachi 624 spectrometer.

N-*Benzoylbenzamidine (Ia).* Benzamidine hydrochloride (3.85 g, 20 mmol) was dissolved in a solution of 2 M sodium hydroxide (25 ml) and acetone (5 ml) below 5 °C, and then benzoyl chloride (2.3 ml, 20 mmol) was gradually stirred in. After about 1 h of continued stirring below 10 °C, the white precipitate was filtered off and washed with water. The crude product melted at 90—92 °C; yield, 4.20 g (94%). Recrystallization from 80% aqueous methanol gave pure Ia; mp 98 °C.

N-*Benzoyl*-p-*toluamidine (Ib).* Using the same procedure, the crude product was obtained; yield, 3.50 g (82%). Recrystallization from aqueous methanol gave pure Ib; mp 129—130 °C.

N-*Benzoyl*-O-*methylisourea (IIa).* *O*-Methylisourea (5.53 g, 50 mmol) was dissolved in 70 ml of 2 M sodium hydroxide below 5 °C, and then benzoyl chloride (5.8 ml, 50 mmol) was gradually stirred in. After the addition, the reaction mixture was stirred below 10 °C for 1 h. The resulting oily material was extracted once with a 30-ml portion and twice with 10-ml portions of ether. After the combined ethereal extracts had been dried (Na_2SO_4), filtered, and concentrated under reduced pressure, colorless, needle-like crystals of *N*-benzoyl-*O*-methylisourea were obtained; yield, 6.60 g (74%); mp 76 °C. Recrystallization from aqueous methanol gave pure IIa; mp 77 °C.

The other *N*-benzoylisoureas (IIb—d) were prepared by the same procedure.

N-*Benzoyl*-N',N'-*pentamethyleneguanidine (III).* Using the same procedure but without acetone, the crude product was obtained; yield, 5.60 g (81%); mp 133—135 °C. Recrystallization from methanol gave pure III; mp 149—150 °C.

3,5-Diphenyl-1,2,4-oxadiazole (IVa). To a stirred suspension of Ia (1.12 g, 5 mmol) in ethanol (8 ml), we gradually added, drop by drop, an ethanolic solution (2 ml) of *t*-butyl hypochlorite (0.60 g, 5.5 mmol) at 0—5 °C. After the mixture had been stirred at the same temperature for 30 min, a 4-ml portion of 2 M sodium hydroxide was added. After the mixture had then been warmed at 70 °C, white needle-like crystals began to appear. After 5 min, the mixture was cooled, and then the precipitate was separated by filtration; IVa, 0.77 g; mp 108 °C. Further IVa was obtained by the addition of water (10 ml) to the filtrate; 0.11 g; mp 105—106 °C. The total yield was 80%. Recrystallization from aqueous ethanol gave a pure product; mp 108 °C; *m/e* 222 (M^+).

3-p-*Tolyl*-*5*-*phenyl*-*1,2,4*-*oxadiazole (IVb)* *and* p-*Tolylurea.* To a stirred suspension of Ib (1.36 g, 5 mmol) in ethanol (8 ml), we gradually added, drop by drop, an ethanolic solution (2 ml) of *t*-butyl hypochlorite (0.60 g, 5.5 mmol) at 0—5 °C. After the mixture had been stirred at the same temperature for 30 min, 4 ml of 2 M sodium hydroxide was added. The reaction mixture was subsequently warmed at 70—75 °C for 5 min and then cooled. The resulting needle-like precipitate was separated by filtration; IVb; yield, 0.54 g (46%). Recrystallization from aqueous ethanol gave pure IVb; mp 103—104 °C; *m/e* 236 (M^+). When the filtrate was evaporated to remove the ethanol, the precipitate, *p*-tolylurea, was filtered off and washed with a small amount of benzene. The yield was 0.16 g (21%). Recrystallization from dioxane-benzene gave a pure product; mp 176—177 °C.

3-Methoxy-5-phenyl-1,2,4-oxadiazole (Va). By the same procedure, but using ether as a solvent, a mixture of *N*-chloro compound of IIa (0.89 g, 5 mmol) and 3 ml of 2 M sodium hydroxide was stirred at room temperature for 60 min. When the reaction mixture was then evaporated under reduced pressure to remove the ether, an oily material was separated. The oily material was crystallized by rubbing with spatera and filtered off; mp 57 °C; yield 0.80 g (91%). Recrystalli-

zation from aqueous methanol gave pure Va; mp 57 °C; *m/e* 176 (M^+).

3-Ethoxy and *3-n*-butoxy-*5*-phenyl-*1,2,4*-oxadiazoles (Vb, d) were obtained by a similar method.

3-Isopropoxy-5-phenyl-1,2,4-oxadiazole (Vc). After working up the reaction mixture (10 mmol) as has been described above, the upper oily material was extracted once with a 10-ml portion and twice with 5-ml portions of dichloromethane. After the combined extracts had then been dried (Na_2SO_4), filtered, and concentrated under reduced pressure, the oily material Vc was obtained (1.95 g, 96%). Distillation under reduced pressure gave a fraction; bp 128—132 °C/6 Torr; 1.50 g (71%); *m/e* 204 (M^+).

3-Piperidino-5-phenyl-1,2,4-oxadiazole (VI). By the same procedure, 4 ml of 2 M sodium hydroxide was added to a solution of a *N*-chloro compound of III (1.16 g, 5 mmol). The mixture, which soon turned reddish yellow, was stirred below 15 °C for 30 min. An orange-yellow precipitate was then filtered off and washed with water; dp 173 °C; yield, 0.67 g (58%). Recrystallization from aqueous ethanol gave a pure product melting at 175 °C (with decomposition); *m/e* 229 (M^+).

Synthesis of Streptolidine from D-Xylose

Shoichi KUSUMOTO, Shinichi TSUJI, Keiyuu SHIMA, and Tetsuo SHIBA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 21, 1976)

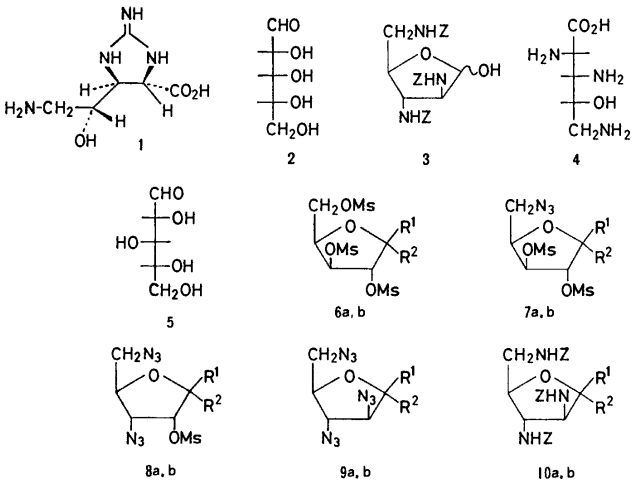
An alternative total synthesis of streptolidine (roseonine, geamine) was achieved starting from D-xylose. Direct azidolysis of methyl 2,3,5-tri-*O*-mesyl-α-D-xylofuranoside (**6a**) afforded methyl 2,3,5-triazido-2,3,5-trideoxy-α-D-arabinofuranoside (**9a**), whereas the β-anomer of **6a** gave only 3,5-diazido-3,5-dideoxy-2-*O*-mesyl-β-D-ribofuranoside (**8b**) indicating that the glycosidic configuration in the furanoside system has a decisive influence on the reactivity of the 2-mesyloxy group. However, the β-anomer of diazide (**8b**) was anomerized to α-anomer which readily undergoes azidolysis to give the triazide (**9a**). The triazide was successively hydrogenated, benzyloxycarbonylated, and then hydrolyzed to give 2,3,5-tris(benzyloxycarbonylamino)-2,3,5-trideoxy-D-arabinofuranose, which was identical with that prepared from D-ribose. Streptolidine could be synthesized from this key intermediate.

In a previous paper,[1] a report was given on the total synthesis of streptolidine (roseonine, geamine)[2] (**1**), a component guanidino amino acid of streptothricin antibiotics, which had been performed starting from D-ribose. Fully controlled substitution of three hydroxyl group in D-ribose (**2**) *via* twelve synthetic steps involving azidolysis of an epimino ring yielded 2,3,5-tris(benzyloxycarbonylamino)-2,3,5-trideoxy-D-arabinofuranose (**3**), which was then oxidized to (2*S*, 3*S*, 4*R*)-2,3,5-triamino-4-hydroxypentanoic acid (**4**) derivative. Guanidination of δ-lactam of **4** with cyanogen bromide afforded streptolidine of the natural configuration. The above complicated synthesis can be improved if simultaneous S_N2 displacement of the three hydroxyl groups on C-2, -3, and -5 of D-xylose (**5**) with nitrogen functions would occur leading to the same key intermediate (**3**). Although a sulfonyloxy group on C-2 of a furanoside or pyranoside resists substitution with azide anion in general, some successful cases of this reaction have recently been reported.[3,4] In the present investigation on the direct azidolysis of methyl 2,3,5-tri-*O*-mesyl-D-xylofuranoside (**6**), we could obtain the compound **3** as expected, thus accomplishing a new route to the synthesis of streptolidine from D-xylose.

Results and Discussion

D-Xylose was treated with hydrogen chloride in methanol and then with mesyl chloride in pyridine to afford a mixture of tri-*O*-mesyl-α and β-D-xylofuranoside (**6a** and **6b**), in which the β-anomer (**6b**) exists predominantly. When the mixture[5] was treated with sodium azide in *N*,*N*-dimethylformamide (DMF) at 100 °C for 2 h and then at 140 °C for 2 h, four azido compounds were formed, which were isolated by column chromatography.

In the NMR spectra (100 MHz) of these compounds, most of the signals of the individual protons were well separated from each other, and could be assigned with the aid of decoupling experiments. They are given in Table 1. The data indicate the number of the remaining mesyloxy groups, the positions of substituents as well as the anomeric configuration in each compound. The main syrupy product (**7**) (37% of the starting mixture) retaining two unchanged mesyl groups was found to be 5-monoazide since only the



Z=$C_6H_5CH_2OCO$, Ms=CH_3SO_2

a: R^1=H, R^2=OCH_3

b: R^1=OCH_3, R^2=H

signals of C-5 protons shifted considerably into higher field. The product is probably a mixture of anomers, being rich in β-form (**7b**) contaminated with a minor amount of α-form (**7a**). The assignment of the monoazide structure was supported by the formation of monobenzamido derivative on hydrogenation of **7** followed by benzoylation. The other two products (**8a** and **8b**, 3.4 and 27%, respectively, of the starting mixture), both being diazides, were assigned to anomers of 3,5-diazide, because the chemical shift values of C-3 and C-5 protons indicate undoubtedly the location of the azide groups on these carbon atoms. The anomeric configurations were determined on the basis of coupling constants. Thus, $J_{1,2}$ value of **8a** (4.5 Hz) shows cis relation of C-1 and C-2 protons, while that of **8b** (0 Hz) shows trans relation, indicating the structure of metyl 3,5-diazido-3,5-dideoxy-2-*O*-mesyl-α- and β-D-ribofuranoside for **8a** and **8b**, respectively.

The fourth product (**9a**) obtained in only a very small amount (0.75% of starting mixture) showed no NMR signal of the mesyl group. On catalytic hydrogenation followed by benzyloxycarbonylation, it afforded tris(benzyloxycarbonylamino) derivative (**10a**) which was differentiated from methyl 2,3,5-tris(benzyloxycarbonylamino)-2,3,5-trideoxy-β-D-arabinofuranoside (**10b**) prepared from D-ribose.[1]

Table 1. Chemical shifts and coupling constants of protons in mesyl and azide derivatives[a)]

	H-1	H-2	H-3	H-4	H_2-5	OCH_3	OMs
6b	5.10	5.10 (J=2)	5.28 dd (J=2, 6)	4.74 q (J=6)	4.41 d (J=6)	3.44	3.08 (3H) 3.14 (3H) 3.16 (3H)

a) Measured on Varian XL-100 spectrometer in $CDCl_3$. The chemical shifts and the coupling constants were recorded in δ values and Hz.

The coupling constant value of $J_{1,2}$=0 Hz in **10a** indicated trans relation of C-1 and C-2 protons. NMR data (Table 1) confirmed the structure of **9a** to be the triazide of the desired configuration, *i.e.*, methyl 2,3,5-triazido-2,3,5-trideoxy-α-D-arabinofuranoside.

The exclusive formation of triazide (**9a**) of α-glycoside structure may suggest that azidolysis of C-2 mesyloxy group proceeds only from the methyl α-glycoside (**6a**) but not from the β-anomer (**6b**) in the starting mixture. In fact, no trace of a triazide was detected when the pure β-glycoside of monomesyl diazide (**8b**) was treated with sodium azide in DMF or HMPA at 140 °C; whereas its α-anomer (**8a**) could be readily converted into the triazide (**9a**) in DMF at 140 °C.

Great differences in the reactivity of 2-sulfonate between both anomers have been observed by Miljković *et al.*[3)] but only in pyranoside systems. They reported that S_N2 type substitution of C-2 mesyloxy groups with a charged nucleophile occurs in methyl β-gluco- and β-mannopyranoside but not in the corresponding α-anomers. In our experiments, however, the substitution reaction of the 2-mesyloxy group occurs only in the α-furanoside. The apparent discrepancy in the reactivity of each anomer of the furanoside and the pyranoside is not surprising since steric situations in the two ring systems differ a great deal.

The exhaustive azidolysis of D-xylose derivative might be utilized as a new direct method leading to the 2,3,5-triaminopentose derivative of desired stereochemistry. Attempts were next made to anomerize the β-glycofuranosides, the main product in Fischer's glycosidation reaction of xylose, to the α-furanoside derivative which can be used as the starting material for the triazide (**9a**). When β-diazide (**8b**) was heated in methanol containing dry hydrogen chloride, anomerization took place giving 16% of α-diazide (**8a**) and 61% of unchanged **8b** which were separated from each other by column chromatography. Use of titanium tetrachloride in methylene chloride gave a similar result. On the other hand, no anomerization occurred on the β-anomer of the trimesylate (**6b**) under similar conditions.

The α-diazide (**8a**) thus obtained was converted into the triazide (**9a**) in 38% yield by heating with sodium azide in DMF at 140 °C for 4 h. This condition seemed to be optimal, since higher temperature caused decomposition of the materials resulting in loss of the yield. In order to increase the yield of triazide, effect of "crown ether"[6)] on the substitution reaction was examined. Addition of 18-crown-6 to the reaction mixture did not improve the reaction. In other solvents such as acetonitrile, benzene, dioxane, toluene, and *o*-xylene, **8a** did not react with sodium azide at all even on addition of 18-crown-6.

After the triazide (**9a**) was converted into the tris(benzyloxycarbonylamino) derivative (**10a**) as described above, the glycoside linkage was hydrolyzed with *p*-toluenesulfonic acid in aqueous dioxane. Comparison of mps, IR and NMR spectra showed that the hydrolysis product was identical with 2,3,5-tris(benzyloxycarbonylamino)-2,3,5-trideoxy-D-arabinofuranose (**3**) previously prepared from D-ribose.[1)] Since the conversion of **3** into streptolidine had been performed through oxidation, deprotection and guanidination successively,[1)] it is now established that streptolidine was formally synthesized also from D-xylose by an alternative and improved method.

Experimental

All melting points are uncorrected. Silica gel 60 (0.063—0.200mm, Merck) was used for column chromatography. TLC and preparative TLC were performed on Silica gel G and H, Merck, respectively.

*Methyl 2,3,5-Tri-O-mesyl-α- and β-D-xylofuranoside (**6a** and **6b**).* A mixture of D-xylose (20.0 g, 0.133 mol) in methanol (500 ml) containing dry HCl (0.5 wt%) was stirred at room temperature overnight. After neutralization with Ag_2CO_3, the mixture was filtered and the solvent was evaporated *in vacuo* to a syrupy residue. To an ice-cooled solution of this residue in pyridine (200 ml) was added mesyl chloride (50 ml, 0.64 mol) dropwise with stirring. The mixture was stirred in an ice bath for 5 h, allowed to stand at room temperature overnight and then evaporated *in vacuo*. The residue was taken up in CH_2Cl_2, washed with water, dried (Na_2SO_4) and evaporated *in vacuo*. Recrystallization from ethyl acetate–hexane afforded a mixture of **6a** and **6b** yield, 35.8 g (68%). The proportion of **6a** to **6b** was determined by preparative TLC on silica gel (benzene–ethyl acetate 1 : 2). From 108.0 mg of the mixture, 9.4 mg of **6a** and 96.4 mg of **6b** were obtained, indicating a ratio

of 9 : 91.

Repeated recrystallization of this mixture from ethyl acetate–benzene afforded pure **6b**; mp 111—112 °C; $[\alpha]_D^{17}$ −18.6° (*c* 1.83, ethyl acetate); NMR, see Table 1.

Found: C, 27.41; H, 4.55; S, 23.89%. Calcd for $C_9H_{18}O_{11}S_3$: C, 27.13; H, 4.55; S, 24.14%.

From the mother liquor of **6b**, the anomer **6a** was isolated by column chromatography on silica gel (benzene–ethyl acetate), and recrystallized from benzene–ethyl acetate; mp 132 °C; $[\alpha]_D^{17}$ +10.8° (*c* 1.97, ethyl acetate).

Found: C, 27.05; H, 4.59; S, 23.87%.

*Azidolysis of a Mixture of **6a** and **6b**.* A mixture of **6a** and **6b** described above (10.0 g, 25.2 mmol) was heated with NaN_3 (11.5 g, 178 mmol) in DMF (150 ml) at 100—110 °C (bath temp) for 2 h, then at 135—140 °C (bath temp) for 2 h. After the mixture had been cooled, the precipitate was filtered off and the solvent was evaporated *in vacuo*. The residue was dissolved in CH_2Cl_2, washed with water, dried ($MgSO_4$) and evaporated *in vacuo*. The residue was subjected to column chromatography on silica gel. A mixture of hexane–ethyl acetate (4 : 1) eluted **9a**, **8b**, **8a**, and **7** in this order.

i) *Methyl 5-Azido-5-deoxy-2,3-di-O-mesyl-α- and β-D-xylofuranoside (**7a** and **7b**)*: Yield, 3.19 g (37%); syrup; NMR see Table 1. This product was hydrogenated in methanol–tetrahydrofuran in the presence of HCl and Pd on charcoal, and then treated with benzoyl chloride and triethylamine to afford monobenzamido derivative; mp 146—147 °C.

Found: C, 42.06; H, 5.03; N, 3.22; S, 15.19%. Calcd for $C_{15}H_{21}O_9NS_2$: C, 42.54; H, 5.00; N, 3.31; S, 15.14%.

ii) *Methyl 3,5-Diazido-3,5-dideoxy-2-O-mesyl-α-D-ribofuranoside (**8a**)*: Yield, 250 mg (3.4% of the starting anomeric mixture, 38% of **6a**); syrup; NMR, see Table 1. This compound was characterized by conversion into crystalline dibenzamido derivative in a similar manner to that described in (i); mp 210 °C; $[\alpha]_D^{19}$ +82.4 °C (*c* 2.08, $CHCl_3$).

Found: C, 55.96; H, 5.36; N, 6.22; S, 7.18%. Calcd for $C_{21}H_{24}O_7N_2S$: C, 56.24; H, 5.39; N, 6.25; S, 7.15%.

iii) *Methyl 3,5-Diazido-3,5-dideoxy-2-O-mesyl-β-D-ribofuranoside (**8b**)*: Yield, 1.98 g (27% of the mixture, 30% of **6b**); mp 59—60 °C; $[\alpha]_D^{14}$ +72.8° (*c* 1.51, ethyl acetate); NMR, see Table 1.

Found: C, 28.75; H, 4.21; N, 28.43; S, 10.90%. Calcd for $C_7H_{12}O_5N_6S$: C, 28.77; H, 4.11; N, 28.77; S, 10.96%.

iv) *Methyl 2,3,5-Triazido-2,3,5-trideoxy-α-D-arabinofuranoside (**9a**)*: Yield, 45 mg (0.75% of the mixture, 8.4% of **6a**); syrup; $[\alpha]_D^{20}$ +195.0° (*c* 2.26, $CHCl_3$); NMR, see Table 1. This compound was hydrogenated in ethanol in the presence of Pd black and HCl. The product was treated with benzyloxycarbonyl chloride and triethylamine to afford methyl 2,3,5-tris(benzyloxycarbonylamino)-2,3,5-trideoxy-α-D-arabinofuranoside (**10a**); mp 204—205 °C; $[\alpha]_D^{21}$ +32.0° (*c* 0.75, $CHCl_3$). NMR: δ 4.78 (1H s, H-1), 5.03 (6H s, $C_6H_5CH_2$), 7.25 (15H, aromatic H).

Found: C, 63.93; H, 6.04; N, 7.50%. Calcd for $C_{30}H_{33}O_8N_3$: C, 63.93; H, 5.90; N, 7.46%.

*Attempts at Azidolysis of **8b**.* A stirred mixture of **8b** (15 mg, 0.05 mmol) and NaN_3 (16 mg, 0.25 mmol) in HMPA (3 ml) was heated and the product was tested by TLC. No reaction occurred at 145 °C (bath temp). When the mixture was heated over 155 °C (bath temp), **8b** decomposed completely, no definite spots on TLC being detected. A similar result was obtained using DMF as solvent.

*Preparation of **8a** by Anomerization of **8b**. With HCl in Methanol*: A solution of **8b** (452 mg) in methanol (50 ml) containing dry HCl (23 wt%) was heated under reflux for 6 h. After the mixture had been cooled, the solvent was evaporated *in vacuo* and the residue was chromatographed on silica gel. Elution with hexane–ethyl acetate (4 : 1) afforded **8b** (274 mg, 61%) and then **8a** (74 mg, 16%).

With $TiCl_4$ in CH_2Cl_2: To a solution of **8b** (520 mg) in CH_2Cl_2 (90 ml) was added $TiCl_4$ (0.25 ml) in CH_2Cl_2 (10 ml) and the mixture was stirred at room temperature for 1 h. On addition of ice, the mixture was stirred until the CH_2Cl_2 layer became clear. The CH_2Cl_2 layer was washed with aq $NaHCO_3$ solution and water, dried (Na_2SO_4), and evaporated *in vacuo*. The residue was chromatographed as above to give **8b** (308 mg, 59%) and **8a** (80 mg, 15%). Prolonged reaction time caused decomposition of the material.

*Triazide (**9a**) from **8a**.* A mixture of **8a** (155 mg, 0.53 mmol) and NaN_3 (240 mg, 3.7 mmol) in DMF (15 ml) was heated at 140—150 °C (bath temp) with stirring for 4 h and then treated as usual. The product (**9a**) was isolated by preparative TLC on silica gel (hexane–ethyl acetate 2 : 1); yield, 48 mg (38%).

*Examination of the Effect of 18-Crown-6 on Azidolysis of **8a**. In DMF*: A mixture of **8a** (1.0 g, 3.4 mmol), NaN_3 (0.88 g, 13.5 mmol), and 18-crown-6 (90 mg, 0.34 mmol) in DMF (100 ml) was heated at 130 °C (bath temp) with stirring for 18 h. By the usual work-up and chromatography, **9a** (0.23 g, 28%) and unchanged **8a** (0.06 g, 6%) were obtained. Without addition of 18-crown-6, but otherwise under the same conditions, the situation did not change; **9a** (0.23 g, 28%) and **8a** (0.06 g, 6%).

In Other Solvents: Mixtures of **8a** (25—50 mg) and NaN_3 (4 mol equivalent) in various solvents (acetonitrile, dioxane, benzene, toluene, or *o*-xylene) were heated under reflux in the presence of 18-crown-6 (1—2 mol equivalent). TLC examination indicated that **9a** was never formed in any of the solvents employed.

*Methyl 2,3,5-Tris(benzyloxycarbonylamino)-2,3,5-trideoxy-α-D-arabinofuranoside (**10a**).* The triazide (**9a**) (300 mg, 1.25 mmol) was dissolved in ethanol (30 ml) and hydrogenated in the presence of Pd black catalyst. After the catalyst had been removed, the mixture was cooled in an ice bath. Triethylamine (0.71 ml, 5.0 mmol) and benzyloxycarbonyl chloride (0.73 ml, 5.0 mmol) were added and the mixture was stirred overnight. Triethylamine (0.36 ml) and benzyloxycarbonyl chloride (0.37 ml) were again added and stirring was continued for further 4 h. The mixture was concentrated *in vacuo*, water was added and the crystalline substance was collected by filtration; yield, 580 mg (83%). Recrystallization was effected from $CHCl_3$; mp 171—173 °C.

Found: C, 62.63; H, 6.03; N, 7.54%. Calcd for $C_{30}H_{33}O_8N_3 \cdot 1/2H_2O$: C, 62.92; H, 5.99; N, 7.34%.

An anhydrous crystals of the same compound showed mp 204—205 °C.

*2,3,5-Tris(benzyloxycarbonylamino)-2,3,5-trideoxy-D-arabinofuranose (**3**).* To a solution of **10a** (600 mg) in dioxane (30 ml) was added 2 M aq solution of *p*-toluenesulfonic acid (30 ml). The mixture was heated under reflux for 1.5 h, concentrated *in vacuo*, and then extracted with $CHCl_3$. The $CHCl_3$ layer was washed with water, dried ($MgSO_4$) and evaporated *in vacuo*. The residue was subjected to a silica gel column. A mixture of $CHCl_3$–ethyl acetate (3 : 1) eluted first unchanged **10a** (197 mg, 30%) and then **3** (177 mg, 30%). The latter was recrystallized from $CHCl_3$; mp 208—210 °C. Its IR and NMR spectra were identical with those of the sample prepared from D-ribose.[1]

Synthesis of Corticotropin Peptides. X. The Synthesis of ACTH(1—18)-OH, ACTH(1—18)-NH_2 and ACTH(1—19)-NH_2*

Ken INOUYE, Fusako SHINOZAKI, Makoto KANAYAMA, and Hideo OTSUKA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553

(Received June 29, 1976)

The final coupling, deprotection and purification processes for the synthesis of octadecapeptides, H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-OH(I) and H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-NH_2 (II), corresponding to the first eighteen amino acid residues of corticotropin (ACTH) are described, in which the *N*-hydroxysuccinimide ester of the N-terminal decapeptide derivative is coupled with the C-terminal octapeptide and octapeptide amide derivatives to give the two protected end products. The same decapeptide active ester is also utilized to the synthesis of a nonadecapeptide, H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-Pro-NH_2 (III), identical with the first nineteen amino acid residues of ACTH. The *in vivo* steroidogenic potencies of the synthetic peptides are compared with that of the synthetic human ACTH (α_h-ACTH) as reference to show that the relative potencies of I, II, and III *vs.* α_h-ACTH are 0.14, 0.48, and 0.47, respectively, as estimated on a molar basis.

In early 1960's considerable effort was devoted to the synthesis of peptides related to corticotropin (ACTH) to obtain a picture of the structural features essential for eliciting the adrenal-stimulating activity. Thus, ACTH(1—19)-OH,[1] ACTH(1—20)-NH_2,[2] ACTH(1—23)-OH,[3] and ACTH(1—24)-OH[4] were synthesized in three different laboratories, and their activities were found to be comparable enough to that of the native hormone. However, a heptadecapeptide ACTH(1—17)-OH[5] was only 15% as active as the nonadecapeptide ACTH(1—19)-OH. We also demonstrated that a hexadecapeptide [Gly^1, $Arg^{15,16}$]-ACTH(1—16)-OH[6] and a heptadecapeptide [Gly^1, Arg^{16}]-ACTH(1—17)-NH_2[7] were only slightly active in adrenal steroidogenesis. These observations suggested that the integrity of the unique Lys-Lys-Arg-Arg sequence in positions 15—18 of the ACTH molecule was crucial for eliciting a high degree of activity. In order to ascertain this point and to find the smallest peptide possessing a moderate adrenal-stimulating potency, we decided to synthesize an octadecapeptide, H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-OH, ACTH(1—18)-OH (I), and an octadecapeptide amide, H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-NH_2, ACTH(1—18)-NH_2 (II). A preliminary account of the synthetic and biological studies of peptides I and II has appeared.[8] The syntheses of the N-terminal decapeptide derivative, Boc-Ser-Tyr-Ser-Met-Glu(OBu^t)-His-Phe-Arg(H^+)-Trp-Gly-O^- (IV),[9] and the C-terminal octapeptide derivatives, H-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-OH (V) and H-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-NH_2 (VI),[10] have already been reported. In this paper the final coupling, deprotection and purification processes to lead to the production of peptides I and II are described in detail. In addition, the synthesis of a nonadecapeptide amide, H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-Pro-NH_2, ACTH(1—19)-NH_2 (III), is also a subject of this paper.

Synthesis of ACTH(1—18)-OH (I) and ACTH(1—18)-NH_2 (II). The final coupling reaction to produce the protected octadecapeptides was carried out by the *N*-hydroxysuccinimide (HOSu) ester method[11] in essentially the same manner as described in the synthesis of [Gly^1]-ACTH(1—18)-NH_2.[12] The protected decapeptide (IV) was converted into the hydrochloride Boc-Ser-Tyr-Ser-Met-Glu(OBu^t)-His-Phe-Arg(HCl)-Trp-Gly-OH and this was esterified with HOSu by means of dicyclohexylcarbodiimide (DCC). For the synthesis of peptide I, the resulting decapeptide active ester hydrochloride was allowed to react with the acetate salt of the N^{α}-free octapeptide derivative (V) in the presence of triethylamine to give Boc-Ser-Tyr-Ser-Met-Glu(OBu^t)-His-Phe-Arg-Trp-Gly-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-OH. The protected octadecapeptide thus obtained was treated with trifluoroacetic acid in the presence of anisole and 2-mercaptoethanol as

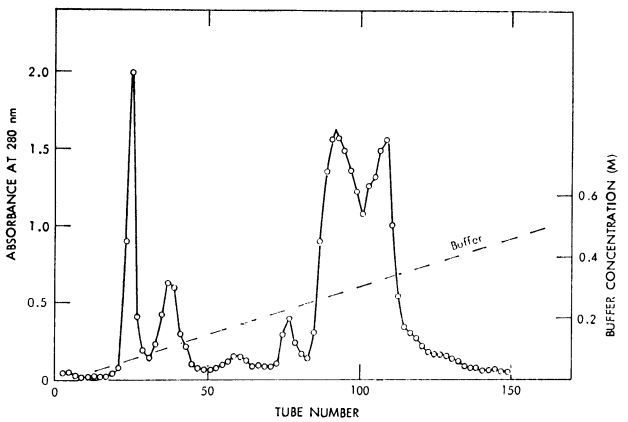

Fig. 1. Carboxymethyl cellulose column chromatography of crude synthetic ACTH(1—18)-OH: sample, 0.28 g; column, Serva, 0.7 meq/g, 1.7×21 cm; buffer, 0—0.6 M ammonium acetate (pH 6.0), 2000 ml; fractionation, 10 ml/tube.

* All the amino acid residues mentioned in this communication are of the L-configuration. Abbreviations used are those recommended by the IUPAC-IUB Commission of Biochemical Nomenclature [*Biochemistry*, **5**, 2485 (1966); *ibid.*, **6**, 362 (1967); *ibid.*, **11**, 1726 (1972)].

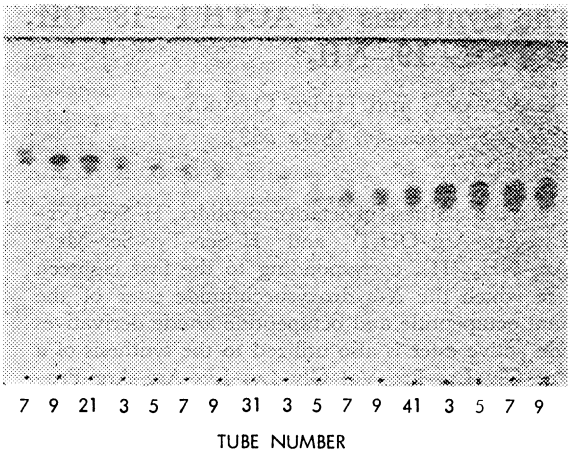

Fig. 2. Examination of fractions by TLC in the partition chromatography of partially purified ACTH(1—18)-OH. Partition chromatography: sample, 0.16 g, derived from tubes 86—115 in Fig. 1; column, Sephadex G-25 (medium), 2.2×50 cm; solvent, 1-butanol–acetic acid–pyridine–water (12:3:4:6); fractionation, 4.4 ml/tube. TLC: on a cellulose plate (precoated, Merck) with 1-butanol–acetic acid–pyridine–water (15 : 3 : 10 : 15) as solvent; detection, Ehrlich reagent.

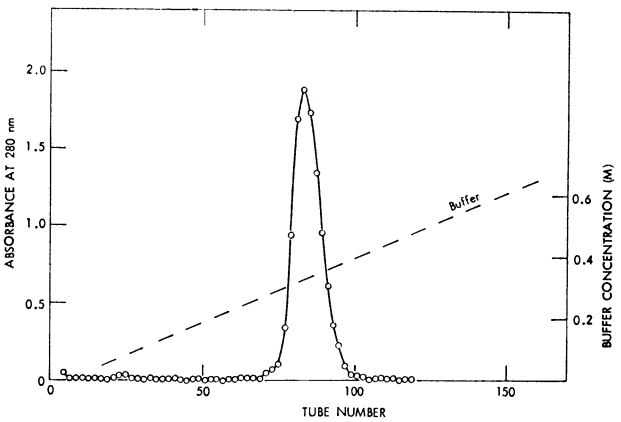

Fig. 3. Rechromatography of partially purified synthetic ACTH(1—18)-OH on a carboxymethyl cellulose column: sample, 0.11 g, fractionated by partition chromatography (Fig. 2, see Experimental for details); column, CM-52 (Whatman), 1.7×18 cm; buffer, 0—0.6 M ammonium acetate (pH 6.0), 1500 ml; fractionation, 10 ml/tube.

scavengers to liberate the desired peptide (I) in the form of trifluoroacetate. This was converted into the corresponding acetate by the treatment with Amberlite CG-400 (acetate form). The resulting crude preparation of peptide I was then purified by carboxymethyl cellulose column chromatography and by partition chromatography on a Sephadex G-25 column (Fig. 1—3). The partition chromatography was performed with a homogeneous mixture, 1-butanol–acetic acid–pyridine–water (12 : 3 : 4 : 6), as solvent[13] and the collected fractions were monitored by the Folin-Ciocalteu method[14] or by TLC more effectively (Fig. 2). The synthesis of peptide II was accomplished in the same manner as described above except that the acetate salt of VI was used as the amine component in the coupling reaction. The overall yields for the final coupling, deprotection and purification processes of peptide I and peptide II were 37 and 26%, respectively.

The synthetic octadecapeptides thus obtained were found to be homogeneous to ninhydrin and the Ehrlich reagent in TLC. Their acid hydrolysates contained the constituent amino acids in the ratios expected by theory with the exception of tryptophan. The tryptophan-tyrosine ratio in intact I and II was determined spectrophotometrically to be unity.[15]

Synthesis of ACTH(1—19)-NH_2 (III). The C-terminal tetrapeptide sequence Lys–Arg–Arg–Pro–NH_2 was synthesized by the step-by-step procedure starting with H–Pro–NH_2 derived from Z–Pro–NH_2[16] by catalytic hydrogenolysis. The two arginines were incorporated in the form of Z–Arg(NO_2) by the DCC method and by the mixed anhydride procedure, respectively, in combination with the removal of benzyloxycarbonyl (Z) group with hydrogen bromide in acetic acid. The resulting N^{α}-free tripeptide was then allowed to react with Z–Lys(Boc)–OSu[10] to afford Z–Lys(Boc)–Arg(NO_2)–Arg(NO_2)–Pro–NH_2 (IX). Compound IX was hydrogenolyzed for removal of the Z and two nitro groups and the product was coupled with Z–Lys(Boc)–Pro–Val–Gly–Lys(Boc)–N_3[10] to give a nonapeptide, Z–Lys(Boc)–Pro–Val–Gly–Lys(Boc)–Lys(Boc)–Arg–Arg–Pro–NH_2 (X), corresponding to positions 11—19 of ACTH.

Compound X was hydrogenolyzed and the resulting N^{α}-free nonapeptide was made react with the decapeptide *N*-hydroxysuccinimide ester, derived from IV, to yield Boc–Ser–Tyr–Ser–Met–Glu(OBu^t)–His–Phe–Arg–Trp–Gly–Lys(Boc)–Pro–Val–Gly–Lys(Boc)–Lys(Boc)–Arg–Arg–Pro–NH_2. This protected nonadecapeptide was treated with trifluoroacetic acid in the presence of anisole and 2-mercaptoethanol as scavengers to liberate peptide III, which was, after conversion into the acetate form, purified by partition chromatography and by ion-exchange chromatography in essentially the same manner as described for peptides I and II. The overall yield for the final coupling, deprotection and purification processes of peptide III was 38%. The purified material behaved as a single component in TLC and its acid hydrolysate contained the constituent amino acids in the ratios expected by theory with the exception of tryptophan. The tryptophan-tyrosine ratio in intact III was determined spectrophotometrically to be unity.[15]

The octadecapeptide amide (II) and the nonadecapeptide amide (III) have been synthesized by two other groups independently.[17,18] The optical rotations of our preparations of peptides II and III were found to differ significantly from those reported by Ramachandran *et al.*[17] Bajusz and Medzihradszky[18] also pointed out this lack of identity in optical rotation between their peptides and those of Ramachandran *et al.*

Biological Activity of ACTH(1—18)-OH (I), ACTH-(1—18)-NH_2 (II) and ACTH(1—19)-NH_2 (III).

TABLE 1. STEROIDOGENIC ACTIVITY OF SYNTHETIC PEPTIDES[19]

Compound	Molecular weight[a]	*In vivo* steroidogenic activity	
		units/mg[b]	units/μmol
ACTH(1—18)-OH (I)	2250	26.8	60.3
ACTH(1—18)-NH_2 (II)	2249	96.7	217
ACTH(1—19)-NH_2 (III)	2346	90.4	212
Synthetic α_h-ACTH[20]	4541	98.6	448

a) As anhydrous free base. b) Third USP Corticotropin Reference Standard was used as reference.

The synthetic peptides obtained above were assayed for the *in vivo* steroidogenic activity by a method based on the elevated levels of 11-hydroxycorticosteroids in the adrenal venous plasma of the hypophysectomized rat in response to intravenous administration of the test sample. The results are shown in Table 1,[19] in which the potencies of peptides I, II, and III are compared with that of the synthetic human hormone (α_h-ACTH).[20]

Table 1 first shows that the octadecapeptide amide (II) is three to four times more active than the corresponding peptide acid (I) in the *in vivo* adrenal steroidogenesis. The similar potentiation effect associated with the C-terminal amidation has been reported with ACTH(1—17)-NH_2 and ACTH(1—19)-NH_2.[17] Imura *et al.* has found that peptide II is inactivated more slowly than peptide I in fresh human plasma.[21] This finding would offer evidence to support the view that the observed higher potency of the peptide amide is a consequence of the increased stability in the biological systems. When the steroidogenic activity was assayed in isolated rat adrenal cells, peptide I and peptide II were found to exhibit virtually the same degree of potency.[22] This is probably due to the absence of carboxypeptidase action in the assay system employed.

Table 1 next shows that ACTH(1—18)-NH_2 (II) and ACTH(1—19)-NH_2 (III) exhibit almost the same potency and they are as active as the synthetic α_h-ACTH when compared by weight. In the table, the potencies are also expressed in terms of units per μmole to compare the synthetic fragments with α_h-ACTH taking account of their molecular weights. Thus, the relative potencies *vs.* α_h-ACTH may be calculated as 0.48 and 0.47 for II and III, respectively, indicating that these fragment peptides are nearly half as active as the intact hormone, as compared on a molar basis. Ramachandran *et al.* also demonstrated that ACTH(1—18)-NH_2 and ACTH(1—19)-NH_2 possessed almost identical potency in the *in vivo* steroidogenesis.[17] From their data the relative potencies *vs.* sheep ACTH (481 USP units/μmol)[17] of the octadecapeptide amide and the nonadecapeptide amide are estimated to be 0.62 and 0.72, respectively.

The biological data obtained above clearly indicate that all the structural features required for the manifestation of steroidogenic activity reside within the first eighteen amino acid sequence of the ACTH molecule. Since it has been reported that ACTH(1—17)-NH_2 is only 23% as active as ACTH(1—18)-NH_2,[17] the octadecapeptide should be the smallest ACTH fragment that is comparable to the intact hormone as a steroidogenic agent. As mentioned above, the C-terminal amide group in ACTH(1—18)-NH_2 appears to be effective only for the stabilization of the peptide *in vivo*. It has been shown that a natural ACTH and a synthetic 39 amino acid peptide are inactivated more slowly than the fragment peptides such as ACTH(1—18)-NH_2, ACTH(1—19)-OH and ACTH(1—26)-OH.[21] Therefore, the C-terminal portion of the ACTH molecule may not be involved in the process of adrenal stimulation, but may play a role in stabilizing the N-terminal half of the hormone in the physiological environment.

Experimental

Thin layer chromatography was (TLC) performed on precoated "silica gel" plates (Kieselgel 60 F_{254}, Merck) or precoated "cellulose" plates (Cellulose F_{254}, Merck).

H–Ser–Tyr–Ser–Met–Glu–His–Phe–Arg–Trp–Gly–Lys–Pro–Val–Gly–Lys–Lys–Arg–Arg–OH Acetate, ACTH(1—18)-OH (I).[8] To a solution of IV (0.16 g, 0.11 mmol)[9] in *N,N*-dimethylformamide (DMF, 4 ml) previously chilled in an ice-bath was added M hydrochloric acid (0.3 ml) and the solution was introduced into ice-cold ethyl acetate (50 ml). The resulting precipitates of the decapeptide hydrochloride (0.17 g) was dissolved in DMF (4 ml) together with *N*-hydroxysuccinimide (HOSu, 0.050 g, 0.44 mmol) and to this was added dicyclohexylcarbodiimide (DCC, 0.091 g, 0.44 mmol) at 0 °C. The mixture was kept at 4 °C overnight, after which it was introduced into ethly acetate-ether (1:1, 100 ml) to give the decapeptide active ester hydrochloride as amorphous precipitates (0.18 g). The active ester thus obtained was added to a solution of the octapeptide acetate [V, prepared from the N^{α}-benzyloxycarbonyl (*Z*) derivative (0.16 g, 0.1 mmol) by catalytic hydrogenolysis][10] and triethylamine (0.056 ml, 0.4 mmol) in DMF (6 ml) and the mixture was kept at 4 °C for 2 days. The product was isolated as precipitates which formed when the reaction mixture was introduced into ethyl acetate (50 ml). The crude protected octadecapeptide thus obtained (0.32 g) was mixed with anisole (0.2 ml) and 2-mercaptoethanol (0.2 ml) and chilled in an ice-bath. To this was added trifluoroacetic acid (5 ml) and the mixture was kept at room temperature for 60 min. The precipitates which formed upon addition of ether were filtered off, washed with ether and dried *in vacuo*. This was then dissolved in water and the solution was passed through a column (1.7×6 cm) of Amberlite CG-400 (acetate form) with additional portions of water. The aqueous solutions were combined and lyophilized to give the deprotected octadecapeptide (0.28 g).

For purification the crude peptide obtained above was chromatographed on a carboxymethyl cellulose column using an ammonium acetate buffer (Fig. 1). The fractions corresponding to a main peak (tubes 86—115) were pooled, evaporated *in vacuo* at a bath temperature of 50 °C and lyophilized (0.16 g). This material was then submitted to partition chromatography on a column of Sephadex G-25 (medium) with 1-butanol-acetic acid-pyridine-water (12:3:4:6) as solvent. Tubes 41—65 containing the desired peptide as a single component, as examined by means of TLC (cellulose) with 1-butanol-acetic acid-pyridine-water (15:3:10:15) as solvent and the Ehrlich reagent as reagent for locating peptide spots (Fig. 2), were combined and evaporated

in vacuo at a bath temperatuer of 45 °C and the residue was lyophilized (0.10 g). Tubes 31—40 containing a less polar impurity in addition to the desired peptide were combined and evaporated *in vacuo*. The residue was rechromatographed on a Sephadex G-25 column (1.7×30 cm) in the same manner as above to give an additional amount of the homogeneous peptide (0.01 g). These preparations were combined (0.11 g) and rechromatographed on a carboxymethyl cellulose column using an ammonium acetate buffer (Fig. 3). The fractions corresponding to a single peak (tubes 77—100) were combined, evaporated and lyophilized to afford the pure octadecapeptide (I) as colorless fluffy powder; yield 0.10 g (37%), $[\alpha]_D^{25.5}$ −61.2±1.9° (*c* 0.5, 0.1 M acetic acid). $\lambda_{max}^{0.1M\ HCl}$ 280 nm ($E_{1cm}^{1\%}$ 25.1), $\lambda_{shoulder}^{0.1M\ HCl}$ 288 nm ($E_{1cm}^{1\%}$ 19.0); $\lambda_{max}^{0.1M\ NaOH}$ 282 nm ($E_{1cm}^{1\%}$ 25.8), 289 nm ($E_{1cm}^{1\%}$ 25.1). TLC (cellulose): a single component (ninhydrin and Ehrlich reagents) in 1-butanol–acetic acid–pyridine–water (15:3:10:15). Amino acid ratios in acid hydrolysate (figures in parentheses represent theoretical values): Lys 2.94 (3), His 1.00 (1), Arg 3.00 (3), Ser 1.72 (2), Glu 1.03 (1), Pro 0.95 (1), Gly 2.00 (2), Val 1.00 (1), Met 0.98 (1), Tyr 0.98 (1), Phe 0.98 (1). The Trp/Tyr ratio in intact I was 0.98 as determined spectrophotometrically.[15]

H–Ser–Tyr–Ser–Met–Glu–His–Phe–Arg–Trp–Gly–Lys–Pro–Val–Gly–Lys–Lys–Arg–Arg–NH_2 Acetate, ACTH(1—18)–NH_2 (II).[8] To a solution of the octapeptide amide acetate [VI, prepared from the N^{α}–Z derivative (0.18 g, 0.12 mmol) by catalytic hydrogenolysis][10] and triethylamine (0.033 ml, 0.24 mmol) in DMF (5 ml) was added the decapeptide *N*-hydroxysuccinimide ester [prepared from IV (0.19 g, 0.13 mmol)[9] in exactly the same manner as described above] and the mixture was kept at 4 °C for 2 days. The crude protected octadecapeptide obtained (0.34 g) was, in the presence of anisole (0.2 ml) and 2-mercaptoethanol (0.2 ml), treated with trifluoroacetic acid (4 ml) at room temperature for 65 min to give the deblocked peptide (0.32 g).

The crude peptide (acetate form) obtained above was chromatographed on a column (1.7×20 cm) of carboxymethyl cellulose (Serva, 0.7 meq/g) using an ammonium acetate buffer (pH 6.0, 2000 ml) with a linear concentration gradient of 0—0.6 M. Ten-ml fractions were collected and their absorption at 280 nm was measured. The fractions corresponding to a main peak (tubes 96—127) were pooled, evaporated *in vacuo* at a bath temperature of 50 °C and lyophilized (0.11 g). This material was then submitted to partition chromatography on a column (2.7×24 cm) of Sephadex G-25 (medium) with 1-butanol–acetic acid–pyridine–water (12:3:4:6) as solvent and 5 ml-fractions were collected. The Folin-Ciocalteu method[14] was effected for monitoring the peptide content of the fractions. Tubes 14—45 were combined and evaporated *in vacuo* at a bath temperature of 45 °C to give a residue which was lyophilized (0.1 g). The partially purified peptide was rechromatographed on a column (1.7×20 cm) of carboxymethyl cellulose (CM-52, Whatman) using an ammonium acetate buffer (pH 6.0, 1500 ml) with a linear concentration gradient of 0—0.6 M. Ten-ml fractions were collected and those corresponding to a single peak (tubes 138—165) were combined, evaporated *in vacuo* and lyophilized to give the pure octadecapeptide amide (II) as colorless fluffy powder; yield 0.086 g (26%), $[\alpha]_D^{25}$ −61.5±2.4° (*c* 0.4, 0.1 M acetic acid). Lit, $[\alpha]_D^{25}$ −92.7° (*c* 0.1, 0.1 M acetic acid);[17] $[\alpha]_D^{20}$ −54.0° (*c* 0.1, 0.1 M acetic acid).[18] $\lambda_{max}^{0.1M\ HCl}$ 280 nm ($E_{1cm}^{1\%}$ 25.8), $\lambda_{shoulder}^{0.1M\ HCl}$ 288 nm ($E_{1cm}^{1\%}$ 19.6); $\lambda_{max}^{0.1M\ NaOH}$ 282 nm ($E_{1cm}^{1\%}$ 26.9), 289 nm ($E_{1cm}^{1\%}$ 26.0). TLC (cellulose): a single component (ninhydrin and Ehrlich reagents) in 1-butanol–acetic acid–pyridine–water (15 : 3 : 10 : 15). Amino acid ratios in acid hydrolysate: Lys 3.02 (3), His 1.04 (1), Arg 3.07 (3), Ser 1.80 (2), Glu 1.04 (1), Pro 1.04 (1) Gly 2.02 (2), Val 1.00 (1), Met 1.00 (1), Tyr 1.00 (1), Phe 0.98 (1). The Trp/Tyr ratio in intact II was 0.94 as determined spectrophotometrically.[15]

H–Ser–Tyr–Ser–Met–Glu–His–Phe–Arg–Trp–Gly–Lys–Pro–Val–Gly–Lys–Lys–Arg–Arg–Pro–NH_2 Acetate, ACTH(1—19)–NH_2 (III). Compound X (0.17 g, 0.1 mmol) was hydrogenolyzed over palladium in methanol containing acetic acid (0.5 ml) for 3 h. Removal of the solvent by evaporation *in vacuo* followed by lyophilization from acetic acid gave the N^{α}-free nonapeptide derivative (0.17 g). This was dissolved in DMF (3 ml) and triethylamine (0.042 ml, 0.3 mmol) was added. To this solution was added the decapeptide *N*-hydroxysuccinimide ester [prepared from IV (0.16 g, 0.11 mmol)[9] as described above] and the mixture was kept at 4 °C for 2 days. The crude protected nonadecapeptide obtained (0.32 g) was, in the presence of anisole (0.2 ml) and 2-mercaptoethanol (0.2 ml), treated with trifluoroacetic acid (5 ml) at room temperature for 60 min to give the deblocked peptide (0.30 g).

The crude peptide obtained above was, after treatment with Amberlite CG-400 (acetate), submitted to a column (1.7×30 cm) of carboxymethyl cellulose (Serva, 0.7 meq/g) using an ammonium acetate buffer (pH 6.0, 2000 ml) with a linear concentration gradient of 0—0.6 M. The fractions (10 ml/tube) corresponding to a main peak (tubes 106—160) were pooled and lyophilized (0.19 g). This material was chromatographed on a Sephadex G-25 column (medium, 1.7×45 cm) with 1-butanol–acetic acid–pyridine–water (12:3:4:6) as solvent and 4.5 ml-fractions were collected. The fractions containing the desired peptide as a single component (tubes 35—47), as examined by TLC, were combined (0.13 g). For final purification this was rechromatographed on a carboxymethyl cellulose column (CM-52, Whatman, 1.7×30 cm) using an ammonium acetate buffer (pH 6.0, 2000 ml) with a linear concentration gradient of 0—0.6 M. The franctions (10 ml/tube) corresponding to a single peak (tubes 158—185) were combined, evaporated and lyophilized to afford the pure nonadecapeptide (III) as colorless fluffy powder; yield 0.11 g (38%), $[\alpha]_D^{26}$ −69.4±2.1° (*c* 0.5, 0.1 M acetic acid). Lit, $[\alpha]_D^{25}$ −102.6° (*c* 0.5, 0.1 M acetic acid);[17] $[\alpha]_D^{20}$ −50.0° (*c* 0.5, 0.1M acetic acid).[18] $\lambda_{max}^{0.1M\ HCl}$ 280 nm ($E_{1cm}^{1\%}$ 23.6), $\lambda_{shoulder}^{0.1M\ HCl}$ 288 nm ($E_{1cm}^{1\%}$ 17.8); $\lambda_{max}^{0.1M\ NaOH}$ 282 nm ($E_{1cm}^{1\%}$ 24.1), 289 nm ($E_{1cm}^{1\%}$ 23.3). Tlc (cellulose): a single component (ninhydrin and Ehrlich reagents) in 1-butanol–acetic acid–pyridine–water (15:3:10:15). Amino acid ratios in acid hydrolysate: Lys 2.98 (3), His 1.00 (1), Arg 3.02 (3), Ser 1.71 (2), Glu 1.06 (1), Pro 1.91 (2), Gly 1.98 (2), Val 1.00 (1), Met 0.98 (1), Tyr 1.00 (1), Phe 0.96 (1). The Trp/Tyr ratio in intact III was 0.95 as determined spectrophotometrically.[15]

Z–Arg(NO_2)–Pro–NH_2 (VII). Z-Pro-NH_2 (3.43 g, 13.8 mmol)[16] was hydrogenolyzed over palladium in methanol for 4 h. The resulting H–Pro–NH_2 (crystalline free base) and Z–Arg(NO_2)–OH (4.42 g, 12.5 mmol) were coupled with DCC (2.58 g, 12.5 mmol) in DMF–acetonitrile (1 : 5, 48 ml) at room temperature overnight. The product was precipitated from methanol–ethyl acetate and then crystallized from methanol; yield 3.14 g (56%), mp 173—174 °C, $[\alpha]_D^{25.5}$ −19.6±0.6° (*c* 1.0, DMF).

Found: C, 49.89; H, 6.03; N, 21.69%. Calcd for $C_{19}H_{27}N_7O_6$: C, 50.77; H, 6.05; N, 21.82%.

Z–Arg(NO_2)–Arg(NO_2)–Pro–NH_2 (VIII). Compound VII (2.65 g, 5.9 mmol) was treated with 25% hydrogen bromide in acetic acid (10 ml) at room temperature for 60 min to give H–Arg(NO_2)–Pro–NH_2 hydrobromide which

was precipitated by the addition of ether (2.85 g).

A solution of Z-Arg(NO_2)-OH (1.77 g, 5 mmol) and tributylamine (1.31 ml, 5.5 mmol) in anhydrous tetrahydrofuran (20 ml) was chilled in an ice-salt bath and ethyl chloroformate (0.53 ml, 5.5 mmol) was added dropwise. The mixture was stirred at the same temperature for 5 min, after which an ice-cold solution of the dipeptide amide hydrobromide obtained above and tributylamine (3.58 ml, 15 mmol) in tetrahydrofuran-water (3 : 1, 20 ml) was introduced. The reaction mixture was stirred at −10—0 °C for 3 h followed by evaporation *in vacuo* at a bath temperature of 40 °C. The sirupy residue, dissolved in 1-butanol-ethyl acetate (1 : 3), was washed with M hydrochloric acid and M sodium hydrogencarbonate, and evaporated *in vacuo*. The crude product thus obtained was chromatographed on a column of silica gel (30 g, Kieselgel 60, Merck) with ethyl acetate-acetic acid-water (4 : 1 : 1) as solvent. The fractions containing the desired product as a major component were collected and evaporated *in vacuo* at a bath temperature of 40 °C, and the residue was precipitated from methanol-ether. The chromatography was repeated until the precipitates became completely homogeneous as examined by TLC on a silica gel plate with ethyl acetate-acetic acid-water (4:1:1) as solvent; yield 0.98 g, $[\alpha]_D^{25.5}$ −36.4±0.8° (*c*, 1.0, methanol).

Found: C, 46.18; H, 6.39; N, 23.82%. Calcd for $C_{25}H_{38}N_{12}O_9 \cdot 2CH_3OH$: C, 45.37; H, 6.49; N, 23.52%.

Z-Lys(Boc)-Arg(NO_2)-Arg(NO_2)-Pro-NH_2 (IX). Compound VIII (0.78 g, 1.2 mmol) was treated with 25% hydrogen bromide in acetic acid (10 ml) at room temperature for 90 min to give H-Arg(NO_2)-Arg(NO_2)-Pro-NH_2 hydrobromide (0.93 g). This was allowed to react with Z-Lys(Boc)-OSu (0.57 g, 1.2 mmol)[10] in DMF in the presence of triethylamine (0.56 ml, 4.0 mmol) at 4 °C overnight. The solvent was evaporated *in vacuo* and the residue dissolved in 1-butanol-ethyl acetate (1:3) was washed with ice-cold M hydrochloric acid and M sodium hydrogencarbonate and evaporated *in vacuo*. The residue was solidified by treatment with ether; yield 0.91 g (87%), $[\alpha]_D^{25}$ −38.9±0.8° (*c* 1.0, methanol). TLC (silica gel): homogeneous (sulfuric acid) in ethyl acetate-acetic acid-water (4 : 1 : 1).

Found: C, 48.76; H, 7.05, N, 21.36%. Calcd for $C_{36}H_{58}N_{14}O_{12} \cdot CH_3OH$: C, 48.78; H, 6.86; N, 21.53%.

Z-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-Pro-NH_2 Acetate (X). Compound IX (0.66 g, 0.75 mmol) was hydrogenolyzed over palladium in 20% acetic acid in methanol (10 ml) for 7 h to give the N^{α}-free tetrapeptide H-Lys(Boc)-Arg-Arg-Pro-NH_2. A 0.60 g-portion (0.65 mmol) was dissolved in tetrahydrofuran-water (5 : 2, 7 ml) and triethylamine (0.20 ml) was added. The resulting solution was combined with an ice-cold solution of Z-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-N_3 [derived from the corresponding hydrazide (0.89 g, 1mmol)][10] in 90% tetrahydrofuran and the mixture was stirred at 4 °C overnight followed by evaporation *in vacuo*. To this were added ethyl acetate (15 ml) and M acetic acid (15 ml) and the mixture was shaken vigorously. The aqueous phase which separated was extracted repeatedly with ethyl acetate. The organic solutions were combined and evaporated *in vacuo*. The residue was again distributed between ethyl acetate (15 ml) and M acetic acid (15 ml), and the organic phase was extracted with M acetic acid repeatedly. The aqueous solutions were combined and evaporated *in vacuo* at a bath temperature of 45 °C. The residue was redissolved in M acetic acid (15 ml) and the solution was extracted with water-saturated 1-butanol repeatedly. The butanol extracts were combined and evaporated *in vacuo* at a bath temperature of 45 °C. The resulting sirupy residue was precipitated from methanol-ether and was then lyophilized to give X; yield 0.78 g (73%), $[\alpha]_D^{25}$ −53.5±0.9° (*c* 1.0, methanol). Tlc (silica gel): homogeneous (ninhydrin, after pretreatment with hydrochloric acid) in ethyl acetate-acetic acid-water (3 : 1 : 1).

Found: C, 51.78; H, 8.00; N, 16.08%. Calcd for $C_{70}H_{119}N_{19}O_{17} \cdot 2CH_3COOH \cdot 4H_2O$: C, 52.56; H, 8.05; N, 15.74%.

Synthesis of Corticotropin Peptides. XIII. The Synthesis of a Hexacosapeptide and a Heptacosapeptide Corresponding to the First Twenty-six and Twenty-seven Amino Acid Residues of Corticotropin (ACTH)*

Ken INOUYE, Yoshie SUMITOMO, and Masaru SHIN

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553

(Received June 29, 1976)

The syntheses are described of a hexacosapeptide H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-Pro-Val-Lys-Val-Tyr-Pro-Asn-Gly-OH (I) and a heptacosapeptide H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-Pro-Val-Lys-Val-Tyr-Pro-Asn-Gly-Ala-OH (II) corresponding to the first twenty-six and twenty-seven amino acid residues, respectively, of corticotropin (ACTH), in which a new protecting group 1-methylcyclohexyloxycarbonyl (Mhoc) is utilized for the temporary protection of the ε-amino function of lysines. The *in vivo* steroidogenic potencies of the synthetic peptides I and II are compared on a molar basis with those of ACTH(1—18)-NH_2 and synthetic human ACTH (α_h-ACTH) to demonstrate that the relative potencies of I and II *vs.* ACTH(1—18)-NH_2 are 2.3 and 2.3—3.8, respectively, and those *vs.* α_h-ACTH are 1.1 and 1.1—1.8, respectively.

The primary structure of porcine corticotropin (ACTH) and that of human ACTH were first proposed by Shepherd *et al.*[1] in 1956 and by Lee *et al.*[2] in 1961, respectively. The proposed structure of porcine ACTH was synthesized by Schwyzer and Sieber[3] in 1963 and that of human ACTH by Bajusz *et al.* in 1967.[4]

In a previous communication we reported the synthesis of a heptacosapeptide corresponding to the first twenty-seven amino acid residues of human ACTH.[5] In 1971, however, Gráf *et al.*[6] followed by Riniker *et al.*[7] revised the amino acid sequences of porcine and human ACTH's. In addition, the structures of bovine and ovine ACTH's have also been revised recently not only to establish the identity between these two mammalian hormones,[8,9] but also to show that the only structural differences among the human, porcine, bovine and ovine hormones are confined to the two positions 31 and 33. Thus, we have carried out the synthesis of ACTH(1—27)-OH according to the revised amino acid sequence, H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-Pro-Val-Lys-Val-Tyr-Pro-Asn-Gly-Ala-OH (II), which differs from the one previously proposed for the human hormone[2] in positions 25 through 27, Asn-Gly-Ala instead of Asp-Ala-Gly. In parallel with peptide II, a hexacosapeptide, H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-Pro-Val-Lys-Val-Tyr-Pro-Asn-Gly-OH, ACTH(1—26)-OH (I), has also been synthesized. For their size peptides I and II may be placed halfway between the nonatriacontapeptide of natural ACTH and the octadecapeptide ACTH(1—18)-NH_2 which is the smallest peptide endowed with all the structural features required for the manifestation of steroidogenic activity.[10] Comparison of I or II with these peptides for the hormonal action will, therefore, provide data important for evaluating the role of the C-terminal half of the ACTH molecule. This paper describes the details of the synthesis of

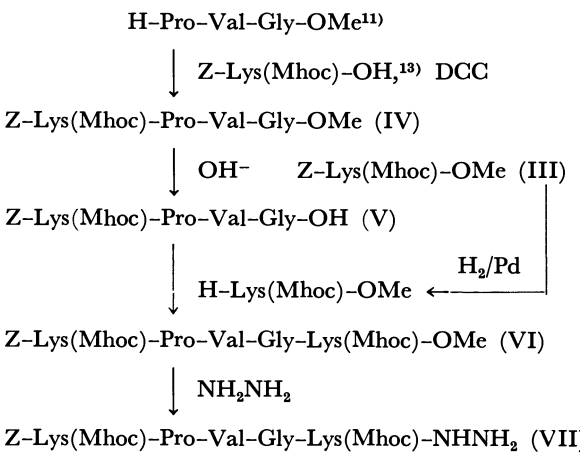

Fig. 1. Synthesis of amino acid sequence 11—15 of ACTH. Mhoc: 1-methylcyclohexyloxycarbonyl.

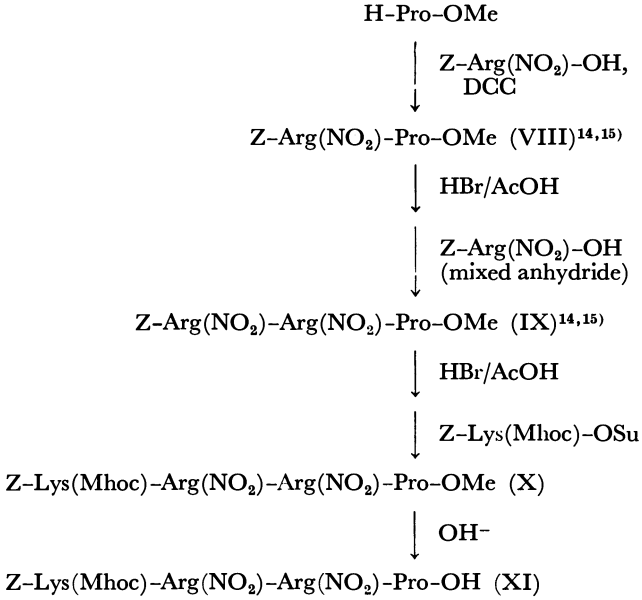

Fig. 2. Synthesis of amino acid sequence 16—19 of ACTH. Mhoc: 1-methylcyclohexyloxycarbonyl.

