a) The weight of Al_2O_3 was calculated from that of $Al(C_9H_6ON)_3$. The conversion factor is 0.1109. b) The weight of Na_2O was calculated by multipling the weight of $NaZn(UO_2)_3(CH_3COO)_9\cdot 6H_2O$ by 0.01495.

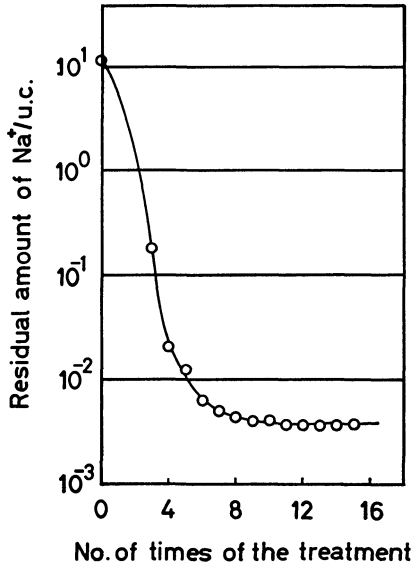

Fig. 1. Residual amount of Na^+ per unit cell in Tl-exchanged zeolites *vs.* the number of times of the treatment.

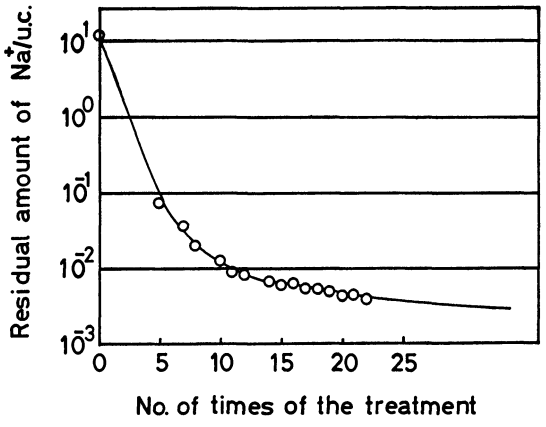

Fig. 2. Residual amount of Na^+ per unit cell in Ba-exchanged zeolites *vs.* the number of times of the treatment.

After equilibration the zeolite and the solution were separated, the zeolite being subjected to the same treatment. The process was repeated. We prepared samples subjected to the treatment 1, 2,……ν-times. The residual amount of sodium in the sample treated n-times, $[Na]_n$, was determined by activation analysis.

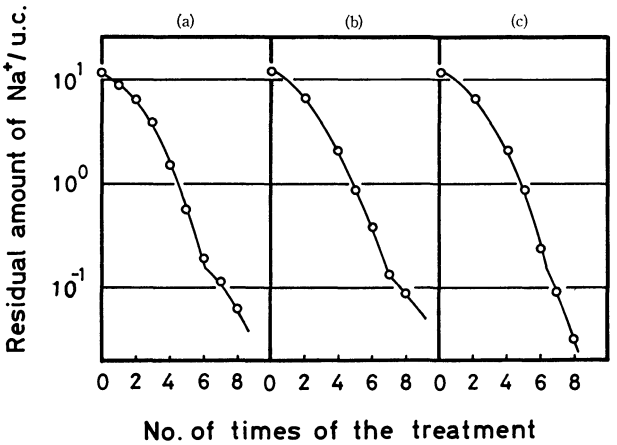

Fig. 3. Residual amount of Na^+ per unit cell in zeolites ion exchanged with dilute solutions.
a): Ba-exchanged zeolite, b): Sr-exchanged zeolite, c): Tl-exchanged zeolite.

The value for $\log [Na]_n$, thus determined, is plotted against n, the number of times of treatment (Figs. 1—3).

Analysis and Discussion

Determination of the Selectivity Coefficient. After repetition of ion exchange, all Na^+ ions on easily exchangeable sites (normal site) are replaced by the ion exchanging cations. Further exchange deals with the Na^+ ions on the δ-site. However, the amount of sodium includes the contribution from a nuclear side-reaction $^{27}Al(n,\alpha)^{24}Na$. This is negligibly small in the initial part of the curves (Figs. 1 and 2) but significant in the final part. The contribution corresponds to a spurious 1.83×10^{-3} Na per unit cell.[20] Subtracting this we obtain the curves for the residual amount (Figs. 4 and 5).

Let us analyze the curve (Fig. 4) by means of the equation

$$[Na]_n = \frac{[Na]_{n-1}}{1+m'(Tl)_s K_\delta(Na,Tl)/\delta} + \frac{m'(Tl)_s K_\delta(Na,Tl)[Na]_\infty/\delta}{1+m'(Tl)_s K_\delta(Na,Tl)/\delta}, \quad (1)$$

where $[Na]_n$ and $[Na]_\infty$ denote the residual amount of sodium after repetition of treatment n-times and infinite number of times, respectively, $K_\delta(Na,Tl)$ the

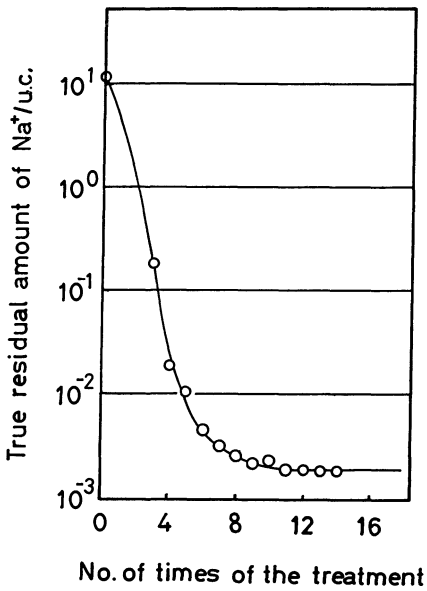

Fig. 4. True residual amount of Na^+ per unit cell in Tl-exchanged zeolites *vs.* the number of times of the treatment.

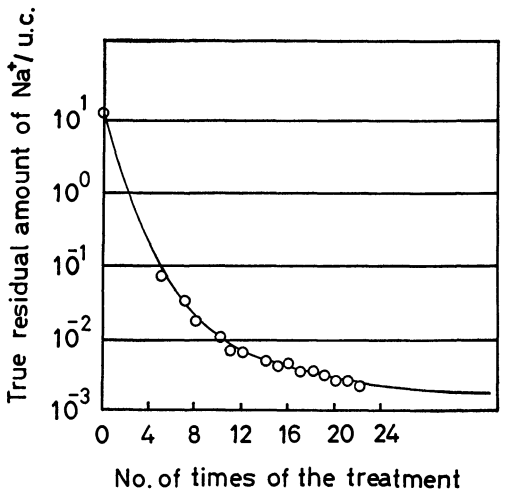

Fig. 5. True residual amount of Na^+ per unit cell in Ba-exchanged zeolites *vs.* the number of the times of the treatment.

selectivity coefficient of the ion exchange reaction between Tl^+ and Na^+ on δ-site, $m'(Tl)_s$ the amount of Tl^+, in mole, contained in the exchanging solution initially loaded. The derivation of Eq. 1 is given in the Appendix. Figure 4 gives the value of $[Na]_\infty$:

$$[Na]_\infty = 1.90\times10^{-3}\,Na^+/u.c.$$

When $[Na]_n$ is plotted against $[Na]_{n-1}$, we have a straight line (Fig. 6). The line crosses a line having a slope of unity at $[Na]_\infty(=1.90\times10^{-3})$. The straight line is represented by

$$[Na]_n = 0.53[Na]_{n-1} + 9.0\times10^{-4}. \quad (2)$$

Comparing Eqs. 1 and 2, we get

$$K_\delta(Na,Tl) = 0.89\ \delta/m'(Tl)_s.$$

Introducing the experimental value $m'(Tl)_s=6.67$, we have

$$K_\delta(Na,Tl) = 0.13\delta.$$

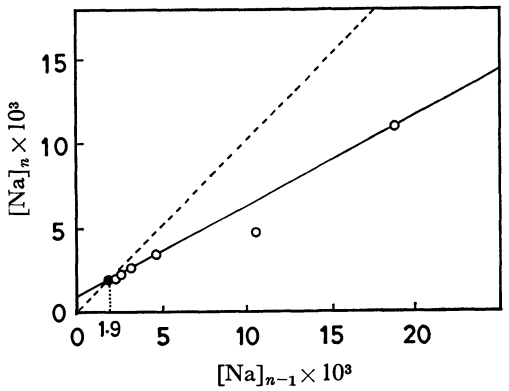

Fig. 6. Plots of $[Na]_n$ *vs.* $[Na]_{n-1}$ for (Na,Tl)–A system. The solid line is a most probable line to the plotts and the broken line is that of unity slope.

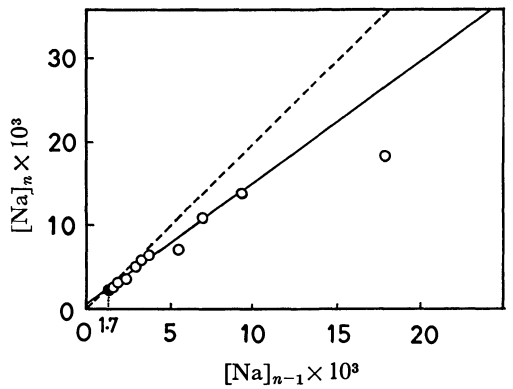

Fig. 7. Plots of $[Na]_n$ *vs.* $[Na]_{n-1}$ for (Na,Ba)–A system. Broken line is that of unity slope.

If we use the δ-value obtained by chemical analysis, the value for $K_\delta(Na,Tl)$ is determined as

$$K_\delta(Na,Tl) = (2.0\pm0.4)\times10^{-2}. \quad (3)$$

Similar analysis can be carried out for a (Na,Ba)–A system by use of the equation

$$[Na]_n = \frac{[Na]_{n-1}}{1+\frac{m'(Ba)_s}{\delta}\sqrt{\frac{2K_\delta(Na,Ba)}{T_n}}} + \frac{[Na]_\infty\frac{m'(Ba)_s}{\delta}\sqrt{\frac{2K_\delta(Na,Ba)}{T_n}}}{1+\frac{m'(Ba)_s}{\delta}\sqrt{\frac{2K_\delta(Na,Ba)}{T_n}}} \quad (1')$$

where $K_\delta(Na,Ba)$ is the selectivity coefficient of the ion exchange reaction between Ba^{2+} and Na^+ on the δ-site and T_n the total normality of the solution. From Fig. 5, $[Na]_\infty$ was chosen for the (Na,Ba)–A as

$$[Na]_\infty = 1.7\times10^{-3}\ Na^+/u.c.$$

Plots of $[Na]_n$ *vs.* $[Na]_{n-1}$ for the system are shown in Fig. 7. A straight line for the plots, passing through the point $[Na]_\infty$, is represented by

$$[Na]_n = 0.77[Na]_{n-1}+3.9\times10^{-4}. \quad (2')$$

From Eqs. 1′ and 2′, we obtain

$$K_\delta(Na,Ba) = 4.5\times10^{-2}\,\delta^2T_n/m'(Ba)_s.$$

Since $m'(Ba)_s=3.33$ and $T_n=0.20$, we have

$$K_\delta(Na,Ba) = 8.0\times10^{-4}\,\delta^2.$$

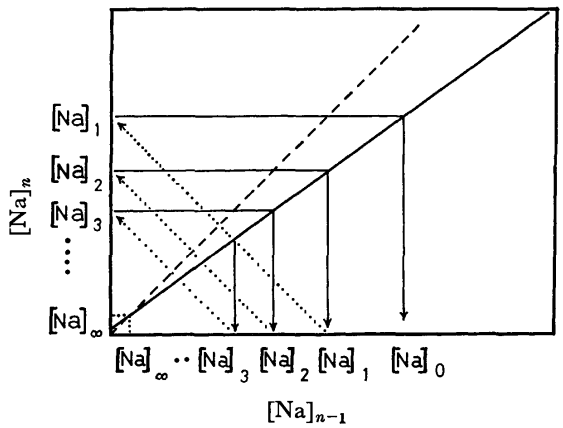

Fig. 8. Schematic diagram which shows a procedure to obtain $[Na]_0$ by using $[Na]_n$-$[Na]_{n-1}$ plotts.

By use of the δ-value determined by chemical analysis, K_δ(Na,Ba) is calculated as

$$K_\delta(\mathrm{Na,Ba}) = (1.8\pm0.4)\times10^{-5}.$$

Determination of the δ-Value. Use of Eq. 1: For the sake of brevity, let us discuss the case of Tl-exchanges.

Introducing Eq. 3 into Eq. 1, we get

$$[\mathrm{Na}]_n = \frac{[\mathrm{Na}]_{n-1}}{1+2.0\times10^{-2}\,m'(\mathrm{Tl})_s/\delta} + \frac{2.0\times10^{-2}m'(\mathrm{Tl})_s[\mathrm{Na}]_\infty/\delta}{1+2.0\times10^{-2}\,m'(\mathrm{Tl})_s/\delta}. \quad (4)$$

When the same experiments are carried out with an unknown sample, values for $[Na]_n$, $[Na]_{n+1}$ *etc.* being measured, its δ-value is determined by means of Eq. 4.

Approximate Methods: The principle of the method is schematically given in Fig. 8. The value for $[Na]_{\nu-1}$ is given from $[Na]_\nu$. The final value for $[Na]_0$ is obtained by repeating the procedure. According to Eq. 1, the $[Na]_0$ value corresponds to the initial amount of sodium in the δ-part. In the present case, we have

$$\delta = 0.12\pm0.05,$$

in agreement with the result of the chemical analysis.

Empirical Methods: When Na–A zeolite is treated with a dilute solution, we obtain curves as shown in Fig. 3. Break points in the curves roughly correspond to the point where easy exchange stops and hard exchange starts. The δ-value is determined from the break as follows.

$\delta = 0.16\pm0.02$ in $BaCl_2$ solution

$\delta = 0.14\pm0.02$ in $SrCl_2$ solution

and

$\delta = 0.15\pm0.04$ in $TlNO_3$ solution.

These values agree with those given by chemical analysis, in spite of the crude procedure.

Conclusion

As compared with the method of Barrer and Meier, the present method is efficient.

Systems (Na,Tl)–A and (Na,Ba)–A were used for determination of the δ-value; the former seems superior.

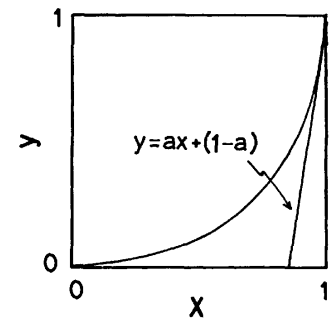

Fig. 9. Ion exchange isotherm for the δ-site. x and y are equivalent cation fractions in a solution and on the δ-site, respectively. Solid line is an asymptote.

Determination of the $[Na]_\infty$ value is easier in (Na, Tl)–A. In the empirical method, systems (Na,Ba)–A and (Na,Sr)–A are superior to system (Na,Tl)–A since Na^+ on the δ-site is not easily replaced by Ba^{2+} or Sr^{2+}, a sharp break appearing in the curve of $\log [Na]_n$ *vs.* n.

Tl^+ and Ba^{2+} do not seem to enter into the δ-part.[15,21] However, the present results show that this is not the case. As for Sr^{2+}, Sherry and Walton concluded that it enters into the δ-part,[21] in line with the present results.

Appendix

An ion exchange isotherm for the δ-site has a form shown in Fig. 9, where x and y are equivalent cation fractions in a solution and on the δ-site, respectively.[15] In the case of (Na,Tl)–A system, they are defined by

$$x = \frac{m(\mathrm{Tl})_s}{m(\mathrm{Tl})_s+m(\mathrm{Na})_s} \quad (5)$$

and

$$y = \frac{m(\mathrm{Tl})_\delta}{m(\mathrm{Tl})_\delta+m(\mathrm{Na})_\delta}, \quad (6)$$

where $m(Tl)_s$ and $m(Tl)_\delta$ denote the amount of Tl^+ in mole unit in the solution and on the δ-site, respectively. In the final range of the exchange, the most part of the δ-site has been occupied by Tl^+ and the final part of the exchange isotherm might converge to an asymptote

$$y = ax + (1-a). \quad (7)$$

Consider the case in which one mole of zeolite is repeatedly treated with a solution having a certain composition. The solution initially contains $m'(Tl)_s$ mole of Tl^+ ion and $r\cdot m'(Tl)_s$ of trace impurity Na^+ ion, where r denotes the proportion of the amount of Na^+ to that of Tl^+. From Eqs. 5, 6 and the material balance, we have

$$(1+r)m'(\mathrm{Tl})_s x = m(\mathrm{Tl})_s,$$
$$\delta y = m(\mathrm{Tl})_\delta,$$

and

$$(1+r)m'(\mathrm{Tl})_s x + \delta y = m(\mathrm{Tl})_t, \quad (8)$$

where $m(Tl)_t$ is the total amount of Tl^+ in the system. From Eqs. 7 and 8, we obtain

$$1-y = \frac{\delta+(1+r)m'(\mathrm{Tl})_s-m(\mathrm{Tl})_t}{\delta+(1+r)m'(\mathrm{Tl})_s/a}.$$

After ion exchange n-times, we get

$$1-y_n=\frac{\delta+(1+r)m'(\mathrm{Tl})_s-m(\mathrm{Tl})_{t,n}}{\delta+(1+r)m'(\mathrm{Tl})_s/a}. \quad (9)$$

From the material balance we have

$$m(\mathrm{Tl})_{t,n}=\delta y_{n-1}+m'(\mathrm{Tl})_s.$$

Introducing this into Eq. 9, we get

$$1-y_n=\frac{\delta(1-y_{n-1})}{\delta+(1+r)m'(\mathrm{Tl})_s/a}+\frac{r\cdot m'(\mathrm{Tl})_s}{\delta+(1+r)m'(\mathrm{Tl})_s/a}$$
$$\approx\frac{\delta(1-y_{n-1})}{\delta+m'(\mathrm{Tl})_s/a}+\frac{r\cdot m'(\mathrm{Tl})_s}{\delta+m'(\mathrm{Tl})_s/a}, \quad (10)$$

where the equation was simplified by the condition $r\ll 1$. In the present experiments, the residual amount of sodium per unit cell, $[\mathrm{Na}]_n$, is measured as a function of n, and is given by

$$[\mathrm{Na}]_n=\delta(1-y_n).$$

Thus Eq. 10 becomes

$$[\mathrm{Na}]_n=\frac{[\mathrm{Na}]_{n-1}}{1+m'(\mathrm{Tl})_s/a\delta}+\frac{r\cdot m'(\mathrm{Tl})_s}{1+m'(\mathrm{Tl})_s/a\delta}. \quad (11)$$

By repetition of ion exchange, $[\mathrm{Na}]_n$ decreases, converging to a definite value:

$$\lim_{n\to\infty}\frac{[\mathrm{Na}]_n}{[\mathrm{Na}]_{n-1}}=1.$$

Combining the above two equation, we get

$$[\mathrm{Na}]_\infty=a\delta r,$$

where $[\mathrm{Na}]_\infty$ is the converged value and determined from the flat part of the curve in Fig. 5. Thus, the unknown parameter r is eliminated from Eq. 11, and we have

$$[\mathrm{Na}]_n=\frac{[\mathrm{Na}]_{n-1}}{1+m'(\mathrm{Tl})_s/a\delta}+\frac{m'(\mathrm{Tl})_s[\mathrm{Na}]_\infty/a\delta}{1+m'(\mathrm{Tl})_s/a\delta}. \quad (12)$$

This shows that when $[\mathrm{Na}]_n$ is plotted against $[\mathrm{Na}]_{n-1}$, we get a straight line which crosses at $[\mathrm{Na}]_\infty$ with a line having a slope of unity.

The slope of straight line in Eq. 7, a, is related to a selectivity coefficient of the exchange reaction on the δ-site. The selectivity coefficient for the (Na,Tl)–A system, $K_\delta(\mathrm{Na,Tl})$, is given by

$$K_\delta(\mathrm{Na,Tl})=\frac{Na_s\cdot Tl_\delta}{Tl_s\cdot Na_\delta},$$

where Tl_s and Tl_δ denote the equivalent cation fractions of Tl^+ in the solution and on the δ-site, respectively. Such an equation was found to hold for the exchange reaction on the δ-site.[13,15] Introducing Eqs. 5 and 6 into the above equation, we have

$$K_\delta(\mathrm{Na,Tl})=\frac{(1-x)y}{x(1-y)}.$$

Since $a=(\mathrm{d}y/\mathrm{d}x)_{x=1}$, we get

$$a=\frac{1}{K_\delta(\mathrm{Na,Tl})}.$$

Eliminating the parameter a from this equation and Eq. 12, we obtain

$$[\mathrm{Na}]_n=\frac{[\mathrm{Na}]_{n-1}}{1+m'(\mathrm{Tl})_sK_\delta(\mathrm{Na,Tl})/\delta}+\frac{m'(\mathrm{Tl})_sK_\delta(\mathrm{Na,Tl})[\mathrm{Na}]_\infty/\delta}{1+m'(\mathrm{Tl})_sK_\delta(\mathrm{Na,Tl})/\delta}. \quad (13)$$

This is the fundamental equation in the present analysis and is reduced to Eq. 1 when numerical values determined experimentally are introduced.

As for the (Na,Ba)–A system, minor changes should be introduced as

$$[\mathrm{Na}]_n=\frac{[\mathrm{Na}]_{n-1}}{1+2m'(\mathrm{Ba})_s/a\delta}+\frac{2m'(\mathrm{Ba})_s[\mathrm{Na}]_\infty/a\delta}{1+2m'(\mathrm{Ba})_s/a\delta} \quad (12')$$

and

$$K_\delta(\mathrm{Na,Ba})=\frac{2Ba_\delta\cdot(Na_s)^2}{(Na_\delta)^2\cdot Ba_s}\cdot T_n,$$

where Ba_δ means the equivalent cation fraction of Ba^{2+} on the δ-site, Ba_s that in the solution and T_n a total normality of the solution. Thus, we have

$$a=\sqrt{\frac{2T_n}{K_\delta(\mathrm{Na,Ba})}}$$

and

$$[\mathrm{Na}]_n=\frac{[\mathrm{Na}]_{n-1}}{1+\frac{m'(\mathrm{Ba})_s}{\delta}\sqrt{\frac{2K_\delta(\mathrm{Na,Ba})}{T_n}}}+\frac{[\mathrm{Na}]_\infty\cdot\frac{m'(\mathrm{Ba})_s}{\delta}\sqrt{\frac{2K_\delta(\mathrm{Na,Ba})}{T_n}}}{1+\frac{m'(\mathrm{Ba})_s}{\delta}\sqrt{\frac{2K_\delta(\mathrm{Na,Ba})}{T_n}}}. \quad (13')$$

The author is grateful to Prof. T. Takaishi, Toyohashi University of Technology, for his support and valuable discussions. He also wishes to thank Prof. Y. Sensui, Rikkyo (St. Paul's) University, for his encouragement and γ-ray spectra measurements. The present work was supported in part by a Grant-in-Aid for Research from the Ministry of Education, Contract No. 443001.

ESR Study of the Spin-labeled Poly(methyl methacrylate) Adsorbed on the Human Tooth and Hydroxyapatite

Harutoshi SAKAI,* Tetsuo ASAKURA,†,†† Kazuomi SUZUKI,† Kozo HORIE,†
Yukihiro MAESHIMA, and Yoshio IMAMURA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

† *Department of Dental Materials, Nihon University of Dentistry at Matsudo, Matsudo, Chiba 271*

(Received November 11, 1980)

The motion and the configurational behavior of the poly(methyl methacrylate) adsorbed on the surfaces of human tooth substances (dentin, enamel, and hydroxyapatite crystal) from a solution were clarified by using the electron-spin-resonance technique. The polymer molecules were more strictly bound by the surfaces of enamel and hydroxyapatite than the dentin. On both enamel and hydroxyapatite, the adsorbed molecules behaved in the same manner in their motion and configuration. However, the segments directly bound by each tooth substance had a much higher degree of motional freedom than those by the silica surface. These results were discussed in relation to the interaction between the polymer and the tooth, and in relation to the clinical adhesive aspects.

Electron spin resonance (ESR), coupled with a spin-labeling technique, has been successfully applied to the study of the adsorption behavior of several polymers.[1-4]

The bound segments in the adsorbed polymers (train) are easily distinguishable from the segments in loops or tails on the basis of the difference in the ESR line shape, which corresponds to the difference in mobility among these segments. Thus, the ESR study is very useful in clarifying the detailed aspects of the interaction between a polymer and a solid surface.

On the other hand, restorative materials which consist of polyfunctional methacrylates and glass filler have often been used to fill the missing tooth produced by dental caries.[5,6] However, the failure of the restorative materials to hold or secondary caries sometimes occur because of a lack of adhesiveness with tooth surface. In order to develop restorative materials which have a good adhesiveness with the tooth, it is necessary to obtain information on the adhesive mechanism between the materials and the tooth surface.

In our previous papers, the interaction between spin-labeled poly(methyl methacrylate) (PMMA) and a silica surface has been studied in detail by means of the ESR method.[3,4] In this paper, the ESR study was performed in order to obtain information on the interaction between PMMA and the surfaces of three tooth substances, *i.e.*, dentin, enamel, and hydroxyapatite.

Experimental

A human tooth, dried at 60 °C for two weeks, was cut into two parts, the enamel and the dentin. Each part was then crushed with a ball mill to obtain a powder which could be used for the adsorption experiments. A sample of finely powdered hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$, was purchased from the Seikagaku Kogyo Co., Ltd. The electron micrographs of these samples were obtained with a HITAC S-500 Scanning Electron Microscope. The diameters of these particles had a wide distribution in each case, 1—10 μm.

† Present address: Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184.

Spin-labeled PMMA was prepared by the method described in a previous paper.[3] The sample used had a number-average molecular weight of 1.2×10^5 and a narrow mol wt distribution. The stereoregularity of the sample was highly isotactic.

The solid powder, 0.2 g, was added to 5 cm^3 of a CCl_4 polymer solution, after which the mixture was stirred for 4 h at 25±2 °C. The adsorbents were centrifuged after the adsorption equilibrium had been attained and separated from the supernatant solutions. The solids were rinsed with pure CCl_4 and 0.1 g of each sample was placed in a quartz sample tube. The ESR signals from the adsorbed polymer were measured on a JEOL JES FE 3-X spectrometer, applying a temperature control. On the other hand, the amount of adsorption was determined by means of ESR measurements of the changes in the polymer concentrations of the supernatant solution before and after the adsorption. The polymer concentration was calculated from the signal intensities of the polymer solution of a constant volume, approximately 0.1 cm^3, relative to those of the standard solutions. The other experimental methods have been described in previous papers.[3,4]

Results and Discussion

The adsorption isotherms of PMMA on three kinds of tooth substances, *i.e.*, dentin, enamel, and hydroxyapatite, in CCl_4 at 25 °C are shown in Fig. 1. Each curve reaches a plateau at a low concentration of the polymer solution, with a slight increase at a higher concentration. This behavior is independent of the kinds of tooth substance. The saturated amount of adsorption, A_s, increased in the order of dentin (10 mg/g), enamel (30 mg/g), and hydroxyapatite (90 mg/g).

Let us now examine in detail the ESR spectra of the spin-labeled PMMA adsorbed on these tooth substances in the unsaturated stages. Figure 2 shows the ESR spectra of the PMMA adsorbed on hydroxyapatite crystals. These spectra can be assumed to be composed of three portions of the local chain, *i.e.*, train, short loop, and long loop.[4] It should be noted that there is a significant change in the ESR line shapes with the degree of adsorption; this corresponds to the change in the conformation of PMMA

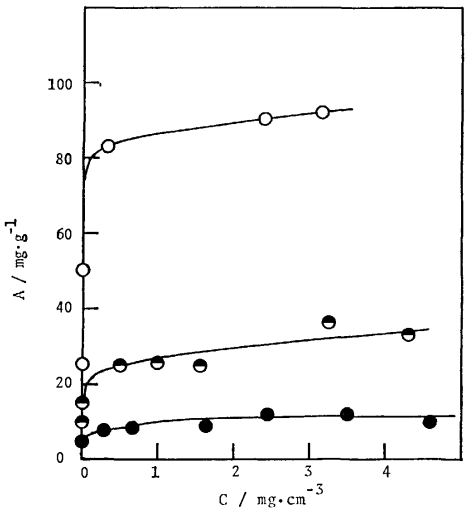

Fig. 1. The adsorption isotherms of PMMA on the tooth substances from CCl_4 dilute solution at 25 °C. ○: On hydroxyapatite, ◓: enamel, ●: dentin.

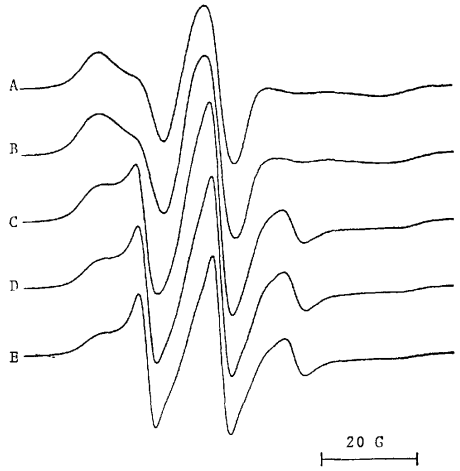

Fig. 2. The ESR spectra of the spin-labeled PMMA adsorbed on hydroxyapatite crystal at 25 °C. The relative amounts of adsorption (θ) are A: 0.3, B: 0.5, C: 0.8, D: 0.9, and E: 1.0, respectively. Here, 1 G is equal to 10^{-4} T.

adsorbed on the hydroxyapatite surface. The adsorbed molecules initially tend to adsorb in a relatively flat conformation (train) and to become more looped as the saturation adsorption is approached. The spectral behavior of PMMA in the unsaturated stage was also qualitatively the same as in the cases of enamel and dentin, as is shown in Fig. 3 and 4 respectively. Moreover, there was no difference between the ESR spectrum of PMMA adsorbed on hydroxyapatite and that adsorbed on enamel, even at the saturated stage ($\theta \approx 1$). Here, θ is the amount of adsorption relative to the maximum amount of adsorption. On the other hand, a looser adsorption behavior was observed in the case of dentin, as is shown in Fig. 4. In order to clarify this difference, the fraction and the correlation time of the segments in the train conformation were calculated when $\theta = 1$. As has been mentioned above, these ESR spectra of the adsorbed PMMA can be assumed to be com-

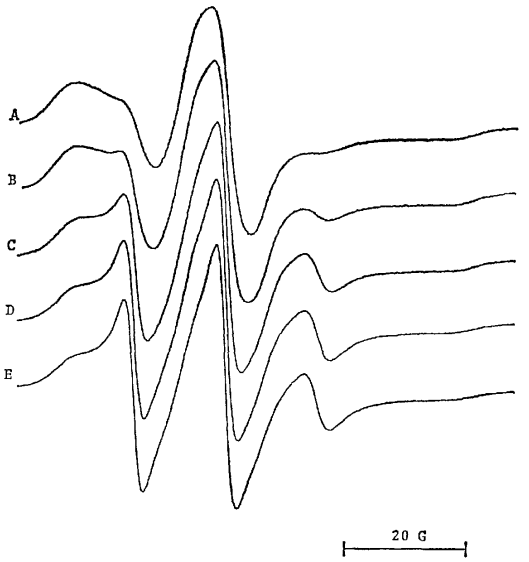

Fig. 3. The ESR spectra of the spin-labeled PMMA adsorbed on enamel at 25 °C. The relative amounts of adsorption (θ) are A: 0.3, B: 0.5, C: 0.8, D: 0.9, and E: 1.0, respectively.

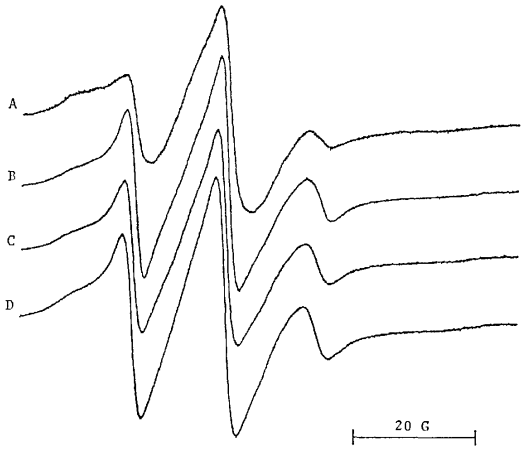

Fig. 4. The ESR spectra of the spin-labeled PMMA adsorbed on dentin at 25 °C. The relative amounts of adsorption (θ) are A: 0.2, B: 0.8, C: 0.9, and D: 1.0, respectively.

posed of three portions of the local chain. The fraction of each portion was evaluated by fitting the spectrum calculated from the superposition of appropriate three model spectra to the observed spectrum on a computer.[4] The correlation time, τ_c, of the bound segments is considered to be in the region of relatively slow motion from 10^{-7} to 10^{-9} s and can be calculated by the following equation, derived by Goldman *et al.*:[7]

$$\tau_c = a(1-S)^b,$$

where $S = A'_z/A_z$, A'_z is one-half the separation width of the hyperfine extrema (W) and where A_z corresponds to the rigid limit value (W_{max}). The parameters, a and b, are dependent on the rotational diffusion models and the intrinsic line-width in the spectrum. In this calculation, the values for the moderate jump diffusion model, $a = 1.10 \times 10^{-9}$ and $b = -1.01$,

Table 1. The correlation time, τ, and the fraction of bound segments of adsorbed PMMA

Sample	τ/s	Segment fraction
Hydroxyapatite	2.2×10^{-8}	0.55
Enamel	2.2×10^{-8}	0.54
Dentin	1.5×10^{-8}	0.44
Silica	$>10^{-6}$	0.48

were used. The results were summarized in the table, together with the data on silica reported previously.[4] The fraction of bound segments decreased considerably, and the mobility increased significantly, in dentin compared with the values for hydroxyapatite and enamel. These results correspond to the difference in composition between dentin and enamel. The composition of dentin on a wet-weight basis is generally considered to be approximately 70% inorganic material, 18% organic material, and 12% water.[8] The inorganic portion consists mainly of hydroxyapatite crystals, while the organic portion consists mainly of collagen. On the other hand, the composition of the enamel is 92—96% inorganic material, 1—2% organic material, and 3—4% water. Most of the inorganic material is hydroxyapatite here, also. Thus, the composition of the inorganic material (hydroxyapatite) decreases considerably in the dried dentin compared with that in the dried enamel used here. The carbonyl groups of PMMA are able to form a hydrogen bond with OH groups in the hydroxyapatite, and this interaction is considered to be a predominant force for the adsorption rather than other van der Waals interactions.[9] Thus, a decrease in the amount of hydroxyapatite in dentin would cause a decrease in the fraction of bound segments and an increase in the mobility of the bound segments compared with the cases of enamel and hydroxyapatite. These conclusions derived from the ESR study are in agreement with the clinical results where polyfunctional methacrylates are found to be more adhesive to enamel than dentin.[10—12]

It should be noted that the motion of PMMA adsorbed on silica is significantly slower than those of PMMA adsorbed on hydroxyapatite, enamel, and dentin; *i.e.*, the correlation time of the bound segments is longer than 10^{-6} s for silica, while it is approximately 10^{-8} s for the tooth substances. Such a difference was also observed in the temperature dependence of the extreme separation width. The spectral change of PMMA adsorbed on enamel is shown in Fig. 5 at various temperatures. The value of W decreased gradually with a rise in the temperature. In contrast, the value remained constant over the wide temperature range of −120 to 70 °C in the case of the bound segments on silica, as has been described previously.[4] These observations indicate that PMMA interacts with

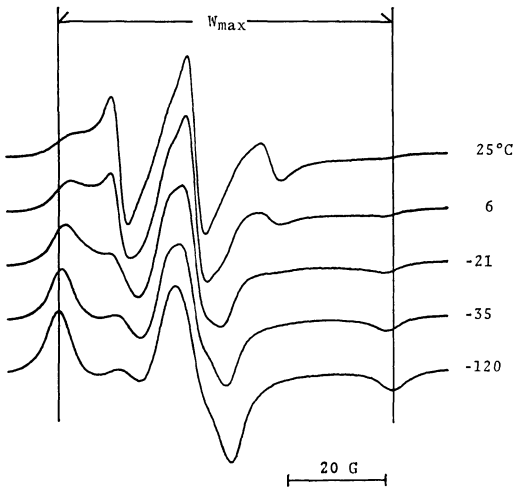

Fig. 5. The ESR spectral change of the spin-labeled PMMA adsorbed on enamel with temperature change. W_{max} is a rigid limit value in the extreme separation widths.

silica more strongly than with a tooth. This is interesting because composite resin, which is widely used as a restorative material for teeth, consists of polyfunctional methacrylates and silica powder.

Thus, the ESR method, coupled with the spin-labeling technique, is very useful in studying the interaction between synthetic polymer and the tooth surface.

The Fluidity and Electrolytic Conductivity of Alkali-metal Chloride/Poly(ethylene oxide)-H_2O Systems. The Effects of the Polymer Concentration and the Temperature

Toshiaki Isono,* Katsuo Takahashi, and Reita Tamamushi

The Institute of Physical and Chemical Research, 2-1 Hirosawa, Wako, Saitama 351

(Received December 17, 1980)

The fluidities of poly(ethylene oxide) (PEO)–H_2O mixtures and the electrolytic conductivities of alkali-metal chlorides in the PEO–H_2O mixtures were measured at different PEO compositions and temperatures (25—50 °C). The extended Walden's rule was found to be satisfied when the fluidity and conductivity were changed by the temperature variation at a constant composition, whereas a large deviation from Walden's rule was observed upon the isothermal variation of the PEO composition. The Arrhenius activation parameters were determined from the temperature dependence of the fluidities and conductivities, and some correlations between pairs of parameters were examined.

The mobility of ions and molecules in solution generally decreases with a decrease in the fluidity of the solution; the simplest relationship between the ionic mobility and fluidity is given by the well-known Stokes law (or Walden's rule);

$$\lambda^\infty/\phi = \text{const}, \quad (1)$$

where λ^∞ is the limiting ionic conductivity, and ϕ, the fluidity of the solution. In viscous solutions containing large polymer molecules, however, the mobility of small particles has been known to show significant deviations from Walden's rule;[1] but it can be approximately represented by the empirical equation;[2-4]

$$\lambda^\infty\phi^{-p} = \text{const}, \quad (2)$$

where $0<p<1$.

Different theoretical approaches, such as the concepts of "microscopic viscosity" and "obstruction effect," have attempted to interpret the influence of large neutral molecules on the mass-transport properties of small ions and molecules.[2,5] From the experimental point of view, it seems important to find empirical correlations between pairs of various physical quantities concerning the mass-transport process; although the physical meaning of some of these correlations may be difficult to understand, they may be expected to provide useful information for the theoretical study of the structure of solutions and the mechanism of mass-transport phenomena.

In the present work, we have measured the fluidities of aqueous solutions containing poly(ethylene oxide)s (PEO) with relative molecular masses of 200—20000 and the electrolytic conductivities of alkali-metal chlorides (MX) in PEO–H_2O mixtures at different polymer concentrations and temperatures. This PEO series was chosen for the following reasons: (i) pure samples of sufficiently low conductivities are available; (ii) aqueous solutions of a wide range of fluidity can be prepared, and (iii) PEO is a material of practical importance, being very much used for surfactants, detergents, drugs, and polymer solvents in chemical reactions. The Arrhenius activation parameters have been determined from the temperature dependence of the fluidity and conductivity, and some phenomenological correlations between pairs of these parameters will be discussed.

Experimental

Materials. The poly(ethylene oxide)s used were Polyethylene Glycols (PEG 200, PEG 4000, and PEG 20000) as supplied by Wako Pure Chemical Industries, Ltd. The average relative molecular masses of these polymers, as determined by the vapor-pressure method, were 200 for PEG 200, 3300 for PEG 4000, and 11700 for PEG 20000.

The samples of alkali-metal chlorides were special-reagent-grade chemicals and were used without further purification.

All solutions were prepared gravimetrically by using redistilled water. In this paper, the composition of the PEO–H_2O mixture is given in terms of the mass fraction of PEO, and the PEO–H_2O mixture is regarded as the solvent of the MX/PEO–H_2O system.

Fluidity and Conductivity Measurements. The PEO–H_2O mixtures used in this work were assumed to be Newtonian fluids, because a preliminary study using a rotational viscometer showed an approximate proportionality between the shearing stress and the velocity gradient.

Cannon-Fenske and Ubbelohde viscometers were used to measure the fluidity of the solutions of $\phi>5$ Pa^{-1} s^{-1} (aqueous solutions of PEG 200 and PEG 4000, and those of PEG 20000 at lower concentrations). Capillary diameters were chosen to give flow times of 60 seconds at least. The fluidities of highly viscous mixtures (aqueous solutions of PEG 20000 at higher concentrations) were measured by means of a falling-ball viscometer consisting of a glass cylindrical tube (inner diameter, 17 mm) and a stainless steel ball (diameter, 1 mm) used in ball bearings. Weld pycnometers were employed to determine the densities of the solutions.

The electrolytic conductivities of 0.1 mol kg^{-1} MX/PEO–H_2O systems were measured by the four-electrode a.c. method that has been described in a previous paper;[6] the electrodes were Pt-wires (diameter, 0.5 mm), and the frequency was 125 Hz, no frequency effect being observed in the range of 60 Hz—1 kHz. This method has definite advantages over the conventional two-electrode method when applied to highly viscous mixtures. The conductivities of the PEO–H_2O mixtures were always less than 1% of those due to the electrolytes and so could be neglected in the calculation of the molar conductivities of MX.

All measurements were made in a constant-temperature water bath which was capable of a controlled temperature of better than T ±0.05 K. The accuracy of the measurements was estimated to be better than ±1% for the molar conductivity, ±0.1% for $\phi>5$ Pa^{-1} s^{-1}, and ±1% for $\phi<1$ Pa^{-1} s^{-1}; no correction of ϕ was made for the kinetic energy term.

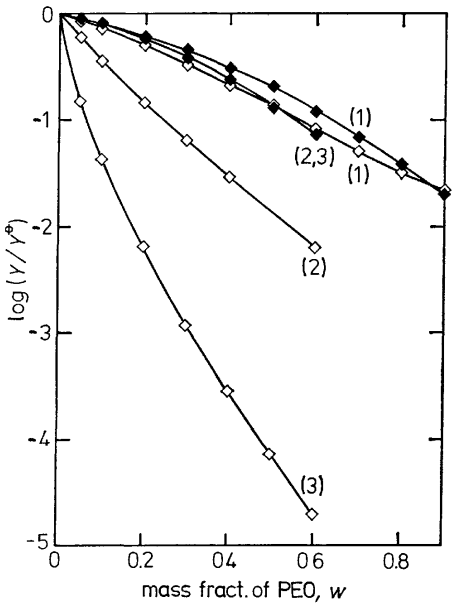

Fig. 1. Changes in the fluidity ($Y=\phi$, —◇—) and the molar conductivity of 0.1 mol kg^{-1} NaCl ($Y=\Lambda$, —◆—) in the PEO–H_2O mixtures at 25 °C as a function of the mass fraction of PEO: (1) PEG 200, (2) PEG 4000, and (3) PEG 20000. Y° represents the fluidity of pure water in the case of $Y=\phi$, and the molar conductivity of 0.1 mol kg^{-1} NaCl in H_2O in the case of $Y=\Lambda$, respectively.

Further details of the experimental procedures and the full experimental data obtained in this work have been reported in a separate paper.[7]

Results and Discussion

Effect of the Polymer Concentration on the Fluidity and Conductivity. The fluidity of a PEO–H_2O mixture and the molar conductivity of MX in the 0.1 mol kg^{-1} MX/PEO–H_2O system are functions of the polymer concentration and the temperature:

$$Y = Y(w,T) \quad ; \quad Y \equiv \phi \text{ and } \Lambda_{MX}, \tag{3}$$

where the symbol Y represents the fluidity (ϕ) and the molar conductivity of MX (Λ_{MX}), w is the mass fraction of PEO, and T is the absolute temperature. The fluidity and conductivity changes produced by the isothermal variation in the polymer concentration are different in nature from those produced by the temperature variation at a constant composition; this difference should be considered when the relationship between the fluidity and conductivity is to be analyzed.[2]

Figure 1 shows the fluidity and conductivity changes in 0.1 mol kg^{-1} NaCl/PEO–H_2O systems at 25 °C as a function of the mass fraction of PEO, w; both the fluidity and conductivity decrease with the increase in w. The change in ϕ with the mass fraction, w, was more pronounced with PEO's of larger relative molecular masses, while the change in Λ_{NaCl} was very much less than that of ϕ and was almost independent of the relative molecular mass of PEO. A similar tendency in the fluidity and conductivity changes with the solution composition has also been known in colloidal solutions (sols and/or gels) including large neutral molecules such as gelatin and agar-agar.[1,2]

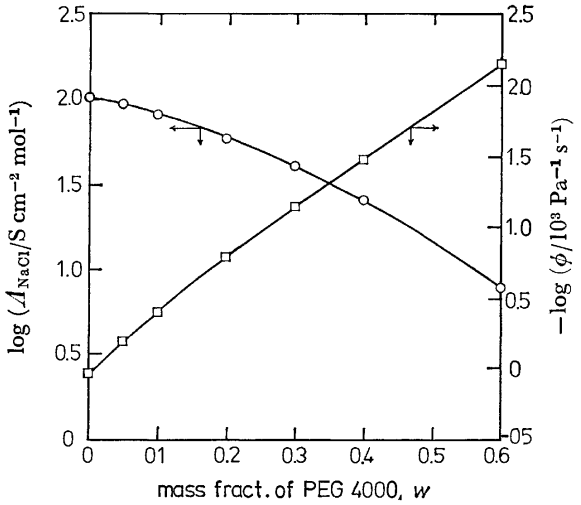

Fig. 2. Composition dependence of the fluidity of PEG 4000–H_2O mixtures and that of the molar conductivity of 0.1 mol kg^{-1} NaCl in PEG 4000–H_2O mixtures (temperature 25 °C): □ and ○ are experimental points; the best-fit equations (4) determined by the least-squares method are shown by solid lines.

Empirically, the isothermal variation in ϕ and Λ_{MX} of the MX/PEO–H_2O system with the mass fraction of PEO can be approximately represented by the equation:

$$\log Y = \sum_{i=0}^{n} a_{i,Y} w^i \quad ; \quad Y \equiv \phi \text{ and } \Lambda_{MX}. \tag{4}$$

In most cases, sufficient accuracy was obtained with $n=3$ for the fluidity of the systems containing PEG 200 and 4000, $n=4$ for the fluidity of the PEG 20000 systems, and $n=2$ for the conductivity. Examples of fitting experimental points by the use of Eq. 4 are given in Fig. 2, where the solid lines represent the empirical equations determined by the method of least-squares.

Temperature Dependence of the Fluidity and Conductivity. The temperature dependence of the fluidities and conductivities of aqueous electrolyte solutions may be represented by an empirical expression of the Arrhenius-type:[8,9]

$$Y = A_Y \exp(-E_Y/RT) \quad ; \quad Y \equiv \phi \text{ and } \Lambda_{MX}, \tag{5}$$

where E_Y and A_Y are the Arrhenius activation energy and the pre-exponential frequency factor respectively for the viscous flow ($Y\equiv\phi$) and the conductivity ($Y\equiv\Lambda_{MX}$). Over a wide range of temperatures, the Arrhenius plot (ln Y *vs.* T^{-1} plot) for the fluidity of aqueous solutions has been known to deviate from linearity,[10] which suggests that the activation parameters (E_Y and A_Y) are temperature-dependent or that the Arrhenius-type expression is inadequate. Within a limited range of temperatures, however, the Arrhenius plot generally gives a reasonably straight line and the activation parameters may be regarded as constant.

Some typical Arrhenius plots for the conductivity of the MX/PEO–H_2O systems are shown in Fig. 3, the plots being almost linear over the temperature

range of 25—50 °C. Similar Arrhenius plots were also obtained for the fluidity of PEO-H_2O mixtures. Tables 1 and 2 present the activation parameters determined from the Arrhenius plots by using the method of least-squares.

Relationship between the Fluidity and Conductivity. The change in the fluidity and conductivity due to the variation of the polymer concentration and temperature can be obtained from Eq. 3 as:

$$dY = \left(\frac{\partial Y}{\partial w}\right)_T dw + \left(\frac{\partial Y}{\partial T}\right)_w dT \tag{6}$$

or:

$$d\ln Y = \left(\frac{\partial \ln Y}{\partial w}\right)_T dw - \frac{1}{T^2}\left(\frac{\partial \ln Y}{\partial T^{-1}}\right)_w dT. \tag{7}$$

	0.5	26.9±0.5	112±2
	0.6	30.6±0.6	119±2

The first term on the right-hand side of Eq. 6 or 7 represents the effect of the polymer concentration on the viscous flow and conductivity at a constant temperature, whereas the second term represents the temperature effect at a constant composition.

Using the empirical equations 4 and 5, we can obtain the following expressions:

$$\left(\frac{\partial \ln Y}{\partial w}\right)_T = 2.303 \sum_{i=1}^{n} i a_{i,Y} w^{i-1} \tag{8}$$

and:

$$\left(\frac{\partial \ln Y}{\partial T^{-1}}\right)_w = -\frac{E_Y}{R}, \tag{9}$$

where n=3 or 4 for the fluidity and n=2 for the conductivity.

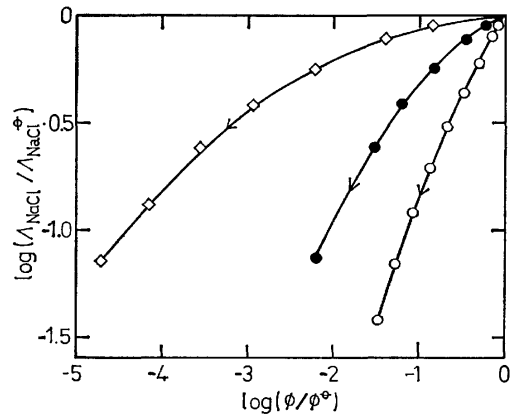

Fig. 4. Plots of $\log(\Lambda_{NaCl}/\Lambda^*_{NaCl})$ against $\log(\phi/\phi^*)$ by the composition variation at 25 °C, where Λ^*_{NaCl} and ϕ^* are the values at $w=0$: —○— PEG 200, —●— PEG 4000, and —◇— PEG 20000. Arrows indicate the direction of increasing PEO-concentration.

From Eqs. 7 and 8, the isothermal change in $\ln \Lambda_{MX}$ with respect to $\ln \phi$ can be given by:

$$\left(\frac{d \ln \Lambda_{MX}}{d \ln \phi}\right)_T = \left(\frac{\partial \ln \Lambda_{MX}}{\partial w}\right)_T \Big/ \left(\frac{\partial \ln \phi}{\partial w}\right)_T = \frac{a_{1,\Lambda} + 2a_{2,\Lambda} w}{a_{1,\phi} + 2a_{2,\phi} w + 3a_{3,\phi} w^2 + 4a_{4,\phi} w^3}. \quad (10)$$

This result suggests that, when the concentration of PEO is changed at a constant temperature, the plot of $\ln \Lambda_{MX}$ against $\ln \phi$ does not give a straight line; in other words, the relation between Λ_{MX} and ϕ deviates from the extended Walden's rule as represented by Eq. 2. Only at sufficiently low concentrations of PEO ($w \ll 1$), the right-hand side of Eq. 10 can be approximated by $a_{1,\Lambda}/a_{1,\phi}$, and the extended Walden's rule may be satisfied.

Similarly, from Eqs. 7 and 9, when the temperature is varied at a constant composition, the change in $\ln \Lambda_{MX}$ with respect to $\ln \phi$ is given by:

$$\left(\frac{d \ln \Lambda_{MX}}{d \ln \phi}\right)_w = \left(\frac{\partial \ln \Lambda_{MX}}{\partial T^{-1}}\right)_w \Big/ \left(\frac{\partial \ln \phi}{\partial T^{-1}}\right)_w = \frac{E_\Lambda}{E_\phi}. \quad (11)$$

Since the activation energies, E_Λ and E_ϕ, are nearly independent of the temperature, the $\ln \Lambda_{MX}$ *vs.* $\ln \phi$ plot by the temperature variation is expected to be linear in accordance with the extended Walden's rule. A comparison of Eqs. 2 and 11 gives the following expression for the p coefficient:

$$p = E_\Lambda / E_\phi. \quad (12)$$

The experimental data are consistent with the above-mentioned consideration. Some examples of the relation between $\log \Lambda_{NaCl}$ and $\log \phi$ upon the isothermal variation in the PEO composition are given in Fig. 4. Upon the variation in the temperature at a constant composition, however, $\log \Lambda_{NaCl}$ changes linearly with $\log \phi$, as is shown in Fig. 5.

Correlations between Pairs of Activation Parameters. The values of the p coefficient as determined from the $\log \Lambda_{MX}$ *vs.* $\log \phi$ plots were nearly independent of the composition of the MX/PEO–H_2O system, the average value being 0.89±0.07. Because of the relationship given by Eq. 12, this result is equivalent to the existence of a linear correlation between E_Λ and E_ϕ, as is shown in Fig. 6. In this figure, the broken line represents the relation, $E_\Lambda/E_\phi = 0.89$ while the solid line corresponds to the best-fit equation:

$$E_\Lambda = (0.97 \pm 0.04) E_\phi - (2.52 \pm 0.92)\text{kJ mol}^{-1}, \quad (13)$$

where ± represents the standard deviation. The relatively large standard deviations for these two lines suggest that the difference between them can not be regarded as very significant.

In contrast to the activation energy (enthalpy term), no significant correlation can be observed between the frequency factors (entropy term), A_Λ and A_ϕ, except in the case of PEG 200–H_2O systems (see Fig. 7).

A number of empirical entropy-enthalpy relationships have been known in the study of chemical reactions, both static and kinetic, in solution.[11,12] The

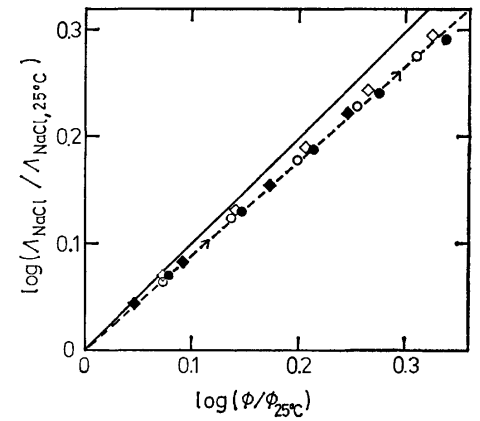

Fig. 5. Plots of $\log(\Lambda_{NaCl}/\Lambda_{NaCl,25°C})$ against $\log(\phi/\phi_{25°C})$ by the temperature variation at constant composition, where $\Lambda_{NaCl,25°C}$ and $\phi_{25°C}$ are the values at 25 °C: —◆— H_2O; —○— PEG 200, $w=0.4$; —●— PEG 4000, $w=0.4$; and —◇— PEG 20000, $w=0.4$. The straight line corresponds to the classical Walden's rule ($p=1$) and the broken line to the extended Walden's rule with $p=0.89$. Arrows indicate the direction of increasing temperature.

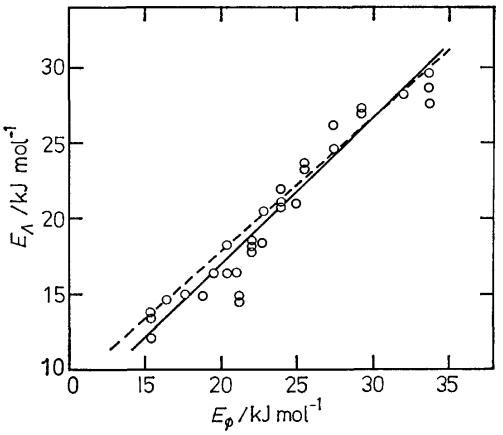

Fig. 6. Correlation between the activation energies for fluidities and molar conductivities of the 0.1 mol kg^{-1} MX/PEO-H_2O systems. The broken line represents Eq. 12 with $p=0.89$ and the solid line represents the best-fit equation (13).

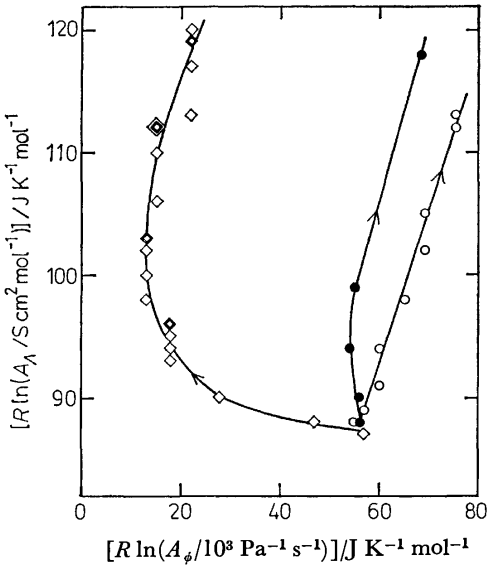

Fig. 7. Plots of $R\ln A_\Lambda$ against $R\ln A_\phi$ of the MX/PEO–H_2O systems: —○— PEG 200, —●— PEG 4000, and —◇— PEG 20000. Arrows indicate the direction of increasing PEO-concentration.

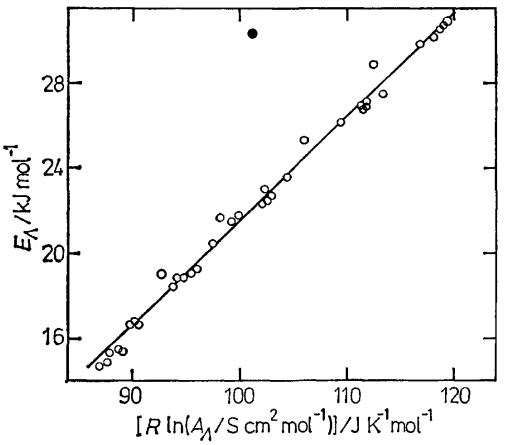

Fig. 8. Correlation between E_Λ and $R\ln A_\Lambda$ (isokinetic relationship) for the molar conductivities of MX in 0.1 mol kg^{-1} MX/PEO–H_2O systems. The solid circle corresponds to the NaCl/pure PEG 200 system, and the solid line represents the best-fit equation (14).

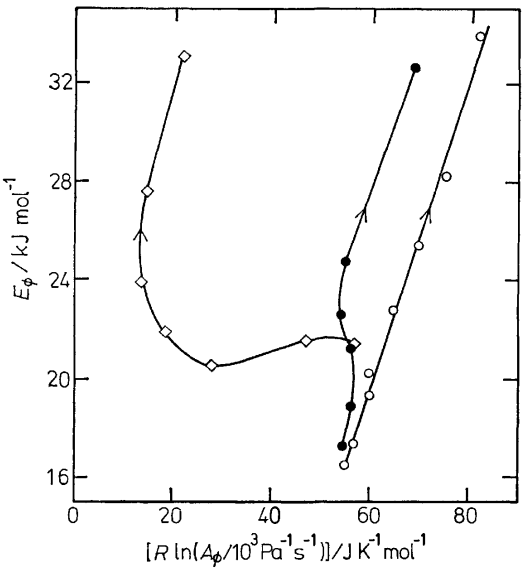

Fig. 9. Plots of E_ϕ against $R\ln A_\phi$ for the fluidity of PEO–H_2O mixtures: —○— PEG 200, —●— PEG 4000, and —◇— PEG 20000. Arrows indicate the direction of increasing PEO-concentration.

analysis of the activation parameters for the viscous flow and conductivity of the MX/PEO–H_2O systems has revealed a good correlation between E_Λ and $\ln A_\Lambda$, but no correlation between E_ϕ and $\ln A_\phi$, as is shown in Figs. 8 and 9. Except for the point corresponding to the NaCl/pure PEG 200 system, the analysis of 37 sets of data in Fig. 8 gives the following equation, representing the E_Λ *vs.* $R\ln A_\Lambda$ relationship:

$$E_\Lambda = T_c R \ln \frac{A_\Lambda}{\mathrm{S\,cm^2\,mol^{-1}}} - (27.5\pm0.74)\ \mathrm{kJ\,mol^{-1}} \quad (14)$$

with $T_c=489.6\pm7.3$ K and the correlation coefficient $r=0.9962$, and where T_c, the slope of the E_Λ *vs.* $R\ln A_\Lambda$ plot, is called the isokinetic or compensation temperature.[12] This relationship means that, in the case of the conductivity of the MX/PEO–H_2O system, the enthalpy of activation is partly compensated for by the entropic term (the enthalpy-entropy compensation effect) upon the variation in the composition of the system. Although the physical meaning of this correlation is not well known, the relation may be expected to originate in the solvent-solute interactions.[11,12] The significant deviation of the NaCl/pure PEG 200 system from the above-mentioned correlation suggests that the thermodynamic factors controlling the electric conduction will be different in pure PEO media from those in solutions containing water.

Conclusion. Our observations on the composition and temperature dependence of the fluidity and conductivity of the 0.1 mol kg^{-1} MX/PEO–H_2O systems can be summarized as follows: (1) The systems exhibited a linear relationship between $\ln \Lambda_{MX}$ and $\ln \phi$ (extended Walden's rule) upon the temperature variation at a constant composition, but not upon an isothermal variation in the PEO-concentration. (2) A good correlation was observed between the activation energies of the viscous flow and the conductivity, but not between the corresponding entropy terms (frequency factors). (3) The conductivity exhibited an enthalpy-entropy compensation effect (the isokinetic relationship) upon a variation in the composition of the system, while such a relationship could not be obtained in the case of the viscous flow.

When the PEO concentration increases at a constant temperature, the molar conductivity of 0.1 mol kg^{-1} MX in PEO–H_2O mixtures will decrease not only upon a lowering of the fluidity, but also by an increase in the ion association due to the decrease in the dielectric constant of the solution. The dielectric constants of PEO–H_2O mixtures have been reported to decrease almost linearly with an increase in the volume fraction of PEO, independent of the molar mass of PEO, in nearly the same way as in the case of dioxane–H_2O mixtures.[13] A rough estimation based on the knowl-

edge concerning the ion-association constants for some alkali halides in dioxane–H_2O mixtures[14] shows that the degree of dissociation of 0.1 mol kg^{-1} MX in the PEO–H_2O mixtures will begin to decrease from unity at the mass fraction of PEO $w \simeq 0.4$ and reach about 0.3 at $w \simeq 0.6$. If the conductivity of the MX/PEO–H_2O system is corrected for the ion-association effect, the deviation from Walden's rule for the ionic mobilities of the ions should become greater than that observed for the molar conductivities. The above-mentioned consideration suggests that the ion-association effect cannot be ignored in discussing the conductivity of the MX/PEO–H_2O system. In this paper, however, no further consideration will be made of the ion-association effect because the present study is intended to examine some phenomenological relationships and not to make detailed mechanistic discussions.

It is suggested that the mechanisms controlling the viscous flow and electric conduction of the MX/PEO–H_2O system may be similar from the enthalpic standpoint, but may be significantly different from the entropic point of view. In the aqueous solutions of PEO, the long-chain polymer molecules will typically exist as random coils and will occasionally from a loosely coupled network. The Arrhenius-type expression (Eq. 5) shows that very low values of the macroscopic fluidity of the solutions containing large PEO molecules can be attributed to the decrease in the pre-exponential factor (entropy term), which is itself due to the formation of the very loose network structure consisting of the polymer chains and which cannot be compensated for by the enthalpy term. For small ions, however, there remain in the solution sufficiently large spaces to move around in, filled with water molecules in the normal condition, and the movement of the ions would not be appreciably disturbed by the low macroscopic fluidity. The correlations between pairs of the activation parameters observed in this study are consistent with the above-mentioned consideration of the ion-transport mechanism in the PEO–H_2O mixtures.

We wish to thank Dr. Yoshihiko Sugiura for the viscosity measurements using a rotational viscometer, and Dr. Haruo Honma for the determination of the relative molecular masses of the PEO samples.

Electrochemical Oxidation-Reduction Properties of Covalently Bound FAD of Cholesterol Oxidase Adsorbed on Mercury Electrode Surface

Tokuji IKEDA,* Shinji ANDO, and Mitsugi SENDA

Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606

(Received January 14, 1981)

Cholesterol oxidase from *Schizophyllum commune* was studied by cyclic d.c. and a.c. voltammetry with a hanging mercury drop electrode. The enzyme gave d.c. and a.c. waves due to covalently bound FAD of the enzyme adsorbed on an electrode surface. The waves were interpreted in terms of d.c. and a.c. voltammetry of a two-step surface redox reaction. The standard surface oxidation-reduction potential of the enzyme adsorbed on the electrode surface, E'_s, was -0.32_5 V *vs.* SCE, the semiquinone formation constant being 1.5 ± 1.0 at pH 7.4 (25 °C). The pH dependence of E'_s was -60 mV/pH (pH 2.0—6.4), -30 mV/pH (pH 6.4—8.5), and -60 mV/pH (pH 8.5—12.0). The apparent charge transfer rate constant of the surface redox reaction was $1.6\pm0.5\times10^3$ s^{-1} at pH 5.4.

Flavoprotein oxidase is a flavin-containing enzyme which catalyzes the oxidation of a substrate by dioxygen.[1] Knowledge of the oxidation-reduction properties of this class of enzymes is important in utilizing the enzymes in electrocatalysis and for understanding the enzymatic reaction. Electrochemical methods seem to be advantageous for the study.[2] Scheller *et al.*[3] studied glucose oxidase from *Penicillium notatum* by differential pulse polarography and observed a wave with a peak at -0.34 V *vs.* SCE (pH 7.0). We[4] have studied glucose oxidase from *Aspergillus nigar* using a.c. polarography and observed a wave with a peak at -0.38 V *vs.* SCE (pH 7.0). Kuznetsov *et al.*[5] studied D-amino acid oxidase from pig kidney and observed an a.c. wave with a peak at -0.36 V *vs.* SCE (pH 7.0). In these flavoproteins FAD is bound to the apoprotein by noncovalent bond.[6] On the other hand the proteins are strongly adsorbed on the electrode surface, and thus FAD might be dissociated from the enzyme on this surface. The polarographic waves of the flavoproteins could, under certain conditions, be the waves due to the redox reaction of FAD dissociated from the enzymes on the electrode surface.

In this study we have investigated cholesterol oxidase from *Schizophyllum commune*, a flavoprotein in which FAD is covalently bound to its apoprotein,[7] by means of cyclic d.c. and a.c. voltammetry with a hanging mercury drop electrode. The enzyme gave d.c. and a.c. waves assignable to the covalently bound FAD of the enzyme adsorbed on the electrode surface. By interpreting the waves by means of cyclic d.c. and a.c. voltammetry of the two-step surface redox reaction,[8] we were able to determine the thermodynamic and kinetic parameters of the electrochemical oxidation-reduction reaction of the enzyme adsorbed on the electrode surface. The results and discussion are presented in this paper.

Experimental

Cholesterol oxidase (from *Schizophyllum commune* (ChOD), Toyobo Co., grade II, lot No. 9316) was used. This was dialyzed against 0.05 mol dm^{-3} phosphate buffer of pH 6.0 before use. The concentration of ChOD was determined spectrophotometrically, the molar extinction coefficient being 1.13×10^4 mol^{-1} dm^3 cm^{-1} at 455 nm.[9]

Voltammetric measurements were performed in the dark in an H-type cell immersed in a thermostat controlled at 25 ± 0.5 °C. The working electrode was a hanging mercury drop electrode (hmde), Metrohm E410, with surface area 0.0187 ± 0.0003 cm^2. The following buffer solutions were used: 0.1 mol dm^{-3} nitric acid–sodium acetate for pH 2.0—4.0; 0.1 mol dm^{-3} acetic acid–sodium acetate for pH 4.0—6.0; 0.1 mol dm^{-3} sodium dihydrogenphosphate–disodium hydrogenphosphate for pH 6.0—8.0; 0.1 mol dm^{-3} nitric acid–tris(hydroxymethyl)methanamine for pH 8.0—9.2; 0.1 mol dm^{-3} borax–sodium hydroxide for pH 9.2—12.0. The ionic strength of the base solution was adjusted to 0.5 mol dm^{-3} with potassium nitrate. All chemicals used were of standard reagent grade.

D.c. and a.c. voltammograms were recorded after a fresh mercury drop from the hmde had been exposed to a test solution for a given period of time, exposure time t_{exp}, and at a constant potential, initial potential E_i. All potentials were measured against a saturated calomel electrode (SCE). Other details on apparatus and methods of electrochemical measurements were reported.[10]

Results and Discussion

Adsorption of ChOD on Electrode Surface. Figure 1 shows a cyclic d.c. voltammogram of 0.33 μmol dm^{-3} ChOD in a solution of pH 7.4. The voltammogram was recorded after $t_{exp}=3$ min at $E_i=-1.4$ V and with a potential sweep rate, v, 0.33 V s^{-1}. Two pairs of peak-shaped anodic and cathodic waves, (I_a and I_c, and II_a and II_c) and a cathodic wave (III_c) appear at -0.33 V, -0.64 V, and -1.2 V, respectively. The waves grow to a certain limit with increasing t_{exp} at a given concentration of ChOD, c_{ChOD}. The peak heights of the waves corrected for base current, i_p, increase linearly with $t_{exp}^{1/2}$ for small t_{exp} values, reaching a saturation value, i_p^{max}, for large t_{exp} values. Figure 2 shows i_p *vs.* $t_{exp}^{1/2}$ plots for wave I_c at three different ChOD concentrations. The slope of the linear part of i_p *vs.* $t_{exp}^{1/2}$ plots is proportional to c_{ChOD}. The results indicate that[10] ChOD is accumulated by adsorption on the hmde surface and the adsorption is controlled by diffusion of ChOD to the electrode surface, the current being assumed to be proportional to the amount of the adsorbed ChOD. The maximum amount of the adsorbed ChOD per unit surface area, Γ_{ChOD}^{max}, was determined to be $4\pm0.5\times10^{-12}$ mol cm^{-2} by means of a theoretical equation,[10] $\Gamma_{ChOD}^{max}=2(D_{ChOD}/\pi)^{1/2}c_{ChOD}i_p^{max}t_{exp}^{1/2}/i_p$, where the diffusion coefficient of

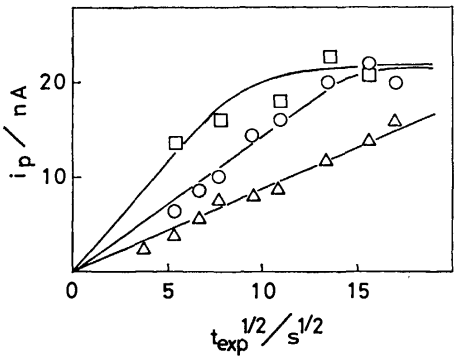

Fig. 2. Plots of i_p against $t_{exp}^{1/2}$ of waves I_c at pH 7.4. c_{ChOD}: (△) 0.24, (○) 0.38, and (□) 0.61 μmol dm^{-3}.

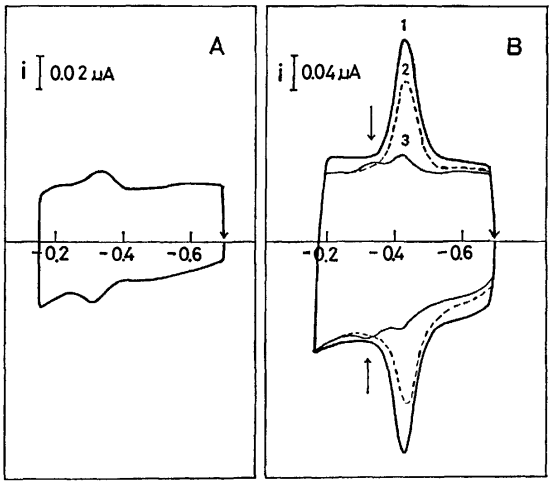
ChOD, D_{ChOD}, was estimated as 7.5×10^{-7} cm^2 s^{-1} on the basis of the diffusion coefficient of proteins[11] of about the same molecular weight as ChOD.

The following experiment gave another evidence that the voltammogram shown in Fig. 1 is due to the surface redox reaction of ChOD irreversibly adsorbed on the electrode surface. The hmde was dipped into 4×10^{-5} mol dm^{-3} ChOD solution allowing ChOD to be adsorbed on the electrode surface, washed gently with distilled water, then immersed in the same solution (Fig. 1) but containing no ChOD. The same cyclic voltammogram as in Fig. 1 was obtained.

Assigment of D.c. Waves of ChOD. The pair of waves II_a and II_c should be assigned to the half-cystine residues[9] of ChOD, since their peak potential coincides with that of the waves of apoferredoxin,[10] an SH-protein, adsorbed on the mercury electrode surface. The dependence of the peak heights, peak potentials, half-peak widths of the waves on the potential sweep rate, and that of the peak potentials on pH were explained by assigning the waves to a surface redox process,[10] $Hg+(RSH)_{ad}\rightleftharpoons(RSHg)_{ad}+H^++e^-$. The height of wave III_c increased with decrease in pH and with increase in the concentration of buffer salts of the test solutions. Riboflavin and its derivatives give catalytic hydrogen evolution current at *ca.* −1.3 V on mercury electrode in neutral and acidic solutions.[12] Thus we conclude that the wave III_c is due to catalytic hydrogen evolution by covalently bound FAD of the enzyme.



(*E vs.* SCE)/V

Fig. 3. (A): Cyclic d.c. voltammogram of 0.61 μmol dm^{-3} ChOD at pH 7.4, t_{exp}=3 min at E_i=−0.7 V and v=0.10 V s^{-1}.
(B): Cyclic d.c. voltammograms of 1.0 μmol dm^{-3} FAD and 0.14 μmol dm^{-3} ChOD at pH 7.4; t_{exp}= (1) 30 s, (2) 5 min, and (3) 20 min at E_i=−0.7 V and v=0.33 V s^{-1}.

The pair of waves I_a and I_c should be attributed to the redox reaction of covalently bound FAD of the enzyme. In order to confirm that the waves are due to FAD bound to the protein and not to the free FAD which might be present in trace amount in the stock solution of ChOD, we compared the voltammogram of ChOD with that of free FAD. FAD was adsorbed on the mercury electrode surface.[13] Figure 3(B) shows cyclic d.c. voltammograms of a solution containing both 1.0 μmol dm^{-3} FAD and 0.14 μmol dm^{-3} ChOD (pH 7.4) at t_{exp}=30 s, 5 min, or 20 min at E_i=−0.7 V. FAD gives a pair of d.c. waves with the peak potential −0.43 V, 100 mV more negative than the peak potential of waves I_a and I_c (Fig. 3(A)), indicating that the latter waves are due to FAD covalently bound to the protein. The peak heights of the waves due to free FAD in the presence of ChOD decrease with increasing t_{exp}, while the waves due to ChOD begin to appear (curves 1, 2, and 3, Fig. 3(B)). This indicates that at the begining of the exposure of hmde to the test dolution the electrode surface is covered dominantly by free FAD (both the diffusion coefficient and the bulk concentration of free FAD are much larger than ChOD), but with the elapse of time the adsorbed free FAD is replaced by ChOD, probably owing to the heigher affinity of ChOD to mercury electrode than FAD.

D.c. Waves of Covalently Bound FAD of ChOD. The anodic and cathodic peak currents, i_{ap} and i_{cp}, the peak potentials, E_{ap} and E_{cp}, and the half-peak widths, $\Delta E_{a,\,p/2}$ and $\Delta E_{c,\,p/2}$, of waves I_a and I_c as a function of the potential sweep rate, v, at pH 7.4 are summarized in Table 1. Q_a and Q_c are the charges required to electrooxidize or electroreduce the

0.05	4.0	4.0	0.32	0.33	60	75	6.2	6.6
0.10	7.6	8.0	0.32	0.33	55	60	5.5	6.9
0.20	14	14	0.32	0.33	60	80	5.3	7.3
0.33	17	18	0.32	0.33	60	70	4.4	5.2

adsorbed ChOD, respectively, and estimated from the area under the waves I_a and I_c corrected for the base current. Peak heights, i_{ap} and i_{cp}, are both proportional to v, the ratio i_{ap}/i_{cp} being unity. The peak potentials and the half-peak widths are both independent of v, and E_{ap} and $\Delta E_{a,p/2}$ coincide with E_{cp} and $\Delta E_{c,p/2}$, respectively. Q_a and Q_c also coincide with each other and are independent of v. The results are in line with theoretical predictions (1) to (4), for two-step surface redox reaction which can be expressed by

$$(\mathrm{Fp.FAD^{ox}H_p})_{ad} + e^- + (q-p)H^+ \rightleftharpoons (\mathrm{Fp.FAD^{sem}H_q})_{ad} \quad \text{I-a}$$

$$(\mathrm{Fp.FAD^{sem}H_q})_{ad} + e^- + (r-q)H^+ \rightleftharpoons (\mathrm{Fp.FAD^{red}H_r})_{ad} \quad \text{I-b}$$

for ChOD adsorbed on the electrode surface. $(\mathrm{Fp.FAD^{sem}H_p})_{ad}$, $(\mathrm{Fp.FAD^{sem}H_q})_{ad}$, and $(\mathrm{Ap.FAD^{red}H_r})_{ad}$ denote the oxidized, intermediate (semiquinone), and reduced forms of the adsorbed ChOD, respectively. Theoretical expressions[8] of the d.c. anodic and cathodic currents in cyclic voltammetry, i_a and i_c, of the two-step surface redox reaction are given in a simplified case[14] by

$$i = i_a = -i_c = FA(F/RT)\Gamma v\rho[\rho(K^{1/2}\rho+2) + (K^{1/2}+2\rho)]/(1+K^{1/2}\rho+\rho^2)^2 \quad (1)$$

where $\rho=\exp[(F/RT)(E-E_s')]$, $E_s'=(E_1'+E_2')/2$, and $K=\exp[(F/RT)(E_1'-E_2')]$, Γ is the amount of adsorbed ChOD per unit surface area, K the semiquinone formation constant defined by $K=[(\mathrm{Fp.FAD^{sem}H_q})_{ad}]^2/[(\mathrm{Fp.FAD^{ox}H_p})_{ad}][(\mathrm{Fp.FAD^{red}H_r})_{ad}]$, and E_s', E_1', and E_2' are the standard surface oxidation-reduction potentials of the redox couples $(\mathrm{Fp.FAD^{ox}H_p})_{ad}/(\mathrm{Fp.FAD^{red}H_r})_{ad}$, $(\mathrm{Fp.FAD^{ox}H_p})_{ad}/(\mathrm{Fp.FAD^{sem}H_q})_{ad}$, and $(\mathrm{Fp.FAD^{sem}H_q})_{ad}/(\mathrm{Fp.FAD^{red}H_r})_{ad}$, respectively. When $K\leqslant 16$, the peak currents are given by

$$i_p = i_{ap} = -i_{cp} = FA(F/RT)\Gamma v[2/(2+K^{1/2})] = (F/RT)Qv/(2+K^{1/2}) \quad (2)$$

where $Q(=Q_a=Q_c)$ is the charge required to electrooxidize or electroreduce the adsorbed ChOD. The peak potentials are equal to E_s':

$$E_p = E_{ap} = E_{cp} = E_s' \quad (3)$$

and the half-peak widths are given by

$$\Delta E_{p/2} = \Delta E_{a,p/2} = \Delta E_{c,p/2} = (2RT/F)\ln[f(K)] \quad (4)$$

where $f(K)$ is a function of K.[8]

The results satisfy the predictions, indicating that $E_p=E_s'=-0.32_5$ V *vs.* SCE at pH 7.4. Thus the K value at pH 7.4 was determined to be 1.8 ± 1.1 by Eq. 2 and 1.1 ± 0.8 by Eq. 4. The values agree,

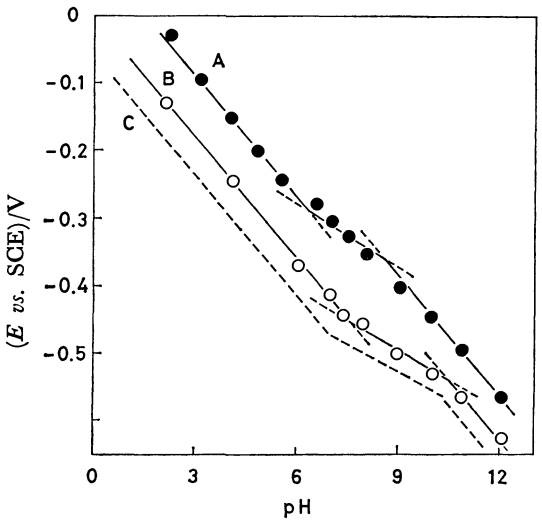

Fig. 4. Plots of $E_p(=E_s')$ against pH; (A): ChOD adsorbed on mercury electrode surface, (B): FAD adsorbed on mercury electrode surface. (C): Broken line represents E_m' *vs.* pH curve for FAD in the bulk of solution (taken from Ref. 13).

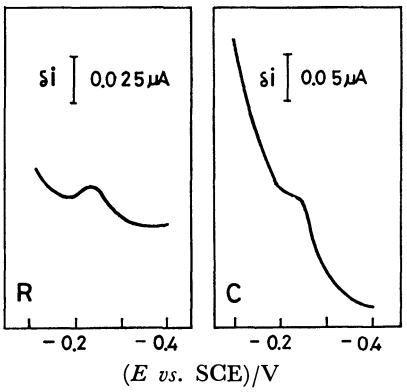

Fig. 5. A.c. voltammograms of 0.67 μmol dm^{-3} ChOD at pH 5.4 (R): Real component and (C): imaginary component at $f=100$ Hz; $t_{exp}=3$ min at $E_i=-0.4$ V and $v=0.02$ V s^{-1}.

giving the average value of $K=1.5\pm1.0$ at pH 7.4. The waves I_a and I_c obtained in the pH region 2—12 satisfy the predictions by Eqs. 1—4. Figure 4(A) shows plot of $E_p(=E_s')$ against pH; three linear relations of $E_p(=E_s')$ against pH, the slopes being −60 mV/pH (pH 2.0—6.4), −30 mV/pH (pH 6.4—8.5), and −60 mV/pH (pH 8.5—12.0). The first and second inflection points, 6.4 and 8.5, indicate the pK of acid dissociation constants[15] of reduced and oxidized forms of ChOD adsorbed on electrode surface, respectively. Plots of $E_p(=E_s')$ *vs.* pH of free FAD

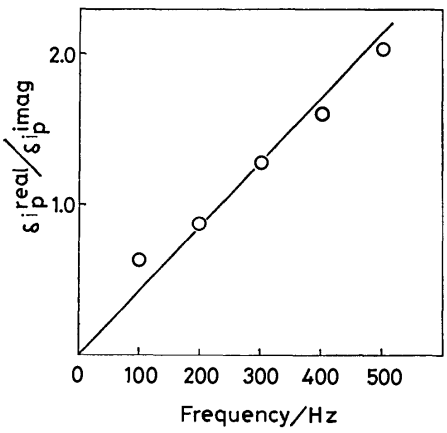

Fig. 6. Dependence of $\delta i_p^{real}/\delta i_p^{imag}$ on f for a.c. waves at pH 5.4.

adsorbed on mercury electrode surface and of the standard oxidation-reduction potential[13] of free FAD in the bulk of solution, $E'_{m,\,FAD}$, are given in Figs. 4(B) and (C), respectively.

No standard oxidation-reduction potential of ChOD in the bulk of solution, $E'_{m,\,ChOD}$, has been determined. We tried to determine $E'_{m,\,ChOD}$ by the potentiometric titration method with dithionate as a titrant using a Pt electrode in the presence of indigo carmine la (Chroma Chemical Co., the standard oxidation-reduction potential being determined as -0.305 ± 0.015 V *vs.* SCE at pH 7.0) as a mediator. We confirmed spectrophotometrically that ChOD can be reduced by dithionate without forming a complex[16] with sulfite, the oxidation product of dithionate. However, the system reached equilibrium only after very long time on each addition of sodium dithionate, preventing accurate determination of $E'_{m,\,ChOD}$. The $E'_{m,\,ChOD}$ value at pH 7.0 was tentatively determined to be $-0.26+0.03$ V *vs.* SCE, which is 210 mV more positive than $E'_{m,\,FAD}$ at pH 7.0. It has been suggested that covalent linkage of flavin to apoprotein shifts the oxidation-reduction potential of the flavin positively, which facilitate catalysis,[17] a model compound hystidyl-8α-flavin being reported to have the standard oxidation-reduction potential 30 mV more positive than that of the nonsubstituted flavin.

The standard oxidation-reduction potential of a redox couple adsorbed on the electrode surface, the standard surface oxidation-reduction potential, can be shifted from the standard oxidation-reduction potential of the redox couple in the bulk of solution. This might be attributed to a difference in adsorption free energy between the oxidized and reduced species, a positive shift being observed with FMN adsorbed on mercury electrode surface.[18] This is also the case with FAD (plots B and C, Fig. 4). In contrast, a negative shift was observed in the case of ChOD. This shift could be attributed not only to a difference in adsorption free energy but also to a change in conformation (surface denaturation) of the protein which could be associated with adsorption of the protein on electrode surface.

A.c. Waves of Covalently Bound FAD of ChOD. In a.c. voltammetry with hmde, ChOD gave a peak-shaped wave at the potential of waves I_a and I_c in the d.c. voltammetry of ChOD with hmde. Figure 5 shows the real and imaginary component of the a.c. voltammogram of anodic scan at pH 5.4. The a.c. voltammogram of cathodic scan coincided both in height and shape with that of anodic scan. The peak potentials of the two components, E_p^{real} and E_p^{imag}, coincide with each other and with the peak potential of the d.c. wave (waves I_a and I_c) at the same pH. $E_p^{real}(=E_p^{imag})$ was independent of a.c. frequency, f, in the range 100—500 Hz. The ratio of the peak current of the real component to that of the imaginary component, $\delta i_p^{real}/\delta i_p^{imag}$, is proportional to f (Fig. 6). The result is in line with the prediction by a simplified equation[8,19] of a.c. voltammograms for the two-step surface redox reaction (I-a and I-b):

$$\delta i_p^{real\prime}\delta i_p^{imag} = 2\pi f/(k_{sap}K^{1/4}), \qquad (5)$$

where k_{sap} is the apparent charge transfer rate constant of the surface redox reaction. From the plot we have $k_{sap}=1.6\pm0.5\times10^3\ s^{-1}$ at pH 5.4, where $K=1.2\pm1.0$. The half-peak widths of the two components at various frequencies at pH 5.4 and their values calculated by equations[8] using the above values of k_{sap} and K are given in Table 2. Agreement between observed and calculated values is fair.

Table 2. Half-peak widths of real and imaginary components of a.c. wave of ChOD adsorbed on HMDE surface at pH 5.4

Frequency / Hz	$\Delta E_{p/2}^{real}$/mV		$\Delta E_{p/2}^{imag}$/mV	
	Obsd	Calcd[a]	Obsd	Calcd[a]
100	60	55	70	72
200	60	60	75	82
300	65	66	—	95
400	70	72	—	110
500	70	76	—	124

a) Calculated by using $K=1.2$ and $k_{sap}=1.6\times10^3\ s^{-1}$.

Thermodynamic and kinetic information on the redox reaction of ChOD adsorbed on an electrode surface would be useful in designing an immobilized ChOD electrode where the electrode functions as an electron acceptor from (or electron donor to) the flavoprotein.

19) In addition to the assumption,[14] it is assumed[8] that $k_{sap}(1)=k_{sap}(2)=k_{sap}$ and $\alpha_n=\beta_n$, where $k_{sap}(1)$ and $k_{sap}(2)$ are respectively the rate constants of the first and second charge transfer steps and α_n and β_n ($n=1$ or 2) are the transfer coefficients for cathodic and anodic charge transfer of the n-th step, respectively.

Transfer Free Energies of Fluoride Ion in Aqueous Mixtures of Some Organic Solvents

Abhijit BHATTACHARYA, Kaushik DAS, Asim Kumar DAS, and Kiron Kumar KUNDU*

Physical Chemistry Laboratories, Jadavpur University, Calcutta-700032, India

(Received June 6, 1980)

Standard free energies of transfer, ΔG_t°, of potassium fluoride (KF) from water to aqueous mixtures of dimethyl sulfoxide (DMSO), *N,N*-dimethylformamide (DMF), acetonitrile (ACN), 1,2-dimethoxyethane (DME), and 2-methoxyethanol (ME) have been determined at 25 °C from emf measurements performed on the double cell: Pb(Hg)–PbF_2/KF(m), solvent/K(Hg)/KF(m), water/PbF_2–Pb(Hg). ΔG_t° values of F^- were obtained from these values using the corresponding values of K^+, as obtained earlier by use of tetraphenylarsonium tetraphenylborate reference electrolyte assumption. In each solvent system $\Delta G_t^\circ(F^-)$ values are found to be increasingly positive with cosolvent composition reflecting the pronounced destabilization of F^- and their relative order : DME > DMSO ≥ DMF ≫ ACN ≈ ME conforms to what is expected from the relative 'aproticity' of the dipolar aprotic cosolvents and that induced in the protic ME by the possible intramolecular H-bonding. The observed larger destabilization of F^- compared to OH^- in ME–water system has been attributed to the H-bonding effect of the protic cosolvent ME and the reverse behaviour in DME–water and DMSO–water systems to the absence of such effect of these cosolvents. Moreover, tests of Feakins-type extrapolation for assigning individual ion contribution using ΔG_t°(KF) values along with those of other potassium halides, provided some important reflections on the inadequacy of such plots made without the data points of F^-.

It is well known that the dipolar aprotic solvents exert pronounced effects on the acidity functions[1] or rates of reactions involving nucleophiles. But the elucidation of the thermodynamic basis of such effects is yet far from complete. Recent years have therefore witnessed increased interests on this topic as are evidenced from various studies[2–7] on the transfer energetics of different ions based on the widely accepted tetraphenylarsonium tetraphenylborate (TATB) assumption[2–8] in various pure and mixed solvents, including some typical dipolar aprotic solvents.

Strikingly enough, although F^- is often used[9] in organic synthesis for proton abstraction reactions in dipolar aprotic solvents because of its possible pronounced "desolvation" in the solvents, transfer free energies of F^- have been reported, so far as we know, only in protic solvent D_2O.[10] So, in continuation of our previous studies[7] on transfer free energies, ΔG_t°, of different ions based on TATB assumption, we are now reporting ΔG_t° of F^- in aqueous mixtures of some dipolar aprotic cosolvents like dimethyl sulfoxide (DMSO), *N,N*-dimethylformamide (DMF), acetonitrile (ACM), and 1,2-dimethoxyethane (DME) and of a protic solvent like 2-methoxyethanol (ME). While the compositions studied in the first three cases are 20, 40, and 60 wt% cosolvents and for DME are 10, 30, and 50 wt%, those for ME are 10, 30, 50, and 70 wt % cosolvent.

For the purpose in view, we have obtained the standard free energies of transfer of potassium fluoride (KF) from water to these mixed solvents by determining the standard emf's (ΔE°) of the double cell I

Pb(Hg)–PbF_2/KF(m), Solvent/K(Hg)/KF(m), Water/PbF_2–Pb(Hg) (I)

using a procedure similar to that used by Voice[10] in D_2O. These values helped evaluate $\Delta G_t^\circ(F^-)$ values as the values for K^+, based on TATB assumption, for each of the solvent systems are known from our previous studies.[7b–e] Moreover, it is well known that Feakins-type extrapolation[11] for assigning individual ion contributions to the ΔG_t° values being usually based on the adjacent data points of three larger sized halide ions, are susceptible to intrinsic limitations of long extrapolation. So, attempts have also been made to test if the inclusion of data point for F^- can improve the extrapolation procedure or not.

Experimental

The fluoride electrode consisting of a two-phase lead amalgam covered with insoluble lead(II) fluoride (PbF_2) was prepared in a manner essentially similar to that described by Voice.[10] The lead amalgam was prepared by electrolysing an aqueous solution (@ 10%) of $Pb(NO_3)_2$ (A.R., B.D.H.) using mercury (triply distilled) pool as cathode and Pt electrode as anode. The amalgam thus prepared was preserved in a sealed bottle under H_2 atmosphere. Before using it was repeatedly washed with a very dilute HNO_3 (AR., B.D.H.) to remove the ash or film, if any, and then by deionized CO_2-free water. The PbF_2 was prepared by mixing aqueous solution of $Pb(NO_3)_2$ and NaF (Merck, GR) with constant stirring. The white precipitate so obtained was filtered, washed repeatedly by magnetic stirring with CO_2- and O_2-free deionized water, and dried.

The base of the Pb(Hg)–PbF_2 electrode was a J-shaped glass tube with two limbs separated by a glass seal and connected electrically through a Pt-wire fused in the glass seal. The longer limb was fitted with a B-19 standard joint to hold the electrode in the cell vessel and the shorter limb at the other end serving as the electrode "cup" contained the electrode materials and was dipped in the cell solution. Before introducing the Pb-amalgam into cups, one each-side of the double cell, the Pb-amalgam was warmed in a closed vessel until it became mobile to attain its two phase character properly. The cooled two-phase amalgam was masked with a thick layer of PbF_2 crystals. It was observed that asymmetry potential was fairly high when a thin layer of PbF_2 was used. But it was considerably reduced if the layer of PbF_2 over Pb-amalgam become thick and was found to be practically within the range of experimental accuracy (± 0.3 mV). So, the measurement of bias potential before each set of experiment was not necessary.

Preparation and preservation of K-amalgam as well as the cell design have been described elsewhere.[12] The solvents used are of the following grades: DME (Reidel), DMSO

(L.R., B.D.H.), DMF (L.R., B.D.H.), ACN (L.R., B.D.H.), and ME (E. Merck). The method of purification of DME,[7f] DMSO,[13a] DMF,[13b] ACN,[13c] and ME[7e] were similar to those described earlier. Triply distilled and CO_2- and O_2-free water was used for the preparation of solvents as well as the cell solutions.

Anhydrous KF (Merck GR) was dried in a vacuum desiccator for about two weeks. Heating at high temperature was avoided due to the possibility of formation of insoluble material as reported earlier.[14] Because of highly hygroscopic nature of KF, F^- concentrations of the stock solutions were checked by standard gravimetric method. Solutions of different materials were made by weight dilution of the stock solutions. General experimental procedure, including the emf measurements with the help of a Leeds Northrup K_4-potentiometer and a moving coil galvanometer (Cambridge Instrument) as a null-point detector, has been described.[12]

The conditions for equilibrium were different for different solvents. Actually, in pure water as well as up to 50 wt% aqueous mixtures of ME the equilibrium was established within around 2 h and the constancy of emf readings to ± 0.2 mV for 1 h was considered to be the criterion of equilibrium and for 70% ME–water solution the equilibrium was attained after about 4 h. In aqueous dipolar aprotic solvents, however, overnight ageing of the electrode in the respective solution was essential to get stable emf readings. The final emf readings were often checked by introducing separate fluoride electrodes or by measuring emf of the cell I taking pair of solutions having exactly same molality.

Results

The observed emf values (ΔE) of the double cell I for different molalities (m) of KF in different cosolvent–water mixtures are listed in Table 1. These were used to construct the following function.[12b]:

$$\Delta E^{o\prime} = \Delta E - 2k[f_s(m) - f_w m)] = \Delta E^\circ_m - 2k\Delta b m, \quad (1)$$

where

$$f(m) = -A_0B_0m^{1/2}(1+a_0B_0m^{1/2})^{-1} - \ln(1+0.002Mm). \quad (2)$$

The subscripts s and w denote the mixed solvent and water respectively, $k=RT/F$, M is the appropriate molecular weight of the solvent, a_0 is the ion-size parameter, A_0B_0 and B_0 are the Debye-Hückel constants in S.I. units as given by[13c]

$$A_0B_0 = 1.824\times10^6 \ln 10 d^{1/2}(\varepsilon_0 T)^{-3/2} \text{ mol}^{-1/2}\text{ kg}^{1/2}, \quad (3)$$

$$B_0 = 50.29\times10^{10} d^{1/2}(\varepsilon_0 T)^{-1/2} \text{ m}^{-1/2}\text{ mol}^{-1}\text{ kg}^{1/2}, \quad (4)$$

where ε_0 is the dielectric constant, d the density of the solvent, T is the temperature in absolute scale. Since alteration of a_0 values caused no significant change in ΔE°_m values, the values of $a_0=0$ was used in all the cases. In Eq. 1 Δb is the difference of b values in the solvent and water, which are empirical constants depending on the nature of solvent, temperature and on the assumed a_0-values.

$\Delta E^{o\prime}$ values were calculated by Eq. 1 and the plots of $\Delta E^{o\prime}$ *vs.* m were found to be linear in all the cases and when extrapolated to $m=0$ yielded the values of ΔE°_m as intercepts. The values of ΔE°_m in the respective solvents are given in Table 2 and are correct within ± 0.3 mV.

Transfer free energies of *KF*, ΔG°_t(KF) from the standard state in water to the standard state in the respective solvents were obtained on mole fraction scale by Eq. 5

$$\Delta G^\circ_t(\text{KF}) = F\Delta E^\circ_m - 2RT \ln(M_s/M_w), \quad (5)$$

where M_w is the molecular weight of water. The ΔG°_t(KF) values are given in Table 2 and correct within ± 0.03 kJ mol^{-1}.

The transfer free energies of F^-, $\Delta G^\circ_t(F^-)$, in all the solvents were evaluated from the respective ΔG°_t(KF) values using the corresponding ionic contributions of K^+, *i.e.* $\Delta G^\circ_t(K^+)$, taken from our earlier work based on TATB method[7b–f] and are presented in Table 2. For the sake of comparison ΔG°_t (i) values of Cl^-, Br^-, and I^-[7b–f] and OH^- [7b,g,h] in some of the mixed solvents, are also presented in Table 2. Moreover, in order to draw important implications of the observed results, ΔG°_t-composition profiles of OH^- for DMSO–water,[7b] DME–water[7h] and ME–water[7g] systems have also been shown in Fig. 1, where those of F^- for all the solvent systems are illustrated.

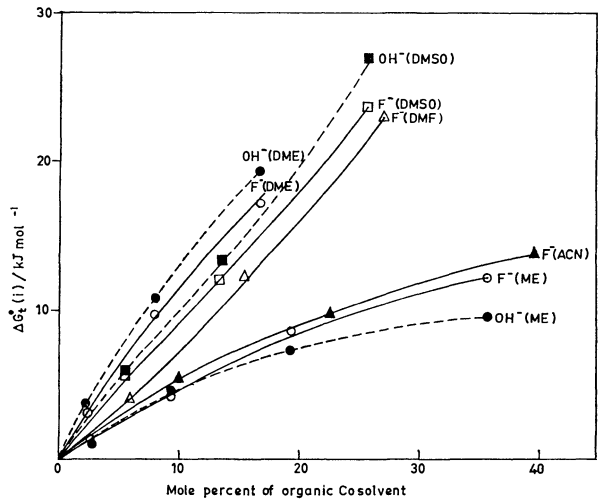

Fig. 1. Variation of $\Delta G^\circ_t(F^-)$ (solid line) and ΔG°_t (OH^-) (dotted line) in various aqueous-organic solvents.

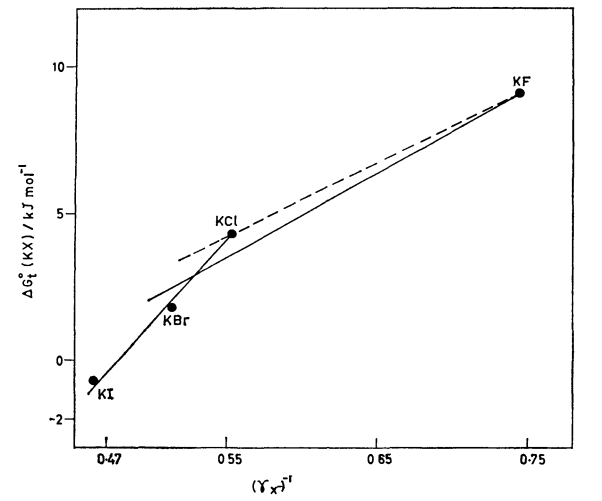

Fig. 2. Typical Feakin's type plots of ΔG°_t(KX) [X=F, Cl, Br, or I] *vs.* $(r_x)^{-1}$ in 40 wt% DMSO–water mixture at 298.16°A.

Tests of Feakins-type extrapolation[11] by use of data points for all the potassium halides *i.e.* from the plots of $\Delta G_t^\circ(KX)$ [X=F, Cl, Br, and I] *vs.* $(r_{x^-})^{-1}$ showed that no straight line was obtainable through the data points for all the four anions simultaneously in any of the solvents. Consequently, in each of the solvent systems, three values of $\Delta G_t^\circ(K^+)$ were evaluated by extrapolating the mean deviation lines through the data points for X=Cl, Br, I, and for X=F, Cl, Br, and the 'ideal' line through the data points for X=F and Cl. These value of K^+ are compared with the corresponding values obtained by TATB in Table 3. Figure 2 illustrates the plots of $\Delta G_t^\circ(KX)$ against $(r_{x^-})^{-1}$ referred to above for 40 wt % DMSO–water system.

Discussion

As Table 2 shows, the transfer free energies of F^- from water to all the aqueous-organic solvents are increasingly positive indicating that the ion becomes increasingly destabilized as the proportion of the cosolvents increases. Thus, the observed destabilization of F^- from this thermodynamic consideration also corroborates the widely recognized phenomenon of increased "desolvation" of the anions caused by the addition of dipolar aprotic solvents. This in fact stems from the increasing loss of hydrogen-bonded stability of the anions[13c] and decreasing interactions with the mixed solvents resulting from the increased proportion of the cosolvents which either have little H-bond donating propensity or sterically shielded interacting positive charge centres. From Table 2 it is also evident that for any given solvent the extent of destabilization of halide ions (X^-) decreases with the increased size of the ions. Expectedly, this is the amalgamated effects of decreasing strength of H-bonded interactions with water on the one hand and increasing strength of "soft-soft"[14] and dispersion interactions[15] between the dipolar aprotic cosolvents and the increasing anion size on the other.

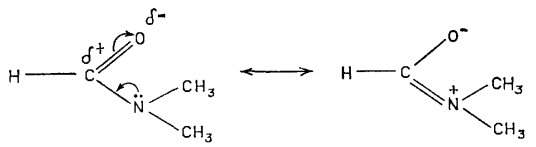
a) R.E.M.: Reference electrolyte method on TATB assumption (Refs. 7b, c, d, e, f).

It is interesting to note, as $\Delta G_t°(F^-)$-composition profiles for the solvents (Fig. 1) show, that at any composition the destabilizing capacity of the cosolvents decreases in the order DME>DMSO≥DMF≫ACN≈ ME. Significantly enough, similar order has also been observed[1] in the enhancement of H_- function by these dipolar aprotic cosolvents, excepting DME, when added to 0.1 m disodium 1,2-ethanediolate solution in 1,2-ethanediol, which of course chiefly reflects the relative destabilization of the 1,2-ethanediolate anion.

As this order reflects the effects of relative "aproticity" of the cosolvents resulting chiefly from the combined effects of relative magnitudes and approachability of the positive charge centres of the cosolvents, these results appear to suggest that the "aproticity" of DMF is slightly less than that of DMSO. Although it is difficult at this stage to differentiate the relative percentages of the two possible forms of DMF: A and B[17] one may wonder if the slightly less destabilization of F^- and other X^- ions relative to those in DMSO–water arises from the weak H-bonding effect of H-atom attached to the positively charged C atom of the form A. Alternatively, the formal positive charge on S atom in

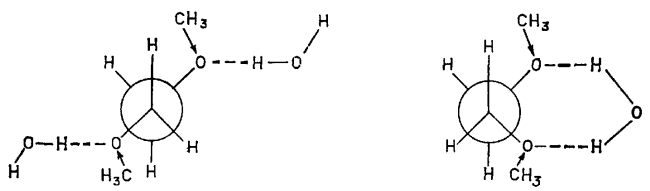


A B

DMSO molecule appears to be sterically more unapproachable than that in DMF molecule, affecting the ion-dipole interactions. Either of these effects will be of course more predominant in the cases of pure solvents than in the mixed solvents as has been observed.[2]

On the other hand, the relatively less destabilization of F^- and other X^- ions in ACN–water mixtures compared to those in DMSO or DMF–water mixtures is indicative of the fact that "aproticity" of ACN is smaller than that of the other two dipolar aprotic solvents as is expected from its relatively smaller size, less shielded positive charge centre and also weak H-bonding propensity.[18] Besides, this is also expected, if, as has been suggested by Kebarle *et al.*,[19] X^- approaches $\begin{matrix}H\\ H\text{-}C\text{-}C\equiv N\\ H\end{matrix}$ molecule along the C_3-axis of the latter and bonding occurs symmetrically through all 3H atoms. Since the overall strength of such H-bonds should increase as the X^- becomes larger and more accommodative,[20] $\Delta G_t^\circ(F^-) \gg \Delta G_t^\circ(Cl^-) > \Delta G_t^\circ(Br^-) > \Delta G_t^\circ(I^-)$, as has been observed.

But strikingly enough, in spite of the fact that ME is a protic solvent with a relatively strong H-bonding centre compared to ACN, the observed comparable destabilization of F^- in these two solvent systems suggests that the inductive effect of CH_3^- group in ME possibly imparts "aproticity" comparable to that of ACN through intramolecular H-bonding[21] or alternatively, makes the protic character of the hydroxylic H atom fairly less than that of pure water. On the other hand, the observed pronounced destabilization of F^- in DME–water system is indicative of the effect of pronounced "aproticity" of DME which results from the absence of any localized positive charge centres suitable for anion solvation. Also, the enhanced negative charge density on the O atoms of two methoxyl groups will also help destabilization of F^-. Apart from these, the DME–water complexes C in water-rich composition which are capable of anion solvation, are likely to be replaced by complexes of the type D in



C D

water deficient composition thus imparting decreasing acidity to the mixed solvents. Moreover, the inductive effect of two CH_3^- groups relayed through co-operative hydrogen bonded structures, diminishes the proticity of the hydrogen-bonded water in the water–cosolvent complexes. All these together are likely to result in the decreasing acidity of the mixed solvents.

It is interesting to note that while in DMSO–water and DME–water mixtures the ΔG_t°-composition profiles for OH^- lie above the corresponding profiles for F^-, the reverse is true in ME–water system (Fig. 1). This larger destabilization of OH^- compared to F^- in DMSO–water and DME–water mixtures can be attributed to its pronounced stabilization in water because of its intrinsic protophilicity and natural propensity of fitting in water structures[13b] and the relatively poor H-bond denating capacity of the aqueous DMSO and DME solutions. But the observed reverse behaviour of OH^- compared to F^- in ME–water system indicates that ME being itself a protic solvent stabilizes the protophilic OH^- through H-bonding more than F^-. Thus, the present results suggest that while the stability of OH^- is governed more by H-bond donating capacity of water and the protic cosolvents, that of F^- is dictated partly by H-bond donating capacity and partly by "aproticity" of the cosolvents, which is chiefly guided by the magnitudes and the location of formal positive charges of the cosolvent dipoles.

Tests of Feakins-type extrapolation using $\Delta G_t^\circ(KF)$ values along with the corresponding values of other potassium halides (Fig. 2) reveral that the "ideal plots' of $\Delta G_t^\circ(KX)$ *vs.* $(r_x)^{-1}$ through the data points of KF and KCl yield single-ion contributions (Table 3) that are nearer to those obtained by TATB method.[7b-e] But those obtained from the mean deviation lines drawn through the data points of KF, KCL, and KBr or of KCl, KBr, and KI are increasingly far off from the respective values by TATB method, indicating that the superimposed soft-soft interactions[20] on Br^- and I^- make the latter plots more untenable.

The authors express their thanks to the Council of Scientific and Industrial Research, New Delhi, for financial assistance.

Ultrasonic Investigation on the Structure of Aqueous Solutions of *N,N*-Dimethylformamide and Dimethyl Sulfoxide

(Received June 23, 1980)

The effects of *N,N*-dimethylformamide and dimethyl sulfoxide on the temperature of adiabatic compressibility minimum (T_β) and sound velocity maximum (T_u) of water have been studied. The structural contributions to the shift in T_β and T_u, $[\Delta T_{\beta\ \mathrm{str.}}]_{\mathrm{exp.}}$ and $[\Delta T_{u\ \mathrm{str.}}]_{\mathrm{exp.}}$, have been found to be negative for both solutes. Both $[\Delta T_{\beta\ \mathrm{str.}}]_{\mathrm{exp.}}$ and $[\Delta T_{u\ \mathrm{str.}}]_{\mathrm{exp.}}$ are higher for dimethyl sulfoxide than *N,N*-dimethylformamide indicating that the sulfinyl group (>SO) is more efficient in structure disruption than the formylimino group (>F). The results have been explained in the light of hydrogen bonding equilibria by the solutes.

In recent years the effect of nonelectrolytes on the hydrogen-bonded structure of water has been studied extensively by observing the non-ideal thermodynamic behavior such as viscosity composition maxima,[1] negative partial molal volumes[2-4] and partial molal heat capacity at infinite dilution.[5-7] The structure of aqueous nonelectrolyte solution may also be investigated by determining the shift in the extrema in various physical properties of water caused by the addition of nonelectrolytes. Effects of nonelectrolytes on the density maximum temperature (DMT) of water have been studied extensively[8-15] and the results have been utilized successfully to classify the solutes as structure promoters and disrupters. Recent studies on the effect of nonelectrolytes on the adiabatic compressibility minimum temperature[16-20] (ACMT) and sound velocity maximum temperature[21,22] (SVMT) have been found to be useful in understanding their structural behavior.

Aqueous solutions of *N,N*-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO) are known to be the best mixtures and reaction media. DMSO and DMF interact with water through hydrogen-bonding, but details of such interactions are not well characterised. The studies on density maximum by Macdonald *et al.*,[11] excess Gibbs free energy by Clever and Piggott[23] and the infrared spectroscopy by Brink and Falk[24] on aqueous DMSO characterise DMSO as a structure disrupter, while studies on standard free energy by Oakenfull and Fenwick,[28] X-ray diffraction and neutron inelastic scattering by Safford *et al.*,[26] partial molar enthalpies by Rallo *et al.*[25] apparent molar volume and heat capacity by de Visser *et al.*[27] on water+DMSO system classify DMSO as a structure promotor. DMF is also representative of a class of solutes[29] including dioxane, dimethylsulfoxide and possibly acetone which are only weakly hydrophobic and probably have little overall influence on the structure of water.

In view of the growing importance of sulfoxides and amides as solutes in biochemical and physicochemical investigations involving water as solvent and also of the fact that contraversial conclusions in particular have been drawn regarding the solute-solvent interactions and structural propensity of DMSO, we have taken up the studies on the effect of DMSO and DMF on SVMT and ACMT of water and the results are reported in this paper.

Experimental

Analar grade DMF and DMSO were used after necessary purification.[30] The purity of the samples were checked by determining their densities at 25 °C using a bicapillary type pycknometer with an accuracy of 2 parts in 10^5, the values being in good agreement with literature data.[4,27] Ultrasonic velocity (u) was determined using a single crystal variable path interferometer working at 3 MHz with an accuracy of $\pm 0.003\%$. The details of the measurement of ultrasonic velocity were reported in a previous paper.[16] Triple distilled degassed water was used to prepare solutions of DMF and DMSO of various concentrations. Ultrasonic velocities and densities were determined at an interval of $\simeq 2$ °C over a range of 5 °C on either side of SVMT and ACMT. The velocities were corrected for diffraction effects following the procedure reported.[31] The adiabatic compressibilities calculated using the formula $\beta = u^{-2}\rho^{-1}$ are accurate to $\pm 0.01\%$. At low concentrations of the organic solute, the temperature dependence of the adiabatic compressibility and ultrasonic velocity in solutions is similar to that of the curves for pure water. Transparent templates of the curves of pure water were used to determine SVMT (T_u) and ACMT (T_β) of solutions. The accuracy of the values of T_β and T_u are ± 0.4 and ± 0.2 °C, respectively.

Results and Discussion

Results of the measurement of adiabatic compressibility and ultrasonic velocity as a function of temperature at different concentrations of dilute aqueous solutions of DMF and DMSO are shown graphically in Figs. 1—4.

Expressions for T_u and T_β in aqueous solutions are obtained by considering the basic expressions for u and β in pure components as a function of temperature and the expression for the β of the solution in terms of the compressibilities of pure components. The details of the derivation were reported.[19] The final expressions are as follows.

$$T_{\beta\ \mathrm{sol.}} = \left[64 - \frac{\phi_2 \alpha_\beta}{\phi_1 0.0032 \times 10^{-11}}\right] \times \left[1 + \frac{\phi_2 \alpha^1_\beta}{\phi_1 0.0016 \times 10^{-11}}\right]^{-1} - \frac{d\beta^E}{dt}(\phi_1 0.0032 \times 10^{-11})^{-1} \times \left[1 + \frac{\phi_2 \alpha^1_\beta}{\phi_1 0.0016 \times 10^{-11}}\right]^{-1}, \quad (1)$$

$$T_{u\ sol.} = \left[74 - \left(\frac{\phi_2}{\phi_1}\right)^2 \left(\frac{W_1}{W_2}\right) \left(\frac{\alpha_u}{0.049}\right) \frac{(u_1)^3}{(u_2)^3}\right] - \left(\frac{W_1}{\phi_1^2}\right) \left(\frac{u_1^3}{0.098}\right) \left[\rho \frac{d\beta^E}{dt} + \beta^E \frac{d\rho}{dt}\right]. \quad (2)$$

Where ϕ_1, ϕ_2 and W_1, W_2 represent the volume fractions and weight fractions of pure water and organic solute, respectively, in solution. α_β and α_β^1 are the coefficients involved in the relation for the adiabatic compressibility as a function of temperature (t) of organic solute given below:

$$\beta_2 = \beta_2^0 + \alpha_\beta t + \alpha_\beta^1 t^2. \quad (3)$$

Where α_u represents the coefficient involved in the expression for temperature dependence of velocity in the organic solute, namely

$$u_2 = u_2^0 - \alpha_u t. \quad (4)$$

Where u_1 and u_2 are velocities in pure water and organic solute, respectively. β^E represents the excess adiabatic compressibility. The values of β_2°, α_β, α_β^1, u_2°, and α_u for DMF and DMSO are evaluated using ultrasonic velocity determined experimentally and density data at different temperatures. The values are given in Table 1.

The shifts produced $\Delta T_\beta = (T_{\beta\ sol.} - T_{\beta\ water})$ and $\Delta T_u = (T_{u\ sol.} - T_{u\ water})$ may be divided into an ideal contribution ($\Delta T_{u\ id.}$ and $\Delta T_{\beta\ id.}$) and structural contribution ($\Delta T_{u\ str.}$ and $T_{\beta\ str.}$) according to Eqs. 1 and 2. The ideal contribution is always negative, but the structural contribution can either be positive or negative, indicating either structure promotion or structure disruption by the solute.

The second terms on the right hand side of Eqs. 1 and 2 represent $\Delta T_{\beta\ str.}$ and $\Delta T_{u\ str.}$, respectively. They can also be obtained experimentally using the following relations.

$$[\Delta T_{\beta\ str.}]_{exp.} = T_{\beta\ exp.} - T_{\beta\ id.}, \quad (5)$$

$$[\Delta T_{u\ str.}]_{exp.} = T_{u\ exp.} - T_{u\ id.}, \quad (6)$$

where $T_{\beta\ id.}$ and $T_{u\ id.}$ are given by the first terms of the right hand sides of Eqs. 1 and 2, respectively. These temperatures correspond to those at which adiabatic compressibility minimum of and sound velocity maximum in the solution would take place if ideal mixing occurs. Since the temperature dependence of ϕ_1 and ϕ is small, ϕ_1 and ϕ_2 used to determine $T_{\beta\ id.}$

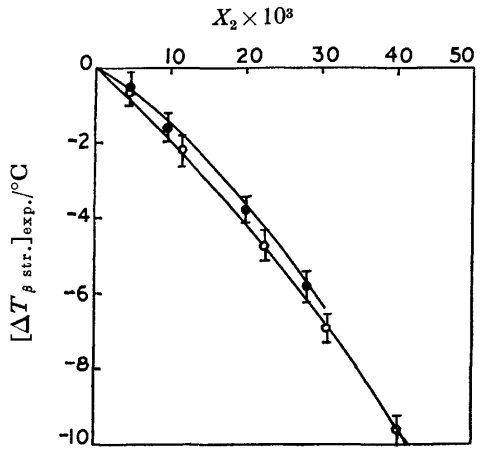

Fig. 5. Structural shifts, $[\Delta T_{\beta\,\mathrm{str.}}]_{\mathrm{exp.}}$, plotted against X_2 of *N,N*-dimethylformamide and dimethyl solfolxide. ●: *N,N*-Dimethyl formamide, ○: dimethyl solfoxide.

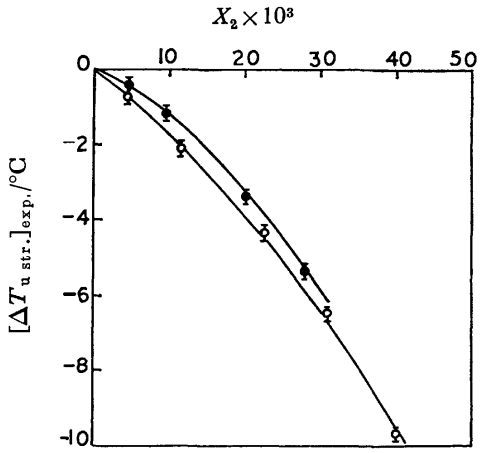

Fig. 6. Structural shifts, $[\Delta T_{\mathrm{u\,str.}}]_{\mathrm{exp.}}$, plotted against X_2 of *N,N*-dimethylformamide and dimethyl sulfoxide. ●: *N,N*-Dimethylformamide, ○: dimethyl sulfoxide.

and $T_{\mathrm{u\,id.}}$ were those calculated at T_β and T_u of the solution found experimentally. Successive approximation method was employed for evaluation of $T_{\mathrm{u\,id}}$. The values of $[\Delta T_{\beta\,\mathrm{str.}}]_{\mathrm{exp.}}$ and $[\Delta T_{\mathrm{u\,str.}}]_{\mathrm{exp.}}$ at different mole fractions (X_2) of DMF and DMSO are given in Tables 2 and 3 and shown graphically in Figs. 5 and 6, respectively. The negative shifts increase with increasing X_2, indicating that both DMF and DMSO promote disruption of the three dimensional structure of water.

The spectroscopic and thermodynamic studies of aqueous DMSO by Fox and Whittingham[32] indicate hydrophobic hydration of DMSO in water, only when DMSO is present in a small amount *i.e.* $X_2 \leq 0.005$. At higher concentration complex formation is predominant. The extrema that have been observed in the excess enthalpy,[32] isothermal compressibility,[33] viscosity[34] and activation volume for benzyl chloride solvolysis[35] around $X_2 \simeq 0.35$ indicate the formation of 2:1 (H_2O:DMSO) complexes, and do not correspond to hydrophobic hydration. As such, DMSO cannot be described as a structure promoter. The structural contribution to the shift in MDT of water for DMSO has been found to be negative,[11] indicating the structure disrupting character of DMSO which supports the present study. Studies on X-ray diffraction and neutron inelastic scattering by Safford *et al.*[26] indicate DMSO as structure promoter. The studies by Brink and Falk[24] show that addition of a few mol% of DMSO to water does not change the average value or the width of distribution of hydrogen-bond energies derived from infrared spectroscopy. The studies on the apparent molar volumes[4,27,36] and heat capacities[27,37] indicate both DMSO and DMF to be weakly hydrophobic. The minimum in the standard free energy of hydrophobic interaction ($\Delta G^\circ_{\mathrm{HI}}$) for both DMSO and DMF around $X_2 \simeq 0.25$ and 0.1 indicates that these solutes strengthen hydrophobic interaction.[28] DMF is weakly hydrophobic. However, the present study indicates that it does not enhance the long-range interaction in water. Ultrasonic velocity and adiabatic compressibility measurements carried out by Endo[38] on water+DMF system over the temperature range 20—50 °C indicate some complex formation, where the number of molecules of water per DMF molecule are 22.8, definitely not of clathrate hydrate type.[39] Thus DMF–water interactions are not of hydrophobic nature. Also ultrasonic absorption measurements made by Kawaizumi *et al.*[40] on this system indicate that added DMF molecules have the same effects as the temperature rise upon the ultrasonic absorption coefficient, and DMF has been characterized as a structure disrupter. The structural contribution to the shift in MDT is negative[12] which further confirms the structure disrupting nature of DMF. Since the structure promoting interactions are sensitive to temperature[20,41–44] different conclusions drawn only reflect the different experimental temperatures, *i.e.* 64 and 74 °C for ACMT and SVMT studies carried out in the present work, 4 °C for MDT studies, and 25 °C for the other studies. It is possible that various experimental techniques correspond to different phenomena.

One may regard the ability of the solute to perturb the structure of water as a sum of group effects as proposed by Wada and Umeda.[8] We see in Figs. 5 and 6 that the structure disrupting tendency of DMSO is greater than that of DMF. Since both solutes have a common dimethyl group, it is clear that the sulfinyl group (>SO) is more efficient in disrupting the structure of water than the formylimino group (>F).

The structural contribution to the shifts in T_β and T_u has also been calculated using the values of $\frac{d\beta^E}{dt}$ at each concentration. The excess adiabatic compressibility β^E was evaluated[11] at each temperature using experimental velocities of pure components and the mixtures. At all concentrations β^E was found to be a linear function of temperature within experimental error. The calculated structural shifts $[\Delta T_{\beta\,\mathrm{str.}}]_{\mathrm{cal.}}$ and $[\Delta T_{\mathrm{u\,str.}}]_{\mathrm{cal.}}$, are also given in Tables 2 and 3 and these values compare well with the experimental ones.

Mixed Monolayers of Long Normal-chain Fatty Acids with Long Normal Alkyl Esters. III. Pentadecanoic Acid-Esters System

Hirosi MATUO,* Kinsi MOTOMURA, and Ryohei MATUURA

Department of Chemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812

(Received June 28, 1980)

The surface pressures of mixed monolayers of pentadecyl acetate, hexadecyl acetate, heptadecyl acetate, and hexadecyl propionate with pentadecanoic acid were measured at various compositions and temperatures. The two-dimensional phase diagram and apparent molar entropy and energy changes were evaluated by means of a previously described thermodynamic treatment. They depend uniquely on the molecular structure of the film-forming substances and on the composition in the mixed monolayer. The phase diagrams of pentadecanoic acid–pentadecyl acetate and pentadecanoic acid–hexadecyl acetate systems are of a complicated type. There are positive and negative regions in the excess apparent molar energy changes. The pentadecanoic acid–heptadecyl acetate and pentadecanoic acid–hexadecyl propionate systems are of the positive azeotropic type. The excess apparent molar energy changes are positive over the whole range of mole fractions.

Previously we have reported unique behavior in the mixed monolayer of the pentadecanoic acid(C_{15})–hexadecyl acetate(HA) system.[1] It has maximum and minimum points in the phase diagram. To investigate this phenomenon in more detail, it is necessary to use esters which have a different chain length of the hydrophobic part from that of HA, such as pentadecyl acetate(PA), heptadecyl acetate(HpA), and hexadecyl propionate(HPr), which has the same chain length as HA, but with a different hydrophilic group. In the present study we have attempted to do experiments with these esters.

Experimental

Pentadecanoic acid(C_{15}) was purified by fractional distillation and recrystallization. Pentadecyl acetate(PA), hexadecyl acetate(HA), heptadecyl acetate(HpA), and hexadecyl propionate(HPr) were synthesized by the usual method[2] and were purified by reduced pressure distillations.

The surface pressure was measured by means of a Wilhelmy-type surface balance. The monolayer was compressed continuously with a constant velocity. The surface pressure-mean area (π-A) curves were reproducible within ± 0.2 mN m^{-1} in the same mean molecular area. Purified benzene was used as the spreading solvent. To prevent the ester from hydrolysis, a 0.1 mol dm^{-3} NaCl solution was used as the substrate; this was prepared from twice-distilled water and sodium chloride (Wako super special grade). The temperature was kept constant within ± 0.1 K during the experiment.

Results and Discussion

Representative π-A curves of the C_{15}–PA, C_{15}–HA,[1] C_{15}–HpA, and C_{15}–HPr systems at 298.2 K are shown in Figs. 1 to 4. These esters and fatty acid spread on the air–water interface formed an expanded monolayer at the experimental temperature. The transition from the liquid expanded to the liquid condensed state was observed for all systems over the whole range of composition. The transition pressure, π^{eq}, corresponds to the surface pressure at the break point of the π-A curve. The variations in π^{eq} with the mole fraction of esters, $x_2^{\pi,eq}$, are very different from each other, as is shown in Fig. 5. These curves depend significantly on the chain length and the structure of the hydrophilic group of esters. The

hydrophilic group of PA, HA, and HpA is the same, that is, acetoxyl group (CH_3COO–), but the carbon number of the hydrophobic group is different in each. On the other hand, the hydrophilic group of HPr is different from that of HA, while the chain length is the same. In the C_{15}–PA system, π^{eq} increases gently with an increase in the mole fraction of the ester in the expanded state, $x_2^{\pi,e}$. There are maximum and minimum points in the C_{15}–HA system, as has previously been mentioned.[1] For the C_{15}–HpA system, a small maximum was observed, while the C_{15}–HPr system has a large maximum.

Recently thermodynamic equations of a multicomponent mixed monolayer in which the contribution of water is incorporated were derived by Motomura.[3-6] When two components are miscible in both the expanded and condensed states, the following equations (Eqs. 209, 201, and 205 in Ref. 6) have been reported:

$$x_2^{\pi,c} = x_2^{\pi,e} + (a^c-a^e)(\partial\pi^{eq}/\partial x_2^{\pi,e})_{T,p} / \{RT/x_1^{\pi,e}x_2^{\pi,e} + (\partial a^e/\partial x_2^{\pi,e})_{T,p,\pi}(\partial\pi^{eq}/\partial x_2^{\pi,e})_{T,p} + \int_0^{\pi}[\partial^2 a^e/(\partial x_2^{\pi,e})^2]_{T,p,\pi}d\pi\}, \quad (1)$$

$$\Delta s^r = [a^c-a^e-(x_2^{\pi,c}-x_2^{\pi,e})(\partial a^e/\partial x_2^{\pi,e})_{T,p,\pi}] \times [(\partial\pi^{eq}/\partial T)_{p,x_2^{\pi,e}}-(\partial\gamma^{\circ}/\partial T)_p], \quad (2)$$

and;

$$\Delta u^r = -(\pi^{eq}-\gamma^{\circ})[a^c-a^e-(x_2^{\pi,c}-x_2^{\pi,e})(\partial a^e/\partial x_2^{\pi,e})_{T,p,\pi}] + \Delta Ts^r, \quad (3)$$

where x_2^{π} is the mole fraction of the second component (ester) in the mixed monolayer; a is the mean area per mole of film-forming components; π^{eq} is the phase-equilibrium surface pressure, which corresponds to that of the break point of the π-A curve; the superscripts c and e represent the condensed and expanded states respectively; Δs^r and Δu^r are the apparent molar entropy and energy changes, and γ° is the surface tension of water.

Now we can obtain two curves; one is the experimental π^{eq}–$x_2^{\pi,e}$ curve, and the other is the π^{eq}–$x_2^{\pi,c}$ curve calculated using Eq. 1. A two-dimensional phase diagram is constructed by means of these two curves. The diagrams of the C_{15}–PA, C_{15}–HA, C_{15}–HpA, and C_{15}–HPr systems at 298.2 K are shown in Figs. 6 to 9. For all systems, two components are miscible in the expanded as well as the condensed states. At the maximum and minimum points, the mole fractions of the expanded($x_2^{\pi,e}$) and condensed ($x_2^{\pi,c}$) phases are equal. According to the previously presented classification of phase diagrams,[7,8] the C_{15}–PA and C_{15}–HA systems are of a complicated type, while the C_{15}–HpA and C_{15}–HPr systems are of a positive azeotropic type.

The apparent molar entropy change of these systems was evaluated by means of Eq. 2. They are shown in Fig. 10. In the C_{15}–PA system, Δs^r decreases gently with an increase in $x_2^{\pi,c}$. The Δs^r of the C_{15}–HA system has a small minimum. The value for the C_{15}–HpA system increases gradually with an increase in $x_2^{\pi,c}$. The C_{15}–HPr system has an obvious minimum. In this way, the apparent molar entropy changes of these systems depend also uniquely on the chain length and structure of the hydrophilic group of esters.

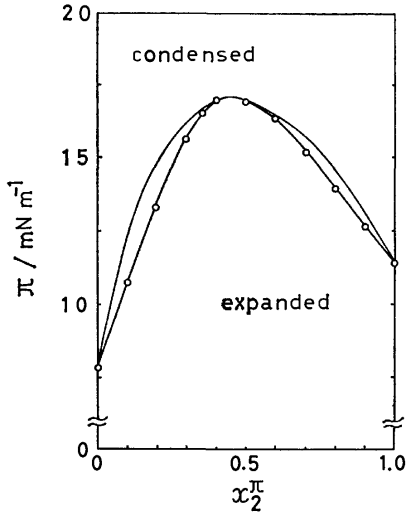

Fig. 9. Phase diagram of the pentadecanoic aicd–hexadecyl propionate mixed monolayer at 298.2 K.

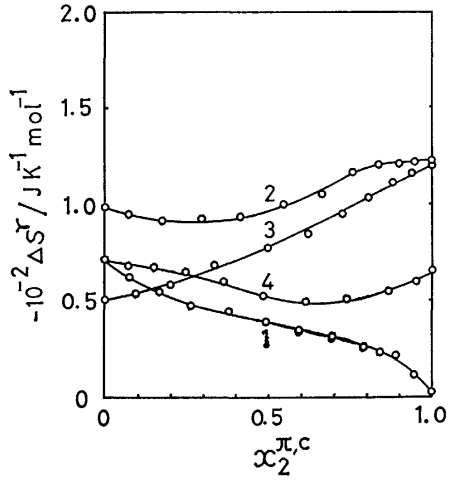

Fig.10. Δs^r *vs.* $x_2^{\pi,c}$ curves of several mixed monolayers.
1: Pentadecanoic acid–pentadecyl acetate system at 298.2 K, 2: pentadecanoic acid–hexadecyl acetate system at 295.7 K, 3: pentadecanoic acid–heptadecyl acetate system at 299.7 K, 4: pentadecanoic acid–hexadecyl propionate system at 298.2 K.

The excess apparent molar energy change is defined by $\Delta u^r - \overline{(\Delta u^r)}$, where $\overline{(\Delta u^r)}$ is the composition average of Δu^r. From Eq. 3 and the above definition, we can now calculate the excess apparent molar energy changes. They are given in Fig. 11. It is interesting that there are positive and negative regions in the energy change. This is why C_{15}–PA and C_{15}–HA systems show complicated phase diagrams. They indicate the following facts: (1) in the positive region, there are mutual interactions between the two components in the mixed monolayer which are weaker than the interactions between the pure component molecules themselves, and (2) in the negative region, there are mutual interactions between the two components in the mixed monolayer which are stronger than the interactions between the pure component molecules themselves. Upon comparing the C_{15}–PA,

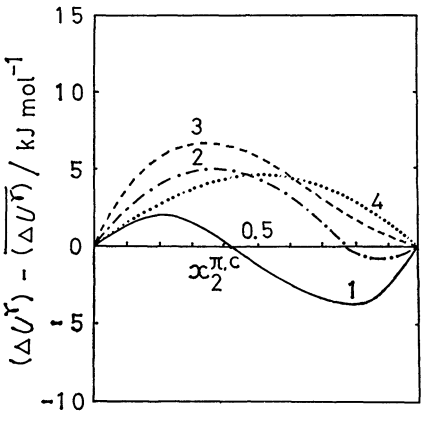

Fig.11. $(\Delta u^r) - \overline{(\Delta u^r)}$ *vs.* $x_2^{\pi,c}$ curves of several mixed monolayers.
1: Pentadecanoic acid–pentadecyl acetate system at 298.2 K, 2: pentadecanoic acid–hexadecyl acetate system at 295.7 K, 3: pentadecanoic acid–heptadecyl acetate system at 299.7 K, 4: pentadecanoic acid–hexadecyl propionate system at 298.2 K.

C_{15}–HA, and C_{15}–HpA systems, we find that the positive region increases with an increase in the chain length of the esters until, in the C_{15}–HpA system, the energy change is positive over the whole range of $x_2^{\pi,c}$. In these C_{15}–PA, C_{15}–HA, and C_{15}–HpA systems, the hydrophilic group of the esters is the same, but the chain length of the esters is different in each. Therefore, the above results show the following facts: (1) interactions between two components in the mixed monolayer decrease with an increase in the difference in chain length between the two components, and (2) in the low $x_2^{\pi,c}$ region, the contribution of the hydrophilic-hydrophilic steric hindrance becomes relatively large. The excess apparent molar energy change of the C_{15}–HPr system is positive over the whole range of $x_2^{\pi,c}$. This also indicate the weaker interactions. This is why C_{15}–HPr system shows a positive azeotropic transformation in mixed monolayers.[5,8,9] HPr has a propyl group(C_3H_8–) in its hydrophilic part, but PA, HA, and HpA have a methyl group(CH_3–) in their hydrophilic parts. The steric hindrance of the propyl group is much larger than that of the methyl group. Therefore, the steric hindrance of the propyl group may be supposed to play an important role in the positive azeotropic transformation.

Effect of Hydrogen Bonding on the Phosphorescence of Benzo[c]cinnoline in Polyhydric Solvents

Hiroyasu Inoue,* Yukimi Hiroshima, and Kôichi Tomiyama
Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama 221

(Received November 27, 1980)

Synopsis. Phosphorescence of benzo[*c*]cinnoline has been found to be enhanced in polyhydric solvents, such as ethylene glycol, glycerol, and aqueous ethanol. Enhancement of the phosphorescence emission can be attributed to the formation of the hydrogen bond in the triplet state of benzo[*c*]cinnoline with the solvent molecules.

Emission characteristics of ortho-diazines, such as pyridazine and benzo[*c*]cinnoline (9,10-diazaphenanthrene, abbreviated hereafter as BCC), have often been discussed.[1] BCC shows intense fluorescence, but its phosphorescence emission efficiency is very low.[2] Recently, Lin and Stikeleather[3] observed enhanced phosphorescence of BCC in the fluorinated alcohols. The alcohols act as a proton-donor in hydrogen bonding with BCC, thus inducing the phosphorescence of the substrate. They suggested that the lack of phosphorescence in hydrocarbon solvents was not due to a nonpopulated triplet state, but rather due to the $T_1 \rightarrow S_0$ radiationless rate being much faster than the radiative rate.

In general, the hydrogen bond between solute and solvent has some influence on the emission properties of the solute. As for cinnoline, for example, it is known that the formation of a hydrogen bond induces phosphorescence, although it is a poor phosphorescer in non proton-donating solvents.[4]

The formation of the hydrogen bond in the ground state BCC with proton-donating solvents was proved from a blue shift of the $n\pi^*$ absorption spectrum.[5] In the lowest excited singlet state of BCC, the hydrogen bond is formed at low temperature, but it is broken at room temperature.[6,7]

In this paper, we will report the enhanced phosphorescence emission of BCC in polyhydric alcohols and aqueous monohydric alcohols, and will discuss the hydrogen bonding in the lowest triplet state of BCC with those solvents.

Experimental

BCC was obtained from Aldrich Chem. Co. and was purified by recrystallization from ethanol. Emission spectra were recorded on a Shimadzu RF-500 spectrofluorimeter at 77 K. Excitation spectra were corrected for the intensity of incident light using a rhodamine B solution.

Results and Discussion

In monohydric alcohols, such as ethanol and 2-propanol, BCC shows no appreciable phosphorescence under our experimental conditions. However, it was found that in mixture of the monohydric alcohols and water (1:1 vol) the phosphorescence emission could be observed around 540 nm with a significant yield. In addition, ethylene glycol and glycerol were also found to be suitable solvents for the appearance of the phosphorescence of BCC. The observed phosphorescence spectra are presented in Fig. 1. None of the emission arises from the solvents used here. Moreover, the possible photochemical change of the sample was not detected.[8] The formation of a dimer of BCC at low temperature as reported by Hoytink *et al.*[9] can be ruled out as an origin of the observed phosphorescence, because polar solvents are used in this study. Hochstrasser and Marzzacco[10] reported the crystalline $T_1 \leftarrow S_0$ absorption spectrum and they assigned the lowest triplet at 5384.6 A (0—0 band) as the $\pi\pi^*$ type. The 0—0 band of $T_1 \leftarrow S_0$ absorption spectrum corresponds in position to that of the phosphorescence observed in this study.

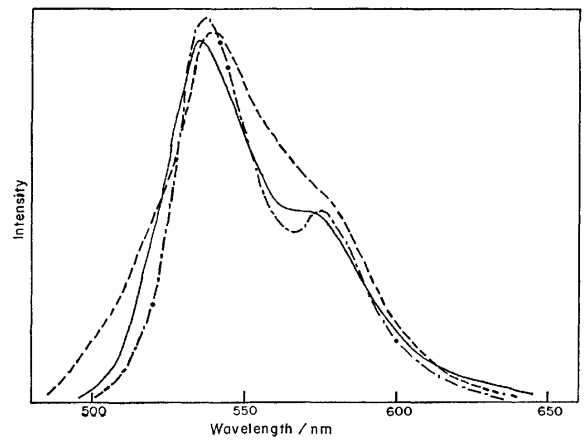

Fig. 1. Phosphorescence spectra of BCC.
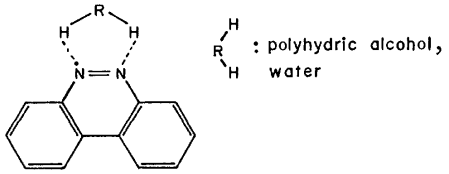
—: In a mixture of ethanol and water (1:1), ——: in glycerol, ---: in ethylene glycol.

It should be noted that the phosphorescence of protonated BCC in 4 mol/dm^3 HCl aqueous 2-propanol, which was reported earlier,[11] was quite similar in shape to the spectra in Fig. 1, though the former has a maximum at somewhat longer wavelength.[12] In the present case, therefore, enhancement of the phosphorescence can reasonably be explained in terms of the hydrogen bonding between the solute and the solvents. In the aqueous alcohols, water seems to act as a proton-donor. It is worth noting that the solvent molecule which is suitable for the emission has at least two hydrogen atoms which can take part in the hydrogen bonding with the aza nitrogen atoms of BCC. Accordingly, the following hydrogen bonds are though to be formed. In fact, ethylene glycol

monoethyl ether, which could not form such hydrogen bonds, did not induce the phosphorescence. Therefore, there is a distinct difference in the hydrogen bonding with the triplet state BCC between the mono- and polyhydric alcohols.



In order to see the difference in hydrogen bonding with the ground (S_0) and the lowest excited singlet (S_1) BCC between mono- and polyhydric alcohols, the absorption and fluorescence spectra were determined at room temperature. Owing to the hydrogen bonding, the $n\pi^*$ absorption band exhibits a large blue shift, thus appearing as a shoulder at the long wavelength of the first $\pi\pi^*$ band in both the mono- and polyhydric alcohols. The shape of the shoulder is the same in both solvents. The wavelengths of the fluorescence maxima in the polyhyric alcohols and the aqueous alcohols are almost the same as those in the monohydric alcohols, *e.g.*, 485 nm in ethylene glycol and 488 nm in ethanol. Therefore, we could not find any differences in hydrogen bonding properties of BCC in the S_0 and S_1 states between the mono- and polyhydric alcohols at room temperature.

Figure 2 shows the excitation spectra of the fluorescence at room temperature and of the phosphorescence at 77 K in glycerol. The phosphorescence excitation spectrum is shifted to somewhat longer wavelengths compared with the fluorescence excitation spectrum which corresponds to the absorption spectrum. This shift suggests that in polyhydric alcohols the hydrogen bonds are strengthened at low temperature, that is, the formation of the hydrogen bonds occurs as illustrated above.

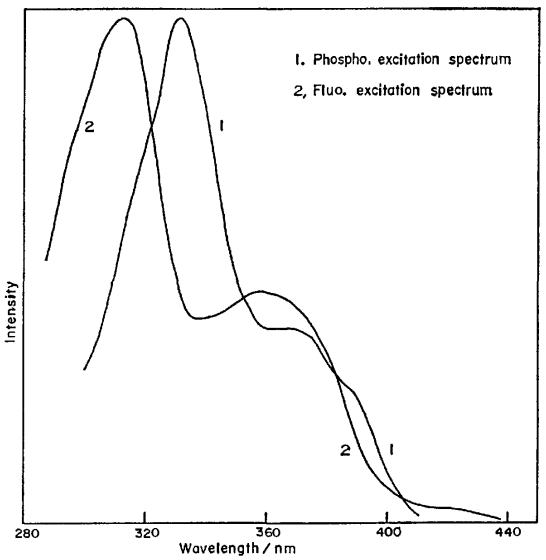


Fig. 2. Excitation spectra of phosphorescence at 77 K (1) and of fluorescence at room temperature (2) in glycerol (5×10^{-5} mol/dm^3).

^{14}N Nuclear Quadrupole Resonance Spectra of $K_2SrCu(NO_2)_6$, $K_2BaCu(NO_2)_6$, and $Cs_2PbCu(NO_2)_6$

Tetsuo Asaji,* Jun Ishikawa, Ryuichi Ikeda, and Daiyu Nakamura
Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya 464

(Received January 24, 1981)

Synopsis. The ^{14}N NQR frequencies of $K_2SrCu(NO_2)_6$, $K_2BaCu(NO_2)_6$, and $Cs_2PbCu(NO_2)_6$ were determined at various temperatures below about 155, 67, and 235 K, respectively. The results are discussed in referring to their crystal structure.

Recently, a number of structural studies[1-8] have been made on the compound $R_2MCu(NO_2)_6$ (R=K, Rb, Cs, NH_4, Tl and M=Pb, Ca, Sr, Ba) and it became obvious that this series of compounds can be classified into two distinct classes through the sort of the bivalent cation M. The compounds containing Pb form cubic crystals in their high-temperature phase and exhibit successive phase transitions with decreasing temperature. In their lowest-temperature commensurate phase, these crystals are thought to have a pseudotetragonal lattice with $c/a<1$.[1-6] On the other hand, the crystals containing the alkali earth metal atoms have a pseudotetragonal lattice with $c/a>1$ at room temperature[6-8] and the occurrence of phase transition has not been reported as yet.

In a preceding paper,[9] we reported the existence of at least two sets of ^{14}N nuclear quadrupole resonance (NQR) frequencies in the low-temperature phase of the former class compounds. However, there remains an unsolved problem on the assignment of the observed frequencies to nonequivalent nitrogen atoms in the crystals. Accordingly, we have undertaken the present investigation of the ^{14}N NQR of the latter compounds to clarify this point.

Experimental

The samples employed for the measurements of NQR and DTA (differential thermal analysis) were synthesized according to the method reported by Reinen *et al.*,[6] and identified by recording X-ray powder patterns. A modified Pound-Watkins type spectrometer operated in a frequency modulation mode[10] was used for the observation of ^{14}N NQR signals. The sample temperature was determined by employing the usual method already described elsewhere.[9] DTA curves were taken by means of a home-made apparatus previously described.[11]

Results and Discussion

Three NQR frequencies ν^{I}, ν^{II}, and ν^{III} defined below are usually observed for ^{14}N nuclei in compounds.

$$\left.\begin{aligned} &\nu^{I} = (3/4h)eQq(1+\eta/3),\ \nu^{II} = (3/4h)eQq(1-\eta/3) \\ &\nu^{III} = (1/2h)eQq\cdot\eta. \end{aligned}\right\} \quad (1)$$

Here, eQq and η denote the quadrupole coupling constant and the asymmetry parameter, respectively. The ν^{I} and ν^{II} frequencies and their signal-to-noise ratios (S/N) determined at various temperatures are given in Table 1.

A single pair of ν^{I} and ν^{II} frequencies was observed for both of $K_2SrCu(NO_2)_6$ and $K_2BaCu(NO_2)_6$. For the former compound ν^{I} and ν^{II} could be detected up to about 110 and 155 K, respectively, while for the latter up to about 45 and 67 K, respectively. Both frequencies of $K_2SrCu(NO_2)_6$ decreased smoothly with increasing temperature up to respective fade-out temperatures, indicating that no phase transition takes place below 155 K. To examine the thermal properties of $K_2SrCu(NO_2)_6$, we carried out the experiment of DTA and found no thermal anomaly in the temperature range of 143—323 K. Accordingly, it can be concluded that $K_2SrCu(NO_2)_6$ retains its crystal symmetry determined at room temperature unaltered down to liquid helium temperature. For $K_2BaCu(NO_2)_6$, the resonance frequencies decreased smoothly with increasing temperature, indicating the absence of phase transition between 2 and 67 K.

The caesium salt, $Cs_2PbCu(NO_2)_6$ yielded two sets of ν^{I} and ν^{II} lines at liquid helium temperature. With increasing temperature, these ν^{I} and ν^{II} lines decreased their frequency smoothly and disappeared in the noise level at about 124 and 235 K, respectively. The latter temperature is lower by 50 K than the lowest transition temperature of the caesium salt.[12]

According to Takagi *et al.*,[8] all the complex ions $[Cu(NO_2)_6]^{4-}$ having an orthorhombic symmetry are crystallographically equivalent in the crystals of $K_2SrCu(NO_2)_6$. Therefore, three kinds of crystallographically nonequivalent nitrogen atoms exist in the crystals: one kind of axially elongated nitrogen atoms (Cu–N: 2.31 Å) and two kinds of equatorial nitrogen atoms (Cu–N: 2.04 and 2.03 Å). The fact that the Sr compound shows only one set of ^{14}N NQR frequencies suggests that only the elongated nitrogen atoms afford detectable NQR signals. The NQR signals of the other nitrogen atoms may be undiscernibly broadened owing to the magnetic disturbance of the Cu(II) unpaired electron situated near to the nitrogen atoms.

The NQR parameters, eQq/h and η obtained at 4.2 K are given in Table 2 with those of $R_2PbCu(NO_2)_6$ for comparison. The $R_2PbCu(NO_2)_6$ type complexes except for $(NH_4)_2PbCu(NO_2)_6$ yield two sets of the parameters.[9] The ammonium salt shows an additional structural phase transition at 94.5 K, above which temperature the salt also yields two sets of the parameters. On the X-ray and neutron diffraction studies of $K_2PbCu(NO_2)_6$, Noda *et al.*[1] interpreted their experimental results in terms of a structural model proposed by Reinen *et al.*[6] In this model, local tetragonal elongation of a complex ion takes place and the axis of the elongation alternates between the a- and b-axis of the pseudotetragonal crystal. Taking into account of the configuration of oxygen atoms, this indicates that there exist two crystallographically different elongated complex ions. Accordingly, there are two nonequivalent nitrogen atoms

Kinetics of the Decarboxylation of Benzylmalonic Acid, Ethylmalonic Acid, and Dimethylmalonic Acid in Hydroxylic Solvents

Mihir K. Biswas and Dilip K. Majumdar*
Department of Chemistry, University of Kalyani, Kalyani 741235, W. Bengal, India
(Received May 6, 1980)

Synopsis. Kinetics of the decarboxylation of benzylmalonic acid, ethylmalonic acid, and dimethylmalonic acid have been shown to follow first order rate equation in several solvents, namely alkanediols and diethylene glycol (DEG), polyethylene glycol (PEG), and polypropylene glycol (PPG). The enthalpy and entropy of activation for the decarboxylation reactions were determined and the plot of ΔH^* *vs.* ΔS^* was found to be linear through all the solvents.

In the present Note, we report the results of our investigations into the kinetics of the decarboxylation of substituted malonic acids in hydroxylic solvents. The experimental set up is the same as was described previoulsy.[1,3,6] The decarboxylation was carried out in a thermostated bath controlled to within ±0.2 °C. The decarboxylation rates were measured by collecting the evolved carbon dioxide gas at atmospheric pressure at various time intervals. The solvents used are: ethylene glycol (Pfizer, India), 1,2-propanediol (B.D.H., L.R.), 1,3-butanediol (B.D.H., England), diethylene glycol (B.D.H., England), polyethylene glycol-400 (B.D.H., England), and polypropylene glycol-425 (Koch-Light, England). Benzylmalonic acid, ethylmalonic acid, and dimethylmalonic acid used were of Fluka, Switzerland. Ethylene glycol and 1,2-propanediol were distilled under reduced pressure before use. The solvents were previously saturated at the reaction temperature by passing a stream of pure and dry carbon dioxide gas. Stoichiometry was checked in all the solvents by collecting carbon dioxide gas when the reaction was complete. In each kinetic run, the amount of acid taken was about 0.17—0.18 g in 25 ml of the solvent.

Results and Discussion

The first order rate constants k given in Table 1 are mean values over at least four kinetic runs. We also observed that the decarboxylation of these acids obeys rate theory equation of Eyring. The thermodynamic parameters, enthalpy and entropy of activation, ΔH^* and ΔS^* have been evaluated and these are given in Table 2.

Figure 1 shows the enthalpy-entropy plot for the decarboxylation reaction of these acids in these solvents as well as in the molten state. Decarboxylation kinetics of benzylmalonic acid in the molten state have been reported by Clark.[7] We have also measured the decarboxylation rate in the molten state of these three acids at several temperatures.[8] It is seen that a straight line can be drawn through all the solvents including the melting point. The data for dimethylmalonic acid, however, is off as will be evident in Fig. 1. This is not unexpected because dimethylmalonic acid was seen to decarboxylate very fast in the molten state and there was some uncertainty in the values of the rate constant.[8] The linearity of $\Delta H^*-\Delta S^*$ plot implies one reaction series for each of these acids in these solvents. The slope of the enthalpy-entropy plot of Fig. 1 gives the isokinetic temperatures, which are very close to the respective melting points of the acids (Table 3). This is in harmony with the conclusions reached by Clark on the decarboxylation kinetics of alkyl-substituted malo-

Table 3. Analysis of the effect of errors in the $\Delta H^*-\Delta S^*$ relationship for the decarboxylation reaction in alkanediols, DEG, PEG, and PPG

Acids	2δ / kcal mol^{-1}	$d(\Delta H^*)$ / kcal mol^{-1}	$d(\Delta H^*/2\delta)$	Isokinetic temp
Benzylmalonic	3.25	11.79	3.6	120°C
Ethylmalonic	2.89	10.70	3.7	111°C
Dimethylmalonic	4.04	16.94	4.2	192°C

nic acids in alkanols and carboxylic acids. Peterson and coworkers,[5] however, suggested the criterion which must be satisfied for any valid conclusions from the linearity of ΔH^* *vs.* ΔS^* plot.

If the total maximum possible error in ΔH^* is 2δ and the range of ΔH^* values is designated as $d\Delta H^*$, then the ratio, $d\Delta H^*/2\delta \gg 1$. The maximum possible error in ΔH^*, may be calculated from the relation,[5,6]

$$\delta = 2R\frac{T'T}{T'-T}\alpha \quad \text{if } \alpha \ll 1.$$

Using this relation, we have given in Table 3 the maximum possible error 2δ in ΔH^*, the range of $d\Delta H^*$ values for a reaction series and the ratio, $d\Delta H^*/2\delta$.

It will be seen that the ratio $d\Delta H^*/2\delta$ is always greater than 1. So the observed linearity of ΔH^* *vs.* ΔS^* plot (Fig. 1) may be regarded as valid. Therefore at the isokinetic temperature, the rate constant is the same for a reaction series in all the solvents.

Diethylene glycol (DEG), polyethylene glycol (PEG), and polypropylene glycol (PPG) differ from the alkanediols in having oxygen in the middle of the chain in addition to having two hydroxyl groups at the ends. Therefore in the solvents, namely, DEG, PEG, and PPG, the activated complex may form either with the ether oxygen or the hydroxyl oxygen and the polarised carbonyl carbon of the acid. Accordingly the enthalpy-entropy plot for malonic acid and methylmalonic acid[4] shows two parallel straight lines-one passing through the alkanediols and the other through DEG, PEG, and PPG. The nature of the activated complex thus significantly differs in the two types of solvents. With benzylmalonic acid, ethylmalonic acid, and dimethylmalonic acid, the bulky substituents are likely to hinder coordination with the lone pair of electrons on ether oxygen of the solvents buried deep in the middle of the chain, so that effective participation of hydroxylic oxygen is only permitted. Thus in the decarboxylation of benzylmalonic acid, ethylmalonic acid, and dimethylmalonic acid the nature of the activated complex will be similar in alkanediols and DEG, PEG, and PPG. So it is natural to expect one straight line passing through all the solvents in respect of decarboxylation of a given acid in the series.

Now it is further noticed that the decarboxylation rate constant in these solvents decreases in the following order:

Benzylmalonic acid, ethylmalonic acid, dimethylmalonic acid. This is also the order in which the electron donating ability of alkyl group namely ethyl- and dimethyl-, decreases. If the Fraenkel[2] mechanism is accepted, then the C–C bond will be broken more easily, when the substituent is an electron attracting group. On the other hand, if the substituent is an electron donating group such as alkyl, the excess negative charge on the carbonyl carbon atom will hinder the process of C–C bond breaking and thus retard the rate of decarboxylation reaction. It is thus expected that the rate of decarboxylation should decrease as the electron donating ability of the substituent increases. The electron donating ability of two methyl-being greater than the ethyl, it is easy to understand the decreasing value of the rate constant as we go from ethylmalonic acid to dimethylmalonic acid. The benzyl group, on the other hand, may act either as an electron sink or as an electron donor; so it is difficult to locate its position in the inductivity scale. However, our kinetic studies suggest that the benzyl group has a low electron donating ability in the decarboxylation reactions-much less than the alkyl substituents. On these considerations we may place them in the following order of decreasing electron donating ability: benzylmalonic acid ethylmalonic acid and dimethylmalonic acid, and this is exactly the order in which the decarboxylation rate constant decreases.

Thanks of the authors are due to Kalyani University for award of a Research Scholarship to one of them (MKB). The authors also thank Dr. A. Mitra for helpful discussion.

Magnetic Properties of Copper(II) Complexes of Phenylboronic Acid

Shuji EMORI, Hisayasu MASUO, and Yoneichiro MUTO*

Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received August 29, 1980)

Synopsis. The magnetic susceptibilities of copper (II) phenylboronate obey the Bleaney-Bowers equation for dinuclear clusters. The exchange integral within the dinuclear copper(II) phenylboronate, J/k, is equal to -195 K. The structures for hydrolysis products of copper(II) phenylboronate are presumed to contain copper(II) phenylboronate dinuclear units connected together by diborate bridges.

Some copper(II) complexes of benzoic acid have copper(II) acetate-type dinuclear structures with strong antiferromagnetic coupling between the copper(II) ions of a pair.[1] It has been proposed that superexchange interaction predominates in the coupling of these compounds. The degree of superexchange depends to a great extent on the electronic structure of the bridging ligands. Although phenylboronic acid is a much weaker acid(pK_a=8.86)[2] than benzoic acid(pK_a=4.18),[3] both are isoelectronic. So copper(II) complexes of phenylboronic acid may also have a similar structure to that of copper(II) acetate monohydrate.[4]

The complex $Cu(PhBO_2H)_2(py)_2$ was obtained by concentrating a pyridine solution of phenylboronic acid and anhydrous copper(II) acetate. This pyridine adduct was warmed on a water bath to convert it into $Cu(PhBO_2H)_2$. When $Cu(PhBO_2H)_2$ is allowed to stand for a few days in air, it is partly hydrolysed into $Cu(PhBO_2H)_{3/2}(B_2O_5H_2)_{1/4}$. If the pyridine solution of this complex is concentrated gently on a water bath, the crystalline $Cu(PhBO_2H)_{4/3}(B_2O_5H_2)_{1/3}$ is obtained.

The magnetic susceptibilities of these complexes were measured at room temperature by the Gouy method. Their effective magnetic moments were calculated from expression 1:

$$\mu_{\text{eff}} = 2.83\sqrt{(\chi_A - N\alpha)\cdot T}, \quad (1)$$

where χ_A is the molar magnetic susceptibility corrected for the diamagnetism of all the atoms in the compounds by the use of Pascal's constants,[5] and $N\alpha$ is the temperature-independent paramagnetism per gram-ion of Cu(II). The $N\alpha$ was assumed to be 60×10^{-6} cgsu.† The results are given in Table 1. For $Cu(PhBO_2H)_2$, the magnetic measurement was made over the temperature range 80—300 K. The cryomagnetic data could be fitted well to the Bleaney-Bowers equation 2[6] for isotropic exchange in a copper-(II) dimer:

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1} + N\alpha, \quad (2)$$

where J is the exchange integral and g is the average g factor. The best fit yields $J/k=-195$ K and $g=2.15$ (Fig. 1). These results suggest the existence of dinuclear clusters in crystals. The values are almost the same as $J/k=-225$ K and $g=2.18$ for copper(II) benzoate.[7] This suggests that this compound has a copper(II) acetate-type of dinuclear structure, as shown in Fig. 2 A.

† The value of the molar magnetic susceptibility in $m^3\,mol^{-1}$(SI) can be obtained by multiplying the value in $cm^3\,mol^{-1}$(cgs) by $4\pi\times10^{-6}$.

TABLE 1. ANALYTICAL DATA AND EFFECTIVE MAGNETIC MOMENTS AT 17 °C

Compound	Cu (%) Found	Cu (%) Calcd	μ_{eff}[a] BM
$Cu(PhBO_2H)_2$	20.8	20.8	1.43
$Cu(PhBO_2H)_2(py)_2$	13.7	13.7	1.79
$Cu(PhBO_2H)_{3/2}(B_2O_5H_2)_{1/4}$	23.4	23.5	1.36
$Cu(PhBO_2H)_{4/3}(B_2O_5H_2)_{1/3}$	24.5	24.5	1.33

a) 1 BM=9.27×10^{-24} Am^2.

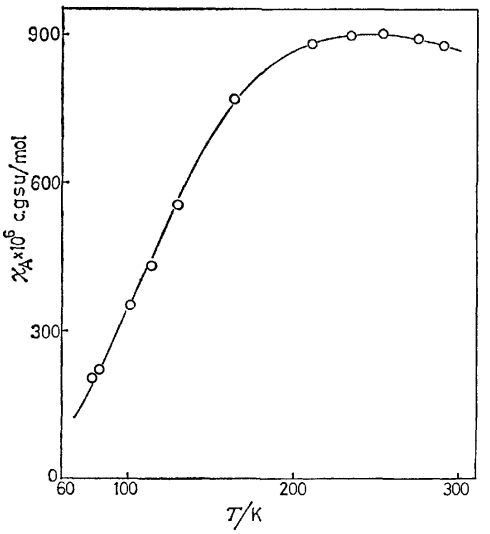

Fig. 1. Observed and calculated magnetic susceptibilities of $Cu(PhBO_2H)_2$: ○, experimental; solid curve, calculated by Eq. 2 with $J/k=-195$ K, $g=2.15$, and $N\alpha=60\times10^{-6}$ cgsu.

On the basis of the analytical data and the reactivity of phenylboronic acid, we assumed that the hydrolysis products, $Cu(PhBO_2H)_{3/2}(B_2O_5H_2)_{1/4}$ and $Cu(PhBO_2H)_{4/3}(B_2O_5H_2)_{1/3}$, have the B and C types of bridging structure shown in Fig. 2, respectively.

Since the magnitude of J should be proportional to the number of bridging ligands involved in the superexchange interaction,[8] the mean exchange integrals for these hydrolysis products can be predicted from Eq. 3 by assuming that no magnetic interaction operates through the >B–O–B< bridge between the dimers:

$$J = \frac{2n+2}{n}J_{PhBO_2H} + \frac{2n-2}{n}J_{B_2O_5H_2} \quad (n=2 \text{ and } 3), \quad (3)$$

where the J_{PhBO_2H} and $J_{B_2O_5H_2}$ are the exchange integrals per single phenylboronate and diborate bridge,

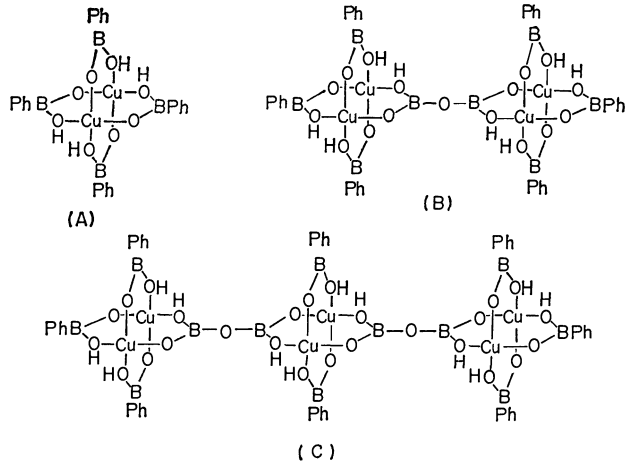

Fig. 2. Schematic representations of probable structure.
(A): $Cu(PhBO_2H)_2$, (B): $Cu(PhBO_2H)_{3/2}(B_2O_5H_2)_{1/4}$,
(C): $Cu(PhBO_2H)_{4/3}(B_2O_5H_2)_{1/3}$.

respectively. The observed magnetic moments of hydrolysis products are the same as the calculated ones (for $n=2$ and 3, 1.36 and 1.33 BM respectively) from the mean exchange integrals obtained with $J_{PhBO_2H}/k=-49$ K (a quarter of the J/k value evaluated by use of Eq. 2) and $J_{B_2O_5H_2}/k=-73$ K.[9,10] This close agreement supports the validity of the postulated structure of hydrolysis products.

The magnitude of superexchange interaction depends to a great extent on the electronic structure of the bridging ligand. Our result, where the J/k value of $Cu(PhBO_2H)_2$ is nearly equal to the value of $Cu(PhCO_2)_2$, can be explained by the isoelectronicity of the ligands. The other result, where the antiferromagnetic interaction operates more strongly in the hydrolysis products than in $Cu(PhBO_2H)_2$, can be explained by considering that diborate groups promote the migration of positive holes to a greater extent than phenylboronate groups.

Dimeric Copper(II) Nitrato and Chloro Complexes with *N*-(3-Dimethylaminopropyl)salicylideneaminato Ligand Protonated at the Terminal Nitrogen

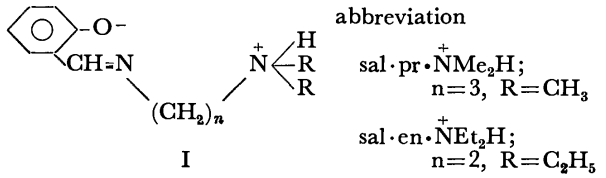
Tadashi Tokii, Toshihiko Tenhiro, and Yoneichiro Muto*

Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received November 10, 1980)

Synopsis. The title complexes have been prepared and characterized. The strong antiferromagnetic interaction observed for the complexes is interpreted in terms of a phenolic-oxygen-bridged dimeric structure with the metal ions in a square-pyramidal geometry.

Previously we reported that chloro[*N*-(3-dimethylaminopropyl)salicylideneaminato]copper(II), Cu(sal·pr·NMe_2)Cl, was obtained in two forms, one monomeric and the other dimeric;[1] the corresponding nitrato complex, Cu(sal·pr·NMe_2)NO_3, was obtained only in a monomeric form.[2] In order to study the effect of structural change upon the magnetic interaction in such complexes, we have prepared copper(II) nitrato and chloro complexes with the Schiff base ligand protonated at the terminal nitrogen, Cu(sal·pr·$\overset{+}{N}Me_2H$)X_2 (X=NO_3 or Cl), from the reaction of HX and Cu(sal·pr·NMe_2)X in ethanol. The analogous complex, Cu(sal·en·$\overset{+}{N}Et_2H$)Cl_2, has also been synthesized (*cf.* formula I).



I

abbreviation

sal·pr·$\overset{+}{N}Me_2H$; n=3, R=CH_3

sal·en·$\overset{+}{N}Et_2H$; n=2, R=C_2H_5

The results of characterization studies on these complexes are presented in this paper.

Experimental

Synthesis. A typical synthetic method is as follows. A solution of one of the acids HX(5 mmol) in ethanol(5 ml) was added to a solution of one of the parent complexes(2 mmol), Cu(sal·pr·NMe_2)NO_3,[2] Cu(sal·pr·NMe_2)Cl (monomeric form)[1] and Cu(sal·en·NEt_2)Cl,[3] in ethanol (50 ml). After the resulting solution had been allowed to stand for several days at *ca.* 5 °C in a freezer, the separated crystals were filtered, washed with ethanol, and dried *in vacuo*. All crystals were orange. Anal. **1.** Cu(sal·pr·$\overset{+}{N}Me_2H$)-$(NO_3)_2$. Found: C, 36.33; H, 4.60; N, 14.01; Cu, 16.02%. Calcd for $C_{12}H_{18}N_4O_7Cu$: C, 36.60; H, 4.61; N, 14.23; Cu, 16.13%. **2.** Cu(sal·pr·$\overset{+}{N}Me_2H$)Cl_2. Found: C, 42.20; H, 5.32; N, 8.22; Cu, 18.65%. Calcd for $C_{12}H_{18}N_2OCl_2Cu$: C, 42.30; H, 5.35; N, 8.22; Cu, 18.65%. **3.** Cu(sal·en·$\overset{+}{N}Et_2H$)Cl_2. Found: C, 43.79; H, 5.69; N, 7.94; Cu, 17.76%. Calcd for $C_{13}H_{20}N_2OCl_2Cu$: C, 44.01; H, 5.68; N, 7.90; Cu, 17.91%.

Physical Measurements. The magnetic susceptibilities in the temperature range 80—300 K were determined by the Gouy method. The IR spectral measurements were made with a Hitachi EPI-G2 IR Spectrophotometer in the 400—4000 cm^{-1} region on Nujol mulls. The reflectance spectra were recorded with a Hitachi Recording Spectrophotometer 323.

The solid curves were obtained as described in text.

Results and Discussion

The variable-temperature magnetic susceptibility data observed for complex **1** have been analyzed by the Bleaney-Bowers equation for isotropic exchange in a copper(II) dimer:[4]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1} + N\alpha, \qquad (1)$$

where each symbol has the usual meaning. The data fit the above expression very well: $-2J=554\ cm^{-1}$, $g=2.16$, and $N\alpha=60\times10^{-6}$ cgs emu† (Fig. 1). For complexes **2** and **3**, the cryomagnetic data at low temperatures have been found to be somewhat higher than those predicted by Eq. 1. This type of behavior is most likely due to a small amount of a monomeric Cu(II) impurity.[5] Assuming the magnetic moment of 1.8 BM†† for the Cu(II) impurity, the magnetic data have been fitted to a modified equation:[5]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1}(1-P) + \frac{0.405P}{T} + N\alpha, \qquad (2)$$

where P is the mole fraction of the Cu(II) impurity. The best fit yields $-2J=554\ cm^{-1}$, $g=2.16$, $N\alpha=60\times10^{-6}$ cgs emu and $P=0.022$ for complex **2** and $-2J=542\ cm^{-1}$, $g=2.20$, $N\alpha=60\times10^{-6}$ cgs emu and $P=0.036$ for complex **3** (Fig. 1).

The IR spectra of the present complexes all show an intence band in the range 1550—1560 cm^{-1} (**1.** 1559; **2.** 1549; **3.** 1550 cm^{-1}), while the corresponding bands in the spectra of the parent monomeric com-

† 1 cgs emu $mol^{-1}=4\pi\times10^{-6}\ m^3\ mol^{-1}$.
†† 1 BM$=9.274\times10^{-24}\ Am^2$.

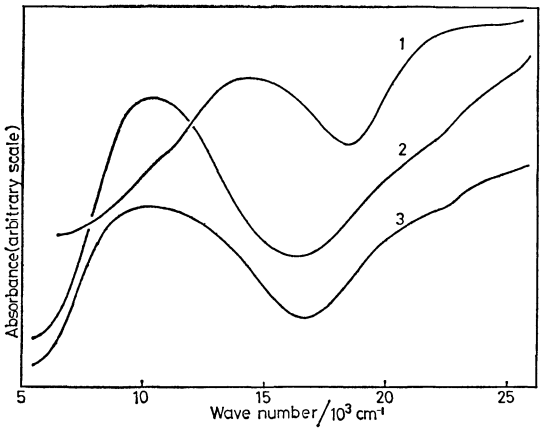

Fig. 2. Reflectance spectra of Complexes **1** (1), **2** (2), and **3** (3).

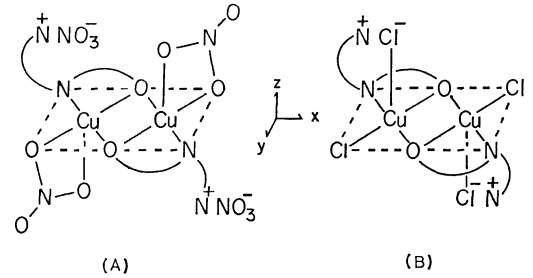

Fig. 3. Schematic representations of probable structure.
(A) Complex **1** and (B) Complexes **2** and **3**.

plexes, $Cu(sal\cdot pr\cdot NMe_2)NO_3$, $Cu(sal\cdot pr\cdot NMe_2)Cl$ and $Cu(sal\cdot en\cdot NEt_2)Cl$, appear at 1541, 1529, and 1530 cm^{-1}, respectively. Such band shift toward higher frequencies (15—20 cm^{-1}) is indicative of the presence of bridging phenolic oxygen atoms in the present complexes.[1,2] The band around 2500—2900 cm^{-1} (**1**. 2900; **2**. 2650; **3**. 2600 cm^{-1}) can be assigned to the $\nu(\overset{+}{N}\text{–H})$ mode, in agreement with the values of 2680 and 2540 cm^{-1} observed for this stretching frequency in *N*-methylpiperidine and triethylamine hydrochlorides.[6] This assignment is further supported by the fact that no band is observed in the same region for the parent monomeric complexes.

The reflectance spectral feature of complex **1** is nearly the same as that of the phenolic oxygen-bridged dimeric copper(II) complex with *N*-ethylsalicylideneaminato ligand, $[Cu(sal\cdot Et)NO_3]_2$, in which the metal ions are five-coordinated with four strong bonds and a weak fifth bond with a nitrato oxygen to complete a rough square-pyramid.[7] Complexes **2** and **3** show a broad band at *ca.* 10000 cm^{-1}: a spectral feature indicative of a five-coordination around the metal ion (Fig. 2).

All these results indicate that the complexes in the present study have a phenolic oxygen-bridged dimeric structure with a five-coordinated Cu(II) geometry. The most probable structures are shown in Fig. 3.

The $-2J$ values determined for the present complexes are more than twice those of $[Cu(sal\cdot pr\cdot NMe_2)X]_2$ ($-2J_{X=Cl}=248$ and $-2J_{X=Br}=260$ cm^{-1}),[1] to which a phenolic oxygen-bridged dimeric structure with the metal ions in a five-coordinated, essentially trigonal bipyramidal, geometry was previously assigned.[1] This result may be taken as evidence in favor of the previous conclusion that the strength of antiferromagnetic interaction in five-coordinated copper(II) dimers containing a $Cu\begin{smallmatrix}O\\O\end{smallmatrix}Cu$ bridging system decreases as the distortion of Cu(II) geometry from square-pyramid toward trigonal-bipyramid increases.[1] On the basis of the difference between the assumed structures, the pronounced difference in magnetic interaction can be explained as follows. In the square pyramidal coordination around the Cu(II) ions in the dimeric species shown in Fig. 3, the overlap of singly occupied $3d_{xy}$ orbitals of the two Cu(II) centers with the oxygen $2p_x$ orbital may yield an efficient pathway for superexchange (*cf.* the coordinate system given in Fig. 3).[8,9] However, a distortion of the Cu(II) geometry from square-pyramid toward trigonal-bipyramid will give rise to a decrease in successive orbital overlap of $Cu(d_{xy})$–$O(p_x)$–$Cu(d_{xy})$, leading to a weakening of spin-coupling, *i.e.*, a decrease in $|-2J|$ value.

The Synthesis of Anthglutin and Its Analogues

Takeshi KINOSHITA,* Hiroko WATANABE, and Sadamasa MINATO†

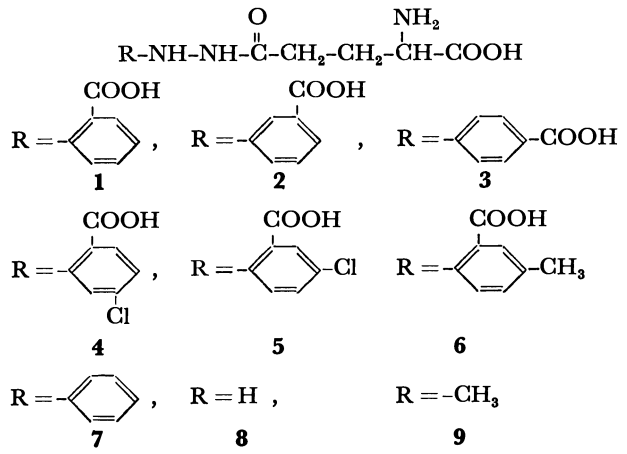
Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140

† *Fermentation Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140*

(Received August 6, 1980)

Synopsis. Anthglutin (1-γ-L-glutamyl-2-(2-carboxyphenyl)hydrazine) and its analogues were synthesized. Their inhibitory activity on γ-glutamyl transpeptidase was measured. 2-Carboxyphenyl derivatives, including anthglutin, showed inhibitory activity, while the other derivatives did not. The 2-carboxyl group seems to be essential for the inhibitory activity.

In previous papers,[1,2] we reported that anthglutin, an inhibitor of γ-glutamyl transpeptidase, was isolated from a cultured medium of Penicillium oxalicum, and Structure (**1**), 1-γ-L-glutamyl-2-(2-carboxyphenyl)hydrazine, was proposed. We have confirmed the structure of anthglutin by the synthesis of 1-γ-glutamyl-2-(2-carboxyphenyl)hydrazine (**1**).



Several compounds related to anthglutin were synthesized and measured for their inhibitory activity on γ-glutamyl transpeptidase (Tables 1 and 2). 2-Carboxyphenyl hydrazine derivatives (**4**—**6**) inhibited an enzyme activity, showing that the 2-carboxyl group of anthglutin is a functional group for the inhibitory activity. As has been shown in a previous paper,[1] the α-carboxyl and α-amino groups of the glutamyl moiety of anthglutin also seem to be essential for forming a complex between the inhibitor and the enzyme.

Experimental

Materials. Commercially available aminobenzoic acid derivatives were used. The *N-t*-BOC-L-glutamic acid α-benzyl ester was obtained from the Sigma Chemical Company. γ-Glutamyl transpeptidase was partially purified by the method of Orlowski and Meister;[3] it was thereby purified about 140-fold from the whole homogenate of the hog kidney.

Synthesis. Carboxyphenylhydrazine compounds were synthesized, according to the method described by Stephenson,[4] from the appropriate aminobenzoic acid compounds. 1-γ-L-Glutamyl-carboxyphenylhydrazine compounds were prepared by condensation between the N-*t*-BOC-L-glutamic acid benzyl ester and the appropriate free base form of the hydrazine, according to the method described by F. Hoffmann-La Roche & Co.[5]

1-γ-L-Glutamyl-2-(2-carboxyphenyl) hydrazine (1). 2-Carboxyphenylhydrazine (0.96 g, 6.31 mmol), the *N-t*-BOC-L-glutamic acid α-benzyl ester (1.05 g, 3.11 mmol), and triethylamine (0.6 ml) were dissolved in dichloromethane (10 ml). To the solution we then added dicyclohexylcarbodiimide (0.88 g, 4.53 mmol) dissolved in dichloromethane (1.0 ml), and the mixture was stirred for 3 h at room temperature. After removing the precipitate thus obtained by filtration, the filtrate was subjected to column chromatography on silica gel, eluting with chloroform–methanol–acetic acid (400:10:1). After the solvent had been removed *in vacuo* at 30 °C, the residue was dissolved in ethanol (20 ml) containing cyclohexene (1.0 ml). To the solution we added palladium–charcoal (5%, 400 mg), after which the mixture was refluxed for 1 h with stirring. The catalyst was removed

2-Carboxy-4-methylphenyl-(**6**)	8.7
Phenyl-(**7**)	>1000.0
N-Unsubstituted (**8**)	Not inhibit
Methyl-(**9**)	Not inhibit

In the presence of the analogues (6.5 μM), inhibition was determined according to a method described previously.[1] Substrate (γ-glutamyl-*p*-nitroanilide), 0.42—4.21 mM; acceptor(glycylglycine), 47.9 mM; enzyme, hog kidney γ-glutamyl transpeptidase; incubation, pH 8.5, 37 °C, 15 min.

by filtration, and the filtrate was evaporated *in vacuo* at 30 °C to dryness to give a white powder. The powder thus obtained was treated with trifluoroacetic acid (1.0 ml) and anisole (0.25 ml) for 1 h in an ice bath.[6] The reaction product was thus precipitated by the addition of ether (25 ml). The precipitate thus obtained was purified on a column of Dowex 2×8 (formate form) according to the method described previously.[1] The product thus obtained (210 mg) was identical with a sample of natural anthglutin (yield, 24%; mp 170—171.5 °C; UV (water): 243 and 322 nm (pH 2.0), and 240 and 307 nm (pH 7.0); $[\alpha]_D^{30}$: +22.6° (*c*, 0.9, 0.05 mol dm^{-3} HCl)), as established by paper chrcmatography and the inhibitory activity (Table 2). Found: C, 51.21; H, 5.32; N, 14.88%. Calcd for $C_{12}H_{15}N_3O_5$: C, 51.24, H, 5.38; N, 14.94%.

Analogues Anthglutin. Analogues of anthglutin (**2**—**6**) were synthesized by the procedure described above using the appropriate hydrazine compound.

The 1-γ-L-glutamyl hydrazine compounds (**7**—**9**) were prepared by condensation between L-pyroglutamic acid and the appropriate free-base form of the hydrazine compound, under reflux overnight in 85% ethanol, according to the method described by Yale *et al.*[7] The results thus obtained are shown in Table 1.

4-Dimethylaminopyridine *N*-Oxide as an Efficient Oxidizing Agent for Alkyl Halides

Shigemi MUKAIYAMA, Junji INANAGA, and Masaru YAMAGUCHI*

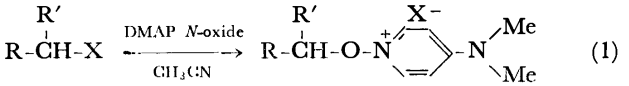
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received October 21, 1980)

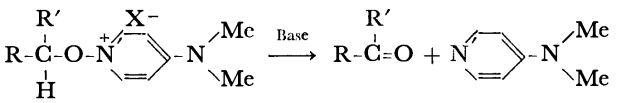
Synopsis. Various types of alkyl halides were converted into aldehydes or ketones in high yields with 4-dimethylaminopyridine *N*-oxide in the presence or absence of DBU.

Oxidation of alkyl halides with pyridine *N*-oxide[1] or trimethylamine *N*-oxide[2] has been known as a unique method to obtain carbonyl compounds. However, the former is only applicable to the relatively active substrates such as benzyl bromide[1a] because of the low nucleophilicity of pyridine *N*-oxide. While trimethylamine *N*-oxide can oxidize alkyl bromides and iodides, the yields are not satisfactory. In this paper is described the use of 4-dimethylaminopyridine *N*-oxide (DMAP *N*-oxide)[3] as an efficient oxidizing agent to afford aldehydes or ketones from primary or secondary alkyl halides, and α-keto esters from α-bromo esters, respectively.

The reaction was carried out in two steps, salt formation (1) and deprotonation (2).



(1)



(2)

X=Br or Cl

Acetonitrile was used as the solvent in which DMAP *N*-oxide was moderately soluble and 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) proved to be the best base for the deprotonation step (2). Alkyl halides were refluxed with the *N*-oxide in acetonitrile until the substrates were consumed, and then DBU was added. The reaction was followed by GLC by using appropriate internal standards. The results are summarized in Table 1.

Benzylic halides were easily oxidized to give the corresponding carbonyl compounds in quantitative yields. Primary alkyl halides (bromide and chloride) were converted into aldehydes. Secondary alkyl bromide also reacted to afford a ketone quantitatively. Cyclohexyl bromide, however, gave cyclohexanone in very low yield, and the formation of a large amount of cyclohexene was observed in the first step (1), though DMAP *N*-oxide is known to have a small pK_a value (3.88)[4] (entry 9).[5]

2-Formylpyridine was obtained in 82% yield by only heating 2-chloromethylpyridine hydrochloride[6] with three molar equivalents of the *N*-oxide in acetonitrile (entry 5).

Sliwa *et al.*[1b] reported the oxidation of α-bromo esters with pyridine *N*-oxide, but this method required the addition of silver nitrate to attain the effective formation of pyridinium salt. With 2.5 equivalents of DMAP *N*-oxide, however, α-bromo esters were rapidly oxidized to α-keto esters.

As is shown in Table 2, not only phenylglyoxylic acid ester but also aliphatic α-keto esters were produced in high yields.

Dimethyl sulfoxide is known to oxidize alkyl halides in a similar fashion.[7] However, it usually requires high reaction temperature (100—150 °C) and is only applicable to primary alkyl iodides, tosylates, or reactive substrates such as benzyl halides.[8] For the

oxidation of α-bromo ester by dimethyl sulfoxide, one example is reported.[9)]

The high yields, mildness of the reaction conditions, and applicability to wide variety of alkyl halides are considered to make the present method synthetically useful one.

Experimental

All starting alkyl halides are commercially available except for 2-chloromethylpyridine hydrochloride[6)] and α-bromo esters which were obtained by esterification of the corresponding α-bromo acids. Products were identified with authentic samples by the comparison of their NMR and/or GLC data.

Two typical examples of oxidation are described below.

Oxidation of 2-Bromopentane. A mixture of 2-bromopentane (38 μl), DMAP *N*-oxide (41 mg), and absolute acetonitrile (0.5 ml) was refluxed for 40 min. Then, DBU (57.3 μl) was added and the reflux was continued. After 16 h quantitative formation of 2-pentanone was observed on GLC by the addition of toluene as an internal standard.

Oxidation of Methyl 2-Bromooctanoate. A mixture of the bromo ester (167 mg), DMAP *N*-oxide (201 mg), and acetonitrile (2 ml) was refluxed for 35 min. After cooling 1.1 equivalents of hydrochloric acid in acetonitrile (1 ml) was added. The resulting mixture was passed through a short silica gel column, concentrated, and chromatographed on preparative TLC (SiO_2, Merck) with benzene giving methyl 2-oxopentanoate[10)] (103 mg, 85%). NMR ($CDCl_3$) δ 0.89 (t, J=5.0 Hz, 3H), 1.0—2.0 (m, 8H), 2.84 (t, J=7.0 Hz, 2H), and 3.88 (s, 3H).

This work was partially supported by a Grant-in-Aid for Scientific Research No. 443008 from the Ministry of Education, Science and Culture.

Alkylation of Thioureas and Related Compounds by Use of Alcohols, Diethyl Azodicarboxylate, and Triphenylphosphine

Hiroshi NAGASAWA and Oyo MITSUNOBU*

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received November 10, 1980)

Synopsis. The alkylation of ambident nucleophiles having a thiocarbonyl group by use of alcohols, diethyl azodicarboxylate, and triphenylphosphine was studied. Selective *S*-alkylation took place in the cases of *N*-benzoyl-*N'*-mono- and -disubstituted thioureas, while selective *N*-alkylation occurred in the reaction of *N*-phenyl-*N',N'*-diethylthiourea. 1-Methoxymethyl-2-thiouracil afforded both *N*-alkylated and *S*-alkylated products.

The reaction of either *N*-benzyloxycarbonylbenzamide[1] or ethyl acetoacetate[2] with an alcohol, diethyl azodicarboxylate (**1**), and triphenylphosphine (**2**) mainly gives *O*-alkylated products. The results indicate that the triphenylalkoxyphosphonium salt formed as a key intermediate of the present reaction[3] is a harder alkylating reagent than alkyl halides or alkyl tosylates.[4]

In order to examine the present alkylating system, we studied the alkylation of other ambident nucleophiles, *N*-acylthioureas and 1-methoxymethyl-2-thiouracile, ambident at N, S, and O, being chosen as reagents.

A series of *N*-benzoylthioureas, PhCO–NH–CS–NR^1R^2 with R^1=H, R^2=*t*-butyl (**3**), R^1=H, R^2=cyclohexyl (**4**), and $R^1=R^2$=ethyl (**5**) was prepared by the reaction of benzoyl isothiocyanate with amines. The reaction of 2-phenylethanol with **3**, **4**, and **5** in the presence of 1.5 molar equivalents each of **1** and **2** proceeded smoothly at room temperature giving the corresponding *S*-alkylated products (**6a**, **7a**, and **8a**) in good to excellent yields (Table 1).[5] The structure was confirmed by the reaction of the products with ammonia at room temperature, the corresponding *N*-benzoylguanidines and bis(2-phenylethyl) disulfide being isolated (Table 2). The reaction of **5** with **1**, **2**, and 2-phenoxyethanol also gave *S*-alkylated product (**8b**) almost quantitatively.

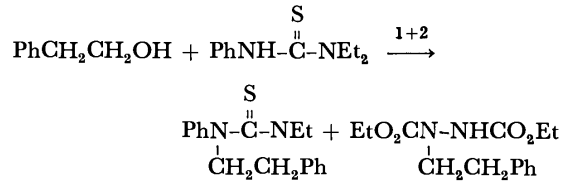
9

Selective *S*-alkylation also took place when sodium salt of **5** was treated with 2-phenylethyl bromide in tetrahydrofuran. Compound **8a** was obtained in 38% yield and 59% of **5** was recovered.

When primary, secondary-diol was allowed to react with **1**, **2**, and **5**, the primary hydroxyl group predominantly reacted to give 2-(hydroxylakyl)isothiourea (**8c**, **8d**). 2,5-Hexanediol also gave 2-(1-methyl-4-hydroxypentyl)isothiourea (**8e**). No detectable amount of bis(amidinothio) derivatives (**9**) could be obtained by preparative layer chromatography.

Contrary to the case of *N*-benzoylthioureas, the reaction of *N*-phenyl-*N',N'*-diethylthiourea with 2-phenylethanol, **1**, and **2** resulted in the formation of *N*-alkylated product in 48% yield rather than *S*-alkylated product. Diethyl 1-phenethyl-1,2-hydrazinedicarboxylate was isolated in 26% yield.



The alkylation of 1-methoxymethyl-2-thiouracil (**10**),[6] a cyclic analogue of **5**, with 2-phenylethanol in the presence of **1** and **2** resulted in the formation of *N*-alkylated (**11**) and *S*-alkylated (**12**) products in 64% and 18% yields, respectively.[7] The change in solvent scarcely affected the product ratio.

Experimental

Alkylation of Thiocarbonyl Compounds. A solution of **1** (259 mg, 1.5 mmol) in tetrahydrofuran (THF, 2 ml) was added dropwise over a period of 15 min to a solution of a thiocarbonyl compound (1 mmol), an alcohol (1 mmol) and **2** (392 mg, 1.5 mmol) in THF (5 ml) at room temperature. After the solution had been stirred for 18 h, the solvent was removed and products were isolated by preparative layer chromatography (Merck PF_{254} 20 cm × 30 cm). The results are summarized in Table 1.

*Ammonolysis of **8a**.* Compound **8a** (215 mg, 0.6 mmol) was treated with ammonia saturated in methanol (10 ml) at room temperature for 72 h. After evaporation, *N*-benzoyl-*N'*,*N'*-diethylguanidine and diphenethyl disulfide were isolated by preparative layer chromatography in 51% and 81% yields, respectively.

*Alkylation of **10**.* A solution of **1** (519 mg, 3 mmol) in THF was added dropwise over a period of 30 min to a solution of **10** (345 mg, 2 mmol), 2-phenylethanol (243 mg, 2 mmol) and **2** (785 mg, 3 mmol) in a mixture of THF (6 ml) and DMF (2 ml) at room temperature. After the solution had been stirred at room temperature for 16 h, **11** and **12** were obtained by preparative layer chromatography (benzene–AcOEt=1:1) in 60% and 17% yield, respectively.

Compound **11** was recrystallized from petroleum ether (bp 30—60 °C); mp 73—75 °C. UV_{max} (MeOH) 282 nm. NMR ($CDCl_3$, 60 MHz) δ 2.75—3.2 (m, $PhCH_2$), 3.35 (s, CH_3), 4.4—4.85 (m, CH_2CH_2N), 5.5 (s, OCH_2), 5.95 (d, N–CH=), 7.1—7.5 ppm (d, O=C–CH= and m, Ph).

Compound **12** was recrystallized from CCl_4; mp 110—113 °C. UV_{max} (MeOH) 238 nm. NMR ($CDCl_3$) δ 2.75—3.2 (m, $PhCH_2$), 3.2—3.7 (s, CH_3, superimposed on m, SCH_2), 5.97 (d, N–CH=), 7.25 (s, Ph), 7.35 ppm (d, O=C–CH=).

7) 1-Methyl-2-methylthio-4(1*H*)-pyrimidinone exhibits UV_{max}(MeOH) 231 nm.[6] Thus the alkylated product which absorbs light at 238 nm was assigned to be **12**.

The Direct Alkylamination of α-Substituted Anthraquinones Promoted by Metal Ions

Masaru MATSUOKA,* Toshio TAKEI, Isao NAKAMURA,
Katsuhira YOSHIDA,† and Teijiro KITAO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591
† *Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780*

(Received December 4, 1980)

Synopsis. The reaction of 1-amino-4-acylaminoanthraquinones with piperidine in the presence of $CoCl_2$ and atmospheric oxygen gave the 2-aminated products in 75—80%, and similar reaction of 1-hydroxyanthraquinone or 1-aminoanthraquinone-2-sulfonic acid with butylamine gave the corresponding 4-aminated products, respectively. The effects of the α-substituents and the role of metal salts were discussed.

In our previous papers,[1-3] the new metal-promoted direct aminations of anthraquinone nucleus were reported. These are useful methods to prepare some aminoanthraquinone (aminoAQ) derivatives as dyes and dye intermediates.

In this paper, these metal-promoted direct aminations were applied to each of 1,4-diaminoAQs, 1-aminoAQ-2-sulfonic acid, and 1-hydroxyAQ which are the important intermediates for the preparation of some anthraquinonoid dyes.

The results of the reaction of 1,4-diaminoAQs with piperidine are shown in Scheme 1 and Table 1. The reaction of **1a** with piperidine resulted only in recovery of **1a** (Run 1). While, 1-amino-4-acylaminoAQs (**1b** and **1c**) gave the corresponding 2-aminated product (Runs 2 and 3). In the case of **1b**, hydrolysis of the 4-acetylamino group of **2b** was observed during the reaction, forming **2a** in 49.5%. The amination site of **1b** and **1c** were determined by ^{1}H-NMR spectra; the proton at 3(or 2)-position of **2a** was found at 6.40 ppm, while those of **2b** and **2c** were shifted downfield to 8.60, 8.66 ppm respectively, because of the deshielding effect of the neighboring 4-acylamino group. 1,4-Bis(benzoylamino)AQ (**1d**) did not react with piperidine, and **1d** was recovered in 93.6% (Run 4). These results imply that the mechanism of the 2-amination of **1** is the same as our previous case of 1-aminoAQ;[1] activation of 2-position by the formation of cobalt complex and reduction by 4-acylation in deactivating ability of 4-amino group play a cooperative roll for formation of 2-aminated products. Diacylation (**1d**) results in losing the ability of the complex formation and the amination does not take place.

TABLE 1. THE REACTION OF **1** WITH PIPERIDINE[a]

Run	Reactant	Time/h	**1**(Recovered)	Products (yield/%)
1	**1a**	50	94.0	None
2	**1b**	24	Trace	**2a** (49.5), **2b** (31.5)
3	**1c**	15	5.5	**2c** (74.5)
4	**1d**	50	93.6	None

a) Reactant (**1**, 2.92 mmol) was stirred with piperidine (50 ml) in the presence of $CoCl_2$ (2.92 mmol for **1b**—**1c**, 5.84 mmol for **1a**) at 30 °C.

The reaction of 1-aminoAQ-2-sulfonic acid (**3**) with butylamine gave the 4-aminated product (**4**), which is a very important compound as dye intermediate. In industry, **4** is produced by two-step method;[4] the bromination of **3** followed by the Ullmann amination of **6** (Path B in Scheme 2). Thus, the direct 4-amination of **3** affords a useful method for preparation of **4** (Scheme 2). The results are summarized in Table 2. Without $CoCl_2$, the amination did not take place at all (Runs 5 and 9). In the presence of $CoCl_2$, **3** gave rise to **4** in 23% yield together with 43% recovery of **3** (Run 6). The increase in molar ratio of $CoCl_2$ rather depressed the yield of **4** and a trace amount of **5** was formed along with **4** (Run 8). The yield of **4** could not be improved at higher temperature (Run 7).

The reaction of **7** with butylamine mainly afforded three products as shown in Scheme 3. The results are summarized in Table 3. The reaction hardly proceeded at room temperature (Run 15) and was carried out at 80 °C. Without metal salts, the reaction scarcely proceeded (Run 11), but an addition of $CoCl_2$ gave **9** in 23% and **10** in 2.4% yield together with 4-butylated product (**8**) in 48% yield (Run 12). A novel butylation of **7** at 4-position forming **8** was observed, but the mechanism was not obvious. The reaction did not proceed smoothly without solvent (Run 13). In the presence of $CuCl_2$, the reduction of copper ion to metal copper occured quantitatively, and a small amount of **8** (11%) and **10** (3%) were yielded (Run 14). From these results, it was concluded that the 4-amination of **7** hardly proceeds because of the

A Novel Synthesis of Phenyl Carboxylates

Shizunobu HASHIMOTO and Isao FURUKAWA*

Department of Applied Chemistry, Doshisha University, Karasuma-imadegawa, Kamigyo-ku, Kyoto 602

(Received December 12, 1980)

Synopsis. The direct synthesis of phenyl carboxylates from phenols and carboxylic acids is reported. The reactions proceeded easily when triphenylphosphine and carbon tetrachloride were used as dehydrating agents in the presence of a tertiary amine at room temperature, thus giving esters in high yields.

It has been known that the direct synthesis of phenyl carboxylates from carboxylic acids and phenols usually fails in the presence of common mineral acids. Therefore, the reaction has been carried out by using a special catalyst such as polyphosphoric acid,[1] a combination of boric acid and sulfuric acid,[2] and polymer-protected aluminium chloride[3] under heating. However, these methods can not be applied to the esters, which are unstable to heat and acid.

We have now investigated the direct acylation of phenols with acids under mild conditions, and have found that the reaction proceeds easily to form phenyl carboxylates when a combination of triphenylphosphine and carbon tetrachloride is used as the dehydrating agent in the presence of triethylamine. The results are shown in Table 1.

Although the reaction proceeded easily at room temperature to give esters in high yields, phenol and acid having a nitro group afforded the esters in a poorer yield because of the simultaneous formation of a colored matter from the phosphine and nitro compound.

Ester formation by the use of triphenylphosphine and carbon tetrachloride was investigated by Appel[4] for the esterification of an alcohol with a carboxylic acid. In this case, a high yield is obtained only when alcohol is added as the last component after reacting phosphine, carboxylic acid, and carbon tetrachloride in the presence of tertiary amine, when the alcohol and acid are added simultaneously into a mixture of phosphine, carbon tetrachloride and tertiary amine, the yield of the ester decreases because of the simultaneous formation of both alkyl halide and ester. On the other hand, the acylations of phenols with carboxylic acids in our work gave only esters in high yields, even when all reactants were reacted simultaneously. This difference may be attributed to the fact that phenol attacks selectively only the carbonyl carbon in the acyloxyphosphonium salt [II] assumed as an intermediate, while alcohol attacks both the phosphorus and the carbonyl carbon.[4]

From these results, we concluded that the esterification of phenols with carboxylic acids in the presence of a tertiary amine, when triphenylphosphine and carbon tetrachloride are used as dehydrating agents, proceeds through the process shown in the following scheme:

$$Ph_3P + CCl_4 \longrightarrow Ph_3\overset{+}{P}CCl_3 \cdot Cl^- \quad [I]$$

Experimental

All the melting and boiling points are uncorrected. All the chemicals used were of an analytical reagent grade. Thin-layer chromatography (TLC) was performed on Merck's silica gel 60 (70—230 mesh). The IR spectra were recorded in KBr on a Shimazu IR-27C spectrometer, and the MS, on a Hitachi RM-50GC spectrometer with 60 eV.

Procedure. A mixture of benzoic acid (24 mmol), phenol (20 mmol), carbon tetrachloride (24 mmol), triethylamine (24 mmol), and triphenylphosphine (24 mmol) in 30 ml of acetonitrile was stirred at room temperature for 4 h. After the acetonitrile has been evaporated, hexane was added to the residue. The hexane solution was filtered off to remove the triphenylphosphine oxide and triethylamine hydrochloride precipitated, washed with an aqueous sodium hydroxide solution, and dried over anhydrous sodium sulfate, and then the hexane was removed. Subsequent distillation or recrystallization of the residual solid gave 3.6 g of phenyl benzoate (91% yield) as white crystals: mp 70—71 °C. A similar procedure has been applied successfully to a variety of substituted phenols, aliphatic, and aromatic carboxylic acids. The resulting products were identified by means of infrared and mass spectral analysis.

A Novel Preparation of Bicyclo[3.2.2]nonanes and Bicyclo[4.2.2]decanes Substituted at the Bridgeheads

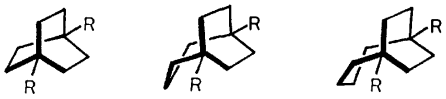
Yasuo SAKAI,* Kaoru TERASHIMA, Yoshito TOBE, and Yoshinobu ODAIRA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received December 23, 1980)

Synopsis. A novel preparation of 1,5-disubstituted bicyclo[3.2.2]nonanes and 1,6-disubstituted bicyclo[4.2.2]-decanes based on the one-pot reaction of [3.2.2]- and [4.2.2]-propellanecarboxylic acids with 2 equiv. of lead tetraacetate, followed by catalytic hydrogenation, is described.

The bicyclo[n.2.2]alkanes, having substituents on each bridgehead carbon atom, are of importance as models for examining through–bond and/or through–space orbital interactions and as a key intermediate for the synthesis of paddlanes.[1] Syntheses of the 1,4-disubstituted bicyclo[2.2.2]octanes (**1**) have been described.[2] However, only a few methods have been worked out for the higher homologues, bicyclo[3.2.2]-nonanes and bicyclo[4.2.2]decanes substituted at the bridgeheads.[2a,3] We have found that the oxidative decarboxylation of [4.2.2]propellanecarboxylic acid (**5**) with lead tetraacetate (Pb(IV)) gives rise to the formation of the cyclopropylcarbinyl type tricyclic acetate (**7**) in high efficiency.[4] Since the oxidation of highly strained bicyclo[*n*.1.0]alkanes with Pb(IV) proceeds with exclusive internal bond cleavage of cyclopropane ring,[5] it may be reasonable to expect the formation of 1,6-disubstituted bicyclo[4.2.2]decane derivatives such as **9** by the reaction of **7** with Pb(IV). In this connection, we wish to report a novel preparation of 1,5-disubstituted bicyclo[3.2.2]nonanes (**2a**, **b**) and 1,6-disubstituted bicyclo[4.2.2]decanes (**3a**, **b**) based on

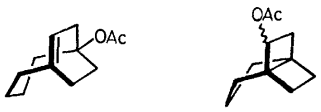


1 **2a** R=OAc, **2b** R=OH **3a** R=OAc, **3b** R=OH

the one-pot reaction of [3.2.2]- and [4.2.2]propellanecarboxylic acids (**4**) and (**5**) with Pb(IV), comprising two successive oxidations by Pb(IV), *i.e.*, oxidative decarboxylation of **4** and **5**, affording the strained tricyclic acetates (**6**) and (**7**), and subsequent oxidative cleavage of internal cyclopropane bond of **6** and **7** leading to the unsaturated diacetates (**8**) and (**9**), followed by catalytic hydrogenation (Scheme 1).

The reaction of **7** with Pb(IV) was examined. When **7** was treated with 1.2 equiv. of Pb(IV) in benzene at 80 °C for 14 h, the bridgehead diacetate (**9**) was obtained as a major product in 76% yield along with 6-acetoxybicyclo[4.2.2]dec-1(8)-ene (**10**)[6] (17%).[7] The structure of **9** was elucidated by the presence of a two-proton singlet at δ 5.83 ppm in the ^{1}H NMR spectrum and the ^{13}C NMR spectrum which showed only seven signals involving a two-carbon doublet at δ 131.56 ppm in the off-resonance decoupled spectrum. No detectable amounts of the triacetates from internal bond cleavage and/or the external bond cleavage products were formed.

The direct preparation of **9** from [4.2.2]propellanecarboxylic acid (**5**) by an one-pot procedure involving two successive Pb(IV) oxidations was attempted. When the reaction of **5** with 2.5 equiv. of Pb(IV) in benzene was carried out at 80 °C for 20 h, the expected product (**9**) was obtained in 58% yield together with **10** in 13% yield.



10 **11**

In order to prepare 1,5-disubstituted bicyclo[3.2.2]-nonanes, the reaction of [3.2.2]propellanecarboxylic acid (**4**) with 1.2 equiv. of Pb(IV) was examined. After 1 h, the bridgehead diacetate (**8**) was obtained as a major product in 47% yield along with the unrearranged 6-acetoxy[3.2.2]propellane (**11**) in 11% yield, while the tricyclic acetate (**6**) could not be detected even in a shorter reaction time. Similarly, the structure of **8** was determined by the ^{1}H NMR (a two-proton singlet at δ 6.04 ppm) and ^{13}C NMR spectra (seven signals involving a two-carbon doublet at δ 132.54 ppm in the off-resonance spectrum). In view of the fact that a considerable amount (30%) of the unreacted acid (**4**) was recovered, it can be assumed that **8** was formed by rapid oxidation of unstable intermediate (**6**) by Pb(IV) as in the case of **7**.

The catalytic hydrogenation of **8** and **9** over Pd/C gave **2a**, mp 72—73 °C, and **3a**,[6] mp 100—102 °C, respectively, in quantitative yields. The reductive cleavage of the diacetates (**2a**) and (**3a**) by lithium

Scheme 1.

aluminum hydride afforded the corresponding diols (**2b**), mp 139—140 °C, and (**3b**), mp 158—160 °C, in moderate yields.

Experimental

Reaction of the Acetate (7) with Pb(IV). A mixture of 91 mg (0.47 mmol) of **7**,[4] 25 mg (0.32 mmol) of pyridine, and 250 mg (0.56 mmol) of lead tetraacetate in 5 ml of benzene was heated at 80 °C with stirring under nitrogen for 14 h. After filtration, the filtrate was washed with 1 mol dm^{-3} hydrochloric acid, sodium hydrogencarbonate solution, and water, and then dried over anhydrous sodium sulfate (Na_2SO_4). Evaporation of the solvent gave 109 mg of light brown oil. The products were analyzed by GLC (10% FFAP and 5% SE-30 columns) and separated by silica-gel column chromatography.

9 (76%); IR 3030, 1715, 1225, 1040, 1000 cm^{-1}; MS *m/e* 252 (M^+); ^1H NMR (CCl_4) δ 1.10—2.60 (m, 18H, s at 1.92), 5.83 (s, 2H); ^{13}C NMR ($CDCl_3$) δ 22.31 (q), 23.24 (t), 29.84 (t), 40.41 (t), 81.36 (s), 131.56 (d), 170.16 (s). Found: C, 66.54; H, 7.99%. Calcd for $C_{14}H_{20}O_4$: C, 66.64; H, 7.99%.

Reaction of [4.2.2]Propellanecarboxylic Acid (5) with Pb(IV). A mixture of 504 mg (2.6 mmol) of **5**,[4] 119 mg (1.5 mmol) of pyridine, and 2.88 g (6.5 mmol) of Pb(IV) in 40 ml of benzene was heated at 80 °C for 20 h. 606 mg of light brown oil was obtained by a similar work-up to that described above. The products were analyzed and separated as above.

Reaction of [3.2.2]Propellanecarboxylic Acid (4) with Pb(IV). A mixture of 2.40 g (14 mmol) of **4**,[3] 670 mg (8.5 mmol) of pyridine, and 8.36 g (17 mmol) of Pb(IV) in 120 ml of benzene was heated at 80 °C for 1 h. The same work-up as above gave 1.89 g of a product mixture, 860 mg (30%) of unreacted **4** being recovered by acidification of the sodium hydrogencarbonate washings followed by ether extraction. The products were analyzed and separated as above.

8 (47%); IR 3030, 1715, 1230, 1190, 1010 cm^{-1}; MS *m/e* 238 (M^+); ^1H NMR (CCl_4) δ 1.60—2.35 (m, 16H, s at 1.91), 6.04 (s, 2H); ^{13}C NMR ($CDCl_3$) δ 20.80 (t), 22.08 (q), 28.87 (t), 34.25 (t), 80.82 (s), 132.54 (d), 169.95 (s). Found: C, 65.50; H, 7.63%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%.

11 (11%; a mixture of epimers); IR 1725, 1220, 1020 cm^{-1}; MS *m/e* 180 (M^+); ^1H NMR (C_6D_6) δ 1.28—2.64 (m, 15H), 4.80 (t, 0.5H), 5.20 (t, 0.5H). Found: C, 73.03; H, 9.09%. Calcd for $C_{11}H_{16}O_2$; C, 73.30; H, 8.95%.

Catalytic Hydrogenation of 8 and 9. **8** and **9** were hydrogenated under atmospheric pressure of hydrogen over 5% Pd/C catalyst in methanol solvent to give **2a** and **3a**,[6] respectively, in quantitative yields. Pure samples of **2a** and **3a** were obtained by recrystallization from hexane–ether.

2a; mp 72—73 °C; IR 1715, 1235, 1200, 1000, 970 cm^{-1}; MS *m/e* 180 (M^+—AcOH); ^1H NMR (CCl_4) δ 1.60—2.40 (m, s at 1.92); ^{13}C NMR ($CDCl_3$) δ 20.02 (t), 22.35 (q), 30.65 (t), 38.54 (t), 82.51 (s), 170.04 (s). Found: C, 64.88; H, 8.52%. Calcd for $C_{13}H_{20}O_4$: C, 64.98; H, 8.39%.

3a; mp 100—102 °C; IR 1715, 1230 cm^{-1}; MS *m/e* 252 (M^+—2), 134 (M^+—2AcOH); ^1H NMR (CCl_4) δ 1.20—2.60 (m, s at 1.88); ^{13}C NMR ($CDCl_3$) δ 22.02 (q), 22.90 (t), 30.97 (t), 38.70 (t), 83.56 (s), 169.33 (s). Found: C, 65.76; H, 8.71%. Calcd for $C_{14}H_{22}O_4$: C, 66.11; H, 8.72%.

Lithium Aluminum Hydride Reduction of 2a and 3a. To a suspension of 1.5 equiv. of lithium aluminum hydride in ether was added dropwise a solution of **2a** or **3a** in the same solvent, the mixture being stirred at room temperature for 2 h. Water and then 1 mol dm^{-3} hydrochloric acid were added carefully. The organic layer was separated and washed with saturated sodium chloride solution and dried over Na_2SO_4. The aqueous layer was extracted with chloroform, the chloroform extracts being washed with saturated sodium chloride solution and dried (Na_2SO_4). Evaporation of both solvents gave **2b** and **3b** as white solids in 60—65% yields which were recrystallized from ether.

2b; mp 139—140 °C; IR 3250, 1030 cm^{-1}; MS *m/e* 156 (M^+); ^1H NMR ($CDCl_3$) δ 1.50—2.20 (m). Found: C, 69.11; H, 10.36%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%.

3b; mp 158—160 °C; IR 3250, 1060, 980 cm^{-1}; MS *m/e* 170 (M^+); ^1H NMR ($CDCl_3$) δ 1.40—2.20 (m). Found: C, 70.34; H, 10.71%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

Studies on Biologically Active Pteridines. VI.[1] Biopterin Conjugated to β-D-Galactosidase and Bovine Serum Albumine

Sadao MATSUURA,* Takashi SUGIMOTO, and Toshiharu NAGATSU†

Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464

† *Laboratory of Cell Physiology, Department of Life Chemistry, Graduate School at Nagatsuta, Tokyo Institute of Technology, Midori-ku, Yokohama 227*

(Received January 16, 1981)

Synopsis. 4-Hydroxy-6-(L-*erythro*-1,2-dihydroxypropyl)-2-(methylthio)pteridine was converted by ethylenediamine to 2-(2-aminoethylamino)analogue of biopterin, which condensed with *N*-hydroxysuccimidyloxy *m*-maleimidobenzoate to give the maleimidobenzamide. The latter compound and β-D-galactosidase afforded a biopterin-galactosidase conjugate which showed the enzyme activity about 40% as compared to the unmodified enzyme.

The biosynthesis of neurotransmitting dopamine and serotonine from phenylalanine and tryptophan requires tetrahydrobiopterin cofactor at the oxygenation step of these amino acids. Therefore, a decrease of biopterin concentration in those tissues generating the neurotransmitting amines may cause neurological disorders. Several examples to support such assumption have been found recently: atypical hyperphenylalaninemia due to deficiency of biopterin[2] and anormalous low biopterin concentrations in human brain from parkinonian patients.[3] Consequently, assay of biopterin in tissue or serum becomes essential for basic and clinical studies of such diseases.

We have recently developed a radioimmunoassay for biopterin, which makes a merit of high specificity, sensitivity, and reproducibility.[4] The method, however, suffers from a disadvantage of using a radioactive antigen. In order to avoid this inherent drawback of radioimmunoassay, we aimed to develop an enzymeimmunoassay for biopterin by using a conjugate of biopterin to β-D-galactosidase as a labelled antigen. This paper describes a synthesis of biopterin conjugated to the galactosidase and to bovine serum albumine (BSA), of which the latter is to be used as an immunogenic antigen.

Previously we synthesized a biopterin-BSA conjugate by a mixed anhydride method, in which 6-(biopterinylamino)caproic acid was condensed to the free amino group of the protein *via* an anhydride and the condensation product was treated with 2 M sodium hydroxide at the final step of preparation.[4] This anhydride method is inapplicable to the present required biopterin-galactosidase conjugate, because alkaline treatment may inactivate the enzyme. Accordingly we sought for a different conjugation method and applied *N*-hydroxysuccimidyloxy *m*-maleimidobenzoate (MBS)[5] to conjugating biopterin to the mercapto groups of galactosidase and BSA. The enzyme contains a number of mercapto groups unconcerned with the enzyme activity and hence the conjugation of biopterin at such sites will not reduce the enzyme activity.

4-Hydroxy-6-(L-erythro-1,2-dihydroxypropyl)-2-(methylthio)pteridine (**1**)[6] underwent aminolysis on heating with ethylenediamine to give the 2-(2-aminoethylamino) analogue (**2**), which was then converted to the *m*-maleimidobenzoyl derivative (**3**) by MBS. Conjugation of **3** with BSA was achieved by incubating BSA with a large excess **3** in a pH 7 phosphate buffer at 25 °C for 1.5 h, and the product was purified by chromatography on Sepharose 6B (Fig. 1). The number of moles of biopterin per mole of BSA was estimated 0.66 from the UV and fluorescence spectra. Conjugation of **3** to β-galactosidase was carried out

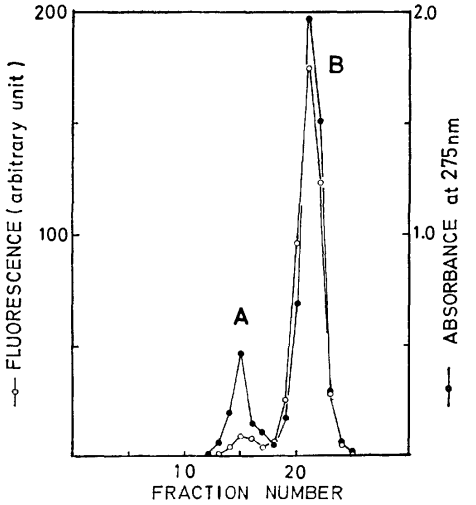

Fig. 1. Purification of biopterin-BSA conjugate on a Sepharose 6B column (1.8×30 cm) eluted by 0.05 M phosphate buffer, pH 7.0. The volume of each fraction was 5 ml. The intensity of fluorescence at 440 nm was measured by exciting at 360 nm. A: Conjugate, B: excess **3**.

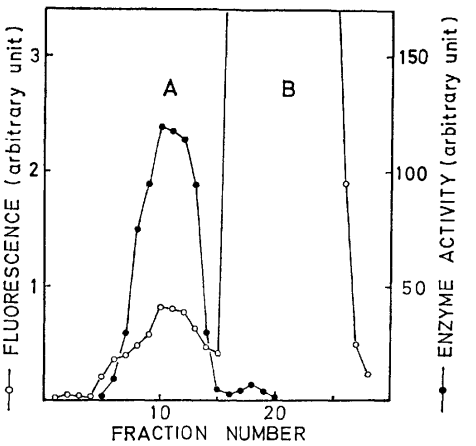

Fig. 2. Purification of biopterin-galactosidase conjugate on Sepharose 6B carried out in the same way as in Fig. 1. The enzyme activity was assayed as described in text.

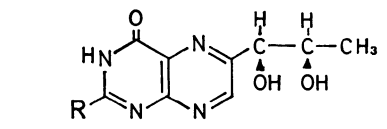

R

1 -S CH3

2 -NH CH2CH2NH2

3 -NH CH2CH2NH CO

4 -NH CH2CH2NH CO S-BSA

5 -NH CH2CH2NH CO S-βGAL

in the same way as above. The chromatography on Sepharose 6B was monitored by fluorescence spectra and by enzyme activity using 4-methylumbelliferyl β-D-galactoside as substrate.[7] As shown in Fig. 2, the enzymically active fractions show fluorescence due to the biopterin moiety, indicating a sucessful conjugation of **3** to galactosidase. The conjugate retained the enzyme activity about 40% as compared to the unmodified enzyme.

An enzymeimmunoassay for biopterin by employing the present synthesized conjugates is under progress and the detail will be reported elsewhere.

Experimental

*2-(2-Aminoethylamino)-4-hydroxy-6-(*L-erythro-*1,2-dihydroxypropyl)pteridine (2).* A solution of **1**[6] (500 mg) in ethylenediamine (5 ml) was heated at 110 °C under nitrogen for 4 h. The solution was fractionated on a Florisil column (2.5×30 cm), eluted gradiently with 0—3% ammonia (1.0 l), and then on a Dowex 50 W×8 column (2.5×20 cm), eluted with 0—3% ammonia. The eluate was evaporated to give a jellied residue, which on standing in a refrigerator for several days crystallized into a pale yellow needles (220 mg) of **2**. The compound darkened at 245 °C; pK_a at −1.0, 0.75, and 8.0 (measured by a spectroscopical method); λ_{max} (log ε) at H_o −3.0: 260 (4.08), 280 (sh., 3.99), 323 (3.65), and 392 (3.74); at H_o −0.25: 255 (4.11), 280 (3.96), 321 (3.75), and 392 (3.68); at pH 5.0: 261 (4.40), 350 (3.82); at pH 10.0: 240 (4.09), 277 (4.27), and 365 (3.88).

N-[*2-[4-Hydroxy-6-(*L-erythro-*1,2-dihydroxypropyl)-2-pteridinyl]-aminoethyl*]-m-*maleimidobenzamide (3).* To a solution of **2** (100 mg) in *N,N*-dimethylformamide (10 ml), MBS[5] (120 mg) was added and the solution was stirred at 25 °C for 2.5 h. The solution was then participated with water (40 ml) and dichloromethane (3×40 ml). The aqueous solution was evaporated *in vacuo* to almost dryness. Addition of tetrahydrofuran (1 ml) and chilling gave a solid (80 mg) of **3** which was used for the next reaction without further purification.

Preparation of Biopterin-BSA Conjugate (4). A solution of **3** (1 mg) in 0.5 ml of 0.1 M phsphate buffer, pH 7.0, was added to a solution of BSA (10 mg) in the same buffer (1 ml). The mixture was stirred at 25 °C for 1.5 h and then fractionated on a Sepharose 6B column (1.8×30 cm), eluted by a 0.05 M phosphate buffer, pH 7.0. The eluate was monitored by the fluorescence spectra and UV absorbance at 275 nm.

Preparation of Biopterin-galactosidase Conjugate (5). A solution of **3** (1 mg) in a 0.1 M phosphate buffer (pH 7.0, 0.5 ml) was added to a solution of β-D-galactosidase from E. Coli [EC 3.2.1.23] (1 mg) in the same buffer (1 ml), and the mixture was stirred at 25 °C for 2 h. Fractionation of the reaction products on a Sepharose 6B column (1.8×30 cm) using a 0.05 M phosphate buffer (pH 7.0) as solvent gave a chromatogram shown in Fig. 2. The enzyme activity was assayed as below.

Assay of β-D-Galactosidase Activity. A mixture of 4-methylumbelliferyl β-D-galactoside (1 mg/30 ml of 0.01 M phosphate buffer, pH 7.0; 50 μl) and 100 μl of each fraction diluted 50-fold by a 0.01 M phosphate buffer (pH 7.0) containing 0.1% BSA was incubated at 37 °C for 10 m. A 0.1 M glycine buffer (pH 10.3; 3 ml) was added to the mixture and the intensity of the fluorescence at 440 nm (excited at 360 nm) was measured on a Hitachi MPF-2A fluorescence spectrometer.

We thank Mrs. N. Nishioka for measuring the fluorescence spectra.

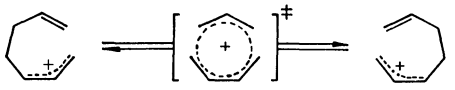
A Cationic [3,4] Sigmatropic Rearrangement[1)]

Mugio NISHIZAWA† and Ryoji NOYORI*
Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya 464
(Received February 3, 1981)

Synopsis. The first example of the cationic [3,4] sigmatropic reaction has been achieved by the reaction of 1,3-dibromo-3-methyl-6-hepten-2-one and diiron nonacarbonyl.

There is currently much interest in electrocyclic reactions which involve carbocations.[2)] In 1971, Dewar has predicted that the [3,4]sigmatropic rearrangement, **1a**⇄**1b**, may take place *via* cyclic six-electron transition state.[3)] However, realization of such symmetry-allowed transformation has not yet been reported to date, at least to our knowledge. Here we report the first example of this type of cationic rearrangement.



1a 1b

When the dibromo ketone **2** was treated with diiron nonacarbonyl in refluxing benzene, the dienone **3** was obtained as the sole isolable product, identical with authentic sample prepared independently. The reductive skeletal change is interpreted in terms of the title pericyclic process *via* the oxyallyl-Fe(II) intermediate **4** (R=H).[4)] The high stability of the resulting carboxonium ion **5** would facilitate the forward reaction. It should be noted that reaction course of the oxyallyl **4** is highly dependent on the substitution pattern of the internal olefinic bond. When the double bond is substituted by carbocation-stabilizing methyl groups, the cationic species **4** (R=CH_3) undergoes the stepwise, double cyclization to give (±)-camphor, **4**→**6**→**7**.[5,6)]

Experimental

2-Methyl-1,6-heptadien-3-one (3). A mixture of the dibromo ketone **2**[7)] (905 mg, 3.18 mmol) and diiron nonacarbonyl (2.13 g, 6.36 mmol) in dry benzene (12 ml) was heated at reflux for 2 h under argon atmosphere. The cooled mixture was filtered through a cotton-celite pad and the filtrate was concentrated under reduced pressure to give crude product (370 mg). The NMR and GLC analysis elucidated that this material contained **3** (80% GLC yield) and some unidentified minor products. An analytical sample (148 mg, 32%) was obtained by the preparative GLC (3% OV-1, 0.64×100 cm column, 100 °C). IR (neat) 3060 (=CH), 1680 (C=C), 1640 (C=C, enone), 1630 (C=C), 910 cm^{-1} (=CH). ^1H NMR (CCl_4) δ 1.85 (d, J=1.5 Hz, CH_3), 2.36 (t, J=7 Hz, =CHC$\underline{H}_2$), 2.70 (t, J=7 Hz, CH_2C=O), 4.94 (d, J=10 Hz, C$\underline{H}_2$=CHCH_2, a proton trans to CH_2), 4.98 (d, J=20 Hz, C$\underline{H}_2$=CHCH_2, a proton cis to CH_2), 5.70 (br s, C$\underline{H}_2$=CCH_3, a proton cis to CH_3), 5.80 (m, C$\underline{H}$=CH_2), 5.90 (s, C$\underline{H}_2$=CCH_3, a proton trans to CH_3). Found: *m/e* 124.08892. Calcd for $C_8H_{12}O$: (M^+), 124.08881.

2-Methyl-1,6-heptadien-3-ol (8). To a solution of 3-butenylmagnesium bromide prepared from 1-bromo-3-butene (1.5 g, 11.1 mmol) and magnesium (365 mg, 15 g-atom) in anhydrous ether (20 ml) was dropwise added a solution of methacrylaldehyde (770 mg, 11.1 mmol) in anhydrous ether (4 ml) over a period of 10 min at 0 °C. After stirring for 1 h at this temperature, aqueous saturated ammonium chloride (10 ml) was added, and the aqueous phase was extracted with ether. The combined organic materials was dried and concentrated. The resulting oil was subjected to column chromatography on silica gel using pentane–ether (8:1) as an eluent. The pure product was obtained as a colorless oil (1.21 g, 87%) after bulb-to-bulb distillation (110—118 °C, 15 mmHg). IR (neat) 3400 (OH), 3080 (=CH), 1640 (C=C), 910 cm^{-1} (=CH). NMR (CCl_4) δ 1.23 (s, OH), 1.76 (s, CH_3), 4.02 (t, H$\underline{C}$OH), 4.7—5.1 (m, 4H, =CH_2), 5.75 (m, C$\underline{H}$=CH_2). Found: C, 76.46; H, 11.27%. Calcd for $C_8H_{14}O$: C, 76.14; H, 11.18%.

Oxidation of 8. A suspension of the hydroxy compound **8** (150 mg, 1.19 mmol) and activated manganese dioxide (400 mg, 4.6 mmol) in pentane (3 ml) was stirred for 72 h at room temperature, and the resulting mixture was filtered through glass paper. The concentrated filtrate was subjected to column chromatography on silica gel using pentane–ether (50:1 and then 5:1) as an eluent to give 18 mg (12%, conversion yield 36%) of **3** and 101 mg (68%) of starting material **8**. The IR and NMR were identical with those of the product obtained from **2** and $Fe_2(CO)_9$.

Synthesis of Hypacrone

Fujio SAKAN,* Yukio MINAMI, Haruhisa SHIRAHAMA,† and Takeshi MATSUMOTO†

Department of Education, Fukui University, Fukui 910

† *Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060*

(Received October 3, 1980)

Synopsis. Hypacrone, an illudoid sesquiterpene, was synthesized from 2,2-dimethyl-4-(3,3-ethano-4,4-ethylenedioxy-1-methylsulfinyl-2-oxopentyl)-1-cyclopentanone which is a key intermediate also in the synthesis of illudins.

Reports were given on the total synthesis of illudins (**1**)[1] employing a sulfoxide **2**[2] as the key intermediate. In this report, we wish to describe the synthesis of another illudoid[3] sesquiterpene, hypacrone (**3**),[4] with use of **2**.

(5) R_1=  , R_2=

(6) R_1=  , R_2= O

Elimination of sulfenic acid was carried out by boiling sulfoxide **2** in toluene for 5 h, diketone **4** being obtained in quantitative yield. Methylation of easily enolizable diketone **4**[5] by means of methyllithium gave **5** which upon deacetalization with a catalytic amount of *p*-toluenesulfonic acid in acetone gave diketone **6**. The spectral data of **6** (IR and NMR) are identical with those of an authentic sample.[4b] The total synthesis of hypacrone (**3**) through **6** was already reported by Nishizawa *et al.*[4b]

Experimental

IR spectra were recorded with a Hitachi EPI-G3 spectrometer. NMR spectra were obtained at 100 MHz on a JEOL JNM-4H-100 instrument using TMS as an internal standard, mass spectra on a JEOL JMS-01SG-2 mass spectrometer.

Diketone ***4***. Sulfoxide **2**(200 mg) was boiled in toluene for 5 h. The resulting reaction mixture was washed with $NaHCO_3$ and then with a NaCl solution, and dried over Na_2SO_4. Removal of the solvent gave a practically pure product **4**(160 mg) which on chromatography on silica gel gave pure **4**(140 mg, 86%) as a slightly yellow oil: IR (neat) 3070, 1700, 1615 and 1045 cm^{-1}; NMR $\delta(CDCl_3)$ 1.10 (6H s and 4H, m), 1.15 (3H, s), 2.50 (2H, bs), 3.73 (2H, bs), 3.95 (4H, m), and 5.95 (1H, bs); MS (*m/e*) 278 (M^+); Anal. Found: C, 69.35; H, 7.82, Calcd for $C_{16}H_{22}O_4$: C, 69.04; H, 7.94%.

Enone ***5***. To a solution of **4**(180 mg) in dry ether (10 ml) was added a 0.8 M ether solution of MeLi (1.2 ml)[6] at −40 to −30 °C under nitrogen atmosphere. After stirring for 2 h the reaction was quenched with a NH_4Cl solution, extraction being carried out with $CHCl_3$. The extracts were washed with a NaCl solution, dried, and evaporated. The crude material was purified by chromatography on silica gel (AcOEt–benzene) affording unchanged **4** (120 mg, 70%) and methylated product **5** (20 mg, 10%) as a colorless oil: IR(neat) 3450, 1695, 1610, and 1045 cm^{-1}; NMR $\delta(CDCl_3)$ 1.07 (4H, m), 1.10 (6H, s), 1.25 (3H, s), 1.47 (3H, s), 2.52 (2H, bs), 2.75 (2H, bs), 3.95 (4H, bs), and 5.96 (1H, bs); MS(*m/e*) 276 (M^+-H_2O); Anal. Found: C, 69.25; H, 8.72, Calcd for $C_{17}H_{26}O_4$: C, 69.36; H, 8.90%.

Diketone ***6***. A solution of acetal **5** (15 mg) and *p*-TsOH (1 mg) in acetone (2 ml) was refluxed for 2 h and quenched with solid $NaHCO_3$. After filtration, the solution was evaporated. Purification of the crude material was carried out by preparative TLC (silica gel, $CHCl_3$–ether) to give the known diketone **6** as a colorless oil: MS(*m/e*) 250 (M^+).[4b]

Thanks are due to Prof. Yuji Hayashi, Osaka City University, for supplying the authentic sample of **6**.

Studies on the Complex Formation between *o*-Quinones and Metal Chlorides in Nitromethane Solution

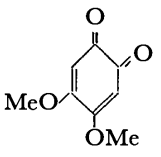
Kazuaki KATAOKA,* Sumihisa KIMURA, Fumiko SHIRAKAWA, and Yoshio SASAKI

Faculty of Pharmaceutical Sciences, Osaka University, Yamadakami 133-1, Suita, Osaka 565

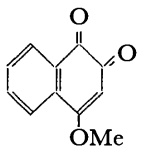
(Received June 21, 1980)

Complex formation between several kinds of metal chlorides and 4,5-dimethoxy-1,2-benzoquinone (**1**) or 4-methoxy-1,2-naphthoquinone (**2**) has been studied by means of NMR and spectrophotometry in CH_3NO_2. Stability constants of the 1 : 1 complex were found to decrease in the order of $SnCl_4 > InCl_3 > ZnCl_2 > BiCl_3 > SbCl_3 > HgCl_2$. $\Delta\delta_{ML}$ and $\Delta\nu_{max}$, which indicate the change in the chemical shift and the wavenumber on the formation of the 1 : 1 complex, were also arranged in the above order. The same order was reproduced from an electrostatic potential. Both $\Delta\delta_{ML}$ and $\Delta\nu_{max}$ were proved to be a convenient scale for the relative acceptor strength of metal chlorides. For the basicity of *o*-quinones, the order of **1**>**2** was obtained from the thermodynamic data and from the negative charge on the carbonyl oxygens. The solute-solvent interaction model was also found appliciable in this system.

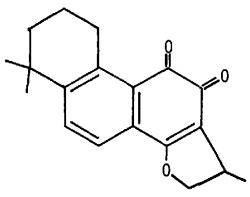
o-Quinones have been reported to form intensively colored complexes with various kinds of metal chlorides.[1,2] An extensive study of these complexes was first carried out by Crowley and Haendler.[2] However, few reports have been published on the study of these complexes in solution, since they are liable to decompose in aqueous and/or polar solvents. Some *o*-quinones having ether type oxygen, such as cryptotanshinone (**3**), were observed to form complexes with $FeCl_3$ in nonaqueous media, and they are more stable than the similar complexes of 1,2-naphthoquinone or 9,10-phenanthraquinone.[3] In the previous work,[4] the complex formation between **3** and some metal chlorides in CH_3CN was examined by spectrophotometry, and the shift of wavenumber $\Delta\nu_{max}$ of the ligand absorption band due to complex formation was correlated to the stability constant K_c. In that work, however, a partial disagreement was observed between the order of $\Delta\nu_{max}$ and that of K_c; this was interpreted by the solvation effect of CH_3CN. In this work, CH_3NO_2 is chosen as a solvent, because it has a modest solubility for the metal chloride and a smaller donor strength than CH_3CN (*e.g.*, the donor numbers of CH_3CN and CH_3NO_2 are 14.1 and 2.7, respectively[5]). 4,5-Dimethoxy-1,2-benzoquinone (**1**) and 4-methoxy-1,2-naphthoquinone (**2**) are used as ligands. ^1H NMR signals of 3,6-H in **1** and 3-H in **2** and absorption bands between 400 and 600 nm are examined in detail.



1



2



3

Experimental

Materials. **1** and **2** were prepared by the methods of Wanzlik[6] and Fieser,[7] respectively. 1,2,6,7,8,9-Hexahydro-1,6,6-trimethylphenanthro[1,2*b*]furan-10,11-dione (**3**) was isolated from the Chinese drug "Tan-shen" by Takiura.[8] Commercially available metal chlorides ($SnCl_4$, $InCl_3$, $SbCl_3$, $BiCl_3$, $ZnCl_2$, and $HgCl_2$) were purified by sublimation or distillation under reduced pressure. Commercially available CH_3NO_2 was purified by distillation after drying over $CaCl_2$, and the remaining water was removed by azeotropic distillation. Residual water in the rectified solvent was checked by the measurement of the degree of dissociation of **3**-$FeCl_3$ complex, which is liable to be decomposed by water,[3] and the data were found to be reproducible.

Preparation of Samples. In order to determine the stoichiometry by the continuous variation method, both solutions of ligand and metal chloride were prepared at the same concentration, and mixed in various ratios. For the determination of K_c, the solutions containing a fixed overall concentration of the ligand and a varying amount of the metal chloride were prepared: In the case of NMR, the concentrations of **1** and **2** were held constant at *ca.* 0.01 and 0.02 M (1 M=1 mol dm^{-3}), respectively, and the maximum concentration of the metal chloride was kept in the range of *ca.* 0.02 ($InCl_3$) to 0.13 M ($HgCl_2$). In the spectrophotometry, the concentrations of **1** and **2** were held constant at *ca.* 2.5×10^{-3} and 0.7×10^{-3} M, respectively, and the maximum concentration of the metal chloride was kept in the range of *ca.* 0.001 ($SnCl_4$) to 0.13 M ($HgCl_2$). The sample solutions were prepared by weight, and their final concentrations were calculated by taking the density of the solutions as equal to that of the pure solvent. These solutions were sealed in the NMR sample tubes or in the stoppered cells. All procedures described above were carried out in a dry box under N_2 atmosphere.

Measurements. Visible absorption spectra were measured on a Shimadzu UV-200 spectrophotometer at 34 °C. The change of absorbance due to complex formation was significant between 460 and 500 nm, and measurements were made at several wavelengths in this range. Proton NMR spectra were measured on a Hitachi R-22 spectrometer (90 MHz) at 34 °C. Chemical shifts of 3,6-H of **1** and 3-H of **2** were determined by a frequency counter within an error of ±0.1 Hz, relative to an internal reference TMS. Signals due to methoxyl groups were masked by the solvent peak. Variable temperature experiments of spectrophotometry were carried

out by using a Tajiri Kikai ECW-108 electronic cooling circulator in the range of 10 to 55 °C. Molar conductances of millimolar solutions of the metal chlorides in CH_3NO_2 were measured at room temperature on a Kyoto Denshi CM-07 conductivity meter. Λ/Ω^{-1} mol^{-1} cm^2: $HgCl_2$; 0, $ZnCl_2$; 1.7, $SbCl_3$; 2.6, $BiCl_3$; 2.4, $InCl_3$; 33.7, and $SnCl_4$; 21.8. The values of molar conductance of their complexes, which were prepared by adding an excess amount of the ligand to the solutions of the metal chlorides, were essentially unchanged from the above values.

Results and Discussion

Complex Formation between o-Quinones and Metal Chlorides in CH_3NO_2. Change of Spectra: **1** and **2** changed color from yellow to vermilion or red violet on addition of metal chloride in CH_3NO_2, suggesting formation of a complex. In the visible region, the absorption maxima of **1** and **2** due to the quinonoid π-π^* transition were observed at 407 and 400 nm, respectively. A typical example of the spectral change of **1** and **2** with metal chloride is shown in Fig. 1. The presence of isosbestic points in all systems except **2**+$InCl_3$ and **2**+$SnCl_4$ suggests the presence of only one kind of complex. It was found that the spectral change of **2** differed from

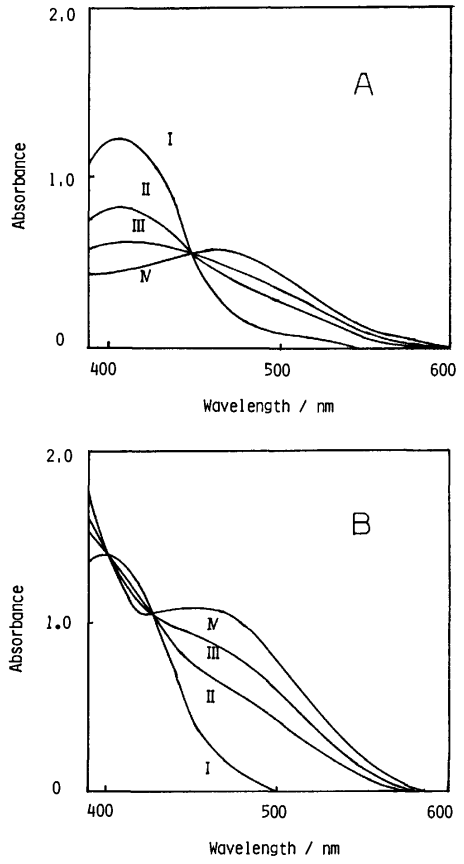


Fig. 1a. Spectral change of *o*-quinones with $ZnCl_2$ in CH_3NO_2. A: Concn of 4,5-dimethoxy-1,2-benzoquinone is maintained at 2.0×10^{-3} M, and concn of $ZnCl_2$ is varied as follows, I; 0, II; 2.0×10^{-3}, III; 3.8×10^{-3}, and IV; 1.0×10^{-2} M. B: Concn of 4-methoxy-1,2-naphthoquinone is maintained at 7.2×10^{-4} M, and concn of $ZnCl_2$ is varied as follows, I; 0, II; 3.6×10^{-3}, III; 5.9×10^{-3}, and IV; 1.0×10^{-2} M.

A: Concn of 4,5-dimethoxy-1,2-benzoquinone is maintained at 2.6×10^{-3} M, and concn of $SnCl_4$ is varied as follows, I; 0, II; 6.4×10^{-4}, III; 1.8×10^{-3}, and IV=3.0×10^{-3} M. B: Concn of 4-methoxy-1,2-naphthoquinone is maintained at 5.7×10^{-4} M, and concn of $SnCl_4$ is varied as follows, I=0, II; 3.7×10^{-4}, III; 7.2×10^{-4}, and IV; 1.0×10^{-3} M.

that of **1** (*cf.* Fig. 1b). Existence of the absorption band in the neighborhood of 400 nm for the complex of **2** with $SnCl_4$ may be due to the red shift of the benzenoid π-π^* transition of **2**, since the latter transition is absent in **1**.[9]

In the ^{1}H NMR spectra, chemical shifts of 3,6-H of **1** and 3-H of **2** were observed at 5.76 and 5.99 ppm, respectively. When metal chloride was added to the solution of the *o*-quinone, the signal of the *o*-quinones was displaced to the downfield site, since the signals of free and complexed species were averaged; the downfield shift means an electron withdrawal by the metal chloride.

The metal chlorides in nonaqueous media are usually treated as nonelectrolytes, arguing from the conductance data.[10] In the present work also, the molar conductance of the metal chloride measured in CH_3NO_2 suggests the lack of dissociation. The relatively large values of the molar conductance found in the cases of $InCl_3$ and $SbCl_4$ are attributed to the hydrolysis of the metal chloride by the residual water in CH_3NO_2. When the ligand was added to the solution of metal chloride, the value of molar conductance remains essentially constant. In this experiment, a large excess amount of the

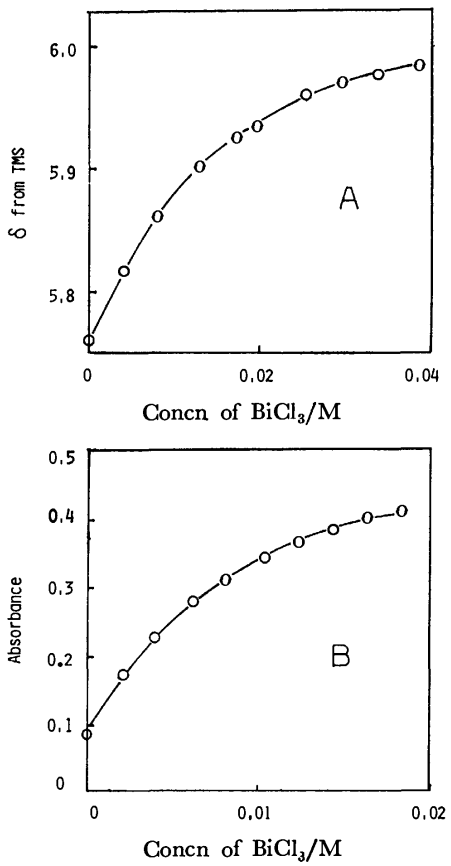

Fig. 2. Concentration dependence of the observed chemical shifts and absorbances. A: NMR method; ○: experimental point, —— : calculated curve with K_c=98.1 M^{-1}, δ_{ML}=6.057 ppm, δ_L=5.760 ppm, and concn of ligand=8.30×10^{-3} M. B: Spectrophotometric method; ○: experimental point, ——: calculated curve with K_c=115 M^{-1}, ε_{ML}=369, ε_L=77 and concn of ligand=1.56×10^{-3} M.

ligand was added, in the case of the metal chloride, giving a small value of K_c. From these results, the metal chloride and its complexes are treated as nonelectrolytes in this work.

Stability Constant and Complex Shift: The continuous variation method supported the formation of a 1 : 1 complex in all cases. To determine K_c, both absorbances and chemical shifts of solutions containing fixed amounts of ligand and varying amounts of metal chloride were measured. The results of the **1**+$BiCl_3$ system are shown in Fig. 2 as an example. The K_c values are calculated as follows. For an equilibrium of the formation of 1 : 1 complex, K_c is expressed as follows:

$$MX_n + L \overset{K_c}{\rightleftharpoons} MX_nL$$

$$K_c = [MX_nL]/[MX_n][L] = C_{ML}/(C_M^\circ - C_{ML})(C_L^\circ - C_{ML}), \quad (1)$$

where MX_n, L, and MX_nL mean metal chloride, ligand, and complex, C_{ML}, C_M° and C_L° are the equilibrium concentration of MX_nL, and the initial concentrations of MX_n and L, respectively. In an equilibrium state, Eqs. 2 and 2′ are appliciable:

$$A_{cal} = \varepsilon_{ML}C_{ML} + \varepsilon_L(C_L^\circ - C_{ML}), \quad (2)$$

$$\delta_{cal} = \delta_{ML}C_{ML}/C_L^\circ + \delta_L(C_L^\circ - C_{ML})/C_L^\circ, \quad (2')$$

where A_{cal}, ε_{ML}, and ε_L are the calculated absorbance and the molar absorption coefficients of MX_nL and L, and δ_{cal}, δ_{ML}, and δ_L are the calculated chemical shift and the chemical shifts of MX_nL and L, respectively. Equations 3 and 3′ are derived from Eqs. 1 and 2 or 2′.

$$A_{cal} = \varepsilon_L C_L^\circ + (\varepsilon_{ML}-\varepsilon_L)\{1+K_cC_M^\circ+K_cC_L^\circ - \sqrt{(1+K_cC_M^\circ+K_cC_L^\circ)^2-4K_c^2C_M^\circ C_L^\circ}\}/2K_c, \quad (3)$$

$$\delta_{cal} = \delta_L + (\delta_{ML}-\delta_L)\{1+K_cC_M^\circ+K_cC_L^\circ - \sqrt{(1+K_cC_M^\circ+K_cC_L^\circ)^2-4K_c^2C_M^\circ C_L^\circ}\}/2K_cC_L^\circ. \quad (3')$$

The root mean square deviations of the calculated and observed shifts were minimized by the curve fitting method. The results are listed in Table 1; the root mean square deviations of NMR and spectrophotometry were always<0.3 Hz and 0.003, respectively. In the case

of **2**+$ZnCl_2$, measurement of NMR spectra was unsuccessful, since the complex precipitated. The term "large" written in Table 1 means that the K_c value is too large to determine from the concentration dependence of the observed shift. However, approximate values of δ_{ML}, λ_{max}, and ε_{max} were obtained directly from the observed data, because the spectra were measured under the conditions where almost all ligands were transformed into the complex due to large K_c. In the case of smaller K_c, the visible absorption spectra were constructed as the sum of absorption bands of free and complexed species; accordingly, the ε_{ML} value at each wavelength of the spectra was calculated from Eq. 3, when C_M° and C_L° were known and the value of K_c was estimated. λ_{max} and ε_{max} of the complex were determined from the calculated spectra given by the calculated ε_{ML}.

The values of K_c determined by NMR and spectrophotometry were comparable with each other, as follows:

$$\log K_c(\text{NMR}) = 1.02 \log K_c(\text{spectrophotometry}) - 0.09 \quad (r=0.993). \quad (4)$$

The linear relation between $\Delta\delta_{ML}$ and $\Delta\nu_{max}$ is obvious as shown in Fig. 3. Furthermore, the other of the above parameters agree with those of K_c.

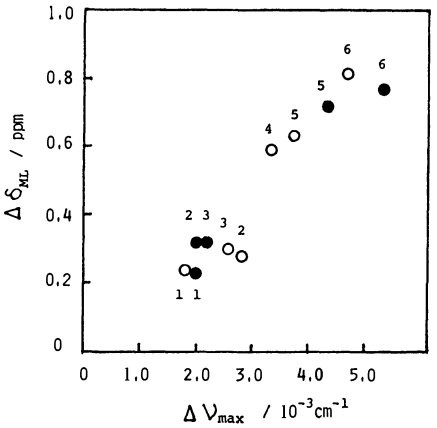

Fig. 3. Relationship between $\Delta\delta_{ML}$ and $\Delta\nu_{max}$.
○: 4,5-Dimethoxy-1,2-benzoquinone, ●: 4-methoxy-1,2-naphthoquinone, 1: $HgCl_2$, 2: $SbCl_3$, 3: $BiCl_3$, 4: $ZnCl_2$, 5: $InCl_3$, and 6: $SnCl_4$.

Electrostatic Model: The relative acceptor strengths of metal chloride toward *o*-quinones decrease in the order of $SnCl_4$>$InCl_3$>$ZnCl_2$>$BiCl_3$>$SbCl_3$>$HgCl_2$. Parameters of the metal ions are unable to explain the above order; this should be ascribed to the molecular (*i.e.*, non-ionic) property of the metal chloride. When the partial charge q on the metal atom of metal chloride was calculated by the method of Sanderson,[11] the electrostatic potential q/r (r means the distance between metal and chlorine) could be estimated. As shown in Fig. 4, the plots of log K_c against q/r are linear. This result suggests that the complex formation of this type is electrostatic in nature, and also supports the assumption that the metal chloride in CH_3NO_2 behaves as a nonelectrolyte.

Basicity of o-*Quinones*: In respect of the electronic

structure of *o*-quinones, the negative charge on the carbonyl oxygen was reported to increase slightly in the order of 1,2-benzoquinone<1,2-naphthoquinone.[12] However, the values of K_c obtained in this work increased in the order of **2**<**1**. This disagreement is probably ascribable either to an inversion of the negative charge on the carbonyl oxygen or to an entropy effect due to the steric effect of aromatic moiety of **2**.

TABLE 2. π-ELECTRON CHARGE DENSITIES OF THE TWO CARBONYL OXYGEN ATOMS OF *o*-QUINONES CALCULATED BY HMO METHOD

o-Quinones	π-Electron density of oxygen atoms	
1,2-BQ	1.463	1.463
1,2-NQ	1.496	1.549
4-MeO-1,2-NQ	1.503	1.607
4,5-$(MeO)_2$-1,2-BQ	1.530	1.530
Cryptotanshinone	1.531	1.647

BQ: Benzoquinone; NQ: naphthoquinone.

In the first place, π-electron density of the carbonyl oxygen was calculated by the HMO method. As shown in Table 2, the contribution of the electron release from the methoxyl group is obvious, but an adequate elucidation of this disagreement is not given by this result alone.

TABLE 3. THERMODYNAMIC DATA OF COMPLEX FORMATION OF *o*-QUINONES WITH $BiCl_3$ AND $HgCl_2$ IN CH_3NO_2 (1 cal=4.184 J)

	Cryptotanshinone	2.8	4.9
$BiCl_3$	4-MeO-1,2-NQ	3.4	3.3
	4,5-$(MeO)_2$-1,2-BQ	4.2	4.1
	Cryptotanshinone	5.3	5.6

BQ: Benzoquinone; NQ: naphthoquinone. a) Error; ±10%. b) Error; ±20%.

Subsequently, thermodynamic data were determined from the temperature dependence of the K_c. These results are summarized in Table 3, where additional data for **3** are listed in order to test the steric contribution on the complex formation. The values of $-\Delta H$ in the complex formation of *o*-quinones with $BiCl_3$ or $HgCl_2$ increase in the same order as K_c. The values of ΔS are proportional to those of ΔH; this finding suggests that the steric contribution is not evident. Therefore, it is concluded that the contribution of the steric effect of aromatic moiety is negligible, and the number of the methoxyl groups influences the order of K_c.

Solute-Solvent Interaction Model. Formerly, the solute-solvent interaction model was established for the study of the weak association by NMR;[13] the solvent molecules play a much larger role in solution than the two solutes. A modified Benesi-Hildebrand type equation (*cf.* Eq. 5) derived from this model was introduced for the estimation of 1 : 1 bound chemical shift $\Delta\delta_{AD}$ and the free energy of the complex formation ΔG_{AD}.[13]

$$1/\Delta\delta_{obsd} = C_S/k\Delta\delta_{AD}\cdot 1/C_A^\circ x + 1/\Delta\delta_{AD}, \quad (5)$$

where C_S and C_A° are the molarity of solvent and the initial concentration of acceptor, respectively, k is the Boltzmann factor ($=\exp(-\Delta G_{AD}/RT)$), and x is C_A°/C_D° when $C_A^\circ<C_D^\circ$, which is approximated to 1.0 when $C_A^\circ>C_D^\circ$. Equation 5 was modified to Eq. 6 in order to use spectrophotometry:

$$1/\Delta\varepsilon_{obsd} = C_S/k\Delta\varepsilon_{AD}\cdot 1/C_A^\circ x + 1/\Delta\varepsilon_{AD}. \quad (6)$$

As both NMR and spectrophotometry are employed in this work, so proof of this model must be evaluated by the comparison of the results obtained from this model with those of the previous section. ΔG_{AD} and $\Delta\delta_{AD}$ or $\Delta\varepsilon_{AD}$ were estimated from the linear relations between $1/C_A^\circ x$ and $1/\Delta\delta_{obsd}$ or $1/\Delta\varepsilon_{obsd}$. For $\Delta\delta$ and $\Delta\varepsilon$, the linear relations illustrated in Figs. 5 and 6 were formulated by Eqs. 7 and 8:

$$\Delta\delta_{AD} = 0.95\cdot\Delta\delta_{ML} + 0.025 \quad (r=0.974), \quad (7)$$

$$\Delta\varepsilon_{AD} = 1.10\cdot\Delta\varepsilon_{ML} + 2.03 \quad (r=0.996). \quad (8)$$

The results of NMR and spectrophotometry for ΔG are expressed in Eqs. 9 and 10, respectively. These results

●: 4-methoxy-1,2-naphthoquinone+MX_n system.

$$\Delta G_{AD} = 0.91\cdot\Delta G_{ML} + 1.77 \quad (r=0.996). \quad (9)$$

$$\Delta G_{AD} = 0.82\cdot\Delta G_{ML} + 2.05 \quad (r=0.994). \quad (10)$$

support the assertion that this model is reliable for the estimation of the thermodynamic parameter.

Lewis Acidity. Generally, Lewis acidity is evaluated by the change of the free energy or enthalpy of the complex formation. However, in the case of the complex formation between metal halide and Lewis base, the determination of the thermodynamic parameters is difficult for the wide range of metal halides. Therefore, several empirical scales have been presented to determine the relative acceptor strength of metal halides toward Lewis bases.[14] If these scales really represent a relative acceptor strength of metal halides, a correlation between them must occur. However, they are only qualitative.

In this work, the correlation between the values of K_c, $\Delta\nu_{max}$, and $\Delta\delta_{ML}$ is acknowledged. This result supports that $\Delta\nu_{max}$ and $\Delta\delta_{ML}$ are valid as a relative acidity scale. Formerly, in the study of the complex formation between benzamide and metal chloride in ether, Satchell *et al.*[15] concluded that the chemical shift was unlikely to represent the relative acidity. Unfortunately, they failed to account for the contribution of the solvation to K_c, since the donor strength of ether is evident. The effect of solvation on the order of K_c is ascertained in CH_3CN and CH_3NO_2; *i.e.*, the order of $ZnCl_2>BiCl_3$ was obtained in the latter, whereas the reverse order was obtained in the former;[4] the contribution of the solvation is considered to be much less for CH_3NO_2. The determination of $\Delta\nu_{max}$ and $\Delta\delta_{ML}$ is usually not so difficult as that of K_c, because the rigorous and quantitative experimental conditions are sometimes unnecessary for the former measurements. Therefore, these two parameters appear to offer a convenient scale for the Lewis acidity of metal halides.

(Received October 27, 1980)

The absorption spectrum of pyrazine has been studied at room temperature in various mixed solvents of cyclohexane and halomethanes such as carbon tetrachloride, chloroform and dichloromethane. With increasing concentration of halomethane, the singlet-singlet (S-S) and singlet-triplet (S-T) $n\rightarrow\pi^*$ absorptions decrease in intensity and become structureless, whereas the S-S $\pi\rightarrow\pi^*$ absorption remains essentially unchanged. The observations are attributed to the complex formation between pyrazine and halomethanes involving the non-bonding electrons in pyrazine. From the concentration and temperature dependences of the $n\rightarrow\pi^*$ absorption spectra, the equilibrium constants, enthalpy and entropy changes have been obtained for the complex formation in all the systems studied. The equilibrium constants obtained from the S-S and S-T $n\rightarrow\pi^*$ absorptions are in good agreement with each other.

As is well known, the electronic spectra of organic compounds exhibit solvent effects. Burawoy,[1] Kasha,[2] and McConnell[3] proved that the solvent effect is useful for characterization of the $\pi\rightarrow\pi^*$ and $n\rightarrow\pi^*$ transitions, showing that the latter transition generally undergoes a blue shift in polar solvents. Brealey and Kasha[4] studied the blue shift of the $n\rightarrow\pi^*$ absorption spectra of benzophenone and pyridazine in hydroxylic mixed solvents, and attributed it to the hydrogen bonding between the solutes and the hydroxylic components of the solvents. But Pimentel[5] suggested that the Franck-Condon principle is significant in the blue shift. Krishna and Goodman[6] reported, on the solvent effects in the $n\rightarrow\pi^*$ absorption and $n\leftarrow\pi^*$ phosphorescence spectra of pyrazine and 2,5-dimethylpyrazine in EPA glass, that the weak hydrogen bonding and Franck-Condon strain resulting therefrom are operative. Baba *et al.*[7] examined the solvent effects on the absorption and fluorescence spectra of diazines, and discussed the dipole moments in the (n,π^*) excited states. Recently, Zalewski *et al.*[8] observed the absorption, fluorescence, and phosphorescence spectra of pyrazine in such matrices as durene, benzene, and cyclohexane, focusing on the nature of the first (n,π^*) excited state.

The present paper deals with the S-S and S-T $n\rightarrow\pi^*$ absorption spectra of pyrazine, which show a blue shift and a blurred structure in the presence of the halomethanes, carbon tetrachloride, chloroform, and dichloromethane. In view of the molecular symmetry of pyrazine and the nonpolar nature of carbon tetrachloride, the blue shift in carbon tetrachloride can not be interpreted in terms of the ground and excited state dipole moments. We here report evidence for the 1 : 1 complex formation between pyrazine and the halomethanes, and the related thermodynamic data obtained.

Carbon tetrachloride as solvent often gives rise to specific interaction with organic compounds such as benzene and pyrazine particularly at low temperatures, that is, to anomalous changes in the absorption and emission spectra.[9-13] In addition, carbon tetrachloride is known to form complexes as an electron acceptor not only with aromatic hydrocarbons[14-16] such as benzene, mesitylene, and hexamethylbenzene, but also with amines[17-19] such as triethylamine, butylamine, and triphenylamine.

Experimental

Pyrazine and all the solvents used were obtained from Wako Pure Chem. Ind., Ltd. Pyrazine was purified by repeated sublimation under vacuum. Cyclohexane (super special grade) was treated several times with a 200-mesh activated silica-gel column, and the benzene contained as an impurity was eliminated. Chloroform (absorption spectro grade) was passed several times just prior to use through a column packed with aluminium oxide Woelm basic (ICN Pharmaceutical Co.) in order to remove the ethanol contained as stabilizer. Carbon tetrachloride and dichloromethane (Dotite spectrosol) were used as received.

The absorption spectra were measured with a Shimadzu UV-200 spectrophotometer, equipped with a temperature-regulated cell holder adapted for the 1-cm cells. Circulating water of a constant temperature maintained the holder temperature constant to an accuracy of $\pm 0.5°$. The temperature was monitored with a thermocouple attached to the reference cell and displayed on a recorder throughout each measurement run. A pair of matched 1-cm fused silica cells were used for the S-S $n\rightarrow\pi^*$ absorption, and a pair of matched 5-cm cells for the S-T $n\rightarrow\pi^*$ absorption.

Results and Discussion

Pyrazine has three different absorptions in the ultraviolet region. One is the S-S $\pi\rightarrow\pi^*$ absorption in the region of 250—270 nm, and the others are the S-S and S-T $n\rightarrow\pi^*$ absorptions in the regions of 310—330 nm and 360—380 nm, respectively. Figures 1 and 2 show the latter two absorption spectra in cyclohexane and in three different halomethanes: carbon tetrachloride, chloroform, and dichloromethane. The spectra in the halomethanes, as in ethanol, are considerably blue-shifted and the vibrational structures are quite blurred compared to those in cyclohexane. The phenomenon is particularly prominent in chloroform and dichloromethane. On the contrary, the $\pi\rightarrow\pi^*$ absorption spectra in the halomethanes show only a slight red shift and the vibrational structure remains

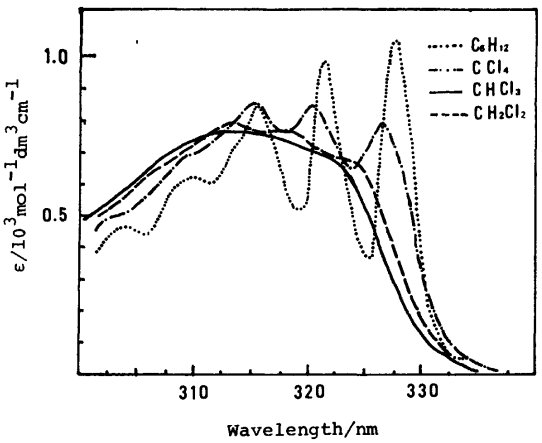

Fig. 1. S-S n→π* absorption spectra of pyrazine in cyclohexane (·····), carbon tetrachloride (·-·-), chloroform (——), and dichloromethane (------).

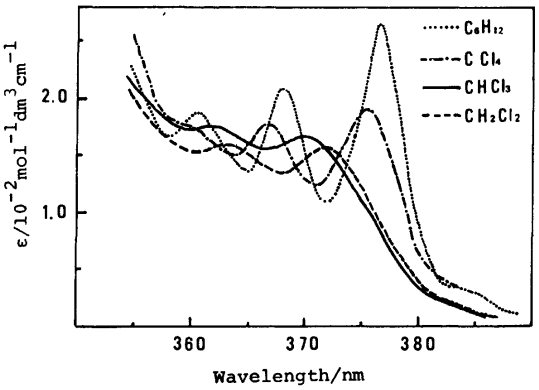

Fig. 2. S-T n→π* absorption spectra of pyrazine in cyclohexane (·····), carbon tetrachloride (·-·-), chloroform (——), and dichloromethane (----).

essentially the same as that in cyclohexane. These findings indicate that pyrazine undergoes a specific interaction with the halomethanes through its non-bonding electrons.

In order to study the interaction quantitatively, the S-S and S-T n→π* absorptions were investigated in detail in ternary systems consisting of pyrazine, the halomethanes, and cyclohexane, where the concentration of pyrazine was kept constant and those of the halomethanes were varied. For the convenience of discussion, the ternary system containing carbon tetrachloride, for example, will be referred to as the carbon tetrachloride system. The S-S and S-T n→π* absorption spectra thus obtained for the carbon tetrachloride system are shown in Figs. 3 and 4, respectively. Similar results have been observed for the chloroform and dichloromethane systems. With any one of the halomethanes, when the concentration of halomethane is relatively low, there always appear isosbestic points in a family of absorption curves, as can be seen in Figs. 3 and 4, suggesting formation of a 1 : 1 complex between pyrazine and the halomethane.

The equilibrium constant K of the complex formation can be determined from the S-S absorption data through the following relation, subject to the condition $[D]_0 \ll [A]_0$:

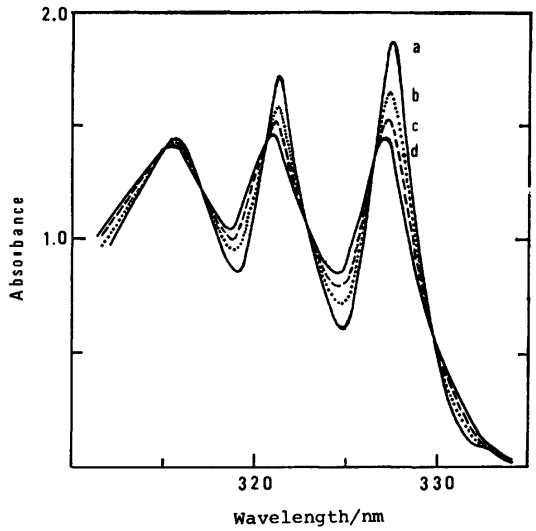

Fig. 3. S-S n→π* absorption spectra of pyrazine in the carbon tetrachloride–cyclohexane mixed solvents at 20 °C. Concentration of pyrazine: 1.654×10^{-3} mol dm^{-3}. Concentration of carbon tetrachloride: (a) 0, (b) 1.200, (c) 2.401, (d) 3.601 mol dm^{-3}.

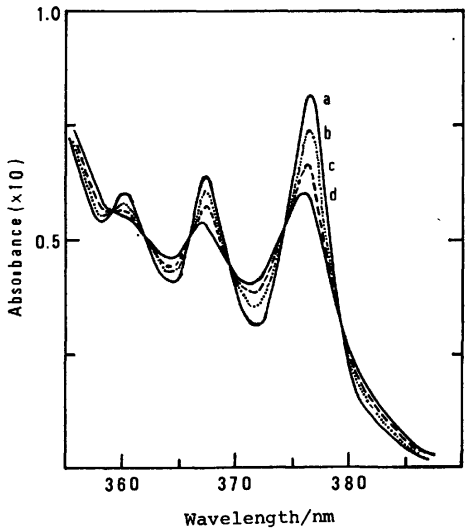

Fig. 4. S-T n→π* absorption specrta of pyrazine in the carbon tetrachloride–cyclohexane mixed solvents. Concentration of pyrazine: 0.622 mol dm^{-3}. Concentration of carbon tetrachloride: (a) 0, (b) 0.999, (c) 3.075, (d) 6.225 mol dm^{-3}.

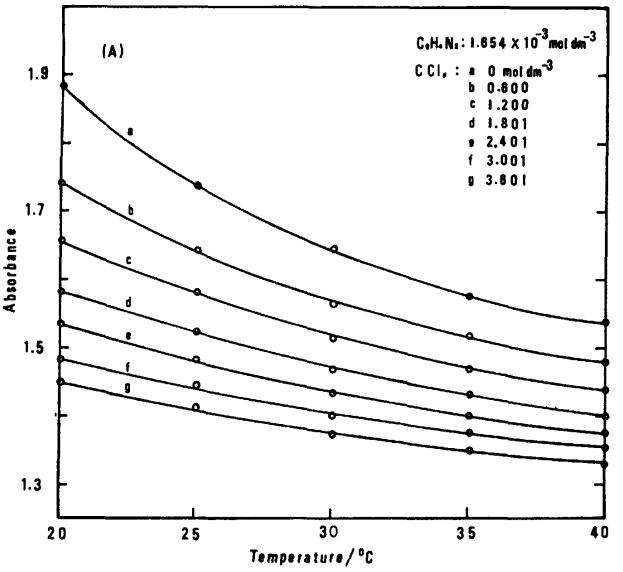
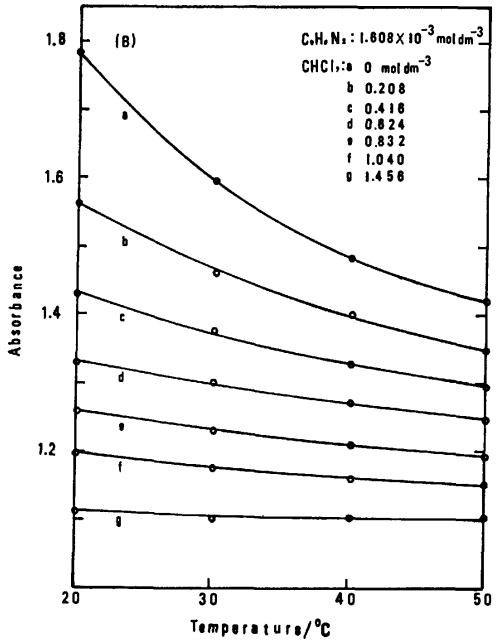
$$d = (1/K)(\varepsilon_D[D]_0 - d)/[A]_0 + \varepsilon_C[D]_0, \qquad (1)$$

where $[D]_0$ and $[A]_0$ are the initial molar concentrations of the donor, pyrazine, and the acceptor, halomethane, d is the absorbance measured with 1-cm optical path, and ε_D and ε_C are the molar extinction coefficients of the free and complexed donor, respectively; the ε_D values were actually determined in cyclohexane. The apparent ε_D value decreases with increasing temperature, owing to the appearance of the hot band around 333 nm in the S-S n→π* absorption region. Therefore, in order to accurately evaluate the temperature dependence of the equilibrium constant K, we adopted the ε_D values measured at the corresponding temperatures. The concentrations of pyrazine used were 1.654×10^{-3}

mol dm^{-3} for the carbon tetrachloride system, and 1.608×10^{-3} mol dm^{-3} for the chloroform and dichloromethane systems, while the concentrations of halomethane covered the ranges of 0.600—3.601, 0.208—1.456, and 0.461—1.384 mol dm^{-3} for the carbon tetrachloride, chloroform, and dichloromethane systems, respectively. In order to estimate the heat of formation ΔH (the enthalpy change) and the entropy change ΔS, measurements were made at the following temperatures: 20, 25, 30, 35, and 40 °C for the carbon tetrachloride system; 20, 30, 40, and 50 °C for the chloroform system; 20, 30, 40, and 48 °C for the dichloromethane system. We monitored the absorption intensities at 327.5 nm and, if possible, those at 321.5 nm, corresponding to the first and second bands, respectively. Figure 5 shows the data thus obtained at 327.5 nm; the corresponding data at 321.5 nm are quite similar. From the K values estimated at the above-mentioned different temperatures, the ΔH values could be evaluated by means of





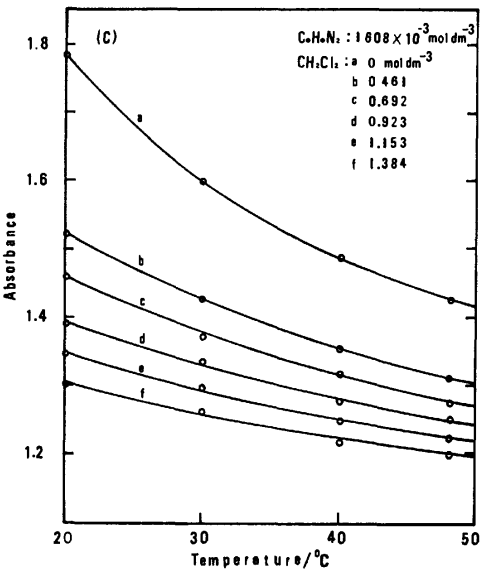


Fig. 5. Temperature dependence of the S-S n→π^* absorption monitored at 327.5 nm in the (A) carbon tetrachloride, (B) chloroform, and (C) dichloromethane systems.

the van't Hoff equation. The plots of d *vs.* $(\varepsilon_D[D]_0-d)/[A]_0$ and $-\ln K$ *vs.* $1/T$ gave fairly good straight-line relationships for any of the ternary systems studied, as exemplified in Figs. 6 and 7. The numerical results thus obtained in the S-S n→π^* absorption region are listed in Table 1, together with those in the S-T region to be described in the following paragraph. The thermodynamic data in Table 1 are found to fall in the ranges of magnitude expected for the molecular complexes.[20]

For the S-T n→π^* absorption, the concentrations of pyrazine used were fairly high because of its very low molar extinction coefficient: they were 0.622, 0.620, and 0.619 mol dm^{-3} for the carbon tetrachloride, chloroform, and dichloromethane systems, respectively. The halomethane concentrations covered the ranges of

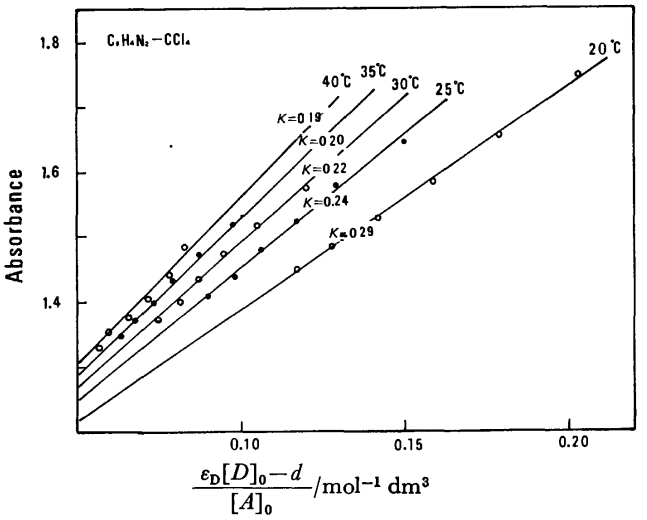

Fig. 6. Temperature dependence of the equilibrium constant K in the carbon tetrachloride system on the basis of the results in Fig. 5(A).

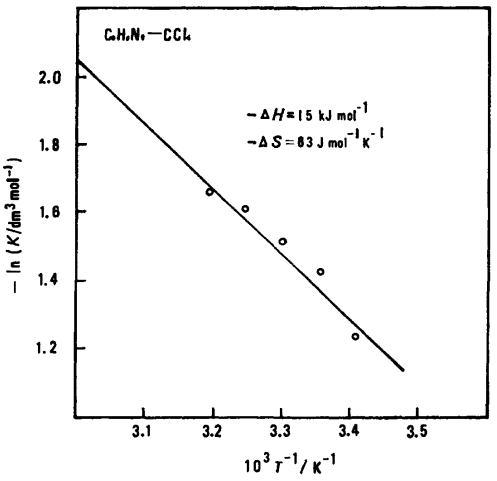

Fig. 7. Evaluation of the enthalpy and entropy changes in the carbon tetrachloride system.

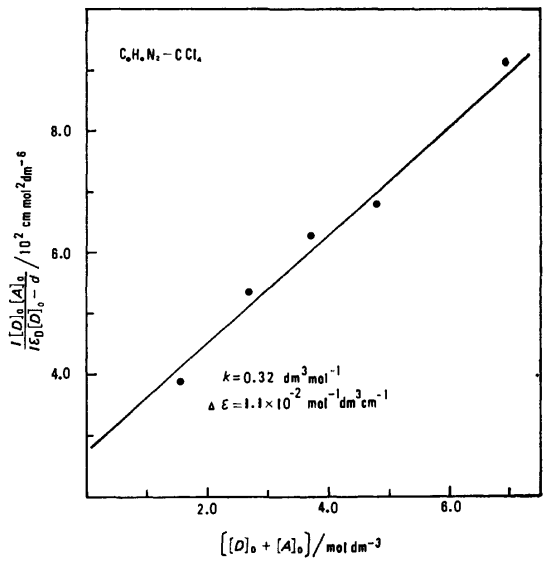

Fig. 8. Evaluation of the equilibrium constant by means of the modified Drago-Rose equation, Eq. 2, from the S-T n→π* absorption data obtained at 376 nm in the carbon tetrachloride system.