* All the amino acid residues mentioned in this communication are of the L-configuration. Abbreviations used are those recommended by the IUPAC-IUB Commission of Biochemical Nomenclature [*Biochemistry*, **5**, 2485 (1966); *ibid.*, **6**, 362 (1967); *ibid.*, **11**, 1726 (1972)] and include Mhoc: 1-methylcyclohexyloxycarbonyl.

peptides I and II.

The pentapeptide derivative (VII) corresponding to positions 11—15 of the ACTH molecule was synthesized according to the procedure illustrated in Fig. 1. This procedure is much the same as that employed for the synthesis of Z-Lys(Boc)-Pro-Val-Gly-Lys-(Boc)-OMe (and $-NHNH_2$)[11,12] except that the ε-amino function of lysines was blocked by the 1-methylcyclohexyloxycarbonyl (Mhoc) groups. The Mhoc group is cleavable by acidolysis in almost the same rate as the Boc group. However, a highly lipophilic nature of the new protecting group would increase the solubility of protected peptides in organic solvents, thus facilitating their chromatographic purification remarkably. A full account of the Mhoc and other new protecting groups will be given elsewhere.[13]

The amino acid sequence 16—19 was synthesized in the form of Z-Lys(Mhoc)-Arg(NO_2)-Arg(NO_2)-Pro-OH (XI) as shown in Figure 2. The two arginines were successively incorporated by the dicyclohexylcarbodiimide (DCC) method and by the mixed anhydride procedure to give IX.[14,15] Removal of the Z group with hydrogen bromide in acetic acid yielded the N^{α}-free tripeptide which was coupled with the *N*-hydroxysuccinimide (HOSu) ester of Z-Lys(Mhoc)-OH to produce X. Saponification of ester X gave the corresponding acid (XI). An alternative synthesis of XI has recently been accomplished by the use of H-Arg(NO_2)-Arg(NO_2)-Pro-OH, derived from Z-Arg(NO_2)-Arg(NO_2)-Pro-OBzl with hydrogen bromide

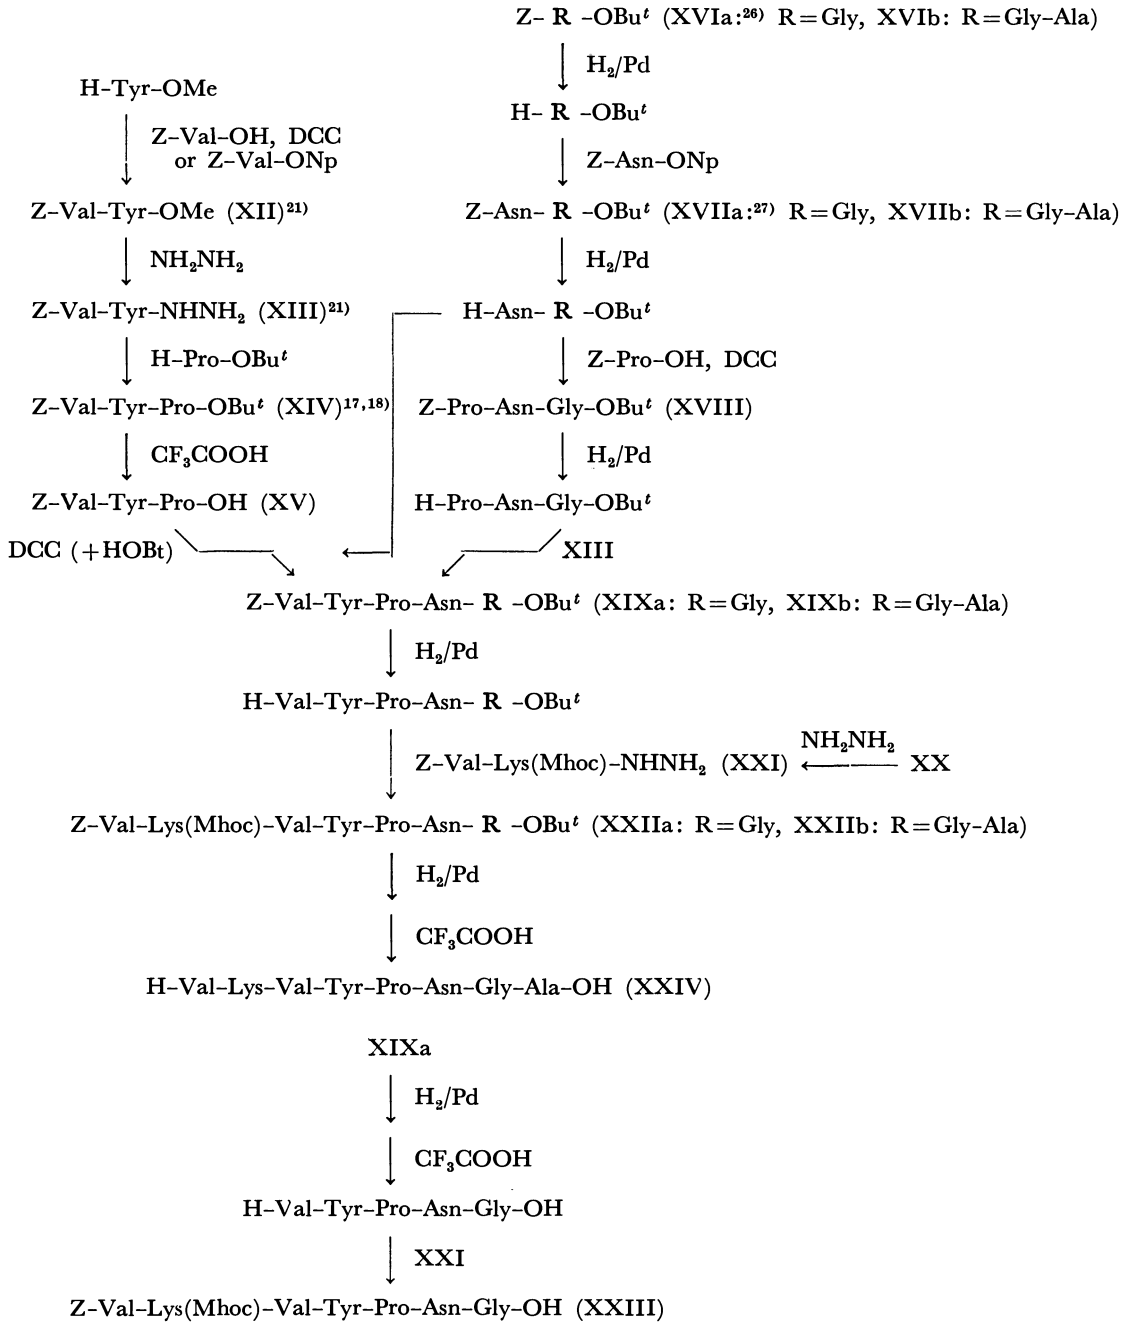

Fig. 3. Snythesis of amino acid sequences 20—26 and 20—27 of ACTH.
Mhoc: 1-methylcyclohexyloxycarbonyl.

in acetic acid, as intermediate.[16] The optical rotation of the product was identical with that of the one derived from the methyl ester. This provides a proof for the optical purity of XI.

The synthetic routes to the amino acid sequences 20—26 and 20—27 are summarized in Fig. 3. The tripeptide derivative XV corresponding to positions 22—24 was derived from the *t*-butyl ester (XIV)[17,18] by the treatment with trifluoroacetic acid. Compound XV could not be obtained from Z-Val-Tyr-Pro-OMe without any danger of racemization, because the methyl ester was remarkably resistant to the action of alkali. In contrast to the methyl ester the corresponding benzyl ester may be used as an intermediate to XV, since Ramachandran and Li have reported that Z-Val-Lys(Tos)-Val-Tyr-Pro-OBzl can be saponified to the corresponding acid in an 84% yield.[19] Coupling of XV with H-Asn-Gly-OBu^t and H-Asn-Gly-Ala-OBu^t by means of the DCC method in the presence of 1-hydroxybenzotriazole (HOBt)[20] gave crystalline compounds XIXa and XIXb, respectively, in moderate yields. Compound XIXa was also obtained by the reaction of Z-Val-Tyr-N_3, derived from the preceding hydrazide (XIII)[21] by the treatment with nitrous acid, with a crystalline tripeptide H-Pro-Asn-Gly-OBu^t (free base) in a comparable yield. Catalytic hydrogenolysis of XIXa and XIXb yielded the N^{α}-free penta- and hexapeptides, which were then acylated with Z-Val-Lys(Mhoc)-N_3, derived from the hydrazide (XXI) with nitrous acid in the usual manner, to give crystalline derivatives XXIIa and XXIIb, respectively, in excellent yields.

A portion of XXIIb was fully deblocked by catalytic hydrogenolysis and subsequent treatment with trifluoroacetic acid to afford an octapeptide (XXIV) corresponding to ACTH(20—27). The acid hydrolysate of XXIV was found to contain the constituent amino acids (and ammonia derived from Asn) in the ratios predicted by theory. Compound XIXa was deprotected in the same manner as above and the resulting pentapeptide was acylated with Z-Val-Lys-(Mhoc)-N_3 to give XXIII in a crystalline form. Compound XXIII may be used as an intermediate for the synthesis of peptides related to the C-terminal half of the ACTH molecule.

The fragment peptides obtained above were assembled as illustrated in Fig. 4, leading to the formation of a hexadecapeptide and a heptadecapeptide corresponding to ACTH(11—26) and ACTH(11—27), respectively. The N^{α}-free peptides, derived from XXIIa and XXIIb by catalytic hydrogenolysis, were coupled with XI by the DCC method in the presence of HOBt[20] to yield XXVa and XXVb, respectively, both of which were purified on silica gel columns with chloroform–methanol systems as solvent. For removal of the N^{α}-benzyloxycarbonyl (Z) group and nitro groups, XXVa and XXVb were hydrogenolyzed; the completion of reaction was checked by TLC and by the disappearance of absorption at 275 nm characteristic of the nitro group. The resulting partially protected peptides XXVIa and XXVIb were then allowed to react with the azide, derived from hydrazide VII with nitrous acid in the usual manner, to give a hexadecapeptide (XXVIIIa) and a heptadecapeptide (XXVIIIb) corresponding to ACTH(11—26) and ACTH(11—27), respectively. They were obtained in moderate yields after purification by silica gel column chromatography with chloroform–methanol systems as solvent. The acid hydrolysates of XXVIIIa and XXVIIIb were found to contain the constituent amino acids in the ratios expected by theory.

A portion of XXVIa was treated with trifluoroacetic acid in the presence of anisole and 2-mercaptoethanol as scavengers to liberate a free undecapeptide XXVIIa, that is ACTH(16—26). In the same manner a free dodecapeptide (XXVIIb) corresponding to ACTH-(16—27) was derived from XXVIb. Both XXVIIa and XXVIIb, purified on a carboxymethyl cellulose column, behaved as a single component in TLC.

The final coupling process for connecting the N-terminal decapeptide with the C-terminal hexadecapeptide and the subsequent deprotection to lead to

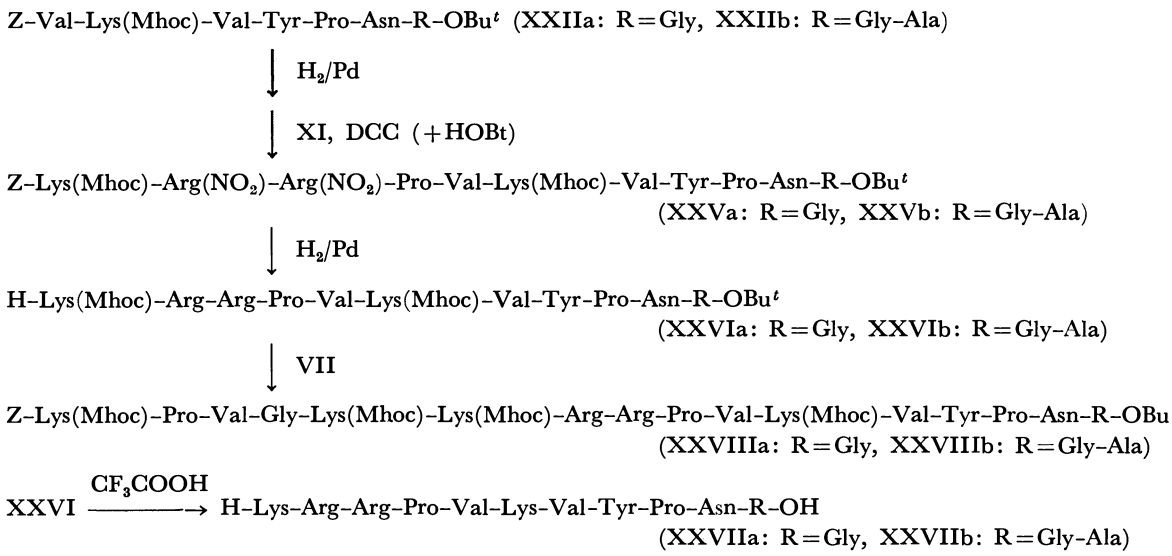

Fig. 4. Synthesis of amino acid sequences 11—26 and 11—27 of ACTH.
Mhoc: 1-methylcyclohexyloxycarbonyl.

the production of a hexacosapeptide, ACTH(1—26)-OH (I), were performed as follows. Boc-Ser-Tyr-Ser-Met-Glu(OBu^t)-His-Phe-Arg(H^+)-Trp-Gly-O^- [22] was converted into the hydrochloride Boc-Ser-Tyr-Ser-Met-Glu(OBu^t)-His-Phe-Arg(HCl)-Trp-Gly-OH and this was esterified with HOSu by the DCC method. The resulting active ester hydrochloride was coupled with the N^{α}-free hexadecapeptide, derived from XXVIIIa by catalytic hydrogenolysis, to give the protected hexacosapeptide, Boc-Ser-Tyr-Ser-Met-Glu(OBu^t)-His-Phe-Arg-Trp-Gly-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-Lys(Mhoc)-Arg-Arg-Pro-Val-Lys(Mhoc)-Val-Tyr-Pro-Asn-Gly-OBu^t. Finally, this was submitted for deprotection to the trifluoroacetic acid treatment in the presence of anisole and 1,2-ethanedithiol as scavengers to liberate hexacosapeptide I as the trifluoroacetate, which was converted into the acetate by passing through a column of Amberlite CG-400 (acetate form). The heptacosapeptide ACTH(1—27)-OH (II) was obtained in exactly the same manner as described above except that the N^{α}-free heptadecapeptide, derived from XXVIIIb by catalytic hydrogenolysis, was used as the amine component in the coupling reaction. The deblocked peptides were then purified by partition chromatography on a column of Sephadex G-25 with 1-butanol-acetic acid-pyridine-water (12 : 3 : 4 : 6) as solvent[10b] and by carboxymethyl cellulose column chromatography in an ammonium acetate buffer. The overall yields of peptide I and peptide II for the final coupling, deprotection and purification processes were 26% and 27%, respectively. These preparations were found to be homogeneous in TLC, and their acid hydrolysates contained the constituent amino acids in the ratios expected by theory except for tryptophan. The Tyr/Trp ratio was 2.0 for both peptides, as determined spectrophotometrically.[23]

The synthetic peptides thus obtained were assayed for the *in vivo* steroidogenic activity by a method based on the elevated levels of 11-hydroxycorticosteroids in the adrenal venous blood of the hypophysectomized rat in response to intravenous administration of the peptide. The results are shown in Table 1,[24] in which the potencies of ACTH(1—26)-OH (I) and ACTH(1—27)-OH (II) are compared with those of ACTH(1—18)-NH_2[10b] and the synthetic human hormone (α_h-ACTH).[25] The *in vivo* steroidogenic potencies of I and II appear to be comparable, although the heptacosapeptide is rather variable and tends to give potencies somewhat higher than that of the hexacosapeptide. When compared on a molar basis, peptide I and peptide II are more than twice as active as the octadecapeptide and equal to, or even more active than, the intact hormone; the relative potencies of I and II *vs.* ACTH(1—18)-NH_2 are 2.3 and 2.3—3.8, respectively, and those *vs.* α_h-ACTH are 1.1 and 1.1—1.8, respectively, as calculated from Table 1. More of the comparative studies including a detailed examination of the time-action relations are obviously needed to evaluate the effect of chain length on biological activity. Such studies are now in progress.

Table 1. Steroidogenic activity of snythetic peptides[24]

Compound	Molecular weight[a]	*In vivo* steroidogenic activity	
		units/mg[b]	units/μmol
ACTH(1—18)-NH_2[10b]	2249	96.7	217
ACTH(1—26)-OH (I)	3105	160	497
ACTH(1—27)-OH (II)	3176	155—259	492—823
Synthetic α_h-ACTH[25]	4541	98.6	448

a) As anhydrous free base. b) The Third USP Corticotropin Reference Standard was used as reference.

Experimental

Thin layer chromatography was (TLC) performed on "silica gel" plates [Kieselgel GF_{254} or Kieselgel $60F_{254}$ (precoated), Merck] or precoated "cellulose" plates (Cellulose F, Merck), and the following solvent systems were employed: A, benzene-ethyl acetate (7 : 3); B, ethyl acetate-methanol (8 : 2); C, chloroform-methanol (9 : 1); D, chloroform-methanol (85 : 15); E, chloroform-methanol (8 : 2); F, chloroform-methanol-acetic acid (95 : 5 : 3); G, chloroform-methanol-acetic acid (90 : 10 : 3); H, chloroform-methanol-acetic acid (8 : 1 : 1); I, chloroform-methanol-acetic acid (80 : 20 : 3); J, 1-butanol-acetic acid-water (4 : 1 : 2); K, 1-butanol-acetic acid-pyridine-water (15 ; 3 : 10 : 12); L, 1-butanol-acetic acid-pyridine-water (15 : 3 : 10 : 15).

Z-Lys(Mhoc)-OMe (III). Z-Lys(Mhoc)-OH, derived from the dicyclohexylamine (DCHA) salt (12.04 g, 20 mmol)[13] by the treatment with Dowex 50W×8 (H^+ form) in 60% ethanol in the usual manner, was esterified with diazomethane to give III as amorphous solid; wt 8.38 g (96%), $[\alpha]_D^{22}$ −9.6± 0.3° (*c* 2.0, acetone). TLC (silica gel): a single component (ninhydrin, after pretreatment with hydrobromic acid) in system A and system B.

Found: C, 63.60; H, 8.07; N, 6.56%. Calcd for $C_{23}H_{34}N_2O_6$: C, 63.57; H, 7.89; N, 6.54%.

Z-Lys(Mhoc)-Pro-Val-Gly-OMe (IV). Z-Lys(Mhoc)-OH, derived from the DCHA salt (15.05 g, 25 mmol)[13] in the usual manner, and H-Pro-Val-Gly-OMe (7.13 g, 25 mmol)[11] were coupled with DCC (5.16 g, 25 mmol) in dichloromethane at 4 °C overnight. The reaction mixture was worked up in the usual manner to give the desired tetrapeptide, which was separated as gelatinous precipitates from ether; wt 11.0 g (64%), mp 71—73 °C, $[\alpha]_D^{23}$ −73.1±1.1° (*c* 1.0, methanol). TLC (silica gel): a single component (sulfuric acid) in system C and system F.

Found: C, 60.88; H, 7.70; N, 10.11%. Calcd for $C_{35}H_{53}N_5O_9$: C, 61.12; H, 7.77; N, 10.18%.

Z-Lys(Mhoc)-Pro-Val-Gly-OH (V). Compound IV (1.38 g, 2 mmol) in methanol (5 ml) was saponified with 2 M sodium hydroxide (2 ml) at 0 °C for 60 min to give V as amorphous solid; wt 1.26 g (92%), $[\alpha]_D^{23}$ −71.1±1.1° (*c* 1.0, methanol). TLC (silica gel): a single component (sulfuric acid) in system G.

Found: C, 59.97; H, 7.84; N, 9.92%. Calcd for $C_{34}H_{51}N_5O_9 \cdot 1/2H_2O$: C, 59.81; H, 7.68; N, 10.26%.

Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-OMe (VI). Compound III (5.21 g, 12 mmol) was hydrogenolyzed over palladium in methanol in the presence of acetic acid (1 ml) for 2 h to give the acetic acid salt of H-Lys(Mhoc)-OMe as a sirupy residue. This was then treated with 50% potassium carbonate at 0 °C in the presence of dichloromethane. The resulting free base and V (6.74 g, 10 mmol) were coupled

with dicyclohexylcarbodiimide (DCC, 2.48 g, 12 mmol) in dichloromethane at 4 °C for 20 h to give VI, which was separated as gelatinous precipitates from ether. Reprecipitation from ethyl acetate–ether afforded the pure material; wt 7.51 g (79%), mp 84—85 °C, $[\alpha]_D^{23}$ −51.1±0.9° (*c* 1.0, methanol). TLC (silica gel): a single component (sulfuric acid) in system C.

Found: C, 61.84; H, 8.37; N, 10.02%. Calcd for $C_{49}H_{77}N_7O_{12}$: C, 61.55; H, 8.12; N, 10.25%.

Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-NHNH$_2$ (VII). Compound VI (6.69 g, 7 mmol) was treated with hydrazine hydrate (3.4 ml, 70 mmol) in methanol (30 ml) at room temperature for 45 h, after which the product was separated as gelatinous precipitates by the addition of ether. Reprecipitation from methanol–ether gave VII in pure form; wt 6.50 g (97%), mp 165—166 °C, $[\alpha]_D^{22.5}$ −52.0±0.9° (*c* 1.0, methanol), −28.3±0.4° [*c* 2.0, *N,N*-dimethylformamide (DMF)]. TLC (silica gel): a single component (sulfuric acid) in system B and system C.

Found: C 60.19; H, 8.46; N, 13.21%. Calcd for $C_{48}H_{77}N_9O_{11}$: C, 60.29, H, 8.12; N, 13.18%.

Z-Lys(Mhoc)-Arg(NO$_2$)-Arg(NO$_2$)-Pro-OMe (X). Compound IX (2.00 g, 3 mmol) was treated with 25% hydrogen bromide in acetic acid (7 ml) at room temperature for 120 min to give H-Arg(NO$_2$)-Arg(NO$_2$)-Pro-OMe hydrobromide (2.44 g).

Z-Lys(Mhoc)-OH, derived from the DCHA salt (1.80 g, 3 mmol)[13] in the usual manner, and *N*-hydroxysuccinimide (HOSu, 0.35 g, 3 mmol) were coupled with DCC (0.62 g, 3 mmol) in acetonitrile at 0 °C for 3 h. The resulting active ester was allowed to react with the N^{α}-free tripeptide ester obtained above in DMF (15 ml) in the presence of triethylamine (1.7 ml, 12 mmol) at 4 °C for 2 days. The product was dissolved in 10% 1-butanol in ethyl acetate and the solution was washed with ice-cold M hydrochloric acid and M sodium hydrogencarbonate, dried over magnesium sulfate and evaporated *in vacuo*. The resulting sirupy residue was reprecipitated from methanol–ether yielded X in pure form; wt 2.40 g (86%), mp 111—119 °C, $[\alpha]_D^{24.5}$ −45.2±0.9° (*c* 1.0, methanol). TLC (silica gel): a single component (sulfuric acid) in system D.

Found: C, 50.67; H, 6.87; N, 18.81%. Calcd for $C_{40}H_{63}N_{13}O_{13}\cdot H_2O$: C, 50.46; H, 6.88; N, 19.13%.

Z-Lys(Mhoc)-Arg(NO$_2$)-Arg(NO$_2$)-Pro-OH (XI). Compound X (2.15 g, 2.3 mmol) in methanol (7 ml) was saponified with sodium hydroxide (4.6 ml) at room temperature for 2 h followed by neutralization with M hydrochloric acid (4.6 ml) at 0 °C and concentration *in vacuo* to remove methanol. The resulting aqueous mixture was extracted three times with 10% 1-butanol in ethyl acetate. The organic extracts were combined, dried over magnesium sulfate and evaporated *in vacuo*. The crude product thus obtained was purified on a silica gel column (100g, Kieselgel 60, Merck) with chloroform–methanol–acetic acid systems (90 : 10 : 3, 400 ml; 85 : 15 : 3, 500 ml; 80 : 20 : 3, 600 ml) as solvent. The fractions were examined by TLC (silica gel, in system I) and those containing the desired compound as a single component were combined and evaporated *in vacuo* to give a residue which was solidified by treatment with ether; wt 1.72 g (80%), mp 137—142 °C, $[\alpha]_D^{21}$ −36.8±0.8° (*c* 1.0, methanol).

Found: C, 50.16; H, 6.79; N, 19.25%. Calcd for $C_{39}H_{61}N_{13}O_{13}\cdot H_2O$: C, 49.94; H, 6.77; N, 19.41%.

Z-Val-Lys(Mhoc)-OMe (XX). Compound III (2.17 g, 5 mmol) was hydrogenolyzed over palladium in 10% acetic acid in methanol for 2 h. The solvent was removed by evaporation *in vacuo* to give an oily residue which was treated with aqueous potassium carbonate at 0 °C in the presence of dichloromethane. The resulting free base of H-Lys(Mhoc)-OMe and Z-Val-OH (1.26 g, 5 mmol) were coupled with DCC (1.03 g, 5 mmol) in dichloromethane at 4 °C overnight to give XX; wt 2.31 g (87%), mp 65—67 °C, $[\alpha]_D^{25}$ −18.7±0.5° (*c* 1.0, methanol). TLC (silica gel): a single component (sulfuric acid) in system G.

Found: C, 63.23; H, 8.24; N, 8.14%. Calcd for $C_{28}H_{43}N_3O_7$: C, 63.02; H, 8.12; N, 7.87%.

Z-Val-Lys(Mhoc)-NHNH$_2$ (XXI). Compound XX (1.87 g, 3.5 mmol) was treated with hydrazine hydrate (1.7 ml) in ethanol (15 ml) at room temperature overnight. The product was reprecipitated from ethanol–ether to afford XXI; wt 1.46 g (78%), mp 147—149 °C, $[\alpha]_D^{25.5}$ −25.8±0.7° (*c* 1.0, acetic acid).

Found: C, 60.80; H, 8.11; N, 13.04%. Calcd for $C_{27}H_{43}N_5O_6$: C, 60.77; H, 8.12; N, 13.12%.

Z-Pro-Asn-Gly-OBu^t (XVIII). Compound XVIIa (4.93 g, 13 mmol) was hydrogenolyzed over palladium in methanol for 4 h to give H-Asn-Gly-OBu^t (free base) as an oil. This was then coupled with Z-Pro-OH (3.24 g, 13 mmol) by means of DCC (2.68 g, 13 mmol) in dichloromethane at 4 °C overnight. The product was repeatedly recrystallized from acetonitrile; wt 4.84 g (78%), mp 146—147.5 °C, $[\alpha]_D^{23}$ −64.6±1.0° (*c* 1.0, methanol). TLC (silica gel): a single component (sulfuric acid) in system G.

Found: C, 57.52; H, 6.73; N, 11.63%. Calcd for $C_{23}H_{32}N_4O_7$: C, 57.97; H, 6.77; N, 11.76%.

Z-Val-Tyr-Pro-Asn-Gly-OBu^t (XIXa). *a)* Via *Val-Tyr-Pro + Asn-Gly.* Compound XVIIa (0.38 g, 1 mmol) was hydrogenolyzed over palladium in methanol for 4 h to give H-Asn-Gly-OBu^t (free base) as an oil.

Compound XIV (0.57 g, 1 mmol) was treated with trifluoroacetic acid (5 ml) at room temperature for 60 min. The solvent was evaporated *in vacuo* and the residue was lyophilized from acetic acid. The resulting powder was dissolved in ethyl acetate and the solution was extracted with 5% sodium hydrogencarbonate three times. The aqueous solutions combined were acidified with hydrochloric acid followed by extraction with ethyl acetate. The combined extracts were dried over magnesium sulfate and evaporated *in vacuo* to give XV as a sirupy residue. This was then coupled with the above dipeptide ester by means of DCC (0.21 g, 1 mmol) in acetonitrile in the presence of 1-hydroxybenzotriazole (HOBt, 0.14 g, 1 mmol) at 4 °C overnight. The crystalline precipitates which had formed were filtered off and recrystallized from acetonitrile (20 ml) to afford XIXa in pure form; wt 0.50 g (66%), mp 152—155 °C, $[\alpha]_D^{22}$ −33.0±2.0° (*c* 0.4, DMF). TLC (silica gel): a single component (sulfuric acid) in system H.

Found: C, 58.79; H, 6.89; N, 10.92%. Calcd for $C_{37}H_{50}N_6O_{10}\cdot H_2O$: C, 58.72; H, 6.93; N, 11.10%.

b) Via *Val-Tyr + Pro-Asn-Gly.* Compound XVIII 2.38 g, 5 mmol) was hydrogenolyzed over palladium in methanol for 4 h to give H-Pro-Asn-Gly-OBu^t (free base) in a crystalline form. This was then coupled with Z-Val-Tyr-N_3 [derived from XIII (2.14 g, 5 mmol) by the treatment with nitrous acid in the usual manner in DMF–ethyl acetate at 4 °C overnight. Evaporation of the solvent *in vacuo* gave a residue which was crystallized from acetonitrile. Recrystallization from the same solvent gave the desired XIXa; wt 2.22 g (59%), mp 154—156 °C, $[\alpha]_D^{23}$ −34.2±1.5° (*c* 0.5, DMF).

Found: C, 58.58; H, 6.84; N, 10.91%.

Z-Gly-Ala-OBu^t (XVIIb). Z-Ala-OH (11.2 g, 50 mmol) was treated with 2-methylpropene (isobutene, 50 ml) in dichloromethane in the presence of sulfuric acid (1.5 ml)

at room temperature for 3 days to give Z-Ala-OBu^t as an oily residue (13.7 g). This was hydrogenolyzed over palladium in methanol for 7 h to yield H-Ala-OBu^t (free base) as an oil (6.97 g).

The alanine ester obtained above was coupled with Z-Gly-OH (9.41 g, 45 mmol) with DCC (9.33 g, 45 mmol) in dichloromethane at 4 °C overnight to give a crude preparation of XVIb (15.9 g). A 1.06-g portion was chromatographed on a column of silica gel (20 g, Kieselgel 60, Merck) with benzene-ethyl acetate (3 : 2) as solvent. The fractions were examined by TLC (silica gel, in the same solvent as that for the column) and those containing the desired compound as a single component were combined and evaporated *in vacuo*; wt 0.95 g (94%), $[\alpha]_D^{24.5}$ $-31.5\pm0.8°$ (*c* 0.9, methanol).

Found: C, 60.77; H, 7.33; N, 8.30%. Calcd for $C_{17}H_{24}N_2O_5$: C, 60.70; H, 7.19; N, 8.33%.

Z-Asn-Gly-Ala-OBu^t (XVIIb). Compound XVIb (6.57 g, 19.5 mmol) was hydrogenolyzed over palladium in methanol for 10 h to give H-Gly-Ala-OBu^t as an oil. This was then coupled with Z-Asn-ONp (7.55 g, 19.5 mmol) in DMF at 4 °C overnight. The product was crystallized from acetonitrile. Recrystallization from the same solvent yielded XVIIb; 6.63 g (74%), mp 159—160 °C, $[\alpha]_D^{23.5}$ $-20.4\pm0.6°$ (*c* 1.0, methanol). TLC (silica gel): a single component (sulfuric acid) in system E.

Found: C, 56.19; H, 6.78; N, 12.56%. Calcd for $C_{21}H_{30}N_4O_7$: C, 55.99; H, 6.71; N, 12.44%.

Z-Val-Tyr-Pro-Asn-Gly-Ala-OBu^t (XIXb). Compound XVIIb (1.80 g, 4 mmol) was hydrogenolyzed over palladium in methanol for 3 h to give H-Asn-Gly-Ala-OBu^t as an oily residue.

Compound XIV (2.27 g, 4 mmol) was treated with trifluoroacetic acid (20 ml) at room temperature for 60 min to give XV, which was isolated in the manner described above in the synthesis of XIXa. Compound XV was coupled with the above tripeptide ester by means of DCC (0.82 g, 4 mmol) in acetonitrile in the presence of HOBt (0.54 g, 4 mmol) at 4 °C overnight. The desired XIXb was isolated in the same manner as described above for XIXa; wt 1.93 g (58%), mp (70) 140—145 °C, $[\alpha]_D^{23.5}$ $-57.2\pm0.8°$ (*c* 1.0, methanol). TLC (silica gel): a single component (sulfuric acid) in system H.

Found: C, 57.82; H, 6.98; N, 12.18%. Calcd for $C_{40}H_{55}N_7O_{11}\cdot H_2O$: C, 58.03; H, 6.94; N, 11.84%.

Z-Val-Lys(Mhoc)-Val-Tyr-Pro-Asn-Gly-OBu^t (XXIIa). Compound XIXa (2.22 g, 3 mmol) was hydrogenolyzed over palladium in acetic acid (20 ml) for 4 h to give H-Val-Tyr-Pro-Asn-Gly-OBu^t acetate as amorphous solid (1.93 g).

To a DMF solution of XXI (1.04 g, 1.95 mmol) previously chilled in an ice-bath were added ice-cold M hydrochloric acid (5 ml) and 2 M sodium nitrite (1.07 ml) and the mixture was shaken at 0 °C for 4 min. The resulting azide was extracted with ethyl acetate and the combined extracts were washed twice with M sodium hydrogencarbonate and dried over magnesium sulfate at 0 °C. This was combined with a solution of the above pentapeptide ester (0.87 g, 1.3 mmol) and triethylamine (0.28 ml, 2 mmol) in DMF and the mixture was kept at 4 °C for 2 days. The crude product was crystallized and recrystallized from methanol-ethyl acetate to afford the pure XXIIa; wt 1.21 g (84%), mp 152—155 °C, $[\alpha]_D^{25}$ $-66.9\pm2.0°$ (*c* 0.5, methanol). TLC (silica gel): a single component (ninhydrin, after preheating at 150 °C) in system H.

Found: C, 60.54; H, 7.72; N, 11.26%. Calcd for $C_{56}H_{83}N_9O_{14}$: C, 60.80; H, 7.56; N, 11.40%.

Z-Val-Lys(Mhoc)-Val-Tyr-Pro-Asn-Gly-OH (XXIII). A 0.81-g portion (1.3 mmol) of H-Val-Tyr-Pro-Asn-Gly-OBu^t acetate obtained above was treated with trifluoroacetic acid at room temperature for 30 min to give the trifluoroacetic acid salt of H-Val-Tyr-Pro-Asn-Gly-OH as amorphous solid (0.88 g).

This pentapeptide was then coupled with Z-Val-Lys-(Mhoc)-N_3 [derived from XXI (0.88 g, 1.65 mmol) in the same manner as described above] in DMF in the presence of triethylamine (0.23 ml, 1.65 mmol) at 4 °C overnight. The crude product was purified on a silica gel column (30 g, Kieselgel 60, Merck) with chloroform-methanol-acetic acid (8 : 2 : 1) as solvent. The fractions were examined by TLC (silica gel, in the same solvent as that for the column) and those containing the desired compound as a single component were combined and evaporated *in vacuo*. The resulting residue was crystallized from methanol-ether; wt 0.90 g (65%), mp 173—177 °C decomp., $[\alpha]_D^{23.5}$ $-33.5\pm1.5°$ (*c* 0.5, DMF). Amino acid ratios in acid hydrolysate (theoretical values are given in parentheses): Lys 0.97 (1), NH_3 1.22 (1), Asp 1.07 (1), Pro 1.00 (1), Gly 1.07 (1), Val 2.00 (2), Tyr 0.97 (1).

Found: C, 57.94; H, 7.31; N, 11.67%. Calcd for $C_{52}H_{75}N_9O_{14}\cdot 3/2\,H_2O$: C, 57.98; H, 7.30; N, 11.70%.

Z-Val-Lys(Mhoc)-Val-Tyr-Pro-Asn-Gly-Ala-OBu^t (XXIIb). Compound XIXb (1.62 g, 2 mmol) was hydrogenolyzed over palladium in methanol for 3.5 h to give the N^α-free hexapeptide ester as a sirupy residue. This was then coupled with Z-Val-Lys(Mhoc)-N_3 [derived from XXI (1.63 g, 3 mmol) in the usual manner as described above] in DMF at 4 °C overnight. The crude product was crystallized and recrystallized from methanol-ethyl acetate to give the pure XXIIb; wt. 2.02 g (86%), mp 214—217 °C decomp., $[\alpha]_D^{24}$ $-25.7\pm0.5°$ (*c* 1.0, DMF). TLC (silica gel): a single component (ninhydrin, after preheating at 150 °C) in system H.

Found: C, 59.89; H, 7.50; N, 11.87%. Calcd for $C_{59}H_{88}N_{10}O_{15}$: C, 60.19; H, 7.53; N, 11.90%.

H-Val-Lys-Val-Tyr-Pro-Asn-Gly-Ala-OH Acetate (XXIV). Compound XXIIb (0.15 g) was hydrogenolyzed over palladium in acetic acid for 2.5 h. The resulting N^α-free peptide was then treated with trifluoroacetic acid (2 ml) in the presence of anisole (0.1 ml) and 2-mercaptoethanol (0.1 ml) at room temperature for 30 min. The precipitates which formed upon addition of ether were filtered off, thoroughly washed with ether and dried *in vacuo*. This was dissolved in water (10 ml) and the solution was passed through a column (0.9 × 10 cm) of Amberlite CG-400 (acetate) with portions of water. The aqueous solutions were combined, concentrated *in vacuo* at a bath temperature of 50 °C and lyophilized to give XXIV; wt 0.10 g (86%), $[\alpha]_D^{26}$ $-74.3\pm2.3°$ (*c* 0.5, 0.1 M hydrochloric acid). TLC (cellulose): a single component (ninhydrin) in system J. Amino acid ratios in acid hydrolysate: Lys 1.11 (1), NH_3 1.14 (1), Asp 1.02 (1), Pro 0.99 (1), Gly 1.07 (1), Ala 1.05 (1), Val 2.00 (2), Tyr 0.95 (1).

Z-Lys(Mhoc)-Arg(NO_2)-Arg(NO_2)-Pro-Val-Lys(Mhoc)-Val-Tyr-Pro-Asn-Gly-OBu^t (XXVa). Compound XXIIa (1.11 g, 1 mmol) was hydrogenolyzed over palladium in acetic acid (10 ml) for 3 h to give the acetic acid salt of H-Val-Lys(Mhoc)-Val-Tyr-Pro-Asn-Gly-OBu^t as fluffy powder (1.15 g). A half portion of this material was dissolved in a mixture of 1-butanol (8 ml) and ethyl acetate (16 ml) and the solution was shaken with 50% potassium carbonate (5 ml) at 0 °C. The organic phase was dried over magnesium sulfate followed by evaporation *in vacuo* to give the free base which was crystallized from methanol-ether; wt 0.46 g, $[\alpha]_D^{21}$ $-36.5\pm1.5°$ (*c* 0.5, DMF).

Compound XI (0.41 g, 0.45 mmol) and the heptapeptide

ester obtained above (0.44 g, 0.45 mmol) were coupled with DCC (0.19 g, 0.9 mmol) in DMF (9 ml) in the presence of HOBt (0.12 g, 0.9 mmol) at 4 °C overnight. The crude product was submitted to chromatography on a silica gel column (100 g, Kieselgel 60, Merck) with chloroform–methanol systems (95 : 5, 500 ml; 90 : 10, 200 ml; 85 : 15, 1200 ml) as solvent. The fractions were examined by TLC (silica gel, in system D) and those containing XXVa as a single component were combined and evaporated *in vacuo* to give a residue which was precipitated from methanol–ether; wt 0.74 g (87%), mp 150—155 °C, $[\alpha]_D^{21.5}$ −78.5±2.3° (*c* 0.5, methanol).

Found: C, 55.62; H, 7.06; N, 16.35%. Calcd for $C_{87}H_{136}N_{22}O_{24}$: C, 55.75; H, 7.31; N, 16.44%.

H–Lys(Mhoc)–Arg–Arg–Pro–Val–Lys(Mhoc)–Val–Tyr–Pro–Asn–Gly–OBu^t Acetate (XXVIa). Compound XXVa (0.94 g) was hydrogenolyzed over palladium in acetic acid (15 ml) for 40 h to give XXVIa; wt 1.09 g $\lambda_{max}^{0.1M\ HCl}$ 275 nm ($E_{1cm}^{1\%}$ 6.8). TLC (cellulose): almost homogeneous in system J.

H–Lys–Arg–Arg–Pro–Val–Lys–Val–Tyr–Pro–Asn–Gly–OH Acetate (XXVIIa). Compound XXVIa (0.33 g) was treated with trifluoroacetic acid (9 ml) in the presence of anisole (0.1 ml) and 2-mercaptoethanol (0.1 ml) at room temperature for 30 min. An aqueous solution of the product was treated with Amberlite CG-400 (acetate) and lyophilized (0.23 g).

A 0.1-g portion of this product was submitted to a column (1.7×21 cm) of carboxymethyl cellulose (CM-52, Whatman) using an ammonium acetate buffer (pH 6, 1500 ml) with a linear concentration gradient of 0—0.6 M. Fractions (7 ml/tube) were collected and their absorption at 275 nm was measured. The fractions corresponding to a major peak (tubes 110—133) were pooled, evaporated *in vacuo* and lyophilized to give XXVIIa as fluffy powder; wt 82 mg, $[\alpha]_D^{23}$ −85.7±3.0° (*c* 0.5, 0.1 M hydrochloric acid). TLC (cellulose): a single component (ninhydrin) in system K. Amino acid ratios in acid hydrolysate: Lys 1.99 (2), NH_3 1.13 (1), Arg 1.92 (2), Asp 1.03 (1), Pro 1.90 (2), Gly 1.00 (1), Val 2.08 (2), Tyr 0.99 (1).

Z–Lys(Mhoc)–Arg(NO_2)–Arg(NO_2)–Pro–Val–Lys(Mhoc)–Val–Tyr–Pro–Asn–Gly–Ala–OBu^t (XXVb). Compound XXIIb (0.47 g, 0.4 mmol) was hydrogenolyzed over palladium in acetic acid for 4 h to give the acetic acid salt of N^{α}-free octapeptide ester. This was dissolved in a mixture of 1-butanol (5 ml) and ethyl acetate (5 ml) and the solution was shaken with 50% potassium carbonate (5 ml) at 0 °C. The organic phase was dried and evaporated *in vacuo* to give the crystalline free base (0.42 g).

Compound XI (0.37 g, 0.4 mmol) and the octapeptide ester obtained above (0.42 g) were coupled with DCC (0.17 g, 0.8 mmol) in DMF (4 ml) in the presence of HOBt (0.11 g, 0.8 mmol) at 4 °C for 2 days. The crude product (1.03 g) was purified on a silica gel column in the same manner as described above for XXVa; wt 0.50 g (64%), mp 150—156 °C, $[\alpha]_D^{26}$ −73.4±2.3° (*c* 0.5, methanol).

Found: C, 54.70; H, 7.31; N, 15.94%. Calcd for $C_{90}H_{141}N_{23}O_{25}\cdot 2H_2O$: C, 54.56; H, 7.38; N, 16.26%.

H–Lys(Mhoc)–Arg–Arg–Pro–Val–Lys(Mhoc)–Val–Tyr–Pro–Asn–Gly–Ala–OBu^t Acetate (XXVIb). Compound XXVb (0.39 g) was hydrogenolyzed over palladium in acetic acid (8 ml) for 21 h. The catalyst was filtered off and the filtrate was lyophilized; wt 0.51 g, $\lambda_{max}^{0.1M\ HCl}$ 275 nm ($E_{1cm}^{1\%}$ 5.0). TLC (cellulose): almost homogeneous in system J.

H–Lys–Arg–Arg–Pro–Val–Lys–Val–Tyr–Pro–Asn–Gly–Ala–OH Acetate (XXVIIb). Compound XXVIb (0.13 g) was deprotected with trifluoroacetic acid (3 ml) in the presence of anisole (0.1 ml) and 2-mercaptoethanol (0.1 ml) at room temperature for 30 min. The product was treated with Amberlite CG-400 (acetate) in the usual manner to give the crude XXVIIb. This was then purified on a carboxymethyl cellulose column in the same manner as described above for XXVIIa; wt. 81 mg, $[\alpha]_D^{23}$ −86.9±2.5° (*c* 0.5, 0.1 M hydrochloric acid). TLC (cellulose): a single component (ninhydrin) in system L. Amino acid ratios in acid hydrolysate: Lys 1.75 (2), NH_3 0.91 (1), Arg 2.04 (2), Asp 1.06 (1), Pro 1.05 (1), Gly 1.05 (1), Ala 1.05 (1), Val 2.00 (2), Tyr 0.88 (1).

Z–Lys(Mhoc)–Pro–Val–Gly–Lys(Mhoc)–Lys(Mhoc)–Arg–Arg–Pro–Val–Lys(Mhoc)–Val–Tyr–Pro–Asn–Gly–OBu^t (XXVIIIa). A solution of VII (0.29 g, 0.3 mmol) in 90% aqueous tetrahydrofuran (5 ml) was chilled in an ice-bath and to this were added ice-cold M hydrochloric acid (0.75 ml) and ice-cold 2 M sodium nitrite (0.17 ml) successively. The mixture was stirred at 0 °C for 5 min, after which triethylamine (0.27 ml, 1.9 mmol) was added. The azide solution thus obtained was combined with a solution of XXVIa (0.28 g, 0.15 mmol) in 95% aqueous DMF (8 ml) and the mixture was stirred at 4 °C overnight. The product (0.51 g) was submitted to chromatography on a silica gel column (50 g, Kieselgel 60, Merck) with chloroform–methanol systems (9 : 1, 300 ml; 8 : 2, 400 ml; 7 : 3, 400 ml) as solvent. The fractions were examined by TLC (silica gel, in system J) and those containing the desired hexadecapeptide as a single component were pooled and evaporated *in vacuo* to give a residue which was precipitated from methanol–ether; wt 0.25 g (64%), mp 170—175 °C decomp., $[\alpha]_D^{23}$ −65.0±2.0° (*c* 0.5, methanol). Amino acid ratios in acid hydrolysate: Lys 3.97 (4), NH_3 1.10 (1), Arg 2.00 (2), Asp 1.12 (1), Pro 3.25 (3), Gly 2.09 (2), Val 3.00 (3), Tyr 1.01 (1).

A sample was reprecipitated from methanol–water and lyophilized from acetic acid for elemental analysis.

Found: C, 54.45; H, 7.45; N, 13.75%. Calcd for $C_{127}H_{205}N_{27}O_{29}\cdot 2CH_3COOH\cdot 10H_2O$: C, 54.74; H, 8.17; N, 13.16%.

Z–Lys(Mhoc)–Pro–Val–Gly–Lys(Mhoc)–Lys(Mhoc)–Arg–Arg–Pro–Val–Lys(Mhoc)–Val–Tyr–Pro–Asn–Gly–Ala–OBu^t (XXVIIIb). Compound XXVIb (0.22 g, 0.1 mmol) and the azide derived from VII (0.19 g, 0.2 mmol) in the manner as described above were coupled in aqueous tetrahydrofuran–DMF in the presence of triethylamine (0.13 ml, 0.9 mmol) at 4 °C overnight. The crude product was purified on a silica gel column in the same manner as described above for XXVIIIa; wt 0.14 g (52%), $[\alpha]_D^{24}$ −64.0±2.0° (*c* 0.5, methanol). TLC (silica gel): almost homogeneous (ninhydrin, after preheating at 150 °C) in system J. Amino acid ratios in acid hydrolysate: Lys 3.72 (4), NH_3 1.17 (1), Arg 1.98 (2), Asp 1.03 (1), Pro 2.98 (3), Gly 2.10 (2), Ala 1.11 (1), Val 3.00 (3), Tyr 0.93 (1).

A sample for elemental analysis was reprecipitated from methanol–water and lyophilized from acetic acid.

Found: C, 55.02; H, 7.99; N, 13.80%. Calcd for $C_{130}H_{210}N_{28}O_{30}\cdot 2CH_3COOH\cdot 8H_2O$: C, 55.32; H, 8.11; N, 13.48%.

H–Ser–Tyr–Ser–Met–Glu–His–Phe–Arg–Trp–Gly–Lys–Pro–Val–Gly–Lys–Lys–Arg–Arg–Pro–Val–Lys–Val–Tyr–Pro–Asn–Gly–OH Acetate, ACTH(1—26)–OH (I). Compound XXVIIIa (0.14 g, 0.05 mmol) was hydrogenolyzed over palladium in methanol containing acetic acid (0.5 ml) for 5 h. Removal of the solvent by evaporation *in vacuo* followed by lyophilization from acetic acid gave the N^{α}-free hexadecapeptide derivative (0.13 g).

To a solution of Boc–Ser–Tyr–Ser–Met–Glu(OBu^t)–His–Phe–Arg–Trp–Gly–OH (0.11 g, 0.075 mmol)[22] in DMF (2 ml) previously chilled in an ice-bath was added M hydro-

chloric acid (0.15 ml) and the solution was introduced into ice-cold ethyl acetate–ether (1 : 1, 50 ml). The resulting precipitates of the decapeptide hydrochloride were dissolved in DMF (3 ml) together with *N*-hydroxysuccinimide (HOSu, 0.035 g, 0.3 mmol) and to this was added DCC (0.062 g, 0.3 mmol) at 0 °C. The mixture was kept at 4 °C overnight, after which it was introduced into ethyl acetate–ether (1 : 1, 50 ml) to give the decapeptide active ester hydrochloride as amorphous precipitates (0.12 g). The active ester thus obtained was added to a solution of the N^{α}-free hexadecapeptide obtained above and triethylamine (0.07 ml) in DMF (3 ml), and the mixture was kept at room temperature for 2 days. The product was isolated as precipitates which formed when the reaction mixture was introduced into ethyl acetate (60 ml). The crude protected hexacosapeptide thus obtained (0.24 g) was mixed with anisole (0.1 ml) and 1,2-ethanedithiol (0.1 ml) and chilled in an ice-bath. To this was added trifluoroacetic acid (5 ml) and the mixture was kept at 0 °C for 60 min. The precipitates which formed upon addition of ether were filtered off, washed with ether and dried *in vacuo*. This was then dissolved in water and the solution was passed through a column (1.1×20 cm) of Amberlite CG-400 (acetate form) with additional portions of water. The aqueous solutions were combined and lyophilized to give the deprotected hexacosapeptide (0.24 g).

The crude peptide obtained above was submitted to partition chromatography on a column (2.0×75 cm) of Sephadex G-25 (medium) with 1-butanol–acetic acid–pyridine–water (12 : 3 : 4 : 6) as solvent and 5-ml fractions were collected. The tubes (no. 25—50) containing the desired peptide as a major component, as examined by TLC (cellulose, in system L) with the ninhydrin and Ehrlich reagents as reagents for locating peptide spots, were combined and evaporated *in vacuo* at a bath temperature of 45 °C and the residue was lyophilized (0.096 g). This was then chromatographed on a column (1.7×20 cm) of carboxymethyl cellulose (CM-52, Whatman) using an ammonium acetate buffer (pH 6.0, 2000 ml) with a linear concentration gradient of 0—0.6 M. Ten-ml fractions were collected and their absorption at 280 nm was measured. The fractions corresponding to a main peak (tubes 134—159) were combined, evaporated and lyophilized (0.051 g). For final purification this was submitted to gel filtration on a column (2.0×75 cm) of Sephadex G-25 (medium) with 0.1 M acetic acid as solvent. Five-ml fractions were collected and those corresponding to a single peak (tubes 20—35), as monitored by absorption at 280 nm, were combined, lyophilized and dried over sodium hydroxide pellets and phosphorus pentoxide *in vacuo* to afford the pure hexacosapeptide (I) as colorless fluffy powder; wt 0.048 g (26%), $[\alpha]_D^{25}$ −87.6±2.5° (*c* 0.5, 0.1 M acetic acid). $\lambda_{max}^{0.1M\ HCl}$ 276.5 nm ($E_{1cm}^{1\%}$ 20.5), $\lambda_{shoulder}^{0.1M\ HCl}$ 288 nm ($E_{1cm}^{1\%}$ 13.7); $\lambda_{max}^{0.1M\ NaOH}$ 283 nm ($E_{1cm}^{1\%}$ 22.9), 289 nm ($E_{1cm}^{1\%}$ 23.5). TLC (cellulose): a single component (ninhydrin and Ehrlich reagents) in system L. Amino acid ratios in acid hydrolysate: Lys 3.80 (4), His 1.00 (1), Arg 3.08 (3), Asp 1.00 (1), Ser 1.80 (2), Glu 1.10 (1), Pro 3.02 (3), Gly 3.05 (3), Val 3.15 (3), Met 1.00 (1), Tyr 2.05 (2), Phe 1.02 (1). The Tyr/Trp ratio in intact I was 1.99 as determined spectrophotometrically.[23]

H–Ser–Tyr–Ser–Met–Glu–His–Phe–Arg–Trp–Gly–Lys–Pro–Val–Gly–Lys–Lys–Arg–Arg–Pro–Val–Lys–Val–Tyr–Pro–Asn–Gly–Ala–OH Acetate, ACTH(1—27)-OH (II). Compound XXVIIIb (0.15 g, 0.05 mmol) was hydrogenolyzed over palladium in methanol containing acetic acid (0.5 ml) for 3 h to give the N^{α}-free heptadecapeptide derivative (0.13 g). This was allowed to react with the decapeptide *N*-hydroxysuccinimide ester [prepared from Boc–Ser–Tyr–Ser–Met–Glu(OBu^t)–His–Phe–Arg–Trp–Gly–OH (0.11 g, 0.075 mmol)[22] in exactly the same manner as described above] in DMF (3 ml) in the presence of triethylamine (0.07 ml) at room temperature for 2 days. The resulting protected peptide (0.24 g) was treated with trifluoroacetic acid (5 ml) at 0 °C for 60 min in the presence of anisole (0.1 ml) and 1,2-ethanedithiol (0.1 ml). The product was then treated with Amberlite CG-400 (acetate form) to give a crude preparation of II (0.23 g).

The crude peptide obtained above was purified by partition chromatography on a column of Sephadex G-25 and by carboxymethyl cellulose column chromatography in the same manner as described above for I. The resulting material (0.054 g) was then submitted to gel filtration on a Sephadex G-25 column with 0.1 M acetic acid as solvent to give the pure heptacosapeptide (II); wt 0.050 g (27%), $[\alpha]_D^{25}$ −86.6± 2.3° (*c* 0.5, 0.1 M acetic acid). $\lambda_{max}^{0.1M\ HCl}$ 276.5 nm ($E_{1cm}^{1\%}$ 21.5), $\lambda_{shoulder}^{0.1M\ HCl}$ 288 nm ($E_{1cm}^{1\%}$ 14.5); $\lambda_{max}^{0.1M\ NaOH}$ 283 nm ($E_{1cm}^{1\%}$ 23.1), 289 nm ($E_{1cm}^{1\%}$ 23.6). TLC (cellulose): a single component (ninhydrin and Ehrlich reagents) in system L. Amino acid ratios in acid hydrolysate: Lys 4.00 (4), His 1.00 (1), Arg 3.10 (3), Asp 1.00 (1), Ser 1.85 (2), Glu 1.08 (1), Pro 3.08 (3), Gly 3.10 (3), Ala 1.08 (1), Val 3.05 (3), Met 0.98 (1), Tyr 1.93 (2), Phe 0.98 (1). The Tyr/Trp ratio in intact II was 1.98 as determined spectrophotometrically.[23]

The authors wish to thank Miss Yuriko Kawana for able technical assistance.

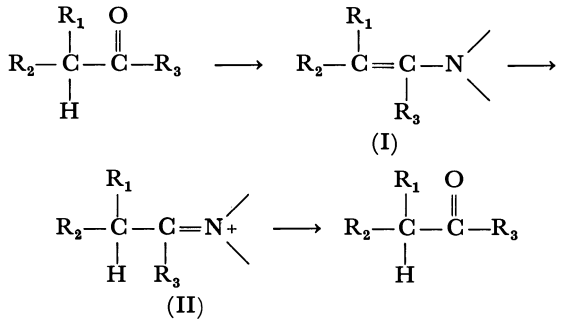
(Received July 6, 1976)

The degree of the optical activations of racemic α-substituted carbonyl compounds *via* the formation of optically active immonium salts and the subsequent hydrolysis were largely affected by acids used for the hydrolysis of the enamines. The ratio of the diastereomeric immonium salts depends on the temperature. There is a relationship between the configuration of the optically activated carbonyl compounds and those of amines used. These suggest that the optical activation is due to the asymmetric transformation.

Enamines are known to be very useful starting materials for various organic syntheses.[1] Asymmetric alkylation and halogenation were reported by Yamada *et al.*[2] Optical activation of racemic α-substituted carbonyl compounds *via* enamine has been studied in our laboratory. Formation of an enamine (I) causes deprotonation from the α-carbon of the racemic α-substituted carbonyl compounds, and formation of the immonium salt (II) causes protonation to the carbon, which is the first step of hydrolysis of the enamine.[3] In an asymmetrical circumstance, it is possible that an asymmetric protonation to the enamine takes place at the step of formation of the salt. On hydrolysis of the salt, the optically active carbonyl compound can be recovered.



In our previous paper, optical activation of racemic α-substituted carbonyl compounds were reported.[4,5] The hydrolysis of the immonium salts consisting of the optically active amine enamine of the racemic α-substituted carbonyl compounds and achiral acid gave the optically active compounds. This paper deals with the mechanism of this optical activation.

Experimental

Optical rotations were determined with a JASCO Digital Automatic Polarimeter Model DIP 181. Gas chromatographic analyses were carried out on a 2 m column of 20% Carbowax 20 M on Cromosorb W with a Hitachi Gas Chromatograph, Model K 53. Nuclear magnetic resonance spectra were obtained with a JNM-PS-100 Spectrometer with tetramethylsilane as an internal standard.

S(+)-2-Methylpiperidine. This was obtained by the procedure described by Kostyanovsky *et al.*[6]

R(−)-2-Methylpyrrolidine. This was prepared according to the method reported in our previous paper.[5]

S(−)-Benzyloxycarbonylcysteic Acid Ethyl Ester. This was prepared by treatment of L-cysteic acid with carbobenzoxy chloride. It was purified *via* its ethyl ester sodium salt. Using 29 g (0.155 mol) of L-cysteic acid, 32.2 g (58.9%) of *S*(−)-benzyloxycarbonylcysteic acid ethyl ester sodium salt, as white needle, was obtained: mp 164—172 °C; $[\alpha]_D^{23}$ −18.4° (*c* 0.74 H_2O); IR (Nujol) 3350 cm^{-1} (ν_{NH}), 1739 cm^{-1} (ν_{CO}), 1690 cm^{-1} (ν_{CO}), 1528 cm^{-1} (δ_{NH}), 1258 cm^{-1} (ν_{CN}); NMR ($CDCl_3$) 1.16 (CH_3, t, *J* 7.2 Hz), 2.96 (S-CH_2, d, *J* 6.0 Hz), 4.13 (COOCH_2, q, *J* 7.2 Hz), 4.40 (CH-N, q), 5.04 (NH, broad), 5.11 (O-CH_2, s), 7.43 (phenyl, 5H). *S*(−)-Benzyloxycarbonylcysteic acid ethyl ester was obtained by treatment of the salt with cation exchange resin (Dowex 50 W). NMR spectrum showed that the peak at 2.96 ppm was shifted to lower field, 3.60 ppm.

Enamines. The preparation of enamines of α-phenylpropionaldehyde and 2-methylcyclohexanone were reported in our previous paper.[4,5] Enamine from piperidine and 2-methylbutanal: bp 36—38 °C (0.7 Torr); IR (film) 1655, 1665 cm^{-1} ($\nu_{C=C}$); NMR ($CDCl_3$) mixture of two geometrical isomers (8 : 3 at room temperature), major isomer, 1.00 (CH_3, t, *J* 7.7 Hz), 1.71 (CH_3, s), 1.98 (CH_2, q, *J* 7.7 Hz), 5.43 (C=CH, s), minor isomer, 1.63 (CH_3, s), 2.18 (CH_2, q, 7.9 Hz), 5.35 (C=CH, s). Enamine from 2-methylpiperidine 2-methylbutanal: Yield 89%; bp 45—46.5 °C (2.2 Torr); IR (film) 1670, 1650 cm^{-1} ($\nu_{C=C}$); NMR ($CDCl_3$) mixture of two geometrical isomers (5 : 2 at room temperature), major isomer 1.73 (CH_3, s), 5.34 (C=CH, s), minor isomer 1.64 (CH_3, s), 5.23 (C=CH, s); $[\alpha]_D^{23}$ −6.79° (neat). Enamine from *S*(+)-2-methylpiperidine and 2-(2-cyanoethyl)cyclohexanone was not isolated.

Hydrolysis. Acid (0.01 mol) was added to a benzene solution (20 ml) of the enamine (0.01 mol) and the mixture was stirred. To the solution in an ice bath, water (20 ml) was added dropwise with vigorous stirring. The reaction was continued until the completion of the hydrolysis which was confirmed gas chromatographically. The benzene layer was separated, washed with water until the amine and the acid were removed completely, and dried over anhydrous Na_2SO_4. In the case of α-phenylpropionaldehyde, it was purified by column chromatography on silica gel (benzene : hexane 1 : 1). The purity was checked by TLC on silica gel (benzene : hexane 1 : 1, R_f 0.38). Optical rotations of carbonyl compounds were measured in benzene. The recoveries were obtained with a gas chromatograph.

Optical Rotation of the α-Phenylpropionaldehyde Recovered at Regular Time Interval. To a benzene solution (50 ml) of the optically active enamine from 2-methylpiperidine and α-phenylpropionaldehyde (2.15 g, 0.01 mol) was added 1 M hydrochloric acid (15 ml, 0.015 mol) under vigorous stirring. After ten minutes, benzene layer was separated, and additional aliquot (50 ml) of benzene was immediately applied to the aqueous layer, and reaction was continued.

TABLE 1. OPTICAL ACTIVATION OF SOME CARBONYL COMPOUNDS *via* OPTICALLY ACTIVE ENAMINES

Amine component	Carbonyl component	Acid component	Recovered carbonyl compound $[\alpha]_D^{23}$ in benzene		ee	Recovery (%)	Lit.
S(+)-2-Methyl-piperidine	α-phenylpropion aldehyde	HCl	−80.8° (*c* 25.0)			91	5
		H_2SO_4	−65.2° (*c* 0.99)			67	
		p-toluene-sulfonic acid	−60.4° (*c* 1.88)			81	
		CH_3COOH	−54.5° (*c* 1.21)			62	
	2-methyl-cyclohexanone	HCl	−2.87° (*c* 42.2)	*R*	20.2[9]	77	5
		CH_3COOH	−0.92° (*c* 30.0)	*R*	6.5	61	
	2-methylbutanal	HCl	−1.82° (*c* 18.9)	*R*	5.7[10]	73	
		CH_3COOH	−0.72° (*c* 25.9)	*R*	2.2	58	
	2-(2-cyanoethyl)-cyclohexanone	HCl	−0.858° (neat)	*R*		84	
		CH_3COOH	−0.099° (neat)	*R*		78	
R(−)-2-Methyl-pyrrolidine	α-phenylpropion-aldehyde	HCl	+51·6° (*c* 8.11)			79	5
	2-methyl-cyclohexanone	HCl	+0.881° (*c* 15.5)	*S*	6.2	60	5

The same treatment was repeated four times at ten minutes intervals. Finally, the aqueous layer was refluxed, and extracted with benzene. Every benzene extract was washed with water and dried, and the optical rotation and the concentration were measured.

Results and Discussion

Optical Activation of Racemic Carbonyl Compounds via *Optically Active Immonium Salts.* Hydrolysis of immonium salts consisting of optically active amine enamines of racemic α-substituted carbonyl compounds and achiral acids gave the corresponding optically active carbonyl compounds. The results are shown in Table 1.

Strong acids were well suited for the introduction of optical activity. This tendency was observed with both six and five membered ring amines. It is known that strong acid components are preferable for the stability of immonium salts.[7] The result suggests that the stability of an immonium salt is an important factor for the introduction of optical activity. This is also supported in the case of the immonium salts consisting of pyrrolidine or piperidine enamine and chiral acids.