0.999—6.225, 0.244—2.493, and 0.326—1.244 mol dm^{-3} for the carbon tetrachloride, chloroform, and dichloromethane systems, respectively. Consequently, the relative concentrations of pyrazine and halomethanes no longer satisfy the condition $[D]_0 \ll [A]_0$. Therefore, the following modified Drago-Rose equation[21] was employed instead of Eq. 1:

$$\frac{l[D]_0[A]_0}{l\varepsilon_D[D]_0-d} = \frac{[D]_0+[A]_0}{\varepsilon_D-\varepsilon_C} + \frac{1}{K(\varepsilon_D-\varepsilon_C)}, \qquad (2)$$

where l is the optical path-length in cm. Equation 2 is applicable to the equilibrium system of relatively small K. The S-T n→π* absorption was studied only at room temperature (20—23 °C), since the 5-cm cells used did not fit the temperature-regulated cell holder. Figure 8 shows the plot of $(l[D]_0[A]_0)/(l\varepsilon_D[D]_0-d)$ *vs.* $[D]_0+[A]_0$, which gives a good straight-line fit. Here, the value of ε_D is 2.64×10^{-2} mol^{-1} dm^3 cm^{-1}, the molar extinction coefficient obtained at 376 nm in cyclohexane. The K's thus derived are listed in Table 1. Regarding Table 1, it should be emphasized that nearly the same values of K were obtained from the two different absorption regions, that is, the S-S and S-T n→π* absorption regions, and that the ε_C values listed as footnotes are in fairly good agreement with those in the

Table 1. Thermodynamic quantities for a 1 : 1 complex formation of pyrazine with halomethanes

a) The K values cited above were obtained at the following temperatures: *a*: 20 °C, *b*: 25 °C, *c*: 30 °C, *d*: 40 °C, *e*: 20—23 °C, *f*: 50 °C, *g*: 48 °C. b) The ε_c values obtained at 327.5 nm are 635, 400, and 560 mol^{-1} dm^3 cm^{-1} for the carbon tetrachloride, chloroform, and dichloromethane systems, while those at 321.5 nm are 613 and 676 mol^{-1} dm^3 cm^{-1} for the latter two systems. Those at 376 nm are *ca.* 1.5×10^{-2} mol^{-1} dm^3 cm^{-1} for the first system, and *ca.* 1.1×10^{-2} mol^{-1} dm^3 cm^{-1} for both the latter two systems.

pure halomethanes.

The results of the absorption measurements can be summarized as follows: (1) When the solvent is changed from hydrocarbon to halomethane, the pyrazine absorption due to the S-S $\pi \rightarrow \pi^*$ transition does not undergo any substantial change, showing only a slight red shift and a little increase in intensity. (2) On the other hand, the S-S and S-T $n \rightarrow \pi^*$ absorptions exhibit remarkable changes, indicating specific interaction of the non-bonding electrons of pyrazine with the halomethanes. (3) By use of the cyclohexane–halomethane mixed solvents, reasonable values could be obtained for the equilibrium constant in the 1 : 1 complex formation between pyrazine and the halomethanes.

In the case of the carbon tetrachloride system, the complex is most probably of the charge-transfer type, whereas in the chloroform and dichloromethane systems, the complexes may be due to charge transfer, hydrogen bonding, or to a combination of both of them. In this connection, we have undertaken a study of the phosphorescence spectra in the ternary systems investigated in this work, and obtained some significant results concerning the charge transfer nature of the complexes. These will be discussed in a separate, subsequent paper.[22]

(Received October 27, 1980)

The phosphorescence and phosphorescence excitation spectra of pyrazine have been studied at 77 K in various mixed solvents of cyclohexane and halomethanes such as carbon tetrachloride, chloroform, and dichloromethane. When the halomethane concentration was low (below 10^{-2} mol dm^{-3}), only the cyclohexane-phase phosphorescence was observed at 77 K; the lower energy components of the well-known doublet band series in the cyclohexane-phase phosphorescence were found to decrease in intensity relative to the higher energy components, with increasing concentration of halomethane. When the halomethane concentration was raised to a range higher than 10^{-1} mol dm^{-3}, where the complex formation between pyrazine and the halomethanes was confirmed through absorption spectroscopy,[1] new phosphorescence bands appeared in the 373—375 nm region for all the systems studied. With further increase of the halomethane concentration, the new bands decreased in intensity or disappeared, and the phosphorescence approached to those in the pure halomethanes. Comparison of the absorption and phosphorescence excitation spectra shows that the new phosphorescence bands result from the 1 : 1 pyrazine–halomethane complexes. The possibility of hydrogen-bonding species formation with chloroform and dichloromethane has been discussed in the light of the phosphorescence spectra studied in the ethanol–cyclohexane mixed solvents.

The phosphorescence spectrum of pyrazine has been extensively studied in various crystalline matrices, rigid glasses, neat crystals, and in the vapor phase.[2-11] One of the unresolved problems is the anomalous phosphorescence of pyrazine observed by Shimada[2] in carbon tetrachloride matrix at 90 K. The phosphorescence shows doublet band-series structure, suggesting the existence of two different kinds of emitters with a separation of 290 cm^{-1}.[3,11] To explore the nature of the doublet structure, McDonald *et al.*[8] investigated the phosphorescence and absorption of pyrazine in carbon tetrachloride and in neat crystals at 77 K. From comparison of the phosphorescence and absorption spectra, they attributed the higher-energy components with origin at 377.4 nm to molecular pyrazine and the lower-energy components with origin at 381.4 nm to microcrystals of pyrazine. It should be noted that their measurements were restricted to concentrations higher than 10^{-4} mol dm^{-3}. In carbon tetrachloride at 77 K, the doublet band-series structure has been found to persist even at a concentration as low as 10^{-7} mol dm^{-3}, where the molecular aggregates or microcrystals are quite unlikely to occur. The anomalous phosphorescence should thus be attributed to a specific interaction between pyrazine and carbon tetrachloride. Such a specific interaction between pyrazine and the halomethanes, carbon tetrachloride, chloroform, and dichloromethane, is the main subject of this work. In order to examine the possibility of hydrogen-bond formation of pyrazine with chloroform and dichloromethane, we have also studied in detail the effect of ethanol on the phosphorescence of pyrazine.

Experimental

Pyrazine and all the solvents used were obtained from Wako Pure Chem. Ind., Ltd. The purification of the chemicals was described in the preceding paper.[1]

Measurements of the phosphorescence and phosphorescence excitation spectra were carried out with a Shimadzu RF-502 spectrophotofluorometer equipped with a cylindrical sector. The slit widths of 0.4 and 1.0 nm were adopted for the excitation and analyzing monochromators, respectively. It is often pointed out that the structures of the low-temperature spectra depend on the method of sample cooling. In this study, rapid cooling was adopted in order to diminish the possibility of formation of molecular aggregates in the course of cooling, since we intended to compare the results in this study with those of the preceding room-temperature study on the complex formation.[1]

Results and Discussion

General Remarks. In order to study the effect of the halomethanes on the phosphorescence spectrum of pyrazine, we have studied the ternary systems consisting of pyrazine, halomethane, and cyclohexane, where the halomethane is carbon tetrachloride, chloroform, or dichloromethane. For the convenience of discussion, the ternary system containing carbon tetrachloride, for example, will be referred to as the carbon tetrachloride system, following the preceding paper.[1] For comparison, we have also studied the ternary system containing ethanol in place of halomethane; this will be referred to as the ethanol system.

Phosphorescence of Pyrazine in Cyclohexane Matrix at 77 K. The phosphorescence spectrum of pyrazine in cyclohexane matrix at 77 K was observed and reexamined as a reference spectrum in some detail to determine the excitation-wavelength and solute-concentration dependences. Figure 1 shows the variation of the phosphorescence spectra with increasing wavelength of the excitation in the S-S n→π* absorption region. The general spectral appearance is quite similar to that reported previously.[3] As is seen in Fig. 1, the pyrazine phosphorescence consists of a doublet band-series structure, in which the origins are located at 377 and 378 nm for the higher and lower energy components, respectively. In addition, we could observe separately the excitation spectra for the higher and lower energy

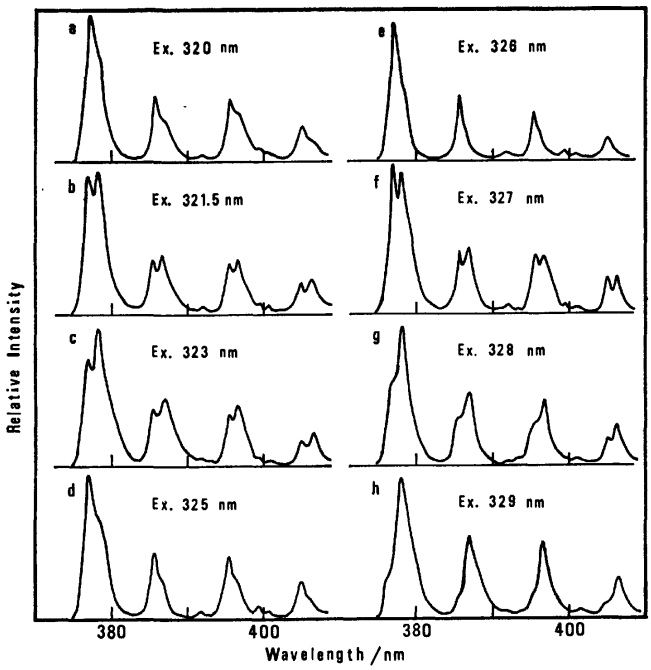

Fig. 1. Excitation-wavelength dependence of the phosphorescence spectrum of pyrazine in cyclohexane matrix at 77 K. Concentration of pyrazine: 1.647×10^{-4} mol dm^{-3}.

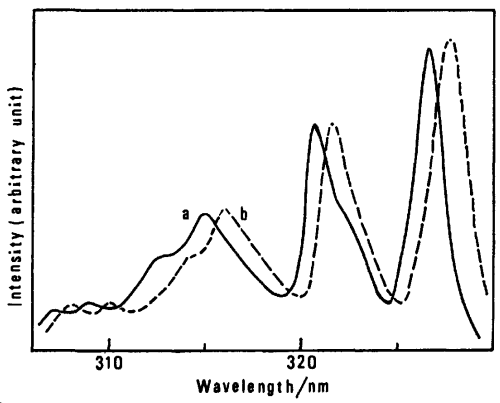

Fig. 2. Excitation spectra of the higher (a) and lower (b) energy components in the phosphorescence of pyrazine in cyclohexane matrix at 77 K. The spectra a and b were monitored at 376.0 and 378.5 nm, respectively. Concentration of pyrazine: 1.647×10^{-4} mol dm^{-3}.

components, as shown in Fig. 2. These observations clearly indicate that there exist at least two, different principal emitters in the cyclohexane matrix at 77 K. For the concentrations of pyrazine in the range of 10^{-7}—10^{-4} mol dm^{-3}, the phosphorescence spectrum remained essentially unchanged. Accordingly, we conclude that, in a cyclohexane solution of the order of 10^{-4} mol dm^{-3}, microcrystals or molecular aggregates are not formed at 77 K, contrary to the statement of McDonald *et al.*[8]

Phosphorescence of Pyrazine in the Ternary System Consisting of Pyrazine, Carbon Tetrachloride, and Cyclohexane at 77 K. Figure 3 shows the effect of carbon tetrachloride on the phosphorescence spectra of pyrazine excited at 324 nm; the relative intensities of the lower and higher energy

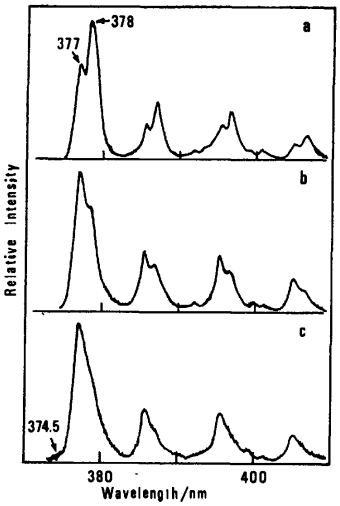

Fig. 3. Spectral changes of the pyrazine phosphorescence excited at 324 nm with the concentration variation of carbon tetrachloride from 10^{-3} to 10^{-1} mol dm^{-3} in the carbon tetrachloride–cyclohexane mixed solvents at 77 K. Concentration of pyrazine: 1.647×10^{-4} mol dm^{-3}. Concentration of carbon tetrachloride: (a) 1.494×10^{-3}, (b) 1.494×10^{-2}, (c) 1.494×10^{-1} mol dm^{-3}.

components, both inherent to the cyclohexane-phase phosphorescence as given in Fig. 1, show a systematic change for the carbon tetrachloride concentrations ranging from the order of 10^{-3} to 10^{-1} mol dm^{-3}; namely, with increasing carbon tetrachloride concentration, the lower energy components of the cyclohexane-phase phosphorescence decrease in relative intensity compared to the higher energy ones. As the concentration of carbon tetrachloride was increased to 10^{-1} mol dm^{-3}, a new phosphorescence band appeared around the 374—375 nm region as a very weak shoulder, and the spectral structure became rather obscure. Quite similar spectral changes were also observed for various excitation wavelengths other than 324 nm in the S-S $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ absorption regions. Therefore, it may be concluded that the doublet band series in the cyclohexane-phase phosphorescence depends not only on the excitation wavelength (Fig. 1), but also on the concentration of carbon tetrachloride (Fig. 3).

On the other hand, when the carbon tetrachloride concentration was increased up to just the same concentrations (in the range 0.562—9.233 mol dm^{-3}) as those used in the preceding paper on the complex formation,[1] the phosphorescence exhibited some complicated and interesting spectral features, as shown in Fig. 4; the pyrazine concentration was kept constant at 1.647×10^{-4} mol dm^{-3}. Such phosphorescence results strongly depend on the excitation wavelengths as well as the carbon tetrachloride concentrations. The excitations at 310, 323, and 324 nm show that the shoulder band in the 374—375 nm region grows with increasing concentration of carbon tetrachloride in the range of 0.5 to 2.0 mol dm^{-3}. In the preceding paper,[1] this concentration range was found to be the most suitable for the observation of the complex formation between pyrazine and carbon tetrachloride. Thus, the shoulder band in the 374—375 nm region seems to have a close connec-

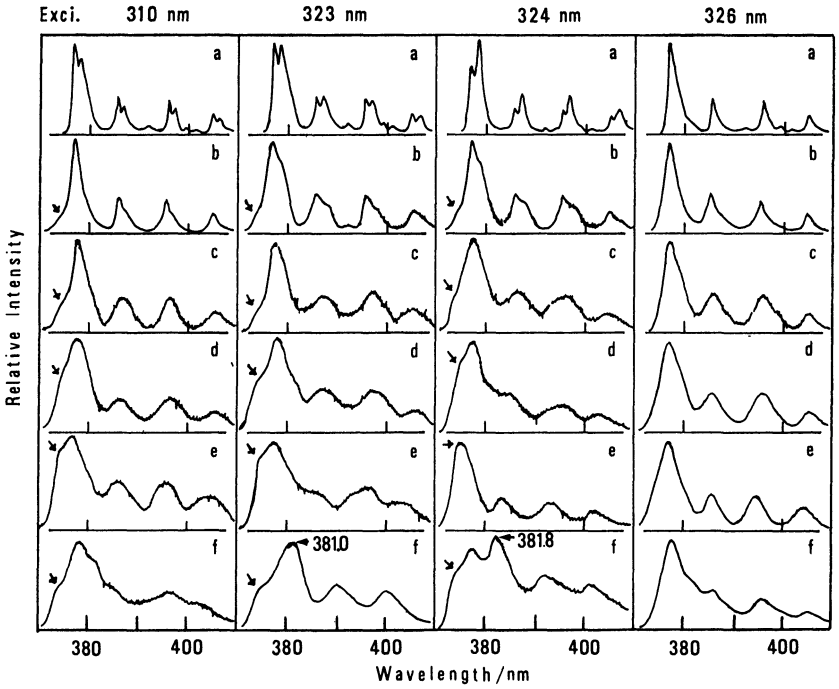

Fig. 4. Spectral changes of the pyrazine phosphorescence in the carbon tetrachloride–cyclohexane mixed solvents at 77 K excited at various wavelengths with the concentration variation of carbon tetrachloride over the range closely related to the complex formation. Concentration of pyrazine: 1.647×10^{-4} mol dm^{-3}. Concentration of carbon tetrachloride: (a) 0, (b) 0.517,(c) 1.022, (d) 1.530, (e) 2.048, (f) 9.223 mol dm^{-3}.

tion with the 1 : 1 charge-transfer complex. At the much higher concentrations, as is seen particularly in the phosphorescence spectra excited at 323 and 324 nm in Fig. 4, the 375-nm band is weaker and then there appears the doublet band-series structure with the origins at 378 and 382 nm, characteristic of the phosphorescence spectrum of pyrazine in carbon tetrachloride matrix at 77 K.

The phosphorescence excitation spectra monitored at the 375-, 378-, and 382-nm bands exhibit the first bands at 324.6, 327, and 330 nm, respectively, as shown in Fig. 5. Thus, the excitation spectra disclose that there are three principal kinds of phosphorescent species in the cyclohexane–carbon tetrachloride mixed solvents at 77 K, when the carbon tetrachloride concentrations are higher than *ca.* 0.5 mol dm^{-3}. Since the excitation spectrum responsible for 375-nm phosphorescence band is in good accord with the blue-shifted absorption spectrum of pyrazine observed in carbon tetrachloride at room temperature,[1] we suggest that the species giving rise to the 375-nm band is the 1 : 1 charge-transfer complex; the phosphorescence of the 375-nm species is much lower in intensity compared with those of the other species.

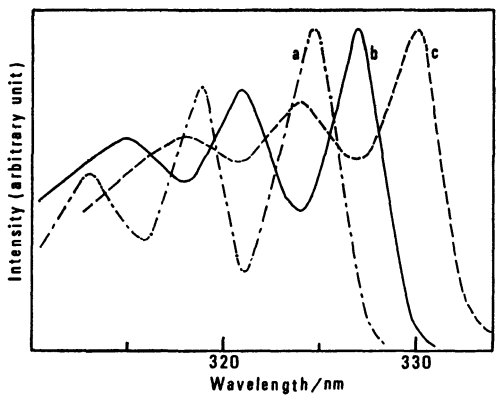

Fig. 5. Excitation spectra monitored at the (a) 375, (b) 378, and (c) 382 nm bands of the phosphorescence of pyrazine in the carbon tetrachloride–cyclohexane mixed solvents at 77 K. Concentration of pyrazine: (a) 1.647×10^{-4}, (b) and (c) 1.444×10^{-4} mol dm^{-3}. Concentration of carbon tetrachloride: (a) 1.530 mol dm^{-3}, (b) and (c) 90 vol%.

Phosphorescence of Pyrazine in the Ternary System Consisting of Pyrazine, Chloroform, and Cyclohexane at 77 K. Excitation-wavelength and chloroform-concentration dependences were also studied for the chloroform system in which the chloroform concentration was varied over the range 10^{-3}—1 mol dm^{-3}. Figure 6 shows the phosphorescence spectra excited at 323 nm; with increasing chloroform concentration, the lower energy components of the cyclohexane-phase phosphorescence decrease in relative intensity compared to the higher energy ones; this result is similar to the case of the carbon tetrachloride system. In this system, one can already see new phosphorescence bands, with the origin at 374.5 nm, at the chloroform concentrations of the order of 10^{-2} mol dm^{-3}. This is consistent with the results of the preceding study on the complex formation; the equilibrium constant for the chloroform

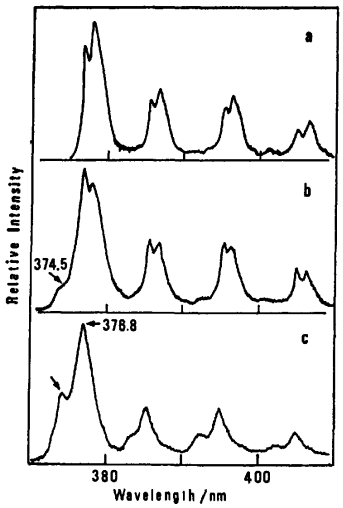

Fig. 6. Spectral changes of the pyrazine phosphorescence excited at 323 nm with the concentration variation of chloroform from 10^{-3} to 10^{-1} mol dm^{-3} in the chloroform–cyclohexane mixed solvents at 77 K. Concentration of pyrazine: 1.647×10^{-4} mol dm^{-3}. Concentration of chloroform: (a) 1.458×10^{-3}, (b) 1.458×10^{-2}, (c) 1.458×10^{-1} mol dm^{-3}.

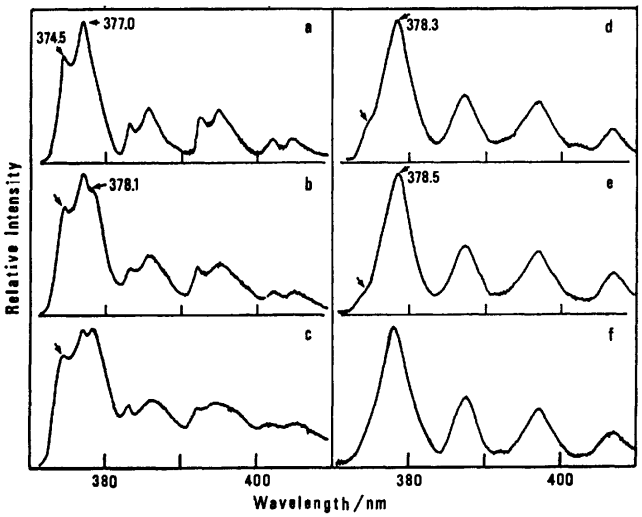

Fig. 7. Spectral changes of the pyrazine phosphorescence in the chloroform–cyclohexane mixed solvents at 77 K excited at 324 nm with the concentration variation of chloroform over the range closely related to the complex formation. Concentration of pyrazine: 1.647×10^{-4} mol dm^{-3}. Concentration of chloroform: (a) 0.219, (b) 0.292, (c) 0.365, (d) 0.693, (e) 0.924, (f) 1.155 mol dm^{-3}.

system is greater than that for the carbon tetrachloride system.[13]

In just the same range of chloroform concentration, 0.2—1.0 mol dm^{-3}, as that studied for the observation of the complex formation,[1] the phosphorescence showed remarkable spectral variations with excitation wavelength and chloroform concentration. The spectra excited at 324 nm are the most typical, and are shown in Fig. 7. In the chloroform concentration of 0.219 mol dm^{-3}, as is seen in Fig. 7, a new phosphorescence band-series with the origin at 374.5 nm clearly appears, while the lower energy components of the cyclohexane-phase phosphorescence completely disappear. With the chloroform concentration of 0.292 mol dm^{-3}, another new phosphorescence band-series, which is quite different both from the 374.5-nm band-series and from the lower energy components of the cyclohexane-phase phosphorescence, begins to appear around 378 nm, while the higher energy components of the cyclohexane-phase phosphorescence eventually disappear with increasing chloroform concentration. When the chloroform concentration is raised to 0.462 mol dm^{-3}, either the 323- or the 324-nm excitation gives exclusively the two new band-series with the origins at 374.5 and 378 nm. With further increase of the chloroform concentration, the intensity of the 374.5-nm band-series decreases; at the concentration of 1.155 mol dm^{-3}, the spectrum is close to that characteristic of the chloroform matrix at 77 K. The new band-series with the origin at 378 nm can thus be attributed to the chloroform-phase phosphorescence in the mixed solvent at 77 K.

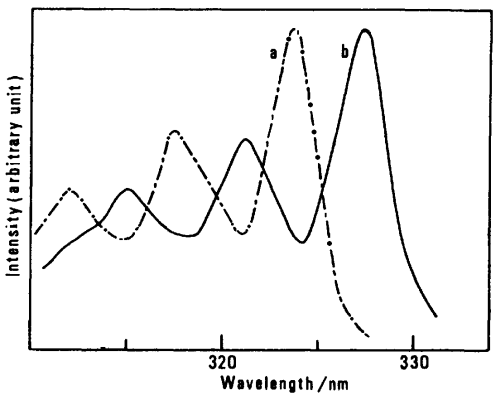

Fig. 8. Excitation spectra of the pyrazine phosphorescence monitored at (a) 373 and (b) 378 nm for the chloroform–cyclohexane mixed solvents at 77 K. Concentration of pyrazine: 8.564×10^{-4} mol dm^{-3}. Concentration of chloroform: 0.462 mol dm^{-3}.

Figure 8 shows the phosphorescence excitation spectra monitored at 373 and 378 nm for the chloroform concentration of 0.462 mol dm^{-3}; the two phosphorescence band-series with the origins at 374.5 and 378 nm are evidently attributable to different emitters. The excitation spectrum responsible for the 374.5-nm phosphorescence band is also blue-shifted in accord with the blue-shifted absorption spectrum in chloroform at room temperature, quite similarly to the case of the carbon tetrachloride system. It should also be noted that the 374.5-nm phosphorescence band-series appears with the strongest intensity in just the same range of chloroform concentration as that suitable for the observation of the 1 : 1 complex formation.[1]

Phosphorescence of Pyrazine in the Ternary System Consisting of Pyrazine, Dichloromethane, and Cyclohexane at 77 K.

Figure 9 shows the changes of the phosphorescence spectrum of pyrazine with the increase of the dichloromethane concentration from 10^{-3} to 10^{-1} mol dm^{-3}. In quite a similar manner to the cases of the carbon

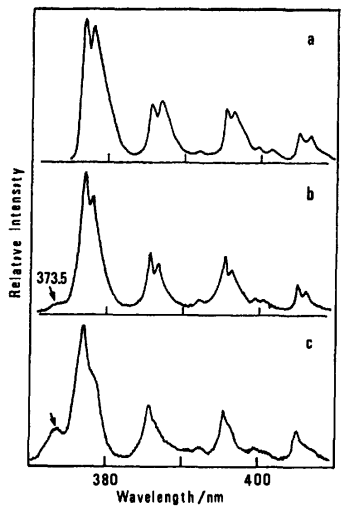

Fig. 9. Spectral changes of the pyrazine phosphorescence excited at 323 nm with the concentration variation of dichloromethane from 10^{-3} to 10^{-1} mol dm^{-3} in the dichloromethane–cyclohexane mixed solvents at 77 K. Concentration of pyrazine: 1.647×10^{-4} mol dm^{-3}. Concentration of dichloromethane: (a) 2.046×10^{-3}, (b) 2.046×10^{-2}, (c) 2.046×10^{-1} mol dm^{-3}.

tetrachloride and chloroform systems, the lower energy components of the cyclohexane-phase phosphorescence decrease with increasing concentration of dichloromethane. At the dichloromethane concentration of 2.0×10^{-2} mol dm^{-3}, a new phosphorescence band appears around 373.5 nm, as in the case of the chloroform system; this reflects the fact that nearly the same equilibrium constants for the complex formation are obtained in both systems at room temperature.[13]

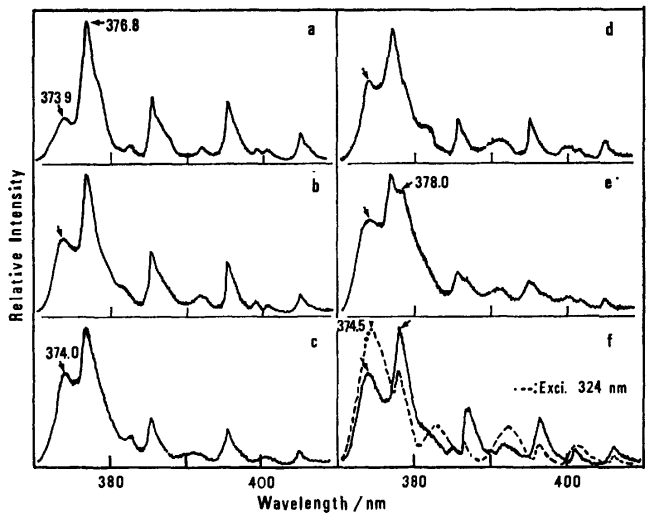

Fig. 10. Spectral changes of the pyrazine phosphorescence in the dichloromethane–cyclohexane mixed solvents at 77 K excited at 323 and/or 324 nm with the concentration variation of dichloromethane over the range closely related to the complex formation. Concentration of pyrazine: 1.444×10^{-4} mol dm^{-3}. Concentration of dichloromethane: (a) 0.255, (b) 0.511, (c) 0.766, (d) 1.021, (e) 1.277, (f) *ca.* 14 mol dm^{-3}.

Figure 10 shows the spectral changes of the phosphorescence excited at 323 and/or 324 nm with the increase of the dichloromethane concentration over just the same range as that studied on the complex formation.[1] At the concentration of 1.277 mol dm^{-3}, another new phosphorescence band appears as a shoulder at 378 nm. As in the cases of the carbon tetrachloride and chloroform systems, the new band is attributed to the dichloromethane-phase phosphorescence in the mixed solvent. In the dichloromethane concentration of about 14 mol dm^{-3}, either the 323-nm or the 324-nm excitation, even with very narrow slit width, no longer gives the higher energy components of the cyclohexane-phase phosphorescence, but gives exclusively the two new phosphorescence band-series mentioned above. The 374-nm band is somewhat dependent on the excitation wavelengths, as is seen in Fig. 10 (f); the 323- and 324-nm excitations give the bands at 373.8 and 374.5 nm, respectively. The excitation spectra monitored at 374 and 378 nm are quite similar to those of the carbon tetrachloride and chloroform systems; the excitation spectrum responsible for the 374-nm phosphorescence band is in accord with the blue-shifted absorption spectrum of pyrazine in dichloromethane at room temperature. Consequently, the 374-nm phosphorescence band can also be closely related to the 1 : 1 complex formation observed in the preceding study.[1]

Phosphorescence of Pyrazine in the Ternary System Consisting of Pyrazine, Ethanol, and Cyclohexane at 77 K. It is generally accepted that pyrazine in the ground state forms a hydrogen bond with ethanol. The ethanol system has been studied in order to examine whether the complexes in the chloroform and dichloromethane systems are of the charge-transfer type or the hydrogen-bonding one. Figure 11 shows the spectral changes of the phosphorescence excited at 323 nm with the increase of the ethanol concentration from 10^{-3} to 10^{-1} mol dm^{-3};

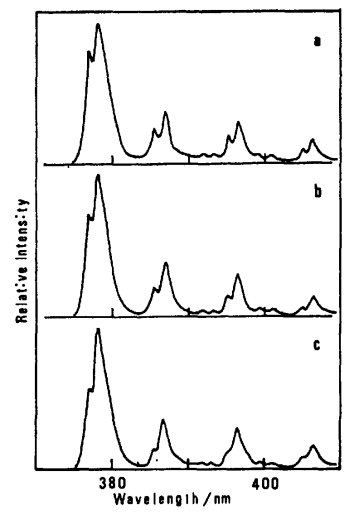

Fig. 11. Spectral changes of the pyrazine phosphorescence excited at 323 nm with the concentration variation of ethanol from 10^{-3} to 10^{-1} mol dm^{-3} in the ethanol–cyclohexane mixed solvents at 77 K. Concentration of pyrazine: 1.647×10^{-4} mol dm^{-3}. Concentration of ethanol: (a) 2.018×10^{-3}, (b) 2.018×10^{-2}, (c) 2.018×10^{-1} mol dm^{-3}.

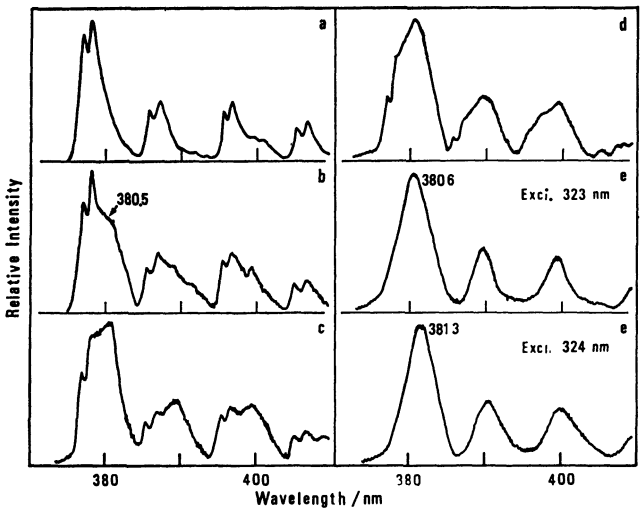

Fig. 12. Phosphorescence spectra of pyrazine excited at 323 and/or 324 nm in the ethanol-cyclohexane mixed solvents at 77 K. Concentration of pyrazine: 1.647×10^{-4} mol dm^{-3}. Concentration of ethanol: (a) 0.404, (b) 0.605, (c) 1.009, (d) 1.715 mol dm^{-3}, and (e) 90 vol%.

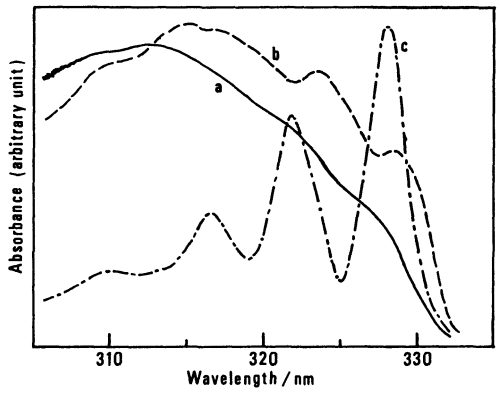

Fig. 13. Absorption and phosphorescence excitation spectra of pyrazine in the ethanol-containing mixed solvents. The absorption spectra a and b were obtained at room temperature and 77 K, respectively, in the mixed solvent of 93 vol% ethanol and 7 vol% methylcyclohexane. The excitation spectrum c monitored at 378 nm was obtained in the mixed solvent of 90 vol% ethanol and 10 vol% cyclohexane. Concentration of pyrazine: (a) and (b) 1.156×10^{-3}, (c) 1.647×10^{-4} mol dm^{-3}.

quite contrary to the cases of the halomethane systems, the lower energy components of the cyclohexane-phase phosphorescence increase in intensity relative to the higher energy ones with increasing ethanol concentration. Figure 12 shows the phosphorescence spectra at the ethanol concentrations ranging from 0.404 to 1.715 mol dm^{-3}. In contrast to the halomethane systems, the ethanol system shows no bands at wavelengths shorter than the higher energy components of the cyclohexane-phase phosphorescence. At ethanol concentrations higher than 0.605 mol dm^{-3}, new bands appear with their origin in the region 380—381 nm. Since the new phosphorescence bands are characteristic of the phosphorescence of pyrazine in ethanol glass at 77 K, they are attributed to the ethanol-phase phosphorescence in the mixed solvent. At a much higher ethanol concentration, 90% by volume, only the ethanol-phase phosphorescence has been observed, as shown in Fig. 12.

In order to examine the phosphorescence efficiences in the hydrogen bonding species, the phosphorescence excitation spectrum, curve c in Fig. 13, has been observed and compared with the absorption spectrum. The absorption spectrum of pyrazine in ethanol at room temperature loses some vibrational structure with blue shift of the spectrum due to hydrogen bonding; this is shown in Fig. 13 as curve a. The absorption spectrum at 77 K, curve b in Fig. 13, exhibits vibrational structure as shoulders at wavelengths longer than the vibrational bands observed in hydrocarbon solvents at room temperature. The absorption spectrum at 77 K is very similar to that observed at the same temperature by Krishna *et al.*[14] The phosphorescence excitation spectrum is apparently different from the absorption spectrum at 77 K. A comparison of the excitation and absorption spectra at 77 K indicates that the phosphorescence in ethanol at least mainly comes from the species which have vibrational structure in the absorption spectrum at 77 K. Therefore, it may be concluded that most of the hydrogen bonding species have very low phosphorescence efficiencies.

Krishna *et al.* proposed that the hydrogen bond was broken in the excited state, and hence the observed phosphorescence spectrum was consistent with the absence of hydrogen bonding in the triplet state; they did not perform any excitation spectrum measurement, however. Combining the results of Krishna *et al.* with our observations, the phosphorescence of pyrazine in ethanol at 77 K is thought to be emitted chiefly from the non-hydrogen bonding species, while the pyrazine molecules are modified by specific interactions such as cohesive forces between the solvent molecules or between the solute and solvent molecules. Thus, the phosphorescence bands observed around the region 373—374 nm in the chloroform and dichloromethane systems would not be attributed to hydrogen bonding species, but to the 1 : 1 charge-transfer complex species.

Origin of the New Phosphorescence Bands in the 373—375 nm Region. With the same halomethane concentrations as those suitable for the observation of the complex formation,[1] every halomethane system exhibits new phosphorescence bands with the origin in the 373—375 nm region; these are obviously different from the normal phosphorescence bands in the pure halomethane at 77 K. The 373—375 nm phosphorescence bands appear most clearly at the following halomethane concentrations: 2.048 mol dm^{-3} for the carbon tetrachloride system (Fig. 4, curve e; excited at 324 nm), 0.365 mol dm^{-3} for the chloroform system (Fig. 7, curve c; excited at 324 nm), and 0.766—1.021 mol dm^{-3} for the dichloromethane system (Fig. 10, curves c and d; excited at 323 nm). It has been previously established that the equilibrium constants for the complex formation

increase in the order of carbon tetrachloride, dichloromethane, and chloroform systems.[13] Accordingly, the chloroform and dichloromethane systems start to exhibit the new 373—375 nm bands at relatively low halomethane concentrations ($\approx 10^{-2}$ mol dm^{-3}) compared to the carbon tetrachloride system, as is seen in curve b of Fig. 6 and curve b of Fig. 9, respectively.

In addition, the excitation spectra of the 373—375 nm bands are blue-shifted in accord with the blue-shifted absorption spectra in the halomethane systems at room temperature. It should be emphasized that the results of the chloroform and dichloromethane systems are quite similar to those of the carbon tetrachloride system where no hydrogen-bonding species occurs. In contrast to the halomethane systems, the ethanol system exhibits no new phosphorescence bands in the 373—375 nm region. As for the relative intensities of the two well-known band series in the cyclohexane-phase phosphorescence of pyrazine, the halomethane systems show changes opposite to those in the ethanol system, with the increase of the halomethane and ethanol concentrations from 10^{-3} to 10^{-1} mol dm^{-3}, as is seen in Figs. 3, 6, 9, and 11. Thus, the halomethane effects on the phosphorescence of pyrazine differ from those of ethanol, and in particular the hydrogen-bonding species are independent of the appearance of the new 373—375 nm bands. In view of these observations, it is concluded that the new phosphorescence bands observed in the 373—375 nm region in the halomethane systems result from the 1 : 1 charge-transfer complexes.

Molecular Structure of Trimethylphosphine-Boron Tribromide as Determined by Gas Electron Diffraction

Kinya IIJIMA, Eiichi KOSHIMIZU, and Shuzo SHIBATA*

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received November 4, 1980)

The molecular structure of trimethylphosphine–boron tribromide $(CH_3)_3P\cdot BBr_3$ has been determined from gas electron-diffraction and vibrational-spectroscopic data. The molecular parameters and their uncertainties were r_g(B–Br)$=2.010\pm0.009$ Å, r_g(P–B)$=1.946\pm0.029$ Å, r_g(C–P)$=1.804\pm0.004$ Å, r_g(C–H)$=1.098\pm0.010$ Å, $\angle$BrBBr$=111.7\pm0.7°$, and $\angle$CPC$=108.0\pm0.7°$. The potential barrier around the P–B bond was also estimated to be about 10 kcal mol^{-1} (1 cal$=4.184$ J).

The molecular structures of trimethylamine–boron trihalides $(CH_3)_3N\cdot BX_3$ have been determined recently in both the gas and solid phases,[1-4] and the following conclusions have been drawn.[2] 1) On the formation of the complex the structural change of the acceptor molecule is greater than that of the donor molecule. 2) There is a correlation between the magnitude of the structural changes of the donor and acceptor molecules and the reorganization energy of the acceptor molecule.[5] 3) The donor-acceptor complex is stabilized and thus the N–B distance is shortened and the B–X distance is lengthened in the solid phase rather than in the gas phase.

On the other hand, the molecular structure of gaseous trimethylphosphine–boron trichloride $(CH_3)_3P\cdot BCl_3$[6] is essentially the same as that in the solid phase[7] and furthermore on the formation of the complex, the CPC angle in the donor molecule increases considerably and the C–P distance decreases, while in the case of the trimethylamine complexes the changes of the corresponding bond angle and distance are opposite. Thus it seems that trimethylphosphine and trimethylamine behave differently as a donor molecule.

In order to understand such interesting properties of trimethylphosphine donor, the structure of gaseous trimethylphosphine–boron tribromide $(CH_3)_3P\cdot BBr_3$ has been determined by an electron-diffraction method. The potential-barrier height of torsional vibration around the P–B bond has also been estimated from the combined analysis of electron-diffraction and vibrational-spectroscopic data.

Experimental

Trimethylphosphine–silver iodide complex was prepared by the procedure described in Ref. 8. The complex was decomposed under vacuum in an oil bath at 200 °C, and trimethylphosphine was collected in a trap cooled by liquid nitrogen after boron tribromide was condensed in advance. The mixture in the trap was warmed up to room temperature and was allowed to react. The crude complex obtained was recrystallized from acetone and water and was purified by repeated sublimations under vacuum.

In the electron-diffraction experiment the sample was vaporized at 200 °C by means of a high temperature nozzle. The photographs were taken using an r^3-sector on Kodak Electron-Image plates at camera distances 293.4 mm and 143.6 mm. The exposure time for the long camera distance was 17 s using an electron-beam current of 0.9 μA. For the short camera distance the exposure time was 65 s using a beam current of 0.8 μA. The pressure of the diffraction chamber was below 1×10^{-5} Torr (1 Torr$=133.3$ Pa) during the experiment. The electron wavelength was determined from the diffraction patterns of thallium chloride;[9] 0.06040 ± 0.00002 Å for the long camera distance and 0.06015 ± 0.00003 Å for the short camera distance. The optical densities of three plates taken at the long camera distance and three plates at the short camera distance were measured at 0.4 mm intervals by means of a digital microphotometer. The electron-diffraction unit and the digital microphotometer used in the present study were described in Ref. 10.

Analysis and Results

Molecular Intensity and Radial Distribution. The scattering intensites in the range of $s=2.5$—14.8 and 7.5—34.6 Å^{-1} were obtained from long and short camera distance plates, respectively. They were leveled by theoretical backgrounds, and then the intensities for each camera distance were averaged. The elastic and inelastic scattering factors were taken from the tables prepared by Schäfer *et al.*[11] and by Cromer and Mann,[12] respectively. The inelastic scattering factor for hydrogen atom was taken from the table by Tavard *et al.*[13]

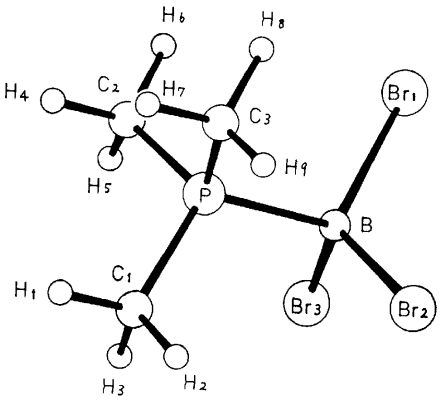

Fig. 1. Numbering of atoms in trimethylphosphine–boron tribromide (symmetry C_{3v}).

The background curves were drawn smoothly, and the molecular intensities shown in Fig. 2 were obtained.[14] Because of the large difference between the atomic numbers of bromine and other atoms in a trimethylphosphine–boron tribromide molecule, N_{ij} functions which fit μ_{ij} over the scattering-angle range for the experiment were calculated[15] and are given in Table 1. The radial distribution corrected by the N_{ij} functions is shown in Fig. 3.

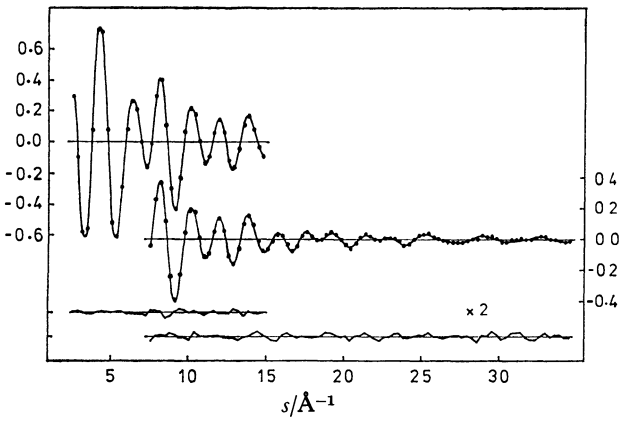

Fig. 2. Molecular intensities for trimethylphosphine–boron tribromide. The two upper curves are long and short camera-distance data. Dots represent observed ones, solid curves calculated ones, and their residuals are shown below.

TABLE 1. COEFFICIENTS OF N_{ij} FUNCTIONS

Force Constant, Mean Amplitude of Vibration, and Shrinkage Effect. Drake *et al.* have studied the IR and Raman spectra of $(CH_3)_3P\cdot BBr_3$ in the solid phase and in solutions by the normal-vibration treatment.[16] We calculated the mean amplitudes of vibration, which are given in Table 5, on the basis of their force field. The calculated values for l(*gauche* Br···C), l(Br···Br), and l(B–Br), however, disagreed with the observed ones obtained from the analysis of electron-diffraction data.

The force field by Drake *et al.* was in disregard of the torsional vibrations around the P–B and C–P bonds. The torsional vibration around the P–B bond contributes significantly to l(*gauche* Br···C), and therefore the force constant of Y(P—B) was estimated so that the calculated l(*gauche* Br···C) is equal to the observed one.[1] The value obtained was 0.31×10^{-18} N m, which corresponds to the potential barrier of 9.9 kcal mol^{-1}.** The upper and lower limits of the barrier were estimated to be 18.2 and 6.7 kcal mol^{-1}, respectively. The force constant for the torsional vibration around the C–P bond was assumed to be 0.08×10^{-18} N m, which was estimated from the potential barrier for trimethylphosphine, 2.6 kcal mol^{-1}.[17] The force constants of K(B–Br) and F(Br···Br) are related mainly to l(B–Br) and l(Br···Br), respectively. These constants were also estimated as K(B–Br)$=2.0\times10^2$ N m^{-1} and F(Br···Br)$=0.30\times10^2$ N m^{-1} by the same method as used for Y(P–B).

TABLE 2. FORCE FIELD FOR $(CH_3)_3P\cdot BBr_3$

f(CH)	4.782	H(BrBBr)	0.44
f(HCH)	0.433	F(BrBr)	0.30†
f(HCP)	0.642	F(PBr)	0.25
f(CPC)	0.81	f(CH/CH′)	0.045
f(CPB)	0.84	f(HCP/HCP′)	−0.109

K(PB)	1.917	f(CPB/CPB′)	−0.06
K(BBr)	2.00†	Y(CP)	0.081†
H(PBBr)	0.42	Y(PB)	0.31†

In the present normal-coordinate calculation, general valence force constants f and Urey-Bradley force constants K, H, F, and Y were used with stretching and repulsion constants in 10^2 N m^{-1}, bending constants in 10^{-18} J rad^{-2}, and torsional constants in 10^{-18} N m. Linear constant F' was assumed as $-0.1F$. The values of the force constants were taken from Ref. 16, but those indicated by dagger were estimated in the present study.

The force constants of $(CH_3)_3P\cdot BBr_3$ modified in the present study are given in Table 2, and the mean amplitudes of vibration and the shrinkage effects,[18] r_a-r_α, calculated on the basis of these force constants are listed in Table 3. The force constants of K(B–Br) and F(Br···Br) obtained by Drake *et al.* (0.96 and 0.44×10^2 N m^{-1}, respectively)[16] are in disagreement with those from the present study. This may be due to the fact that the electron-diffraction experiment was carried out in the gas phase while the spectroscopic experiment was done in the solid phase and in solutions.

** The systematic error of the mean amplitude was taken into consideration because R_2 was slightly small as seen in Table 6, but it was quite small and thus the height of the potential barrier was not varied.

The numbering of the atoms is shown in Fig. 1. The calculated values were obtained for the same temperature (473 K) as the experiment was carried out.

Analysis of Electron Diffraction Intensities. The molecular parameters of $(CH_3)_3P \cdot BBr_3$ were determined by the least-squares analysis of molecular intensities. It was assumed that the molecule has a staggered form of C_{3v} symmetry with the methyl groups which also have C_{3v} symmetry in a staggered form with respect to the C–P bonds. The geometrical parameters determined by the least-squares analysis were as follows: r(B–Br), r(P–B), r(C–P), r(C–H), r(Br···Br), r(C···C), and ∠PCH. The mean amplitudes not listed in Table 5 and the shrinkage corrections for all the atomic pairs were fixed to the values listed in Table 3. The asymmetry parameter, κ, for the C–H bond was assumed to be 1.2×10^{-5} Å^3 by a diatomic approximation.[19] The asymmetry parameters for the other atomic pairs were ignored.

The r_α parameters determined by the least-squares calculation are listed in Table 4, where the r_g parameters and the limits of error are also listed. The random errors were given by 2.6 times the errors in least-squares calculations. The systematic errors were estimated from the errors in both the measurements of camera distance (0.04%) and wavelength (0.06%). The mean

Bond distance: Å unit; bond angle: degree unit. The values in the gas phase represent r_g parameters. a) Ref. 6. b) Ref. 7. c) Present study. d) Ref. 22. e) Ref. 20. f) Ref. 21.

amplitudes and their limits of error obtained from the least-squares analysis and the calculated mean amplitudes are listed in Table 5. The large errors in the distances and the mean amplitudes for the B–Br and P–B bonds are probably attributable to the large correlation between their parameters.

The correlation matrix is listed in Table 6, and the best-fit theoretical molecular intensities are shown in Fig. 2. The calculations of the mean amplitudes and the shrinkage effects and the least-squares analysis were carried out on a HITAC 8800/8700 computer in the Computer Center of the University of Tokyo.

Discussion

On the formation of the $(CH_3)_3P\cdot BBr_3$ complex, the B–Br distance increases by 6.2% and the BrBBr angle decreases by 6.9% (Table 7), while the C–P distance decreases by 2.3% and the CPC angle increases by 9.5%. The ratios of the changes in the B–Br and C–P distances are in good agreement with the corresponding ones in $(CH_3)_3P\cdot BCl_3$.[6] The P–B distances in both complexes are also equal to each other in the gas phases. These structural changes represent that the valence orbital of the phosphorus atom in the donor molecule changes from p^3 to sp^3 and the valence orbital of the boron atom in the acceptor molecule from sp^2 to sp^3 on the formation of a complex.

On the other hand, in the solid phase the P–B distance in $(CH_3)_3P\cdot BBr_3$ is smaller than in the gas phase with the increment of the B–Br distance and the decrement of the BrBBr angle though these changes are not large as compared with their experimental errors. This is consistent with the foregoing remarks that the force constant of K(B–Br) is larger and the F(Br···Br) is smaller in the gas phase than in the solid phase. Thus it appears that the P–B dative bond in $(CH_3)_3P\cdot BBr_3$ is enhanced in the solid phase as well as the N–B bond in $(CH_3)_3N\cdot BX_3$.

Comparing the molecular structures of trimethylphosphine-boron trihalide complexes with those of trimethylamine-boron trihalide complexes, the boron-halogen bond distances in the trimethylphosphine complexes are a little larger than those in the trimethylamine complexes (r_g(B–Cl) = 1.836 ± 0.002 Å for $(CH_3)_3N\cdot BCl_3$ and r_g(B–Br) = 2.001 ± 0.003 Å for $(CH_3)_3N\cdot BBr_3$).[2] A stronger donor gives a larger change in an acceptor molecule on the formation of a complex, and thus it seems that trimethylphosphine is a stronger donor for boron trichloride and boron tribromide than trimethylamine.

The rotational barrier around the P–B bond of $(CH_3)_3P\cdot BBr_3$ is apparently higher than that of $(CH_3)_3P\cdot BCl_3$, 3.8 ± 0.7 kcal mol^{-1}.[6] It is interesting to note that this order is inverse to the order obtained for the trimethylamine complexes, $(CH_3)_3N\cdot BCl_3$ and $(CH_3)_3N\cdot BBr_3$.[2] The height of the rotational barriers for these complexes may be dominated by the repulsion due to the nonbonded atomic pairs, such as $Br_1\cdots H_6$ in the case of $(CH_3)_3N\cdot BBr_3$, which have the shortest distances among the atomic pairs between the methyl groups and halogen atoms. The above order for the trimethylamine complexes will be understandable because the $Br_1\cdots H_6$ distance (2.79 Å) in $(CH_3)_3N\cdot BBr_3$ is greater than the $Cl_1\cdots H_6$ distance (2.69 Å) in $(CH_3)_3N\cdot BCl_3$. However, the order for the trimethylphosphine complexes cannot be likewise understood because the $Br_1\cdots H_6$ distance (3.25 Å) in $(CH_3)_3P\cdot BBr_3$ is nearly equal to the $Cl_1\cdots H_6$ distance (3.27 Å) in $(CH_3)_3P\cdot BCl_3$.

Computer Counting of the Number of Water Molecules in the First Layer of Crystalline Water Clathrate

Iwao TABUSHI,* Yo-ichi KIYOSUKE, and Kazuo YAMAMURA
Department of Synthetic Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received November 4, 1980)

Semiempirical calculation of the number of water molecules in the first layer of water clathrates in crystalline state was developed by computer aided construction of hydrogen-bonded network of water molecules. In the generalized thermodynamic considerations on four possible types of "unit clathrate," van der Waals stabilization energy, "strain" energy of the unit clathrate, and entropy term due to the motional freedom of the guest were taken into account for the calculation of free energy change for the formation of the water clathrate. The results of calculations on 37 hydrophobic organic molecules well represented the trend of the reported experimental data of X-ray studies. The present calculation also disclosed such a large unfavorable strain energy (8.72 kcal·mol^{-1})† of pentakaidecahedron that it counteracts the van der Waals stabilization. The result is in a good agreement with the fact that pentakaidecahedral cavity is rarely seen in the gas hydrates. Most importantly, these semiempirical calculations of the energetics of water clathrates afforded valuable new insights into water assembly and may be extended to give better understandings of structured water in biological system and of water clusters that develop around apolar solutions in water.

Hydrophobic interaction is assumed to be one of the most significant factors that determine protein conformation and has provided a physicochemical basis for the concept of highly specific molecular recognition that many biological macromolecules exhibit.[1] Studies on properties of an apolar solute in water are particularly relevant to water structure study for elucidation and semiempirical determination of the hydrophobic interaction.[1,2a] However, the progress of an "iceberg" theory has been retarded by contradictory results from thermodynamic and spectroscopic studies.[2b-e] Moreover, no definitive evidence for the presence of strengthened water clusters around or in proximity to the hydrophobic surface of a solute molecule was obtained from spectroscopic experiments such as NMR.[2c,f]

Assumption of a generalized hypothetical process proposed for the molecular recognition between relatively simple host and guest and application of semiempirical force field potentials were found to claim a great advantage of the first layer model of water clusters in thermodynamic considerations.[3] Thus, in our most recent theoretical treatise on chemical model of biological molecular recognition, the observed free energy change for inclusion complexing of a hydrophobic guest by α-cyclodextrin in water could be successfully reproduced by applying the above concept of water clusters. Némethy and Scheraga had shown that the work requisite to break icelike structured water (water clusters) is proportional to the number of water molecules in the first layer of the water clusters developed around an apolar solute.[4a] Their treatment of cluster model has been continuously generalized and improved by use of modified partition function, incorporating the effects of cooperative hydrogen bonding on the continuous distribution of all possible cluster size.[4a-c]

Most importantly, the breaking of the water clusters around the guest is one of the most important and crucial factors associated with the process of biological molecular recognition and, in this context, greater sophistication is necessary in non- or semi-empirical evaluation of the number of water molecules in the first layer of water clusters around a guest molecule in order to derive the thermodynamic parameters rigorously. Fortunately a lot of insight have been accumulated into crystalline water clathrates from experiments,[5] although there is no direct physicochemical evidence from experiments for the presence of water clusters in a liquid state.[2]

A variety of hydrogen-bonded networks of water molecules in the crystalline state are thus far known, whose cavity includes various types of organic molecules. The unit structure of the water clathrate varies from dodecahedron composing of 20 water molecules to hexakaidecahedron composing of 28 water molecules, yet the actual hydrates involving so-called structure I or II have composite ratios of polyhedral cavities to form the complicated structures of the hydrate lattice.[5]

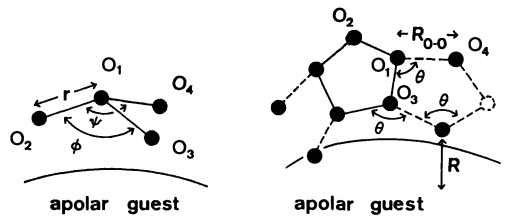
A semiempirical calculation of the number of water molecules in the first layer of water clathrate, the *unit clathrate*, was studied, by constructing and characterizing the hydrogen-bonded networks by computer method. Such the approach made a further progress in theoretical considerations of crystalline water clathrates, structured water in proteins[4d] and other molecules of biological interest, cyclodextrin[4e,f] being one of the simplest examples. In this article the authors wish to report the computer counting of the number of water molecules in the first layer for 37 hydrophobic molecules, where the predicted numbers are in good agreement with reported experimental data. In the extented procedure of the computer evaluation of the number of water molecules, we employed a fit criterion based on the thermodynamic consideration which takes van der Waals stabilization energy, "strain" energy of a polyhedron, and motional freedom of the guest into account. The present theoretical analyses have led us to the conclusions that (1) the rotational freedom of the guest is more critical than the van der Waals interaction for the stabilization of unit clathrates (2) pentakaidecahedron has too large "strain" energy to form a stable unit clathrate (3) a pentagon of hydrogen-bonded five water molecules is most appropriately used as the

† 1 cal=4.18 J.

metastable unit for the semiempirical constructions of the first layer of unit water clathrates. The energetics of water networks based on the semiempirical model was for the first time successfully developed to a simple expedient for the calculation of the number of water molecules. We are now in an advanced stage of the investigation of the water structure around apolar organic molecules in liquid water.

Method of Calculation

General Consideration of Network Construction and Computer Counting of Water Molecules. In Fig. 1a are shown fundamental parameters necessary to construct the hydrogen-bonded network of water molecules for the first layer model where r is the distance between two hydrogen-bonded oxygen atoms, and ϕ and ψ are bond angles defined by $O_2O_1O_3$ and $O_2O_1O_4$ in Fig. 1a, respectively. The fourth coordination of O_1 is neglected (first layer approximation), *viz.*, the hydrogen bond of O_1 to the water molecule in the second layer is regarded substantially the same as that in the bulk water.[6]



$R_{o-o}=2.8\pm0.1$ Å $\theta=108\pm5.8°$ $R_{vdw}\leq R\leq R_{vdw}+1.7$

Fig. 1. (a) Illustration of the distance r and the angles ψ, ϕ defined by hydrogen bond axis in the local structure of hydrogen-bonded networks of water molecules in the first layer of water clathrates. (b) Illustration of the distance R_{o-o} and the angle θ defined for the computer counting based on the method of "pentagon paving."

As preliminary trial of the network construction, we take three hydrogen bonds and van der Waals interaction between the guest and the surrounding network into consideration. Then, Cartesian coordinates (χ_j) of O_1 and O_2 are correlated by simple equations (1)—(3) to those of O_3 and O_4, of neighbored water molecules, where subscripts i and g refer to oxygen and guest,

$$\sum_{j=x,y,z}(\chi_{ji}-\chi_{j1})^2 = r^2 \quad (i=2,\ 3,\ \text{or}\ 4) \tag{1}$$

$$\sum_{j}(\chi_{j1}-\chi_{j2})(\chi_{j1}-\chi_{j2}) = r^2\cos\phi \ \text{ or } \ r^2\cos\psi \tag{2}$$

$$\sum_{j}(\chi_{ji}-\chi_{jg})^2 = R_{vdw}^2 \quad (i=1,\ 2,\ 3,\ \text{or}\ 4) \tag{3}$$

respectively, and R_{vdw} is the distance between the oxygen and the guest molecule.[7] Parameters were taken from structure I: $r=2.8$ Å, $\phi=\psi=108°$, and $R_{vdw}=3.32$ Å.[5] According to the requirements (1)—(3), consecutive determinations of coordinates of oxygen atoms were carried out for the case of argon, but the number of 12 obtained as the result of the iterative computer counting was much smaller than the X-ray results of 20 water molecules constructing a dodecahedron.[5]

Method of Pentagon Paving. Attempts to improve the disadvantage of the above somewhat complicated but still unsatisfactory treatment introduced to maximize both the vdw attractive interaction and the hydrogen bond energy, were made by introducing a pentagon which is composed of hydrogen-bonded five water molecules (Fig. 1b), since it is known that the pentagon is the important unit structure of the most stable forms of crystalline water[5] (structure I). The computer counting was executed iteratively, constructing pentagons in turn so as to satisfy geometrical relationships (4)—(6), where R_{o-o} is the distance between two

$$\sum_{j=x,y,z}(\chi_{ji}-\chi_{j1})^2 = R_{o\text{-}o}^2 \quad (i=2,\ 3,\ \text{or}\ 4) \tag{4}$$

$$\sum_{j}(\chi_{ji}-\chi_{j1})(\chi_{j2}-\chi_{j1}) = R_{o\text{-}o}^2\cos\theta \quad (i=3\ \text{or}\ 4) \tag{5}$$

$$\sum_{j}(\chi_{ji}-\chi_{j1})(\chi_{j3}-\chi_{j1}) = R_{o\text{-}o}^2\cos\theta \quad (i=2\ \text{or}\ 4) \tag{6}$$

hydrogen-bonded oxygen atoms, θ is the angle defined by three oxygen atoms (O–O\O), and χ are Cartesian coordinates of oxygen atom.[8]

Additional assumptions made for the present model are the followings: (1) The maximal allowancy of deformations of R_{o-o} and θ are 2.8 ± 0.1 Å and $108\pm5.8°$, respectively. Crystallographic data of water clathrate revealed that experimental values of R_{o-o} fall in the range of 2.8 ± 0.1 Å,[5p,g] and the allowancy of angle deformation ($\pm5.8°$) was, therefore, estimated on a basis of energetic equivalence to the bond deformation of 0.1 Å (0.112 kcal·mol^{-1}).

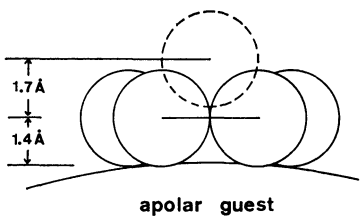


Fig. 2. A water molecule in contact with the pentagon illustrates the geometrical limit of the first layer water molecule ($R_{vdw}+1.7$ Å).

(2) A second water molecule comes into contact with the pentagon at a distance of 1.7 Å from the oxygen (Fig. 2). We, thus, assigned the distance of $R_{vdw}+1.7$ Å to the geometrical limit allowed for the first layer molecule, although the definition is a conceptual clue to the present semiempirical approach.

Fit Criterion Based on Thermodynamic Considerations. In view of the facts that hexagon appears in structure I and II which include relatively large guest molecules, four most probable polyhedra were employed as a *unit clathrate*; dodecahedron, tetrakaidecahedron, pentakaidecahedron, and hexakaidecahedron. At first the free energy change for the formation of the unit clathrate should be taken into the thermodynamic considerations.[8b] For the present purpose, all of possible free energies were introduced: van der Waals stabilization between the guest and the unit clathrate (ΔE_{vdw}),[9a] the "strain" energy of the hydrogen-bonded network of water molecules (ΔE_{strain}),[9b] and motional freedom

of the guest in the cavity (ΔS^g). The free energy change, ΔG, relevant to the formation of unit cell[9c] of crystalline water clathrate now can be calculated using Eq. 7. The number of water molecules in the first layer was calculated as shown in Scheme I, by combining the free energy calculation with the computer aided preconstruction of the network of water molecules for each postulated unit clathrate.

$$\Delta G = \Delta E_{vdw} + \Delta E_{strain} - T\Delta S^g$$
$$\Delta S^g = \Delta S^g_{rot} + \Delta S^g_{trans} + \Delta S^g_{vib} \quad (7)$$

	dodecahedron	tetrakaidecahedron	pentakaidecahedron	hexakaidecahedron
Guest	fit?	fit?	fit?	fit?
	yes	yes	yes	yes
Number of water molecule	20	24	26	28

Scheme 1.

Through the optimization of the atomic coordinates of the included guest molecule, the energy of van der Waals interaction (E_{vdw}) was maximized using Hill's potential[9d] (Eq. 8),

$$E_{vdw} = -2.25\varepsilon(r^*/r)^6 + 8.28 \times 10^5\varepsilon \exp(-r/0.0736r^*), \quad (8)$$

where r refers to the interatomic distance, r^* is the sum of the van der Waals radii of the two interacting atoms, and ε is a parameter which is defined individually for each pair of the two interacting atoms.[10]

The strain energy of the unit clathrate was calculated by use of semi-empirical force field potentials. The bond-stretching energy associated with the longitudinal deformation of the hydrogen bond is calculated by Eq. 9, where ΔR is the deviation from the equilibrium length of O···O distance (2.76 Å).[11] ΔE_θ and ΔE_α (Eqs. 10, 11) are angle strains relevant to deformations

$$\Delta E_R = \frac{1}{2}k_R(\Delta\bar{R})^2 \quad (9)$$

$$\Delta E_\theta = \frac{1}{2}k_\theta(\bar{R}-\bar{r})\bar{r}(\Delta\theta)^2 \quad (10)$$

$$\Delta E_\alpha = \frac{1}{2}k_\alpha r^{-2}(\Delta\alpha)^2 \quad (11)$$

$$\Delta E_{strain} = \Delta E_R + \Delta E_\theta + \Delta E_\alpha$$

of O–H···O angle and H–O–H angle, respectively, where R and r are the O···O and O–H bond lengths, respectively, and $\Delta\theta$ and $\Delta\alpha$ are the deformations from the equilibrium angles of O–H···O (180°) and H–O–H (109°28′), respectively. Reported parameters k_R= 22.7 kcal·mol^{-1}·Å^{-1}, k=12.7 kcal·mol^{-1}·Å^{-2}·rad^{-2}, and k_α=78.4 kcal·mol^{-1}·Å^{-2}·rad^{-2} were used.[11]

As to the motional freedom of the apolar guest,[9e] we calculated rotational freedom that makes largest contribution to the entropy term (ΔS^g). The vibrational entropy of a guest is assumed to be unchanged when the guest is sorbed within a unit clathrate of any cavity size. This assumption is supported by the following evaluation, *i.e.*, even a significant frequency change of 5 cm^{-1} for one vibration (1000 cm^{-1}) should accompany a very small entropy change of only 0.03 cal·deg^{-1}·mol^{-1}. One-dimensional, two-dimensional, and three-dimensional rotational entropies are given by Eqs. 12, 13, and 14, respectively, where N_A is Avogadro's number, κ is the Boltzman constant, h is the Planck constant, I is the moment of inertia, σ is the symmetry number, and T is the absolute temperature.

$$S^g_{rot(1\text{-}D)} = N_A\kappa\left\{\frac{1}{2}+\frac{1}{2}\ln\frac{8\pi^2 I\kappa T}{h^2}-\ln\sigma_1\right\} \quad (12)$$

$$S^g_{rot(2\text{-}D)} = N_A\kappa\left\{1+\ln\frac{8\pi^2 I\kappa T}{h^2\sigma_2}\right\} \quad (13)$$

$$S^g_{rot(3\text{-}D)} = N_A\kappa\left\{\frac{3}{2}+\frac{1}{2}\ln\frac{(8\pi^2\kappa T)^3 I_1 I_2 I_3}{h^6}-\ln\sigma_3\right\} \quad (14)$$

Calculations were aided by a digital computer FACOM M-190 OSIV/F4 at the Data Processing Center of Kyoto University.

Results and Discussion

The pentagon method was applied to eleven hydrophobic molecules and the counted number of water molecules in the first layer is listed in Table 1. The calculated results well reproduce experimental data. It is shown that rare gases and even methane or acetylene

can form a dodecahedron unit clathrate. In the case of chlorine molecule, the computer constructed network of twenty water molecules was found to have a structure of distorted dodecahedron, and each pentagons is to some extent constrained to take a puckered form. Further analyses of the results have disclosed that, incomplete constructions of water networks were seen for much larger molecules such as ethane, benzene, bromine, and iodine, and some portion of hydrophobic surfaces of those molecules are left uncovered by water molecules, four to eight more positions being open for water molecules to occupy in the region of the first layer (<1.7 Å). An advantageous clue to a priori prediction of the number of water molecules in the first layer is (a) thermodynamic consideration (*vide infra*) or (b) general modification of the paving method by incorporating the distribution of other possible diagrams than pentagon as well as with an improved concept of the first layer.

Table 3 shows the van der Waals energy and the quantitative effect of the strain energy of the polyhedron (Table 2) on the stabilization of the unit clathrate. It is apparent that the van der Waals stabilization energy decreases moderately and monotonously with the increase of the cavity size. However, since pentakaidecahedron and hexakaidecahedron have much larger strain energies (8.72 and 5.46 kcal·mol^{-1}, respectively) than the two smaller polyhedra (Table 2), the energy of the unit clathrate formation ($E_{vdw}+E_{strain}$) no longer correlates with the cavity size. For example, ethylene is most stabilized on forming the dodecahedron unit clathrate ($E=-5.29$ kcal·mol^{-1}), while the destabilization was greatest ($E=+3.45$ kcal·mol^{-1}) when it forms the pentakaidecahedron unit clathrate. Thus, the different extent of the contribution of E_{vdw} which counteracts E_{strain} resulted in a marked difference of formation energy ($E_{vdw}+E_{strain}$) of four unit clathrates (Table 3).

Remarkable van der Waals stabilizations obtained for cyclopropane ($E_{vdw}=-11.78$ kcal·mol^{-1}) and methyl bromide ($E_{vdw}=-10.98$ kcal·mol^{-1}) in dodecahedron, or isobutane ($E_{vdw}=-15.92$ kcal·mol^{-1}) and I_2 ($E_{vdw}=-15.01$ kcal·mol^{-1}) in tetrakaidecahedron, are most easily rationalized as a result of ideal fit of these molecules with the corresponding cavity size. Experimental values of ΔH for gases sorbed within preconstructed dodecahedral cavity are reported for only a few inert gases: Ar, $\Delta H=-6.1$ kcal·mol^{-1}; Kr, $\Delta H=-6.7$ kcal·mol^{-1}.[12] Therefore, the calculated values of E_{vdw}(−4.82 and −6.93 kcal·mol^{-1} for Ar and Kr, respectively) account for the most portion of the reported enthalpy changes. It is apparent from the results of Table 3 that the large portion of the net stabilization of the water clathrates originates in the large van der Waals stabilization, and the numbers of water molecules observed have been well reproduced by the present semi-empirical calculation. It has been approved, therefore, that many hydrates are stabler than ice I, those melting points being even higher than 0 °C.[1] In cases of small gas molecules (He, Ne, and H_2), however, the van der Waals attractive energy was too small to compensate the large strain energy of the unit clathrate (1.1 to 8.7 kcal·mol^{-1}). Thus the crucial magnitude of the strain energy resulted in no (or little) net stabilization of unit water clathrates of these molecules (Table 3). This result may explain why no X-ray study is thus far reported on these molecules.

In eight water clathrates (Ar, Kr, CH_4, C_2H_6, CH_2=CH_2, CH≡CH, CH_3F, and CH_3Cl), the present calculation gave the number of 20, *i.e.*, the dodecahedral unit brings more stabilization with these molecules than the tetrakaidecahedron does. Despite the above, two experimental numbers, 20 and 24, are known for those water clathrates[5] (structure I). It is most likely that the ensemble of the unit clathrate of dodecahedron alone hardly stabilizes the gross ice lattice. The enthalpy changes for the formation of structure I and structure II are reported by Child as 180 and 200 cal·mol^{-1}, respectively.[13a] This fact strongly indicates that even these actual clathrates have additional lattice energy, since the calculated energy (Table 2) predicts *ca.* one half of the observed value, *viz.*, 91 cal·mol^{-1} for 1 : 3 hybrid of dodecahedron and tetrakaidecahedron (structure I) and 110 cal·mol^{-1} for 12 : 8 hybrid of dodecahedron and hexakaidecahedron (structure II). This strongly indicates that, for the theoretical treat-

ment of the lattice formation from unit clathrates, a semiempirical approach should be introduced to the mechanism of the strain relief over the gross crystalline lattice.

In addition, an exclusively new insight was given by the present calculations into the motional freedom of apolar molecules sorbed in water clathrates. In cases of relatively large molecules such as benzene, CS_2, and isobutane, a general trend is to be noted that the calculated number, 24, for those molecules (Table 3) is always smaller than the experimental value of 28. It is easily rationalized that in larger unit clathrates those molecules are endowed with much freedoms of restricted motions.[14] In Table 4 are listed the calculated entropies together with the rotational freedoms allowed for selected molecules. In Table 5 are given the numbers of water molecules predicted in the first layer of the water clathrate. As typically shown for propane, benzene, or CS_2, the rotational entropy drastically increases by the change of unit clathrate from pentakaidecahedron to hexakaidecahedron. As the result, the formation of hexakaidecahedral unit clathrate becomes more favorable, since the calculated ΔG value is large in the negative sign compared with those of other polyhedra (Table 5). In the case of benzene, the correct number of 28 was obtained. The results of Table 5 clearly indicate that the present calculation gives satisfactory number of water molecules in the first layer of unit clathrate, after the correction from rotational entropy term (see Table 5) is made. It is concluded, therefore, that the free energy minimization of unit clathrate can be used as the criterion for the formation of crystalline water clathrate.

The extraordinarily large strain energy of pentakaidecahedron (Table 2) rationalizes a fact that this unit structure is rare in the gas hydrates,[15] despite its appropriate cavity size for the accommodation of a relatively large guest molecule, or those large values of E_{vdw} in negative sign (Table 2) that is the intrinsically favorable factor for the formations of water clathrates.

In conclusion, it has been shown that the van der Waals interaction, the strain energy of the hydrogen-

a) kcal·mol^{-1}. b) In parentheses are shown the number of water molecules of the penultimate unit clathrate which is the second most stable and less stable only within 2 kcal·mol^{-1} than the most stable unit clathrate.

bonded networks of water molecules, and the rotational freedom of the bound guest are the most important term which govern the formation of the water clathrates with hydrophobic molecules. The present study successfully provides the semiempirical basis for *a priori* computation of the number of water molecules in the first layer of the crystalline water clathrate and the present method may be fruitful enough to be extended to the significant problems of water clusters in solutions.

6) A water molecule adjacent to the pentagon (first layer molecules) can independently form stable hydrogen bond, irrespective of the presence of an apolar solute, *i.e.*, as a safe approximation the local structure of water molecules in the second layer and at farther position was assumed to closely resemble that of bulk water.

7) We have encountered a difficulty that the number of sites possibly occupied by oxygens rapidly increases as the execution proceeds. A simple way of the counting to save the computing time was; two independently assigned positions of new oxygen atoms were compared after every loop of computer mapping, and if a site is judged to be doubly occupied within an error of 0.1 Å, then the computer program excludes one and reassigns a new serial number for all oxygens.

8) a) The pentagon method (Eqs. 4—6) employs preferential release of the strain energy (bond length and bond angle strain varying from 1.1 to 8.7 kcal·mol^{-1}) of an unit clathrate since van der Waals stabilization decreases only gradually with the increase of the distance of water molecule from the apolar guest. It, therefore, lightens restriction on the number of water molecules, leading to incorporation of sufficiently remote water molecules. The maximum limit allowed for the remote molecules is given by the elimination of the second layer water molecules from the present counting (Fig. 2). b) We deal with many different guest molecules which are in the gaseous state or in the liquid state at 0 °C, 1 atm. Therefore, it was necessary to constitute crystalline water clathrate from appropriate number of water molecules and a guest molecule, both in the same appropriate standard state, to allow comparison of the different ways that water molecules from the networks around apolar guest molecules of different shape and different size. Thus, for the present thermodynamic calculation, the clathrate was constituted from ice I and a guest molecule whose motional freedoms are freezed in a hypothetical isolated state.

9) a) At $r=\infty$, where r is the interatomic distance between the water molecule and the guest molecule, E_{vdw} equals zero. Therefore, the E_{vdw} value which was calculated by using Eq. 8 equals the van der Waals stabilization, ΔE_{vdw}. b) The "strain" energy of the unit clathrate, ΔE_{strain}, is given by $\Delta E_R+\Delta E_\theta+\Delta E_\alpha$ and designates the energy to form the unit clathrate from ice I whose "strain" energy is zero. c) Configuration change of a unit cell should be reflected in that of neighbors but as the first order approximation these trans-

mitting configuration effect is neglected in the present calculation. d) T. L. Hill, *J. Chem. Phys.*, **16**, 399 (1948), R. E. Hawkins, D. W. Davidson, *J. Phys. Chem.*, **70**, 1889 (1966). e) Based on the definition mentioned in Ref. 8b, motional freedom of the guest molecule allowed in the cavity is taken into the account. The rotational freedom of the guest molecule in the cavity made the largest contribution to ΔS^g, while the translational freedom should be negligible and the vibrational freedom is unchanged as discussed in the text.

10) a) Parameter ε is a geometrical mean of values for each of the two interacting atoms.

Resonance Energies of the Arenium Ions and Their Relevance to the Electrophilic Substitution Reactions

Jun-ichi AIHARA†

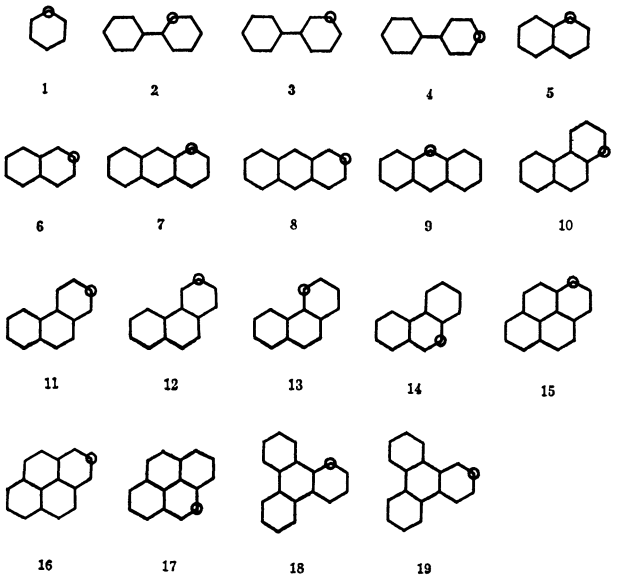
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 12, 1981)

Hyperconjugative interaction through the methylene group was incorporated in the framework of the Hückel molecular orbital model. Resonance energies of the arenium ions, derived from typical benzenoid hydrocarbons, were calculated using the graph theory of aromaticity. It was found that even a benzenium ion has a considerable degree of aromaticity. In general, the arenium ion with large localization energy has both large resonance energy due to hyperconjugation and large positive charge density at the methylene group. These two quantities are possibly responsible for the competition between substitution and addition reactions on the benzenoid hydrocarbons. An aromatic transition state tends to choose a reaction path to substitution products, at least, for these compounds.

It is widely known from the chemistry of aromatic hydrocarbons that solutions of these compounds in strong acidic media, such as concentrated sulfuric acid, show an intense color even if the pure compound is colorless.[1,2] The formation of an arenium ion, *i.e.*, a proton addition complex, is responsible for this phenomenon. An aromatic hydrocarbon is, therefore, characterized as a base, and the corresponding arenium ion as the conjugate acid. The cyclic π-electron system of an aromatic hydrocarbon is the electron source often sought not only by a proton but also by the reagent electrophile.[3,4] The arenium ions have been firmly established as intermediates in electrophilic substitution reactions, as well as numerous acid-catalyzed transformations of aromatics.[5,6] Thus, it is quite understandable that a considerable effort has been expended over the past years to elucidate the electronic structures of the arenium ions through their characterization by various theoretical as well as experimental methods.[1,2]

Above all, it has been argued that aromatic character of an aromatic hydrocarbon would be retained partly in the arenium ion.[7] This viewpoint is closely associated with possible hyperconjugation which should occur between the CH_2 group and the remaining π-electrons of the ring.[7,8] It has also been argued that the residual aromaticity in the arenium-type intermediate might be responsible for the occurrence of electrophilic substitution reactions.[4] The theoretical treatment of hyperconjugation shows that it should occur not only with the CH_2 group but also when one of the hydrogen atoms is replaced by any substituent group.[7,8] In this paper, I will first estimate the extent of hyperconjugation acting through the CH_2 group, and analyze in detail the electronic structure of arenium ions derived from typical benzenoid hydrocarbons. Our graph theory of aromaticity[9] will be applied to them to evaluate the resonance energies due to hyperconjugation. All the results will be examined in conjunction with the tendency of the benzenoid hydrocarbons to undergo electrophilic substitution reactions.



† Present address: Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422.

Hyperconjugation through the CH_2 Group

The graph theory of aromaticity has been described several times,[9,10] so it is not repeated here. The theory is based on the simple Hückel molecular orbital (HMO) model. The addition of a proton to the aromatic hydrocarbon destroys the sp^2-hybridized valence state of one of the carbon atoms, denoted by C*, and converts it into an sp^3-hybridized tetrahedral valence state.[7,8] In the arenium ion thus formed, one finds a CH_2 group adjacent to the remaining π-electron system. One hydrogen is believed to be above and the other below the plane,[11] the two hydrogens being denoted by H′ and H″.

In order to keep the algebra as simple as possible, we take one of the methylene orbital ϕ to be the composite bond orbital of π-symmetry,[12,13] namely,

$$\phi = \frac{1}{2}(\phi_1 - \phi_2), \qquad (1)$$

where ϕ_1 and ϕ_2 are the σ-bond orbitals localized along the C*–H′ and C*–H″ bonds, respectively. This constitutes a quasi-π orbital which functions like a π orbital in linear combinations with the $2p_z$ orbitals of the ring carbon atoms, in such a way as to yield a partial restoration of cyclic conjugation. This is nothing other than hyperconjugative interaction.

In order to incorporate the methylene orbital of π-symmetry in the HMO bonding model, two parameters,

h and k, must be determined for it. Here, h is related to the Coulomb integral for the quasi-π orbital, and k to the resonance integral for hyperconjugative interaction of this orbital with one of the adjacent $2p_z$ orbitals. By analogy with a hyperconjugative methyl orbital,[3] the value $h=2.0$ and $k=0.7$ may be applied to the methylene quasi-π orbital, too. Haddon recently reexamined hyperconjugation through the methylene group,[14] and suggested that a little smaller k value (≈ 0.5) might be more preferable for the methylene quasi-π orbital. At least, it gives a more reasonable diamagnetic anisotropy of cyclopentadiene.[14]

Heilbronner *et al.* adopted the simple bond orbital model to analyze the photoelectron spectra of cyclic alkanes,[13] and estimated the self-energy for the C–H bond orbital, A_{CH}, to be -15.67 eV and the cross term between two vicinal bond orbitals, $B_{CH,CH}$, to be -2.19 eV. In the simple HMO model, the self-energy corresponds to the Coulomb integral and the cross term to the resonance integral. From Eq. 1 the self-energy for the methylene quasi-π orbital can be set equal to $A_{CH}-B_{CH,CH}=-13.48$ eV. This represents a Coulomb integral for the methylene quasi-π orbital. For aromatic hydrocarbons, the resonance integral between two adjacent $2p_z$ orbitals has been estimated to be -2.7——-3.0 eV.[15] Then the Coulomb integral for each carbon $2p_z$ orbital lies in the -5.8——-6.5 eV range, depending upon the value adopted for the resonance integral. If we take all these numerical values into account, the $h=2.5$ value will become more suitable for the methylene quasi-π orbital.

Table 1. Energy separation between two occupied π orbitals for three dienes

Species	Experimental energy separation[a] eV[b]	HMO/β $h=2.0$ $k=0.5$	HMO/β $h=2.5$ $k=0.6$
1,4-Pentadiene	0.50	0.188	0.191
Cyclopentadiene	2.04	0.814	0.845
1,4-Cyclohexadiene	1.06	0.366	0.382

a) Ref. 16. b) 1 eV$=9.6525\times10^4$ J/mol.

Once this h value is adopted, the k value must next be determined in harmony with it. The simplest way of doing so is to make reference to the energy separations between the first and second π orbitals in such hydrocarbons as 1,4-pentadiene (0.50 eV), cyclopentadiene (2.04 eV), and 1,4-cyclohexadiene (1.06 eV).[16] The k value suitable for reproducing these energy separations were about 0.6. For this point, see Table 1. The set of HMO parameters suggested by Haddon, $h=2.0$ and $k=0.5$,[14] can likewise reproduce these energy separations. Conversely speaking, this kind of reproducibility supports the existence of hyperconjugative interaction through the CH_2 group. The above two sets of HMO parameters were employed to calculate resonance energies of arenium ions. For simplicity, all discussion will be made using the results based on our way of parametrization (*i.e.*, $h=2.5$ and $k=0.6$).

Resonance Energies of the Arenium Ions

Table 2 contains resonance energies of nineteen arenium ions derived from seven benzenoid hydrocarbons, together with their localization energies.[17] These resonance energies were calculated according to our graph theory of aromaticity.[9,10] An aromatic compound is characterized by the positive resonance energy, the magnitude of which indicates the degree of aromatic stabilization.[9,10,18] All energetic quantities are given in units of β or its absolute value β.

First, the simplest arenium ion, a benzenium ion, is predicted to have resonance energy of 0.094 β. If we adopt an effective β value reported for the resonance energies of benzenoid hydrocarbons ($\beta=3.562$ eV),[18] this resonance energy corresponds to 7.7 kcal/mol.†† Resonance energy of benzene is 0.273 β or 20.8 kcal/mol,[19,20] so the resonance energy of the benzenium ion amounts to about one-third that of benzene. Considering that benzene is one of highly aromatic compounds, the resonance energy of the benzenium ion is obviously far from negligible. Resonance energies of α-pyrone, γ-pyrone, furan, [10]annulene, and azulene are 0.044, 0.010, 0.010, 0.159, and 0.151, respectively, all in units of β.[9] Thus, the benzenium ion is much more aromatic than some weakly aromatic compounds, such as pyrones and furan, and is comparable in aromaticity to [10]annulene and azulene if the molecular sizes are taken into consideration.[21] As the benzenium ion is a monocyclic conjugated system, the whole resonance energy can be attributed to the hyperconjugative interaction through the CH_2 group; any resonance energy could not be anticipated without hyperconjugation.

In the case of polycyclic arenium ions, the situation is somewhat different. The contribution of the CH_2 group to aromaticity must be estimated relative to the resonance energy of some appropriate reference structure. A hypothetical compound with the same geometry but lacking conjugative interaction between the CH_2 group and the remaining π-electron system will serve for this purpose. The same structure has been used to calculate the localization energy.[17] The increment of resonance energy on introducing the hyperconjugative interaction in this reference structure can be interpreted as resonance energy due to hyperconjugation or hyperconjugative resonance energy (HRE). The HRE's are also listed in Table 2. It should be stressed that these HRE's are never negligible, either. Many of the polycyclic arenium ions indeed have HRE's comparable to that of the benzenium ion.

Hyperconjugative Resonance Energy and Electrophilic Substitution Reactions

The occurrence of electrophilic substitution reactions has been long regarded as an excellent indication of aromaticity.[3-16,22] However, we can easily show that

†† 1 $cal_{th}=4.184$ J.

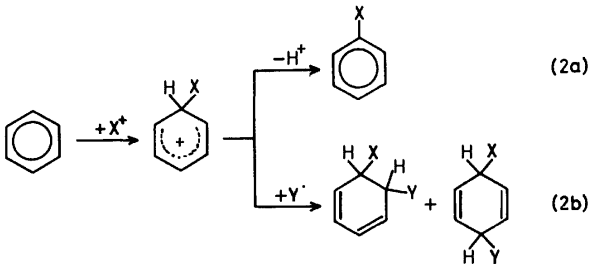
less aromatic compounds, in general, undergo electrophilic substitution reactions more rapidly. For example, furan undergoes substitution reactions much more rapidly than benzene when an appropriate electrophile attacks them.[23] In line with this, furan often reacts with electrophiles to form addition products.[23] Therefore, the tendency to undergo electrophilic substitution reactions is a vague criterion of aromaticity.[24]

In this connection, it seems quite likely that an electrophilic substitution reaction is not always an exothermic reaction. Let us consider the following pair of reactions: Suppose here that X and Y are hydrogen



atoms. Heats of hydrogenation of benzene and 1,3-cyclohexadiene are 49.8 and 55.6 kcal/mol, respectively, in the gas phase.[25] 1,4-Cyclohexadiene also give a heat of hydrogenation comparable to that of 1,3-diene.[20] As stated before, benzene is highly aromatic with resonance energy of 20.8 kcal/mol.[19,20] If resonance energy of a given cyclic conjugated system were about 6 kcal/mol smaller than that of benzene, there would be no preference for substitution to addition reactions. Heats of reaction would become comparable for reactions of the types 2a and 2b. Many compounds are really considerably less aromatic than benzene.[9,10] Accordingly, such a situation might often be encountered even if X^+ and Y^- in Eq. 2 are replaced by an appropriate electrophile and nucleophile, respectively. In fact, it has been found that addition-accompanied substitution occurs in the chlorination of relatively simple benzenoid hydrocarbons, such as biphenyl and naphthalene.[26] As the situation is like this, the question may be raised why electrophilic substitution occurs preferentially.

By the way, localization energy (LE) has been successfully related to the rate of electrophilic substitution reaction.[3-6,17,27] The Wheland intermediate which appears during the reaction[17] is iso-π-electronic with a corresponding proton addition complex. According to the Hammond postulate,[28] the transition state must closely resemble the Wheland intermediate, because it is much higher in energy than the reactant and product. The effect of hyperconjugation has been neglected in the original LE theory,[3-6,17] but the present study shows that it must decrease the energy of the intermediate by 0.26—0.48 β (Table 2).

Now, let us return to the point. Stock suggested that the residual aromaticity in the transition state might be necessary for the occurrence of electrophilic substitution reactions.[4] The existence of this kind of resonance energy has already been clarified. The positive HRE is related exactly to the residual aromaticity. In this sence, Stock's suggestion appears to be worthy of serious consideration.

In order to obtain a clue to this problem, HRE was plotted against LE for the nineteen arenium ions (Fig. 1). Here and in Fig. 2, LE's defined for the systems with $h=0.0$ and $k=0.0$ are used. It was then found that HRE is closely related to LE, in such a manner that, when LE is large, HRE is large, too. This trend does not depend upon the type of the site to which a proton is attached. For example, the 9-anthracenium ion has both smaller LE and HRE than any other arenium ion investigated. The largest HRE is given by the 2-pyrenium ion, which necessarily has the largest LE. Since an electrophilic reaction takes place mostly *via* a Wheland intermediate with the smallest LE,[3-6] we might say that the reaction occurs mostly *via* the Wheland intermediate with the smallest HRE. This implies that most electrophilic reactions occur at the sites which are least favorable to the occurrence of substitution reactions.

This viewpoint is based on the fact that an aromatic species generally has not only thermodynamic but also

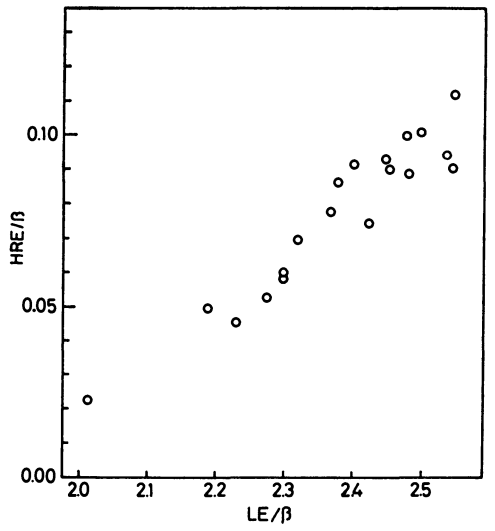


Fig. 1. Plot of hyperconjugative resonance energy (HRE) against localization energy (LE) for nineteen arenium ions.

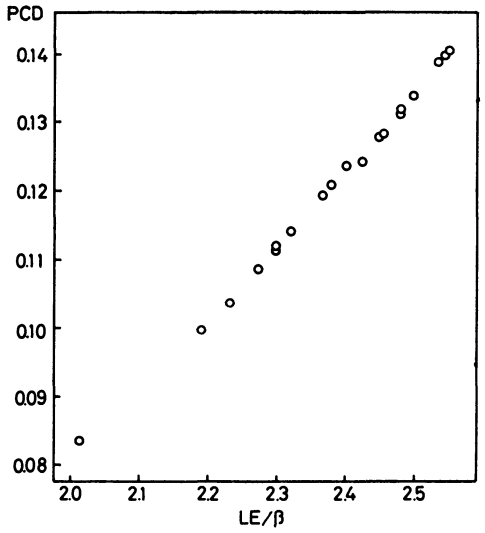

Fig. 2. Plot of positive charge density in the methylene quasi-π orbital (PCD) against localization energy (LE) for nineteen arenium ions.

kinetic stability.[29-31] In 1971, Hess and Schaad showed that the energy separation between the highest occupied molecular orbital and the lowest unoccupied molecular orbital is a linear function of the resonance energy per π-electron (REPE) for a variety of benzenoid hydrocarbons.[18,29] The REPE is a measure of aromatic stabilization, normalized with respect to the number of π electrons. Recently, Haddon and Fukunaga found an analogous relationship for the annulenes.[30] It then follows that an aromatic compound with larger resonance energy tends to retain its cyclic conjugated system, resisting addition-type reactions. Assigning such an attribute to the arenium ion and Wheland intermediates, we can reasonably infer that a highly aromatic intermediate would tend to refrain from taking paths to addition products. Addition products obviously break the cyclic conjugated system of the intermediate. On the other hand, a poorly aromatic intermediate would be willing to take paths to addition products.

The above inference is in fact supported by the work of de la Mare's group.[26] They studied the chlorination of benzenoid hydrocarbons with a molecular chlorine. The chlorine is a highly selective reagent.[32] It was found that significant proportions of by-products were formed by addition of chlorine or chlorine acetate derived from chlorine and acetic acid solvent.[26] There seems to be a general tendency for addition to become prominent as the reactivity of the hydrocarbon increases. Thus, the order of proportions of addition to substitution products was phenanthrene>naphthalene>triphenylene>biphenyl$\gg$benzene. This is exactly the same order as that of the overall reaction rates.[26] Anthracene probably comes first.[3] It is widely known that the 9 position of anthracene has a greater tendency toward electrophilic addition than the 9 position of phenanthrene.[4,33] It has been accepted that the overall reaction rate is determined by the smallest LE conceivable in the compound.[3,4] A greater overall reaction rate corresponds to the smaller LE, and a greater

proportion of the addition products to the smaller HRE. Competition between substitution and addition reactions can thus be related to the aromatic character of the Wheland intermediate.

Here, there is an exception to the order of experimental reaction rates; it is phenanthrene *vs.* naphthalene. LE of the 9-phenanthrenium ion is comparable to that of the 1-naphthalenium ion. However, the greater reactivity of phenanthrene than naphthalene is experimentally commonplace, and has been observed is several substitution reactions.[33] Unfortunately, this problem is beyond the scope of the HMO model, and should be treated by more sophisticated methods.[27]

Charge Density in the Methylene Quasi-π Orbital

When substitution occurs, the Wheland intermediate loses a proton to the nucleophile, and so reverts to an aromatic π-electron ring, now substituted with the electrophilic group.[3-6] It is noteworthy that salts of substituted benzenium ions can be isolated as crystalline materials or observed by spectroscopic techniques in non-nucleophilic solvents.[1,2,34] In this view, we may expect that, the greater the positive charge density (PCD) in the methylene orbital is, the easier should it be to remove hydrogen as a proton. If PCD is low in the methylene orbital, the chance that nucleophilic addition occurs to the remaining π-electron system would be great. In this connection, Dixon regarded the charge density on the protons of the CH_2 group as a measure of proton loss, leading to overall substitution.[12]

We can examine this effect by means of the present bonding model. Hyperconjugation permits a considerable migration of negative charge into the ring from the methylene quasi-π orbital. The PCD is induced as a result of partial equalization of the charge distribution. Table 2 and Fig. 2 indicate how the positive charge in the methylene quasi-π orbital correlates with LE for the benzenoid hydrocarbons studied. We see therefrom that PCD is almost linearly related to LE and, hence, to the overall reaction rate. This suggests that the leaving ability of hydrogen as a proton might be enhanced in the case of the arenium ions with large LE's. In other words, proton loss occurs more readily to restore the fully aromatic sextet when there is more extensive delocalization of the positive charge. This indicates that PCD reflects the magnitude of HRE straightforwardly. Accordingly, the tendency of a benzenoid hydrocarbon to undergo electrophilic substitution, predicted from the PCD, bears a close resemblance to the tendency predicted from the HRE. Both are naturally in good accord with experiment. The two effects seem to enhance cooperatively the preference for substitution reactions. In our chemical sence, it seems that HRE tends to avoid adding a nucleophile to the π-electron system, while PCD tends to eliminate a proton, both resulting in the same substitution reaction.

However, it should be stressed that HRE is not always a single determinant for the occurrence of substitution reactions. For example, pyrene is much more reactive than phenanthrene.[3,4,27,33] but the addition products have not been observed appreciably. Since HRE is at most 8 kcal/mol for any compound, the other factors, such as the size of an electrophile and a steric effect in the addition product, cannot be neglected in tracing a reaction path. By inspecting the molecular model, it was found that every ring in pyrene might be subject to some steric restriction when it undergoes an addition reaction. The restriction appears very severe in the case of addition reactions starting from the 1-pyrenium-type intermediate. In such a case, addition-elimination routes to substitution products become important.

Concluding Remarks

Three of the most characteristic properties of aromatic compounds are the thermodynamic stability, the diamagnetic susceptibility exaltation, and the tendency to undergo electrophilic substitution reactions. The first two properties can be analyzed consistently in terms of our graph theory of aromaticity.[9,10,35] For the first time, this theory succeeded in unifying the two concepts.[35] Along with these physical properties, the tendency to undergo electrophilic substitution reactions has been widely used as a purely chemical criterion of aromaticity.[22,36]

As stated before, this criterion is quite empirical. To make matters worse, it is not always related to aromaticity.[24,36] The tropylium ion, accepted as an example of a nonbenzenoid aromatic species, does not react with electrophiles.[36] On the contrary, a 2,3-dihydro-1,4-diazepinium ion undergoes many electrophilic substitution reactions, although it has no cyclic conjugated system.[36] In this sence, there is an obvious limitation in the present approach. It does not apply to the Wheland intermediates which are aromatically- or hetero-atom-stabilized species.[37] For example, the aromatically-stabilized intermediates are those derived from azulene and calicene. The azulenium and 2-calicenium ions are both Hückeloid aromatic cations with substituents. The hetero-atom-stabilized systems are exemplified by the Wheland intermediates derived from pyrrole and a 2,3-dihydro-1,4-diazepinium ion.

Electrophilic substitution is indeed a complicated chemical process.[5,6,38] To the best of my knowledge, there have been few logical approaches to the competition between substitution and addition reactions. Therefore, the present approach might be regarded as a first significant step forward, although its application is limited to benzenoid hydrocarbons. This approach not only unveiled some important features of aromatic substitution, but also enabled us to trace reaction routes to substitution products more closely than before. All the reasoning is relatively simple and understandable.

In summary, I have considered both the ability of the CH_2 group to function as a hyperconjugator and the ability to dissociate a proton. HRE represents the energy difference between a real hyperconjugative system and its hyperconjugative reference structure. Stock's suggestion that electrophilic substitution might

occur *via* an aromatic transition state[4] has been verified and generalized in terms of HRE. It was theoretically conciliated with Dixon's measure of proton loss defined using PCD.[12] If the Wheland intermediate were absolutely olefinic in nature, a significant proportion of addition products would be obtained, because there is no tendency for polyenic cations to undergo electrophilic substitution reactions. In general, if the parent compound is not aromatic, the corresponding proton addition complex has no HRE. This might be the main reason why electrophilic substitution is limited mostly to aromatic compounds.

The use of the facilities of the Hokkaido University Computing Center is gratefully acknowledged.

Optical Properties of Undoped and AsF_5 Doped "Poly(4,4'-biphenylylene)" Films

Atsushi WATANABE, Hitoshi FUJIMOTO, Masashi TANAKA,* and Jiro TANAKA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received September, 3, 1980)

Optical absorption and reflection measurements are carried out on undoped and AsF_5 doped films of "poly(4,4'-biphenylylene)" over a wide wavelength region (300—50000 cm^{-1}). In the doped polymer, the free carrier absorption band appears in the IR region and the dc conductivity is estimated from the observed spectrum. The obtained value (σ_0=376 S cm^{-1}) is two orders of magnitude larger than the value (σ_0=2 S cm^{-1}) observed by the conductivity measurement. The discrepancy may be due to the existence of many cracks on the films.

There is now a large and rapidly growing interest in conducting derivatives of organic polymers. Polymers such as doped polyacetylene,[1] doped poly(*p*-phenylene),[2] doped polypyrrole,[3-5] and doped poly(thio-*p*-phenylene)[6,7] were reported to exhibit high electrical conductivity. Polyacetylene is obtained as flexible and crystalline film, however, it is insoluble and infusible. Other polymers, such as electrochemically prepared polypyrrole, poly(thio-*p*-phenylene) are insoluble in common solvents.

We have recently reported the conducting polymer prepared by AsF_5 oxidation of benzene soluble polymer: "poly(4,4'-biphenylylene)."[8] In the present paper, we describe about the electrical and optical properties of pure and AsF_5 doped "poly(4,4'-biphenylylene)."

Experimental

"Poly(4,4'-biphenylylene)" was readily prepared by heating a suspension of the 4,4'-benzidinebis(diazonium) chloride–CuCl complex in pure water (80 °C, 1 h),[9,10] although poly(*p*-phenylene)[11,12] was synthesized by direct polymerization as is shown in Fig. 1. The dark-brown polymer was then separated into two fractions by extraction with benzene. The soluble portion was fractionally precipitated by adding petroleum ether and separated into two fractions by extraction with acetone.

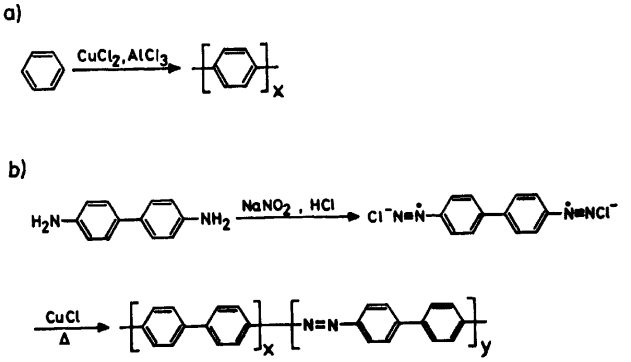

Fig. 1. Preparation of a) poly(*p*-phenylene), b) "poly(4,4'-biphenylylene)."

Reaction of AsF_5 gas with the benzene soluble and acetone insoluble polymer produced a blue-black material and the doped level were adjusted by doping time under 200 mmHg (1 mmHg=133.322 Pa) of AsF_5 gas. For the sample doped for 40 h, the uptake of AsF_5 measured by weight increases corresponds to *ca.* one AsF_5 molecule per phenyl group.

The film was made by dropping the dioxane solution of "poly(4,4'-biphenylylene)" on the four probe plate and then drying. The films were doped with AsF_5 and pumped for about one hour. After that, the doped films were connected to an apparatus for measuring the dc conductivity. The electrical conductivity was measured under nitrogen by the standard four probe method.

The absorption spectra of pure and AsF_5 doped films on a KBr or quartz plate were measured *in vacuo* with Hitachi IR 260-50 (300—4000 cm^{-1}) and Carl Zeiss M4Q (4000—50000 cm^{-1}) spectrophotometers. The reflection measurement of pure thick "poly(4,4'-biphenylylene)" film on a glass plate was made with Hitachi IR 260-50 and a microscopic spectrophotometer (4000—50000 cm^{-1}) made in our laboratory. It consists of an Olympus microscope, a Carl Zeiss Ultrafluar lens (×10), a Nikon crystal mount, a HTV 928 photomultiplier and a PbS tube, and an Intel 8080 microcomputer for data processing.

The Kramers-Kronig (K-K) transformation of the reflection spectra and the best fit of the absorption and reflection spectra by SALS program were made on a Facom M-200 computer of Nagoya University.

Results and Discussion

"Poly(4,4'-biphenylylene)" was identified to be a copolymer of 1,4-biphenyldiyl and azo-1,4-biphenyldiyl compounds (x : y=4 : 1).[9,10] Accordingly, the excited wave function (Ψ_e) of this polymer can be expressed by the superposition of the locally excited configurations of polyphenyl (Φ_{ph}) and azo (Φ_{azo}) groups and the charge transfer (Φ_{CT}) configurations between these two groups.[13]

$$\Psi_e = c_1\Phi_{ph} + c_2\Phi_{azo} + c_3\Phi_{CT} \quad (1)$$

and the transition moment between the ground (Ψ_0) and excited states can be given as follows,

$$(\Psi_e|M|\Psi_o) = c_1(\Phi_{ph}|M|\Psi_0) + c_2(\Phi_{azo}|M|\Psi_o). \quad (2)$$

However, the azo group has a weak absorption band at 350 nm whose intensity has been reported to be ε=5.[14] Therefore, the second term of the right side in Eq. 2 can be neglected and the visible absorption spectra of "poly(4,4'-biphenylylene)" may be considered to be similar to that of polyphenyl group. A benzene molecule has six π-electrons which are considered free to delocalize along the phenyl ring. These π-electrons form two single and two double degenerate π-orbitals (ϕ_i, i=1—6). In the polyphenyl system, π-bands $\psi_i(k)$ can be expressed by the linear combination of π-orbitals in each ring

$$\phi_i(k) = \frac{1}{\sqrt{N}}\sum_n e^{ikR_n}\phi_n^i \quad (i=1\text{—}6). \tag{3}$$

The energies $\varepsilon_i(k)$ of π-bands are calculated according to MO theory,

$$\begin{aligned}
\varepsilon_1(k) &= \alpha + 2\beta + \tfrac{1}{3}\beta' \cos(ka)\\
\varepsilon_2(k) &= \alpha + \beta - \tfrac{2}{3}\beta' \cos(ka)\\
\varepsilon_3(k) &= \alpha + \beta\\
\varepsilon_4(k) &= \alpha - \beta + \tfrac{2}{3}\beta' \cos(ka)\\
\varepsilon_5(k) &= \alpha - \beta\\
\varepsilon_6(k) &= \alpha - 2\beta - \tfrac{1}{3}\beta' \cos(ka),
\end{aligned} \tag{4}$$

where β is the resonance integral between successive carbon atoms in the same ring and β' in the different ring. All π-electrons are filled in the three bands of $\varepsilon_1(k)$, $\varepsilon_2(k)$, and $\varepsilon_3(k)$ as is shown in Fig. 2-a.

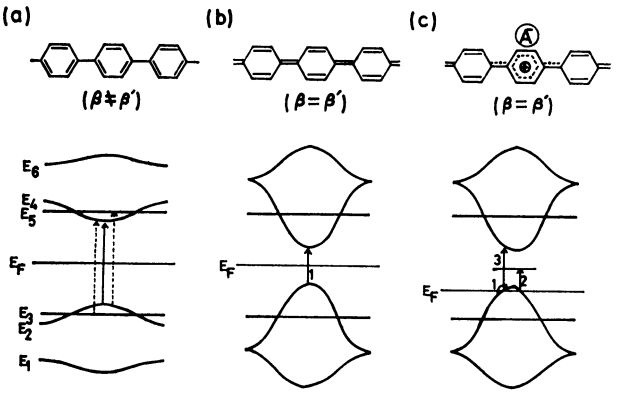

Fig. 2. Electronic structure of the polyphenyl system.

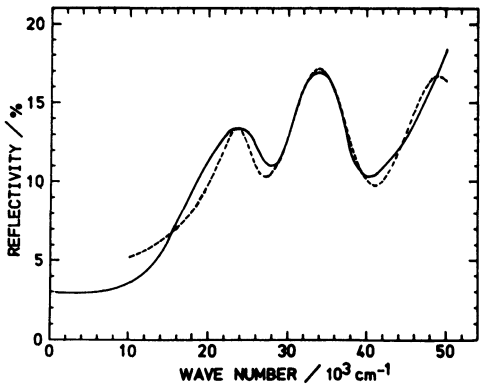

Fig. 3. Reflection spectra of "poly(4,4'-biphenylylene)." ——: Observed, ------: calculated (SALS).

Figure 3 shows the reflection spectrum of the pure polymer film of "poly(4,4'-biphenylylene)." The first band at 24000 cm^{-1} has the reflectivity of 13.4% and the second band at 34000 cm^{-1} has that of 17.1%. The third band is located in the region of higher wave number than 50000 cm^{-1}. Accordingly, the first band at 24000 cm^{-1} can be assigned to the transition from the $\varepsilon_2(k=0)$ band to the $\varepsilon_4(k=0)$ band. The second band consists of the overlap of two transitions of $\varepsilon_2(k=0)\rightarrow\varepsilon_5(k=0)$ and $\varepsilon_3(k=0)\rightarrow\varepsilon_4(k=0)$. The dielectric function of pure "poly(4,4'-biphenylylene)" can be expressed by the following equation.[15]

$$\varepsilon(\omega) = 1 + \sum_j \frac{\Omega_j^2}{\omega_j^2 - \omega^2 - i\omega\gamma_j}, \tag{5}$$

where

$$\Omega_j = \left(\frac{4\pi N_j e^2}{m} f_j\right)^{1/2}. \tag{6}$$

ω_j and γ_j are the transition energy and the band width of the j-th band. N_j is the number density of electron contributing to the j-th band, f_j is the oscillator strength of the j-th band and m is the electron mass.

The reflectivity R can be expressed by using the dielectric function of Eq. 5,[15-17]

$$R = \frac{1+|\varepsilon|-\sqrt{2(|\varepsilon|+\varepsilon_1)}}{1+|\varepsilon|+\sqrt{2(|\varepsilon|+\varepsilon_1)}} \tag{7}$$

and

$$|\varepsilon| = \sqrt{\varepsilon_1^2+\varepsilon_2^2}, \tag{8}$$

where ε_1 and ε_2 are the real and imaginary parts of the dielectric function. The parameters Ω_j, ω_j, and γ_j of undoped "poly(4,4'-biphenylylene)" can be determined by the best fit of the calculated reflection values to the observed spectra. The obtained parameters are shown in Table 1 and the best fit curve is plottted in Fig. 3 for comparison with the experimental curve.

The absorption coefficient $\alpha(\omega)$ based on these parameters can be obtained by the following equations,[15]

$$\alpha(\omega) = \frac{4\pi}{cn(\omega)}\omega\varepsilon_2(\omega) \tag{9}$$

and

$$n(\omega)^2 = \{\sqrt{\varepsilon_1^2+\varepsilon_2^2}+\varepsilon_1\}/2. \tag{10}$$

In Fig. 4, the obtained absorption spectrum is depicted together with the solution spectrum and the absorption spectrum calculated by the Kramers-Kronig transformation of the reflection spectrum.

Figure 5 shows the temperature dependence of the conductivity of the films doped with various concentrations of AsF_5. The room temperature conductivity was about $\sigma \simeq 2$ S cm^{-1} for the film doped for 40 h under

a) Data of the "poly(4,4'-biphenylylene)" doped for 22 h under 200 mmHg of AsF_5 gas.

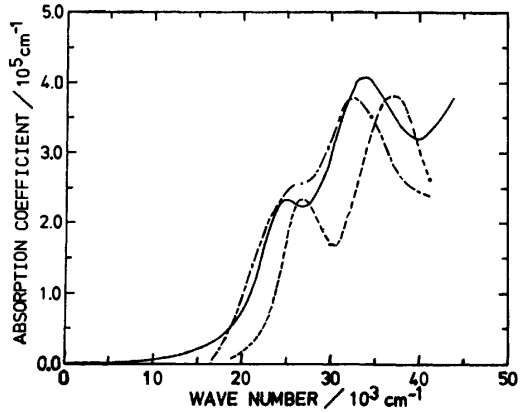

Fig. 4. Absorption spectra of pure "poly(4,4'-biphenylylene)."
------: Observed (dioxane solution), ——: calculated (SALS), —·—: calculated (Kramers-Kronig).

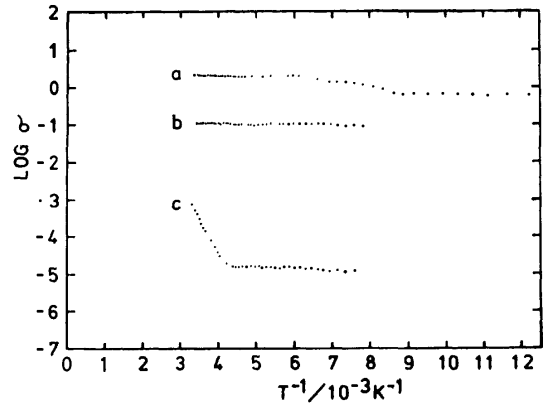

Fig. 5. Temperature dependence of the conductivity of the films doped with various concentrations of AsF_5.
a: 40 h, b: 20 h, c: 3 h.

200 mmHg of AsF_5 gas, although the conductivity for the undoped material is less than 10^{-4} S cm^{-1}. The plots of log σ *vs.* $1/T$ give straight lines near room temperature and the approximate thermal activation energy can be determined by the initial slope of $1/T$ plots. The resulting activation energy is about 0.36 eV for the sample doped for 4 h and reaches to almost zero for the films doped for more than 20 h.

Figures 6 and 7 are the visible and IR absorption spectra of thin "poly(4,4'-biphenylylene)" films doped with various concentrations of AsF_5. On doping the film with AsF_5, the absorption intensity of the 27000 cm^{-1} band decreases and the new band appears at about 18500 cm^{-1}. An isosbestic point at 23200 cm^{-1} may be explained by an equilibrium between the highly conjugated polymer ($\beta=\beta'$) and the twisting polymer ($\beta\neq\beta'$). That is, each phenyl ring seems to twist about the central bond in the pure polymer and $|\beta'|$ is smaller than $|\beta|$. For the lightly doped polymer, each phenyl group lies in the same plane and π-electrons become to be highly conjugated between phenyl rings ($|\beta'|=|\beta|$). As a consequence, the first band at 27000 cm^{-1} shifts to the shorter wave number region as is shown in Fig. 2-b. After that, doping produces the broad band in

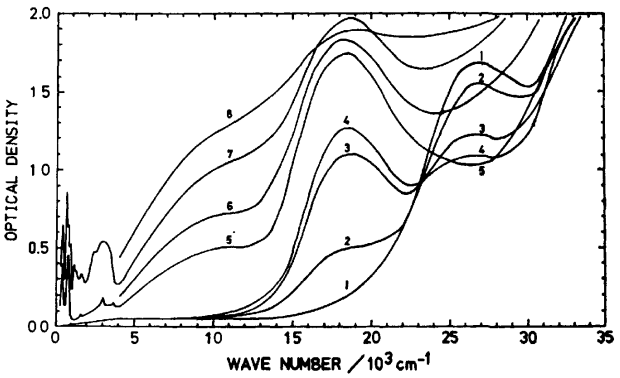

Fig. 6. Absorption spectra of AsF_5 doped "poly(4,4'-biphenylylene)."
1: 0 min, 2: 5 min, 3: 30 min, 4: 1 h, 5: 3 h, 6: 19 h, 7: 22 h, 8: 32 h.

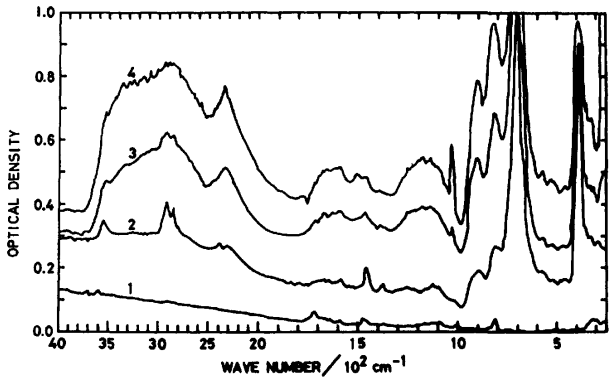

Fig. 7. IR absorption spectra of AsF_5 doped "poly(4,4'-biphenylylene)."
1: 0 min, 2: 2 h, 3: 4 h, 4: 22 h.

the region of 5000 cm^{-1} to 10000 cm^{-1} and a background absorption in the IR region in addition to the vibrational bands of $AsF_6^-H_3O^+$ at 400, 700, and 3000 cm^{-1}.[18] Figure 2-c shows that the Fermi level comes below the top of $\varepsilon_2(k)$ band by transfering a few π-electrons to AsF_5 molecules and the impurity level appears at the midpoint of the gap between the $\varepsilon_2(k)$ and $\varepsilon_4(k)$ bands. This broad band may be explained by the transition band from the $\varepsilon_2(k)$ band to the impurity level.

The maximum absorption coefficient of the 27000 cm^{-1} band of the pure film is determined to be 2.6×10^5 cm^{-1} in Fig. 4. Accordingly, the absorption coefficient of the AsF_5 doped film can be estimated as is shown in Fig. 8. Then, the parameters of the dielectric function of the doped film were decided by the optimum fit of Eq. 7 to the experimental data. The best fitted parameters are shown in Table 1. The calculated absorption spectrum based on these values is plotted for comparison with the experimental curve in Fig. 8.

The band 1 has the zero transition energy $\omega_j=0$ and is the back ground absorption in the IR region which can be assigned to the intraband transition. This means that doping makes the π-electrons in the polymer to be transferred to the AsF_5 molecule according to the following reaction,

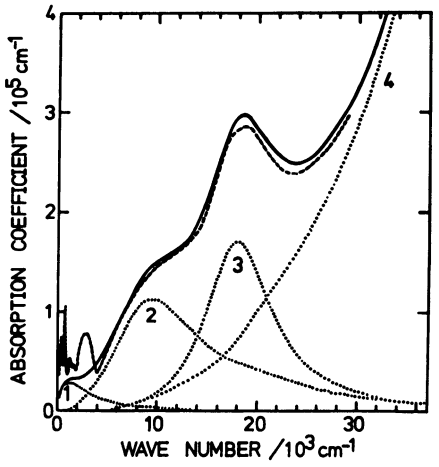

Fig. 8. Absorption spectra of "poly(4,4'-biphenylylene)" doped with AsF_5 (22 h).
——: Calcualted (SALS), ·····: calculated(SALS), ------: observed.

$$3AsF_5 + 2e \longrightarrow 2AsF_6^- + AsF_3 \quad (11)$$

and one of the π-bands becomes partially unfilled. The plasma frequency of the first band is given in Table 1.

$$\Omega_1 = \left(\frac{4\pi Ne^2}{m^*}\right)^{1/2} = 8678.9\,\mathrm{cm}^{-1} \quad (12)$$

Then, the number density (N) of the free carriers in the AsF_5 doped film can be estimated to be about $8\times10^{20}\,\mathrm{cm}^{-3}$ by substituting $m^*=m$ to the next equation,

$$N = \frac{\Omega_1^2 m^*}{4\pi e^2}. \quad (13)$$

This value corresponds to 1.4% of the total π-electrons ($6\times10^{22}\,\mathrm{cm}^{-3}$) in the polymer film, judging from the density of the film ($\rho=1.38\,\mathrm{g/cm}^3$). This means that a few holes in the unfilled π-band contribute to the transport phenomenon.

Furthermore, the dc conductivity, σ_0, is given by the following equation,[15]

$$\sigma_0 = \frac{\Omega_1^2}{4\pi\gamma_1} \quad (14)$$

and is calculated by using the observed plasma frequency, Ω_1, and the band width, γ_1. The obtained value ($\sigma_0\simeq376\,\mathrm{S\,cm}^{-1}$) is two orders of magnitude larger than the observed values ($\sigma_0\simeq2\,\mathrm{S\,cm}^{-1}$) of the dc conductivity of AsF_5 doped films. The discrepancy may be due to the existence of many cracks on the film.

Electrical and Optical Properties of a Stable Synthetic Metallic Polymer: Polypyrrole

Atsushi WATANABE, Masashi TANAKA,* and Jiro TANAKA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received February 26, 1981)

Absorption and reflection spectra of the polypyrrole films prepared by electrochemical polymerization are shown over the wide wavelength region and the best fit of the calculated reflection spectra is presented to the observed spectra. Electrical conductivity of the film is measured as a function of temperature and a plot of log σ *vs.* $T^{-1/4}$ gives a straight line over the 4.2—300 K region. Furthermore, the thermoelectric-power, S, of the polypyrrole film is shown in the form of S *vs.* T on a linear scale. Based on these results, the conduction mechanism of polypyrrole film is discussed.

In recent years, many polymers such as polysulfur nitride, $(SN)_x$,[1] and AsF_5 doped polyacetylene, $(CH)_x$[2,3] have arrested attention because they exhibited metallic properties. These discoveries have encouraged the search for other polymeric systems with greater chemical stability and plasticity.

Diaz *et al.*[4-7] have synthesized a strongly adhered, durable film; polypyrrole, by electrochemical polymerization of pyrrole on platinum surface. The films have shiny blue-black color and show metallic properties like $(SN)_x$ and doped $(CH)_x$. The room temperature electrical conductivity of the present films is as high as 4.4 Ω^{-1} cm^{-1}. The films are stable in air.

In the present paper, we report the absorption spectra in the 250—4000 cm^{-1} region, the reflection spectra in the 250—33000 cm^{-1} region. The electrical conductivity and the thermoelectric-power of polypyrrole are measured over the wide temperature range and the conduction mechanism of polypyrrole is discussed based on these experimental results.

Experimental

The black films of polypyrrole (*ca.* 0.8 μm thick) were synthesized as described by Diaz *et al.*[4-7] Polypyrrloe was prepared on a platinum surface (1.0 × 3.0 cm^2) by passing 24 mC/cm^2 of charge in a cell containing 0.54 g (0.1 mol/dm^3) of Et_4NBF_4 and 0.10 g (0.06 mol/dm^3) of pyrrole in 25 cm^3 of 99% aqueous acetonitrile. The films adhere to the electrode surface strongly. The films were washed with distilled water and dried at room temperature in air. Tetraethylammonium tetrafluoroborate (Et_4NBF_4) was prepared by neutralizing 10% aqueous solution of tetraethylammonium hydroxide with 42% aqueous hydrofluoroboric acid.[8] Pyrrole and lithium perchlorate ($LiClO_4$) were products of Nakarai Chemicals Ltd. and they were used as received.

The absorption spectra of the thin polypyrrole film were measured with Hitachi IR 260-50 (250—4000 cm^{-1}), and the reflection spectra of polypyrrole film were measured with Hitachi IR 260-50 and a microscopic spectrophotometer (4000—33000 cm^{-1}) made in our laboratory. It consists of an Olympus microscope, a Carl Zeiss Ultrafluar lens (×10), a Nikon crystal mount, a HTV 928 photomultiplier and a PbS cell, and an Intel 8080 microcomputer for data processing.

The best fit of the calculated reflection spectra of polypyrrole film to the observed spectra were made on a Facom M-200 computer of Nagoya University by using SALS program.

For the thermoelectric-power measurements, a rectangular sample (4 × 15 mm^2) was mounted lengthwise between two copper blocks using pressure contacts. A temperature difference (ΔT) was established by heating one of the copper blocks, and the voltage generated by the thermal gradient across the sample was measured. The ΔT across the sample was measured with a copper-constantan differential thermocouple.

Results and Discussion

Figure 1 shows the IR absorption and reflection spectra of thin polypyrrole film prepared by using Et_4NBF_4 as supporting electrolyte. The color of the films prepared with Et_4NBF_4 is shiny black and the films prepared by using $LiClO_4$ is brown-black. IR absorption spectra show the bands characteristic of pyrrole confirming the presence of the pyrrole rings in the polymer.[9] For example, the skeletal stretching of the pyrrole ring is found at 1500 cm^{-1} region, the =C–H in-plane deformation is found at 1300 and 1180 cm^{-1}, the =C–H out-of-plane bending at 775 cm^{-1}, and the ring breathing at 920 cm^{-1}. The peak near 1035 cm^{-1} is assigned to the BF_4^- ion since this band is observed in the spectra of Et_4NBF_4 in KBr disk.

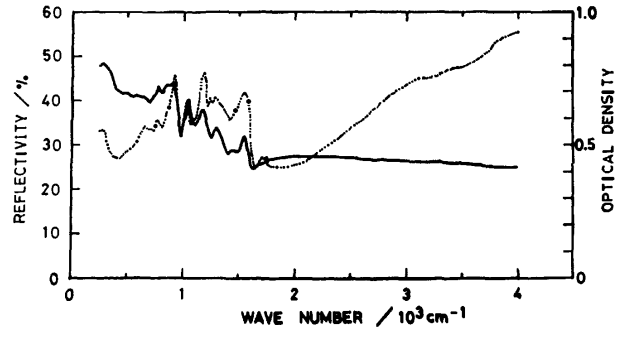

Fig. 1. Comparing between the absorption and the reflection spectra of polypyrrole film prepared by using Et_4NBF_4 in the IR region.
·····: Absorption spectrum, ——: reflection spectrum.

Figure 2 shows the reflection spectra of polypyrrole films prepared by different supporting electrolytes. The reflectivity in the lower energy region increases and a broad band around 3000—4000 cm^{-1} region is intensified with increasing conductivities. The lower energy

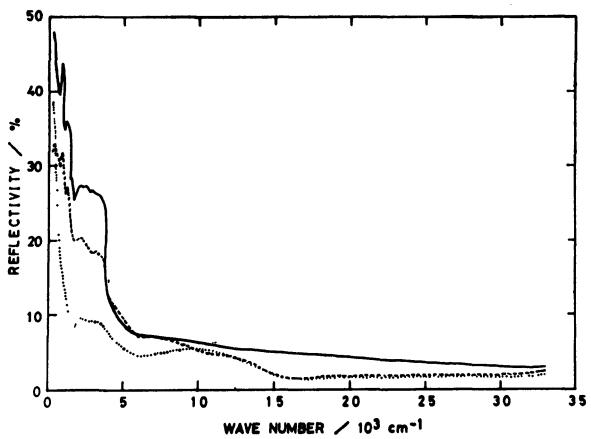

Fig. 2. Reflection spectra of polypyrrole film prepared by using different supporting electrolytes.
——: Et_4NBF_4 (σ_{295K}=4.4Ω^{-1} cm^{-1}), ------: Et_4NBF_4 (σ_{295K}=0.74 Ω^{-1} cm^{-1}), ……: $LiClO_4$ (σ_{295K}=0.016 Ω^{-1} cm^{-1}).

transition may be assigned to the zero-band gap transition. The origin of the peak around 3000 cm^{-1} region is not evident, but it may be correlated with the number of carriers because the intensity is enhanced with the conductivity.

Even if the same supporting electrolyte was used, the reflection spectra of the films were not the same from each other due to polymerization conditions. Comparing the reflection spectra of the films prepared with Et_4NBF_4, the film of lower dc conductivity (σ_{295K}=0.74 Ω^{-1} cm^{-1}) is shown to have a lower reflectivity throughout whole spectral region than the film of higher d.c. conductivity (σ_{295K}=4.4 Ω^{-1} cm^{-1}). The reflectivity at 300 cm^{-1} is 48% for the films of higher conductivity but 38% for the films which has lower d.c. conductivity.

It is noteworthy that the reflectivity is lower for the films prepared by using $LiClO_4$ which has the d.c. conductivity of σ_{295K}=0.016 Ω^{-1} cm^{-1}. However, the broad bands are clearly found at 3000 cm^{-1} and at 6000—16000 cm^{-1} region.

The dielectric function of a linear chain of zero-band gap may be expressed by the following equation,[10]

$$\varepsilon(\omega) = \varepsilon_{core} - \frac{\omega_p^2}{\omega^2 + i\omega\gamma}, \quad (1)$$

where

$$\omega_p = \left(\frac{4\pi Ne^2}{m^*}\right)^{1/2}. \quad (2)$$

γ is the band width, N is the number density of free carrier, and m^* is the effective electron mass.

The reflectivity R can be expressed by the following equation,[10-12]

$$R = \frac{1+|\varepsilon|-\sqrt{2(|\varepsilon|+\varepsilon_1)}}{1+|\varepsilon|+\sqrt{2(|\varepsilon|+\varepsilon_1)}}, \quad (3)$$

and

$$|\varepsilon| = \sqrt{\varepsilon_1^2+\varepsilon_2^2}, \quad (4)$$

where ε_1 and ε_2 are the real and imaginary parts of the dielectric function. Accordingly, the best fit of Eq. 3 to the observed reflection spectrum except the broad band around 3000—4000 cm^{-1} is obtained by using the following parameters with Eq. 1,

$$\omega_p = 17230\ \text{cm}^{-1},$$

$$\gamma = 39340\ \text{cm}^{-1},$$

and

$$\varepsilon_{core} = 2.4.$$

By using these values, the relaxation time is calculated as

$$1/\tau = 2\pi c\gamma = 7.41 \times 10^{15}\ \text{s}^{-1},$$

and we obtain

$$\tau = 0.135 \times 10^{-15}\ \text{s}.$$

This value is same magnitude with the value (σ_0= 0.277×10^{-15} s) obtained for the $ClSO_3H$ heavily doped polyacetylene.[11] The calculated reflection spectrum based on these values is in good agreement with the observed curve except the 3000—4000 cm^{-1} region as is shown in Fig. 3.

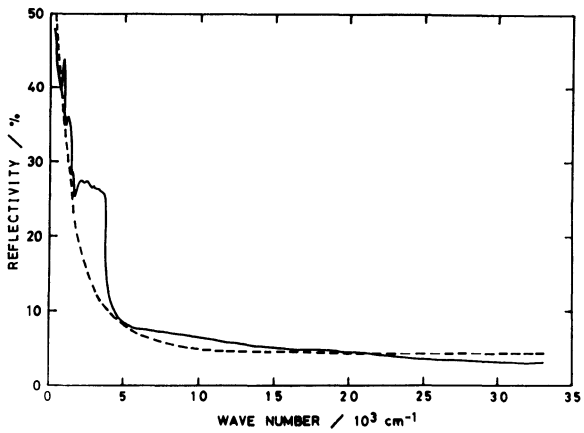

Fig. 3. Observed and calculated reflection spectra of polypyrrole film prepared by using Et_4NBF_4.
——: Observed spectrum, ------: calculated spectrum.

Then, the number density, N, of the free carrier in the polypyrrole film can be estimated as 3×10^{21} cm^{-3} by substituting $m^* = m_e$ to the next equation,[10-12]

$$N = \frac{\omega_p^2 m^*}{4\pi e^2}. \quad (5)$$

This value corresponds to *ca.* 5% of the total π-electrons (7×10^{22} cm^{-3}) which is estimated from the density of the film (ρ=1.48 g/cm^3).[5] This means that a few holes in the filled π-band contribute to the transport phenomenon.

Furthermore, the dc conductivity, σ_0, is given by the following equation,[10-12]

$$\sigma_0 = \frac{\omega_p^2}{4\pi\gamma}. \quad (6)$$

The value is calculated by using the observed plasma frequency, ω_p, and the band width, γ. The obtained value ($\sigma_0 \simeq 126$ Ω^{-1} cm^{-1}) is two order of magnitude larger than the observed value ($\sigma_0 \simeq 4.4$ Ω^{-1} cm^{-1}) of the d.c. conductivity of polypyrrole prepared by using Et_4NBF_4.

The difference between these two values may be

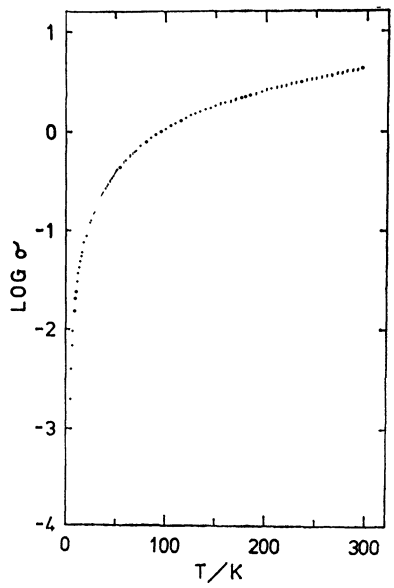

Fig. 4. Electrical conductivity of polypyrrole film prepared by using Et_4NBF_4 in the form of log σ *vs.* T.

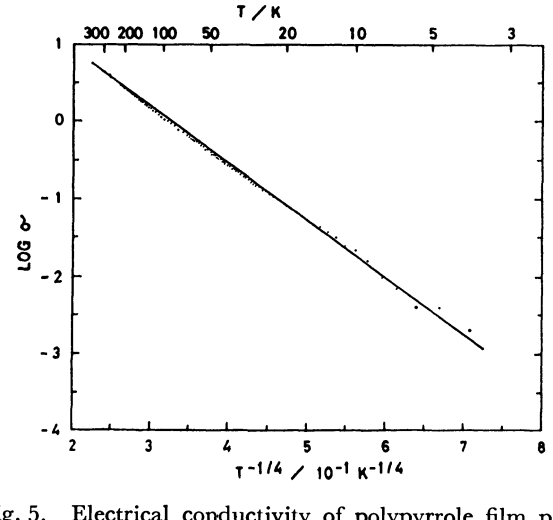

Fig. 5. Electrical conductivity of polypyrrole film prepared by using Et_4NBF_4 in the form of log σ *vs.* $T^{-1/4}$.

explained by the mechanism as shown below. Namely the temperature dependence of the electrical conductivity was measured on the polypyrrole films prepared by using Et_4NBF_4 as shown in Fig. 4 in the form of log σ *vs* T. A plot shows a smooth curve from $\sigma_{295K}=4.4\ \Omega^{-1}$ cm^{-1} to $\sigma_{4.2K}=6.72\times10^{-4}\ \Omega^{-1}\,cm^{-1}$. In fact, a plot of log . *vs.* $T^{-1/4}$ gives a straight line over the temperature region of 4.2—300 K as is shown in Fig. 5. The straight line is expressed by

$$\log\sigma = -7.35\ T^{-1/4} + 2.385. \tag{7}$$

Such behavior suggests a hopping model for the conduction mechanism. That is, the resistivity ($\rho=1/\sigma$) of the film is composed of the sum of the resistivity ($\rho_0=1/\sigma_0$) in the polypyrrole chain and the resistivity ($\rho_h=1/\sigma_h$) between the chains,

$$\rho = \rho_o + \rho_h. \tag{8}$$

The intrachain conductivity, σ_0, can be explained by

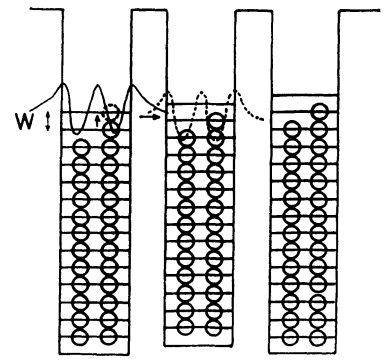

Fig. 6. A conduction mechanism of the hopping electron between the polypyrrole chain.

the conduction mechanism for the band model and corresponds to the optically determined value ($\sigma_0\simeq$ 126 $\Omega^{-1}\,cm^{-1}$), which is larger than the conductivity, σ_h, between the chains. Accordingly, the observed conductivity, σ, of the film may be correlated with the conductivity, σ_h, for the hopping electron between the chains. Mott[13] presented a conduction mechanism for a hopping process, which is depicted in Fig. 6. Every time an electron moves between the polymer chains, an electron just below the Fermi level jumps normally to a state just above it with energy W, and transfers from the one chain to the adjacent chain, of which the wave function overlaps that of the first chain. The hopping probability is then of the form,

$$\sigma \sim \nu_{ph}\exp(-2\alpha R - W/kT), \tag{9}$$

where α denotes the rate of a fall-off of the envelope of the wave function. The average spacing, W, between energy levels can be written by the density of state, $N(E)$, and the mean distance, a, between atoms as follows,

$$W = 1/(4\pi/3)a^3N(E). \tag{10}$$

If $a\simeq R$, the maximum conductivity can be found at $R\simeq(9/8\pi\alpha kTN(E))^{1/4}$ and can be expressed by the following equation,

$$\sigma \sim A\exp\{-(Q/kT)^{1/4}\}, \tag{11}$$

where

$$Q = 1.5/\alpha^3N(E). \tag{12}$$

A good consistency between the observed and the theoretical relation of log σ *vs.* $T^{-1/4}$ means that the mechanism of the conduction of polypyrrole films can be expressed by a hopping model.

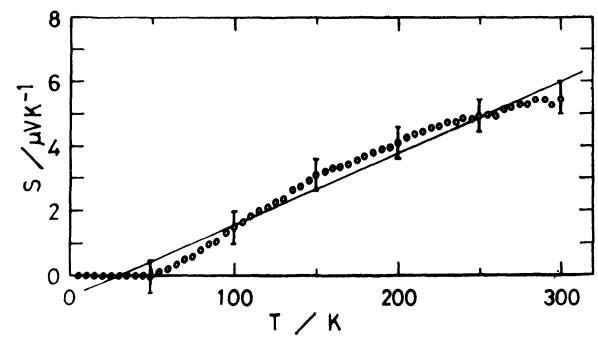

Fig. 7. Thermoelectric-power of polypyrrole film prepared by using Et_4NBF_4 in the form of S *vs.* T.

Thermoelectric-power, S, of the polypyrrole films is shown in Fig. 7, where S *vs.* T is plotted on a linear scale. The room temperature value of the thermoelectric-power is 6 μV/deg. The thermoelectric-power decreases with lowering temperature in a manner typical of a metal and the straight line in Fig. 7 is expressed by

$$S = 0.022\,T - 0.6 \quad (\mu\text{V/deg}). \tag{13}$$

The sign of S is positive in the range above 27.3 K indicating a p-type behavior. It means that the conduction occurs by the hole conduction.

For a nearly filled metallic band system (*i.e.* p-type), the thermoelectric-power can be written as follows,[13]

$$S = \frac{\pi^2}{3}\frac{k^2T}{e}\frac{\mathrm{d}\ln\sigma}{\mathrm{d}E}. \tag{14}$$

In the case that the interchain conduction occurs by hopping electrons, the thermoelectric-power can be expressed by using Eq. 9 as follows,[13]

$$S = \frac{\pi^2}{3}\frac{k}{e}\left(kT\frac{\mathrm{d}\ln\sigma_o}{\mathrm{d}E} - \frac{\mathrm{d}W}{\mathrm{d}E}\right). \tag{15}$$

$|S|$ is linearly increasing with T, and it falls down at certain temperature given by

$$T = \left(\frac{\mathrm{d}W}{\mathrm{d}E}\right)\Big/\left(k\frac{\mathrm{d}\ln\sigma_o}{\mathrm{d}E}\right) \tag{16}$$

and these theoretical predictions are in good agreement with the observed tendencies. The same result was obtained by Kanazawa *et al.*[14]

Determination of the Specific Heat Capacities of Aqueous Solutions of Pentose

Fumio KAWAIZUMI,* Shigemi KUSHIDA, and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received March 17, 1981)

A laboratory-constructed isoperibol twin calorimeter of dry shield type (*J. Chem. Thermodyn.*, **13**, 89 (1981)) was used for measurements of the specific heat capacities of aqueous solutions of D-xylose, D-ribose, D-, and L-arabinose at *ca.* 30 °C. The partial molar heat capacity at infinite dilution, $C^{\infty}_{p,2}$ was determined. Values of $C^{\infty}_{p,2}$ obtained are: D-xylose 281±2, D-ribose 271±2, D-arabinose 278±3, and L-arabinose 270±4 J K^{-1} mol^{-1}. Measurements of the heat capacity of these pentoses in the solid state, $C^{*}_{p,2}$ were carried out and the parameter $\Delta C^{\infty}_{p,2} \equiv C^{\infty}_{p,2} - C^{*}_{p,2}$ was evaluated. Values of $\Delta C^{\infty}_{p,2}$ are smaller than the corresponding values for hexose obtained previously. Similarly as had been the case for hexose, the additivity parameters of the group contribution on $C^{\infty}_{p,2}$ of solute estimated from the data on other nonelectrolytes were not acceptable for pentose. From this point the interactions working between solute of saccharide and the solvent water are considered to have characters largely different from those of other nonelectrolyte.

In the realm of the chemistry of aqueous solution of non-electrolyte, urea and saccharides, such as glucose and sucrose, have often been taken as the most basic solutes. This is because of the facts that these solutes are stable chemicals easily available at very high purity and that many physicochemical behaviors of their aqueous solutions are quasiideal, or at least vary linearly with the content of solute up to the moderate concentration. In addition to these facts, saccharide molecules have following two important features: First, they exist in cyclic structure. Secondly, they contain both many hydrophilic and hydrophobic groups and these groups having opposite nature are arranged in close proximity in each other.

Effect of hydrophobic molecule and group of a molecule on water structure, namely, hydrophobic interaction, has attracted attention of many investigators. Measurements of specific heat capacity of a solute are one of the most powerful methods to investigate the role played by hydrophobic group.[1] Furthermore, in spite of the rapid development of solution calorimetry stimulated by the commercial production of Picker's flow calorimeter,[2] data of the specific heat capacity of solutions of saccharide were rather scare. This situation pushed us to take the measurement of the specific heat capacity of aqueous solutions of saccharides, and results on hexose (D-fructose, D-galactose, D-glucose, and D-mannose), disaccharide (lactose and maltose), and trisaccharide raffinose have already been reported.[3]

In the present paper, results of the similar measurement on four kinds of pentose, D-xylose, D-ribose, D- and L-arabinose will be presented. To obtain the values of the partial molar heat capacity at infinite dilution, $C^{\infty}_{p,2}$, measurements of the specific heat capacity of the sample solutions were done at ten different concentrations of solute.

Experimental

Materials. D-Xylose and L-arabinose were supplied from Nakarai Chemical Co., Ltd. while D-arabinose and D-ribose were those of Pfanstiehl Laboratories Inc. The best quality obtainable was used. Samples were dried in an electric vacuum oven held in the temperature range 90—95 °C, (for D-ribose, in the temperature range 70—75 °C as its melting point is at 86 °C). These samples were used without further purification both for solution and solid state calorimetry. Water contents of the samples determined from the decrease of mass in drying process are as follows (expressed in wt%):

D-xylose	D-ribose	D-arabinose	L-arabinose
0.056	0.267	0.356	0.175

Solution Calorimetry. Specific heat capacities of aqueous solutions of pentose were determined using a laboratory-constructed isoperibol twin calorimeter of dry shield type. The heat reservoir of the calorimeter is an aluminium block which was kept at 30±0.1 °C. As details of this calorimeter and procedures of measurements have already been reported previously,[3,4] a brief mention may be sufficient here: i) Into one of the Dewar vessels, 100 grams of solution to be examined are introduced, while the other Dewar contains always 100 g of pure water as a reference liquid. ii) Two heaters with resistance of 45.45 and 45.42 Ω are connected in series and the e.m.f. applied to the terminals of the heaters was 20.0$_0$ V. This electric power was supplied from a stabilized source, Hewlett Packard Model 6266 B. iii) The temperature rise of the solution in Dewar vessel due to the supplied electric energy was 1—2 °C and the temperature differences between the two solutions in Dewar vessels in five minutes were detected by a pair of thermistors, amplified by laboratory-made bridge and then recorded on a strip-chart recorder. The time of five minutes was read off on the recorder chart from the instance of the sudden change of the voltage.

Calibration of the Solution Calorimeter. The calibration of this calorimeter was re-taken as an initial step of the present work. As before,[3,4] the calibration was carried out using aqueous solutions of NaCl and urea for which very accurate values of the specific heat capacity have been given.[2] Following relation was obtained between the specific heat capacity of the solution C_p and the potential difference in five minutes, ΔV.

$$C_p = A + B(\Delta V) + C(\Delta V)^2.$$

On expressing C_p and ΔV in J K^{-1} g^{-1} and V, respectively, the constants A, B, and C become:

$$A = 4.1299 \pm 0.006 \text{ J K}^{-1}\text{ g}^{-1}$$

$$B = -0.0673 \pm 0.0004 \text{ J K}^{-1}\text{ g}^{-1}\text{ V}^{-1}$$

$$C = 0.0014 \pm 0.00006 \text{ J K}^{-1}\text{ g}^{-1}\text{ V}^{-2}.$$

It may seem to be strange that the introduction of 100 g

of pure water in each of the Dewar vessels does not give rise to the result of $\Delta V=0$. The phenomenon of residual heat capacity difference of the present calorimeter may be ascribed to the inequality of the weight of the two Dewar vessels (207 and 191 g).

The concentration of sample solution was corrected for the water content of the sample.

Calorimetry of Pentose in Solid State. The determination of the specific heat capacity of the pentose in solid state was carried out in Governmental Industrial Research Institute, Osaka. An apparatus, Type SH-2000 manufactured by Tokyo Rikoh Co. Ltd. was used. Specific heat capacity data obtained are those of average values in the temperature range 28—41 °C.

Results

Solution Calorimetry. Specific heat capacities of the aqueous solutions of pentose determined in the present study are summarized in Table 1. The table contains the values of ϕ_{Cp}, apparent molar heat capacity of solute, and the values of $m\phi_{C_p}$ given by the equation

$$m\phi_{C_p} = (1000 + mM_2)C_p - 1000C_{p_1},$$

where C_{p1} is the specific heat capacity of the pure solvent, water (4.1785 J K^{-1} g^{-1}), M_2 is the molar mass, and m is the molality of the solute. Similarly as in our previous work,[3,5] values of ϕ_{C_p} at infinite dilution, $\phi^{\circ}_{C_p}=C^{\infty}_{p.2}$ were determined by the least-squares fitting of the relationship,

$$m\phi_{C_p} = bm + cm^2.$$

Evidently $C^{\infty}_{p.2}$ is equal to the coefficient b.

Specific Heat Capacities of Pentose in the Solid State. Results are given in Table 2. Values of $C^{*}_{p.2}$ of D-xylose, D-arabinose, and L-arabinose are equal while a little difference is observed between these values and that of D-ribose. If an estimation procedure of the specific heat capacity of saccharide in the solid state mentioned in a previous work[3] is adopted, the calculation leads to 184 J K^{-1} mol^{-1} for furanose form of pentose. In this calculation numbers of bond taken for the stretching and vibration are for C–C, C–O, C–H, and O–H bonds, 4, 6, 6, and 4, respectively, and the number of internal rotation is 5. The excellent agreement of this value with those in Table 2 supports the estimated value of $C^{*}_{p.2}$ of raffinose in the solid state reported in our previous work.[3]

Discussion

In Table 2 are summarized the final results of the present work, where h is the hydration number. Hydration number was calculated from the data of the apparent molar compressibility[6] on the assumption that hydration waters are those bounded to solute which have the same compressibility as that of ice. For the sake of comparison, results on hexose obtained in our previous work[3] are also included in Table 2. Values of $C^{\infty}_{p.2}$ and $\Delta C^{\infty}_{p.2}$ are both positive, but smaller than the corresponding values of hexose. It has been demonstrated that the value of $C^{\infty}_{p.2}$ of a nonelectrolytic solute in aqueous solution can be assigned to the contribution of each component group of the solute.[7,8] In a word, the additivity rule holds for the quantity $C^{\infty}_{p.2}$. The application of the additivity parameters to saccharides, without taking account of the cyclic form of saccharide molecules, gives for pentose 161 J K^{-1} mol^{-1}, a value much smaller than those found in the present determination. This fact is not a new finding. Similar significant differences have already been found between estimated and experimental values of $C^{\infty}_{p.2}$ for monosaccharide hexose, disaccharide and trisaccharide.[3] Therefore it can be said that saccharide is not a "standard" solute as often is considered, but a solute showing very characteristic features from the point of thermochemical behavior of its aqueous solutions. The characteristic behavior of saccharide molecules in aqueous solutions

TABLE 2. VALUES OF $C^{\infty}_{p.2}$, $C^{*}_{p.2}$, $\Delta C^{\infty}_{p.2}$ (AT *ca.* 30 °C), AND HYDRATION NUMBER h (at 25 °C) OF PENTOSE AND HEXOSE IN AQUEOUS SOLUTION

	$C^{\infty}_{p.2}$ / J K^{-1} mol^{-1}	$C^{*}_{p.2}$ / J K^{-1} mol^{-1}	$\Delta C^{\infty}_{p.2}$ / J K^{-1} mol^{-1}	h / mol/mol
D-Xylose	281±2	184	97	2.6_7

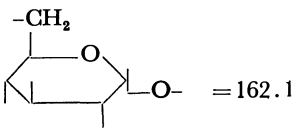
a) Value obtained from the data found in Ref. 11. b) Value determined by the present authors. c) In Ref. 6, the distinction between D- and L-form is not mentioned. In our request, Dr. Høiland answered that they used L(+)-arabinose. d) Value found in Ref. 10.

may be interpreted as follows: The group contribution of $C^{\infty}_{p.2}$ have generally been derived for solutes which are monofunctional or α,ω-bifunctional molecules. For such solutes, effects of functional groups are isolated. However, as mentioned in the introductory part of this paper, in saccharide molecule, many functional groups are arranged in close proximity of each other on the cyclic skeleton of the molecule. As a result, effects of functional groups are overlapping and the values assigned to the contribution of each functional group on the partial molar heat capacity $C^{\infty}_{p.2}$ are not acceptable for solute of saccharide. Following values of $C^{\infty}_{p.2}$ have been observed:[3] for disaccharide lactose, 619±16 and maltose 614±20, and for trisaccharide raffinose, 931±7 J K^{-1} mol^{-1}. The $C^{\infty}_{p.2}$ varies from pentose to hexose, and from monosaccharide to di- and trisaccharide, in proportion to the molecular dimension of the saccharide molecule concerned. Therefore, the additivity rule of $C^{\infty}_{p.2}$ holds for saccharide, though the additivity parameters for saccharide should largely be different from the corresponding values obtained for other nonelectrolyte solutes. Experimental values of $C^{\infty}_{p.2}$ are much higher than those obtained by the application of the additivity rule. It follows that with regard to the contribution of group $-CH_2$, –OH, and –O– (ether), assigned respectively as 90, 9, and −57 J K^{-1} mol^{-1},[7] effects of $-CH_2$ and –OH groups seem to be strengthened, while those of –O– (ether) weakened.

Effects of solute upon the structure of solvent water are well reflected in the value of $\Delta C^{\infty}_{p.2}$, rather than that of $C^{\infty}_{p.2}$, as the intrinsic contribution of the solute in the pure state must be subtracted from the partial molar quantity, $C^{\infty}_{p.2}$. In Table 2, as the numerical values of $C^{*}_{p.2}$ are approximately constant for pentose, differences in $\Delta C^{\infty}_{p.2}$ result from differences in $C^{\infty}_{p.2}$. Values of $\Delta C^{\infty}_{p.2}$ increase with the molecular dimension of saccharide molecules, similarly as for the case of $C^{\infty}_{p.2}$. And the contribution of the structural unit of saccharide molecule to the quantity $\Delta C^{\infty}_{p.2}$ remains roughly constant in hexose, di- and trisaccharides. Here, the structural unit of saccharide is meant by



=162.1

Measurements on dextrans have shown[9] that the values of $\Delta C^{\infty}_{p.2}$ calculated for structural unit of dextran decrease with molecular weight and for dextran of M_w equal to 2.0×10^6, the value of $\Delta C^{\infty}_{p.2}$ amounts only to 3 J K^{-1} mol^{-1}.

In contrast to $C^{\infty}_{p.2}$ and $\Delta C^{\infty}_{p.2}$, hydration numbers vary randomly with solute species. Here, the term hydration corresponds to the existence of the compressed water molecules attached to solute. Hydration of saccharide is mainly ascribed to the effect of hydrophilic group –OH in the molecule. The fact that hydration number does not vary proportionally with the number of –OH group contained in saccharide molecule has been interpreted in terms of the intramolecular h dration bonding and the steric hindrance effect.[10]

The difference in the $\Delta C^{\infty}_{p.2}$ values of two stereoisomers of L- and D-arabinose is just the limit of experimental precision. This difference might be related to that the stable form of L-arabinose is pyranose form in solution, in contrast to furanose form of D-arabinose. In order to obtain further information on differences in the behavior of D- and L-arabinose, we have taken the determination of the hydration number of D- and L-arabinose at 25 °C. An ultrasonic interferometer which had long been used in our laboratory and a pycnometer were used. Results of this determination are included in Table 2, which indicate that the two stereoisomers of arabinose have the same amount of hydration. After considering these facts, it seems improper to place so much emphasis on the difference of values of $\Delta C^{\infty}_{p.2}$ of D- and L-arabinose.

The authors wish to express their thanks to Mr. Itsuki Uehara of Governmental Industrial Research Institute, Osaka, for the measurement of specific heat capacity of pentose in the solid state. The authors are also grateful to Associate Professor Hiroyasu Nomura of Nagoya University for his valuable suggestion and discussion.

Ion Association of Some 2 : 2 Electrolytes in Water at 25 °C. III. A New Interpretation of Experimental Results and the Determination of Formation Constants of Inner-sphere Ion-pairs

Haruhiko YOKOYAMA* and Hideo YAMATERA**

(Received September 22, 1980)

The results of previous studies on ion association were re-examined. The formation constants of inner-sphere ion-pairs were obtained for several bivalent-metal sulfates by estimating the formation constants of outer-sphere ion-pairs with the help of the ion-association theory. The interactions between metal and sulfate ions were discussed by comparing these results.

Ion association usually refers to the formation of pairs of ions existing in the close vicinity of each other. In this concept, ion-pairs may be considered to be a chemical species, which is in equilibrium with the free ions in solution:

$$M^{n+} + A^{n-} \rightleftharpoons M^{n+}A^{n-}. \quad (1)$$

Sometimes they are classified into more than one chemical species, *e.g.* outer-sphere ion-pairs and inner-sphere ion-pairs, according to whether or not the ions of a pair are separated by at least one solvent molecule:

$$M^{n+} + A^{n-} \rightleftharpoons M^{n+}A^{n-}(os) \rightleftharpoons M^{n+}A^{n-}(is). \quad (2)$$

Another concept of ion-pairs has been shown in a previous paper.[1] There we have extended the Debye-Hückel theory[2] of strong electrolyte solutions, making approximation to the next higher order beyond that considered in the Debye-Hückel treatment. An expression was obtained for the chemical potential of an arbitrary central ion. This was compared with the corresponding Debye-Hückel expression. An extra term appearing in our equation arises from the excess interaction of the central ion with a counter-ion, since the probability of finding the latter in the vicinity of the central ion is greater than that assumed in the Debye-Hückel approximation. Although the counter-ion has probabilities of being found at various distances from the central ion and therefore of making different extents of contribution to the chemical potential of the latter, the total effect of the excess interactions can be regarded as equivalent to the effect of the conventional ion-pair formation. Accordingly, our concept of ion association complements the Debye-Hückel theory, which is not a good approximation for solutions of multivalent electrolytes and of solvents having a low dielectric constant.

The ion association expressed by Eq. 1 or 2 also complements the Debye-Hückel theory, since the free ions are regarded in these equations as hypothetical ions behaving in accordance with the Debye-Hückel theory. Therefore the above two concepts of ion association may be related to each other. From this point of view, we have derived the following expression for the ion-association constant at infinite dilution of a symmetrical electrolyte:

$$K = \frac{8\pi Na^3}{1000} \sum_{n=1}^{\infty} \frac{b^{2n+2}}{(2n+2)\,!\,(2n-1)}, \quad (3)\dagger$$

where N represents the Avogadro number, a the closest distance of approach between ions, and b the Bjerrum parameter given by $b = z^2e^2/\varepsilon kTa$.

It should be noted that Eq. 3 resulted from the consideration of the chemical potentials of the free and paired species, not from the counting of their numbers; however, the limiting expression ($b \to \infty$) of Eq. 3:

$$K(b \to \infty) = \frac{4\pi Na^3}{1000} \cdot \frac{\exp(b)}{b},$$

is the same as the corresponding limiting expression derived from the Bjerrum equation for ion-association constant,[1] which was obtained by counting the number of ions within the critical distance of a central ion.

Equation 3 has been utilized in the vapor-pressure osmometric, spectrophotometric, and conductivity investigations of several electrolytes for determining the *best* values of K and a.[3,4] Thus, when an appropriate value was chosen for a, the ion-association constant derived from the experimental results agreed with that predicted by the theoretical expression. Such a value of a was larger than the sum of the crystallographic radii of cation and anion ($r_M + r_A$) of each electrolyte, but smaller than the sum plus the diameter of a water molecule ($r_M + r_A + 2r_{H_2O}$, $r_{H_2O} = 1.4$ Å). From the viewpoint that the solvent is a continuous medium, the result can reasonably be taken as implying that the ions are hydrated to some extent. However, if a structual or microscopic view is taken of ions dissolved in water, the result can be interpreted as indicating that hydrated cations and anions may sometimes come so near to each other as to displace water molecules in the coordination spheres of ions to form inner-sphere ion-pairs. The latter view is preferred, since the water molecules in the first sphere of a bivalent-metal ion are strongly oriented or coordinated to the metal ion and consequently may have a different dielectric constant from that of the water in bulk. Then the solvent may not be regarded as a continuous medium of a certain dielectric constant, nor the ions as rigid spheres. Moreover, the interaction between ions may not be solely electrostatic in the first sphere of the ion. Thus, the conditions assumed in

† There are some misprints in our 1975 paper.[1] Equation 31 of the 1975 paper should be the same as Eq. 3 of the present paper ("when $b \to \infty$" should be deleted). For other misprints, refer to "Corrections" of the journal [*Bull. Chem. Soc. Jpn.*, **48**, 3002 (1975)].

deriving the Debye-Hückel theory[2] and our ion-association theory[1] may not be satisfied. Therefore, the value of a obtained in previous investigations[3,4] may not have a definite physical meaning, but may be only a measure of the closest distance of approach between ions. In this paper, another interpretation of the experimental results will be made by using the ion-association theory in a different way.

Basic Viewpoint

In this paper, we shall classify ion-pairs into inner-sphere ion-pairs and outer-sphere ion-pairs, and define an inner-sphere ion-pair as a pair of positive and negative ions with an inter-ionic distance less than the distance, $r_M+r_A+2r_{H_2O}$, which will be denoted by a_{os} in the following discussion. Then, for ions not forming an inner-sphere ion-pair, the so-called closest distance of approach can be taken to be equal to a_{os}. With this greater distance than usually assumed, the solvent may be reasonably approximated by a medium of a certain dielectric constant, and non-electrostatic interactions of the hydrated ions with further water molecules may be justifiably disregarded. Thus the theory is expected to give a satisfactory prediction for the formation of such outer-sphere ion-pairs.

The inner-sphere ion-pair can be regarded as a kind of neutral molecule, the presence of which has only a negligible effect on the theoretical treatment of very dilute solutions. Therefore, the theoretical ion-association constant can be derived in essentially the same way as that for Eq. 3[1] by employing the parameter a_{os} instead of a. The *theoretical* ion-association constant obtained here refers to the formation of all the ion-pair species†† except the inner-sphere ion-pair, namely to the formation of outer-sphere ion-pairs, for which the constant K_{os} becomes:

$$K_{os}=\frac{8\pi N a_{os}^3}{1000}\sum_{n=1}^{\infty}\frac{b^{2n+2}}{(2n+2)\,!\,(2n-1)} \qquad (4)$$

On the other hand, analysis of the *experimental* data by taking a_{os} as "the closest distance of approach of ions" gives us the overall constants for the ion-pair formation, K_Σ. When the value of K_Σ is larger than K_{os}, it is reasonable to assume the formation of inner-sphere ion-pairs in solutions. With such an assumption, we can estimate the formation constant of the inner-sphere ion-pair, K_{is}, from the difference of K_Σ and K_{os}.

Recently, Fuoss has proposed a new method of analysis of conductivity data for a purpose similar to ours but from a viewpoint different from ours.[5] He introduced the critical distance R as the closest distance of approach of unpaired ions (free ions), which is assumed to be equal to the sum of the radii of the Gurney cospheres of cation and anion. Ion-pairs are classified into solvent-separated pairs (diffusion pairs) and contact pairs (nearest-neighbor pairs). The solvent-separated pair is defined as a pair of a cation and an anion separated by at least one solvent molecule. His concept for the contact pair is similar to ours for the "inner-sphere ion-pair" as defined above, whereas that for the solvent-separated pair is very different from ours for the "outer-sphere ion-pair." That is, the solvent-separated pair is restricted to the pair of ions existing within the critical distance R of each other, and its formation constant is assumed to be given by the Fuoss 1958 equation[6] for the ion-pair formation, $K_R=4\pi NR^3\exp(b)/3000$.[5] His concept is specific in the respect that the solvent-separated pairs contribute to the transport current to the same extent as do the unpaired ions.

Fuoss's new method is of interest from the viewpoint that it precludes various problems at the vicinity of ions. However, some questions may be raised about his method: how his concept of ion-association can be thermodynamically connected with the Debye-Hückel theory; how the discontinuity at the distance of R can be justified; and what is the reasoning for the solvent-separated pair being equivalent to unpaired ions in the ionic conductance. On the other hand, our method of analysis of experimental data, which is simpler than Fuoss's method, has no adjustable parameter except for the distance a_{os} with a definite physical meaning, and is connected complementarily with the Debye-Hückel theory by Eq. 3.

Analysis of Experimental Data

The osmotic coefficient was measured on $MgSO_4$, $CaSO_4$, and $MnSO_4$ solutions with a vapor-pressure osmometer. The absorption at 250 nm was measured for copper sulfate solutions and mixed electrolyte solutions of copper sulfate and another bivalent-metal sulfate such as $MgSO_4$, $CaSO_4$, $MnSO_4$, and $ZnSO_4$. The experimental procedures and results have been described in previous papers.[3,4] In the present study, use was made of these experimental data as well as conductivity data given in the literature,[7-14] which are available for $CoSO_4$, $NiSO_4$, and $CdSO_4$ in addition to those mentioned above.

The analysis was made from the viewpoint described above: that is, with a a_{os} value characteristic of each electrolyte, the value of K_Σ was obtained from experimental data. In estimating a_{os}, r_M was assumed to be equal to Pauling's radius[15] and r_A to be 2.8_8 Å.[3] The former assumption seems to be reasonable, because the ionic radii of bivalent transition-metal ions from manganese(II) to zinc(II) obtained from X-ray scattering measurements in aqueous solutions[16] are in agreement with Pauling's radii within 0.1 Å.

The procedure used for deriving K_Σ values from experimental data of each kind is essentially the same as described in the previous papers,[3,4] except for the following modifications: (1) the parameter a_{os} was substituted for a; (2) the conventional expression for the concentration of the ion-pair, [MA], was (formally) replaced by the sum of the concentrations of outer-sphere ion-pairs and inner-sphere ion-pairs; (3) in the analysis of spectrophotometric data, in particular, the

†† A pair of cation and anion may not necessarily be divided strictly into two categories: a pair of the pure free ions and the pure ion-pair. There may be pairs which do not fully exhibit the characteristics of ion-pairs. These partial ion-pairs may be counted as fractions of an ion-pair.

conventional molar extinction coefficient, ε_{MA}, was (formally) replaced by $(\varepsilon_{MA(os)}K_{os}+\varepsilon_{MA(ls)}K_{ls})/K_{\Sigma}$, where $\varepsilon_{MA(os)}$ and $\varepsilon_{MA(ls)}$ are the extinction coefficients of the respective ion-pair species. The last two formal substitutions have arisen from the use of Eq. 2 instead of Eq. 1, and do not affect the K_{Σ} value to be obtained.

Results and Discussion

The experimental K_{Σ} values are given in Table 1, together with the values of K_{os} calculated by the use of Eq. 4. In each case, the value of K_{Σ} is larger than that of K_{os}, showing that the inner-sphere ion-pairs exist in the solution. Table 1 also lists the values of $K_{ls}(=K_{\Sigma}-K_{os})$ and K_{ls}/K_{Σ} for each electrolyte. We also calculated the values for K_{ls}/K_{Σ} based on a similar (but not exactly the same) definition, using the results of ultrasonic absorption studies;[17-19] the values are 0.10 for $MgSO_4$,[17] 0.48 for $MnSO_4$,[18] and 0.50 for $CuSO_4$,[19] which are close to those obtained in the present study. This implies that the above assumptions are reasonable.

The K_{ls} values for the first-row transition-metal ions (Table 1) appears to follow the order of the Irving-Williams series.[20] In order to discuss the formation of inner-sphere ion-pairs in more detail, we re-analyzed the conductivity data at various temperatures between 0 °C and 45 °C presented by Katayama.[8,11] The values of K_{Σ} and K_{ls} at each temperature were obtained in the same way as described above and their logarithmic values were plotted against T^{-1}. However, the plots showed curvatures like those found with the transition-metal dicarboxylates.[21,22] Therefore, according to the previously outlined procedure,[21,22] we evaluated the standard enthalpy and entropy of the ion-pair formation. The results are shown in Table 2. An approximately

a) Ten experimental data points between 0 °C and 45 °C were used for the evaluation of ΔH° and ΔS° values. The variation of log K with temperature was expressed by the equation $\log K=A+BT+CT^2$ (K represents K_{Σ} or K_{ls}) and the parameters A, B, and C were determined by the least-squares method. The values of the enthalpy and entropy changes were calculated from the equations $\Delta H^{\circ}=2.303\,RT^2(B+2CT)$ and $\Delta S^{\circ}=(\Delta H^{\circ}-\Delta G^{\circ})/T$. Uncertainties were estimated by using different combinations of experimental results at nine temperatures for the calculation of A, B, and C.

linear relationship exists between ΔH°_{is} and ΔS°_{is} and between ΔH°_{Σ} and ΔS°_{Σ} except for the case of magnesium sulfate. In each electrolyte, the values of ΔH°_{is} and ΔS°_{is}, are positive and larger than those of ΔH°_{os} and ΔS°_{os}, respectively; the difference is relatively small in the ΔS° values, however. The entropy changes favor the formation of both inner-sphere and outer-sphere ion-pairs, while the enthalpy changes oppose the reactions. Although the $T\Delta S^\circ$ terms predominate over the ΔH° terms, the differences between the ΔH° terms are significant for relative magnitudes of the formation constants given in Table 1.

The largest ΔH°_{is} value is shown by $MgSO_4$, reflecting the facts that the magnesium ion has the smallest ionic radius and accordingly the strongest hydration. The ΔH°_{is} value is considerably smaller for $NiSO_4$, in spite of the fact that the nickel ion has a radius close to that of the magnesium ion. This suggests that some interaction may exist between nickel and sulfate ions in addition to the electrostatic one. A similar argument seems to hold for the other transition-metal sulfates.

The enthalpy change is less unfavorable for cobalt and nickel sulfates than for zinc sulfate. On the contrary, the entropy change is more favorable for zinc sulfate. Such tendencies have also been observed with the malonates, succinates, and phthalates of these metals.[22,23] As regards the coordination of the acetate ion to the zinc ion, the comparatively large and positive enthalpy and entropy changes for the formation of ZnL_2 from ZnL^+ (where L=acetate ion) are considered to be consistent with the tendency of Zn(II) to form tetrahedral complexes.[23] If we take into account the above information and the ability of the dicarboxylate and sulfate ions to act as bidentate ligands, the formation of inner-sphere ion-pairs with the zinc ion would cause at least in part the change of the coordination number of the zinc ion from six to four. This will lead to increased positive ΔH° and ΔS° values, because a greater number of coordinated water molecules are released.

The speculation described above might seem to be opposed by the X-ray diffraction study[16] on aqueous zinc sulfate and zinc perchlorate solutions, which shows that the zinc ion is surrounded by six oxygen atoms in the solution. However, this does not seem to exclude the possibility that part of the zinc ions in inner-sphere ion-pairs are surrounded by four oxygen atoms; a majority of the zinc ions in the solutions exist as free ions and outer-sphere ion-pairs, and thus the decrease in the coordination number occurring in part on the formation of inner-sphere ion-pairs may have escaped detection.

The relatively large values of K_{is}, ΔH°_{is}, and ΔS°_{is} for $CdSO_4$ appear to show that more than one water molecule are released by the entrance of one sulfate ion into the inner-sphere of a cadmium ion; this may be supported by the fact that a cadmium ion in the $CdSO_4 \cdot 8/3\,H_2O$ is surrounded by sulfate ions (4 O of $2SO_4^{2-}$) and water molecules ($2H_2O$) in an entirely different way from that observed in the other metal sulfates.[24]

Conclusion

The theoretical formation constant for the outer-sphere ion-pairs was estimated by assuming a parameter a_{os} for the closest distance of approach for outer-sphere ion-pairs. Although some arbitrariness may be involved in the estimation of the a_{os} values, the present treatment has the merit of removing the theoretical difficulties encountered at the close vicinity of the ions in the application of the Debye-Hückel and ion-association theories.[1,2] Then from the re-analysis of various experimental data, the thermodynamic parameters were obtained for the formation of inner-sphere ion-pairs. The trends shown by the obtained parameters are consistent with other experimental findings and give useful information regarding the formation of inner-sphere ion-pairs.

(Received October 1, 1980)

The crystal and molecular structure of the title complex has been determined by the X-ray diffraction method. The crystal was triclinic, space group $P\bar{1}$, $a=6.750(2)$, $b=9.214(4)$, $c=5.206(2)$ Å, $\alpha=102.57(6)$, $\beta=103.44(6)$, $\gamma=100.70(3)°$, $Z=1$, $D_x=1.702(3)$, $D_m=1.72(3)$ mg m^{-3}, μ(Mo $K\alpha$) = 1.89 mm^{-1}, and the final R value was 0.034 for 1175 reflections. The molecular arrangement has a center of symmetry and a distorted octahedron is formed around the central cobalt(II) atom; each methylthioacetato ligand forms a chelate ring by coordinating through a sulfur atom and a carbonyl oxygen atom, and two water molecules also coordinate to the central metal. Its amorphous anhydride as well as the other type anhydride, which resembles the bis(propylthioacetato)cobalt(II) hexamer in its infrared and visible spectra, is obtained by the dehydration process.

Alkylthioacetato complexes have interesting properties and they have been studied by many authors. We have already reported about their syntheses and spectroscopic properties.[1-5] Yamasaki also studied them,[6] and Pettit has shown the formation constants of their silver complexes.[7,8] More recently, many kinds of complexes containing the multi-dentates of this type of ligand were synthesized and actively investigated by Jones and others.[9-14]

One of the special properties of this type of complexes is the formation of a polymer-type structure, where the ligand bridges metal atoms. The hexamer of bis(propylthioacetato)cobalt(II) and bis(isopropylthioacetato)copper(II) dihydrate are the examples.[15,16] In the case of phenoxyacetato complexes of copper(II), the same type of the hexamer was already reported by Carruthers;[17] however, it was also shown that the ligand was able to form complexes with other structures.[18-21]

In the case of alkylthioacetato complexes, only a few structural reports have been published yet. We judge from the syntheses that the most stable form of the alkylthioacetates of cobalt(II), nickel(II), and copper(II) is the dihydrate, $ML_2 \cdot 2H_2O$ (some of which may be the diaqua complexes; here HL=alkylthioacetic acid), which are easily obtained from the aqueous solution. Therefore, we have started the structural research of this type of complexes. Although powder or fiber-like crystals of them were easily obtained, the formation of the single crystals suitable for the X-ray diffraction study was not easy. The single crystals of the title complex, obtained after many attempts, were used for its crystal and molecular structure determination.

The structural changes between the diaqua complex and the anhydride complex are also shown in the later part of this paper.

Experimental

Syntheses of Diaquabis(methylthioacetato)cobalt(II); $[Co(CH_3 \cdot S \cdot CH_2 \cdot CO_2)_2(H_2O)_2]$. The ligand was obtained by the slight modification of the method of Larsson:[22] a condensation reaction between dimethyl sulfate (in place of methyl iodide) and mercaptoacetic acid in the presence of sodium hydroxide in aqueous medium. The crude cobalt(II) complex was obtained by the reaction between cobalt(II) chloride and the sodium salt of the ligand in aqueous solution in the presence of a little sodium hydrogencarbonate. Then the concentrated aqueous solution of the complex was left standing for several weeks at 6 °C, and the crystals came out. Although many large crystals which looked like single crystals under microscopic observation were obtained, almost all of them consisted of many needle-like crystals in parallel, so they gave broad spots on Weissenberg photographs. From the 37 samples tried, only 2 crystals were obtained which could be used to obtain the diffraction data. Analyses of the complex. Found: Co, 19.38; C, 23.61; H, 4.61%, magnetic moment 4.8_2 BM** (per 1 mol of cobalt). Calcd for $CoC_6H_{14}S_2O_6$, Co, 19.31; C, 23.61; H, 4.62%.

Dehydration of Diaquabis(methylthioacetato)cobalt(II). When the title complex was heated to 140—150 °C for a few hours in air, the dark-red powder anhydride was obtained, this is amorphous, judging from the X-ray powder pattern. Analyses of the product. Found: Co, 21.90; C, 26.65; H, 3.84%, magnetic moment 4.9_0 BM** (per 1 mol of cobalt). Calcd for $CoC_6H_{10}S_2O_4$: Co, 21.89; C, 26.77; H, 3.74%. When the product was heated at 150 °C continuously, it decomposed slowly.

When the title complex was dehydrated by evaporating its benzene–ethanol mixed solvent solution two times, and then its benzene solution about five times (at 80 °C using rotary vacuum evaporator), another type of anhydride was obtained. (To complete the dehydration process, preferably, the anhydride obtained by the above mentioned process is to be kept in refluxed *p*-xylene for several hours.) The product was red-violet powder. Analyses Found: Co, 21.78; C, 27.15; H, 3.71%, magnetic moment 4.8_2 BM** (per 1 mol of cobalt). Calcd for $Co_6C_{36}H_{60}S_{12}O_{24}$: Co, 21.89; C, 26.77; H, 3.74%. As shown later, their infrared and visible spectroscopic properties of this anhydride resemble those of the bis(propylthioacetato)cobalt(II) hexamer *p*-xylene adduct,[15] and it is tentatively named as the hexamer-type anhydride.

X-Ray Measurement. The single crystals obtained were needle-like ones and were pale-red in color; they were stable in air. As they were too brittle, a crystal $0.4 \times 0.2 \times 0.2$ mm in size was used for X-ray measurement, without any additional reshaping process.

** 1 BM = $9.274078(36) \times 10^{-24}$ J T^{-1}.

The crystallographic data are as follows: $CoC_6H_{14}S_2O_6$, F.W.=305.24, triclinic, space group $P\bar{1}$, a=6.750(2), b=9.214(4), c=5.206(2) Å, α=102.57(6), β=103.44(6), γ=100.70(3)°, Z=1, D_x=1.702(3), D_m=1.72(3) mg m^{-3}, μ(Mo $K\alpha$)=1.89 mm^{-1}. The reflections within the range of $2\theta < 60°$ were collected on a Philips 1100 automated four-circle diffractometer, using Mo $K\alpha$ radiation (0.7107 Å) and applying the ω—2θ scan technique. The 1175 independent reflections with $|F_o| > 3\sigma(|F_o|)$ were used for the structure refinement. The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption and extinction.

All the calculations were carried out on a HITAC 8700/8800 computer at the Computer Center of The University of Tokyo, using the local version of UNICS program.[23] The atomic scattering factors were taken from the tables.[24]

Structure Determination. The structure was solved by the heavy-atom method. The positions of the cobalt and sulfur atoms were deduced from a three-dimensional Patterson map, and all the other non-hydrogen atoms were successively located by Fourier syntheses; their positions and their thermal parameters were refined by a repeated block-diagonal least squares method. Then the positions of all hydrogen atoms were obtained from a difference Fourier synthesis, and were also refined. In the last cycle of the refinement with anisotropic temperature factors for all non-hydrogen atoms, all the parameter shifts were less than one-third of the corresponding standard deviations. The final R value was 0.034.[25]

The Other Measurements. Magnetic moments of the solid powder samples were measured using a Gouy balance, at 25 °C.

The simultaneous thermogravimetric (TG) and differential thermal analysis (DTA) were carried out with Rigaku Denki M-8075 using a sample weighing 10 mg in each operation, with the heating rate of 10 °C min^{-1} in air, using α-alumina as the reference.

The infrared spectra of the samples were obtained by means of a JASCO infrared spectrophotometer, type 403G, using Nujol and hexachloro-1,3-butadiene mull.

The visible absorption spectra of the samples were obtained by a Hitachi 124 spectrophtometer, and their reflectance spectra by the same instrument using the appropriate attachment.

Results and Discussion

The final atomic parameters are listed in Table 1,[26] the atomic distances and the bond angles in Table 2. A perspective drawing of the complex and the numbering scheme of atoms are shown in Fig. 1, and a projection of the structure along b^* in Fig. 2. The crystal consists of discrete molecules of $[Co(CH_3 \cdot S \cdot CH_2 \cdot CO_2)_2(H_2O)_2]$, except for weak hydrogen bondings. The molecules has a center of symmetry, occupied by a cobalt atom. As shown in Fig. 1, the central metal in this complex is in a deformed octahedral environment, elongated in both the coordinated sulfur atom directions. Methylthioacetato ligand forms a five-membered chelate ring, coordinating through a sulfur atom and a carbonyl oxygen atom. Two water molecules also coordinate to the cobalt atom. The value of the magnetic moment of the complex shows no interaction between cobalt atoms.

The Co–S distance is 2.531(1) Å, which is almost the same as that in the bis(propylthioacetato)cobalt(II) hexamer,[15] and which is slightly longer than that of the four, five or six-membered ring chelate dithiolato complexes of cobalt(II).[27–29] As the sum of the covalent bond radii (Pauling) of Co(II) and S is 2.36 Å, the Co–S bond of this chelate is a little weaker than that of the common sulfur-coordinated cobalt(II) complexes. The distance C(1)–O(1) (where O(1) of the ligand coordinates to Co), is 1.278(3) Å; this is longer than C(1)–O(2): 1.228(4) Å. Therefore, the carboxyl group of the ligand is in rather a covalent character in the chelate, because the bond length C(1)–O(1) and C(1)–O(2) should be about equal when it has the ionic character.

The coordinated water molecule forms hydrogen bonds with the O(1) atom of the complex which is

located next in the c-axis direction, as well as with the O(2) atom of the complex next in the a-axis direction. The crystal preferably grows in the c-axis direction, and a needle-like one is commonly obtained. The crystal cleaved along both of (100) and (010) planes, although the cleavage along the former plane must break hydrogen bondings between complexes.

The results of the simultaneous TG and DTA of [diaquabis(methylthioacetato)cobalt(II)] and of [diaquabis(propylthioacetato)cobalt(II)] are shown in Fig. 3. Their general features resemble each other, although the methylthioacetate is dehydrated in the higher temperature region. At the second step, a drastic mass loss occurs at about 230—300 °C in both cases. Their DTA curves show that several endo- and exo-thermal reactions occur in this region, and the complexes are completely decomposed into some tar-like

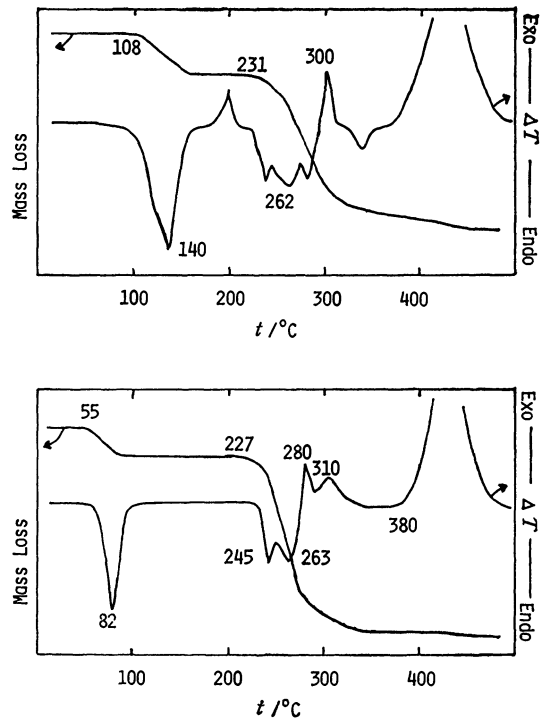

Fig. 3. Thermogravimetric and differential thermal analysis curves of a) diaquabis(methylthioacetato)-cobalt(II) (upper), and b) diaquabis(propylthioacetato)cobalt(II) (lower) (10 °C min^{-1}).

materials. The TG curve of the methylthioacetate shows a plateau between 140—230 °C. The anhydride corresponding with this region is an "amorphous anhydride" obtained by heating the diaqua complex at about 140—150 °C; this fact was determined from the X-ray powder pattern. From the propylthioacetate, the same type of anhydride was also obtained by the same process, but by heating at a lower temperature (100—110 °C).

When diaquabis(propylthioacetato)cobalt(II) was dehydrated by evaporation together with a benzene–ethanol mixture, and then with benzene, the obtained product was the amorphous anhydride; this has similar spectroscopic properties to those of the one obtained by heating the solid diaqua complex in air. However, when the amorphous anhydride was dissolved in some non-polar solvent, such as benzene, carbon tetrachloride, or xylene, and dried at room temperature, the anhydride hexamer or its organic solvent adducts were obtained. Its hexamer *p*-xylene adduct, used for the crystallographic analysis, was obtained by the gradual dissolution of petroleum ether into a xylene solution of the amorphous anhydride at room temperature.[15]

The infrared spectra of diaquabis(methylthioacetato)-cobalt(II), its amorphous anhydride, and its hexamer-type anhydride form, and those of diaquabis(propylthioacetato)cobalt(II) and its anhydride hexamer (*p*-xylene adduct), are all shown in Fig. 4. Although the wave number of each corresponding peak differs in some extent, the general features of the spectra of their diaqua complexes, and of the spectra of their hexamer or hexamer-type anhydride, are almost identical in the

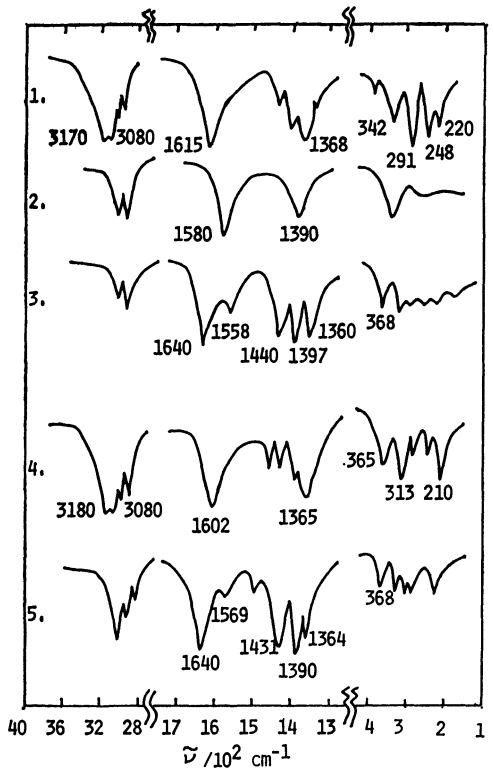

Fig. 4. Infrared spectra of the complexes. 1—3) Bis(methylthioacetato)cobalt(II); 1) diaqua complex, 2) amorphous anhydride, 3) hexamer-type anhydride. 4, 5) Bis(propylthioacetato)cobalt(II); 4) diaqua complex, 5) hexamer *p*-xylene adduct.

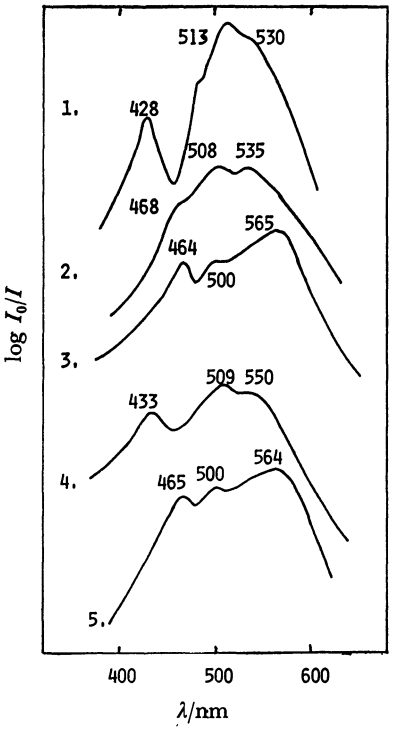

Fig. 5. Reflectance spectra of the complexes. 1—3) Bis(methylthioacetato)cobalt(II); 1) diaqua complex, 2) amorphous anhydride, 3) hexamer-type anhydride. 4, 5) bis(propylthioacetato)cobalt(II); 4) diaqua complex, 5) hexamer *p*-xylene adduct.

wave number region shown. The ν(O–H) peaks of both diaqua complexes appear at about 3100 cm^{-1} (split into 2 peaks), which is lower than those of common crystalline water in metal complexes. This fact is explained by the coordination of water to the central metal, as shown by the structure analysis of the title complex, diaquabis(methylthioacetato)cobalt(II). The wave numbers of ν_{as}(COO) and of ν_s(COO) are characteristic of each type of the complexes. In the case of both diaqua complexes, these peaks appeared at 1602 or 1615 and 1365 or 1368 cm^{-1}, those of the hexamer appeared as a strong ν_{as}(COO) peak at 1640 cm^{-1} (with a small one at 1569 or 1558 cm^{-1}), and the characteristic triplet ν_s(COO) peaks with the maxima at 1431 or 1440, 1390 or 1397, and 1364 or 1360 cm^{-1}. (The causes of the splitting and the shift of the peaks have not been analysed in detail, yet. At this stage, only the correspondence of those peaks in their general features was shown). As shown in Fig. 4, the amorphous anhydride of the methylthioacetate shows infrared spectral peaks different from those of either the diaqua complex or the hexamer-type one, in their maximum wave numbers as well as in their shapes. The far-infrared spectra of both types of complexes, diaqua and hexamer-type, also show characteristic patterns.

The reflectance spectra of these products are shown in Fig. 5. As in the case of infrared spectra, the spectra of the diaqua complexes of cobalt(II) methylthioacetate and of propylthioacetate are almost identical. Moreover, those of their hexamer-type anhydrides exhibit the same features.

From these infrared and reflectance spectral results, the diaqua complexes and the hexamer-type anhydrides of the methylthio- and propylthioacetate are likely to have the same types of structure. Their amorphous anhydrides have a structure different from the other two. It is likely to be in a polymer-type structure, but this is not yet clarified.

Although the hexamer of the propylthioacetate of cobalt(II) is soluble in many non-polar organic solvent, the methylthioacetate cannot be dissolved in benzene, xylene, toluene, or carbon tetrachloride at ambient temperature. The 1,1,2,2-tetrachloroethane solution of the methylthioacetate, stable at room temperature, can be obtained when its anhydride (hexamer-type one) is heated with the solvent and cooled.

The hexamer-type anhydride of methylthioacetate and propylthioacetate, dissolved in some non-polar organic solvent, show spectral patterns similar in their features. These patterns are similar to their reflectance spectra, too. Consequently, the hexamer structure shown by the crystallographic analysis of the propylthioacetate is kept in the solution, and the methylthioacetate complex is likely to have the same of a very similar structure in both its solid and its solution state. Beer's law is followed in the concentration region of 0.04—0.01 mol dm^{-3} (per monomer cobalt(II) complex). The high absorption coefficients of peaks, as well as the complicated splittings, correspond to the deformation from the octahedral configuration to an approximately

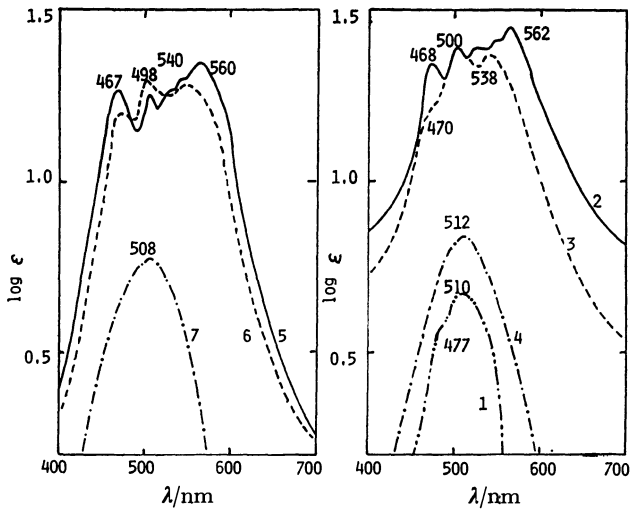

Fig. 6. Absorption spectra of the complexes in solution. 1) Cobalt(II) chloride hexahydrate in water, 2—4) bis(methylthioacetato)cobalt(II); 2) hexamer-type anhydride in 1,1,2,2-tetrachloroethane, 3) hexamer-type anhydride in the mixed solvent of 1,1,2,2-tetrachloroethane and ethanol (4 : 1, v/v), 4) diaqua complex in water (0.07 mol dm^{-3}), 5—7) bis(propylthioacetato)cobalt(II); 5) hexamer *p*-xylene adduct in benzene, 6) hexamer *p*-xylene adduct in the mixed solvent of benzene and ethanol (4 : 1, v/v), 7) diaqua complex in water (0.07 mol dm^{-3}).

squarepyramid one (Co–S is weak and elongated), around the cobalt(II) atoms.[15,30]

As shown in Fig. 6, when ethanol or some such slightly polar solvent was added to the solution of the hexamer-type anhydride mentioned above, the spectral pattern changed, and the destruction of the hexamer structure was suggested. The features of the spectra of their solutions in pure alcohols resemble those of their aqueous solution, although their absorption coefficients are higher.

When the diaqua complexes of both the alkylthioacetates were dissolved in water, the solutions showed neither the peak at 430 nm nor the shoulder about 530 nm, in their reflectance spectra. The spectra of their aqueous solution resemble those of the aqueous solution of cobalt(II) chloride. However, the intensities of the peak maxima of the former ones are higher than that of the latter one, when the former solutions are in higher concentrations (about 0.05—0.1 mol dm^{-3}). The absorption coefficients decrease as the concentration decreases, and the value tends to coincide with that of the hexaaquacobalt(II) ion. This fact shows that the methylthioacetate of cobalt(II) is decomposed in its aqueous solution, and that the ligand is almost completely dissociated in its dilute aqueous solution.

The authors wish to thank Professor Yoichi Iitaka of the Faculty of Pharmaceutical Sciences, The University of Tokyo, for the collection of the intensity data of X-ray diffraction.

Preparation of Graphite Intercalation Compounds of Thiazyl Salts

Tsuyoshi NAKAJIMA,* Masayuki KAWAGUCHI, and Nobuatsu WATANABE

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 22, 1980)

Thiazyl salts prepared from $S_3N_3Cl_3$ and MCl_3(M=Sb, Fe, Al) were intercalated into flaky or powdery natural graphite in CCl_4 or $SOCl_2$. Intercalation compounds prepared are $C_{24}S_4N_4\cdot 2SbCl_5$ [2nd stage, I_c(repeat distance) $=12.81\pm0.02$ Å], $C_{9.5}\cdot 0.2(S_3N_3Cl_3\cdot FeCl_2)\cdot 0.8(SOCl_2\cdot FeCl_2)$ [2nd stage, $I_c=12.77\pm0.03$ Å], $C_{11}S_3N_3Cl_3\cdot 2.4FeCl_2$ [a mixture of 1st and higher stage compounds, $I_c=9.17\pm0.05$ Å] and $C_{24}\cdot 0.4(S_3N_3Cl_3\cdot 2AlCl_2)\cdot 0.6(SOCl_2\cdot 2AlCl_2)$ [a mixture of 2nd and 3rd stage compounds, $I_c=12.89\pm0.03$ Å, 16.23 ± 0.03 Å]. Electrical conductivity of pyrolytic carbon–$S_4N_4\cdot 2SbCl_5$ [3rd stage] is higher than that of original pyrolytic carbon by one order.

In recent years, attention has been given to graphite intercalation compounds showing metallic behavior, *i. e.* high electrical conductivity. Alkali metal, acid or some halide compounds have such properties. Graphite compounds intercalated by strong Lewis acids such as SbF_5, AsF_5 are also of interest.[1] Most chlorides or fluorides of metals in higher oxidation states are hygroscopic and unstable. In many cases, their graphite intercalation compounds also have similar properties. However, such halides are stabilized to some extent forming ionic complexes with anion donor halides. Graphite intercalation compounds of the ternary system might be considered to be effective for preparing stable compounds with high electrical conductivity.

Ternary system compounds were prepared by the reaction of six-membered ring compound $S_3N_3Cl_3$ with metal chlorides ($SbCl_3$, $FeCl_3$, $AlCl_3$) in CCl_4 or $SOCl_2$ containing graphite. Electrical conductivity was measured for a relatively stable compound with pyrolytic carbon host, obtained in a form suitable for measurement.

Experimental

Flaky natural graphite from Madagascar consisting of two different grain sizes of over 500 μm(80%) and 297—500 μm (20%), and powdery natural graphite of less than 44 μm, were used. Purity was 99.4% after purification with a hydrogen fluoride solution. Trithiazyl trichloride $S_3N_3Cl_3$ (yellow crystals, mp 91 °C) was prepared by the usual method.[2] Commercial $SbCl_3$, $FeCl_3$, and $AlCl_3$ were used without further purification. All the reactions were carried out under nitrogen or dry atmosphere. Graphite intercalation compounds prepared were analysed by means of X-ray diffractometry and elemental analysis. The X-ray diffraction pattern for a moisture-sensitive compound was taken by wrapping the sample in thin, transparent poly(vinyl chloride) resin. Elemental analysis was performed at the Laboratory for Organic Elemental Microanalysis, Faculty of Pharmaceutical Science, Kyoto University for C, N, Cl, and at Kyoto Science Research Institute of Shimadzu Seisakusho Corporation for Sb, Fe, Al, and S. A-axis electrical conductivity was measured for pyrolytic carbon (PC), PC–$S_4N_4\cdot 2SbCl_5$, and PC–$SbCl_5$ by the 4-point DC-bridge method. The host material was a pyrolytic carbon plate (Nihon Carbon Comp. Ltd.) deposited at 2100 °C and further treated at 2400 °C.

The compounds were prepared as follows.

1) $C_{24}S_4N_4\cdot 2SbCl_5$. Flaky graphite (1.416 g), $SbCl_3$ (4.433 g, 19.4 mmol) and $S_3N_3Cl_3$ (1.589 g, 6.50 mmol) were added to 60 ml of dry CCl_4 in a 100 ml glass flask. The solution was then heated at 55 °C in an oil bath and stirred for 12 d. The reaction was completed in 1—2 h, a red-brown compound being precipitated from the solution. After 3 d, flaky graphite began to expand with insertion of the product. It took over a week for thiazyl salt to be intercalated completely. The product was filtered under nitrogen or dry atmosphere and dried in a vacuum.

2) $C_{9.5}\cdot 0.2(S_3N_3Cl_3\cdot FeCl_2)\cdot 0.8(SOCl_2\cdot FeCl_2)$ and $C_{11}S_3N_3Cl_3\cdot 2.4FeCl_2$. Flaky graphite (1.024 g), $FeCl_3$ (2.038 g, 12.60 mmol), $S_3N_3Cl_3$ (1.537 g, 6.28 mmol), and powdery graphite (0.693 g), $FeCl_3$ (1.397 g, 8.50 mmol), $S_3N_3Cl_3$ (1.040 g, 4.25 mmol) were added to 40 ml of $SOCl_2$. Each solution was then heated at 50 °C and stirred for 7 and 8 d, respectively. The compounds were isolated in the same way as for *1)*.

3) Reaction of Flaky Graphite with $S_3N_3Cl_3+2AlCl_3$. Flaky graphite (0.975 g), $AlCl_3$ (1.276 g, 9.57 mmol) and $S_3N_3Cl_3$ (1.170 g, 4.78 mmol) were added to 40 ml of $SOCl_2$. The solution was then heated. The compound was isolated in the same way as for *1)*.

4) PC–$S_4N_4\cdot 2SbCl_5$ *and PC–*$SbCl_5$. PC–$S_4N_4\cdot 2SbCl_5$ was prepared by the same method as for *1)*. PC(1 cm², *ca.* 0.1 cm in thickness) and $SbCl_5$ (70 g) were added to 15 ml of dry CCl_4 in a 100 ml flask. The solution was then heated at 100 °C in oil bath and stirred for 10 d.

Results and Discussion

Intercalation of $S_4N_4\cdot 2SbCl_5$. The reaction of $S_3N_3Cl_3$ with $SbCl_3$ gave two different compounds according to the mole ratio of the reactants: in the 1 : 1 reaction, ten-membered S, N ring compound $S_5N_5\cdot SbCl_6$ was crystallized from acetonitrille in orange color, in the 1 : 3 reaction, eight-membered ring compound $S_4N_4\cdot SbCl_5$ was isolated. The compounds were identified by IR spectra[3,4] and elemental analysis. IR (KBr): s (broad) 1166, s (broad) 1121, m 733, w 681, w 630 and vs 545 cm^{-1}. Elemental analysis: Found: S, 28.6; N, 12.6; Cl, 37.6; Sb, 21.1%. Calcd for $S_5N_5\cdot SbCl_6$: S, 28.4; N, 12.4; Cl, 37.7; Sb, 21.6%.

$$S_3N_3Cl_3 + SbCl_3 \xrightarrow[CH_3CN]{R.T.} S_5N_5\cdot SbCl_6 \quad (1)$$

IR (KBr): vs 1058, vs 976, s 808, vs 788, w 684, vs 512, m 413 cm^{-1}. Elemental analysis: Found: S, 24.7; N, 11.5; Cl, 36.9; Sb, 24.4%. Calcd for $S_4N_4\cdot SbCl_5$: S, 26.5; N, 11.6; Cl, 36.7; Sb, 25.2%.

$$S_3N_3Cl_3 + 3SbCl_3 \xrightarrow[CH_2Cl_2 \text{ or } CCl_4]{R.T.} S_4N_4\cdot SbCl_5 \quad (2)$$

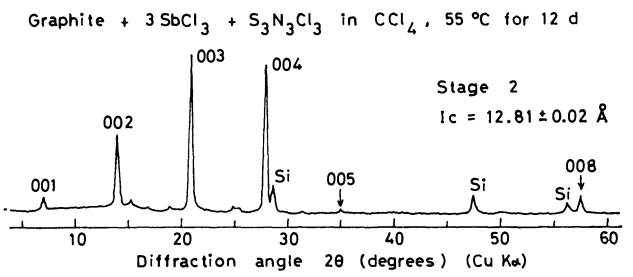

Fig. 1. X-Ray diffraction pattern for $C_{24}S_4N_4 \cdot 2SbCl_5$.

S_5N_5 ring is not as stable as S_4N_4 ring. Repeated recrystallization resulted in the change of the crystal structure from $S_5N_5 \cdot SbCl_6$ to $S_4N_4 \cdot SbCl_5$. When reaction (2) was carried out in the presence of graphite, a brown intercalation compound was obtained after 12

$$\text{Flaky graphite} + S_3N_3Cl_3 + 3SbCl_3 \xrightarrow[CCl_4]{55\,^\circ C} C_{24}S_4N_4 \cdot 2SbCl_5 \quad (3)$$

d. The X-ray diffraction pattern for this compound is shown in Fig. 1. The compound was so stable that the diffraction pattern could be taken without wrapping the sample. The repeat distance I_c is 12.81 ± 0.02 Å from the observed $(00l)$ diffraction lines. The result of elemental analysis for this compound coincides with $C_{24}S_4N_4 \cdot 2SbCl_5$. Found: C, 26.6; S, 10.8; N, 4.8; Cl, 32.4; Sb, 21.5%. Calcd for $C_{24}S_4N_4 \cdot 2SbCl_5$: C, 26.9; S, 12.0; N, 5.2; Cl, 33.1; Sb, 22.8%.

In general, the repeat distance of 1st stage compounds of metal chlorides is in the range of 9—10 Å.[5] 1st stage compound $C_{12}SbCl_5$ has 9.42 Å as the repeat distance,[5] indicating that the interlayer spacing of graphite is expanded by 6.07 Å with intercalation of $SbCl_5$. S_4N_4 reacts with metal chlorides ($SbCl_5$, $FeCl_3$, $AlCl_3$ *etc.*) to give mono- and diadducts.[4,8] The intercalant $S_4N_4 \cdot 2SbCl_5$ is regarded as a diadduct of S_4N_4. Considering that the dimension of monoadduct $S_4N_4 \cdot SbCl_5$ is *ca.* 6 Å,[7] it is possible that the intercalant $S_4N_4 \cdot 2SbCl_5$ is oriented between the interlayer spacing of 6.11 Å ($=12.81-3.35\times2$). Thus, $C_{24}S_4N_4 \cdot 2SbCl_5$ is assigned to a 2nd stage compound.

DTA and TG curves of $C_{24}S_4N_4 \cdot 2SbCl_5$ were obtained to determine the decomposition temperature. Decomposition of the intercalant began at *ca.* 150 °C and was completed at *ca.* 250 °C through $S_4N_3Cl \cdot SbCl_3$.

Reaction of Graphite with $S_3N_3Cl_3$+2FeCl$_3$. $S_3N_3Cl_3$ reacts with $FeCl_3$ to give 1 : 1 or 1 : 2 adduct.[9] In this case, $SOCl_2$ used as a solvent also forms an adduct with $FeCl_3$.[9] When the reaction was carried out in $SOCl_2$ containing flaky graphite, a black intercalation compound was isolated after 1 week. The repeat distance is calculated to be 12.77 ± 0.03 Å from the $(00l)$ diffraction lines shown in Fig. 2. The composition was derived from the elemental analysis as $C_{9.5} \cdot 0.2(S_3N_3Cl_3 \cdot FeCl_2) \cdot 0.8(SOCl_2 \cdot FeCl_2)$. The prepared compound contains much solvent.

$$\text{Flaky graphite} + S_3N_3Cl_3 + 2FeCl_3 \xrightarrow[SOCl_2]{50\,^\circ C} C_{9.5} \cdot 0.2(S_3N_3Cl_3 \cdot FeCl_2) \cdot 0.8(SOCl_2 \cdot FeCl_2) \quad (4)$$

Found: C, 29.2; S, 11.6; N, 2.2; Cl, 38.4; Fe, 14.4; (O), 3.5%. Calcd for $C_{9.5} \cdot 0.2(S_3N_3Cl_3 \cdot FeCl_2) \cdot 0.8(SOCl_2 \cdot FeCl_2)$: C, 29.6; S, 11.8; N, 2.2; Cl, 38.6; Fe, 14.5; (O), 3.3%.

$FeCl_2$ forms 1st stage intercalation compound with the composition $C_{4.7}FeCl_2$ and the repeat distance 9.56 Å.[5] The number of carbon is 9.5 per one intercalated molecule, in line with twice that for 1st stage compound. The repeat distance also indicates that the compound is a 2nd stage one.

The compound decomposed on exposure to the air, accompanied by decrease in weight and release of chlorine gas. After being left to stand for several hours, the diffraction lines for initial graphite appeared on the diffraction pattern.

When powdery graphite was used as host material instead of flaky graphite, another intercalation compound $C_{11}S_3N_3Cl_3 \cdot 2.4FeCl_2$ containing no solvent was formed.

$$\text{Powdery graphite} + S_3N_3Cl_3 + 2FeCl_3 \xrightarrow[SOCl_2]{50\,^\circ C} C_{11}S_3N_3Cl_3 \cdot 2.4FeCl_2 \quad (5)$$

Found: C, 19.9; S, 13.5; N, 6.3; Cl, 41.8; Fe, 18.9%. Calcd for $C_{11}S_3N_3Cl_3 \cdot 2.4FeCl_2$: C, 19.4; S, 14.1; N, 6.2; Cl, 40.6; Fe, 19.7%.

This is also black and a mixture of 1st and higher stage compounds. Powdery graphite has a much greater surface area than flaky graphite. However, no pure 1st stage compound could be obtained. The observed repeat distance for 1st stage compound is 9.17 ± 0.05 Å, and the strong peak at 27.2° corresponds to $(00l)$ line of higher stage compounds (Fig. 3). The characteristic of this compound is similar to that of $C_{9.5} \cdot 0.2(S_3N_3Cl_3 \cdot FeCl_2) \cdot 0.8(SOCl_2 \cdot FeCl_2)$.

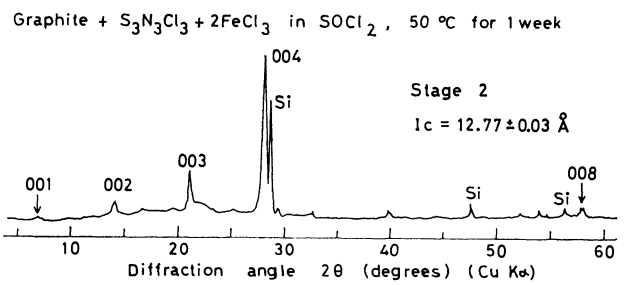

Fig. 2. X-Ray diffraction pattern for $C_{9.5}$ 0.2 ($S_3N_3Cl_3$-$FeCl_2$)0.8($SOCl_2FeCl_2$).

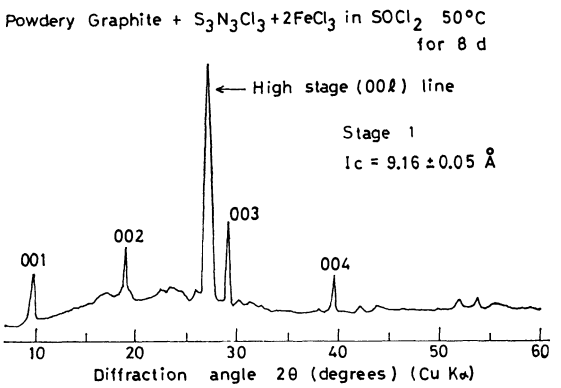

Fig. 3. X-Ray diffraction pattern for $C_{11}S_3N_3Cl_3 \cdot 2.4FeCl_2$.

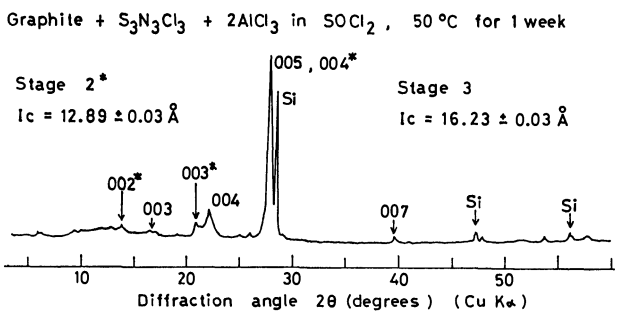

Fig. 4. X-Ray diffraction pattern for $C_{24}\cdot 0.4(S_3N_3Cl_3\text{-}2AlCl_2)\cdot 0.6(SOCl_2\cdot 2AlCl_2)$.

Reaction of Graphite with $S_3N_3Cl_3+2AlCl_3$. $S_3N_3Cl_3$ reacts also with $AlCl_3$ to give 1 : 1 or 1 : 2 adduct.[9] Reaction of flaky graphite with the adduct gave a green-black compound. X-Ray diffraction pattern (Fig. 4) indicates the coexistence of 2nd and 3rd stage compounds. No pure 2nd stage compound was obtained even by the reaction for *ca.* one month. The reaction rate from 3rd stage to 2nd stage might be low in this system. Their repeat distances are 12.89 ± 0.03 Å and 16.23 ± 0.03 Å, respectively. From the elemental analysis, the composition is approximated to $C_{24}\cdot 0.4(S_3N_3Cl_3\cdot 2AlCl_2)\cdot 0.6(SOCl_2\cdot 2AlCl_2)$.

$$\text{Flaky graphite} + S_3N_3Cl_3 + 2AlCl_3 \xrightarrow[SOCl_2]{50\,^\circ C} C_{24}\cdot 0\ 4(S_3N_3Cl_3\cdot 2AlCl_2)\cdot 0\ 6(SOCl_2\cdot 2AlCl_2) \quad (6)$$

Found: C, 44.1; S, 9.1; N, 2.2; Cl, 30.7; Al, 7.4; (O), 5.8%. Calcd for $C_{24}\cdot 0.4(S_3N_3Cl_3\cdot 2AlCl_2)\cdot 0.6(SOCl_2\cdot 2AlCl_2)$: C, 44.1; S, 8.8; N, 2.6; Cl, 34.7; Al, 8.3; (O), 1.5%.

A considerable discrepancy exists between analytical and calculated values for chlorine. The compound is very hygroscopic and unstable. As soon as it was taken out from a flask into the air, it decomposed liberating chlorine gas. The color turned from green-black to black. Analytical error occurred probably because of such property. Some unknown peaks appeared on the X-ray diffractogram for a decomposed compound, no peak corresponding to the original graphite being observed. The black substance may be a kind of residual compound.

Electrical Conductivity Measurement. The results of a-axis electrical conductivity for PC, PC–$SbCl_5$, and PC–$S_4N_4\cdot 2SbCl_5$ are given in Table 1. Both PC–$SbCl_5$ and PC–$S_4N_4\cdot 2SbCl_5$ were confirmed to be 3rd stage compounds by means of X-ray diffractometry. The electrical conductivity of PC–$SbCl_5$ and PC–$S_4N_4\cdot 2SbCl_5$ is obviously higher than that for original PC by one order. The chemical bond between S_4N_4 and $SbCl_5$ is the coordination of antimony atom of $SbCl_5$ as a Lewis acid to nitrogen atom of S_4N_4, the intercalant $S_4N_4\cdot 2SbCl_5$ having partially ionic character represented by $S_4N_4^{\delta+}\cdot 2SbCl_5^{\delta-}$.[7] It is likely that $S_4N_4\cdot 2SbCl_5$ is comparable with $SbCl_5$ in its ability as an electron acceptor which removes an electron from graphite and leaves behind a delocalized hole. Insertion of S_4N_4 increases the stability of the intercalation compound as compared with PC–$SbCl_5$.

Table 1. Electrical conductivities of PC, PC–$SbCl_5$, and PC–$S_4N_4$2$SbCl_5$ at 25 °C

Compound	σ_a/Ω^{-1} cm^{-1}
Pyrolytic carbon	3.9×10^3
PC–$SbCl_5$ (3rd stage)	4.1×10^4
PC–$S_4N_4\cdot 2SbCl_5$ (3rd stage)	4.4×10^4

The authors thank Dr. Rokuro Fujii, Government Industrial Research Institute, Osaka, for his assistance in the electrical conductivity measurement.

The *trans-cis* Isomerization of Potassium Diaquabis(oxalato)chromate(III) in Various Organic Solvent-Water Mixtures

Kengo UCHIDA* and Yoshinobu TAKINAMI

Department of Chemistry, Faculty of Science, Hirosaki University, Bunkyo-cho, Hirosaki 036

(Received October 31, 1980)

Kinetics of the *trans-cis* isomerization of $K[Cr(ox)_2(H_2O)_2]$ have been investigated in binary mixed solvents, including ethanol–, dioxane–, and acetone–water mixtures. The first-order rate constant decreases with an increase in the concentration of an organic solvent. A similar decrease by the addition of an organic solvent was observed in the presence of univalent and bivalent cations. These results are in contrast to those for the analogous malonato complex, and suggest that both dissociation and twist mechanisms are involved in the reaction.

Extensive investigations of the isomerization kinetics of *trans*-diaquabis(oxalato)chromate(III) ion have been reported.[1–12] A dissociation mechanism, where a bond rupture at Cr–oxalato is the rate determining step, has been reported and this has been supported by the catalytic effect of various cations,[1,3,11] while a twist mechanism has been suggested by Ashley and Lane.[13]

On the other hand, the studies on the influence of solvents are very few.[6] The authors have found that the rate of the isomerization of an analogous malonato complex increased with an increase of the concentration of organic solvents.[14] In this work, we have studied the effect of solvents on the rate of the isomerization. As the isomerization is catalyzed by some cations, the catalytic reaction is expected to be accelerated in organic solvents, because the reaction is ionic and depends on the relative permittivity of the solvent. Nevertheless, the reactions in the presence of univalent and bivalent cations are found to be retarded with increasing concentration of the organic solvent. We have also studied the reaction mechanism.

Experimental

Materials. Potassium *trans*-diaquabis(oxalato)chromate (III), *trans*-$K[Cr(ox)_2(H_2O)_2]\cdot 3H_2O$, was prepared by the standard method.[15] As considerable amount of by-products, $[Cr(ox)(H_2O)_4]^+$ and $[Cr(ox)_3]^{3-}$, were contained. The product was purified by using an ion exchange chromatography.[9] The absorption spectra (λ_{max}=400 nm (ε_{max}= 19.2), 532 nm (19.0)) agreed well with those reported in the literature.[4,9] The stock solutions containing the investigated cations were prepared by dissolving the chlorides of the cations in redistilled water. The chlorides of a guaranteed reagent grade were recrystallized from distilled water. Organic solvents of a guaranteed reagent grade were purified by the usual methods,[16] and ultraspecial grade solvents were used without further purification.

Procedures. Experimental methods were described previously.[14] The rates of the reactions were determined spectrophotometrically at the wavelength of 415 nm at 25.0 °C. The concentration of the complex was 8.0×10^{-3} mol dm^{-3} in all cases. The pH value of the solution was not adjusted but remained constant at about 4.5 throughout the reactions.

Results and Discussion

In the absence of excess cations, the isomerization rates were determined in aqueous mixtures of ethanol, dioxane, acetone and *N*-methylacetamide. The isomerization obeys good first-order kinetics even after 90% reaction, and the rate constant, k_{obsd}, decreased with increasing concentration (mole fraction) of the organic solvents, contrary to the case of the analogous malonato

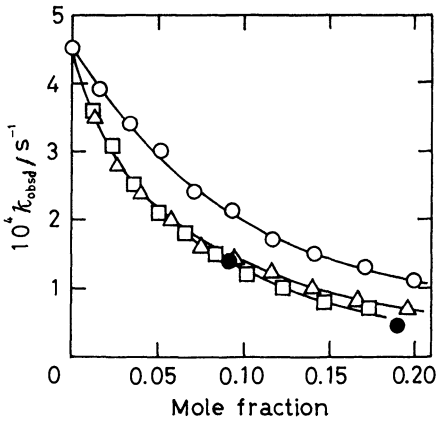

Fig. 1. Effects of the concentration of organic solvents on k_{obsd} in the absence of excess cation.
○: Ethanol, □: dioxane, △: acetone, ●: *N*-methylacetamide.

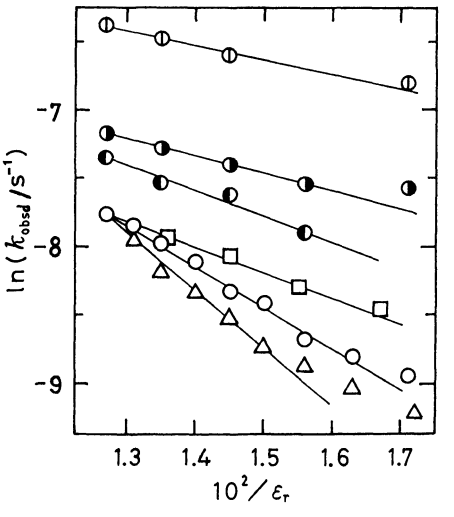

Fig. 2. Plots of $\ln(k_{obsd}/s^{-1})$ *vs.* the reciprocal of relative permittivity.
○: Ethanol, □: dioxane, △: acetone, ◐: $[Ca^{2+}]$= 0.0157 mol dm^{-3} (ethanol), ◑: $[Ca^{2+}]$=0.0314 mol dm^{-3} (ethanol), ⓘ: $[Sr^{2+}]$= 0.331 mol dm^{-3} (ethanol).

complex.[14] The results are shown in Fig. 1. As the relative permittivity, ε_r, of the solvents increased, k_{obsd} increased smoothly except in the solution of *N*-methylacetamide and formamide. Plots of $\ln k_{obsd}$ *vs.* $1/\varepsilon_r$ were found to be linear, though deviations could be seen in the high concentrations of the organic solvents. The ε_r values were properly interpolated from known values.[17] The plots are shown in Fig. 2. Even if the ε_r value was the same, different k_{obsd} values were obtained in other solvents. Therefore k_{obsd} did not depend on the ε_r value only.

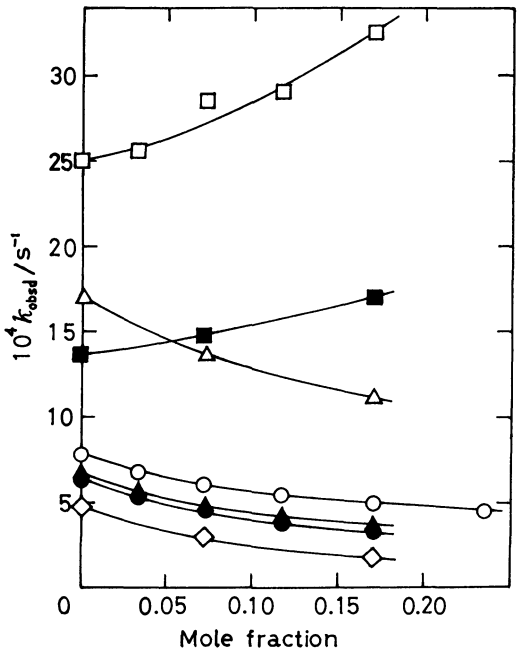

Fig. 3. Effects of the concentration of ethanol on k_{obsd} in the presence of some cations.
□: $[La^{3+}]=0.0040$ mol dm^{-3}, ■: $[La^{3+}]=0.0020$ mol dm^{-3}, △: $[Sr^{2+}]=0.331$ mol dm^{-3}, ▲: $[Sr^{2+}]=0.031$ mol dm^{-3}, ○: $[Ca^{2+}]=0.031$ mol dm^{-3}, ●: $[Ca^{2+}]=0.016$ mol dm^{-3}, ◇: $[K^+]=0.99$ mol dm^{-3}.

It has been shown that the rates in aqueous solutions are accelerated by the addition of cations, M^{n+}.[1,3,11] A similar acceleration was observed in a mixture of an organic solvent and water. The effects of the solvents on k_{obsd} in the presence of cations are shown in Fig. 3 and Table 1. The k_{obsd} values decreased with increasing concentration of the organic solvents, whereas they increased in the presence of La^{3+} in most of the solvents except *N*-methylacetamide, whose ε_r value is larger than that of water. The k_{obsd} value was also given by

$$k_{obsd} = k_o + k_M[M^{n+}], \quad (1)$$

when the ionic strength of the solution was kept constant by the addition of potassium chloride. The results are shown in Fig. 4, where the dashed curves mean the k_{obsd} values when the ionic strength was not adjusted. The acceleration effect of K^+ could be neglected, compared with those of the bivalent and the tervalent cations. Some k_M values are listed in Table 2.

Generally a rate constant, k, for an ionic reaction is given by

Table 1. The k_{obsd} values in various solvents in the presence of some cations

Cation	[Cation] / mol dm^{-3}	$10^4 \times k_{obsd}$ / s^{-1}

a) I=0.10. b) I=0.020. c) I=0.032.

$$\ln k = \ln k^\circ - \frac{z_A z_B e^2}{d_{AB} \kappa T} \cdot \frac{1}{\varepsilon_r}, \quad (2)$$

where z_A and z_B are charge numbers of ion A and B, respectively, e is the elementary charge, d_{AB} the radius of an activated complex, κ the Bolzmann constant, T temperature, and k° the k value when ε_r is extrapolated to infinity.[18] Plots of $\ln k_{obsd}$ *vs.* $1/\varepsilon_r$ gave a straight line, as shown in Fig. 2. The slope of the plot should be positive when a complex anion reacts with a catalytic cation. However, the observed results were completely contrary to that expected from Eq. 2.

According to the Brønsted-Bjerrum theory, the logarithm of the ionic reaction rate constant, k_M, is generally given for a dilute solution by

$$\ln k_M = \ln k_{M,o} + 2Qz_A z_B \varepsilon^{-3/2} I^{1/2}, \quad (3)$$

where $k_{M,o}$ is the k_M value when ionic strength, I, is zero, and Q is given by

$$Q = (2\pi L)^{1/2} e^3 / (1000)^{1/2} (\kappa T)^{3/2}, \quad (4)$$

where L is the Avogadro constant.[18] The $k_{M,o}$ value may be obtained from the plot of $\ln k_M$ *vs.* $I^{1/2}$. Strictly speaking, however, this method was not applicable when some cations were added to change the ionic strength of the solution, because the acceleration effect of these cations could not be neglected completely, especially in the study of the effect of a univalent cation. The k_M value decreased with increasing ionic strength. Therefore, the $k_{M,o}$ values were evaluated from Eq. 3 by subtracting the calculated second term of the right side of the equation from $\ln k_M$.

The plots of $\ln k_{M,o}$ *vs.* $1/\varepsilon_r$ were linear, as shown in Fig. 5, and the slope became positive when the bivalent and the tervalent cations were added. As the concentration of the organic solvent increased, k_0 in Eq. 1 decreased rapidly and k_M also decreased as the second term of the right side of Eq. 3 decreased, while $k_{M,o}$ increased. Consequently, in the presence of bivalent cations, k_{obsd} apparently decreased as ε_r decreased. On the other hand, the increase in $k_{M,o}$ in the presence of La^{3+}, was very large and k_{obsd} did not decrease with the concentration of the organic solvent. When the univalent cation was added, $k_{M,o}$ was small, and unfortunately the relationship between $\ln k_M$ and $1/\varepsilon_r$ was not clear. The radius of the activated complex, d_{AB}, may be obtained from the slopes of the plots in Fig. 5 and the values of 1.5 nm for Sr^{2+}: 1.4 nm for Ca^{2+} and 1.0 nm for La^{3+} were obtained tentatively. The values were slightly greater than those expected for the free ions. The ion of La^{3+} has a large charge and might come closer to the complex than the bivalent cations.

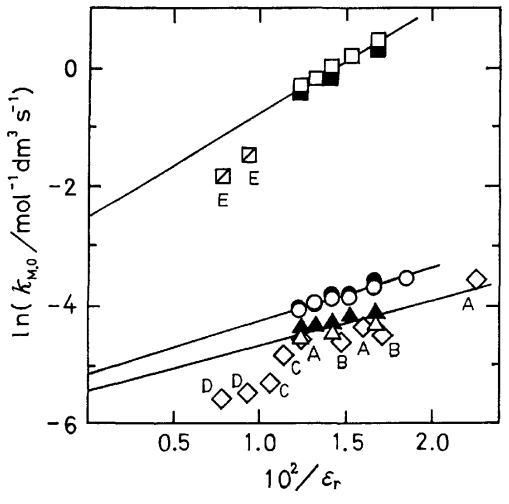

Fig. 5. Plots of $\ln(k_{M,o}/\mathrm{mol^{-1}\,dm^3\,s^{-1}})$ *vs.* the reciprocal of relative permittivity in ethanol–water system except A—E.
○: $[Ca^{2+}]=0.031$ mol dm^{-3}, ●: $[Ca^{2+}]=0.016$ mol dm^{-3}, △: $[Sr^{2+}]=0.33$ mol dm^{-3}, ▲: $[Sr^{2+}]=0.031$ mol dm^{-3}, ◇: $[Sr^{2+}]=0.33$ mol dm^{-3}; A: dioxane–H_2O, B: acetone–H_2O, C: formamide–H_2O, D: *N*-methylacetamide–H_2O, □: $[La^{3+}]=0.0040$ mol dm^{-3}, ■: $[La^{3+}]=0.0020$ mol dm^{-3}, ⊡: $[La^{3+}]=0.015$ mol dm^{-3} in *N*-methylacetamide–H_2O; E.

Although much work has supported a dissociation mechanism, a twist mechanism can not be excluded, since the activation parameters are more suitable for the twist mechanism,[13] and the ligand water is not liberated easily.[19] Then the reaction may involve two mechanisms. One is independent of ionic effects and would be the twist mechanism, the rate constant of which is k_0. Another is dependent on the cations and the dissociation mechanism would be predominant, the rate constant of which is k_M. When $\ln k_{obsd}$ was plotted *vs.* $1/\varepsilon_r$, without dividing k_{odsd} into k_0 and k_M, some linear plots of negative slope were obtained, as shown in Fig. 2, but the positive slopes, which are expected for reactions between ions of the opposite sign, were not obtained. With an increase in the concentration of the organic solvent, the k_0 value decreased, but on the other hand the $k_{M,o}$ value increased. These results suggest the existence of two different mechanisms. If the intermediate with a unidentate oxalato ligand formed by the dissociation is stabilized with an increase in the ε_r value of solvent, it is unreasonable that k_{obsd} becomes small in *N*-methylacetamide–water system. The ε_r value of *N*-methylacetamide is 182 and is much larger than that of water.[17] Kelm *et al.*[6] explained this decrease in terms of Grundwald-Winstein's Y-parameter. The rapid decrease of k_0 with an increase in the concentration of the organic solvent could be elucidated by such a solvent effect.

The authors wish to thank Professor Taro Isobe for useful suggestions during this work.

Transition-metal Complexes of Pyrrole Pigments. XXI. One-electron Oxidation of Water Mediated by a Cobalt(III)-Tetradehydrocorrin Complex†

Yukito MURAKAMI,* Yasuhiro AOYAMA, and Toshito TADA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received December 3, 1980)

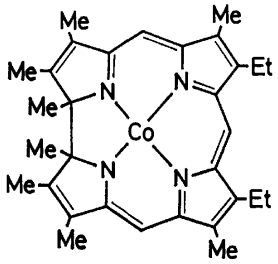
The cobalt(III) complex of tetradehydrocorrin (TDHC), having pK_{a1} 6.15 and pK_{a2} 11.50 for successive acid-dissociation of axial aqua ligands, undergoes auto-reduction to the cobalt(II) complex in aqueous carbonate solutions. Kinetic analysis of the reaction indicates the following mechanism: a one-electron transfer from the axial hydroxo ligand to the metal site, subsequent homolytic cleavage of the Co-OH bond, and finally scavenging of the resulting hydroxyl radical with the carbonate ion. At relatively low concentrations of the carbonate ion, the scavenging step is rate-determining; while at $[CO_3^{2-}] \geqq 1.0 \times 10^{-2}$ mol dm^{-3} for [Co^{III}(TDHC)] of 7.62×10^{-5} —1.27×10^{-5} mol dm^{-3}, the initial bond homolysis becomes rate-determining. Analysis of the kinetic data in reference to relevant electrode potentials indicates that the powerful oxidation ability of Co^{III}(TDHC) is responsible for one-electron oxidation of the hydroxo ligand. Reduction of Co^{III}(TDHC) also takes place in the absence of the carbonate ion, the apparent rate increasing with rise of pH in the range 11—12; deprotonation of the hydroxyl radical, which may prevent the hydroxyl radical and the cobalt(II) species from backward recombination, takes place. The one-electron oxidation of the hydroxo ligand was also significantly accelerated by addition of acetonitrile or *t*-butyl alcohol.

The photosynthetic oxidation of water to dioxygen occurring in the photosystem-II has led to challenges to the discovery of chemical systems capable of oxidizing water. The manganese ion is believed to be an essential component of photosystem-II.[1] Thus, various types of manganese complexes,[2–5] mononuclear and binuclear, in homogeneous solutions or as coated on metal surfaces,[6,7] have been studied as models of biological water oxidation. Other homogeneous metal complex systems as regards water oxidation include the tris-(bipyridine) and tris(phenanthroline) complexes of iron(III),[8] osmium(III),[8,9] and ruthenium(III).[10] Another system of great importance employs heterogeneous noble-metal oxides such as RuO_2 which can mediate, when dispersed in aqueous media, oxidation of water to dioxygen by agents which have appropriate redox potentials such as $Ru(bpy)_3^{3+}$.[11,12]

Water can be oxidized most readily by a four-electron transfer process from a thermodynamic viewpoint; one-electron oxidation of water ($E^0 = +2.8$ V *vs.* SHE) or even hydroxide ion ($E^0 = +2.0$ V *vs.* SHE) is much less favorable than the four-electron process ($E^0 = +1.229$ V *vs.* SHE).[13] The four-electron transfer is not achieved by using ordinary mononuclear metal complexes in homogeneous phase even if the complexes have appropriate redox potentials, since such complexes can, in principle, oxidize water by a one-electron transfer process. However, clarification of the one-electron water-oxidation mechanism seems not only to provide a basis for understanding the mechanism of photosynthetic oxygen evolution reactions but also to offer relevant information for designing more elaborated multi-electron oxidation catalysis in homogeneous phase. No unambiguous demonstration has been presented for the direct one-electron oxidation of water or hydroxide ion, either free or metal-coordinated, with metal complexes, although the auto-reduction of manganese-(IV)–hematoporphyrin would involve such a process.[3]

† Contribution No. 615 from this Department.

The present study is based on the finding that a cobalt(II)-tetradehydrocorrin complex undergoes facile reduction to the corresponding cobalt(I) complex in an aprotic solvent with hydroxide ion.[14] In the course of our research on the mechanistic aspects of this and related reactions, we have investigated the reduction behavior of a cobalt(III) complex of tetradehydrocorrin in aqueous media, and demonstrated the one-electron oxidation of water as coordinated to the metal site in the form of the axial hydroxo ligand.



Co(TDHC)

Results

Formation of Co^{III}(TDHC). The cobalt(III) complex of 8,12-diethyl-1,2,3,7,13,17,18,19-octamethyltetradehydrocorrin (abbreviated as TDHC), Co^{III}-(TDHC), was obtained by oxidation of [Co^{II}(TDHC)]-ClO_4[14,15] in water–methanol (99 : 1 v/v); air-oxidation or chemical oxidation either with hypochlorite or chlorine, oxidation being carried out in acidic media. The apparent first-order rate constant for the air-oxidation at 20 °C was proportional to hydrogen ion concentration ($0.01 \leqq [H^+] \leqq 0.1$ mol dm^{-3}):[16] $k/s^{-1} = 0.29[H^+]$, as in the case of a related AD–didehydrocorrin complex.[17] The initial product, hydrogen peroxide, could not be detected since each peroxide readily oxidizes two more molecules of the cobalt(II) complex.[16] In fact, the oxidation rate was much larger in the presence of varying amounts of hydrogen peroxide than

in its absence and linearly dependent on $[H_2O_2]$: $k/s^{-1}=2.8\times10^{-3}+k'[H_2O_2]$ at $[H^+]=9.8\times10^{-3}$ mol dm^{-3} where $k'=196$ dm^3 mol^{-1} s^{-1}. The electronic spectrum of Co^{III}(TDHC) was dependent neither on the method of preparation described above nor on the nature of acid employed (hydrochloric, perchloric, or sulfuric acid). This indicates that a simple diaqua ligation takes place at the axial sites of Co^{III}(TDHC) in acidic media. The air-oxidation rate of Co^{II}(TDHC) was not affected to any detectable extent even in the presence of an equimolar amount of hydrogen cyanide, although the product was the aquacyano derivative, $[(CN)(H_2O)Co^{III}(TDHC)]^+$. This indicates that no cyanide ion is involved in the oxidation of Co^{II}(TDHC) and the oxidation product, $[(H_2O)_2Co^{III}(TDHC)]^{2+}$, is subsequently converted into $[(CN)(H_2O)Co^{III}$-(TDHC)$]^+$.

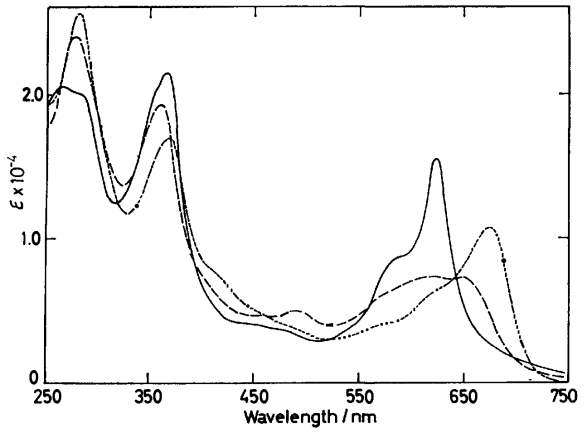


Fig. 1. Electronic absorption spectra of diaqua (——), aquahydroxo (— —), and dihydroxo (·····) species of Co^{III}(TDHC) in water–methanol (99.2 : 0.8 v/v) at 10 °C.

The spectral feature of Co^{III}(TDHC) varies as the axial ligands change from diaqua through cyanoaqua to dicyano in a similar manner as observed for the cobalt(III) complexes of AD–didehydrocorrin and cobinamide.[17] The successive acid dissociation of the two axial aqua ligands (Eq. 1) was confirmed by spectrophotometric titration of Co^{III}(TDHC) at 10 °C over a wide pH range: pK_{a1} 6.15 and pK_{a2} 11.50.[18] The choice of temperature (10 °C) is simply due to the fact that the reaction of the complex takes place at higher temperatures. Figure 1 shows the electronic spectra of the diaqua, aquahydroxo, and dihydroxo species.

$$\left[\begin{matrix}OH_2\\ |\\ Co^{III}\\ |\\ OH_2\end{matrix}\right]^{2+} \underset{}{\overset{pK_{a1}\ 6.15}{\rightleftharpoons}} \left[\begin{matrix}OH\\ |\\ Co^{III}\\ |\\ OH_2\end{matrix}\right]^{+} \overset{pK_{a2}\ 11.50}{\rightleftharpoons} \left[\begin{matrix}OH\\ |\\ Co^{III}\\ |\\ OH\end{matrix}\right] \quad (1)$$

Carbonate- and Hydroxide-induced Reduction of Co^{III}(TDHC). In aqueous carbonate solutions containing methanol (0.8% by volume) at 38.4 °C, Co^{III}(TDHC) underwent facile reduction to Co^{II}(TDHC) in quantitative yield. The product was identified by electronic spectroscopy and vapor pressure osmometric molecular weight determination. It was also converted into $(CN)_2Co^{III}$(TDHC),[15,19] which was identified by electronic and NMR spectroscopy. The results preclude any possible modification of the TDHC structure during the course of reduction. When the conversion Co(III)→Co(II) was followed spectrophotometrically, clear isosbestic points were observed at 264, 354, 443, and 579 nm. At carbonate concentrations greater than 1.0×10^{-2} mol dm^{-3} for $[Co^{III}(TDHC)]$ of 1.27×10^{-5} —7.62×10^{-5} mol dm^{-3}, the reduction of Co^{III}(TDHC) followed first-order kinetics with respect to Co^{III}-(TDHC) with the first-order rate constant independent of carbonate concentration; linear first-order plot almost to 100% conversion for any given run and no dependence of the rate constant on initial concentration of the complex. The first-order dependence of the reaction on Co^{III}(TDHC) rules out the participation of any equilibria involving a dimer such as the hydroxo-bridged one. The limiting (or leveled-off) rate constant (Fig. 2) depends neither on pH (Table 1) nor on concentration of chloride or perchlorate ion; for added chloride (0.07 mol dm^{-3}) or perchlorate (0.008 mol dm^{-3}) in addition to the carbonate ion, the rate constant remained the

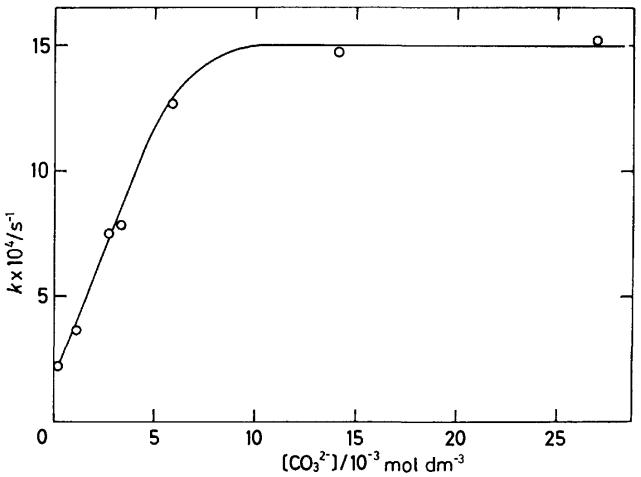

Fig. 2. Correlation of first-order rate constant with carbonate concentration for reduction of Co^{III}(TDHC) in water–methanol (99.2 : 0.8 v/v) at 38.4 °C and pH 9.5±0.2.

Table 1. Apparent first-order rate constants for carbonate- and hydroxide- induced reduction of Co^{III} (TDHC)[a]

Effective anion	pH	k/s^{-1}
Carbonate (0.11 mol dm^{-3})[b]	9.3	1.5×10^{-3}
(0.082 mol dm^{-3})[b]	9.7	1.5×10^{-3}
(0.082 mol dm^{-3})[b]	11.0	1.5×10^{-3}
Hydroxide[c]	10.7	2.6×10^{-4}
	11.4	6.1×10^{-4}
	11.7	8.1×10^{-4}
	12.2	1.1×10^{-3}
	13.1	*ca.* 1×10^{-4}

a) In water containing methanol (0.8% by volume) at 38.4 °C; initial concentration of Co^{III} (TDHC), 3.81×10^{-5} mol dm^{-3}. b) Total concentration of carbonate and hydrogencarbonate. c) Carbonate-free sodium hydroxide solution used.

Table 2. Activation parameters for homolysis of Co(III)–OH bond[a)]

Entry	Medium (composition)[b)]	$\Delta H^{\ddagger}$ / kcal mol^{-1}	$\Delta S^{\ddagger}$ / cal deg^{-1} mol^{-1}	$\Delta G^{\ddagger}$ / kcal mol^{-1}
1	H_2O–CH_3OH (99.2 : 0.8)	23.9	+4.7	22.4
2	H_2O–CH_3CN–CH_3OH (85.5 : 13.7 : 0.8)	21.6	+1.4	21.2
3	H_2O–CH_3CN–CH_3OH (77.3 : 21.9 : 0.8)	18.7	−6.6	20.8
4	H_2O–t-C_4H_9OH–CH_3OH (77.3 : 21.9 : 0.8)	18.5	−7.1	20.7

a) At 38.4 °C. Initial concentartion of Co^{III} (TDHC), 3.81×10^{-5} mol dm^{-3}. Other experimental conditions ([CO_3^{2-}], pH, temperature range): entry number 1, (1.5×10^{-2} mol dm^{-3}, 9.4, 20.0—47.7 °C); 2, (0.19 mol dm^{-3}, 11.4, 20.0—38.4 °C); 3, (0.19 mol dm^{-3}, 11.5, 24.5—38.4 °C); 4, (0.19 mol dm^{-3}, 11.9, 20.0—38.4 °C). b) Volume percent.

same. The rate constant showed linear dependence on [CO_3^{2-}] at lower concentrations of the carbonate ion (Fig. 2). Methanol (0.8% by volume) involved in the reaction medium as a cosolvent could be eliminated or replaced by acetonitrile or *N*,*N*-dimethylformamide at 0.8% by volume without affecting the limiting rate constant. Phosphate and borate ions in place of carbonate were less effective for promoting the reduction of Co^{III}(TDHC). The activation parameters were obtained at a carbonate concentration in the rate-saturation range (1.5×10^{-2} mol dm^{-3}, refer to Fig. 2) for the temperature range 20.0—47.7 °C (Table 2). Another important aspect of the carbonate-induced reduction is the photo-catalysis. Co^{III}(TDHC) (3.81×10^{-5} mol dm^{-3}) in 6.5×10^{-2} mol dm^{-3} carbonate was completely reduced to the Co(II) species at 0 °C in 90 min under irradiation with a 100-W high pressure mercury lamp from a distance of 11 cm, while the conversion was less than 10% in the dark in a period of 180 min under otherwise identical conditions.

In the absence of buffer salts, the reduction of Co^{III}-(TDHC) did occur with concomitant formation of hydrogen peroxide as detected by iodometry. The apparent first-order rate increased with rise of pH from 10.7 to 12.2 and approached the limiting rate constant

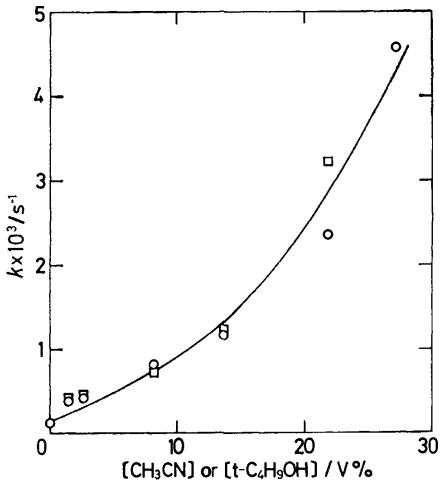

Fig. 3. Correlation of first-order rate constant with content of organic solvents for reduction of Co^{III}-(TDHC) in water–acetonitrile (○) and in water–*t*-butyl alcohol (□), both containing 0.19 mol dm^{-3} carbonate and 0.8% (v/v) methanol, at 20.0 °C.

for the carbonate-induced reaction (Table 1). The reaction was also photo-catalyzed in a similar way to that observed for the carbonate-induced reaction. The proton dissociation with pK_{a2} 11.50 resulted in an appreciable reduction in reactivity as seen from the rate constant at pH 13.1.

In the presence of the carbonate ion at rate-saturation level (0.19 mol dm^{-3}), the reduction of Co^{III}(TDHC) was facilitated by added organic cosolvents such as acetonitrile and *t*-butyl alcohol (Fig. 3). The activation parameters obtained are summarized in Table 2. The rate-acceleration upon addition of organic cosolvents is brought about by favorable activation enthalpy changes.

Discussion

Formation of Hydroxyl Radical and Its Scavenging. In order to establish the mechanism involved in the reduction of Co^{III}(TDHC) in aqueous carbonate solutions, we must identify the reductant (or species being oxidized), elucidate the electron transfer mechanism, and clarify the specific role of the carbonate ion. As regards the product, Co^{II}(TDHC), the TDHC ligand remains intact, no concomitant oxidation of the macrocyclic ligand taking place. This is in marked contrast to the base-induced reduction of Ni(III)[20] and Co(III)[21] complexes of N_4-macrocycles. An outer-sphere oxidation of water is highly unlikely because of the gross mismatch of the reduction potential (+0.59[17] or +0.54 V *vs.* SCE[22] in methanol) of L_2Co^{III}(TDHC) (L being a solvent molecule coordinated at the axial site) and the one-electron oxidation potential of water (E^0 = +2.8 V *vs.* SHE). A possibility that the free hydroxyl ion would act as a stoichiometric reductant can also be ruled out since the carbonate-induced reaction rate is independent of the pH in the range 9.3—11.0 (Table 1). Thus, the present oxido-reduction must be an intramolecular process involving the axial hydroxo ligand.[22] In view of one-electron transfer stoichiometry and the fact that the carbonate ion, which has no effect on the electronic spectrum of the present complex, is a powerful hydroxyl radical scavenger,[23-26] we can formulate the mechanism as follows: a reversible one-electron transfer from an axial hydroxo ligand to Co(III) and subsequent dissociation of the axial bond, followed by scavenging of the resulting

hydroxyl radical with the carbonate ion[27] (Eq. 2).

$$\text{Co(III)-OH} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{Co(II)} + \cdot\text{OH}$$

$$\xrightarrow{k_2[CO_3^{2-}]} \text{Co(II)} + OH^- + CO_3^{\cdot-} \quad (2)$$

$$(CO_3^{\cdot-} \longrightarrow \text{further reaction})$$

The proposed mechanism involving homolytic cleavage of the Co(III)-OH bond is consistent with the photochemical acceleration as well as the observed dependency of the rate on carbonate concentration (Fig. 2). At relatively low concentrations of carbonate, the $k_2[CO_3^{2-}]$ process is rate-determining as reflected on the rate which is linearly dependent on the carbonate concentration. As the carbonate concentration is raised to the level where $k_2[CO_3^{2-}] \gg k_{-1}$, the k_1 process becomes the rate-determining step for which the rate is independent of carbonate concentration. The validity of Eq. 2 should be further examined by kinetic analysis of the data under steady state treatment. A steady state approximation is applied with respect to the hydroxyl radical, the steady state concentration, $[\cdot OH]_{ss}$, being given by

$$[\cdot OH]_{ss} = \frac{k_1[Co(III)]}{k_{-1}[Co(II)] + k_2[CO_3^{2-}]} \quad (3)$$

Eq. 3. The rate law for disappearance of Co^{III}(TDHC) is then represented by Eq. 4. A simple first-order

$$-\frac{d[Co(III)]}{dt} = k_1[Co(III)] - k_{-1}[Co(II)][\cdot OH]_{ss}$$

$$= k_2[CO_3^{2-}][\cdot OH]_{ss}$$

$$= \frac{k_1k_2[Co(III)][CO_3^{2-}]}{k_{-1}[Co(II)] + k_2[CO_3^{2-}]} \quad (4)$$

kinetics is derived under the conditions $k_2[CO_3^{2-}] \gg k_{-1}[Co(II)]$ with first-order rate constant k_1. Under the other extreme conditions as represented by $k_{-1}[Co(II)] \gg k_2[CO_3^{2-}]$, Eq. 4 is simplified to Eq. 5. The kinetic data for runs at carbonate concentrations of 2.3×10^{-4} and 1.7×10^{-3} mol dm^{-3} (the lowest two concentrations employed here) were satisfactorily analyzed by means of Eq. 5 or its integrated form, Eq. 6.[28]

$$-\frac{d[Co(III)]}{dt} = \frac{k_1k_2}{k_{-1}}[CO_3^{2-}]\frac{[Co(III)]}{[Co(II)]} \quad (5)$$

$$[[Co(III)] - [Co(III)]_0 \ln[Co(III)]]_0^t = \frac{k_1k_2}{k_{-1}}[CO_3^{2-}]t \quad (6)$$

Except for the early stage of reaction, a plot of $-d[Co(III)]/dt$ *vs.* $[Co(III)]/[Co(II)]$ yielded a straight line with the slope $k_1k_2[CO_3^{2-}]/k_{-1}$ (Fig. 4), where k_1 is the limiting rate constant in Fig. 2 (1.5×10^{-3} s^{-1}) (see Experimental). It is reasonable to assume that the highly exothermic k_{-1} process is diffusion-controlled, *i. e.*, $k_{-1} \cong 10^{10}$ dm^3 mol^{-1} s^{-1}. The k_2 values are calculated to be: 6×10^7 and 2×10^7 dm^3 mol^{-1} s^{-1} for runs at carbonate concentrations of 2.3×10^{-4} and 1.7×10^{-3} mol dm^{-3}, respectively. These values are comparable to the rate constant for bimolecular reaction of the hydroxyl radical with the carbonate ion obtained from a pulse-radiolysis study:[24] 4.2×10^8 dm^3 mol^{-1} s^{-1}.[29] The activation enthalpy as large as 23.9 kcal mol^{-1} and the positive activation entropy (+4.7 cal deg^{-1} mol^{-1}) (Table 2) for the k_1 process are consistent

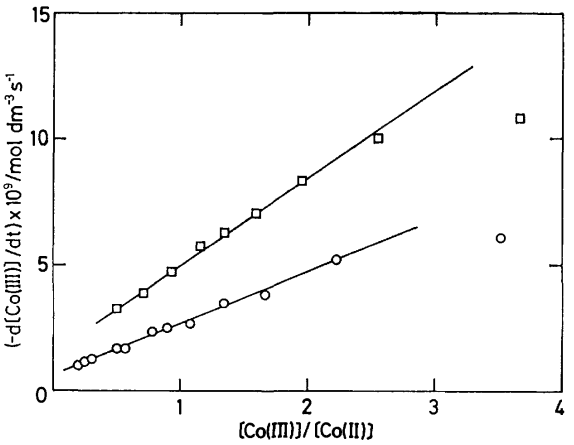

Fig. 4. Analysis of kinetic data (Eq. 5) for reduction of Co^{III}(TDHC) in water–methanol (99.2 : 0.8 v/v) in the presence of 2.3×10^{-4} mol dm^{-3} (○) and 1.7×10^{-3} mol dm^{-3} (□) carbonate at 38.4 °C.

with a highly endothermic unimolecular dissociation process.

Correlation with Electrode Potentials. Judging from the Co(II)/Co(III) redox potential for Co^{II}(TDHC) in methanol (+0.59[17] or 0.54 V *vs.* SCE[22]) and the one-electron oxidation potential of the hydroxide ion in water (+2.0 V *vs.* SHE),[13] the standard free energy change for an outer-sphere oxidation of the free hydroxide ion by L_2Co^{III}(TDHC) (L being a solvent molecule) would amount to *ca.* 27 kcal mol^{-1} and the process would proceed quite slowly at ordinary temperatures. The intramolecular oxidation of the hydroxo ligand can be regarded, from a thermodynamic viewpoint, as an oxidation of the coordination-free hydroxide ion by *naked* Co^{III}(TDHC) whose Co(II)/Co(III) potential may be assumed equivalent to that in a non-coordinating solvent; +0.97 V *vs.* SCE in CH_2Cl_2.[17] The accompanying free energy change would be reduced from 27 kcal mol^{-1} for an outer-sphere oxidation to *ca.* 18 kcal mol^{-1}. In the light of such evaluation, the free energy of activation for the bond dissociation (k_1 process), $\Delta G^{\ddagger} = \Delta H^{\ddagger} - T\Delta S^{\ddagger}$, 22.4 kcal mol^{-1} (Table 2) is reasonable in magnitude. In order to get further insight into the correlation with electrode potential, the kinetic data were analyzed on the basis of simplified reaction scheme; a reversible electron transfer between *naked* Co^{III}(TDHC) (*Co(III)*) and OH^- followed by scavenging of the hydroxyl radical with the carbonate ion as given by Eq. 7.

$$Co(III) + OH^- \underset{k_{-1}'}{\overset{k_1'}{\rightleftharpoons}} \text{Co(II)} + \cdot\text{OH}$$

$$\xrightarrow{k_2[CO_3^{2-}]} \text{Co(II)} + OH^- + CO_3^{\cdot-} \quad (7)$$

Under the conditions where scavenging is the rate-determining process, the apparent first-order rate constant is given by $(k_1'/k_{-1}')k_2[CO_3^{2-}]$; $(k_1'/k_{-1}')k_2$ corresponds to the slope (0.21 dm^3 mol^{-1} s^{-1}) of the linear portion of rate constant *vs.* $[CO_3^{2-}]$ profile in Fig. 2. If k_2 is taken for the range of 6×10^7 (calculated as above) through 1×10^9 dm^3 mol^{-1} s^{-1} (based on pulse radiolysis), the hypothetical equilibrium constant,

$K=k_1'/k_{-1}'$, would be in the range 3.5×10^{-9}—2.1×10^{-10}. A value of 1.23—1.16 V *vs.* SCE is obtained for $E_{Co(II)/Co(III)}$ at 38.4 °C ($E_{OH\cdot/OH^-}=+2.0$ V *vs.* SHE) by means of

$$-RT\ln K=\Delta G^0=F(E_{OH\cdot/OH^-}-E_{Co(II)/Co(III)}), \quad (8)$$

where F and E denote Faraday constant and electrode potential, respectively. The redox potential is consistent with the kinetic parameters based on Eq. 7 and close to the observed one in CH_2Cl_2 (+0.97 V *vs.* SCE). The argument may indicate that the one-electron oxidation of the hydroxide ion can be expected in the light of powerful oxidation capacity of Co^{III}(TDHC). In fact, the Co(II)/Co(III) redox potential of +0.97 V *vs.* SCE seems exceptional for the cobalt complexes of pyrrole pigments; +0.3 V for Co(etioporphyrin) in butyronitrile[30] and −0.26 V for Co(octaalkylcorrole) in CH_2Cl_2.[31]

Effects of Organic Cosolvents. Acetonitrile and *t*-butyl alcohol are known as potential hydroxyl radical scavengers. The scavenging efficiency of such solvents, however, does not seem to be the primary origin for the rate acceleration (Fig. 3) since the presence of sufficient amount of carbonate (0.19 mol dm^{-3}) assures that we are dealing with the rate-determining homolytic k_1 process which is free from the scavenging effect exercised by such organic solvents. Thus, the rate acceleration by organic cosolvents added must be solely due to their medium effects. The solvation status must change along the Co(III)–OH bond homolysis from highly solvated anionic hydroxo ligand at the initial state to the neutral hydroxyl radical which requires less solvation by water. As the content of an organic solvent increases, solvation of the hydroxo ligand becomes less effective with the consequence that the hydroxo ligand is less stabilized on the one hand and the surrounding water molecules get more translational freedom on the other at the ground state of reaction, resulting in the reduction of activation enthalpy with the compensating change in activation entropy. This is what was observed (Table 2). A major contributor to the potential energy to be overcome in the oxidation of both hydroxide ion and hydroxo ligand would be the stabilization of the ground state through solvation of such reactants. Desolvation of both hydroxide ion and hydroxo ligand, even to a small extent, would result in significant enhancement of their oxidation since the hydration energy of the hydroxide ion in water is greater than 100 kcal mol^{-1}.[32]

Reduction of Co^{III}(TDHC) without Radical Scavenger. Concerning the reduction of Co^{III}(TDHC) in the pH range 11—12 (Table 1) in the absence of the carbonate ion or other potential anions, the following remarks are given. (1) The reaction is photo-catalyzed in a manner similar to that in the carbonate system; (2) in reference to the mechanism for the carbonate system (Eq. 2), the hydroxide ion can never be regarded as a hydroxyl radical scavenger; and (3) the reaction rate increases with increasing [OH^-], approaching the limiting value for the carbonate-induced reaction. The pH-rate correlation seems to reflect the proton dissociation equilibrium (inactive form$\rightleftharpoons$active form$+H^+$) with pK_a around 11.5. This can not be referred to the conversion from the aquahydroxo into the dihydroxo form (Eq. 1) with pK_{a2} 11.50 in spite of numerical coincidence, since a sharp rate reduction is observed at pH 13.1 where the dihydroxo species predominates (Table 1). Thus, the reactive species should be the aquahydroxo species whose population becomes smaller while the overall rate constant increases with increasing pH. As an alternative and highly plausible equilibrium, we suggest the proton-dissociation of the hydroxyl radical whose pK_a is 11.8.[24] The hydroxyl radical is a super-oxidant and its most likely fate in the absence of its scavenger would be recombination with the Co(II) complex, *i. e.*, oxidation of the Co(II) species by the hydroxyl radical. This reverse process would not be effective for the anionic conjugate base ($O^{\cdot-}$) which is considered to be a far less effective oxidant. Under these circumstances, the dimerization of $O^{\cdot-}$ to peroxide, a well characterized reaction,[33] may compete with the backward recombination of the hydroxyl radical with the Co(II) species

$$\begin{aligned} &H_2O\text{-}Co(III)\text{-}OH \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} H_2O\text{-}Co(II) + \cdot OH \\ &\underset{-OH^-;\ k_{-2}'}{\overset{OH^-;\ k_2'}{\rightleftharpoons}} H_2O\text{-}Co(II) + O^{\cdot-} + H_2O \\ &\qquad\qquad\qquad\qquad\qquad\qquad \hookrightarrow H_2O_2 \end{aligned} \quad (9)$$

(Eq. 9). This mechanism is consistent with the observed pH-dependence of reaction rate for the pH range 11—12. It involves the deprotonation of the hydroxyl radical and its subsequent reaction, and is thus important for water oxidation since the process requires no additional radical scavengers. It is unfortunate that the accidental coincidence of the pK_a values of the second aqua ligand of the complex and the hydroxyl radical makes a detailed analysis of the kinetic data difficult.

Conclusion

(1) One-electron oxidation of a hydroxo ligand coordinated to Co^{III}(TDHC) does take place in aqueous media. The Co(III)–OH bond undergoes homolytic cleavage to yield the hydroxyl radical first. This is an effective and conventional process for water oxidation. (2) For effective progress of the reaction, there must be some mechanism by which the back recombination of the hydroxyl radical and the Co(II) species can be prevented or depressed. (3) Oxidation of the hydroxide ion and possibly other anions, coordinated or not coordinated to metal complexes, may be accelerated by addition of organic cosolvents to aqueous media *via* a desolvation mechanism.

Experimental

Instruments and Materials. Electronic spectra were obtained with thermostated quartz cells (1-cm path length) set in either a Union Giken SM-401 high sensitive spectrophotometer or a Hitachi 124 spectrophotometer. ^1H NMR spectra were taken on a Hitachi R-24B spectrometer with tetramethylsilane as an internal reference. A Hitachi-Perkin Elmer 115 vapor pressure osmometer was used to determine molecular weights. pH-Measurements were carried out with a Beckman Expandomatic SS-2 pH meter equipped with a Metrohm EA-125 combined electrode, calibrated against standard aqueous buffers.

(8,12-Diethyl-1,2,3,7,13,17,18,19-octamethyltetradehydrocor-

rinato)cobalt(II) perchlorate, $[Co^{II}(TDHC)]ClO_4$, was prepared according to the procedure of Dolphin *et al.*[15] Found: C, 59.62; H, 5.92; N, 8.91%. Calcd for $C_{31}H_{37}ClCoN_4O_4$: C, 59.67; H, 5.98; N, 8.98%. Water was deionized and distilled with a Pyrex distilling apparatus. Acetonitrile and *t*-butyl alcohol were fractionally distilled just before use. All the other chemicals were of analytical grade.

Formation of Co^{III}(TDHC) and Acid Dissociation of Its Diaqua Complex. Oxidation of a reddish-purple solution of $[Co^{II}(TDHC)]ClO_4$ by three different oxidants (air, hypochlorite, and chlorine) under acidic conditions gave a greenish-blue solution of Co^{III}(TDHC) as confirmed by electronic spectroscopy. For air oxidation, the simplest procedure, a methanol solution of Co^{II}(TDHC) (1 part) was mixed with water (100 part) containing an appropriate amount of an acid and the mixture was exposed to the air at room temperature. Under anaerobic conditions neither oxidation nor spectral change was detected. For oxidation by hypochlorite or chlorine, a 100-μl sample of a methanol solution of Co^{II}(TDHC) (4.65×10^{-3} mol dm^{-3}) was injected into a deoxygenated 0.01-mol dm^{-3} HCl solution (3 ml) containing 2 μl of aqueous NaOCl solution (10% active chlorine) and 7 μl of saturated aqueous Cl_2 solution, respectively, at room temperature. Oxidation took place almost instantaneously.

A methanol solution of Co^{II}(TDHC) (4.65×10^{-3} mol dm^{-2}, 30 μl) was added to 3 ml of water containing an appropriate amount of hydrochloric acid, and hydrogen peroxide or hydrogen cyanide for specified experiments, at 20.0 ± 0.1 °C; the absorbance change at 490 nm then being measured at the same temperature. As regards the preparative scale experiment, 15 mg (2.4×10^{-5} mol) of Co^{II}(TDHC) was oxidized in water (50 ml) containing methanol (0.5 ml) and 1-mol dm^{-3} HCl (0.5 ml). The cobalt complex was extracted into dichloromethane, and the aqueous layer was found to be free of hydrogen peroxide by iodometric analysis. Co^{III}(TDHC) was relatively stable only when diluted in acidic aqueous media and quite readily reconverted into the original Co(II) complex during the course of isolation such as extraction with organic solvents (dichloromethane, benzene, and ether), precipitation from aqueous solution by adding an organic solvent, careful concentration (with partial regeneration of Co^{II}(TDHC)), and evaporation of aqueous solutions (with complete conversion into Co^{II}(TDHC)).

Spectra were recorded for a series of solutions of Co^{III}(TDHC) (2.79×10^{-5} mol dm^{-3}) in aqueous buffers at various pH (2.13—13.45) and at 10.0 °C. The absorbance at 620 nm ($2.13\leqq pH\leqq10.22$) or at 670 nm ($8.10\leqq pH\leqq13.45$) was plotted against pH, and the pK_a values for acid dissociation of the coordinated water molecules were determined graphically. The buffer systems used were as follows: pH 2.13—3.30, HCl; 3.75—5.58, acetate; 6.25—7.75, phosphate; 8.10, borate; 9.25—10.93, carbonate; 10.20—13.45, NaOH.

Kinetic Measurements. Acidic solutions of Co^{III}(TDHC) were prepared by mixing 30 μl of a methanol solution of Co^{II}(TDHC) (4.65×10^{-3} mol dm^{-3}) and water (appropriate amount) containing 30 μl of 1-mol dm^{-3} HCl and the resulting solutions were allowed to stand at room temperature for at least 30 min. Acetonitrile or *t*-butyl alcohol (appropriate amount) was added for specified experiments. No inorganic salts were added to the solutions unless otherwise stated because of their possible contribution to scavenging of the hydroxyl radical. The solutions were then placed in a specially designed quartz cell (1-cm path length) set in a spectrophotometer and preequilibrated at desired temperatures under nitrogen atmosphere. The reaction was initiated by injecting an appropriate amount of aqueous Na_2CO_3–$NaHCO_3$ (1.0 or 2.0 mol dm^{-3}) or aqueous NaOH (18.8 mol dm^{-3}). The final solutions were adjusted at a constant volume of 3.66 ml with 3.81×10^{-5} mol dm^{-3} of Co^{III}(TDHC). The course of reaction was followed by monitoring the absorbance change at 490 nm (an absorption maximum for Co^{II}(TDHC)). The concentrations of carbonate ion were calculated from the known amounts of ($[CO_3^{2-}]+[HCO_3^-]$) and pH of the solutions measured for every kinetic runs, in reference to the pK_a value of carbonate. The pK_a of carbonate in mixed solvents was independently determined by potentiometric titration: 10.7 in water–acetonitrile (86.3 : 13.7 v/v), and 10.6 in water–*t*-butyl alcohol (86.3 : 13.7 v/v). Analyses of kinetic data according to Eq. 5 were performed by evaluating [Co(II)] and [Co(III)] first at an appropriate time interval and then taking the average value for each time interval (Δt): $-d[Co(III)]/dt=([Co(III)]_t-[Co(III)]_{t+\Delta t})/\Delta t$; $[Co(III)]/[Co(II)]=([Co(III)]_t+[Co(III)]_{t+\Delta t})/([Co(II)]_{t+\Delta t}+[Co(II)]_t)$. Activation parameters were calculated as follows: $E_a=\Delta H^{\ddagger}+RT$ (E_a, activation energy from Arrhenius plot), $k_{38.4°C}=(kT/h)\exp(-\Delta G^{\ddagger}/RT)$, and $\Delta G^{\ddagger}=\Delta H^{\ddagger}-T\Delta S^{\ddagger}$.

Reduction of Co^{III}(TDHC) in Carbonate Solutions: Formation of Co^{II}(TDHC). A solution of Co^{III}(TDHC), prepared from $[Co^{II}(TDHC)]ClO_4$ (29 mg) in water (1 l) containing 1 mol dm^{-3} HCl (10 ml) and methanol (10 ml), was mixed with 110 ml of 1.0 mol dm^{-3} aqueous Na_2CO_3 solution. The mixture was allowed to stand at 40 °C for 30 min with occasional swirling, at room temperature for 4 h to complete the Co(III)→Co(II) conversion, and then extracted with dichloromethane (100 ml×2). The extract was washed with a saturated $NaClO_4$ solution (50 ml), dried (Na_2SO_4), and evaporated to give $[Co^{II}(TDHC)]ClO_4$ (25 mg, 86%). Its electronic spectrum and molecular weight (measured by vapor pressure osmometry for methanol solutions) were identical with those of the authentic sample. The Co(II) complex thus obtained was dissolved in methanol (10 ml), and potassium cyanide (30 mg) was added. The mixture was allowed to stand at room temperature for 10 h, the solvent was removed *in vacuo*, and the residue was extracted with chloroform. Evaporation of chloroform gave $(CN)_2Co^{III}$(TDHC)[15] (17 mg, 65% from the initial Co(II) complex): electronic and NMR spectra were identical with those of the authentic sample. ^1H NMR ($CDCl_3$): δ 6.91 (s, 2H, C(5)–H and C(15)–H), 6.87 (s, 1H, C(10)–H), 2.86 (q, 4H, $C\underline{H}_2CH_3$), 2.45 (s, 12H, CH_3's on C(3), C(7), C(13), and C(17)), 2.33 (s, 6H, CH_3's on C(2) and C(18)), 1.34 (t, 6H, $CH_2C\underline{H}_3$), and 0.76 (s, 6H, CH_3's on C(1) and C(9)).

Reduction of Co^{III}(TDHC) in the Absence of Carbonate: Detection of Hydrogen Peroxide. A solution of Co^{III}(TDHC), prepared in a manner similar to that described above by air oxidation of Co^{II}(TDHC) in acidic aqueous media with or without methanol (1%), was carefully concentrated at temperatures below 30 °C. A 10-ml portion of the resulting solution (*ca.* 1×10^{-3} mol dm^{-3} in Co^{III}(TDHC)) was mixed anaerobically with an appropriate amount of carbonate-free aqueous NaOH; pH of the solution, 12.3. The mixture was allowed to stand at room temperature for 40 min. The Co^{II}(TDHC) complex precipitated from the solution was removed by filtration, and the amount of hydrogen peroxide in the filtrate was determined by iodometric analysis. A solution to be examined was purged with argon for 5 min, and 10% aqueous KI solution (1 ml) and 4 mol dm^{-3} aqueous H_2SO_4 (2 ml) were added. After being bubbled with argon for 5 min, the mixture was titrated with 5.0×10^{-3} mol dm^{-3} aqueous $Na_2S_2O_3$; 30% yield at best on the basis of the Co(III) complex used. The low yield of hydrogen peroxide was at least due to its further reaction with Co^{II}(TDHC) to give unidentified product(s), as independently confirmed by spectrophotometric means.

(1977), Chap. 12.
28) The data shown in Fig. 2 have a non-zero intercept. This may be due to small rate contribution from scavenging of the hydroxyl radical with the hydrogencarbonate ion and from hydroxide-induced process (Table 1). The hydrogencarbonate-induced process is neglected in order to obtain a reasonable estimate of the scavenging rate constant for the hydroxyl radical with carbonate, the scavenging rate constant with hydrogencarbonate being 28 times smaller than that with carbonate.[24]
29) The linear correlations in Fig. 4 are for the range of $[Co(III)]/[Co(II)] \leqq 2.5$; *i.e.*, $[Co(II)] \geqq 1.0 \times 10^{-5}$ mol dm^{-3} ($[Co]_T = 3.81 \times 10^{-5}$ mol dm^{-3}); $k_{-1}[Co(II)] \geqq (10^{10})(1.0 \times 10^{-5}) = 10^5$. The product of calculated k_2 and [carbonate] is $(6 \times 10^7)(2.3 \times 10^{-4}) = 1.4 \times 10^4$ or $(2 \times 10^7)(1.7 \times 10^{-3}) = 3.4 \times 10^4$. Thus, the assumption, $k_{-1}[Co(II)] \gg k_2[carbonate]$, is satisfied for 2.3×10^{-4} mol dm^{-3} carbonate and to a lesser extent for 1.7×10^{-3} mol dm^{-3} carbonate. The calculated k_2 values are one- to two-order of magnitude (if corrected for temperature difference) smaller than that from the pulse radiolysis study. Since the experimental conditions are not identical, the difference may not be meaningful, but it could be due to an oversimplification of the k_{-1} process. The radical pair described as (Co(II)+·OH) in Eq. 2 would be more accurately represented as $\{Co(II) \cdot OH\} \rightleftharpoons Co(II) + \cdot OH$; an equilibrium between the intimate radical pair within a common solvent cage and the solvent separated radical pair. Recombination of the Co(II) species and ·OH in the cage would be much faster than in the bimolecular encounter process. If the limiting rate constant k_1 is to represent the true homolytic rate constant (*i.e.*, scavenging of the hydroxyl radical derived therefrom takes place with a 100% efficiency) and if the pulse-radiolysis rate for the scavenging step is the same under the present kinetic conditions, $k_{-1} \cong 10^{11}$—10^{12} dm^3 mol^{-1} s^{-1} (regarded as the effective recombination rate constant including the contribution from the in-cage process).

A Novel Cationic Optically Active Complex of Platinum(II) Containing 2-Methyl-2-butene and *o*-Benzenediamine. The Circular Dichroism Spectrum and Kinetics of Olefin Exchange

Shin'ya MIYA, Kazuo KASHIWABARA,† and Kazuo SAITO*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

†*Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464*

(Received January 23, 1981)

An optically active cationic olefin complex, [PtCl(*o*-benzenediamine)((*S*)-2-methyl-2-butene)]$B(C_6H_5)_4$ was obtained for the first time as crystal stable in air at room temperature. It deteriorates slightly in solution, but is still stable enough to be characterized. Comparison of its CD spectrum with that of related complexes disclosed that the coordinating atoms at the *cis* sites to the olefin have a dominant influence upon the CD pattern in the region 20000—35000 cm^{-1}, as compared with those at the *trans* site. Substitution of *cis*-1,2-dichloroethylene for the coordinated (*S*)-2-methyl-2-butene (*S*-mbn) proceeds in accordance with the second order rate law; there is no contribution of the solvent path. The second order rate constant is smaller than that of *trans*-[$PtCl_2$(pyridine)-(*S*-mbn)]. The steric effect of the *o*-benzenediamine at the transition state seems responsible for the small rate rather than the basicity of the ligand at the *trans* site to mbn.