Table 2 shows that the degree of the optical activation and direction of the optical rotation were affected by both the structure and the strength of acidity of chiral acids. *S*(+)-Cysteic acid has an amino group, a carboxyl group and a sulfonyl group. *S*(−)-*N*-Benzyloxycarbonylcysteic acid ethyl ester has neither a free amino group nor a free carboxyl group, but a sulfonyl group. *S*(−)-*N*-Benzyloxycarbonylalanine has a carboxyl group. The direction of the optical rotation of the recovered carbonyl compounds in the case of *S*(−)-*N*-benzyloxycarbonylcysteic acid ethyl ester was opposite to that in the case of *S*(+)-cysteic acid or *S*(−)-*N*-benzyloxycarbonylalanine. This means that *S*(+)-cysteic acid has the inner salt structure, ^-O_3S–CH_2–$\underset{\displaystyle NH_3^+}{\underset{|}{CH}}$–COOH, and its carboxyl group is used to form immonium salts. The degrees of the optical rotation in Table 2 suggest that sulfonic acid

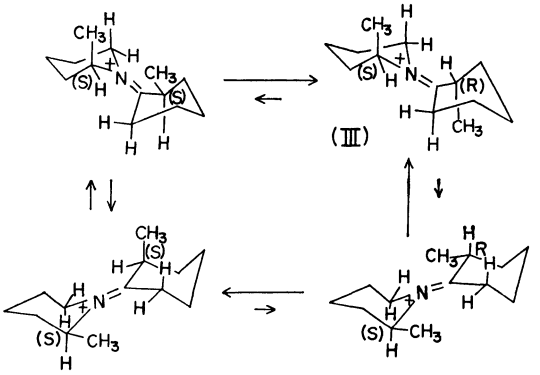


Fig. 1.

was superior to carboxylic acid, and *S*(+)-cysteic acid react with enamines as an carboxylic acid. One of the reasons of the low optical rotation of recovered α-phenylpropionaldehyde in the case of L-tartaric acid, D-camphoric acid and D-quinic acid[4] may be the weak acidity of these acids.

Table 1 also shows that carbonyl compounds with *R*-configuration was obtained by the use of *S*-amines as the amine components. In the case of 2-methylcyclohexanone, the result was interpreted by the stability of the immonium salt. As there are large interactions between the equatorial methyl group and the hydrogen on the α-methylene of the ring, the structure (III), in which two methyl groups occupies the axial positions, was most stable. When *S*-amine is used as the amine component, introduced asymmetric carbon into the enamine is an *R*-configuration. In the case of the asymmetric alkylation to cyclohexanone enamine, the same results were observed.[2]

Optical Rotation of the α-Phenylpropionaldehyde Recovered at Regular Time Intervals. Considering the mechanisms of the optical activation, there are (1) asymmetric synthesis, (2) asymmetric transformation, and (3) asymmetric destruction. It is known that the proton at the β-carbon of the enamine grouping is easily exchanged.[8] In our previous paper,[5] HCl salt of the enamine was hydrolyzed with rich D_2O

TABLE 2. OPTICAL ACTIVATION OF SOME CARBONYL COMPOUNDS FROM THE IMMONIUM SALTS CONSISTING OF CHIRAL ACIDS AS THE ACID COMPONENT

Amine component	Carbonyl component	Acid component	Recovered carbonyl compound			Lit.
			$[\alpha]_D^{23}$ in benzene		Recovery (%)	
Piperidine	α-Phenylpropion-aldehyde	D-10-Camphorsulfonic acid	+16.2° (c=3.67)		89.6	4
		S(+)-Cysteic acid	−1.06° (c=4.25)		82.0

(c) The same part of the spectrum, probe temperature 70 °C. (×4)

and deuterated α-phenylpropionaldehyde was recovered. The isotope labeling experiment suggests that this optical activation is not due to the asymmetric synthesis. To see whether this activation is due to asymmetric destruction or not, variations in optical activity of the recovered α-phenylpropionaldehyde during the enamine hydrolysis were followed at ten minute intervals. After the reaction for 40 min, to ascertain the completion of hydrolysis, concentrated hydrochloric acid was added to the residual water phase and the solution was refluxed. Gas chromatographically, no α-phenylpropionaldehyde could be detected in the benzene extract of the solution. Total recovery of the aldehyde was 87.3%. It seems that some of the aldehyde was lost when the benzene extract was washed with water. As shown in Table 3, the directions of the optical rotation of all fractions were the same. This result clearly shows that the optical activation was not due to asymmetric destruction.

Studies of the NMR Spectra. Dry HCl gas was

Table 3.

Reaction time (min)	$[\alpha]_D^{23}$	Recovery (%)
10	+10.7°	64.2
20	+10.5°	19.4
30	+14.5°	3.7
40	(+)	trace
Recovered from aqueous layer		0
Total recovery		87.3

bubbled slowly into a $CDCl_3$ solution of optically active 2-methylpiperidine enamine of α-phenylpropionaldehyde and a slightly yellow solution of the corresponding immonium salt was obtained. NMR spectrum of the solution shows that the immonium salt was a mixture of two diastereomeric isomers (Fig. 2(a).). An increase in temperature as high as 70 °C gradually changed the region of the methyl groups (B) at the asymmetric carbon atoms in NMR spectra from (b) to (c). The major methyl proton signal at 23 °C (1.69 ppm, J 7.5 Hz) was changed to the minor one at 70 °C (1.68 ppm, J 7.3 Hz). On the contrary, the minor methyl proton signal at 23 °C (1.66 ppm, J 7.5 Hz) was changed to the major one at 70 °C (1.65 ppm, J 7.3 Hz). This result suggests that the ratio of the two diastereomers was controlled thermodynamically. Thus the mechanism of the optical activation is considered to be an asymmetric, reversible protonation to the enamine and successive hydrolysis of the immonium salt. The spectra of the D_2SO_4 salt and CD_3COOD salt were also obtained. The former has many unassignable peaks. The latter shows that the formation of immonium salt was incomplete by the addition of an equimolar CD_3COOD to the enamine. These spectra may suggest that H_2SO_4 and CH_3COOH are not so good as HCl for the optical activation.

A Macrocyclic Enzyme Model System. An Electrostatic-Hydrophobic Double-Field Catalysis by a [20]Paracyclophane in the Deacylation of *p*-Nitrophenyl Hexadecanoate†

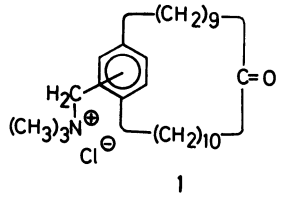
Yukito MURAKAMI,* Yasuhiro AOYAMA, Kazuyuki DOBASHI, and Masaaki KIDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 9, 1976)

The catalytic functions of 10-oxo[20]paracyclophanyl-22(23)-methyltrimethylammonium chloride (**1**) in the hydrolysis and aminolysis reactions of *p*-nitrophenyl hexadecanoate (PNPP) were investigated in 1% (v/v) methanol–1% (v/v) dioxane–water over the pH 9—10 region at 40.0 °C and μ=0.2 (NaCl) with the initial PNPP concentration of 1.00×10^{-5} M. The paracyclophane (0.88×10^{-5} M) accelerated the hydrolysis of PNPP by one order of magnitude at pH 9.7. The presence of either ethanolamine or glycine in the **1**-catalyzed deacylation of PNPP resulted in further rate enhancement. The rate enhancement was brought about by the aminolysis reaction of PNPP with the amines as confirmed by the product analysis. The greater reactivity of glycine relative to that of ethanolamine was attributed to the electrostatic interaction between the anionic carboxylate group of glycine and the cationic ammonium group of **1**. The novel electrostatic-hydrophobic double-field catalysis was discussed for the glycinolysis reaction.

[20]Paracyclophanes have been shown to function as host molecules in aqueous media for the incorporation of *p*-nitrophenyl carboxylates bearing a sufficiently long alkyl chain *via* hydrophobic interaction.[1-6] An efficient acyl transfer from the bound substrate to either oxime[1-5] or amino group[6] placed on the paracyclophane skeleton has been observed. In the absence of an effective nucleophile on the macrocycle, the bound substrate would be susceptible to an attack by any nucleophile present in the bulk phase. In such occasions, the reactivity of the bimolecular deacylation reaction would be controlled by the geometry and spatial orientation of a bound substrate against an attacking nucleophile as well as by the approaching mechanism played by the latter species. This state of affairs should be even more pronounced when the macrocycle carries a functional group which may interact with a nucleophile. In this study, we have investigated the hydrolysis and aminolysis of *p*-nitrophenyl hexadecanoate as catalyzed by a [20]-paracyclophan-10-one carrying a quaternary ammonium group on its benzene ring (**1**). The specific catalytic function of the ammonium group is to be characterized from the kinetic viewpoints.



1

Experimental

Materials. 10-Oxo[20]paracyclophanyl-22(23)-methyltrimethylammonium chloride (**1**) was prepared as described previously.[4] The crude product was purified by repeated high speed liquid chromatography using a Hitachi 635 liquid chromatograph equipped with a column of Hitachi gel 3019, methanol being used as an eluant. *p*-Nitrophenyl hexadecanoate was the product of E. Merck, Darmstadt, West Germany and used after inspection of its purity by elemental analysis. Glycine obtained from commercial source was recrystallized from water. Ethanolamine was distilled *in vacuo* immediately before use.

Kinetic Measurements. Rates of *p*-nitrophenoxide liberation were measured at 400 nm. Each run was initiated by adding 30 μl of 1.0×10^{-3} M *p*-nitrophenyl hexadecanoate in dioxane to 2.97 ml of a reaction medium which was preequilibrated at 40.0±0.1 °C in a thermostatted cell set in a Hitachi 124 recording spectrophotometer. The reaction medium was prepared by mixing 30 μl of a stock solution of **1** in methanol with 2.94 ml of an aqueous buffer solution of $Na_2B_4O_7$–Na_2CO_3, or otherwise either of glycine–sodium glycinate or ethanolamine–ethanolammonium chloride. The ionic strength was maintained constant at 0.2 with sodium chloride.

pH *and* pK_a *Measurements.* pH-Values of the buffer solutions were measured at 40.0±0.1 °C with a Beckman expandomatic SS-2 pH meter equipped with a Metrohm EA-125 combined electrode after calibration with a combination of appropriate standard buffers. The potentiometric titrations were carried out at 40.0±0.1 °C and μ=0.20 (NaCl) with sodium hydroxide to determine pK_a values of glycine and ethanolamine.

Analysis of Glycinolysis Product. A solution of *p*-nitrophenyl decanoate (100 mg) and **1** (1.53×10^{-3} mmol) in a mixture of glycine buffer (pH 9.7, 1000 ml containing 0.07 mol of glycine, 0.03 mol of sodium hydroxide, and 0.07 mol of sodium chloride) and dioxane (70 ml) was stirred at room temperature for 65 h. The reaction mixture was acidified (pH 2) with hydrochloric acid and then extracted with ether (100 ml×2) and chloroform (100 ml×3). The combined extracts were extracted with 5% aqueous sodium hydroxide. The aqueous extract was acidified and extracted with ether (100 ml×3). After drying over sodium sulfate, the ether extract was evaporated to give an oil (30 mg) which was subsequently chromatographed on a column (2.4×10 cm) of silica gel (Wako gel C-100) after esterification with excess diazomethane. *p*-Nitrophenol (15 mg) and methyl decanoate (small amount) showing a C=O stretching band (neat) at 1730 cm^{-1} were eluted with benzene and benzene–chloroform (1 : 1), respectively. Further elution with chloroform afforded glycinolysis product **2** (15 mg). IR (neat): 3320

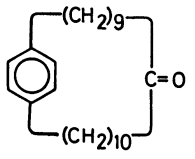
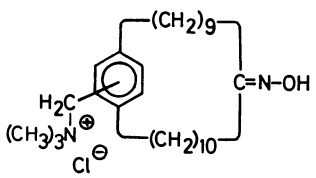
Results and Discussion

The hydrolysis of *p*-nitrophenyl hexadecanoate (PNPP) was accelerated by the ammonium salt (**1**) in reference to the spontaneous hydrolysis under the same conditions: initial PNPP concentration of 1.00×10^{-5} M, $\mu=0.2$ with NaCl, in 1%(v/v)methanol–1% (v/v)dioxane–water, at 40.0±0.1 °C. The observed rates are 1.3×10^{-4} and 0.14×10^{-4} s^{-1} for catalyzed and spontaneous reactions at pH 9.7, respectively. The rate enhancement is significant for the presence of a small amount of **1** (0.88×10^{-5} M). The catalytic effect of **1** must be developed by the quaternary ammonium group since [20]paracyclophan-10-one (**3**)



3



4

which lacks in a positive charge showed no acceleration effect in the PNPP hydrolysis. Two kinetically indistinguishable mechanisms can be cited for the catalytic function of **1**. The ammonium group concentrates anionic hydroxide ions around it as in cationic micelles.[7)] Alternatively, the ammonium group may serve as a super acid which neutralizes a negative charge developing at the carbonyl oxygen of bound PNPP in the transition state in a manner as predicted for the deacylation of PNPP catalyzed by 10-hydroxyimino [20] paracyclophanyl - 22 (23) - methyltrimethyl - ammonium chloride (**4**).[4)] There is a significant difference between these two mechanisms. The former involves the direct electrostatic interaction between the positive ammonium group of the catalyst and the hydroxide ion of nucleophilic nature prior to the rate-determining step while the latter does not. In order to examine this criterion, the kinetic behavior of glycine in the deacylation of PNPP was investigated in reference to that of ethanolamine which has a similar pK_a (amine) as glycine. Glycine is a nucleophile of significant choice since it contains a neutral amino nucleophile as well as an anionic carboxylate having a potentiality to interact electrostatically with the ammonium group of **1**.

A large excess of ethanolamine (0.05 M) in the absence of **1** gave out some 1.5-fold increase in the deacylation rate of PNPP at pH 9.70, whereas glycine hardly affected the reaction rate in the same concentration range. The **1**-catalyzed deacylation of PNPP, on the other hand, was enhanced with glycine (0.05 M) by a factor of 4 relative to the **1**-catalyzed alkaline hydrolysis without added glycine. Ethanolamine also showed a similar enhancement effect but to a lesser extent. The effect of pH variation in the pH range 8.8—10.4 at a constant amine concentration (0.05 M) and the effect of an amine concentration in the 0.01—0.1 M range at constant pH (9.70) on the **1**-catalyzed deacylation were investigated to go through a more critical assessment of the effects of amine bases. The observed first-order rate constants (k_{obsd}) for the deacylation of PNPP are summarized in Tables 1 and 2. The pH-rate and amine concentration-rate correla-

Table 2. Effects of concentration changes of glycine and ethanolamine on the *p*-nitrophenol release from PNPP as catalyzed by **1** at pH 9.70±0.02, μ=0.2 (NaCl), and 40.0±0.1 °C[a)]

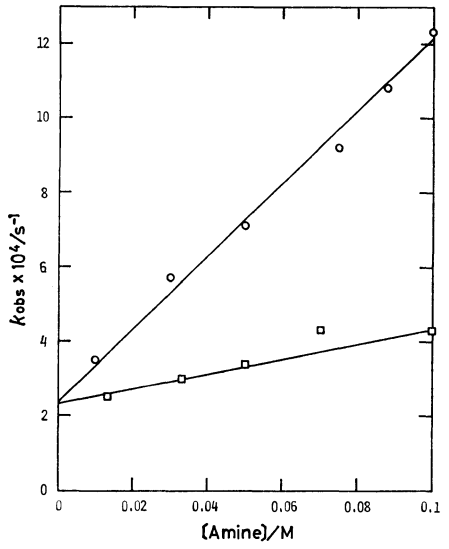

Fig. 2. Correlations between first-order rate constant for the *p*-nitrophenol release from PNPP as catalyzed by **1** (1.53×10^{-5} M) and concentrations of glycine (○) and ethanolamine (□) at pH 9.70±0.02, μ=0.2 (NaCl), and 40.0±0.1 °C.

tions are shown in Figs. 1 and 2, respectively. Aminolysis by the added amine may certainly be responsible for the rate enhancement. That the aminolysis was actually taking place was confirmed by the product analysis using *p*-nitrophenyl decanoate instead of hexadecanoate as a substrate; the decanoate ester in a glycine buffer (pH 9.7) containing a catalytic amount of **1** afforded the glycinolysis product. Judging from the nucleophilicities of glycine and hydroxide toward *p*-nitrophenyl acetate, second-order rate constants being respectively 155 and 890 $M^{-1}\,min^{-1}$ at 25 °C,[8)] the kinetic effect of glycine observed for the present system is surprisingly small. This is most likely ascribed to a steric factor pertaining to such a bulky substrate as PNPP and its complex with **1**.

At constant pH (9.70), the **1**-catalyzed deacylation rate (k_{obsd}) can be correlated linearly with the amine concentration (Fig. 2); $k_{obsd}=\kappa(OH)+k_{amine}[Amine]$ where $\kappa(OH)$[9)] represents the hydrolysis rate factor as a function of pH and k_{amine} the catalytic rate constant effected by the presence of glycine or ethanolamine. It is evident that the k_{amine} value for glycine is 5 times as large as that for ethanolamine. Thus, a novel reaction mechanism must take place in the degradation of PNPP effected by glycine in consistent with the following facts. Firstly, the basicities of glycine and ethanolamine are mutually comparable; the pK_a (amine) values determined potentiometrically under the kinetic condition are 9.4 and 9.3 for glycine and ethanolamine, respectively. The difference in nucleophilic reactivity between the two bases toward a *p*-nitrophenyl ester would be in a neighborhood of 1.2-fold judging from the rate-basicity correlation established for amine bases in the deacylation of *p*-nitrophenyl acetate.[8)] Secondly, there is a good reason to expect that a hydrophobic environment provided by the inclusion complex formed between **1** and PNPP would favor the attack of neutral ethanolamine rather than that of charged glycine. In fact the deacylation of PNPP in the absence of **1** was moderately accelerated by ethanolamine but hardly affected by glycine (*vide supra*). Furthermore, the uncharged paracyclophane (**3**) was confirmed qualitatively to show a rate enhancement effect in the aminolysis but not in the hydrolysis of PNPP; ethanolamine was found to show greater enhancement effect than glycine in the aminolysis reaction. Thirdly, steric interaction between an amine nucleophile and the inclusion complex formed between **1** and PNPP may possibly be an important factor governing the reactivity of the amine. However, it is unreasonable that ethanolamine is more bulky than glycine.[10)]

On the basis of these considerations, the enhanced reactivity of glycine should be ascribed to the favorable electrostatic interaction between the negative carboxylate group of glycine and the positive ammonium group of **1** into which PNPP is incorporated (Fig. 3). If there is no special interaction between an amine and **1**, an amine nucleophile attacks unimolecularly on the substrate and the deacylation rate (k_{obsd}) is given by $k_{obsd}=\kappa(OH)+k_{amine}[Amine]$, where $\kappa(OH)$ represents the hydrolysis rate factor[9)] and is evaluated from line C in Fig. 1. Thus, ($k_{obsd}-\kappa$-

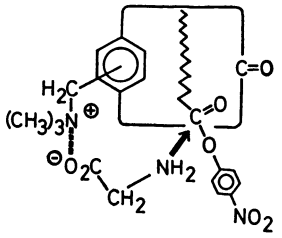

Fig. 3. A plausible reactiom mechanism for the glycinolysis of PNPP: the anionic carboxylate group of glycine is anchored on the ammonium group and the amine nucleophile attacks on PNPP which is incorporated into the hydrophobic cavity of **1**.

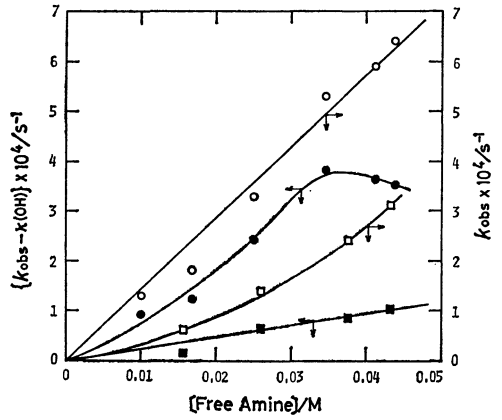

Fig. 4. Correlations between PNPP-deacylation rate and free amine concentration at constant total concentration of amine species (0.05 M) based on the data shown in Fig. 1:
(○, ●), glycine; (□, ■), ethanolamine.

(OH)) should give a linear correlation with the concentration of free amine evaluated from its pK_a value while the total concentration of amine is maintained constant. This is what is observed for the ethanolamine system (Fig. 4). Such a correlation, however, fails to be applied to the glycine system. Free glycine concentrations correlate more satisfactorily in a linear manner with k_{obsd} rather than $(k_{obsd}-\kappa(OH))$ (Fig. 4), and the $(k_{obsd}-\kappa(OH))$ curve is bent down beyond pH 9.7. These results are indicative of an important difference in kinetic behaviors of the two amines. The glycinate ion in a large excess amount seems to exclude the hydroxide ion from the vicinity of the ammonium group of **1** and the glycinolysis becomes a major reaction for the glycine system in a whole pH region studied.

The present work has made a step toward the development of an effective organic double-field catalyst (C) with which the two reacting molecules (A and B) are complexed through two different kinds of interaction forces effected by functions (C_A and C_B) placed in C (Fig. 5). The reactivity and selectivity of the bimolecular reaction of A and B would be much affected by such complexation. The present work demonstrates that the ammonium salt (**1**) should be

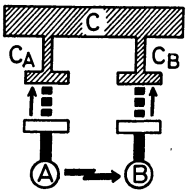

Fig. 5. Schematic representation of double-field catalysis:
A and B, reacting molecules; C, catalyst; C_A and C_B, catalytic functions of different nature provided by the catalyst.

regarded as a hydrophobic-electrostatic double-field catalyst. The hydrophobic field provided by the polymethylene chain and benzene ring incorporates the substrate (PNPP), while the electrostatic field provided by the ammonium group exhibits a kinetically significant interaction with the anionic carboxylate of the other reactant, glycine (Fig. 3). Another important role played by the hydrophobic cavity of [20]paracyclophanes is the deaggregation of carboxylic esters bearing a long alkyl chain. Such carboxylic esters are known to exist in a self-aggregated form in bulk phase.[11] The incorporation into the hydrophobic cavity tends to set the substrate more or less in an elongated form so that the site of ester bond becomes open and susceptible to the attack of nucleophile.

A Study of the 1,3,5-Trialkylbenzenes with Aluminum Chloride-Hydrogen Chloride Systems

Nobuyoshi NAMBU, Nobumoto HIRAOKA, Kenji SHIGEMURA, Sawako HAMANAKA, and Masaya OGAWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564

(Received July 10, 1976)

The "red-oil" complex layers of systems of 1,3,5-trialkylbenzenes (Me_3B, Et_3B, i-Pr_3B, and s-Bu_3B) with $AlCl_3$–HCl were prepared and studied by means of ^1H NMR and ^{13}C NMR spectroscopy. The results show that the 2,4,6-trialkylbenzenium ion is evidently formed in the complex layer of the $AlCl_3$–HCl system, much as in other superacid systems, and that those ions from i-Pr_3B and s-Bu_3B are substantially stable, even at room temperature. The molar ratios of i-Pr_3B and s-Bu_3B to HAl_2Cl_7 are almost 1. On the other hand, the molar ratios of Me_3B and Et_3B to HAl_2Cl_7 are 4.5 and 1.9 respectively. These two complex layers are considered to be formed by both 1,3,5-trialkylbenzene and its protonated product, and to be in a certain equilibrium state as a result of proton exchange at room temperature.

Many investigations of benzenium ions by using NMR have been reported in recent years,[1] and most of them have been carried out in various superacids, such as HF–BF_3, HSO_3F, and HF–SbF_5, at low temperatures. In the Friedel-Crafts reaction, alkylbenzene–$AlCl_3$–HCl systems are frequently used in commercial processes. However, the structures and compositions of the above systems have not yet been ascertained. The reasons for this are that the measurement of the NMR spectrum is difficult at low temperatures because of the solidification of the system, and that it is hard to obtain at room temperature because of the disproportionation process.

In a previous paper,[2] we reported that some of the methylbenzenes are stable in the system at room temperature, and are scarcely disproportionated even at room temperature. In order to obtain further information about the structure and composition of the "red-oil" complex layer (complex layer) in the system, we will now deal with the system of 1,3,5-trialkylbenzenes with $AlCl_3$–HCl and the formation of the stable benzenium ions by using NMR.

Experimental

Materials. The mesitylene (Me_3B) was commercially available in a high purity. The 1,3,5-trialkylbenzenes were known; they were prepared from mono- or di-alkylbenzene by Friedel-Crafts type reactions. The purities of the 1,3,5-triethyl-, 1,3,5-triisopropyl-, and 1,3,5-tri-s-butylbenzenes (Et_3B, i-Pr_3B, and s-Bu_3B respectively) were 96, 100, and 98% respectively, as determined by means of VPC analysis. All the alkylbenzenes dried over metallic Na were distilled just before use.

Preparation of Complex Layers. The complex layers of the systems of 1,3,5-trialkylbenzenes with $AlCl_3$ were prepared by the method reported previously.[2] After the reaction had been completed, the complex layer was separated as a lower layer, leaving colorless hydrocarbon as an upper layer. The volumes of the two layers were almost equal. The lower layer was then pipetted out and measured. This layer is substantially stable and keeps for several days at room temperature.

Measurements. The ^{13}C NMR spectra were obtained using a JNM-PS-100/EC-100 spectrometer equipped with a Fourier transform recorder at 25.15 MHz under a complete proton decoupling. The pulse width and repetition time were 12 μs (about $\pi/4$ pulse) and 6s respectively. The spectra were observed at 6250 Hz (data point 8191) in a 10 mmϕ tube with an external lock standard contained in a 3 mmϕ tube, holding acetone-d_6 and TMS, coaxially centered. All chemical shifts are referred to this TMS standard. The ^1H NMR spectra were also obtained using a JNM-PS-100 spectrometer, with external TMS (capillary) as the reference.

Analyses of Hydrocarbons. Hydrocarbons in both the upper and lower (complex) layers were analyzed by means of VPC after each layer had been decomposed with water. The analyses were made on a Shimadzu GC-3AF apparatus, fitted with a 3 m × 3 mm column packed with Apiezon grease L 10% and with an ionization detector, at 160 and 200 °C.

Analyses of Aluminum and Chlorine.[3] The aluminum and chlorine in the complex layer were determined by the oxine and mercury-titration methods respectively.

Results and Discussion

Analyses of Complex Layers. As was described in our previous paper,[2] the formation of a reaction system, that is, a complex layer and a hydrocarbon layer, requires a limited amount of HCl evolved by moisture contained in $AlCl_3$. In this study, when suitable amounts of alkylbenzene and $AlCl_3$ were used, it was

possible to obtain two layers apparently equal in volume. The data of the disproportionated products of 1,3,5-trialkylbenzene obtained in the reaction with $AlCl_3$ and HCl at 2 °C are listed in Table 1. The contents of the hydrocarbons in both upper and lower layers, that is, the hydrocarbon layer and the complex layer respectively, were separately analyzed by means of VPC.

The results indicate that the disproportionation of 1,3,5-trialkylbenzene scarcely proceeds at all. These relations held constantly up to about 30 °C. To obtain the contents of $AlCl_3$ and HCl in the complex layer, Al and Cl were analyzed and the molar ratios of Al, Cl, and alkylbenzene were estimated, as is shown in Table 2.

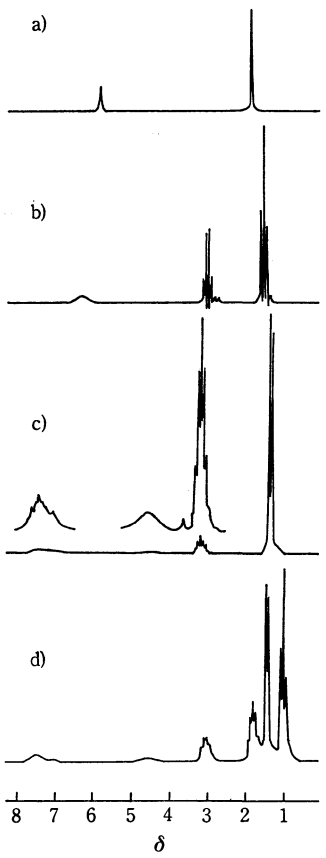

Fig. 1. 100 MHz ^1H NMR spectra of complex layers of 1,3,5-trialkylbenzenes with aluminum chloride–hydrogen chloride at 30 °C.
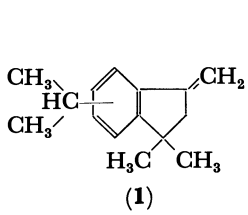
a) 1,3,5-Trimethylbenzene. b) 1,3,5-Triethylbenzene. c) 1,3,5-Triisopropylbenzene. d) 1,3,5-Tri-*s*-butylbenzene.

The molar ratio of Al/Cl was 1/3.5 for all the complex layers. This means that HAl_2Cl_7,[4)] made up of 2 mol of $AlCl_3$ and 1 mol of HCl, plays an important role in the formation of the complex layer. The molar ratio of 1,3,5-trialkylbenzene/HAl_2Cl_7 decreased with an increase in the alkyl carbon numbers as follows; 4.5 for Me_3B, 1.9 for Et_3B, 1.3 for *i*-Pr_3B, and 1.1 for *s*-Bu_3B. Therefore, the constituents of the complex layers are somewhat different from each other.

^1H NMR Spectra of Complex Layers. The ^1H NMR spectrum of each complex layer is shown in Fig. 1.

The ring protons of Me_3B and Et_3B exhibited considerably sharp singlet signals at δ 6.0 and 6.4 respectively, but those of *i*-Pr_3B and *s*-Bu_3B were each detected as a set of two broad signals, at about δ 7.5 and 4.6 respectively. The former is a signal of the ring protons, H_3 and H_5, of 2,4,6-trialkylbenzenium ions, while the latter is attributable to the methylene protons, H_1, of 2,4,6-trialkylbenzenium ions, which correspond to those reported by Olah *et al.* in their investigation with superacid. Therefore, the singlets of the ring protons of Me_3B and Et_3B, which unusually shifted to a high field, probably result from the fusions of the ring signals of 1,3,5-trialkylbenzene and the 2,4,6-trialkylbenzenium ion.

In the spectrum of *i*-Pr_3B, a weak singlet signal was observed at δ 3.69; it increased in intensity with the temperature. When this signal was detected somewhat intensely, 1,1-dimethyl-3-methylene-5- or -6-isopropylindan (**1**)[5)] was also found in the products. From this fact, and reference to the chemical shifts of the phenyl isopropyl cation, which were shown by Olah *et al.*[6)] and Farnum,[7)] the singlet signal is assigned to methyl protons of the 3,5-diisopropyl phenyl isopropyl cation (**2**).



(**1**)

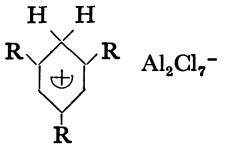
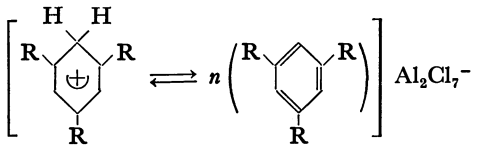
the presence of some other alkylbenzenes produced by disproportionation. The other complex layers were not contaminated by significant disproportionated products. The methylene signals of the 2,4,6-trialkylbenzenium ions were observed at about δ 50 for *i*-Pr_3B and *s*-Bu_3B, but not for Me_3B and Et_3B. The latter complex layers, which were measured at sufficiently low temperatures, apparently gave methylene signals in the spectrum. The chemical shifts of the 2,4,6-trialkylbenzenium ions are shown in Table 3, compared with those cited in the literature.

The results show that the 2,4,6-trialkylbenzenium ion is evidently formed in the complex layer of the $AlCl_3$–HCl system, much as in other superacid systems, and that those ions from *i*-Pr_3B and *s*-Bu_3B are substantially stable even at room temperature. As the molar ratios of *i*-Pr_3B and *s*-Bu_3B to HAl_2Cl_7 are almost 1 (1.3 for *i*-Pr_3B and 1.1 for *s*-Bu_3B), the complex layer may mainly consist of the following product:



R=*i*-Pr, *s*-Bu

On the other hand, the molar ratios of 1,3,5-trialkylbenzenes to HAl_2Cl_7 in the complex layers of Me_3B and Et_3B are 4.5 and 1.9 respectively. These two complex layers are considered to be formed by both 1,3,5-trialkylbenzene and its protonated product, and to be in a certain equilibrium state by means of proton exchange as follows:



R=Me (n=3.5), Et (n=0.9)

In these states, the spectra of complex layers may exhibit fused signals between 1,3,5-trialkylbenzene and the 2,4,6-trialkylbenzenium ion. The chemical shift of the fused signal may be estimated by means of the molar ratio of two components. An example of calculation for Me_3B will be given:

	Molar ratio	Unsubstituted carbon		Me substituted carbon	
		C_1	C_3, C_5	C_2, C_6	C_4
	3.5	127.6		137.7	
	1.0	54.5	134.8	193.3	193.3
		108.0		193.3	
Fused signal (calcd)		123.3		150.1	
Fused signal (obsd)		123.3		151.6	

The calculated chemical shift of the fused signal agreed fairly well with the observed one. In the case of

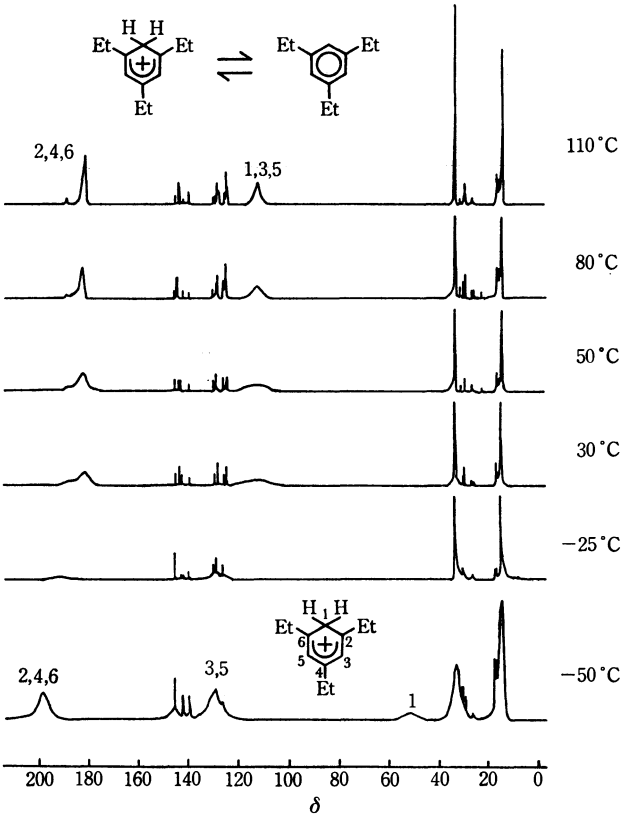


Fig. 3. Temperature-dependent ^{13}C NMR spectra of 1,3,5-triethylbenzene complex layer.

Et_3B, the calculated chemical shift of unsubstituted carbon (δ 113.8) agreed with the observed one (δ 114.0), but that of methyl-substituted carbon (δ 172.6) showed a considerable difference from the observed one (δ 182.5). This difference results from the existence of disproportionated products in the case of Et_3B.

Temperature-dependent ^{13}C NMR Spectra of the Et_3B Complex Layer. The ^{13}C NMR spectra of the Et_3B complex layer were measured in the temperature range from −50 to 110 °C; the results are shown in Fig. 3. A lot of small sharp signals observed at about δ 140 and 30 are attributable to the formation of disproportionated products. The spectrum obtained at −50 °C apparently exhibited a ring methylene signal, which indicates the presence of the 2,4,6-triethylbenzenium ion. In the spectrum at −25 °C, the weak, broad signals of ring carbons are interpreted as indicating that the life-time of the two components decreases through the critical range in the proton exchange at this temperature. At elevated temperatures the signals tend to coalesce in a singlet and to sharpen with the increase in the temperature.

All these pieces of evidence support the idea that some parts of the 1,3,5-trialkylbenzene in the complex layer are protonated by HAl_2Cl_7 and are in a certain equilibrium state with other parts by means of proton exchange.

Reactions of Transition Metal Dihydrides. VII. Further Investigations on Charge-Transfer Interaction between σ-Basic Metal Hydrides and Organic π-Acceptors

Akira NAKAMURA and Sei OTSUKA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received July 10, 1976)

Charge transfer (CT) absorptions between transition metal polyhydrides, *e.g.* MH_2Cp_2 ($Cp=\eta$-C_5H_5; M=Mo, W), $FeH_2(dppe)_2$, $MH_4(dppe)_2$(dppe=$Ph_2PCH_2CH_2PPh_2$; M=Mo, W), and organic π-acceptors such as maleic anhydride were measured. The position of the CT bands gave an I_p value of 6.3 eV for WH_2Cp_2. The value indicates transfer of electron from the filled non-bonding metal orbital to the acceptors. Role of the electron donor-acceptor interactions prior to insertion or substitution of transition metal hydrides is discussed.

Electron transfer reactions of transition metal complexes are receiving considerable attention in modern inorganic chemistry.[1] In many cases, the transfer of electron accompanies a change in formal oxidation state of the metal. In some cases partial transfer of an electron (electron donor accepter interaction or charge transfer) can be observed between metal compounds and organic substances. Our primary concern here is with the intermolecular charge transfer (CT) interactions. Thus, ferrocene forms a green CT-complex[2] with TCNE, whereas cobaltocene ($CoCp_2$ Cp: η-C_5H_5) and nickelocene ($NiCp_2$) give ionic salts, *e.g.* $(Cp_2M)^+(TCNE)^-$, resulting from complete electron transfer.[3] An X-ray structure of the ferrocene/TCNE adduct[4] revealed the charge transfer between the Cp ring and π-orbital of TCNE. A similar structure has been reported for CT complexes of arenechromium tricarbonyls with 1,3,5-trinitrobenzene.[5] H. Kobayashi *et al.* have proposed participation of a metal orbital in the charge transfer observed in arenechromium tricarbonyl/TCNE[6] systems. The ease of electron transfer, in principle, depends on the relative energy levels and electronic configuration of the metal orbitals of these organometallic complexes and on those of the accepting orbitals of organic molecules. This electron donor-acceptor interaction is generally an unobservable low-evergy process, occurring prior to such reactions as olefin π-complex formation and olefin insertion, both of which constitute essential steps in olefin catalysis.

We have been interested in the electron-donating property of various transition metal hydrides and phosphine complexes as they are important in olefin catalysis or organic synthesis in general. During studies on the reactivity of MH_2Cp_2 compounds (M=Mo, W; Cp=η^5-C_5H_5) we were able to observe CT interactions between these metal σ-bases and organic π-acids, and found that the interactions could be influential for the kinetic behavior observed in the subsequent olefin insertion reactions.[7] In addition, this has an important bearing on the olefin catalysis. The absence of study experimentally identifying interactions of this type prompted us to report our study which shed light on the nature of the interactions.

Results

Charge Transfer Complexes. When a concentrated solution of metallocene hydrides, MH_2Cp_2 (M=Mo and W), in toluene or acetonitrile, was mixed with π-acidic olefins such as maleic anhydride or fumaronitrile, immediate coloration, ranging blue to red, occurred. The color is due to the charge transfer absorption band as shown by a trend in the absorption maximum observed when the π-acidity is systematically varied (Table 1). It is important to exclude air from the interacting systems to successfully record the spectra. In many cases, the coloration fades on standing even under nitrogen for *ca.* 1 h. The extreme air-sensitivity of the hydrides and the weakness of the charge transfer absorption made quantitative spectral measurements very difficult. Therefore, no attempt was made to estimate the formation constants of the charge transfer complexes.

The charge transfer bands observed with *N,N*-dimethylaniline, a typical organic donor, are also listed in Table 1 to facilitate the comparison with the data of the metal σ-donor, WH_2Cp_2. An essentially constant shift ($\approx$7000 cm^{-1}) in the maxima is apparent by comparing *N,N*-dimethylaniline with WH_2Cp_2. Hence WH_2Cp_2 has a lower I_p than that of dimethylaniline. Since the I_p of the dimethylaniline is 7.1 eV,[8] the I_p value for WH_2Cp_2 will be 6.3 eV. The estimated I_p value is in good agreement with the I_p data obtained by an ESCA[9] (6.4 eV), and by an photocurrent measurement[10] (6.3 ± 0.1 eV), but different from one by a molecular orbital calculation (8.3 eV).[11]

The variation of polarity of the solvent from CH_2Cl_2 to benzene caused a moderate blue shift (20000 cm^{-1} to 19200 cm^{-1}) of the maxima of charge transfer band for the system WH_2Cp_2/citraconic anhydride. The approximate value of the extinction coefficient (ε: 5×10^3) in neat citraconic anhydride was as expected for the charge transfer absorption. These characteristics of the spectra unambiguously indicate the absorption maxima to be real charge transfer band.

Substitution with a methyl group on the Cp rings in MH_2Cp_2 molecule did not significantly affect the band. Thus, $WH_2(C_5H_4CH_3)_2$[12] exhibited a blue color (λ_{max} at 528 nm) in neat citraconic anhydride. MoH_2Cp_2 and $MoH_2(C_5H_4CH_3)_2$[12] exhibited almost the same pale blue color when mixed with phenylmaleic anhydride in toluene. The color turned to deep brown in 1 h at room temperature. In comparison with the tungsten congener, the molybdenum hydride, MoH_2Cp_2, did not show a clear absorption maximum even with maleo- or fumaronitrile in toluene. The coloration is very similar to the case with the tungsten hydride. The similarity

a) 0.002—0.01 mol/l for WH_2Cp_2 as donor. b) Shoulder. c) Inaccurate due to faint absorption.

indicates that the I_p value[9] for MoH_2Cp_2 is essentially identical to WH_2Cp_2. The failure to observe clear maxima for MoH_2Cp_2/π-acceptor systems may be due to the instability of the hydride $[MoH_2Cp_2]^{\delta+}$ with partial positive charge in solution. Although trihydrido cation, $[MoH_3Cp_2]^+$, is coordinatively saturated and thermally stable, the dihydrido cation, $[MoH_2Cp_2]^+$, is thermally unstable as evidenced by reaction between MoH_2Cp_2 and TCNE as described below. Generally tungsten hydride complexes are much more inert to olefins than the corresponding molybdenum hydride complexes.[12]

Although formation constants of the CT complexes of metallocene hydrides have not been measured, the intensity of the coloration implies that the values are low. Small formation constants have been recorded in systems such as polypermethylsilane/TCNE.[13] Due to the small formation constants, we could not measure the exact absorption maximum, especially with MoH_2Cp_2 as the donor. A faint coloration due to the CT absorption was observed in the following interactions: $MoH_2Cp_2/Ph_2C{=}C(CN)_2$, faint red; MoH_2Cp_2/pyromellitic dianhydride, faint blue (in CH_3CN).

$$\{MoH_2Cp_2\}^{\delta+}\{NCCH{=}CHCN\}^{\delta-} \xrightarrow{80°C} Cp_2Mo(H)(CH\text{-}CH_2CN)(CN) \quad (1)$$

$$\{MoH_2Cp_2\}^{\delta+}\{NCCH{=}CHCN\}^{\delta-} \xrightarrow{CH_2{=}CHCO_2CH_3} Cp_2Mo(H)(CH\text{-}CH_3)(CO_2CH_3) \quad (2)$$

$$Cp_2Mo(H)(CH\text{-}CH_3)(CO_2CH_3) \xleftarrow{CH_2{=}CHCO_2CH_3} MoH_2Cp_2$$

The deep red solution of the CT complex, MoH_2Cp_2/fumaronitrile, gave a hydrido-σ-alkyl complex on heating to 80 °C in toluene (Eq. 1). An attempted reaction of the CT complex with methyl acrylate did not give the acrylate insertion product which can be readily prepared by the reaction with MoH_2Cp_2 even at 0 °C (Eq. 2). Similar insertion of fumaronitrile into one of the W–H bonds in $\{WH_2Cp_2\}^{\delta+}\{NCCH{=}CHCN\}^{\delta-}$ did not occur at 80 °C.

The interaction of metallocene monoalkyl-hydrides, *e.g.* $Cp_2MoH[CH(CN)CH_2CN]$ with π-acceptors *e.g.* TCNE, did not give rise to charge transfer absorptions.

A rhenium hydride, $ReHCp_2$, also exhibited a CT maximum with trinitrobenzene at 540 nm and with citraconic anhydride at 480 nm in CH_3CN.

The interaction in mixture of MH_2Cp_2 and π-acceptors was investigated by physical methods such as the infrared and NMR spectroscopy and conductivity measurements. Thus, evaporation of a solution of an equimolar mixture of WH_2Cp_2 and maleonitrile gave a deep red solid which shows a new somewhat broad IR $\nu_{C\equiv N}$ band at 2200 cm^{-1} in addition to the bands due to the free olefin at 2237 and 2256 cm^{-1}. Similarly, evaporation of the solution containing fumaronitrile gives an orange solid which is contaminated by crystals of the starting materials and also shows a new ν_{CN} band at 2200 cm^{-1}. Conductivity measurement of the CT mixture dissolved in CH_2Cl_2 clearly shows some increase in conductivity as compared with the value of each component at the same concentration. The molar conductivity ($\Lambda = 1.0 \times 10^{-3}\ \Omega^{-1}\ cm^2\ mol^{-1}$) suggests presence of solvent-separated ions in small concentrations and yet provides firm evidence for the presence of an intimate ion pair together with the CT complex in the solution.

A similar, but weaker, red coloration was observed for systems, MoH_2Cp_2/PhCH=CHCN, or /$CH_3CH{=}CHCN$. No physical evidence has been obtained for these weakly interacting systems. The tungsten analog, WH_2Cp_2, behaves similarly to the Mo derivative, but the red coloration is still weaker. The red C_6D_6 solutions of a system, MoH_2Cp_2/maleonitrile or WH_2Cp_2/maleonitrile, were examined by ^1H NMR spectroscopy. The signals observed were almost identical to those of the each component only. These results are in agreement with the small formation constants of the CT complexes. Consistently, the IR spectrum of the concentrated solution showed only a weak peak at 2200 cm^{-1}, in addition to the ν_{CN} of unchanged maleonitrile.

Electron Transfer Complexes. Formation of the ionized species was demonstrated in the reaction of

MH_2Cp_2 with strong π-acids. Thus, tetracyanoethylylene (TCNE) was mixed, at -35 °C in toluene or in CH_2Cl_2, with dilute solutions of MH_2Cp_2 (M=Mo and W) to give deep brown precipitates, soluble only in polar, coordinating solvents. When the components are mixed in high concentrations, evolution of H_2 was observed in small amounts. The composition and the visible spectrum (in DMSO) of the product depend on the reaction conditions. Thus, elemental analysis indicated compositions, $MoH_2Cp_2\cdot(TCNE)_n$, $n=1$—1.5 and $WH_2Cp_2\cdot(TCNE)_n$, $n=1$—1.5. $ReHCp_2$ behaves similarly, and instantly gives brown precipitates from benzene solution. Infrared CN stretching frequencies (2150, 2200 cm^{-1}), visible, and conductivity data (see Experimental) suggest an ionized structure[14] analogues to the known ionic compounds, $Cr(C_6H_6)_2{}^+TCNE^-$.[3] The ^1H NMR spectrum in dimethyl-d_6 sulfoxide exhibited only a broadened signal at δ 5.5 indicating its paramagnetism, but the bulk magnetic moment was not measurable.

Tetracyanoquinodimethane (TCNQ) also gives deep brown precipitates from benzene solutions of MH_2Cp_2. In acetonitrile, the addition of MH_2Cp_2 at first gave a deep red solutions which then became deep green. The visible spectrum (in CH_3CN) indicated the presence of $TCNQ^-$.[14] The deep green powder obtained by evaporation had a composition, $[WH_2Cp_2\cdot(TCNQ)_2]$ with λ_{max} (in CH_3CN) 780, and 820 nm. 9,10-Phenanthrenequinone when mixed with MH_2Cp_2 (M=Mo, W) in benzene instantly produces deep purple precipitates which revert to the starting materials on dissolution in dimethyl sulfoxide. No coloration due to the CT interaction of WH_2Cp_2 was observed with anthraquinone, azobenzene, or succinic anhydride.

Electron Donor-Acceptor Interactions of Coordinatively Saturated Transition Metal Hydrides. Coordinatively saturated hydride complexes, *e.g.* $MH_4(dppe)_2$ (M=Mo, W, dppe=$Ph_2PCH_2CH_2PPh_2$) or $MH_2(dppe)_2$ (M=Fe, Ru), exhibit σ-basicity towards CF_3CO_2H and also an electron transfer with TCNE or TCNQ in acetonitrile, as evidenced by the visible peaks of $TCNE^-$ or $TCNQ^-$. The ratio of donor/acceptor in the interactions were investigated for the $MoH_4(dppe)_2$/TCNE system and found to be 1 : 2 by the visible spectrum. The electric conductivity in CH_3CN was found to be $\Lambda_m=64\ \Omega^{-1}\ cm^2$ at ambient temperature. The value for the $MoH_4(dppe)_2$/TCNQ was $\Lambda_m=49\ \Omega^{-1}\ cm^2$. Strong green coloration was observed when these interactions were examined in benzene or toluene. The band positions in benzene vary with the different donors; *e.g.* $MoH_4(dppe)_2$/TCNE 613 nm, $Mo(N_2)_2(dppe)_2$/TCNE 617 nm, $WH_4(dppe)_2$/TCNE 630 nm (at $-30°$ in toluene), $FeH_2(dppe)_2$/TCNE 639 nm.

The green color due to the CT band of $MoH_4(dppe)_2$/TCNE slowly changed to purple on standing for a day. A deep purple powder obtained by evaporation had a composition near $Mo(TCNE)_2(dppe)_2$ which can be separated by alumina chromatography into at least seven components differing in color. Low-valent phosphine complexes, *e.g.* $CoH(dppe)_2$, $Ni(dppe)_2$, $NiI_2(PPh_3)_2$, and $CoI_2(PPh_3)_2$, transfer an electron to TCNE when mixed in CH_3CN. No CT absorptions have been detectable even in non-polar solvents, such as benzene.

Discussion

Transition metal complexes in low-valent states are readily oxidized by electron transfer when some electron acceptors are allowed to react with it. The one- and two-electron transfer processes have long been important research fields in inorganic chemistry. However, only a few examples has been known for *charge transfer* complex formation arising from the non-bonding orbitals of low-valent transition metal compounds (metal donors) to organic acceptors. The paucity of examples for the charge transfer complexes with metal donors seems to be due to the ease of electron transfer from the non-bonding metal orbitals. For example, only very low energy barrier exists to remove one electron from octahedrally coordinated cobalt(II) ions. Our successful observation of a clear charge transfer absorption band for a system, MH_2Cp_2/π-acceptors, can be ascribed to the sufficient energy barrier of Cp_2MH_2 molcules to loose one electron. The charge transferred state is stabilized presumably due to the high potential energy of the positively charged species, $[MH_2Cp_2]^+$. Indeed, the dihydridometallocene cation, formed by addition of TCNE into a benzene solution/suspension of MH_2Cp_2, slowly decomposes with evolution of hydrogen at room temperature. A qualitative energy profile of the processes are schematically shown in Fig. 1.

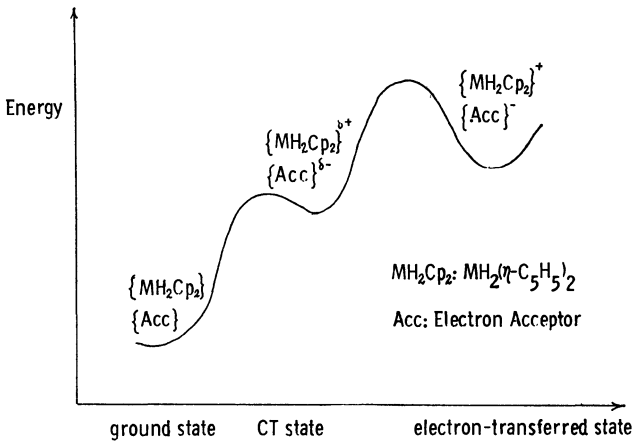

Fig. 1. A qualitative energy profile of the electron transfer process between metallocene dihydrides and electron acceptors.

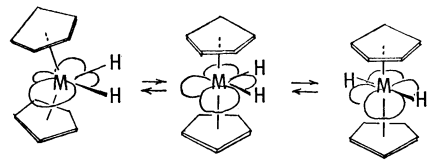
The relative instability of the cationic species thus seems to be the prerequisite to observe charge transfer states. Some organic electron donors such as *N,N,N',N'*-tetramethyl-*p*-phenylenediamine and their derivatives form relatively stable cationic species through one-electron transfer. In contrast to these delocalized electron donors, aliphatic or simple aromatic monoamines do not form stable cationic species but form charge transfer complexes with relevant acceptors.[8] Metallocene hydrides thus resemble these monoamines in their ability to form charge transfer complexes. The present systems represent rare cases where the charge transfer from the essentially non-bonding metal orbital is possible.



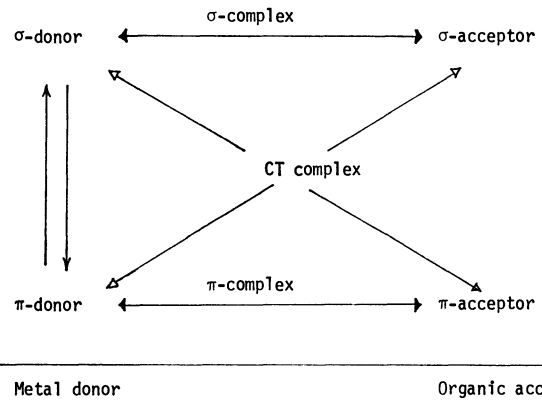
σ-basic π-basic

ground state thermally excited state

Fig. 2. Shape of an essentially non-bonding metal orbital of $MH_2(\eta\text{-}C_5H_5)_2$ molecules.

The interaction of low-valent transition metal compounds with π-acidic molecules frequently leads to π-complex formation. The propensity for the π-complex formation is especially pronounced with labile low-valent compounds of d^8- of d^{10}-metals, *e.g.* $Pt(PPh_3)_4$. Although the I_p values[15] of these compounds are in a range (6—8 eV) suitable for the charge transfer complex formation with relevant acceptors, no evidence of the charge transfer has been recorded so far. Ligand dissociation from these low-valent compounds affords a metal site of strong π-basicity which rapidly combines with the π-acceptor. Therefore unless ligand substitution process in the donor molecules is prevented either thermodynamically or kinetically, stable charge transfer complexes should not be observable.

WH_2Cp_2 molecule seems to be sufficiently inert to π-complex formation as the shape of the HOMO defines its σ-basic property at the wedged ground-state structure and the π-complex formation with π-accepting olefins is forbidden by the orbital symmetry restriction.[16] In the thermally excited parallel metallocene structure, π-basic property is expected as illustrated in Fig. 2. Thus, thermal reaction of WH_2Cp_2 with diethyl maleate gives $Cp_2W(EtO_2C\text{–}CH{=}CH\text{–}CO_2Et)$ through the initial insertion into one of the W–H bonds[17] followed by reductive elimination producing a strong metal π-base, Cp_2W. The insertion has been proposed to proceed *via* incipient π-complex formation with WH_2Cp_2 in the parallel metallocene structure.



Scheme 1. Idealized schemes of interaction between metal donors and organic acceptors.

Scheme 1 shows a simplified scheme for the interactions between metal donors and organic acceptors with an emphasis on the symmetry property of interacting orbitals. It is to be noted that the symmetry properties of the metal donor orbitals will be altered by a change in the stereochemistry or coordination number. The energy barrier for the change generally increases with an increase in the strength of the metal-ligand bonding.[18] In particular, the molybdenum analog of metallocene hydrides, MoH_2Cp_2, undergoes the stereochemical change more readily than the corresponding tungsten complex.[12] In other words, MoH_2Cp_2 is stereochemically more non-rigid than WH_2Cp_2. This trend is in agreement with the general tendency in the non-rigidity of transition metal hydrides[18] and also explains the different behavior of these metallocene hydrides toward electronegative olefins. Thus, MoH_2Cp_2 readily inserts methyl acrylate into one of the Mo–H bonds at 20 °C and the CT complex, MoH_2Cp_2/fumaronitrile, is also slowly transformed to the insertion products (*cf.* Eqs. 1 and 2). By contrast, the tungsten hydride, WH_2Cp_2, forms CT complexes but no insertion products at 20 °C. Since the olefin insertion has been proposed[16] to proceed by incipient formation of a metal-olefin π-complex, the inertness of WH_2Cp_2 seems to be due to its reluctance to undergo polytopal rearrangement to give the thermally-excited π-basic form shown in Fig. 2.

Conclusions

Clear charge transfer absorption maxima were observed for the first time in the interaction of π-basic metallocene hydrides, MH_2Cp_2, with π-acidic organic molecules.[7] The *charge transfer* arises from the filled nonbonding metal orbital as indicated by the substituent effect on the Cp rings of MH_2Cp_2 and also by the I_p value calculated from the charge transfer absorption maxima. *Electron transfer* occurs between MH_2Cp_2 and strong π-acids like TCNE. The formation of charge transfer or electron transfer complexes of MH_2Cp_2 retards the olefin insertion into the M–H bonds. Hence, we feel that these electron-donor-acceptor interactions between metal σ-bases and organic π-acids are not prerequisite to π-complex formation of olefin insertion.

Experimental

Material and Apparatus. Metallocene hydrides (MH_2Cp_2, M=Mo, W and $ReHCp_2$),[19] $MH_4(dppe)_2$ (M=Mo, W),[18] and $MH_2(dppe)_2$ (M=Fe, Ru)[20] were prepared by literature methods. Maleonitrile was prepared from maleamide by dehydration with P_2O_5. The other organic acceptors are commercial products and were purified when necessary. Electronic, vibrational, and ^1H NMR spectra were measured by a Hitachi Model EPS-3T, a Hitachi-Perkin Elmer Model 225, and Jeol JMN-60HL, respectively. Electric conductivity was measured by a Yanagimoto's Conductivity Outfit MY-7 using white platinum plates as electrodes. These physical measurements with air-sensitive metal complexes were performed under pure nitrogen in solvents previously saturated with nitrogen.

Measurement of the Charge Transfer Spectra. Saturated toluene solutions of MH_2Cp_2 (M=W or Mo) were mixed with organic acceptor in question and the supernatant liquor was taken out by a syringe to a 2 mm cell for immediate examination by the visible spectra. When liquid acceptors, *e.g.* maleonitrile or citraconic anhydride, were to be examined, the measurement was also performed in neat liquids. The visible spectra of interacting CT couples, $MH_4(dppe)_2$/TCNE (M=

Mo, W) or $MH_2(dppe)_2$/TCNE (M=Fe, Ru) were recorded similarly in toluene.

Investigation of Physical Property of Interacting Mixtures of MH_2Cp_2 (M=Mo or W) with Fumaro- or Maleonitrile at Ambient Temperature. *a) Visible Spectrum*: An equimolar fresh solution of MoH_2Cp_2 and fumaro- or maleonitrile in dichloromethane (0.1 mmol/l) showed no maximum in the visible absorption. A difference spectrum revealed an increased absorption in the equimolar mixed solution (0.06 mmol/l) at 360—450 nm region without maximum. Experimental difficulty, however, precluded quantitative data. When the amount of fumaronitrile is increased to 2—4 times molar in excess, the absorption around 500 nm increased and when a more concentrated solution (0.1 mol/l) was made, the spectrum began to show a distinct shoulder at 490 nm (ε 10000). By contrast, WH_2Cp_2 showed a clear absorption maximum with many organic acceptors in toluene or in CH_3CN (*cf.* Table 1).

b) Conductivity: Conductivity was measured by a Yanagimoto MY-7 with white platinum electrodes at 1 cm apart, under nitrogen when necessary. A dichloromethane solution (0.1 mmol/l) of MoH_2Cp_2 containing 10-fold excess fumaronitrile showed low molar conductivity, $0.1\times10^{-3}\ \Omega^{-1}$ $cm^2\ mol^{-1}$ at 23 °C. Each reagent showed no conductivity in dichloromethane. The result in acetonitrile was complicated by low conductivity of each reagent, but a value $2\times10^{-3}\ \Omega^{-1}$ $cm^2\ mol^{-1}$ was found in reddish orange solution made from MoH_2Cp_2 and excess fumaronitrile.

c) ^1H NMR Spectrum: An orange equimolar mixture of MoH_2Cp_2 and fumaro- or maleonitrile freshly dissolved in C_6D_6 or in $(CD_3)_2CO$ failed to give any unambiguous evidence for the formation of an stable adduct as judged from the chemical shift values of the observed peaks, which differ only *ca.* 0.1 ppm from that of free olefins. Similar results were obtained for WH_2Cp_2 as a donor. Observed change in the value from that of the free olefins may indicate difference in extent of solvation because the solvent effect was exceptionally large in C_6D_6.[21] On standing for a few hours at room temperature, weak signals due to the hydride-alkyl complex[16] appear.

d) IR Spectrum: Solution spectra of the fresh mixture of MoH_2Cp_2 or WH_2Cp_2 and fumaronitrile (ν_{CN} at 2246 cm^{-1}) in toluene or in acetone revealed a weak new $\nu_{C\equiv N}$ band at 2200 cm^{-1}. On standing the solution of MoH_2Cp_2 containing fumaronitrile, a strong $\nu_{C\equiv N}$ band (at 2190 cm^{-1}) of the hydrido-alkyl complex appeared.[16] The hydrido-alkyl complex did not form from WH_2Cp_2 even at higher temperatures.

Interaction of MH_2Cp_2 (M=W and Mo) with Tetracyanoethylene(TCNE). Dropwise addition of a dilute TCNE solution in toluene (0.13 g in 10 ml) into WH_2Cp_2 dissolved in toluene (0.03 g in 5 ml) at −35 °C gave a deep purple floculent precipitate which changed to deep brown on further addition. It was filtered, washed, and dried to give a dark brown powder soluble in dimethyl sulfoxide (DMSO) and also in *N*-methylformamide. Attempted purification by recrystallization has been unsuccessful. Elemental analysis roughly corresponded to $WH_2(C_5H_5)_2(C_6N_4)_{1.5}$. IR (Nujol) in cm^{-1}, $\nu_{C\equiv N}$, 2200 broad, 2130 broad, 1600 broad. Visible maxima (DMSO) in nm, 398, 415, 570 shoulder. ^1H NMR spectrum (DMSO-d_6) was obscured by some paramagnetic impurities although the most part was diamagnetic as confirmed by magnetic susceptibility measured in the same solution. The solution had a weak electrolytic property ($\Lambda_m=3.6\ \Omega^{-1}\ cm^2$) in DMSO at 20 °C which somewhat increased on standing. The sample prepared by the inverse addition had similar analytical data but a different visible spectrum (λ_{max} (in nm) at 393, 420 sh, 450 sh). The corresponding reaction of MoH_2Cp_2 with TCNE evolved a small amount of hydrogen, giving a deep brown amorphous powder soluble in DMSO; $[Mo(C_5H_5)_2H_2(C_6N_4)_{1-1.5}]$, IR (Nujol) in cm^{-1}, 2200 broad, 2130 broad, 1650—1600 broad. No maximum was observed in the visible spectrum in DMSO. $\Lambda_m=6\ \Omega^{-1}\ cm^2$ in DMSO at 20 °C. The rhenium hydride, $ReHCp_2$, instantly gave brown precipitates on mixing with a TCNE solution in benzene. The IR spectrum was similar to those obtained by reaction MH_2Cp_2 with TCNE.

Metal-Assisted Terpenoid Synthesis. IV.[1] Nickel-Catalyzed Reactions of 1,3-Dienes with Ketones. A New Synthesis of Long Chain Tertiary Alcohols

Susumu AKUTAGAWA

Central Research Laboratory, Takasago Perfumery Co. Ltd., 31-36, 5-Chome, Kamata, Ohta-ku, Tokyo 144

(Received July 17, 1976)

Catalytic reactions of 1,3-butadiene with ketones were carried out with a nickel-ligand system to give stereoselectively tertiary alcohols having a (2*Z*, 5*E*)-2,5,7-octatrienyl- or a (2*Z*, 6*E*, 9*E*)-2,6,9,11-dodecatetraenyl chain. Similar reactions of isoprene gave a mixture of terpenic and apoterpenic alcohols. A possible reaction scheme was discussed in terms of an insertion of the carbonyl group to a σ-allyl end of octadienyl or dodecatrienyl nickel complexes.

Despite extensive studies on telomerization of conjugated dienes with various protic substances[2] including carbonyl-activated methylene compounds, no report has been given on the catalytic formation of tertiary alcohols from ketones and oligodienes. A closely related reaction may be the secondary alcohol formation in the palladium-catalyzed reactions of 1,3-butadiene with aldehydes.[3a-d] A nickel catalyst system has been found to be effective for the synthesis of tertiary alcohols of types **1** and **2**. The reaction provides a convenient synthetic route for long chain alcohols, some of which are useful for terpenoid synthesis.