Asymmetric coordination of prochiral olefins to square planar complexes gives several circular dichroism (CD) peaks in the region 20000—45000 cm^{-1}. The pattern is largely dependent on the absolute configuration of the coordinated olefin,[1] but also on the ligands including asymmetric nitrogen donor atoms.[2,3] Studies were carried out on stereoselectivity accompanied by the olefin exchange of platinum(II) complexes of the types $[PtCl_3(olefin)]^-$ and [PtCl((*S*)-amino carboxylate)-(olefin)] both kinetically and thermodynamically in organic solvents.[4,5] However, all the known optically active platinum(II) olefin complexes are chargeless or negatively charged. Cationic platinum(II) complexes containing η^2-olefin are unstable.[6] Uguagliati *et al.* identified $[PtCl(C_2H_4)(bpy)]^+$ (bpy, bipyridine) as reaction intermediate. However, it liberates the ethylene almost instantaneously to give $[PtCl_2(bpy)]$.[7] Theophanides and Kong[8] suggested the formation of solid complex $[PtCl(C_2H_4)(en)]^+$ (en, ethylenediamine), which was not characterized because it decomposed quickly to give *cis*-$[PtCl_2(en)]$. Recently Tiripichio *et al.* obtained cationic complex $[PtCl(C_2H_4)\{(CH_3)_2NCH_2CH_2N(CH_3)_2\}]ClO_4$, the structure determined by the X-ray diffraction method,[10] and proposed the decomposition mechanism. They found that the cationic complex is stable enough to be characterized by recrystallization from water, and IR and ^1H NMR spectra.

We have synthesized a cationic optically active platinum(II) complex containing prochiral 2-methyl-2-butene (mbn) and *o*-benzenediamine (*o*-bzda) for the first time and compared the CD spectrum and the kinetics of olefin exchange reaction with those of related complexes.[1-5] The influence of various ligands *cis* and *trans* on the asymmetric olefin as well as of the overall charge of the complex is discussed.

Experimental

Preparation. The cationic optically active complex containing *o*-benzenediamine (*o*-bzda) and 2-methyl-2-butene (mbn), [PtCl(*o*-bzda)(*S*-mbn)]$B(C_6H_5)_4$, was prepared from optically active *trans*(*N*, mbn)-[PtCl(*S*-pro)(*S*-mbn)][3] (pro, prolinate) by the following method with retention of configuration. The original complex was converted into $P(C_6H_5)_4$-[$PtCl_3$(*S*-mbn)] by the method of Miya *et al.*[11] The complex (3.0×10^{-4} mol) was dissolved in methanol (25 cm^3) and treated with $NaB(C_6H_5)_4$ (3.0×10^{-4} mol) and *o*-bzda (3.0×10^{-4} mol). The white precipitate was removed to leave a yellow filtrate which was treated with $NaB(C_6H_5)_4$ (3.0×10^{-4} mol). Dripping of water first gave a small amount of yellowish precipitate, which was filtered off. Further dripping of water gave colorless crystals, which were washed with cold water, recrystallized from methanol and dried *in vacuo*. Found: C, 57.74; H, 5.26; N, 3.85%. Calcd for $C_{35}H_{38}N_2PtBCl$: C, 58.00; H, 5.40; N, 3.73%.

cis and *trans*(*N*, tbn)-[PtCl(*S*-pro)(*S*,*S*-btn)] (*S*-pro, (*S*)-prolinate; tbn, *trans*-2-butene),[3] *trans*-[$PtCl_2$(4-X-py)(*S*-mbn)][11] (4-X-py, 4-substituted pyridine; X=NH_2, H, and Cl), *trans*-[$PtCl_2$(4-X-ani)(*S*-mbn)][11] (4-X-ani, 4-substituted aniline; X=H, Cl, and CH_3) and *cis*-[$PtCl_2$((*S*)-α-methylbenzylamine)(*S*-mbn)][12] were synthesized by the methods reported. The solvents were purified by the usual methods.

Measurement. The visible and ultraviolet absorption and CD spectra were recorded with a Hitachi 323 spectrophotometer and a JASCO J-40 spectropolarimeter, respectively, at room temperature in acetone, acetonitrile, benzene, dichloromethane or ethanol. The rate of olefin exchange between $[PtCl(o\text{-bzda})(S\text{-mbn})]^+$ (3.0×10^{-3} mol dm^{-3}) and 1,2-dichloroethylene (dce) (0.1 to 5 mol dm^{-3}) was measured by recording the change in CD strength at 28170 cm^{-1} with time at 17.0 °C in acetone. Since the complex decomposes slightly with lapse of time, freshly prepared sample solutions were used. The results were analysed by a method previously reported.[11]

Results and Discussion

Synthesis. The formation of $[PtCl_3(S\text{-mbn})]^-$ from the (*S*)-prolinato complex proceeds with full retention of configuration in HCl.[11] The substitution of *o*-bzda for the two chloride ions proceeded quickly in methanol. The white precipitate first formed on the addition of $NaB(C_6H_5)_4$ was $(C_6H_5)_4P^+\cdot B(C_6H_5)_4^-$. The CD measurement suggests that the substitution causes no significant inversion of the coordinated olefin. (*vide infra*) The colorless product is stable in crystalline state. It is insoluble in benzene and dichloromethane, and

soluble in acetone and ethanol. The solutions turn slowly yellow, giving a black precipitate after a few days. However, the decomposition rate is amazingly smaller than that of the bpy[7] and en[8] complexes. It is remarkable that *o*-bzda gives a stable cationic platinum(II) complex containing η^2-olefin in spite of the fact that the diamine is believed to be a poor bidentate ligand to metal ions. The stability of this cationic complex might be comparable to that of $[PtCl(C_2H_4)\{(CH_3)_2NCH_2CH_2N(CH_3)_2\}]ClO_4$ prepared by Maresca *et al.*[9]

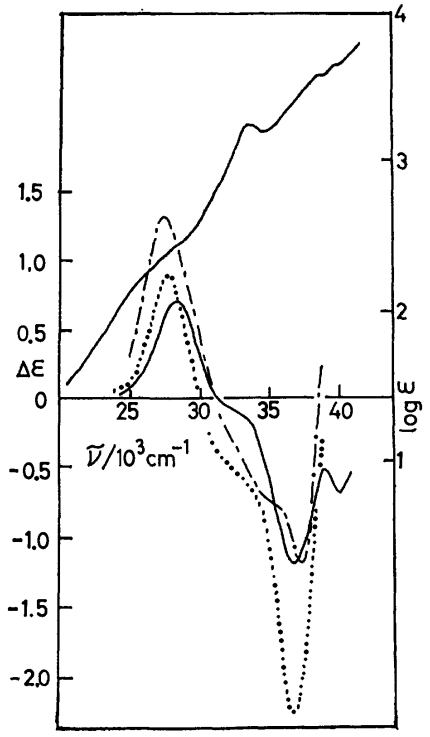

Fig. 1. Absorption and CD spectra in visible and UV region, 1) $[PtCl(o\text{-bzda})(S\text{-mbn})]B(C_6H_5)_4$ in ethanol (——), 2) The differential CD between *cis*(*N*, tbn)-[PtCl(L-pro)(*S*,*S*-tbn)] and *cis*(N, ethylene)-[PtCl(L-pro)(ethylene)] in acetonitrile (·····), 3) The differential CD between *cis*-$[PtCl_2((S)\text{-}\alpha\text{-methylbenzylamine})(S,S\text{-tbn})]$ and *cis*-$[PtCl_2((S)\text{-}\alpha\text{-methylbenzylamine})(ethylene)]$ in acetone (— · — · —).

Absorption and CD Spectra. The spectra are shown in Fig. 1 together with those of related complexes. The absorption spectrum of $[PtCl(o\text{-bzda})(S\text{-mbn})]^+$ changes slowly, the CD intensity decreasing in line with absorption change. However, the apparent rate constant is *ca.* 4×10^{-6} s^{-1} at 17.0 °C, affecting neither the spectroscopic measurement nor the kinetic study of olefin exchange with dce. (*vide infra*) The UV absorption gives a peak at 33000 cm^{-1} with log ε=3.22 and some peaks in the region 36000—39000 cm^{-1}. There is no absorption peak in the range 20000—30000 cm^{-1}, assigned to that of d-d transitions in platinum(II) olefin complexes,[3] but only a shoulder at *ca.* 28000 cm^{-1}. Such broad absorption spectra in the whole range would provide no useful means in investigation on the detailed spectroscopic properties.

On the other hand, the CD spectrum shows distinct strong peaks at 28300 and 37000 cm^{-1}. The former can be attributed to the d-d transition and the latter to the charge transfer between the metal and ligands, or intraligand transitions. The CD spectral data are summarized in Table 1 together with those of related complexes. CD spectra in the d-d transition region are generally affected by environmental changes around a metal ion. On the basis of the additivity rule held in platinum(II) olefin complexes,[4] we can estimate the contribution of asymmetric olefin in various types of complexes. Two cases are shown in Fig. 1, for L-prolinate and α-methylbenzylamine complexes, the differential CD spectra between the complexes containing (*S*,*S*)-*trans*-2-butene and ethylene being calculated. Although the solvents are not common because of the solubility of the complexes, the three CD patterns in Fig. 1 are very similar to each other, despite the big difference in overall charge and the donating atoms. The three complexes have Cl and N in common at the *cis* positions to the olefin, and N, O, and Cl at the *trans* site. The *trans* ligand appears to give only a minor contribution to the CD pattern and even to the peak energy, so far as the ligating atom at the *cis* site remains unchanged.

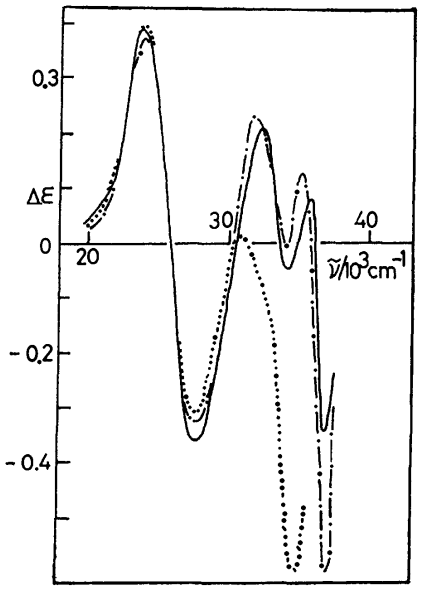

Fig. 2. CD spectra of *trans*-$[PtCl_2(4\text{-X-py})(S\text{-mbn})]$ in dichloromethane, X=NH_2 (·····), X=H (——), X=Cl (— · — · —).

This is also supported by the CD pattern of the complexes *trans*(*N*,mbn)-$[PtCl_2(4\text{-X-py})(S\text{-mbn})]$ and *trans*(*N*,mbn)-$[PtCl_2(4\text{-X-ani})(S\text{-mbn})]$. (Figs. 2 and 3) The changes of substituents X on both pyridine and aniline derivatives give no significant influence on the CD spectra, peak positions and strengths in the d-d transition region. In the higher frequency region, only the 4-aminopyridine complex shows a different spectrum from the other two. The strong peak of the 4-aminopyridine complex at 35000 cm^{-1} corresponds to the peaks of the aniline derivatives at the same position. The 4-aminopyridine ligand has two coordinate functions to a metal ion, the amino group and the pyridine

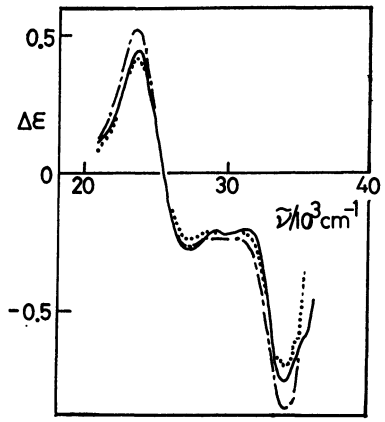

Fig. 3. CD spectra of *trans*-[$PtCl_2$(4-X-ani)(*S*-mbn)] in benzene, X=CH_3 (·····), X=H (——), X=Cl (—·—).

nitrogen atom. We have no definite evidence for the coordination mode, but the coordination through the pyridine nitrogen atom is highly probable from the fact that the CD spectrum of the 4-aminopyridine complex is in fair agreement with those of other pyridine derivative complexes in the d-d transition region (Table 1).

Comparison of the CD spectra between *cis*[2] and *trans*(*N*,C_2H_4)-[PtCl(*S*-pro)(C_2H_4)],[3] and between [$PtCl_3$(*S*,*S*-tbn)]$^-$ [4] and *cis*-[$PtCl_2$(α-methylbenzylamine)(*S*,*S*-tbn)][12] also indicates that the change in ligating atoms at the *cis* position to the olefin causes a big difference in the CD pattern, while that at the *trans* site gives only a slight difference. Since, the η^2-olefin gives a very remarkable *trans* influence, the variety of the ligating atom at the *trans* site should be cancelled, whereas change in atoms at the *cis* site causes a significant difference.

CD peaks at around 37000 cm^{-1} (Fig. 1) are also similar to each other despite the difference of the ligating atoms, so that the CD components might be due to the charge transfer between platinum(II) and olefins which are common in these three complexes.

Kinetics of Olefin Exchange. The rate of the following reaction was followed by recording the decrease in CD strength at 28170 cm^{-1} in the presence of a large excess of free *cis*-1,2-dichloroethylene(dce).

$$[PtCl(o\text{-bzda})(S\text{-mbn})]^+ + \text{dce} \longrightarrow [PtCl(o\text{-bzda})(\text{dce})]^+ + \text{mbn} \quad (1)$$

The observed rate constant is independent of the initial concentration of the complex ($\simeq 10^{-3}$ mol dm^{-3}) (Table 2), and proportional to that of free dce without intercept as shown in Fig. 4. Hence, the rate is expressed by,[11]

$$\text{Rate} = k_2[\text{complex}][\text{dce}]. \quad (2)$$

The concentration of free *o*-bzda added does not affect the rate in the concentration range 0—2.4×10^{-4} mol dm^{-3} (Table 2). We see that addition of $NaB(C_6H_5)_4$ does not affect the rate of olefin exchange. The complex seems to be in ion-paired in acetone, the observed rate

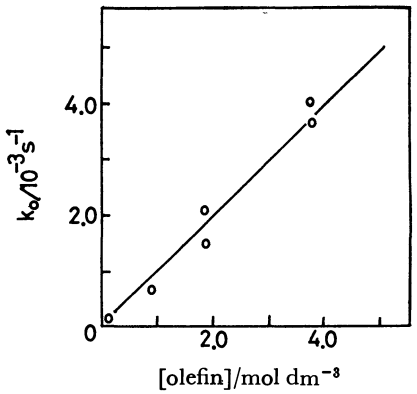

Fig. 4. Dependence of the observed first order rate constant for the substitution of *cis*-1,2-dichloroethylene for the (*S*)-2-methyl-2-butene in *trans*-[PtCl(*o*-bzda)-(*S*-mbn)]$B(C_6H_5)_4$ in acetone at 17 °C, [complex]= 0.0030 mol dm^{-3}.

constants reflecting those of the ion-pairs rather than those of the free complex cation. The counter anions play an important role to stabilize the cationic complex. Bulky anions such as perchlorate or tetraphenylborate are good counter anions to stabilize the cationic complex, but not small ones such as chloride.[9] Strong ion-paired interactions between the complex cation and bulky anions might be a key effect to prevent nucleophilic attacks by reacting species such as solvent molecules or halides, stabilizing cationic olefin complexes.

The k_2 in Eq. 2 reflects the rate of direct olefin exchange, which should proceed by the S_N2 mechanism. The *o*-bzda ligand remains coordinated throughout the olefin exchange reaction, and the contribution of solvolysed species[11] being ignored. The result is compared with those of the related complexes in Table 3.

Table 3. Second order rate constants of the substituon of 1,2-dichloroethylene for some 2-methyl-2-butene complexes of platinum(II)

Complex	k_2/dm^3 mol^{-1} s^{-1}	pK_a
[PtCl(*o*-bzda)(*S*-mbn)]$^{+}$ [a]	1.09×10^{-3}	4.6

trans-[$PtCl_2$(py)(*S*-mbn)][b]	4.66×10^{-2}	5.2

a) In acetone at 17.0 °C; k_2 for Eq. 2. b) From Ref. 11.

The basicity of the nitrogen base *trans* to the olefin in [$PtCl_2$(4-X-py)(*S*-mbn)] and [$PtCl_2$(4-X-ani)(*S*-mbn)] is the most important factor ruling the rate of olefin exchange.[11] The *o*-bzda complex has a much smaller k_2 than that of the pyridine complex, despite their similar pK_a values. Difference in the ligating atom at the *cis* site (Cl and N) could be responsible for the difference. However, the kinetic *cis* effect is understood to be in the percentage range of tens to hundreds and can not account for the big difference by 40 times. The difference may be ascribed to the presence of overall charge or of the chelate ring. The (*S*)-proline has pK_a 10.6 and the chargeless complex with one chelate gives $k_2=1.03\times10^{-3}$ dm^3 mol^{-1} s^{-1}. Its $\log k_2$ *vs.* pK_a plot falls almost on the common straight line for *trans*-[$PtCl_2$(4-X-py)(*S*-mbn)] and *trans*-[$PtCl_2$(4-X-ani)(*S*-mbn)] (figure in Ref. 11); *i. e.* the (*S*)-prolinato ligand does not seem to give significant effect on the rate expressed by Eq. 2.

The positive charge of the complex would decrease the effective electron density on platinum(II), and the nucleophilic attack of dce can be facilitated rather than retarded. Thus the overall plus charge cannot be the cause of slow substitution. Neither is its instability in organic solvents responsible for the slow exchange of olefin. Coordinated aniline derivatives in *trans*-[$PtCl_2$(ani)(*S*-mbn)] are replaced by donating solvent molecules to give *e. g.*, *trans*-[$PtCl_2$(S)(*S*-mbn)] (S, solvent molecule), which also participated in the olefin exchange.[11] If such a replacement had taken place prior to the attack of the nucleophilic olefin, the observed rate constant should have depended on the added free *o*-bzda concentration, as was the case for the complexes containing aniline derivatives.[11]

The *o*-bzda chelate may have a significant steric stress due to the rigid aromatic ring, particularly in the transition state; the trigonal bipyramidal intermediate may be formed with difficulty to decrease the second order rate constant. It is interesting that bulky ligands such as *N*,*N*,*N*′,*N*′-tetramethylethylenediamine stabilize the cationic platinum(II) olefin complex, probably preventing the nucleophilic attack by reacting species on a η-bonded olefin.[9] The *o*-bzda ligand might also have this effect.

The work was carried out with a Grant-in-Aid (No. 400016) from the Ministry of Education, Science and Culture.

Five-coordinate Copper(II) Complexes with a Thio Group as Type II Copper Models

Takeshi SAKURAI,* Shinnichiro SUZUKI, and Akitsugu NAKAHARA
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received February 23, 1981)

Five-coordinate copper(II) complexes with a thio group were synthesized as non-blue copper(II) models by reactions of copper(II) perchlorate and condensation products of 2-pyridinecarbaldehyde or salicylaldehyde and bis(2-aminoethyl) sulfide or 2-aminoethyl 3-aminopropyl sulfide. In the complexes where thio group is coordinated to copper(II) at an equatorial position, the ESR spin Hamiltonian parameters $g_{//}$ and $A_{//}$ prominently decreased, and charge transfer bands due to sulfur to copper appeared at 300—350 nm and occasionally at 400—500 nm. On the other hand, complexes with a thio group at an axial position afforded slightly smaller $A_{//}$ values and charge transfer bands with lower intensity in the similar regions. The biological significance of a sulfur donation to non-blue copper(II) has been discussed.

Among the three types of copper ions found in copper-proteins the "non-blue" (type II) copper displays no remarkable properties as "blue"(type I) copper or "ESR-nondetectable"(type III) copper. The associated ESR parameters of the type II coppers are similar to those of common tetragonal copper(II) complexes: $-A_{//}$ values are in the range of 15—20($\times 10^{-4}$) cm^{-1} and $g_{//}$ values are of 2.2—2.3. The visible absorption spectra arising from type II copper have also been considered to be the same with those of low molecular weight copper(II) complexes,[1] although they are often obscured by the type I and III coppers in multi-copper oxidases such as laccase, ceruloplasmin, and ascorbate oxidases. Having no conspicuous properties, the type II copper has thus been unfamiliar compared with coppers of the other types.

However, non-blue coppers in galactose oxidase[2] and amine oxidase[3] have been convinced to be in the environment of square-pyramid based on their d-d absorption spectra. Although there are only limited data on the protein ligands around type II copper, coordination of 2 to 4 imidazolyl groups and some oxygens has been reasonably proposed. Of special interest is the suggestion that a thio group is possibly coordinated to type II copper in galactose oxidase[4,5] and amine oxidase.[3] Here we report spectral properties of five-coordinate copper complexes with a thio group in an equatorial or an axial position as non-blue copper models.

In this work, several quinquedentate ligands with a thio group were synthesized by condensation of bis(2-aminoethyl) sulfide (abbreviated as aes) or 2-aminoethyl 3-aminopropyl sulfide(aps) and 2-pyridinecarbaldehyde-(pca) or salicylaldehyde(sal). Copper(II) complexes of these sulfur-containing ligands were prepared and the effects of sulfur coordination at an equatorial or an axial position on absorption and ESR spectra were comparatively studied.

Materials. Copper(II) perchlorate hexahydrate and salicylaldehyde were purchased from Nakarai Chemicals Ltd., *N*-(2-bromoethyl)phthalimide from Wako Chemicals Ltd., *N*-(3-bromopropyl)phthalimide from Aldrich, and 2-pyridinecarbaldehyde was obtained from Merck AG and distilled. All other reagents used were of the highest grade commercially available.

Preparation of Complexes. Cu(pca=aps=pca): Sulfur-containing diamine, aps, was prepared according to Amundsen *et al.*[6] To this was added twice amounts of pca in aqueous ethanol to give the 2 : 1 pca : aps Schiff base, which was treated with $Cu(ClO_4)_2 \cdot 6H_2O$, and was allowed to stand at room temperature. Blue crystals were isolated as perchlorate, and was recrystallized from H_2O–EtOH. Found: C, 35.79; H, 3.48; N, 9.81%. Calcd for $CuC_{17}H_{20}N_4S(ClO_4)_2$: C, 35.52; H, 3.51; N, 9.75%.

Cu(pca=aes=pca), Cu(sal=aps) and Cu(sal=aes=sal): These complexes were synthesized by the same method as Cu(pca=aps=pca). Found: C, 34.43; H, 3.44; N, 10.35%. Calcd for $CuC_{16}H_{18}N_4S(ClO_4)_2$(Cu(pca=aes=pca)): C, 34.26; H, 3.23; N, 9.99%. Found: C, 35.79; H. 4.17; N, 6.95%. Calcd for $CuC_{12}H_{17}N_2OS(ClO_4)$ (Cu(sal=aps)): C, 36.00; H, 4.28; N, 7.00%. Found: C, 42.94; H, 3.90; N, 5.62%. Calcd for $CuC_{18}H_{18}N_2O_2S \cdot 2H_2O \cdot 2/3\ NaClO_4$ (Cu-(sal=aes=sal)) C, 42.59; H, 4.37: N, 5.62%. The results of elemental analysis for Cu(sal=aes=sal) was only explainable

by assuming the presence of some coprecipitated $NaClO_4$, which was hardly removed. The product was, however, used for the spectroscopic and ESR measurements without further treatment, since there was no fear of serious effect.

Cu(pca=aps=pca): The condensed product of pca and aps in ethanol was reduced with $NaBH_4$ untill the yellow color of the Schiff base faded out, and the excess of $NaBH_4$ was treated with HCl. After filtration, the filtrate was mixed with $Cu(ClO_4)_2 \cdot 6H_2O$ to give blue crystals. Recrystallization was performed once from aqueous ethanol. Found: C, 27.90; H, 4.16; N, 7.52%. Calcd for $CuC_{17}H_{24}N_4S(ClO_4)_2 \cdot 7H_2O$: C, 27.64; H, 4.23; N, 7.58%.

Cu(pca-aes-pca), Cu(sal=aps=sal), and Cu(sal=aes=pca): These complexes were prepared by the same method as described for Cu(pca=aps=pca). Found: C, 33.58; H, 3.96; N, 9.84%. Calcd for $CuC_{17}H_{24}N_2O_2S \cdot 2H_2O \cdot 1/2NaClO_4$(Cu(sal=aps=sal)): 45.16; H, 5.59; N, 5.55%. Found: C, 37.49; H, 4.06; N, 4.98%. Calcd for $CuC_{18}H_{22}N_2O_2S \cdot 2H_2O \cdot NaClO_4$(Cu(sal=aes=sal)): C, 37.17; H, 4.51; N, 4.82%.

Spectral Measurements and Instruments. Absorption spectra were recorded on 1 cm- or 1 mm-path length cell in the range 260—1100 nm with a Hitachi 323 spectrophotometer at room temperature. Electron spin resonance (ESR) spectra of copper complexes were recorded using a JEOL JES-FE1X instrument at 77 K. Magnetic field was calibrated on a Mn(II) in MnO(ΔH_{3-4}=8.69 mT) and g values were calibrated based on Li-TCNQ(g=2.0025). *N,N*-dimethylformamide was used as solvent.

Results

Absorption spectra of pca-containing complexes exhibited the splitted d-d bands, indicating the successful formations of five-coordinate complexes. Charge transfer bands arising from thio group appeared at 315—340 nm in most cases (Fig. 1). Although the complex Cu(pca=aes=pca) did not exhibit an apparent peak in this region, molar absorptivity of this complex was observed to be five times larger than those of the complexes which have no sulfide ligand (*i.e.* Cu(pca=pda=pca), where pda represents 1,5-pentanediamine). Another charge transfer peak was observed at 462 nm, though it was not certain whether or not the peak arose from charge transfer of thio group to copper. This was because of the fact that pca Schiff base complexes devoid of thio group occasionally exhibited a peak in this region.

ESR parameters and absorption spectral data of each complex are tabulated in Table 1. Cu(pca=aps=pca), Cu(pca-aps-pca), and Cu(pca-aes-pca) have similar spin Hamiltonian parameters: $g_{//}$ values are in the range 2.17—2.21 and $-A_{//}$ values of 16.7—17.1($\times 10^{-4}$) cm^{-1}. The prominently lowered $g_{//}$ values and $-A_{//}$ values indicate that the electron density around the copper(II) ion is appreciably reduced because of the sulfur donation in an equatorial position, since these complexes are five coordinate as clearly indicated in the splitting of d-d bands. On the other hand, Cu(pca=aes=pca) exhibited a larger $g_{//}$ value, suggesting a formation of entirely different donor setting around the copper(II) ion. The weaker contribution of sulfur donation on ESR spectrum seems to be due to the binding of the soft group at an apical position.[7] The

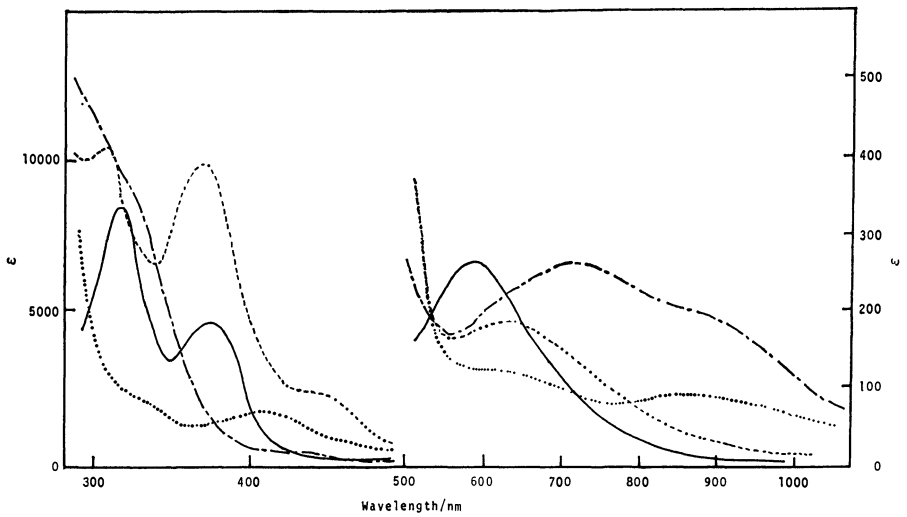

Fig. 2. Absorption spectra of Cu(sal=aps) (——), Cu(sal=aps=sal) (—·—), Cu(sal=aes=sal) (------), and Cu(sal=aes=sal) (·····).

obscured charge transfer band around 350 nm also would favor this interpretation. Copper(II) complex of the Schiff base of salicylaldehyde and aps, Cu(sal=aps=sal), was not isolated as quinquedentate complex but was as a quadridentate planar complex Cu(sal=aps) which contained N_2OS donor set, in spite of being employed twice amount of sal for preparation. The complex exhibited a symmetrical sharp d-d absorption at 584 nm and a charge transfer band at 316 nm (Fig. 2). In line with this, the use of *N*-(2-aminoethyl)-3-aminopropylamine(aea) in place of aps also gave highly square planar quadridentate complex, Cu(sal=aea). The symmetrical d-d absorption appeared in a similar region at 563 nm, but no peak was found in 300—400 nm, indicating that the peaks appeared in this region in figures are charge transfer bands due to sulfur group to copper. In contrast with the above, the reduced Schiff base complex, Cu(sal=aps=sal) afforded the quinquedentate form, exhibiting the splitted d-d bands at 720 and 910 nm. The absorption bands at 320 (shoulder) and 440 nm might be the sulfur to copper(II) charge transfer bands. The former would be attributed to $S(\sigma)\rightarrow Cu$ and the latter to $S(\pi)\rightarrow Cu$.[8] Although Cu(sal=aes=sal) did not exhibit the clearly splitted d-d bands, the rather broader d-d band would imply a formation of square-pyramidal copper(II) complex. Charge transfer bands were clearly observed at 304 and 450 nm. The reduced Schiff base complex, Cu(sal=aes=sal), also gave distinctly splitted d-d bands at 600 and 865 nm and charge transfer bands at *ca.* 330 and 405 nm.

The effect of coordination of the thio group in an equatorial position has been recognized in the smaller $-A_{//}$ values (Table 2). The pronounced instance is the difference in the $-A_{//}$ values of 17.9 and 19.8($\times 10^{-4}$) cm^{-1} for Cu(sal=aps) and Cu(sal=aea), respectively. The similar coordination effect of the thio group can be realized also in the pair Cu(sal=aes=sal) and Cu(sal=aes=sal). The $-A_{//}$ value for Cu(sal=aes=sal) increases *ca.* 1×10^{-4} cm^{-1}, suggesting that the thio group occupies an axial position in this complex similarly to the case of Cu(pca=aes=pca).

Discussion

Of eight complexes, which were tried to prepare in this work, quinquedentate complexes with N_4S or N_2O_2S donor set were isolated and characterized to display apparently splitted d-d transition bands or a broader d-d absorption band. Charge transfer bands of sulfur to copper were disclosed to appear at 300—350 nm and occasionally at 400—500 nm. The band at 300—350 nm was very clear when the sulfur occupies an equatorial position. As for the reason it may be considered that $p(\sigma)$ orbital of sulfur and $d_{x^2-y^2}$ orbital of copper(II) well overlap each other, hence strong charge transfer will occur between these orbitals. On the other hand, overlapping of $p(\pi)$ and $d_{x^2-y^2}$ orbitals can be attributed only through a torsion of these orbitals. Accordingly, the band at 400—500 nm is occasionally

Table 2. ESR parameters and absorption spectral data for the copper (II) complexes

Complex	ESR parameters			Absorption spectral data λ_{max}/nm, ε			
	$g_{//}$	$g_{\perp}$	$-A_{//}\times 10^4$ / cm^{-1}	CT band		d-d band	
Cu(sal=aps)	2.20	2.05	17.9	316 (8740)		584 (176)	
Cu(sal=aps=sal)	2.20	2.05	18.1	320_{sh} (9390)	440 (426)	720 (250)	910 (173)
Cu(sal=aes=sal)	2.21	2.06	17.8	304 (10200)	450 (2260)	639 (184)	
Cu(sal=aes=sal)	2.23	2.05	18.7	330 (2170)	405 (1750)	600 (126)	865 (92)

absent itself or is not very clear even if it appeared. When the sulfur atom binds copper(II) at an axial position, charge transfer from sulfur to copper might be permitted between either $p(\pi)$ and $d_{x^2-y^2}$ or $p(\sigma)$ and d_{z^2} orbitals. These transitions might appear at 330—350 nm and possibly even at 405—460 nm. The difference in the position of sulfur donor sensitively affects the ESR spin Hamiltonian parameters. When the sulfur occupies an equatorial position, both $g_{//}$ and $-A_{//}$ values will appreciably decrease, because the covalent character of Cu–S bond may weaken the electron density of central metal ion.[9] On the other hand, binding of sulfur at an axial position only lowers $-A_{//}$ value a little as compared with those of ordinary tetragonal copper(II) complexes. The parameter, $g_{//}$, does not seem sensitively reflect the sulfur donation in the axial position. The similar effect of soft donor ligation at an axial position of copper(II) has been reported in some cases.[7,8]

The d-d absorptions of non-blue coppers including those of multi-copper oxidases have been observed in the region of 600—1000 nm.[10-13] The presence of charge transfer bands at 314 and 450 nm has been reported for galactose oxidase[2] and in the range 300—500 nm for amine oxidase.[3] In addition, non-blue coppers of multi-copper oxidases have been considered to have a close relation to the absorptions in the regions.[10-13] These bands, even though not all of them, can be attributed to the charge transfer bands of sulfur to copper as described above. Some investigators reported that a SH group participates in the catalytic cycle of galactose oxidase[14] and amine oxidase,[15] although it is not certain whether or not the SH groups are coordinated to copper. If a sulfido group is coordinated to copper(II) ion, it must occupy an axial position, since the ESR parameters of non-blue coppers in enzymes do not suggest the binding of the SH group in an equatorial position. ESR parameters, $g_{//}$ and $-A_{//}$, of non-blue coppers were reported as 2.27 and 18.7×10^{-4} cm^{-1}, 2.29 and 16.9×10^{-4} cm^{-1}, 2.25 and 19×10^{-4} cm^{-1}, 2.21 and 20×10^{-4} cm^{-1}, and 2.22 and 19×10^{-4} cm^{-1} for galactose oxidase, amine oxidase, ceruloplasmine, ascorbate oxidase and laccase, respectively.[17]

The non-blue coppers are not considered to alter the valence state in the course of the catalytic cycles differing from blue coppers, though Hamilton *et al.*[18] considered bivalent state of copper is not active in galactose oxidase. At any rate, coordination chemistry of non-blue coppers does not seem favorable to the alteration of valence state of copper(II).[19,20] The axial sulfur, if it really exists, might be considered to supply electrons *via* copper(II) ion to molecular oxygen.

Solubility Isotherms of Systems Containing Optically Active Tris(ethylenediamine)cobalt(III) Ion. II.[1] Reciprocal Salt-pairs, (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$)-(I^-, (R,R)-$C_4H_4O_6^{2-}$), at 25 °C

Akira Fuyuhiro,* Kazuaki Yamanari, and Yoichi Shimura

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received February 3, 1981)

A four-component solubility isotherm consisting of (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$)-(I^-, (R,R)-$C_4H_4O_6^{2-}$)-H_2O was determined at 25 °C. It was found that four double salts *rac*-$[Co(en)_3]I_3\cdot H_2O$, Λ-$[Co(en)_3]I(d\text{-}C_4H_4O_6)\cdot 2H_2O$, Λ-$[Co(en)_3]_{0.48}\cdot\Delta$-$[Co(en)_3]_{0.52}(d\text{-}C_4H_4O_6)_{1.5}\cdot 5H_2O$, and Δ-$[Co(en)_3]I(d\text{-}C_4H_4O_6)\cdot nH_2O$ exist, six invariant points appearing. Application of this phase diagram to practical optical resolution is discussed in comparison with a system containing Br^-. Some models of phase diagram for effective optical resolution in reciprocal salt-pairs are proposed.

In a previous paper,[1] we reported on the determination of the solubility isotherm of reciprocal salt-pairs of the system (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$)-(Br^-, d-H_2tart^{2-}) at 25 °C (d-H_2tart^{2-}=(R,R)-$C_4H_4O_6^{2-}$), which revealed the region of the well-known diastereomer Λ-$[Co(en)_3]Br(d\text{-}H_2tart)\cdot 5H_2O$, establishing excellent optical resolution of $[Co(en)_3]^{3+}$. On the other hand, the system containing I^- instead of Br^- has not been hitherto used for optical resolution. Thus, it is desirable to confirm the existence of a diastereomer Λ-$[Co(en)_3]I(d\text{-}H_2tart)\cdot nH_2O$, the extent of region it occupies, whether optical resolution of $[Co(en)_3]^{3+}$ is possible, and what kind of solid exists in the region corresponding to that of gelatinous precipitate in the system of Br^-.

In order to clarify these questions, the solubility isotherm of reciprocal salt-pairs (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$)-(I^-, d-H_2tart^{2-}) was determined at 25 °C and the solubility of Λ- and *rac*-$[Co(en)_3]I_3$, and Λ- and Δ-$[Co(en)_3]I(d\text{-}H_2tart)$ was measured in the range 5—60 °C. The isotherm is discussed as regards fundamental models of optical resolution in reciprocal salt-pairs.

Experimental

Materials. *$[Co(en)_3]I_3\cdot H_2O$*: The Λ-, Δ-, and *rac*-$[Co(en)_3]I_3\cdot H_2O$ were obtained by the method of Broomhead *et al.*[2] Found: C, 11.29; H, 4.06; N, 13.16%. Calcd for Λ-$[Co(en)_3]I_3\cdot H_2O$: C, 11.30; H, 4.11; N, 13.17%. Found: C, 11.36; H, 4.06; N, 13.12%. Calcd for Δ-$[Co(en)_3]I_3\cdot H_2O$: C, 11.30; H, 4.11; N, 13.17%. Found: C, 11.31; H, 4.12; N, 13.13%. Calcd for *rac*-$[Co(en)_3]I_3\cdot H_2O$: C, 11.30; H, 4.11; N, 13.17%.

$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$: The Λ- and Δ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$ and the Λ-$[Co(en)_3]_{0.48}\cdot\Delta$-$[Co(en)_3]_{0.52}(d\text{-}H_2tart)_{1.5}\cdot 5H_2O$ diastereomers were the same as reported.[1]

$[Co(en)_3]I(d\text{-}H_2tart)\cdot nH_2O$: The Λ- and Δ-$[Co(en)_3]I(d\text{-}H_2tart)\cdot nH_2O$ diastereomers were prepared by mixing solutions of Λ-$[Co(en)_3]I_3$ and Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$, and Δ-$[Co(en)_3]I_3$ and Δ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$, respectively, in a 1 : 2 mole ratio. Found: C, 21.85; H, 5.85; N, 15.34%. Calcd for Λ-$[Co(en)_3]I(d\text{-}H_2tart)\cdot 2H_2O$: C, 21.83; H, 5.86; N, 15.27%. Found: C, 21.40; H, 5.88; N, 14.78%. Calcd for Δ-$[Co(en)_3]I(d\text{-}H_2tart)\cdot 2.5H_2O$: C, 21.48; H, 5.95; N, 15.03%.

Measurements. The solubility in water was determined in molality.[1] Since the CD intensity of $[Co(en)_3]^{3+}$ is affected by coexisting d-H_2tart^{2-}, the CD spectra of $[Co(en)_3]^{3+}$ were measured under calibrated conditions in HBr solution. The concentration of I^- was determined by titration with a $AgNO_3$ solution. The solid phases were identified by elemental analysis, absorption and CD spectra. Optical densities were measured with a JASCO UVIDEC-1 spectrophotometer and CD with a JASCO MOE-1 spectropolarimeter.

Results and Discussion

The solubility data are given in Tables 1 and 2, and Figs. 1—5. A saturated solution is expressed as a point defined by summing up the position vectors of the solubility of the component salt(s) contained.[3]

Binary Systems between 5 and 60 °C. As regards the binary solubility of the complexes (Table 1), the solubility ratio of *rac*-$[Co(en)_3]I_3$/Λ-$[Co(en)_3]I_3$ is 0.362 (5 °C) and 0.312 (60 °C), not being so small as in the corresponding bromide (0.173 (5 °C) and 0.294 (60 °C)). The ratio indicates[4] that the iodide as well as bromide are not spontaneously resolvable. This is also evident from the ternary system (Fig. 1). The Λ-$[Co(en)_3]I(d\text{-}H_2tart)$ diastereomer is more soluble below 28 °C than Λ-$[Co(en)_3]Br(d\text{-}H_2tart)$, which is unusual since a metal complex bromide is generally more soluble than the corresponding iodide. On the other hand, the

a) Positions of points shown in Figs. 1—5. b) Number of components. c) Reported data for C, D, G_1, G_2, $D \leftrightarrow G_1$, and $G_1 \leftrightarrow G_2$[1] are not shown. Values in parentheses are estimated errors and calculated from twice the standard deviations of measurements repeated 3—11 times.

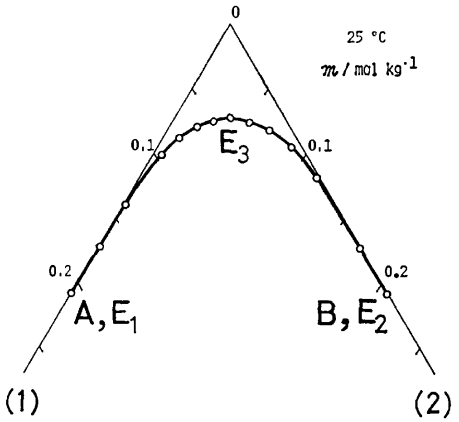

Fig. 1. Solubility isotherm of the ternary system, *Λ*-[Co(en)$_3$]I$_3$(1)–*Λ*-[Co(en)$_3$]I$_3$(2)–H$_2$O, at 25 °C. Solubility is presented in molality *m* of anhydrous salt.

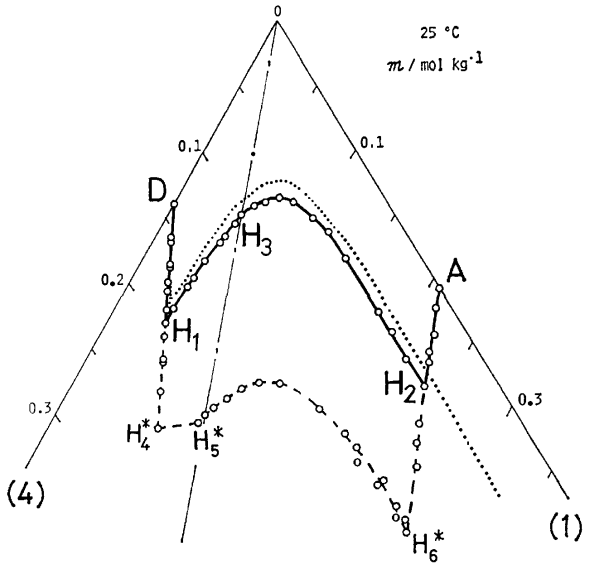

Fig. 2. Solubility isotherm of the ternary system, *Λ*-[Co(en)$_3$] (*d*-H$_2$tart)$_{1.5}$(4)–*Λ*-[Co(en)$_3$]I$_3$(1)–H$_2$O, at 25 °C. Solubility is presented in molality *m* of anhydrous salt. ----- and *: metastable state, ·····: the corresponding system of Br$^-$ at 25 °C (*Λ*-[Co(en)$_3$] (*d*-H$_2$tart)$_{1.5}$(4)–*Λ*-[Co(en)$_3$]Br$_3$(1)–H$_2$O).

solubility of *Δ*-[Co(en)$_3$]I(*d*-H$_2$tart) cannot be compared with that of *Δ*-[Co(en)$_3$]Br(*d*-H$_2$tart) because of the formation of gelatinous precipitate in the latter diastereomer. The solubility ratio of *Δ*-[Co(en)$_3$]I(*d*-H$_2$tart)/*Λ*-[Co(en)$_3$]I(*d*-H$_2$tart) is 1.40 (5 °C) and 2.54 60 °C).

Ternary System Λ-[*Co(en)*$_3$]*I*$_3$–Δ-[*Co(en)*$_3$]*I*$_3$–*H*$_2$*O*. This system at 25 °C (Fig. 1) is similar to the corresponding system of Br$^-$. The central solid phase is the racemic compound *Λ*-[Co(en)$_3$]·*Δ*-[Co(en)$_3$]I$_6$·2H$_2$O= *rac*-[Co(en)$_3$]I$_3$·H$_2$O, which occupies such a wide region ($E_1E_3E_2$) that the invariant points E_1 and E_2 exist nearly on the side axes. The solubility of racemic iodide at 25 °C (0.0720 mol kg^{-1} (E_3)) is lower than that of racemic bromide (0.178 mol kg^{-1}). The difference is considerably responsible for optical resolution in the four-component system described below.

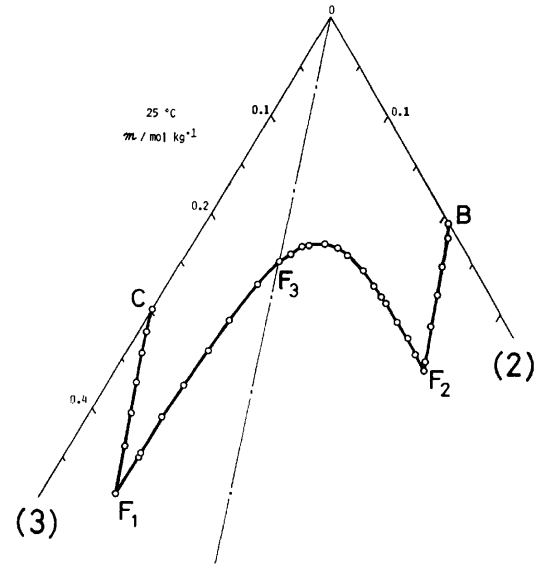

Fig. 3. Solubility isotherm of the ternary system, *Δ*-[Co(en)$_3$] (*d*-H$_2$tart)$_{1.5}$(3)–*Δ*-[Co(en)$_3$] I$_3$(2) – H$_2$O, at 25 °C. Solubility is presented in molality *m* of anhydrous salt.

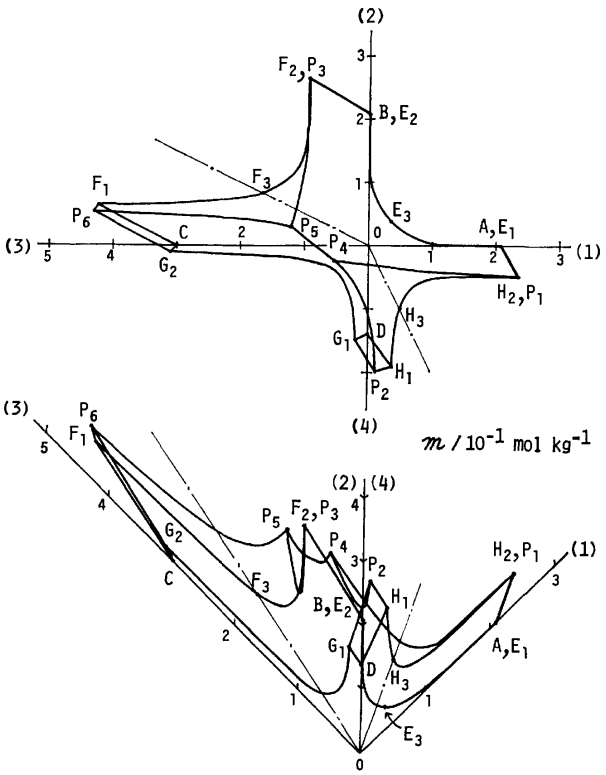

Fig. 4. The plane projection (upper) and the side elevation of solubility isotherm of the system, (*Λ*-[Co(en)$_3$]$^{3+}$, *Δ*-[Co(en)$_3$]$^{3+}$)–(I$^-$, *d*-H$_2$tart^{2-})–H$_2$O, at 25 °C. Solubility is presented in molality *m* of anhydrous salt. (1): *Λ*-[Co(en)$_3$]I$_3$, (2): *Δ*-[Co(en)$_3$]I$_3$, (3): *Δ*-[Co(en)$_3$](*d*-H$_2$tart)$_{1.5}$, (4): *Λ*-[Co(en)$_3$](*d*-H$_2$tart)$_{1.5}$.

Ternary System Λ-[*Co(en)*$_3$](d-*H*$_2$*tart)*$_{1.5}$–Λ-[*Co(en)*$_3$]*I*$_3$–*H*$_2$*O*. This system consists of only *Λ*-salts (Fig. 2). The region $H_1H_3H_2$ shows a diastereomer of double salt *Λ*-[Co(en)$_3$]I(*d*-H$_2$tart)·2H$_2$O, its isotherm being

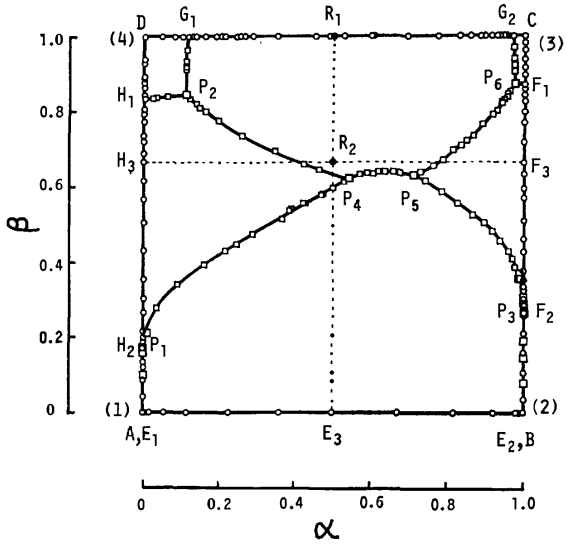

Fig. 5. The clinographic projection of solubility isotherm of the system, (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$)–(I^-, d-H_2tart^{2-})–H_2O, at 25 °C.
α: mole fraction of Δ-$[Co(en)_3]^{3+}$ to all the cations, β: mole fraction of (d-$H_2tart)_{1.5}^{3-}$ to $\{(I_3)^{3-}+(d\text{-}H_2tart)_{1.5}^{3-}\}$, (1): Λ-$[Co(en)_3]I_3$, (2): Δ-$[Co(en)_3]I_3$, (3): Δ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$, (4): Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$, □: solubilities of four-components, ○: solubilities of two- or three-componts.

located a little lower than that of bromide double salt Λ-$[Co(en)_3]Br(d\text{-}H_2tart)\cdot 5H_2O$. The binary solubility of Λ-$[Co(en)_3]I(d\text{-}H_2tart)$ (H_3, m=0.148 mol kg^{-1} at 25 °C) is larger than that of Λ-$[Co(en)_3]Br(d\text{-}H_2tart)$ (m=0.135 mol kg^{-1}). The line AH_2 appears in a region different from that for the corresponding bromide double salt because of the solubility difference between Λ-$[Co(en)_3]Br_3$ and Λ-$[Co(en)_3]I_3$.

Some metastable states were measured in the system containing I^-; the supersaturated solutions coexist with the metastable solids, Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$ on H_1H_4* and Λ-$[Co(en)_3]I_3\cdot H_2O$ on H_2H_6*. The composition of a paste-like solid phase on H_4*H_5* is unknown. The line H_5*H_6* expresses the metastable isotherm for Λ-$[Co(en)_3]I(d\text{-}H_2tart)\cdot H_2O$. However, this monohydrated diastereomer did not appear as a stable solid in the binary system at 5—60 °C (Table 1). On the other hand, the corresponding bromide double salt Λ-$[Co(en)_3]Br(d\text{-}H_2tart)$ exists as a monohydrated solid phase above 47 °C.

Ternary System Δ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$–$\Delta$-$[Co(en)_3]I_3$–$H_2O$. In this system (Fig. 3), which differs entirely from the corresponding bromide system where the central part of the isotherms is blank owing to the appearance of a gelatinous substance, the isothermal line $F_1F_3F_2$, on which a saturated solution is in equilibrium with the solid Λ-$[Co(en)_3]I(d\text{-}H_2tart)\cdot nH_2O$ can be measured. Point F_3 denotes the binary solubility of Λ-$[Co(en)_3]I(d\text{-}H_2tart)$.

The Solubility Isotherm of Reciprocal Salt-pairs, (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$)–(I^-, d-H_2tart^{2-})–H_2O.
The ternary systems described above constitute a part of the system of reciprocal salt-pairs. This four-component body was projected on three planes,[3] the plane projection and the side elevation (Fig. 4), and the clinographic projection (Fig. 5). The upper side in Fig. 5 represents the ternary system, Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$–$\Lambda$-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$–$H_2O$, being common between two systems of X^-=Br^- and I^-, (Λ-$[Co(en)_3]^{3+}$, Λ-$[Co(en)_3]^{3+}$)–(X^-, d-H_2tart^{2-})–H_2O. Eight solid phases appear, the composition of each phase corresponding to the following solid: A=Λ-$[Co(en)_3]I_3\cdot H_2O$, B=Λ-$[Co(en)_3]I_3\cdot H_2O$, C=Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$, D=$\Lambda$-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$, E_3=*rac*-$[Co(en)_3]I_3\cdot H_2O$, F_3=Λ-$[Co(en)_3]I(d\text{-}H_2tart)\cdot nH_2O$, (close of R_1)=Λ-$[Co(en)_3]_{0.48}\cdot\Lambda$-$[Co(en)_3]_{0.52}(d\text{-}H_2tart)_{1.5}\cdot 5H_2O$, and H_3=Λ-$[Co(en)_3]I(d\text{-}H_2tart)\cdot 2H_2O$. The present system essentially resembles the corresponding bromide system except for two aspects: (a) appearance of the region of Λ-$[Co(en)_3]I(d\text{-}H_2tart)\cdot nH_2O$, $P_3F_2F_3F_1P_6P_5P_3$, though in the bromide system the corresponding region could not be measured because of the formation of the gelatinous precipitate, and (b) a different combination of phase boundaries. If the gelatinous precipitate in the bromide system is assumed to be a solid phase, the regions of Λ-$[Co(en)_3]Br(d\text{-}H_2tart)\cdot 5H_2O$ and the gelatinous precipitate coexist on the boundary line. On the other hand, the corresponding regions of Λ-$[Co(en)_3]I(d\text{-}H_2tart)\cdot 2H_2O$ ($H_1H_3H_2P_1P_4P_2H_1$) and Λ-$[Co(en)_3]I(d\text{-}H_2tart)\cdot nH_2O$ do not coexist, and the regions of *rac*-$[Co(en)_3]I_3\cdot H_2O$ ($E_1E_3E_2P_3P_5P_4P_1E_1$) and Λ-$[Co(en)_3]_{0.48}\cdot\Lambda$-$[Co(en)_3]_{0.52}(d\text{-}H_2tart)_{1.5}\cdot 5H_2O$ ($G_1P_2P_4P_5P_6G_2R_1G_1$) coexist on the boundary P_4P_5. Since Λ-$[Co(en)_3]Br(d\text{-}H_2tart)\cdot 5H_2O$ and Λ-$[Co(en)_3]I(d\text{-}H_2tart)\cdot 2H_2O$ have almost the same solubility (H_3) and the upper side of the iodide system is the same as that of the bromide system, the positions of H_1 and P_2 or the lines H_1P_2 and G_1P_2 are almost the same as the corresponding points or lines in the bromide system. The line P_2P_4 is located at almost the same position as in the bromide system on the clinographic projection. However, the location of the line P_1P_4, on which *rac*-$[Co(en)_3]X_3\cdot nH_2O$ and Λ-$[Co(en)_3]X(d\text{-}H_2tart)\cdot nH_2O$ (X=Br and I) coexist, differs in the two systems. This results from the solubility difference between *rac*-$[Co(en)_3]Br_3$ and *rac*-$[Co(en)_3]I_3$ (E_3), irrespective of a similar solubility for Λ-$[Co(en)_3]Br(d\text{-}H_2tart)$ and Λ-$[Co(en)_3]I(d\text{-}H_2tart)$ (H_3).

Application to Optical Resolution. The line of α=0.5 (R_1E_3) in Fig. 5 is a "racemic line" where the concentrations of Λ-$[Co(en)_3]^{3+}$ and Λ-$[Co(en)_3]^{3+}$ are equal. If a region of a diastereomer containing only one enantiomer spreads across the "racemic line," such an isotherm can be used for perfect optical resolution. In the present system at 25 °C, the region of Λ-$[Co(en)_3]I(d\text{-}H_2tart)\cdot 2H_2O$ spreads across the "racemic line" and the system can be used for optical resolution. However, the useful region is too narrow to be used effectively.

Let us consider the following case of optical resolution of *rac*-$[Co(en)_3]X_3$ (X=Br or I) by the addition of x mol of $Ag_2(d\text{-}H_2tart)$ at 25 °C ($0\leqq x\leqq 1.5$).

$$rac\text{-}[Co(en)_3]X_3 + xAg_2(d\text{-}H_2tart) \longrightarrow$$
$$rac\text{-}[Co(en)_3]^{3+} + (3-2x)X^- + xd\text{-}H_2tart^{2-} + AgX\downarrow$$

In the case of $x=1$ (R_2 in Fig. 5) the first precipitate is Λ-$[Co(en)_3]_{0.48}$·Δ-$[Co(en)_3]_{0.52}$(d-$H_2tart)_{1.5}$·$5H_2O$, not Λ-$[Co(en)_3]X$(d-H_2tart)·nH_2O. Optical resolution is successful in the range $0.43<x<0.97$ in the bromide system.[1] Similarly in the case of iodide system optical resolution will be accomplished only in the range $0.89<x<0.95$. The maximum yield corresponding to P_4 will become only 15.7% for Λ-$[Co(en)_3]^{3+}$ (7.8% for *rac*-$[Co(en)_3]^{3+}$).

Thus, the solubility difference between Λ-$[Co(en)_3]I$-(d-H_2tart) and Δ-$[Co(en)_3]I$(d-H_2tart) is not directly related to whether optical resolution is successful or not.

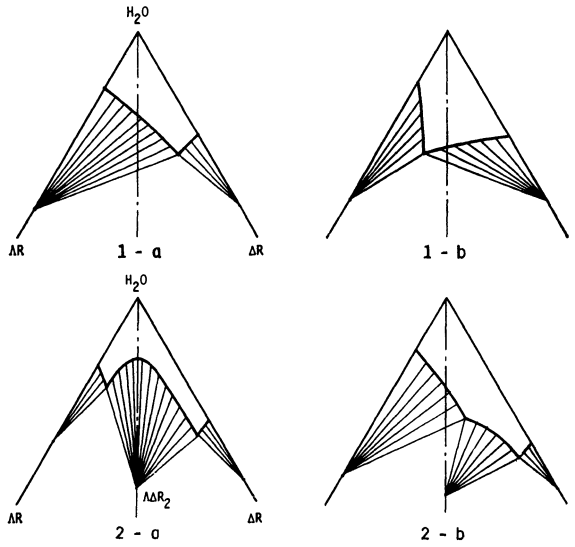

Fig. 6. Models of solubility isotherm of the ternary system ΛR–ΔR–H_2O for optical resolution.
Λ^+ and Δ^+:a pair of enantiomers, R^-: a resolving agent.

Models of Phase Diagram for Optical Resolution. The simplest phase diagram applicable to optical resolution is the ternary system ΛR–ΔR–H_2O shown in Fig. 6, where ΛR is the less soluble diastereomer. Model **1-a** can be used for optical resolution and involves the practical examples Λ-$[Co(ox)(en)_2]$(d-H_3tart)·Δ-[Co-(ox)$(en)_2$](d-H_3tart)–H_2O and Λ-$[Co(ox)(en)_2]$·Δ-[Co-(edta)]–Δ-$[Co(ox)(en)_2]$·Δ-[Co(edta)]–H_2O.[5] Model **1-b** can also be available, and the diastereomer obtained is the more soluble ΔR and not the less soluble ΛR. Model **2-a** can not be used because of the formation of pseudoracemate $\Lambda\Delta R_2$ in the central part. In model **2-b** optical resolution is possible in spite of the formation of the pseudoracemate. Such a case is exemplified by the system Λ-$[Co(ox)(en)_2]$(d-bcs)–Δ-$[Co(ox)(en)_2]$(d-bcs)–H_2O at a temperature below 19 °C (d-bcs^-= (1*R*,3*S*,4*S*,7*R*)-$C_{10}H_{14}OBrSO_3^-$).[6] If we assume that **2-b** is a special case, the possibility of optical resolution of the ternary system depends upon whether the pseudoracemate $\Lambda\Delta R_2$ exists or not, and not on the solubility difference between the pair of diastereomers ΛR and ΔR.

Figure 7 shows several representative models of clinographic projections for the systems of reciprocal salt-pairs effective for optical resolution, (Λ^+, Δ^+)–(X^-, R^-)–H_2O. Effective optical resolution requires that the region of a diastereomer (ΛR, for example) spreads across the "racemic line." Model **3** without any double salt is effective for optical resolution. The upper side of **3** corresponds to the ternary system of **1-a**, introduction of a fourth ion X^- not being important. In **4** there exist two effective diastereomers ΛR and Λ_2XR which include the opposite enantiomer to each other. The upper side of **5** corresponds to **2-b** but the introduction of X^- makes the optical resolution possible: the ΛR diastereomer will be obtained in the coexistence of X^-. Similarly, in model **6** optical resolution is unsuccessful in the absence of X^-, and the effective diastereomer is a double salt Λ_2XR. The systems (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$)–(X^-, d-H_2tart^{2-})–H_2O, X^-=Br^- and I^-, belong to a variety of **6**. Two kinds of diastereomers ΛR and Λ_2XR can be utilized in **7**.

(Received September 4, 1980)

Various types of modified nickel catalysts were prepared and their enantioface-differentiating (asymmetric) abilities were examined. It was found that the presence of aluminum or related metal compounds in the catalyst was unfavorable for the effective enantioface-differentiating catalyst. The modification with a solution containing tartaric acid and inorganic salt gave a high enantioface-differentiating ability to Raney nickel and reduced nickel catalyst. Among the modified nickel catalysts examined, the Raney nickel modified with tartaric acid and sodium bromide gave the best result with respect to the hydrogenation activity and enantioface-differentiating ability (optical yield 88%). NaBr adsorbed on Raney nickel was found to inhibit the nonenantioface-differentiating hydrogenation.

An asymmetrically modified Raney nickel catalyst (MRNi) is easily prepared by soaking Raney nickel catalyst (RNi) in a solution of an optically active substance.[1] This is the most suitable catalyst for the enantioface-differentiating (asymmetric) hydrogenation because of its high hydrogenation activity and its preparative convenience. Our research group has been continuing the studies to improve the enantioface-differentiating ability (e.d.a.) of MRNi.

Recently, we succeeded in obtaining an improved MRNi with a sufficient e.d.a.[2] The improved catalyst can be prepared by the modification of RNi with a solution containing tartaric acid (TA) and NaBr (TA–NaBr–MRNi). An optical yield of near 90% was attained in the hydrogenation of methyl acetoacetate (MAA) to methyl 3-hydroxybutyrate (MHB) over this catalyst.

This paper will present our approach leading to the development of TA–NaBr–MRNi and the role of adsorbed NaBr in the enantioface-differentiating rocess.

Results and Discussion

TA–MNi and TA–NaBr–MHNi. Asymmetrically modified nickel catalysts (MNi) can be prepared from many kinds of nickel catalysts.[3] The e.d.a.'s of various TA–MNi's are listed in Table 1. The degrees of e.d.a.'s were evaluated by the optical yields (%) of the hydrogenation of MAA to MHB.

The use of the activated nickel prepared by the liquid phase reaction (Entries 1—5) resulted in poor optical yields (below 44%), while the use of the catalyst activated by a dry process (Entries 6—9) resulted in high optical yields (55—82%).

It is well known that Raney type catalysts (Entries 1—3) and Urushibara catalyst (Entry 4) contain some amounts of impurities (Al, Mg, Si, Zn, or derivatives of their cations). The rather poor results listed in Entries 1—4 could be considered to be caused by existence of these impurities in the catalyst. When RNi was modified with a solution containing TA and $NaAlO_2$, the resulting TA–MRNi (Entry 5) showed a lower e.d.a. than that of the conventional TA–MRNi (Entry 1). From the facts mentioned above, it can be concluded that the uses of nickel catalysts containing either Al, Mg, Si, Zn, or related metal compounds are not desirable for obtaining TA–MNi with high e.d.a.

The activated nickels prepared by thermal decomposi-

9	$Ni(CO)_4$[c]	4.1	85	0.6	11.5	THF/23	0.2	85	58—75

a) Degree of e.d.a. was evaluated by optical yield (%) of hydrogenation of MAA over MNi. b) The pH of modifying solution was adjusted with $NaAlO_2$ instead of NaOH. c) The Ni powder prepared from $Ni(CO)_4$ was supplied by Metal Foil and Powder MFG Co..

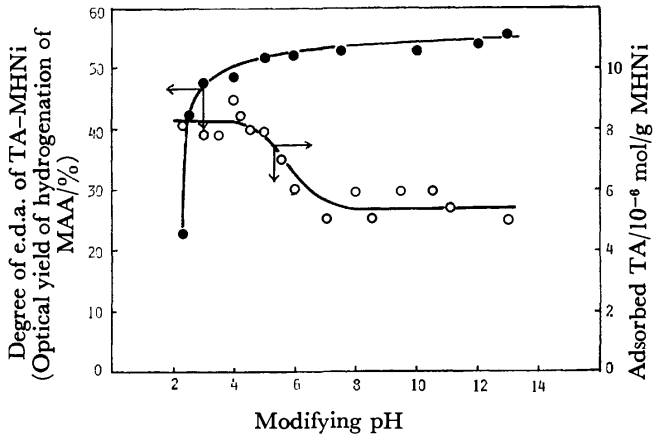

Fig. 1. Relationship between modifying pH and degree of e.d.a. of TA–MHNi(optical yield of hydrogenation of MAA over TA–MHNi) or amount of adsorbed TA. HNi was prepared from NiO supplied by Wako Pure Chemical Industries, Ltd. Amount of HNi: 0.8 g. Modification: at 0 °C for 1 h. Hydrogenation :MAA (17.5 ml) was subjected to hydrogenation at 100 °C.

tion of nickel formate, by hydrogenolysis of nickel oxide (HNi), and by decomposition of nickel carbonyl gave TA–MNi's with rather high e.d.a.'s. Among the catalysts examined, HNi modified with TA (TA–MHNi) gave the best result with respect to the e.d.a.

It was known that the e.d.a. of TA–MRNi was strongly affected by the modifying pH.[4] Thus, the relation between the modifying pH and the e.d.a. of TA–MHNi was examined in order to find out the optimal modifying pH. The results are shown in Fig. 1. Figure 1 also shows the relation between the modifying pH and the amount of TA adsorbed on HNi. The e.d.a. of TA–MHNi was found to increase steeply with increasing pH and settle down at a constant value at the pH range from 3 to 13. The adsorbed amount of TA at below pH 4 is greater than that at above pH 4. Thus, the poor e.d.a. of TA–MHNi at below pH 3 cannot be explained on the basis of the amount of adsorbed TA. It is reasonable to assume that the difference between the e.d.a. at below pH 3 and that at the pH range from 3 to 13 results from the difference in the adsorption mode of TA.[5] The counter ions of adsorbed TA are expected to be Ni^{2+} and H^+ in the pH region intrinsic to the solution of the free TA and to be Na^+ under neutral and basic conditions.

The e.d.a. of TA–MHNi was found to be sensitive to the preparative variations and purity of NiO. That is, differences in the manufacturer and the lot number of NiO caused a significant difference in the e.d.a. of TA–MHNi (Table 2). There was a relation between the colour of NiO powder and the e.d.a. of the resulting TA–MHNi. In general the light green NiO powder tended to give TA–MHNi with high e.d.a., while the dark green one tended to give TA–MHNi with low e.d.a.

Weight ratio of Ni to support=50 to 50. Amount of supported Ni: 1.2 g. Modification: at pH 4.1, 85 °C for 1 h. Hydrogenation conditions were the same as those described in Footnote of Table 2 except for the hydrogenation temperature (85 °C). a) Kieselguhr was supplied by Wako Pure Chemical Industries, Ltd. b) Activated alumina was supplied by ICN Woelm Laboratories, Inc. c) Optical yield (%) of hydrogenation of MAA over TA–MNi.

Orito and his coworkers reported that Ni–Pd catalyst supported on kieselguhr gave an excellent catalyst for the enantioface-differentiating hydrogenation of MAA to MHB.[6] More than 90% of the optical yield was reported when the catalyst was modified with TA. We also prepared HNi's supported on various kinds of supports and the effects of supports were examined. As found in Table 3, no significant increase of e.d.a. was attained by the uses of nickel catalysts supported on kieselguhr, TiO_2, ZrO_2, and Al_2O_3. The e.d.a. of TA–MHNi supported on kieselguhr was observed to be affected by the sort of kieselguhr. Kieselguhrs well purified by acid or/and alkali washing (Shimalite SP-25, -35, and -55) gave TA–MHNi's with lower e.d.a.'s than that of unpurified one (Shimalite SP-17). It is reasonable to assume that minor components in kieselguhr are dissolved into the modifying solution and some of them serve as supplementary modifying reagents to increase the e.d.a.

We have often noticed that small amounts of impurities in the supplied water used for the modification

Amount of HNi: 0.8 g. Modification: at pH 4.0, 100 °C for 1 h. Hydrogenation: MAA (11.5 ml) in methyl propionate (23 ml) and AcOH (0.2 ml) was subjected to hydrogenation at 100 °C. a) Optical yield (%) of hydrogenation of MAA over MHNi.

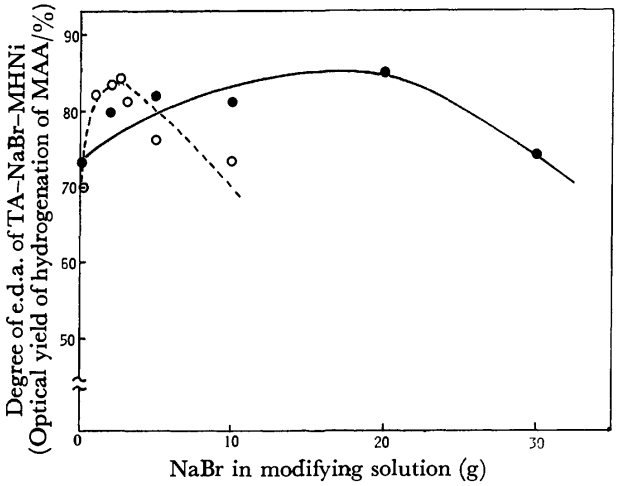

Fig. 2. Relationship between amount of NaBr in modifying solution and degree of e.d.a. of TA–NaBr–MHNi (optical yield of hydrogenation of MAA over TA–NaBr–MHNi).
TA–NaBr–MHNi: NiO was supplied by Wako Pure Chemical Industries, Ltd. (—●—) or Nihon Kagaku Sangyo, Co., Ltd. (—○—). Modification: at pH 4, 100 °C for 1 h. Hydrogenation was carried out under the same conditions as those described in footnote of Table 2.

process affected significantly the e.d.a. of the resulting catalyst. This finding led us to the idea that investigation of supplementary compounds in the modifying solution would enable us to develop a more effective enantioface-differentiating catalyst.

In the course of studies on the effect of supplementary modifying reagents on the e.d.a. of MHNi, it was found that the use of some kinds of inorganic salts increased the e.d.a. (Table 4). Among inorganic salts examined, NaBr was the best supplementary compound in giving a high e.d.a. As shown in Fig. 2, the e.d.a. of TA–NaBr–MHNi increased with the amount of NaBr in the modifying solution, reached a maximum value, and then decreased. The optimal amount of NaBr in the modifying solution was affected by the sort of NiO sample. Under the optimal conditions, TA–NaBr–MHNi showed a sufficient e.d.a. (optical yield, 86%). However, the main disadvantage of TA–NaBr–MHNi is the lack of high hydrogenating activity. The hydrogenation of MAA over TA–MHNi had to be performed at above 100 °C. Under these conditions, the yield of MHB can never be satisfactory because of the formation of by-products (*e.g.*, methyl 3-(3-hydroxybutyryloxy) butyrate). Thus, the preparation of an aluminum free catalyst with high hydrogenating activity was strongly required.

In this regard, our investigation attempted to develop a procedure for elimination of aluminum from the RNi surface in order to prepare a highly active and aluminium free catalyst.

Acid-treated RNi (RNi–A). Aluminium easily dissolves into water by the reaction with hydroxy acids to give highly water soluble products (aluminium chelates). Therefore, the selective elimination of aluminium from RNi was expected, when RNi was treated with a large amount of aqueous solution of hydroxy acid such as TA or glycolic acid (GA) under acidic conditions at a high temperature. A significant decrease of aluminium content was observed on this treatment (from 6% of Al content of the conventional RNi to less than 3% of Al content of GA-treated RNi (RNi–A (GA)) or TA-treated RNi (RNi–A (TA)).[7] Since the corrosion of nickel also took place during this treatment, the surface state of the resulting catalyst was no longer the same as that of RNi.

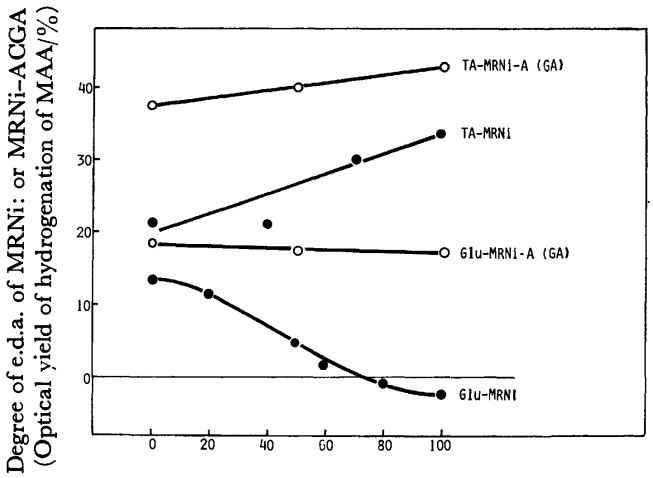

Fig. 3. Relationship between modifying temperature and degree of e.d.a. of MRNi (optical yield of hydrogenation of MAA over MRNi) or MRNi–A (GA). Amount of RNi or RNi–A (GA): 0.6 g. Modification: at pH 5 for 1.5 h. Hydrogenation: MAA (17.5 ml) was subjected to hydrogenation at 60 °C.

Figure 3 shows the e.d.a. of RNi–A (GA) modified with glutamic acid (Glu–MRNi–A (GA)) or TA–MRNi–A (GA), together with the e.d.a. of the conventional Glu–MRNi or TA–MRNi.[8] The e.d.a. of Glu– or TA–MRNi–A (GA) was higher than that of RNi modified with the same modifying reagent. The e.d.a. of MRNi–A (GA) was not affected by the modifying temperature, while that of the conventional MRNi changed significantly with the change in the modifying temperature. The results indicated that the GA-treatment gave a well stabilized and favorable catalyst

TABLE 5. EFFECT OF TA-TREATMENT ON e.d.a. OF TA-MRNi

Catalyst	Modifying conditions		$[\alpha]_D^{20}$ of the product	Degree of e.d.a.[a]
	pH	Temp/°C		
RNi-A (TA)	5.0	0	−14.23	62
RNi	5.0	0	−9.05	40
RNi	3.2	100	−8.99	39

Amount of catalyst: 0.8 g. Hydrogenation conditions were the same as those described in the Footnote of Table 4. a) Optical yield (%) of hydrogenation of MAA.

for the enantioface-differentiating hydrogenation. The hydrogenating activity of RNi-A (GA) was found to be high enough to carry out the hydrogenation of MAA at 60 °C.

The treatment with TA instead of GA functions as acid-treatment as well as modification. Table 5 shows the e.d.a. of TA-MRNi-A (TA) prepared in the following sequence: TA-treatment at 100 °C→water-washing→TA-modification at pH 5, 0 °C. It can be seen that the TA-treatment resulted in a significant increase of e.d.a. The hydrogenation over TA-MRNi-A (TA) was completed in 3—5 h at 100 °C, while the hydrogenation over TA-MHNi required 10—15 h to be completed at the same temperature. The TA- or GA-treatment of RNi was found to be effective for improvement of the e.d.a. of MRNi without sacrificing the hydrogenating activity. The nature of this catalyst was also found to be very close to that of HNi. It was expected that the TA-NaBr modification of RNi-A gave a catalyst with higher e.d.a. than that of TA-MRNi-A. With this expectation, RNi-A (TA) was modified with an aqueous solution containing TA and NaBr at pH 5.0, 0 °C. The resulting catalyst (TA-NaBr-MRNi-A) exhibited a high e.d.a. (optical yield 82%) and a high hydrogenating activity.

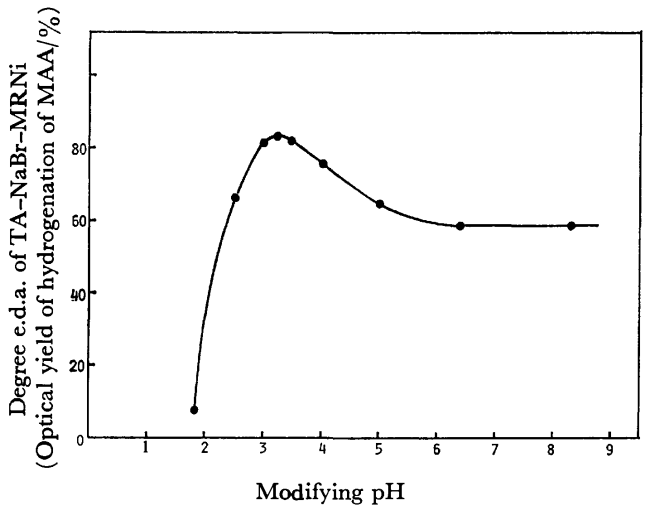

Fig. 4. Relationship between modifying pH and degree of e.d.a. of TA-NaBr-MRNi (optical yield of hydrogenation of MAA).
RNi (0.8 g) was modified with a solution containing TA (1 g) and NaBr (10 g) at 100 °C. The hydrogenation of MAA was carried out under the same conditions as those described in footnote of Table 4.

TA-NaBr-MRNi. In order to prepare TA-NaBr-MRNi-A directly from the conventional RNi, we treated RNi with an acidic aqueous solution containing TA and NaBr at 100 °C. The e.d.a. of TA-NaBr-MRNi thus obtained was examined by the enantioface-differentiating hydrogenation of MAA to MHB.

Figure 4 shows the relationship between the modifying pH and the e.d.a. of TA-NaBr-MRNi. The modification at pH 1.8 resulted in a low e.d.a. and low hydrogenating activity. The modification at pH 3.0—3.5 gave the best result with respect to the e.d.a. (optical yield 83%). The RNi modified with a mixture of TA and NaBr at above pH 3.5 exhibited a lower e.d.a. than that of RNi modified at pH 3.0—3.5 with the same modifying reagents.

Further improvement of e.d.a. was attained when the modification procedure was repeated. Thus, RNi treated three times with a solution containing TA and NaBr at pH 3.2, 100 °C, gave a catalyst with the highest e.d.a. The optical yield of the hydrogenation of MAA to MHB reached 88%. Table 6 shows e.d.a.'s of the catalysts prepared by repeated modifications together with the amount of Al^{3+} and Ni^{2+} eliminated from RNi by repeated modifications.

TABLE 6. AMOUNTS OF IONS ELIMINATED BY MULTI-MODIFICATIONS AND e.d.a. OF MULTI-MODIFIED RNi

Times of modification	Amounts of eliminated ions		Degree of e.d.a.[a]
	Ni^{2+}(mg)	Al^{3+}(mg)	
1	137	27	83
2	257	30	86
3	368	32	88

RNi (0.8 g) was modified with an aqueous solution of TA (1 g) and NaBr (10 g) at pH 3.2, 100 °C. Hydrogenation conditions were the same as those described in the Footnote of Table 4. a) Optical yield (%) of hydrogenation of MAA over MRNi.

As can be seen in Table 6, only a small amount of Al^{3+} was found in the modifying solution at the second and third steps. This fact indicates that most of the aluminium and its derivatives on the catalyst surface were eliminated by a single treatment of RNi with TA and NaBr at pH 3.2, 100 °C.

Figure 5 shows the relationship between the amount of NaBr in the modifying solution (pH 3.0, 4.0, or 5.0) and the e.d.a. of the resulting catalyst. The optimal amount of NaBr was affected by the modifying pH. In our research, increasing the modifying pH value tended to increase the optimal amount of NaBr. The use of an excess amount of NaBr resulted in a remarkable decrease of the e.d.a. The e.d.a. of TA-NaBr-MRNi prepared under the optimal amount of NaBr at each modifying pH increased in the following order: pH 5<pH 4< pH 3.

The effects of various kinds of inorganic salts on the e.d.a. of MRNi were examined with the intention of

Amount of RNi: 0.8 g. Modifying pH: at pH 3.0 (—△—), pH 4.0 (—●—), and pH 5.0 (—○—). Modifying temperature: at 100 °C.
The hydrogenation was carried out under the same conditions as those described in Foothnote of Table 4.

Table 7. Enantioface-differentiating hydrogenation of MAA over TA–inorganic salt–MRNi

Inorganic salt in the modifying solution(g)	$[\alpha]_D^{20}$ of the product	Degree of e.d.a.[a)]
None	−8.99	39
NaBr (10)	−19.07	83
NaF (3)	−13.95	61
NaCl (10)	−16.55	72
NaI (5×10^{-4})	−11.74	51
Na_2SO_4(10)	−12.95	56
$NaH_2PO_4\cdot2H_2O$ (1)	−8.19	36
$NaNO_3$ (0.1)	−12.17	53
$NiBr_2$ (1)	−14.36	63
$LiBr\cdot H_2O$ (10)	−14.25	62

Amount of RNi: 0.8 g. Modification: at pH 3.2, 100 °C for 1 h. Hydrogenation conditions were the same as those described in the footnote in Table 4. a) Optical yield (%) of hydrogenation of MAA over MRNi.

finding out the best compound to use as the supplementary modifying reagent. The modification was carried out with a mixture of TA and inorganic salt at the optimal modifing pH (pH 3.2) deduced from the results shown in Figs. 4 and 5. Table 7 shows the e.d.a.'s of TA–inorganic salt–MRNi's together with e.d.a. of TA–MRNi. In general the enhancements of the e.d.a.'s were observed by the addition of inorganic salt. The results shown in Table 7 indicate that the kinds of cations in the supplementary modifying reagents affect the e.d.a.'s of the resulting catalysts like the kinds of anions do. These results are in accord with the fact that there are large effects of the alkali ions on the e.d.a. of TA–MRNi.[4)] In the case of NaI, a large amount of NaI in the modifying solution resulted in the loss of the hydrogenating activity of the catalyst. Among inorganic salts examined, NaBr was found to be the most effective inorganic salt in giving TA–inorganic salt–MRNi with high e.d.a.

From the results described in this section, it turned out that the modification of RNi with TA and NaBr under acidic conditions gave TA–NaBr–MRNi with a rather higher e.d.a. than that of TA–NaBr–MRNi–A. This simple preparative method of TA–NaBr–MRNi is easily applicable for large scale production.

Role of NaBr Adsorbed on RNi. The preceding section dealt with the preparative method of TA–NaBr–MRNi for practical purposes. As can be seen in Fig. 5, the e.d.a. of the catalyst was very much affected by the modifying pH, modifying temperature, and the amount of NaBr in the modifying solution. RNi is an unstable catalyst and the e.d.a. of the resulting MRNi is very sensitive to the modifying conditions whereas RNi–A is a well stabilized one (Fig. 3). Thus, the complicated results shown in Fig. 5 may be caused, at least in part, by the unstability of RNi. Apart from the practical purposes, it is necessary to use a stabilized catalyst such as RNi–A for the studies on the role of adsorbed NaBr in improvement of the e.d.a.

In this regard, the catalysts used for this experiment were prepared from RNi–A under mild modifying conditions. TA–MRNi–A and TA–NaBr–MRNi–A for this experiment were prepared as follows: RNi was pretreated with an aqueous solution of TA at pH 3.2, 100 °C and then modified with a solution of TA or that of TA and NaBr at pH 5, 0 °C. The surface states of TA–MRNi–A and TA–NaBr–MRNi–A can be considered to be similar to that of RNi–A. The e.d.a.'s of these types of the catalysts were high and comparable to those of TA–MRNi and TA–NaBr–MRNi prepared in one step at pH 3.2, 100 °C.

Figure 6 shows the relationship between the amount of NaBr in the modifying solutions and the amount of adsorbed NaBr or TA. The addition of the first small amount of NaBr in the modifying solution resulted in a noticeable decrease of adsorbed TA. However, no further decrease of adsorbed TA was observed with the further addition of NaBr in the modifying solution.

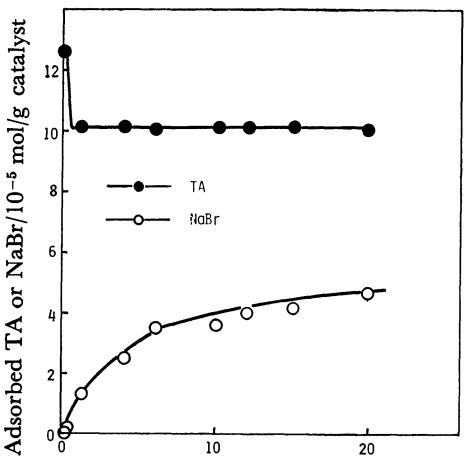

Fig. 6. Relationship between amount of NaBr in modifying solution and amount of adsorbed TA or NaBr.
Catalyst: a 1 g portion of RNi–A (TA). Modification: at pH 5, 0 °C for 1 h.

On the other hand, the amount of adsorbed NaBr increased with the amount of NaBr in the modifying solution. These results can be explained well on the basis of the idea that there are at least two types of areas on RNi-A: one (area-I) prefers to adsorb TA, and the other (area-II) prefers to adsorb NaBr. The increment of adsorbed TA in the absence of NaBr in the modifying solution (Fig. 6; at the point of NaBr=0) may be caused by the adsorption of TA on area-II. On hydrogenation over TA–NaBr–MRNi-A, the enantioface-differentiating hydrogenation may take place over area-I with the aid of adsorbed TA and the non-enantioface-differentiating hydrogenation may take place over area-II. The e.d.a. of TA–MRNi-A was on the line of TA–NaBr–MRNi-A, as will be seen in Fig. 7. This finding suggests that optically active MHB can not be produced over area-II, even when TA was adsorbed on this area.

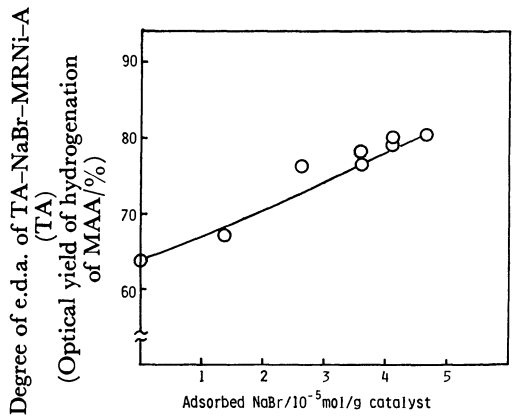

Fig. 7. Relationship between amount of adsorbed NaBr and degree of e.d.a. of TA–NaBr–MRNi-A (TA) (optical yield(%) of hydrogenation of MAA).
Amount of catalyst and modifying conditions were same as those described in Footnote of Fig. 6. The hydrogenation was carried out under the same conditions as those described in Footnote of Table 4.

Figure 7 shows the relationship between the adsorbed amount of NaBr and the e.d.a. of the catalyst. The e.d.a. increased monotonously with the amount of adsorbed NaBr. When the fact that the amount of adsorbed TA is constant under the experimental conditions is taken into account, it is reasonable to assume that the amounts of the optically active MHB produced are not changed by the increase of NaBr adsorbed on the catalyst. The enhancement of the e.d.a. with the amount of adsorbed NaBr results from the decrease of racemic MHB produced over unmodified area-II, because of the deactivation of area-II by the adsorption of NaBr.

In order to compare the hydrogenating activities of TA–MRNi-A and TA–NaBr–MRNi-A, the rates of hydrogenations of acetone over these two catalysts were compared. The time courses of the hydrogenation is shown in Fig. 8. The hydrogenation over TA–NaBr–MRNi-A was found to proceed more slowly than that over TA–MRNi-A. This finding is consistent with the above ideas that NaBr is adsorbed on a different area (area-II) from that (area-I) on which TA is adsorbed

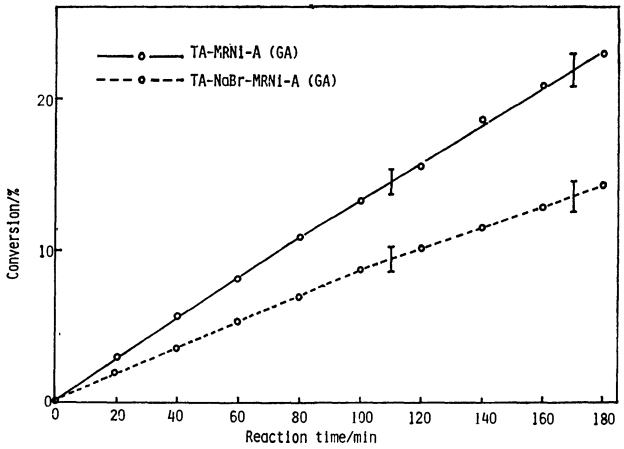

Fig. 8. Time courses of hydrogenation of acetone.
Modifying solution: TA (2 g) or TA (2 g)+NaBr (20 g) were dissolved in deionized water (200 ml). Modification: at pH 5, 0 °C for 1 h.

and that the adsorbed NaBr reduces the formation of MHB over area-II.

The areas occupied by TA, MAA, and TA···MAA complex can be assumed to be $2—4\times10^{-19}$, $2—4\times10^{-19}$, and $4—8\times10^{-19}$ m²/molecule, respectively, which are the silhouette areas of their CPK models. The areas are variable, depending on the adsorption modes of these molecules, and cannot be determined unequivocally at the present stage. When the results of adsorption studies by Welch *et al.*[9] are taken into account, these molecules are too large to cover the parts of small pores and capillaries in the catalyst. Thus, it is difficult to evaluate the e.d.a. of TA–NaBr–MRNi-A simply based on the surface area measured with the BET method and the amounts of adsorbed TA and NaBr.

Although the concepts of areas-I and -II are not directly related to the real surface area of the catalyst, they are informative for understanding the surface state of the catalyst under working conditions.

As a whole, it can be concluded that NaBr adsorbed on RNi inhibits the non-enantioface-differentiating hydrogenation to improve the e.d.a. of TA–MRNi.

Experimental

The optical rotations and visible spectra were measured with a Perkin-Elmer 241 Polarimeter and Hitachi 124 Spectrophotometer, respectively.

Raney Nickel Catalyst. The Ni–Al alloy (Ni/Al=42/58) was leached by adding it portion by poriton to 20 ml of a 20% aqueous solution of NaOH. The Ni–Si alloy (Ni/Si=50/50) was also leached by adding it to 30 ml of a 20% aqueous solution of NaOH. The resulting suspension was kept at 100 °C for 1 h. After removal of the alkaline solution by decantation, the catalyst was washed 15 times with 30 ml portions of deionized water. The Ni–Mg alloy (Ni/Mg=50/50) was leached, using 300 ml of a 3% aqueous solution of tartaric acid. The resulting suspension was kept at room temperature for 45 min. The catalyst was washed 15 times with 30 ml portions of deionized water.

Unless otherwise stated the Ni–Al alloy was used as the Raney alloy in this study.

Reduced Nickel Catalyst. Greenish NiO was reduced for 1 h at 350 °C under a hydrogen stream of 8 l/h.

Catalyst from Nickel Formate. Well-dried nickel formate prepared from nickel chloride and sodium formate was thermally decomposed at 250—300 °C under a pressure of 20—25 mmHg for 1 h.

Urushibara Nickel-A. This was prepared by the procedure of Urushibara *et al.*[10]

Supported Nickel Catalyst. The various types of supported nickel catalysts (weight ratio of Ni to support=50/50) were prepared by a precipitation method. $Ni(NO_3)_2 \cdot 6H_2O$ and the corresponding quatity of kieselguhr, activated alumina, TiO_2, or ZrO_2 were mixed in deionized water. Into the suspension was added dropwise an aqueous solution of Na_2CO_3 with vigorous stirring. After the end of addition of Na_2CO_3, stirring was continued for 1 h. The precipitate was collected by filtration and washed 3 times with water. The residue was dried at 110 °C for 24 h and pulverized in a mortar. The powder was heated to 500 °C and allowed to stand for 3 h at this temperature. The supported NiO thus obtained was reduced for 1 h at 350 °C under a hydrogen stream (8 l/h) just before the modification.

GA-treated Raney Nickel Catalyst. After treatment of RNi (0.8 g) with 100 ml of a 1% aqueous solution of GA at pH 3.2, 100 °C for 1 h, the catalyst was washed 3 times with 30 ml portions of water. Subsequently, the catalyst was treated with 30 ml of 1 M NaOH at 100 °C for 1 h and washed 15 times with 30 ml portions of water.

TA-treated Raney Nickel Catalyst. RNi (0.8 g) was treated with TA under the same conditions as above. The resulting catalyst was washed 3 times with 30 ml portions of water and then subjected to the modification with TA or TA+NaBr.

Modifying Solution. *1)*: TA (1 g) or TA (1 g) and an appropriate amount of inorganic salt were dissolved in deionized water (100 ml), and the pH of the solution was adjusted with 1 M NaOH (the amount of inorganic salt and the value of pH were specified in the text in each case).

2): (*S*)-Glutamic acid (1 g) was dissolved in deionized water (100 ml), and the pH of the solution was adjusted to pH 5 with 1 M NaOH.

Modification. The nickel catalyst was soaked in the modifying solution for 1 h under the conditions stated in the table in the text. After removal of the solution by decantation, the modified catalyst was washed successively with a 10 ml portion of water, two 50 ml portions of methanol, and a 25 ml portion of the reaction solvent.

Hydrogenation of MAA. The hydrogenation of MAA was carried out in a 100 ml autoclave under 110—130 kg/cm² of initial hydrogen pressure at the specified temperature. After removal of the catalyst, fractional distillation gave MHB. The optical purity of the product was calculated based on the value of $[\alpha]_D^{20}=22.95$ (neat) for optically pure MHB.

Optically Pure MHB. The quinine salt of 3-hydroxybutyric acid, obtained by hydrolysis of MHB ($[\alpha]_D^{20}$ −19.50 (neat)), was recrystallized five times from water.[11] Decomposition of the quinine salt and esterification of the free acid with diazomethane gave (*R*)-(−)-MHB with $[\alpha]_D^{20}$ −22.95 (neat) (the observed value (l=1 dm); α_D^{20} −24.23 (neat), and the specific gravity; $d_{20}=1.056^{6}$). Optically pure (*S*)-(+)-MHB was obtained from MHB ($[\alpha]_D^{20}$ +19.50 (neat)) in the same procedure as described above, except for the use of acetone as the solvent for recrystallization.[11] The value of $[\alpha]_D^{20}$ of (*S*)-isomer was $[\alpha]_D^{20}$ +22.77 (neat) (the observed value (l=1 dm); α_D^{20} +24.05 (neat)).

Determinations of Ni^{2+} and Al^{3+} in the Modifying Solution. The combined Ni^{2+} and Al^{3+} content in the modifying solution was determined by the EDTA titration method at pH 3.0—3.3, 95—100 °C, using Cu-PAN as the indicator.[12] The Ni^{2+} content in the solution was determined by the EDTA titration method at pH 10—12, using murexide as the indicator and triethanolamine as the masking reagent for Al^{3+}.[12] The difference between these two determinations represented the Al^{3+} content in the modifying solution.

Determination of TA Adsorbed on the Catalyst. A 1 g portion of MRNi-A (TA) or a 10 g portion of TA-MHNi was suspended in 25 ml of 1 M NaOH solution at 100 °C for 1 h. The supernatant was collected by decantation and the remaining catalyst was washed with four 15 ml portions of water. After combination of the supernatant and the washings, the solution was acidified with 10 ml of 1.5 M H_2SO_4 and then was made up to 100 ml with water. The amount of TA was determined colorimetrically by the method reported by G. R. Christian.[13]

Determination of NaBr Adsorbed on the Catalyst. The amount of NaBr adsorbed on the catalyst was determined by Volhard's titrimetric method.[14] A 1 g portion of TA-NaBr-MRNi-A (TA) was decomposed with 15 ml of 60% HNO_3 in the presence of a known amount of $AgNO_3$. The resulting solution was back-titrated with NH_4SCN.

Hydrogenation of Acetone. A 1.6 g portion of RNi-A (GA) was modified with TA or TA+NaBr and then washed successively with a 20 ml portion of water, two 100 ml portions of methanol, and a 50 ml portion of acetone. After removal of the solution by decantation, the modified catalyst suspended in acetone (30 ml) was introduced into an autoclave (100 ml capacity). The hydrogenation of acetone was conducted under 90 kg/cm² of initial hydrogen pressure at 28 °C. The conversion of acetone to 2-propanol was calculated based on the depression of hydrogen pressure.

The authors wish to express their thanks to Nihon Kagaku Sangyo Co., Ltd. and Wako Pure Chemical Industries, Ltd. for their gifts of NiO samples. The present work was supported in part by a Grant-in-Aid for Scientific Research No. 403531 from the Ministry of Education, Science and Culture.

cis-β-Alkoxystyrenes such as *cis*-β-methoxy-, *cis*-β-ethoxy-, and *cis*-β-isopropoxystyrene were autoxidized as neat at room temperature in the dark even in the absence of any radical generator. UV-irradiation and the use of a radical generator facilitated the oxygenation of these olefins. These oxidations afforded the corresponding epoxides or their derivatives in considerable yields as well as carbonyl compounds resulting from oxidative cleavage of the double bonds. The mechanisms for these oxidations are proposed to involve free-radical chain pathways and charge-transfer complexes between the olefins and oxygen which play an important role in the initiation steps.

Autoxidation of olefins usually affords allylic hydroperoxides, carbonyl compounds formed by cleavage of the double bond, and the remaining polyperoxide residues, but scarcely gives epoxides.[1-4] Dye-sensitized photooxygenation of olefins affords, through singlet oxygen mechanism, hydroperoxides, endoperoxides, and dioxetanes which are often converted into carbonyl compounds, and the formation of epoxides is also only a minor path.[5] However, Shimizu and Bartlett showed that epoxides arose efficiently when biacetyl or benzil was employed as a sensitizer on photooxidation of olefins.[6] Previously we observed that direct irradiation of β-alkoxystyrenes under oxygen led to an oxidative cleavage of the double bond *via* a different pathway from singlet oxygen mechanism.[7] During the course of the investigation, we have found the following noticeable facts: (1) *cis*-β-methoxystyrene (**1a**) as neat or in concentrated solution is sensitive to oxygen at room temperature in the dark even in the absence of any radical generator, while this olefin is not reactive with oxygen in dilute solution at room temperature or as neat at 0 °C in the dark; (2) UV-irradiation of the olefin without dye sensitizer accelerated the oxygenation in dilute solution at room temperature and also as neat at 0 °C; (3) a radical generator effected the autoxidation of the olefin at 50 °C; (4) all these ways of oxygenation of the olefin led to nearly the same distribution of the products, the corresponding epoxide and carbonyl compounds (benzaldehyde and methyl formate). This work was undertaken to investigate the nature of these oxygenations under photochemical and/or thermal conditions using alkoxystyrenes (**1**), 2-methoxy-1,1-diphenylethylene (**2**), 2-phenylpropene (**3**), and 2-methyl-1,1-diphenylpropene (**4**) as substrates. The results are described in detail and the possible reaction mechanism is discussed below.

Results and Discussion

Oxidation Products. *1) Autoxidation in the Absence of Radical Generator in the Dark*: *cis*-β-Methoxy- (**1a**), *cis*-β-ethoxy-(**1b**), and *cis*-β-isopropoxy-styrene (**1c**) were found to be sensitive to molecular oxygen as neat and in concentrated solution (*ca.* 50 vol%) even in the absence of any radical generator at room temperature in the dark. Thus, a highly purified specimen of neat **1a** (432 mg, 3.16 mmol) was stirred overnight under oxygen atmosphere at room temperature in the dark until **1a** was almost consumed. The NMR, GLPC, and chemical examination of the reaction mixture showed the formation of *trans*-2-methoxy-3-phenyloxirane (**5a**, 28%), benzaldehyde (47%), and methyl formate (8%). Likewise, **1b** and **1c** were autoxidized to benzaldehyde and alkyl formates; however, the corresponding epoxides and their isolable derivatives were not detected among the products. The results are summarized in Table 1. At 0 °C the olefins were not oxidized. When dissolved in solvents such as benzene, acetonitrile, and methanol (*ca.* 0.5 mol/dm³), the olefins were scarcely consumed by stirring under oxygen at room temperature for several hours.

2) Photooxidation: To conduct oxygenation effectively, **1a**, **1b**, **1c**, 2-methoxy-1,1-diphenylethylene (**2**), 2-phenylpropene (**3**), and 2-methyl-1,1-diphenylpropene (**4**) were irradiated as neat or in solution under oxygen atmosphere with a high pressure mercury lamp, and the products were determined as summarized in Table 2.

Direct irradiation of **1a**, **1b**, and **1c** under oxygen afforded the corresponding epoxides or their derivatives depending upon the substituents and the solvents employed in addition to benzaldehyde and methyl, ethyl, and isopropyl formate, respectively. In a typical run employing a neat olefin, **1a** (100 mg, 0.75 mmol) was irradiated in a stream of oxygen for 4 h with a 400-W high pressure mercury lamp through a Pyrex wall at room temperature until **1a** was almost completely consumed as revealed by NMR spectra. The NMR, GLPC, and chemical examination of the reaction mixture showed the formation of benzaldehyde (47%), benzoic acid (6%), and *trans*-2-methoxy-3-phenyloxirane (**5a**, 9%). The epoxide was isolated by pre-

parative GLPC and its *trans*-configuration was confirmed by its NMR spectrum.[8] On treatment of the reaction mixture with deuterated water, NMR signals due to the epoxide instantaneously disappeared because of its high sensitivity to moisture.

A control experiment showed that an authentic specimen of the *trans*-epoxide was recovered unchanged after being left under the reaction conditions, which rules out the possibility that benzaldehyde and the formate ester would be produced through decomposition of the epoxide formed as an intermediate. Photooxidation of **1b** and **1c** likewise afforded the corresponding oxidative cleavage products; however, the corresponding epoxides and their isolable derivatives were not detected among the reaction products (Table 2).

Irradiation of **1a**, **1b**, and **1c** as neat under oxygen at 0 °C also afforded benzaldehyde and the corresponding alkyl formates. Epoxide **5a** was also formed in the case of **1a**. The product distributions were very similar to those in the reaction at room temperature.

It is noticeable that the photooxidation of **1a**, **1b**, and **1c** in methanol gave 2-alkoxy-2-methoxy-1-phenylethanols (**6**) in considerable yields in addition to the cleavage products, benzaldehyde and its dimethyl acetal (Table 2). The resulting 2,2-dimethoxy- (**6a**), 2-ethoxy-2-methoxy- (**6b**), and 2-isopropoxy-2-methoxy-1-phenylethanol (**6c**) were isolated from the reaction mixtures by preparative GLPC and identified by NMR spectra. Formation of these products is reasonably accounted for by polar addition of the solvent methanol to the epoxides once formed as intermediates under the reaction conditions as confirmed by irradiation of **5a** in methanol under oxygen atmosphere yielding **6a**. These results indicate that the photooxidation of **1b** and **1c** also gives the corresponding epoxides which nevertheless seem too unstable to be isolated. Their instability is in keeping with the facts that these epoxides could not be prepared under similar conditions to those employed for the preparation of **5a**, and that **5a** was extremely sensitive to water.

The use of benzene and acetonitrile as solvent on photooxidation of **1a**, **1b**, and **1c** gave only the cleavage products regardless of the alkoxyl substituents and the polarity of the solvents employed (Table 2).

Likewise, photooxidation of **2** in benzene and acetonitrile gave the corresponding epoxide (**7**) together with the oxidative cleavage products, benzophenone and methyl formate. In methanol 2,2-dimethoxy-1,1-diphenylethanol (**8**) was obtained instead of the epoxide (Table 2). The epoxide (**7**) and alcohol (**8**) were isolated

by preparative GLPC and characterized by comparison of their IR and NMR spectra with those of authentic specimens.

$$\underset{\mathbf{2}}{Ph_2C{=}CHOMe} \xrightarrow{h\nu,\ O_2} Ph_2C{=}O + HCO_2Me + \underset{\mathbf{7}}{Ph_2C(O)CHOMe} \xrightarrow{MeOH} \underset{\mathbf{8}}{Ph_2C(OH)CH(OMe)_2}$$

Photooxidation of 2-phenylpropene (**3**)[9] and 2-methyl-1,1-diphenylpropene (**4**) led to the formation of the oxidative cleavage products and the corresponding epoxides (Table 2), although their oxidation proceeded much more slowly than that of **1**.

3) Autoxidation in the Presence of Radical Generator: To investigate the mechanism for the oxygenation of these olefins their autoxidation with a radical initiator was carried out. Autoxidation of neat β-alkoxystyrenes (**1**) with azobisisobutyronitrile (AIBN) as an initiator at 50 °C afforded the same products as did the photooxidation; benzaldehyde and alkyl formates were produced along with epoxide **5a** from **1a**. To examine the effect of oxygen pressure on the product yields autoxidation of **1a** (1 mmol) containing AIBN (0.02 mmol) was carried out at 50 °C for 5.5 h under varying partial pressures of oxygen diluted with nitrogen in a total pressure of 760 Torr (1 Torr=133.322 Pa). The yields of benzaldehyde and the epoxide were determined by GLPC as depicted in Fig. 1, which shows that the yield of the epoxide increased with decreasing oxygen pressure and that the maximum yield (about 60%) was attained at nearly 40 Torr of the partial pressure of oxygen.

Mechanisms for Oxygenations. When **1**'s were stirred as neat under oxygen in the presence of hydroquinone, the well-known radical inhibitor, at room temperature, the olefins were recovered unchanged. Hydroquinone also inhibited the photooxygenation of **1**'s as neat or in benzene solution. Addition of 1,4-diazabicyclo[2.2.2]octane (DABCO) also inhibited autoxidation of **1a** at room temperature without a radical generator and at 50 °C in the presence of AIBN. Since it has been shown that oxidation by singlet oxygen is inhibited by DABCO but usually not by hydroquinone,[10] these results indicate that free singlet oxygen plays no role in the present oxygenation, and the production of the *trans*-epoxide from **1a** requires a stepwise mechanism by way of a freely rotating intermediate.

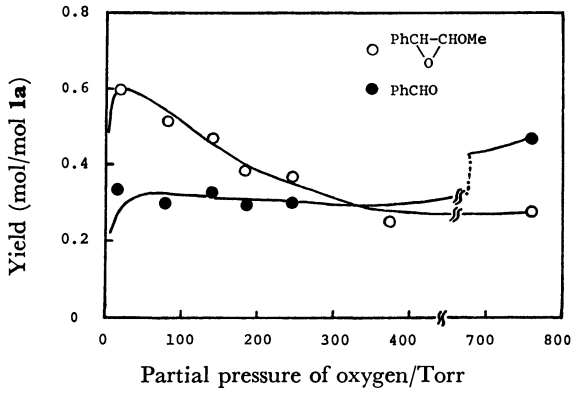

Fig. 1. Effect of oxygen pressure on the yield of autoxidation products of *cis*-β-methoxystyrene (**1a**).

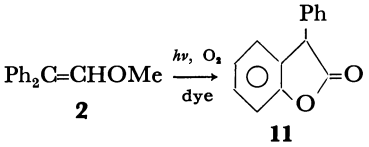
Actually, the products from the oxygenations of **1**'s are different from those resulting from their dye-sensitized photooxygenation, which gave neither epoxides nor their derivatives. Thus, Methylene Blue-sensitized photooxygenation of *trans*-β-ethoxystyrene in dichloromethane was reported to give benzaldehyde and ethyl formate,[11] and recently it was demonstrated that the use of diacenaphtho[1,2-*b* : 1′,2′-*d*]thiophene as sensitizer on photooxygenation of *cis*- and *trans*-β-methoxystyrene at −78 °C led to 1,4-cycloaddition of singlet oxygen across the side chain β-carbon and the *ortho*-carbon of the aromatic ring, and that the *cis*-isomer reacted much more rapidly than the *trans*-isomer under the same conditions.[12] Also, the direct photooxygenation of **2** gave the completely different products from 3-phenyl-2,3-dihydrobenzofuran-2-one (**11**) which was reported to arise on dye-sensitized photooxygenation of **2** through 1,4-cycloaddition of singlet oxygen.[13]



Furthermore, treatment of a mixture of **1a** and 1-methylcyclohexene or 2,3-dimethyl-2-butene, which is known to be highly susceptible to singlet oxygen, with oxygen in the absence of an initiator in the dark at room temperature resulted in exclusive oxidation of **1a** accompanied by nearly quantitative recovery of the added olefin.

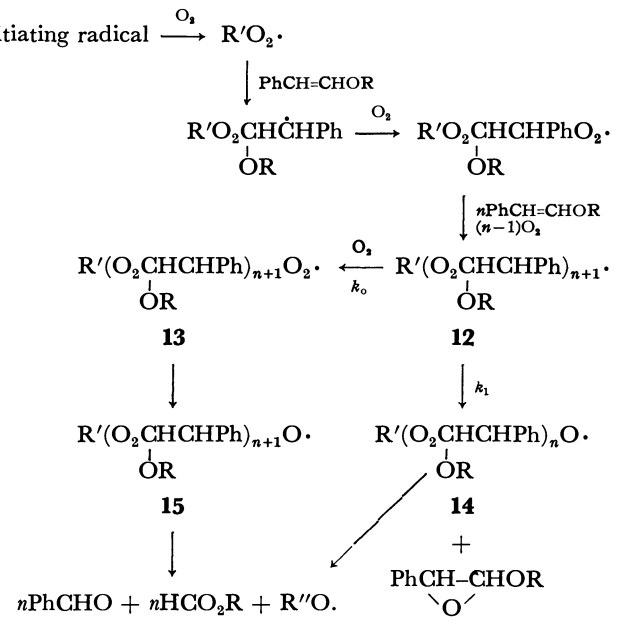
These findings, therefore, strongly indicate that the direct photooxygenation of **1**'s as well as their autoxidation in the presence and absence of an initiator involves triplet molecular oxygen without intervention of singlet oxygen.

The effect of oxygen pressure on the yield of the epoxide, combined with the product distribution and the effects of the additives, strongly suggests that the autoxidation of the present olefins in the dark proceeds through a mechanism similar to that proposed previously by Mayo for autoxidation of styrene and related olefins.[1] In Mayo's mechanism, alternating addition of styrene molecules and molecular oxygen results in copolymeric radicals, which finally either afford polymeric peroxides or undergo scission to benzaldehyde, formaldehyde, and phenyloxirane (*cf.* Scheme 1); the yields of these products are changed with the partial pressure of oxygen.

In the present work, however, it is remarkable that

epoxide **5a** was produced in a moderate yield, for example, *ca.* 30%, even at 760 Torr oxygen pressure, and the maximum yield, *ca.* 60%, was attained at a lower oxygen pressure, *ca.* 40 Torr. This is in contrast to the autoxidation of styrene which afforded phenyloxirane in a very low yield (1%) at 760 Torr oxygen pressure and increased its yield to the maximum value (27%) at a very low partial pressure of oxygen (1 Torr).[14]

Comparison of the present photooxygenation with the autoxidation in the product distribution and the behavior toward inhibitors mentioned above indicates that the photooxygenation mechanism is quite similar to that of the autoxidation except for the initiation steps. According to Scheme 1 described below, the intermediate benzylic radicals (**12**) will add to oxygen to give peroxyl radicals (**13**) (rate constant: k_0) or undergo intramolecular substitution on the peroxide linkage to afford the epoxide and alkoxyl radicals (**14**) (rate constant: k_1). Peroxyl radicals **13** give, through bimolecular interaction, alkoxyl radicals (**15**). Alkoxyl radicals **14** and **15** undergo scission into carbonyl compounds or again react with the olefin to give the benzylic radicals.



Scheme 1.

No production of polymeric peroxides together with efficient production of the epoxide in the oxidation of **1a** shows that benzylic radicals **12** resulting from **1a**, compared with the corresponding benzylic radicals arising from styrene, more facilely undergo the intramolecular substitution on the peroxide linkage in preference to growing up to polymeric matters.

Formation of Complexes between the Olefins and Oxygen. In order to get insight into the mechanism for the initiation of the free-radical chain oxidation of the alkoxystyrenes, particularly in the absence of any initiator, spectroscopic examination was carried out for the possible formation of charge-transfer complexes between these olefins and oxygen in view of the fact that several aromatic compounds form charge-transfer complexes with oxygen.[15–17] When a stream of oxygen was passed into a cyclohexane solution of **1a** at 0 °C, a new broad band appeared at 305—400 nm with the maximum at 307 nm. When argon was bubbled through the solution, this new band completely disappeared. When the measurements were carried out at 23 °C, the new band decreased in intensity to one-fourth by bubbling with argon. These facts indicate reversible formation of a charge-transfer complex between **1a** and oxygen. Styrene was reported to develop a similar absorption band, when a neat sample was saturated with oxygen at atmospheric pressure, at 305—350 nm with the maximum at 310 nm, which was shifted to shorter wavelengths by dilution with a solvent.[15]

In order to evaluate electron donating abilities of the olefins, their charge-transfer interaction with tetracyanoethylene (TCNE) was investigated. When **1a** or styrene was dissolved with TCNE in dichloromethane, charge-transfer bands appeared. The association constant, K, and extinction coefficient of the complex, ε_{CT}, were determined from concentration dependence of the optical density of the complex according to Benesi-Hildebrand's equation,[18]

$$C_0/A = 1/K\varepsilon_{CT}D_0 + 1/\varepsilon_{CT},$$

where C_0 and D_0 are the initial concentrations of the acceptor and donor, respectively, and A is the absorbance for unit cell path length. The results for **1a**/TCNE and styrene/TCNE are listed in Table 3.

The results for styrene/TCNE accord with those reported by Cooper *et al.*[19] Comparison of **1a** with styrene in the wavelength of the absorption maximum, λ_{CT}, and the association constant, K, shows that **1a** is a stronger donor to give a more stable charge-transfer complex than styrene.

The energy of the charge-transfer transition for the complexes formed by a series of donors with the same acceptor is related to the donor ionization potential, I_D:[19,20]

$$h\nu_{CT} = aI_D + b,$$

where a and b are constant. When the values of a and b

$PhCH=CH_2$	480	2.56	1330	0.60	8.34,[a] 8.40[b]	0.30

a) Values evaluated from the equation by Farrell and Newton.[20] b) Adiabatic values from photoelectron spectra of *cis*-β-methoxystyrene[21] and styrene.[22]

proposed by Farrel and Newton[20] for substituted benzene/TCNE complexes are used, the relationship is expressed by

$$h\nu_{CT} = 0.82I_D - 4.28 \text{ (eV)}.$$

This relationship leads to a much lower value of the ionization potential for **1a**, 7.70 eV, than for styrene, 8.34 eV,[19] which are in reasonable agreement with the values observed by photoelectron spectroscopy, 7.54 for **1a**[21] and 8.40 eV for styrene.[22] This result is in keeping with a fact that **1a** exhibits a much lower oxidation potential (1.00 V) than styrene (>1.95 V).[21,23]

As described above, **1a** forms the charge-transfer complex with oxygen more efficiently than styrene. Therefore, it is not unreasonable to suppose that the charge-transfer complex plays an important role in generating free radicals both thermally and on ultraviolet irradiation to initiate the radical chain oxidation.[24]

Experimental

The IR and UV spectra were recorded on a Hitachi 215 infrared spectrometer and a JASCO UVIDEC-1 spectrophotometer, respectively. The NMR spectra were recorded on a Hitachi R-24 and a JEOL JNM-MH-100 spectrometer. Gas-liquid phase chromatographic analysis was performed on a Hitachi 163 and a Shimadzu GC-4CM-PF gas chromatograph equipped with a flame ionization detector, and a Hitachi 023 gas chromatograph was used for preparative purposes.

Materials. *cis*-β-Methoxystyrene (**1a**),[25] *cis*-β-ethoxystyrene (**1b**),[26] and *cis*-β-isopropoxystyrene (**1c**) were prepared by heating phenylacetylene with potassium hydroxide in the corresponding alcohols.

cis-β-Isopropoxystyrene (**1c**), bp 58 °C/2 Torr (1 Torr= 133.322 Pa); IR (liq): 2975, 1650 cm^{-1}; NMR (CCl_4): δ 1.31 (d, 6H), 3.94 (septet, 1H), 5.06 (d, J=7.0 Hz, 1H), 6.04 (d, J=7.0 Hz, 1H), and 6.9—7.5 (m, 5H); Found: C, 81.05; H, 8.64%. Calcd for $C_{11}H_{14}O$: C, 81.43; H, 8.69%.

2-Methoxy-1,1-diphenylethylene (**2**)[27] and 2-methyl-1,1-diphenylpropene (**4**)[28] were prepared by the Wittig reactions employing benzophenone. *trans*-2-Methoxy-3-phenyloxirane (**5a**)[29] and 3-methoxy-2,2-diphenyloxirane (**7**) were prepared from reactions of 2-chloro-2-phenylethanal and 2-chloro-2,2-diphenylethanal with sodium methoxide, respectively, according to the method reported by Kirrmann *et al.*[29] The latter epoxide was irradiated in methanol to give 2,2-dimethoxy-1,1-diphenylethanol (**8**).

3-Methoxy-2,2-diphenyloxirane (**7**), mp 49—51 °C; NMR (CCl_4): δ 3.30 (s, 3H), 4.55 (s, 1H), and 7.1—7.3 (m, 10H).

2,2-Dimethoxy-1,1-diphenylethanol (**8**), bp 140 °C/1 Torr; NMR (CCl_4): δ 2.91 (s, 1H), 3.25 (s, 6H), 4.48 (s, 1H), and 7.1—7.4 (m, 10H); Found: C, 74.56; H, 7.05%. Calcd for $C_{16}H_{18}O_3$: C, 74.39; H, 7.02%.

On treatment of 2-chloro-2-phenylethanal with sodium ethoxide and sodium isopropoxide, epoxides could not be isolated. Epoxidation of **1b** and **1c** with *m*-chloroperoxybenzoic acid[30] or *N*-bromosuccinimide/sodium hydroxide[30] was also unsuccessful. 2-Methyl-2-phenyloxirane (**9**)[31] and 2,2-dimethyl-3,3-diphenyloxirane (**10**)[32] were prepared by epoxidation of 2-phenylpropene (**3**) and **4** with *m*-chloroperoxybenzoic acid, respectively.

Photooxidation of Olefins. Typical procedures are described below for *cis*-β-methoxystyrene (**1a**).

Without Solvent. Liquid **1a** (100 mg, 0.75 mmol) in a Pyrex tube was irradiated in an oxygen stream with a 400-W high pressure mercury lamp for 4 h at room temperature. GLPC and NMR analyses of the reaction mixture showed almost complete consumption of **1a** and the formation of benzaldehyde (47%), benzoic acid (6%), methyl formate, and *trans*-2-methoxy-3-phenyloxirane (**5a**, 9%). The product distribution was determined by GLPC using internal standards and authentic reference materials on Polypropylene glycol 4025 (5%) and diethylene glycol succinate polyester–H_3PO_4 (5%) columns at 130 and 180 °C, respectively. The epoxide was isolated from the reaction mixture by preparative GLPC on polyethylene glycol (10%) at 150 °C and identified by comparing its IR and NMR spectra with those of an authentic sample. On addition of D_2O to the reaction mixture, signals due to the epoxide disappeared instantaneously in the NMR spectrum.

Liquid **1a** (134 mg, 1 mmol) was irradiated similarly under oxygen atmosphere at 0 °C for 4 h. GLPC and NMR analyses of the reaction mixture showed the formation of benzaldehyde, epoxide **5a**, and methyl formate. The product distribution was found to be very similar to that in the reaction at room temperature.

In Methanol. A solution of **1a** (56 mg, 0.42 mmol) in methanol (1 ml) was irradiated in a Pyrex tube under oxygen atmosphere with a 400-W high pressure mercury lamp for 4 h at room temperature. After almost all the solvent was removed by rotary evaporation, the reaction mixture was subjected to GLPC analysis, which revealed the formation of benzaldehyde (trace), dimethoxyphenylmethane (51%), benzoic acid (5%), and 2,2-dimethoxy-1-phenylethanol (**6a**, 27%). The product **6a** was isolated from the reaction mixture by preparative GLPC, and identified by comparing its IR and NMR spectra with those of an authentic sample,[33] which was prepared by irradiation of **5a** in methanol; NMR (CCl_4): δ 2.50 (s, 1H, exchangeable with D_2O), 3.15 (s, 3H), 4.05 (d, J=6 Hz, 1H), 4.60 (d, J=6 Hz, 1H), and 7.0—7.2 (m, 5H).

2-Ethoxy-2-methoxy-1-phenylethanol (**6b**) and 2-isopropoxy-2-methoxy-1-phenylethanol (**6c**) were similarly isolated from the photooxidation mixtures of *cis*-β-ethoxystyrene (**1b**) and *cis*-β-isopropoxystyrene (**1c**) in methanol, respectively. The structures were determined by comparing their NMR spectra with that of **6a**. The NMR spectra showed that each of the ethanols consisted of two stereoisomers.

2-Ethoxy-2-methoxy-1-phenylethanol (**6b**), bp 76 °C/1 Torr; NMR(CCl_4): δ 0.92 and 1.13 (t, J=6 Hz, 3H), 3.29 and 3.09 (s, 3H), 3.3—3.8 (m, 2H), 4.09 (broad s, 1H), 4.18 (d, J= 6.5 Hz, 1H), 4.47 (d, J=6.5 Hz, 1H), and 7.0—7.4 (m, 5H); Found: C, 67.00; H, 7.88%. Calcd for $C_{11}H_{16}O_3$: C, 67.32; H, 8.21%.

2-Isopropoxy-2-methoxy-1-phenylethanol (**6c**), bp 84 °C/1 Torr; NMR(CCl_4): δ 0.65—1.25 (m, 6H), 3.0 (broad s, 1H), 3.11 and 3.36 (s, 3H), 3.50 and 3.82 (m, 1H), 4.25 (d, J=6 Hz, 1H), 4.43 (d, J=6 Hz, 1H), and 7.0—7.4 (m, 5H); Found: C, 68.41; H, 8.61%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.62%.

2,2-Dimethoxy-1,1-diphenylethanol (**8**) was isolated similarly from the reaction mixture of 2-methoxy-1,1-diphenylethylene (**2**) in methanol. The structure was determined by comparing its NMR spectrum with that of an authentic sample.

In Benzene and Acetonitrile. Photooxidation was performed in a similar way to that in methanol. The reaction mixtures were, after rotary evaporation, analyzed quantitatively by GLPC.

3-Methoxy-2,2-diphenyloxirane (**7**) was isolated from the reaction mixture in benzene by preparative GLPC and

identified by comparison of its IR and NMR spectra with those of an authentic sample.

Autoxidation of cis-*β*-*Methoxystyrene (**1a**) in the Dark without Initiator.* Neat **1a** (432 mg, 3.16 mmol) was stirred overnight at room temperature under oxygen atmosphere in the dark. GLPC analysis of the reaction mixture revealed almost complete consumption of **1a** and the formation of benzaldehyde (47%), benzoic acid, methyl formate (8%), and **5a** (28%).

A solution of **1a** (134 mg, 1.0 mmol) in methanol (2 ml) was stirred for 10 h under oxygen at room temperature in the dark. GLPC analysis of the reaction mixture showed a quite low consumption of **1a** and the formation of trace amounts of benzaldehyde and **6a**.

*Effect of Oxygen Pressure on the Product Yields in Autoxidation of **1a**.* Neat **1a** (134 mg, 1.0 mmol) containing azobisisobutyronitrile (6.8 mg, 0.04 mmol) was stirred at 50 °C for 5.5 h in the dark under an atmosphere of varying partial pressures of oxygen (760—40 Torr) diluted with nitrogen (760 Torr in the total pressure). The yields of benzaldehyde and **5a** were determined by GLPC as shown in Fig. 1.

Effects of Hydroquinone, Diazabicyclo[2.2.2]octane (DABCO), and Olefins on the Oxygenations of β-Alkoxystyrenes. As an example, a solution of **1a** (134 mg, 1.0 mmol) and hydroquinone (11 mg, 0.1 mmol) in benzene (2 ml) was irradiated under oxygen atmosphere for 6 h at room temperature in a Pyrex tube with a 400-W high pressure mercury lamp. No consumption of **1a** was confirmed by GLPC analysis.

Neat **1a** (134 mg, 1.0 mmol) was stirred overnight with hydroquinone (11 mg, 0.1 mmol) at room temperature under oxygen atmosphere in the dark. GLPC analysis of the sample revealed almost no consumption of **1a** and the formation of no oxidation products. Neat **1b** and **1c** were also not consumed under similar conditions.

Neat **1a** (134 mg, 1.0 mmol) was similarly stirred with DABCO (11 mg, 0.1 mmol) instead of hydroquinone under oxygen. The olefin was almost completely recovered as revealed by GLPC analysis.

Neat **1a** (134 mg, 1.0 mmol) was stirred overnight with azobisisobutyronitrile (16 mg, 0.1 mmol) and DABCO (11 mg, 0.1 mmol) under oxygen at 50 °C. GLPC analysis of the sample showed almost no consumption of **1a**.

Neat **1a** (134 mg, 1.0 mmol) was stirred for 6 h with 2,3-dimethyl-2-butene or 1-methylcyclohexene (0.5 mmol) under oxygen at room temperature in the dark. NMR and GLPC analyses of the reaction mixture showed the formation of benzaldehyde, methyl formate, and **5a** and almost no consumption of the butene or the cyclohexene.

Charge-Transfer (C-T) Absorption Spectra of Sytrene Derivatives. C-T Spectra with Molecular Oxygen. Samples of **1a** (neat or 0.3 mol/dm^3 in cyclohexane) were placed in a sample cell and a reference cell, and a stream of oxygen was passed for several minutes through the sample in the sample cell. Spectra were measured at 0 and 23 °C. Immediately after a spectrum was recorded, argon was passed through the sample and a spectrum was again measured. The band observed under oxygen atmosphere completely disappeared at 0 °C by argon bubbling; however, at 23 °C the band remained at one-fourth of the intensity under oxygen atmosphere.

C-T Spectra with Tetracyanoethylene (TCNE). Solutions of the C-T complexes were prepared immediately before measurements by mixing dichloromethane solutions of TCNE (0.01 mol/dm^3) with solutions of **1a** (0.23—0.34 mol/dm^3) or styrene (3.7—8.0 mol/dm^3) in the same solvent. The spectra were measured at 23 °C by a conventional method using a Hitachi 200-20 spectrophotometer. In a reference cell was placed a dichloromethane solution of a donor at the same concentration as in a sample cell.

Iminodimagnesium Reagents. Condensation Reaction with Ketones. Direct Preparation of Anils and a Hydrazone of Xanthone

Masao Ōkubo,* Saeko Hayashi, Mayumi Matsunaga, and Yumiko Uematsu

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840

(Received September 26, 1980)

The condensation reaction of ketones with iminodimagnesium reagents ($RN(MgBr)_2$) derived from various primary amines as well as 1,1-disubstituted hydrazines was investigated. *N*-Arylimines and 1-methyl-1-phenylhydrazones of diaryl ketones were prepared, their yields being affected by the electronic and positional effects of substituents of reagent and substrate. Direct preparation of some anils of xanthone and its 1-methyl-1-phenylhydrazone was achieved by use of the corresponding iminodimagnesium reagents.

Aryliminodimagnesium reagents ($ArN(MgBr)_2$, aryl-IDMg) derived from methoxy-substituted anilines were reported recently[1] to be condensed with benzophenones and fluorenone (Scheme 1, R=*o*- and *p*-$MeOC_6H_4$; R^1 and R^2=aryl).

$$R\text{-}NH_2 + 2EtMgBr \longrightarrow R\text{-}N(MgBr)_2 + 2EtH\uparrow$$

$$R\text{-}N(MgBr)_2 + O{=}C\begin{matrix}R^1\\R^2\end{matrix} \longrightarrow R\text{-}N{=}C\begin{matrix}R^1\\R^2\end{matrix}$$

Scheme 1.

No extensive studies have been carried out on reagents of this type.[2,3] In order to find the characteristics of IDMg reaction with ketones, we carried out the reaction of diaryl ketones and acetophenone with IDMg reagents derived from arylamines and alkylamines as well as 1,1-disubstituted hydrazines, the results being reported in this paper. Xanthone, which is unreactive towards "carbonyl reagents," gives condensation products by this method.

Results and Discussion

All the experiments 1—24 were carried out in tetrahydrofuran (THF) under nitrogen atmosphere, with use of equimolar amounts of ketones and IDMg reagents except for 11 and 12. Product yields are given in Tables 1—3. The reaction time at room temperature and at 55—60 °C were not optimized and the molar ratio of reagents with ketones was fixed; the yields indicate the reactivity of both components used in individual experiments.

Effect of Alkyl Group of Reagents and Substrates. Applicability of the method to the condensation of alkylamine with benzophenone and to that of arylamine with enolizable ketone has been studied.

When benzophenone was treated with *t*-butyl-IDMg at 50 °C for 2 h, 25% yield of *N*-benzhydrylidene-*t*-butylamine **1** was detected by NMR of the product mixture obtained after quenching with aqueous ammonium chloride. When the same ketone was treated with less hindered isobutyl-IDMg at room temperature for 192 h, the yield of the corresponding imine **2** estimated by NMR after quenching with absolute methanol was *ca.* 50%. A by-product, diphenylmethanol, was formed in *ca.* 50% yield. Since **1** and **2** undergo hydrolysis easily, their isolation by column chromatography was difficult even by use of silica gel dried at 120 °C for 2 h.

An attempt to condense acetophenone with *p*-methylphenyl-IDMg by heating at 60 °C for 5 h was unsuccessful. Even by quenching with absolute methanol, TLC of the product mixture shows the presence of only trace amounts of *N*-(α-methylbenzylidene)-*p*-methylaniline **3** and the aldol condensation product, 1,3-diphenyl-2-buten-1-one: formation of the latter is reasonable since similar basic anilinomagnesium reagents (PhN(R)MgBr, R=H and Me)[4] were used as catalyst for the aldol condensation. An authentic sample of **3** was also hydrolyzed during the treatment with silica gel.

The easily hydrolyzable nature of ketimines **1**—**3** can be ascribed to the insufficient conjugation system as compared with those having three aryl groups around the >C=N– groups (*vide infra*). The results indicate that the method is not suitable for preparing ketimines from alkylamines and enolizable ketones; the reported method using a Lewis acid, $TiCl_4$,[5] is preferable. In the following experiments, aryl-IDMg and diaryl ketones were used.

Aryl-IDMg and Diaryl Ketones. Electronic as well as positional effects of substituents of aryl-IDMg and those of diaryl ketone were examined (Table 1).

m-Methoxyphenyl-IDMg gives anil **4** in moderate yield in the reaction with a 2-methyl-substituted benzophenone; *o*-methylphenyl-IDMg, however, gives anil **5** in poor yield in the reaction with the same ketone. Sterically much hindered 2,4,6-trimethylphenyl-IDMg does not undergo condensation with unhindered 4-methylbenzophenone, but does with planar and less hindered fluorenone; the yield of **7** is low.

p-Chlorophenyl-IDMg, which is less reactive due to the electron-attracting effect of the substituent, can be condensed with a 2-methyl-substituted benzophenone, the yield of **8** being moderate. The IDMg reagent derived from 2-aminopyridine, which is also less reactive due to chelation of the ring nitrogen atom to the Mg atom, gives no condensation product with 2-methylbenzophenone, but does with fluorenone.

Formation of by-products, diarylmethanols, should originate from the initially formed ketyl radicals, which abstract hydrogen from the solvent molecule when the subsequent addition process is slow. The initial formation of ketyl radicals due to electron-transfer from Grignard reagent to benzophenones was discussed.[6]

Aryl-IDMg and 2-Methoxybenzophenones. Condensation of phenyl-IDMg with 2-methoxybenzophenone was accompanied by replacement of the *o*-methoxyl

Table 1. Effect of substituents on the reaction of $ArN(MgBr)_2$ with benzophenones and fluorenone

Anil No.	$ArN(MgBr)_2$ Ar	Ar^1–CO–Ar^2 Ar^1	Ar^2	Yield of the anil/%[a]	By-product
4	3-$MeOC_6H_4$	2-MeC_6H_4	4-MeC_6H_4	57

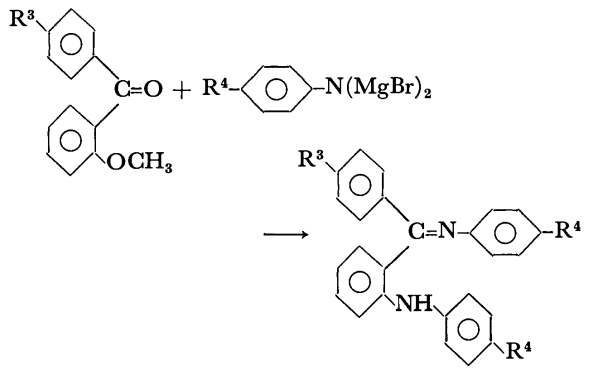
12	4-MeC_6H_4[c]	2-$MeOC_6H_4$	4-MeC_6H_4	20	

a) Heated at 55 °C for 10—20 h. b) Fluorenone. c) Reaction conditions are given in the text. d) Reagent containing metallic Mg was used.

group, leading to the formation of 2-anilino-substituted anil (Scheme 2, R^3 and R^4=H).[1] However, the "normal" anil **11** (Table 1) was obtained by treating 2-methoxy-4′-methylbenzophenone with five molar equivalents of *p*-methylphenyl-IDMg at 55 °C for 10 h: **11** was recovered unchanged after treatment with three molar equivalents of the reagent at 55 °C for 6 h.



Scheme 2.

In the reaction carried out in order to examine the effect of equimolar excess of metallic magnesium, the condensation-replacement product **12** was obtained (Scheme 2, R^3 and R^4=Me) in 20% yield. The metal dissolved smoothly with intense purple coloration due to the formation of ketyl radicals developed from the metal surface. The condensation-replacement reaction[1] is thus due to the accidental presence of excess metallic magnesium after the preparation of EtMgBr.

The high radical concentration caused by the efficient electron-donor, metallic magnesium, is one reason for the methoxyl replacement. Similar methoxyl replacement in Grignard reaction *via* electron-transfer process was discussed.[7]

Aryl-IDMg and Xanthone. Xanthone does not undergo condensation with hydroxylamine and phenylhydrazine owing to the electron-releasing resonance effect of the ethereal oxygen atom. So far the oxime and the hydrazone have been obtained after the conversion of ketone into more reactive thioketone.[8] The anil was obtained indirectly from 2,2′-dihydroxybenzophenone by strong heating with aniline.[9] The nonreactivity

Table 2. Reaction of $ArN(MgBr)_2$ with xanthone

Anil No.	$ArN(MgBr)_2$ Ar	Yield of the anil/%[a]
13	4-MeC_6H_4	86
14	2-MeC_6H_4	0
15	4-$MeOC_6H_4$	53
16	3-$MeOC_6H_4$	50
17	4-ClC_6H_4	0
18	2-Pyridyl	0

a) Heated at 55—60 °C for 10—20 h.

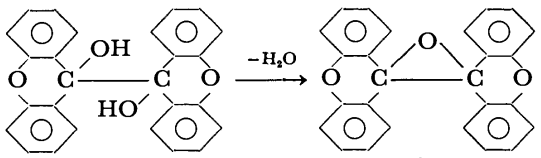
of xanthone towards amino-functional reagents and its normal reactivity towards Grignard reagents[10] led us to examine the reaction with IDMg (Table 2).

The ketone can be condensed satisfactorily with *p*-methyl-, *p*- and *m*-methoxyphenyl-IDMg giving anils **13**, **15**, and **16** after heating for more than 10 h. No anil **13** was formed after heating of the reaction mixture for 2 h in contrast with the moderate yields of benzophenone anils by heating for only 30 min.[1] IDMg reagents derived from *o*-methyl- and *p*-chloroaniline as well as 2-aminopyridine, less reactive in the reaction with benzophenones, gave no expected products.

In spite of the lower reactivity, anils of xanthone have been prepared directly for the first time.

IDMg Reagents Derived from 1,1-Disubstituted Hydrazines and Diaryl Ketones. The IDMg reagent derived from 1-methyl-1-phenylhydrazine was found to be useful (Table 3): diaryl ketones including xanthone give excellent yields of the hydrazones **19**, **21**, and **24** after heating for a short time except much hindered 2,3,5,6-tetramethylbenzophenone which was recovered unchanged.

The reagent derived from 1,1-dimethylhydrazine is not effective, which resembles the results obtained with



Scheme 3.

use of the reagents derived from alkylamines. By-products should be derived from the ketyl radicals. The epoxide **25** isolated from the reaction mixture with xanthone indicates the intermediate formation of the corresponding pinacol (Scheme 3).[11]

Characteristics of IDMg Reaction with Ketones. Taking the previous results[1] into account, characteristics of the reaction can be summarized as follows.

i) Arylamines, 1-methyl-1-phenylhydrazine, and diaryl ketones are favorable components, but not alkylamines, 1,1-dimethylhydrazine and enolizable ketones,

ii) Steric hindrance effect caused by *o*-methyl group of diaryl ketone is overcome when the IDMg reagent is unhindered, and *vice versa*,

iii) Strongly electron-donating methoxyl group, unfavorable to Lewis acid catalyzed condensation, is favorable to the IDMg method,[1]

iv) Xanthone gives anils when reactive aryl-IDMg reagents are used,

v) IDMg reagent derived from 1-methyl-1-phenylhydrazine gives excellent yields of hydrazones of diaryl ketones including xanthone, and

vi) Initial electron-transfer from IDMg reagent to ketones is suggested.

Experimental

Melting points are uncorrected.

Materials. Commercial *t*-butylamine, isobutylamine, all the anilines, 2-aminopyridine, acetophenone, benzophenone, 4-methylbenzophenone, fluorenone, xanthone, 1,1-dimethylhydrazine, and 1-methyl-1-phenylhydrazine were used. 2-Methyl- and 2,4′-dimethylbenzophenone were prepared by the Friedel-Crafts method. 2-Methoxy-4′-methylbenzophenone (mp 64—65 °C) was prepared by the addition of 4-methylphenylmagnesium bromide to 2-methoxybenzaldehyde followed by chromium(VI) oxide oxidation in acetic acid. 2,2′-Dimethylbenzophenone (mp 72 °C) was prepared by treatment of 2-methylbenzoyl chloride with 2-methylphenylmagnesium bromide. Authentic sample of *N*-(α-methylbenzylidene)-*p*-methylaniline **3** was prepared according to the reported method.[12]

Procedures. A typical procedure for IDMg reaction was described.[1] All the experiments were carried out using 5—10 mmol of reagents and substrates in 40—50 ml THF: reaction conditions and yields of isolated products are given in the text and in Tables 1—3.

Column chromatography (Wakogel C-200, petroleum benzine–benzene–diethyl ether = 10 : 1 : 1) was applied to the isolation of products except **13** and **19**: all the condensation products were eluted faster than the unreacted ketones. The isolated crystalline products were recrystallized from ethanol.

Products. Presence of diarylmethanols in product mixtures was confirmed by TLC as well as the NMR signal at 5.4—5.7 ppm characteristic of their benzylic protons.

The NMR spectrum of epoxide **25** (8.48—8.52 (4H, m) and 7.12—7.92 (12H, m)) resembles closely that of xanthone. The IR spectrum, resembling also that of the ketone, has another absorption band at 1070 cm^{-1} assignable to ν(C–O–C) vibration. Found: C, 83.02; H, 4.29; O, 12.69%. Calcd for $C_{26}H_{16}O_3$: C, 82.97; H, 4.25; O, 12.76%.

Imine, anil or hydrazone, melting point, NMR data, and result of elemental analysis are as follows: Imine **2**: an oil; NMR (CCl_4): δ=7.18—7.98 (10H, m), 3.16 (2H, d), 2.00 (1H, m), 0.97 (6H, d). The Adsorption of Nucleic Acid Bases by Raney-nickel, -cobalt, and -copper

Keisuke MITA,* Kazuhiko HOTTA, and Shoji WATANABE
Osaka Municipal Technical Research Institute, Ogimachi, Kita-ku, Osaka 530
(Received October 18, 1980)

The order of the relative affinity of adenine (A), guanine (G), cytosine (C), thymine (T), and uracil (U) to Raney-nickel, Raney-cobalt and Raney-copper was determined in an alkaline solution by means of a column-chromatographic method. These bases could be placed in these orders: G>A>C>U>T for Raney-nickel, G>C>A>T~U for Raney-cobalt, and A~G~C>T~U for Raney-copper. It was also found that these Raney-metals could be placed in the following order as to ability to distinguish those bases: Raney-nickel≫Raney-cobalt> Raney-copper.

It has been well known that metallic nickel powder can induce lung cancer.[1,2] Some investigators consider that the interaction between DNA and the nickel ion leached from metallic nickel is directly responsible for producing cancer.[1,3] The reactions of nucleic acids, nucleotides, nucleosides, or bases with the nickel ion have, therefore, been studied by many workers.[2,4,5] Although it has been known that the nickel ion interacts with both nucleic acid bases and phosphate portions in DNA, there have been few reports concerning the precise interaction sites of nucleic acids with the nickel ion.

In the present work, we determined the order of the relative affinities of adenine, guanine, cytosine, thymine, and uracil for metallic nickel, cobalt, and copper by means of a column-chromatographic method and tried to estimate the interaction sites of nucleic acid with the metal ions. Raney-nickel (R-Ni), Raney-cobalt (R-Co), and Raney-copper (R-Cu) were used as the metals because of their high surface area and well-known surface properties.[6,7]

Experimental

R-Ni (Ni: 2.5 g), R-Co (Co: 10 g), and R-Cu (Cu: 10 g) were prepared from commercial Raney metal–aluminium alloys (Al/metal: 50 atom%) by leaching out the aluminium with a 13% sodium hydroxide solution for 1 h at 70, 50, and 50 °C respectively. After washing with distilled water, each sample was packed in a 1-cm-diameter column, which was fitted at the bottom with a cotton to retain the sample, to a height of approximately 5, 20, or 20 cm respectively. A 0.2 mol dm^{-3} sodium hydroxide solution containing two or three kinds of bases at 2.0 mmol dm^{-3} was allowed to flow into the column at a rate of 10 ml/h. The effluent was collected by fraction collecter. The concentration of each base in the effluent fractions could then be determined by using the absorption spectra of the fractions and by solving Eq. 1:

$$\begin{aligned}
\frac{A_\alpha}{A_\alpha}x + \frac{B_\alpha}{B_\beta}y + \frac{C_\alpha}{C_\gamma}z &= S_\alpha\,, \\
\frac{A_\beta}{A_\alpha}x + \frac{B_\beta}{B_\beta}y + \frac{C_\beta}{C_\gamma}z &= S_\beta\,, \\
\frac{A_\gamma}{A_\alpha}x + \frac{B_\gamma}{B_\beta}y + \frac{C_\gamma}{C_\gamma}z &= S_\gamma\,,
\end{aligned} \tag{1}$$

where A_α, A_β, and A_γ are the absorbances of a 0.1 mol dm^{-3} H_2SO_4 or 0.1 mol dm^{-3} NaOH standard solution containing known quantities of base-A at the maximum absorption wavelengths of base-A (α), base-B (β), and base-C (γ) respectively. Moreover B_α, B_β, and B_γ are the absorbances of base-B, and C_α, C_β, and C_γ, those of base-C at the wavelengths of α, β, γ respectively. S_α, S_β, and S_γ are the absorbances of the standard solutions containing a known quantity of the effluent fraction at the wavelengths of α, β, and γ, while x, y, and z are the concentrations of base-A, base-B, and base-C respectively in the fraction.

The uncertainty of the method is determined by mixing these bases in different known proportions and by estimating the base contents in the mixtures by means of Eq. 1. The experimental conditions are shown in Table 1.

Results and Discussion

It has been known that the fraction of the metallic surface is in the range of 55—85% for conventional preparations of Raney-metals, and the residual fraction is considered to be alumina.[7] In order to examine whether or not the nucleic-acid bases can be absorbed by alumina, a 0.2 mol dm^{-3} sodium hydroxide solution containing these bases was allowed to flow into a column packed with γ-alumina. Since the adsorption of these bases by γ-alumina could not be observed, the possibility of adsorption by alumina on Raney-metals can be disregarded.

In the present work, Raney-cobalt or Raney-copper column is packed with an amount four times that of the

Table 1. Experimental conditions

Bases A	Bases B	Bases C	Standard solution	Wavelength/nm α	Wavelength/nm β	Wavelength/nm γ	Uncertainties %
Guanine,	Uracil,	Cytosine	0.2 mol dm^{-3} H_2SO_4	248,	260,	276	5
Adenine,	Guanine,	Thymine	0.2 mol dm^{-3} NaOH	269,	274,	291	20
Guanine,	Adenine,	Cytosine	0.2 mol dm^{-3} H_2SO_4	248,	262.5,	276	5
Adenine,	Cytosine		0.2 mol dm^{-3} H_2SO_4	262.5,	276		5
Uracil,	Thymine		0.2 mol dm^{-3} NaOH	284,	291		20

Raney-nickel column, because the amount of the bases adsorbed at saturation for R-Ni is about four times those of R-Co and R-Cu. Therefore, it can be considered that the effluent volume/time·metallic surface area is nearly same in each column.

Figures 1—3 show the breakthrough curves of a guanine-uracil-cytosine mixture for R-Ni, R-Co, and R-Cu respectively. It can be seen from Figs. 1 and 2 that the relative affinities of these three bases for R-Ni and R-Co can be placed in this order: guanine>cytosine >uracil. In the case of R-Cu, on the other hand, the relative affinities of these bases can be placed in this order: guanine~cytosine>uracil, because the breakthrough curves exhibit no differences between guanine and cytosine, as is shown in Fig. 3. By comparing the breakthrough curves in Figs. 1—3 with each other, it can be seen that these Raney-metals can be placed

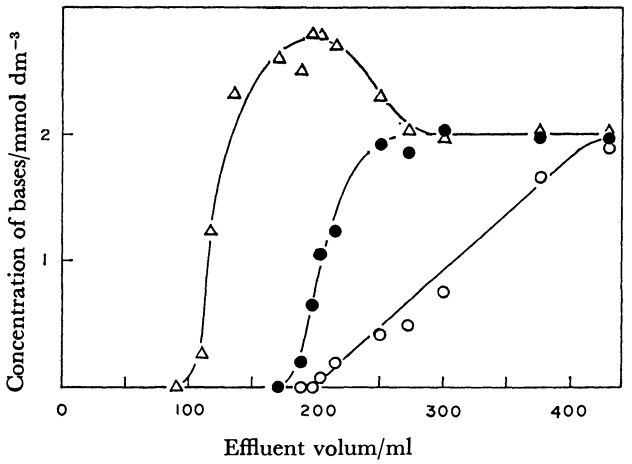

Fig. 1. Breakthrough curves on R-Ni for 0.2 mol dm^{-3} NaOH solution containing guanine (○), cytosine (●) and uracil (△) at the concentration of 2 mmol dm^{-3} respectively.
R-Ni: 2.5 g as nickel, column: 1.0×5 cm, flow rate: 10 ml/h.

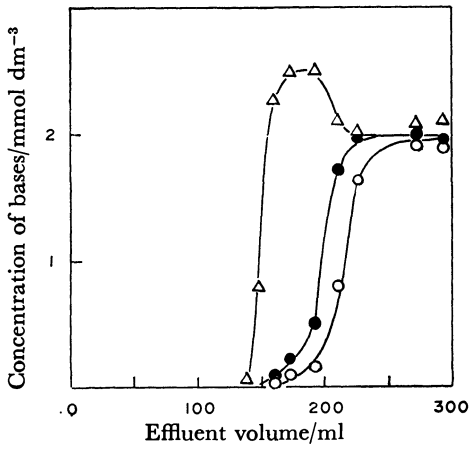

Fig. 2. Breakthrough curves on R-Co for 0.2 mol dm^{-3} NaOH solution containing guanine (○), cytosine (●) and uracil (△) at the concentration of 2 mmol dm^{-3} respectively.
R-Co: 10 g as cobalt, column: 1.0×20 cm, flow rate: 10 ml/h.

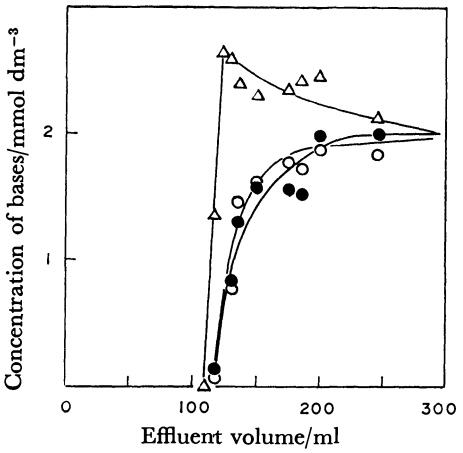

Fig. 3. Breakthrough curves on R-Cu for 0.2 mol dm^{-3} NaOH solution containing guanine (○), cytosine (●) and uracil (△) at the concentration of 2 mmol dm^{-3} respectively.
R-Cu: 10 g as cupper, column: 1.0×20 cm, flow rate: 10 ml/h.

in the following order of ability to distinguish these bases: R-Ni>R-Co>R-Cu.

The breakthrough curves of a guanine-adenine-thymine mixture for R-Ni, R-Co, and R-Cu were found to give patterns similar to Figs. 1—3 respectively. It was shown from the breakthrough curves that, among these three bases, thymine exhibits the weakest affinities for Raney-metals. From these results and Figs. 1—3, it appeared that these five bases can be classified into two groups, one of which exhibits relatively strong affinities (guanine, adenine, and cytosine) for Raney-metals, while the other exhibits relatively weak affinities (uracil and thymine).

Figures 4—6 show the breakthrough curves of a guanine-adenine-cytosine mixture for R-Ni, R-Co, and R-Cu respectively. It appears from Fig. 4 that the relative affinities of these three bases for R-Ni can be placed in this order: guanine>adenine>cytosine. On the other hand, it can be seen from Fig. 5 that the relative affinities of these bases for R-Co can be placed in this order: guanine>cytosine>adenine. It may be noted that a reversed order of adenine and cytosine is observed for R-Co. This difference between R-Ni and R-Co was also confirmed by the breakthrough curves of the cytosine-adenine mixture, as shown in Fig. 7. In the case of R-Cu, however, no differences in these three bases could be detected, as is shown in Fig. 6.

Figure 8 shows the breakthrough curves of a uracil-thymine mixture for R-Ni, R-Co, and R-Cu. It appears that the relative affinities of these two bases can be placed in this order: uracil>thymine for R-Ni, while in the case of R-Co and R-Cu no differences between the relative affinities of these two bases was observed within the limits of experimental error.

In conclusion, the present experiment has made it obvious that the relative affinities of these five bases can be placed in these orders: guanine>adenine> cytosine>uracil>thymine for R-Ni, guanine>cytosine> adenine>thymine~uracil for R-Co, and adenine~ guanine~cytosine>thymine~uracil for R-Cu. It is

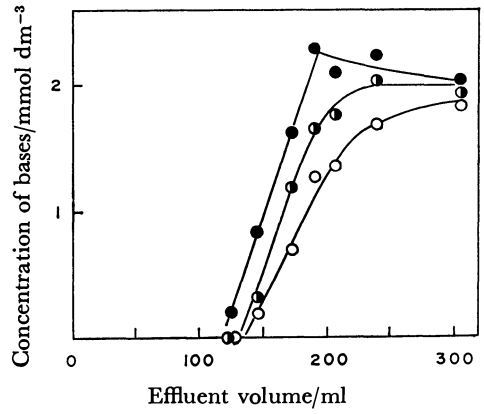

Fig. 4. Breakthrough curves on R-Ni for 0.2 mol dm^{-3} NaOH solution containing adenine (◑), guanine (○) and cytosine (●) at the concentration of 2 mmol dm^{-3} respectively.

R-Cu: 10 g as cupper, column: 1.0×20 cm, flow rate: 10 ml/h.

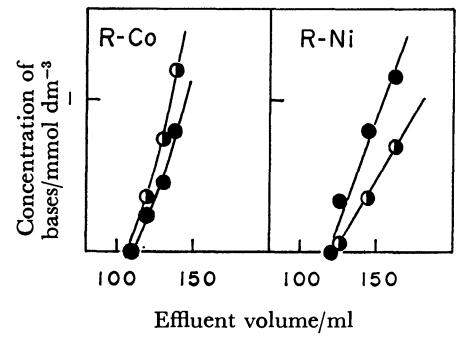

Fig. 7. Breakthrough curves on R-Ni and R-Co for 0.2 mol dm^{-3} NaOH solution containing adenine (◑) and cytosine (●) at the concentration of 2 mmol dm^{-3} respectively.
R-Ni: 2.5 g as niekel, 1.0×5 cm column, R-Co: 10 g as cobalt, 1.0×20 cm column, flow rate: 10 ml/h.

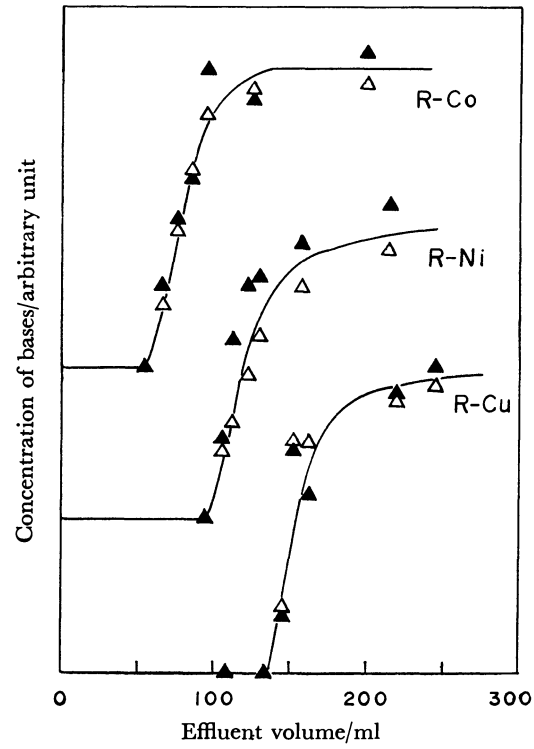

Fig. 8. Breakthrough curves on R-Ni, R-Co, and R-Cu for 0.2 mol dm^{-3} NaOH solution containing thymine (▲) and uracil (△) at the concentration of 2 mmol dm^{-3} respectively.
R-Ni: 2.5 g as nickel, R-Co: 10 g as cobalt, R-Cu: 10 g as cupper, flow rate: 10 ml/h.

also obvious that the ability of Raney-metals to distinguish these bases can be placed in this order: R-Ni> R-Co>R-Cu.

It has been reported that Cu(II),[8-13] Mn(II),[14,15] and Co(II)[14] ions bind mainly to guanine among the bases in nucleic acids. It has also been reported that the antitumor *cis*-dichlorodiammineplatinum(II) complex indicates a preferential binding to guanine,[16-20] followed by adenine[18,21] in DNA. It has also been established that the Ni^{2+}–AMP complex is far more stable than Co^{2+}–AMP complex.[22] On the other hand,

the formation of a stable Co^{2+}–CMP complex has been reported.[23,24] Such similarities of behavior between Raney-metals and their metal ions may suggest that the order of the relative affinities of these bases for the nickel ion is similar to that for Raney-nickel. It would also be interesting to determine whether or not the large ability of Raney-nickel to distinguish these bases is reflected by that of the nickel ion.

Reaction of Organic Tin(II) Compound with Carbonyl Compound

Ikuko WAKESHIMA* and Ichiro KIJIMA

Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received October 22, 1980)

The reactions of organic tin(II) compounds bearing Sn–OC bonds with carbonyl compounds, C_6H_5COR (R=C_6H_5CO, C_6H_5, and H) and *p*-benzoquinone, have been investigated. The tin(II) compound reacted with benzil and *p*-benzoquinone to yield the corresponding oxidative addition products. However, the oxidative addition reaction did not occur in benzophenone and benzaldehyde.

We have reported the preparation of organic tin(II) compounds having a high volatility and an excellent solubility toward organic solvents.[1] The chemical behavior of the tin(II) compounds[2–5] has been studied by several research groups: for example, we reported on the reactions of the tin(II) compounds with alkyl halides and heterocumulenes.[2] We describe here a further study on the reactivity of tin(II) compounds, $Sn(OR)_2$, (R=$(CH_3)_2NCH_2CH_2$–, C_2H_5–, *o*-$C_2H_5OCOC_6H_4$–, $CH_3\overset{|}{C}$=$CHCOCH_3$, and $CH_3\overset{|}{C}$=$CHCO_2C_2H_5$), with carbonyl compounds such as benzil, benzophenone, benzaldehyde, and *p*-benzoquinone; the structural analogy of the tin(II) compound with a carbene is important here.

Results and Discussion

The reaction of bis(2-dimethylaminoethoxo)tin(II) (**1**) with benzil in refluxing THF for 6 h afforded yellow powders in 46% yield. The structure of the product was determined as bis(2-dimethylaminoethoxo)(1,2-diphenyl-1,2-ethenediolato)tin(IV), on the bases of the elemental analysis ($C_{22}H_{30}N_2O_4Sn$), the IR spectrum which has no band attributable to $\nu_{C=O}$ (1655 cm^{-1}), and the formation of 1,2-diphenylvinylene dibenzoate when the product was treated with benzoyl chloride. The structure was also supported by its hydrolyzate: on hydrolysis, the product gave benzoin, which appeared to be formed by a rapid tautomerization of the unsaturated glycol, 1,2-diphenyl-1,2-ethenediol.

These facts suggest that compound (**1**) can be oxidized by benzil to a tetravalent tin compound, as shown in Eq. 1:

$$Sn\left(OCH_2CH_2N\begin{matrix}CH_3\\CH_3\end{matrix}\right)_2 + C_6H_5COCOC_6H_5 \longrightarrow \left(\begin{matrix}CH_3\\CH_3\end{matrix}NCH_2CH_2O\right)_2 Sn\begin{matrix}O\text{-}C\\O\text{-}C\end{matrix}\begin{matrix}C_6H_5\\C_6H_6\end{matrix} \quad (1)$$

The reaction proceeded more readily in THF and ethyl alcohol than in benzene (see Table 1).

The reaction of various organic tin(II) compounds with benzil was also examined in THF. The results, as summarized in Table 2, reveal that i) organic tin(II) compounds containing Sn–OC bond are more effective reducing agents for benzil than tin(II) chloride, which is a polymer of intermolecularly coordinated Cl→Sn bond; ii) in the organic tin(II) compounds, the oxidative addition reaction of **1** is the best for benzil, while that of diphenoxotin(II) (**4**) is the worst; iii) the reactivity of alkoxotin(II) compounds (**1** and **2**) is superior that of the conjugated chelate tin(II) compounds (**3**, **5**, and **6**); and finally; iv) the reaction of the monomeric tin(II) compounds (**1** and **3**) proceeds far more readily than that of the corresponding associated tin(II) compounds (**2** and **4**).

From these facts, it may be concluded that the migration of 5s electrons on the tin(II) atom in the intermediate (a), as indicated in Eq. 2, play an important role in the reaction with benzil and that, of the organic tin(II) compounds, the monomeric organic tin(II) compound bearing an electron releasing group behaves most effectively toward benzil.

Table 1. Solvent effect on the reaction[a] of bis(2-dimethylaminoethoxo)tin(II) with benzil

Solvents	Hydrolyzate	
	Yield/%[b]	P[c]
Benzene	90	1.03
Ethyl alcohol	91	1.62
Tetrahydrofuran	95	1.76

a) Reaction conditions: [$Sn(OR)_2$]/[benzil]=1, time: 6 h; temp: benzene 80 °C, ethyl alcohol 78 °C, THF 67—68 °C. b) Based on the weight of benzil used in the reaction. c) Proportion ([benzoin]/[benzil]) of benzoin the hydrolyzate.

Table 2. Hydrolyzates of products from the reaction[a] of various organic tin (II) compounds with benzil in THF

$Sn(OR)_2$ R	Hydrolyzates	
	Yield/%[b]	P[c]
$(CH_3)_2NCH_2CH_2$-(**1**)	95	1.76

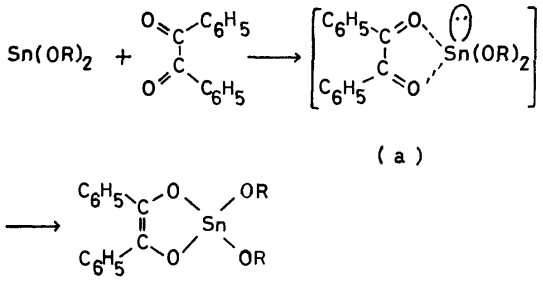
 (**3**)	87	0.41
 (**4**)	80	0.09
$CH_3\overset{|}{C}$=$CHCOCH_3$ (**5**)	83	0.14
$CH_3\overset{|}{C}$=$CHCO_2C_2H_5$ (**6**)	81	0.15
$SnCl_2$	86	0.03

a) Reaction conditions: [$Sn(OR)_2$]/[benzil]=1, time; 6 h, temp; 67—68 °C. b) Based on the weight of benzil used in the reaction. c) Proportion ([benzoin]/[benzil]) of benzoin in the hydrolyzate. d)Associated in nature.



(a) (2)

Compound **2** reacted unsatisfactorily with benzaldehyde in THF at 68—69 °C to give only traces of cinnamaldehyde and benzyl alcohol. Although the reaction was conducted under drastic conditions (no solvent, at 145±5 °C) for 3 h, there was no increase in the yields of cinnamaldehyde and benzyl alcohol. Therefore, it seems that the reaction of compound **2** with benzaldehyde proceeds neither through the oxidative addition reaction (Eq. 1) nor through the intermolecular oxidative coupling reaction (Eq. 3), but rather in a way similar to the Meerwein-Pondorf reaction, as shown in Eqs. 4 and 5:

$$Sn(OC_2H_5)_2 + 2\ C_6H_5CHO \not\longrightarrow (C_2H_5O)_2Sn(O\text{-}CH(C_6H_5)\text{-}O\text{-}CH(C_6H_5)) \quad (3)$$

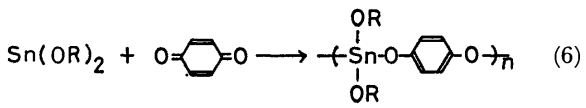
$$Sn(OC_2H_5)_2 + C_6H_5CHO \longrightarrow (C_2H_5O)Sn(OCH_2C_6H_5) + CH_3CHO \quad (4)$$

$$C_6H_5CHO + CH_3CHO \xrightarrow[H_2O]{Sn(OC_2H_5)_2} C_6H_5CH{=}CHCHO. \quad (5)$$

Compound **1** did not react at all with benzophenone in THF at 67 °C after 6 h.

The reaction of **1** and **5** with *p*-benzoquinone in benzene were investigated. As indicated in Table 3, it was found that each reaction readily gave the corresponding oxidative addition products in excellent yields.

The products were only soluble in common organic solvents with great dificulty and decomposed at high temperature. No chracteristic absorption band of *p*-benzoquinone presented itself. Therefore, the oxidative addition product is considered to be a polymer, as shown below:



(6)

R=$-CH_2CH_2N(CH_3)_2$, $CH_3C(CH_3)$=CHCOCH$_3$.

Although **5** was a less effective reducing agent for benzil, the reaction with *p*-benzoquinone took place easily to afford the oxidative addition compound. Therefore, it seems that the possibility of the oxidative addition reaction of organic tin(II) compounds depends greatly on the half-wave potentials of the carbonyl compounds: *p*-benzoquinone, benzil, benzaldehyde, and benzophenone have half-wave potentials of −0.146(2), −0.27(2), −0.94(1), and −0.94(1) SCE, respectively. The parenthesized-figure indicates the number of electrons involved in the reaction.

Experimental

All reactions were carried out in a nitrogen atmosphere dried with liquid nitrogen. The melting and boiling points are uncorrected. IR spectra were recorded with a Hitachi EPI-S2 spectrometer, and mass spectra were taken on Hitachi RMU-7 model double-focusing spectrometer. The CHN elemental analyses were carried out with a Yanagimoto MT-2 CHN corder. Gas chromatography was performed on a Yanagimoto model GCG-2, using SE-30 column.

Tin content was determined by chelate titration with M/100 EDTA aqueous solution. Benzil was determined by the redox titration with a chromous sulfate solution.[6] *p*-Benzoquinone was purified by sublimating a commercial extra-pure grade at 70—80 °C/20 mmHg (1 mmHg=133.322 Pa) just prior to use. Benzaldehyde and benzophenone were purified by distillation before use.

Reaction of Organic Tin(II) Compounds with Benzil in a 1 : 1 Molar Ratio. Benzil (50 mmol) was added to a solution or a suspension of organic tin(II) compound (50 mmol) in 100 ml of solvent. After the mixture was refluxed for 6 h, the reaction mixture was evaporated to dryness under reduced pressure. The residue was hydrolyzed with 100 ml of water (5 ml)–benzene (80 ml)–acetone(15 ml) solution. After separating the resulting solids by filtration, the solid was extracted with acetone in a Soxhlet extractor in order to obtain the benzoin. Subsequently, the mother liquor was combined with the extract and distilled *in vacuo* at a temperature below 155 °C (bath temperature) to isolate the hydrolyzate. Bp 118—138 °C/0.3 mmHg. The results are shown in Tables 1 and 2.

Isolation of Bis(2-dimethylaminoethoxo)(1,2-diphenyl-1,2-ethenediolato)tin(IV): Compound **1** (14.7 g, 50 mmol) and benzil (10.5 g, 50 mmol) were dissolved in 53 ml of THF. The mixture was heated at 68 °C for 6 h. Yellow powders precipitated during the reaction were filtered off, washed with THF, and dried: yield 12.0 g (47.5%). Found: C, 52.31; H, 6.01; N, 5.45; Sn, 23.05%. Calcd for $C_{22}H_{30}N_2O_4Sn$: C, 52.30; H, 5.94; N, 5.54; Sn, 23.62%. *m/e*: 505 (M^+). Mp 154 °C (dec).

Isolation of 1,2-Diphenylvinylene Dibenzoate: Benzoyl chloride (44.9 g, 106 mmol) was added drop by drop to the reaction mixture of **1** (7.3 g, 24.9 mmol) and benzil (5.2 g, 24.7 mmol) at 30—40 °C. After being warmed for 1 h, it was allowed to stand for 2 d at room temperature and then hydrolyzed with 100 ml of 9% hydrochloric acid. The resulting solids were

Table 3. Reaction with *p*-benzoquinone

Sn(OR)$_2$ R	Reaction conditions: Molar ratio [Quinone]/[Sn]	Reaction conditions: Time h	Products: Yield %	Products: Mp (dec) °C	Products: Sn Found(Calcd) (%)	Products: IR ν/cm^{-1}
$(CH_3)_2NCH_2CH_2-$	1	3	100	220	28.98(29.45)	1220
$CH_3C(CH_3)$=CHCOCH$_3$	1	5	95	245	27.69(27.93)	1210

isolated and extracted with diisopropyl ether. The ether solution was washed with 5% sodium carbonate aqueous solution, then with water, and evaporated to dryness. After removing the unreacted benzil under a reduced pressure, the residue was recrystallized from benzene–hexane (1/1 volume ratio) solution, giving 2.5 g of 1,2-diphenylvinylene dibenzoate with mp 156—158 °C (lit,[7] 158 °C); white powder. Found: C, 78.85; H, 4.68%. Calcd for $C_{28}H_{20}O_4$: C, 79.98, H, 4.79%. IR (KBr disk): $\nu_{C=O}$ 1720 cm^{-1}; ν_{C-O} 1082 cm^{-1}.

Reaction with p-*Benzoquinone.* A solution of 1.95 g (18 mmol) of *p*-benzoquinone in 37 ml of benzene was added drop by drop to **1** (5.31 g, 18 mmol) in benzene (20 ml) at 22—24 °C and then the solution was refluxed with stirring in an oil bath for 2 h. The precipitated solids were isolated by filtration, washed with benzene, and dried. Yield 7.25 g (100%).

The reaction of compound **5** was also carried out in a similar way.

Reaction with Benzaldehyde. Compound **2** (8.4 g, 40 mmol) and benzaldehyde (48.9 g, 461 mmol) were heated at 66 °C for 11 h. After filtrating the reaction mixture, traces of ethyl alcohol and cinnamaldehyde from the mother liquor were detected by gas chromatography. The residue in the filtrating flask was hydrolyzed with an aqueous diisopropyl ether. The solvent was removed by distillation; a trace of benzyl alcohol was found in the distillation flask.

The reaction under drastic conditions (no solvent, reaction temperature 145±5 °C, reaction time 3 h) was performed in a similar way. The presence of acetaldehyde, ethyl alcohol, cinnamaldehyde, and benzyl alcohol was confirmed by gas chromatography.

Reaction with Benzophenone. The mixture of **1** (16.2 g, 54.9 mmol) and benzophenone (10.3 g, 56.5 mmol) in 55 ml of THF was refluxed for 6 h. No decrease in Sn^{2+}% was observed. After removal of THF under a reduced pressure, the residue was hydrolyzed with 100 ml of water (15 ml)–benzene (80 ml)–acetone (15 ml) solution. The resultant solids were filtered off and then the mother liquor was evaporated to dryness. The solids were distilled *in vacuo*; 10 g of benzophenone (bp 153 °C/1 mmHg) was recovered.

The present work was partially supported by a Grant-in-Aid for Scientific Research No 555348 from the Ministry of Education, Science and Culture.

Synthesis of β-Substituted Tetramethyltetraazacyclotetradecatetraene and Its Metal(II) Complexes

Takao TOKUMITSU* and Takayuki HAYASHI

Department of Chemistry, Faculty of Science, Yamaguchi University, Yoshida, Yamaguchi 753

(Received October 27, 1980)

N,N'-Bis(1-methyl-3-thioxo-1-butenyl)ethylenediamine (**3**) was prepared by the reaction of *N,N'*-bis(1-methyl-3-oxo-1-butenyl)ethylenediamine with phosphorus pentasulfide in pyridine. The reaction of **3** with ethylenediamine gave 5,7,12,14-tetramethyl-1,4,8,11-tetraazacyclotetradeca-4,6,11,13-tetraene (**4**) in a 46% yield. The reactivity of the β positions of **4** and its metal(II) complexes (M=Cu, Ni, Pd) toward various electrophilic reagents was explored, and some β,β'-bissubstituted tetraaza macrocyclic compounds (substituent=Cl, $SC_6H_4NO_2$(o), N_2Ph) and their metal complexes were prepared, respectively. The former also reacted with metal(II) acetates to afford the same metal complexes.

The preparations and reactivities of tetraaza macrocycles and their metal complexes containing enamino imines conjugated systems have attracted considerable attention as models for natural tetraaza macrocycles, such as porphyrins and corrins. It is also interesting to elucidate the reactivity of the β positions of their macrocyclic ligands and metal complexes. Fischer *et al.*[1] have reported that the β positions of 5,14-dihydrodibenzo[*b,i*][5,9,14,18]tetraaza[14]annulene (**1**) react with *p*-chlorobenzenediazonium salt to give a 7,16-bis(*p*-chlorophenylazo)substituted derivative. The reaction of **1** with ethyl 1-chloro-3,3-dicyanopropenoate has also been found to yield a 7,16-bis(ethoxycarbonyl)-substituted derivative.[2] While nickel(II) complex of **1** reacted with bromine to give an octabromo derivative substituted into benzene nuclei.[2] Holm *et al.*[3] have found that some β,β'-bisphenylated macrocycles are prepared by the reaction of 4-phenyl-1,2-dithiolium salt with diamine. Jäger[4] has also reported the template synthesis of some macrocyclic metal complexes with COR or COOR groups at the β positions. This cyclization appears dependent on the presence of a carbonyl-containing group.[5] The macrocycle, 5,7,12,14-tetramethyl-1,4,8,11-tetraazacyclotetradeca-4,6,11,13-tetraene (**4**), without the substituents at the β positions has been prepared by the reaction of ethylenediamine with 4-amino-2-ethyl-2-oxonia-3-pentene[3b,5] and/or *N,N'*-bis(1-methyl-3-thioxo-1-butenyl)ethylenediamine (**3**), which is prepared from *N,N'*-bis(3-ethyl-3-oxonia-1-methyl-1-butenyl)ethylenediamine and sodium hydrogensulfide.[3a,6] In all these preparations, triethyloxonium tetrafluoroborate is required as a catalyst, and the yield is generally low.

We synthesized **4** without using the specific and expensive catalyst, and elucidated the electrophilic substitution reactivity of the β positions of the free ligand, **4**, and its metal(II) complexes (**6**).

Results and Discussion

The compound, **3**, was synthesized by means of reaction of *N,N'*-bis(1-methyl-3-oxo-1-butenyl)ethylenediamine (**2**) with phosphorous pentasulfide in pyridine in a 34% yield. The macrocycle, **4**, was obtained in the highest yield (46%) when **3** was refluxed with an equimolar amount of ethylenediamine in benzene for 24 h. By these reactions, **4** could be synthesized without using the expensive and specific catalyst.

The macrocycle, **4**, reacted with *N*-chlorosuccinimide (NCS) of 2.2 molar ratio at 5 °C in the dark under a nitrogen atmosphere to give 6,13-dichloro-5,7,12,14-tetramethyl-1,4,8,11-tetraazacyclotetradeca-4,6,11,13-tetraene (**5a**) in a 25% yield; the addition of 4.4 molar ratio gave 6,6,13,13-tetrachloro-5,7,12,14-tetramethyl-1,4,8,11-tetraazacyclotetradeca-4,7,11,14-tetraene (**8**) in a 42% yield. Under these conditions, it is considered that the reactions proceed by an ionic mechanism. Their structure was established by analytical and spectral data. That is to say, the NMR spectrum of **5a** showed the same pattern as that of **4**, except that absorption of –CH= protons in the vicinity of 4.5 ppm was missing. That of **8** also lacked the absorptions for –CH= and NH protons, and the protons of four CH_3 and four

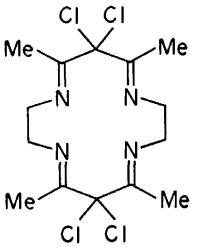
–CH_2– were equivalent and appeared as singlets. The IR spectrum in 1600 cm^{-1} region of **8** showed only one strong absorption at 1660 cm^{-1}, which was assigned to νC=N.[7] The mass spectrum showed the parent ion peak at *m/e* 384, and the UV spectrum exhibited an absorption maximum at 250 nm (ε, 580). This shows that **8** does not have a conjugated system. Compound **8** may be formed by Cl^+ attacking at the 6- and 13-

positions of **5a**, followed by the elimination of NH protons, analogously to the gem-dibromination of the β position of 1,4-diazepines.[8] The melting points, analytical data, and spectral data for the products are presented in Tables 1 and 2.



8

The reaction of **4** with *o*-nitrobenzenesulfenyl chloride in acetonitrile in the presence of triethylamine gave 5,7,12,14-tetramethyl-6,13-bis(2-nitrophenylthio)-1,4,8,-11-tetraazacyclotetradeca-4,6,11,13-tetraene ((**5b**) in a 25% yield. The NMR spectrum showed multiplet absorption for aromatic protons of 8H amount, and the IR spectrum showed strong absorptions at 1515 and 1337 cm^{-1}, which were assigned to $\nu_{as}NO_2$ and ν_sNO_2, respectively.

Compound **4** also reacted with benzenediazonium salt to give 5,7,12,14-tetramethyl-6,13-bis(phenylazo)-1,4,8,11-tetraazacyclotetradeca-4,6,11,14-tetraene(**5c**) in a 61% yield. Because this material is slightly soluble in $CDCl_3$, DMSO-d_6, pyridine-d_5, *etc.*, the NMR signal of NH protons of **5c** could not be detected. However, the IR spectrum showed a weak absorption centered at 3200 cm^{-1}, which was assigned to the intramolecular hydrogen bonded νNH, and showed no absorptions for the non-conjugated νC=N in the region of 1640—1690 cm^{-1}.[1,7] In contrast with the coupling product of **1**, which appears to exist as a hydrazo tautomer,[1] these results suggest that **5c** exists in a chelated azo form.

The metal(II) complexes, **6** (M=Cu, Ni, Pd), of **4** reacted with *o*-nitrobenzenesulfenyl chloride in the presence of pyridine to give 6,13-bis(2-nitrophenylthio)-substituted metal complexes (**7b**) in 83% (M=Ni) and 61% (M=Pd) yield, respectively, and **6** (M=Cu) gave decomposition products.

The reaction of **6** (M=Cu, Ni, Pd) with benzenediazonium salt also gave 6,13-bis(phenylazo)-substituted metal complexes (**7c**) in 53% (M=Cu), 97% (M=Ni) and 89% (M=Pd) yield, respectively.

The reaction of **6** (M=Ni, Pd) with benzoyl chloride in the presence of pyridine gave 6,13-dibenzoyl-substituted metal complexes (**7d**) in 57% (M=Ni) and 62% (M=Pd) yield, respectively, and **6** (M=Cu) also gave decomposition products. The structure of **7d** (M=Ni, Pd) was established as follows: the IR spectrum showed νC=O at 1625 and 1626 cm^{-1}, and NMR spectrum showed multiplet absorptions for 10H aromatic protons at 7.5—8.5 ppm; there was no absorption of the methine protons.

The free ligands, **5b** and **5c**, reacted with the metal(II) acetates (M=Cu, Ni, Pd) in DMF and/or DMSO to yield the corresponding metal complexes **7b** and **7c** in 79—90% yield, respectively. The complexation of **5a** gave decomposition products. The structures of these products were confirmed by direct comparison of the spectral data with the corresponding products derived from **6b** and **6c** and mixed examination. The **7b** (M=Cu), which could not be obtained by the reaction of **6** (M=Cu) with *o*-nitrobenzenesulfenyl chloride, was easily obtained by the reaction of **5b** with copper acetate in a 81% yield.

Attempts to synthesize other β,β'-disubstituted derivatives of **4** and **6** such as 6,13-dinitro-, 6,13-dibromo-, 6,13-diiodo-, 6,13-diformyl-, and 6,13-dithiocyano-derivatives were all unsuccessful, and **4** and **6** gave decomposition products, respectively. It thus appears that the substrates or products are unstable under these reaction conditions.

It is considered that the electrophilic reactivity of the β positions of the free ligand, **4**, and its metal(II) complexes, **6**, which are stabilized by the delocalization of π-electrons, may be attributed to their meneidic or regenerative character, as well as that of enamino ketones,[9] vinamidines and its salts[10] and the metal complexes of β-diketones.[11]

The IR spectra for the free ligands, **5a**, **5b**, and **5c**, show a broad absorption at 3200 cm^{-1} and a strong absorption at 1560—1576 cm^{-1} which are associated with νNH and δNH by the shift to lower frequencies owing to the replacement of active protons by deuterium ions. A strong absorption observed in the range of 1586—1607 cm^{-1} may be assigned to the νC=C+νC=N, which shift into the range of 1553—1571 cm^{-1} upon complex formation. The νC=O of the β-substituents and the νC=C+νC=N for the chelate rings of **7d** (M=Ni, Pd) are observed in both lower frequencies at 1625 or 1626 cm^{-1} and at 1537 or 1539 cm^{-1}, respectively. This seems to indicate that the β,β'-dicarbonyl groups have highly conjugated with the chelate rings.

The NMR spectra for the free ligands, **5a**, **5b**, and **5c**, show a broad signal of NH protons at 11.7 and 13.2 ppm except **5c**, and a sharp singlet of N–CH_2– and C–CH_3 at 3.50—3.60 ppm and at 2.13—2.20 ppm, respectively. The signals of the N–CH_2– and the C–CH_3 for the metal complexes also are sharp singlets. These results, together with the results from the IR spectra, have shown that these free ligands exist in an intramolecular hydrogen bonded chelate structure, which seems to be symmetric structure delocalized of π-electrons through the enamino imine conjugation[12] analogous to their metal complexes.

The visible and UV spectra of the free ligands, **5a**, **5b**, and **5c**, display two—four absorption bands in the range of 250—420 nm. The spectral features for these metal complexes are more complicated, and **7b** and **7c** (M=Cu, Ni, Pd) exhibit one or two new absorption peaks in the range of 466—570 nm, which may be assigned to π-π^* transitions within a ligand molecule and/or charge-transfer transitions. **7d** (M=Ni, Pd) also exhibit two or three similar absorption peaks in the range of 418—550 nm.

Experimental

The Schiff base, *N,N'*-bis(1-methyl-3-oxo-1-butenyl)ethylenediamine (**2**) was prepared according to the method of Martell *et al.*[13] The IR, NMR, and UV spectra were

recorded with JASCO IRG, Hitachi R24B, and Hitachi 124 spectrometers respectively. The mass spectra were determined with a JEOL JMS-D100 mass spectrometer. All the melting points are uncorrected.

Preparation of **3**: To a solution of **2** (22.4 g, 0.1 mol) in pyridine (50 ml) was slowly added powdered phosphorus pentasulfide at room temperature. The reaction mixture was stirred for 5 h, and then poured into 2 l of water. The mixture was neutralized by sodium hydrogencarbonate and filtrated. The residue was recrystallized with ethanol to give 8.8 g (34%) of **3**; mp 152—153 °C. Found: C, 56.15; H, 8.05; N, 10.77; S, 24.75%.

Preparation of **4**: A solution containing **3** (5.1 g, 20 mmol) and ethylenediamine (1.2 g, 20 mmol) in benzene (120 ml) was refluxed for 24 h. Removal of solvent, addition of ethanol, filtration, and recrystallization from ethanol gave 2.3 g (46%) of **4**; mp 223—224 °C (lit,[5] mp 226—228 °C, yield 15%).

Reaction of **4** *with NCS*: To a soution of **4** (1.24 g, 5 mmol) in chloroform (10 ml) was added NCS (1.5 g, 11 mmol) under a nitrogen atmosphere in the dark at 5 °C and stirred for 1 h. The resulting succinimide was removed by filtration, and the filtrate was evaporated to dryness under reduced pressure. The residual solid was recrystallized with ethanol to give 0.4 g (25%) of **5a**; MS *m/e*: 316 (M^+). The melting points, analytical data, and spectral data for the products were tabulated in Tables 1 and 2. The addition of 3.0 g (22 mmol) of NCS gave **8** in a 42% yield (from EtOH); MS *m/e*: 384 (M^+).

Preparation of **5b**: To a solution of **4** (2.5 g, 10 mmol) and triethylamine (3.0 g, 30 mmol) in acetonitrile (100 ml) was slowly added a solution of *o*-nitrobenzenesulfenyl chloride (4.2 g, 22 mmol) in acetonitrile (30 ml) under a nitrogen atmosphere, and then refluxed with stirring for 3 h. The reaction mixture was poured into water, and the resulting precipitation was separated by filtration. The products were isolated by column chromatography on silica gel ($CHCl_3$) to give 1.4 g (25%) of **5b**; MS *m/e*: 554 (M^+).

Preparation of **5c**: To 30 ml of a solution, neutralized by sodium acetate, containing 11 mmol of benzenediazonium chloride, was added a diluted acetic acid solution containing 1.2 g (5 mmol) of **4** with stirring at 5 °C. This mixture was then stirred for 2 h at this temperature and for 2 h at room temperature. The reaction mixture was poured into water, and filtrated. The collected solid was recrystallized with DMF to give 1.4 g (61%) of **5c** as yellow powder; MS *m/e*: 456 (M^+).

Preparation of the Metal(II) Complexes, **6**, *of* **4**: Copper(II) and nickel (II) complexes of **4** were synthesized by the method of Holm *et al.*[5] Palladium(II) complex was synthesized by the reaction of equimolar amounts of palladium acetate and **4** in hot ethanol; yield 74% (from $CHCl_3$).

General Procedure for the Reaction of **6** *with* o-*Nitrobenzenesulfenyl Chloride*: To a solution of **6** (5 mmol) and pyridine (11 mmol) in chloroform (150 ml) was added *o*-nitrobenzenesulfenyl chloride (11 mmol) under a nitrogen atmosphere at room temperature, and refluxed for 4 h. The reaction mixture was evaporated *in vacuo*, and recrystallization of the residue from solvent afforded the corresponding **7b**. **7b** (M=Ni): yield 83% (from benzene). **7b** (M=Pd): yield 61% (from $CHCl_3$–EtOH).

General Procedure for the Reaction of **6** *with Benzenediazonium Salt*: To an aqueous solution (100 ml) containing benzenediazonium chloride (11 mmol) and neutralized with sodium acetate, was slowly added a diluted acetic acid solution (80 ml) of **6** (5 mmol) at 5 °C; the mixture was then stirred at room temperature for 2—3 h. The reaction mixture was poured into water, and the resulting precipitate was removed by filtration and washed with ethanol. The product was purified by stirring with about 20 times of DMF. **7c** (M=Cu): yield 53%. **7c** (M=Ni): yield 97%. **7c** (M=Pd): yield 89%.

General Procedure for the Reaction of **6** *with Benzoyl Chloride*: To a solution of **6** (2 mmol) and pyridine (4.4 mmol) in dichloromethane (100 ml) was added benzoyl chloride (4.4 mmol) at room temperature, and the mixture was refluxed for 4 h. After removal of the solvent, the residue was recrystallized. **7d** (M=Ni): yield 57% (from $CHCl_3$–EtOH). **7d** (M=Pd): yield 62% (from $CHCl_3$).

Complexation of **5**: The free ligands, **5**, reacted with the metal(II) acetates of a small excess in DMF and/or DMSO for 15 min at 120 °C to give the corresponding metal complexes **7**. **7b** (M=Cu): yield 81% (from DMF). **7b** (M=Ni): yield 98% (from benzene). **7b** (M=Pd): yield 81% (from $CHCl_3$–EtOH). **7c** (M=Cu): yield 90%. **7c** (M=Ni): yield 88%. **7c** (M=Pd): yield 79%. The complexations of **5a** gave decomposition products.

Other Electrophilic Substitutions: The compounds, **4** and **6**, reacted with acetic anhydride and nitric acid or copper nitrate, *N*-bromosuccinimide, *N*-iodosuccinimide, bromine, Vilsmeier reagent, thiocyanogen, *etc.*, to give products which decomposed during the reactions or the separations.

Photochemical Reactions of Aromatic Compounds. XXXVI.[1] The Photoreactions of Anthracene with Some Selected Tertiary Aromatic Amines in Polar Media

Masahide YASUDA, Chyongjin PAC,* and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received October 31, 1979)

The photoreaction of anthracene with *N,N*-dimethylaniline in acetonitrile gave 9-(*p*-dimethylaminophenyl)-9,10-dihydroanthracene in a good yield, along with 9,10-dihydroanthracene and 9,9′,10,10′-tetrahydro-9,9′-bianthryl. This photoreaction was found to depend on the polarity of the solvent as well as on its protic or aprotic nature. With *N,N*-dimethyl-*m*-toluidine, a similar 1 : 1 adduct was obtained, while the reduced anthracenes were mainly formed in the photoreactions with *N,N*-dimethyl-*o*- and *p*-toluidines. The mechanisms were discussed in terms of the dissociation into the ion radicals as well as their reactivities.

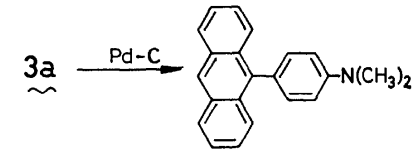
The arene–amine systems are typical electron acceptor-donor pairs for exciplex formation[2] and photochemical electron-transfer reactions.[3] The photoreactions of such systems usually afford adducts of arenes with amines and reduced arenes,[3-7] depending on the structures of the amines as well as on the polarity of solvent. In a previous paper,[4] we reported that the photoreaction of anthracene (A) with *N,N*-dimethylaniline (DMA) in acetonitrile gives mainly 9-(*p*-dimethylaminophenyl)-9,10-dihydroanthracene (**3a**), along with the reduced anthracenes (**1** and **2**) while the irradiation of a benzene solution results in the exclusive dimerization of A. In this paper, we wish to report on the photoreactions of A with some selected tertiary aromatic amines in polar media.

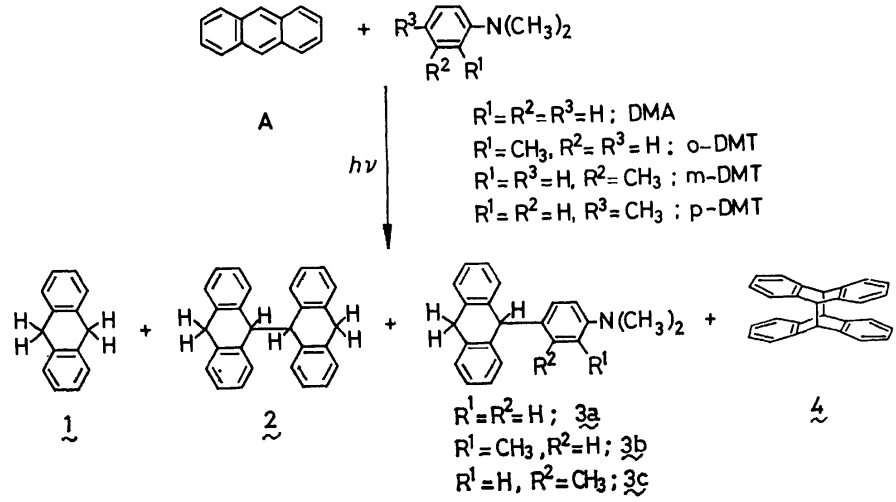
Results

Photoreactions of A with the Tertiary Amines in Acetonitrile. The irradiation was carried out for dry acetonitrile solutions in a Pyrex vessel, using a high-pressure mercury lamp at room temperature. Table 1 lists the isolated yields of the products. The hydrocarbon products (**1**, **2**, and **4**) are known compounds and were unambiguously identified by direct comparison with respective authentic samples. The structures of **3a** and **3c** were indicated by their elemental composition and their spectral properties. For example, the ^{1}H NMR spectrum of **3a** consisted of a sharp singlet at δ 2.75 (N–CH_3), a broad doublet at δ 3.88 (C_{10}–H_2), a broad triplet at δ 5.1 (C_9–H), an A_2B_2 signal at δ 6.7 (*p*-C_6H_4–), and a multiplet at δ 7.2 (other aromatic protons), strongly supporting the structure assigned. When a *p*-cymene solution of **3a** was refluxed over 5% Pd–C, 9-(*p*-dimethylaminophenyl)anthracene, which is a known compound,[8] was obtained in a 90% yield.

Table 1. Product distribution in the photoreactions of anthracene with the tertiary aromatic amines in acetonitrile

Amines	Isolated yields/%			
	1	**2**	**3**	**4**
DMA	8	20	70	0
o-DMT	54	32	trace	0
m-DMT	16	25	60	0
p-DMT	72	21	0	0





Scheme 1.

It is notable that the photoreaction with DMA and *m*-DMT mainly gave the adducts (**3a** and **3c**), whereas **1** and **2** are the exclusive products with *o*- and *p*-DMT. In the case of *o*-DMT, the formation of **3b** was indicated by the ^{1}H NMR spectrum of a mixture, which showed a sharp singlet at δ 2.15, a sharp singlet at δ 2.52, a broad doublet at δ 3.87, and a very broad singlet at δ 5.12 in an area ratio of *ca.* 3 : 6 : 2 : 1. However, its formation was too small for an unambiguous determination of the structure to be made. On the other hand, no adduct of A with *p*-DMT was isolated.

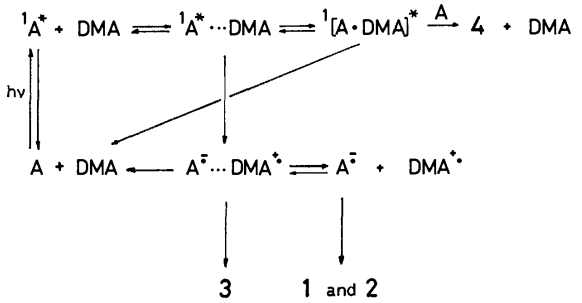
Table 2. Solvent effect on the photoreactions of anthracene with *N*,*N*-dimethylaniline and *N*,*N*-dimethyl-*p*-toluidine

	Solvents	Isolated yields/%			
		1	**2**	**3**	**4**
DMA	C_6H_6	0	0	0	100
	Et_2O	2	10	trace	85
	EtOH	45	20	30	0
	MeCN	8	20	70	0
p-DMT	EtOH	46	50	—	0
	MeCN–EtOH (9 : 1)	52	47	—	0
	MeCN	72	21	—	0

Solvent Effects on the Photoreactions of A with DMA and p-*DMT.* The photoreaction with DMA depends not only on the polarity of the solvent, but also on its protic or aprotic nature, as is shown in Table 2. The formation of **4** was exclusive in benzene and predominant in diethyl ether, while the combined yields of **1**, **2**, and **3a** were over 90% in such highly polar solvents as acetonitrile and ethanol. The formation of **3a** is favored in acetonitrile, which is a typical, aprotic polar solvent. On the other hand, **1** and **2** are mainly formed in ethanol. Moreover, it was found that the photoreaction with *p*-DMT in acetonitrile affords **1** in a good yield. Ethanol diminished the yields of **1**, though the combined yields of **1** and **2** were invariably high.

Discussion

Aromatic hydrocarbon–tertiary aromatic amine pairs have been extensively investigated as typical exciplex-formation systems and have been well established to dissociate into the ion radicals in polar media.[2,9] Therefore, the observed effect of solvent polarity can be interpreted in terms of a complete electron transfer from DMA to the excited singlet state of A (^{1}A*). Scheme 2 delineates the mechanistic reaction pathways; ^{1}[A·DMA]* and A$^-$····DMA^{+}· represent the exciplex and the ion pair respectively.

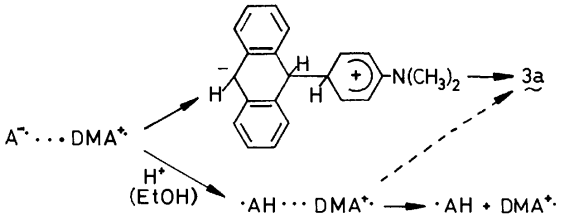


Scheme 2.

In a benzene solution, ^{1}A* forms the exciplex with DMA at the diffusion-controlled limit without any dissociation into the ion radicals.[9] Saltiel and his co-workers have demonstrated that the photodimerization of A in benzene in the presence of DMA proceeds *via* an interaction of the exciplex with A, probably involving a termolecular exciplex, ^{1}[A·A·DMA]*.[10] This mechanism holds for the present photoreaction in benzene since ^{1}A* is completely quenched by DMA under the conditions employed.

Although the photodimerization is still dominant in diethyl ether, the formation of **1** and **2** is notable, perhaps suggesting the occurrence of a partial dissociation into the ion radicals in this solvent; the pyrene–DMA pair is known to dissociate into the ion radicals upon the photoexcitation in moderately polar solvents.[11] In acetonitrile and ethanol, the ionic-dissociation process evidently overcomes the exciplex formation as well as other chemical and physical pathways from the exciplex, thus leading to the complete lack of the photodimerization. In other words, the photoreactions in these solvents are closely related with the chemistry of the ion radicals.

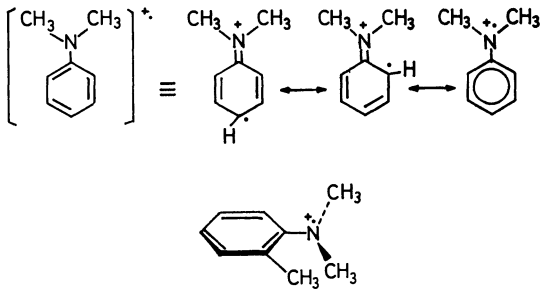
In this regard, it should be noted that the formation of **3a** is more favored in acetonitrile than in ethanol. Since ethanol is a good proton donor for anion radicals, the free anion radical of A and probably also A$^-$· in the ion pair are easily protonated in ethanol.[12] On the other hand, such a rapid protonation of A$^-$· can not be expected in acetonitrile, since possible proton donors in this solvent may be impurities involving water. This argument may lead to the conclusion that the ion pair is a precursor of the formation of **3a**; a radical-coupling reaction between A$^-$· and DMA$^+$· may compete with the charge neutralization between them. The protonation of A$^-$· in the ion pair should result in the loss of the Coulombic force binding the ion pair. As a result, the radical pair, ·AH···DMA$^+$·, will rapidly diffuse out from the solvent cage, thus making a radical-coupling reaction less possible.



Although a similar mechanism operates for the formation of **3b** and **3c**, the photoreaction with *o*-DMT clearly indicates that the structures of the aromatic amines also affect the reaction courses from the ion pair. It is well known that DMA has a coplanar structure between the dimethylamino group and the benzene ring in the solid state;[13] the structure in solution would again be coplanar, or almost so. This might also be

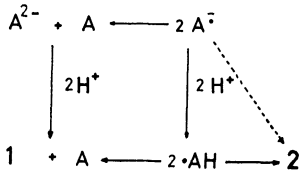
true for *m*-DMT and *p*-DMT. Therefore, odd electrons of the cation radicals would populate the benzene ring, perhaps largely at the ortho and para positions. Thus, the cation radical of DMA and *m*-DMT can undergo the radical-coupling reaction with $A^{-}\cdot$ at the para position, where the steric hindrance is much less.

On the other hand, coplanarity seems to be largely lost in the case of *o*-DMT because of steric hindrance by the ortho methyl group. Therefore, the spin density of odd electrons on the benzene ring of *o*-$DMT^{+}\cdot$ would be much lower than that of the cation radicals of DMA and *m*-DMT, leading to a lower reactivity of *o*-$DMT^{+}\cdot$ at the benzene ring toward the radical-coupling reaction.

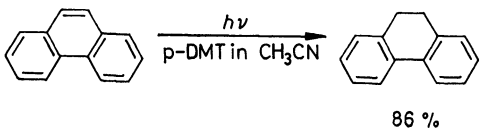


In the case of *p*-$DMT^{+}\cdot$, the para position is blocked by the methyl group and the ortho position is sterically hindered for the radical-coupling reaction. In the cases of *o*- and *p*-DMT, therefore, the escape of the ion radicals from the solvent cage would predominate.

The formation of **1** and **2** evidently arises from the disproportionation and dimerization of $A^{-}\cdot$ and/or ·AH. In protic media, the precursor is certainly ·AH, whereas both ($A^{-}\cdot$) and (·AH) exist in acetonitrile. In the photoreaction with *p*-DMT, as a solvent acetonitrile is more suitable for the formation of **1** than is ethanol. It should be noted that the presence of 10 vol% ethanol in acetonitrile lowered the yields of **1**. Therefore, it may be suggested that $A^{-}\cdot$ predominantly undergo disproportionation, whereas both disproportionation and dimerization occur with ·AH in a *ca.* 1 : 1 ratio.



Since the photoreaction with *p*-DMT in acetonitrile gave **1** in a relatively high yield, the *p*-DMT–acetonitrile pair can be expected to be a favorable reaction system for the photo-Birch reduction of aromatic hydrocarbons. Therefore, the photo-Birch reduction of phenanthrene was attempted, using the *p*-DMT–acetonitrile system; 9,10-dihydrophenanthrene was thus obtained in an 86% yield.



86 %

Experimental

The melting points were determined on a Yanagimoto hot stage and are uncorrected. The ^{1}H NMR spectra were measured on a JEOL JNM-PS-100 spectrometer, with tetramethylsilane as the internal standard. The IR spectra were taken on a Shimadzu IR-400 spectrometer, and the mass spectra, on a Hitachi RMU-6E. The UV spectra were measured on a Hitachi 124 spectrometer. The GLC was carried out on a Shimadzu GC-3BF apparatus using a column of SE-30 (5% on Celite 545, 0.75 m).

Materials. Spectral-grade acetonitrile was distilled three times over P_2O_5 and then twice over CaH_2 before use. The ethanol was distilled over CaH_2 and then over C_2H_5ONa before use. The diethyl ether was distilled over $LiAlH_4$. The benzene was washed three times with concentrated sulfuric acid, with a saturated sodium hydrogencarbonate solution, and three times with water, and was then distilled over P_2O_5. The tertiary aromatic amines (Tokyo Kasei) were distilled *in vacuo* before use. The anthracene (Nakarai Chemicals) was recrystallized five times from a mixture of benzene–ethanol and then sublimed. The phenanthrene was recrystallized three times from ethanol and then sublimed.

Photoreaction of Anthracene with the Amines. General Procedure: The experimental procedures used for the irradiation and isolation of the products were essentially identical in all the runs. A solution (150 ml) containing anthracene (0.5 g, 2.8 mmol) and an amine (5 g, 37 mmol) in a Pyrex vessel was bubbled with a nitrogen stream for 20 min and then irradiated with an Eikosha PIH-300 high-pressure mercury lamp under cooling with water. Except in the case of the benzene solution, the anthracene was not completely dissolved before the irradiation. The progress of the reaction was followed by GLC, and it was confirmed that the irradiation for 24 h resulted in the complete consumption of anthracene. During the irradiation, solids different from anthracene were precipitated except for a few cases where the yields of **2** or **4** are low (see Tables 1 and 2). The filtration of the solids gave **2** or **4**. After the removal of the solvent from the filtrate, vacuum distillation gave the starting amine (4—4.5 g). The remaining semisolids were dissolved into a minimal volume of benzene and then chromatographed on silica gel (Merck, 70—230 mesh). Elution with hexane and then with 10% benzene in hexane gave a mixture of **1** and **2**, to which hot hexane was then added; the filtration of the insoluble solids gave **2** while the evaporation of the filtrate left almost pure **1**. Further elution with a 1 : 1 benzene–hexane mixture gave **3a**—**c**. Tables 1 and 2 summarize the isolated yields of the photoproducts.

The **1** (mp 108 °C) was recrystallized from methanol and was identical to commercially available 9,10-dihydroanthracene (Tokyo Kasei) in all respects. The **2** (mp 245—246 °C) was recrystallized from benzene and identified as 9,9′,10,10′-tetrahydro-9,9′-bianthryl by direct comparison with an authentic sample prepared according to the known method.[14]

The **3a** was recrystallized from a benzene–ethanol mixture; mp 148—149.5 °C; UV (CH_3CN): $\lambda(\varepsilon)=266$ (2.3×10^4) and 306 nm (2.6×10^3); IR (KBr): 3000 (w), 2900 (w), 1610, 1520, 1470, 1450, 1350, 1230, 1200, 1190, 1160, 1060, 1040, 945, 865, 830, 800, 735, and 710 cm^{-1}; MS: 299 (M^{+}, 36%), 178 (40%), and 121 (100%); ^{1}H NMR ($CDCl_3$): δ 2.75 (s, 6H), 3.88 (br d, $J=2$ Hz, 2H), 5.10 (br t, $J=2$ Hz, 1H), 6.45—7.05 (A_2B_2q, $J=9$ Hz, 4H), and 7.06—7.40 (m, 8H); Found: C, 88.52; H, 7.12; N, 4.44%. Calcd for $C_{22}H_{21}N$: C, 88.25; H, 7.07; N, 4.68%.

The **3c** had a mp of 134—135.5 °C (from benzene–ethanol);

UV (CH_3CN): $\lambda(\varepsilon)=263$ (2.3×10^4) and 306 nm (2.6×10^3); IR (KBr): 3030 (w), 3000 (w), 2900—2820 (br, w), 2790, 1605, 1560, 1510, 1470, 1440, 1420, 1360, 1290, 1225, 1200, 1170, 1125, 1095, 1060, 960, 840, 830 (sh), 810, 800, 760, and 740 cm^{-1}; MS: 313 (M^+, 50%), 178 (43%), and 135 (100%); ^1H NMR ($CDCl_3$): δ 2.03 (s, 3H), 2.90 (s, 6H), 4.08 (br d, $J=3$ Hz, 2H), 5.20 (br t, $J=3$ Hz, 1H), 6.45—6.60 (m, 1H), 6.62 (br s, 1H), 6.90—7.41 (m, 9H); Found: C, 88.30; H, 7.41; N, 4.48%. Calcd for $C_{23}H_{23}N$: C, 88.13; H, 7.40; N, 4.47%.

Aromatization of ***3a*** *to 9-(*p*-Dimethylaminophenyl)anthracene.* A *p*-cymene solution (4 ml) containing **3a** (0.1 g) and 5% Pd–C (0.1 g) was bubbled with a nitrogen stream for 20 min and then refluxed for 1.5 h. After the filtration of the Pd–C, evaporation left yellow-green solids (90 mg). Recrystallization from benzene gave pure 9-(*p*-dimethylaminophenyl)-anthracene; mp 252—253 °C (lit,[8] 258 °C); Found: C, 88.62; H, 6.40; N, 4.83%. Calcd for $C_{22}H_{19}N$: C, 88.85; H, 6.44; N, 4.71%.

Photo-Birch Reduction of Phenanthrene with p-*DMT.* An acetonitrile solution (150 ml) containing phenanthrene (0.5 g, 2.8 mmol) and *p*-DMT (5 g, 37 mmol) was irradiated for 24 h; the complete consumption of phenanthrene was confirmed by GLC. After the removal of the solvent, 200 ml of diethyl ether was added to the remaining oil. The ether solution was washed with 150 ml of dilute hydrochloric acid (1 mol dm^{-3}) and three times with brine, and then dried ($MgSO_4$). The evaporation of the ether left an oil, which was then distilled *in vacuo* to give an oil (432 mg, bp 183—184 °C/25 mmHg†). This oil, which was confirmed by GLC to consist of only one component, was identical to commercially available 9,10-dihydrophenanthrene in all respects. To the hydrochloric acid solution sodium hydrogencarbonate was added until the solution became alkaline to litmus. The oil separated was extracted with three 50-ml portions of diethyl ether. The ether layer was dried ($MgSO_4$), evaporated, and then distilled *in vacuo* to give 4.0 g of *p*-DMT.

† 1 mmHg=133.322 Pa.

CIDNP Studies of the Thermal Decomposition of Arylazo Aryl Sulfones

Masato YOSHIDA,* Naoki FURUTA, and Michio KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received November 4, 1980)

^{1}H-and ^{13}C-CIDNP spectra were obtained during the thermal decomposition of several arylazo aryl sulfones (Ar–N=N–SO_2–Ar') in tetrachloroethylene or 1,1,2,2-tetrachloroethane at 100 °C. An enhanced absorption from the C_1 of the starting material, azo sulfone, was observed; this indicates that the decomposition of azo sulfone proceeds by means of one-bond fission. The formation of sulfones ($ArSO_2Ar'$) and sulfinic esters (ArO(SO)Ar') as recombination products in a solvent cage was established from the signs of polarization (enhanced absorption or emission).

Arylazo aryl sulfones (**1**) decompose unimolecularly when they are heated in neutral or weakly basic media;[1] the generation of an aryl and sulfonyl radical pair has been proposed on the basis of kinetics,[2] product studies,[3] or the spin trapping of free radicals generated from the arylazo aryl sulfones.[4] In the case of aliphatic azo

$$\mathrm{Ar{-}N{=}N{-}S{-}Ar' \longrightarrow Ar\cdot + N_2 + Ar'S\cdot} \quad (1)$$

compounds such as α,α'-azobisisobutyronitrile, solvent-cage products of the geminate radical pair are the main products. On the other hand, the homolysis of arylazo aryl sulfones gives the expected cage product, sulfones ($ArSO_2Ar'$), in only a small yield. These sulfones may be either cage-recombination products or products of the induced decomposition of the azo sulfones by aryl radicals. We have, therefore, studied the ^{1}H-and ^{13}C-CIDNP spectra (chemically induced dynamic nuclear polarization) observed during the thermolysis of several arylazo aryl sulfones in order to clarify the details of the reaction mechanism; the results will be presented in this paper.

Results and Discussion

The thermal decomposition of arylazo aryl sulfones (**1a—g**) was carried out in tetrachloroethylene or 1,1,2,2-tetrachloroethane.

Decomposition of Azo Sulfones in Tetrachloroethylene. The rate of the decomposition of **1a** in tetrachloroethylene was determined by following the evolution of the nitrogen gas by the method described in Ref. 2. The reaction was first-order in **1a**, and the rate constant was calculated to be 6.10×10^{-4} s^{-1} (90.8 °C). This value is comparable to those in ethylbenzene, chlorobenzene, or nitrobenzene.[2] The decomposition products of **1a** are shown in Table 1.

When the ^{1}H-NMR spectra of **1a—d** and **1f—g** were observed at 100 °C, strong CIDNP signals appeared in the field of the aromatic-proton region for about 15 min. No CIDNP signal was, though, observed in the field of the methyl-proton region. Since **1e** is rather stable and decomposes very slowly at 100 °C,[1] no CIDNP signal could be observed. To prevent the acid-catalyzed heterolysis of **1**, the ^{1}H-NMR spectra were observed in the presence of 2 mol of triethylamine per mol of azo sulfones. The CIDNP spectrum of **1a** under these conditions is shown in Fig. 1. Enhanced absorption signals were observed in the field of δ 7.89—7.72 and 7.10, and strong emission signals were observed at δ 7.30 and 7.20. The intensity of the CIDNP

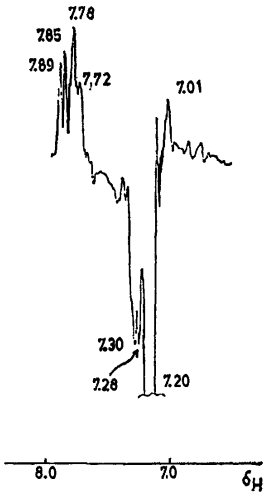

Fig. 1. ^{1}H-CIDNP spectrum in the thermal decomposition of **1a** in the presence of triethylamine in tetrachloroethylene at 100 °C.

Table 1. Products of thermal decomposition of **1a** in tetrachloroethylene

Product	Yield/mol%	Product	Yield/mol%
$PhCCl{=}CCl_2$	21.9	*p*-$CH_3C_6H_4SO_2Cl$	16.9
PhCl	6.1	*p*-$CH_3C_6H_4SO_2Ph$	6.5
PhH	4.9	*p*-$CH_3C_6H_4SO_2OPh$	27.7
Ph–N=N–Ph	3.5	*p*-$CH_3C_6H_4SO_2SC_6H_4CH_3$-*p*	14.1
		p-$CH_3C_6H_4SO_3H$	*ca.* 20

signal at δ 7.20 was very high when triethylamine was added. The ^{1}H-NMR spectrum of 2,4,6-trideuteriophenylazo *p*-tolyl sulfone (**1a**-d_3) at 100 °C was also observed. The enhanced absorption at δ 7.89—7.72 and the emission of δ 7.30 observed in **1a** disappeared, while an enhanced absorption appeared at δ 7.31. The strong emission at δ 7.20 was still observed with **1a**-d_3. From the results described above, and by comparison with the chemical shift of the authentic samples, some signals were assigned as is shown below:

Enhanced absorption	at δ 7.89 —7.72	*o*-H of the phenyl group of phenyl p-tolyl sulfone(**2a**)
Emission	at δ 7.30	*o*-H of α,β,β-trichlorostyrene
Emission	at δ 7.20	Benzene

The assignment of the ^{13}C-CIDNP signals can be expected to be easier than that of the ^{1}H-CIDNP signals, so the ^{13}C-NMR spectrum of **1a** at 100 °C was observed. CIDNP signals were also obtained in the field of the aromatic region for more than 20 min. The intensity of the CIDNP signals as a whole increased when pyridine was added to prevent acid-catalyzed heterolysis. The observed CIDNP spectrum of **1a** in the presence of pyridine is shown in Fig. 2, while the chemical shifts and assignments of the CIDNP signals are tabulated in Table 2. The signals were assigned by comparison with the chemical shifts of the authentic samples of the products, shown in Table 2.

Table 2. ^{13}C-CIDNP data for thermal decompositin of **1a**[a)]

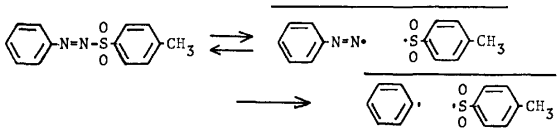
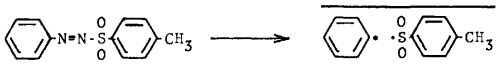
On the basis of the CIDNP data, the following conclusions could be drawn:

1) As has been mentioned before, azo sulfones decompose unimolecularly. Mechanistically, there may be two possible decomposition modes: one is the one-bond fission to give an aryldiazenyl sulfonyl radical pair (Eq. 2), while the other is the two-bond fission to give an aryl radical, a sulfonyl radical, and nitrogen simultaneously (Eq. 3). The observation of the enhanced



(2)



(3)

absorption of the C_1 of **1a** itself indicates that the decomposition of **1a** is reversible, and so it must take place by means of one-bond fission. The sign in the net polarization (Γ_{ne}), as calculated according to Kaptein's rule[5)] agrees with the observed mode:

	μ	ε	Δg	a	Γ_{ne}	obsd
C_1	−	+	−	+[6)]	+	A

$g<2.0010$[7)](Ph-N=N•); 2.0041[8)](•$SO_2C_6H_4CH_3$-*p*)

2) If one assumes that the sulfone (**2a**) obtained from the decomposition of **1a** is the cage product, the sign in the net polarization (Γ_{ne}), as calculated according to Kaptein's rule, again agrees with the observed mode:

	μ	ε	Δg	a	Γ_{ne}	obsd
C_1	−	+	−	+[9)]	+	A
$C_{1'}$	−	+	+	+[10)]	−	E

$g=2.00234$[11)](Ph•)

The observation of the CIDNP signals of sulfone (**2a**) and the coincidence of the signs mentioned above indicate that **2a** is the cage product from the phenyl *p*-toluenesulfonyl singlet-radical pair.

3) As is shown in Table 1, phenyl *p*-toluenesulfinate (**3a**) was not detected among the decomposition products of **1a**. In the ^{13}C-CIDNP spectra of **1a** shown in Fig. 2, however, the emission and enhanced absorption signals of this sulfinic ester (**3a**) were observed for 2.5—3.5 min. Also, the sign of the net polarization (Γ_{ne}), as calculated according to Kaptein's rule, agrees with the observed results if one assumes that **3a** is the cage product:

	μ	ε	Δg	a	Γ_{ne}	obsd
C_1	−	+	−	+	+	A
$C_{1'}$	−	+	+	+	−	E

Since **3a** is unstable,[12)] it could not be isolated as a product of the decomposition of **1a**. The ^{13}C-CIDNP study described here shows that not only the sulfone (**2a**), but also the sulfinic ester (**3a**) is generated as the

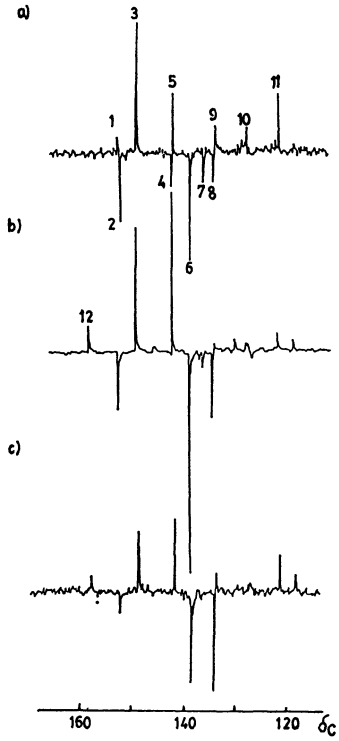


Fig. 2. ^{13}C-CIDNP spectra in the thermal decomposition of **1a** in the presence of pyridine in tetrachloroethylene.
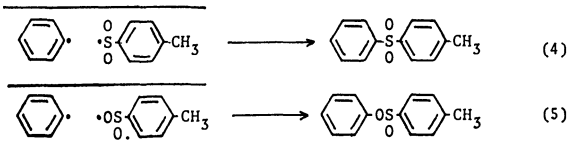
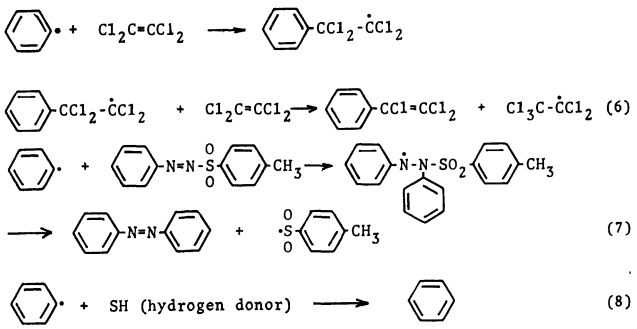
After a) 2.5—3.5, b) 8—9, and c) 20—21 min heating of **1a** in NMR probe at 100 °C.

cage product from the phenyl *p*-toluenesulfonyl radical



pair. These findings clearly establish that the sulfonyl radical is ambident and acts as either an S- or O-centered radical.

Scavenged products of the escaped phenyl radical in which polarization is maintained should show emission signals (memory effect). The formation of α,β,β-trichlorostyrene (**4**), azobenzene (**5a**), and benzene can be explained by the following mechanism:



Scheme 1.

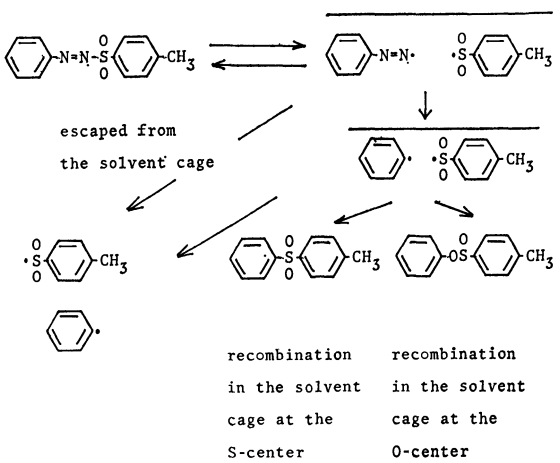
These reaction mechanisms are supported by the following experimental findings:

(i) When a large amount of the azo sulfone (**1a**) was present at the beginning of the decomposition, the intensity of the CIDNP signal of azobenzene (**5a**) was very strong, but toward the end of the reaction it decreased. On the other hand, the intensity of the CIDNP of α,β,β-trichlorostyrene (**4**) increased toward the end of the reaction.

(ii) When the ^{13}C-NMR spectrum of a mixture of **1a** and **1c** was measured at 100 °C, the CIDNP signal of 4-chloroazobenzene (4-ClC_6H_4–N=N–Ph **5b**) also appeared. This shows that the escaped phenyl radical attacks both **1a** and **1c**. As has been mentioned before, the rate of the decomposition of **1a** was first-order in **1a**, but a high concentration of azo sulfone at the beginning of the decomposition may favor the induced decomposition (Eq. 7).

(iii) The intensity of the emission of the benzene proton (δ 7.20) was strengthened in the presence of triethylamine. This shows that the escaped phenyl radical abstracts hydrogen from the *N*-ethyl group in the presence of triethylamine.

In conclusion, ^{1}H-and ^{13}C-CIDNP studies support the idea that the thermal decomposition of **1a** in a solvent cage occurred according to Scheme 2 and that the reaction mechanism of the escaped phenyl radicals is explained by Scheme 1.



Scheme 2.

Decomposition of Azo Sulfones in 1,1,2,2-Tetrachloroethane. The decomposition of azo sulfone in 1,1,2,2-tetrachloroethane, which may act as a hydrogen donor, was also studied. The rate of the decomposition of **1a** at 90.1 °C was determined by measuring the amount of nitrogen gas by the method described in Ref. 2. It followed a first-order rate equation in **1a** at the beginning of the reaction and they increased toward the end of the reaction. This may be explained by the acid-catalyzed ionic decomposition due to the formation of sulfinic or sulfonic acid. The decomposition products of **1a**, as summarized in Table 3, show that the products and their yields in 1,1,2,2-tetrachloroethane were different from those in tetrachloroethylene.

When the ^{1}H-NMR of **1a** was measured in 1,1,2,2-tetrachloroethane at 100 °C, a strong emission signal was observed at δ 7.29, just as in tetrachloroethylene.

Table 3. Products of thermal decomposition of **1a** in 1,1,2,2-tetrachloroethane

Product	Yield/mol%	Product	Yield/mol%
PhH	36.0	$PhSO_2C_6H_4CH_3$-*p*	8.1
PhCl	14.8	*p*-$CH_3C_6H_4SO_2Cl$	9.6
Cl_2C=CHCl	17.3	*p*-$CH_3C_6H_4SO_2OPh$	18.5
Ph–N=N–Ph	1.3	*p*-$CH_3C_6H_4SO_2SC_6H_4CH_3$-*p*	12.6
		p-$CH_3C_6H_4SO_3H$	*ca.* 20

In the presence of 2 mol of triethylamine per mol of azo sulfone, the intensity of the emission signal at δ 7.29 increased, but not so markedly as in the case of tetrachloroethylene. These CIDNP signals were assigned to benzene. The escaped phenyl radical mainly abstracts hydrogen from the solvent, since the solvent is the hydrogen donor.

Experimental

The ^{1}H-NMR spectra were taken with a Hitachi R-20B spectrometer. The ^{13}C-NMR spectra were taken with a JEOL Fx-60 FT-NMR spectrometer.

Materials. All the arylazo aryl sulfones except **1e** were prepared from the substituted benzenediazonium chlorides and sodium salts of the substituted benzenesulfinic acid.[1] Compound **1e** was prepared from *p*-dimethylaminobenzenediazonium tetrafluoroborate and sodium *p*-toluenesulfinate in water.

Products of Thermal Decomposition of 1a. After the decomposition was complete, the reaction mixture was washed with a 5% aqueous solution of sodium carbonate. The benzene, chlorobenzene, and trichloroethylene were then determined by gas chromatography. The other products listed in Table 1 or 3 were separated by column chromatography on Florisil. Each product was identified by means of its mp, IR, and ^{1}H-NMR spectra. The sodium carbonate extracts were concentrated under reduced pressures and made weakly acidic by the addition of hydrochloric acid, and the *p*-toluenesulfonic acid in the solution was precipitated as its *S*-benzylisothiuronium salt.

CIDNP Spectra. A solution of azo sulfone (*ca.* 0.2 mol/l) in tetrachloroethylene or 1,1,2,2-tetrachloroethane was inserted in a NMR probe which had been heated at 100 °C, and the ^{1}H-NMR or ^{13}C-NMR was measured.

Proton Equilibria of 5-Dimethylamino-1-naphthalenesulfonyl Group Conjugated to Bovine Serum Albumin. II. Neighboring Effects in Urea and Guanidinium Chloride Solutions

Nobuo IKUTA,† Eisaku NOMURA, Joichi KOGA,* and Nobuhiko KUROKI

Department of Applied Chemistry, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received November 18, 1980)

Protonation to the fluorescent probe, 5-dimethylamino-1-naphthalenesulfonyl group, which had been conjugated to bovine serum albumin, was investigated in aqueous solutions of urea and guanidinium chloride. pK values not less than those of the free probe were present even in the positive range of net charge on the protein at high concentration of the denaturants. This was interpreted in terms of the electrostatic and nonpolar effects based on short-range interaction between the probe and its neighboring residues. These effects were substantiated by the reduction of the disulfide bonds in the protein and by the variation of the dielectric constant of the local environment surrounding the probe.

Studies on the acid-base equilibria of optical probe-protein conjugates have been carried out in order to clarify the short-range interaction among the constituent residues.[1-6] A report was given on the acid-base equilibria of the fluorescent probe, 5-dimethylamino-1-naphthalenesulfonyl group (DNS) conjugated to bovine serum albumin (BSA) with various degrees of conjugation.[6] It was found that the apparent dissociation constant, K_a, of the dimethylamino moiety of the DNS–BSA conjugates with less than 1.0 mol of the probe per mol of the protein changes according to the conformational change by acid denaturation. However, the pK_a values of the DNS conjugates at various pH were less than the theoretical values estimated from the Debye-Hückel electrostatic shielding effect on the surface of the protein. The deviation might be ascribed in part to the effect of the nonpolar environment surrounding the probe owing to its hydrophobicity in the basic form.

In order to evaluate the effect of the nonpolar environment, the behavior of the pK_a values of the DNS conjugate was studied at various concentrations of denaturants, such as urea and guanidinium chloride (GuHCl). The denaturants interact strongly with peptide backbone,[7,8] enhancing the solubility of nonpolar groups either by altering the bulk properties of the solvent or through more localized effect.[7,9,10] The former weakens interpeptide hydrogen bonds, the latter reducing hydrophobic interactions. Thus, the denaturation on urea or GuHCl makes the conformational state of the protein less compact and simultaneously, brings about the lowering in hydrophobicity or non-polarity inside the protein. We might expect that the change in the pK_a value is influenced by only the charge of the protein at high concentrations of the denaturants.

The results of the variation of pK_a values at such high concentrations of the denaturants show that the negatively charged groups are present in the neighborhood of the probe in the positive range of the net charge of the protein. The neighboring effect due to the electrostatic interaction is maintained by the disulfide bonds in the protein even in the denaturant solutions.

† Present address: Osaka Municipal Technical Research Institute, Kita-ku, Osaka 530.

Experimental

Materials. The DNS–BSA conjugate used in this experiment was prepared as described previously[6] and contained less than 1.0 mol of the probe per mol of the protein. Such a degree of conjugation has no influence on the conformation of the protein.[6] The reductive cleavage of the disulfide bonds of the DNS–BSA conjugate in 6 M (1 M= 1 mol dm^{-3}). urea or GuHCl solution were accomplished by dithiothreitol (DL-*threo*-1,4-dimercapto-2,3-butanediol) and iodoacetamide according to the procedure of Bewley *et al.*[11] Water was deionized and then distilled. Urea and GuHCl were recrystallized from methanol–water solution. Electrolytes of reagent grade were used without further purification.

Fluorescent Measurements. Solutions of the DNS–BSA conjugate with 1.1×10^{-5} M of the protein were prepared by taking requiste amounts of a stock solution of the DNS–BSA conjugate, solid urea or GuHCl, and water in volumetric flasks. Measurements of the pH and fluorescent spectra of the solutions were carried out as reported[6] with the excitation wavelength taken at 340 nm where only the probe in the basic form absorbs light. In order to obtain the true emission spectra, the measured emission spectra were corrected by using the known emission spectrum of quinine sulfate as a standard.[12]

Potentiometric Titration. Potentiometric titration was carried out in order to determine the number, $\bar{Z}_H$, of proton bound to the protein. The solution of BSA with an appropriate concentration of the denaturants was dialyzed for 48 h against the same concentration of CO_2-free denaturant solution at 25 °C. The protein concentration was in the range 10^{-4} M, about 10 times that for the fluorescent measurements for obtaining the accurate values of $\bar{Z}_H$. Titration of 30 mL (1 L=1 dm^3) of prepared solutions was carried out under nitrogen atmosphere at 25 °C with a Hitachi-Horiba F-7AD pH meter equipped with a Hitachi-Horiba 6326-05C combination electrode. Titrant, 0.5 M HCl, was added with a Mitamura Riken Mechanical Buret (syringe type; a minimum volume of readings, 2.5 μL). The solvent containing the corresponding denaturant was titrated in the same way. No difference in titration curves between the unconjugated and conjugated proteins could be detected in the case of 0.01 M NaCl, 6 M GuHCl, and 8 M urea; the unconjugated protein was employed in the other cases.

Results and Discussion

Fluorescence of DNS Conjugate. The fluorescence

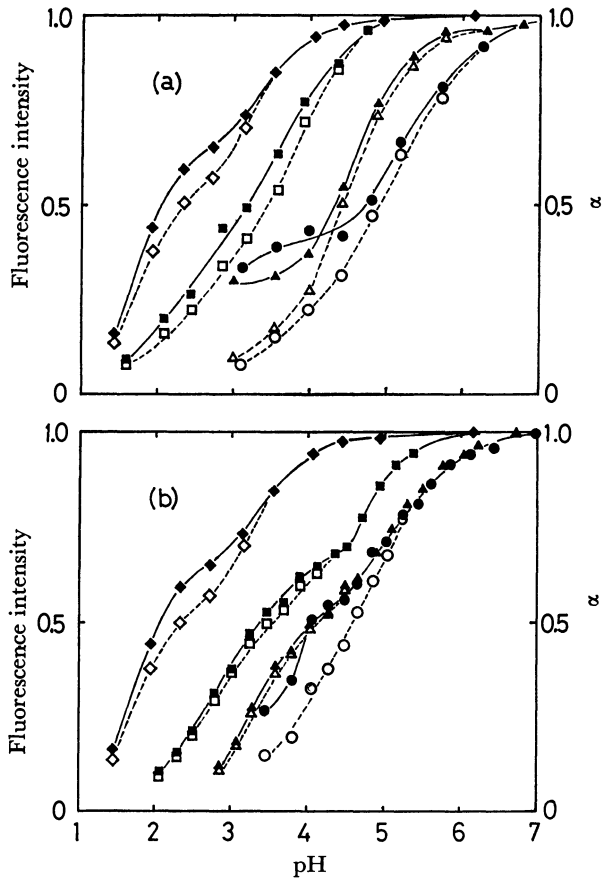

Fig. 1. Variation of fluorescence intensity (open symbols) and fraction in the basic form (closed symbols) of the DNS–BSA conjugate as a function of pH in denaturant solutions. (a) Concentration of urea: 8 M (○, ●), 4 M (△, ▲), 2 M (□, ■), and 0 M (◇, ◆). (b) Concentration of CuHCl: 6 M (○, ●), 4 M (△, ▲), 2 M (□, ■), and 0 M (◇, ◆). Fluorescence intensity is defined by taking a maximum in the intensities measured at each concentration of the denaturants as 1.0. α is calculated with Eq. 2.

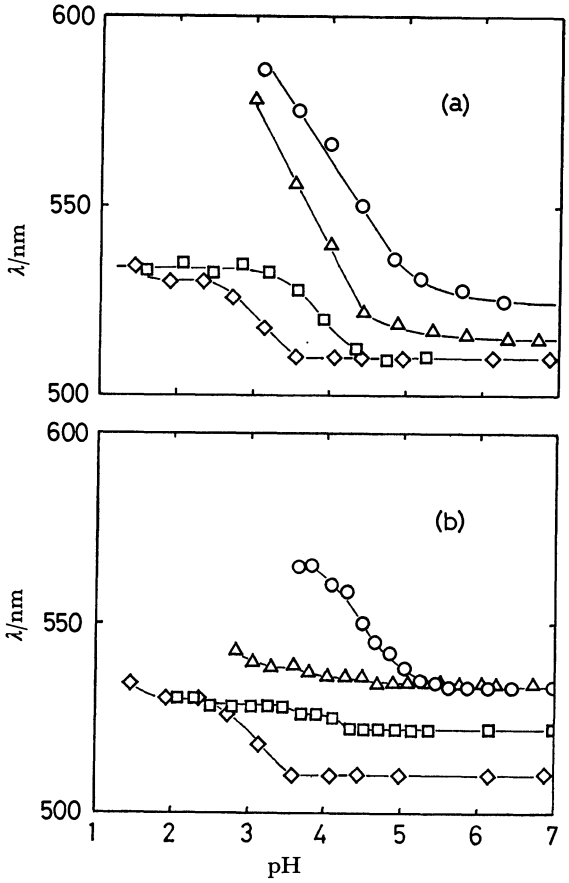

Fig. 2. Plots of peak wavelength of the fluorescence of the DNS–BSA conjugate against pH of the denaturant solutions. (a) Concentration of urea: 8 M (○), 4 M (△), 2 M (□), 0 M (◇). (b) Concentration of GuHCl: 6 M (○), 4 M (△), 2 M (□), 0 M (◇).

intensities of the DNS–BSA conjugate obtained at different concentrations of urea and GuHCl are shown as a function of pH in Figs. 1(a) and 1(b), respectively. In the absence of denaturants the 0.01 M NaCl solution was employed. A maximum in all the fluorescence intensities measured at each denaturant concentration is arbitrarily assigned the numerical value of 1.0 on the ordinates in the figures. Each sigmoid curves can be ascribed in part to the acid-base equilibrium of the conjugated probe since the protonation of the probe quenches the fluorescence, only the probe in the basic form giving the fluorescence.[16]

The peak wavelengths corresponding to the fluorescence in the solutions of urea and GuHCl are also shown in Figs. 2(a) and 2(b), respectively. The peak shifts progressively to higher wavelengths both with an increase of the denaturant concentration and with a decrease of the pH value, reaching 590 nm for the most acidic solution of 8 M urea and 6 M GuHCl. The shift is closely dependent on the change of the polarity of the environment surrounding the probe. Similar shifts in peak wavelength was observed in the fluorescence of DNS–amino acid conjugates in various organic solvents.[13–15] This type of change in the fluorescence with change of solvent polarity has been explained theoretically in terms of the differences in solvent interaction energies of the ground and excited states arising from differences in the polarities or dielectric constants of the states.[13,14] Thus, with increase in the dielectric constant of the organic solvent the peak shifts to higher wavelength, the quantum yield of the fluorescence decreasing. Variation of the peak wavelength and quantum yield with the dielectric constant of solvent was reported by Abe *et al.* for the fluorescence of three DNS–amino acid conjugate, *viz.* DNS–L-alanine, DNS–L-leucine, and DNS–L-phenylalanine, in various organic solvents.[15]

pK_a *Values in Denaturant Solutions.* The relative fluorescence intensities (Fig. 1) change not only with quenching by the protonation of the probe but also with the change in quantum yield of the probe in the basic form.[16] The relative fluorescence intensity, F, should be corrected in order to calculate the true fraction, α, of the probe in the basic form.

Since the fluorescence observed arises from the basic form,[16] F can be related to the quantum yield, Φ, and the concentration, C, of the basic form:

$$F \propto I_0 \varepsilon C \Phi,$$

where I_0 is the strength of the incident beam, and ε the molar absorption coefficient of the basic form at 340 nm. Factors ε and I_0 are constant, while C is dependent upon the degree of the protonation to the probe, Φ changing with the peak wavelength, λ, of the fluorescence measured at each pH value of a denaturant solution. When the fluorescence at different pH values of the solution give the peak wavelengths, λ_1 and λ_2, the relation between the relative fluorescence intensities, $F(\lambda_1)$ and $F(\lambda_2)$, can be written as

$$\frac{F(\lambda_1)}{F(\lambda_2)} = \frac{C_1\Phi(\lambda_1)}{C_2\Phi(\lambda_2)}, \quad (1)$$

where $\Phi(\lambda_1)$ and $\Phi(\lambda_2)$ are the quantum yields giving the corresponding wavelengths, and C_1 and C_2 the respective molarities of the probe in the basic form existing in the solution with the different pH values. If $F(\lambda_2)$ is taken as the fluorescence intensity in the case where all the probe becomes the basic form, α is equal to C_1/C_2, so that

$$\alpha = \frac{F(\lambda_1)\Phi(\lambda_2)}{F(\lambda_2)\Phi(\lambda_1)}. \quad (2)$$

When λ_1 is equal to λ_2, the α value is equal to the ratio $F(\lambda_1)/F(\lambda_2)$. Then, the relative intensity of $F(\lambda_1)$ is identical with the α value if $F(\lambda_2)$ is taken as 1.0 (Fig. 1).

Since the peak wavelength was shifted, $\Phi(\lambda_1)/\Phi(\lambda_2)$ was evaluated from the results obtained by Abe *et al.*[15] The α values calculated by Eq. 2 are shown by closed symbols in Figs. 1(a) and 1(b). The maximum of all the measured fluorescence intensities is taken as the α value of 1.0. The apparent dissociation can be calculated from the α and pH values by the following Henderson-Hasselbalch equation:

$$pK_a = pH - \log\frac{\alpha}{1-\alpha}. \quad (3)$$

The pK_a values in urea and GuHCl solutions are shown as a function of pH in Figs. 3(a) and 3(b), respectively.

Neighboring Effect on pK_a. The pK_a values determined at each pH value increased with an increase in concentrations of the denaturants, suggesting that the probe inside the protein is exposed to the solvent according to the concentration of the denaturants which weaken the hydrophobic interaction between the probe and the nonpolar residues. In the absence of the hydrophobic interaction, the shift of pK_a from the logarithm of the reciprocal of dissociation constant, pK_0, of the free probe can be attributed to the electrostatic interaction between the probe and the charged residues. Taking only the long-range electrostatic effect of the protein based on the Debye-Hückel theory into account,[17] the pK_a values in the range of positive net charge of the protein might be less than the pK_0 values.

The pK_0 values were determined for 1.0×10^{-5} M of DNS-glycine conjugate as a model of the free probe in the corresponding solution: 3.94 in 0.01 M NaCl; 3.93, 4.00, and 4.17 in 2, 4, and 8 M urea; 3.99, 4.00, and 3.99 in 2, 4, and 6 M GuHCl, respectively. The results show that the dissociation constant gives about 4.0 in pH units, either in the presence or in the absence of the denaturants. The value of 4.0 is shown by a dashed line in Fig. 3.

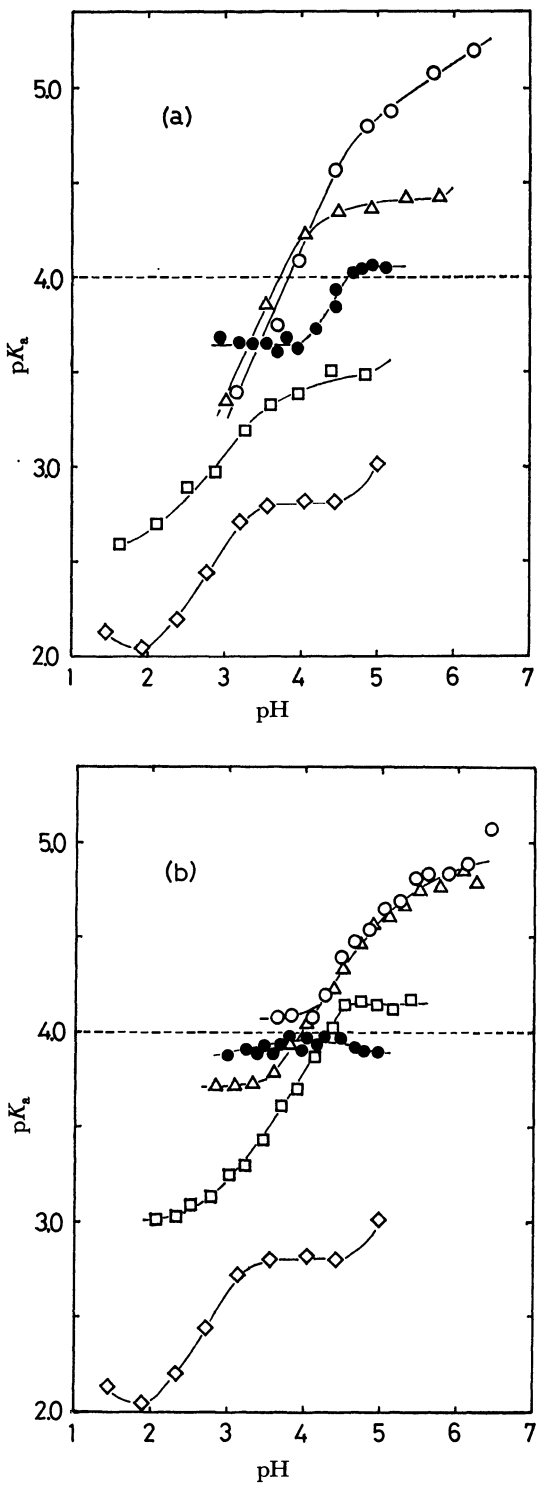

Fig. 3. Apparent pK_a values as a function of pH in the solution of urea (a) and GuHCl (b). Open symbols are obtained for the DNS-BSA conjugate with disulfide bonds at the same concentration of the denaturants as those in Fig. 2. Closed circles are obtained for the DNS-BSA conjugate with disulfide bonds ruptured by the reduction at 6 M of urea (a) and of GuHCl (b).

The pK_a values are not less than the pK_0 values under high concentration of the denaturants. This can be at least anticipated to involve a contribution of the electrostatic effect of negatively charged residues

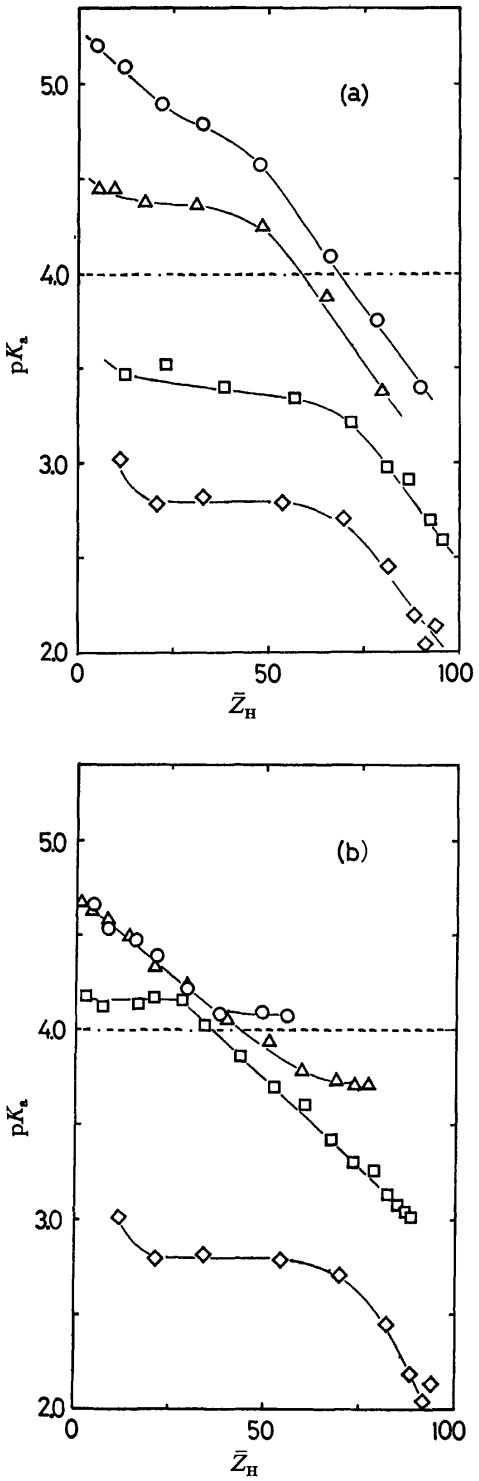

Fig. 4. Apparent pK_a values as a function of $\bar{Z}_H$ in the solutions of urea (a) and GuHCl (b). Symbols are the same as in Fig. 2.

on the acid-base equilibrium of the probe, since the positively charged residues apparently weaken the basic properties of the probe. If we assume that the electrostatic effect is attributable to only the long-range electrostatic interaction, the phenomenon should appear in the range of negative net charge of the protein. The net charge, $\bar{Z}_H$, from the isoelectric point, p*I*, of the protein was determined at various pH in each denaturant solution. The p*I* values were 5.3 in 0.01 M NaCl; 6.4, 6.6, and 7.0 in 2, 4, and 8 M urea; 5.3, 5.3, and 5.6 in 2, 4, and 6 M GuHCl. The pK_a values are plotted in Fig. 4 as a function of $\bar{Z}_H$ instead of pH. The pK_a values not less than the pK_o values are observed even in the range of positive $\bar{Z}_H$ values. This makes it impossible to account for the acid-base equilibrium at the high concentration of the denaturants in terms of the long-range electrostatic interaction. A possible explanation for the observed behavior may be the contribution of the short-range electrostatic interaction between the probe and the negatively charged residues situated in the neighborhood of the probe.

Variation of pK_a *in Reduction of Disulfide Bonds.* Proteins denatured by urea and GuHCl exist as random coils, but the transition to the denatured state is often incomplete even at the highest denaturant concentrations, especially when the native conformation is stabilized by disulfide bonds.[18] It is possible that the local structures surrounding the disulfide bonds maintain the structure of the native protein even in the concentrated denaturant solution. Since a molecule of BSA has seventeen of cystine with a disulfide group as seen from the complete data for the primary structure of BSA reported by Brown,[19] the fixed structures around such disulfide bonds might contribute largely to the neighboring effect on the acid-base equilibrium of the probe.

For the sake of confirmation, the disulfide bonds in the DNS–BSA conjugate were subjected to reductive cleavage by dithiothreitol in 6 M of urea or GuHCl solutions. The pK_a values for the DNS–BSA conjugate with the reduced disulfide bonds were determined in these denaturant solutions (Fig. 3). The values do not exceed the pK_o values in the denaturant solutions, *i.e.*, 4.17 in 8 M urea and 3.99 in 6 M GuHCl in the range of pH measured. The results showing that the neighboring effect disappears with the reduction of the protein suggest that the disulfide bonds play a significant role for fixing the relative situation of the probe and the ionized residues even in the denaturant solutions.

The change of pK_a against pH in the case of the reduced protein was not so remarkable as that in the case of unreduced one. $\bar{Z}_H$ values for the reduced protein were not dentermined, the pK_a values for the reduced DNS–BSA conjugate being less than those for the unreduced one in lower pH range. This suggests that the acid-base equilibrium of the probe is affected remarkably by the positively charged residues, as well as negatively charged residues, according to the dissociation of the ionizable group surrounding the probe.

Dielectric Constant of the Environment Surrounding the Probe. Appearance of the electrostatic neighboring effect is manifested by the lowering of the hydrophobicity around the probe. However, the hydrophobicity should also affect the shift of pK_a as the nonpolar neighboring effect. Since the denaturants weaken the hydrophobic interaction between the nonpolar residues, the local environment surrounding probe might have a solvent-like polarity with a high dielectric constant.

The change of such a local environment can be recognized as that of the medium in which the probe

exist. The nonpolar neighboring effect might be related to the medium effect in organic-water solvents. If a neutral species in the basic form, B^0, which gives a pK_0 value in water exists in a medium with a dielectric constant, D, the pK_a value in the medium can be written as

$$pK_a - pK_0 = \frac{e^2}{2.3rkT}\left(\frac{1}{D_w}-\frac{1}{D}\right), \quad (4)$$

where e, k, and D_w are proton charge, Boltzman constant, and dielectric constant of water, respectively, and r is the mean radius of the ions which forms HB^+ and X^- in the protonation of B^0 by an acid, HX, if these ions are regarded as rigid spheres. The relation is derived from Born's model to account for the medium effect theoretically.[20] Equation 4 shows that the shift of pK_a from pK_0 is proportional to $(1/D_w - 1/D)$.

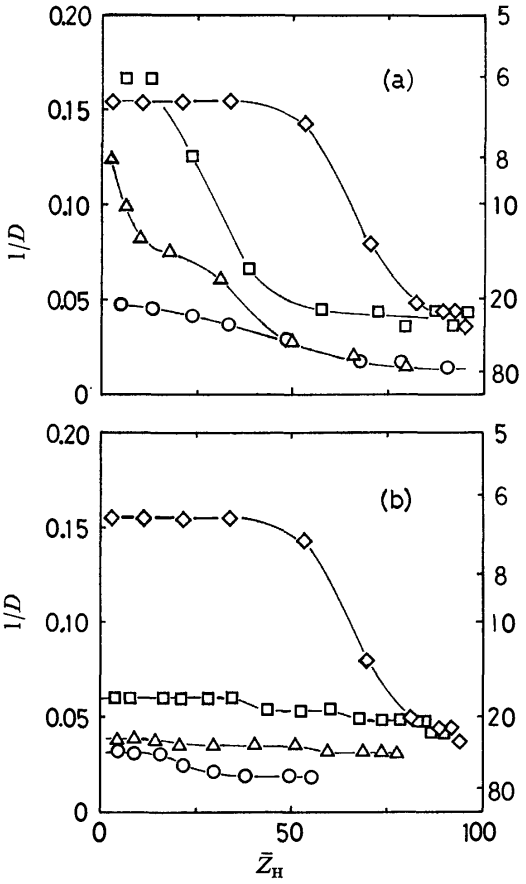

Fig. 5. Plots of the reciprocal of dielectric constant surrounding DNS as a function of $\bar{Z}_H$ in the solutions of urea (a) and GuHCl (b). Symbols are the same as in Fig. 2.

The dielectric constant of the local environment surrounding the probe was estimated by the peak wavelength of the fluorescence of the probe from the data for the fluorescence of DNS–amino acid conjugates in organic solutions.[15] The $1/D$ values estimated are shown as a function of $\bar{Z}_H$ in Fig. 5. In urea solution the $1/D$ values in the lower $\bar{Z}_H$ range decrease remarkably with an increase of the concentration of urea (Fig. 5(a)). This suggests that the nonpolar or medium effects appear in the absence of urea, especially in the lower $\bar{Z}_H$ range. The fact that the pK_a values in 0.01 M NaCl are almost constant in such a range of $\bar{Z}_H$ can be attributed to the nonpolar effect rather than the electrostatic effect. The nonpolar environment is unlikely to give rise to the presence of the electrostatic neighboring effect.

On the other hand, for higher $\bar{Z}_H$ values, the $1/D$ values approach the reciprocal of the dielectric constant of water (=0.0125), either in the presence or in the absence of urea. Thus, the nonpolar effect on pK_a can be ignored at the highest $\bar{Z}_H$ value. The shift of pK_a at such a $\bar{Z}_H$ value might be attributed to the long-range or short-range electrostatic effects. The pK_a values in aqueous solutions in the absence of the denaturants were less than those estimated from the Linderstrøm-Lang equation, especially when the protein formed an expanded state by the protonation.[6] The result can also be interpreted in terms of the short-range electrostatic interaction between the probe and the positively charged residues. The interaction might be caused by the disulfide bonds, similar to the electrostatic interaction between the probe and negatively charged residues in the presence of the denaturants.

In GuHCl solution (Fig. 5(b)), the $1/D$ values behave like those in urea solutions but give a low constant value even in 2 M of GuHCl solution. This is ascribed to the difference of the two denaturants; urea is a neutral molecule and GuHCl is a salt species. In a GuHCl solution with a high ionic strength, it is likely that the neighboring effect is due to the electrostatic interaction rather than the nonpolar interaction as compared with urea solutions.

The following conclusion is made. (1) The shift of pK_a from pK_0 is mainly attributed to the neighboring effects between the probe and its surrounding residues in the case of the unreduced protein. (2) The neighboring effects are attributed to the electrostatic and nonpolar interactions: The former effect is due chiefly to the exposure of the probe to the solvent-like environment by the protonation on the protein or by the denaturants employed, the latter to the probe being buried in the nonpolar environment.

The present work was partially supported by a Grant-in-Aid for Development Research from the Ministry of Education, Science and Culture.

Epicubebol and Related Sesquiterpenoids from the Brown Alga *Dictyopteris divaricata*[1]

Minoru Suzuki, Nobuhiko Kowata, and Etsuro Kurosawa*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 25, 1980)

Epicubebol has been isolated from the methanol extracts of the brown alga *Dictyopteris divaricata* as the major constituent. Cadinane-type sesquiterpenes, cubebenes, δ-cadinene, cubenol, and epicubenol, as well as two sesquiterpene methyl ethers as minor constituents have also been obtained from the extracts.

Recently many interesting secondary metabolites such as diterpenes[2,3] and sesquiterpene-substituted hydroquinones[4] have been obtained from the brown algae of the family Dictyotaceae. This prompted us to reinvestigate the constituents of the brown alga *Dictyopteris divaricata* (Okam.) Okamura ("Ezoyahazu" in Japanese) in this family.[5] We wish to report the isolation and structures of several cadinane-type sesquiterpenoids from this alga.

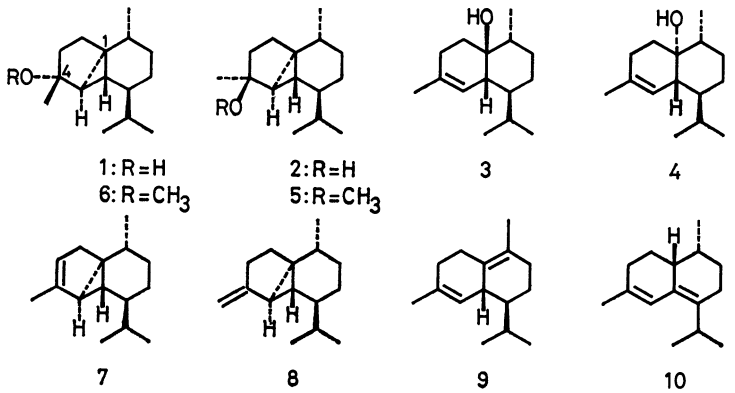
The neutral methanol extracts, obtained from freshly collected algae, were fractionated by column chromatography over neutral alumina. The fraction eluted with hexane gave a mixture of sesquiterpene hydrocarbons consisting of (−)-α-cubebene (**7**),[6] (−)-β-cubebene (**8**),[6] (+)-δ-cadinene (**9**), and other hydrocarbons. The fraction eluted with benzene was subjected to a combination of column and thin-layer chromatography over silica gel to yield compounds **3**, **4**, **5**, and **6** as minor components. The fraction eluted with ether was subjected to repeated thin-layer chromatography to give compound **1** as the major component.

Compound **1**, colorless oil, $[\alpha]_D^{21}$ −42°, was analyzed for $C_{15}H_{26}O$ by mass spectroscopy *m/e* 222 (M^+). Its IR spectrum showed hydroxyl absorption at ν_{max} 3380 cm^{-1}, and its ^1H NMR spectrum signals due to two cyclopropane protons at δ 0.35 and 0.77 (each 1H, m), a tertiary methyl group at 1.25 (3H, s), and three secondary methyl groups at 0.90, 0.93, and 0.99 (each 3H, d, J=7 Hz), two of which being ascribable to the isopropyl group on the basis of the base peak at *m/e* 161 [$M^+-H_2O-CH(CH_3)_2$] in the mass spectrum of **1**. The tertiary nature of the hydroxyl group was shown by its resistance to acetylation with acetic anhydride in pyridine and by the presence of a quaternary carbon at δ 80.0 ppm in the ^{13}C NMR spectrum. Since the ^{13}C NMR spectrum indicates no sp^2 carbon, compound **1**, having three degrees of unsaturation, should be a tricyclic sesquiterpene alcohol including a cyclopropane ring.

Treatment of **1** with $SOCl_2$ in CH_2Cl_2–pyridine at −7—−9 °C gave (−)-α-cubebene (**7**), (−)-β-cubebene (**8**), and (+)-δ-cadinene (**9**) in a low yield. On the other hand, treatment with TsOH in benzene at room temperature afforded (+)-δ-cadinene (**9**) as a major product and (−)-zonarene (**10**)[7] as a minor one. This indicates that compound **1** is cubebol (**2**), previously isolated from the oil of cubeb *Piper cubeba* L.,[8,9] or epicubebol (**1**) synthesized from (−)-α-cubebene (**7**) by oxymercuration-demercuration reaction.[9] Comparison of the spectral data show **1** to be identical with epicubebol (**1**). Isolation of epicubebol (**1**) as a natural product seems to have been carried out for the first time.

Compounds **3** and **4** were found to be identical with epicubenol (**3**) and cubenol (**4**), respectively, which have also been isolated from the cubeb oil,[10] by comparison of spectral data. **3** and **4** were derived from **1** on treatment with TsOH in benzene and also with dil HCl in dioxane–water[11] (see Experimental).

Compound **6**, $C_{16}H_{28}O$ (*m/e* 236; M^+), $[\alpha]_D^{24}$ −23°, displayed a ^1H NMR spectrum very similar to that of epicubebol (**1**) except for the signal due to the methoxyl group at δ 3.13 (3H, s), suggesting that **6** would be the methyl ether derivative of **1**. Spectral similarity between compounds **5** and **6** indicates that **5** would be the stereoisomer at C-4 of **6**, *viz.* the methyl ether derivative of cubebol (**2**). This was confirmed by the following reaction. Treatment of **1** with methanol containing a catalytic amount of H_2SO_4 at room temperature resulted in the formation of **5** (13%) and **6** (13%), suggesting that these methyl ethers are artifacts which were generated during the course of extraction. Thus, extraction of the alga was performed with ether instead



of methanol, no methyl ether derivatives, **5** and **6**, being obtained from the ether extracts as expected.

In previous studies,[5] no epicubebol (**1**), which exists as the major component of the extracts in the present study, was isolated. In contrast, no dictyopterols, dictyopterone, δ-cadinol, and other sesquiterpenes except for (−)-α-cubebene[12] could be detected in the present study. The difference in the results between the present and the previous studies seems to depend mainly upon the isolation procedure. In the previous studies, after distillation of the extracts with steam, fractional distillation was employed for fractionation of the neutral components, whereas we have treated the extracts at low temperature (below 35 °C) and further with rapid column and thin-layer chromatography. On heating at *ca.* 130 °C, epicubebol (**1**) gave (−)-α-cubebene, (−)-β-cubebene, and (+)-δ-cadinene together with (−)-*trans*-calamenene. By prolonged contact with silica gel, **1** turned into (+)-δ-cadinene, (−)-zonarene, and other hydrocarbons.

Recently 4,10-epoxymuurolane, which appears to be derived from epicubebol, has been isolated from the brown alga *Dilophus fasciola* together with several cadinane-type sesquiterpenes.[13]

It is interesting that the marine alga produces epicubebol (**1**) instead of cubebol (**2**) which has been isolated from the terrestrial plant.

Experimental

IR spectra were measured on a JASCO A-102 spectrometer and ^{1}H NMR spectra on a JEOL JNM-PS-100 spectrophotometer, TMS being used as an internal reference in CCl_4. The ^{13}C NMR spectrum was obtained with a Bruker SXP4-100 spectrophotometer in $CDCl_3$. The optical rotations were measured in $CHCl_3$. Aluminum oxide (Merck, activity II—III) and silica gel (Merck, Kieselgel 60, 70—230 mesh) were used for column chromatography. Silica gel (Merck, Kieselgel GF_{254} (Type 60)) was used for preparative thin-layer chromatography (PTLC).

Isolation. *Dictyopteris divaricata* was collected at Oshoro Bay, Hokkaido, during the months April—August 1980. No distinct difference was observed between the extracts in each collection. Half-dried alga (2.2 kg), collected in April, was extracted with methanol, and the resulting solution was concentrated under reduced pressure. The residue was percolated with ether, and the ether solution was shaken with 5% $NaHCO_3$ and saturated brine, and then dried over anhydrous Na_2SO_4. After evaporation of the solvent, a neutral oil (104 g) was obtained. This was fractionated by column chromatography over neutral alumina. Elution with hexane gave a mixture of sesquiterpene hydrocarbons from which (−)-α-cubebene (**7**) (0.04% of the neutral oil), (−)-β-cubebene (**8**) (1%), and (+)-δ-cadinene (**9**) (0.8%) were detected by comparison of the retention times in GLC with those of authentic samples. Elution with benzene gave an oily substance which was subjected to a combination of silica-gel column and PTLC to yield **3** (0.1%), **4** (0.02%), **5** (1.5%), and **6** (1.5%) (in order of decreasing porality) along with an unidentified alcohol. Elution with ether gave a mixture of alcohols which was repeatedly chromatographed on PTLC to yield **1** (13%) together with phytols, cholesterol, and at least two unidentified alcohols.

1: Colorless oil; $[\alpha]_D^{21}$ −42° (*c* 1.54); IR, ν_{max} (film) 3380, 1370, 1180, 1110, and 910 cm^{-1}; ^{1}H NMR, δ 0.35, 0.77 (each 1H, m), 0.90, 0.93, 0.99 (each 3H, d, J=7 Hz) and 1.25 (3H, s); ^{13}C NMR, δ 80.8 (s), 44.6 (d), 39.9 (d), 36.6 (t), 34.9 (s), 33.6 (d), 31.8 (d), 30.2 (t), 29.8 (t), 27.0 (t), 25.3 (d), 25.0 (q), 20.0 (q), 19.8 (q), and 19.1 (q); MS, *m/e* (relative intensity) 222 (12), 207 (83), 204 (9), and 161 (100). The IR (film and CCl_4) and ^{1}H NMR ($CDCl_3$) spectra were consistent with those of epicubebol.

3: Colorless oil; $[\alpha]_D^{25}$ −96° (*c* 0.94); The spectral properties were identical with those reported [10] for epicubenol.

4: Colorless oil; $[\alpha]_D^{20}$ −33° (*c* 0.13); The spectral properties were identical with those reported[10] for cubenol.

5: Colorless oil; $[\alpha]_D^{23}$ −82° (*c* 1.36); IR, ν_{max} (film) 1370, 1310, 1205, 1140, 1070, and 885 cm^{-1}; ^{1}H NMR, δ 0.74 (1H, m), 0.91 (6H, d, J=6 Hz), 0.96 (3H, d, J=6 Hz), 1.14 (3H, s), and 3.14 (3H, s); MS, *m/e* 236 (1), 221 (69), 204 (18), 161 (65), and 41 (100).

6: Colorless oil; $[\alpha]_D^{24}$ −23° (*c* 0.60); IR, ν_{max} (film) 1370, 1110, 1090, 1075, and 865 cm^{-1}; ^{1}H NMR, δ 0.35 (1H, m), 0.90, 0.94, 0.96 (each 3H, d, J=7 Hz), 1.21 (3H, s), and 3.13 (3H, s); MS, *m/e* 236 (1), 221 (100), 204 (8), and 161 (57).

*Dehydration of **1** with Thionyl Chloride.* A solution of **1** (107 mg) and thionyl chloride (0.04 ml) in dry dichloromethane (6 ml) and pyridine (1 ml) was allowed to stand at −7—−9 °C for 5 min. The mixture was then poured into ice-cooled water and extracted with ether. The ether solution was washed with saturated brine and dried over anhydrous Na_2SO_4. A residual substance obtained after removal of the solvent was chromatographed on alumina column. Elution with hexane gave a mixture of hydrocarbon (20 mg), GLC of which revealed that the mixture consists of (−)-α-cubebene (**7**) (20%), (−)-β-cubebene (**8**) (1.5%), (+)-δ-cadinene (**9**) (40%), and other hydrocarbons. Elution with ether gave unreacted **1** (25 mg).

*Dehydration of **1** with p-Toluenesulfonic Acid.* A solution of **1** (97 mg) and *p*-toluenesulfonic acid (2 mg) in benzene (5 ml) was stirred at room temperature for 30 min. After evaporation of benzene, the residual oily products were subjected to column chromatography on alumina. Elution with hexane gave a mixture of hydrocarbons (87 mg) consisting of (+)-δ-cadinene (**9**) (70%) and (−)-zonarene (**10**) (1%). Purification of (+)-δ-cadinene was carried out by preparative GLC. **10** was identified as (−)-zonarene by comparison of the retention time in GLC with that of an authentic sample. Elution with ether gave a mixture of alcohols which was further chromatographed on PTLC to afford epicubenol (**3**) (4 mg), cubenol (**4**) (2 mg), and **1** (1 mg).

*Conversion of **1** into **3** and **4**.* A small amount of dil HCl was added to a solution of **1** (97 mg) in dioxane (6 ml) and water (2.5 ml), and the mixture was allowed to stand at room temperature for 30 h. Water was added and extraction was carried out with ether. The ether solution was washed with saturated brine, dried over anhydrous Na_2SO_4, and evaporated to give an oily residue. The residue was chromatographed on alumina column. Fraction eluted with ether was further subjected to repeated PTLC to give epicubenol (**3**) (11 mg), cubenol (**4**) (4 mg), and **1** (24 mg) along with unidentified alcoholic compounds and ketonic compounds.

*Methanolysis of **1**.* A solution of **1** (65 mg) and a catalytic amount of concd H_2SO_4 in methanol (20 ml) was allowed to stand at room temperature for 2 h with continuous stirring. The mixture was then concentrated *in vacuo*. Water was added and extraction was carried out with ether. The ether solution was washed with 5% $NaHCO_3$ and saturated brine, and then dried over anhydrous Na_2SO_4. After evaporation of the solvent, the residual oil was chromatographed on silica-gel column to give **5** (9 mg), **6** (9 mg), and **1** (44 mg).

*Thermal Reaction of **1**.* **1** (100 mg) was placed in a flask

fitted with condenser which was immersed in an oil bath maintained at 130 °C under nitrogen atmosphere. After 5 h the reaction products were separated by column chromatography over alumina to yield a hydrocarbon fraction (54 mg) which was further subjected to preparative GLC to give (−)-α-cubebene (**7**) (21 mg), (−)-β-cubebene (**8**) (11 mg), (+)-δ-cadinene (**9**) (11 mg), and (−)-*trans*-calamenene (4 mg). The structure of *trans*-calamenene was identified by comparison of the IR and ^{1}H NMR spectra with reported[14] for calamenene. Unchanged **1** (33 mg) was recovered.

The authors are grateful to Prof. Akira Yoshikoshi, Tohoku University, for the spectral data of cubebenes, cubebol, and epicubebol, and also to Mr. Nobuyasu Enoki, Hokkaido University, for providing (−)-zonarene and its spectral data.

Oxidative Cleavage Reaction of 3-Substituted Indoles Catalyzed by CuCl–Pyridine Complex under Oxygen

Jiro Tsuji,* Hiroaki Kezuka, Hiroshi Takayanagi, and Keiji Yamamoto

Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received January 20, 1981)

Oxidative cleavage of 3-methylindole using a catalytic amount of copper(II) salts with added pyridine under an oxygen atmosphere was studied. Smooth cleavage of 3-methylindole took place to give 2-formamidoacetophenone in 73—80% yield, whereas exclusive formation of a hydrate compound derived from 3,3′-dimethyl-3,3′-bi-3*H*-indole resulted under anaerobic conditions. Clean oxidative cleavage of *N*-acetyltryptamine, methyl 3-indolylacetate, and methyl 2-acetamido-3-(3-indolyl)propionate was also achieved, constituting a mimic of tryptophan-2,3-dioxygenase.

We have reported the oxidative cleavage reaction of catechol and phenol using CuCl–pyridine complex under oxygen to give methyl *cis,cis*-muconate in high yields as a non-enzymic model for pyrocatechase.[1]

As an extension of our studies on the metal salt-catalyzed liquid-phase oxidation, which includes oxidative cleavage of *o*-phenylenediamine to *cis,cis*-mucononitrile,[2] oxidation of various olefins to carbonyl compounds,[3] and facile oxidative conversion of acid hydrazides to the corresponding acids,[4] we attempted an oxidative cleavage of an indole ring as a non-enzymic model for tryptophan-2,3-dioxygenase. Although indole derivatives related to tryptophan are fairly sensitive to oxidation, controlled oxidation to give rise to the cleavage of the indole ring is rather limited.[5] We have recently disclosed clean oxidative cleavage of 3-methylindole catalyzed by CuCl–pyridine complex under oxygen.[6] There has been reported an independent study on the oxidative cleavage of 2- and 3-substituted indoles using a CuCl–pyridine–O_2 system.[7]

Tryptophandioxygenase is an important enzyme which selectively cleaves the indole ring of tryptophan and several studies on its model reaction have been reported. Photosensitized oxygenation of tryptophan and related indole derivatives gave the cleaved product.[8,9] Nishinaga reported a successful oxidative cleavage of various indole derivatives using cobalt-Schiff base complexes as catalyst to give 2-formamidoacetophenone derivatives in high yields.[10] Manganese phthalocyanine-catalyzed oxidative cleavage of 3-methylindole gave similar results.[11] More recently, copper-Schiff base complex-catalyzed oxidation of tryptophan has been reported.[12]

In this paper we describe the oxidative cleavage reaction of several 3-substituted indoles under the optimum conditions so far examined using CuCl–pyridine complex under oxygen.

Results and Discussion

Catalytic Oxidation Using Copper(II) Salts. 3-Methylindole: Oxidative cleavage reaction of 3-methylindole using various copper(II) salts as a catalyst under an oxygen atmosphere was studied. Although copper(II) salts such as copper(II) acetate and methoxide did act as a catalyst effectively in the presence of oxygen, copper(I) chloride was principally used in order to compare the catalytic behavior for the oxidative cleavage of 3-methylindole with that for catechol oxidation.

Prior to the reaction, copper(I) chloride dissolved in pyridine–dichloromethane was oxidized until oxygen absorption ceased. Usually about one-fourth mole of oxygen per mole copper(I) used was found to be absorbed, substantiating the equation:[1d]

$$2\,CuCl + 1/2\,O_2 \xrightarrow{\text{pyridine}} CuCl_2 \cdot CuO.$$

Results of screening of the reaction conditions indicated that an added pyridine is crucial and that the choice of solvent has a considerable effect on the reaction rate and the yield of the cleaved product, dichloromethane being satisfactory. Also relative amounts of pyridine to the solvent seem to be important.

The reaction proceeded smoothly at ambient temperature (15—20 °C) with absorption of additional oxygen during the course of 3—6 h. Under the best conditions so far examined, 2-formamidoacetophenone was obtained in 73—80% yield. Results are summarized in Table 1.

It is of interest to note that overall oxygen uptake roughly parallels yields of the cleaved product, except for entries **1a** and **1b**, regardless of the molar ratios of the substrate to catalyst in the range of 3.3 to 0.5.

Under the same conditions as entry **1f** 2,3-dimethylindole underwent oxidative cleavage to form 2-acetamidoacetophenone in 50% yield.