The reactions of conjugated dienes with ketones were carried out at 70 °C for 10 h in the presence of a nickel catalyst (5 mol % of dienes) either prepared *in situ* by reducing an equimolar mixture of acetylacetonatonickel(II) and a ligand with triethyl aluminum or treating bis(cyclooctadienyl)nickel(0) with an equimolar amount of the ligand. The products were identified by means of VPC and IR, UV, mass and NMR spectroscopy. The physical properties of **1a—e** and **2** are summarized in Table 1. The reaction of 1,3-butadiene

Table 1. Spectral data of the products

Product	NMR[a] (δ)	IR[b] (cm^{-1})	UV[c] (nm)	Bp (°C/Torr)
1a	1.18 (6H, s), 2.15 (2H, d, J=7.0 Hz), 2.82 (2H, t, J=8.0 Hz), 3.12 (1H, s), 4.90—5.32 (3H, ABX), 5.51 (2H, q, J=7.0 Hz), 5.63—7.01 (2H, m, J=16.0 Hz)	3365, 1800, 1640, 1598, 1150, 973, 952, 900	238 (ε 18000)	72/15

2 **3**

with acetone was effected with Ni–P (O–*o*-Me–C_6H_4)$_3$ to give a mixture of **1a** and **2** in 62 and 16% yields, respectively (based on reacted 1,3-butadiene). Similar results were obtained using other ligands, such as PPh_3 or $P(OPh)_3$. However, catalyst activity was rather low (65% conversion for PPh_3 and 70% for $P(OPh)_3$) as compared to that of P(O–*o*-Me–C_6H_4)$_3$ (81%). A small amount of 1,3-butadiene dimers and higher products[4] were also formed. The *cis*-geometry of the C4—5 and *trans* geometry of the C7—8 double bonds in **1a** can be deduced from the olefin proton coupling constants, 7, and 16 Hz, respectively. The structure of **2** was deduced from the hydrogenated product; an alkanol obtained was identical with the authentic 2-methyl-2-tetradecanol in their physical and spectral properties. The NMR spectroscopy of **2** showed the presence of two *trans*-double bonds at C8 and C11 (5.60—7.01, 4H, m, J=16.0 Hz) and a *cis*-double bond at C4 (5.51, 2H, m, J=7.0 Hz). The regioselective linear linkage of three 1,3-butadiene molecules in **2** is noteworthy in view of the unavoidable formation of branched isomers in the catalytic linear oligomerization of the diene. Similarly the reactions of methyl isopropyl ketone and acetophenone with 1,3-butadiene gave **1b** and **1c** in 55 and 52% yields, respectively. Bulkier ketones such as diisopropyl ketone gave no alcohol. No alcohol formation was observed with propionaldehyde. Typical results are given in Table 2.

The rate of reaction of isoprene with acetone was small as compared to that of the reaction of 1,3-butadiene.

Table 2. Reactions[a] of 1,3-butadiene with carbonyl compounds

No.	Carbonyl compound[b]	Conversion (%)	Dimers (%)	Alcohols (%)[c]	Higher products (%)
1.	Me_2CO	81	15	**1a**(62) **2** (16)	7

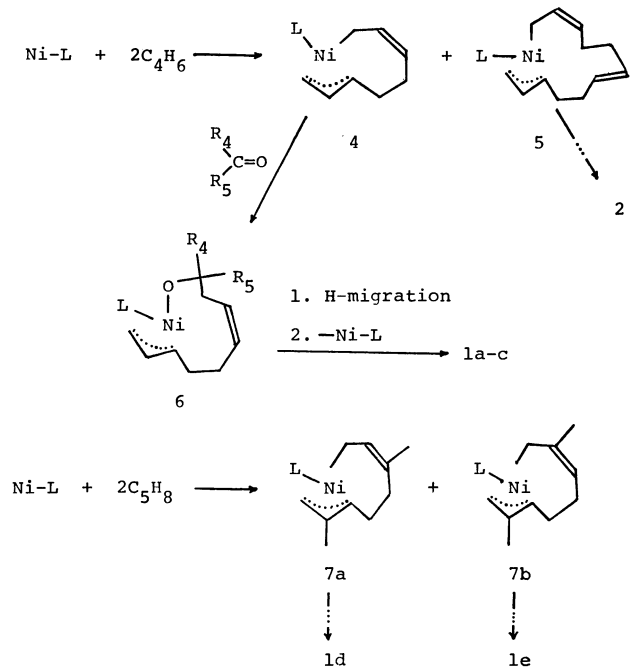
6.	P(*n*-C_4H_9)$_3$	22	70	0	30	

a) Reaction conditions: Ni(COD)$_2$/ligand/isoprene/acetone 1/1/200/70 at 70 °C for 10 h. b) Based on reacted isoprene. c) Calculated by VPC.

The reaction with isoprene gave two isomeric alcohols **1d** and **1e**, together with a relatively large amount of the dimers. The structure of **1d** is related to that of terpenoids. (*Z*)-2,5,9-Trimethyl-4,8-decadien-2-ol (**3**), for example, can be readily derived from partial hydrogenation of **1d**.

The nature of the ligand affects the activity and regioselectivity. As shown in Table 3, electron-donating trialkylphosphines, like P(*n*-C_4H_9)$_3$, completely suppress the reaction, while electron-accepting phosphites facilitate the reaction. The bulkier the phosphite ligand, the higher the selectivity for **1e**.

The requirement of a phosphite ligand suggests the importance of the low valence state of nickel in the catalysis. This is in contrast to the linear trimerization of isoprene[5] where a Ni(II) species, formation of which is assisted by coordination of an electron-donating ligand, plays an important role. One conspicuous feature of the products is the *cis*-configuration of the inner double bond nearest to the alcohol carbon. This leads to a reaction scheme involving a nucleophilic



attack of the carbanionic allyl end of the dimer or the trimer ligand on the carbonyl carbon in intermedates **4**, **7a**, or **7b** and **5**. The subsequent step will be the formation of **6**, where hydrogen migration from a methylene group, adjucent to the π-allyl group, to the carbonyl oxygen atom will take place to give the alcohols and to regenerate the catalyst. Baker *et al.*[6] observed a similar insertion of an aldehydic carbonyl group into a metal–allyl bond of dodecatrienyl nickel complex in the stoichiometric reaction. However, because of hydrolysis of the product they isolated alcohols of dodecatrienyl derivatives.

The stereoselective formation of the *cis*-double bond in the alkoxy ligand of **6** is accounted for by the preferential insertion of the carbonyl group into the σ-allylic end of **4**. The *anti*-configuration of the π-allylic part in **6** appears to be responsible for the *trans* configuration of the conjugated part of the products.

Although regioselective head to tail coupling of isoprene for the linear oligomerization has been achieved with suitable ligands such as trialkylarsines or aminophosphines,[5] no such regioselectivity was achieved in this reaction (run 5, Table 3).

Experimental

Reaction of 1,3-Butadiene with Carbonyl Compounds. Typical Procedure: To a mixture of $Ni(acac)_2$ (5.0 mmol) and $P(O\text{-}o\text{-}Me\text{-}C_6H_4)_3$ (5.0 mmol) in 65 ml (*ca.* 0.8 mol) of 1,3-butadiene was added a hexane solution of $AlEt_3$ (25 mmol) at -10 °C and subsequently 0.2 mol of a carbonyl compound. After being heated at 70 °C for 10 h, the catalyst was deactivated with a small portion of methanol and the whole reaction mixture was fractionally distilled. The dimer fraction (bp 50—65 °C/30 Torr) consists of 4-vinylcyclohexene, 1,5-cyclooctadiene and 1,3,6-octatriene (VPC, capillary column, PEG 2000, 45 m×0.2 mm). The main fraction consists of **1a**—**c** and **2**. The analytical samples were obtained by preparative VPC (PEG 4000 on Chromosorb W, 3 m×2 cm).

Hydrogenation of (4Z,8E,11E)-2-Methyl-4,8,11,13-tetradecatetraen-2-ol. Catalytic hydrogenation (Pd on charcoal, 10 kg/cm², 25 °C in AcOEt) of **2** gave 2-methyl-2-tetradecanol, *m/e* 228 (2%, M^+), 210 (98%, M^+-H_2O), which was identical with an authentic sample prepared by the reaction of $n\text{-}C_{12}H_{25}MgBr$ with Me_2CO in IR and VPC (capillary column, PEG 2000, 45 m×0.2 mm).

Reaction of Isoprene with Acetone. General Procedure: To a solution of bis(cyclooctadieneyl)nickel(0) (1 mmol) and ligand (1 mmol) in 20 ml (*ca.* 0.2 mol) of isoprene was added 4 ml (*ca.* 0.08 mol) of acetone at 0 °C. The mixture was stirred at 80 °C for 10 h. After deactivation of the catalyst with methanol, the reaction products were distilled to give isoprene dimers, a mixture of C_{13} alcohols and the higher products.[4] Isoprene dimer fraction for every case consisted of dipentene, 1,5-dimethyl-5-vinyl-1-cyclohexene and 1,5- and 1,6-dimethyl-1,5-cyclooctadiene. Preparative VPC (PEG 4000 on 60—80 Chromosorb W, 3 m×2 cm) was used to separate the mixture of **1d** and **1e**.

(Z)-2,5,9-Trimethyl-4,8-decadien-2-ol (Dimethylnerylcarbinol) (3). Partial hydrogenation of 150 mg of **1d** was carried out (10 wt.% of PtO_2, 755 mmHg, 21 °C) to give **3** as an oil, bp 85 °C/5 Torr: IR (neat) cm^{-1}; 3490 and 1145 (alcohol), 842 (*cis*-C=CH-); *m/e* 196 (2%, M^+), 178 (95%, M^+-H_2O); NMR (CCl_4) δ, 1.18 (6H, s), 1.62—1.79 (6H, s), 2.19 (2H, d, J=7.0 Hz), 2.75—2.82 (4H, m), 3.45 (1H, s), 5.28 (1H, t, J=8.0 Hz) and 5.95—6.05 (1H, m). These data and the retention time of VPC (capillary column) were identical with those of the authentic sample prepared by treating (*Z*)-4,8-dimethyl-3,7-nonadienoic acid with an excess of MeMgI.

The author wishes to express his sincere thanks to Professor S. Otsuka, Osaka University, for his valuable suggestions and discussions. Thanks are also due to Mr. T. Yamamoto and Mr. K. Ueda for technical assistance.

Synthesis of 3′-Deoxykanamycin B (Tobramycin)[1]

Yasushi TAKAGI, Toshiaki MIYAKE,* Tsutomu TSUCHIYA, Sumio UMEZAWA, and Hamao UMEZAWA

Institute of Bioorganic Chemistry, 1614 Ida, Nakahara-ku, Kawasaki 211
**Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223*

(Received July 20, 1976)

3′-Deoxykanamycin B (tobramycin) was prepared from kanamycin B. 3′,4′:4″,6″-Di-*O*-cyclohexylidene derivative (**2**) of penta-*N*-ethoxycarbonylkanamycin B was 2″-*O*-benzoylated and the 3′,4′-*O*-cyclohexylidene group was selectively and quantitatively removed by treatment with 1 mol equivalent of water in *N*,*N*-dimethylformamide (DMF) to give the de-3′,4′-*O*-cyclohexylidene derivative (**4**). Regioselective tosylation in pyridine at −20 °C gave the 3′-*O*-tosyl derivative (**5**) in 70% yield. Despite the 1,3-diaxial interaction in the transition state, replacement of the tosyl group with iodide was successfully performed in high yield with NaI in DMF. Hydrogenolysis of the iodo derivative (**6**) and subsequent removal of the protecting groups gave 3′-deoxykanamycin B (**10**) in ≈25% overall yield from kanamycin B. Confirmation of the 3′-deoxy group was performed by measurement of $\Delta[M]_{TACu}$ of 3′-deoxyneamine which was obtained from **10** by hydrolysis.

In recent papers[2-7] we synthesized a number of deoxy derivatives of aminoglycoside antibiotics and were able to establish the importance of having a 3,4-dideoxy or a 3-deoxy aminohexose moiety at the C-4 of 2-deoxystreptamine portion of aminoglycoside antibiotics to overcome inactivation by phosphorylating enzymes present in resistant bacteria. The present paper lies on the same line and describes the synthesis of 3′-deoxykanamycin B (tobramycin[8]) starting from kanamycin B.

Penta-*N*-ethoxycarbonylkanamycin B[2] (**1**) was treated with 1,1-dimethoxycyclohexane in *N*,*N*-dimethylformamide (DMF) in the presence of *p*-toluenesulfonic acid to give 3′,4′:4″,6″-di-*O*-cyclohexylidene derivative (**2**). Benzoylation of **2** gave 2″-*O*-benzoyl derivative (**3**). Selective removal of the 3′,4′-*O*-cyclohexylidene group of **3** was first effected[1] by hydrolysis in methanol in the presence of catalytic amount of *p*-toluenesulfonic acid (25 °C for 24 h). In this case, a mixture of **3**, 4″,6″-*O*-cyclohexylidene (**4**), and decyclohexylidenated derivatives was obtained from which **4** was isolated in a yield of 70—80%. Further experiment showed that when a solution of **3** in DMF was treated with 1 mol equivalent of water in the presence of *p*-toluenesulfonic acid, the 3′,4′-*O*-cyclohexylidene group was selectively removed to give **4** in a yield of 96% without purification by column chromatography. Evidence for the removal of the 3′,4′-*O*-cyclohexylidene group was the fact that **4** was led to 3′-deoxykanamycin B at the end of this synthesis.

Regioselective 3′-*O*-tosylation of **4** was successfully carried out by treating **4** in cold pyridine (−20 °C) with *p*-toluenesulfonyl chloride for 9 days to give the 3′-*O*-tosyl derivative (**5**) in 70% yield.

Replacement of the tosyloxy group with iodide was carried out with 50% sodium iodide in DMF to give the 3′-iodo derivative (**6**) in 91% yield although the configuration at C-3 remains unconfirmed. Generally, the 3-sulfonyloxy group in an α-D-glucopyranoside is known to be resistant to displacement by a nucleophile owing to 1,3-diaxial type interaction[9,10] occured between axial 1-*O*-aglycon group and the nucleophile attacking the C-3 in the transition state. The successful iodination may be due to the neighboring group participation[11] of the 2-acylamino group.

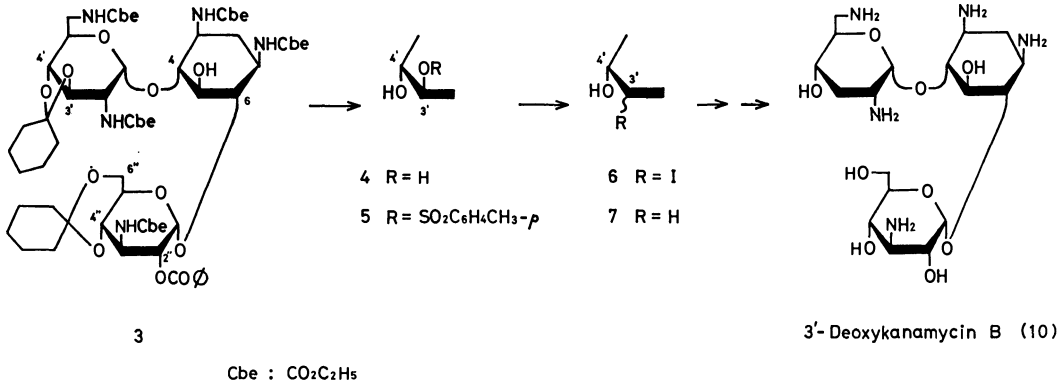
The iodo derivative (**6**) was hydrogenated with Raney nickel to give 3′-deoxy derivative (**7**) quantitatively. Hydrolysis of **7** with barium hydroxide removed its benzoyl and ethoxycarbonyl groups to give 4″,6″-*O*-cyclohexylidene-3′-deoxy derivative (**8**, major) and an unidentified compound (**9**, minor) which is probably a ureido-type compound[12] formed between N-1 and N-3 of 2-deoxystreptamine moiety judging from the mobility in electrophoresis. Finally, treatment of **8** with 50% acetic acid removed the cyclohexylidene group to afford 3′-deoxykanamycin B (**10**).

TABLE 1. THE $\Delta[M]_{TACu}$ VALUES MEASURED AT 20° C

	$\Delta[M]_{TACu}$
Paromamine	−203°[14]
3′-Deoxyparomamine[15]	+988°
Neamine	−183°
3′-*O*-Methylneamine	+730°[4b]
4′-*O*-Methylneamine	−200°[4b]
3′-Deoxyneamine[8] (**11**)	+648°

In order to confirm the structure of **10**,**10** was partially hydrolyzed with 6 M hydrochloric acid. Major components of the hydrolyzate were found to be 3′-deoxyneamine (**11**) and 3-amino-3-deoxy-D-glucose, the latter being identified, on paper chromatogram, by comparison of the R_f value and coloration with those of authentic sample. The structure of **11** was proved on the basis† of $\Delta[M]_{TACu}$[13] values (Table 1). TACu can form complex with vicinal amino and hydroxyl groups when they have ≈60° dihedral angle, showing approximately $\Delta[M]$ ±900°, the sign being decided depending on counterclockwise and clockwise rotation (measured from the front to the rear) in the Newman projection of

† Regarding the $\Delta[M]_{TACu}$ values of 3′-deoxykanamycin B (**10**) and structurally related compounds, we previously reported in a short communication,[1] and the results supported the structure of **10**. The $\Delta[M]_{TACu}$ studies on **11** and related compounds described here were performed in order to confirm the previous conclusion.



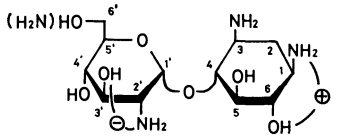


Fig. 1. The complex-forming sites and the signs for contribution to $\Delta[M]_{TACu}$ in paromamine and neamine.

$-(NH_2)CH-CH(OH)-$. TACu can not form complex with two vicinal hydroxyl groups, and, with 6-amino and 4-hydroxyl groups in a glycopyranoside structure, only small contribution in magnitude was observed.[13] As depicted in Fig. 1, paromamine or neamine can form complexes in two sites, but the two contributions are almost cancelled owing to the opposite sign of the values. In the cases of 3'-deoxyparomamine, 3'-*O*-methylneamine and 3'-deoxyneamine (**11**), the complex can be formed only at 1-NH_2 and 6-OH of the 2-deoxystreptamine portion. The value of **11** ($\Delta[M]_{TACu}$ +648°), therefore, substantiated its structure.

Antibacterial spectrum was reported[1] already with other structurally related antibiotics.

Experimental

NMR spectra were recorded at 60 and 100 MHz with Varian A-60D and HA-100 spectrometers, respectively. Infrared spectra were determined in KBr discs with Hitachi 285 grating infrared spectrophotometer. Thin-layer chromatography (TLC) was carried out on Wakogel B-5 with sulfuric acid spray for detection. For column chromatography, silica gel (Wakogel C-200) was used unless otherwise stated. Paper-chromatography (PPC) was carried out on Toyo Roshi No. 50 with 1-butanol–pyridine–water–acetic acid (6:4:3:1, Solvent A) as the developer, descending for 18 h, and colorized with 0.25% ninhydrin in pyridine. Paper electrophoresis was conducted in a Savant LT48A apparatus (Savant Instrument, Inc.) on Toyo Roshi No. 51 in formic acid–acetic acid–water (1:3:36) at 3500 V for 15 min, and after drying the paper in a hood, it was colorized as stated above.

3',4':4'',6''-Di-O-cyclohexylidene-penta-N-ethoxycarbonylkanamycin B (2). To a hot solution (≈50 °C) of **1** (522 mg) in dry DMF (2.5 ml), 1,1-dimethoxycyclohexane (0.5 ml) and anhydrous *p*-toluenesulfonic acid (26 mg) were added and the solution was heated at the temperature under reduced pressure (20—30 Torr) to remove the generated methanol by coevaporation with the solvent. After 1 h, 1,1-dimethoxycyclohexane (0.5 ml) was added and the reaction was continued for further 1 h. TLC (chloroform–ethanol 12:1) then showed two components (monocyclohexylidene derivative, R_f 0.15, minor; and **2**, R_f 0.33, major). Further reaction with additions of the above reagent did not change the ratio of the products. The solution was poured into a mixture of benzene and aqueous sodium hydrogencarbonate and the mixture was stirred vigorously for a while. After centrifugation, the powder appeared between the two layers was collected, washed with water, and dried to give a monocyclohexylidene derivative (27 mg). The benzene layer was concentrated to give a solid, which was dissolved in methanol and **2** was precipitated by addition of water, 506 mg (82%), $[\alpha]_D^{20}$ +99° (*c* 1, methanol).

Found: C, 53.50; H, 7.32; N, 6.77%. Calcd for $C_{45}H_{73}N_5O_{20}$: C, 53.83; H, 7.33; N, 6.98%.

2''-O-Benzoyl-3',4':4'',6''-di-O-cyclohexylidene-penta-N-ethoxycarbonylkanamycin B (3). A solution of **2** (4.95 g) and benzoyl chloride (3.07 g) in pyridine (60 ml) was heated at 50 °C for 1.5 h. After addition of water (0.5 g), the solution was concentrated to a half volume, and poured into aqueous sodium hydrogencarbonate. The resulting precipitate was washed with water and dried to give a solid of **3** (5.44 g, 99%), mp 152—154 °C, $[\alpha]_D^{20}$ +99° (*c* 1.4, methanol).

Found: C, 56.46; H, 6.76; N, 6.07%. Calcd for $C_{52}H_{77}N_5O_{21}$: C, 56.36; H, 7.00; N, 6.32%.

2''-O-Benzoyl-4'',6''-O-cyclohexylidene-penta-N-ethoxycarbonylkanamycin B (4). A solution of **3** (55.1 mg) in DMF (1.1 ml) containing water (0.9 mg, 1 mol equivalent for **3**) and anhydrous *p*-toluenesulfonic acid (1.9 mg, 0.2 mol equivalent for **3**) was kept at room temperature for 43 h. The solution showed on TLC with chloroform–ethanol 12:1 only one major product (R_f 0.26) (*cf.* **3**, R_f 0.45; decyclohexylidene derivative, R_f 0). After addition of 2.5% aqueous sodium hydrogencarbonate (0.1 ml) with stirring, the solution was concentrated *in vacuo* to give a solid, which was thoroughly washed with water to give a solid of **4** (49.0 mg, 96%), $[\alpha]_D^{20}$ +147° (*c* 0.6, DMF).

Found: C, 53.49; H, 6.41; N, 6.69%. Calcd for $C_{46}H_{69}N_5O_{21}$: C, 53.74; H, 6.76; N, 6.81%.

2''-O-Benzoyl-4'',6''-O-cyclohexylidene-penta-N-ethoxycarbonyl-3'-O-tosylkanamycin B (5). To a solution of **4** (106.4 mg) in dry pyridine (2 ml) at −20 °C, *p*-toluenesulfonyl chloride (99.6 mg, 5 mol equivalents for **4**) was added and the solution was kept at −20 °C for 9 days. The solution showed, on TLC (chloroform–2-propanol 10:1), three spots of R_f 0.24 (**5**, major), 0.28 (4'-*O*-tosyl isomer, trace) and 0.3 (di-*O*-tosyl isomer, trace). After addition of water (0.08 ml) followed by standing the solution at room temperature for 1 h, the solution was concentrated *in vacuo* to a syrup, which was dissolved in chloroform. The solution was washed successively with 5% aqueous potassium hydrogensulfate, water, 5% aqueous sodium hydrogencarbonate, and water, dried over $MgSO_4$,

and concentrated. The resulting solid (113.8 mg) was triturated with acetone (2 ml×2) and the acetone-soluble material (104.2 mg) was chromatographed on a column of silica gel with chloroform–2-propanol (15: 1) to give **5** (85.6 mg, 70%) and a mixture of 4′-*O*-tosyl and 3′,4′-di-*O*-tosyl isomers (18 mg). The acetone-insoluble component was found to be 4′-*O*-tosyl isomer[16] (9.6 mg). Compound **5**, mp 149—150 °C, $[\alpha]_D^{20}$ +88° (*c* 1, methanol); IR (KBr): 1720, 1530; 1175 cm^{-1} ($\nu_s SO_2$).

Found: C, 53.90; H, 6.58; N, 5.67; S, 3.00%. Calcd for $C_{53}H_{75}N_5O_{23}S$: C, 53.84; H, 6.40; N, 5.93; S, 2.71%.

NMR ($CDCl_3$) δ: 2.42 (3H, s, CH_3 of Ts).

*2″-O-Benzoyl-4″,6″-O-cyclohexylidene-3′-deoxy-penta-N-ethoxycarbonyl-3′-iodokanamycin B (**6**).* A mixture of **5** (282 mg) and sodium iodide (3 g) in DMF (6 ml) was stirred at 100 °C for 20 h. The resulting reddish brown solution, which soon solidified on cooling, was extracted with chloroform and the chloroform solution was concentrated with aid of toluene. The solid obtained was dissolved in chloroform and the solution was washed successively with saturated aqueous sodium chloride, aqueous sodium thiosulfate, and water, dried over $MgSO_4$, and concentrated to give a brown solid (247 mg, 91%). Slight impurities were removed by chromatography on a column of silica gel with chloroform–2-propanol (14: 1) to give a solid of **6** (195 mg, 72%).

Found: C, 48.75; H, 6.09; N, 6.57; I, 11.45%. Calcd for $C_{46}H_{68}N_5O_{20}I$: C, 48.55; H, 6.02; N, 6.15; I, 11.15%.

*2″-O-Benzoyl-4″,6″-O-cyclohexylidene-3′-deoxy-penta-N-ethoxycarbonylkanamycin B (**7**).* To a solution of **6** (133 mg) in dioxane (1.3 ml), Raney nickel was added and the mixture was hydrogenated (50 p.s.i.) at room temperature for 1.5 h. After filtration, the solution was treated as above with fresh Raney nickel 3 times more in every 1.5 h intervals. Concentration of the solution gave a solid of **7** (114 mg, 96%), $[\alpha]_D^{20}$ +86° (*c* 0.76, methanol).

Found: C, 54.58; H, 6.80; N, 6.84%. Calcd for $C_{46}H_{69}N_5O_{20}$: C, 54.59; H, 6.87; N, 6.92%.

*3′-Deoxykanamycin B (**10**).* A mixture of **7** (90.6 mg) and barium hydroxide ($Ba(OH)_2 \cdot 8H_2O$, 650 mg) in decarbonated water (0.7 ml) was stirred at 100 °C for 10 h. The solution showed, on PPC, two spots of R_f 0.16 (**8**, major) and 0.22 (**9**, minor), and, on paper electrophoresis, also showed two spots (R_f of **9** is 0.79 of that of **8**). After addition of 5% aqueous sulfuric acid (2.0 ml), the mixture was stirred at 50 °C for 1.5 h. Barium sulfate precipitated was removed by filtration and it was washed with hot water thoroughly. The filtrate and washings were combined, concentrated, and, to the concentrate, acetone was added to give a pale brown solid. The crude **8** (64.3 mg) was dissolved in 50% acetic acid (0.65 ml) and the solution was heated at 80 °C for 3 h. The solution was concentrated and then concentrated with additions of water to give a pale brown solid (62 mg). The aqueous solution of the solid was subjected to column chromatography of Dowex 1X2 (OH form, 1.1 ml) resin with water and from the eluate, colorless solid (free base, 37.5 mg) was obtained. The solid was chromatographed on a column of CM-Sephadex C-25 (NH_4 form) with 0—0.15 M ammonia, the concentration being linearly increased. From the faster moving fractions, an unidentified compound (9.3 mg, a ureido-type compound?) was obtained, and from the slower moving fractions, 3′-deoxykanamycin B base (**10**) was isolated as a monohydrate, 28.5 mg (65%), $[\alpha]_D^{20}$ +129° (*c* 1, water) (lit,[8] +128°). $R_{f\ \text{kanamycin B}}$ 1.25 (PPC, by solvent A).

Found: C, 44.92; H, 8.09; N, 14.61%. Calcd for $C_{18}H_{37}N_5O_9 \cdot H_2O$: C, 44.53; H, 8.10; N, 14.43%.

NMR (D_2O) δ: 1.1—2.3 (4H m, H-2 and 3′).

*3′-Deoxyneamine (**11**).* Compound **10** (100 mg as base) was dissolved in 6 M hydrochloric acid (2 ml) and the solution was heated at 100 °C for 2 h. The solution showed, on PPC, five spots of R_f 0.3 (3-amino-3-deoxy-D-glucose), 0.16 (trace, 2,6-diamino-2,3,6-trideoxy-D-ribohexose), 0.12 (trace, 2-deoxystreptamine), 0.06 (**11**), and 0.03 (trace, **10**). After concentration, the resulting syrup was chromatographed on a column of Dowex 1X2 (OH form) resin with water. The free sugars were retained in the column. The eluate was concentrated and the resulting syrup was chromatographed on a column of CM-Sephadex C-25 (NH_4 form) with 0—0.15 M ammonia, the concentration being linearly increased. 2-Deoxystreptamine (0.5 mg), **10** (6.1 mg) and **11** (54 mg, 78%) were eluted in the order of mobility. 3′-Deoxyneamine (**11**), $[\alpha]_D^{20}$ +122° (*c* 0.3, water); $[\alpha]_{436}^{20}$ +230° (*c* 0.3, water), $[\alpha]_{436}^{20}$ +430° (*c* 0.3, TACu[13]); $\Delta[M]_{TACu}$ is +648°.

Found: C, 44.39; H, 8.30; N, 17.26%. Calcd for $C_{12}H_{26}N_4O_5 \cdot H_2O$: C, 44.43; H, 8.70; N, 17.27%.

Coenzyme Models. VII. Micellar Catalysis of Acid-Catalyzed Hydration of 1-Dodecyl-1,4-Dihydronicotinamide*

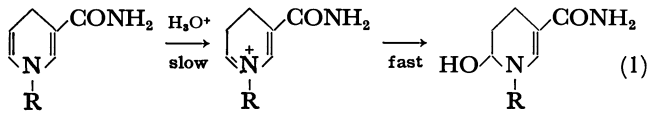
Seiji SHINKAI, Reiko ANDO, and Toyoki KUNITAKE

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received July 26, 1976)

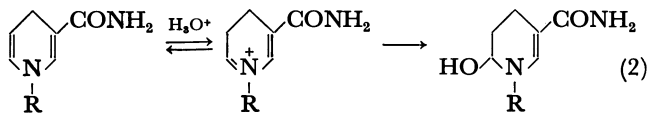
The acid-catalyzed hydration reaction of 1-dodecyl-1,4-dihydronicotinamide was examined in cationic(CTAB) and anionic (SDS) micelles. The H_3O^+-catalysis(k_H) was negligibly small in the presence of the CTAB micelle and 225—521 M^{-1} s^{-1} in the presence of the SDS micelle, the difference being about 10^7-fold. The catalysis by carboxylic acids (k_{HA}) was considerably suppressed in the CTAB micelle, but was promoted in the SDS micelle, suggesting the development of a cationic charge on a nitrogen atom of dihydropyridine at the rate-determining step. Brönsted plots for log k_{HA} in the CTAB and SDS micelles *vs.* pK_a of carboxylic acids gave straight lines with the slope of −0.8, the line for SDS being higher by two orders of magnitude than that for CTAB. These results indicate that a cationic charge (*e.g.*, the lysine residue of alcohol dehydrogenase located very close to the bound NADH) may protect the NADH from hydration decay.

It has been established that NADH (reduced form of nicotinamide adenine dinucleotide) and its model compounds, 1,4-dihydronicotinamide derivatives rapidly decompose in aqueous acidic media.[1] The decomposition causes shifts of the characteristic UV absorption band of dihydronicotinamides in the 340—360 nm region downward to around 290 nm with isosbestic points.[1] The 290 nm-absorbing compound was later confirmed to be a 6-hydroxy-1,4,5,6-tetrahydronicotinamide by X-ray crystallography.[2] The following reaction scheme (Eq. 1 or 2) was thus suggested by Johnston and others,[1] in which the protonation of dihydronicotinamide is involved in the rate-determining step.



(1)

or



(2)

The biological importance of this reaction was pointed out by Meinhart and co-workers,[3] since NADH bound to glyceraldehyde-3-phosphate dehydrogenase is characterized by a change in the UV spectrum similar to that of the acid-catalyzed hydration of dihydronicotinamides.

In the previous paper,[4] we demonstrated a striking effect of micelles on the acid-catalyzed hydration of 1,4-dihydronicotinamide derivatives. The hydration rates were accelerated by an anionic micelle of sodium dodecylsulfate (SDS), in accord with the fact that the anionic environment would result in the acceleration of the protonation step in the hydration reaction as seen in acetal hydrolyses.[5,6] On the contrary, a cationic micelle of cetyltrimethylammonium bromide (CTAB) pronouncedly depressed the hydration rate of 1-dodecyl-1,4-dihydronicotinamide (NDNH; R=$CH_3(CH_2)_{11}$–); the rate being 414-fold slower than that in SDS. To our knowledge this was the first example that the reaction involving NADH analogs is subject to the microenvironmental effects.

* Contribution No. 394 from this Department.

In this paper, we wish to report further investigations on the micellar catalysis of the hydration reaction, which was conducted in order to evaluate the respective rate constants for three catalytic species, water, oxonium ion, and buffer acid in the presence of micelles. NDNH was employed as substrate, since it undergoes the largest micellar effect in the hydration reaction.[4] Surfactants chosen were CTAB and SDS.

Surfactants: $CH_3(CH_2)_{11}SO_4Na$ (SDS)

$CH_3(CH_2)_{15}N^+(CH_3)_3Br^-$ (CTAB)

Experimental

Materials. Surfactants were products of Wako Pure Chemical Ind. SDS (biochemical use) was used without further purification. CTAB was recrystallized from ethanol before use. Preparation of NDNH was reported previously.[4]

Kinetics. The kinetic measurements were carried out at 30±0.1 °C at a calculated ionic strength (with KCl) using a Hitachi 124 spectrophotometer. The reaction was initiated by mixing NDNH (alcohol solution) with a buffered, aqueous solution of surfactant, and the rate of hydration was estimated by monitoring the disappearance of absorbance at 357 nm, which is characteristic of 1,4-dihydronicotinamides. The pseudo-first-order rate constants (k_{obsd}) thus obtained can be satisfactorily described by Eq. 3, in which k_0 is the reaction rate with water, and k_H and k_{HA} are the catalytic constants for oxonium ion and buffer acid, respectively.

$$k_{obsd} = k_0 + k_H[H_3O^+] + k_{HA}[HA] \quad (3)$$

One can separately determine $k_0+k_H[H_3O^+]$ and k_{HA} from the slope and the intercept of k_{obsd} *vs.* [HA] plots.[1] Although it was desirable to lower the ionic strength as much as possible in order to obtain large micellar effects, the data measured in the absence of added salts did not give linear plots: the lower the buffer concentration, the faster is the rate of hydration. When ionic strength (defined here as $[A^-]$+[KCl added], the concentration of surfactants was always held constant above their CMC) was maintained constant, the plots showed excellent linear relationships ($r>0.99$). Thus, the two kinetic term could be determined by the least-squares method.

Results

Hydration Reaction in the Presence of the CTAB Micelle. In Fig. 1, pseudo-first-order rate constants (k_{obsd}) for the

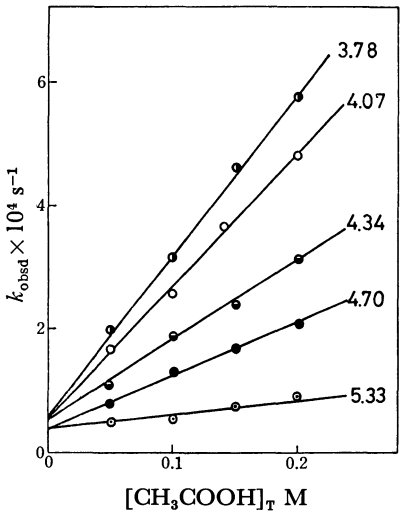


Fig. 1. Pseudo-first-order rate constants for hydration of NDNH in the presence of 1.0×10^{-3} M CTAB plotted as a function of the concentration of acetic acid. 30 °C, μ=0.2, 8.7 vol% ethanol. Numbers in Figure denote pH values.

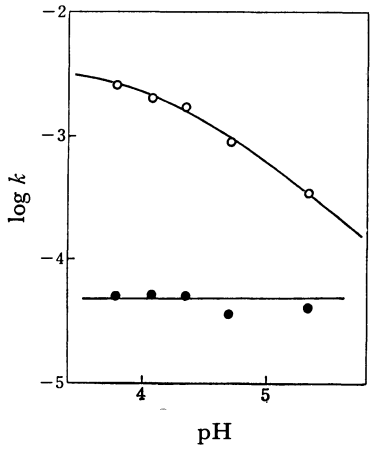

Fig. 2. pH *vs.* log $k_{HA} \cdot [CH_3COOH]_T$ (○) and log $(k_0 + k_H[H_3O^+])$ (●) for the CTAB catalysis.

hydration of NDNH in the presence of the CTAB micelle were plotted against the total concentration of acetic acid, $[CH_3COOH]_T = [CH_3COOH] + [CH_3COO^-]$. The concentration of surfactant ($[CTAB] = 1.0 \times 10^{-3}$ M) and ionic strength (μ=0.2) were kept constant. The slope, which corresponds to the buffer-catalyzed term (Eq. 3), increased with lowering pH. In contrast, the intercepts which are equal to the sum of k_0 and $k_H[H_3O^+]$ were found to be essentially independent on pH. Figure 2 gives the plots of logarithmic rate constants against pH. The apparent, buffer-catalyzed term (k_{HA}') showed a kinetic pK_a at around 4.60, which is in accord with the potentiometric pK_a value (4.62) of acetic acid. Thus, the true second-order rate constant (k_{HA}) for the undissociated species of acetic acid can be related to k_{HA}' by Eq. 4,

$$k'_{HA} = \frac{a_H}{K_a + a_H} k_{HA} \qquad (4)$$

where K_a denotes the acid dissociation constant of acetic acid. The solid curve in Fig. 2 was depicted from Eq. 4 by using pK_a=4.62 and $k_{HA} = 3.81 \times 10^{-3}\ M^{-1}\ s^{-1}$.

Since the $k_0 + k_H[H_3O^+]$ term is not dependent on pH, the k_H term must be negligibly small in the presence of the CTAB micelle, and the k_0 term is equal to $5.0 \times 10^{-5}\ s^{-1}$ under the given condition.

Hydration Reaction in the Presence of the SDS Micelle. It has been noted that the hydration rate of 1,4-dihydropyridine derivatives is conspicuously accelerated in the presence of the SDS micelle at extremely low ionic strength.[4] However, this rate acceleration by the SDS micelle is suppressed at higher ionic strengths (Fig. 3), and the hydration rate of NDNH in the SDS micelle at $([CH_3COOK] + [KCl]) > 0.01$ is not much different from that of 1-propyl-1,4-dihydronicotinamide in a non-micellar system (*vide post*).

Buffer dilution and pH change were carried out at $([CH_3COOK] + [KCl]) = 0.03$. The pH of the reaction mixture was confirmed not to vary from pH measurements before and after the reaction. At lower ionic strengths, it was extremely difficult to maintain the pH

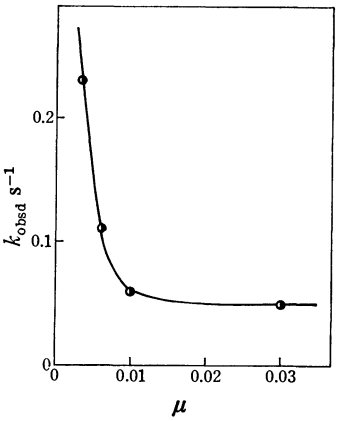

Fig. 3. Pseudo-first-order rate constants for hydration of NDNH in the presence of 5.0×10^{-2} M SDS plotted as a function of ionic strength. 30 °C, 8.7 vol% ethanol, pH 3.80.

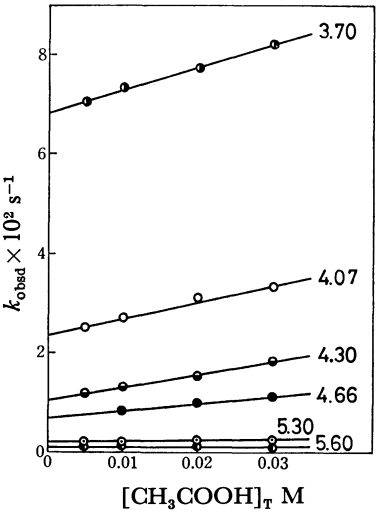

Fig. 4. Pseudo-first-order rate constants for hydration of NDNH in the presence of 5.0×10^{-2} M SDS plotted as a function of the concentration of acetic acid. 30 °C, μ=0.03, 8.7 vol% ethanol. Numbers in figure denote pH values.

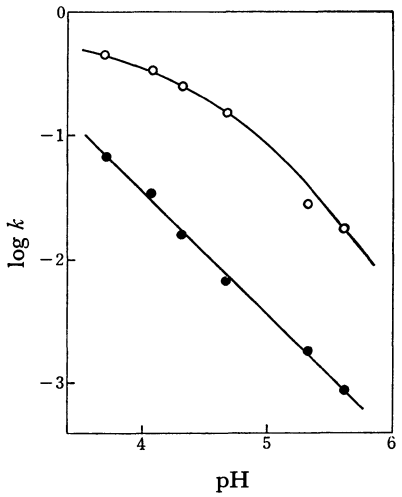

Fig. 5. pH *vs.* log $k_{HA}\cdot[CH_3COOH]_T$ (○) and log $(k_0+k_H[H_3O^+])$ (●) for the SDS catalysis.

of the reaction system constant. The results are illustrated in Fig. 4. Excellent linear correlations are demonstrated between k_{obsd} and $[HA]_T$ (correlation coefficient better than 0.99 in all cases). The hydration reaction in the presence of the SDS micelle is catalyzed by both H_3O^+ and HA, since both of the slope and the intercept increase by lowering pH of the reaction system in Fig. 4. The k_{HA}'-pH plots of Fig. 5 showed a kinetic pK_a at 4.68, which again coincides with the potentiometric pK_a of acetic acid (4.62). The theoretical curve in Fig. 5 was obtained from Eq. 4 for $k_{HA}=0.581$ M^{-1} s^{-1} and $pK_a=4.68$, which produced the best fit to the experimental plots.

Figure 5 also gives log $(k_0+k_H[H_3O^+])$ plotted against pH. The linear relation of slope of −1.0 indicates that the H_3O^+-catalysis is predominant, and the following rate constants are obtained: $k_0\approx 0$ s^{-1} (negligibly small compared with the $k_H[H_3O^+]$ term) and $k_H=341$ M^{-1} s^{-1}.

The rate constants determined by the acetate-buffer dilution and by the pH change are summarized in Table 1.

Hydration Catalyzed by Miscellaneous Carboxylic Acids. Five different carboxylic acids were examined as buffer in addition to acetic acid, *i.e.* α-chloroacetic acid, malonic acid, decanoic acid, hippuric acid, and isobutyric acid. Buffer dilutions were carried out at one pH at the constant surfactant concentration. From the slope and the intercept were determined the rate constants for each carboxylic acid, and the k_{HA} values were evaluated by using the potentiometric pK_a values. The results are recorded in Table 2. It is seen from Table 2 that the k_H terms are again suppressed by the CTAB micelle. It is also worth mentioning that the k_{HA} values in the presence of the CTAB micelle are decreased by more than 100 times as compared with those in the presence of the SDS micelle.

Table 1. Rate constants for the hydration reaction of NDNH catalyzed by acetic acid at 30 °C

Micelle	k_0 s^{-1}	k_H $M^{-1}s^{-1}$	k_{HA} $M^{-1}s^{-1}$
None[a)]	d)	260	0.15
CTAB[b)]	5×10^{-5}	$\sim0(<10^{-4})$	0.00381
SDS[c)]	d)	341	0.581

a) Determined for 1-propyl-1,4-dihydronicotinamide; 25 °C, $\mu=0.48$.[1)] b) $[CTAB]=1.0\times10^{-3}$ M, $\mu=0.2$ (KCl), 8.7 vol% ethanol. c) $[SDS]=5.0\times10^{-3}$ M, $\mu=0.03$ (KCl), 8.7 vol% ethanol. d) Too small to determine as compared with other terms.

Discussion

Since NDNH is not soluble by itself in aqueous solutions, one may assume that it is solubilized in the micellar phase. This assumption is very important in discussing the micellar catalysis, for partitioning of the substrate between the micellar phase and the bulk phase frequently gives rise to complications of the micellar systems.

Although our previous study showed that an anionic micelle accelerated the hydration reaction and that an cationic micelle decelerated,[4)] the contribution of each catalytic species, water, oxonium ion, and buffer acid, remained ambiguous. The k_0 value of 1-propyl-1,4-dihydronicotinamide in a non-micellar system was previously evaluated to be 2.6×10^{-5} s^{-1} (25 °C)** by Johnston and co-workers.[1)] This value is very close to

Table 2. Rate constants for the hydration reaction of NDNH catalyzed by various carboxylic acids at 30 °C

Carboxylic acid	pK_a[a)]	Rate Constant in SDS k_H $M^{-1}s^{-1}$	SDS k_{HA} $M^{-1}s^{-1}$	CTAB $k_0\times10^5$ s^{-1}	CTAB k_H $M^{-1}s^{-1}$	CTAB k_{HA} $M^{-1}s^{-1}$
1. $ClCH_2COOH$	2.84	521	12.3	5	~0	0.0810
2. $C_6H_5CONHCH_2COOH$	3.10	494	7.67

4. $CH_3(CH_2)_8COOH$	4.82	304	0.905			
5. *iso*-C_3H_7COOH	4.86	311	0.641	5	~0	0.00203
6. $^-OOCCH_2COOH$	5.65	225	0.0368	3	~0	0.00085

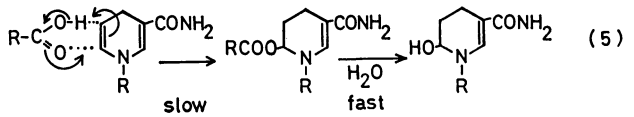
a) Determined potentiometrically in the absence of micelles at 30 °C.

** Johnston *et al.*[1)] reported $k_{H_2O}=4.7\times10^{-7}$ M^{-1} s^{-1}. This value was multiplied by 55 to give $k_0(s^{-1})$.

$k_0=5.0\times10^{-5}$ s^{-1} obtained for NDNH in the presence of the CTAB micelle. Therefore, the k_0 term is little affected by the micelle. On the other hand, the results shown in Table 1 clearly demonstrate that rate suppression observed in the CTAB micelle is largely derived from the lack of the H_3O^+-catalysis. Apparently, oxonium ion cannnot catalyze the hydration reaction of 1,4-dihydronicotinamide if it is trapped in the Stern layer of the CTAB micelle ($k_H\approx0$). It has been noticed that cationic micelles have inhibitory effect upon the acid-catalyzed reactions. Typical examples are seen in the hydrolyses of orthoesters and acetals which involve proton transfer from the acid to the substrate.[7]

Table 1 shows that the k_{HA} value for acetic acid is *ca.* 40-fold smaller in the CTAB micelle than in the nonmicellar system. This term is associated with the catalysis by neutral species (undissociated acetic acid), so that it is unlikely that this rate suppression is related to the proximity effect of the micelle. Instead, this would reflect the fact that the formation of such a positively charged intermediate be destabilized by the cationic environment of the CTAB micelle.

An alternate reaction mechanism for the k_{HA} term involves a concerted catalysis.[1] Carboxylic acids can donate both a proton and an anion simultaneously as shown in Eq. 5. This possibility cannot be ruled out kinetically because it is equivalent to Eqs. 1 and 2.



(5)

As can be seen from Eq. 5, the concerted mechanism produces a less charged intermediate. The pronounced lowering of the k_{HA} value observed in the presence of the CTAB micelle is incompatible with this supposition. Therefore, the concerted reaction is unlikely under the present condition. Johnston *et al.*[1] and Kim and Chaykin[2] are similarly against the concerted mechanism.

The SDS micelle enhanced both the k_H and k_{HA} values. Apparently, the magnitude of the rate enhancements is not very large because of the use of high ionic strength which suppresses the reaction. The high ionic strength was necessitated due to the high buffer concentration employed. As shown in Fig. 3, the k_{obsd} value rapidly increased with decreasing ionic strength. This rate variation is probably related to the change in the k_H term, for oxonium ion would be adsorbed on the SDS micelle in competition with added salts. Unfortunately, however, the k_H value at the very low ionic strength could not be evaluated (see Experimental section).

Figure 6 gives Brönsted plots for the k_{HA} term in micellar systems. Both plots gave approximately linear relations with the slope of -0.8, and the difference in the intercept between CTAB and SDS was about two orders of magnitude. The SDS micelle provides much more favorable environments for the carboxylic acid-catalyzed hydration reaction than the CTAB micelle.

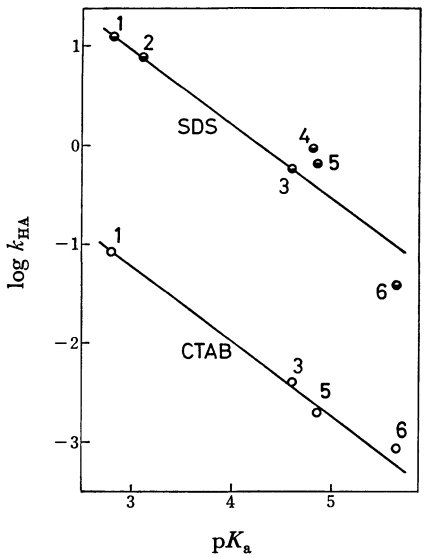


Fig. 6. Brönsted relationship. Numbers in figure correspond to carboxylic acids in Table 2.

This difference would become more conspicuous by lowering the ionic strength of the reaction system.

The plot for malonic acid (Fig. 6) was lowered by the 0.4 log unit in the relation for the SDS micelle. In contrast, the plot for malonic acid is slightly deviated to the upper part from the CTAB line, the deviation, however, being rather small. These deviations are obviously due to electrostatic repulsion and attraction, respectively.*** and would be more clearly demonstrated at the lower ionic strength.

In conclusion, the acid-catalyzed hydration reaction of 1,4-dihydronicotinamides is very sensitive to the micellar environmental effects. In particular, the k_H value in the presence of the CTAB micelle is suppressed by a factor of 10^7 as compared with the nonmicellar system. Similarly, the reactivity of NADH and its analogs must be greatly affected by the enzymatic microenvironments.

Coenzyme Models. VIII. Reduction of the Schiff Base of Pyridoxal Analogs by 1,4-Dihydronicotinamide*

Seiji SHINKAI, Sumihiro SHIRAISHI, and Toyoki KUNITAKE

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka, 812

(Received July 26, 1976)

Reduction of Schiff bases by 1-benzyl-1,4-dihydronicotinamide (BzlNH) was performed in refluxing methanol. Protonated imines such as *N*-(*p*-nitrobenzylidene)benzylamine hydrochloride (**1H**$^+$) and *N*-(4-nitrosalicylidene)-benzylamine hydrochloride (**1(OH)H**$^+$) were reduced to the corresponding aminomethyl derivatives. The NMR product analysis for the reaction of BzlNH and **1H**$^+$ in refluxing ethanol-*d* established that the solvent deuteron was not incorporated into the aminomethylene product. **1(OH)**, unprotonated species, was partially reducible, whereas **1** was totally unreactive. The facile reduction of **1** occurred in the presence of several amine hydrochlorides ($NEt_3 \cdot HCl$, imidazole hydrochloride, *N,N,N',N'*-tetramethylethylenediamine dihydrochloride). These results show that the *ortho* hydroxyl group of **1(OH)** facilitates imine reduction not only by polarization of the Schiff base *via* hydrogen bonding but also by proton transfer. The relative reactivity of the Schiff base to the BzlNH reduction is: **1H**$^+$, **1**$+NEt_3 \cdot HCl \geqq$**1(OH)H**$^+ >$**1(OH)**$>$**1**(unreactive) This order is similar to that found in "*trans*-Schiffization" between semicarbazide and the Schiff base of pyridoxal and its analogs, as reported by Cordes and Jencks.

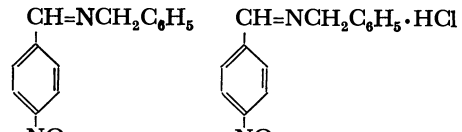
The nicotinamide adenine dinucleotide and its reduced form (NAD and NADH) serve as coenzymes in a very large number of enzymatic oxidation-reduction reactions.[1] As for example, NAD-dependent dehydrogenases catalyze the stereospecific, direct transfer of a hydride ion (or its equivalent) to aldehyde substrates.[2] Steffens and Chipman[3] and Creighton *et al.*[4] proposed a kinetically detectable complex as an intermediate along the reaction path in model systems. Contrary to this proposition, Kurz and Frieden[5] concluded that the enzyme-substrate transition state is analogous to that pictured for simple S_N2 nucleophilic substitution with "hydride" ion acting as the nucleophilic agent. In any case, it is clear that substantial charge transfer from NADH to substrate occurs in the rate-determining step, and that substrates are significantly activated by electron-withdrawing substituents.

The enzymatic reduction of pyridoxal-5'-phosphate has been investigated in detail.[6,7] Recently, it was reported that the nonenzymatic reduction of pyridoxal and its analogs by 1,4-dihydropyridines did occur at ambient conditions and that the *ortho*-hydroxyl group facilitated the "hydride" acceptability of the carbonyl group.[8-10] Intrestingly, the reduction rate for the respective pyridoxal species was parallel to the rates of other reactions which were catalyzed by these pyridoxals; imine formation, general base-catalyzed *trans*-amination, *etc.*[10]

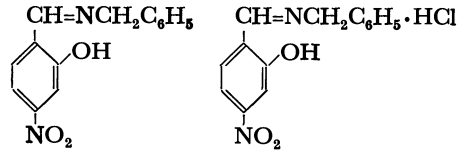
Imines show higher affinities toward the carbonyl agents than the corresponding carbonyl compounds.[11,12] A typical example would be a "*trans*-Schiffization" reaction demonstrated by Cordes and Jencks.[12] According to their detailed examination, the Schiff base is inherently more reactive than pyridoxal-5'-phosphate toward semicarbazide, and the protonated Schiff base is further activated. These results suggest that protonated imines (iminium salts) would be suitable substrates for the reduction by NADH. In fact, the enzymatic reduction of the iminium group of N^5,N^{10}-methenyl-tetrahydrofolic acid to N^5,N^{10}-methylene-tetrahydrofolic acid by NADPH,[13] and the nonenzymatic reduction of a thiazolium salt (Vitamin B_1 analogue)[14] and the iminium group of steroid derivatives to the corresponding amine[15] have been reported.

The object of the present investigation is to examine the reaction of 1-benzyl-1,4-dihydronicotinamide (BzlNH) with the Schiff base of pyridoxal analogs, *p*-nitrobenzaldehyde and 4-nitrosalicylaldehyde, and to establish the relative susceptibility of these Schiff bases toward the "hydride" reduction. In order to avoid the complication which arises from the reversible imine formation, we isolated Schiff bases, *p*-nitrobenzylidene-benzylamine (**1**), *N*-(4-nitrosalicylidene)benzylamine (**1** (**OH**)), and their hydrochlorides (**1H**$^+$ and **1(OH)H**$^+$, respectively), and carried out the reaction in refluxing anhydrous methanol.

Schiff base:

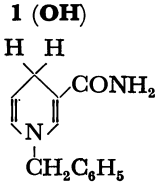


1 **1 H**$^+$



1 (OH) **1 (OH)H**$^+$

BzlNH:



Experimental

Materials. 4-Nitrosalicylaldehyde was prepared according to the method of Tsumaki *et al.*,[16] and was identified by the NMR and IR (KBr disc) methods, and by the elemental analysis. Mp 134—135 °C (lit,[16] 133—134 °C. Found: C, 50.43; H, 3.02; N, 8.40%. Calcd for $C_7H_5O_4N$: C, 50.31; H, 3.02; N, 8.38%.

* Contribution No. 404 from this Department.

The preparation of Schiff bases was conducted according to the Matsuo's method.[17] Equimolar amounts of aldehyde and benzylamine were refluxed in anhydrous methanol for 1 h. The solvent was evaporated *in vacuo*, and the residual yellow solid was recrystallized from benzene and petroleum ether. The products were identified by NMR and IR spectroscopies and elemental analysis. Elemental analysis for **1** (**OH**), Found: C, 65.48; H, 4.70; N, 10.92%. Calcd for $C_{14}H_{12}N_2O_3$: C, 65.61; H, 4.73; N, 10.93%. Other results are summarized in Table 1.

Table 1. Characterization of Schiff bases and their hydrochloride salts

	Mp (°C)	IR (KBr) $\nu_{C=N}$ (cm^{-1})	NMR ($CDCl_3$) N-CH_2- (ppm)	NMR ($CDCl_3$) N=CH-
1	54—55	1635	4.84	8.35
1H$^+$	105—110			
1(OH)	88—89	1630	4.81	8.45
1(OH)H$^+$	176—179	1660		

The Schiff base was dissolved in anhydrous ether, and dry hydrogen chloride gas was introduced into the solution. White needles precipitated were collected, and recrystallized from anhydrous methanol. The analytical results are also recorded in Table 1.

N-Benzyl-4-nitro-2-hydroxybenzylamine hydrochloride (**2(OH)H**$^+$), the product expected for the BzlNH reduction of **1(OH)H**$^+$, was prepared by the sodium tetrahydroborate reduction of **1(OH)**. A solution of **1(OH)** (0.40 g, 1.6 mmoles) in 20 ml of methanol was stirred at 0—5 °C and a solution of sodium tetrahydroborate (0.06 g, 1.6 mmoles) in 10 ml of methanol was added from a dropping funnel. Subsequently, the reaction mixture was heated at 45 °C on a steam bath for 6.5 h. The solvent was evaporated *in vacuo*, the residual brown solid being extracted with water and ether. The ether layer was separated, and evaporated to dryness. The solid was again taken in anhydrous ether, from which (**2(OH)H**$^+$) was recovered by introducing dry hydrogen chloride gas. Recrystallization of the resulting precipitates from methanol–ether gave colorless powders; yield 21%, mp 210—213 °C. IR (KBr): 1525, 1340 cm^{-1} (nitro). NMR (Me_2SO-d_6): benzyl-CH_2, 4.13, 4.20 ppm, 4H; benzene rings, 7.3—7.8 ppm, 8H. Found: C, 56.93; H, 5.12; N, 9.43%. Calcd for $C_{14}H_{14}N_2O_3 \cdot HCl$: C, 57.05; H, 5.13; N, 9.45%.

The preparation of 1-benzyl-1,4-dihydronicotinamide (BzlNH) was described elsewhere.[18]

Reaction of Schiff Base and BzlNH. All the reactions were carried out in refluxing anhydrous methanol. A typical example for the reaction of **1H**$^+$ and BzlNH is stated below. A solution of **1H**$^+$ (0.64 g, 2.3 mmoles) and BzlNH (0.72 g, 3.4 mmol) in 20 ml of anhydrous methanol was refluxed for 9.5 h. The solvent was evaporated *in vacuo*, and residual oil was extracted with ether and water (pH 9 with *ca.* 0.05 M borate and 1 mM triethylamine hydrochloride). The ether layer was evaporated to dryness, again taken in ether, and dry hydrogen chloride gas was introduced. Recrystallization of the light yellow precipitates from methanol–ether gave almost colorless powders; yield 19%, mp 210—220 °C. The product was identified to be *N*-benzyl-*p*-nitrobenzylamine hydrochloride (**2H**$^+$). IR (KBr): 1510, 1350 cm^{-1} (nitro). NMR (Me_2SO-d_6): benzyl-CH_2, 4.17, 4.30 ppm, 4H; benzene ring, 7.3—7.6 ppm, 5H; *o*-proton of benzene ring, 7.87 ppm, 2H; *m*-proton of benzene ring, 8.25 ppm, 2H. Found: C, 59.55; H, 5.40; N, 9.78%. Calcd for $C_{14}H_{14}N_2O_2 \cdot HCl$: C, 60.33; H, 5.42; N, 10.05%.

Product Analysis. NMR was recorded by using a Varian A-60 instrument. The purity of the recovered products was examined by a Hitachi High Speed Liquid Chromatograph, Type 635 (Hitachi Gel 3018, methanol). UV absorption spectra were taken by a Hitachi 124 spectrophotometer at 30 °C.

Results

Spectral Study of the Reaction. The decrease in the absorption of BzlNH in refluxing methanol was followed at 354 nm (λ_{max} of BzlNH) in the absence and the presence of the Schiff base, **1** or **1(OH)** (Fig. 1).

Aliquots (3 ml) of the reaction mixture were withdrawn at appropriate intervals and scanned in the UV range at 30 °C. Figure 2 shows that the absorption of BzlNH decreases in the presence of **1(OH)**. In contrast, no significant spectral change was observed in the presence of **1** and in the absence of the Schiff base. The absorbance decrease at 354 nm in the presence of **1(OH)** was accompained by the increase in the absorption band at 250—280 nm and at 400—440 nm, but no significant increase occurred near 290 nm (Fig. 1). If the acid-catalyzed decomposition of 1,4-dihydronicotinamide occur, the product (1,4,5,6-tetrahydronicotinamide derivative) would give rise to a new, strong absorption at around 290 nm.[18-20] Therefore, the decrease in the BzlNH absorbance may be attributed to the disappearance of BzlNH due to the hydrogen transfer reaction. Apparently, the *ortho*-hydroxyl group facilitates the reaction, as in the pyridoxal-catalyzed reactions.

Reaction of BzlNH with Schiff Bases and Their Hydrochloride Salts. Introduction of hydrogen chloride gas to an ether solution obtained from the reaction of

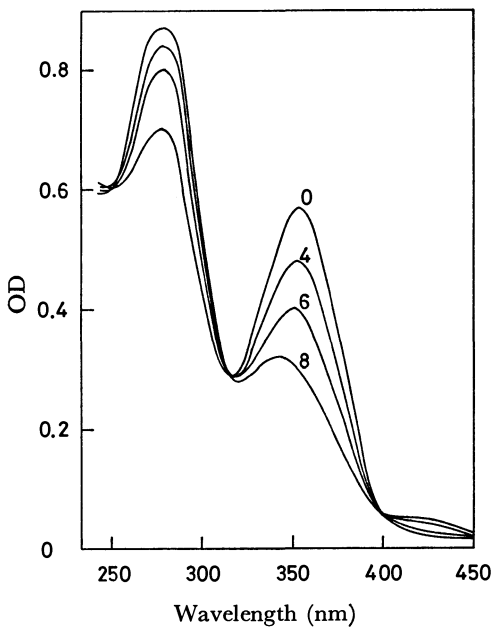


Fig. 1. Spectral changes in the reaction of 1-benzyl-1,4-dihydronicotinamide (BzlNH: 5.65×10^{-5} M) with 4-nitrosalicylidene–benzylamine (**1(OH)**: 5.34×10^{-5} M) in refluxing methanol. Numbers indicate the reaction time (h).

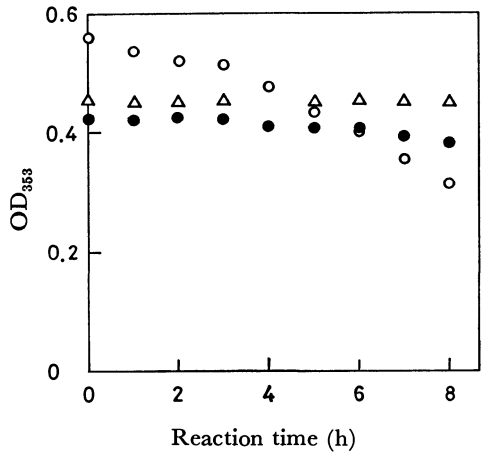

Fig. 2. Time dependence of the absorbance of BzlNH (353 nm) in the presence and the absence of the Schiff base:
○: [BzlNH]=5.65×10^{-5} M, [**1**(**OH**)]=5.34×10^{-5} M; ●: [BzlNH]=5.65×10^{-5} M, [**1**]=5.50×10^{-5} M; △: [BzlNH]=5.65×10^{-5} M.

1(**OH**) and BzlNH gave oily products. A TLC study (silica gel, ethyl acetate) showed that the oil is a mixture of *N*-benzyl-4-nitro-2-hydroxybenzylamine hydrochloride, **2**(**OH**)**H**$^+$ (R_f=0.64—0.65), **1**(**OH**)**H**$^+$ (R_f=0.40—0.42), and BzlNH or 1-benzylnicotinamide (R_f=0—0.23). The product analysis by liquid chromatograph (Table 2) established that it contained 38 mol% of **2**(**OH**)**H**$^+$ and 62 mol% of **1**(**OH**)**H**$^+$ (Table 2; the amount of BzlNH could not be determined because its retention time was too long).

On the other hand, the product obtained from the reaction of **1** and BzlNH displayed a broad melting point (135—156 °C), and was identified to be a mixture of benzylamine hydrochloride and BzlNH by liquid chromatography. These results, together with the spectral evidence, are explained by reaction schemes 1 and 2.

Table 2. Product analysis of the reaction of BzlNH and schiff bases

Schiff base	Recovered products[a] (%)				Yield of the reduced product (%)[c]
	$PhCH_2NH_2$·HCl	**2**H$^+$	**1**(**OH**)**H**$^+$	**2**(**OH**)**H**$^+$	
1	100	0			0
1+NEt_3·HCl[b]	0	100			26
1+Imidazole·HCl[b]	0	100			15
1+$(Me_2NCH_2)_2$·2HCl[b]	0	100			13
1H$^+$	0	100			19
1(**OH**)			62	38	
1(**OH**)+NEt_3·HCl[b]			79	21	
1(**OH**)**H**$^+$			7	93	8

a) Semi-quantitative analyses were performed by using high speed liquid chromatography: 260 nm for **2H**$^+$ and 280 nm for **1**(**OH**)**H**$^+$ (ε=18180) and **2**(**OH**)**H**$^+$ (ε=5980). b) [Amine hydrochloride]=*ca.* 10 [Schiff base]. c) Determined after recrystallization for **2H**$^+$. The low yields are due to the loss in the extraction with ether, products being poorly soluble in ether.

The hydrochloride of Schiff bases was more easily reduced by BzlNH. **1**(**OH**)**H**$^+$ was converted almost exclusively to **2**(**OH**)**H**$^+$ (93%, Table 2). Interestingly, **1H**$^+$ was also susceptible to the BzlNH reduction, though the free Schiff base was totally unreactive. The product showed a single spot (R_f=0.71) on TLC, and was confirmed to be pure *N*-benzyl-*p*-nitrobenzylamine hydrochloride, **2H**$^+$ (see Experimental). Thus, the role of the *ortho*-hydroxyl group becomes less important if the Schiff base is activated by protonation.

In order to prove direct hydrogen transfer from BzlNH to the Schiff base, the reaction of BzlNH and **1H**$^+$ was performed in ethanol-*d* (99%). The recovered **2H**$^+$ (24% yield, mp 207—222 °C) again showed a single spot on TLC. As described in Experimental, the NMR spectrum of **2H**$^+$ obtained in non-deuterated ethanol possessed the peaks of the methylene hydrogen at 4.17 and 4.30 ppm (δ) with 1 : 1 intensity. The NMR spectrum of **2H**$^+$ obtained in ethanol-*d* possessed similar methylene peaks. These results prove that no deuterium was incorporated to the 1-methylene group in the reaction in the deuterated medium. Therefore, the reduction of the Schiff base must occur *via* direct hydrogen transfer as in some enzymatic reductions.[2]

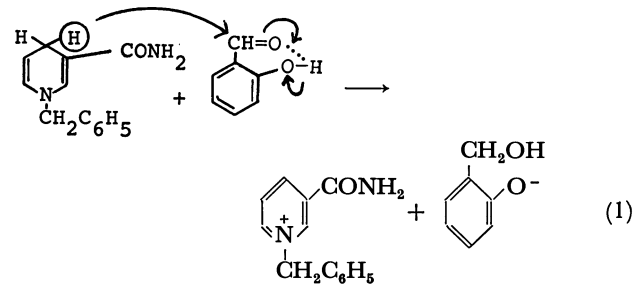
Reaction in the Presence of Amine Hydrochlorides. The susceptibility of the Schiff base to the BzlNH reduction was evaluated in the presence of amine hydrochlorides such as triethylamine hydrochloride. The reduction of **1**(**OH**) was hardly affected by the addition of triethylamine hydrochloride (10-fold of **1**(**OH**); Table 2). In contrast, **1** was readily converted to **2H**$^+$ in the presence of triethylamine hydrochloride in 23% yield. Other hydrochlorides similarly facilitated the reduction of **1**. Therefore, these hydrochlorides may replace the role played by the *ortho*-hydroxyl group of **1**(**OH**).

Discussion

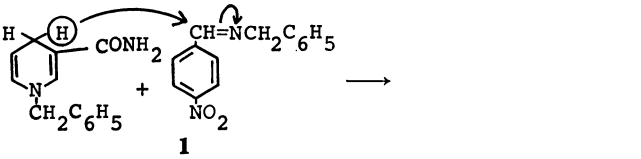
Until recently, the nonenzymatic reduction by 1,4-dihydropyridines has been limited to highly electron-deficient carbonyl compounds such as hexachloroacetone,[21] trifluoroacetophenone,[3] chloranil,[22] thiobenzophenone,[23] *etc.* Some alcohol dehydrgenases contain Zn(II) at the active site,[24] and the chelation and hydrogen bonding with substrates facilitate the hydrogen transfer.[25] The use of these interactions to facilitate NADH-mediated oxidation-reduction reactions has largely escaped attention in model studies. More recently, however, the nonenzymatic transformation of the carbonyl group to the corresponding alcohol was found to be significantly catalyzed by Zn(II)[26] and Mg(II)[27] and by *ortho*-phenolic hydroxyl groups.[8-10] For example, *m*-nitrobenzaldehyde and 4-pyridinecarbaldehyde are not reduced by 1,4-dihydropyridines, whereas 5-nitrosalicylaldehyde and 3-hydroxy-4-pyridinecarbaldehyde serve as substrates.[8,10] These results clearly substantiate the importance of hydrogen bonding in lowering the activation energy for the reduction of the carbonyl function.

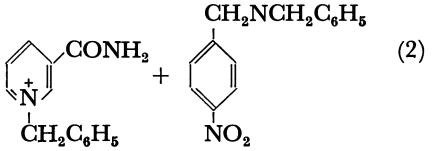
In the reaction of 1-substituted dihydronicotinamides

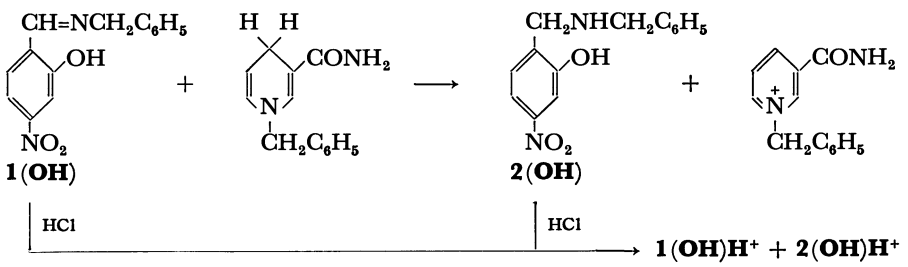
and carbonyl substrates, the transfer of the hydride anion or its equivalent would produce an unstable, alkoxide anion. When pK_a of this anion is considerably low due to the electron-withdrawing substituents, the reduction would be rather facile. Hexachloroacetone and trifluoroacetophenone belong to this class of the substrate. On the other hand, for the substrate with relatively high pK_a, the proton transfer to the carbonyl group prior to or at the transition state of the reaction could avoid the formation of energetically unfavorable alkoxide anions. Supposedly, the *ortho* hydroxyl groups of salicylaldehyde and 3-hydroxy-4-pyridinecarboxaldehyde can facilitate the reduction not only by polarization of the carbonyl group *via* hydrogen bonding but also by the efficient, intramolecular proton transfer (Eq. 1). This situation is similar to the ester cleavage reaction: *i.e.*, esters with good leaving groups are cleaved simply by the nucleophilic attack, while esters with poor leaving groups have to be cleaved by assistance of the general acid catalysis.[28]



Thus, the BzlNH reduction of Schiff bases possesses a feature which is common to the amide cleavage. The simple nucleophilic cleavage of amide substrates produces the amine anion (pK_a *ca.* 27), which is so unstable that it almost certainly does not occur without the assistance of the acid catalysis.[29] Similarly, the BzlNH reduction of the Schiff base primarily produces the amine anion (Eq. 2), which would be energetically unfavorable. Therefore, appropriate proton sources are required for this reaction.







Scheme 1.

Although Schiff bases are more reactive to the nucleophilic attack than the corresponding carbonyl functions,[12] **1** did not undergo the BzlNH reduction. In contrast, **1(OH)** was reducible by BzlNH in refluxing methanol due to the presence of the *ortho* hydroxyl group as a proton source. The role of the hydroxyl group of **1(OH)** may be complicated, however. The Schiff base nitrogen is basic, so that a zwitterionic species (>C=N$^+$H–: **1(OH)-Z**) may be present in addition to the neutral species (**1(OH)-N**). Thus, two reaction paths become possible as depicted in Scheme 3; that is, one involves the concerted proton transfer from the *ortho* hydroxyl group and the other involves the preequilibrium proton transfer to the Schiff base. Fortunately, the distribution of the chemical species of pyridoxal and its Schiff base in methanol (27 °C) have been reported by Matsushima and Martell.[30] They demonstrated the presence of two species, zwitterionic (418 nm) and neutral (337 nm), for pyridoxalidenevaline. The UV spectrum of **1(OH)** recorded in dry methanol at 30 °C showed an absorption maximum at 353 nm, but not at longer wavelengths beyond 400 nm. This absorption maximum is reasonably attributed to **1(OH)-N**, and **1(OH)-Z** exists little under this condition. At refluxing temperature, however, the reaction path *via* **1(OH)-Z** may not be ruled out, since the formation of the zwitterionic form could be increased by raising the temperature. We consider both reaction paths to be plausible, though **1(OH)-N** probably being the major reacting species.

Since the reaction media were not buffered, the progress of the BzlNH reduction would produce the phenoxide anion of **2(OH)** as illustrated in Scheme 3. However, in the presence of the unreacted **1(OH)**, the prototropic equilibrium of Eq. 3 must be overwhelmingly shifted to the right because the acidity of the two phenol groups are rather different.

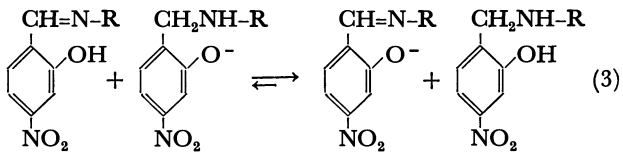


Figure 1 shows that a new, weak absorption band appears at 400—440 nm toward the end of the reaction. This peak may be ascribed to the anionic species of **1(OH)** (*cf.* λ_{max} for the 2-cyano-5-nitrophenolate anion is at 410 nm[31]). A similar spectral observation has been made for the 1,4-dihydronicotinamide reduction of 3-hydroxy-4-pyridinecarbaldehyde in refluxing methanol.[10] The anionic species of **1(OH)** will be much less

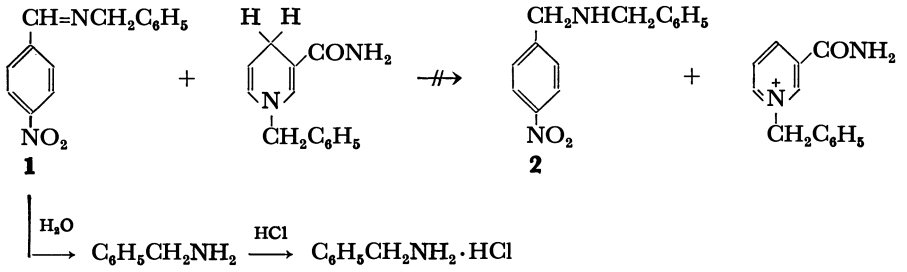
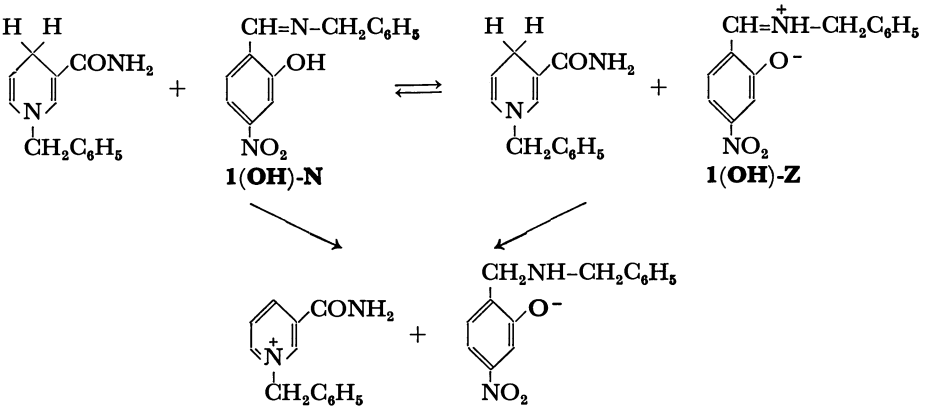


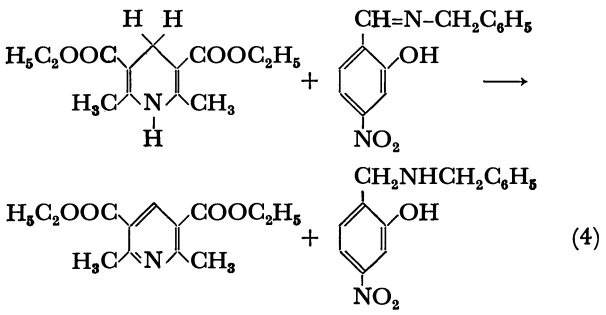
Scheme 2.



Scheme 3.

reactive in the BzlNH reduction, because of its increased electron density. This can explain why the reduction of **1**(**OH**) did not conclude even after refluxing for 9.5 h in methanol (Table 2).

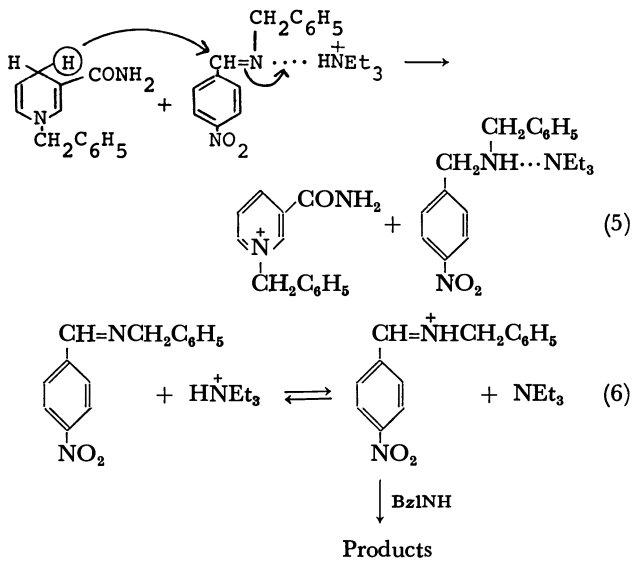
The reaction of **1**(**OH**) with Hantzsch ester (HE: 2,6-dimethyl-3,5-bis(ethoxycarbonyl)-1,4-dihydropyridine) did not yield an anionic species,[32] since HE can supply two hydrogenes (presumably, one as a "hydride" and the other as a proton: Eq. 4).



(4)

1(**OH**)**H**$^+$ was converted in 93% yield to **2**(**OH**) under the same reaction conditions (Table 2). Conceivably, **1H**$^+$ and **1**(**OH**)**H**$^+$ are quite reactive because (1) the protonated iminium group is prone to accept the "hydride" and (2) the product is not the energetically unfavorable anion.

Interestingly, addition of triethylamine hydrochloride and other amine hydrochlorides greatly improved the reactivity of **1** (Table 2). It is evident that these amine hydrochlorides act as the proton source. Here again, two proton transfer mechanisms are possible: the concerted and preequilibrium mechanisms (Eqs. 5 and 6).



(5)

(6)

Products

Equation 5 is a termolecular reaction, and entropically unfavorable. The pK_a value of *N*-(*p*-nitrobenzylidene)-*t*-butylamine was determined by Cordes and Jencks[33] to be 5.40, and is much lower than that of triethylamine (10.65).[34] Thus, the formation of **1H**$^+$ (Eq. 6) in the presence of only 10 times excesses of triethylamine hydrochloride is considered to be insignificant. It cannot be decided at present which reaction path is preferable.

In conclusion, the present study indicates the following order of the reactivity of the Schiff base toward the BzlNH reduction.

1H$^+$, **1** + NEt_3·HCl,

$\geqq$ **1** (**OH**)**H**$^+$ > **1** (**OH**) > **1** (unreactive).

This is in good accord with that demonstrated for the "*trans*-Schiffization,"[12] and suggests that the reduction by 1,4-dihydronicotinamide has the S_N2-type nature. Also suggested is that the reduction of the Schiff base can be acid-catalyzed, though the detailed mechanism (general acid or specific acid) was not established. These results may have important bearing with the interaction between the Schiff base and NADH in biological systems.

Regioselectivity of Palladium(II)-Induced Intramolecular Cyclization of 2-(3-Methyl-2-butenyl)phenol

Takahiro HOSOKAWA,* Shinji YAMASHITA, Shun-Ichi MURAHASHI, and Akio SONODA

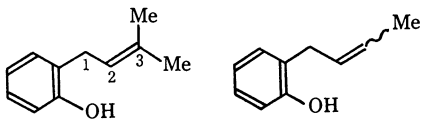
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received July 27, 1976)

Reaction of 2-(3-methyl-2-butenyl)phenol (**1**) with $PdCl_2$ gives 2,2-dimethylchromene (**3**) and 2,2-dimethyl-4-methoxychroman (**4**) (six-membered products) predominantly, together with trace amounts of 2-isopropylbenzofuran (**5**) and 2-isopropenyl-2,3-dihydrobenzofuran (**6**) (five-membered products). The reaction involves attack of the oxygen atom of the phenoxyl group at 2- or 3-position of the allylic side chain. Addition of various sodium carboxylates to the reaction mixture changes the regioselectivity. In the presence of sodium salts of carboxylic acids bearing electron-releasing substituents, nearly equal amounts of five and six-membered products are formed. The presence of sodium salts of carboxylic acids bearing electron-withdrawing substituents results in the predominant formation of the six-membered products. These results are discussed on the basis of alternation of reactive Pd(II) species. Results obtained from 2-(2-butenyl)phenol (**2**) are also reported.

In 1973 a synthetic process of 2-substituted benzofurans *via* palladium(II)-induced intramolecular cyclization of 2-allylphenols was reported.[1] Thereafter, the cyclization has been applied to unsaturated ketoximes[2] and alcohols[3] for synthesizing various heterocyclic compounds.[4]

During the course of investigations on the cyclization of 2-allylphenols, it has been found that the cyclization of 2-(3-methyl-2-butenyl)phenol (**1**) involves attack of the oxygen atom of the phenoxyl group on either 2- or 3-position of the allylic side chain, and that the regioselectivity depends on the ligands of palladium(II) salts. Similar results were also obtained from the cyclization of 2-(2-butenyl)phenol (**2**). In order to elucidate factors controlling the regioselectivity, the reaction of **1** with palladium(II) salts, $PdCl_2$ or $Pd(OAc)_2$, was carried out in the presence of various sodium carboxylates. In the present paper, we report the effect of sodium carboxylates on the palladium(II)-induced cyclization of **1**.



1 **2**

Results and Discussion

The reaction of **1** with $PdCl_2$ in aq methanol at 35 °C for 3 h in the air gave a 43% combined yield of six-membered products **3** and **4** (**3**: **4**=32: 11), along with

TABLE 1. PRODUCT DISTRIBUTION IN THE REACTION OF **1** WITH $PdCl_2$ OR $Pd(OAc)_2$ IN THE PRESENCE OF NaOAc[a]

Run	Molar ratio NaOAc/ PdX_2	Cyclized products: Yield[b] (%)	Ratio **3** : **5** : **6**	Unreacted **1** (%)
	X=Cl			
1	2	20	55 : 25 : 20	63
2	6	26	54 : 23 : 23	63
3	16	34	50 : 21 : 29	52
4	30	46	48 : 17 : 35	14
5	50	61	46 : 16 : 38	5
	X=OAc			
6	0	22	41 : 5 : 54	36
7	6	49	45 : 16 : 39	9
8	30	48	44 : 17 : 39	9

a) The reaction was carried out by using 0.5 mmol of **1**, 0.25 mmol of palladium(II) salt, and the corresponding amount of NaOAc in 9.5 ml of MeOH and 0.5 ml of H_2O at 35 °C for 3 h in the air. b) Yield was determined by GLC, and based on **1** used.

trace amounts of benzofurans **5** and **6** in less than 2% yields. Addition of NaOAc to the reaction mixture or the use of $Pd(OAc)_2$ instead of $PdCl_2$ caused a change in the product distribution (Table 1); that is, substantial amounts of benzofurans **5** and **6** were formed along with chromene **3**, but no other product such as **4** was detected. The results given in Table 1 indicate the following. (1) In the $PdCl_2$ system, the total product yield increases by increasing the amount of added NaOAc, accompanied by an increase in the relative yield of **6** and a decrease in that of **5** and **3** (runs 1—5). (2) In the $Pd(OAc)_2$ system, the product distribution changes with the addition of six-fold excess of NaOAc (runs 6—7), further addition of NaOAc giving no significant effect (runs 7—8). (3) In the $PdCl_2$ system, the product distribution approaches that in the $Pd(OAc)_2$–NaOAc system by increasing the amount of added NaOAc (runs 5 and 7). The results suggest that both reaction systems involve analogous reactive Pd(II) species, and excess acetate ion must displace the chloride ligands in $PdCl_2$.[5]

Table 2. Product distribution in the reaction of **1** with $PdCl_2$ in the presence of various sodium carboxylates or sodium chloride[a)]

Run	Sodium Salts	pK_a[b)] (H_2O)	Cyclized products: Yield[c)] (%)	Ratio **3**	**4**	**5**	**6**	Unreacted **1** (%)
1	NaCl[d)]		32	89:	9:	2:	1	55
2	CF_3COONa	0.23	45	82:	10:	6:	2	36
3	$CCl_2HCOONa$	1.25	36	80:	4:	8:	8	51
4	CFH_2COONa	2.57	43	60:	2:	21:	17	42
5	CH_3COONa	4.75	34	50:	—:	21:	29	51
6	CH_3CH_2COONa	4.87	62	50:	—:	17:	33	6
7	$(CH_3)_3CCOONa$	5.05	71[e)]	51:	—:	12:	37	3

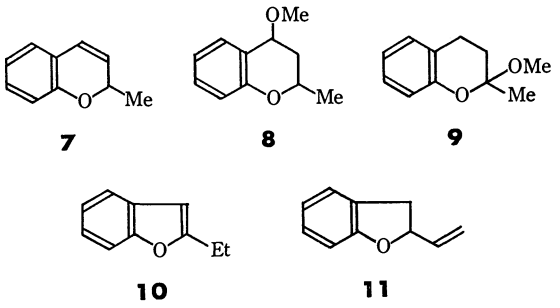
a) The reaction was performed by using 16 molar equivalents of sodium carboxylate to $PdCl_2$ under the conditions described in footnote a) in Table 1. b) A. Albert and E. P. Serjeant, "Ionization Constants of Acids and Bases," John Wiley & Son Inc., New York (1962), p. 124. c) Yield was determined by GLC, and based on charged **1**. d) 4 molar equivalents of NaCl to $PdCl_2$ was used. e) Reaction time was 1 h.

This is supported by the examination of absorption spectra of $PdCl_2$ in the presence of NaOAc. The solution of $PdCl_2$ in aq methanol showed a maximum absorption at 422 nm. Addition of NaOAc shifted the maximum to a shoulder peak around 400 nm,[6)] which is similar to a spectrum of $Pd(OAc)_2$ in the presence of NaOAc.

On the basis of these results, we have carried out the reaction of **1** with $PdCl_2$ in the presence of various sodium carboxylates (16 molar equiv to $PdCl_2$) or NaCl.[7)] The results summarized in Table **2** are as follows. (1) Formation of the six-membered products (**3** and **4**) predominates that of the five-membered products (**5** and **6**), when the reaction is performed in the presence of either sodium salts of carboxylic acids bearing electron-withdrawing group (runs 2—4) or NaCl, and the relative ratio of **3**+**4**/**5**+**6** (regioselectivity) correlates well with pK_a values of the corresponding carboxylic acids; thus, the higher ratio is observed with the lower pK_a value. (2) In the presence of sodium salts of carboxylic acids bearing electron-releasing group (runs 5—7), the amounts of six- and five-membered products formed are nearly equal, the ratio **3**/**5**+**6** not changing a great deal. These results can be ascribed to an alternation of reactive Pd(II) species through co-ordination of sodium carboxylates to $PdCl_2$, and the change in electron density of palladium appears to affect the regioselectivity. The following facts should be noted here. Firstly, in the reaction using $(CH_3)_3CCOONa$, if the total product yield is calculated on the basis of $PdCl_2$ used, it becomes 142%, suggesting that the reaction involves a catalytic process. When the reaction was carried out under an atmosphere of nitrogen or argon instead of air, the yield was reduced to ≈60% (≈30% based on charged **1**). Thus the catalytic process would be effected by oxygen in air. However, the relative ratios among the cyclized products did not change. Secondly, no double bond isomerization of **1** recovered took place.

From these results we propose the following explanation for the regioselectivity of the cyclization. The cyclization would proceed *via* co-ordination of olefin to the reactive Pd(II) species, as has been generally accepted in many organic reactions using palladium(II).[8)] On the co-ordinated olefin, an extensive positive charge may be induced by a decrease in electron density on palladium, if the reactive Pd(II) species bears electron-withdrawing ligands. Nucleophilic attack of the oxygen atom would thus occur predominantly at the 3-position of the allylic side chain, since a positive charge at this position is highly stabilized by two methyl groups. If so, one factor controlling the regioselectivity would be the electron density of palladium. This may be supported by the following results. (1) The use of $Pd(OCOCF_3)_2$ also led to a predominant formation of **3**. (2) The reaction of **1** with $Hg(OAc)_2$ (a more electrophilic reagent[9)] than palladium(II)) in aq. methanol followed by $NaBH_4$ reduction gave a six-membered product, 2,2-dimethylchroman, as the sole product.

The reaction of 2-(2-butenyl)phenol (**2**) with palladium(II) salts gave cyclized products such as **7**, **8**, **9**, **10**, and **11**. As shown in Table 3, the reaction using $PdCl_2$ alone gives six-(**7**+**8**+**9**) and five-membered product (**10**) in the ratio 89: 21. The result shows a tendency similar to the case of **1**. Addition of NaOAc to $PdCl_2$ or the use of $Pd(OAc)_2$ instead of $PdCl_2$ leads to none of the six-membered products, only the five-membered products **10** and **11** being formed. Hence, the facile formation of the six-membered product(s) from **1** would be also governed by a favorable attack of Pd(II) on a less crowded carbon (2-position) of the allylic side chain of **1**.



7 **8** **9** **10** **11**

Table 3. Product distribution in the reaction of **2** with palladium(II) salts[a)]

Palladium(II) salts	Cyclized products: Yield (%)	**7**	**8**	**9**	**10**	**11**
$PdCl_2$	34[b)]	50 :	11 :	18 :	21 :	—[c)]
$PdCl_2$–NaOAc[d)]	40[e)]	— :	— :	— :	52 :	58
$Pd(OAc)_2$[f)]	65	— :	— :	— :	29 :	71

a) Palladium(II) salt was reacted with two molar equivalents of **2** in aq MeOH at 35 °C for 3 h in the air. b) The yield, based on charged **2**, was estimated from a mixture of isolated products by GLC. c) The ratio was determined by GLC peak areas. d) 16 molar equivalents of NaOAc to $PdCl_2$ was used. e) The yield was determined by GLC with biphenyl as an internal standard, and based on charged **2**. f) Data from Ref. 1b.

Experimental

Materials. 2-(2-Methyl-2-butenyl)phenol (**1**) was synthesized by C-alkylation of sodium phenoxide with 4-bromo-2-methyl-2-butene[10] according to the procedure of Hurd and Hoffman.[11] 2-(2-Butenyl)phenol (**2**) was prepared as reported previously.[1b] Palladium(II) chloride was prepared from a solution of palladium metal in *aqua regia* by diluting with aq hydrogen chloride and heating to dryness. Palladium(II) acetate was prepared by the method of Wilkinson *et al.*[12]

*Reaction of **1** with Palladium(II) Salts. A) Analyses of Product Distributions*: A suspension of palladium(II) salt ($PdCl_2$ or $Pd(OAc)_2$, 0.25 mmol) and a given amount of NaOAc in MeOH (4.5 ml)–H_2O (0.5 ml) was stirred at 35 °C for 10 min in the air, and then a mixture of allylphenol **1** (0.081 g, 0.5 mmol) and appropriate amount of biphenyl (internal standard for GLC analysis) in MeOH (5 ml) was added to the suspension, stirring being continued for 3 h. Product distributions were analyzed by gas chromatography (a JEOL Model JGC-20KFP gas chromatography) equipped with a FID detector using 10% PEG-20 M Celite Column (1 m×4 mm). Peaks attributed to chromene **3**, benzofurans **5** and **6**, chroman **4**, biphenyl (internal standard), and unreacted **1** appeared with retention times of 10.0, 11.6, 14.3, 20.3, and 28.8 min, respectively, under the conditions of injection temperature 300 °C and column temperature 120 °C which was raised up at the rate of 5 °C/min after 7 min. The results are summarized in Table 1.

Analyses of product distribution in the presence of various sodium carboxylates were performed by the same procedure, the results being given in Table **2**. All the product yields are based on **1** used. Isolation, purification, and identification of cyclized products were carried out as follows.

*B) Isolation and Identification of 2,2-Dimethylchromene (**3**) and 2,2-Dimethyl-4-methoxychroman (**4**)*: For isolation of cyclized products **3** and **4**, the reaction was carried out by using a catalytic amount of $PdCl_2$. A mixture of **1** (1.620 g, 10 mmol), $PdCl_2$ (0.035 g, 0.2 mmol), and $CuCl_2$ (0.670 g, 5 mmol) in MeOH (25 ml)–H_2O (2 ml) was stirred at 65 °C under a slow stream of oxygen. After 24 h, the reaction mixture was filtered and extracted with ether. The ether extract was washed with water and dried over $MgSO_4$. The solvent was removed *in vacuo* and the residue was distilled under reduced pressure, giving 1st fraction (0.506 g) at 85—90 °C/4 mmHg and 2nd fraction (0.658 g) at 101—105 °C/4 mmHg. GLC analyses showed that the 1st fraction contained chromene **3**, chroman **4**, unreacted **1**, and an unidentified product in 55, 15, 9, and 21% on GLC peak areas, respectively, and the 2nd fraction in 27, 28, 15, and 30%. The unidentified compound is a phenolic material since it can be removed from the mixtures by treating with Claisen's alkali. Although its isolation was unsuccessful owing to decomposition during the course of preparative GLC, the compound is probably 2-(2-methoxy-3-methylbutyl)phenol. The other products were isolated by preparative GLC using 10% PEG-20 M Celite Column at 165 °C. 2,2-Dimethylchromene (**3**), NMR (CCl_4), δ 1.37 (s, 6H), 5.44 (d, J=10 Hz, 1H), 6.18 (d, J=10 Hz, 1H), and 7.1—6.4 (m, 4H). (Found: C, 82.41; H, 7.48%. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.55%). The spectral properties of this compound were identical with those of the authentic sample prepared by the method of Campbell *et al.*[13] 2,2-Dimethyl-4-methoxychroman (**4**), NMR (CCl_4), δ 1.27 (s, 3H, Me), 1.35 (s, 3H, Me), 1.92 (d, J=7 Hz, 2H, C-3 proton), 3.32 (s, 3H, OMe), 4.27 (t, J=7 Hz, 1H, benzylic proton), and 7.2—6.2 (m, 4H); IR, cm^{-1} 1608 (m), 1580 (s), 1482 (s), 1485 (s), 1367 (m), 1258 (s), 1203 (s), 1128 (s), 1090 (s), 920 (s), 908 (m), and 748 (s); Found: C, 75.19; H, 8.53%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%. The position of the methoxyl group was assigned on the basis of the downfield shift of benzylic proton (δ 4.27) caused by both phenyl ring and methoxyl group. The benzylic protons of 2,2-dimethylchroman (see below) show resonance at δ 2.72 as a triplet. The assignment is also supported by comparison with the NMR spectrum of 2-methyl-4-methoxychroman (**7**).

*C) Isolation and Identification of 2-Isopropylbenzofuran (**5**) and 2-Isopropenyl-2,3-dihydrobenzofuran (**6**)*: For the isolation of **5** and **6**, allylphenol **1** (1.620 g, 10 mmol) was similarly reacted with a catalytic amount of $Pd(OAc)_2$ (0.046 g, 0.2 mmol) in the presence of $Cu(OAc)_2 \cdot H_2O$ (0.998 g, 5 mmol) for 48 h. The usual work-up followed by distillation (~105 °C/6 mmHg) gave an oil (1.260 g) which contained largely unreacted **1**. The distillate was then treated with Claisen's alkali, and the organic products were extracted with petroleum ether. The extract was washed with water and dried over $MgSO_4$. Removal of the solvent afforded colorless oil (0.358 g) which was found to contain **3**, **5**, and **6** in the ratio 47: 3: 50 on GLC peak areas. Isolation of these products was performed by preparative GLC under the same conditions as above. 2-Isopropylbenzofuran (**5**), NMR (CCl_4), δ 1.41 (d, J=7 Hz, 6H, Me) 3.06 (h, J=7 Hz, 1H), 6.31 (s, 1H, C-3 proton), 7.1—7.3 (m, 2H), and 7.3—7.5 (m, 2H): IR, cm^{-1} 1582 (s), 1592 (s), 1462 (s), 1425 (s), 1223 (s), 1158 (m), 930 (m), 783 (s) and 725 (s); Found: C, 82.45; H, 7.61%. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.55%. 2-Isopropenyl-2,3-dihydrobenzofuran (**6**), NMR (CCl_4), δ 1.70 (broad s, 3H, Me), 2.89 (dd, J=16 and 8 Hz, 1H, C-3 proton), 3.21 (dd, J=16 and 8.5 Hz, 1H, C-3 proton), 4.74 (broad s, 1H, olefinic proton), 4.94 (broad s, 1H, olefinic proton), 4.95 (t, J=8 Hz, 1H, C-2 proton), 6.58 (2H, phenyl proton), and 6.86 (2H, phenyl proton): IR, cm^{-1} 1643 (w), 1590 (s), 1476 (s), 1458 (s), 1368 (m), 1318 (m), 1210 (s), 1160 (w), 1090 (w), 1010 (m), 950 (m), 890 (m), 850 (m), and 738 (s): Found: C, 82.31; H, 7.54%. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.55%.

*D) Reaction of **1** with $Pd(OCOCF_3)_2$*: $Pd(OCOCF_3)_2$ was prepared by the procedure of Wilkinson *et al.*[12] $Pd(OCOCF_3)_2$ (0.083 g, 0.25 mmol) was reacted with **1** (0.081 g, 0.5 mmol) according to the same procedures as above. GLC analysis showed that **3**, **5**, and **6** were formed in 45% combined yield, based on charged **1**, in the ratio 83: 14: 3. The yield was determined with biphenyl as an internal standard.

*Reaction of **1** with $Hg(OAc)_2$.* $Hg(OAc)_2$ (0.318 g, 1 mmol) was reacted with **1** (0.162 g, 1 mmol) in MeOH (19 ml)–H_2O (1 ml) at 35 °C for 3 h. The reaction mixture was extracted with ether, washed with water, and dried over $MgSO_4$–$NaHCO_3$. After evaporation of ether, the residue was dissolved in carbon tetrachloride. Organomercurial, probably 3-acetoxymercuri-2,2-dimethylchroman, was precipitated (0.247 g, 59%) by adding petroleum ether to the solution. The mercurial (0.247 g, 0.59 mmol) was added to a solution of $NaBH_4$ (0.022 g, 0.58 mmol) in 2 M sodium hydroxide (2 ml). The reaction mixture was stirred for 45 min at 15 °C, and extracted with ether. The extract was washed with water and dried over $MgSO_4$. Removal of ether gave a colorless oil (0.079 g, 83%) which was found to contain only 2,2-dimethylchroman by GLC analysis. 2,2-Dimethylchroman, NMR (CCl_4), δ 1.28 (s, 6H, Me), 1.73 (t, 2H, J=7 Hz, C-3 proton), 2.72 (t, 2H, J=7 Hz, benzylic proton), and 7.1—6.4 (m, 4H): (Found: C, 81.58; H, 8.78%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.). The structure was confirmed by comparison with an authentic sample prepared by hydrogenation of **3** with palladium on charcoal.

*Reaction of 2-(2-Butenyl)phenol (**2**) with $PdCl_2$.* A mix-

ture of *cis*- and *trans*-**2** (*cis*/*trans*=1/1.9) was reacted with $PdCl_2$ (0.177 g, 1 mmol) in MeOH (38 ml)–H_2O (2 ml) at 35 °C for 5 h in the air. After filtration of precipitated metallic palladium, organic products were extracted with ether in the usual way. After removal of ether, the residue was subjected to alumina column chromatography (Al_2O_3, 8 g). Elution with petroleum ether (50 ml) gave colorless oil (0.110 g) containing **7**, **8**, **9**, and **10** in the ratio 50: 11: 18: 21 on GLC peak areas and unidentified products in less than 4%. The combined yield of cyclized products was approximately 34% based on charged **2**. These products were isolated by preparative GLC using 5% PEG-20 M Celite Column at 125 °C. 2-Methylchromene (**7**), NMR (CCl_4), δ 1.32 (d, 3H, J=6.5 Hz, Me), 4.90 (ddq, 1H, J=6.5, 3, and 1.8 Hz, C-2 proton), 5.56 (dd, 1H, J=3 and 9 Hz, olefinic proton), 6.28 (dd, 1H, J=9 and 1.8 Hz, olefinic proton), and 7.5—6.7 (m, 4H); Found: C, 82.25; H, 6.82%. Calcd for $C_{10}H_{10}O$: C, 82.16; H, 6.90%. 2-Methyl-4-methoxychroman (**8**), NMR (CCl_4), δ 1.40 (d, 3H, J=6.5 Hz, Me), 1.62 (ddd, 1H, J=13, 9.5, and 3 Hz, C-3 proton), 2.05 (ddd, 1H, J=13, $\approx$1, and $\approx$2 Hz, C-3 proton), 3.33 (s, 3H, OMe), 4.10 (dd, 1H, J=3 and $\approx$2 Hz, benzylic proton), 4.32 (m, 1H, C-2 proton), 6.7—6.9 (m, 2H), and 7.0—7.3 (m, 2H). Found: C, 73.98; H, 7.75%. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%. The assignment of structure **8** is supported by the double irradiation experiment in NMR. Double irradiation of benzylic proton (δ 4.10) simplified the signals of C-3 protons (δ 1.62 and 2.05), showing two sets of double doublet (J=13 and 9.5 Hz and J=13 and $\approx$1 Hz). The signals of C-3 protons were transformed into two sets of broad doublet by irradiating on the C-2 proton (δ 4.32). The multiplet of C-2 proton was simplified by double irradiation of the methyl signal at δ 1.04 to show a broad doublet (J=9.5 Hz). The C-2 proton signal was also simplified by double irradiation of C-3 proton at δ 1.62 and 2.05 to show a doublet of quartet, in each case, bearing coupling constants of J=6.5 and $\approx$1 Hz, and J=6.5 and 9.5 Hz, respectively. 2-Methyl-2-methoxychroman (**9**) was identified by comparison with the spectral data reported by Dolby *et al.*[14] (Found: C, 74.29; H, 7.69%. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%). Identification of 2-ethylbenzofuran (**10**) and 2-vinyl-2,3-dihydrobenzofuran (**11**) was described previously.[2b]

Reaction of **2** *with* $PdCl_2$ *in the Presence of NaOAc.* Allylphenol **2** (0.445 g, 3 mmol) was reacted with $PdCl_2$ (0.276 g, 1.5 mmol) in the presence of NaOAc (1.968 g, 24 mmol) in MeOH (57 ml)–H_2O (3 ml) at 35 °C for 3 h in the air. GLC analysis showed that only benzofurans **5** and **6** were formed in 40% combined yield based on charged **2**, in the ratio 52: 58. The yield was determined with biphenyl as an internal standard.

Synthesis of 1-*N*-[(*S*)-4-amino-2-hydroxybutyryl]-3′-deoxyribostamycin[1] (3′-Deoxybutirosin B)

Daishiro IKEDA,* Fumiko NAGAKI,* Tsutomu TSUCHIYA, Sumio UMEZAWA, and Hamao UMEZAWA

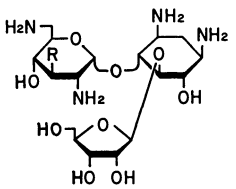
**Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223*

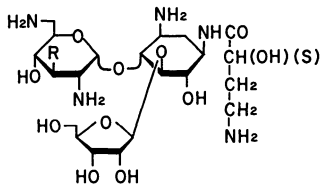
(Received July 28, 1976)

3′-Deoxybutirosin B (**13**) was prepared from ribostamycin by way of the following reaction sequences: 1) selective 3′-*O*-arylsulfonylation, 3′-iodination, and 3′-deoxygenation; 2) 1,6-cyclic carbamate formation,selective hydrolysis of the carbamate and acylation of the free 1-NH_2 group with an active ester of (*S*)-4-amino-2-hydroxybutyric acid. The structure of **13** was confirmed by comparison of its $\Delta[M]_{TACu}$ value with those of butirosin B and 4′-deoxybutirosin B.

As reported in a previous paper,[2] 3′-deoxyribostamycin exhibits antibacterial activity against various bacteria including those which produce kanamycin-neomycin phosphotransferase II[3] (P-ase II). 3′-Deoxyribostamycin, however, does not inhibit the growth of resistant organisms which produce kanamycin-neomycin phosphotransferase I[4] (P-ase I). On the other hand, butirosin B,[5] 1-*N*-[(*S*)-4-amino-2-hydroxybutyryl]-ribostamycin, inhibits the growth of resistant organisms producing P-ase I but not those producing P-ase II.



Ribostamycin R : OH
3′-Deoxyribostamycin R : H



Butirosin B R : OH
3′-Deoxybutirosin B R : H

The titled compound, 3′-deoxybutirosin B is, therefore, expected to be active against both kinds of resistant bacteria.

This paper describes the synthesis of the titled compound starting from ribostamycin. This synthesis is an extension of the method[6] developed by us and involves the following reaction sequences: 1) removal of the 3′-hydroxyl group of ribostamycin by selective 3′-*O*-arylsulfonylation followed by iodination and hydrogenolysis of the iodine group in a similar fashion as reported in the synthesis[7] of tobramycin (3′-deoxykanamycin B) from kanamycin B; 2) coupling of (*S*)-4-amino-2-hydroxybutyryl group with the free 1-NH_2 group which is produced by way of 1,6-cyclic carbamate[8] formation followed by its selective cleavage.

Tetra-*N*-benzyloxycarbonyl-3′,4′:2″,3″-di-*O*-cyclohexylidene-5″-*O*-(1-methoxycyclohexyl) ribostamycin[9] (**1**) was treated with dilute acetic acid to split the acid-sensitive 5″-*O*-protecting group selectively. Treatment of the demethoxycyclohexyl derivative (**2**) with sodium hydride in *N*,*N*-dimethylformamide (DMF) gave the

Z : $CO_2CH_2C_6H_5$

1,6-cyclic carbamate (**3**) as described in a previous paper.[8] Acetylation of **3** gave the 5″-*O*-acetyl derivative (**4**), from which the 3′,4′-*O*-cyclohexylidene group was selectively removed in a weakly acidic medium quantitatively.

Treatment of the partially decyclohexylidenated derivative (**5**) with *p*-toluenesulfonyl chloride or *o*-nitrobenzenesulfonyl chloride in pyridine at −37 °C successfully gave the selectively sulfonylated derivatives **6** and **7**, respectively.

Replacement of the 3′-*O*-tosyl or 3′-*O*-*o*-nitrobenzenesulfonyl group of **6** or **7** with iodide was carried out with 50% sodium iodide in DMF to give the 3′-iodo derivative (**8**). This iodination might be due to the participation by the 2′-acylamino group, as described in the preparation of tobramycin.[7] In the iodination, **7** reacted with sodium iodide more smoothly than **6**. Hydrogenation of **8** with Raney nickel in dioxane in the presence of triethylamine gave the 3′-deoxy derivative (**9**).

Selective opening of the 1,6-carbamate was successfully performed by use of a limited amount of barium hydroxide in dioxane, as reported in a previous paper,[8] to give **10**. To the free 1-NH_2 group, then, (*S*)-4-benzyloxycarbonylamino-2-hydroxybutyryl group was introduced by using an active ester (**11**)[10] prepared from (*S*)-4-benzyloxycarbonylamino-2-hydroxybutyric acid, *N*-hydroxysuccinimide, and dicyclohexylcarbodiimide. Catalytic hydrogenolysis of the *N*-benzyloxycarbonyl groups of the amide (**12**) followed by removal of the 2″,3″-*O*-cyclohexylidene group with aqueous hydrochloric acid gave 3′-deoxybutirosin B (**13**). The compound had strong antibacterial activity[1] against various strains of both usual and resistant bacteria.

To confirm the structure of **13**, its $\Delta[M]_{TACu}$ value[11] was measured, as well as those of butirosin B and 4′-deoxybutirosin B,[12] to be +410°, −398°, and −528°, respectively. The facts that butirosin B and 4′-deoxybutirosin B had similar values in sign and magnitude and that **13** had a value of +800—900° larger than that of butirosin B or 4′-deoxybutirosin B show that **13** has no 3′-hydroxyl group, which renders **13** impossible to form a Cu-complex between 2′-NH_2 and 3′-OH groups, the contribution being estimated to be $\Delta[M]_{TACu} \approx -900°$.

Experimental

NMR spectra were recorded at 60 MHz with Varian A-60D spectrometer. Infrared spectra were determined in KBr discs with Hitachi 285 grating infrared spectrophotometer. Thin-layer chromatography (TLC) was carried out on Wakogel B-5 with sulfuric acid spray for detection unless otherwise stated. For column chromatography, silica gel (Wakogel C-200) was used.

Tetra-N-*benzyloxycarbonyl-3′,4′ : 2″,3″-di*-O-*cyclohexylideneribostamycin (2).* A solution of **1**[9] (4.50 g) in a mixture of 40% acetic acid–acetone (1 : 5, 92 ml) was heated at 37 °C for 7.5 h. The solution was poured into a mixture of chloroform (400 ml) and an aqueous saturated sodium hydrogencarbonate solution (200 ml) with stirring. The organic layer separated was washed with water, dried (Na_2SO_4), and concentrated to give a solid (4.50 g). The solid contained two components, **1** (TLC, R_f 0.84 with benzene–ethyl acetate=5 : 3) and **2** (R_f 0.35). The mixture was chromatographed over silica gel firstly with benzene–ethyl acetate (5 : 3) containing 0.5% triethylamine,* and **1** (1.11 g) was eluted. The developing solvent was then changed to benzene–ethyl acetate (1 : 1) containing 0.5% triethylamine to give **2**, 2.58 g (84%), mp 103—107 °C, $[\alpha]_D^{20}$ +23° (*c* 2, $CHCl_3$).

Found: C, 63.51; H, 6.47; N, 4.85%. Calcd for $C_{61}H_{74}N_4O_{18}$: C, 63.64; H, 6.48; N, 4.87%.

3,2′,6′-Tri-N-*benzyloxycarbonyl-3′,4′ : 2″,3″-di*-O-*cyclohexylideneribostamycin 1,6-Carbamate (3).* To an ice-cold solution of **2** (0.99 g) in dry DMF (11.5 ml), 50% oily sodium hydride (86 mg) was added and the mixture was stirred for 2 h in the cold under atmosphere of nitrogen. The mixture became clear after 30 min. The solution, after neutralization with acetic acid, was poured into a mixture of chloroform-saturated sodium chloride solution (1 : 1, 200 ml) with vigorous stirring. The organic layer separated was washed with water, dried (Na_2SO_4), and concentrated to give a pale yellow syrup. It was chromatographed over silica gel with benzene–ethyl acetate (1 : 1) containing 0.1% triethylamine. From the earlier and the later fractions, **2** (0.08 g) and **3** (0.62 g, 69%) were isolated, respectively. Compound **3**: mp 115—118 °C, $[\alpha]_D^{20}$ +26° (*c* 2, $CHCl_3$); IR: 1770 (cyclic carbamate[13]), 1715 (carbamate), 1520 (amide II) cm^{-1}.

Found: C, 62.07; H, 6.44; N, 5.50%. Calcd for $C_{54}H_{66}N_4O_{17}$: C, 62.18; H, 6.38; N, 5.37%.

5″-O-Acetyl-3,2′,6′-tri-N-*benzyloxycarbonyl-3′,4′ : 2″,3″-di*-O-*cyclohexylideneribostamycin 1,6-Carbamate (4).* Compound **3** was treated with acetic anhydride and pyridine in a usual manner to give **4** (98%), mp 110—113 °C, $[\alpha]_D^{20}$ +20° (*c* 1.5, $CHCl_3$); IR: 1770, 1730 (sh), 1715, 1520 cm^{-1}; NMR ($CDCl_3$) δ: 2.05 (3H, s, Ac).

Found: C, 61.72; H, 6.28; N, 4.92%. Calcd for $C_{56}H_{68}N_4O_{18}$: C, 61.98; H, 6.32; N, 5.16%.

5″-O-Acetyl-3,2′,6′-tri-N-*benzyloxycarbonyl-2″,3″*-O-*cyclohexylideneribostamycin 1,6-Carbamate (5).* A solution of **4** (2.96 g) in a mixture of acetone–60% acetic acid (1 : 1, 120 ml) was heated at 60 °C. After 1 h, the solution contained only **5** (TLC, R_f 0.15 with benzene–ethyl acetate=1 : 2), **4** (R_f 0.6) disappearing completely. The solution was concentrated *in vacuo* and the concentrate was extracted with chloroform. The organic layer was washed successively with aqueous sodium hydrogencarbonate, water, dried (Na_2SO_4), and concentrated to give a solid of **5** (2.75 g), which was purified by reprecipitation from chloroform–hexane, 2.61 g (95%), mp 109—112 °C, $[\alpha]_D^{20}$ +11° (*c* 2, $CHCl_3$); IR: 1760 (m), 1730 (sh), 1700, 1520 cm^{-1}; NMR ($CDCl_3$) δ: 2.03 (3H, s, Ac), 1.2—1.85 (≈11H).

Found: C, 59.59; H, 6.04; N, 5.33%. Calcd for $C_{50}H_{60}N_4O_{18}$: C, 59.75; H, 6.02; N, 5.57%.

5″-O-Acetyl-3,2′,6′-tri-N-*benzyloxycarbonyl-2″,3″*-O-*cyclohexylidene-3′*-O-*tosylribostamycin 1,6-Carbamate (6).* To a solution of **5** (1.77 g) in dry pyridine (38 ml), *p*-toluenesulfonyl chloride (1.91 g, 5 mol equivalents for **5**) was added and the solution was heated at 37 °C for 18 h and then additionally at 60 °C for 1 h. The solution showed, on TLC with benzene–ethyl acetate (1 : 1), a major spot (**6**, R_f 0.4) accompanied with other two minor spots of R_f 0.06 (**5**) and 0.6 (4′-*O*-tosyl isomer ?). Water (0.3 ml) was added and the solution was concentrated to give a reddish syrup. The chloroform solution of the syrup was washed successively with aqueous potassium hydrogensulfate, aqueous sodium hydrogencarbonate, and water, dried (Na_2SO_4), and concentrated. The resulting yellow syrup was chromatographed over silica gel with benzene–ethyl acetate (1 : 1) and from the fraction containing the major component, **6** was isolated as a colorless solid, 1.55 g (76%),

* Triethylamine was added in order to prevent removal of the cyclohexylidene groups during the chromatography.

mp 110—112 °C, $[\alpha]_D^{20}$ +13° (*c* 1.7, $CHCl_3$); IR: 1770 (cyclic carbamate), 1720 (carbamate), 1740 (sh, ester), 1520 (amide II); NMR ($CDCl_3$) δ: 2.05 (3H, s, Ac), 2.38 (3H, s, CH_3(Ts)).

Found: C, 59.30; H, 5.78; N, 4.72; S, 2.66%. Calcd for $C_{57}H_{66}N_4O_{20}S$: C, 59.06; H, 5.74; N, 4.83; S, 2.77%.

*5″-O-Acetyl-3,2′,6′-tri-*N*-benzyloxycarbonyl-2″,3″-O-cyclohexylizene-3′-O-(o-nitrobenzenesulfonyl)ribostamycin 1,6-Carbamate (7).* Compound **5** was treated with *o*-nitrobenzenesulfonyl chloride in a similar manner as described for **6** to give **7** (66%), mp 114—116 °C, $[\alpha]_D^{14}$ +6.5° (*c* 2.3, $CHCl_3$); NMR ($CDCl_3$) δ: 2.02 (3H, s, Ac).

Found: C, 56.25; H, 5.40; N, 5.75; S, 2.88%. Calcd for $C_{50}H_{63}N_5O_{22}S$: C, 56.51; H, 5.34; N, 5.88; S, 2.69%.

*5″-O-Acetyl-3,2′,6′-tri-*N*-benzyloxycarbonyl-2″,3″-O-cyclohexylidene-3′-deoxy-3′-iodoribostamycin 1,6-Carbamate (8).*

A. From **6**: To a solution of **6** (0.58 g) in dry DMF (10 ml), sodium iodide (6 g, dried at 100 °C *in vacuo*) was added and the mixture was stirred at 100 °C for 10 h under the atmosphere of nitrogen. The reddish-brown solution, which soon solidified on cooling, was extracted with chloroform and the organic solution was concentrated with several additions of toluene. The resulting solid was extracted again with chloroform and the solution was washed successively with saturated sodium chloride solution, aqueous sodium thiosulfate, and water, dried (Na_2SO_4), and concentrated. The brown solid was chromatographed over silica gel with benzene–ethyl acetate (1: 1) to give a solid of **8**, 324 mg (58%), mp 108—110 °C, $[\alpha]_D^{15}$ +5° (*c* 3, $CHCl_3$); NMR ($CDCl_3$) δ: 2.1 (3H, s, Ac).

Found: C, 54.23; H, 5.49; N, 5.02; I, 11.05%. Calcd for $C_{50}H_{59}N_4O_{17}I$: C, 53.86; H, 5.34; N, 5.03; I, 11.38%.

B. From **7**: Compound **7** was treated similarly as described above except that the reaction period and the developing solvent on column chromatography were changed to 1.5 h and benzene–ethyl acetate (2: 3). Yield of **8** was 65%.

*5″-O-Acetyl-3,2′,6′-tri-*N*-benzyloxycarbonyl-2″,3″-O-cyclohexylidene-3′-deoxyribostamycin 1,6-Carbamate (9).* To a solution of **8** (310 mg) in dioxane (9 ml), triethylamine (0.04 ml) was added, and the solution was hydrogenated with Raney nickel at 80 °C for 1 h under atmospheric pressure of hydrogen. After filtration, the solution was repeatedly hydrogenated with twice additions of fresh Raney nickel and triethylamine. Concentration of the solution gave a solid, which was chromatographed over silica gel with benzene–ethyl acetate (1: 2) to give **9**, 192 mg (70%), mp 97—99 °C, $[\alpha]_D^{13}$ +5° (*c* 1, $CHCl_3$).

Found: C, 60.35; H, 6.20; N, 5.52%. Calcd for $C_{50}H_{60}N_4O_{17}$: C, 60.72; H, 6.11; N, 5.66%.

*3,2′,6′-Tri-*N*-benzyloxycarbonyl-2″,3″-O-cyclohexylidene-3′-deoxyribostamycin (10).* To a solution of **9** (156 mg) in dioxane (3 ml), 0.1 M barium hydroxide solution (2.4 ml, 1.5 mol equivalents for **9**) was added and the mixture was stirred at 60 °C for 1 h. TLC (with benzene–methanol 4: 1) showed a single spot of **10** (R_f 0.5, ninhydrin positive) and none of **9** (R_f 0.8). After introduction of carbon dioxide followed by centrifugation, the solution was concentrated to dryness. The solid was extracted with dioxane and, after centrifugation, the supernatant layer was concentrated. The resulting solid (151 mg) still contained a trace of inorganic salt, however, it was chromatographically homogeneous and was used without purification for the next step. IR: 1700 cm^{-1} (carbamate).

*3,2′,6′-Tri-*N*-benzyloxycarbonyl-1-*N*-[(S)-4-benzyloxycarbonylamino-2-hydroxybutyryl]-2″,3″-O-cyclohexylidene-3′-deoxyribostamycin (12).* To a solution of **10** (370 mg) and triethylamine (0.04 g) in THF (8 ml), the active ester[10] (**11**, 170 mg) was added and the solution was kept at room temperature overnight. The solution was concentrated and the residue was chromatographed over silica gel with chloroform–2-propanol (10: 1). The fractions containing the major component (**12**, R_f 0.42 on TLC with the above solvent system) were collected and concentrated to give a solid of **12**, 186 mg (40% based on **9**), mp 102—106 °C, $[\alpha]_D^{18}$ +2.5° (*c* 1, $CHCl_3$).

Found: C, 59.44; H, 6.21; N, 5.87%. Calcd for $C_{59}H_{73}N_5O_{19}\cdot 2H_2O$: C, 59.44; H, 6.51; N, 5.87%.

*1-*N*-[(S)-4-Amino-2-hydroxybutyryl]-3′-deoxyribostamycin (3′-Deoxybutirosin B) (13).* To a solution of **12** (178 mg) in dioxane (4.3 ml), water (1.4 ml) was added and the slight opalescent solution was hydrogenated with palladium black under atmospheric pressure of hydrogen. After 2 h, the solution showed, on TLC with a system of $CHCl_3$–CH_3OH–17% NH_4OH (2: 2: 1), two ninhydrin positive spots (R_f 0.4, major; and R_f 0.7, slight). The solution was filtered and the filtrate was concentrated to dryness. The residue was dissolved in a drop of 1 M aqueous hydrochloric acid and the solution was heated at 60 °C for 1 h. The solution then showed, on TLC with a system of $CHCl_3$–CH_3OH–17% NH_4OH (1: 4: 3) (detected by 0.2% ninhydrin in pyridine) a major spot at R_f 0.27. Addition of acetone gave precipitates, which were charged on a column of CM-Sephadex C-25 (NH_4 form) and, after washing the column with water, elution was effected with aqueous ammonia with linear increase in ammonia concentration (0.1—0.4 M). The eluate containing **13** was concentrated to give a solid, 35 mg (37%), $[\alpha]_D^{24}$ +27° (*c* 2, H_2O); IR: 1640, 1560 cm^{-1}.

Found: C, 43.44; H, 7.26; N, 11.45%. Calcd for $C_{21}H_{41}N_5O_{11}\cdot H_2CO_3$: C, 43.92; H, 7.20; N, 11.64%.

The authors wish to express their thanks to Dr. H. Kawaguchi, Director of Research Institute, Bristol Banyu Co. Ltd., for the kind supply of 4′-deoxybutirosin B.

Quantitative Analysis of Organocalcium Halides by Double Titration

Nariyoshi KAWABATA,* Hisao NAKAMURA, and Shinzo YAMASHITA

Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received July 30, 1976)

The principle of Gilman's double titration method for organolithium compounds was applied to the quantitative analysis of organocalcium halides. Chloroform was found to be useful as a reactive halide which completely decomposed organocalcium halides, but did not react with other alkali. The method gave satisfactory analysis for methyl-, propyl- and phenylcalcium iodides.

Simple acid titration for the quantitative analysis of organocalcium halides (RCaX) usually gives too high values.[1] The quantitative analysis of organocalcium halides based on the amount of hydrocarbon (RH) evolved by the addition of water, alcohol or carboxylic acid usually gives reliable results. However, when R is a higher alkyl or aryl group, the analytical procedure gives satisfactory results only immediately after preparation of the organocalcium halides, since they react slowly with ethereal solvents to give the same hydrocarbon (RH), which remains in the system. Quantitative analysis based on the amount of carboxylic acid produced by carboxylation of organocalcium halides is not useful when R is an alkyl group, since the carboxylation does not give the corresponding carboxylic acid quantitatively.[1,2] The present work was undertaken to establish a useful, convenient, and reliable method for the quantitative analysis of organocalcium halides by application of Gilman's double titration method to organolithium compounds.[3-5] No successful result was available in the literature on quantitative analysis of organocalcium compounds by the double titration method.

Results and Discussion

In order to obtain accurate results in the Gilman's double titration method, it is necessary to completely decompose the organolithium compounds by the addition of a reactive halide before the second titration. The halide should not react with alkali other than the organolithium compounds. Thus the first problem was to find a suitable halide which rapidly reacts with organocalcium halides but not with other alkali. Benzyl chloride is not adequate for this purpose, since it reacts very slowly with organocalcium halides.[6] Bryce-Smith and Skinner[1] reported that preliminary attempts to use benzyl chloride in a double titration procedure for organocalcium halides gave no promising results. We attempted to use a variety of organic halides which were more reactive than benzyl chloride toward organocalcium halides.

First we carried out a double titration on a supernatant layer of phenylcalcium iodide in diethyl ether using carbon tetrachloride, chloroform, dibromomethane, and 1,2-dibromoethane. These halides were allowed to react with phenylcalcium iodide for 5—10 min at room temperature before the second titration. The standard molarity was determined based on the amount of benzoic acid obtained by carboxylation. Vapor phase chromatographic analysis showed neither benzophenone nor triphenylmethanol in the products of carboxylation indicating the adequacy of the above molarity as a standard. Chloroform gave satisfactory results which are given in Table 1. Carbon tetrachloride gave a too high value, probably due to the reaction of the chloride with alkali other than phenylcalcium iodide. On the other hand, dibromomethane and 1,2-dibromoethane gave too low values, apparently due to slow reactions of these halides with phenylcalcium iodide.

Table 1. Analysis of phenylcalcium iodide solution in diethyl ether[a]

Organic halide	Molarity: Total alkali	Molarity: By double titration	Molarity: Standard[b]	Error (%)
CCl_4	0.501	0.369	0.292	+26
$CHCl_3$	0.501	0.291	0.292	0
CH_2Br_2	0.501	0.189	0.292	−35
$BrCH_2CH_2Br$	0.501	0.189	0.292	−35

a) Phenylcalcium iodide was prepared by the reaction of 5.0 mmol of iodobenzene with 6.5 mmol of calcium metal in 10 ml of diethyl ether. The analysis was carried out for a supernatant layer of phenylcalcium iodide in diethyl ether at room temperature, and the reaction with organic halides was carried out for 5—10 min at room temperature before the second titration. b) The standard molarity was determined from the amount of benzoic acid evolved by carboxylation.

The mode of titration in a uniform suspension of phenylcalcium iodide in diethyl ether was similar to that in solution (Table 2). Although excess calcium metal was used in the preparation of phenylcalcium iodide, chloroform gave satisfactory results. Probably the reaction of the halide with excess calcium metal was

negligibly slow under the conditions. Thus, the double titration method can be satisfactorily applied to suspensions in diethyl ether, although experimental error would be more significant since it is not easy to take out a homogeneous sample.

Chloroform gave satisfactory results for a supernatant layer of phenylcalcium iodide in tetrahydrofuran (Table 3).

TABLE 3. ANALYSIS OF PHENYLCALCIUM IODIDE SOLUTION IN TETRAHYDROFURAN[a)]

Organic halide	Molarity			Error (%)

$CHCl_3$	0.821	0.490	0.485	+1
CH_2I_2	0.223	0.120	0.163	−26
CH_2I_2	0.821	0.390	0.485	−20
CH_2ClI	0.223	0.105	0.163	−26
CH_2ClI	0.821	0.350	0.485	−28

a) See footnote (a) in Table 1. b) See footnote (b) in Table 1.

Two series of experiments were carried out on a uniform suspension of phenylcalcium iodide in tetrahydrofuran (Table 4). In series A, excess iodobenzene was used in the preparation of phenylcalcium iodide. Chloroform gave satisfactory results. In series B, excess calcium metal was used in the preparation of phenylcalcium iodide. Each titration gave too high values, probably due to the reaction of the halides with calcium metal which remained unchanged in the suspension of phenylcalcium iodide. Thus, the double titration method can be satisfactorily applied to suspensions in tetrahydrofuran in the absence of unchanged calcium metal.