As is discussed below, intervention of a 3*H*-indol-3-yl radical, which is formed by facile one electron transfer from 3-methylindole to Cu(II) species followed by deprotonation, is likely responsible for the subsequent oxygenation to result in the cleavage of the indole ring. Thus, the most effective species for the oxidative cleavage of 3-methylindole would be Cu(II) ion coordinated with pyridine, which is, in turn, able to transfer molecular oxygen effectively to the intermediate 3*H*-indol-3-yl radical.

3-Substituted Indoles. Oxidative cleavage of *N*-acetyltryptamine, methyl 3-indolylacetate, and methyl 2-acetamido-3-(3-indolyl)propionate was carried out under the conditions aforementioned.

These reactions were found to be rather sluggish and the latter two substrates underwent cleavage with relatively low conversions as compared with 3-methylindole even after 24 h of reaction period. All results obtained are summarized in Table 2.

A few points deserve comments. Steric demand of R

Table 1. Copper(II)-catalyzed oxidation of 3-methylindole to 2-formamidoacetophenone under oxygen[a)]

Entry	Cu(II) salt (mmol)	Pyridine (ml)	Solvent (ml)	O_2 Uptake[b)] (mmol)	Yield[c)] %

$[CuCl_2 \cdot CuO]$[d)]	2.0	0 (dimer,[c)] 59)	16

a) 3-Methylindole (1.0 mmol), Cu(II) salt (4.0 mmol) in dichloromethane (25 ml) with added pyridine under argon. Stirred at room temperature for 4 d. b) Prepared *in situ* from anhydrous MeOLi and $CuCl_2$ in dry THF. c) Hydrate compound (II) (R=Me) derived from 3,3′-dimethyl-3,3′-bi-3*H*-indole (III) (R=Me). Duplicated results. d) Pretreated CuCl with requisite amounts of oxygen:

$$2CuCl + 1/2O_2 \xrightarrow{py} CuCl_2 \cdot CuO \quad (cf.\ \text{Ref. 1}).$$

groups at the 3-position apparently affects the reaction rate, reflecting low conversions of the cleavage. The same is true for cobalt-salen complex-catalyzed oxidative cleavage of these 3-substituted indoles.[10)] Cobalt complex-catalyzed oxidation of methyl 3-indolylacetate in methanol resulted in a side chain oxidation rather than a ring cleavage, whereas the present copper complex-catalyzed reaction afforded methyl 2-formamidobenzoylacetate in 48% yield.

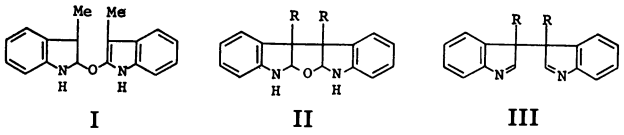
Generally, yields of the cleaved products attained under the present reaction conditions are much superior to those reported,[7)] using CuCl–pyridine–O_2 system without dichloromethane. Selecting simply a solvent, one can improve significantly the yield of oxidative cleavage of 3-substituted indoles, as is seen from Table 1 with respect to 3-methylindole.

Cu(II) as an Oxidant. 3-Methylindole was treated with excess copper(II) salts (4 equiv.) with added pyridine in dichloromethane solution at room temperature under an argon atmosphere. TLC monitoring of the reaction mixture revealed that very slow cleavage took place to give 2-formamidoacetophenone as a sole product in moderate yields with recovery of appreciable amounts of the starting 3-methylindole even after four days. Results obtained are given in Table 3. Although the reaction rate was found to be much slower than that found under oxygen as mentioned above, it is obvious that both copper(II) chloride and acetate are capable of initiating selective cleavage of 3-methylindole.

The most striking, however, is the fact that no cleaved product was obtained when copper(II) methoxide, prepared *in situ* from copper(II) chloride and two equivalents of anhydrous lithium methoxide in tetrahydrofuran (THF), was used as an oxidant. The results are confirmed by duplicated runs. Similar results were also obtained with a dichloromethane solution of copper(I) chloride with added pyridine, which was allowed to absorb a requisite amount of oxygen, followed by purging excess oxygen thoroughly with argon (see Experimental).

The sole product obtained in these two sets of reactions was white crystalline material which had exactly the same melting point after recrystallization from chloroform as well as analytical data as one previously obtained by Dobeneck[13)] in the oxidation of 3-methylindole with iron(III) chloride, and characterized as an ether (I). Acid catalyzed dimerization of 3-methylindole occurs readily, but the resulting dimer has indoline-

indole moieties joined at their 2-positions,[14] while radical dimerization of 3-substituted indoles has been suggested without any structure characterization.[15]



I II III

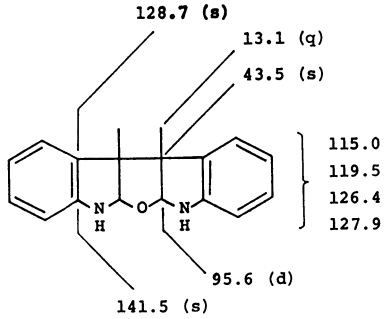


Fig. 1. ^{13}C NMR Data for II (R=Me), δ/ppm (OFR splitting are given in parentheses).

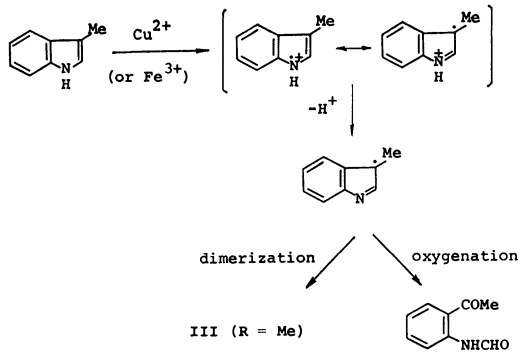
However, the structure (I) assigned by Dobeneck[13] was now found to be erroneous. ^1H and ^{13}C NMR (Data given in Fig. 1) as well as MS data of the products prepared by using either Cu(II) or Fe(III) salt indicate a symmetric structure of compound (II) (R=Me), which is obtained as one diastereomer and is most probably derived from addition of water to a rather unstable 3,3′-dimethyl-3,3′-bi-3*H*-indole III (R=Me). III is a 3*H*-indole-3*H*-indole dimer, the dimeric bond being formed at 3-position in the 3*H*-indole moiety.

It has been reported that such oxidants as potassium hexacyanoferrate(III) and manganese oxide are insufficient for radical generation from indolic nitrogen. Successful oxidative dimerization of indolylmagnesium halides with iron(III) chloride has already been described[16] to form intermediate III (R=CH_2CH_2-NHMe).

It appears to be difficult to account for exactly why the two reaction paths were observed in the course of oxidation of 3-methylindole using four different copper(II) salts under apparent anaerobic conditions. However, the exclusive formation of a dimer (III) (R=Me), which is trapped as compound (II) (R=Me), from 3-methylindole in certain cases may now be rationalized by the following scheme.



Facile one electron transfer from 3-methylindole at the nitrogen atom to copper(II) (as well as to iron(III)) followed by deprotonation gives an intermediate 3*H*-indol-3-yl radical, which may or may not coordinate to the copper species. The radical undergoes either dimerization under rigorous anaerobic conditions, if any, to give III or oxygenation with oxygen presumably adsorbed on certain copper salts present in the reaction mixture to afford selectively 2-formamidoacetophenone.[17] The scheme is consonant with the fact that attempted reaction of 1,3-dimethylindole under oxygen resulted in complete recovery of the starting material. It is confirmed that 3-ethylindole also formed the corresponding dimeric compound (II) (R=Et). However, the significant role of the anionic ligands of copper(II) species is still unclear at present.

Experimental

Apparatus. For the present oxidative cleavage reactions was throughout used a three-neck, round-bottomed 50 ml flask equipped with a magnetic stirrer, a Hershberg dropping funnel, a serum cap, and a three-way stopcock which was connected either with an oxygen gas buret or with an argon balloon.

Copper(II) Salts. $CuCl_2$ and $Cu(OAc)_2 \cdot H_2O$ were used as received. Anhydrous $Cu(OAc)_2$ commercially available was dried *in vacuo* prior to use. $Cu(OMe)_2$ was prepared *in situ* by the following procedure. A brown suspension of $CuCl_2$ (0.588 g, 4.2 mmol) and LiOMe (0.34 g, 8.6 mmol) in THF (20 ml) was stirred for 1 h under argon. The reaction mixture turned green was evaporated to dryness *in vacuo* and used in dichloromethane for the oxidation immediately. For "Cu reagent," CuCl–pyridine–O_2 system, a typical run is as follows. A clear green solution of CuCl (0.398 g, 4.0 mmol) dissolved under argon in dichloromethane (20 ml) and pyridine (2 ml) was exposed to oxygen with stirring. Oxygen uptake (about 1 mmol) ceased within 1 h, during which time the solution turned to a dark green suspension. The "Cu reagent" thus prepared was used either under oxygen for cleavage reactions or after purging excess oxygen with argon for anaerobic reactions.

Catalytic Oxidative Cleavage of 3-Methylindole. Using "Cu reagent," the following is the best procedure; "Cu reagent" was prepared as above using CuCl (0.050 g, 0.5 mmol), dichloromethane (10 ml), and pyridine (0.5 ml). Into the dropping funnel was placed a solution of 3-methylindole (0.131 g, 1 mmol) in dichloromethane (10 ml). The solution was added dropwise to the "Cu reagent" under oxygen over 1 h. After additional 1.48 mmol of oxygen was absorbed within 4 h, the reaction mixture was hydrolyzed with 40 ml of 3 mol dm^{-3} HCl. The organic layer was separated and aqueous layer was extracted with dichloromethane. The combined organic layer was washed with brine three times and dried over $MgSO_4$. The dichloromethane was removed by evaporation and the residue was purified by column chromatography (silica gel, dichloromethane as eluent) to give 2-formamidoacetophenone in 73% yield: mp 77—78 °C (lit,[10] mp 79—80 °C); ^1H NMR ($CDCl_3$) δ 2.64 (s, 3H), 6.94—8.01 (m, 3H), 8.35—8.87 (m, 2H), and 11.51 (s, broad, 1H); IR (KBr) 3250, 2890, 1690, and 1660 cm^{-1}.

Similarly, a solution of 2,3-dimethylindole (0.022 g, 0.15 mmol) in dichloromethane (2.0 ml) was added dropwise to

the "Cu reagent" prepared from CuCl (0.009 g, 0.09 mmol) and pyridine (0.8 ml) dissolved in dichloromethane (2.0 ml) under oxygen atmosphere. Oxygen uptake ceased within 4 h, and the reaction mixture was worked up as above. Purification of the product by column chromatography gave 2-acetamidoacetophenone in 50% yield: mp 73—75 °C (lit,[18] mp 74—75 °C); ^{1}H NMR ($CDCl_3$) δ 2.20 (s, 3H), 2.63 (s, 3H), 6.85—7.94 (m, 3H), 8.56—8.78 (m, 1H), and 11.61 (s, broad, 1H); IR (KBr) 3250, 1690, and 1655 cm^{-1}.

$Cu(OAc)_2$ (0.09 g, 0.5 mmol) was dissolved in a solution of dichloromethane (10 ml) and pyridine (0.5 ml) under oxygen. In a similar manner as above, the solution of 3-methylindole (0.131 g, 1 mmol) in dichloromethane (10 ml) was added for 1 h. The mixture was stirred for 6 h, during which time slow absorption of oxygen (1.6 mmol) was observed. The reaction mixture was worked up as usual and 2-formamidoacetophenone was obtained in 81% yield.

$Cu(OMe)_2$ was prepared as above using $CuCl_2$ (0.060 g, 0.44 mmol) and LiOMe (0.033 g, 0.87 mmol). The oxidative cleavage of 3-methylindole (0.117 g, 0.89 mmol) under oxygen provided 2-formamidoacetophenone in 55% yield.

Oxidative Cleavage of 3-Substituted Indoles. Oxidation of *N*-acetyltryptamine (0.218 g, 1 mmol) with the "Cu reagent" was carried out under oxygen atmosphere. Stirring was continued for 22 h. Usual workup provided 2-(3-acetamidopropionyl)formanilide in 68% yield: mp 117—118 °C; NMR ($CDCl_3$) δ 1.94 (s, 3H), 2.96—3.78 (m, 4H), 6.38—6.78 (m, 1H), 6.88—7.93 (m, 3H), 8.26—8.79 (m, 2H), and 11.32 (s, broad, 1H); IR (KBr) 3330, 2920, 1675, and 1645 cm^{-1}.

Oxidation of methyl 2-acetamido-3-(3-indolyl)propionate (0.260 g, 1 mmol) with the "Cu reagent" under oxygen provided methyl 2-acetamido-3-(2-formamidobenzoyl)propionate in 57% yield (based on 68% conversion): mp 160—162 °C (hexane–CH_2Cl_2); NMR ($CDCl_3$) δ 2.01 (s, 3H), 3.74 (s, 3H), 4.74—5.09 (m, 1H), 6.42—6.78 (m, 1H), 6.98—8.01 (m, 3H), 8.34—8.90 (m, 2H), and 11.36 (s, broad, 1H); IR (KBr) 3260, 2950, 1755, 1695, and 1655 cm^{-1}. Found: C, 57.78; H, 5.58; N, 8.94%; Calcd for $C_{14}H_{16}N_2O_4$: C, 57.53; H, 5.52; N, 9.58%. MS *m/e* (rel intensity) 292 (3) (M^+); 167 (37), 149 (100), 148 (42), 71 (40), 57 (70), 43 (52), 41 (41).

Oxidation of methyl 3-indolylacetate (0.175 g, 1 mmol) as above with the "Cu reagent" gave methyl (2-formamidobenzoyl)acetate in 48% yield (based on the 79% conversion): mp 40 °C; NMR ($CDCl_3$) δ 3.76 (s, 3H), 4.06 (s, 2H), 7.01—7.99 (m, 3H), 8.47—8.98 (m, 2H), and 11.37 (s, broad, 1H); IR (KBr) 3280, 1725, 1690, and 1600 cm^{-1}.

Cu as an Oxidant. $CuCl_2$ (0.538 g, 4 mmol) was dessolved in a solution of dichloromethane (20 ml) and pyridine (2 ml). As in the case of catalytic oxidative reaction but under argon atmosphere, the solution of 3-methylindole (0.131 g, 1 mmol) in dichloromethane (5 ml) was added dropwise for 1 h. Stirring was continued for 4 d. Work up of the reaction mixture as usual, afforded 2-formamidoacetophenone in 34% yield.

Oxidation of 3-methylindole (0.131 g, 1 mmol) as above with $Cu(OAc)_2 \cdot H_2O$ (0.799 g, 4 mmol) or anhydrous $Cu(OAc)_2$ (0.727 g, 4 mmol) after 4 d afforded 2-formamidoacetophenone in 48 and 67% yields, respectively.

Oxidation of 3-methylindole was carried out under argon for 4 d with $Cu(OMe)_2$ prepared *in situ* described as above. Purification of the product by column chromatography (silica gel, dichloromethane as eluent) gave compound (II) (R=Me) which was thought to consist of two diastereomers: mp 165—167 °C. Recrystallization from chloroform afforded one diastereomer as white crystals: mp 202—204 °C; ^{1}H NMR ($CDCl_3$) δ 1.32 (s, 6H), 4.94 (s, 2H), and 6.45—7.35 (m, 10H); ^{13}C NMR ($CDCl_3$) data are given in Fig. 1; IR (KBr) 3400, 3350, 2960, 1605, 1475, 1295, 1265, 1090, 1050, 885, 805, 755, and 745 cm^{-1}. Found: C, 77.40; H, 6.41; N, 10.06%. Calcd for $C_{18}H_{18}N_2O$: C, 77.67; H, 6.52; N, 10.06%; MS *m/e* (rel intensity) 278 (6) (M^+), 263 (19), 261 (19), 260 (84), 259 (28), 246 (21), 245 (100), 232 (41), 217 (15), and 130 (16).

Compound (II) (R=Me) was dissolved in MeOH containing HCl. After the solution was warmed for 10 min, 3-methylindole and 3-methyl-2-indolinone were obtained. *N,N'*-Dimethyl derivative of II (R=Me) is known to undergo similar cleavage reaction.[19]

Oxidation of 3-Methylindole with $FeCl_3$ and Et_2NH. Oxidation of 3-methylindole (0.508 g, 3.9 mmol) with $FeCl_3$ (1.32 g, 8 mmol), Et_2NH (2.1 ml, 20 mmol), and Et_2O (26 ml) according to Dobeneck's[13] procedure afforded the same product which was obtained by the oxidation with $Cu(OMe)_2$ or "Cu reagent" as an oxidant. Yield 32%.

Oxidation of 3-Ethylindole with $Cu(OMe)_2$. Oxidation of 3-ethylindole (0.145 g, 1 mmol) with $Cu(OMe)_2$ under argon provided compound (II) (R=Et) in 50% yield which was also found to be a mixture of two diastereomeric isomers mp 41—54 °C; ^{1}H NMR ($CDCl_3$) δ 0.68 (t, J=7 Hz, 3H), 1.79 (q, J=7 Hz, 2H), 5.31 (5.02) (s, 1H), and 6.42—7.50 (m, 5H); ^{13}C NMR ($CDCl_3$) Compound (IIa) (R=Et): δ 9.5, 22.1, 47.4, 98.3, 109.5, 118.5, 127.4, 128.0, 129.5, and 149.4; Compound (IIb) (R=Et): δ 8.8, 23.8, 43.5, 95.4, 115.2, 119.0, 126.4, 127.8, 128.1, and 142.6; IR (KBr) 3380, 2960, 1605, 1480, 1260, and 740 cm^{-1}; MS *m/e* (rel intensity) 306 (5) (M^+), 277 (30), 259 (17), 162 (20), 161 (18), 146 (36), 145 (26), 132 (19), and 130 (100).

The authors thank Mr. Y. Nakamura for ^{13}C NMR measurements, and Prof. T. Hino for informing us of his early work on indole derivatives.

The Pschorr Cyclization of Aromatic Amines with *t*-Butyl Thionitrate in Nonaqueous Media

Shigeru OAE,* Kazuyuki IIDA, Kōichi SHINHAMA, and Toshikazu TAKATA
Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305

(Received January 23, 1981)

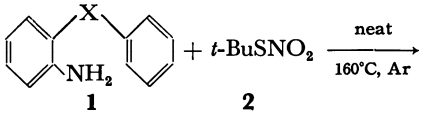
The Pschorr cyclization of various arylamines with *t*-butyl thionitrate under nonaqueous conditions gave the corresponding cyclic products in moderate yields. The same reaction was also found to proceed readily with *p*-toluenesulfonyl nitrite at room temperature. Treatment of *o*-aminophenyl allyl ether or sulfide with *t*-butyl thionitrate resulted in the intramolecular Meerwein arylation to the olefinic bond affording 3-chlorochroman or -thiochroman, though the yield was low. The plausible mechanism of the Pschorr cyclization with *t*-butyl thionitrate is discussed.

During the course of our study on oxidation of aliphatic and aromatic thiols, disulfides and sulfinic acids with N_2O_4, the corresponding thionitrites, thionitrates and sulfonyl nitrites have been found to be the key intermediates, which are also very useful in synthetic reactions. Namely, diazotization reaction of aromatic amines,[1] nitrosation of secondary amines, and sulfenylation of carbanion[2] are readily promoted in good yields in nonaqueous reaction media. These are remarkably effective reagents for diazotization of aromatic amines due partly to the relatively weak S–N bond as compared to O–N bond of alkyl nitrite. The Gomberg-Bachmann reaction which is used for synthesis of biphenyl from aromatic diazonium salt, has also been carried out using the thionitrates.[1] Thus, various aromatic amines have been allowed to react with the thionitrate in aromatic solvents such as benzene affording biphenyl derivatives in good yields.

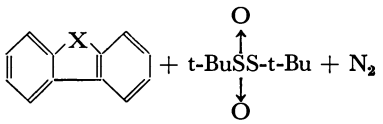
While all these reactions we have studied are intermolecular coupling of two aromatic rings, we now have applied the reaction to an intramolecular reaction, *i.e.* the Pschorr cyclization,[3] which is known to be an effective reaction for one-step synthesis of cyclic compounds, used often for syntheses of natural products.[4,5] This paper deals mainly with the Pschorr cyclization of various aromatic amines with *t*-butyl thionitrate, together with the intramolecular Meerwein arylation to give cyclic products.

Results and Discussion

When various aromatic amines bearing two aromatic rings (**1**) such as 2-aminobenzophenone (**1a**, 1.0 mmol) were treated with *t*-butyl thionitrate (**2**, 1.5 mmol) without solvent at 160 °C for 0.5 h the corresponding cyclization product (**3**) was obtained as the main product. *t*-Butyl thionitrate (**2**) was in turn converted to *S*-*t*-butyl 2-methylpropane-2-thiosulfonate (**4**) during



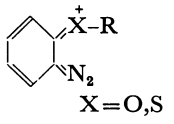
1 **2**



3 **4**

the cyclization. Other unidentified products were in the form of tar or resin. Generally, the Pschorr reaction is known to be accompanied with a few side reactions such as reduction of diazonium ion which produces arene, reductive coupling which affords symmetrical biphenyls, halogenation and phenol formation.[3] Therefore, the yield of the cyclized product in the usual Pschorr reaction is generally low.[3] In this reaction, a small amount of the reduced product, *i. e.* benzophenone, was also obtained, however formation of phenol and reductive coupling derivatives were not observed in this reaction in nonaqueous media.

The Pschorr cyclization of several aromatic amines which possess different bridging group of X in (**1**) with *t*-butyl thionitrate (**2**) has been examined and the yields of the corresponding cyclic products are listed in Table 1. Since the Pschorr reaction is an intramolecular condensation reaction, the ready access of the two reaction centers in the ground state is considered to be quite important for successful cyclization. Namely, the two carbon atoms that are eventually linked together would preferably be in a close vicinity with each other. The most favorable bridging group (X, **1**) is the rigid ethylenic linkage of ethyl (*E*)-2,3-diphenylpropenate (**1g**), which would assume a planar structure by conjugation between the two aromatic rings through an ethylenic group, thus placing the two reaction centers of two aromatic rings in a close vicinity. In fact, ethyl (*E*)-2,3-diphenylpropenate (**1g**) gave ethyl 9-phenanthrenecarboxylate (**3g**) as the main cyclic product in a very good yield in the Pschorr reaction with *t*-butyl thionitrate (**2**). In the case of ether (**1b**) and sulfide (**1c**, **1d**, **1e**), the yield of cyclized products were rather low. Contribution of the following *o*-quinonoid structure (**5**)



5

in the ground state of the diazonium salts of both the ether (**1b**) and sulfide (**1c**, **1d**, **1e**) may be partly responsible not only for the low yields of the desired products but also for the undesired resin-forming side reactions, while the distant two reaction centers would not favor the recombination.[3] When 2-aminodiphenylamine (**1f**) was treated with the thionitrate, 1-phenylbenzotriazole (**3f**) instead of carbazol, a desired product,

was obtained. The same result was obtained in the ordinary Pschorr cyclization with nitrous acid in an aqueous media.[3]

In searching the optimum reaction conditions, several runs were carried out (see Table 2). Although the cyclization is an intramolecular reaction, the reaction without solvent was found to offer higher yield of cyclization at higher temperatures, however the best yield of cyclic product was attained in the reaction in DMSO. The Pschorr reaction with nitrous acid in aqueous media is usually carried out in the presence of copper[3] or copper(I) oxide.[7] However when copper or copper(I) oxide was added into our reaction system, the cyclic adduct, fluorenone (**3a**), was not obtained but a complex mixture was obtained.

Meanwhile, the Pschorr reaction of *o*-substituted aromatic amines was also found to proceed smoothly with *p*-toluenesulfonyl nitrite (**6**), which has been shown by us to be a new still more powerful nitrosating agent in certain cases, was used instead of *t*-butyl thionitrate.[1] Namely, aromatic amine (**1**, 1.0 mmol) was treated with three equivalents of *p*-toluenesulfonyl nitrite (**6**, 3.0 mmol) at room temperature for 1—2 h in dry acetonitrile under argon atmosphere. In this case, the reaction was carried out at room temperature instead

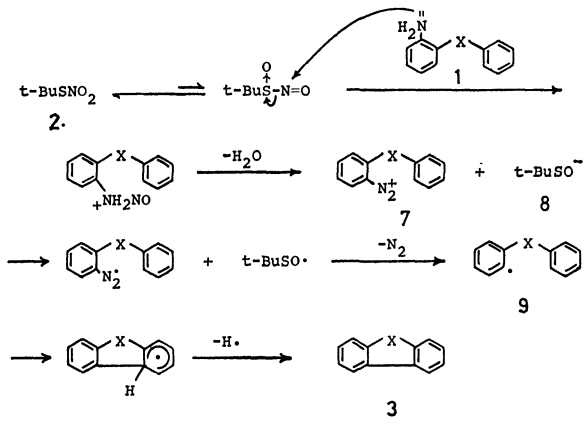
of higher temperatures at which reaction was performed with *t*-butyl thionitrate, since *p*-toluenesulfonyl nitrite (**6**) decomposes at a higher temperature. However the yield of the cyclic adduct was relatively higher than that in the reaction with *t*-butyl thionitrate (see Table 3).

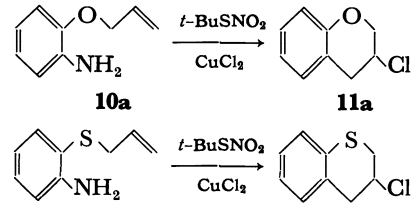
As to the mechanism of the Pschorr cyclization, there are two conceivable pathways, *i. e.* ionic and homolytic paths.[6-8] While thermal decomposition of diazonium salts in acidic media has been believed to take place *via* the ionic process, the reaction has been considered to proceed *via* the homolytic pathway, when the counter anion of diazonium ion is a good reducing agent or the reaction is catalyzed by copper. Since the sulfenate anion derived from the thionitrate (**2**) is considered to be a good reducing agent, while a large amount of tarry material is formed in the reaction, we propose the following free-radical mechanism for this reaction (Scheme 1). The gas evolved in the Gomberg-Bachmann



Scheme 1.

reaction of arylamines with aromatic hydrocarbon using *t*-butyl thionitrate[1] was analyzed as N_2 gas by mass spectrometry upon conducting the reaction carefully in a degassed anhydrous system. Therefore, the Pschorr cyclization of aromatic amine with *t*-butyl thionitrate is considered to be initiated by the nucleophilic attack of aromatic amine to nitrogen atom of *t*-butyl thionitrate, like in the aqueous Pschorr reaction. The diazonium ion (**7**) formed after the dehydration may be reduced to the diazo radical by sulfenate anion (**8**), a good reducing agent, which upon release of N_2 gas, gives aryl radical (**9**) that undergoes intramolecular coupling to afford cyclic product (**3**) after hydrogen abstraction. Besides the intramolecular cyclization there may be some intermolecular arylation or a similar side reaction which may be responsible for the formation of much unidentified tarry materials.

Meanwhile, the reaction of diazonium halides derived from aromatic amines with olefinic compound in the presence of copper salt is known as the Meerwein arylation reaction.[9] The Meerwein arylation to olefinic compounds has been found to take place with *t*-butyl thionitrate and addition products were obtained in moderate yields.[1] When an aromatic amine which possesses allyloxy or allylthio group (**10**) at the ortho position was treated with 1.4 equivalent of *t*-butyl



thionitrate (**2**) in the presence of copper(II) chloride in dry acetonitrile at room temperature, the cyclization product (**11**) was obtained as the result of the intramolecular Meerwein arylation despite the lack of any electron-withdrawing substituent on the vinyl group to enhance the Meerwein addition of aryl group. This may be the first example of the intramolecular Meerwein arylation to afford heterocyclic compounds.

Thus, we may conclude that the Pschorr cyclization of *o*-aminophenyl derivatives proceeds quite well with *t*-butyl thionitrate in nonaqueous media and the reaction is useful especially for ring closure reactions of such compounds as *cis*-stilbene or its ester derivatives which are relatively unstable under acidic conditions used in the usual Pschorr cyclization with nitrous acid in strong acids.

Fig. 1. Apparatus for analysis of the gas evolved in the Gomberg-Bachemann reaction with *t*-butyl thionitrate.

Experimental

General. All melting points were taken on a Yanako instrument and were uncorrected. IR spectra were taken on a Hitachi 260-50 spectrometer. NMR spectra were recorded with a Hitachi Perkin-Elmer R-20 spectrometer in $CDCl_3$ using TMS as the internal standard. Mass spectra were

taken with a Hitachi RMU-6MG mass spectrometer. Shimadzu GC-6A instrument was used for gas chromatography using N_2 gas as a carrier gas. Elemental analyses were carried out by the Chemical Analysis Center at this University.

*t-Butyl Thionitrate (**2**) and p-Toluenesulfonyl Nitrite (**6**).* These title compounds were prepared from the corresponding thiol and sulfinic acid with dinitrogen tetraoxide, according to the methods reported earlier.[1]

*Preparation of Ethers (**1b**, **1h**, and **10a**) and Sulfides (**1c**, **1d**, and **1e**).* 2-Nitrodiphenyl ethers and sulfides were prepared by the reaction of *o*-chloronitrobenzene with alkaline salts of desired alcohols or thiols in the presence of a catalytic amount of tetrabutylammonium bromide as a phase transfer catalyst.[10] The yields of the ethers and sufides were nearly 90%. The nitro compound was reduced by the Fe–HCl system,[11] yielding the amine in *ca.* 80% yield.

*2-Aminodiphenyl Ether (**1b**)*: Colorless crystals; mp 44—45 °C (from benzene–hexane) (lit,[12] 43—44 °C); NMR ($CDCl_3$) δ 3.65 (b, 2H, NH_2), 6.46—7.49 (m, 9H, ArH).

*2-Aminodiphenyl Sulfide (**1c**)*: Colorless crystals; mp 41 °C (from benzene–hexane) (lit,[13] 41—42 °C); NMR ($CDCl_3$) δ 4.18 (b, 2H, NH_2), 6.51—7.86 (m, 9H, ArH).

*2-Aminophenyl p-Tolyl Sulfide (**1d**)*: Colorless crystals; mp 47 °C (from hexane–ether) (lit,[14] 48.5—49.0 °C); NMR ($CDCl_3$) δ 2.22 (s, 3H, CH_3), 4.15 (b, 2H, NH_2), 6.52—7.53 (m, 8H, ArH).

*2-Aminophenyl 4-Chlorophenyl Sulfide (**1e**)*: Colorless crystals; mp 33 °C (from ether), bp 194 °C (bath temp)/4 mmHg† (lit,[15] bp 164—166 °C/0.45 mmHg); NMR ($CDCl_3$) δ 4.20 (b, 2H, NH_2), 6.57—7.59 (m, 8H, ArH).

*2-Aminophenyl Benzyl Ether (**1h**)*: Colorless crystals; mp 38 °C (from ether) (lit,[16] 39—40 °C); NMR ($CDCl_3$) δ 3.90 (b, 2H, NH_2), 5.60 (s, 2H, CH_2), 6.63—7.58 (m, 9H, ArH); IR (KBr) 3900 and 3730 (NH_2), 1600, 1210, 724 cm^{-1}.

*2-Aminophenyl Allyl Ether (**10a**)*: Pale yellow oil; bp 136 °C (bath temp)/4 mmHg (lit,[17] bp 129—130 °C/10 mmHg); NMR ($CDCl_3$) δ 3.74 (s, 2H, NH_2), 4.34—4.55 (m, 2H, CH_2), 5.05—5.51 (m, 2H, $=CH_2$), 5.70—6.30 (m, 1H, CH), 6.33—6.93 (m, 4H, ArH); IR (neat) 3890 and 3700 (NH_2), 3100 (=CH), 1600, 1210, 730 cm^{-1}.

*2-Aminodiphenylamine (**1f**).* Commercially available 2-nitrodiphenylamine was reduced by the same system of Fe–HCl.[11] Yield *ca.* 80%. Colorless crystals; mp 80 °C (from hexane) (lit,[18] 78—80 °C); NMR ($CDCl_3$) δ 3.36 (b, 2H, NH_2), 5.10 (b, 1H, NH), 6.51—7.34 (m, 9H, ArH).

*2-Aminobenzophenone (**1a**).* Commercially available compound (Tokyo Kasei Kogyo Co.) was used.

*Ethyl (E)-3-(2-Aminophenyl)-2-phenylpropenate (**1g**).* (*E*)-3-(2-nitrophenyl)-2-phenylpropenic acid was obtained by the Perkin condensation using *o*-nitrobenzaldehyde and phenylacetic acid,[19] and then esterified in ethanol. The nitro compound was reduced to the amino compound by the Fe–HCl system.[11] Yellow crystals; mp 96—97 °C (from benzene–hexane); NMR ($CDCl_3$) δ 1.19 (t, J=6.9 Hz, 3H, CH_3), 3.80 (b, 2H, NH_2), 4.27 (q, J=6.9 Hz, 2H, CH_2), 6.24—7.53 (m, 9H, ArH), 7.82 (s, 1H, =CH); IR (KBr) 3800 and 3690 (NH_2), 1680 (C=O), 1620 (C=C), 1520, 1240, 700 cm^{-1}; Found: C, 76.28; H, 6.38; N, 5.15%. Calcd for $C_{17}H_{17}NO_2$: C, 76.38; H, 6.41; N, 5.23%.

*Preparation of Sulfides (**1i** and **10b**).* *o*-Nitrobenzenethiol was treated with benzyl bromide or allyl bromide, giving the corresponding sulfides in *ca.* 90% yields by the usual method.[20] The nitro compounds then were reduced by the Fe–HCl system.[11]

*2-Aminophenyl Benzyl Sulfide (**1i**)*: Colorless crystals; mp 45 °C (from benzene–hexane) (lit,[16] 45 °C); NMR ($CDCl_3$) δ 3.87 (s, 2H, CH_2), 4.24 (b, 2H, NH_2), 6.44—7.40 (m, 9H, ArH); IR (KBr) 3860 and 3670 (NH_2), 1595, 1440, 695 cm^{-1}.

*2-Aminophenyl Allyl Sulfide (**10b**)*: Pale yellow oil; bp 135—138 °C (bath temp)/4 mmHg (lit,[21] bp 120 °C/4 mmHg); NMR ($CDCl_3$) δ 3.34 (d, J=6.4 Hz, 2H, CH_2), 4.27 (s, 2H, NH_2), 4.69—5.12 (m, 2H, $=CH_2$), 5.48—6.22 (m, 1H, =CH), 6.46—7.43 (m, 4H, AtH); IR (neat) 3880 and 3680 (NH_2), 3100 (=CH), 1595, 1465, 740 cm^{-1}.

*The Pschorr Cyclization of Amines (**1**) with t-Butyl Thionitrate (**2**).* *t*-Butyl thionitrate (**2**, 1.5 mmol) was added with syringe to melted 2-aminobenzophenone (**1a**, 1.0 mmol) at 160 °C under argon. Vigorous reaction occurred and gas evolved. After heating and stirring the mixture at the same temperature for 0.5 h, the mixture was cooled and a portion of the mixture was subjected to GLC to determine the yield. Fluorenone (**3a**) was identified by comparing the GLC and TLC with those of authentic samples, and the yields were determined by GLC. Other compounds (**3d**—**3i**) were isolated by preparative TLC or column chromatography (silica gel, eluent: benzene–hexane=1 : 6) and recrystallized from adequate solvent.

*2-Methyldibenzothiophene (**3d**)*: Colorless crystals; mp 86 °C (from ethanol) (lit,[22] 88—89 °C); NMR ($CDCl_3$) δ 2.59 (s, 3H, CH_3), 7.20—8.20 (m, 7H, ArH).

*2-Chlorodibenzothiophene (**3e**)*: Colorless crystals; mp 125—126 °C (from ethanol) (lit,[23] 113—114 °C); IR (KBr) 1420, 1089, 755, 725 cm^{-1}; MS (70 eV) *m/e* (rel intensity) 220 (38%, M^++2), 218 (100%, M^+), 183 (14%, $C_6H_4SC_6H_3^+$).

*1-Phenylbenzotriazole (**3f**)*: Colorless crystals; mp 85—87 °C (lit,[18] 89—90 °C); IR (KBr) 1592, 1494, 1055, 745 cm^{-1}; MS (70 eV) *m/e* (rel intensity) 195 (23%, M^+), 167 (100%, $C_6H_4N^+C_6H_5$), 77 (25%, $C_6H_5^+$).

*Ethyl 9-Phenanthrenecarboxylate (**3g**)*: Coloress crystals; mp 58—59 °C (from ethanol) (lit,[23] 61 °C); NHR ($CDCl_3$) δ 1.64 (t, J=7.1 Hz, 3H, CH_3), 4.48 (q, J=7.1 Hz, 3H, CH_2), 7.42—8.97 (m, 9H, ArH); IR (KBr) 1700, (C=O), 1440, 1290, 1240, 1030 cm^{-1}; MS (70 eV) *m/e* (rel intensity) 250 (100%, M^+), 205 (99%, $C_{14}H_9C{\equiv}O^+$), 177 (54%, $C_{14}H_9^+$).

*6H-Dibenzo[b, d]pyran (**3h**)*: Oil; NMR ($CDCl_3$) δ 5.07 (s, 2H, CH_2) (lit,[25] δ 5.07, s), 6.84—7.81 (m, 8H, ArH); MS (70 eV) *m/e* (rel intensity) 182 (74%, M^+), 181 (100%, $C_6H_4O^+CHC_6H_4$).

*6H-Dibenzo[b, d]thiopyran (**3i**)*: Colorless crystals; mp 73—74 °C (lit,[26] 75.5 °C); MS (70 eV) *m/e* (rel intensity) 198 (91%, M^+), 197 (100%, $C_6H_4S^+CHC_6H_4$).

*The Pschorr Cyclization of Amines (**1a**, **1b**, and **1h**) with p-Toluenesulfonyl Nitrite (**6**).* A mixture of 2-aminobenzophenone (**1a**, 1.0 mmol) and dry acetonitrile (5 ml) was added onto *p*-toluensulfonyl nitrite (**6**, 3.0 mmol) under argon. Evolution of the gas was observed. Then the solution was stirred for 1 h at room temperature. The cyclic products were identified by comparison of the GLC and TLC with those of authentic samples, and yields were determined by GLC.

*The Intramolecular Meerwein Arylation of Amines (**10a** and **10b**) with t-Butyl Thionitrate (**2**) and Copper (II) Chloride.* *t*-Butyl thionitrate (**2**, 1.4 mmol) was added slowly to the solution of 2-aminophenyl allyl ether (**10a**, 1.0 mmol) and well-dried anhydrous copper (II) chloride (1.2 mmol) in dry acetonitrile (10 ml) under argon with vigorous stirring at room temperature. The solution was stirred further for 1 h. Then cyclic product, 3-chlorochroman (**11a**), was directly isolated by column chromatography (silica gel, eluent: hexane).

*3-Chlorochroman (**11a**)*: Pale yellow oil; NMR ($CDCl_3$) δ 3.43—3.90 (m, 3H, CH_2 and CH), 4.29—4.71 (m, 2H, OCH_2), 6.67—7.35 (m, 4H, ArH); MS (70 eV) *m/e* (rel intensity) 200

† 1 mmHg=133.322 Pa.

13%, $M^+ +2$), 168 (38%, M^+), 119 (100%, $[C_7H_5{=}O]CH_2^+$), 91 (31%, $C_6H_5CH_2^+$); Found: C, 63.65; H, 5.45%. Calcd for C_9H_9ClO: C, 64.10; H, 5.38%.

*3-Chlorothiochroman (**11b**)*: Pale yellow oil; NMR ($CDCl_3$) δ 3.16—3.75 (m, 5H, CH_2, CH and SCH_2), 6.97—7.27 (m, 4H, ArH); MS (70 eV) *m/e* (rel intensity) 186 (11%, $M^+ +2$), 184 (27%, M^+), 135 (100%, $[C_7H_5{=}S]CH_2^+$), 91 (14%, $C_6H_5CH_2^+$); Found: C, 58.51; H, 4.92%, Calcd for C_9H_9ClS: C, 58.53; H, 4.91%.

Determination of Gas Evolved in The Gomberg-Bachmann Reaction of p-*Chloroaniline with* t-*Butyl Thionitrate.* A mixture of *t*-butyl thionitrate (1.4 mmol) in dry benzene (1 ml) was placed in the flask A of the special apparatus shown in Fig. 1, freezed with liquid nitrogen bath and degassed three times using the vacuum line. After the stopcock C was closed, solid *p*-chloroaniline (0.7 mmol) was added from bent tube B, then the mixture was stirred and heated at 80 °C with an oil bath for 5 h. The gas evolved was pumped into the gas sampler D by teppler pump E. The gas obtained was introduced into the mass spectrometer for identification.

Branched-chain Sugars. XXIV. Synthesis of Methyl 6-Deoxy-3-*C*-methyl-β-D-gulopyranoside (Methyl β-Virenoside)[1]

Namgi HONG, Ken-ichi SATO, and Juji YOSHIMURA*

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 277

(Received February 7, 1981)

Methyl 6-deoxy-3-*C*-methyl-β-D-gulopyranoside (methyl β-virenoside) was prepared from D-galactose. An attempted synthesis of the virenoside by the inversion at *C*-4 of methyl 6-deoxy-3-*C*-methyl-α-D-allopyranoside was unsuccessful.

Virenose is a new naturally occuring branched-chain sugar found as a component of the antitumor antibiotic virenomycin produced by *Actiomyces virens* sp. nov.[2] Kulyaeva and her coworkers have reported the isolation of virenose as a methyl glycoside and established its absolute configuration as methyl 6-deoxy-3-*C*-methyl-β-D-gulopyranoside (**1**) from NMR, MS, and IR spectral data, and $[M]^{cupra\ A,B}$ rotational values.[3]

It is one of the most common branched-chain sugars, 6-deoxy-3-*C*-methylhexoses.[4] For the introduction of *C*-methyl branching, it is known that the reaction of methylmagnesium iodide and methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*threo*-[5] and -α-D-*erythro*-hexopyranosid-3-uloses,[6] and methyl 4,6-*O*-benzylidene-α-D-*ribo*-hexopyranosid-3-ulose[7] gave the corresponding branched-chain sugars having the desired configuration at *C*-3 position. This paper describes the synthesis of **1** from methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-*xylo*-hexopyranosid-3-ulose obtained from D-galactose,[8] though another synthesis *via* the configurational inversion at *C*-4 of methyl 2,3-di-*O*-benzyl-6-deoxy-3-*C*-methyl-4-*O*-(methylsulfonyl)-α-D-allopyranoside (**6**) derived from D-glucose was unsuccessful.

Results and Discussion

Methyl 4,6-*O*-benzylidene-3-*C*-methyl-α-D-allopyranoside[7] obtained from D-glucose through five steps conversions was converted into the corresponding 2,3-di-*O*-benzyl derivative (**2**) in 78% yield by treating with sodium hydride and benzyl bromide in dimethyl sulfoxide. The benzylidene group of **2** was removed by refluxing in 70% acetic acid to produce **3** in 78% yield. Monotosylation of **3** in pyridine gave the corresponding 6-*O*-tosylate (**4**) in 80% yield. Reduction of **4** in tetrahydrofuran with lithium aluminium hydride gave methyl 2,3-di-*O*-benzyl-6-deoxy-3-*C*-methyl-α-D-allopyranoside (**5**) in 65% yield.

For the inversion of the configuration at *C*-4 of **5**, oxidation-reduction method was tried at first. Oxidation of **5** with dimethyl sulfoxide and trifluoroacetic anhydride gave the corresponding 4-ulose (**7**) in 78% yield. However, reduction of **7** with sodium borohydride gave only **5**. Because the conformation of **7** is deduced to be *C*1, the above result is attributed to the steric hindrance of the axial benzyloxy group at *C*-3. As the second procedure, the S_N2 inversion at *C*-4 was tried. Usual mesylation of **5** gave the corresponding 4-*O*-mesylate (**6**) in 83% yield. Unfortunately, all attempts for the conversion of **6** into the 4-*O*-benzoyl derivative (**9**) of

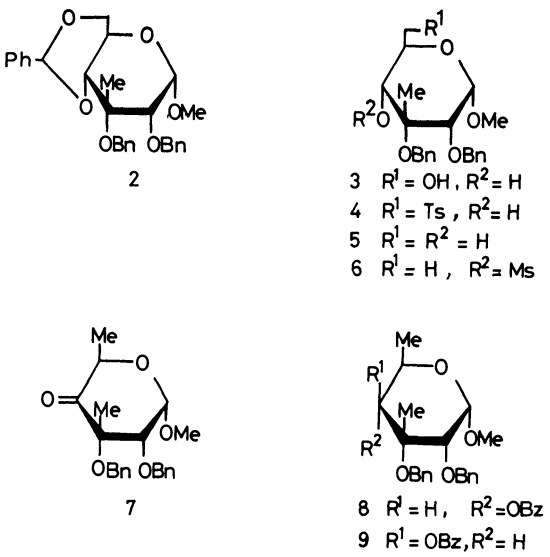

Fig. 1.

D-*gulo* configuration by treatment with sodium benzoate were failed. Treatment of **6** in hexamethylphosphoric triamide at 180 °C for 24 h gave an ester exchange product, methyl 4-*O*-benzoyl-2,3-di-*O*-benzyl-3-*C*-methyl-α-D-allopyranoside (**8**) in 30% yield, which is identical with that obtained by benzoylation of **5**.

On the other hand, oxidation of methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-galactopyranoside[9] with dimethyl sulfoxide and trifluoroacetic anhydride in dichloromethane gave the corresponding 3-ulose (**10**) in 80% yield. Reaction of **10** in benzene with methylmagnesium iodide gave predominantly one compound (**11**), which was separated by column chromatography from a trace of the corresponding 3-epimer in 85% yield. This result indicates that the Grignard reagent attacks the carbonyl function from the equatorial side as was in the case of the corresponding 2-deoxy-3-ulose.[5] Treatment of **11** with acetone in the presence of anhydrous copper(II) sulfate and catalytic amount of sulfuric acid gave the 2,3-*O*-isopropylidene derivative (**12**) in high yield, indicating the presence of *cis*-hydroxyl groups in **11**.

Reaction of **11** with *N*-bromosuccinimide in carbon tetrachloride in the presence of excess barium carbonate afforded methyl 4-*O*-benzoyl-6-bromo-6-deoxy-3-*C*-methyl-α-D-gulopyranoside (**13**) in 75% yield. The reduction of **13** in benzene with tributylstannane in the presence of α,α'-azobisisobutyronitrile gave the corresponding 6-deoxy derivative (**14**) in 70% yield. Base-catalyzed removal of the 4-*O*-benzoyl group of **14** gave

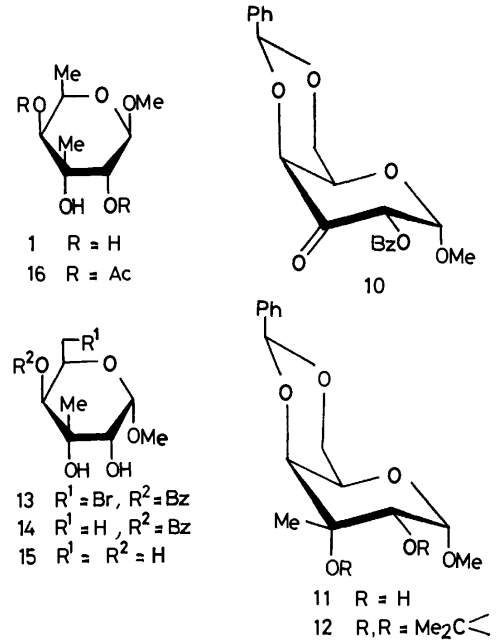

Fig. 2.

the de-*O*-benzoylated product (**15**) in 65% yield. Anomerization of **15** in methanol with cationic ion-exchanger IR-120 by refluxing for 20 h gave crystalline methyl β-D-virenoside (**1**) in 80% yield. The physical constants of **1** are in good agreement with those reported[2)] (Table 1). The usual acetylation of **1** gave the corresponding 2,4-diacetate (**16**).

Experimental

All the melting points are uncorrected. The solutions were evaporated under reduced pressure at a bath temperature not exceeding 45 °C. Specific rotations were measured in a 0.5-dm tube with a Carl Zeiss LEP-Al polarimeter by the use of chloroform as the solvent. The IR spectra were recorded with a Hitachi Model EPI-G2 spectrometer. The NMR spectra were taken with a JEOL PS-100 spectrometer using tetramethylsilane as an internal standard in deuteriochloroform unless otherwise stated. Chemical shifts and coupling constants were recorded in δ and Hz units and IR frequencies in cm^{-1}.

*Methyl 2,3-Di-*O*-benzyl-4,6-*O*-benzylidene-3-*C*-methyl-α-*D*-allopyranoside (2).* To a suspension of sodium hydride (0.5 g, 20.8 mmol) and methyl 4,6-*O*-benzylidene-3-*C*-methyl-α-D-allopyranoside (2 g, 6.75 mmol) in dry dimethyl sulfoxide (15 ml) was added gradually benzyl chloride (1.7 g, 13.4 mmol). The mixture was then heated for 1 h at 70 °C on a water-bath, poured into ice water, and then extracted with chloroform. The extract was washed with water, dried with anhydrous magnesium sulfate, and evaporated to give a syrup that was purified on a preparative TLC (benzene–ethyl acetate 10 : 1) to give a colorless syrup (2.5 g, 78%). $[\alpha]_D^{13}$ +58° (*c* 0.4), NMR: 7.1—7.3 (3×Ph; m), 5.40 (PhCH; s), 4.96 and 4.69 (2×$PhCH_2$; each s), 4.72 and 3.32 (H-1 and H-2; each d, $J_{1,2}$=4.0), 4.60—4.18 (H-6 and H-6′; m), 3.60 (H-5; m), 3.30 (H-4; d, $J_{4,5}$=8.0), 3.42 (OMe), 1.46 (CMe). Found: C, 72.96; H, 6.68%. Calcd for $C_{29}H_{32}O_6$: C, 73.10; H, 6.72%.

*Methyl 2,3-Di-*O*-benzyl-3-*C*-methyl-α-*D*-allopyranoside (3).* A solution of **2** (1.2 g, 2.5 mmol) in 70% acetic acid (4 ml) was kept for 10 h at room temperature, evaporated, and the residue was purified on a preparative TLC (toluene–chloroform–methanol 4 : 4 : 1) to give a syrup in 80% (0.78 g) yield. $[\alpha]_D^{13}$ +41.4° (*c* 0.6); NMR: 7.32 (Ph; s), 5.20—4.48 (2×$PhCH_2$; m, J=10.5), 4.77 and 3.35 (H-1 and H-2; each d, $J_{1,2}$=4.0), 3.30 (H-4; d, $J_{4,5}$=10.0), 3.7—3.9 (H-5, H-6, and H-6′; m), 3.41 (OMe), 2.2 and 2.45 (2×OH; each broad s), 1.48 (CMe). Found: C, 68.23; H, 7.31%. Calcd for $C_{22}H_{28}O_6$: C, 68.04; H, 7.21%.

*Methyl 2,3-Di-*O*-benzyl-3-*C*-methyl-6-*O*-(p-tolysulfonyl)-α-*D*-allopyranoside (4).* Reaction of **3** (5 g, 12.8 mmol) in dry pyridine (20 ml) with *p*-toluenesulfonyl chloride (2.7 g, 14.2 mmol) at room temperature overnight and usual work-up of the reaction mixture gave **4** (5.2 g, 75%) as a syrup. $[\alpha]_D^{13}$ +41° (*c* 1.5); NMR: 7.32 (Ph; m), 5.16—4.44 (2×$PhCH_2$; m. J=10.5), 4.73 and 3.32 (H-1 and H-2; each d, $J_{1,2}$=4.0), 3.33 (H-4; d, $J_{4,5}$=10.0), 4.0—4.4 (H-5, H-6, and H-6′; m), 3.38 (OMe), 2.41 (PhMe), 1.46 (CMe). Found: C, 64.32; H, 6.34%. Calcd for $C_{29}H_{34}O_8S$: C, 64.20; H, 6.27%.

*Methyl 2,3-Di-*O*-benzyl-6-deoxy-3-*C*-methyl-α-*D*-allopyranoside (5).* Lithium aluminium hydride (1.0 g, 32.5 mmol) was gradually added to a solution of **4** (4 g, 7.4 mmol) in dry tetrahydrofuran (100 ml), and the mixture was boiled for 6 h. A small amount of ethyl acetate and water were successively added to the reaction mixture, and the precipitate formed was filtered and washed with ether. The filtrate and washings were evaporated to a syrup, which was purified on a preparative TLC (benzene–ethyl acetate 10 : 1) to give syrupy **5** (1.78 g, 65%). $[\alpha]_D^{12}$ +43.6° (*c* 1.0); NMR: 7.32 (Ph; m), 5.10—4.80 ($PhCH_2$×2; m, J=10.5), 4.71 and 3.34 (H-1 and H-2; each d, $J_{1,2}$=4.0), 2.93 (H-4; dd, $J_{4,5}$=10.0, $J_{4,OH}$=12.0), 3.40 (OMe), 1.44 (CMe), 2.35 (OH; d), 1.20 (H-6; d). Found: C, 70.55; H, 7.32%. Calcd for $C_{22}H_{28}O_5$: C, 70.96; H, 7.52%.

*Methyl 2,3-Di-*O*-benzyl-6-deoxy-3-*C*-methyl-4-*O*-(methylsulfo-*

nyl)-α-D-allopyranoside (6). Methanesulfonyl chloride (0.6 g, 5.2 mmol) was added to a solution of **5** (1 g, 2.7 mmol) in dry pyridine (5 ml) cooled in an ice-water bath. The resulting solution was kept for 12 h at room temperature, poured into water, and then extracted with chloroform. The extracts were washed with saturated aqueous sodium hydrogencarbonate and water. Evaporation of the dried extract gave a syrupy **6** (1 g, 83%), $[\alpha]_D^{13}$ +79.5° (*c* 0.9); NMR: 7.36 (Ph; s), 5.10—4.56 ($PhCH_2\times2$; m, J=10.5), 4.68 and 3.31 (H-1 and H-2; each d, $J_{1,2}$=4.0), 4.19 (H-4; d, $J_{4,5}$=10.0), 4.45 (H-5; oct, $J_{5,6}$=6.0), 3.40 (OMe), 2.99 (Ms), 1.48 (CMe), 1.25 (H-6; d). Found: C, 61.62; H, 6.61%. Calcd for $C_{23}H_{30}O_7S$: C, 61.33; H, 6.66%.

Methyl 4-O-Benzoyl-2,3-di-O-benzyl-6-deoxy-3-C-methyl-α-D-allopyranoside (8). *i)* : A solution of **5** (0.6 g, 1.32 mmol) and sodium benzoate (0.38 g, 2.6 mmol) in hexamethylphosphoric triamide (6 ml) was heated at 180 °C for 24 h, filtered, and then poured into water. The resulting solution was extracted with chloroform. The extract was washed with water and evaporated. The residue was extracted with ether again, and the usual work-up of the extract gave a syrup (0.42 g) which was purified on a preparative TLC (toluene–ethyl acetate 16 : 1) to give **8** (0.18 g, 30%) as a syrup. $[\alpha]_D^{14}$ +26.9° (*c* 0.5); NMR: 8.10—7.8 and 7.50—7.30 ($2\times$Ph; m), 5.52 (H-5; m, $J_{5,6}$=6.0), 4.4—4.8 ($2\times PhCH_2$; m), 4.90 and 3.68 (H-1 and H-2; each d, $J_{1,2}$=4.0), 3.87 (H-4; d, $J_{4,5}$=6.0), 3.48 (OMe), 1.52 (CMe), 1.47 (H-6; d). Found: C, 73.25; H, 6.78%. Calcd for $C_{29}H_{32}O_6$: C, 73.11; H, 6.72%.

ii) : To a solution of **5** (0.1 g, 0.27 mmol) in dry pyridine (5 ml) was added benzoyl chloride (0.1 g, 0.7 mmol), and the usual work-up after 10 h gave **8** (0.9 g, 71%) identical with that obtained above.

Methyl 2,3-Di-O-benzyl-6-deoxy-3-C-methyl-α-D-ribo-hexopyranosid-4-ulose (7). To a solution of dry dimethyl sulfoxide (0.5 g, 6.4 mmol) and dry dichloromethane (2 ml) was added successively trifluoroacetic anhydride (0.54 g, 4.0 mmol) in dichloromethane (2 ml) with stirring during 10 min at −78 °C, and then a solution of **6** (0.5 g, 1.34 mmol) in dichloromethane (2 ml). The reaction mixture was stirred at −78 °C for 20 min, neutralized with triethylamine (4 ml), and extracted with chlorofolm. The extract was washed with water, and then evaporate to give a syrup which was chromatographed on a silica-gel column (toluene–ethyl acetate 16 : 1) to afford **7** (0.38 g, 78%). $[\alpha]_D^{14}$ +101° (*c* 0.4). IR: 1740 (C=O); NMR: 7.4—7.2 ($2\times$Ph; m), 4.9—4.5 ($PhCH_2$; m), 4.80 and 3.59 (H-1 and H-2; each d, $J_{1,2}$=4.0), 4.50 (H-5; q, $J_{5,6}$=6.0), 1.20 (H-6; d), 3.51 (OMe), 1.51 (CMe). Found: C, 71.77; H, 7.21%. Calcd for $C_{22}H_{26}O_5$: C, 71.35; H, 7.02%.

Methyl 4,6-O-Benzylidene-2-O-benzoyl-α-D-xylo-hexopyranosid-3-ulose (10). A similar oxidation of **7** to that of **5** gave the corresponding 3-ulose (**10**) in 80% yield. $[\alpha]_D^{27}$ +142° (*c* 1.8); IR: 1730 (C=O); NMR 7.8—8.2 and 7.2—7.6 ($2\times$Ph; m), 5.59 (PhCH), 6.1 and 5.36 (H-1 and H-2; each d, $J_{1,2}$=3.8), 4.54 (H-4; d, $J_{4,5}$=1.5), 3.97 (H-5; m), 4.15 (H-6′; dd, $J_{5,6}$=2.0), 4.42 (H-6; dd, $J_{6,6'}$=13, $J_{5,6}$=1.5), 3.48 (OMe). Found: C, 65.65; H, 5.42%. Calcd for $C_{21}H_{20}O_7$: C, 65.62; H, 5.21%.

Methyl 4,6-O-Benzylidene-3-C-methyl-α-D-gulopyranoside (11). To a suspension of magnesium turning (4.5 g, 185 mmol) in dry ether (150 ml) was added methyl iodide (25 g, 176 mmol) dropwise with stirring at room temperature. After 20 min, **10** (15 g, 39 mmol) was added to the Grignard solution with the aid of a small amount of benzene. After stirring for 6 h, the reaction mixture was worked up in the usual way to give a syrupy **11** in 85% (10.1 g) yields. $[\alpha]_D^{28}$ +102° (*c* 1.0); NMR: 7.2—7.52 (Ph; m), 5.50 (PhCH), 4.86 (H-1; d, $J_{1,2}$=3.8), 3.78 (H-2; dd, $J_{2,OH}$=12.0), 3.77 (H-4; s), 3.90 (H-5; broad s), 4.30 (H-6; dd, $J_{6,6'}$=13, $J_{5,6}$=2.0), 4.04 (H-6′; dd, $J_{5,6'}$=2.0), 3.3 (3-OH), 3.46 (OMe), 2.64 (2-OH; d), 1.35 (CMe). Found: C, 60.75; H, 6.64%. Calcd for $C_{15}H_{20}O_6$: C, 60.81; H, 6.76%.

Methyl 4,6-O-Benzylidene-3-C-methyl-2,3-O-isopropylidene-α-D-gulopyranoside (12). A suspension of **11** (0.38 g, 1.28 mmol) and copper(II) sulfate (0.4 g, 2.5 mmol) in dry acetone (2 ml) containing catalytic amount of sulfuric acid was stirred for 12 h, filtered, and then evaporated to dryness. The residue was extracted with chloroform, and the usual work-up of the extract gave a syrup which was purified on a TLC (benzene–acetone 5 : 1) to give pure **12** as a syrup (0.35 g, 81%). $[\alpha]_D^{26}$ +8.6° (*c* 0.6); NMR: 7.5—7.2 (Ph; m), 5.50 (PhCH), 5.18 and 3.71 (H-1 and H-2; each d, $J_{1,2}$=1.2), 4.18 (H-4; s), 4.0 (H-5; m), 4.34 (H-6; dd, $J_{6,6'}$=12.2, $J_{5,6}$=2.0), 3.92 (H-6′; dd, $J_{5,6'}$=2.0), 3.62 (OMe), 1.46, 1.50 and 1.52 ($3\times$CMe; each s). Found: C, 64.31; H, 7.33%. Calcd for $C_{18}H_{24}O_6$: C, 64.28; H, 7.14%.

Methyl 4-O-Benzoyl-6-bromo-6-deoxy-3-C-methyl-α-D-gulopyranoside (13). A suspension of **11** (8 g, 0.028 mol), *N*-bromosuccinimide (8.96 g, 0.05 mol), and barium carbonate (8.8 g, 0.04 mol) in dry carbon tetrachloride (150 ml) was boiled for 7 h, filtered, and the filtrate was worked up in the usual way to give **13** as a syrup in 75% (8.5 g) yield. $[\alpha]_D^{27}$ +120.7° (*c* 1.8); NMR: 7.9—8.1 and 7.3—7.5 (PhCO; m), 4.92 and 3.79 (H-1 and H-2; each d, $J_{1,2}$=3.8), 5.26 (H-4; s), 4.46 (H-5; dd, $J_{5,6'}$=8.0, $J_{5,6}$=4.0), 3.44 (H-6′; dd, $J_{6,6'}$=11.0), 3.26 (H-6; dd), 3.54 (OMe), 1.26 (CMe). Found: C, 48.31; H, 5.20%. Calcd for $C_{15}H_{19}O_6Br$: C, 48.00; H, 5.06%.

Methyl 4-O-Benzoyl-6-deoxy-3-C-methyl-α-D-gulopyranoside (14). To a solution of **13** (5 g, 0.013 mol) in anhydrous benzene (100 ml) was added tributylstannane (7.5 g, 0.025 mol) and catalytic amount of α,α′-azobisisobutyronitrile. The mixture was refluxed for 15 h, concentrated and the tin compound in the residue was removed on a silica gel column using hexane as the eluent. Thereafter, the elution with benzene–acetone (10 : 1) gave syrupy **14** in 70% (2.7 g) yield, which was crystallized from ethyl acetate. Mp 133—134 °C, $[\alpha]_D^{28}$ +142° (*c* 1.0); NMR: 8.0—8.16 and 7.30—7.60 (PhCO; m), 4.87 (H-1: d, $J_{1,2}$=4.0), 3.78 (H-2; dd, $J_{2,OH}$=12.0), 5.12 (H-4; s), 4.41 (H-5; q, $J_{5,6}$=6.0), 3.84 (OH-3; s), 3.52 (OMe), 2.40 (OH-2; d), 1.25 (CMe), 1.17 (H-6; d). Found: C, 60.64; H, 6.89%. Calcd for $C_{15}H_{20}O_6$: C, 60.81; H, 6.76%.

Methyl 6-Deoxy-3-C-methyl-α-D-gluopyranoside (15). A solution of **14** (1.5 g, 5 mmol) and sodium (0.4 g, 17 mmol) in dry methanol (60 ml) was refluxed for 4 h, and concentrated to dryness. The residue was extracted several times with dichloromethane, and the usual work-up of the extract gave **15** as a syrup in 65% yield. $[\alpha]_D^{27}$ +123° (*c* 0.3); NMR (CD_3OD): 4.79 and 3.58 (H-1 and H-2; each d, $J_{1,2}$=4.0), 4.25 (H-5; q, $J_{5,6}$=6.0), 3.13 (H-4; s), 3.48 (OMe), 1.26 (CMe), 1.17 (H-6; d). Found: C, 49.85; H, 7.29%. Calcd for $C_8H_{16}O_5$: C, 49.99; H, 8.39%.

Methyl 6-Deoxy-3-C-methyl-β-D-gulopyranoside (Methyl β-D-Virenoside) (1). A suspension of **15** (0.3 g, 1.6 mmol) and cationic resin (IR-120, 1.5 g) in dry methanol (40 ml) was refluxed for 24 h. The anomerization could be monitored by TLC. The reaction mixture was filtered, and the filtrate was evaporated. The residual syrup was purified on a preparative TLC (chloroform–methanol 4 : 1) to give **1** in 80% (0.24 g) yield, which was crystallized from hexane–chloroform. Found: C, 49.74; H, 8.24%. Calcd for $C_8H_{16}O_5$: C, 49.99; H, 8.39%.

Methyl 2,4-Di-O-acetyl-6-deoxy-3-C-methyl-β-D-gulopyranoside

(16). Acetylation of **1** (30 mg, 0.16 mmol) with acetic anhydride in pyridine for 24 h at room temperature, and the usual work-up of the mixture and purification of the product by a preparative TLC (benzene–aceton 5 : 1) gave **16** in 82% (25 mg) yield, which was recrystallized from methanol. Found: C, 52.27; H, 7.34%. Calcd for $C_{12}H_{20}O_7$: C, 52.16; H, 7.30%.

Restricted Rotation Involving the Tetrahedral Carbon. XXXIX. 9-(2-Methoxy-1-methylethyl)triptycene Derivatives[1]

Masahiko Suzuki, Gaku Yamamoto, Hiromi Kikuchi, and Michinori Ōki*

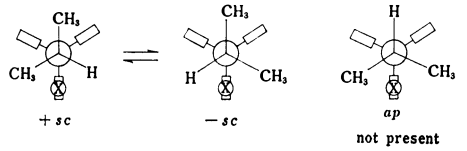
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received February 20, 1981)

9-(2-Methoxy-1-methylethyl)triptycenes were prepared from 9-(2-methoxy-1-methylethyl)anthracene and corresponding benzynes to examine the feasibility of isolating rotational isomers of 9-isopropyltriptycene derivatives at room temperature. They afforded crystalline *ap* forms which underwent internal rotation with activation energies of *ca.* 23 kcal/mol. 9-(2-Acetoxy-1-methylethyl)-1,2,3,4-tetrachlorotriptycene gave similar results. Based on the results, the barrier to rotation of 9-isopropyl-1,2,3,4-tetrabromotriptycene was reexamined to show that it must be corrected as 23.5 kcal/mol at 175 °C.

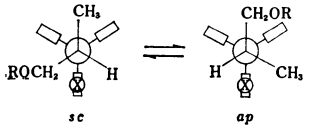
Stable rotamers of triptycene derivatives carrying a *t*-alkyl group in 9-position have been isolated at room temperature.[2] It is also possible to isolate rotamers of a compound carrying a primary alkyl group in 9-position of triptycene at room temperature, if it carries three substituents in three peri-positions which are close to the alkyl group.[3] To date, however, no rotamers have been isolated of compounds which carry a *s*-alkyl group in 9-position of triptycene. The possibility of the isolation has long been suggested because 9-isopropyltriptycenes were shown to have barriers to rotation of more than 23 kcal/mol (1 cal=4.18 J):[4] it is suggested that if the barrier is over 23 kcal/mol, the rotamer is stable at room temperature.[5]

The problem for isolating the rotamers of 9-isopropyltriptycene is that they exist as a pair of enantiomers and a diastereomeric *ap* form is not found for the steric reasons: it is necessary to resolve the racemate into enantiomers. Although a functionality for the resolution



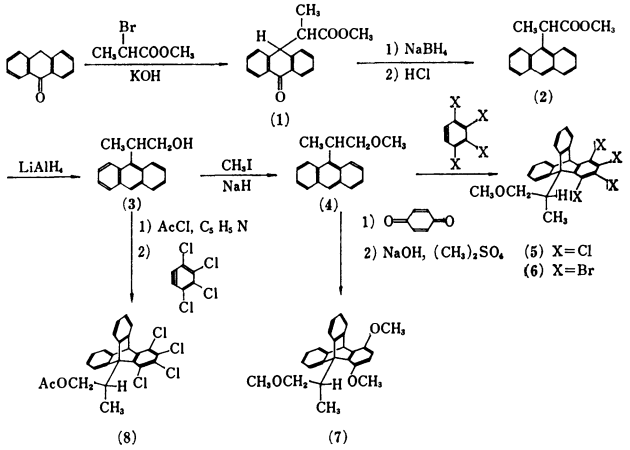
may be introduced into these compounds, the similar results may be obtained by modifying the isopropyl group, because modifying a methyl of the isopropyl group should produce diastereomers, if the rotation in question is slow, which should be separable by ordinary physical methods. Thus we introduced a methoxyl or an acetoxyl group to one of the methyls of the isopropyl group. This paper reports the results of such an investigation.

There is a problem of naming the stereochemistry of these comformations, as discussed elsewhere,[1] because the conformations involve a chiral center. However, we should like to use *ap* and *sc* as designated for simplicity of the discussion: although, in principle, there is another *sc* form in which a methyl and an $ROCH_2$ group flank the substituted benzeno bridge, in practice that conformation is nonexistent for the steric reasons because



it is a substituted derivative of the *ap* conformation of 9-isopropyltriptycenes.

The compounds examined in this study were prepared in the following way. Anthrone was alkylated with methyl 2-bromopropionate in the presence of a base and the resulted ester (**1**) was reduced with sodium tetrahydridoborate to corresponding alcohols which were dehydrated with hydrochloric acid to produce an anthracene-ester (**2**). The ester was reduced with lithium tetrahydridoaluminate to afford the corresponding alcohol (**3**). The alcohol was methylated with sodium hydride and methyl iodide. Treatment of the methyl ether (**4**) with tetrahalobenzynes afforded desired triptycenes (**5** and **6**). Treatment of the methyl ether (**4**) with *p*-benzoquinone followed by enolization of the adduct and then methylation gave a 1,4-dimethoxytriptycene (**7**). Acetylation of the alcohol (**3**) followed by treatment with tetrachlorobenzyne afforded 1,2,3,4-tetrachloro-9-(2-acetoxy-1-methylethyl)triptycene (**8**).



Experimental

10-(1-Methoxycarbonylethyl)anthrone (1). To a mixture of 35 g (0.18 mol) of anthrone and 29 g (0.174 mol) of methyl 2-bromopropionate in 200 mL of methanol was added with stirring a solution of 10 g (0.179 mol) of potassium hydroxide in 150 mL of methanol during a 3 h period at room temperature under a nitrogen atmosphere. Insoluble anthrone was filtered off and the filtrate was concentrated. The residue was taken up in dichloromethane and the solution was washed with water, aqueous ammonium chloride, and then water. The solution was dried over magnesium sulfate

and evaporated to give 42 g (86%) of an oil which was directly used for the next preparation. ^{1}H NMR ($CDCl_3$, δ): 0.63 (3H, d, J=7.5 Hz), 2.91 (1H, dq, J=7.5, 4.5 Hz), 3.70 (3H, s), 4.83 (1H, d, J=4.5 Hz), 7.2—7.7 (6H, m), 8.1$_5$—8.4 (2H, m).

9-(1-Methoxycarbonylethyl)anthracene (2). To a solution of 35 g (0.125 mol) of 10-(1-methoxycarbonylethyl)anthrone in 500 mL of methanol was added 35 g (0.925 mol) of sodium tetrahydridoborate with ice-cooling and the mixture was allowed to stand for 15 min. The mixture was treated with ice and dilute hydrochloric acid and extracted with dichloromethane. The extract was washed and evaporated. The residue was taken up in 300 mL of benzene and the solution was shaken with 300 mL of concentrated hydrochloric acid for 10 min. The benzene layer was separated, washed, and dried. Evaporation of the solvent afforded 31 g (94%) of the desired compound. Recrystallization from acetone–pentane gave a pure sample, mp 117—119 °C. Found: C, 81.69; H, 5.83%. Calcd for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10%. ^{1}H NMR ($CDCl_3$, δ): 1.80 (3H, d, J=7 Hz), 3.54 (3H, s), 5.10 (1H, q, J=7 Hz), 7.3—7.6 (4H, m), 7.8—8.3 (4H, m), 8.38 (1H, s).

9-(2-Hydroxy-1-methylethyl)anthracene (3). A solution of 227 mg (0.86 mmol) of 9-(1-methoxycarbonylethyl)anthracene in 20 mL of dry ether was added to a slurry of 65.3 mg (1.72 mmol) of lithium tetrahydridoaluminate in 30 mL of dry ether and the mixture was stirred for 30 min at room temperature. The excess of the hydride was decomposed with ethyl acetate. The whole was treated with dilute hydrochloric acid and the ether layer was washed with aqueous sodium hydrogencarbonate and then with water, and dried over magnesium sulfate. Evaporation of ether afforded an oil in 192 mg (96.5%) yield. The crude product was directly used for the next reaction. ^{1}H NMR ($CDCl_3$, δ): 1.69 (3H, d, J=7 Hz), 4.24 (2H, br d, J=7 Hz), 4.3—4.7 (1H, m), 7.0—7.6 (4H, m), 7.8—8.1 (2H, m), 8.1—8.5 (3H, m).

9-(2-Methoxy-1-methylethyl)anthracene (4). A mixture of 0.32 g (13 mmol) of sodium hydride, 621 mg (2.64 mmol) of 9-(2-hydroxy-1-methylethyl)anthracene and 10 mL of tetrahydrofuran was stirred for 30 min at room temperature. To the mixture was added 1.6 mL (26 mmol) of methyl iodide and the whole was stirred overnight. The excess of the hydride was decomposed with ethanol and then with water and the mixture was extracted with ether. The ethereal extract was washed with dilute hydrochloric acid and then with aqueous sodium hydrogencarbonate and dried over magnesium sulfate. After evaporation of the solvent, the residue was chromatographed on silica gel, dichloromethane–hexane (1 : 3) being used as an eluent. The desired product was obtained in 429 mg (65%) yield. The product was directly used for the next reaction. ^{1}H NMR ($CDCl_3$, δ): 1.70 (3H, d, J=7.2 Hz), 3.27 (3H, s), 3.77 (1H, dd, J=5.1, 9.0 Hz), 4.11 (1H, dd, J=8.6, 9.0 Hz), 4.35—4.80 (1H, m), 7.0—7.5 (4H, m), 7.7—8.0 (2H, m), 8.1—8.5 (3H, m).

1,2,3,4-Tetrachloro-9-(2-methoxy-1-methylethyl)triptycene (5). To a boiling solution of 429 mg (1.72 mmol) of **4** and 0.9 mL of isopentyl nitrite in 10 mL of dichloromethane was added 1.18 g (4.29 mmol) of tetrachloroanthranilic acid[6] in 10 mL of acetone in 1 h under a nitrogen atmosphere. The mixture was heated for another hour. Insoluble materials were filtered off and the filtrate was evaporated. The residue was submitted to silica gel chromatography and eluted with hexane–dichloromethane (1 : 1). A mixture of the desired material and the starting material (6 : 4) was obtained. Treatment of the mixture with the benzyne was repeated. An eluted fraction from silica gel was recrystallized from tetrahydrofuran–hexane to give 198 mg (25%) of the desired compound, mp 190—192 °C. Found: C, 62.03; H, 3.72; Cl, 30.28%. Calcd for $C_{24}H_{18}OCl_4$: C, 62.09; H, 3.91; Cl, 30.55%. When the crystals of the compound were dissolved in chloroform-*d* at low temperatures, the ^{1}H NMR signals could be attributed to the *ap* conformation (δ): 1.97 (3H, d, J=7.2 Hz), 3.45 (3H, s), 3.8—4.6 (3H, m), 5.94 (1H, s), 6.7—7.9 (8H, m). On standing at room temperature, the solution exhibited a set of NMR signals which could be attributed to the *sc* conformation of which signals were obtained by subtracting those due to the *ap* conformation from those of the mixture. *sc* ($CDCl_3$, δ): 1.78 (3H, d, J=7.2 Hz), 3.48 (3H, s), 3.8—4.6 (3H, m), 5.94 (1H, s), 6.7—7.9 (8H, m).

1,2,3,4-Tetrabromo-9-(2-methoxy-1-methylethyl)triptycene (6). To a boiling solution of 1.10 g (4.40 mmol) of **4** and 2.1 mL of isopentyl nitrite in 20 mL of dichloromethane was added 5.5 g (12.1 mmol) of tetrabromoanthranilic acid[7] in 20 mL of acetone in 30 min. The mixture was heated for another hour and filtered. The filtrate was concentrated and the residue was chromatographed as above. The obtained crystals were recrystallized from acetone–pentane to give the desired product, mp 220—222 °C, in 818 mg (29%) yield. Found: C, 44.98; H, 2.83; Br, 50.29%. Calcd for $C_{24}H_{18}OBr_4$: C, 44.89, H, 2.83; Br, 49.79%. The following ^{1}H NMR data ($CDCl_3$, δ) were obtained as were described for **5**. *ap*: 1.93 (3H, d, J=7.2 Hz), 3.41 (3H. s), 3.8—4.7 (3H, m), 5.97 (1H, s), 6.8—7.9 (8H, m). *sc*: 1.74 (3H, d, J=6.3 Hz), 3.48 (3H, s), 3.8—4.7 (3H, m), 5.97 (1H, s), 6.8—7.9 (8H, m).

1,4-Dimethoxy-9-(2-methoxy-1-methylethyl)triptycene (7). A solution of 1.47 g of **4** and 0.95 g of *p*-benzoquinone in 8 mL of acetonitrile was heated overnight under reflux. The acetonitrile and the benzoquinone were washed off with hot water. The residue was treated with a small portion of aqueous sodium hydroxide and then with a small portion of dimethyl sulfate. The process was repeated several times to use a total of 0.75 g of sodium hydroxide in 5 mL of water and 1 mL of dimethyl sulfate. After one night, the mixture was poured into water and the mixture was extracted with benzene. The benzene solution was dried and evaporated. The residue was chromatographed on silica gel, using eluents from hexane–dichloromethane (1 : 1) to dichloromethane. Some fractions were taken up in pentane–dichloromethane to remove anthraquinone as an insoluble material. The desired product, mp 218—220 °C, crystallized out on addition of pentane. Yield was 741 mg (32.6%). Found: C, 80.66; H, 6.61%. Calcd for $C_{26}H_{24}O_3$: C, 80.80; H, 6.78%. The crystals of this compound, on dissolution in chloroform-*d* at −40 °C, gave ^{1}H NMR signals of the almost pure *ap*-form but the isomerization was much faster than other compounds. From these results, the crystals may be assumed to be composed of the pure *ap*-forms. The following ^{1}H NMR data ($CDCl_3$, δ) were obtained as described for other compounds. *ap*: 1.88 (3H, d, J=6.3 Hz), 3.41 (3H, s), 3.63 (3H, s), 3.72 (3H, s), 3.9—4.2 (3H, m), 5.77 (1H, s), 6.42 (2H, s), 6.8—7.8 (8H, m). *sc*: 1.79 (3H, d, J=6.3 Hz), 3.46 (3H, s), 3.67 (3H, s), 3.72 (3H, s), 3.9—4.2 (3H, m), 5.77 (1H, s), 6.42 (2H, s), 6.8—7.8 (8H, m).

9-(2-Acetoxy-1-methylethyl)-1,2,3,4-tetrachlorotriptycene (8). A solution of 1.154 g (4.89 mmol) of **3** in 50 mL of benzene was mixed with 0.8 mL of pyridine and 0.5 mL of acetyl chloride. The mixture was treated, after 10 min, with ethanol and then with water. The aqueous layer was removed and the organic layer was washed with dilute hydrochloric acid and then with aqueous sodium hydrogencarbonate. Evaporation of the solvent and chromatography of the residue on silica gel, using dichloromethane–hexane (1 : 1), afforded a yellow oil of 9-(2-acetoxy-1-methylethyl)anthracene in

1.349 g (99.3%) yield. ^{1}H NMR ($CDCl_3$, δ): 1.72 (3H, d, J=7.2 Hz), 1.97 (3H, s), 4.4—5.1 (3H, m), 7.1—7.6 (4H, m), 7.8—8.1 (2H, m), 8.2—8.5 (3H, m).

A solution of the acetate (1.349 g or 4.85 mmol) and 2.6 mL of isopentyl nitrite in 20 mL of dichloromethane was treated with 4.00 g (14.6 mmol) of tetrachloroanthranilic acid in 30 mL of acetone as described in the preparation of **5**. The single treatment with the benzyne afforded 404.8 mg (17%) of the desired compound, mp 218—220 °C, on recrystallization from acetone–hexane after chromatography. Found: C, 61.14; H, 3.45; Cl, 28.86%. Calcd for $C_{25}H_{18}O_2Cl_4$: C, 61.00; H, 3.69; Cl, 28.81%. The following ^{1}H NMR data ($CDCl_3$, δ) were obtained as described above. *ap*: 1.96 (3H, d, J=6.3 Hz), 2.24 (3H, s), 4.3—5.2 (3H, m), 5.94 (1H, s), 6.9—7.8 (8H, m). *sc*: 1.76 (3H, d, J=6.3 Hz), 2.11 (3H, s), 4.3—5.2 (3H, m), 5.94 (1H, s), 6.9—7.8 (8H, m).

^{1}H NMR Spectra and Kinetic Data. ^{1}H NMR spectra were obtained on a Hitachi R-20B spectrometer equipped with a temperature variation accessory and operating at 60 MHz.

Rates of isomerization at room temperature were obtained by observing the change of ^{1}H NMR spectra as chloroform-*d* solutions in a probe of the NMR spectrometer. Temperatures were read directly by a thermocouple. The data were treated as the first order reversible reaction. Dynamic NMR spectra were obtained as hexachlorobutadiene solutions and the line shapes were simulated with the use of the modified Binsch program.[8] The temperature was calibrated with the use of the chemical shift differences of the protons of ethylene glycol. Some selected rate constants ($ap \rightarrow sc, s^{-1}$) are given below (numericals in parentheses are temperatures in °C). **5**: 0.82 (116.7), 1.23 (122.7), 1.67 (125.8), **6**: 0.80 (116.6), 1.32 (123.7), 1.76 (127.3), **7**: 0.76 (114.5), 1.22 (120.3), 1.61 (124.0), **8**: 0.52 (126.0), 0.61 (129.2), 0.93 (133.9), 1.33 (138.0).

These data were put into the Eyring equation and the kinetic parameters were obtained.

Results and Discussion

Assignment of Conformations. Assignment of conformations poses a difficult problem. We have succeeded in assigning conformations of ethenoanthracene derivatives by looking at aromatic proton signals of NMR spectra[2] but this method is apparently not applicable to the present case. The only differences are found in chemical shifts of protons due to methyl groups in the 9-substituents. One of the possibilities which give a solution to the problem is to utilize the chemical shifts of the methyl protons. In triptycene derivatives which carry a *t*-butyl group in the 9-position, the two methyl groups which are close to a peri-subsituent (usually a halogen) give a ^{1}H NMR signal at a lower magnetic field than that which is *ap* to the substituent.[9] This is reasonable if we assume van der Waals shift because the two groups are in a congested state. It is also true for other tertiary alkyl groups: methyls in an *ap* conformation which possesses the methyls $\pm sc$ to the peri-substituent give ^{1}H NMR signals at a lower field which corresponds to one of the methyls, that gives its signal at a lower magnetic field, in $\pm sc$ conformations.[10] If these generalities are applicable to the present case, then a conformation which gives the methyl signal at a lower field than another must be *ap*. However, since the steric requirements of a *t*-alkyl and a *s*-alkyl group are so different that the deformation of the molecules in question may differ to some extent. Indeed, 1,2,3,4,5,6,7,8-octachloro-9-isopropyltriptycene in which both methyl groups in the isopropyl are flanked by a tetrachlorobenzo and a benzo groups give a methyl signal at a higher magnetic field: it corresponds to a higher one of the two methyls in 1,2,3,4-tetrachloro-9-isopropyltriptycene.[4] We may have to wait to draw a definite conclusion until direct unambiguous evidence such as X-ray crystallography is obtained. We tentatively assign here, therefore, that, by taking advantage of the analogy from the *t*-alkyl compounds, it is the *ap* conformation that gives methyl proton signals at a relatively low magnetic field. Then the crystalline forms which we obtain by recrystallization are *ap* and those which appear on dissolution are *sc*.

Rotational Barriers. Rates of rotation at room temperature, as examined by the classical method, and free energies of activation are given in Table 1. Every compound examined was, at least, almost pure *ap* form

Table 1. Rates of rotation ($ap \rightarrow sc$) and equilibrium constants of 9-[2-methoxy(or acetoxy)-1-methylethyl]triptycenes

6	0.41 (132)	24.1±1.7	2.2±4.4	23.4
7	0.96 (124)	22.2±0.4	−2.3±1.1	22.9
8	0.56 (138)	25.7±1.9	3.9±4.5	24.5

soon after the dissolution in chloroform-*d*. The dimethoxy compound (**7**) was no exception but it isomerized fast at room temperature. Thus, although it was possible to isolate *ap* isomers, we had to abandon isolation of *sc* isomers at room temperature.

As expected from a minute difference in structures, compounds **5** and **8** exhibit similar barriers to rotation. The barriers observed are in good agreement with those obtained by dynamic NMR study of 9-isopropyltriptycenes except the bromo compound (**6**): the barriers to rotation of 9-isopropyl compounds have been reported to be 23.6 ± 1.9, 25.5 ± 2.3, and >26 kcal/mol for compounds carrying a methoxyl, chloro, and bromo group in the peri-position, respectively.[4] Disagreement of the data obtained prompted us to reexamine the barrier to rotation of 1,2,3,4-tetrabromo-9-isopropyltriptycene. We found that the coalescence temperature of the methyl signals of the isopropyl group in the ^{1}H NMR spectrum was 175 °C instead of >200 °C as reported. From the coalescence temperature and the chemical shift difference, the free energy of activation for rotation was calculated to be 23.5 kcal/mol, which is in accordance with the data investigated here. Probably some accidental mishaps caused errors in reading the temperature in the literature.

The results obtained by the dynamic NMR study are given in Table 2. They are generally in good agreement with the data obtained by the classical method. Although the barriers to rotation of these compounds might be considered similar from the free energies of activation at 298 K, yet we can point out that the methoxy compound (**7**) has a lower barrier. The tendency is usually more revealing in the rate constants than the free energies but the difference is obscure in the rate constants obtained by the line shape analysis (see Experimental section). Rather the difference is definite in the rates of rotation at ambient temperatures (Table 1). If we can take the difference between the bromo (**6**) and the chloro compound (**5**) significant, the chloro compound does exhibit a higher barrier to rotation.

We have recently reported that the barriers to rotation in triptycene systems having a *t*-alkyl group show an interesting trend. Namely, in [1-cyano(or methoxycarbonyl)-1-methylethyl]triptycene series, barriers to rotation are higher if that compound carries no substituent in the peri-position[11] than those carrying a substituent in the peri-position.[10] Investigation of a series of 1-substituted 9-(2-phenyl-1,1-dimethylethyl)-triptycenes has revealed that there is a maximum barrier to rotation when the 1-substituent is medium-sized.[12] Thus the results reported here supplement that there is a same trend in the triptycene series which carries a *s*-alkyl group. The only difference is that, whereas the maximum barrier to rotation in the *t*-alkyl series has been observed at the substituent of a methoxyl or a fluoro, it is a chloro (and a bromo) in the case presented here. This shift must be caused by the fact that congestedness in molecules is much more severe in the *t*-alkyl compounds than in the *s*-alkyl compounds in the ground state.

We wish to thank the Ministry of Education, Science and Culture for a Grant-in-Aid for Fundamental Scientific Research which supported this work.

The Reaction of 2,4,6-Triphenyl-1,3-oxazinylium Perchlorate with Amino Compounds

Isao SHIBUYA

National Chemical Laboratory for Industry, Yatabe, Ibaraki 305

(Received October 27, 1980)

The reaction of 2,4,6-triphenyl-1,3-oxazinylium perchlorate with various kinds of amino compounds was studied. Primary amines and semicarbazides gave pyrimidinium perchlorates. *o*-Phenylenediamine, *o*-aminobenzamide, and *o*-aminothiophenol afforded 2,4-diphenyl-1,5-benzodiazepine, 2-phenyl-4-hydroxyquinazoline, and 2-phenyl-1,3-benzothiazole respectively. Benzoylhydrazine, 4-pyridinecarbohydrazide, and 4-phenylthiosemicarbazide all led to pyrazoline derivatives. *N,N*-Dimethylhydrazine yielded two chain products competitively, while *N,N'*-dimethylhydrazine gave 1,2-dimethyl-3,5-diphenyl-1,2,4-triazolylium and 1,2-dimethyl-3,5-diphenylpyrazolylium perchlorate competitively. It was thus shown that 2,4,6-triphenyl-1,3-oxazinylium perchlorate reacts with amino compounds in a complicated fashion to afford various heterocyclic compounds and other derivatives.

It has been reported that pyrylium salts react with various kinds of amino compounds to afford numerous derivatives.[1] 1,3-Oxazinylium salts, the *N*-analogs of pyrylium salts, can also be expected to give many derivatives when treated with amino compounds; however, their behavior has not yet been studied so closely. A 1,3-oxazinylium cation may be supposed to be reactive with nucleophiles at the 2-, 4-, and 6-positions. Since the 1,3-oxazinylium ring is unsymmetrical, its 2- and 6-positions are not equal to each other. This suggests that the cation behaves toward nucleophiles in a more complicated fashion than does a pyrylium cation. On the other hand, it has been known that carbanions derived from active methylenes, enamines, or ethyl diazoacetate always attack at the 6-position of the 2,4,6-triphenyl-1,3-oxazinylium cation to afford pyridine, butadiene, or 1,3-oxazepine derivatives.[2,3] In this study, the reaction of 2,4,6-triphenyl-1,3-oxazinylium perchlorate (**1**) with various kinds of amino compounds, such as primary amines, disubstituted hydrazines, hydrazides, and semicarbazides, was attempted; consequently, some interesting results were obtained.

Results and Discussion

The starting material, **1**, was obtained by the reaction of 2,4,6-triphenyl-4*H*-1,3-oxazine with trityl perchlorate.[4]

Primary Amines and Semicarbazides. It has been reported that the reaction of 2,4,6-triphenylpyrylium salt (**2**) with primary amines gives 1-substituted 2,4,6-triphenylpyridinium salt (**3**).[5] On the other hand, upon refluxing with aniline, methylamine, semicarbazide, 4-phenylsemicarbazide, the glycine ethyl ester, or *O*-methylhydroxylamine in dioxane–triethylamine, **1** afforded 1-substituted 2,4,6-triphenylpyrimidinium perchlorate (**4a**—**f**), which correspond to **3**. These data are summarized in Table 1. For the formation of **4a**—**f**, two probable reaction courses were postulated, as is shown in Scheme 1. In order to determine the real reaction course, **1** was treated with aniline under mild conditions to isolate a white powder of **5** (63%). **5** was regarded as the intermediate of the above reaction, because **5** gave **4a** almost quantitatively upon treatment with perchloric acid in acetic anhydride. In its IR spectrum, the presence of the absorption at 1681 cm^{-1}, assigned to C=O stretching, suggested that **5** is

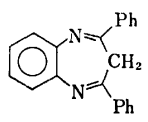
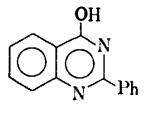
Scheme 1.

one of the two chain compounds (**5A** and **5B**; R=C_6H_5) in Scheme 1. According to ^{13}C NMR spectrum, the absorption assigned to a benzoyl carbon (*δ ca.* 190) was absent, whereas a carbamoyl carbon (*δ* 166.03 or 165.04) was present. The structure of **5** was thus determined to be **5A**; in addition, it was inferred that the reaction of **1** with these primary amines and semicarbazides takes Path A in Scheme 1 to afford **4a—f**.

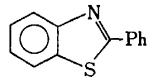
o-Substituted Anilines. The reaction of *o*-aminophenol, *o*-phenylenediamine, *o*-aminobenzamide, or *o*-aminothiophenol with **1** under the same conditions as above gave 1-(*o*-hydroxyphenyl)-2,4,6-triphenylpyrimidinium perchlorate (**4g**, 62%), 2,4-diphenyl-1,5-benzodiazepine (**6**, 80%), 2-phenyl-4-hydroxyquinazoline (**7**, 32%), or 2-phenyl-1,3-benzothiazole (**8**, 68%) respectively. The data of **4g** are also listed in Table 1; **6**, **7**, and **8** were identified by direct comparison with authentic samples.[6-8] These facts suggest that, in



6



7

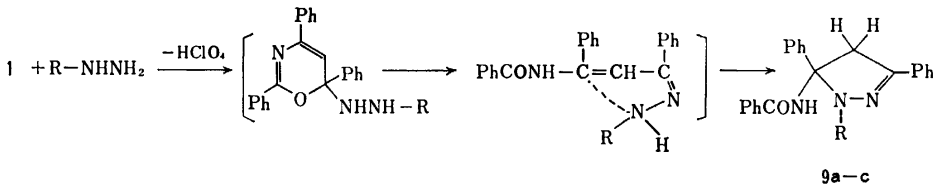


8

the formation of **6**, the reaction was initiated by the attack of *o*-phenylenediamine at the 6-position of the oxazinylium cation, while *o*-aminobenzamide and *o*-aminothiophenol attacked the 2-position of the cation to produce **7** and **8**. It was thus found that these anilines, which have active hydrogen at their ortho-positions, behave in a complicated fashion toward **1**, and produce derivatives with different structures.

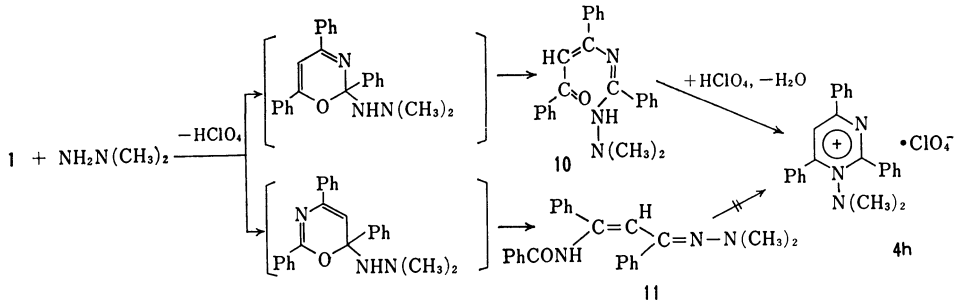
Benzoylhydrazine, 4-Pyridinecarbohydrazide, and 4-Phenylthiosemicarbazide. On treatment with these reagents, **1** gave **9a—c** in 50, 32, and 40% yields respectively. Their ^1H NMR spectra had two characteristic absorptions, at *δ* 3.61—3.80, and 4.02—4.74, which were assigned to a pyrazolinic methylene with a geminal coupling constant (J=18 Hz),[9] while their IR spectra have three common absorptions, at 3280—3340 (N–H), 1665—1686 (C=O), and 1520—1530 cm^{-1} (C=N). These data suggested that **9a—c** have the same skeletal structure. The ^{13}C NMR spectrum of **9a**, as determined by means of the ^1H-off-resonance method, showed the presence of a methylene (*δ* 48.23), a quarternary (*δ* 82.26), and two carbamoyl carbons (*δ* 167.71, 154.17). These spectral results and analytical data confirmed that **9a** is 1-benzoyl-3,5-diphenyl-5-benzoylamino-2-pyrazoline, and that both **9b** and **9c** are also pyrazoline derivatives. The mechanism for the formation of **9a—c** was demonstrated to be as is shown in Scheme 2; this mechanism is similar to that of the reaction of **2** with hydroxylamine or phenylhydrazine which gives oxazoline or pyrazoline compounds.[9,10]

N,N-Dimethylhydrazine. When treated with this reagent under mild conditions, **1** gave a main product, **10** (49%), and also a small amount of **11** (9%) competitively. The analytical data showed that both **10** and **11** are adducts of the anion of this reagent and the oxazinylium cation. The M^+ value was observed at *m/e* 369, though their MS spectra were quite different from each other. Their ^{13}C NMR spectra showed that **10** has a benzoyl carbon (*δ* 190.28), whereas **11** has a carbamoyl carbon (*δ* 165.47). Their IR and UV spectra were also different from each ether. When treated with dilute perchloric acid, **10** easily afforded 1-dimethylamino-2,4,6-triphenylpyrimidinium perchlorate (**4h**); however, **11** afforded no pyrimidinium salt, even upon treatment with 70% perchloric acid. On

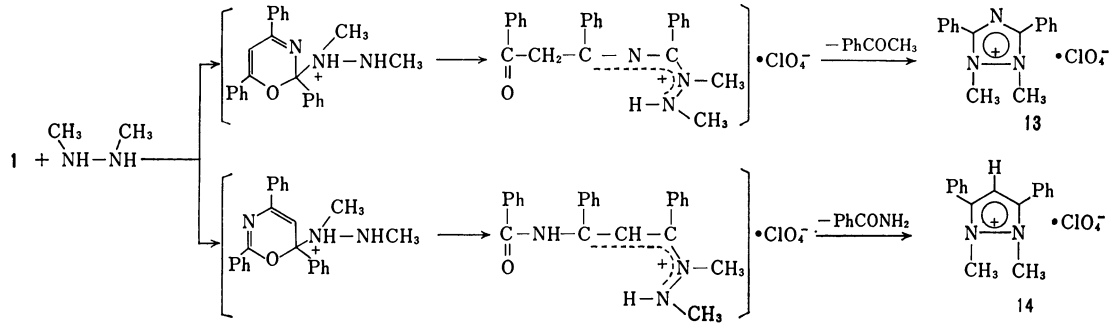


9a: R=–COPh, **9b**: R=–CO–  ·$HClO_4$, **9c**: R=–CSNHPh.

Scheme 2.



Scheme 3.



Scheme 4.

the basis of these results, it seems certain that the reaction course to produce them takes the paths shown in Scheme 3.

N,N'-*Dimethylhydrazine.* On treatment with this reagent, **1** gave **12** in a good yield. The analytical results of **12** agreed almost entirely with 1,2-dimethyl-3,5-diphenyl-1,2,4-triazolylium perchlorate (**13**), but its IR and ^{1}H NMR spectra suggested that **12** was a mixture of **13** and 1,2-dimethyl-3,5-diphenylpyrazolylium perchlorate (**14**). Pure samples of **13** and **14** were obtained by the reaction of this reagent with 3,5-diphenyl-1,2,4-dithiazolylium and with 3,5-diphenyl-1,2-dithiolylium salt respectively.[11,12] The constituent ratio of **13** and **14** in **12** was estimated to be 3 : 1 by the use of the integral ratio of the signals at δ 4.24 (**13**, 18.5) and 4.12 (**14**, 6.0) in the ^{1}H NMR spectrum of **12**. Therefore, the reaction of **1** with this reagent proceeds as is shown in Scheme 4, and yields **13** and **14** competitively.

Hence, it is proved that 2,4,6-triphenyl-1,3-oxazinylium perchlorate reacts with amino compounds not only at the 6-position, but also at the 2-position, and that the reaction produce various heterocyclic compounds and other derivatives.

Experimental

The melting points of all the products were measured in a capillary tube with a Mettler FPl apparatus at the rate of 2 °C/min. The IR spectra were measured in KBr pellets with a JASCO-403G spectrometer. The UV spectra were recorded on a Hitachi 200-10 instrument in an ethanol solution, while the MS spectra were recorded on a Hitachi RMU6E spectrometer with a direct inlet at 70 eV. The ^{1}H and ^{13}C NMR spectra were obtained with a Varian FT-80 instrument, using tetramethylsilane as the internal standard.

*1-Substituted 2,4,6-Triphenylpyrimidinium Perchlorate (**4a**—**g**).* Into a solution of aniline, methylamine hydrochloride, semicarbazide hydrochloride, 4-phenylsemicarbazide, glycine ethyl ester hydrochloride, *O*-methylhydroxylamine hydrochloride, or *o*-aminophenol (1.5 mmol) and triethylamine (0.3 ml) in dioxane (2 ml), **1** (0.42 g, 1 mmol) was stirred at room temperature for 10 min, after which the mixture was refluxed for 1 h. The solvent was then distilled out under reduced pressure. The resulting residue was washed with 1 mol dm^{-3} perchloric acid (5 ml) and then recrystallized from ethanol to give pyrimidinium perchlorates (**4a**—**g**). Their data are listed in Table 1.

*Reaction of **1** with Aniline under Mild Conditions.* Into a solution of aniline (0.14 g, 1.5 mmol) and triethylamine (0.3 ml) in dioxane (2 ml), **1** (0.42 g, 1 mmol) was stirred at room temperature and then the mixture was allowed to stand for 5 d. The mixture was poured into dilute perchloric acid, and the resulting precipitate was recrystallized from methanol to give 0.25 g (63%) of **5**; mp 172.5 °C. IR, 1681, 1622, 1544, 1479, and 1296 cm^{-1}; ^{13}C NMR (HMPA-d_{18}), δ 122.10, 127.15—131.03, 135.07, 138.41, 143.42, 165.04, and 166.03. Found: C, 83.33; H, 5.49; N, 6.83%. Calcd for $C_{28}H_{22}N_2O$; C, 83.46; H, 5.51; N, 6.69%.

*Conversion of **5** to 1,2,4,6-Tetraphenylpyrimidinium Perchlorate (**4a**).* Into a solution of **5** (0.30 g) in acetic anhydride (2 ml), 70% perchloric acid (4 drops) was stirred at room temperature, after which the mixture was allowed to stand overnight. The mixture was poured into ether, and the resulting precipitate was collected by filtration and washed with ether to give a white powder of **4a** (0.34 g, 94%).

*Reaction of **1** with o-Substituted Anilines.* *o*-Phenylenediamine, *o*-aminobenzamide, and *o*-aminothiophenol (1.5 mmol) were treated with **1** (1 mmol) by the same procedure as was used in the preparation of **4a**—**g**. The resulting residues were washed with dilute perchloric acid and recrystallized from methanol to give **6** (0.24 g, 80%), **7** (0.07 g, 32%), and **8** (0.14 g, 68%) respectively. The IR spectrum of each of them could be completely superimposed on that of the

corresponding authentic samples.[6-8]

*1-Substituted 3,5-Diphenyl-5-benzoylamino-2-pyrazolines (**9a**—**c**).* Benzoylhydrazine, 4-pyridinecarbohydrazide, and 4-phenylthiosemicarbazide (1.5 mmol) were treated with **1** (1 mmol) by the same procedure as was used in the preparation of **4a**—**g**. The resulting residues were recrystallized from methanol, ethanol, or acetonitrile to yield **9a** (0.22 g, 50%), **9b** (0.17 g, 32%), or **9c** (0.19 g, 40%) respectively. Their data are shown below.

9a: mp, 165.8 °C; IR, 3280, 1667, 1640, 1530, 1447, 1416, and 1338 cm^{-1}; UV, λ_{max} (ε) 293 nm (21400); ^1H NMR ($CDCl_3$), δ 3.64 (d, J=18), 4.74 (d, J=18), 7.22—8.40, ^{13}C NMR ($CDCl_3$), δ 48.23 (-CH_2-), 82.26 (-$\dot{C}$-), 124.07, 126.89—134.46, 142.39, 154.17, and 167.71. MS, *m/e* 445 (M^+), 324 ([M−$PhCONH_2$]$^+$), 295, 220, 121 ([$PhCONH_2$]$^+$), and 105 ($PhCO^+$). Found: C, 78.24; H, 5.23; N, 9.53%. Calcd for $C_{29}H_{23}N_3O_2$; C, 78.24; H, 5.20; N, 9.43%.

9b: mp, 231.2 °C; IR, 3300—3050, 1665, 1651, 1520, 1480, 1432, 1345, and 1100 cm^{-1}; UV, λ_{max} (ε) 321 nm (29900); ^1H NMR (C_5D_5N), δ 3.61 (d, J=18), and 4.47 (d, J=18). Found: C, 61.39; H, 4.23; N, 10.50; Cl, 6.63%. Calcd for $C_{28}H_{23}N_4O_6Cl$; C, 61.49; H, 4.24; N, 10.24; Cl, 6.48%.

9c: mp, 164.7 °C; IR, 3340, 1686, 1523, 1487, 1450, and 1327 cm^{-1}; UV, λ_{max} (ε) 280 nm (21500); ^1H NMR (C_5D_5N), δ 3.80 (d, J=18), 3.84 (*s*), and 4.02 (d, J=18); ^{13}C NMR (DMF-d_7), δ 50.46 (-CH_2-), 83.67 (-$\dot{C}$-), 124.93, 127.87—132.46, 139.50, 143.73, 152.58, 167.31, and 173.89; MS, *m/e* 476 (M^+), 220, 135, 121, and 105. Found: C, 73.17; H, 5.13; N, 11.68; S, 6.65%. Calcd for $C_{29}H_{24}N_4SO$; C, 73.08; H, 5.07; N, 11.75; S, 6.72%.

Reaction of N,N-*Dimethylhydrazine with **1**.* Into a solution of *N,N*-dimethylhydrazine (0.10 g, 1.6 mmol) and triethylamine (0.3 ml) in dioxane (2 ml), **1** (1 mmol) was stirred at room temperature. After the mixture had been allowed to stand for 5 d, it was poured into water and the resulting precipitate was purified by preparative thin-layer chlomatography (silica gel; benzene–acetic acid, 50 : 1) to give orange-yellow needles of **10** (0.18 g, 49%) and pale yellow granules of **11** (0.03 g, 9%). Their data are shown below.

10: mp, 152.6 °C (ethanol); IR, 3060—2780, 1592, 1560, 1537, 1494, 1325, 1306, and 1295 cm^{-1}; UV, λ_{max} (ε) 257 (15900), and 367 nm (14200); ^1H NMR ($CDCl_3$), δ 2.76 (s, 6H), 6.18 (s, 1H), 6.90—8.14 (m, 16H); ^{13}C NMR ($CDCl_3$), δ 46.74 (-CH_3), 99.31 (=CH-), 127.62—139.56, 153.06, 158.26, and 190.26; MS, *m/e* 369 (M^+), 310, 264 ([M−PhCO]$^+$), and 105. Found: C, 78.13; H, 6.30; N, 11.37%. Calcd for $C_{24}H_{23}N_3O$; C, 78.02; H, 6.27; N, 11.37%.

11: mp, 150.1 °C (ethanol); IR, 3060—2780, 1670, 1618, 1498, 1478, 1310, 1298, and 1272 cm^{-1}; UV, λ_{max} (ε) 248 (44200), and 299 nm (sh, 28400); ^1H NMR ($CDCl_3$), δ 2.88 (s, 6H), 6.16 (s, 1H), 7.30—8.12 (m, 15H), and 10.90 (s, 1H); ^{13}C NMR ($CDCl_3$), δ 47.54 (CH_3-), 112.13 (=CH-), and 127.19—138.30, 143.17, 156.69, 165.47; MS, *m/e* 369 (M^+), 248 ([M−$PhCONH_2$]$^+$), 105, and 104. Found: C, 77.95; H, 6.27; N, 11.51%. Calcd for $C_{24}H_{23}N_3O$; C, 78.02; H, 6.27; N, 11.37%.

*Conversion of **10** into 1-Dimethylamino-2,4,6-triphenylpyrimidinium Perchlorate (**4h**).* Into a solution of **10** (0.37 g, 1 mmol) in acetonitrile (2 ml), 1 mol dm^{-3} perchloric acid (2 ml) was stirred after which the mixture was allowed to stand at 0—5 °C overnight. The precipitate was collected by filtration and washed with ether to give **4h** (0.43 g) almost quatitatively. The data of **4h** are shown in Table 1.

*Reaction of **1** with* N,N′-*Dimethylhydrazine.* Into a solution of *N,N′*-dimethylhydrazine dihydrochloride (0.20 g, 1.5 mmol) in 2 mol dm^{-3} MeONa–MeOH (2 ml), **1** (1 mmol) was stirred at room temperature for 10 min, and then the mixture was refluxed for 1 h. The reaction mixture was poured into dilute perchloric acid. The resulting precipitate was collected by filtration and recrystallized from methanol to give **12** (0.27 g). IR, 1544, 1487, 1453, 1420, 1111, 1090, 740, 717, and 691 cm^{-1}; ^1H NMR (DMSO-d_6), δ 3.36, 4.12, 4.24, 7.32, 7.62—8.02. Found: C, 55.32; H, 4.61; N, 11.86; Cl, 10.13%.

*1,2-Dimethyl-3,5-diphenyl-1,2,4-triazolylium Perchlorate (**13**) and 1,2-Dimethyl-3,5-diphenylpyrazolylium Perchlorate (**14**).* *N,N′*-Dimethylhydrazine dihydrochloride (1.5 mmol) was treated with 1 mmol of 3,5-diphenyl-1,2,4-dithiazolylium salt[11] or 3,5-diphenyl-1,2-dithiolylium salt[12] by the same procedure as above. Their data are shown below.

13: yield 25%, mp 152.0 °C (methanol); IR, 1606, 1544, 1485, 1450, 1418, 1392, 1115, 1087, 742, 718, 693 cm^{-1}; ^1H NMR (DMSO-d_6), δ 3.38, 4.24, and 7.62—8.02. Found: C, 54.85; H, 4.59; N, 12.14; Cl, 10.12%. Calcd for $C_{16}H_{16}N_3ClO_4$: C, 54.94; H, 4.61; N, 12.01; Cl, 10.12%.

14: yield 46%; mp, 187.4 °C (methanol); IR, 3120, 1565, 1494, 1476, 1434, 1396, 1111, 1092, 766, and 693 cm^{-1}; ^1H NMR (DMSO-d_6), δ 3.38, 4.12, 7.34, and 7.72. Found: C, 58.55; H, 4.87; N, 8.17; Cl, 10.14%. Calcd for $C_{17}H_{17}N_2ClO_4$; C, 58.55; H, 4.91; N, 8.03; Cl, 10.16%.

The Oxidation of 3,3-Diphenyl-2-propenoic Acid with Manganese(III) Acetate

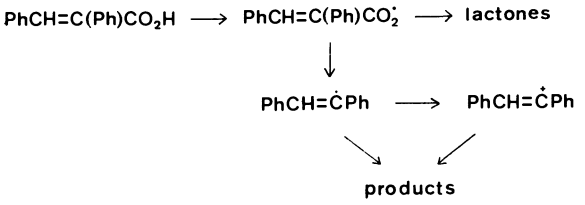
Kazu KUROSAWA* and Tsuyoshi TSUJITA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860

(Received November 8, 1980)

The oxidation of 3,3-diphenyl-2-propenoic acid with manganese(III) acetate in boiling acetic acid gave 3,3-diphenyl-2-propenyl acetate, 4-acetoxymethyl-5,5-diphenyltetrahydro-2-furanone, 3,3-diphenyl-2-propenal, 5,5-diphenyl-2,5-dihydro-2-furanone, 4-acetoxy-5,5-diphenyltetrahydro-2-furanone, benzophenone, and 2-oxo-5,5-diphenyltetrahydro-4-furancarboxylic acid. The reaction pathways are discussed.

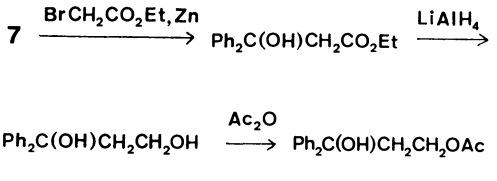
In a previous report[1] we described the oxidation of (*E*)-2,3-diphenyl-2-propenoic acids with manganese(III) acetate. The results were explained in terms of the formation of an acyloxy radical, a vinyl radical, and a vinyl cation from (*E*)-2,3-diphenyl-2-propenoic acid and the subsequent reactions of these intermediates (Scheme 1). We have now examined the oxidation of 3,3-diphenyl-2-propenoic acid (**1**) with manganese(III) acetate; the results will be described in this paper.



Scheme 1.

When 3,3-diphenyl-2-propenoic acid (**1**) was oxidized with manganese(III) acetate in the molar ratios of 1 : 3, 1 : 4, and 1 : 6 in boiling acetic acid, 3,3-diphenyl-2-propenyl acetate (**2**), 4-acetoxymethyl-5,5-diphenyltetrahydro-2-furanone (**3**), 3,3-diphenyl-2-propenal (**4**), 4-acetoxy-5,5-diphenyltetrahydro-2-furanone (**5**), 5,5-diphenyl-2,5-dihydro-2-furanone (**6**), and benzophenone (**7**) were obtained. When the oxidation was conducted in acetic acid containing acetic anhydride, 2-oxo-5,5-diphenyltetrahydro-4-furancarboxylic acid (**8**) was obtained, along with other products (**2**—**4**, and **6**), but **5** and **7** were not obtained. The results are summarized in Table 1. The structures of the products were determined by means of a study of their IR, NMR, and MS spectra, by elemental analyses, and by comparison with authentic samples.

3,3-Diphenyl-2-propenyl acetate (**2**) was obtained in the oxidation; the yield first increased with the increase in the molar ratio of the oxidant to the substrate, and then it decreased, suggesting that **2** could be further oxidized. In fact, the oxidation of **2**, prepared separately (Scheme 2), with manganese(III) acetate gave Compounds **3**, **4**, and **7** (Entry 8), **3** being the main product. The fact that only a small amount of **7** was formed from **2** indicates that **7** in Entries 1, 3, and 5 was not mainly formed *via* **2**. It seemed that the reaction of **1** with manganese(III) acetate would give an acyloxy radical (**A**), which then decomposed to a 2,2-diphenylethenyl radical (**B**), and that the latter reacted with the carboxymethyl radical formed from manganese(III) acetate to give 4,4-diphenyl-3-butenoic acid (**9**) (Scheme



Scheme 2.

Table 1. The reaction of 3,3-diphenyl-2-propenoic acid (**1**) and related compounds with manganese(III) acetate in boiling acetic acid containing acetic anhydride

Entry	Substrate	Molar ratio of substrate : oxidant : Ac_2O	Time / min	Recovered substrate / %	Yield/%[a]

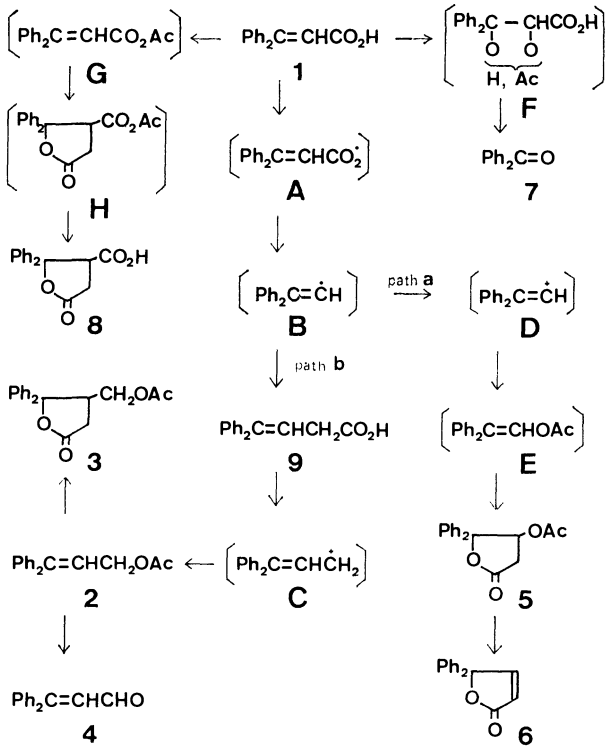
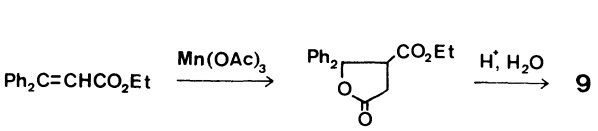
12	**10**	1 : 3 : 6	60	9	4					9		71

a) The yields are based on the amount of the substrate used. b) **1** was pre-treated with excess acetyl chloride before the reaction.



Scheme 3.

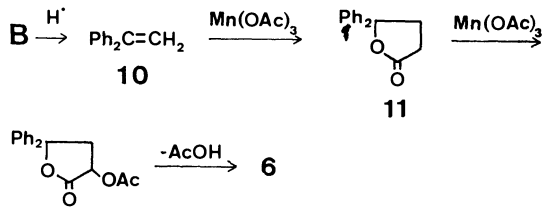


Scheme 4.

3, Path b). However, **9** could not be found in the products. Therefore, **9** was synthesized separately (Scheme 4) and treated with manganese(III) acetate. As a result, **2** was obtained as a single product (Entry 11), showing that **9** is a possible precursor of **2**.

4-Acetoxymethyl-5,5-diphenyltetrahydro-2-furanone (**3**) was obtained as the main product in the oxidation of **1** with manganese(III) acetate in Entries 2—6; the yield increased much with the increase in the oxidant. The oxidation of **2** with manganese(III) acetate in acetic acid containing acetic anhydride gave **3** almost exclusively (Entry 9).

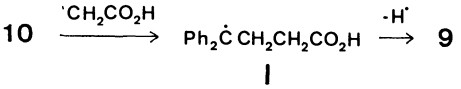
Benzophenone (**7**) was obtained in a fairly large quantity, although it could not be separated from **2** because they have the same R_f values on TLC. However, on HLC it clearly showed two peaks corresponding to those of authentic samples. It is also interesting to note that benzophenone (**7**) was not formed in the reactions of **1** and **2** when acetic anhydride was added. It is known that the yield of lactones increases in the reaction of olefins with mangenese(III) acetate with a lowering of the water content in the reaction mixture.[2] It seems possible to assume that there are pathways which afford a hydroxy acetate like **F** and then **7** in the oxidation of **1** and **2**, and that these pathways do not operate under anhydrous conditions. It has been reported that the cleavage of the double



Scheme 5.

bond of chalcones in the oxidation with manganese(III) acetate gave a benzaldehyde,[3] although the reaction pathway was not shown.

As another interesting feature of the reaction, it gave 5,5-diphenyl-2,5-dihydro-2-furanone (**6**) in very low yields (Entries 1, 3, and 5). We oxidized **2**, **8**, and **9**, but none of them gave the lactone (**6**). It seemed possible that acetoxylation of 5,5-diphenyltetrahydro-2-furanone (**11**), followed by decomposition, might give the lactone (**6**), as is shown in Scheme 5. The oxidation of 1,1-diphenylethylene (**10**) with manganese(III) acetate gave **11** as the major product, together with **2** and **7** in minor quantitities (Entry 12), but it did not give **6**. The formation of **2** from **10** can be explained as follows. The addition of a carboxymethyl radical to **10** gives a radical, **I**, which then loses a hydrogen radical to yield **9** and then **2** (Scheme 6). One of the minor



Scheme 6.

fractions isolated from the reaction of **1** with manganese(III) acetate in acetic acid showed a peak at $\delta=1.69$ corresponding to an acetoxyl group. The purification of the fraction by repeated TLC failed to give a pure compound, but the NMR spectrum showed three aliphatic protons, at $\delta=2.45$ (1H, dd, $J=2.5$ and 18.0 Hz), $\delta=2.72$ (1H, $J=6.0$ and 18.0 Hz), and $\delta=6.25$ (1H, dd, $J=2.5$ and 6.0 Hz). Since the chemical shift ($\delta=1.69$) for the acetoxyl group is higher than the normal one ($\delta=2$), and since the J value of 18.0 Hz for methylene protons adjacent to a carbonyl function is comparable to those of cyclic compounds, the structure of this compound must be 4-acetoxy-5,5-diphenyltetrahydro-2-furanone (**5**). When the fraction was heated in acetic acid under reflux, it gave **6**. Thus, it is most probable that **6** was formed from **5**.

3,3-Diphenyl-2-propenal (**4**) was obtained as a minor product which might have been formed from **2** by further oxidation with manganese(III) acetate and hydrolysis during the work-up.

The formation of 2-oxo-5,5-diphenyltetrahydro-4-furancarboxylic acid (**8**) in the reaction containing acetic anhydride seems to indicate that **1** forms an anhydride with acetic anhydride and then reacts with the carboxymethyl radical. The reaction of **1** which had been pretreated with acetyl chloride gave **8** in a much improved yield (Entry 7). Since the reaction of **8** with manganese(III) acetate gave **2** and **3** (Entry 10), therefore, it seems that **8** could be decarboxylated to give **9** which

yielded **2** and **3**. However, **8** cannot be a real precursor for **2** and the other compounds in the oxidation of **1**, because if **8** were first formed and then oxidized to **2**, **3**, and **4** during the prolonged reaction time in the reaction in acetic acid, the total yield of **2**, **3**, **4**, and **8** should be roughly equal to that in the reaction in acetic acid containing acetic anhydride. However, this was not the case. For example, the total yield (20%) of **2**, **3**, **4**, and **8** in Entry 1 was less than that (40%) in Entry 2. The above possible reaction pathways are summarized in Scheme 3.

Experimental

All the 60 MHz ^{1}H NMR spectra were recorded with a Hitachi R-24 spectrometer, while the 100 MHz ^{1}H NMR spectrum was taken on a JEOL MH-100 spectrometer, with TMS as the internal standard. The IR spectra were recorded for the chloroform solution with a JASCO IRA-1 grating spectrometer, while the MS spectra were taken with JMS-01 SG-2 and Hitachi M-80 plus M-003 instruments. Liquid chromatography (HLC) was carried out with a Mitsubishi ALTEX 310/330 instrument, eluting with 60% aqueous methanol using a HY-ODS-SU column 4.6 mm in diameter and 250 mm in length. The melting points were determined on a Yanagimoto micro-melting point apparatus and were not corrected.

Materials. The 3,3-Diphenyl-2-propenoic acid (**1**) was prepared by the standard procedure[4] from benzophenone. The ethyl 3,3-diphenyl-2-propenoate[5] was prepared by the dehydration of ethyl 3-hydroxy-3,3-diphenylpropanoate[4] with thionyl chloride in pyridine.

3-Acetoxy-1,1-diphenyl-1-propanol. To ethyl 3-hydroxy-3,3-diphenylpropanoate (1.95 g) in anhydrous diethyl ether (100 ml), we added lithium aluminium hydride (80 mg), after which the mixture was stirred at 0 °C for 14 h. After the addition of 1 M (1 M = 1 mol dm^{-3}) sulfuric acid (50 ml), the reaction mixture was extracted with diethyl ether. The combined ethereal extract was washed with a saturated solution of sodium chloride and then evaporated. The resulting 1,1-diphenyl-1,3-propanediol was treated with a mixture of acetic anhydride (5 ml) and pyridine (10 ml) at room temperature for 17 h. The reaction mixture was poured into iced water, and the precipitate was collected and recrystallized from light petroleum to give 3-acetoxy-1,1-diphenyl-1-propanol (1.80 g, 92%), mp 84—85 °C; IR 1740 (OAc) and 3560 cm^{-1} (OH); NMR ($CDCl_3$) δ=1.88 (3H, s, OAc), 2.61 (2H, t, J=7.0 Hz, $-CH_2-$), 2.79 (1H, s, OH), 4.16 (2H, t, J=7.0 Hz, $-CH_2-$), and 7.1—7.6 (10H, m, 2×Ph). Found: C, 75.48; H, 6.49%. Calcd for $C_{17}H_{18}O_3$: C, 75.53; H, 6.71%.

3,3-Diphenyl-2-propenyl Acetate (2). A solution of 3-acetoxy-1,1-diphenyl-1-propanol (1.40 g) in pyridine (10 ml) was treated with thionyl chloride (1.24 g) at 0 °C for 19 h. The reaction mixture was poured into 1 M sulfuric acid (100 ml) and then extracted with benzene (50 ml). The benzene layer was washed with 1 M sulfuric acid (30 ml) and then evaporated, giving **2** (1.21 g, 86%). The analytical sample was distilled under reduced pressure; bp 150—155 °C (bath temp)/0.1 mmHg (1 mmHg = 133.322 Pa); IR 1738 cm^{-1} (OAc); NMR (CCl_4) δ=1.97 (3H, s, OAc), 4.54 (2H, d, J=7.0 Hz, $-CH_2-$), 6.15 (1H, t, J=7.0 Hz, >CH–), and 7.2 (10H, m, 2×Ph); MS *m/e* 252.1187 (Calcd for $C_{17}H_{16}O_2$: 252.1150) (59%, M$^+$), 209 (61%), 192 (100%), and 103 (82%).

Ethyl 2-Oxo-5,5-diphenyltetrahydro-4-furancarboxylate. A mixture of ethyl 3,3-diphenyl-2-propenoate (504 mg), manganese(III) acetate dihydrate[6] (1.61 g), acetic acid (20 ml), and acetic anhydride (3 ml) was heated under reflux for 43 min. The reaction mixture was poured into water (50 ml), and the precipitate was collected. Recrystallization from ethanol gave ethyl 2-oxo-5,5-diphenyltetrahydro-4-carboxylate (513 mg, 90%); mp 147—148 °C; IR 1742 (COOEt) and 1780 cm^{-1} (lactone); NMR ($CDCl_3$) δ=0.92 (3H, t, J=7.0 Hz, $-CH_3$), 2.71 (1H, dd, J=8.5 and 18.0 Hz, –CH–), 3.02 (1H, dd, J=4.5 and 18.0 Hz, –CH–), 3.75 (2H, m, $-CH_2-$), 4.20 (1H, dd, J=8.5 and 4.5 Hz, –CH–), and 7.2—7.8 (10H, m, 2×Ph). Found: C, 73.40; H, 5.65%. Calcd for $C_{19}H_{18}O_4$: C, 73.53; H, 5.85.

4,4-Diphenyl-3-butenoic Acid (9). A mixture of ethyl 2-oxo-5,5-diphenyltetrahydro-4-furancarboxylate (572 mg), 3 M hydrochloric acid (100 ml), and ethanol (100 ml) was heated under reflux for 21 h. After the removal of the ethanol and the hydrochloric acid, the resulting mixture was extracted with benzene; then the benzene solution was extracted with a saturated sodium hydrogencarbonate solution. The aqueous solution was separated and acidified with concd hydrochloric acid. The precipitate was collected and recrystallized from a mixture of carbon tetrachloride–light petroleum to give 4,4-diphenyl-3-butenoic acid (115 mg, 25%); mp 109—111 °C; IR 1725 (COOH) and 2400—3400 cm^{-1} (COOH); NMR ($(CD_3)_2SO$) δ=3.06 (2H, d, J=8.0 Hz, $-CH_2-$), 6.26 (1H, t, J=8.0 Hz, =CH–), and 7.3 (10H, m, 2×Ph); MS *m/e* 238.1008 (Calcd for $C_{16}H_{14}O_2$: 238.0994) (66%, M$^+$), 193 (85%), 178 (53%), and 115 (100%).

Oxidations of 3,3-Diphenyl-2-propenoic Acid (1), 3,3-Diphenyl-2-propenyl Acetate (2), 2-Oxo-5,5-diphenyltetrahydro-4-furancarboxylic Acid (8), 4,4-Diphenyl-3-butenoic Acid (9), and 1,1-Diphenylethylene (10). The general procedure for the oxidation of 3,3-diphenyl-2-propenoic acid (**1**) and the other compounds (**2**, **8**, **9**, and **10**) was as follows. A mixture of the substrate (2 mmol), manganese(III) acetate dihydrate (4—12 mmol), acetic acid (30 ml), and acetic anhydride (when it was needed) (10 ml) was heated under reflux until the dark color of Mn(III) ion disappeared (the time is shown in Table 1). After the removal of the acetic acid, 1 M sulfuric acid (30 ml) was added to the mixture, which was then extracted with benzene (30 ml). The benzene solution was washed with aqueous sodium hydrogencarbonate and evaporated under reduced pressure. The products were separated on TLC (Wakogel B 10), with chloroform as the developing solvent, and then recrystallized. The aqueous sodium hydrogencarbonate solution was acidified with concd hydrochloric acid and extracted with chloroform, which gave acidic products. The yields are summarized in Table 1.

Oxidation Products. *3,3-Diphenyl-2-propenyl Acetate (2)*: Liquid (this was identical with an authentic sample).

4-Acetoxymethyl-5,5-diphenyltetrahydro-2-furanone (3): Mp 119—120 °C (EtOH); IR 1752 (OAc) and 1780 cm^{-1} (lactone); NMR (C_6H_6) δ (100 MHz) = 1.60 (3H, s, OAc), 2.12 (2H, d, J=6.0 Hz, $-CH_2-$), 3.16 (1H, m, –CH–), 3.40 (1H, dd, J= 8.0 and 11.5 Hz, –CH–), and 3.94 (1H, dd, J=4.5 and 11.5 Hz, –CH–). Found: C, 73.39; H, 5.97%. Calcd for $C_{19}H_{18}O_4$: C, 73.53; H, 5.85%.

3,3-Diphenyl-2-propenal (4): Liquid (lit,[7] mp 44 °C); IR 1680 cm^{-1} (CHO); NMR ($CDCl_3$) δ=6.56 (1H, d, J=9.0 Hz, =CH–) 7.35 (10H, m, 2×Ph), and 9.49 (1H, d, J=9.0 Hz, CHO); MS *m/e* 208.0896 (Calcd for $C_{15}H_{12}O$: 208.0888) (100%, M$^+$), 207 (99%), 178 (39%), 165 (22%), 152 (14%), 131 (19%), and 102 (38%).

4-Acetoxy-5,5-diphenyltetrahydro-2-furanone (5): Liquid (this compound was obtained as a mixture; its NMR data are given in the text).

5,5-Diphenyl-2,5-dihydro-2-furanone (6): Mp 128—128.5 °C

(EtOH) (lit,[8] mp 131—131.5 °C); IR 1680 (C=C) and 1770 cm^{-1} (lactone); NMR ($CDCl_3$) δ=6.11 (1H, d, J=6.0 Hz, =CH–), 7.26 (10H, m, 2×Ph), and 7.87 (1H, d, J=6.0 Hz, =CH–); MS *m/e* 236 (41%, M^+), 131 (100%), 105 (83%), and 77 (69%).

Benzophenone (7): This was obtained as a mixture of **2** and **7**; it was found by HLC to be identical with authentic samples. The yields were estimated from the NMR spectrum.

2-Oxo-5,5-diphenyltetrahydro-4-furancarboxylic Acid (8): Mp 191—192 °C (CCl_4); IR 1740 (COOH) and 1780 cm^{-1} (lactone); NMR ($(CD_3)_2SO$) δ=2.78 (2H, m, $-CH_2-$), 4.29 (1H, dd, –CH–) (AB_2 system, J_{AB}=6.3 Hz), and 7.1—7.8 (10H, m, 2×Ph); MS *m/e* 282 (5%, M^+), 238 (5%), 183 (100%), 105 (50%), and 77 (20%). Found: C, 72.01; H, 4.89%. Calcd for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00%.

5,5-Diphenyltetrahydro-2-furanone (11): Mp 90 °C (EtOH) (lit,[9] mp 90 °C); IR 1778 cm^{-1} (lactone); NMR (CCl_4) δ= 2.2—3.0 (4H, m, $-CH_2-CH_2-$), and 7.25 (10H, m, 2×Ph).

We wish to thank Professor Hideto Shosenji of the Department of Synthetic Chemistry, Faculty of Technology, Kumamoto University, for his measurement of the 100 MHz ^1H NMR spectrum, and Dr. Shinzaburo Hishida of the Hitachi Co. Ltd., Katsuda, and Mr. Shuichi Ueda at the Taiho Pharmaceutical Co. Ltd., Tokushima, for their measurements of the MS spectra. We also wish to thank Professor John F. W. McOmie for his helpful discussion and for reading the manuscript.

Configuration and Conformation of the Photoisomers of *N*-[*p*-(Dimethylamino)benzylidene]anilines

Masato YOSHIDA* and Michio KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

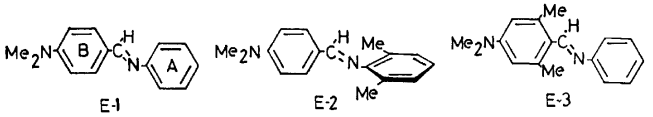
(Received December 5, 1980)

The UV, ^{1}H-NMR, and ^{13}C-NMR spectra of the photoisomers produced by irradiation of *N*-[*p*-(dimethylamino)benzylidene]anilines at low temperature have been studied. The results suggested that the photoisomers have Z structures and the imino benzene rings are twisted around the Ar–N axis out of Ar–CH=N plane due to the steric repulsion between the two rings.

N-Benzylideneanilines (Ar'CH=NAr) are formally related to stilbenes (Ar'CH=CHAr) and azobenzenes (Ar'N=NAr), but differ from the latter in that *Z* (cis) isomers have not yet been isolated. The possibility of the existence of *E*-*Z* isomerism in *N*-benzylideneanilines has interested chemists for many decades. It was reported that the irradiation of a solution of (*E*)-*N*-benzylideneaniline at 200 K converts it reversibly into a photoisomer with a different UV absorption.[1] We investigated the photoisomerism of many substituted *N*-benzylideneanilines (*p*-R'-C_6H_4CH=NC_6H_4-R-*p*) by the measurement of UV spectra, and found that various *N*-benzylideneanilines are converted into their photoisomers upon irradiation by a high pressure mercury lamp at 77 K (liq. N_2) or 200 K (Dry Ice–EtOH or Dry Ice–acetone).[2] Recently, ^{1}H-NMR spectroscopy has been applied to the problem of configuration of the photoisomers of *N*-benzylideneanilines.[3,4] In this paper we report UV, ^{1}H-NMR, and ^{13}C-NMR spectra of the photoisomers of *N*-[*p*-(dimethylamino)benzylidene]-aniline and its methyl or dimethyl derivatives produced by photoirradiation, and discuss the configuration and conformation of the photoisomers. *N*-[*p*-(Dimethylamino)benzylidene]aniline and its methyl or dimethyl derivatives were chosen for this study because they have strong absorption maxima at wavelengths greater than 300 nm, and are most easily converted to the photoisomers.

Results and Discussion

The UV spectra of the following three compounds and their photoisomers produced by photoirradiation at 77 K in M. P. (methylcyclohexane–isopentane 1 : 1) matrix are shown in Fig. 1. When *E*-**1**—*E*-**3** were



irradiated at the wavelength corresponding to the longest wavelength absorption maxima, they were converted to their photoisomers; these also absorbed the light and reverted to *E* forms. Therefore, the photoequilibrium between the photoisomer and the *E* form depends upon the wavelength of the light used. In order to determine the characteristics of the UV spectra of these isomers, it is desirable to have almost 100% conversion to photoisomers. This could be achieved by

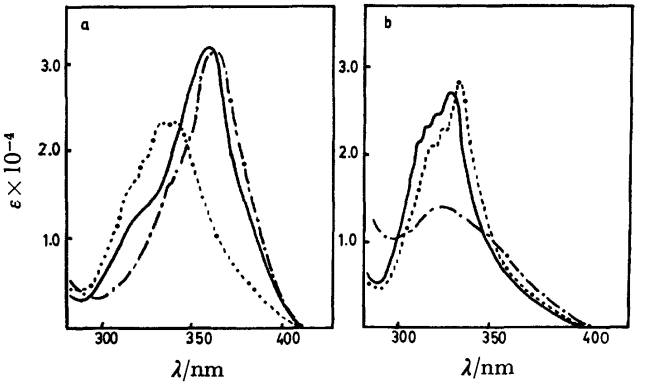


Fig. 1. The UV spectra of (a) *E*-**1** (——), *E*-**2** (- - -), and *E*-**3** (—·—), and (b) their photoisomers in methylcyclohexane–isopentane 1 : 1 at 77 K.

choosing monochromatic light of 366 nm for irradiation.