TABLE 4. ANALYSIS OF PHENYLCALCIUM IODIDE SUSPENSION IN TETRAHYDROFURAN[a)]

Organic halide	Molarity			Error (%)
	Total alkali	By double titration	Standard[b)]	
Series A[c)]				
$CHCl_3$	0.776	0.512	0.502	+2
CH_2I_2	0.776	0.417	0.502	−17
CH_2ClI	0.776	0.379	0.502	−25
Series B[d)]				
$CHCl_3$	0.834	0.625	0.490	+28
CH_2I_2	0.834	0.614	0.490	+25
CH_2ClI	0.834	0.598	0.490	+22

a) The analysis was carried out for a uniform suspension of phenylcalcium iodide in tetrahydrofuran at room temperature, and the reaction with organic halides was carried out for 5—10 min at room temperature before the second titration. b) The standard molarity was determined from the amount of benzoic acid evolved by carboxylation. c) Phenylcalcium iodide was prepared by the reaction of 7.0 mmol of iodobenzene with 6.5 mmol of calcium metal in 10 ml of tetrahydrofuran. d) Phenylcalcium iodide was prepared by the reaction of 5.0 mmol of iodobenzene with 6.5 mmol of calcium metal in 10 ml of tetrahydrofuran.

Chloroform gave satisfactory results for suspensions of methylcalcium iodide in diethyl ether (Table 5). The standard molarity was determined from the amount of methane evolved by the addition of acetic acid. Carbon tetrachloride also showed satisfactory results in contrast to the case of phenylcalcium iodide. The reaction of carbon tetrachloride with alkali other than methylcalcium iodide seems to be insignificant. Dibromomethane and 1,2-dibromoethane gave better results when allowed to react with methylcalcium iodide at room temperature for a period of time before the second titration.

$BrCH_2CH_2Br$	0.453	0.097(5)	0.331	−71

a) Methylcalcium iodide was prepared by the reaction of 5.0 mmol of methyl iodide with 6.5 mmol of calcium metal in 10 ml of diethyl ether. The analysis was carried out for a uniform suspension of methylcalcium iodide in diethyl ether at room temperature. b) The number in parentheses indicates the time in min of the reaction of methylcalcium iodide with organic halides at room temperature before the second titration. c) The standard molarity was determined from the amount of methane evolved by the addition of acetic acid.

TABLE 6. ANALYSIS OF METHYLCALCIUM IODIDE SUSPENSION IN TETRAHYDROFURAN[a)]

Organic halide	Molarity			Error (%)
	Total alkali	By double titration	Standard[b)]	
$CHCl_3$	0.394	0.306	0.299	+2
$CHCl_3$[c)]	0.422	0.254	0.196	+30
CH_2I_2	0.394	0.276	0.299	−8
CH_2ClI	0.394	0.243	0.299	−19
CH_2Br_2	0.394	0.255	0.299	−15

a) Methylcalcium iodide was prepared by the reaction of 7.0 mmol of methyl iodide with 6.5 mmol of calcium metal in 10 ml of tetrahydrofuran. The analysis was carried out for a uniform suspension of methylcalcium iodide in tetrahydrofuran at room temperature, and the reaction with organic halides was carried out at room temperature for 5—10 min before the second titration. b) The standard molarity was determined from the amount of methane evolved by the addition of acetic acid. c) Methylcalcium iodide was prepared by the reaction of 5.0 mmol of methyl iodide with 6.5 mmol of calcium metal in 10 ml of tetrahydrofuran.

tion. Bromotrichloromethane gave a too high value. In this case, the reaction mixture of the halide with methylcalcium iodide was already acidic before the second titration.

Chloroform gave satisfactory results for a uniform suspension of methylcalcium iodide in tetrahydrofuran in the absence of unchanged calcium metal (Table 6).

In a double titration on a uniform suspension of propylcalcium iodide in diethyl ether, propylcalcium iodide was prepared in diethyl ether. Most of the solvent was removed by evaporation under reduced pressure at room temperature and replaced by cyclohexane. The analysis was carried out for the suspension of propylcalcium iodide. The standard molarity was determined based on the amount of propane evolved by the addition of acetic acid. The replacement of diethyl ether by cyclohexane was carried out in order to make the standard molarity more accurate by decreasing the amount of propane dissolved in the solvent and that of vaporized solvent. Cyclohexane can easily be frozen. Another aliquot of the suspension was taken out and added to diethyl ether containing reactive organic halides at room temperature. The reaction of propylcalcium iodide with the halides was carried out at room temperature for 10 min before the second titration. The results are given in Table 7. Chloroform and dibromomethane gave satisfactory results.

Chloroform gave satisfactory results for a uniform suspension of propylcalcium iodide in tetrahydrofuran (Table 8).

From the results, the reactivity of organic halides toward organocalcium halides appears to be in the order bromotrichloromethane>carbon tetrachloride>chloroform>dibromomethane>1,2-dibromoethane>benzyl chloride. Of these halides we recommend chloroform for the double titration, since it gave satisfactory results for methyl-, propyl-, and phenylcalcium iodides. Only 5—10 min was sufficient to destroy the organocalcium halides at room temperature, the coloration during the course of titration not being significant.

Table 7. Analysis of propylcalcium iodide suspension in diethyl ether[a)]

Organic halide	Molarity: Total alkali	Molarity: By double titration	Molarity: Standard	Error (%)
CCl_4	0.693	0.112	0.129	−13
$CHCl_3$	0.693	0.121	0.129	−6
CH_2Br_2	0.693	0.126	0.129	−2
$BrCH_2CH_2Br$	0.693	0.050	0.129	−61

a) Propylcalcium iodide was prepared by the reaction of 5.0 mmol of propyl iodide with 6.5 mmol of calcium metal in 10 ml of diethyl ether, most of the solvent being removed by evaporation under reduced pressure at room temperature and replaced by cyclohexane. The standard molarity was determined from the amount of propane evolved by the addition of acetic acid to the suspension. The double titration was carried out for the suspension in diethyl ether at room temperature. The reaction of propylcalcium iodide with organic halides was carried out at room temperature for 10 min before the second titration.

Table 8. Analysis of propylcalcium iodide suspension in tetrahydrofuran[a)]

Organic halide	Molarity: Total alkali	Molarity: By double titration	Molarity: Standard[b)]	Error (%)
$CHCl_3$	0.487	0.242	0.240	+1
$CHCl_3$	0.259	0.080	0.086	−7
CH_2I_2	0.487	0.229	0.240	−5
CH_2I_2	0.259	0.064	0.086	−26
CH_2ClI	0.487	0.178	0.240	−26
CH_2ClI	0.259	0.043	0.086	−50

a) Propylcalcium iodide was prepared by the reaction of 8.0 mmol of propyl iodide with 6.5 mmol of calcium metal in 10 ml of tetrahydrofuran. The analysis was carried out for a uniform suspension of propylcalcium iodide in tetrahydrofuran at room temperature, and the reaction with organic halides was carried out at room temperature for 5—10 min before the second titration. b) The standard molarity was determined from the amount of propane evolved by the addition of acetic acid.

The double titration method using chloroform as a reactive halide gave good results for a solution of phenylcalcium iodide. The method can be applied to uniform suspensions of methyl-, propyl-, and phenylcalcium iodides in tetrahydrofuran in the absence of unchanged calcium metal, and to those in diethyl ether even in the presence of some amount of unchanged calcium metal, although experimental error would be significant because of the difficulty to take out a uniform sample.

Thus, double titration using chloroform would be useful as a method for quantitative analysis for organocalcium halides, although its accuracy would compare unfavorably with the Gilman procedure for organolithium compounds, since many organocalcium halides are poorly soluble in organic solvents and we must use suspensions instead of solutions.

Experimental

Vapor phase chromatographic analysis was performed on a Shimadzu GC-4A gas chromatograph using columns of Chromosorb 101 (80—100 mesh), active charcoal (60—80 mesh) and polyethylene glycol 20 M on Celite 545 (60—80 mesh) for benzoic acid, methane and propane, and other products, respectively.

Materials. Calcium metal of higher purity (Mitsuwa Chemicals, Ltd., Osaka) was rasped in dry liquid paraffin. Particle size of the rasped calcium was 0.1—0.3 mm. Organocalcium halides were prepared in diethyl ether or in tetrahydrofuran. The organocalcium halides were immediately subjected to double titration, or left to stand at room temperature for several days before analysis. Organic halides were purified by distillation after being dried with calcium chloride or phosphorus pentoxide. Purification of diethyl ether, tetrahydrofuran, cyclohexane, and nitrogen was carried out as described.[7,8)] Carbon dioxide was dried with concentrated sulfuric acid and molecular sieves.

Analytical Procedure. A 2 or 3 ml aliquot of the solution or suspension of organocalcium halides to be analyzed was taken out with a hypodermic syringe and hydrolyzed with 30

ml of distilled water in a 100 ml beaker and acidified with excess standard 0.5 M hydrochloric acid, and titrated with standard 0.1 M sodium hydroxide solution using phenolphthalein as an indicator to give the total alkali present. A second aliquot was taken out and added to 10 ml of diethyl ether or tetrahydrofuran containing 1 ml of the organic halide in a 100 ml Erlenmeyer flask under a nitrogen atmosphere. The mixture was stirred at room temperature for the prescribed time, after which it was hydrolyzed with distilled water, acidified with excess standard 0.5 M hydrochloric acid and titrated with a standard 0.1 M sodium hydroxide solution, phenolphthalein being used as the indicator. In the second titration, the end point sometimes became obscure due to the coloration of the system, but the coloration was not significant when chloroform was used.

The standard molarity of phenylcalcium iodide was determined from the amount of benzoic acid evolved after carboxylation. Carboxylation was carried out at −30 °C for 2 h, and acidified by the addition of 6 M hydrochloric acid. The amount of evolved benzoic acid was determined by vapor phase chromatography.

The standard molarity of methylcalcium iodide and propylcalcium iodide was determined from the amount of methane and propane evolved by the addition of acetic acid at −70 and −10 °C, respectively. The total amount of evolved gas was determined by a gas burette, the gas being analyzed by vapor phase chromatography. The gas usually contained a small amount of hydrogen.

Direct Observation of Dienol Intermediates in Photochemical Deconjugation of an α,β-Uusaturated Ketone. Photoisomerization of 1-Acetylcyclooctene[1]

Ryoji Noyori, Hiroshi Inoue, and Masao Katô

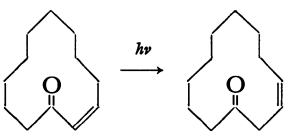
Department of Chemistry, Nagoya University, Chikusa, Nagoya 464

(Received August 30, 1976)

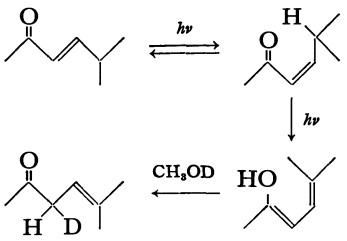
The photolysis of 1-acetylcyclooctene in acetonitrile solution leads to 3-(α-hydroxyethylidene)cyclooctene (two stereoisomers). Structures of the stable 1,3-dienols have been elucidated on the basis of their spectral data and chemical behavior. The dienols are highly air-sensitive. Upon heating, or by the action of an acid or base, they are converted to 3-acetylcyclooctene. In methanol-*O*-*d*, 3-acetylcyclooctene-3-*d* is formed. These findings provide the first, unambiguous evidence for the intervention of 1,3-dienol intermediates in photochemical deconjugation of an α,β-unsaturated ketone into the β,γ isomer.

Photo-irradiation of open-chain α,β-unsaturated ketones which bear hydrogen atom(s) at the position γ to the carbonyl function causes facile double bond migration to give the corresponding β,γ-unsaturated ketones.[2] Large-membered cyclic enones also undergo photoisomerization.[3] The deconjugation reaction is of

$$RCOCH{=}CHCH_2R' \xrightarrow{h\nu} RCOCH_2CH{=}CHR'$$



great synthetic value, because (1) the reaction proceeds under neutral and thermally moderate conditions and (2) the nonconjugated enone products are usually less stable compared with the starting conjugated enones. The reaction is considered to proceed *via* the mechanism outlined in Scheme 1, where the reaction of 5-methyl-3-hexen-2-one is exemplified. First, exposure of the α,β-unsaturated ketone leads to a photo-equilibrated mixture of the *trans* and *cis* isomers. The *cis* enone in an n, π* excited state[2] can abstract a γ-hydrogen atom to produce a 1,3-dienol, which upon ketonization results in the formation of the β,γ-isomer. The existence of the unstable dienol species has been suggested by the fact that photolysis in methanol-*O*-*d* affords 3-deuterio-5-methyl-4-hexen-2-one.[2b] However, none of these intermediates has been definitely characterized yet.[4] This paper describes direct observation of such a dienol intermediate in the photochemical deconjugation of enones, which provides unambiguous evidence for the mechanism involving dienol species.[5]



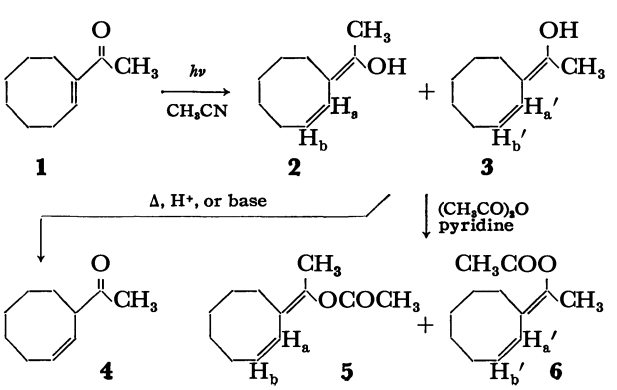
Scheme 1.

Results and Discussion

1-Acetylcyclooctene (**1**), taken as the enone substrate, was prepared by the titanium tetrachloride-catalyzed reaction of cyclooctene and acetyl chloride. The α,β-unsaturated ketone has characteristic IR bands (neat film) at 1668 (C=O) and 1638 cm^{-1} (C=C). The UV absorption maxima in acetonitrile solution occur at 233 (log ε 4.00) (π-π* band) and 319 nm (log ε 0.89) (n-π* band). All photolyses were effected in a well-deoxygenated solution placed in a Pyrex tube. A 200-W high-pressure mercury lamp was used as a light source and a 10% aq copper sulfate solution (1-cm depth) was employed as filter (<350-nm cut-off). Progress of the reaction was monitored spectroscopically.

Photolysis of the Enone **1** *in Acetonitrile.* A 5% solution of **1** in acetonitrile was placed in a Pyrex NMR tube and irradiated at room temperature under nitrogen atmosphere. The reaction was monitored by NMR. When the irradiation was continued for 10 h, the starting enone **1** was consumed completely and new alcoholic products (*vide infra*) were produced in *ca.* 80% yield. The products consisted of a 5: 1 mixture of two stereoisomers. The same ratio was obtained by GLPC analysis after conversion to the trimethylsilyl ethers by treating the reaction aliquot with *N*,*O*-bis(trimethylsilyl)acetamide. The photoreaction with more diluted solution (2.7×10^{-3} M) of **1** in acetonitrile proceeded in quantitative yield, as was indicated by monitoring the photolysis by UV spectroscopy. The absorption maximum of the enone at 233 nm was cleanly replaced by a new absorption band, λ_{max} 255 nm (log ε ≈4.0). The new products were identified as the dienols **2** and **3** on the basis of the following spectral and chemical evidence.

Infrared Spectrum of the Dienols **2** *and* **3**. Proof of the dienol structure was gained by the IR spectra shown



in Fig. 1. The photolysate exhibited a strong O–H strech at 3450 cm^{-1}, olefinic absorption at 1656 cm^{-1}, and C–O band at 1191 cm^{-1}, in accord with the assigned structures **2** and **3**. A carbonyl group is not present in the new products. A small absorption band was observed at $\approx$1700 cm^{-1}, but there were considerable variations in relative intensity of the band depending on the individual photolysis conditions. Therefore, apparently this is due to the presence of some impurities in the reaction mixture.

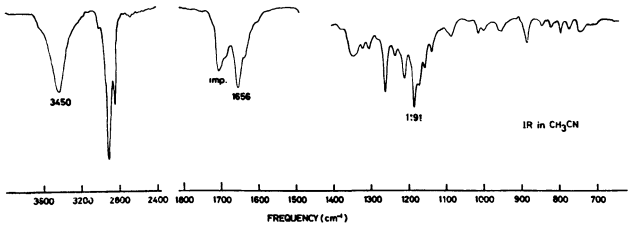


Fig. 1. Infrared spectrum of the photolysate of **1** (5% CH_3CN solution).

NMR Spectrum of the Dienols 2 and 3. Figure 2 shows the NMR signals arising from the olefinic protons of the photoproducts. The spectrum can be explained only in terms of a 5:1 mixture of the dienols **2** and **3**. The observed coupling constants were: $J_{Ha-Hb}=J_{Ha'-Hb'}=12$ Hz and $J_{Hb-CH_3}=8$ Hz. The splitting patterns bear a close resemblance to those of 3-methylenecyclooctene; the endocyclic vinylic protons (δ 5.50 (C-2) and 6.20 (C-1)) are coupled to each other with $J=12$ Hz. Occurrence of the Ha signal at a lower field, δ 6.48, than that of Ha′, δ 6.14, should be ascribed to the anisotropic effect of the enol oxygen. The spectrum at the higher field, even when taken in CD_3CN, is rather complicated by overlapping with signals of high molecular weight by-products (<20%) and CHD_2CN. However, the spectrum exhibited distinct singlets at δ 1.88 and 1.82 arising from the vinylic methyl groups of **2** and **3**, respectively. The signal assignments were further confirmed by double resonance techniques; when Hb and Hb′ were irradiated, Ha and Ha′ appeared as singlets, while irradiation of Ha changed the signal pattern of Hb into a triplet with $J=8$ Hz.

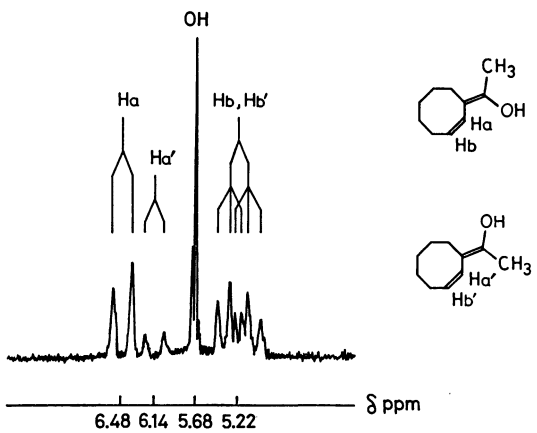

Fig. 2. NMR spectrum of the photolysate of **1** (5% CH_3CN solution, 60 MHz, tetramethylsilane as internal standard).

Intermolecular exchange of the hydroxylic protons is not rapid and hence the NMR absorption for each stereoisomer occurred separately. The chemical shift values, δ 5.68 and 5.71, are intermediate between that of ordinaryl alcoholic protons and that of phenolic protons;[6] methyl alcohol and phenol (4% acetonitrile solution, room temperature) give the OH signals at δ 2.45 (quartet) and 6.96, respectively. The low exchangeability of the OH protons should be ascribed to the moderate acidity and the intermolecular hydrogen-bonding with solvent acetonitrile. The hydroxy signals disappeared upon addition of an excess of methanol-*O-d*.

Stability of the Dienols 2 and 3. The dienols produced by photolysis of **1** were highly air-sensitive. When air was introduced to the acetonitrile solution, the dienols disappeared immediately and dimeric and polymeric substances were formed. When the acetonitrile solution was concentrated *in vacuo* at room temperature, polymerization of the products took place. The dienols, however, were quite stable in dilute acetonitrile solution covered by inert gas and remained virtually unchanged for 3 days at ambient temperature. Under forcing conditions, or with added acids or bases, the dienols were converted irreversibly to β,γ-(and α,β-)unsaturated ketones. The product ratio is dependent on the reaction conditions (Table 1). Heating at 100 °C gave an 83:17 mixture of the β,γ-unsaturated ketone **4** and the starting enone **1**. Addition of a trace amount of sulfuric acid led to a similar mixture of the enones. On the other hand, treatment with potassium *tert*-butoxide produced the β,γ isomer exclusively. When pyridine was added to the acetonitrile solution, the NMR signal due to the OH proton disappeared spontaneously but the isomerization proceeded very slowly. When the mixture stood for 4 days at 25 °C, **4** was formed as a sole product.

Table 1. Ketonization of the dienols **2** and **3**[a]

Additive	Solvent	Reaction conditions	Yield %[b]	**4**:**1** ratio[b]
None	CH_3CN	25 °C, 3 days	0	—
None	CH_3CN	100 °C, 2 h	80	83:17
None	CH_3OH	25 °C, 4 days	100	100:0
H_2SO_4[c]	CH_3CN	25 °C, <30 s	100	75:25
t-C_4H_9OK[c]/ t-C_4H_9OH	CH_3CN	25 °C, <30 s	80	100:0
$(C_2H_5)_3N$[d]	CH_3CN	25 °C, <30 s	52	100:0
Pyridine[d]	CH_3CN	0 °C, 4 days	~100	100:0

a) A 5:1 mixture of **2** and **3** in acetonitrile was used as starting material. b) Determined by NMR analysis using benzene as internal standard. c) A trace amount was used. d) Excess reagent was used.

The structure of the enone **4** was fully substantiated by the analytical and spectral data. The nonconjugated enone **4** gave an IR carbonyl band at 1710 cm^{-1}. The presence of an acetyl group and a disubstituted double bond was confirmed by the three-proton NMR singlet at δ 2.10 and two-proton multiplet at δ 5.66, respectively.

Acetylation of the Dienols. Owing to high air-sensitivity, the dienols **2** and **3** could not be isolated from the acetonitrile solution. However, the corresponding acetates were stable enough to isolated and their characteri-

zation provided further chemical evidence for the dienol structure. Thus treatment of a mixture of **2** and **3** in acetonitrile with acetic anhydride–pyridine at −20 °C furnished an 83: 17 mixture of the acetates **5** and **6** in 60% yield together with the enone **4** (40%). The acetoxy derivatives **5** and **6** separated by preparative GLPC were identical with samples which were prepared independently by the reaction of the enone **1** and acetic anhydride in the presence of *p*-toluenesulfonic acid (**5**: **6** ratio in the latter case was 24: 76). UV absorption maximum of both acetates occurred at ≈240 nm (log ε 4.0—4.1). The IR spectra exhibited characteristic bands at 1755—1753 and 1206 cm^{-1} due to the acetate moieties. The NMR spectra exhibited singlets at δ 1.87 (broad) and 2.07 (sharp), indicating the presence of vinylic and acetyl methyl groups, respectively. The signal patterns in the olefinic region are given in Figs. 3 and 4. The vinylic proton Ha (or Ha′) is coupled to Hb (or Hb′) with J=12 Hz and appeared as a doublet. The Hb (or Hb′) signal is further split by coupling with the adjacent methylene protons (J=7 Hz). The stereochemistry of these isomers could be distinguished by examining the intermolecular nuclear Overhauser effect (NOE).[7] When the vinylic methyl protons of **6** were saturated by double irradiation, the Ha′ signal showed a 19±1% increase in integrated intensity. By contrast, irradiation of the methyl group in **5** resulted in no change in the signal intensity of Ha (0±1%). These results indicate that the methyl protons and Ha′ proton in **6** are in close proximity but the methyl group and Ha proton in **5** are not.

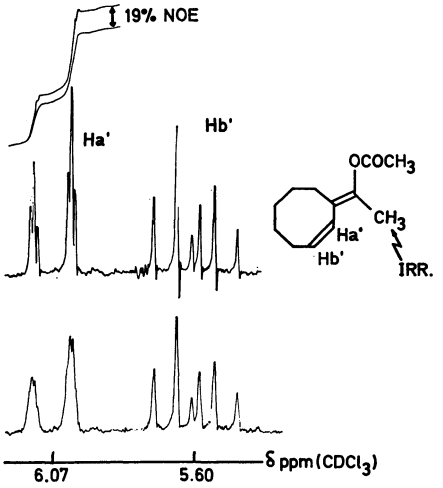

Fig. 3. Measurement of NOE in **6** (10% $CDCl_3$ solution, 100 MHz, tetramethylsilane as internal standard). Upper: spectrum taken with irradiation at the methyl group. Lower: normal spectrum.

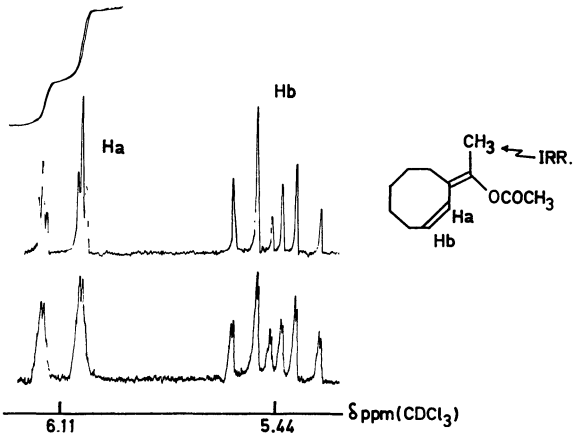

Fig. 4. Measurement of NOE in **5** (10% $CDCl_3$ solution, 100 MHz, tetramethylsilane as internal standard). Upper: spectrum taken with irradiation at the methyl group. Lower: normal spectrum.

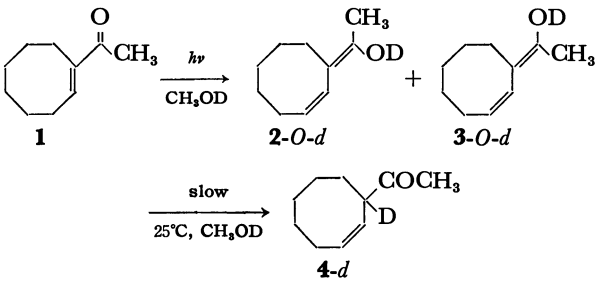
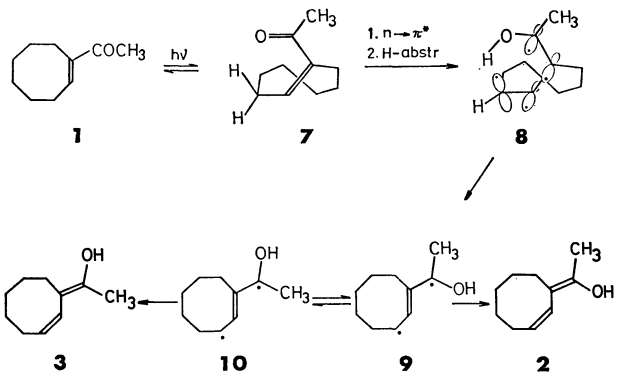
Photolysis of the Enone 1 in Methanol. The enone **1** in methanol has in UV region a π-π* and n-π* band at 234 (log ε 4.00) and 306 nm (log ε 0.89), respectively. When the enone **1** in methanol-*O*-*d* placed in an NMR tube was exposed to light of wavelength >350 nm for 10 h, the dienols **2**-*O*-*d* and **3**-*O*-*d* were produced. These dienols are remarkably stable even in the alcoholic solvent. The NMR spectrum of the photolysate was practically the same as that obtained in the acetonitrile (Fig. 2) except for the lack of the OH signal. When stood at room temperature, the dienols were isomerized slowly. After 4 days, the deuterated β,γ enone **4**-*d* was



formed as a sole product. NMR analysis of the isolated product indicated the isotopic purity of *ca.* 95%; in going from **4** to the deuterated product **4**-*d*, a multiplet at δ 3.4 srising from the CHCOCH$_3$ proton vanished almost completely.

Photolysis of the Enone 1 under Other Conditions. Neither the dienols **2** and **3** nor the enone **4** was produced by the photolysis of **1** in nonpolar solvents such as benzene, cyclohexane, carbon tetrachloride, chloroform, or carbon disulfide. Irradiation of **1** in pyridine or dimethyl sulfoxide gave the deconjugation product **4**. Attempted sensitization of the photoreaction (benzophenone in acetonitrile, acetophenone in acetonitrile, or acetone as solvent) has not been successful.

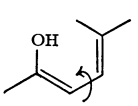
Mechanism of the Dienol Formation from 1. The photochemical formation of the dienols **2** and **3** from the enone **1** is best explained by a mechanism outlined in Scheme 2. The conjugated enone **1** is known to undergo photochemical *cis-trans* isomerization, establishing an equilibrium between **1** and **7**.[8] The *trans* isomer **7** contains a torsionally strained double bond and is much less stable than the starting *cis* enone **1**. Therefore, this isomer with a short lifetime, reverting thermally to **1**, is contained in rather low concentration in the equilibrium mixture. Fortunately, however, the labile isomer **7**, owing to a reduction in the symmetry-forbiddenness of the n-π* transition, has the enhanced extinction coefficient in the >300-nm region and can absorb incident light



Scheme 2

more efficiently than the major *cis* isomer **1**.[8] Inspection of models indicates that the γ-hydrogen abstraction by the n, π^* carbonyl oxygen through a cyclic transition state is feasible only with such *trans* enone **7**. Although the spin multiplicity of the n, π^* state that causes this hydrogen abstraction is uncertain as yet, the observation can be simply accounted for by assuming the involvement of the triplet species.[2] Thus the twisted triplet biradical **8** initially formed from **7** is stabilized by changing the geometry to give the sterically less constrained, interconvertible biradicals **9** and **10**. Subsequent decay to the ground state affords the dienols **2** and **3**. The production of these two isomers even at an early stage of the reaction as well as the lack of noticeable time-dependency of the isomeric ratio (5: 1 by NMR analysis) is in accord with this consideration. However, the stereoisomeric biradicals **9** and **10** could also be formed *via* the possible long-lived, singlet biradical **8** arising from the excited singlet enone **7**. Finally, thermal or catalyzed ketonization of the dienol intermediates concludes the overall photo-induced deconjugation reaction of the α,β-unsaturated ketone.

Origin of the High Stability of the Dienol Species. The existence of the simple dienols **2** and **3** as long-lived species seems highly unusual.[9] Full account for this observation is open to further detailed studies. At present, the following three factors are conceived to be contributing to the stability. First, the dienols **2** and **3** have the fairly rigid *s-trans* diene structure. The restriction of conformational freedom may preserve stability through double bond conjugation. On the other hand, in the ordinary photoisomerization of α,β-unsaturated ketones, the initially formed dienols have an open-chain *s-cis* dienoid structure. The flexible dienols are liable to ketonize through conformational change accompanying loss of the conjugation (*cf.* **11**). Secondly, the dienol-enone isomerization **2**→**4** (or **3**→**4**) is accompanied by decrease in the number of sp^2-hybridized carbons in the eight-membered skeleton (three to two). The favoring of sp^2 configuration in eight-membered rings over sp^3 structure[10] may be one source of the unusual stability. Finally, the presence of strong intermolecular hydrogen bonding between the dienols and the acetonitrile solvent may be an additional stabilization factor.[11]



11

Experimental

General. NMR spectra were measured with a JEOL CO JMN-C-60H or C-100H spectrometer. Unless otherwise stated, tetramethylsilane was used as internal standard. IR spectra were recorded with a Japan Spectroscopic Co. DS-402G spectrometer, with a polystyrene film used for calibration. Air-sensitive solutions were transferred to a cell with a syringe which had been previously wet with nitrogen-saturated solvent to preclude air leakage along the barrel. UV spectra were taken with a Perkin-Elmer 202 spectrometer. Mass spectra were taken with a Hitachi RMU-6C spectrometer. Analytical gas-liquid partition chromatography (GLPC) was performed on a Yanagimoto Model G-8 instrument, equipped with a 2 mm×2 m column of Apiezon grease L (5%) on Chromosorb W and a flame ionization detector using nitrogen as carrier gas. The column temperature was maintained at 160 °C. In quantitative analyses, areas under the peaks in the chromatogram were measured by the cut-and-weigh method. Preparative GLPC was done on a Yanagimoto Model GCG-3D instrument using helium as carrier gas and a 4 mm×2 m column of Apiezon grease L (10%) on Chromosorb W. All irradiations were effected externally using a 200-W high-pressure mercury arc through 10% aq $CuSO_4$ filter solution (1 cm depth).

Materials. Solvents for photochemical reactions were purified by simple distillations and stored under nitrogen atmosphere. Acetonitrile was dried by distillation from P_2O_5 (four times) and anhydrous K_2CO_3. The solvent was further purified by simple distillation under nitrogen. 1-Acetylcyclooctene (**1**), bp 75—85 °C (3 mmHg), was prepared by the method of Cantrell and Shechter from cyclooctene and acetyl chloride.[12] As the Lewis acid catalyst, titanium tetrachloride was used in place of stannic chloride. Usually, the material was freshly purified by preparative GLPC before each photolytic experiment.

*Photolysis of **1** in Acetonitrile.* A 5% acetonitrile solution of **1** was placed in a Pyrex NMR tube and deoxygenated by bubbling slowly with pure nitrogen for 30 min. The solution covered by nitrogen was irradiated at room temperature. Progress of the reaction was monitored by NMR analysis. After 10-h irradiation, the starting material was consumed completely and a 5: 1 mixture of the dienols **2** and **3** was formed. Its NMR spectrum is given in Fig. 2; δ 5.22 (dt, J=12 and 8 Hz, Hb and Hb'), 5.68 (s, OH of **2**), 5.71 (s, OH of **3**), 6.14 (d, J=12 Hz, Ha'), and 6.48 (d, J=12 Hz, Ha). The OH signals disappeared upon addition of an excess of CH_3OD. Yield determined on the basis of added benzene standard was *ca.* 80%. The photolysate obtained by the reaction in CD_3CN showed NMR signals at δ 1.88 and 1.82 (singlets) due to the olefinic methyl groups of **2** and **3**. Results of the decoupling experiments were in accord with the assignments. The photolysate in an NMR tube was transferred with a syringe into an NaCl IR cell which had been flushed with nitrogen, and subjected to IR measurement (Fig. 1).

A 2.7×10^{-3} M solution of **1** in acetonitrile was deoxygenated by four freeze(−78 °C)-pump(0.008 mmHg)-thaw cycles, transferred directly to a UV cell (1 cm×1 cm), and sealed under nitrogen atmosphere. The photolysis was conducted by external irradiation (>350 nm) and the reaction course was monitored by UV analysis. The absorption of **1**, λ_{max} 233 nm, was cleanly replaced by a new band, λ_{max} 252 nm (log $\varepsilon \approx 4.0$). After a 6 h irradiation, the reaction was complete.

*Preparation of the Dienol Acetates **5** and **6**.* An acetic anhydride solution (170 ml) containing **1** (1.2 g, 80 mmol) and

p-toluenesulfonic acid (1.5 g, 80 mmol) was slowly distilled under atmospheric pressure through a short column. About 4 h were required until the final volume was reduced to 70 ml. Most of the acetic anhydride then was removed under reduced pressure. The residue was dissolved in ether, treated with ice-cooled 5% aq sodium hydroxide and then with water, and dried over $MgSO_4$. Concentration followed by distillation gave an oil (830 mg), bp 95—100 °C (3 mmHg). GLPC analysis gave three peaks at 4.7 (71%, **6**), 5.4 (22%, **5**), and 6.6 min (7%). Each component was collected by preparative GLPC. **5**, UV (95% C_2H_5OH) 241 nm (log ε 4.15); IR (neat) 1755 and 1206 cm^{-1} (acetate); NMR (CCl_4) δ 1.59 (m, 6H, CH_2), 1.87 (broad s, 3H, $=C(OCOCH_3)C\underline{H}_3$), 2.07 (sharp s, 3H, $COCH_3$), 2.2—2.6 (m, 4H, allylic CH_2), 5.44 (dt, 1H, J=12 and 7 Hz, Hb), and 6.11 (d, 1H, J=12 Hz, Ha); the exact mass spectrum *m/e* 194.1310 (calcd for $C_{12}H_{18}O_2$: 194.1307). **6**, UV (95% C_2H_5OH) 239 nm (log ε 3.98); IR (neat) 1753 and 1206 cm^{-1} (acetate); NMR (CCl_4) δ 1.55 (m, 6H, CH_2), 1.87 (broad s, 3H, $=C(OCOCH_3)C\underline{H}_3$), 2.07 (sharp s, 3H, $COCH_3$), 2.2—2.5 (m, 4H, allylic CH_2), 5.60 (dt, 1H, J=12 and 7 Hz, Hb'), and 6.07 (d, 1H, J=12 Hz, Ha'); exact mass spectrum *m/e* 194.1300 (calcd for $C_{12}H_{18}O_2$: 194.1307). The nuclear Overhauser effects in the NMR of **5** and **6** were measured in the well-deoxygenated $CDCl_3$ solutions. The results were shown in Figs. 3 and 4. The third component was produced in only a small amount and was not isolated in an analytically pure state. Based on the following spectral data, it was tentatively assigned as 1-(α-acetoxyvinyl)-cyclooctene. IR(neat) 1757 (acetate), 1635 and 1608 (C=C), 1214 and 1184 (acetate), and 871 cm^{-1} ($=CH_2$); NMR (CCl_4) δ 1.49 (m, 8H, CH_2), 2.12 (s, 3H, $COCH_3$), 2.2—2.5 (m, 4H, allylic CH_2), 4.64 and 4.93 (d, 1H each, J=2 Hz, $=CH_2$), and 5.78 (t, 1H, J=8 Hz, =CH); mass spectrum *m/e* 194 (M^+).

*Acetylation of the Dienols **2** and **3**.* *(a) Analytical Scale*: Under nitrogen atmosphere a 5-μl portion of a 5: 1 mixture of **2** and **3** in acetonitrile (photolysate of **1**) was added to a mixture of pyridine (10 μl) and acetic anhydride (5 μl) which had been cooled at −20 °C in a semimicro sampling tube. GLPC analysis of the mixture revealed the formation of **4** (42%, 2.8 min), **5** (48%, 6.6 min), and **6** (10%, 4.7 min).

(b) Preparative Scale: A solution of **1** (500 mg; 3.3 mmol) in acetonitrile (12 ml) was divided in three Pyrex tubes (0.8 cm × 4 cm), deoxygenation by bubbling with purified nitrogen for 10 min, and irradiated under the above described conditions. The photolysate obtained after 18-h irradiation was treated with a mixture of pyridine (0.2 ml) and acetic anhydride (0.3 ml) for 1 h at room temperature. The solutions were combined and concentrated *in vacuo*. The residue was dissolved in ether, washed with water, and dried over $MgSO_4$. Concentration and distillation (90—100 °C (3 mmHg)) gave an oil (256 mg). GLPC analysis of the oil afforded three peaks at 2.8 (80%, **4**), 4.7 (3%, **6**), and 6.6 min (15%, **5**). Each component was isolated by preparative GLPC and identified on the basis of its spectral properties. The dienol acetates **5** and **6** were compared with the authentic samples. Spectral characteristics of 3-acetylcyclooctene (**4**)[13] were: IR (neat) 1710 (C=O) and 1360 cm^{-1} ($COCH_3$); NMR (CCl_4) δ 1.60 (m, 8H, CH_2), 2.10 (s, 3H, $COCH_3$), 2.20 (m, 2H, allylic CH_2), 3.37 (m, 1H, $C\underline{H}COCH_3$), and 5.66 (m, 2H, =CH); mass spectrum *m/e* 152 (M^+).

Found: C, 78.95; H, 10.69%. Calcd for $C_{10}H_{16}O$: C, 78.89; H, 10.57%.

*Silylation of the Dienols **2** and **3**.* A 5-μl portion of the photolysate of **1** in acetonitrile was mixed with *N,O*-bis(trimethylsilyl)acetamide (10 μl) in a semimicro sampling tube under nitrogen atmosphere at room temperature. GLPC analysis of the mixture revealed eluates at 2.8 (28%), 7.7 (14%), and 8.8 min (60%). The first peak was due to **4**, and the latter two were assigned as the silyl ethers of **2** and **3**.

*Examination of the stability of **2** and **3**.* The stability of the dienols was examined under various conditions. When air was admitted to an acetonitrile solution of **2** and **3**, polymeric substances were formed immediately. A solid dimer was separated from the solution; mass spectrum *m/e* 302 (M^+); IR (KBr) 1656 cm^{-1} (C=O). The exact structure remains to be determined. The dienols, however, were fairly stable under inert gas atmosphere. The dienols were allowed to react in an NMR tube under conditions described in Table 1.

*Photolysis of **1** in Methanol-O-d.* The enone **1** (35 mg, 0.23 mmol) was dissolved in methanol-*O*-*d* (0.5 ml, E. Merck, deuterium content >99%) in an NMR tube, deoxygenated, and irradiated as described above. After a 10 h irradiation, **1** was consumed completely to yield the dienols **2**-*O*-*d* and **3**-*O*-*d*. NMR in the olefinic region was identical with that taken in acetonitrile except the absence of OH signals. After the solution stood at 25 °C for 4 days, the signals due to these dienols vanished completely and the peaks due to the enone **4**-*d* appeared. GLPC analysis of the aliquot exhibited a single peak with retantion time of 2.8 min (identical with that of **4**) except for the solvent peak. Concentration of the photolysate, followed by distillation (bath temp 75—85 °C (3 mmHg)) gave 3-acetylcyclooctene-3-*d* (**4**-*d*) as a colorless oil. NMR analysis (CCl_4) revealed the isotopic purity of *ca.* 95%; δ 1.60 (m, 8H, CH_2), 2.10 (s, 3H, $COCH_3$), 2.20 (m, 2H, allylic CH_2), and 5.66 (m, 2H, =CH). Mass spectrum *m/e* 153 (M^+).

We thank Professor Akira Tatematsu of Meijo University for obtaining the exact mass spectra. We are also grateful to Drs. Toshiaki Nishida and Iwao Miura of Nippon Electric-Varian for the measurement of NOE effects.

A Study of the Solubilization of Polar Oily Materials by Sodium Dodecyl Sulfate

Keizo OGINO, Masahiko ABE, and Nobuo TAKESITA

Faculty of Science and Engineering, Science University of Tokyo, 2641, Yamazaki, Noda, Chiba 278

(Received May 21, 1976)

The difference due to carbon-chain lengths and kinds of polar groups in the solubilizing phenomenon caused by Sodium Dodecyl Sulfate (SDS) of polar normal fatty acids and polar normal alcohols has been studied in terms of the amount of solubilization, the viscosity, and the surface tension. The amount of solubilization decreased with an increase in the number of carbon atoms in the molecules of oily materials, and it was larger for normal fatty acids than for normal higher alcohols with the same number of carbon atoms in the molecule. It was found that the oily materials of a greater amount of solubilization exhibited a small viscosity and a small rate of the reduction of surface tension.

Solubilization is a phenomenon in which a solution of a surfactant in concentrations beyond the critical micelle concentration (CMC) dissolves a variety of organic compounds to yield a transparent solution. This results from the solution of the substances into the micelles. The structure of the micelles has been described by McBain[1] and by Hartley and coworker,[2] but it is still a matter of controversy. Among the ways of incorporating the solubilizate into the micelles, which are closely related to the structure of the micelles, are (a) adsorption on the surface of the micelles; (b) deep penetration of the palisade layer and (c) dissolution in the hydrocarbon core, these methods have been described by Kolthoff,[3] Riegleman,[4] and Mulley respectively.[5]

In this study normal fatty acids and normal higher alcohols with different polarities were solubilized by SDS, and the mechanism of the solubilization was investigated by measuring the amount of solubilization, the values of the CMC, the relative viscosities, and the surface tension. We found that the amount of solubilization decreased with an increase in the number of carbon atoms in the molecules of polar oily materials, and was larger for fatty acids than for alcohols with the same number of carbon atoms in the molecule.

As regards the CMC, the smaller the number of carbon atoms in the molecules of polar oily materials, the greater the reduction in CMC compared with that of SDS alone. It has been found that the CMC of SDS solubilizing an oily material is given by:

$$\mathrm{CMC} = A\sqrt{N_c} + B$$

where A and B are experimental constants and N_c is the number of carbon atoms in the molecules of the oily materials.

The relative viscosities of SDS solutions of oily materials increased with an increase in the number of carbon atoms in the molecules of oily materials, and they were larger for normal higher alcohols than for normal fatty acids with the same number of carbon atoms in the molecules.

The rate of the reduction of surface tension increased with an increase in the number of carbon atoms in the molecules of polar oily materials; it was greater for alcohols than for fatty acids with the same number of carbon atoms in the molecules. The surface tension at the saturation of solubilization exhibited a constant value, regardless of the kinds of oily materials added.

To summarize, it was found from this experiment that the oily materials of greater amounts of solubilization exhibited a smaller viscosity and a smaller rate of reduction in the surface tension.

Experimental

Materials. *Surfactant*: Sodium Dodecyl Sulfate (SDS) of a regent grade was extracted with ether and recrystallized from ethanol.

Polar Oily Materials: The octanoic acid (C_8), decanoic acid (C_{10}), dodecanoic acid (C_{12}), and tetradecanoic acid (C_{14}) were the purest grade products of Wako-Junyaku and were more 99% pure; The octyl alcohol (C_8, bp 179.5 °C), decyl alcohol (C_{10}, bp 228—232 °C), dodecyl alcohol (C_{12}, bp 86.5 °C), tetradecyl alcohol (C_{14}, bp 255—259 °C), and hexadecyl alcohol (C_{16}, bp 190 °C) were the purest grade products of Wako-Junyaku.

Apparatus and Conditions. When polar oily materials are added to a SDS solution, beyond the saturation point they are emulsified and the solution becomes turbit. The following procedure was used for the determination of the limits of solubilization. Into several 100 ml glass-stoppered flasks, 50 ml portions of a solution of a given concentration of SDS were placed; then varying amounts of polar oily materials were added to them, and the mixtures were shaken while being stirred for 12 h in a thermostat at 40 °C, followed by setting until a solubilization equilibrium was established. After the equilibrium had been established, the turbidity of the solution was measured with an Electro photocolorimeter, Hirama 2B type, with a cell 10.0 mm in length at 655 nm. The turbidity concentration obtained was extrapolated to zero in order to obtain the amount of solubilization. The CMC of SDS was determined from the solubilities of the polar oily materials in SDS solutions of various concentrations.

The relative viscosities of the solutions solubilizing oily substances were measured at 40.0 °C$\pm$0.1 with an Ubelohde viscometer with appropriate auxiliary equipment to keep atmospheric moisture off as far as possible. The time of flow was determined with a stop watch of a 0.1 s precision; the overall fluctuations of the time measured were within$\pm$0.1 to 0.2 s. The specific gravity was determined by using a pycnometer with a capacity of about 25 ml.

The effective specific volume of 1 g of a SDS including a polar oily material was calculated from the values of the relative viscosity.[6]

The surface tensions of the solubilized solutions were measured at 40.0 °C$\pm$0.1 with a Wilhelmy tensiometer, Shimadzu ST-1 type, equipped with a glass plate.

Results and Discussion

Solubilizing Power and CMC of SDS. The difference due to the carbon-chain lengths and the kinds of polar groups in the solubilization caused by SDS solutions has been studied. Figure 1 shows the optical densities of various concentrations of SDS solutions with an increase in the amounts of dissolved octanoic acid. The rapid increase in I_0/I began when emulsion droplets first appeared. The point of the intersection of the curves representing the optical density with the horizontal axis is considered to give the solubility of octanoic acid in the SDS solution. Plots of the solubility of materials in SDS of various concentrations which were obtained in the manner described above are shown in Figs. 2 and 3. As is evident from the figures, the solubility remained constant near null until the critical concentration was reached, beyond which point it showed a sharp increase in the SDS micelles due to solubilization. The slopes of these lines and the intersections of the horizontal

axis with these lines are the solubilizing power and the CMC respectively. Figure 4 shows the change in the solubilizing power with an increase in the number of carbon atoms in the molecules of oily materials. As is evident from Figs. 1, 2, and 3, the solubility and the solubilizing power decreased with an increase in the number of carbon atoms in the molecules of oily materials, and they were larger for normal fatty acids than for normal higher alcohols with the same number of carbon atoms in the molecule. This result is considered to be due to the decrease in the magnitude of the dipole moment with the increase in the number of carbon atoms in the molecule of the oily material and to the difference in polar groups between normal fatty acids and normal higher alcohols with the same number of carbon atoms in the molecule.[7]

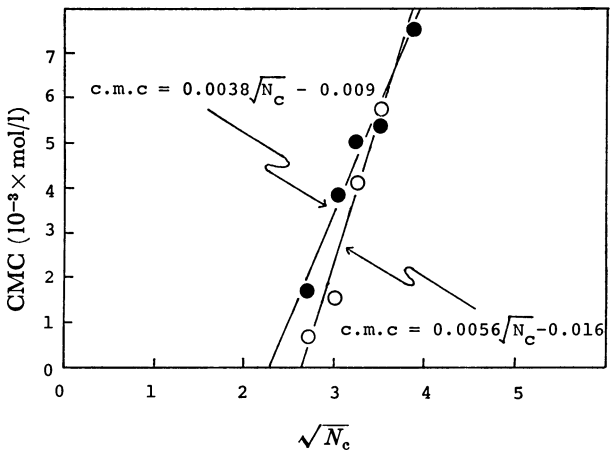

Fig. 6. Relationship between the CMC of SDS and the carbon number of oily materials.
N_c is the number of carbon atoms in the molecules of oily materials.
○=Normal fatty acids; ●=normal higher alcohols.

As is shown in Figs. 2 and 3, the CMC of SDS with oily materials was smaller than that of SDS alone (6.94×10^{-3} mol/l) and decreased with a decrease in the number of carbon atoms in the molecules of the oily materials. As may be seen from Fig. 5, this is considered to be due to the fact that the deep penetration of polar molecules into the palisade layer caused the surface charge density to decrease, leading to a reduction of the free energy of mixing.[8] Figure 6 shows the effect of oily materials added on the CMC of SDS; the following equations can be written:

for normal fatty acids,

$$\mathrm{CMC} = 0.0056\sqrt{N_c} - 0.016$$

for normal higher alcohols,

$$\mathrm{CMC} = 0.0038\sqrt{N_c} - 0.009$$

where N_c is the number of carbon atoms in the molecules of the oily materials.

Relative Viscosity and Effective Specific Volume. Figure 7 shows the relative viscosities of the solutions which were produced by solubilizing oily materials using SDS of a given concentration (6.94×10^{-3} mol/l). The arrows in the figure indicate the limits of solubilization in Figs. 2 and 3. For a given concentration of oily materials, the relative viscosity of the solution increased with an increase in the number of carbon atoms in the molecules of oily materials. For the same number of carbon atoms in the molecules of oily materials, the relative viscosity of the normal higher alcohols was larger than for normal fatty acids. Past the limit of solubilization, the relative viscosities of octanoic acid, of decanoic acid, and of octyl alcohol remained approximately constant; on the other hand, that of decyl alcohol and dodecyl alcohol continued to grow. This is considered to be because emulsification occurs and because the effect which polar materials have on relative viscosities under the states of dispersion of emulsion seems to become greater. As may be seen from Fig. 4, there are inflection points in solubilizing power: at a dodecyl alcohol for normal higher alcohols and at a dodecanoic acid for normal fatty acids. According to the study of the rolling-up phenomenon of polar oily materials in SDS solutions,[9] both octanoic acid and octyl alcohol were

immediately dissolved or solubilized by SDS solutions, a decanoic acid–SDS solution system occurred simultaneously with solubilization and molecular complex formation at the interface, and a molecular complex was formed at the decyl alcohol and dodecyl alcohol/SDS solution interface. In consideration of the above findings, there must be same changes in the properities of decyl alcohol and decanoic acid. According to Klevens,[7] when the non-polar parts of the solubilizates, polar compounds, become too large to overcome the effects of polar groups in the molecules, the solubilizates exhibit behavior resembling that of hydrocarbons, giving rise to a so-called transition solubilization phenomenon, which represents properties intermediate between polar compounds and hydrocarbons.

Based on the relative viscosity, η_r, obtained from Guth and Simha's equation,[10-13] which is a form of Einstein's equation extended to more concentrated solutions:

$$\eta_r = 1 + 2.5\phi + 14.1\phi^2$$

where ϕ is the volume fraction occupied by the spherical particles, the effective specific volume of 1 g of SDS including oily materials, V, is expressed as follows:[6,10]

$$V = \phi/C$$

where C is the concentration of the solution in g/ml. The specific volumes of octanoic acid, octyl alcohol, and decanoic acid changed at the limit of solubilization. From the standpoint of the solubilizing phenomenon, a comparison of polar oily materials based on fixed concentrations is not always appropriate. Therefore, a comparison of the relative viscosity, η_r, with the effective specific volume, V, at the saturation of an solubilized oily material is shown in Table 1. As may be seen from

Table 1. Comparison of the relative viscosity with the effective specific volume at the saturation of oily materials

	N_c	Limits of solubilization (mol/l)	η_r	V (ml/g)
Normal fatty acids	C_8	2.50×10^{-2}	1.040	2.65
	C_{10}	1.00×10^{-2}	1.094	8.58
Normal higher alcohold	C_8	1.83×10^{-2}	1.042	3.40
	C_{10}	0.13×10^{-2}	1.020	3.49
	C_{12}	0.08×10^{-2}	1.050	8.65
SDS alone				1.3

Table 1, as for the relative viscosity there was no apparent regularity, as in Fig. 7. With the effective specific volume, V, the order of increasing specific volume is; octanoic acid<octyl alcohol<decyl alcohol<decanoic acid<dodecyl alcohol; on the other hand, the order of increasing limits of solubilization is; dodecyl alcohol< decyl alcohol<decanoic acid<octyl alcohol<octanoic acid. The oily materials of a greater amount of solubilization in the SDS micelle exhibits a smaller effective specific volume. This result is considered to be due to the difference in the penetration of micelles through the palisade layer resulting from the difference in polar groups.

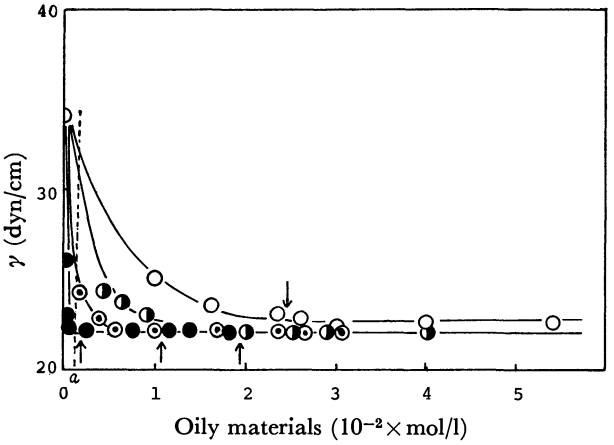

Fig. 8. Surface tension of solutions which is produced by dissolving oily materials in a given concentration of SDS (6.94×10^{-3} mol/l).
○=Octanoic acid; ⊙=decanoic acid; ◑=octyl alcohol; ●=decyl alcohol.
Arrows show the limit of solubilization of oily materials in 6.94×10^{-3} mol/l of SDS.

Surface Tension. Figure 8 shows the surface tensions of solutions which are produced by dissolving oily materials in given concentrations of SDS (6.94×10^{-3} mol/l). The rate of the reduction of the surface tension increased with an increase in the number of carbon atoms in the molecules of oily materials; it was larger for normal higher alcohols than for normal fatty acids with the same number of carbon atoms in the molecule. At the limits of solubilization (arrows in the figure), all the oily materials showed constant values of about 22 dyn/cm, this value remaining fixed even after the formation of a state of emulsion. Nakagawa and his coworkers,[14] with the aid of the electron spin resonance (ESR) spectra and the nuclear magnetic resonance (NMR) spectra, suggested that the lifetime of the benzene molecules in SDS micelles saturated with benzene was 10^{-4} s. It is considered that polar molecules adsorbed onto the air-water interface are en route to transition to polar oily molecules within the micelles or in the solution and are responsible for the reduction of the surface tension.

In connection with the difference in the reduction of the surface tension at a constant concentration of oily material (a in Fig. 8), it is generally true that normal fatty acids and normal higher alcohols with 12 or less carbon atoms form a gaseous membrane when spread over the surface of water at room temperatures. At a constant concentration of oily materials, the more hydrophobic the materials, the more tendency for the materials to reduce the surface tension by adsorbing onto the air-water interface. The fact that the surface tension shows a constant value of about 22 dyn/cm above the saturation of solubilization may be ascribed to the approximately equal contributions of polar materials to the surface tension in the emulsion state, regardless of the kinds of polar oily materials.

The changes in the amount of solubilization and in the relative viscosity, due to the difference between the carbon chain lengths and the kinds of polar groups,

result from the difference in the penetration of the palisade layer of the micelles; the difference in the surface tension results from the difference in the state of adsorption of the molecules of oily materials at the air-water interface.

Nuclear Spin-lattice Relaxation in $Sn(CH_3)_4$

Tooru HASEBE,* Gen SODA, and Hideaki CHIHARA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560

(Received August 6, 1976)

Synopsis. Nuclear magnetic relaxation T_1 of solid $Sn(CH_3)_4$ increased monotonously with temperature between 77 and 217 K. The activation energy for intramolecular methyl reorientation was 2.6 ± 0.3 kJ mol^{-1}. From measurements on the liquid phase, the apparent activation energy associated with the relaxation process was 8.6 kJ mol^{-1}. Differential thermal analyses revealed the existence of another unstable solid phase.

Tetramethylstannane $Sn(CH_3)_4$ was studied by nuclear magnetic resonance by Smith[1] who measured the spin-lattice relaxation time T_1 by the method of signal decay. We have re-examined the solid and the liquid phases of $Sn(CH_3)_4$ by calorimetry and NMR. This Note will describe the NMR results and point out some new features which supplement the previous studies.

Differential Thermal Analyses

Unlike its lighter homologues $C(CH_3)_4$[2] and $Si(CH_3)_4$[3], $Sn(CH_3)_4$ has no plastic crystal phase below its triple point. However, differential thermal analyses revealed that an unstable solid phase appeared when the liquid is cooled through the freezing point. This unstable phase spontaneously transforms itself to the stable phase which has the melting point at 217 K. We were not able to hold the unstable phase long enough to make NMR measurements, and it was not made certain whether it was a plastic crystal phase.

NMR Line Width

The temperature dependence of the NMR line-width was measured on a polycrystalline specimen; the width remained constant at 5.7 ± 0.6 G from 20 K to the melting point**. Corresponding to this, the second moment was 9.0 ± 1.0 G^2, which roughly agrees with 8.4 G^2 calculated on the basis of fully excited intramolecular methyl reorientation. When measured with a specimen of poorer purity (99.8 moles per cent), a narrow absorption peak was super-imposed on a broad signal, which was also reported by Smith. However, a purer specimen*** (better than 99.99 moles per cent) did not show the narrow peak.

Spin-Lattice Relaxation Time

The spin-lattice relaxation time T_1 at 10 MHz was measured between 77 K and the melting point by $\pi/2$-τ-$\pi/2$ pulse sequences and between 182 K and 244 K (undercooled and normal liquid) by π-τ-$\pi/2$ pulses. The results are shown in Fig. 1. In the solid state, the T_1 values here obtained show a monotonous increase with temperature and are shorter than the values reported by Smith by a factor of 2: There is no trend of levelling off above 160 K either. On the assumption that we are looking at extreme narrowing case, $\omega\tau_c \ll 1$, which we believe plausible, the activation energy for intra-methyl reorientation was derived as 2.6 ± 0.3 kJ mol^{-1} in comparison with Smith's value[1] 1.93 ± 0.05 kJ mol^{-1} and with Durig's value[4] 3.35 kJ mol^{-1} derived from far infrared study.

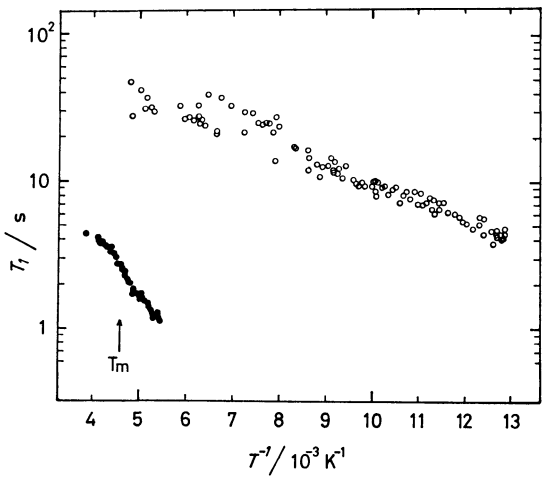

Fig. 1. A semilog plot of T_1 *vs.* the inverse temperature for $Sn(CH_3)_4$ as observed at 10 MHz. (●) liquid phase, (○) crystal phase.

From the T_1 in the liquid state, an apparent activation energy was obtained as 8.6 ± 1.0 kJ mol^{-1}. It is interesting to note that this is close to the enthalpy of fusion[5] 9.24 ± 0.05 kJ mol^{-1}. It is difficult to assess the mode or modes of motion responsible for the relaxation in this temperature region, but it is likely that self-diffusion is at least partly responsible for that.

The authors would like to express gratitude to Dr. T. Atake for purification of $Sn(CH_3)_4$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (12), 3685—3686 (1976)

Studies of the π,π^* Absorption Bands of 2,6-Dimethyl-4-pyrone

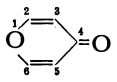
Akira KUBOYAMA, Yoshikuni SATO,[1] and Hiroshi ARANO

National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo 151

(Received December 12, 1975)

Synopsis. The π,π^* S-S absorption spectra of 2,6-dimethyl-4-pyrone in solutions up to the vacuum UV region were obtained. Based on the results of the MO calculations, the assignment and characterization of the observed π,π^* bands were studied, together with the assignment of the π,π^* bands near 250 nm of 4-pyrone.

Previously, we have theoretically and experimentally studied the π,π^* singlet-singlet absorption bands of *p*-[2] and *o*-quinones[3] and α-santonin[4] up to the vacuum UV region. 4-Pyrone is one of the fundamental unsaturated carbonyl compounds in organic and biological chemistry. As for the π,π^* absorption spectra of 4-pyrones, heretofore, only the π,π^* bands near 250 nm have been investigated.[5] In this work, we have studied the π,π^* absorption spectrum of 2,6-dimethyl-4-pyrone (II) up to the vacuum UV region in the same manner as in the previous works. The assignment of the π,π^* bands near 250 nm of 4-pyrone (I) has also been studied.



4-Pyrone (I)

The absorption spectra were measured in the same manner as in the previous works. The solvents used—heptane and 1,1,1,3,3,3-hexafluoro-2-propanol (HFP)—were the same as those used previously. Commercially available II was purified by the zone-melting method after being purified by vacuum sublimation (mp 133.6—134.5 °C).

As the electronic integral values in the Pariser-Parr-Pople method,[6] various kinds of integral values were tentatively used, based on the results obtained in the previous calculations.[2-4] Finally, the following integral values were chosen in this work. The core Coulomb integral of the carbonyl oxygen atom and the core resonance integral of the conventional C–C single bonds were taken as −14.00 and −1.50 eV, respectively. Otherwise, the intergral values used were the same as those used in the calculations of *p*-benzoquinone[2] and α-santonin.[4] For the oxygen atom of the 1-position, its core Coulomb integral, its Coulomb electron repulsion integral, and the core resonance integral of the C–O bonds were taken as −27.00, 19.46,[7] and −1.20 eV, respectively. As for the effect of methyl-group substitution, the core Coulomb integral of the substituted carbon atoms was taken as −9.00 eV, considering only the inductive effect of alkyl group, as in the previous works.[2,3] In the calculations, all the singly-excited configurations were included. As the dimention of the π-electronic system of I, that of the C_{2v} symmetry estimated by Norris *et al.*[8] from the microwave spectrum was used.

In Fig. 1, three π,π^* bands can be found, among which the strongest band is in the vacuum UV region.[9]

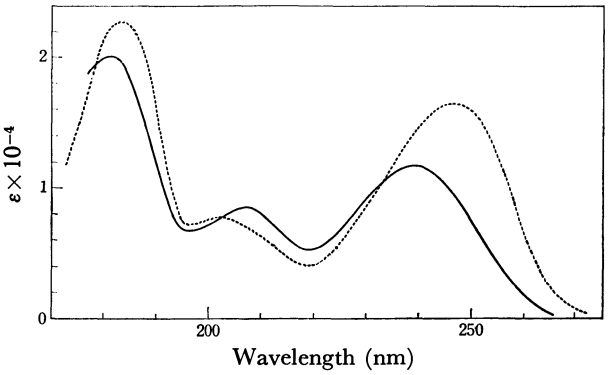


Fig. 1. Absorpion spectra of II in solutions.
——: Heptane, ------: HFP.

These three π,π^* bands are denoted as Bands A, B, and C in order of wavelength. A relatively large red-shift and a large intensity enhancement of Band A in the HFP solution in comparison with that in the heptane solution are noticeable. A strong hydrogen-bond between the oxygen atom of the 1-position of II and HFP may not be formed because of the steric hindrance caused by the two methyl groups of II. II is known to have a relatively strong basicity and this basicity is ascribed to the lone-electron-pair of the carbonyl oxygen atom.[5b,10] Therefore, the above-mentioned fact may be due to the strong hydrogen-bond formation between the carbonyl oxygen atom of II and HFP.

TABLE 1. WAVELENGTHS (λ), MOLAR ABSORPTION COEFFICIENTS (ε), AND OSCILLATOR STRENGTHS (f) OF THE ABSORPTION MAXIMA OF II

Heptane			HFP			Band name
λ(nm)	ε	f	λ(nm)	ε	f	
238.5	11800	0.25	246	16450	0.35	A
207	8550	≈0.17	202.5	7810	≈0.16	B
181	20200	0.5	183	22800	0.52	C

In Table 2, the first column denotes the numbering of the states in order of increasing excitation energies (calculated). In this table, the data on the higher excited states with small f values have been omitted. In view of the calculated results in Table 2, Band A is thought to consist of the $^1A_1$ (the No. 1 state)←$^1A_1$ and $^1B_2$ (the No. 2 state)←$^1A_1$ transition bands, but mostly of the former. On the other hand, in the spectrum of I in the hexane solution, obtained by Efimov *et al.*,[5e] the band near 250 nm corresponding to Band A has a shoulder on its long wavelength-side and the large distance (*ca.* 2800 cm^{-1}) between its peak and this shoulder shows that the main band and this shoulder belong to separate π,π^* bands. A similar spectrum for I in the

a) The data for I and II are those in the hexane and heptane solutions, respectively. b) The values for I and II are molar absorption coefficient and oscillator strength, respectively.

ethanol solution has been reported by Franzosini *et al.*[5a,11] Therefore, as is shown in Table 2, the main band and the shoulder may be reasonably assigned to the $^1B_2$ (the No. 1 state)←$^1A_1$ and $^1A_1$ (the No. 2 state)← $^1A_1$ bands of I, respectively.

As for Band B, the assignment based on the calculated results is not clear. Band C may be safely assigned to the $^1A_1$ (the No. 7 state)←$^1A_1$ band, in view of the large f value of this transition, as is shown in Table 2. Therefore, it may be concluded that both Bands A and C are polarized almost along the symmetry axis of II. According to the calculated results, Band A has the character of the intermolecular charge-transfer band[12] from the oxygen atom of the 1-position to the carbonyl group, and the excited state of Band C is greatly localized in two vinyl groups, as in the case of Band D of α-santonin.[4] In the HFP solution, the strong hydrogen-bond formation between II and HFP, mentioned above, may intensify this character of Band A. So, the noticeable solvent effect for Band A in the HFP solution, mentioned above, may be reasonably explained on the basis of this characteristic of Band A.

As is seen in Table 2, the calculated excitation energy of the lowest $^1A_1$ state (the No. 1 state) of II is 0.09 eV greater than that of the corresponding state (the No. 2 state) of I. On the other hand, the corresponding state of 3,5-dialkyl-4-pyrone is 0.153 eV smaller than that of I. Based on the calculated results, therefore, the main band near 250 nm of I may be expected to be at longer wavelengths than Band A and at shorter wavelengths than the corresponding band of 3,5-dialkyl-4-pyrone, respectively. This expectation is verified in the case of Band A, as is seen in Table 2.

Enthalpy-Controlling Adsorption of Hydrocarbons on 1,3,5-Trinitrobenzene as Revealed by Gas Chromatography

Masamichi AKIMOTO and Etsuro ECHIGOYA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received June 9, 1976)

Synopsis. Equilibrium adsorption constants for a series of olefins and paraffins on 1,3,5-trinitrobenzene were enhanced upon increasing the electron-donating nature of the hydrocarbons; the trend in the adsorption constants was entirely due to variations in the enthalpy change of adsorption rather than the entropy one. These results are characteristics of the adsorption in which the donation of electrons from a hydrocarbon molecule is strongly predominant.

The importance of adsorption in heterogeneous catalysis has often been pointed out. However, it is very difficult to clarify the mechanism of electron transfer on the adsorption by means of spectroscopy. Hence, it would be very useful if the electron transfer could be estimated by measuring the effect of the enthalpy and the entropy changes on the adsorption constant. Cvetanovic and co-workers[1] showed in their gas chromatographic studies on the adsorption of olefinic hydrocarbons on 1,3,5-trinitrobenzene (TNB) that the retention time of olefins increased with the increase in their electron-donating nature. A similar trend was also observed on NiO, for which the important role of the donation of electrons from olefin molecules was discussed.[2] The present study attempted to find a correlation between the electron transfer in the adsorption of noncyclic hydrocarbons on TNB and the trends in the thermodynamic parameters of the adsorption constant by investigating the effect of hydrocarbon structure on the adsorption constant, which can be determined by means of gas chromatography. Furthermore, the enthalpy change of the adsorption observed was discussed in relation to the electron-donating nature of hydrocarbons.

Experimental

Column packing (20 wt% TNB on 60—80 mesh Chromosorb P) was prepared according to the method proposed.[1] This was packed in a stainless steel pipe (3 mm i.d., 4 m) and was pretreated with a helium current (30 NTPml/min) for 2 h at room temperature. Helium was used as a carrier gas. The mixture (olefin 10 vol%, paraffin 10 vol%, and N_2 80 vol%) was injected into the column using an U-shaped bypass injector whose volume was 0.56 NTPml. Here, the saturated hydrocarbon has the same skeletal structure as that of the olefinic one.

By means of gas chromatography, the equilibrium adsorption constant and the heat of adsorption were determined using the following equation.[3]

$$\mu/T = (R/V_g)n_m e^{\Delta S/R} e^{Q/RT}$$

where T: temperature (K); R: gas constant; V_g: void volume in the column; ΔS: entropy change of adsorption; n_m: amount of sample required for making monolayer coverage; Q: heat of adsorption, $Q=-\Delta H$; ΔH: enthalpy change of adsorption; K: equilibrium adsorption constant $K=e^{\Delta S/R}\,e^{Q/RT}$; μ: relative retention time, $\mu=(t-t_0)/t_0$; t_0 and t are the retention times of N_2 and the sample, respectively.

Results and Discussion

Figure 1 shows the linear plot of μ_{ol}/T *vs.* $1/T$ for olefin adsorption. Values of μ_{ol}/T, μ_p/T, and heats of adsorption for a series of hydrocarbons are summarized with the ionization potential of the hydrocarbons (Table 1). These values are enhanced upon decreasing the ionization potential of the hydrocarbons, *i.e.*, upon increasing their electron-donating nature, as was report-

Butane	1.15	6.31	—	10.71

a) Ethane, ethylene 200 K; propane, propylene 256 K; butane, butene 294 K. b) Reference: ethylene, propylene (4); 1-butene (5); 2-butene, 2-methylpropene (6); paraffin (7).

ed earlier.[1] So long as the same column is used, V_g is constant, and n_m is expected to be constant for butene isomers. In the case of propylene and ethylene, n_m is either at least equal to that of butene or it increases with decreasing the shape of the hydrocarbon molecule. Hence, the sequence of μ/T observed agrees with that of the adsorption constants. Table 1 also shows that each trend in the adsorption constants is entirely due to variations in the heat of adsorption. Taking subscript 1 to mean the most weakly adsorbed butene (1-butene), the difference in the entropy changes for other butene isomers (subscript 2), $\Delta(\Delta S)=\Delta S_2-\Delta S_1$, was calculated (Table 1). The sequence of $\Delta(\Delta S)$ suggests that the entropy change occurs in the same order as that of the enthalpy change. Therefore, it was concluded that the increment in the adsorption constant should be attributed to that in the enthalpy change rather than the entropy one. This enthalpy-controlling nature is also the case for paraffin adsorption (Table 1). Furthermore, the enhancement in the enthalpy change upon decreasing the ionization potential shows the presence of a close relationship existing between the strength of the electron donation and the enthalpy change. TNB is a strong electron-acceptor. Hence, this can be reasonably understood by assuming that these hydrocarbons donate their electrons to TNB in proportion to their electron-donating nature.

It is also instructive to discuss the relative retention time $(t_{ol}-t_0)/(t_p-t_0)$. Since $RT\ln[(t_{ol}-t_0)/(t_p-t_0)]=RT\ln(K_{ol}/K_p)=-(\Delta G_{ol}-\Delta G_p)=-\Delta(\Delta G)$, this procedure elucidates the effect of the double bond on the adsorption constant of the olefin. Table 2 indicates that the increase in $-\Delta(\Delta G)$ by introduction of the olefinic bond is due to the rise in the relative enthalpy change $-\Delta(\Delta H)$ rather than the relative entropy one $-\Delta(\Delta S)$. This enthalpy-controlling character is also inherent to the adsorption in which the donation of electrons from an olefin to the adsorbent plays a very important role in the adsorption.

Table 2. Thermodynamic parameters of the K_{ol}/K_p

System	$-\Delta(\Delta G)$ [cal/g-mol] at 290 K	$-\Delta(\Delta H)$ [cal/g-mol]	$-\Delta(\Delta S)$ [cal/g-mol K]

Electrical Conductivity Changes in α-FeOOH and β-FeOOH upon Surface Dehydration

Katsumi KANEKO and Katsuya INOUYE

Department of Chemistry, Faculty of Science, University of Chiba, Yayoi-cho, Chiba 280

(Received July 5, 1976)

Synopsis. The electrical conductivity of α-FeOOH and β-FeOOH, preheated at 100—140 °C *in vacuo*, was determined over the temperature range from 0 to 140 °C. The conductivity increased considerably with a rise in the preheating temperature. The increase appears to be due to Fe^{2+} ions produced by surface dehydration in the preheating.

Among the polymorphs of iron(III) hydroxide oxide (the so-called ferric oxyhydroxide), α-FeOOH, β-FeOOH, and γ-FeOOH occur naturally as minerals and as major components of the corrosion product of iron-base alloys. Each iron(III) hydroxide oxide has the characteristic structure.[1-3] It has been known that iron(III) hydroxide oxides are transformed into iron oxides (α-Fe_2O_3 or γ-Fe_2O_3) at around 300 °C in air according to this formula:

$$2\,FeOOH \longrightarrow Fe_2O_3 + H_2O.$$

However, when FeOOH crystals are heated under 10^{-5} Torr, the decomposing dehydration begins at temperatures as low as 100 °C.[4] In the preceding papers,[5,6] the present authors reported that the electrical conductivity of γ-FeOOH increases remarkably with a rise in the preheating temperature in the range of 100—140 °C under 10^{-5} Torr, and that this behavior can be explained by the formation of excess d-electrons due to dehydration. It was proposed that excess d-electrons migrate in γ-FeOOH crystals by means of the small-polaron hopping mechanism.[6]

In this work, the effect of the preheating temperature (100—140 °C) on the electrical conductivity will be examined for α-FeOOH and β-FeOOH in order to discuss the mechanism of carrier formation in comparison with the case of γ-FeOOH.

The α-FeOOH and β-FeOOH used in this study were the same samples as those examined earlier.[7] The pretreatment of the samples was also identical to that carried out for γ-FeOOH.[6] The conductivity of the compressed specimens, formed by applying a pressure of 150 kg/cm², was measured over the temperature range from 0 to 140 °C and at various frequencies (d.c., 200 Hz—10 MHz) by a method described previously.[8] The current-voltage characteristics for d.c. indicated that the contact between the specimen and an electrode was nearly ohmic.

The effect of oxygen on the dc conductivity was examined for α-FeOOH and β-FeOOH, evacuated at 10^{-5} Torr and 140 °C, by supplying oxygen of 0.1 Torr at 30 °C.

The total iron and Fe^{2+} contents were determined by conventional titration methods.[6,7]

The electrical conductivity at d.c. and in the lower-frequency range increased with the preheating temperature in the range from 100 to 140 °C. The variation in the conductivity, σ_{dc}, at 30 °C with the preheating temperature is shown in Fig. 1 (a). The Fe^{2+} concentration also increased with the preheating temperature (Fig. 1 (c)).

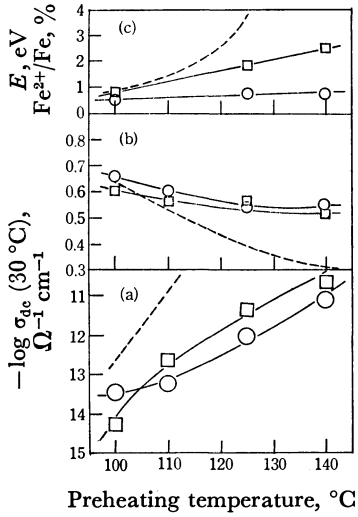

Fig. 1. Variations of (a) the logarithm of d.c. electrical conductivity at 30 °C, (b) activation energy of conductivity at d.c., and (c) Fe^{2+} concentration, with the preheating temperature for α-FeOOH (○) and β-FeOOH (□). The broken lines show the results on γ-FeOOH.[6]

It was found that logarithm of σ_{dc} is proportional to the reciprocal of the measuring temperature (0—140 °C), as is shown in Figs. 2 and 3 for α-FeOOH and β-FeOOH respectively. The notations α(β)-100, α(β)-110, α(β)-125, and α(β)-140 denote α-FeOOH or β-FeOOH samples preheated at 100, 110, 125, and 140 °C respectively. These linear relations have previously been found for γ-FeOOH.[6] The activation energy at

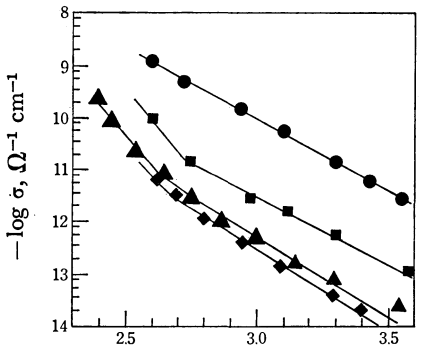

Fig. 2. The temperature dependence of electrical conductivity at d.c. for α-100 (◆), α-110 (▲), α-125 (■), and α-140 (●).

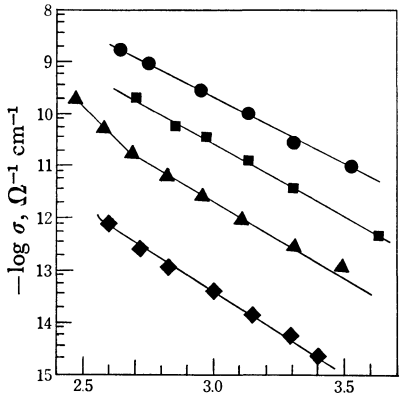

Fig. 3. The temperature dependence of electrical conductivity at d.c. for β-100 (◆), β-110 (▲), β-125 (■), and β-140 (●).

d.c., calculated from the linear relation below 100 °C, was less than 1 eV and decreased slightly with the preheating temperature, as is shown in Fig. 1 (b). The activation energy above 100 °C was 1—1.5 eV. The activation energy generally decreased with an increase in the frequency. The conductivity at higher frequencies varied slightly with the measuring temperature.

It was confirmed that the a.c. conductivity σ_{ac} ($=\sigma - \sigma_{dc}$) was proportional to f^s ($0.5<s<1$) in the frequency range of 200 Hz—1 MHz. The constant s, representing the frequency dependence of the conductivity, decreased with an increase in the measuring temperature.

The exposure to oxygen of α-FeOOH and β-FeOOH preheated at 140 °C resulted in a lowering of the electrical conductivity at d.c. to less than a half of the initial value within 2 h.

The surface property of α-FeOOH and β-FeOOH crystals is characterized by their predominant surfaces, namely, the (100) planes for both α-FeOOH and β-FeOOH. The structures of these predominant surfaces were discussed in a previous paper.[9] The OH groups aligned in the c direction on surfaces are connected with each other by hydrogen bonding. The dehydration of an OH^- pair below 150 °C *in vacuo* appears to proceed through the formation of a quasi-molecular water by means of the following mechanism:

$$2\,OH^- \longrightarrow H_2O + V_o^- + O^-,$$

where V_o^- denotes the mono-charged oxygen vacancy. The dehydration causes an increase in the Fe^{2+} concentration by providing electrons from V_o^- to Fe^{3+}, which results in an increase in the conductivity.

α-FeOOH has OH^- pairs only at the surface, whereas β-FeOOH has the pairs not only on the surface, but also in pores in parallel to the c-axis (see Ref. 9). For γ-FeOOH, on the other hand, the dehydration occurs on the surface as well as in the bulk of the crystal.[6] The increase in the Fe^{2+} concentration with the pretreating temperature, in the order γ-FeOOH>β-FeOOH>α-FeOOH (Fig. 1 (c)), is pertinent to both the ability to dehydrate by the mechanism mentioned above and the difference in the surface area for each crystal form. The BET surface areas are in the following decreasing order[7]: γ-FeOOH: 124 m²/g, α-FeOOH: 65 m²/g, and β-FeOOH: 34 m²/g.

The conductivity is assumed to follow the small-polaron hopping mechanism of excess d-electrons formed by the same surface dehydration for α-FeOOH and β-FeOOH as for γ-FeOOH. This assumption is supported by the frequency-dependence of the conductivity and the small activation energy of the conduction, and further by the fact that the mobility calculated from the conductivity and the Fe^{2+} concentration is less than 10^{-7} cm² V^{-1} s^{-1} at 30 °C. It was explained in the case of γ-FeOOH[6] that a decrease in the activation energy is due to an increase in the Fe^{2+} concentration and that the conductivity increase with the preheating temperature is caused by the increase in the interaction between Fe^{2+} ions. The same mechanism may also be applied to α-FeOOH and β-FeOOH. However, the decrease in activation energy with the preheating temperature for α-FeOOH and β-FeOOH is smaller than that for γ-FeOOH (Fig. 1 (b)). A lower interaction between Fe^{2+} ions in α-FeOOH and β-FeOOH than γ-FeOOH is presumed, because the Fe^{2+} concentration is considerably lower in α-FeOOH and β-FeOOH than in γ-FeOOH. It is noteworthy that the conductivity increase with the preheating temperature is less marked for α-FeOOH and β-FeOOH than for γ-FeOOH.

The decrease in the d.c. conductivity observed when oxygen was introduced into the evacuated sample indicates that electrons once formed by the dehydration are consumed by chemisorbed oxygen molecules at surface defects.

This research has been partially supported by the Government Science Research Grant of the Ministry of Education.

Oxidation-Reduction Potentials in the Formation of Anion Radicals

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo, 060

(Received May 15, 1976)

Synopsis. The oxidation-reduction potentials in the formation of anion radicals were determined by using the equilibrium constant of the preferred electron transfer reaction between anion radicals in acetonitrile solution.

The 7,7,8,8-tetracyanoquinodimethane (TCNQ), 2,3-dicyano-*p*-benzoquinone (*p*-H_2QCy_2) and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (*p*-Cl_2QCy_2) molecules are known to be strong electron acceptors and to form stable anion radical salts with some diamagnetic counter cations.[1-3]

Several years ago,[4] we reported on the preferred electron transfer reaction between anion radicals in solution. When *p*-X_2QCy_2 (X=H or Cl) was added to an acetonitrile solution of the sodium salt of the TCNQ anion radical, the oxidation-reduction reaction was found to take place simply through a one-electron transfer from the TCNQ anion radical to *p*-X_2QCy_2. This reaction was expressed by the following oxidation-reduction equilibrium:

$$TCNQ^- + p\text{-}X_2QCy_2 \rightleftarrows TCNQ + p\text{-}X_2QCy_2^-, \quad (1)$$

where X=H or Cl. It was assumed that the activity coefficients of the solutes were unity, since their concentrations were as dilute as 10^{-5} mol/l. In this case, the equilibrium constant, K, of this reaction was simply expressed by

$$K = \frac{[TCNQ][p\text{-}X_2QCy_2^-]}{[TCNQ^-][p\text{-}X_2QCy_2]}. \quad (2)$$

The value of K in acetonitrile solution at 20±1 °C was determined spectrophotometrically as $K=30$ for the case of X=H, while it was $K \geq 2 \times 10^3$ for the case of X=Cl.[4] At that time, we related the values of K to the half-wave potentials in polarography or to the electron affinities of the neutral *p*-X_2QCy_2 molecules. In the present paper, we obtained oxidation-reduction potentials in the formation of anion radicals, because attempts have scarcely been made to obtained such values.

The occurence of the equilibrium of Eq. 1 means that[5]

$$E_0(TCNQ, TCNQ^-) - \frac{RT}{F}\ln\frac{[TCNQ^-]}{[TCNQ]} = E_0(p\text{-}X_2QCy_2, p\text{-}X_2QCy_2^-) - \frac{RT}{F}\ln\frac{[p\text{-}X_2QCy_2^-]}{[p\text{-}X_2QCy_2]}, \quad (3)$$

where $E_0(TCNQ, TCNQ^-)$ and $E_0(p\text{-}X_2QCy_2, p\text{-}X_2QCy_2^-)$ represent the standard oxidation-reduction potentials of

$$TCNQ + e \rightleftarrows TCNQ^-, \quad (4)$$

$$p\text{-}X_2QCy_2 + e \rightleftarrows p\text{-}X_2QCy_2^-. \quad (5)$$

They were assumed to be reversible electrode reactions in acetonitrile solution. In Eq. 3, R, T, and F are the gas constant, the observed temperature and the Faraday constant, respectively. Eq. 3 leads to

$$E_0(p\text{-}X_2QCy_2, p\text{-}X_2QCy_2^-) - E_0(TCNQ, TCNQ^-) = \frac{RT}{F}\ln K. \quad (6)$$

When the spectrophotometrically determined values of K are put into Eq. 6, we have

$$E_0(p\text{-}H_2QCy_2, p\text{-}H_2QCy_2^-) = E_0(TCNQ, TCNQ^-) + 0.09\ V, \quad (7)$$

$$E_0(p\text{-}Cl_2QCy_2, p\text{-}Cl_2QCy_2^-) \geq E_0(TCNQ, TCNQ^-) + 0.19\ V. \quad (8)$$

The absolute values of $E_0(p\text{-}X_2QCy_2, p\text{-}X_2QCy_2^-)$, (X=H or Cl), will be determined from these relations if the value is once given for $E_0(TCNQ, TCNQ^-)$. Although no definite value has been determined for $E_0(TCNQ, TCNQ^-)$, we obtained, in a previous paper,[6] the relationship of Eq. 9 by analyzing spectrophotometrically the oxidation-reduction reaction between TCNQ and iodide ion in acetonitrile solution:

$$E_0(TCNQ, TCNQ^-) = E_0(I_2, 2I^-) + 0.045 \pm 0.004\ V, \quad (9)$$

where $E_0(I_2, 2I^-)$ represents the standard oxidation-reduction potential for the following reversible electrode reaction in acetonitrile solution:

$$I_2 + 2e \rightleftarrows 2I^-. \quad (10)$$

Therefore, by using Eqs. 7, 8, and 9, the values for $E_0(p\text{-}X_2QCy_2, p=X_2QCy_2^-)$, (X=H or Cl), versus $E_0(I_2, 2I^-)$ are obtained as is shown in Table 1.

Table 1. The data on the oxidation-reduction potentials in the formation of the TCNQ, *p*-H_2QCy_2, and *p*-Cl_2QCy_2 anion radicals in acetonitrile solution

Oxidation-reduction system	Oxidation-reduction potential, V
$I_2+2e \rightleftarrows 2I^-$	$E_0(I_2, 2I^-)$
$TCNQ+e \rightleftarrows TCNQ^-$	$E_0(I_2, 2I^-)+0.045\pm0.004$
$p\text{-}H_2QCy_2+e \rightleftarrows p\text{-}H_2QCy_2^-$	$E_0(I_2, 2I^-)+0.14$
$p\text{-}Cl_2QCy_2+e \rightleftarrows p\text{-}Cl_2QCy_2^-$	$\geq E_0(I_2, 2I^-)+0.24$

The oxidation-reduction potentials in acetonitrile solution are found to range, with increasing the electron-accepting strength, as $E_0(I_2, 2I^-) < E_0(TCNQ, TCNQ^-) < E_0(p\text{-}H_2QCy_2, p\text{-}H_2QCy_2^-) < E_0(p\text{-}Cl_2QCy_2, p\text{-}Cl_2$-

QCy_2^-). These oxidation-reduction potentials in the formation of ion radicals are important not only for the electrochemical study, but also for the investigation on the mechanism of certain chemical reactions involving ion radical molecules. The values of the oxidation-reduction potentials in the present paper were obtained by analyzing spectrophotometrically the oxidation-reduction reaction between anion radicals in solution, but an attempt is currently under way to measure those values of E_0 (TCNQ, $TCNQ^-$), E_0(p-X_2QCy_2, p-X_2-QCy_2^-), (X=H or Cl), directly by electrochemical method.

A Simple Method for Measuring Mass Spectra of Ions with Excess Kinetic Energy

Susumu TAJIMA,* Mitsuo NAKAMURA,* Tadashige AZAMI,* and Toshikazu TSUCHIYA

*Department of Engineering Chemistry, Gunma Technical College, Toribacho, Maebashi, Gunma 371
National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received March 9, 1976)

Synopsis. Mass spectra of ions with excess kinetic energy have been measured by applying a small negative voltage to the repeller electrode.

An important function of mass spectrometry is determination of the structure of organic compounds,[1] but this is not easy, since many rearrangement ions appear in an ordinary mass spectrum. Thus it is desirable to obtain mass spectra that are free of rearrangement ions and consist only of simple cleavage ions.

Recently, a method for measuring mass spectra of ions with excess kinetic energy was reported by Tsuchiya and Horii.[2] They used a modified ion source equipped with a metal gauze electrode between the exit slit and the focus slit. The electrode was kept at a potential a little higher than that of the ionization chamber. The term KE mass spectrum (kinetic energy mass spectrum) was given to the spectrum measured from the ion source. From the fact that simple cleavage ions consist of two kinds of ions, one with thermal energy only and the other with additional excess kinetic energy, and that the rearrangement ions usually have no kinetic energy with exception of a few instances,[3,4] they concluded that a large portion of the KE mass spectra consists of ions produced by simple cleavage, and that KE mass spectra might facilitate the determination of the structure of organic compounds. However, the method is not suitable for measuring both KE and ordinary mass spectra with an analytical mass spectrometer, since the ion source has to be modified in order to measure the KE mass spectra. A simple method for measuring the KE mass spectra with use of a commercial mass spectrometer is needed.

In the present note a simple method for measuring the KE mass spectra is reported. By applying a small negative voltage to the repeller electrode ($-V_r$), the KE mass spectra can be easily obtained without any modification of the ion source. However, the same KE mass spectra as those obtained by Tsuchiya and Horii[2] cannot be expected by the present method, sicnce the potential energy distribution inside the ionization chamber differs in the two methods.

Experimental

The mass spectra were obtained with a Hitachi RMU-5B mass spectrometer. A small negative voltage to the repeller electrode is supplied from the circuit (Fig. 1) by controlling the value of the 20-turn potentiometers R_r and R_r' (Sakae Tsushin Kogyo Co., Ltd.). The connections to the repeller electrode and ionization chamber are made by replacing the clips, so that the normal experimental condition can be recovered easily.

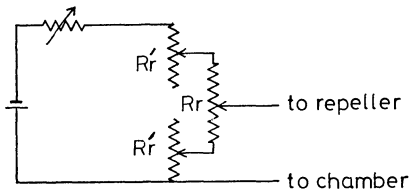

Fig. 1. Diagram of the modified electric circuit for the repeller voltage.

Other conditions of measurement were: electron accelerating voltage, 80 V; ion accelerating voltage, 2000 V; trap current, 60 μA; temperature of ion source, 250 °C; temperature of sample manifold, 20—25 °C.

The intensities of the ions in the KE mass spectra were about one-hundredth of those in ordinary mass spectra.

The samples (Kanto Kagaku Kogyo Co., Ltd.) were used without further purification.

Results and Discussion

In the usual type of mass spectrometer, a small positive voltage is applied to the repeller electrode (V_r) to draw out the ions efficiently from the ion source. Consequently, both ions with no excess kinetic energy, and those with some kinetic energy are pushed out from the ion source. However, when a small negative voltage is applied to the repeller electrode ($-V_r$), only the ions with a kinetic energy greater than half the value of the repeller voltage can emerge from the ion source. Thus it becomes possible to measure the KE mass spectra by

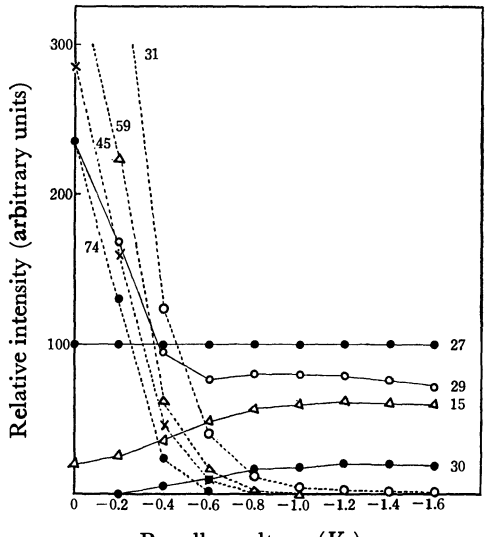

Fig. 2. Variation of the relative intensity for several intense fragment ion peaks of diethyl ether *vs.* repeller voltage.

applying an appropriate negative voltage to the repeller electrode ($-V_r$).

The intensities of several intense fragment ion peaks for diethyl ether are shown in Fig. 2 as a function of repeller voltage (V_r). The intensity of $C_2H_3^+$ (*m/e* 27) is taken as a reference. We see that the molecular ion (*m/e* 74) and the rearrangement ion (*m/e* 31), a large number of which being considered to have no excess kinetic energy, decrease rapidly with decrease in the value of V_r. While simple cleavage ions, *m/e* values of which are larger than a half of the *m/e* value of the molecular ion, *i.e.*, *m/e* 59 and *m/e* 45 ions, also decrease with the V_r value. The intensities of some simple cleavage ions (*m/e* 29, 15 *etc.*,) which are smaller in *m/e* than a half of that of the molecular ion remain approximately constant between -1.0 and -1.6 V (V_r). This implies that a reproducible KE mass spectrum can be obtained at -1.0 —— -1.6 V by our method.

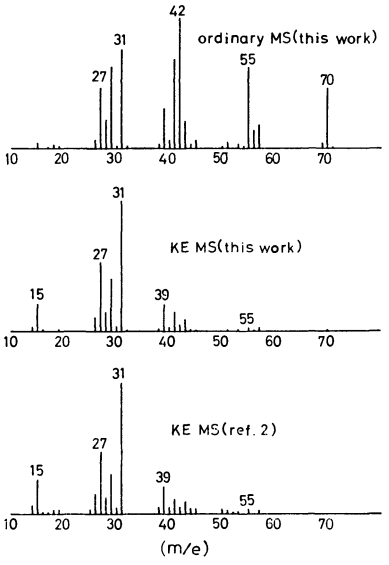

Fig. 3. KE mass spectra and ordinary mass spectrum of pentyl alcohol.

The KE mass spectrum measured at -1.5 V (V_r) and the ordinary mass spectrum (10 V (V_r)) of pentyl alcohol are shown in Fig. 3 together with the KE mass spectrum of Tsuchiya and Horii.[2] The KE mass spectrum measured by our method is close to the theirs, but differs from the ordinary one.

An analytical mass spectrometer can be used readily to measure the KE mass spectrum, since we can obtain the KE mass spectrum by this method without any modification of the ion source.

The authors wish to thank Mr. Takeshi Satō, Mr. Masanori Suzuki, and Mr. Minoru Imai of this College for their help in measuring the spectra. They are also indebted to Mr. Hirokazu Hanaoka, Gunmaken Industrial Research Laboratory, for valuable discussions.

Preparation of γ-FeOOH by Aerial Oxidation of Iron(II) Chloride Solution

Shuichi HAMADA and Kenshi KUMA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received May 26, 1976)

Synopsis. Detailed conditions for preparing γ-FeOOH by aerial oxidation of iron(II) chloride solution were studied. The upper limit of temperature for obtaining only the γ-FeOOH decreased with increases in the pH value and the initial concentration of Fe(II) ions. The shapes of the prepared γ-FeOOH particles were examined in connection with the oxidizing conditions.

The kind of aerial oxidation products of iron(II) salt solutions has been well known to be dependent on the preparative conditions. No detailed conditions for preparing the γ-FeOOH, one of the iron(III) hydroxide oxides, have been studied, though its formation has been reported.[1-5] In this work, such preparative conditions for γ-FeOOH as the concentration of Fe(II) ions, the reaction temperature, and the acidity were studied. Furthermore, the shapes of the prepared γ-FeOOH particles were examined in connection with the oxidizing conditions.

Experimental

The iron(II) chloride solution was used as the starting material. The dissolved oxygen was removed by passing nitrogen into the iron(II) chloride solution before the oxidation. The Fe(II) ions were oxidized at the specified temperatures and acidities by bubbling air, free from carbon dioxide, through a glass filter at a constant flow rate with vigorous stirring.

As the acidity of the solution increased with the progress of oxidation, the pH value of the reaction mixture was kept within ±0.15 of the specified acidity by using a pH-stat model HS-2A, from Toa Electronics Ltd., and aqueous ammonia, except for solutions at higher basicities. The air was bubbled for 3 h after the reaction ended under the same conditions in order to age the precipitates. The oxidation product was washed with water until chloride ions were no longer detectable, followed by air-drying for 3 weeks.

The X-ray powder diffraction patterns of the products were taken using Fe*K*α radiation with a Rigaku Denki Geigerflex, model D-3F, X-ray diffractometer. The identification of the products and the estimation of their relative amounts were carried out by using the diffraction peaks at (020) and (031) of the γ-FeOOH, that at (110) of the α-FeOOH, and those at (311) and (440) of the Fe_3O_4.

The shapes of the prepared γ-FeOOH particles were observed with the magnifications of from 10000 to 30000 times by using an electron microscope, model HU-200F, from Hitachi Seisakusho.

Results and Discussion

The final oxidation products of the iron(II) chloride solution were identified as the γ-FeOOH, the α-FeOOH, and the Fe_3O_4: the β-FeOOH was not detectable in this work, though Kiyama *et al.*[6] have reported the formation of β-FeOOH together with γ-FeOOH. In order to estimate the conditions for preparing the pure γ-FeOOH, the kind of products and their relative amounts were examined over a wide range of oxidizing conditions.

The influence of the flow rate of air on the kind of products was determined to be as follows:

Flow rate (l/min)	0.1	1.0	2.4	2.8
	α-, γ-FeOOH	γ-FeOOH	α-, γ-FeOOH	

(pH 6.5, 25°C, and 0.064 mol/l)

Though the flow rate range for preparing only the γ-FeOOH was not found at higher concentrations of Fe(II) ions under the same conditions of the pH and the temperature, the relative amount of the γ-FeOOH was large enough in the flow rate from 1.0 to 2.4 l/min even at higher concentrations. Therefore, subsequent oxidations were carried out at the constant flow rate of 2.0 l/min.

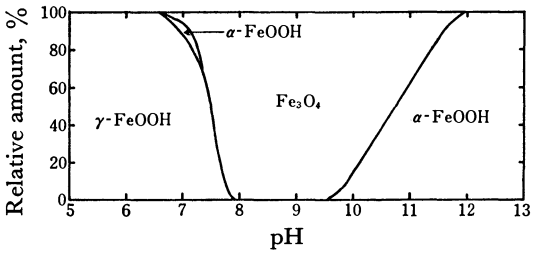

Fig. 1. Relationship between relative amounts of products and acidity.
Temp; 25 °C, init. concn; 0.064 mol/l, flow rate; 2 l/min.

Figure 1 shows the relationship between the relative amounts of the products and the acidity. Only the γ-FeOOH was obtained up to pH 6.5 by the aeration at 25 °C in the 0.064 mol/l solution, though only the Fe_3O_4 was obtained in the pH range from about 8.0 to 9.5. Misawa *et al.*[7,8] also reported the formation of Fe_3O_4 by the solid state oxidation of $Fe(OH)_2$ formed in a slightly alkaline solution of iron(II) chloride. Even if the aeration was allowed to continue, the Fe_3O_4 was no longer completely oxidizable into the γ-FeOOH. This solid state oxidation is considered to be difficult

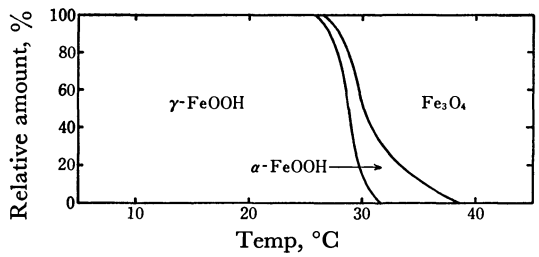

Fig. 2. Relationship between relative amounts of products and reaction temperature.
pH; 6.5, init. concn; 0.064 mol/l, flow rate; 2 l/min.

because the OH groups must be introduced into the Fe_3O_4 lattice which has a cubic close-packed structure of oxygen.[9]

Figure 2 shows the relationship between the relative amounts of the products and the reaction temperature. Only the γ-FeOOH was obtained below 25 °C, while the formations of the α-FeOOH and the Fe_3O_4 were observed at the temperatures higher than 25 °C.

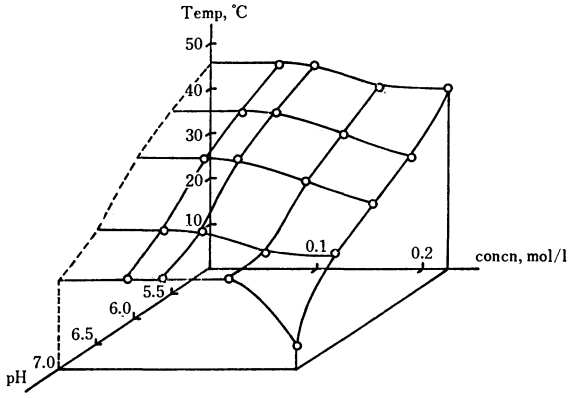

Fig. 3. Upper limit of temperature for preparing only γ-FeOOH as functions of initial concentration and acidity.
Flow rate; 2 l/min.

The critical conditions for preparing only the γ-FeOOH around neutrality varied according to changes in the temperature, the concentration of Fe(II) ions, and the acidity. A curved surface in Fig. 3 shows the upper limit of temperature for obtaining only the γ-FeOOH as the functions of the concentration and the acidity in the ranges from 0.064 to 0.224 mol/l and from pH 5.0 to 7.0 respectively. At the temperatures above this curved surface, the α-FeOOH and/or the Fe_3O_4 were precipitated with the γ-FeOOH. The upper limit of temperature for forming only the γ-FeOOH was found to decrease as both the pH value and the concentration increased, as is shown in Fig. 3. The reaction mixture showed a gradual change in color as follows:

pH 6.0 (higher temp)—7.0

light green → dark greenish blue → yellowish brown

pH 5.0—6.0 (lower temp)

faint green → reddish brown

The γ-FeOOH was formed *via* the green rust I,[1,10] its oxidation intermediate, under the former conditions, but it was formed directly from the solution without passing through the green rust I in the latter cases.[11] Bernal *et al.*[1] stated that the green rust I formed only in neutral and slightly alkaline solutions of iron(II) chloride. Misawa *et al.*[8] proposed a mechanism for direct formation of γ-FeOOH: after the $FeOH^+$ ions have been oxidized, the $Fe(OH)_2^+$ ions dimerized into $[(OH)_2Fe–O–FeOH]^+$ and then polymerized into $[n FeOOH \cdot Fe(OH)_2]^+$ by forming oxo-bridges, Fe–O–Fe, followed by precipitation of γ-FeOOH.

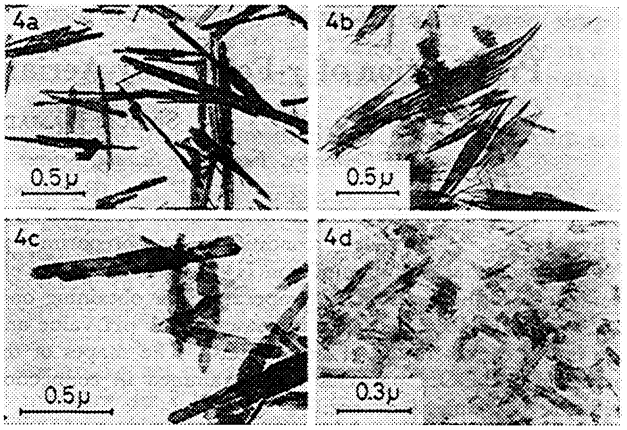

Fig. 4. Shapes and sizes of γ-FeOOH particles prepared as several conditions.
a; pH 6.0, 30 °C, 0.096 mol/l, b; pH 6.5, 15 °C, 0.224 mol/l, c; pH 6.0, 25 °C, 0.096 mol/l, d; pH 6.0, 10 °C, 0.064 mol/l.

The shape and the size of γ-FeOOH particles were extremely dependent on the preparative conditions. Needle-like particles were obtained in the oxidation just below the upper limit of temperature for preparing only the γ-FeOOH at pH 6.0—7.0, while irregularly shaped plate particles were precipitated at lower temperatures for pH 6.5—7.0, as is shown in Figs. 4a and 4b. On the contrary, elongated hexagonal plate particles were obtained at lower temperatures at pH 6.0, as is shown in Fig. 4c. When the γ-FeOOH was formed without formation of the green rust I as the intermediate, the particles lost their uniformity in shape; in particular, fine particles showing broad X-ray powder diffraction peaks were obtained at much lower temperatures, as is shown in Fig. 4d.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (12), 3697—3698 (1976)

The Relationship between the Atmospheric Carbon Dioxide Concentration and the Carbon-14 Activity in Tokyo

Sakuji IKEDA, Hideki SHIRAKAWA, and Iwakazu HATTORI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received June 4, 1976)

Synopsis. Measurements of the atmospheric CO_2 concentration and the ^{14}C activity in Tokyo were carried out. The activity of ^{14}C in the CO_2 decreased with an increase in the atmospheric CO_2 concentration, indicating that increases in the atmospheric CO_2 are caused only by the burning of fossil fuels.

Studies of atmospheric CO_2 have been carried out either by the measurement of the concentrations or by ^{14}C-activity measurement. Thus, measurable increases on a global scale have been reported for the atmospheric CO_2 concentrations at several locations; thus, the increases are not the result of local influences.[1] An alternative evidence for the global increases caused by the burning of carbonaceous fossil fuels is the Suess effect,[2] which is the decrease in atmospheric ^{14}C concentrations caused by the combustion of ^{14}C-free fossil fuels.

Since the increments in the atmospheric carbon dioxide concentration at any site reflect the emissions of CO_2 from man-made combustion sources as well as from natural sources, it is not possible to identify the type of source only by the concentration measurement; simultaneous measurements with the ^{14}C activity in the atmospheric CO_2 are necessary to identify the type of source and to quantify the fossil CO_2 in the atmosphere. The source analysis in the atmospheric CO_2 would be of value in studies not only of air pollution but also of the circulation of carbon and of climatic influence.

Toward this purpose, we have been conducting measurements of atmospheric CO_2 and ^{14}C concentrations in Tokyo since April, 1975. This note is a brief report on the atmospheric CO_2 based on one year of measurement.

Experimental

The concentration of atmospheric CO_2 was continuously recorded by means of a Shimadzu Model URA-2S nondispersive infrared CO_2 analyzer at the Ookayama campus of this Institute (35°35′54″ N, 135°42′18″ E). The sampling probe was set on the roof of the building of this Research Laboratory about 20 m above the ground. The CO_2 was collected two or three times a month. Each time about one mole of CO_2 was collected as sodium carbonate by bubbling air, at the rate of 50 l/min for 24 h, through 3 l of a carbonate-free solution containing 5 mol of sodium hydroxide. The collection was almost quantitative. The carbonate thus obtained was then converted into benzene according to the benzene-radiocarbon-dating process.[3] The samples were counted in a modified Packard Tri-Carb Model 3390 liquid scintillation spectrometer. The activity of ^{14}C was given as the disintegration per minute per gram carbon (dpm/g-C). Calibration curves for the correction of the counting efficiencies of the samples were made by the use of a series of unquenched and least-quenched 10^5 dpm standards prepared from toluene-^{14}C of $5.92\times10^5\pm3\%$ dpm/g (Packard Instrument Co., Inc.). The standard deviations quoted (1σ) describe the uncertainties associated with toluene-^{14}C, standard preparation, and measurements of the sample, the standard, and the background. The activity of the NBS oxalic acid reference standard was 14.39 ± 0.46 dpm/g-C.

Results and Discussion

Figure 1 indicates the mean monthly CO_2 concentrations from April, 1975, through March, 1976. The maximum and minimum mean hourly concentrations observed through the month are also illustrated in the figure. The seasonal variation is obvious. Since the variation is negatively correlated with the air temperature in Tokyo, since the estimated amount of total fossil fuel consumption, including mobile fuels, in Tokyo during the winter season is double that in summer, and since an extremely high concentration is observed during the winter season, especially at low wind speeds, it can be considered that the principal origin of this variation

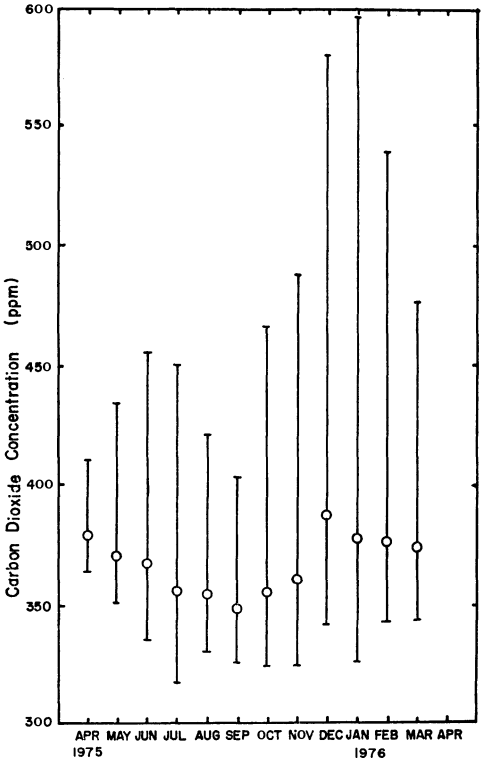

Fig. 1. Mean monthly atmospheric CO_2 concentrations in Tokyo.
Open circles represent mean monthly value. The upper and the bottom limits indicate the maximum and the minimum mean hourly values, respectively, observed through the month.

is due to the combustion of fuels for heating purposes.

The CO_2 concentrations generally decreased with an increase in the wind speed, but never fell for below the values of 317—325 ppm, which can be regarded as the background concentration in air coming into Tokyo. The atmospheric ^{14}C activities (δ ^{14}C % above the modern reference) in 1970 were reported to be 50—59% at Monaco,[4] 44.7—56.4% at Taipei, Taiwan,[5] and 50.4—53.1% at Trnava, Czechoslovakia.[6] The scattered values would appear to indicate a local Suess effect, although the investigations stated that the sampling sites were far from local pollution. Taking into consideration the recent trend of atmospheric ^{14}C activities to decrease as a result of various mixing processes of ^{14}C produced by nuclear weapons testing, coupled with the global Suess effect, the ^{14}C activity in the background CO_2 in 1975 was estimated to be 50.0% above the modern reference or 20.5 dpm/g-C.

The relationship between the atmospheric CO_2 concentrations and the ^{14}C activities is shown in Fig. 2. The smooth curve in the figure represents the calculated relationship under the assumptions that the CO_2 increments from the background concentration are caused only by the fossil CO_2, and that the background concentration and ^{14}C activity in the CO_2 are 325 ppm and 20.5 dpm/g-C respectively. The overall agreement between the observed values and the smooth curve strongly suggests that increases in the atmospheric CO_2 concentration in Tokyo are caused only by the burning of fossil fuels. In fact, the estimated amount of fossil CO_2 released into atmosphere over Tokyo in 1975 reached 7.5×10^{13} g, whereas natural emissions from green areas in Tokyo were estimated to be less than 1.8×10^{11} g/year. On the other hand, the CO_2 from human resipiration and from the decomposition of human excreta can be calculated to be 0.42×10^{13} g/year based on the population in Tokyo and the amount of food consumed. The activity of the ^{14}C in the CO_2, of course, is almost the same as that in natural CO_2.

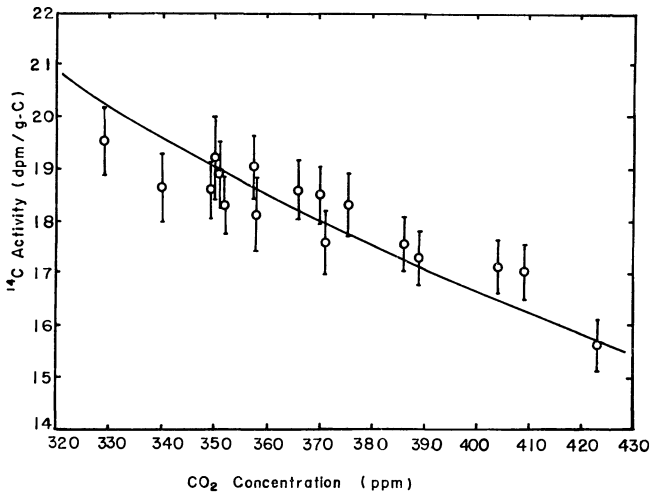

Fig. 2. Relationship between atmospheric CO_2 concentration and ^{14}C activity.
The solid curve represents the calculated relationship by the fossil CO_2.

An analysis with increased precision could be achieved by measurements of the background levels of both the atmospheric CO_2 concentration and the ^{14}C activity in air coming into the observed site, because the background concentrations of atmospheric CO_2 show seasonal variation and have increased at least 1.0 ppm per year after 1969,[1] fluctuations of atmospheric ^{14}C activity as a result of causes have also been observed.[7]

We wish to thank Miss Kyoko Hyakkoku for her assistance in the benzene synthesis and CO_2 measurement.

This work was supported in part by a grant from the Ministry of Education, No. 943015, in 1974 and 1975.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (12), 3699—3700 (1976)

Amination of Decyl Alcohol over the Binary Metal Oxide Catalysts

Yusaku TAKITA, Yasuo NISHIDA,* and Tetsuro SEIYAMA

Department of Materials Science and Technology, Faculty of Engineering, Kyushu University, Higashi-ku, Fukuoka 812
**Sumitomo Rubber Industry LTD., Fukiai-ku, Kobe 651*

(Received June 12, 1976)

Synopsis. Catalytic amination of decyl alcohol was examined over binary oxide catalysts containing molybdenum, and the selective formation of decylamine was observed over TiO_2–, SnO_2–, and Fe_2O_3–MoO_3 catalysts. The reaction was often accompanied by the formation of 1-decene. It was found that catalytic activity for the amination of aliphatic alcohol was associated with the acidic property of metal oxide catalysts.

Olefins, alcohols and carbonyl compounds can be catalytically aminated by ammonia in the heterogeneous system.

$$\text{R-CH=CH-R}' + \text{NH}_3 \longrightarrow \text{R-CH}_2\text{-CH(NH}_2\text{)-R}'$$

$$\text{R-OH} + \text{NH}_3 \longrightarrow \text{R}_n\text{NH}_{3-n} + n\text{H}_2\text{O} \quad (n=1\text{—}3)$$

$$\text{R-C(=O)-H} + \text{NH}_3 + \text{H}_2 \longrightarrow \text{RCH}_2\text{NH}_2 + \text{H}_2\text{O}$$

Since the amination of aliphatic alcohols involves intermolecular dehydration, the catalytic activity might be associated with acidic property of catalysts, as in the case of intramolecular dehydration of alcohols. In fact, most of the catalysts such as SiO_2–Al_2O_3,[1] Co_3O_4–CuO–Kieselguhr,[2] metal sulfate[3] which are claimed to be effective for the reactions show notable acidity. Since only a few studies have been carried out on the catalytic amination of aliphatic alcohols, we have examined the amination of decyl alcohol by NH_3 over the various binary oxide catalysts containing molybdenum.

$$n\text{-}C_{10}H_{21}\text{-OH} + \text{NH}_3 \longrightarrow n\text{-}C_{10}H_{21}\text{NH}_2 + \text{H}_2\text{O}$$

Experimental

SnO_2–MoO_3 catalyst was prepared by conventional methods from ammonium paramolybdate and tin(II) hydroxide precipitated from aqueous tin(II) chloride solution with ammonia. Other catalysts were prepared from respective metal nitrates and ammonium paramolybdate. The reaction was carried out in an ordinary flow reactor with a fixed catalyst bed under an atmospheric pressure at contact time of about 0.32 g s cm^{-3}. The composition of feed gas is given in Table 1. All the products were analyzed by gas chromatography except for didecylamine. The analysis of didecylamine was carried out chemically,[4] no didecylamine being detected.

Results and Discussion

The results of amination of decyl alcohol over various catalysts are given in Table 1. Decylamine was formed in a considerable yield at temperatures below 350 °C over TiO_2–, SnO_2–, Fe_2O_3–MoO_3 catalysts. A small amount of decylamine was also obtained over the Cr_2O_3–MoO_3 catalyst but no amination proceeded over the Mn_2O_3–MoO_3 catalyst. In addition to the amination reaction, 1-decene and its decomposition products such as lower olefins and their aminated compounds were formed with increasing selectivity at higher temperature. This indicates that only 1-decene is formed by the intramolecular dehydration of decyl alcohol, without any further double bond isomerization of 1-decene. It was confirmed that no amination of 1-decene with ammonia took place under similar conditions.

Table 1. Amination of decyl alcohol over the binary oxide catalysts

Catalyst	Temperature (°C)	Conversion of decyl alcohol (%)	Selectivity (%)		
			Decylamine	1-Decene	Others
TiO_2–MoO_3	260	11.2	68.7	31.3	
	300	26.6	46.6	53.4	
	340	49.2	14.5	85.5	Tr
	380	52.9	Tr	91.1	8.9
SnO_2–MoO_3	250	15.1	50.3	49.7	
	300	47.9	26.5	73.5	
	350	57.4	1.9	97.2	0.9
Fe_2O_3–MoO_3	300	13.2	37.1	62.9	
	350	37.7	10.8	79.2	10.0
Cr_2O_3–MoO_3	300	7.3	13.5	86.5	
	350	30.0	5.7	92.3	
Mn_2O_3–MoO_3	300	—	—	—	
	380	17.2	—	97.1	2.9

Catalyst; 1.20 g, Feed gas; decyl alcohol 4.2 cm^3/min, ammonia 8.4 cm^3/min, H_2 4.2 cm^3/min, N_2 2.1 cm^3/min.

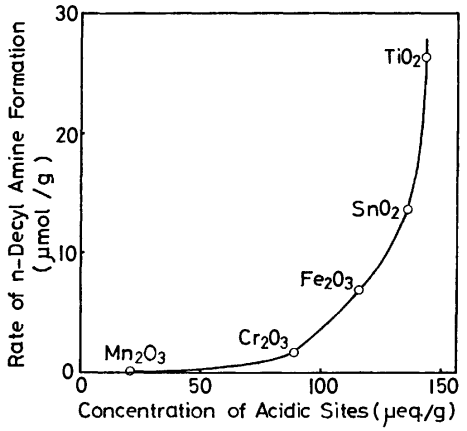

Fig. 1. Relation between activity of amination and concentration of acidic sites.
Catalyst; metal oxide–MoO_3 (9: 1).
Reaction temperature; 300 °C.

This suggests that ammonia, a stronger base than olefin, retards the adsorption of 1-decene onto acidic sites. It is unlikely that decyl cation is formed from decyl alcohol in the course of amination, although it is known that such a cation can be an intermediate in the usual isomerization of olefin over an acidic catalyst.

The acidity of the catalysts measured by butylamine titration using Dimethyl Yellow indicator ($pK_a < +3.3$) is correlated with the catalytic activity at 300 °C (Fig. 1). We see that catalytic activity increases with the acidity of catalysts, though the dependence far exceeds a linear relation. It is difficult to analyze the deviation from linearity. However, an explanation might be given by taking into account the acid strength. The acidic sites actually effective for the amination might be limited to only those with sufficient acid strength and such sites might increase with the change of catalysts more steeply than the measured total acidic sites. X-Ray diffraction patterns of these catalysts show formation of no solid solution. Appearance of $Fe_2(MoO_4)_3$ was detected only in the case of Fe_2O_3–MoO_3. However, metal oxides combined with molybdenum oxide are not considered as simple carriers, since acidic properties of catalysts were shown to be enhanced in the mixed systems. We consider from Fig. 1 that the intermolecular dehydration process involved in the amination is catalyzed by acidic sites. This is in contrast to the Ni–Al_2O_3 or Fe catalyzed amination of aliphatic alcohol by ammonia under hydrogen pressures, for which it was reported[5] that the catalysis is irrespective of acidic property of the catalyst.

Photochemical Addition Reactions of Methanol and Ethanol to 1,4-Diaminoanthraquinone

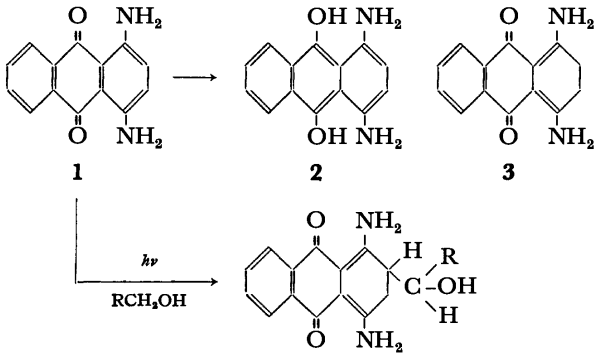
Kimiho YAMADA, Hideto SHOSENJI, Seiki FUKUNAGA,* and Kazuyoshi HIRAHARA

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received March 29, 1976)

Synopsis. Photochemical reactions of 1,4-diaminoanthraquinone in methanol and/or ethanol yielded solvent adducts, **4a** and **4b**. The reactions proceeded *via* an upper triplet state. The quantum yields were 0.013—0.019 at 280 nm.

Anthraquinone compounds undergo various photochemical reactions.[1] The photoreductions have been the most extensively studied. 9,10-Anthracenediol is, as is well known, formed on the irradiation of anthraquinone in a reducing solvent.[2]



4a: R=H
4b: R=CH_3

Several works have been undertaken on the photofading reactions of 1,4-diaminoanthraquinone (**1**) and its homologues because of their industrial importance as dyestuffs. A 9,10-anthracenediol compound (**2**) or its leuco-tautomer (**3**) has been proposed as a product, by analogy with anthraquinone.[3] In the present investigation, however, we observed solvent addition reactions; that is, compounds **4a** and **4b** were obtained on the irradiation of **1** in methanol and ethanol respectively. Similar photoinduced solvent additions have been reported for unsaturated ketones,[4] lactones,[5] and acridines.[6]

Results and Discussion

The irradiation of air-free solutions of **1** yielded the solvent adducts, **4a** and **4b**. The adducts were isolated by preparative thin-layer chromatography (TLC) in 30—40% yields. Neither **2** nor **3** was detected in the reaction mixture.

The wavelength effects on the reaction were investigated by irradiation with monochromatic lights of various wavelengths. No substantial reaction was observed for the light at visible-region band which is assigned to the charge-transfer (CT) transition associated with the charge migration from the amino group to the carbonyl group.[7] The light shorter than 300 nm gave rise to the degradation of **1**. It should be noted that the sunlight still has enough intensity in this wavelength region to cause troublesome photofading of dyed fabrics. The quantum yields for the disappearance of **1** were below 0.02 and reached their maxima around 280 nm, as is shown in Fig. 1. According to Inoue *et al.*, the band at 280 nm is $\pi\pi^*$ in nature and is polarized along the axis parallel to the C=O bond.[7]

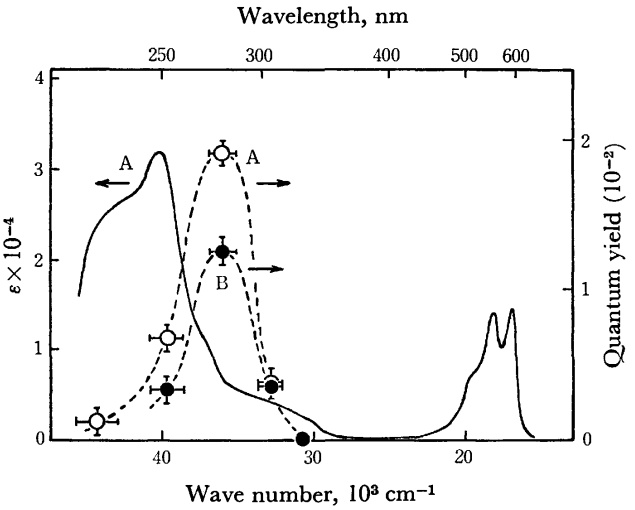


Fig. 1. Electronic spectrum of **1** and quantum yields for its disappearance. A: Ethanol solution; B: methanol solution.

The reaction undoubtedly proceeded *via* a triplet state, as is indicated by the fact that the photo-addition was sensitized by acetophenone and benzophenone[8] and quenched by piperylene. Neither phenanthrene nor biacetyl sensitized the reaction. Hence, the triplet energy for the reaction was estimated to be 62—68 kcal/mol.[9] This is close to the anthracene triplet energy of 62.7 kcal/mol.[10]

Davies *et al.* distinguished between the photoreduction in alcoholic solutions of "strong" sensitizers, such as, for example, anthraquinonesulfonates, and "weak" sensitizers, such as aminoanthraquinone.[11] The former have the lowest triplet of the $n\pi^*$ type, which abstracts hydrogen efficiently from the substrates to initiate the reaction. On the other hand, the CT triplet lies below the $n\pi^*$ triplet in the weak sensitizer. The CT state of **1** does not cause any significant reaction. Evidently the reaction is associated with the upper triplet. The participation of an upper triplet was also pointed out in the photoreduction of 1-dimethylaminoanthraquinone.[12] There still remains a question which character, $n\pi^*$ or $\pi\pi^*$, the triplet has in the present reaction.

* Present address: Nippon Kayaku Co., Ltd., Shimo, Kita-ku, Tokyo 115.

Radical-chain processes have been proposed for the photoinduced solvent-addition reactions of 2-cyclopentenone[4c] and α,β-unsaturated lactones[5] from the facts that the quantum yields exceeded unity[4c,5] and that the same adducts could be obtained in the thermal radical reactions.[5] It might seem that the low quantum yields in the present photoreactions do not afford positive support to the radical-chain mechanism. However, **4b** can be prepared by decomposing azobis(isobutyronitrile) in the ethanol solution of **1**. It can, thus, be presumed that the quantum yield for the solvent addition remains far below unity even if the mechanism involves a radical-chain processes, because **1** gives so low a quantum yield for the triplet formation,[10] and the active triplet might decay rapidly through a subsequent internal conversion to the inactive CT triplet, leaving a really small quantum yield to initiate the radical process. One cannot overlook other possibilities as well, such as a radical cage reaction or nonradical processes.

Experimental

The IR spectra were obtained on a Hitachi-Perkin-Elmer Model 125 spectrophotometer. The UV spectra were taken on a Shimadzu UV-200 or a Hitachi 101 spectrometer. The proton NMR spectra were recorded with a Hitachi R-24 spectrometer at 60 MHz, using tetramethylsilane as the internal standard.

Materials. Compounds **1** and **3** were supplied by the Nihon Kayaku Co., Ltd., and were purified by recrystallization. All the other compounds were commercially available and were recrystallized before use. The methanol and ethanol were purified by the usual methods.

Photochemical Reaction. Solutions of 100 mg of **1** in 400 ml of alcohols were irradiated under nitrogen for 10 h at room temperature using an internal 100 W high pressure mercury lamp. The reaction period could be reduced to one-tenth by sensitizing the solution with 150 mg of benzophenone, while employing Pyrex as a filter. Each reaction mixture contained one main fluorescing product, along with unreacted starting meterials and traces of unidentified by-products, as revealed by silica gel TLC with a benzene–ethyl acetate–methanol mixture (5: 5: 1) as the eluent. The R_f values were in this order: **4a**<**4b**<**3**. The adducts were isolated by preparative TLC as yellow powders in 30—40% yields. The low yields are mainly attributable to the poor recovery by the isolation. The products decomposed above 150 °C without showing definite melting points. They gave UV spectra which quite resembled that of **3**. Their structures were determined from the following data.

1,4-Diamino-2-hydroxymethyl-2,3-dihydroanthraquinone (**4a**): IR (KBr) 2925 (ν_{CH}, alkyl), 1610 ($\nu_{C=O}$) and 1055 cm^{-1} (ν_{C-O}); NMR (CF_3CO_2H) τ 1.1—1.6 (m; C^5–H and C^8–H), 1.6—2.0 (m; C^6–H and C^7–H), 5.4—5.8 (m; methylene of CH_2OH) and 5.8—6.5 (m; C^2–H and C^3–H). Found: C, 58.57; H, 5.30; N, 8.85%. Calcd for $C_{15}H_{14}N_2O_3 \cdot 2H_2O$: C, 58.82; H, 5.88; N, 9.12%.

1,4-Diamino-2-(α-hydroxyethyl)-2,3-dihydroanthraquinone (**4b**): IR (KBr) 2970 (ν_{CH}, alkyl), 1612 ($\nu_{C=O}$) and 1110 cm^{-1} (ν_{C-O}); NMR (CF_3CO_2H) τ 1.1—1.5 (m; C^5–H and C^8–H), 1.5—2.0 (m; C^6–H and C^7–H) 5.2—5.8 (m; methyne of $CHOHCH_3$), 6.1—6.5 (m; C^2–H and C^3–H) and 8.37 (d, J=6.0 Hz; methyl). In a pyridine solution the methyl signal splits into a pair of doublets, situated at τ 8.5 (J=6.0 Hz) and 8.6 (J=6.0 Hz). The splitting is considered to arise because the photoadduct is a mixture of the diastereomers. The separation of the diastereomers was attempted using TLC, but it was unsuccessful. Found: C, 60.28; H, 5.27; N, 8.98%. Calcd for $C_{16}H_{16}N_2O_3 \cdot 2H_2O$: C, 60.00; H, 6.25; N, 8.75%.

The isolated adducts were both relatively stable to air under room conditions, but they gradually oxidized on the TLC plate when exposed to air. UV, IR, and NMR analyses suggested the formation of 2-hydroxymethyl- and 2-(α-hydroxyethyl)-1,4-diaminoanthraquinone.

Quantum Yield. Degassed solutions of 2×10^{-5} mol/l in 1 cm quartz cells were irradiated at 25±1 °C with monochromatic lights of various wavelengths, using a Nihon Bunko CRM-FA Spectral Irradiator equipped with a 2-kW xenon lamp and a 105 Integrator to monitor the light quanta irradiated. Potassium tris(oxalato)ferrate(III) actinometry was employed to calibrate the integrator at each selected wavelength. The light quanta transmitted by the reaction cells were also measured with other potassium tris(oxalato)ferrate(III) actinometer placed immediately behind the cells.

Thermal Radical Reaction. A solution of 10 mg of **1** and 200 mg of azobis(isobutyronitrile) in 100 ml of ethanol was kept at 64 °C for 5 h under nitrogen. After a work-up, the TLC analysis of the reaction mixture revealed the presence of **4b**, along with recovered **1**. The IR spectrum of the isolated product was identical with that of the photochemically obtained one.

The authors wish to thank Professor J. Malcolm Bruce of Manchester University for his valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (12), 3703—3704 (1976)

On the Mechanism of Uncatalyzed Reduction of Triphenylmethyl Chloride with Triethylgermane[1)]

Hideki SAKURAI and Kunio MOCHIDA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received August 3, 1976)

Synopsis. Reduction of triphenylmethyl chloride with triethylgermane in benzene proceeds by a free-radical mechanism as evidenced by the observation of an ESR spectrum of the triphenylmethyl radical. However, the reduction involves apparently an ionic mechanism in a polar solvent such as dichloromethane and nitromethane.

Corey and West first reported that triphenylmethyl chloride can be reduced with hydrosilanes in high yield under moderate conditions without any added catalyst.[2)]

$$Ph_3CCl + R_3SiH \longrightarrow Ph_3CH + R_3SiCl$$

Ionic mechanisms, especially a four-centered[2,3)] and an ion-pair mechanism[4)] have been proposed to this reaction.

The fact that triphenylmethyl chloride can also be reduced with hydrogermanes without catalyst is not surprising because of the known capability of hydrogermanes to reduce organic halides.[5)] However, we report here that the reduction proceeds through a free radical mechanism in non-polar solvents such as benzene.

Reduction of triphenylmethyl chloride with triethylgermane was affected strongly by the nature of a solvent employed. Thus, in a polar solvent such as dichloromethane and nitromethane, the reduction takes place very rapidly even at room temperature.

$$Ph_3CCl + Et_3GeH \longrightarrow Ph_3CH + Et_3GeCl$$

However, in benzene it was required to raise the reaction temperature to 80 °C for completion of the reduction. Interestingly, a strong ESR signal of the triphenylmethyl radical was observed as shown in Fig. 1 after a benzene solution of triphenylmethyl chloride containing triethylgermane in an ESR tube was heated for a few seconds at 80 °C. This fact strongly indicates that the reduction with organogermane in benzene should proceed by a free-radical mechanism.

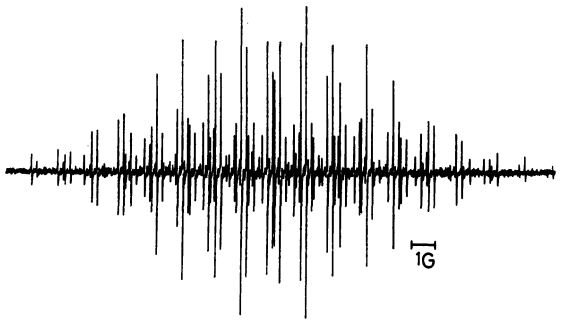

Fig. 1. ESR spectrum of the triphenylmethyl radical, a_{o-H}=2.53G, a_{m-H}=1.11G, a_{p-H}=2.77G.

$$Et_3GeH \longrightarrow Et_3Ge\cdot + (\cdot H)$$

$$Ph_3CCl + Et_3Ge\cdot \longrightarrow Ph_3C\cdot + Et_3GeCl$$

$$Ph_3C\cdot + Et_3GeH \longrightarrow Ph_3CH + Et_3Ge\cdot$$

However, when dichloromethane, nitromethane, or diethyl ether was employed as a solvent, instead of benzene, no ESR signal was observed under various conditions. When triphenylmethyl chloride was dissolved in dichloromethane or nitromethane, color of the solution immediately turned to deep yellow due to the formation of the triphenylmethyl cation. Addition of triethylgermane to the colored solution caused immediate fading with concurrent formation of both triphenylmethane and triethylchlorogermane. These facts suggest that the reduction of triphenylmethyl chloride with hydrogermane in a polar solvent proceeds by an ionic mechanism.

The nature of the initiation step is uncertain, but probably a trace amount of oxygen plays a role. Photochemical generation of the triphenylmethyl radical from triphenylmethyl chloride is known,[6)] but no free radical was detected by ESR for a solution of triphenylmethyl chloride in benzene heated at 80 °C. Therefore, thermal generation of the triphenylmethyl radical is unimportant at least under the conditions.

Incidentally, the ESR spectrum of the triphenylmethyl radical obtained in this study is extremely well-resolved compared to those reported previously.[7)] Generation of free radicals for the ESR studies by reduction with triorganosilanes is well documented,[8)] but no modification using hydrogermane has been reported. We have found recently that reduction of organic halide with hydrogermane has several advantages even for generation of very unstable radicals.[9)]

Experimental

Materials. Triethylgermane[10)] and triphenylmethyl chloride[11)] were prepared according to the literature.

Reduction of Triphenylmethyl Chloride with Triethylgermane in Dichloromethane. Triphenylmethyl chloride (0.17 g, 0.60 mmol) was added to a solution of triethylgermane (0.48 g, 3.01 mmol) in dichloromethane (2.0 ml). The mixture was kept at room temperature for 30 min. GLC analysis showed formation of triphenylmethane (0.13 g, 0.53 mmol) in 88.0% yield.

Another run with a mixture of triphenylmethyl chloride (0.030 g, 0.10 mmol) and triethylgermane (0.160 g, 1.0 mmol) in dichloromethane (0.5 ml), which was subjected to react for 5 min at room temperature, gave triphenylmethane in 46% yield.

Reaction of Triphenylmethyl Chloride with Triethylgermane in Benzene. A mixture of triphenylmethyl chloride (0.49 g, 1.74 mmol) and triethylgermane (1.40 g, 8.71 mmol) in ben-

zene (2.0 ml) was placed in an ampoule which was bubbled with dry nitrogen, sealed and immersed in a constant-temperature bath kept at 80 °C for 2 h. Triphenylmethane (0.37 g, 1.52 mmol, 87.4% yield) was identified and analyzed by GLC.

Another mixture of triphenylmethyl chloride (0.030 g, 0.1 mmol) and triethylgermane (0.160 g, 1.0 mmol) in benzene (0.5 ml) was heated at 80 °C for a few second. GLC analysis showed formation of triphenylmethane in 41% yield.

ESR Measurement. Triethylgermane (0.100 g, 0.62 mmol) was added to a solution of triphenylmethyl chloride (0.011 g, 0.045 mmol) in benzene (0.01 ml) placed in an ESR tube. The tube was bubbled with dry nitrogen and immersed in a constant-temperature bath kept at 80 °C for a few second. Then the ESR spectrum of triphenylmethyl radical was recorded with a Varian E-12 spectrometer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (12), 3705—3706 (1976)

Reaction of Tetramethylurea with Photoexcited Carbonyl Compounds

Yuji TSUJIMOTO, Akihiro NAKAHARA, Yoshiyuki NISHIMURA, Takuji MIYAMOTO, and Yoshinobu ODAIRA

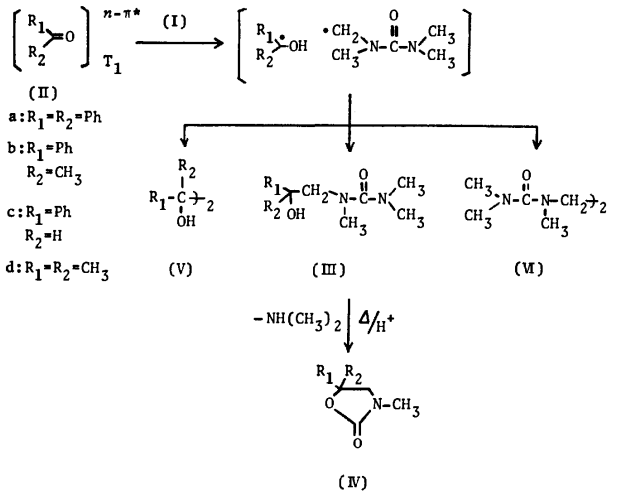
Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita-shi, Osaka 565

(Received May 31, 1976)

Synopsis. The photoreaction of tetramethylurea (I) with some carbonyl compounds (II) afforded in good yields the respective urea derivatives (III), which were converted into 2-oxazolidinones (IV).

Many studies have been carried out on the photochemistry of amides, and some interesting photoreactions such as photocyclization of α,β-unsaturated amides,[1] photooxidation of *N*-alkylamides,[2] and photoamidation to unsaturated systems[3] have been found. It has been reported that a new photobenzoylation of the olefin takes place preferentially in the photoreaction of *N,N*-dimethylbenzamide with 1,1-diphenylethylene.[4] On the other hand, little is known of the photoreactions of ureas except for the photolysis of tetramethylurea in vapor phase.[5] The present study was undertaken to see whether photochemical hydrogen abstraction from tetramethylurea (I) by n-π^* photoexcited carbonyl compounds (II) can occur. We wish to report that hydrogen abstraction occurs very easily to give the urea derivatives (III) in good yields, and that 2-oxazolidinones (IV) can be prepared from the obtained ureas (III). In the present study, benzophenone (II-a), acetophenone (II-b), benzaldehyde (II-c), and acetone (II-d) were used as carbonyl compounds.

Irradiation of I and II-a in acetonitrile through a Pyrex filter for 10 h afforded the urea (III-a) and 2-oxazolidinone (IV-a) in 46 and 4% yields, respectively, together with the pinacol (V-a) and the dimeric urea (VI). The photoreaction of I with II-b under the same conditions as above gave rise to the urea (III-b) and 2-oxazolidinone (IV-b) in 30 and 11% yields, respectively, along with the pinacol (V-b) and VI. Similarly, the photoreaction with II-c gave the urea (III-c) and 2-oxazolidinone (IV-c) in 26 and 11% yields, the urea (III-d) being obtained in 24% yield with II-d.



Scheme 1.

From the results, it was proved that photochemical hydrogen abstraction from I occurred very efficiently.

Concerning the formation of IV obtained as by-products, it was clarified by the following experiments that IV-a—d were derived from III-a—d. When III-a was heated in benzene for 10 h, IV-a was obtained almost quantitatively. In the above reaction, the presence of acid enhanced the rate of cyclization. Consequently, in the case of ureas (III-b—d), each cyclization was carried out with acid. The reaction is illustrated in Scheme 1.

The hydrogen abstraction from I by n-π^* triplet of II results in the formation of a carbinol radical and a ureidomethyl radical, which are precursors of three sets of the coupling products III, V, and VI. III can undergo cyclization to 2-oxazolidinones (IV), accompanied by the elimination of dimethylamine by heat or with acid.

Experimental

Material. Commercial tetramethylurea (I) and carbonyl compounds (II) were purified by the usual methods before use. Dimeric urea (VI) was prepared by the reported method.[6]

General Procedure for Photoreaction. Carbonyl compounds (II) and three molar excess of tetramethylurea (I) were dissolved in acetonitrile. After the solution was bubbled with nitrogen for 10 min, it was irradiated with a 500 W high-pressure mercury lamp through a Pyrex filter for 10 h at room temperature. After evaporation of the solvent, unreacted I was recovered *in vacuo*, and the residue was chromatographed on silica gel, except in the case of acetone (II-d). Dimeric urea (VI) was eluted with ether–benzene (4:6), and confirmed by comparison with an authentic sample.

Photoreaction of I with Benzophenone (II-a). A solution of I [7.0 g, 0.06 mol] and II-a [3.6 g, 0.02 mol] in acetonitrile (40 ml) was irradiated. The following products were isolated. Elution with benzene–petroleum ether gave benzopinacol (V-a) [527 mg, 30%], and the first elution with ether–benzene (2:8) gave 2-oxazolidinone (IV-a) [206 mg, 4%], mp 137—140 °C; Mass *m/e* 253 (M^+); IR (KBr) 1750, 740, 700 cm^{-1}; NMR (CCl_4) δ, 2.8 (s, 3H), 4.0 (s, 2H), 7.0—7.5 (m, 10H). Found: C, 75.67; H, 5.79; N, 5.47%. Calcd for $C_{16}H_{15}NO_2$: C, 75.87; H, 5.97; N, 5.53%. Next elution with ether–benzene (2:8) gave urea (III-a) [2.65 g, 46%] mp 147—148.5 °C; Mass *m/e* 298 (M^+); IR (Nujol) 3400, 1630, 750, 700 cm^{-1}; NMR (CCl_4), 2.5 (s, 3H), 2.64 (s, 6H), 4.0 (s, 2H), 5.5 (s, 1H), 7.0—7.6 (m, 10H). Found: C, 72.28; H, 7.48; N, 9.23%. Calcd for $C_{18}H_{22}N_2O_2$: C, 72.45; H, 7.43; N, 9.39%.

Photoreaction of I with Acetophenone (II-b). A solution of I [26.1 g, 0.23 mol] and II-b [8.9 g, 0.07 mol] in acetonitrile (150 ml) was irradiated. The work-up as above gave the following products: Pinacol (V-b) [3.94 g, 44%], mp 123—125 °C [lit,[7] 122 °C (racemic), 117—118 °C (meso)], urea (III-b) [5.30 g, 30%], mp 155—158 °C; Mass *m/e* 236 (M^+);

IR (Nujol) 3400, 1590, 760, 700 cm^{-1}, 2-oxazolidinone (IV-b) [1.61 g, 11%], Mass *m/e* 191 (M^+); IR (neat) 1740, 760, 690 cm^{-1}; NMR (CCl_4) δ, 1.65 (s, 3H), 2.8 (s, 3H), 3.5 (s, 2H), 7.0—7.5 (m, 5H).

Photoreaction of I with Benzaldehyde (II-c). A solution of I [20.9 g, 0.18 mol] and II-c [6.4 g, 0.06 mol] in acetonitrile (60 ml) was irradiated. The work-up as above gave the following products: Pinacol (V-c) [1.29 g, 11%], mp 137—138 °C [lit,[8] 137.5—138 °C], urea (III-c) [3.40 g, 26%], mp 88—90 °C; IR (KBr) 1600 cm^{-1}; Mass *m/e* 222 (M^+); NMR ($CDCl_3$) δ, 2.8 (s, 6H), 2.9 (s, 3H), 3.1, 3.6 (ABX *octet*, $J_{ab}=15$ Hz, $J_{ax}=9$ Hz, $J_{bx}=3$ Hz, 2H), 4.9 (ABX *q*, 1H), 5.4 (s, 1H), 7.0—7.5 (m, 5H). Found: C, 64.75; H, 8.29; N, 12.48%. Calcd for $C_{12}H_{18}N_2O_2$: C, 64.84; H, 8.16; N, 12.60%. 2-Oxazolidinone (IV-c) [1.17 g, 11%], IR (neat) 1750 cm^{-1}.

Photoreaction of I with Acetone (II-d). A solution of I [23.9 g, 0.21 mol] and II-d [4.0 g, 0.069 mol] in acetonitrile (60 ml) was irradiated. After evaporation of the solvent, unreacted I was recovered *in vacuo*. The remaining residue was distilled under reduced pressure (0.5—0.8 Torr). Besides VI, the urea (III-d) was obtained, [2.78 g, 24%], bp 86 °C (0.55 Torr); IR (neat) 1600 cm^{-1}; Mass *m/e* 174 (M^+); NMR (neat) δ, 1.25 (s, 6H), 2.8 (s, 6H), 3.0 (s, 3H), 3.3 (s, 2H), 4.7 (s, 1H).

Cyclization of III to 2-Oxazolidinones (IV). 3-Methyl-5,5-diphenyl-2-oxazolidinone (IV-a): A solution of III-a [344 mg, 1.15 mmol] in benzene (15 ml) was refluxed for 10 h. Evaporation of the solvent gave crude product (IV-a) [300 mg, 100%]. Recrystallization from benzene afforded a sample identical with the authentic sample. 3,5-Dimethyl-5-phenyl-2-oxazolidinone (IV-b): A solution of III-b [140 mg, 0.59 mmol] in chloroform (5 ml) containing a trace of sulfuric acid was stirred for 4 h at room temperature. After the mixture had been washed with water, the organic layer was dried over calcium chloride. Evaporation of the solvent gave crude product (IV-b) [96 mg, 85%]. 3-Methyl-5-phenyl-2-oxazolidinone (IV-c): A solution of III-c [98 mg, 0.44 mmol] in benzene (3 ml) with a trace of sulfuric acid was stirred for 1 h. The same work-up as above gave crude product (IV-c) [29 mg, 37%]. 3,5,5-Trimethyl-2-oxazolidinone (IV-d): A solution of III-d [90 mg, 0.51 mmol] in chloroform (5 ml) containing a trace of sulfuric acid was stirred for 4 h at room temperature. The same work-up as above gave crude product (IV-d) [54 mg, 80%]. Separation by GLC (10% FEAP) gave an analytical sample, Mass *m/e* 129 (M^+); IR (neat) 1740 cm^{-1}; NMR (CCl_4) δ, 1.4 (s, 6H), 2.75 (s, 3H), 3.15 (s, 2H).

Substituent Effects on Photochemical Extrusion of Phosphorus Group from 3-Phospholene System

Hideo TOMIOKA, Shigehiro NAKAMURA, Tsutomu OHI, and Yasuji IZAWA*

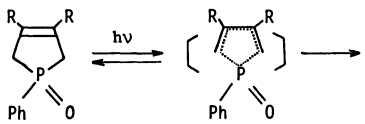
Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514

(Received June 17, 1976)

Synopsis. The rate of photo-extrusion of phenylphosphinidene oxide from 1-phenyl-3-phospholene 1-oxide was enhanced by β-methylation. It was found that the photo-extrusion can be extended to the generation of phenylphosphinidene, but attempts to generate other phosphorus intermediates *i.e.*, metaphosphite and methylphosphinidene oxide, were unsuccessful.

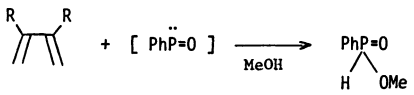
During the course of a study of the photochemical reactions of phosphorus heterocycles,[1] it was found[2] that 1-phenyl-3-phospholene 1-oxide upon UV irradiation efficiently cleaves to diene and phenylphosphinidene oxide (**3**) which is trapped by alcohol to give phosphinates (**4**). The reaction was shown[3] to proceed *via* excited singlet state of **1a**. In view of an increasing interest in the reactive phosphorus intermediate,[4] analog of carbene and nitrene, we have examined the substituent effects on the present reaction in an attempt to extend it to the generation of other important phosphorus intermediates, *e.g.*, metaphosphite and phosphinidenes.

Photolysis of a methanol solution of **1a** in a quartz tube was monitored by GLPC, which revealed a gradual disappearance of the starting material along with the formation of butadiene and methyl phenylphosphinate (**4**). The reaction was incomplete, more than 70% of starting material being recovered after 3 h irradiation.



1 a R=H
b R=Me

2



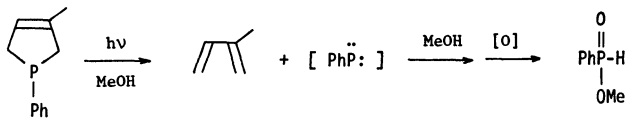
3 4

In contrast, a similar irradiation of 3,4-dimethyl derivative (**1b**) resulted in almost complete consumption of the starting material within *ca.* 1 h, being accompanied by efficient formation of 3,4-dimethylbutadiene and phosphinate (**4**) in nearly quantitative yields. Since apparent rates of disappearance are not always an indication of relative rates, the relative rates (k_r/k_{r_0}) of the photo-extrusion were calculated using quantum yields of the reaction (ϕ_r) and fluorescence (ϕ_f) and absorption spectrum according to the following equation:[5]

$$k_r/k_{r_0} = \phi_r\phi_{f_0}k_f/\phi_{r_0}\phi_f k_{f_0}$$

where k_f = rate constant for fluorescence calculated from the absorption spectrum. This gives the value k_r/k_{r_0} = 467. Alkylation in the β-position reduces the rate of thermal sulfur dioxide extrusion from sulfolene system by stabilizing the starting sulfolene.[6] Thus a large rate enhancement by β-methylation in the present photo-extrusion reaction is especially noteworthy in this connection. An explanation of the result should include, at least in part, the stabilization of incipient diene by β-methyl group in the transition state (**2**) of the cleavage.

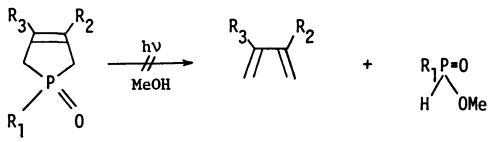
The photo-extrusion reaction was found to occur also in 1-phenyl-3-phospholene (**5**). Thus, irradiation of **5** in methanol under nitrogen gave isoprene as the sole low-boiling product detectable with GLPC. Evidence



5 6 4

for the intervention of phenylphosphinidene (**6**) was provided by the formation of phosphinate (**4**) (20%) in the reaction mixture after oxidation. A possible formation of **4** should also be considered by the photolysis of phospholene 1-oxide resulting from the oxidation of **5** during the course of irradiation. However, this was ruled out since **4** could not be detected before oxidation. The reaction was much more complicated than that of the oxide, being accompanied by the formation of more than fourteen by-products which were detected by GLPC but not further characterized.

In order to examine whether the reaction can be applied to the generation of other phosphorus intermediates, the photochemical behavior of other 3-phospholene systems in alcohol was investigated. Irradiation of 1-ethoxy derivative (**7a**) in ethanol, however, gave no detectable amounts of diene and diethyl phosphite (**8a**) by GLPC. Introduction of phenyl group as a chromophor on ring carbon (**7b**) or oxygen atom (**7c**)



7 8

a R_1=OEt, R_2=R_3=Me
b R_1=OEt, R_2=R_3=Ph
c R_1=OPh, R_2=Me, R_3=H
d R_1=R_2=Me, R_3=H

also did not lead to the extrusion reaction, while these compounds were gradually photolyzed to give mainly intractable oil. Methyl derivative (**7d**) was recovered unchanged even after prolonged irradiation.

It can be concluded that the presence of the phenyl group on phosphorus atom is required for photochemical extrusion of the phosphorus group from the 3-phospholene system, indicating that the stabilization of incipient unshared electrons on phosphorus in the transition state of the cleavage is so stringent as to allow the present reaction to be utilized in general for the generation of phosphorus intermediates.

Experimental

GLPC analysis were performed on a Yanagimoto instrument, Model G-80. GLPC column A was prepared from 10% β,β'-dioxypropionitrile on Diasolid L (5.0 mm × 2.0 m); column B consisted of 10% SE-30 on Diasolid L (5.0 mm × 2.0 m).

H^1 NMR spectra were determined on a JEOL JNM-MH-100 NMR spectrometer. UV and fluorescence spectra were measured with Shimadzu UV 250 recording spectrometer and Hitachi MPF-2A spectrofluorometer, respectively.

Materials. All the 3-phospholene 1-oxides were prepared by cyclo-addition of dienes with phosphonous dihalides, followed by hydrolysis of the resulting adducts.[7] 3-Phospholene (**5**) was prepared[8] by trichlorosilane reduction of the corresponding phospholene 1-oxide.

Irradiations. All the irradiations were carried out using a Halos 300 W high-pressure mercury lamp unless otherwise stated. For analytical purposes, solutions (5.0 ml) of 3-phospholene 1-oxide (50 mg) in methanol were sealed in quartz tubes and irradiated at room temperature. The analyses of the reaction mixture were done by means of GLPC using column A for low-boiling products and column B for high-boiling one. Quantum yields were determined with 254 nm light from the monochrometer using potassium ferrioxalate solution as an actinometer.

Irradiation of 1-Phenyl-3-phospholene (5) in Methanol. To 250 ml of methanol which had been rigorously degassed by bubbling nitrogen was added 2.0 g of freshly distilled 3-phospholene (**5**) under nitrogen and the solution was irradiated using a water-cooled quartz immersion well under nitrogen. The reaction monitored by GLPC revealed a buildup of complex product mixtures as well as isoprene. The irradiation was interrupted when approximately 80% of the starting material had disappeared (*ca.* 6 h). No methyl phosphinate (**4**) was detected. Oxygen was bubbled through the resulting solution under vigorous stirring in the dark until all phosphines were oxidized to oxides. Evaporation of volatile components under reduced pressure at 30 °C gave viscous oil which was chromatographed on silica gel (Woelm Activity II) and eluted with ethyl ether. The foreband gave methyl phenylphosphinate (**4**) (210 mg, 20%), identical with an authentic sample as confirmed by NMR and IR.

The authors wish to thank Japan Synthetic Rubber Co. for the supply of dienes.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (12), 3709—3710 (1976)

Synthesis of Dibenzo[*d,j*]-6,8-bisdehydro-oxa-[13]annulene

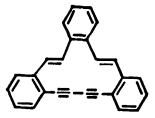
Jūro OJIMA,* Akihiko KIMURA, and Masahiko IKEGUCHI

Faculty of Literature and Science, Toyama University, Gofuku, Toyama 930

(Received July 7, 1976)

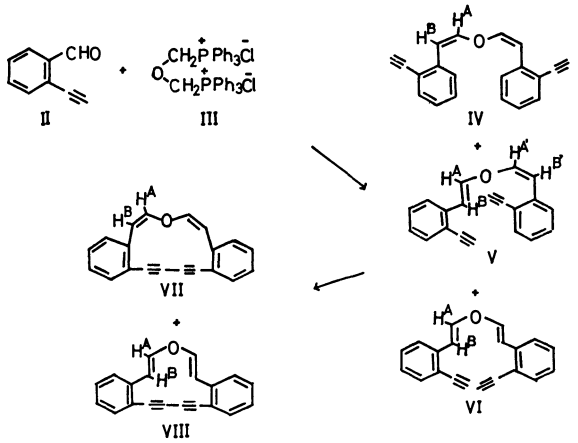
Synopsis. The title compound (VII or VIII) has been synthesized from *o*-ethynylbenzaldehyde (II) by the Wittig reaction with the salt (III) followed by the oxidative coupling. The examination of the NMR spectra suggests that both of VII and VIII are atropic molecules.

In a previous paper, we have reported a synthesis of tribenzo[*a,e,i*]-11,13-bisdehydro[14]annulene (I) by a double Wittig reaction followed by the oxidative coupling starting from *o*-ethynylbenzaldehyde (II).[1] As an extension of our work on benzofused annulenes, we attempted to synthesize a corresponding oxygen analogue, *i.e.*, dibenzo[*d,j*]-6,8-bisdehydro-oxa-[13]annulene according to the same sequence of reactions used in preparation of I.



I

The synthesis of the title compound (VII or VIII) was carried out as follows.



Wittig reaction of II and dimethyl ether-α,α′-bis(triphenylphosphonium chloride) (III)[2] in *N,N*-dimethylformamide by means of ethanolic lithium ethoxide at 80 °C led to, together with the recovered aldehyde, a mixture of acyclic compound in 14% yield from which IV, V, and VI were isolated in a ratio of *ca.* 3: 2: 1, respectively. Configuration of each isomer was confirmed by IR and NMR spectra. Oxidation of the mixture (IV, V, and VI) with copper(II) acetate in pyridine[3] at 60 °C afforded unstable *cis-cis* isomer (VII) and *trans-trans* isomer (VIII) in 6 and 17% yields, respectively.

Wittig reaction between *o*-ethynylcinnamaldehyde[4] and the salt (III) was also attempted to prepare a higher vinylogue of VIII. However, all attempts to obtain the corresponding acyclic compound were unsuccessful in cases using either phenyl lithium in ether or ethanolic lithium ethoxide as a base.[5]

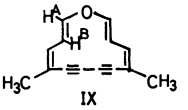


Table 1. ^{1}H-NMR data of VII-IX in $CDCl_3$ (τ-values; internal standard, TMS; *J* values in Hz in parentheses)

	VII[a]	VIII[a]	IX[b]
H^A	3.21d (8)	2.95d (13)	3.87d (13.5)
H^B	3.73d (8)	3.67d (13)[c]	5.09dd (9.5, 13.5)
benzenoid H	1.8—2.4m	2.4—2.7m	

a) At 60 MHz. b) At 100 MHz. c) We assigned the high field signal to H^B proton by reference to the chemical shifts of the related compounds.[7]

The NMR spectral data of the protons of VII and VIII together with those of IX reported by Wife and Sondheimer[7] are summarized in Table 1. The chemical shift of olefinic protons of VII or VIII, particularly of the inner protons, H^B is in normal region. Thus, it is apparent that both of VII and VIII are atropic. Support for this interpretation is given by comparison of the inner H^B proton chemical shift of VII or VIII with that of the closely related annulene IX which was shown to be weakly diatropic (Table 1). The chemical shift of H^B of VII or VIII is at lower field than that of IX.

Experimental

All melting points are not corrected. The alumina used for column chromatography is Brockmann, Act. II—III. The IR and UV spectra were taken on a Hitachi EPI-S2 and a Hitachi 124 spectrophotometers, respectively. Shoulders in UV spectra are indicated by sh. The NMR and mass spectra were taken on JEOL-MH-60 at 60 MHz and JEOL-JMS-OI-SG-2 spectrometers, respectively. The chemical shifts are given in τ-values with respect to TMS as the internal standard, and the coupling constants are given in Hz.

Dimethyl Ether-α,α′-bis(triphenylphosphonium chloride) (III).[2] Triphenylphosphine (52.4 g, 0.2 mol) and α,α′-dichlorodimethyl ether (11.2 g, 0.1 mol)[8] were heated in dry *N,N*-dimethylformamide for 7 h. The mixture was then cooled, the resulting crystals were collected and washed with ether–*N,N*-dimethylformamide. Recrystallization from chloroform and drying *in vacuo* at 80 °C afforded 43.8 g (69%) of III,[2] mp 294—296 °C.

The Isomeric Bis[2-(o-ethylphenyl)vinyl]ether (IV), (V), and (VI). Lithium ethoxide prepared from lithium (0.354 g,

* Correspondence should be addressed to this author.

0.051 g atom) in ethanol (114 ml) was added dropwise with stirring under nitrogen atmosphere at 80 °C for 1 h to *o*-ethynylbenzaldehyde (II, 5.68 g, 0.044 mol) and dimethyl ether-α,α′-bis(triphenylphosphonium chloride) (III, 14.2 g, 0.022 mol) in *N,N*-dimethylformamide (437 ml). After completion of addition, the reaction mixture was stirred for further 2 h under an atmosphere of nitrogen at 80—85 °C, and cooled. The mixture was then poured into water (1000 ml) and extracted thoroughly with ether. The ethereal extracts were washed with dilute hydrochloric acid, aqueous sodium hydrogencarbonate and saturated sodium chloride solutions successively, dried over sodium sulfate, and evaporated to give a pale yellow liquid. The oil was dissolved in ether and chromatography on alumina with light petroleum as eluent gave a mixture of acyclic compd (0.82 g, 14, 29% based on consumed II) as an oil from early fractions, Mass: *m/e* 270 (M^+, 25), 160 (100); mol. wt., 270.3. The following fractions eluted with the same solvent afforded the recovered aldehyde (II, 2.98 g). The mixture was again dissolved in ether and absorbed onto alumina (100 g). Careful elution with light petroleum resulted in separation of three isomers. Early fractions gave *cis-cis* isomer (IV) (0.26 g, 4.5%) as an unstable colorless liquid, IR (neat): 3250 (-C≡CH), 2100 (-C≡C-), 1650, 1595 (C=C), 700 cm^{-1} (*cis* C=C), UV (EtOH): λ_{max} 229 sh, 237, 243, 268 sh, 275, 285 sh, 320 sh nm, NMR ($CDCl_3$): 2.4—3.0 (m, 8H, phenyl H), 3.80 (d, $J=7$, 2H, H^A), 4.15 (d, $J=7$, 2H, H^B), 6.73 (s, 2H, -C≡CH). The next material eluted was *cis-trans* isomer (V) (0.163 g, 2.8%) as a colorless oil. IR (neat): 3300 (-C≡CH), 2090 (-C≡C-), 1640, 1595 (C=C), 940 (*trans* C=C), 700 cm^{-1} (*cis* C=C), UV (EtOH): λ_{max} 230 sh, 237, 243, 268 sh, 274, 290 sh, 320 sh nm, NMR ($CDCl_3$): 2.4—3.1 (m, 9H, phenyl H and H^A), 3.77 (d, $J=13$, 1H, H^B), 3.83 (d, $J=8$, 1H, $H^{A'}$), 4.21 (d, $J=8$, 1H, $H^{B'}$), 6.77 (s, 2H, -C≡CH). The last fractions gave *trans-trans* isomer (VI) (0.079 g, 1.34%) as a colorless liquid. IR (neat): 3250 (-C≡CH), 2100 (-C≡C-), 1640, 1600 (C=C), 1000, 940 cm^{-1} (*trans* C=C), UV (EtOH): λ_{max} 230 sh, 237, 243 sh, 273, 290 sh, 320 sh nm, NMR ($CDCl_3$): 2.4—3.1 (m, 10H, phenyl H and H^A), 3.75 (d, $J=13$, 2H, H^B), 6.67 (s, 2H, -C≡CH).

The Isomeric Dibenzo[d,j]-*6,8-bisdehydro-oxa-*[*13*]*annulene (VII), (VIII).* A soln of a mixture of IV, V, and VI (0.6 g, 0.002 mol) in pyridine (15 ml) was added dropwise to a stirred soln of copper(II) acetate monohydrate (5.1 g) in pyridine (20 ml) for 10 min at 50 °C, and the reaction mixture was stirred for further 2 h at 60—65 °C. The precipitate formed on cooling and diluting with benzene (100 ml) was washed with benzene (50 ml×2). Then the filtrate was washed with 6% hydrochloric acid until it was acid to litmus, and saturated sodium chloride solution successively, and dried over sodium sulfate. The residual dark red liquid obtained after evaporation of the solvent was chromatographed on alumina (80 g) with light petroleum as eluent. Early fractions gave *cis-cis* isomer (VII) (35 mg, 6%) as unstable white crystals (mp 104—106 °C) which turned to brownish mixtures when exposed to air and light in neat state, IR (KBr disk): 2100 (-C≡C-), 1640, 1595 (C=C), 705 cm^{-1} (*cis* C=C), UV (EtOH): λ_{max} 248, 264 sh, 275, 308, 328, 355 sh nm, NMR: see Table 1. The following fractions afforded *trans-trans* isomer (VIII) (100 mg, 17%) as relatively stable white needles (from benzene), mp 172 °C (dec), Mass: *m/e* 268 (M^+, 30), 239 (100); mol. wt., 268.3, IR (KBr disk): 2100 (-C≡C-), 1640, 1595 (C=C), 930 cm^{-1} (*trans* C=C), UV (EtOH): λ_{max} (ε) 237 (30800), 258 sh (15500), 277 (20000), 311 (5960), 352 (7250), 353 nm (6790), NMR: see Table 1.

The authors wish to thank Dr. Terry M. Cresp, University College London, for kindly providing unpublished data, and Miss Chikako Uwai for experimental help. This research was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (974151, 1974), which is gratefully acknowledged.

The Reaction of Benzofuran with Manganic Acetate

Akira KASAHARA, Taeko IZUMI, Akio SUZUKI, and Toru TAKEDA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received July 20, 1976)

Synopsis. The oxidation of benzofuran with manganic acetate in a mixture of acetic acid and acetic anhydride yielded four products: 2-(acetoxymethyl)benzofuran, 3a,8b-dihydrofuro[3,2-*b*]benzofuran-2(3*H*)-one, bis(2-benzofuranyl)methane, and 2-benzofuranylacetic acid.

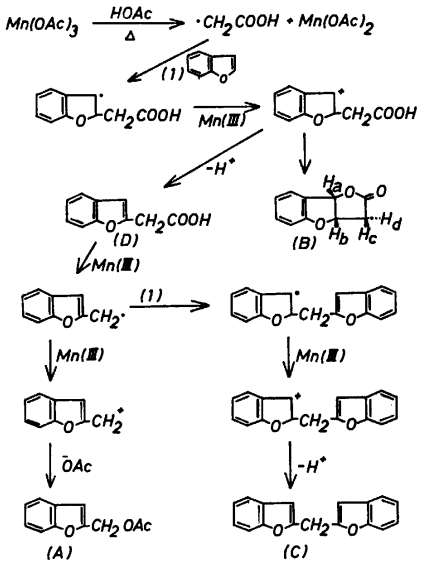
Previously, Heiba *et al.*[1] reported a novel one-step synthesis of γ-lactones by the reaction of olefins with manganic acetate in acetic acid; they suggested that a free radical mechanism involving the selective generation and oxidation of organic free radicals is present. The oxidation of aromatic hydrocarbons by manganic acetate was also described by the same authors.[2]

It is considered that benzofuran (I) possesses a generally aromatic character, plus some characteristics of an enol ether. The present investigation deals with the manganic acetate oxidation of I.

Results and Discussion

In a mixture of acetic acid and acetic anhydride, I and manganic acetate were heated to reflux until the dark brown color of the Mn(III) had disappeared. 2-(Acetoxymethyl)benzofuran (**A**) and 3a,8b-dihydrofuro-[3,2-*b*]benzofuran-2(3*H*)-one (**B**) were obtained as the main products and bis(2-benzofuranyl)methane (**C**) and 2-benzofuranylacetic acid (**D**) as the minor products.

In general, the thermolysis of manganic acetate leads almost exclusively to the formation of $\cdot CH_2COOH$ radical.[2,3] Spagnolo *et al.*[4] reported that, in I, the attack by the free radicals mainly occurs at the 2-position. Consequently, in the reaction of I with manganic acetate, the attack by the $\cdot CH_2COOH$ radical most likely occurs at the 2-position of I; this mechanism is shown in Scheme 1. The mechanism to account for the formation of **B** and **D** is similar to the one suggested for the olefin-manganic acetate oxidation.[1] Heiba *et al.*[2] reported that the oxidation of anisole with manganic acetate leads to the formation of a mixture of *o*-, *m*-, and *p*-methoxybenzyl acetate, and also suggested that *o*-, *m*-, and *p*-methoxyphenylacetic acid, formed primarily from the reaction of anisole with $\cdot CH_2COOH$ radicals, are the precursors of these products. Van Der Ploeg *et al.*[3] also showed that phenylacetic acid is decarboxylated by manganic acetate, leading to the formation of benzyl radicals. Therefore, the formation of **A** and **C** may well be attributed to the reaction of **D** with manganic acetate, followed by the formation of 2-benzofuranylmethyl radicals.



Scheme 1

Experimental

The melting and boiling points are uncorrected. The IR and mass spectra were measured using a Hitachi 215 spectrophotometer and a Model RMU-6M mass spectrometer at 70 eV. The NMR spectra were obtained on a Hitachi Model R-22 (90 MHz), using tetramethylsilane as an internal standard (δ, ppm). Column chromatography was carried out on Kanto-Kagaku silica gel.

Materials. The preparation of the following compounds has already been reported: manganic acetate dihydrate[2] and benzofuran (I).[5]

The Reaction of Benzofuran (I) with Manganic Acetate. A solution of I (9.44 g, 0.08 mol) in 50 ml of acetic acid was refluxed under nitrogen with 5.36 g (0.02 mol) of manganic acetate dihydrate, in the presence of 12 ml of acetic anhydride, until the brown manganic color disappeared. The reaction mixture was diluted with water and extracted several times with ether. The ether extracts were then dried and evaporated. The residue was chromatographed on silica gel with hexane as the eluent.

The first elution with hexane gave 0.40 g (42%[6]) of **A**, bp 156—157 °C/16 Torr. Found: C, 69.61; H, 5.37%. Calcd for $C_{11}H_{10}O_3$: C, 69.46; H, 5.30%. IR spectrum (oil film): 3030, 1740 (C=O), 1590, 1240 (-OAc), 830, 810, 760, 750 cm^{-1}. NMR spectrum: δ 1.95 (s, 3H, CH_3), 5.10 (s, 2H, CH_2), 6.62 (s, 1H, H on C_3), 7.00—7.50 ppm (m, 4H, H on benzene ring). Mass spectrum *m/e* (rel. intensity): 190 (22) (M^+ for $C_{11}H_{10}O_3$), 148 (10) ($M^+-CH_2=C=O$), 131 (100) (M^+-OAc). The physical constants and IR and NMR spectra were identical with those of 2-(acetoxymethyl)benzofuran, which was prepared by acetylation of 2-benzofuranylmethanol.[7]

The second elution with hexane gave 0.37 g (21%[6]) of **B**, mp 111—112 °C (ethanol). Found: C, 68.03; H, 4.38%. Calcd for $C_{10}H_8O_3$: C, 68.18; H, 4.58%. IR spectrum (KBr): 3050, 3000, 2980, 1770 (C=O), 1610, 1480, 1240 (O-C=O), 1040, 740 cm^{-1}. NMR spectrum: δ 2.95 (s, 1H, H_d), 3.00 (d, 1H, $J_{b,c}$=2 Hz, H_c), 5.35 (d-d, 1H, $J_{a,b}$=6 Hz,

$J_{b,c}$=2 Hz, H_b), 5.99 (d, 1H, $J_{a,b}$=6 Hz, H_d), 7.00—7.50 ppm (m, 4H, H on benzene ring). Mass spectrum *m/e* (rel. intensity); 176 (65) (M^+ for $C_{10}H_8O_3$), 131 (100) (2-benzofuranyl–CH_2^+). After hydrolysis of **B** with potassium hydroxide solution, the treatment of the reaction product with hot acetic anhydride led to 2-benzofuranylacetic acid, mp 97—98 °C.[8] From these results, **B** was identified as 3a,8b-dihydrofuro[3,2-*b*]benzofuran-2(3*H*)-one.

The following elution with hexane–benzene (1: 1) gave 0.042 g (3%[6]) of **C**, mp 73—74 °C (methanol). Found: C, 82.43; H, 4.96%. Calcd for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87%. IR spectrum (KBr): 3050, 2930, 1600, 1580, 1445, 810, 790, 750 cm^{-1}. NMR spectrum: δ 4.18 (s, 2H, CH_2), 6.46 (s, 2H, H, on C_3 and C_3'), 7.10—7.50 ppm (m, 8H, H on benzene rings). Mass spectrum *m/e* (rel. intensity): 248 (15) (M^+ for $C_{17}H_{12}O_2$), 131 (100) (2-benzofuranyl–CH_2^+). **C** is identical in all respects with bis(2-benzofuranyl)methane, which was prepared by Wolff-Kishner reduction of bis(2-benzofuranyl) ketone.[9]

The elution with chloroform gave 0.032 g (0.2%[6]) of **D**, 2-benzofuranylacetic acid, mp 97—98 °C (lit,[7] mp 97—99 °C).

Photo-induced Reaction of 2-Alkoxy-3-bromo-1,4-naphthoquinones with Acetylenes: Formation of 2-Aryl-substituted Naphtho[2,3-*b*]furan-4,9-diones

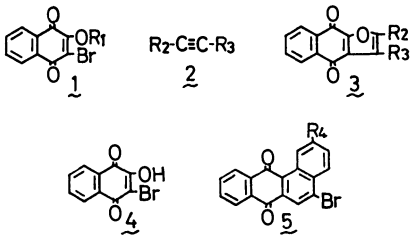
Tetsuo OTSUKI

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received July 31, 1976)

Synopsis. 2-Aryl-substituted naphtho[2,3-*b*]furan-4,9-diones **3** were obtained as a major product in the photochemical reaction of 2-alkoxy-3-bromo-1,4-naphthoquinones with acetylenes.

The photochemical reaction of 2-alkoxy-3-bromo-1,4-naphthoquinones with several acetylenes has been investigated. One of the major products in the reaction was product **3**. Interestingly, the reaction product is of a quite different type from that of the reaction of 2-alkoxy-3-bromo-1,4-naphthoquinone with olefins.[1] Pappas and Farid,[2] on the other hand, have reported the photochemical reaction of 2-alkoxy-1,4-naphthoquinones with acetylenes, but their products were cyclobutene derivatives, which are different from those of the present reaction.



As a typical example, the photochemical reaction of 2-bromo-3-methoxy-1,4-naphthoquinone with phenylacetylene is described. On irradiating the benzene solution of 2-bromo-3-methoxy-1,4-naphthoquinone **1a** ($R_1=CH_3$) and phenylacetylene **2a** ($R_2=C_6H_5$, $R_3=H$) by means of a high pressure Hg arc lamp, 2-phenylnaphtho[2,3-*b*]furan-4,9-dione **3a** ($R_2=C_6H_5$, $R_3=H$) was obtained as a major product (63% yield), accompanying with **4** and **5a** ($R_4=H$). Otherwise, **3a** can be synthesized from 2-hydroxy-1,4-naphthoquinone and phenylacetaldehyde by four reaction steps,[3] but the overall yield is not so good (about 13%). Therefore, this photochemical reaction could provide a new synthetic route to 2-arylnaphtho[2,3-*b*]furan-4,9-diones, though the applicability is rather limited. The reductive acetylation of **3a** gave 4,9-diacetoxy-2-phenylnaphtho[2,3-*b*]furan. Product **4** is likely to be the by-product of a side-reaction since it is formed on irradiation of **1a** in benzene. The structure of **5a** ($R_4=H$), which is produced in trace, was deduced by comparison of its spectral data with those of benz[*a*]anthracene-7,12-diones.[1]

The similar reaction was found to proceed in other combinations of quinones and acetylene derivatives (Table 1). The change of relative yields of **3** against those of **4** would be explicable in terms of the reactivity of the acetylenes used. Diphenylacetylene **2g** ($R_2=R_3=C_6H_5$), for example, may be hard to react with **1**, presumably due to its steric requirements. The alkyl group lost in the course of the photochemical reaction was detected as ethyl bromide (GLC) in the case of the reaction of **1b** ($R_1=C_2H_5$) with **2a**. As mentioned above, Pappas and Farid and their co-workers obtained cyclobutene derivatives in the photochemical reaction of 2-alkoxy-1,4-naphthoquinones with acetylenes.[2] Their products were different from those of the present investigation; the difference probably originates from the presence of the labile C–Br bond in the quinones examined by the present author. The pathway of the present reaction may be formularized as the following:

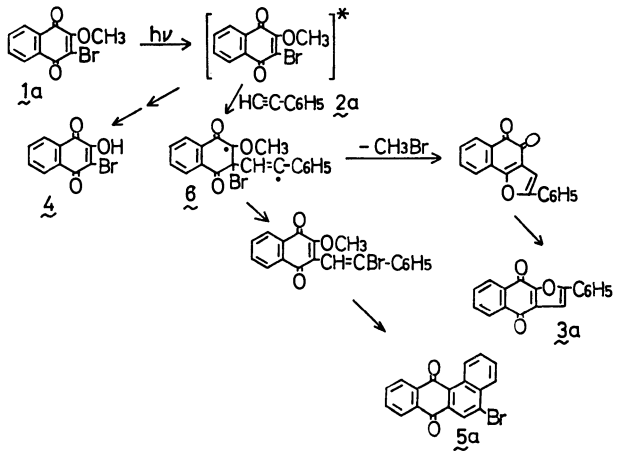


Table 1. The yield of the product in the photochemical reaction

1	2	3	4	5
1a ($R_1=CH_3$)	**2a** ($R_2=C_6H_5$, $R_3=H$)	**3a**: 63% ($R_2=C_6H_5$, $R_3=H$)	8%	**5a**: trace ($R_4=H$)
1a ($R_1=CH_3$)	**2b** ($R_2=p$-CH_3-C_6H_4, $R_3=H$)	**3b**: 38% ($R_2=p$-CH_3-C_6H_4, $R_3=H$)	10%	**5b**: 9% ($R_3=CH_3$)

1b ($R_1=C_2H_5$)	**2a** ($R_2=C_6H_5$, $R_3=H$)	**3a**: 7% ($R_2=C_6H_5$, $R_3=H$)	36%	**5a**: trace ($R_4=H$)

Experimental

Starting Materials. 2-Bromo-3-methoxy-1,4-naphthoquinone and 2-bromo-3-ethoxy-1,4-naphthoquinone were prepared by the bromination of the corresponding 2-alkoxy-1,4-naphthoquinones.[4] Phenylacetylene, diphenylacetylene, and 1-hexyne were commercially available and subjected to the reaction without further purification. The other acetylenes were synthesized from substituted acetophenones.[5]

General Procedure. The benzene solution (20 ml) of a 2-alkoxy-3-bromo-1,4-naphthoquinone (0.5 mmol) and an acetylene derivative (1.0 mmol) was irradiated by means of a high pressure Hg arc lamp (300 W). After the consumption of the quinone (about 8 h), the reaction mixture was extracted with saturated sodium hydrogencarbonate solution. From the alkaline soluble fraction, 2-bromo-3-hydroxy-1,4-naphthoquinone **4** was isolated.[6] On purification of the alkaline insoluble organic layer by using TLC on silica gel, 2-substituted naphtho[2,3-*b*]furan-4,9-dione **3** and 2-substituted 5-bromobenz[*a*]anthracene-7,12-dione **5** were obtained.

Identification of the Products. *2-Phenylnaphtho[2,3-b]furan-4,9-dione (**3a**)*: Red needles from benzene–hexane, mp 250.0—251.0 °C. Found: C, 78.60; H, 3.57%. Calcd for $C_{18}H_{10}O_3$: C, 78.82; H, 3.68%. Mass: *m/e*=274 (M^+). IR (KBr disk): 1670 cm^{-1} (C=O). NMR ($CDCl_3$): δ; 7.18 (1H, s), 7.34—7.54 (3H, m), 7.64—7.96 (4H, m), 8.14—8.30 ppm (2H, m). UVmax ($CHCl_3$): 421 nm (ε: 4.3×10^3), 290 (2.8×10^4), 270 (2.4×10^4).

*2-p-Tolylnaphtho[2,3-b]furan-4,9-dione (**3b**)*: Yellow plates from benzene–hexane, mp 266.5—267.0 °C. Found: C, 79.32; H, 4.31%. Calcd for $C_{19}H_{12}O_3$: C, 79.15; H, 4.19%. Mass: *m/e*=288 (M^+). IR (KBr disk): 1670 cm^{-1} (C=O). NMR ($CDCl_3$): δ; 2.40 (3H, s), 7.14 (1H, s), 7.16—7.40 (2H, m), 7.70—7.90 (4H, m), 8.16—8.36 ppm (2H, m). UVmax ($CHCl_3$): 437 nm (ε: 5.3×10^3), 295 (3.2×10^4), 273 (2.5×10^4).

*2-p-Ethylphenylnaphtho[2,3-b]furan-4,9-dione (**3c**)*: Yellow crystals, mp 186.0—189.0 °C. Mass: *m/e*=302 (M^+). IR (KBr disk): 1685 cm^{-1} (C=O). NMR ($CDCl_3$): δ; 1.24 (3H, t, J=8 Hz), 2.70 (2H, q, J=8 Hz), 7.16 (1H, s), 7.34 (2H, d, J=10 Hz), 7.70—7.90 (2H, m), 7.84 (2H, d, J=10 Hz), 8.12—8.32 ppm (2H, m).

*2-p-Propylphenylnaphtho[2,3-b]furan-4,9-dione (**3d**)*: Yellow crystals, mp 167.0—169.0 °C. Mass: *m/e*=316 (M^+). IR (KBr disk): 1665 cm^{-1} (C=O). NMR ($CDCl_3$): δ; 0.96 (3H, t, J=6 Hz), 1.70 (2H, m), 2.68 (2H, t, J=8 Hz), 7.16 (1H, s), 7.34 (2H, d, J=6 Hz), 7.72—7.90 (2H, m), 7.84 (2H, d, J=6 Hz), 8.08—8.16 ppm (2H, m).

*2-p-t-Butylphenylnaphtho[2,3-b]furan-4,9-dione (**3e**)*: Yellow crystals, mp 169.0—172.0 °C. Mass: *m/e*=330 (M^+). IR (KBr disk): 1660 cm^{-1} (C=O). NMR ($CDCl_3$): δ; 1.36 (9H, s), 7.16 (1H, s), 7.52 (2H, d, J=8 Hz), 7.68—7.84 (2H, m), 7.86 (2H, d, J=8 Hz), 8.10—8.30 ppm (2H, m).

*2-Butylnaphtho[2,3-b]furan-4,9-dione (**3f**)*: Yellow crystals, mp 160 °C. IR (KBr disk): 1680 cm^{-1} (C=O). NMR ($CDCl_3$): δ; 0.80—2.30 (9H, m), 6.42 (1H, s), 7.68—7.86 (2H, m), 8.04—8.22 ppm (2H, m).

*5-Bromo-2-methylbenz[a]anthracene-7,12-dione (**5b**)*: Yellow crystals from petroleum ether, mp 180.0—182.0 °C. Mass: *m/e*=352, 350 (M^+). IR (KBr disk): 1665 cm^{-1} (C=O). NMR ($CDCl_3$): δ; 2.62 (3H, s), 7.30—8.42 (7H, m), 9.84 ppm (1H, br s). UV max ($CHCl_3$): 414 nm (ε: 2.4×10^3), 364 (sh) (2.5×10^3), 333 (3.4×10^3), 290 (3.1×10^4), 251 (2.6×10^4).

*5-Bromo-2-ethylbenz[a]anthracene-7,12-dione (**5c**)*: Yellow crystals, mp 146.0—151.0 °C (dec). Mass: *m/e*=366, 364 (M^+). IR (KBr disk): 1665 cm^{-1} (C=O). NMR ($CDCl_3$): δ; 1.40 (3H, t, J=8 Hz), 2.98 (2H, q, J=8 Hz), 7.50—8.40 (7H, m), 9.62 ppm (1H, br s).

*5-Bromo-2-propylbenz[a]anthracene-7,12-dione (**5d**)*: Yellow crystals, mp 149.0—151.0 °C. Mass: *m/e*=380, 378 (M^+). IR (KBr disk): 1667 cm^{-1} (C=O). NMR ($CDCl_3$): δ; 1.02 (3H, t, J=6 Hz), 1.80 (2H, m), 2.90 (2H, t, J=8 Hz), 7.50—8.40 (7H, m), 9.80 ppm (1H, br s).

*5-Bromo-2-t-butylbenz[a]anthracene-7,12-dione (**5e**)*: Yellow crystals, mp 161.0—164.0 °C. Mass: *m/e*=394, 392 (M^+). IR (KBr disk): 1667 cm^{-1} (C=O). NMR ($CDCl_3$): δ; 1.52 (9H, s), 7.40—8.40 (7H, m), 9.98 ppm (1H, br s).

*The Reductive Acetylation of **3a**.* **3a** (10 mg) was refluxed with 3 ml of acetic anhydride and 100 mg of zinc dust for 30 min and filtered. The filtrate was poured into 10 ml of water and extracted with 20 ml of ether. Purification by using TLC on silica gel afforded 4,9-diacetoxy-2-phenylnaphtho[2,3-*b*]furan: white needles, mp 211—214 °C (yield: 54%). Mass: *m/e*=360 (M^+). IR (KBr disk): 1765 cm^{-1} (C=O). NMR ($CDCl_3$): δ; 2.56 (3H, s), 2.60 (3H, s), 6.96 (1H, s), 7.32—7.56 (5H, m), 7.76—8.00 ppm (4H, m).

The present author wishes to express his sincere gratitude to Professor Kazuhiro Maruyama, Kyoto University, for his fruitful suggestions and invaluable encouragements; he also thanks the Ministry of Education, Japan, for a Grants-in-Aid (No. 911503 and 943019).

Synthesis of 1-Azido-5-methyl-4-hexen-2-one and Its Catalytic Dimerization

Takao KATAGIRI, Akira AGATA, Kunihiko TAKABE, and Juntaro TANAKA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432

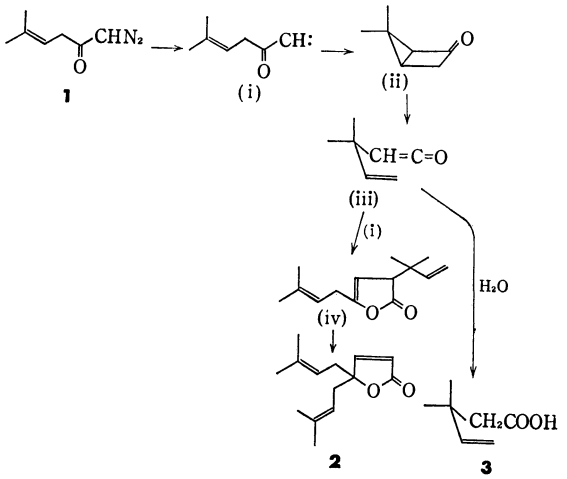
(Received May 28, 1976)

Synopsis. 1-Azido-5-methyl-4-hexen-2-one was synthesized easily from 4-methyl-3-pentenenitrile which was prepared from isoprene. This compound is quite stable. Its catalytic dimerization gave 4,4-bis(3-methyl-2-butenyl)-2-butenolide.

Lokensgard *et al.*[2] studied the decomposition of 1-azido-3-cyclopentenyl-2-propanone and they proposed a mechanism for the decomposition. In this paper, the synthesis and the catalytic dimerization of an acyclic β,γ-unsaturated diazoketone, 1-azido-5-methyl-4-hexen-2-one (**1**), are reported.

The catalytic dimerization of **1** gave a main compound (**2**). The structure of **2** was confirmed to be as follows: The MS showed that **2** was the condensed dimer of **1**. The PMR spectrum showed that the two 3-methyl-2-butenyl groups were equivalent. Since the chemical shifts of the methylene in the above groups were in a higher field than that of **1**, the above groups did not attach to the next carbon of a carbonyl group. Moreover, the coupling constants of the lower olefinic protons (J=6.0 Hz) agreed with that of 2-butenolide.[3] In the IR spectrum, signals at 1750 cm^{-1} for the carbonyl in a five membered lactone and at 1790 cm^{-1} (as the shoulder) were observed, and **2** might be an α,β-unsaturated γ-lactone. From these data, **2** was identified as 4,4-bis(3-methyl-2-butenyl)-2-butenolide (**2**).

The mechanism of the formation of **2** might be as shown in the reaction scheme. Since the acid (**3**) could be obtained when the reaction was quenched with water at the early stage of the reaction, **2** may be produced through the intermediates (ii), (iii), and (iv) as suggested by Lokensgard *et al.*[2]



Experimental

Synthesis of 1-Azido-5-methyl-4-hexen-2-one (1). 1-Chloro-3-methyl-2-butene (60 g), which was prepared from isoprene,[4] was reacted with CuCN(45 g) in benzene (30 ml) in the presence of KI (0.5 g) at 10—20 °C for several hours. From the reaction mixture, 4-methyl-3-pentenenitrile was isolated by the fractional distillation (bp 62—63 °C/15 Torr, 26 g). The nitrile was hydrolyzed by 60 g of 30% aqueous KOH, and 23.7 g of 4-methyl-3-pentenoic acid was obtained. This acid was chlorinated with 30 g of thionyl chloride, and 4-methyl-3-pentenoyl chloride was obtained (bp 60—61 °C/20 Torr, 22.4 g). This chloride was dissolved in ether (30 ml) and the solution was added dropwise into an ether solution (50 ml) of diazomethane, which was prepared from 25 g of nitrosomethylurea, under cooling at 0—5 °C for 3 h. After the addition, the solution was kept at room temperature for 12 h. Careful distillation gave a yellow oil (bp 68—69 °C/3 Torr, 5.3 g). The oil was analyzed by GLC (Apiezon L, 100 °C) (98% purity). This showed the following spectral data: PMR (δ, CCl_4) 1.64 (s, 3H, $=CCH_3$), 1.76 (s, 3H, $=CCH_3$), 2.93 (d, 2H, J=7.0 Hz, $-CH_2-$), 5.12 (s, 1H, $-CHN_2$), 5.24 (t, 1H, J=7.0 Hz, $-CH=$). IR (cm^{-1}) 2110, 1640.

Catalytic Dimerization of 1. A benzene solution (30 ml) of **1** (5.8 g) was added dropwise to a suspension of 1.0 g of CuO in 100 ml of benzene under reflux with vigorous stirring. After the evolution of nitrogen ceased and the catalyst was removed by filtration, the product was distilled (bp 98—102 °C/3 Torr, 2.8 g). The GLC showed that this distillate contained 84% of a main compound (**2**).

4,4-Bis(3-methyl-2-butenyl)-2-butenolide (2): MS (*m/e*) 220 (M^+), 69 (Base ion, $C_5H_9^+$). PMR (δ, CCl_4) 1.62 (s, 6H, $=CCH_3$), 1.72 (s, 6H, $=CCH_3$), 2.41 (d, 4H, J=7.0 Hz, $-CH_2-$), 5.00 (t, 2H, J=7.0 Hz, $-CH=$), 5.94 (d, 1H, J=6.0 Hz), 7.23 (d, 1H, J=6.0 Hz). IR (cm^{-1}) 1750, 1790. Found: C, 76.22; H, 9.20%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

In the other run, when water was added to the reaction mixture as soon as the evolution of nitrogen ceased, a different fraction (bp 65—70 °C/3 Torr) than (**2**) was obtained (15% based on (**1**)). This fraction contained 3,3-dimethyl-4-pentenoic acid (**3**) mainly. (**3**): MS (*m/e*) 128 (M^+). PMR (δ, CCl_4) 1.20 (s, 6H, $-C(CH_3)_2$), 2.34 (s, 2H, $-CH_2-$), 5.06 (dd, 1H, J=1.5 Hz, and 10.5 Hz, $\begin{matrix}H\\ \diagdown\\ C=C\\ H\diagup \quad \diagdown H\end{matrix}$), 5.07 (dd, 1H, J=1.5 Hz and 18.0 Hz, $\begin{matrix}\quad H\\ \diagdown\\ C=C\\ H\diagup \quad \diagdown H\end{matrix}$), 6.07 (dd, 1H, J=10.5 Hz and 18.0 Hz, $\begin{matrix}\quad H\\ \diagdown\\ C=C\\ H\diagup \quad \diagdown H\end{matrix}$), 12.27 (s, 1H, $-COOH$). IR (cm^{-1}) 3450, 1710, 995, 915. Found: C, 65.55; H, 10.02%. Calcd for $C_7H_{12}O_2$: C, 65.59; H, 9.94%.