Compound *E*-**1** was shown to have a planar structure from the UV spectra.[5] As described in our previous paper, the UV spectrum of *E*-**2** is quite similar to that of *N*-[*p*-(dimethylamino)benzylidene]-*t*-butylamine, and so we conclude that the UV absorption band of *E*-**2** shown in Fig. 1a is due to the conjugated system of the benzylidene benzene ring (ring B) and C=N group, with little contribution from the imino benzene ring (ring A).[2] The UV spectrum of *E*-**3** is similar to that of *E*-**1**, so it should also have a planar structure. In the photoisomers, the UV spectrum of **1** is quite similar to that of **2**, but different from that of **3** (Fig. 1b). And the UV spectra of the photoisomers of **1** and **2** are almost the same as that of *E*-**2**. These features of the photoisomers of *N*-[*p*-(dimethylamino)benzylidene]anilines can be explained by the structure of the photoisomers proposed in Fig. 2. The photoisomer of **1** has *Z*-configuration and ring A is greatly twisted around the Ar–N axis; ring B and CH=N group compose a conjugated system with little contribution from ring A. The conformation of ring A of the photoisomer of **2** is the

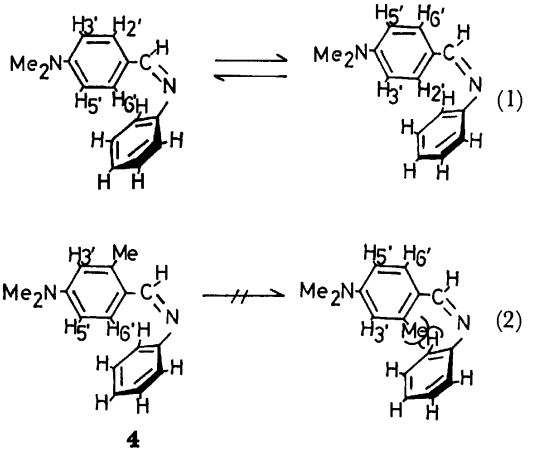
same as that of the photoisomer of **1**, because the 2- and 6-methyl groups on ring A do not act as steric hindrances. On the other hand, ring B of the photoisomer of **3** is twisted due to the steric repulsion between the 2- and 6-methyl groups on ring B and ring A.

As shown in our previous paper, the UV spectra of the photoisomers of *p*-substituted *N*-benzylideneanilines (*p*-R′-C_6H_4CH=NC_6H_4-R-*p*) do not vary with the substituents R but with the substituents R′, and are quite similar to those of corresponding *N*-benzylidene-2,6-dimethylanilines (*p*-R′-C_6H_4CH=NC_6H_2-Me_2-2,6-R-4). These results support the idea that the photoisomers of *N*-benzylideneanilines have the structure shown in Fig. 2a.

^{1}H-NMR chemical shifts of *E*-**1** and (*E*)-*N*-(4-dimethylamino-2-methylbenzylidene)aniline (**4**) and their photoisomers were also studied. The aromatic protons of these compounds were assigned by comparison with ^{1}H-NMR chemical shifts of **1**-2,4,6-d_3, **4**-2,4,6-d_3, and **4**-2,4,6,3′,5′-d_5 and their photoisomers. The chemical shifts are summarized in Table 1.

$H_{2'}$ and $H_{6'}$ of the photoisomer of **1** resonate at a field higher than those of *E*-**1**. The significant change in $H_{2'}$ and $H_{6'}$ (0.76 ppm) can be ascribed to the diamagnetic shielding by ring A, since $H_{2'}$ or $H_{6'}$ in photoisomer is located above ring A, as shown in Fig. 2a. In **1** or its photoisomer, the signals of $H_{2'}$, $H_{6'}$, $H_{3'}$, and $H_{5'}$ are AA′BB′ type quartets. This shows that ring B freely rotates around the Ar–C bond within the NMR time scale, although this ring lies in the plane common to the C=N bond most of the time (Eq. 1). Therefore, the upfield shifts observed in $\delta_{H_{5'}}$ and $\delta_{H_{3'}}$ in **1** upon irradiation must be the average of the shifts of the $H_{6'}$, affected by the diamagnetic shielding from the ring A, and of $H_{2'}$, little affected by such shielding. If the rotation of ring B around the Ar–C bond could be restricted, the real upfield shift in $H_{6'}$ upon irradiation should be observed. So the NMR spectra of (*E*)-*N*-(4-dimethylamino-2-methylbenzylidene)aniline and its photoisomer were investigated. In the photoisomer of **4** the 2-methyl group should be situated far from ring A and thus should avoid the steric repulsion of the methyl group and ring A, as shown in Eq. 2. A large upfield shift of 1.38 ppm upon irradiation was observed in $H_{6'}$. This is approximately twice that observed in the $H_{2'}$ and $H_{6'}$ in **1** (0.76 ppm), in accordance with our



4

expectation. The upfield shift in $H_{5'}$ (0.51 ppm) is also about two times that observed in the $H_{3'}$ and $H_{5'}$ in **1** (0.25 ppm). The fact that $H_{5'}$ is not equivalent to $H_{3'}$ shows the restriction of the rotation.

If one assumes that the ring A is twisted around the Ar–N axis by 90° and that ring B and CH=N group are on the same plane, the theoretical shielding effect on $H_{6'}$ according to the ring currents model proposed by Johnson and Boby[6)] is more than 4 ppm (ρ(Å)=0.79, z(Å)=1.46; ρ and z are two components of the radius vector from the center of shielding ring A to $H_{6'}$. ρ lies in the plane of ring A and z is the component along the hexad axis.). This theoretical value is quite different from the observed one (1.38 ppm). However, the shielding on $H_{6'}$ from ring A is sensitive to the dihedral angle of the Ar–C axis (θ_C). For example, the theoretical shielding is about 2 ppm at $\theta_C=30°$ (ρ(Å)=1.52, z(Å)=1.60) and about 0.5 ppm at $\theta_C=45°$ (ρ(Å)=2.01, z(Å)=1.80). So it is reasonable to assume a little twist of ring B, although ring B is conjugated with C=N.

From the results obtained by the studies with UV and ^{1}H-NMR, the following conclusions may be drawn about the configuration and conformation of the photoisomers of *N*-[*p*-(dimethylamino)benzylidene]-anilines.

1) The photoisomer of *N*-[*p*-(dimethylamino)benzylidene]aniline has *Z*-configuration and is stable only below 200 K; consequently, it has not been isolated.

2) For the steric repulsion of two rings in *Z*-configuration, ring A is twisted greatly around Ar–N axis, so

Table 2. ^{13}C-NMR chemical shifts of **1**, **2**, and their photoisomers[a)]

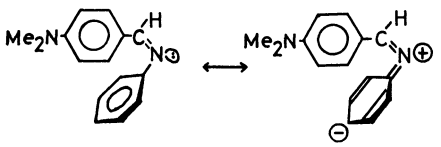
C-2′,6′	130.9	133.0	130.5	131.7
C-3′,5′	111.8	111.2	111.8	111.6

a) In ppm downfield from internal TMS. b) δ_{C-1}, $\delta_{C-1'}$, $\delta_{C-4'}$, and $\delta_{C-\alpha}$ in **1** and **2**, and $\delta_{C-2,6}$ in **2** could not be determined because of their long spin-lattice relaxation times.

that ring A does not conjugate with C=N; but the twist of ring B around Ar–C axis is small enough to allow conjugation with C=N.

Such ease of twist of ring A in (*Z*)-*N*-[*p*-(dimethylamino)benzylidene]aniline may be ascribed to the energy gain by delocalization of the N lone pair electrons to ring A upon the twist of the ring, as shown in Eq. 3. In order to investigate the electron density of ring A, we determined ^{13}C-NMR chemical shifts of *E*- and *Z*-**1**, and *E*- and *Z*-**2**; the results are summarized in Table 2.



(3)

δ_{C-4} of *Z*-**1** resonates at a field higher than that of *E*-**1** by 2.6 ppm, while there is no difference in the δ_{C-4} of 2 between *E* and *Z* forms. The δ_{C-4} of *Z*-**1** is also similar to those of *Z*-**2** and *E*-**2**. $\delta_{C-2,6}$ of *Z*-**1** resonates at a field higher than that of *E*-**1** by 3.3 ppm while $\delta_{C-3,5}$ of *Z*-**1** is similar to that of *E*-**1**. Ring A of *E*-**2**, *Z*-**1**, and *Z*-**2** are greatly twisted around the Ar–N axis, as stated before, and the twist of ring A causes the upfield shifts of $\delta_{C-2,6}$ and δ_{C-4}. In order to find the reason of the upfield shift of δ_{C-4} by the twist of ring A, ^{13}C-NMR chemical shifts of *N*-benzylideneanilines with various dihedral angles (θ_N) around the Ar–N axis were determined (Table 3). An X-ray diffraction study has shown that ring A in **6** is twisted about 50° around the Ar–N axis.[7)] The smaller extinction coefficients in **8** and **9** compared with that of **6** have been ascribed to the greater twist of ring A around the Ar–N axis, because of the steric hindrance involving methyl groups and ortho or alpha hydrogens.[8)] The extinction coefficent of **7** is not much different from that of **6**, and this suggests that the extents of twist of ring A are similar in **6** and **7**. This is reasonable because the methyl group of **7** can be situated far from the methine hydrogen and no interaction between them may take place. The higher field resonance in C-4 of **5** than that of benzene (δ=128.5) should be due to the resonance shown in Eq. 4. Twisting of ring A around the Ar–N axis is expected to decrease such resonance, and downfield shifts of the C-4 signals should be expected. However, δ_{C-4} values of **8** and **9**, in which ring A is twisted around the Ar–N axis, are observed at a much higher field than that in **5** ($\delta_{C-4}(\mathbf{5})-\delta_{C-4}(\mathbf{8})$=2.19, and $\delta_{C-4}(\mathbf{5})-\delta_{C-4}(\mathbf{9})$= 2.61). This difference cannot be ascribed to the electron-donating effect of the methyl groups. Because methyl substituents do not affect $\delta_{C\text{-meta}}$ greatly[9)] and also δ_{C-4} value in **7** is similar to that of **6**. The finding that δ_{C-4} of **9** possessing α-methyl group is similar to that of **8** possessing methyl groups at **2** and **6** positions on ring A suggests that the twist of ring A around the Ar–N axis causes the upfield shifts observed in **8** and **9**. The upfield shifts actually observed for the C-4 signals of **8** and **9**, in comparison with that of **5**, indicate the existence of the delocalization of N-lone pair electrons to ring A by the resonance shown in Eq. 5. In **8** or **9**, the resonance shown in Eq. 4 should not be possible and the resonance shown in Eq. 5 must be important. The greater electron density on C-4 of **8** and **9** in comparison with that of **5**, which is reflected in the ^{13}C-NMR chemical shift, suggests that the increased contribution of resonance (5) outweighs the decreased contribution of resonance (4). In **6** or **7**, in which ring A is twisted by about 50°, the chemical shift of C-4 is about the same as that of **5**. These results indicate that increased contribution of resonance (4) is approximately equal to the decreased contribution of resonance (5). So we have clarified that the upfield shifts of δ_{C-4} of *N*-benzylideneanilines by the twist of ring A were caused by the delocalization of the N-lone pair to ring A.

a) Chemical shifts of the other carbons of these compounds have been reported in our previous paper : M. Yoshida, H. Minato, and M. Kobayashi, *Chem. Lett.*, **1976**, 1097. b) Ref. 5. c) Ref. 8.

The steric repulsion of the two rings in (*Z*)-*N*-[*p*-(dimethylamino)benzylidene]aniline should be decreased by the preferential twist of ring A around Ar–N axis, because the twist of ring A is energetically more favorable than that of ring B for the stabilization by the delocalization of N-lone pair to ring A. The delocalization of the N-lone pair was reflected in the ^{13}C-NMR chemical shifts of *Z*-**1** and *Z*-**2**.

Experimental

UV spectra were taken with a Hitachi EPS-3T spectrometer. ^{1}H- and ^{13}C-NMR spectra were taken with a JEOL Fx-60 FT-NMR spectrometer.

UV spectra at low temperatures were measured in a sample cell cooled to 77 K with liquid nitrogen in a quartz Dewar bottle. As a solvent, M. P. (methylcyclohexane–isopentane 1 : 1) was used. For volume contraction, a correction factor of 0.8 was used.[10]

An acetone-d_6 solution ($\approx 10^{-3}$ mol dm^{-3}) of an *N*-benzylideneaniline in a Pyrex tube (10 mm) was cooled in a Dry Ice–acetone bath and irradiated through a quartz Dewar bottle with a 500 W high pressure mercury lamp until about 100% isomerization was attained. Then ^{1}H-NMR spectrum of the photoisomer of an *N*-benzylideneaniline was immediately determined at 198 K. Since this photoisomerization is complete only in dilute concentrations, spectra were determined by use of a Fourier transform NMR spectrometer (accumulation 100—500).

The ^{13}C-NMR spectrum of the photoisomer of an *N*-benzylideneaniline was determined in a similar way (Concentration of the solution, 10^{-2} mol dm^{-3}; pulse flipping angle, 60°; sampling time, 900 ms; data points, 4096; accumulation, 5000; pulse interval, 1 s).

N-[*p*-(Dimethylamino)benzylidene]anilines were prepared by heating mixtures of corresponding aldehydes and amines. Samples were purified by repeated recrystallization. The details were described in our previous papers.[3] (Melting points in °C: **1**, 99—101; **2**, 41—43; **3**, 84.5—85.5; **4**, 83—85.)

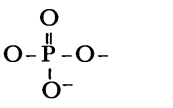
(Received July 28, 1980)

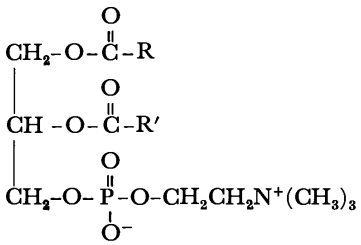
The infrared spectra of phosphatidyl and related compounds were studied with respect to their side-chain effects on solubility. It was clarified that the existence of a hydrogen-bonding between chloroform and a phosphate group is essential for these phosphatidyl compounds to form stable solutions in chloroform. The existence of double alkyl-chains and acyloxyl groups is clarified to be very useful for those compounds to have a strong solvent-phobic character without losing their solubility in solvents. The role of a choline moiety was also clarified. The details of the analysis of the infrared intensity were also described. It was emphasized that the intensity enhancement due to hydrogen-bond formation can be quantitatively related to the enthalpy change due to hydrogen-bond formation.

In our previous publications,[1-3] the infrared spectra of some water-soluble surfactants have been reported. On the basis of the quantitative analysis of the absorption intensity, it has been shown that molecules that dissolve in chloroform form a complex with several solvent-chloroform molecules. The bonding between a surfactant and the solvent chloroform has been shown to be of the hydrogen-bond type.

The present study concerns itself with a further study of the solubilities, in chloroform, of the molecules which have a phosphate group:



by the use of the infrared spectra and solubility data. Our special interest lies in the solubility of the phosphatidyl compounds, which have this structure:



with respect to:

1) the role of a phosphate group (a polar group),
2) the role of a choline moiety (an end group),
3) the role of an acyloxyl group, and
4) the role of double alkyl chains,

to the solubilities in chloroform. We focus our attention on the infrared-absorption band of chloroform-*d*, which is related to the hydrogen bonding between chloroform-*d* and a phosphate group. If we can get quantitative knowledge about the hydrogen bonding between chloroform-*d* and a phosphate group, we can relieve the effects of the other moieties on the solubilities.

Experimental

Meterials. The chloroform-*d* was purchased from Merck and Co., Ltd., and was dried over zeorite A-3. The chloroform was purchased from Wako Pure Chemical Industries, Ltd., and was dried over zeorite A-3 after eliminating the ethanol by column chromatography on alumina. The samples used in this study were both synthesized and natural products. The purities of these samples were checked by means of thin-layer chromatography. The samples are (with the abbreviations in parentheses): (**1**) propylphosphorylcholine (C_3PC), (**2**) butylphosphorylcholine (C_4PC), (**3**) pentylphosphorylcholine (C_5PC), (**4**) heptylphosphorylcholine (C_7PC), (**5**) decylphosphorylcholine (C_{10}PC), (**6**) tetradecylphosphorylcholine (C_{14}PC), (**7**) octadecylphosphorylcholine (C_{18}PC), (**8**) *rac*-1,2-dipalmitoylglycerol-3-phosphorylcholine (DL-di-$C_{16:0}$PC), (**9**) palmitoylglycerolphosphorylcholine ($C_{16:0}$-g-PC), (**10**) 1,2-dioctadecanoylglycerol-3-phosphorylcholine (L-di-$C_{8:0}$PC), (**11**) *rac*-1,2-dilauroylglycerol-3-phosphorylcholine (DL-di-$C_{12:0}$PC), (**12**) 1,2-dilinoleoylglycerol-3-phosphorylcholine (L-di-$C_{18:2}$PC), (**13**) 1,3-dipalmitoylglycerol-2-phosphorylcholine (di-$C_{16:0}$-β-PC), (**14**) *rac*-1-palmitoylglycerol-3-phosphorylcholine (DL-$C_{16:0}$-lyso-PC), (**15**) spingomyelin from beef brain (beef brain $C_{21:0,3}$, or spm.), (**16**) phosphatidylcholine from soy beans (soybean PC, or L-di-$C_{17.5:1.4}$PC), (**17**) *rac*-1,2-dipalmitoylglycerol-3-phosphoryl-*N*,*N*-dimethylethanolamine (DL-di-$C_{16:0}$diMePE), (**18**) *rac*-1,2-dipalmitoylglycerol-3-phosphoryl-*N*-methylethanolamine (DL-di-$C_{16:0}$MePE), (**19**) phosphatidylethanolamine from pig brain (pig PE, or L-di-$C_{19.5:2.1}$PE), and (**20**) phosphatidylserine from pig brain (pig PS, or L-di-$C_{18.9:1.6}$PS).

Absorption Measurements. The absorption spectra were recorded with a JASCO IR-G grating spectrometer at a resolution of 1 cm^{-1}. The spectra of chloroform-*d* solutions containing the acceptor in the concentration range from 0 to 0.5 M were measured with a KBr cell having a thickness of about 0.1 mm. The thickness of the sample cell was checked by the interference-fringe method.

Sample solutions containing various amounts of the solute molecule were prepared in a dry-box just before measurements by weighing the solute and chloroform-*d* in the sample flask. Since all of the solutes are very hygroscopic, they were dried over P_2O_5 under a reduced pressure at 60 °C for more than two days. The elimination of water from the sample solution was confirmed by observing the infrared spectra in the region of 2000—4000 cm^{-1}.

All the measurements were done at 20±2 °C, and the absorption spectra of the C-D stretcing vibration for the frequency region of 2000—2500 cm^{-1} were measured with a resolution of 1 cm^{-1} and a scanning speed of 33.3 cm^{-1}/min. The absorption due to chloroform-*d* was eliminated, when

necessary, by the use of a variable-pathlength cell on the reference side. The thickness of the variable cell was adjusted so that the absorption band of chloroform-*d* at 2254 cm^{-1} disappeared completely.

Measurement of Physical Constants. The refractive index and the specific gravity of the solution were measured, with an Abbe refractometer and a picnometer respectively, at the same time as the absorption measurements.

The solubility was determined by a weight method. A sample was weighed in an NMR tube with a radius of 5 mm after having been dried over P_2O_5 under reduced pressure for 2 d. After dried chloroform-*d* has been added and the tube had beed sealed, the solubility was determined by weighing the sealed tube.

Results and Discussion

Infrared Spectra of Chloroform Solution. All the molecules studied in the resent work have a phosphate group and show high solubilities in chloroform. As these substances are hardly soluble at all in nonpolar solvents and only slightly soluble in non-hydrogen-bonding polar solvents, the solubilities in chloroform suggest the existence of strong hydrogen-bonding between the solute and solvent molecules. Actually, the infrared spectra of chloroform-*d* show remarkable changes in the fundamental bands of chloroform-*d*. The ν_1 vibration (the C-D stretching) changes its frequency about -20 to -50 cm^{-1} from that of pure liquid chloroform-*d*, that is, 2254 cm^{-1}. We will hereafter designate the ν_1 band occurring at 2254 cm^{-1} as an F-band.

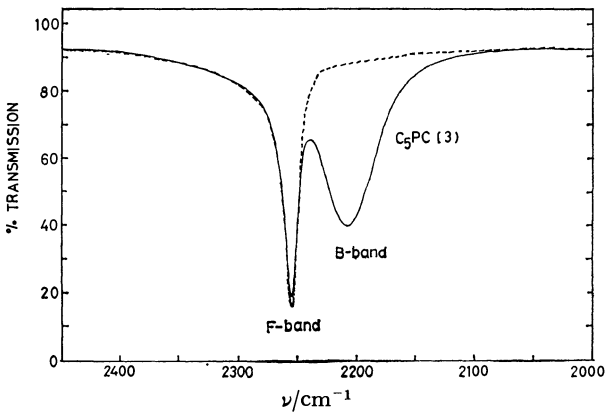


Fig. 1. Infrared spectra of C-D stretching vibration of chloroform-*d*: - - -pure liquid chloroform-*d*, ——C_5PC solution.

Figure 1 shows a typical example of the C-D stretching vibration spectra of the chloroform-*d* solution. The band at 2207 cm^{-1} is related with the chloroform-*d* molecule, which forms a hydrogen bonding with a phosphate group. We will hereafter designate this band as a B-band. For the molecules which have hydrogen-bonding sites other than a phosphate group, on the other hand, additional bands whose frequencies are higher than that of the B-band are observed. Figure 2 shows the spectra corresponding to those molecules which have an acyloxyl group in addition to a phosphate group. The reference spectra for a chloroform-*d*–methyl palmitate system is also shown in Fig. 2 in order to clarify the location of the absorption band due to the hydrogen-bond formation between chloroform and an acyloxyl group. Figure 3 shows the spectra corresponding to a group of molecules which have an acyloxyl group and a double bond in addition to a phosphate group. The spectra for a chloroform-*d* solution of methyl oleate and methyl linoleate are also shown as reference spectra in order to show the location of the additional bands which are related with the hydrogen bonding between chloroform and an acyloxyl group or between chloroform and a double bond. Figure 4 shows the spectra corresponding to a group of molecules which have a hydroxyl group in addition to phosphate and acyloxyl groups and a double bond. The spectrum for a chloroform-*d* solution of 1-pentanol is also included

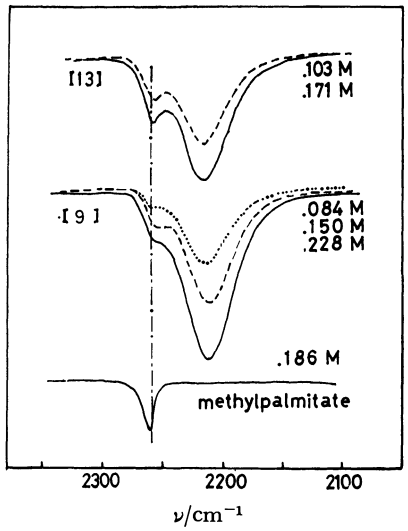

Fig. 2. Infrared spectra of C-D stretching vibration of chlrorform-*d* (solutions of these molecules having an acyloxyl group, (**9**) and (**13**)).

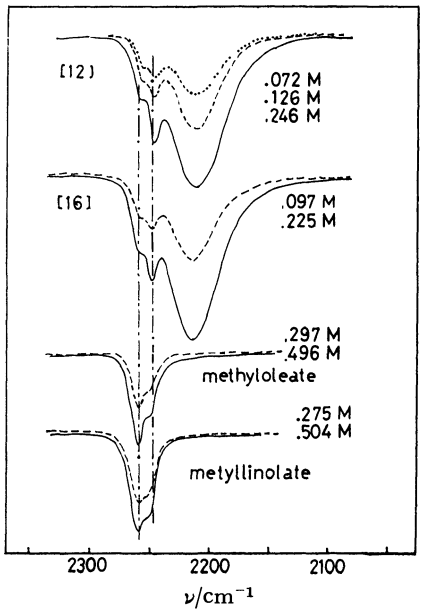

Fig. 3. Infrared spectra of C-D stretching vibration of chloroform-*d* (solutions of these molecules having a double bond and an acyloxyl group, (**12**) and (**16**)).

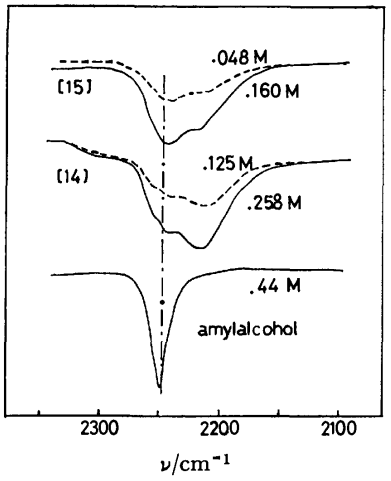

Fig. 4. Infrared spectra of C-D stretching vibration of chloroform-*d* (solutions of these molecules having a double bond, an acyloxyl group, and a hydroxyl group).

a) * Phase separation (see the text).

in Fig. 4 as a reference. Attention must be paid for the fact that, in the spectra of Figs. 2—4, the F-bands are completely cancelled out when pure liquid chloroform-*d* is put in the reference side of the spectrometer.

The half-band width, $\Delta\nu_{1/2}$, and the frequency shift, $\nu^\circ-\nu$, for a B-band are listed in Table 1, where ν° is the maximum absorption frequency of the F-band. For the sake of simplicity, we do not describe in detail the spectral information for any of these hydrogen-bonding bands other than the B-bands.

Determination of Absolute Intensities. In order to determine the absolute intensities, the absorption spectra for F- and B-bands of chloroform-*d* solutions containing various amounts of the solute molecule were measured in each system. We will here begin by considering the spectra which are composed of one F-band and one B-band only, that is, the spectra for those molecules which have only one phosphate group.

The relative intensities of the F- and B-bands are defined as

$$I_f = \frac{1}{l}\int_{\text{band (F)}} \ln(I_0/I)\mathrm{d}(\ln\nu) \qquad (1)$$

and

$$I_b = \frac{1}{l}\int_{\text{band (B)}} \ln(I_0/I)\mathrm{d}(\ln\nu)$$

where the subscripts b and f refer to the bonded and free states (or to the B- and F-bands) respectively. The integration covers the entire band area.

The molar concentration of chloroform-*d* in the solution

$$C_{CDCl_3} = C_f + C_b \qquad (2)$$

was determined from the observed weight concentration and the density of the solution. After being corrected for the local-field effect,[4] the relative intensities, I_f and I_b, are reduced to the values at the molar concentration of pure liquid chloroform-*d*, $C^\circ_{CDCl_3}=12.30$ M, thus:

$$I_f^* = f_d f_c I_f$$
$$I_b^* = f_d f_c I_b \qquad (3)$$

and

$$f_c = 12.30/C_{CDCl_3}$$
$$f_d = 9n_D/(n_D^2+2)^2, \qquad (4)$$

where n_D is the refractive index of the solution.

Now the absolute intensities, Γ_f and Γ_b, are defined as:

$$C_b^*\Gamma_b = I_b^*$$
$$C_f^*\Gamma_f = I_f^* \qquad (5)$$

and

$$(C_f^*+C_b^*) = f_c(C_f+C_b) = C^\circ_{CDCl_3}. \qquad (6)$$

Equations 5 and 6 give the relation:

$$\frac{I_f^*}{\Gamma_f} + \frac{I_b^*}{\Gamma_b} = C^\circ_{CDCl_3} \qquad (7)$$

or

$$I_b^* = -(\Gamma_b/\Gamma_f)I_f^* + \Gamma_b C^\circ_{CDCl_3}.$$

By plotting I_b^* against I_f^* at a series of concentrations, a straight line with a slope of $-(\Gamma_f/\Gamma_b)$ is generated as long as the absolute intensities, Γ_f and Γ_b, are constant over the concentration range employed. The extrapolated I_f^* value at $I_b^*=0$ corresponds to the Γ_f value for pure liquid chloroform-*d*, and may be compared with the Γ_f^* value directly observed for pure liquid chloroform-*d*.

The above procedure can be expanded for the case where a solute molecule has many hydrogen-bonding sites. If we focus our attention especially on the B-band, *i. e.*, the hydrogen-bonded absorption band which is related with a phosphate group, Eqs. 6 and 7 are modified to:

$$C_f^* + C_b^* + \sum_n \frac{I_{bn}^*}{\Gamma_{bn}} = C^\circ_{CDCl_3} \qquad (8)$$

or

$$\frac{I_f^*}{\Gamma_f} + \frac{I_b^*}{\Gamma_b} + \sum_n \frac{I_{bn}^*}{\Gamma_{bn}} = C^\circ_{CDCl_3}, \qquad (9)$$

where the subscript bn refers to the bonded states which are related with these sites other than a phosphate group. If we assume a complete association of the

(1 : 1) type for the hydrogen-bonding between chloroform and these sites,[5] the third term on the left-hand side of Eq. 8 or 9 can be expressed as:

$$\sum_n C^*_{bn} = nC_s f_c, \tag{10}$$

where n is the number of hydrogen-bonding sites other than a phosphate group, and C_s, the concentration of the solute. Thus, Eq. 9 is reduced to:

$$\frac{I^*_f}{\Gamma_f} + \frac{I^*_b}{\Gamma_b} = C^\circ_{CDCl_3} - nC_s f_c = C^\circ_{CDCl_3}\left(\frac{C_{CDCl_3} - nC_s}{C_{CDCl_3}}\right). \tag{11}$$

Eq. 11 indicates that this relation holds:

$$\frac{I^{**}_f}{\Gamma_f} + \frac{I^{**}_b}{\Gamma_b} = C^\circ_{CDCl_3} \tag{12}$$

if we define I^{**}_f and I^{**}_b as:

$$I^{**}_f = f'_c I^*_f = f'_c f_c f_d I_f$$
$$I^{**}_b = f'_c I^*_b = f'_c f_c f_d I_b \tag{13}$$

and:

$$f'_c = \frac{C_{CDCl_3}}{C_{CDCl_3} - nC_s}. \tag{14}$$

In Fig. 5, the plots of I^*_b *vs.* I^*_f (or I^{**}_b *vs.* I^{**}_f) for C_5PC (or $C_{16:0}$-g-PC) are shown. It can be seen from the figures that a linear relationship exists between I^*_b and I^*_f (or I^{**}_b and I^{**}_f). Consequently, the validity of Lambert-Beer's law was verified in these concentration ranges. It can also be seen from the figures that the extrapolated I^*_f (or I^{**}_f) values at $I^*_b=0$ (or $I^{**}_b=0$) are almost the same for these systems. For the chloroform-*d*–C_3PC system, for example, Γ_f and Γ_b were 106 and 2268 cm²/mol respectively. The absolute intensities observed by this method are summarized in Table 2. The values of Γ_f are fairly identical for all the systems. It must be added here that the beautiful linear relationship between I^{**}_b and I^{**}_f of Fig. 5b (for $C_{16:0}$-g-PC) confirms the validity of the assumption used in the derivation of

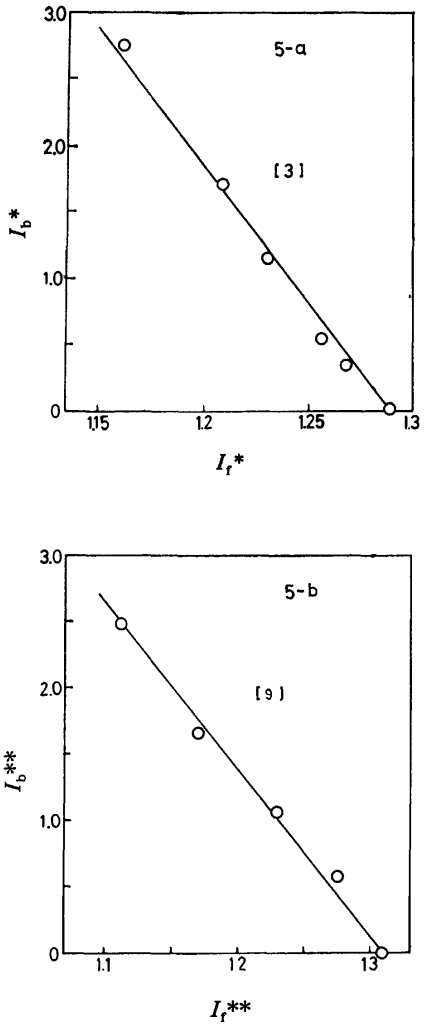

Fig. 5. (a) I_b^* *vs.* I_f^* plot for the chloroform-*d*–C_5PC system. (b) I_b^{**} *vs.* I_f^{**} plot for the chloroform-*d*–(**9**) system.

Eq. 10.

Determination of the Solvation Number for a Phosphate Group. At a low concentration of the proton acceptor, the phosphate groups of all the acceptor molecules are considered to be bonding to chloroform-*d* molecules.[6] Therefore, the ratio of the concentration, C_b, of the bonded chloroform-*d* to the concentration, C_s, of the solute, C_b/C_s, corresponds to the number of the chloroform-*d* molecule attached to one phosphate group. Using the observed Γ_b value, C_b is determined as:

$$C_b = f_d I_b/\Gamma_b. \quad (15)$$

As C_s is known, the C_b/C_s ratio can easily be determined. We call this ratio the solvation number, n_s, for a phosphate group. The calculated results for n_s are summarized in Table 2. As an example, the detailed data for the C_3PC system are shown in Table 3. The solvation number obtained in this case is 2.8—3.1 (see n_s of Table 2). Therefore, it is concluded that about three chloroform-*d* molecules and one C_3PC (or one phosphate group in C_3PC) form a complex molecule in solution.

Table 3. Relative intensities of the C-D stretching vibrations of the chloroform-*d*–C_3PC system (n_D is the refractive index, and *d* is the specific gravity of this solution)

Sample No.	Wt% of C_3PC	n_D	*d*	I_f^*	I_b^*
1	0	1.4470	1.48	1.300	0
2	0.337	1.4476	1.478	1.293	0.142
3	0.504	1.4474	1.476	1.287	0.215
4	0.676	1.4475	1.475	1.282	0.274
5	0.808	1.4476	1.474	1.284	0.340
6	0.990	1.4477	1.473	1.281	0.392

Spectroscopic Informations and Solubility Parameter. It has been established that there exists a considerable correlation between the frequency shift, $\nu^\circ-\nu$, and the intensity enhancement, Γ_b/Γ_f, due to hydrogen-bond formation, so long as the type of hydrogen-bonding is not very different.[7] We prefer, for the reason described in the Appendix, a $(\sqrt{\Gamma_b}-\sqrt{\Gamma_f})$ value as an appropriate intensity enhancement parameter to a (Γ_b/Γ_f) value. In Fig. 6, the observed $(\sqrt{\Gamma_b}-\sqrt{\Gamma_f})$ values are plotted against the $(\nu^\circ-\nu)$ values. Obviously, the observed data points fall on two different lines, indicating that the (**1**)—(**16**) group is related with a similar type of hydrogen bonding. Actually, the (**1**)—(**16**) molecules all have a choline moiety, while the (**17**)—(**20**) molecules have either a 2-(dimethylamino)ethanol, 2-(methylamino)ethanol, a 2-aminoethanol, or a serine moiety instead. Thus, the nature of the hydrogen bonding between chloroform-*d* and a phosphate group is dependent on the number of methyl groups attached to an amino group. The (**18**), (**17**), and (**8**) molecules are typical examples of those molecules having mono-, di-, and trimethylamino groups respectively.

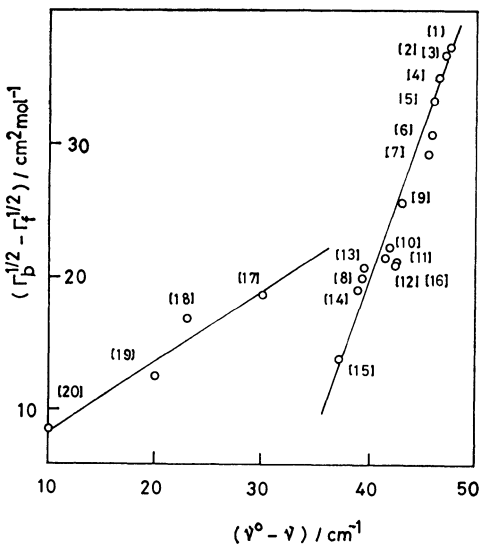

Fig. 6. $(\Gamma_b-\Gamma_f)$ *vs.* $(\nu^\circ-\nu)$ plot for the chloroform-*d* solutions of the molecules (**1**)—(**20**).

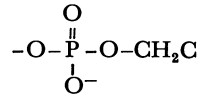
Table 2 shows the absolute intensities and the solvation numbers observed for various acceptor molecules. It may be seen from Table 2 that several solvent molecules attach to a phosphate group by forming a strong hydrogen bond. For a series of alkyl phosphorylcholines ((**1**)—(**7**)), for example, the absolute intensity of the B-band, Γ_b, is largest for C_3PC. As the intensity enhancement originates from the hydrogen-bond formation, the intensity difference, $(\sqrt{\Gamma_b}-\sqrt{\Gamma_f})$, can represent the strength of the hydrogen bonding between chloroform-*d* and a phosphate group. Therefore, the product:

$$E_s = \bar{n}_s \cdot (\sqrt{\Gamma_b} - \sqrt{\Gamma_f}), \quad (16)$$

where $\bar{n}_s$ is a mean solvation number, is an appropriate estimate of the stabilization energy of one acceptor molecule through hydrogen-bond formation with a chloroform-*d* molecule in solution. We call this product, E_s, a spectroscopic solubility parameter.

The last column of Table 2 shows the calculated E_s values. The results indicate that the E_s value takes almost identical values for those molecules which have this group:

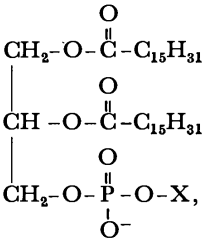


Hereafter, we will designate this group (PC) and call it the PC-group. For all the molecules which have a PC-group, the stabilization energies due to the hydrogen bonding between chloroform-*d* and a phosphate group are almost the same. In case a weak hydrogen bond is formed (*i. e.*, a small Γ_b), a larger number of solvent molecules are attached to a phosphate group. In case a strong hydrogen bond is formed, on the other hand, only a few solvent molecules are attached to a phosphate group. As is shown in the Appendix, $E_s=100$ is equivalent to an enthalpy change of about 2.5 kcal/mol. Therefore, the existence of a phosphate group is essential for these molecules to give a solubility in chloroform.

Side-chain Effects on Solubilities. By comparing the solubility values given in Table 1 and the E_s values of Table 2, a few important conclusions can be drawn as to the effects of the side chains and the molecular

structure on the solubilities.

First, let us compare the solubility data for the (**8**), (**17**), (**18**), (**19**), and (**20**) molecules, whose molecular structures are:



where X is:

(**8**) $-(CH_2)_2N^+(CH_3)_3$ (2-(trimethylammonio)ethyl),

(**17**) $-(CH_2)_2N^+H(CH_3)_2$ (2-(dimethylammonio)ethyl),

(**18**) $-(CH_2)_2N^+H_2(CH_3)$ (2-(methylammonio)ethyl),

(**19**) $-(CH_2)_2N^+H_3$ (2-ammonioethyl),

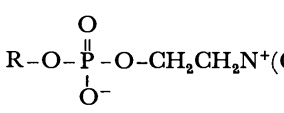
or (**20**) $-(CH_2)-CH(COO^-)-N^+H_3$ (serine).

As has been described in the preceding paragraph, the stregth and the nature of the hydrogen bonding between chloroform and a phosphate group are quite different for these molecules (see Fig. 6). The observed solubility decreases in magnitude in this order;

$$(8) > (17) > (18) > (19),\ (20).$$

The spectroscopic information shows that both the solvation number and the strength of the hydrogen bonding between chloroform and a phosphate group decrease in this order, resulting in a rapid decrease in the spectroscopic solubility parameter. This rapid decrease in the E_s value may arise from the intramolecular hydrogen-bond formation between a N–H group and a phosphate group.[8] If the hydrogen atoms of the NH_3 group are replaced by methyl radicals, this type of hydrogen-bond cannot be formed (see the structures of (**19**) and (**20**)). It must be added that the slight solubility of the (**19**) and (**20**) molecules arises from the existence of the unsaturated bonds. The corresponding synthesized sample (*rac*-1,2-dipalmitoylglycerol-3-phosphorylethanolamine or *rac*-1,2-dipalmitoylglycerol-3-phosphorylethanolserine) is insoluble in chloroform, so the spectroscopic study could not be performed. Anyway, the end group, X, must be a 2-(trimethylammonio)ethyl group in order to show a high solubility in chloroform. The (**8**) molecule will be used as the reference sample in the following discussion.

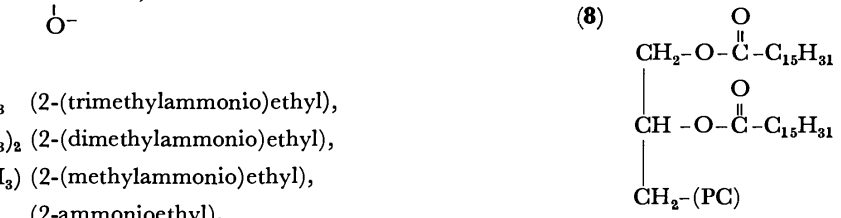
Secondly, let us compare the (**1**)—(**7**) molecules, whose molecular structures are:



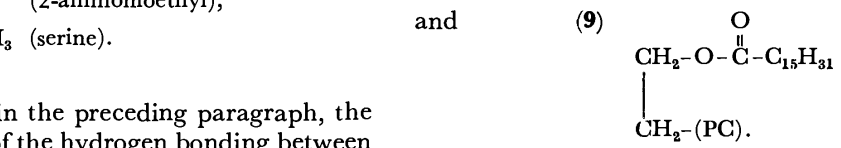
where R is an alkyl chain. The solubility decreases with the increase in chain-length ((**3**)—(**7**)). Although the strength of hydrogen bonding between chloroform and a phosphate group decreases with the increase in the chain length, the solvation number increases at the same time, thus keeping the spectroscopic solubility parameter almost constant for all the molecules. Therefore, the gradual increase in solubility with the increase in the chain-length may be ascribed to the solvent-phobic character of the alkyl chains. In fact, the solubilities of *n*-$C_{20}H_{41}$PC and *n*-$C_{22}H_{45}$PC are observed to be about 0.002 mol/l at room temperature. The abnormal solubility values for the (**1**) and (**2**) molecules will be referred to in a later paragraph in view of the mixing state of these alkylphosphorylcholines and chloroform.

Thirdly, let us compare the (**8**) and (**9**) molecules, whose molecular structures are:

(**8**)

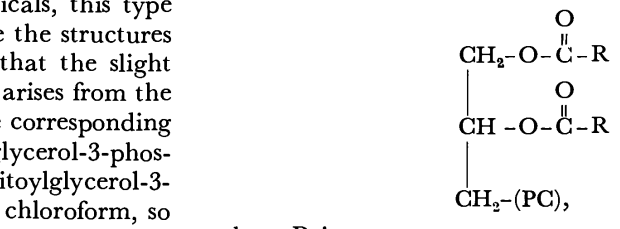


and (**9**)



On passing from a single alkyl-chain to double chains, the solubility decreases from 1.0 to 0.7 mol/l. This change is not so much as is expected for a long-chain alkylphosphorylcholine, probably because the effect of the alkyl chains is compensated for by the stabilization energy due to hydrogen bonding between the chloroform and an acyloxyl group. Again, the solubility parameters, E_s, are almost the same for these two molecules. An acyloxyl group plays a role in the solubility in chloroform second in importance only to a phosphate group.

Fourthly, let us compare the (**10**), (**11**), and (**12**) molecules with the (**8**) molecule. The molecular structures of these molecules are;



where R is:

(**8**) $-C_{15}H_{31}$,

(**10**) $-C_7H_5$,

(**11**) $-C_{11}H_{23}$,

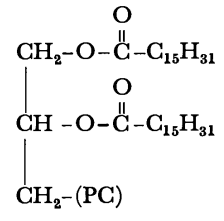
or: (**12**) $-(CH_2)_3-(CH_2-CH=CH)_2-(CH_2)_7CH_3$.

The solubilities of these molecules do not change so much with the change in the alkyl chain length as is seen for a series of alkylphosphorylcholines. Here again, the solubility-parameter values are almost constant. It must be emphasized that these molecules are distinguished from the long-chain alkylphosphorylcholines by having two long chains. That is to say, this type of molecule can have long alkyl chains without losing their solubilities in chloroform. The existence of the long alkyl chains might increase the solvent-phobic character of these molecules. The variety of alkyl chains might produce the variety of the characters of

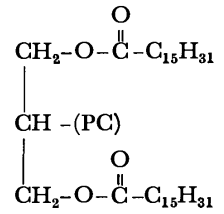
these molecules in solutions.

Lastly, let us compare the (**13**), (**14**), and (**15**) molecules with the (**8**) molecule. The structures of these molecules are:

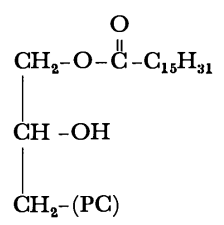
(**8**)



(**13**)

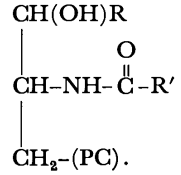


(**14**)



and

(**15**)



The (**14**) and (**15**) molecules are specified as having a hydroxyl group and/or an imino group. In these molecules, the hydrogen-bonding sites are expected to be deactivated because of the intramolecular hydrogen-bond formation between a phosphate group and the hydroxyl or imino group. If the intramolecular hydrogen-bond is formed, the solvation number, n_s, can be expected to decrease. In fact, the observed solvation number is quite small for the (**14**) molecule in comparison with the (**8**) molecule. Probably, the phosphate group and hydroxyl group from an intramolecular hydrogen bond. This situation is reflected in the low solubility value observed for the (**14**) molecule. In the case of the (**15**) molecule, on the other hand, the n_s value is observed to be slightly larger than that of the (**8**) molecule. This suggests that the intramolecular hydrogen bond is not formed in this molecule. As the strength of the hydrogen bonding between a phosphate group and solvent molecules is relatively small (see the $(\sqrt{\Gamma_b}-\sqrt{\Gamma_f})$ value), the resultant E_s value is relatively small, although the solvation number is relatively large. This situation might be responsible for the observed low solubility value.

The (**13**) molecule is an isomer of the (**8**) molecule. As can naturally be expected, the spectroscopic and physical parameters are quite similar in these two molecules, because the polar group and the side-chain groups are essentially the same. The positional difference of a PC-group does not change the solubility and the spectroscopic solubility parameter very much.

Mixing States of Alkylphosphorylcholines. In the preceding, we have left C_3PC and C_4PC out of our discussion in considering the effects of the alkyl chains on the solubilities for a series of alkylphosphorylcholines, although C_3PC and C_4PC have very low solubilities in chloroform (see Table 1). The (**3**)—(**7**) molecules dissolve into chloroform homogeneously so long as the solute concentration is lower than the solubilities. In the cases of C_3PC and C_4PC, however, their chloroform solutions separate into two solution phases if the solute concentrations exceed the solubility values of Table 1. The upper layers are relatively solute-rich solutions, while the lower layers are chloroform-rich solutions.

The concentration of the lower layers are 0.06 and 0.15 mol/l for C_3PC and C_4PC respectively. The spectroscopic information in Tables 1 and 2 was obtained for these lower layers, because the upper layers were so viscous and seemed unstable.

Taking the observed Γ_b and n_s values into account, we may explain those phenomena as follows. The C_3PC (or C_4PC) molecule forms a very stable complex molecule which is composed of one C_3PC (or C_4PC) and three chloroform molecules. The hydrogen bonding between chloroform molecules and a phosphate group is so strong that the complex molecule is precipitated as it is when the solute concentration exceeds 0.06 (or 0.15) mol/l. The sudden increase in solubility on passing from C_4PC to C_5PC may, therefore, suggest some kind of aggregate formation in the chloroform solutions of the (**3**)—(**7**) molecules. This aggregate formation may not correspond to micelle formation in the usual sense, because the critical solution temperature (CST) could not be observed for these solutions. Perhaps this aggregate has a structure analogous to that which has been clarified to be composed of a few solute molecules doubly solvated by chloroform molecules.[9] It must be emphasized that CST was observed for the alkylphosphorylcholines with longer chains, like *n*-$C_{20}H_{41}PC$ or *n*-$C_{22}H_{45}PC$ at about 40 °C. The mixing states of alkylphosphorylcholines, especially those of short alkyl chains, suggest ideas for future work into the problem.

Concluding Discussion. The main conclusions drawn from the above discussion are:

1) The hydrogen-bonding between chloroform and a phosphate group is the main factor in determining the solubility. The stabilization energy due to this type of hydrogen bonding is almost the same for all the molecules studied. When a weak hydrogen-bond is formed, a large number of solvent molecules are attached to the phosphate group, and *vice versa*. This situation may be helpful for the stabilization of those solutions in which the number of solvated molecules changes from time to time.

2) The hydrogen bonding between chloroform and an acyloxyl group may contribute to the stabilization of a long-chain molecule in a chloroform solution. With the help of the acyloxyl group, these molecules can exhibit various solvent-phobic characters when the long alkyl chains are changed without losing their solubility

in the solvent.

3) The existence of the double chains is also helpful in enabling these molecules to have a strong solvent-phobicity without losing their solubility.

4) The existence of any groups which can form intramolecular hydrogen bonding with a phosphate group can lower the solubilities of these solute molecules. A hydroxyl group is a good example of this.

Appendix. Derivation of Intensity Enhancement Parameter.

We will describe the relation between the intensity-enhancement parameter, $(\sqrt{\Gamma_b}-\sqrt{\Gamma_f})$, and the excess enthalpy, $-\Delta H$, originating from hydrogen-bond formation.

Tsubomura[10] proposes that, in a hydrogen-bonded system like

$$\text{A}\text{——}\text{H}\cdots\text{B},$$

where A and B refer, respectively, to an acid and a base, the intensity change of the A–H stretching vibration is to be attributed to charge-transfer forms in the wave function. It is assumed that the wave function of the ground state of the complex may be expressed by this formula:

$$\Psi = c_1\Psi_1 + c_2\Psi_2, \tag{A1}$$

where c_1 and c_2 are constants normalized to unity, $c_1^2+c_2^2=1$, and Ψ_1 and Ψ_2 are the wave functions associated with the following resonance structure:

Structure 1: A——H B covalent A–H bond

Structure 2: A^- H——B^+ covalent H–B bond. (with charge transfer)

Therefore, the dipole moment, p, of the hydrogen-bonded system is:

$$p = \langle\Psi|p|\Psi\rangle \simeq p_1 + c_2^2 p_2, \tag{A2}$$

where p_1 and p_2 refer to the dipole moments corresponding to Structures 1 and 2 respectively. The derivative of p with respect to the normal coordinate, Q, which corresponds to the A–H stretching vibration, is:

$$\left(\frac{\partial p}{\partial Q}\right) = \left(\frac{\partial p_1}{\partial Q}\right) + 2c_2 p_2\left(\frac{\partial c_2}{\partial Q}\right) \tag{A3}$$

with these definition of the absolute intensities, Γ_f and Γ_b, of the A–H stretching vibration:

$$\Gamma_f = \left(\frac{N_0\pi}{3c^2\omega}\right)\left(\frac{\partial p_1}{\partial Q}\right)^2,$$

$$\Gamma_b = \left(\frac{N_0\pi}{3c^2\omega}\right)\left(\frac{\partial p_2}{\partial Q}\right)^2. \tag{A4}$$

Eq. A3 is reduced to:

$$\sqrt{\Gamma_b} - \sqrt{\Gamma_f} = \sqrt{\frac{N_0\pi}{3c^2\omega}}\,2c_2 p_2\left(\frac{\partial c_2}{\partial Q}\right). \tag{A5}$$

Based upon the same model and the same order of approximation, the stabilization energy due to hydrogen-bond formation is calculated to be:[11]

$$-\Delta H = c_2 W_{12} - \Delta H_0, \tag{A6}$$

where W_{12} is a resonance energy term, $\langle\Phi_1|\tilde{H}|\Phi_2\rangle$ ($\tilde{H}$ being a Hamilton operator), and $-\Delta H_0$ is a stabilization energy due to an interaction other than hydrogen bonding. If $-\Delta H_0$ is ralatively small, as is usually the case for ordinaty intermolecular interactions, Eq. A6 becomes:

$$-\Delta H = c_2 W_{12} \tag{A7}$$

combination of Eqs. A5 and A7 leads to this relation:

$$\sqrt{\Gamma_b} - \sqrt{\Gamma_f} = -\left(\frac{2N_0\pi}{3c^2\omega}\right)^{1/2}\frac{p_2}{W_{12}}\left(\frac{\partial c_2}{\partial Q}\right)\Delta H, \tag{A8}$$

where N_0 is the Avogadro constant; c, the velocity of light, and ω the frequency of light.

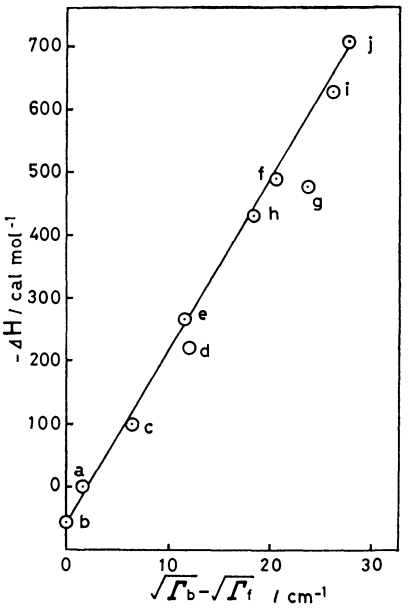


Fig. A1. $-\Delta H$ *vs.* $(\sqrt{\Gamma_b}-\sqrt{\Gamma_f})$ plot for the chloroform-*d* solutions of: (a) chloroform-*d*, (b) carbon tetrachloride, (c) benzene, (d) *p*-xylene, (e) 1,2,4-trichlorobenzene, (f) ethyl acetate, (g) acetone, (h) dibutyl ether, (i) diethyl ether, (j) diisopropyl ether.

In Fig. A1, the observed excess enthalpy values for chloroform solutions of various acceptors are plotted against the observed intensity difference values, $\sqrt{\Gamma_b}-\sqrt{\Gamma_f}$. Attention should be paid to the fact that the absolute intensity of the C–D stretching vibration of a carbon tetrachloride solution was chosen as Γ_f in this case. Obviously, a fine linear relation holds between the $-\Delta H$ and $(\sqrt{\Gamma_b}-\sqrt{\Gamma_f})$ values. Thus, we can safely conclude that the coefficient of the right-hand side of Eq. A8 is almost constant for a hydrogen bonding of a similar type. Conversely, it is very desirable to use the $(\sqrt{\Gamma_b}-\sqrt{\Gamma_f})$ value as a good estimate of the stabilization energy due to hydrogen-bond formation.

Incidentally, the E_s value defined by Eq. 16 can be converted into the excess enthalpy value. It may be seen from Fig. A1 that $E_s=100/\text{cm}^{-1}$ is equivalent to $-\Delta H=2.5$ kcal/mol.

The Crystal Structure of the Charge-transfer Complex of Dibenzotetrathiafulvalene-Tetracyanoquinodimethane, DBTTF-TCNQ

Hayao KOBAYASHI* and Jyuzo NAKAYAMA†

Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274

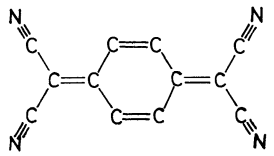
† *Department of Chemistry, Faculty of Science and Engineering, Saitama University, Urawa, Saitama 333*

(Received September 29, 1980)

The crystal of the charge-transfer complex of dibenzotetrathiafulvalene-7,7,8,8-tetracyanoquinodimethane, DBTTF-TCNQ, belongs to the triclinic system; $a=10.309(8)$, $b=8.281(2)$, $c=7.727(3)$ Å, $\alpha=110.03(4)$, $\beta=109.80(4)$, $\gamma=72.05(3)°$, space group $P\bar{1}$ with $Z=1$. The structure has been determined by the X-ray method. DBTTF and TCNQ stack alternately along [011] to form mixed columns; this phenomenon is responsible for the low electrical conductivity of DBTTF-TCNQ. The intermolecular distance between DBTTF and TCNQ is 3.303 Å. The charge-transfer complexes of DBTTF with TNB, TCNE, DDQ, and fluoro-TCNQ were examined by means of X-ray photographs. It is shown that the DDQ complex, exhibiting a high conductivity, has segregated uniform columns of donors and acceptors, such as were not found in the other complexes.

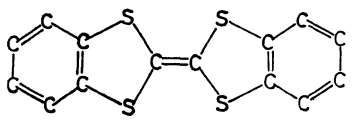
Since the discovery of the metallic conductivity of the organic compound, TTF-TCNQ (tetrathiafulvalene-tetracyanoquinodimethane), by Ferrais, Cowan, Walatka, and Perlstein, and by Coleman, Cohen, Sandman, Yamagishi, Garito, and Heeger in 1973,[1] many high-conducting organic materials have been reported. Recently, Jerome, Mazaud, Ribault, and Bechgaard have discovered an organic superconductor.[2]

High conductivity is associated with a crystal structure in which the planar donor and/or acceptor molecules are stacked to form columns.[3] Unlike TTF-TCNQ, however, DBTTF-TCNQ is insulating ($\sigma_{R.T.}\approx10^{-6}$ $(\Omega\,cm)^{-1}$ [4]). This paper will report the crystal and molecular structure of DBTTF-TCNQ and the molecular arrangements in the crystals of several DBTTF complexes.



TCNQ

7,7,8,8-Tetracyanoquinodimethane [2,2′-(2,5-Cyclohexadiene-1,4-diylidene)bis(propanedinitrile)]



DBTTF

Dibenzotetrathiafulvalene [2-(1,3-Benzodithiol-2-ylidene)-1,3-benzodithiole]

Experimental

Black lath-like crystals of DBTTF-TCNQ were prepared by a diffusion method, acetonitrile solutions of the two compounds being used. The lattice constants as determined by a Rigaku automated four-circle diffractometer are listed in Table 1. The crystals belongs to the triclinic system. The intensity data were collected with monochromated Mo K_α radiation by the ω-2θ scan technique up to $2\theta=60°$. The reflections were scanned at the rate of 4° min^{-1} in 2θ. Three standard reflections were measured after every 50 reflections. No significant intensity variation was observed during the course of the experiment. The crystal used had approximate dimensions of $0.3\times0.3\times0.06$ mm. No corrections for absorption and extinction were made.

Solution and Refinement of the Structure. The structure was solved by the heavy-atom method. Patterson maps were computed on the basis of 1415 independent reflections of $|F_o|\geqq3\sigma$. A refinement of the structure was performed by the block-diagonal, least-squares method. Anisotropic temperature factors were used for non-hydrogen atoms, whiel isotropic ones were used for the hydrogen atoms found by the difference Fourier synthesis. The final R value was 0.089. The weighting scheme used was: $\omega=1/[a+b|F_o|+c|F_o|^2]$ for $|F_o|\geqq6.19$ (absolute scale), $a=12.37$, $b=1.0$, $c=0.015$; $\omega=0.1$ otherwise. The atomic scattering factors were taken from

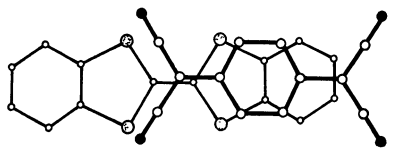

Fig. 3. Projection of DBTTF onto the plane of TCNQ.

as calculated through the DBTTF and TCNQ moieties, are listed in Table 3. The dihedral angle between these two planes is about 3.0°. TCNQ is almost planar: the largest deviation of the atoms from the TCNQ plane is 0.02 Å. DBTTF is slightly one-planar: the dihedral angle between the plane of the ethylenetetrathio group and that of the *o*-phenylene group is about 3°. The short intermolecular distance of 3.303 Å and the mode of intermolecular overlap suggest that the charge-transfer interaction is important. Figure 3 shows the projection of DBTTF onto the TCNQ plane. The charge-transfer interaction requires a large overlap integral between the electron-donating and -accepting orbitals.[6,7] Since the highest occupied molecular orbital of DBTTF and the lowest unocuupied molecular orbital of TCNQ are of different symmetries with respect to inversion (B_{1u}(DBTTF), B_{2g}(TCNQ)),[8] the direct overlap is unfavorable in DBTTF–TCNQ. This may be the reason why DBTTF is shifted from the position just above TCNQ.

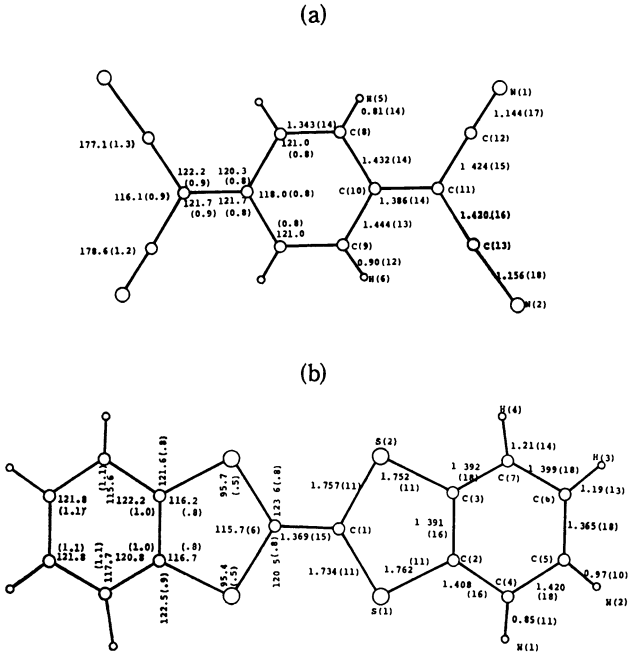

Fig. 4. Bond lengths and angles (e.s.d.'s in parentheses). (a): TCNQ, (b): DBTTF.

Molecular Geometry. The bond lengths and angles are shown in Fig. 4. It is well-known that the bond lengths of TCNQ depend on the size of the negative charge of the molecule ($TCNQ^{-\rho}$).[9,10] In Table 4, the bond lengths of TCNQ in DBTTF–TCNQ are compared with those of TCNQ° (neutral molecule)[11] and $TCNQ^{-}$ (alkali-TCNQ).[12] The averaged bond lengths

of TCNQ in the present complex resemble those of TCNQ° rather than those of $TCNQ^-$. If we assume that the bond length (l) and the formal charge (ρ) are linearly related, ρ can be estimated to be $|l_i(\rho)-l_i(0)|/|l_i(1)-l_i(0)|$ (i=a,b,..(Table 4)), where $l_i(\rho)$ is the bond length of $TCNQ^{-\rho}$. The values of ρ were calculated for TTF–TCNQ[13] in order to confirm the validity of this assumption; the terminal C–N bond was not used. The mean value of ρ (0.6) is consistent with the degree of charge transfer determined by X-ray diffuse-scattering experiments (ρ=0.59[14]). For TCNQ in the present complex, the mean value of ρ is 0.25, which indicates that DBTTF–TCNQ is a non-ionic complex.

The bond lengths of the TTF skeleton in DBTTF are compared with those of TTF°, TTF^+, and $TTF^{+0.59}$ in Table 4. No simple correlation between l and ρ, as in TCNQ, is observed. The *a* bond tends to elongate, while the *b* bond tends to contract, with an increase in the positive charge on TTF. This change accords with the variation in bond orders estimated on the basis of the wave function of TTF.[8] The lengths of the *a* and *b* of DBTTF are intermediate between those of TTF° and TTF^+. The *d* length of TTF is approximately equal to the length of typical C=C double bonds. The *d* bond of DBTTF is much longer, however, its length is almost equal to the C–C bond length of the benzene molecule. In addition, the *c* bond of DBTTF is fairly long. Consequently, DBTTF may be regarded as a "composite molecule" comprised of ethylenetetrathio and *o*-phenylene groups.

Molecular Arrangements in Some DBTTF Complexes. Many charge-transfer complexes containing TTF and/or TCNQ (or their analogues) exhibit high electrical conductivities.[18,19] Some of them are regarded as "organic metals." High-conducting complexes hitherto known crystallize in segregated uniform stacks, in which donors and acceptors stack separately to form parallel columns. As has been described in the preceding section, the molecular arrangement in DBTTF–TCNQ differs from those in organic metals. The mixed-column structure of DBTTF–TCNQ well interprets the low conductivity ($\sigma_{R.T.}\approx10^{-6}$ $(\Omega\ cm)^{-1}$).[4]

Besides DBTTF–TCNQ, several DBTTF complexes were prepared in order to examine the relationship between the structure and the conductive properties. The acceptors used were tetracyanoethylene (TCNE), 1,3,5-trinitrobenzene (TNB), 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), and 2,2'-(2-fluoro-2,5-cyclohexadiene-1,4-diylidene)bis(propanedinitrile) (TCNQ(F)). The preliminary crystal data are: DBTTF–TCNE, monoclinic, $P2_1/c$, a=6.92, b=6.61, c=20.81 Å, β=99.6°; DBTTF–TNB, monoclinic, $P2_1/c$, a=7.44, b=13.91, c=14.47 Å, β=90.1°. The crystal habits and the diffraction patterns of these black crystals suggest that donors and acceptors stack alternately to form mixed columns and that the columns in DBTTF–TCNE and DBTTF–TNB are parallel to the b and a axes respectively. The crystal of DBTTF–TCNQ(F) has a lattice period of about 9.3 Å along the needle axis, indicating that this crystal also does not have segregated uniform columns. The electrical conductivities of these DBTTF complexes are very low ($\sigma_{R.T.}<10^{-4}$ $(\Omega\ cm)^{-1}$).[20] In contrast, DBTTF–DDQ is highly conducting ($\sigma_{R.T.}\approx$ 70 $(\Omega\ cm)^{-1}$).[20] Oscillation photographs around the needle axis show a lattice spacing of about 3.7 Å, indicative of segregated uniform columns of DDQ and DBTTF.

The authors are grateful to Dr. G. Saito for his gift of TCNQ(F).

The Initial Sintering of Alkaline Earth Oxides in Water Vapor and Hydrogen Gas

Tomoyasu Ito,* Masato Fujita, Masahiro Watanabe, and Taneki Tokuda
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158
(Received October 15, 1980)

The initial sintering (crystallite growth and surface-area diminution) of freely dispersed powders was studied. For MgO in H_2O vapor, the sintering rate at 1073 K was directly proportional to the water-vapor pressure, P_{H_2O}, in the range of 27—2700 Pa, and the apparent activation energy, E, for the sintering was 137 kJ mol^{-1}. These facts lead to the conclusion that, in this system, the surface migration of O^{2-} caused by the repetition of the adsorption-desorption cycle of the H_2O molecule is rate-determining step for the sintering. For CaO in H_2O vapor, the rate-determining step appears to be migration on and/or near the surface of a cation vacancy produced by the H_2O adsorption, judging upon the facts that the sintering rate at 873 K was proportional to $P_{H_2O}^{0.34}$ in the range of 11—1600 Pa and that E was 79.4 kJ mol^{-1}. For MgO in H_2 gas, the sintering rate at 1123 K was approximately proportional to the hydrogen pressure in the range of 3.3—66.5 kPa and E was 310 kJ mol^{-1}, indicating that the sintering in H_2 was caused by H_2O vapor formed upon the desorption of the surface hydroxyl groups which had been produced by a heterolytic dissociative adsorption of H_2.

Imperfections on the surface of polycrystalline oxide powders are known to have some remarkable effects on their adsorption behavior and catalytic nature. The properties and degrees of imperfections are controlled by the calcination conditions of the oxides. One of the most significant conditions is the atmosphere. Previously we have studied the initial sintering in 2.7 kPa water vapor of MgO powders originating from magnesium oxalate and reported a marked acceleration effect of H_2O vapor.[1] A similar enhanced sintering for MgO in H_2O vapor has been reported by several workers: (1) Anderson *et al.*[2] studied initial sintering at a relatively high temperature (1323 K) and suggested an adsorption-desorption cycle mechanism, but they did no kinetic analysis of their sintering data; (2) Razouk *et al.*[3] reported mainly changes in the micropore structure of MgO powders with sintering, and (3) Aihara *et al.*[4] studied changes in the crystallite size of MgO powders with sintering in 100-kPa H_2O vapor and proposed an enhanced surface-diffusion mechanism. However, none of these studies has given clear evidence for the proposed mechanisms. A systematic investigation of initial sintering under strictly controlled experimental conditions seems to be necessary in order to clarify its mechanism.

In this paper, the initial sintering (which means the surface-area diminution and/or crystallite growth in the present study) of freely dispersed MgO powders was studied under various H_2O pressures, and the mechanism of enhanced sintering was clarified by a kinetic analysis of the data on the pressure dependence of the sintering rate. A similar sintering study for CaO was carried out and compared with the case for MgO. Since a hydrogen molecule may be expected to produce a water molecule upon adsorption on the oxide surface at high temperatures, the sintering of MgO was also studied in a hydrogen atmosphere.

Experimental

The processes for the sintering measurements were: (1) powders of 0.1-g magnesium oxalate dihydrate (0.33-g calcium hydroxide for CaO) in a Pt crucible mounted in a silica vessel were decomposed at 723 K (523 K for CaO) for 16 h under evacuation; then the resulting oxide was slowly heated to 1073 or 1123 K (873 K for CaO) and maintained at this temperature for 16 h under evacuation (this corresponds to sintering time= 0); (2) after cooling, the specific surface area was measured *in situ*; (3) after the sample had again been heated rapidly to the sintering temperature, H_2O vapor or H_2 gas was admitted into the sintering vessel and the sintering was carried out in a closed system for a prescribed duration; (4) then Processes (2) and (3) were repeated, and the surface-area-diminution curves were obtained, and (5) finally, the crystallite size of sintered powders was measured by means of an X-ray diffractometer. For MgO in H_2O vapor, an alternative method was used, a batch process consisting of the measurements of the surface area and crystallite size for each sintering run.

The hydrogen (Takachiho Chemicals, purity of 99.99% or more) was predried through a trap at 77 K. The specific surface area was measured by the BET method of oxygen adsorption at 77 K. For several samples, the distribution curve of the micropores smaller than 30 nm in diameter was obtained by the Cranston and Inkley method.[5] For the determination of the crystallite size, the (420) and (220) diffraction lines were used for MgO and CaO respectively. The crystallite size obtained by this method was somewhat larger ($<$10%) than that obtained by means of an electron micrograph.[1] For some samples, a volumetric adsorption amount of H_2 at the temperature used in the sintering was measured using a Pirani gauge. The equilibrium pressures in the adsorption study were around 10 Pa, much lower than that in the sintering study. Because a large part of the adsorption was completed within 5 min, this 5-min value is assumed to be an equilibrium-adsorption amount.

The magnesium oxalate dihydrate was prepared by two methods. The first batch (designated by MO-6) was prepared by a reaction of magnesium nitrate with ammonium oxalate, and the second batch (designated by MO-9), by a reaction of magnesium sulfate with ammonium oxalate. The magnesium oxalate dihydrate used was MO-6 unless otherwise stated in the text. The calcium hydroxide was prepared by burning calcium oxalate in air and by subsequent hydration with water free from carbon dioxide. The impurities, as determined by an atomic-absorption spectrometer, were as follows (weight ppm): MO-6: Mn=1.3, Fe$<$6.6; MO-9: Mn=4.6, Fe$<$8.6; $Ca(OH)_2$: Na=9.3, K$<$10, Mg=54. The emission spectra showed Ca in a concentration of 4—180 ppm in MO-6.

Results

MgO in H_2O Vapor. The crystallite growth curves at 1073 K are shown in Fig. 1. The magnesium oxide powders before sintering had a crystallite size of about 7 nm. No appreciable growth occurred under evacuation ($<10^{-3}$ Pa), but water vapor exhibited remarkable positive effects for the growth rate. It has been established[1,4] that a crystallite growth rate is empirically expressed by:

$$\frac{dD}{dt} = \frac{k'_D}{D^{n'}}, \tag{1}$$

or by its integrated form:

$$D^n - D_0^n = k_D t, \tag{2}$$

where D is the crystallite size (D_0 is D at $t=0$), t is the sintering time, n ($=n'+1$) is a constant determined experimentally, and k_D [$=k_D'(n'+1)$] is the rate constant

for crystallite growth. The curves in Fig. 1 were well fitted to Eq. 2 if an appropriate value of n was given. Therefore, the rate constants calculated by Eq. 2 were used for a quantitative comparison of the sintering rate, although this equation has no important physical meaning. In Fig. 2 the pressure dependence of k_D is shown ($n=6.5$); the resultant straight line with a slope of 1.0 means that k_D is directly proportional to the water-vapor pressure, P_{H_2O}. Crystallite growth curves at various temperatures are shown in Fig. 3. The rate constants calculated by Eq. 2 gave an apparent activation energy for the crystallite growth of 137 kJ mol^{-1} which agrees with that obtained by Aihara *et al.*[4]

If the secondary agglomeration between crystallites is ignored, an ideal specific surface area, S_x, as calculated from the observed crystallite size, is expressed by:

$$S_x = \frac{6}{\rho} \cdot \frac{1}{D}, \tag{3}$$

where ρ is the density of the sample. For the MgO powders sintered in water vapor, the observed specific surface area, S, was roughly proportional to the inverse of the crystallite size observed, and the degree of the secondary agglomeration scarcely changed at all during the sintering ($S/S_x=0.55$—0.65). These facts indicate that the surface-area reduction was a direct consequence of the crystallite growth. Therefore, an equation similar to Eq. 2 is also applicable to the surface-area diminution:

$$S^m - S_0^m = k_s t, \tag{4}$$

where m ($\approx -n$) is a constant determined experimentally, S_0 is S at $t=0$, and k_s is the rate constant for the surface-area decrease. The temperature dependence of k_s gave an apparent activation energy of 131 kJ mol^{-1}, which is in good agreement with that for k_D.

The micropore distributions are shown in Fig. 4 for several samples sintered at 1073 K for 2 h. No samples had micropores below 1.5 nm in diameter. As the sintering proceeded, micropores with smaller diameters disappeared preferentially and larger ones grew. The

resultant micropore volumes are summarized in Table 1.

CaO in H_2O Vapor. The surface area decreases upon the sintering in various P_{H_2O} values at 873 K are shown in Fig. 5. Calcium oxide powders, before sintering, had a specific surface area of about 80 $m^2\ g^{-1}$; this area decreased little during sintering under evacuation. On the other hand, H_2O vapor accelerated the sintering for CaO, which was more remarkable than for MgO. Although there is some scatter, a value of $m=-3.2$ nearly satisfied Eq. 4 for this sintering system. It can be found from Fig. 6 that k_s is proportional to $P_{H_2O}^{0.34}$ in the range of 11—1600 Pa. Figure 7 illustrates the reduction of S at various sintering temperatures for $P_{H_2O}=610$ Pa. The apparent activation energy as estimated by Eq. 4 was 79.4 kJ mol^{-1}, which is smaller than that for MgO in H_2O vapor. The values of S/S_x were in the range of 0.5—0.6 for all the samples, and no important changes in the secondary agglomeration were observed during the sintering process. The micropore distributions for three samples sintered to different extents are shown in Fig. 8. No samples had micropores below 2.5 nm in diameter. As the sintering proceeded, micropores with smaller diameters rapidly disappeared,

as in the case of MgO. The micropore volumes are summarized in Table 2.

MgO in H_2 Gas. Figure 9 shows the change of S in an H_2 atmosphere at 1123 K. Hydrogen evidently increased the sintering rate, but its efficiency was far less than that of H_2O. A value of -6.0 for m in Eq. 4 gave the best fit for all the observed data. The pressure dependence of k_s is shown in Fig. 10; the slope of the straight line obtained was 0.9. The sintering-rate constants observed at three temperatures (1023, 1073, and 1123 K) in 33.3 kPa H_2 gave an apparent activation energy of 310 kJ mol^{-1}, more than twice that in an H_2O atmosphere.

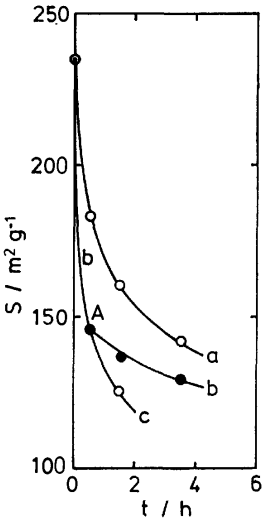

Fig. 11. Effect of Pre-oxidation on surface area decrease of MgO powders (MO-9 origin) sintered at 1123 K in hydrogen gas of 20 kPa.
Pretreatment: (a) no oxidation (normal sintering), (b) 1 h evacuation after oxidation by 13.3 kPa oxygen gas for 1 h at 1123 K, and (c) 1 h evacuation after re-oxidation at point A in curve (b).

If the sample was oxidized by O_2 before sintering, an unusual sintering behavior was observed. Figure 11 shows the sintering of MgO (MO-9 origin) at 1123 K in a 20 kPa H_2 atmosphere. Curve (a) illustrates a normal sintering (namely, without O_2 pretreatment), while Curve (b) shows the sintering of the sample pretreated by 13.3 kPa O_2 at 1123 K for 1 h and a subsequent outgassing for 1 h. In this case, the rate constant in the first run (before Point A) was about 4 times larger than that after the second, the latter being of a magnitude comparable to that of Curve (a). If the

sample was reoxidized at Point A, a faster rate was also observed in the second run, as is shown by Curve (c). The amounts of H_2 adsorbed at 1123 K on MgO (MO-9 origin) with a specific surface area of 210 $m^2\,g^{-1}$ were 14.1, 1.2, and 13.1×10^{18} molecule g^{-1} after oxidation for 1 h followed by evacuation for 1 h, evacuation for 1 h after the first H_2 adsorption, and reoxidation after the second H_2 adsorption respectively. It is, therefore, understandable that the sintering rate depends on the adsorption amount. Similar behavior was also observed for MgO prepared from MO-6, though the sintering rates were different between MO-9 and MO-6.

Discussion

Sintering Mechanism in H_2O Vapor. Because no appreciable sintering occurred in a vacuum, it can easily be understood that the enhanced sintering in H_2O vapor was caused by the adsorption effect. Unfortunately, we have little information on the chemisorption of H_2O on alkaline earth oxides at high temperatures. Previously we reported an IR study of H_2O adsorbed on MgO, revealing that only hydroxyl groups (two types, namely, free and hydrogen-bonded OH^-) were present at 773 K, while physisorbed molecules coexisted below 673 K.[6] This suggests that the species adsorbed on MgO in the present study are also hydroxyl groups. The adsorption amounts (in terms of the apparent surface coverage) thus far reported are 0.15[7] (in 0.8 kPa H_2O vapor at 923 K) and <0.005[2] (in 0.6 kPa at 1273 K). The expected coverages on MgO in the present case, typically carried out at 1073 K, may, therefore, be of the order of 0.01—0.02. For CaO, the adsorbed species may also be hydroxyl groups, but the adsorption amounts appear to be considerably larger than for MgO because of its stronger interaction with a water molecule and because of the lower temperature used for the sintering.

Possible sintering mechanisms include: (1) a diffusion mechanism (surface, grain-boundary, and bulk); (2) a viscous-flow mechanism; (3) an evaporation-condensation mechanism, and (4) an adsorption-induced space-charge mechanism. Furthermore, we must consider (5) the adsorption-desorption-cycle mechanism (anion-exchange mechanism) proposed by Anderson *et al.*,[2] because the free surface of the powders used is relatively large. This mechanism gives a mode of transport for a surface O^{2-} ion through the process by which, upon the desorption of an H_2O molecule, an oxygen ion from the surface may be removed in the desorbing H_2O molecule, leaving the O^{2-} of the original H_2O in an adjacent position on the surface. Of the five possibilities mentioned above, Mechanisms (3) and (4) can be disregarded because of the too low vapor pressure and because of no generation of a new space charge respectively. Mechanisms (1) and (2) both depend on an equilibrium amount of H_2O adsorbed on the oxide under the present experimental conditions [in Mechanism (1), the rate is proportional to the adsorbed amounts to the first power, and in (2), to the second power], and Mechanism (5) depends on the frequency of the adsorption-desorption cycle of H_2O molecules under a dynamic adsorption equilibrium. Therefore, we will consider these two cases in more detail.

In the first case, a sintering rate constant, k, is proportional to the equilibrium adsorption amount, v, to the first or the second power. Because an H_2O molecule can be assumed to be adsorbed on a cation-anion pair site (designated by S) on the surface and results in the formation of OH^-, the adsorption equilibrium near the surface is expressed by:[8]

$$S + H_2O \overset{K_1}{\rightleftharpoons} 2\,OH^- + V_M, \tag{5}$$

where V_M is the cation vacancy and K_1 is an equilibrium constant. From Eq. 5,

$$v \equiv [V_M] = \frac{1}{2}[OH^-] = \left\{\frac{K_1}{4}\cdot[S]\cdot P_{H_2O}\right\}^{1/3}. \tag{6}$$

On the other hand, v can also be expressed by:

$$v = [S]_0 - [S] = [S]_0\theta, \tag{7}$$

where θ is the (apparent) surface coverage and where the subscript 0 refers to a state before the adsorption. By substituting Eq. 7 into Eq. 6 and by differentiating its logarithmic form, we obtain:

$$\frac{d\ln v}{d\ln P_{H_2O}} = \frac{1}{3}\cdot\frac{3-3\theta}{3-2\theta}. \tag{8}$$

If k is proportional to v [Mechanism (1)], then

$$l \equiv \frac{d\ln k}{d\ln P_{H_2O}} = \frac{1}{3}\cdot\frac{3-3\theta}{3-2\theta}, \tag{9}$$

that is, k is proportional to $P_{H_2O}^{l}$ at a coverage of θ. If k is proportional to v^2 [Mechanism (2)], then

$$l = \frac{2}{3}\cdot\frac{3-3\theta}{3-2\theta}. \tag{10}$$

In the second case, k is proportional to the frequency, R, of the adsorption-desorption cycle. When the absolute-rate theory is applied, R depends on where the rate-determining step is. If, for example, an adsorption process is rate-determining, the following two reaction schemes are possible:

$$\left.\begin{aligned} &H_2O + S \overset{K_2}{\rightleftharpoons} I \\ &I \xrightarrow{k_2} 2\,OH^- + V_M, \end{aligned}\right\} \tag{11}$$

and

$$\left.\begin{aligned} &H_2O + S \overset{K_3}{\rightleftharpoons} 2\,I \\ &I \xrightarrow{k_3} OH^- + \frac{1}{2}V_M, \end{aligned}\right\} \tag{12}$$

where I designates an activated complex and where k_i and K_i are the rate constant and the equilibrium constant respectively. The former corresponds to an undissociated activated complex, and R is expressed by:

$$R = k_2\cdot[I] = k_2\cdot K_2\cdot[S]\cdot P_{H_2O}, \tag{13}$$

while the latter corresponds to a dissociated activated complex:

$$R = 2k_3\cdot[I] = 2\,k_3\cdot K_3^{1/2}\cdot[S]^{1/2}\cdot P_{H_2O}^{1/2}. \tag{14}$$

A further examination of other cases (*e. g.*, the presence of a pre-adsorption equilibrium, and the desorption process being a rate-determining step) revealed that either Eq. 13 or 14 is applicable to every case (except for

the constants in them). Therefore, the frequency of the adsorption-desorption cycle is expressed by either:

$$\left.\begin{aligned} R &= c \cdot [S] \cdot P_{H_2O} \\ \text{or} \\ R &= c \cdot [S]^{1/2} \cdot P_{H_2O}^{1/2}, \end{aligned}\right\} \quad (15)$$

where c is a constant. In a manner similar to the first case, we can obtain final expressions corresponding to the two cases in Eq. 15:

$$l = \frac{3-3\theta}{3-2\theta} \quad (16)$$

$$l = \frac{1}{2} \cdot \frac{3-3\theta}{3-2\theta}. \quad (17)$$

Figure 12 shows the values of l in Eqs. 9, 10, 16, and 17. Now we can compare the observed data with the calculated values.

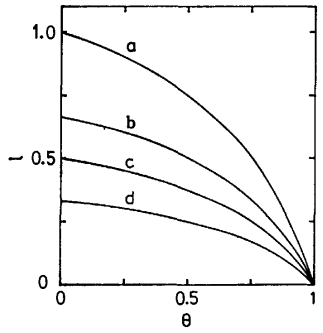

Fig. 12. Dependence of sintering rate constant on apparent surface coverage.
(a): Eq. 16 [mechanism (5)], (b): Eq. 10 [mechanism (2)], (c): Eq. 17 [mechanism (5)], and (d): Eq. 9 [mechanism (1)].

MgO in H_2O Vapor. The experimental facts were that l equals 1 in the P_{H_2O} range of 27—2700 Pa at 1073 K and that the apparent activation energy of the crystallite growth is 137 kJ mol^{-1}. It may be found from Fig. 12 that l becomes 1 only when $\theta \approx 0$ in Eq. 16. As has been described previously, $\theta \approx 0$ (say, $\theta < 0.1$) was fulfilled in the present case. It may be concluded, therefore, that, for MgO in H_2O vapor, an anion-exchange mechanism is operative and that surface O^{2-} ions move on the surface by repeating the adsorption-desorption cycle of H_2O molecules. The measurement of the isotopic-exchange-reaction rate of oxygen atoms between H_2O and surface O^{2-} at high temperatures can afford useful information, but we could not succeed in its measurement because of the too rapid exchange rate and because of the peculiar nature of H_2O vapor. We can see, however, on the basis of simple gas kinetics, that each adsorbing center of the oxide surface is subjected to a collision with an H_2O molecule $\approx 10^5$ times per second under typical sintering conditions and that the time of residence of an H_2O molecule at the surface is sufficient for the molecule to interact with the surface.[2] On the other hand, the cations may easily move on or near the surface by the diffusion of the V_M formed.

There are no micropores with diameters $<$1.5 nm in any sample (Fig. 4). Therefore, the sintering by the anion-exchange mechanism is thought to proceed mainly, not through condensation between two surface OH^- ions of adjacent crystallites in a micropore, thus forming an oxygen bridge between the crystallites and to form a closed micropore, but through condensation between two adjacent OH^- ions on a crystallite, thus leading to an enhanced surface mobility which causes the disappearance of smaller crystallites and the growth of larger ones. This picture is in accord with the finding that S/S_x did not change appreciably during the sintering.

Eastman *et al.*[8] and Mackenzie *et al.*[9] suggested an association of two OH^- and V_M in Eq. 5 and the formation of a complex such as $2OH^- \cdot V_M$. However, this seems not to be valid in the present case considering the two facts that: (1) a completely linear relationship between k and P_{H_2O} holds, even for $P_{H_2O} < 100$ Pa (Fig. 2), and (2) for the CaO sintering, k is proportional to $P_{H_2O}^{0.34}$, suggesting non-association between adsorbed species, even though much more OH^- and V_M are present compared to the case of MgO.

CaO in H_2O Vapor. It was found experimentally that l equals 0.34 in the P_{H_2O} range of 11—1600 Pa at 873 K and that the apparent activation energy for k is 79.4 kJ mol^{-1}. From Fig. 12, $l = 0.34$ is possible in the four cases; namely, $\theta \approx 0$ in Eq. 9, $\theta \approx 0.75$ in Eq. 10, $\theta \approx 0.85$ in Eq. 16, and $\theta \approx 0.6$ in Eq. 17. However, it seems to be impossible, unless $\theta \approx 0$ or 1, that a constant value of l is maintained during about a 150-fold change in P_{H_2O} (11—1600 Pa). Thus, Eqs. 10, 16, and 17 can be excluded, and only the case of $\theta \approx 0$ in Eq. 9 is applicable; that is, the sintering proceeds through a diffusion mechanism ($\theta \approx 0$ suggests that the adsorbed species are present not only on the surface, but also beneath the surface). We must then determine which of the adsorbed species, V_M or OH^-, is concerned with the rate-determining step. It may be possible for an anion on the surface to migrate by means of an anion-exchange mechanism, by analogy with MgO, and a cation in CaO is less movable than one in MgO because of the larger cation size and heavier atomic mass. Therefore, we suggest that V_M is the rate-determining species and that it moves on and/or near the surface layer.

Let us now look at the apparent activation energy of the sintering rate. If the above mechanism is assumed to be valid, k is expressed by:

$$k = k_d \cdot [V_M], \quad (18)$$

where k_d is a diffusion coefficient of V_M. By substituting Eq. 6 into Eq. 18, assuming P_{H_2O}=constant and [S]= constant (because of $\theta \approx 0$), and differentiating by temperature, T, the logarithmic form of a resultant equation, we obtain:

$$\frac{d \ln k}{dT} = \frac{d \ln k_d}{dT} + \frac{1}{3} \cdot \frac{d \ln K_1}{dT}. \quad (19)$$

Using an Arrhenius equation and a van't Hoff equation, we then obtain:

$$E = E_d - \frac{Q}{3}, \quad (20)$$

where E is the apparent activation energy for the sintering rate, E_d is the activation energy for the diffusion of V_M, and Q is the heat of the adsorption of Eq. 5. Unfortunately, there are no appropriate values for E_d and Q. However, if we are allowed to use, as E_d, the value of 118 kJ mol^{-1} of the activation energy for Ca^{2+} bulk-diffusion at 1273—1673 K[10] and, as Q, the 96 kJ mol^{-1} of the heat of the dissociation reaction,[11] $Ca(OH)_2 \rightleftharpoons CaO + H_2O$, then we obtain E=86 kJ mol^{-1}. On and/or near the surface, E_d and Q are probably smaller than those in bulk, but the resultant E as a difference between them may be expected to be not far from the observed value of 79.4 kJ mol^{-1}. This suggests the validity of the concepts that, for CaO in H_2O vapor, a diffusion of V_M on and/or near the surface is rate-determining and that the anion easily migrates on the surface by means of an anion-exchange mechanism.

Sintering Mechanism in H_2. It has been established that H_2 is adsorbed on MgO at high temperatures, and that the higher the temperature, the more the adsorption amount.[12-14] The adsorbed species have been identified as hydroxyl groups by Lisachenko *et al.*[12] Therefore, the desorption from the heated sample under a dynamic adsorption equilibrium can produce an H_2O molecule from two adsorbed OH^-.[12,14] If the resultant pressure of H_2O vapor present in the 10 kPa H_2 atmosphere reaches only 0.1 Pa, it is possible to explain the observed sintering shown in Fig. 9. Unfortunately, we failed to confirm, by the use of a mass-spectrometer, the presence of water vapor in a large excess of H_2 or D_2 gas after the sintering because of its too small quantity, the presence of background peaks, the easy adsorption of water vapor onto the wall, *etc.* However, as has previously been described, the amount of H_2 adsorbed on MgO at 1123 K was 1.2×10^{18} molecule g^{-1} even for the second run, which corresponds to an H_2O partial pressure of 100 Pa if all the adsorbed species are assumed to be desorbed as H_2O molecules. Therefore, it is very possible that the actual partial pressure of H_2O in H_2 reaches 0.1 Pa. Below we will discuss the sintering mechanism based upon the view that the initial sintering in H_2 is caused by the H_2O molecules formed.

It was found experimentally for MgO in H_2 gas that l equals 0.9 in the H_2 pressure range of 3.3—66.5 kPa at 1123 K and that the apparent activation energy for the sintering is quite large, 310 kJ mol^{-1}. The formation of hydroxyl groups upon the H_2 adsorption may be possible through: (1) the reduction of trace amounts ($<$100 ppm) of the transition elements present; (2) a reaction with an O^- ion[15] present on the activated surface; (3) the reduction of Mg^{2+}, and (4) the heterolytic dissociation of H_2 into H^+ and H^-. Mechanisms (1)—(3) are, however, unimportant in the present case because of the disagreements with the actual concentrations and/or with the actual pressure dependences. Therefore, we will consider Mechanism (4) in some detail. Unfortunately, the direct observation of a Mg–H (possibly Mg^{2+}–H^-) stretching frequency by means of the IR spectra is very difficult at the temperatures used in the sintering study. However, recently Coluccia *et al.*[16] reported on the IR spectra upon the H_2 adsorption at room temperature on MgO activated at high temperatures, and proved the formation of O–H and Mg–H bonds. According to our temperature-programed desorption study,[17] these adsorbed species remain on the surface up to around 700 K, even under a high vacuum. Thus, a similar adsorption scheme appears to be possible for the present sintering experiment. This adsorption equilibrium is expressed by:

$$\left.\begin{aligned} H_2 + O^{2-} &\overset{K_4}{\rightleftharpoons} OH^- + H^- + V_M \\ 2\,OH^- + V_M &\overset{K_5}{\rightleftharpoons} H_2O + O^{2-}. \end{aligned}\right\} \quad (21)$$

Therefore,

$$P_{H_2O} = K_4 \cdot K_5 \cdot \frac{[OH^-]}{[H^-]} \cdot P_{H_2}, \quad (22)$$

where P_{H_2O} and P_{H_2} are the partial pressures of H_2O and H_2 respectively. Equation 22 shows that, unless the change in P_{H_2} is large, P_{H_2O} is approximately proportional to P_{H_2}. This agrees with the experimental facts, for the sintering rate in H_2O vapor is simply proportional to P_{H_2O}, as has been mentioned previously. The activation energy of the sintering for this mechanism is expected to be larger than that in a pure H_2O vapor by the heat of reaction necessary for Eq. 21. Though qualitative, this can explain the observed results (137 kJ mol^{-1} for H_2O and 310 kJ mol^{-1} for H_2). It may be concluded, therefore, that the enhanced sintering in H_2 gas proceeds by means of an anion-exchange mechanism caused by H_2O vapor which has been produced upon the heterolytic dissociative adsorption of H_2 on the surface at a high temperature (Eq. 21).

Prior to the sintering, the MgO sample was usually preevacuated at 1123 K for a long time without oxidation. On the other hand, the sample preoxidized at 1123 K exhibited a remarkable sintering upon the first H_2 admission (Fig. 11). This is explicable by considering that each adsorption equilibrium of the four possible mechanisms on OH^- formation described above was shifted to the oxidation side and subsequent admission of H_2 produced more H_2O vapor than usual.

Guilliatt *et al.*[18] carried out a crystallite-growth study of MgO in the H_2 atmosphere of, not a closed, but a flowing system, and found no substantial effectiveness of an H_2 gas for sintering. On the other hand, in the closed (static) system used in the present study, some remarkable effects were observed. One must pay much attention to these differences in the experimental conditions upon the measurements of various properties of solids, such as their sintering behavior and electric conductivity.

(Received December 4, 1980)

The structures of *cis*- and *trans*-4-aminomethyl-1-cyclohexanecarboxylic acids were studied by proton and carbon-13 NMR, and by semiempirical molecular orbital methods (CNDO/2 and MNDO). Both isomers exist in zwitter ionic forms in aqueous solution. It was found that the most stable conformations for them are all staggered forms: the diequatorial conformer in the *trans* form and the axial carboxyl group in the *cis* form. These preferred conformers are similar to those in crystalline states. In these conformers the deformation is very small in the cyclohexane ring of the *trans* form. The atomic distance between the nitrogen of amino group and the carbon of carboxyl group in the preferred conformer of *trans* form is 0.65 nm and that in *cis* form is 0.55 nm. This distance of 0.65 nm will play an important role in the antifibrinolytic effect.

There are two geometrical isomers, *i.e.*, *trans* and *cis* isomers, in 4-aminomethyl-1-cyclohexanecarboxylic acid. The *trans* one (TAMCHA) is used as an orally active antifibrinolytic drug and its modified compounds are synthetic protease inhibitors,[1] while the biological activity of the *cis* one (CAMCHA) is quite weak.[2]

According to the study of Mangyo[3] on the relationship between the structures of various ω-amino carboxylic acids and their biological activities, their antifibrinolytic activities depend on the atomic distances between the nitrogen of amino group and the carbon of carboxyl group, and on the isoelectric point.

Conformations of the *trans* isomer[4] and hydrogen halide salts of both isomers[5] were studied by crystallography; however, the biologically active conformation in aqueous solution was not expected to be similar to that in the solid state. In this paper we report the conformations of both isomers in aqueous solutions determined by NMR; we seek some clues to the difference in their biological activities.

Experimental

Samples and Reagents. All reagents and solvents used in this research were analytical grade and were used without further purification. TAMCHA and CAMCHA were prepared from ethyl *p*-(acetamidomethyl)benzoate.[6] The nitrates of Eu(III), Pr(III), Nd(III), Gd(III), and La(III) with purity more than 99.9% were purchased from Wako Chemical Co. They were used as NMR shift and/or relaxation reagents.

NMR Measurements. The proton NMR spectra of TAMCHA and CAMCHA were observed on a Varian EM-360A (60 MHz) spectrometer using a frequency-sweep mode and a JEOL FX-100 spectrometer operating at 99.6 MHz using Fourier transform (FT) mode. Their carbon-13 NMR spectra were observed on a JEOL-PS-100 spectrometer linked with a PFT-100 FT system at 25.14 MHz and a JEOL FX-100 spectrometer operating at 25.05 MHz using FT mode. The probe temperature was kept at 30 °C. Sodium 3-(trimethylsilyl)propionate-2,2,3,3-d_4 (TSP-d_4) was used as an external reference for determinations of proton and carbon-13 chemical shifts. Data were accumulated in an attached computer using 1000 Hz and 5000 Hz sweep widths for proton and carbon-13, respectively, in 8192 points (resolution: 0.2 Hz for proton and 1.2 Hz for carbon-13).

The lanthanoid induced shifts were observed with TAMCHA in D_2O solution by a successive dilution method.[7,8] The initial concentration of TAMCHA was 0.05 M (1 M=1 mol dm^{-3}) for the measurements with Eu(III), Pr(III), Nd(III), and La(III); the molar ratio (ρ) of each lanthanoid ion to the substrate was kept at a fixed value (1.0). The perturbed proton relaxation times were obtained from Gd(III) solution.[9,10] Small amounts of Gd(III) nitrate solution were added successively to the 0.20 M solution of TAMCHA. The concentration of Gd(III) was varied from 5.81 to 118.50 μM at intervals of 5—20 μM; 2-methyl-2-propanol (*ca.* 20 mM) was used as an internal standard. Proton spin-lattice relaxation times (^{1}H-T_1) were measured by the inversion-recovery method using a standard 180 °-t-90 ° pulse sequence, where t is the time in seconds between the 180 ° and 90 ° pulses. The 90 ° pulse recycle times were chosen to be at least five times the longest ^{1}H-T_1 time to be measured. Samples for ^{1}H-T_1 measurement were thoroughly deoxygenated with nitrogen in order to prevent any paramagnetic effect of oxygen molecules on T_1 values.

Data Analysis and MO Calculations. The computer programs "NMR-LAOCN-4A"[11] and "FINITE"[12] were applied to analyze the proton NMR chemical shifts in TAMCHA. The electronic densities and the total energies of TAMCHA and CAMCHA were calculated by CNDO/2[13] and MNDO.[14]

Results and Discussion

Assignments. Structures and notations of each atom of TAMCHA and CAMCHA are shown in Fig. 1. 100-MHz proton NMR spectra of both isomers are shown in Fig. 2. Their carbon-13 NMR titration curves are shown in Fig. 3.

Most carbon signals of both isomers were easily assigned by the aid of the off-resonance proton decoupling technique. Carbon pairs (C_2,C_6) and (C_3,C_5) in the spectrum of CAMCHA were assigned, as shown in Fig. 3, from the consideration of the gamma effect.[15]

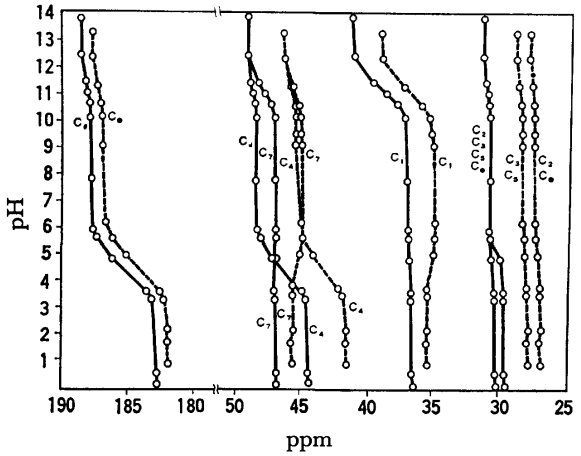

Fig. 3. The pH dependence of the carbon-13 chemical shifts of AMCHA in 15% (W/V) D_2O solution at 30 °C.
——: TAMCHA, ----: CAMCHA.

In the proton NMR spectra of TAMCHA and CAMCHA, the H_A and H_B protons were observed at 2.85 and 2.96 ppm, respectively; they showed a doublet structure due to spin coupling with the H_C proton. The triplet-like signal at 2.11 ppm in TAMCHA and the quartet-like signal at 2.34 ppm in CAMCHA were assigned to the H_L proton because of the selectively proton decoupled carbon-13 NMR spectra and the titration curves of proton NMR shown in Fig. 4. The H_L proton signal of CAMCHA appeared at lower field (by 0.1—0.2 ppm) than that of TAMCHA. An anisotropic effect[16] of the carbon-carbon bond suggest

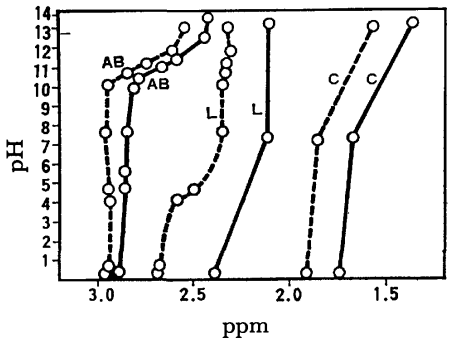

Fig. 4. The pH dependence of the proton chemical shifts of AMCHA in 1% (W/V) D_2O solution at 30 °C.
——: TAMCHA, ----: CAMCHA.
See Fig. 1 about AB, L, C.

that the H_L proton is equatorial and the carboxyl group is axial in CAMCHA.

The signal at 1.67 ppm in TAMCHA was assigned to the H_C proton by the homo-decoupling technique. Other protons of TAMCHA were assigned, as shown in Fig. 2, because of the lanthanoid-induced shift, which produced a fine signal separation while keeping the original spectral pattern.

In the case of CAMCHA, the multiplicity of the H_L proton signals varied on the addition of shift reagent. This trend would suggest some conformational change (such as chair-chair inversion). The assignments of other proton signals were difficult at this stage.

Spin Coupling Constants of TAMCHA. Observed vicinal spin coupling constants are listed in Table 1. $^3J_{AB,C}$ is the representative of $^3J_{A,C}$ and $^3J_{B,C}$ because there is no chemical shift difference between H_A and H_B. Similar notations hereafter are used with similar meanings. Five values among them, *i.e.*, $^3J_{AB,C}$, $^3J_{DE,HI}$, $^3J_{FG,HI}$, $^3J_{HI,L}$, and $^3J_{JK,L}$ were estimated from the 100 MHz proton NMR of TAMCHA to be approximately 6.7, 2.0, 11.0, 11.5, and 3—4 Hz, respectively. The homo-decoupling technique reduced the Pr(III) shifted spectrum to a five-spin system. Refined values of $^3J_{HI,L}$ and $^3J_{JK,L}$ were obtained as 12.04 and 2.49 Hz, respectively, by a computer simulation.[11]

Cyclohexane Ring Conformation of TAMCHA. To clarify whether the observed vicinal coupling constants correspond to those of the chair form, the finite perturbation theory[12] (INDO approximation) was applied. Simple model compounds which are supposed to include some parts of the chair form and of the boat form of the TAMCHA molecule were chosen and calculated. Results are shown in Table 2, in which J_g, J_t, J_c, and J_s denote vicinal coupling constants between two protons in *gauche*, *trans*, *cis*, and *skew* positions, respectively. With α-amino acids, the experimental value of J_g was 2.60 Hz and that of J_t was 13.56 Hz;[17] similar values were also obtained in calculation.

Qualitative results suggest that the observed values were those of the chair form.

Aminomethyl Group Conformation. Three conformers around the C_1–C_7 bond were possible in the aminomethyl group of TAMCHA and CAMCHA. The Newman projections of the possible conformers are

	$^3J_{C,G}=13.7_2$ (J_t)		$^3J_{K,L}=2.7_5$ (J_g)
(III)	$^3J_{L,H}=14.3_0$ (J_t)	(VI)	
	$^3J_{L,I}=13.6_7$ (J_t)		
	$^3J_{L,J}=2.3_2$ (J_g)		
	$^3J_{L,K}=2.1_6$ (J_g)		

a) Calculations were carried out by the finite perturbation theory[12] (INDO approximation). The geometrical parameters for calculations are shown in (VI). The bond angles were assumed as a tetrahedral about sp^3 atom and 120.0° about sp^2 atom. b) J_g, J_t, J_c and J_s denote vicinal coupling constants between two protons in *gauche*, *trans*, *cis*, and *skew* positions, respectively.

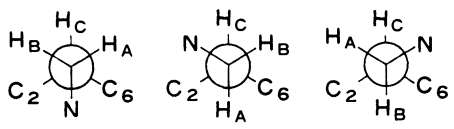

Fig. 5. The possible conformers about the C_1–C_7 bond of AMCHA.

shown in Fig. 5. In solutions TAMCHA and CAMCHA exist as a mixture of these rapidly interconverting rotational isomers. By assuming that J_t, the coupling constant between two hydrogens in the *trans* position with respect to each other, and J_g, the coupling constant between *gauche* hydrogens, are constant for all three isomers, observed vicinal coupling constants $J_{C,A}$ and $J_{C,B}$ are given by

$$J_{C,A} = P_a J_g + P_b J_t + P_c J_g \quad (1)$$

$$J_{C,B} = P_a J_g + P_b J_g + P_c J_t \quad (2)$$

$$P_a + P_b + P_c = 1, \quad (3)$$

where P_a, P_b, and P_c are the populations of the conformers a, b, and c. Strictly speaking, P_b would not be equal to P_c because of a small amount of rotation in the carboxyl group around the C_4–C_8 bond. But because spin-spin coupling is induced through this bond and the carboxyl group is far from the C_1–C_7 bond, P_b can be assumed to be equal to P_c. The fact that only one J value was observed in the present study suggested that $J_{C,A}$ could be equal to $J_{C,B}$ (A_2X spin system assumption). P_a, P_b, and P_c were calculated from Eqs. 1, 2, and 3 with the values J_t(13.84 Hz) and J_g(2.32 Hz) obtained from the model compound (II). P_a and P_b (equal to P_c) are estimated to be 0.240 and 0.380 in TAMCHA

(J_{obsd} was 6.7 Hz); the values in CAMCHA are 0.170 and 0.415 (J_{obsd} was 7.1 Hz). The following equilibrium would be described by either an equilibrium constant K or a free energy ΔG:

$$P_b(=P_c) \rightleftharpoons P_a;\ K = P_a/P_b;\ \Delta G = -RT\ln K.$$

The values of K are 0.632 and 0.410, and the ΔG values (at 30 °C) are 1.159 and 2.248 kJ mol^{-1} in TAMCHA and CAMCHA, respectively.

Table 3. The observed relaxation and shift ratios for TAMCHA

^1H[a]	Relaxation ratio	Shift ratio		
	Gd(III)	Eu(III)	Nd(III)	Pr(III)
L	1.00	1.00	1.00	1.00
JK	0.89	0.69	0.59	0.61
HI	0.54	0.40	0.54	0.59
C	0.21	0.19	0.13	—[b]
DE	0.18	0.24	0.25	—[b]
FG	0.17	0.29	0.32	—[b]
AB	0.01	0.12	0.15	0.15

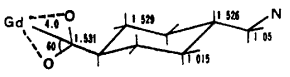
a) See Fig. 1. b) Observation was difficult due to the overlapping of other signals.

Relative Relaxation Rate and Relative Induced Shift. To confirm the above results, NMR observations were carried out with additions of shift and/or relaxation reagents. The relative values of the relaxation rate in the presence of Gd(III) are listed in Table 3 with respect to relaxation rate of H_L. Values of paramagnetically induced shift by Eu(III), Nd(III), and Pr(III) are also listed in Table 3, where the shift of H_L is chosen as a reference. These were values obtained after the subtraction of complex formation shifts, which were determined by an addition of diamagnetic La(III). The relative induced shift depends on the inter-atomic vector between the lanthanoid ion and the i-th nucleus (r_i^{-3}) and the angle between this vector and the principal axes of symmetry of the complex,[18] while the relative relaxation rate is approximately proportional to the (r_i^{-6}) term.[9,10,19] Roughly speaking, the conformation obtained from the shift and/or relaxation reagent experiments is consistent with the above results. There remain small discrepancies between them. The calculated atomic distance between Gd(III) and ^1H based on the geometry,[8,20] shown in the footnote in Table 4, are listed in Table 4. The observed relative relaxation rate and the calculated values of r_i suggest that a small deformation was produced in the cyclohexane ring, especially at the bond angles of C_2–C_3–C_4 and C_4–C_5–C_6 or the bond angle of C_8–C_4–H_L.

Table 4. The calculated atomic distance between Gd(III) and ^1H

^1H	L	H,I,J,K	F,G	C	D,E	A	B
r_{Ln-^1H}/nm[a]	0.595	0.607	0.801	0.810	0.826	0.997	1.018

a) The geometrical parameters for calculation are given below. As shown in Table 3, the ratios of shifts of different nuclear resonances were found to be independent of the lanthanoid ion; the lanthanoid ion was assumed to be located on the bisector of the O–C–O angle.[8,20]



The small deformation in the cyclohexane ring could also be illustrated by the R-value.[21] The relationship between the torsional angle (ϕ) and the R-value in a ring compound is given by

$$R = J_{trans}/J_{cis} \quad (4)$$

$$\cos\phi = (3/(2+4R))^{1/2}, \quad (5)$$

where J_{trans} and J_{cis} are the vicinal coupling constants between two protons in *trans* and *cis* positions, respectively. The R-value of C_3–C_4 bond (or C_4–C_5 bond) of TAMCHA was found to be 4.83 from the refined values listed in Table 1, and the torsional angle about C_3–C_4 bond (or C_4–C_5 bond) was calculated to be 68 degrees from Eq. 5.

Protonation. Lowering of pH values caused the downfield shifts of all proton signals and the upfield shifts of all carbon signals (except the signals of C_1 and C_7). These shifts were observed at pK_1 corresponding to protonation of carboxyl group; they might be accounted for by the changes of the net charges which are produced by the protonation of amino group.[22] Each carbon-hydrogen bond is polarized to C^-–H^+ structure by this protonation and the electron on the hydrogen atom is transmitted onto the positively charged nitrogen atom through the carbon skeleton.

Table 5. Total electron densities of each atom in AMCHA calculated by the CNDO/2 method

	TAMCHA		CAMCHA[a]

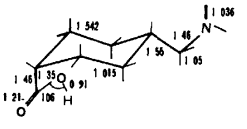
a) The geometrical parameters of CAMCHA for calculation were as follows. b) See text.



The downfield shifts of the proton signals are due to the decreases in the total charge densities on the protons and the upfield shifts of the carbon signals are the increases in the total charge densities on the carbons. To estimate quantitatively these polarization effects, the electron densities were calculated by the CNDO/2 method; the results are shown in Table 5. The difference of the net charge on each atom between the neutral molecules and the cationic ones give the qualitative explanation for the protonation shifts, except for the few atoms marked with asterisks.

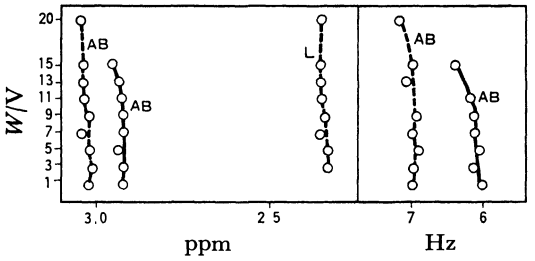


Fig. 6. The concentration dependence of the proton chemical shifts (left) and the proton coupling constants (right) of AMCHA in D_2O solution at 30 °C and 60 MHz.
——: TAMCHA, ----: CAMCHA.
See Fig. 1 about AB, L.

Association. The dependences of the chemical shifts and the coupling constants on the concentration are shown in Fig. 6. A strong hydrogen bond is formed between the solute and the solvent D_2O,[23] and no association of the solute molecules occurred in solutions with the concentration below *ca.* 9% (*ca.* 5.73 mM). The titration curves of carbon-13 chemical shifts (Fig. 3) were drawn at the concentration of 15%, where the association can take place. Small shifts were observed with C_4 and C_8 of TAMCHA and CAMCHA at pK_2 (the protonation of amino group) and the C_1 and C_7 chemical shifts of CAMCHA showed some anormaly in the acidic region.

Semiempirical Molecular Orbital Calculations. To estimate the most stable conformation of TAMCHA and CAMCHA, the conformational energies were calculated by the semiempirical molecular orbital method. The changes of the conformational energies which were caused by the rotations of the aminomethyl group and the carboxyl group were calculated by the CNDO/2 method, based on the assumption that the cyclohexane ring conformations were chair forms free from strain. The calculation was carried out by changing the rotational angle around the C_4–C_8 bond at 30-degree intervals, keeping the N atom *trans* to the position of C_2 to find out the smallest conformational energy value; then the rotational angle around the C_1–C_7 bond was changed at 30- or 60-degree intervals, keeping the carboxyl group fixed. The results are shown in Fig. 7 where the minimum of energy is put to zero as a standard. The curves of the electronic energies were related smoothly with the change of rotational angles, while abnormal changes were observed in the curves of the total energies, in which the contributions of the

——: Total energies, ----: Electronic energies.

core-core repulsion energies to the electronic energies are taken into account. The CNDO/2 method is inadequate to estimate the energy differences among the conformers.[24] As shown in Table 6, the conformer (IV) was more unstable than that (V) in the calculation of CAMCHA, but this result is inconsistent with the experimental result of the proton NMR. The energies of the conformers were, therefore, calculated by the MNDO method[25,26] at the energy minimum points of the CNDO/2 method. The results are, in this calculation, consistent with proton NMR results.

The energy difference between the diaxial and the diequatorial conformers was also calculated. The results showed the conformer (III) was less stable than (I) by 130.42 kJ mol^{-1} (Table 6), and no equilibrium among them was expected. In the case of CAMCHA, the chair-chair inversion conformer (VI) was more stable than (IV) by 44.617 kJ mol^{-1}. The most probable conformer (IV) would be changed to the conformer (VI) by an addition of the shift reagent. This seems to correspond to the change of the spin-coupling pattern in the proton NMR spectrum due to an addition of the shift reagent.

The Atomic Distance (r_{N-C}) between the Nitrogen of Amino Group and the Carbon of Carboxyl Group. The r_{N-C} was a function of the rotation around the C_1–C_7 bond (aminomethyl group rotation). Mangyo related the

antifibrinolytic activities of ω-amino carboxylic acids with the distances of r_{N-C}, and concluded that the distance of 0.65 nm is the most active, from the comparison between molecular models with all staggered form and with diequatorial conformation.[3)]

This paper has shown that the most stable conformer of TAMCHA in aqueous solution is the conformer (I) in which the deformation is very small in the cyclohexane ring, that it is a similar conformer to that in the crystal, and that the distance of r_{N-C} is 0.65 nm. CAMCHA exists in aqueous solution as the conformer (IV) in which r_{N-C} is 0.55 nm and does not agree with that value. 6-Aminohexanoic acid is another antifibrinolytic drug and the r_{N-C} of the active conformation is also thought to be the same value of conformer (I). The antifibrinolytic drug is said to interact with plasminogen or plasmine and the distance r_{N-C} of these drugs will play an important role in the antifibrinolytic effect.

The authors wish to express their thanks to Messrs. Atsushi Tomonaga and Hiroshi Chuman of this laboratory for their helpful discussions.

On the Extractability of Univalent Cation as Dibenzo-18-crown-6 Complexes with Picrate Ion

Yuko HASEGAWA,* Hiroji WAKABAYASHI, Manabu SAKUMA, and Tatsuya SEKINE
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received December 18, 1980)

The solvent extractions of alkali metal(I) with dibenzo-18-crown-6 (the nomenclature recommended by IUPAC is 2,3,11,12-dibenzo-1,4,7,10,13,16-hexaoxacyclooctadeca-2,11-diene) as the picrate into chloroform and benzene were studied at 25°C and compared with those of other univalent ions. The extraction constants of the metal ions ($K_{ex0}=[ME^+A^-]_{org}[M^+]^{-1}[E]_{org}^{-1}[A^-]^{-1}$), are in the sequence of $Tl^+\simeq K^+>Rb^+>NH_4^+\geq Ag^+>Cs^+>Na^+$, but the extraction constants of the metal complexes ($K_{ex}=[ME^+A^-]_{org}\times[ME^+]^{-1}[A^-]^{-1}$) are $NH_4^+\simeq Tl^+\simeq Rb^+\simeq K^+>Cs^+\simeq Ag^+>Na^+$.

The effects of the ionic size, the diluent, and the counter ion on the solvent extraction of univalent metal ions as cyclic polyether complexes were studied previously[1-5] and also recently.[6-10]

Although some early studies[4,11] pointed out that the extraction of metal ions with crown ethers is closely connected with the extractability of the complexes formed, not much has been reported about the extraction of metal ions with crown ethers in connection with the extractability of the complex formed in aqueous solutions. The present work was undertaken in order to learn the relation between the extraction of metal ions and the extractability of the complex. For this purpose, the extraction of alkali dibenzo-18-crown-6 (DBC) complexes with picrate ion was studied and the results were compared with those of thallium(I),[8] silver(I) and ammonium ions.[10]

Experimental

All of the procedures were performed at 25±0.5 °C, as done previously.[8,10] A seven milliliter portion of an aqueous solution containing lithium picrate and one of the alkali metal ions was equilibrated in a stoppered glass tube with an equal volume of chloroform or benzene containing DBC. The concentrations of the metal ions which were back-extracted from the organic phase into 0.1 mol dm^{-3} perchloric acid and that in the equilibrated aqueous phase were determined by flamephotometry. In the cases of sodium(I) and potassium(I), blank tests were necessary to correct the measured concentration of the back-extracts. The distribution ratio, D, was defined as:

$$D=\frac{\text{the total concentration of M(I) in the organic phase}}{\text{the total concentration of M(I) in the aqueous phase}}.$$

Results and Discussion

The statistical treatment was reported previously.[8,10] The extraction constants for the cation and the complex are defined as (here E is DBC and A^- picrate ion):

$$K_{ex0}=[ME^+A^-]_{org}[M^+]^{-1}[E]_{org}^{-1}[A^-]^{-1}, \quad (1)$$

$$K_{ex}=[ME^+A^-]_{org}[ME^+]^{-1}[A^-]^{-1}. \quad (2)$$

When $[M^+]\gg[ME^+]$, the distribution ratio can be written as

$$D=[ME^+A^-]_{org}/[M^+]=K_{ex0}[E]_{org}[A^-] \text{ and } K_{ex}\beta_1[E][A^-], \quad (3)$$

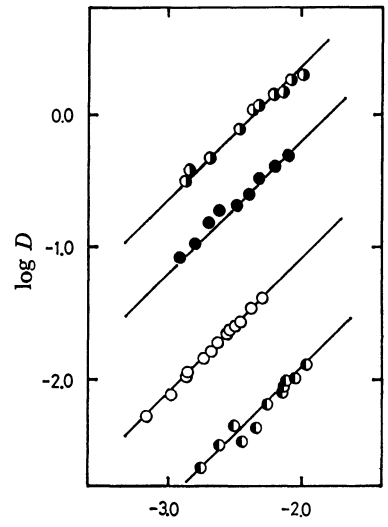

Fig. 1. Distribution ratio K^+ (◑), Rb^+ (●), Cs^+ (○), and Na^+ (◐) as a function of DBC concentration in benzene. The picrate concentration was 1×10^{-2} mol dm^{-3}. The solid lines were calculated using K_{ex0} values in Table 1.

where $\beta_1=[ME^+][M^+]^{-1}[E]^{-1}$. Then $K_{ex}=K_{ex0}K_d\beta_1^{-1}$ where $K_d=[E]_{org}/[E]$.

Figure 1 shows the distribution ratio of alkali metal ions in the benzene system as a function of the DBC concentration and Fig. 2 shows those in the chloroform system; the slope of the curves is always unity in these figures. The slope was also found to be unity for the curves obtained as a function of the picrate concentration at a constant DBC concentration. These results show that the stoichiometry in the extracted species in the organic phase should be 1 : 1 : 1 with respect to the metal ion, DBC, and picrate anion. Thus no correction for Eq. 3 due to the dissociation of the complexes was necessary. The extraction constants K_{ex0} and K_{ex} calculated from these data are listed in Table 1, together with those previously reported. Figure 3 shows the correlation of the values of log K_{ex0} and log K_{ex} with the ionic diameters of the cations.

When these metal ions are extracted with DBC, the more stable the complexes, the better the extraction which is expected. The marked difference in the extraction of the metal ions which is seen from the

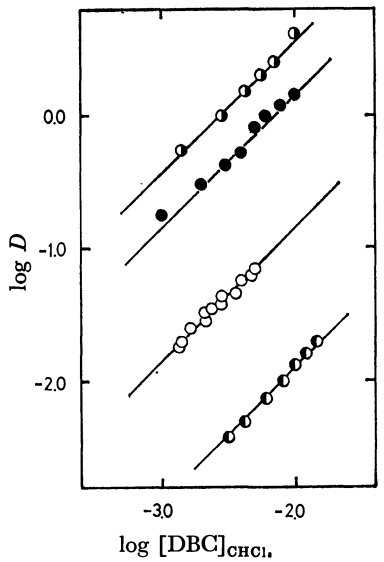

Fig. 2. Distribution ratio of K^+ (◑), Rb^+ (●), Cs^+ (○), and Na^+ (◐) as a function of DBC concentration in chloroform. The picrate concentration was 1×10^{-2} mol dm^{-3}. The solid lines were calculated using K_{ex0} values in Table 1.

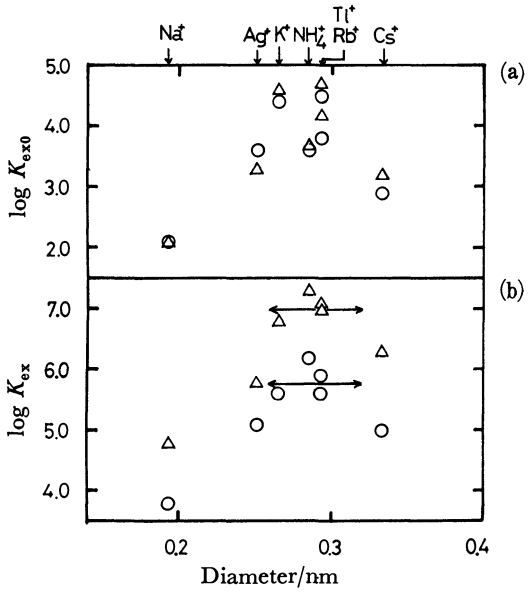

Fig. 3. Extraction constants of univalent metal ions (a) and the complexes (b) with DBC *vs.* the diameters of the ions in benzene system (○), and in chloroform (△). The arrow lines show the hole size of DBC.[2]

values of K_{ex0} in Table 1 should primarily be caused by the difference in the stability of the complexes formed in the aqueous phase. However, the extraction of the metal ions should also be affected by the extractability of the complexes. This property is represented by K_{ex} in Eq. 2. The factors affecting the extractability include:

i) Larger ion-pairs should be extracted better for otherwise identical systems. This hydrophobic tendency, however, is similar for the ion-pairs in the present study because the crown ether is always DBC and the counter-ion picrate.

ii) Stronger attractions of water molecules to the complex should cause poorer extraction. The poorer extractions of sodium(I), silver(I), and caesium(I) complexes, as seen from the K_{ex} values in Table 1, may be attributed to stronger hydrations of them (most probably of the central metal ion). The sodium(I) complex is especially poorly extracted. At present, the authors can not make any reasonable explanation for this markedly strong hydration, although Frensdorff[2] also pointed out that the extractability of sodium-dicyclohexyl-18-crown-6 complex is almost two decades lower than that of potassium complex, when the anion was picrate and the solvent was dichloromethane.

The hydration of a metal ion should be reduced by complexation with crown ethers.[3,4,11] When the size of the central metal ion is larger than the hole, the ion may project over the polyether ring. In such a case, the hydration should be stronger than that of a central metal ion fitting better with the crown ether, for example, potassium(I) for DBC. The lower K_{ex} value of the caesium(I)–DBC complex may be explained by this type of stronger hydration and thus both the instability and the stronger hydration of the caesium(I)–complex should cause the poorer extraction of caesium(I) (represented by K_{ex0}). Hydration of extracted crown ether complexes of alkali metal in nitrobenzene was previously reported.[13] The present authors have no clear explanation for these high K_{ex} values of the ammonium complex, which is much less stable than the other complexes. One possible reason for this may be inaccuracy of the stability constant of the ammonium–DBC complex which was used for the estimation of the K_{ex} values; this value was noted to be somewhat inaccurate.[12]

iii) The extraction of the free crown ether is better into chloroform than into benzene. This may be explained in terms of stronger interactions of the former diluent molecules with DBC. The same tendency is also observed among the metal–DBC complexes and

the diluent effect is somewhat larger with the complexes than with the reagent, except for sodium and silver. The relatively better extraction of the silver complex into benzene than the other metal complexes was explained in terms of the stronger interactions of benzene with the central silver ion due to the π-electrons.[10]

Liquid Crystal Formation in Binary Systems. III.[1] Effect of the Central Double Bond Linkage on the Induction of Nematic Liquid Crystals

Kotaro ARAYA and Yoshio MATSUNAGA*

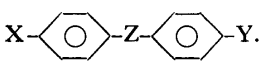
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 18, 1980)

The effect of central double bond linkage on the induction of liquid crystals has been examined employing eight binary mixtures of potentially mesomorphic electron donors and acceptors of the type 4-X-C_6H_4-Z-C_6H_4-OC_2H_5-4. The central linkage Z is -N=N-, -CH=N-, or -CH=CH- group. The terminal substituent X is a dimethylamino group in the donor compounds and a nitro group in the acceptor compounds. A stable nematic liquid crystal is observable with the systems of azo-azo and azo-azomethine compounds. When the acceptor is the nitro derivative of stilbene, a 2 : 3 molecular complex is formed and no liquid crystal can be found, irrespective of whether the partner is an azo or azomethine compound. The latent induction of nematic liquid crystals in these combinations has been proved by studies on the phase diagrams of the pseudo-binary systems with a reference nematogen, azoxydianisole. The nematic liquid crystal-isotropic liquid transition temperatures of both the component compounds and the equimolar mixtures depend on the central double bond linkage: the order is -CH=CH-$>$-N=N-$>$-CH=N-. On the other hand, the order of -N=N- and -CH=N- groups is reversed in the extent of the induction of nematic liquid crystals.

In an earlier paper of this series, we reported that nematic and smectic liquid crystals can be induced by mixing of electron donors and acceptors of the type 4-X-C_6H_4-CH=N-C_6H_4-Y-4.[1] The donor molecules with a dimethylamino group as X or Y and the acceptor molecules with a nitro group as X or Y were employed in that work. The remaining terminal substituents were selected from short alkoxyl groups. The component compounds themselves were designed to be not mesomorphic. Nevertheless, they should be considered potentially mesomorphic because a liquid crystal of variable composition appears in the mixtures. The extrapolation of the observed liquid crystal-isotropic liquid transition curve to 0 mol% or 100 mol% gives a finite temperature. In other words, the strength of orientational cohesive forces in the molten component compound is not sufficient to produce a liquid crystal where the long axes of the molecules are essentially parallel. The induction or the enhancement of the thermal stability of liquid crystals in the above-mentioned mixtures was found to be maximum at a mole ratio of 1 : 1. The molecular arrangement characteristic of liquid crystals in the mixture was supposed to be achieved by supplementing the orientational cohesive forces with an electron donor-acceptor interaction. This sort of intermolecular interaction is well known to produce the alignment of the planar component molecules in ordinary crystals.

The above-mentioned Schiff bases belong to the class of compounds of the least complex structure for mesogens: that is,



The variation of the nematic liquid crystal-isotropic liquid (N-I) transition temperatures of such single compounds with the nature of central double bond linkage Z is known to be fairly regular. The efficiency for central linkages in promoting N-I transition temperature was concluded by Knaak *et al.* to decrease in the order:

-CH=CH-$>$-N=N-$>$-CH=N-.[2]

We took up two azobenzenes and a stilbene in order to find out how the induction of liquid crystals in binary systems is affected by the central linkages. The terminal substituents other than dimethylamino and nitro groups in the present work were limited to the ethoxyl group. Only with this alkoxyl group did the induced nematic liquid crystals appear as stable single phases in the binary systems which comprise Schiff bases.[1]

Experimental

Materials. 4-Dimethylamino-4′-ethoxyazobenzene (DMAEA) was prepared by the method described by Vorländer and Wolferts: *p*-phenetidine was diazotized and coupled with *N,N*-dimethylaniline dissolved in acetic acid.[3] The supercooled melt was reported to be transformed into a liquid crystal, but neither the transition temperature nor the kind of the phase was given by them. 4-Ethoxy-4′-nitroazobenzene (ENA) was obtained by boiling 4-hydroxy-4′-nitroazobenzene in ethanolic solution with ethyl bromide and sodium ethoxide for about 1 h.[4] 4-Ethoxy-4′-nitrostilbene (ENS) was synthesized by the condensation reaction between *p*-nitrophenylacetic acid and *p*-ethoxybenzaldehyde in the presence of a small amount of piperidine. This is analogous to the preparation of the methoxy compound given by Pfeiffer.[5] The Schiff bases (azomethine compounds) were made by the condensation between *p*-X-benzaldehyde and *p*-Y-aniline. In contrast to the azobenzene and stilbene, these molecules are asymmetric and will be represented by their substituents (X, Y). Binary mixtures were prepared by the procedure given in our previous paper.[1]

Measurements. The calorimetric measurement and examination of the texture were carried out as described in our earlier work.[1]

Results and Discussion

Component Compounds. The melting points and N-I transition temperatures of the component compounds are listed in Table 1. It must be noted that the former values are higher than the latter in all the cases. The transition temperatures in this table have been deduced by the extrapolation of the N-I transition curves observed in the binary systems with mesomorphic

Table 1. Melting points (T_m) and nematic liquid crystal-isotropic liquid transition temperatures (T_t) of the component compounds

Compound	T_m/°C	T_t/°C
4-(Dimethylamino)-4′-ethoxyazobenzene	151.5[a]	117
4-Ethoxy-4′-nitroazobenzene	157[b]	110
4-Ethoxy-4′-nitrostilbene	145	115
N-[4-(Dimethylamino)benzylidene]-4-ethoxyaniline	147[c]	97.5
N-(4-Ethoxybenzylidene)-4-(dimethylamino)aniline	138	102
N-(4-Nitrobenzylidene)-4-ethoxyaniline	122[d]	85
N-(4-Ethoxybenzylidene)-4-nitroaniline	114[e]	90

a) 151 °C according to Vorländer and Wolferts (Ref. 3). b) 155 °C according to Baly *et al.* (Ref. 4). c) 147.3 °C according to Dave and Lohar (Ref. 6). d) 123.5 °C according to Dave and Lohar (Ref. 6). e) 121 °C according to Malthete *et al.* (Ref. 7).

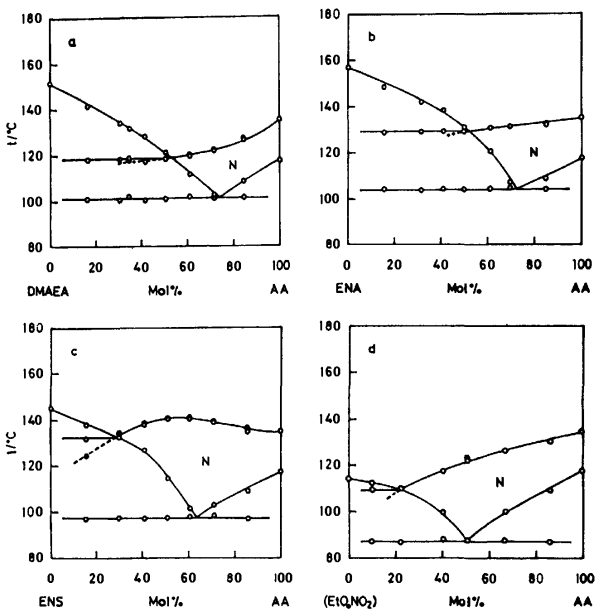


Fig. 1. Phase diagrams of (a) the 4-(dimethylamino)-4′-ethoxyazobenzene–azoxydianisole, (b) 4-ethoxy-4′-nitroazobenzene–azoxydianisole, (c) 4-ethoxy-4′-nitrostibene–azoxydianisole, and (d) *N*-(4-ethoxybenzylidene)-4-nitroaniline–azoxydianisole systems.

azoxydianisole (AA). This reference mesogen exhibits a nematic liquid crystal which is stable between 117.5 and 135°C. The phase diagrams of the systems with DMAEA, ENA, ENS, and (EtO, NO_2) are presented in Fig. 1. The open and shaded circles show the transitions recorded on the calorimetric curves during the processes of heating and cooling respectively. The phase appearing below the transitions, indicated solely by shaded circles, is metastable. When the azobenzene has an electron-donating dimethylamino group, the N-I transition curve is slightly concave upwards (see Fig. 1a). The eutectic point in this system is located at 101 °C and 74 mol% of AA. The enantiotropic N-I transition curve meets the freezing point curve of the azobenzene at 118.5 °C and 53 mol% of AA. The transition to a nematic liquid crystal of the supercooled melt could be observed down to 35 mol% of AA. At this composition, the curve is almost horizontal. As mentioned above, Vorländer and Wolferts noted that a liquid crystal can be formed when the melt of DMAEA is sufficiently supercooled. We failed to observe this; however, the latent N-I transition temperature of DMAEA is located at about 117 °C, if we judge by the extrapolation of the transition curve.

When an electron-withdrawing nitro group is attached to one of the component molecules, the N-I transition curve tends to be convex upwards (see Figs. 1b, c, and d). The extrapolation to 0 mol% of AA gives about 110 °C for the latent transition temperature of ENA, 115 °C for that of ENS, and 90 °C for that of (EtO, NO_2). The phase diagram of the (NO_2, EtO)–AA system can be reproduced from the data given by Dave and Lohar.[6] The N-I transition temperatures, therefore, can be arranged in the following order:

$$\text{DMAEA} > (\text{EtO}, \text{Me}_2\text{N}) > (\text{Me}_2\text{N}, \text{EtO})$$

and

$$\text{ENS} > \text{ENA} > (\text{EtO}, \text{NO}_2) > (\text{NO}_2, \text{EtO}),$$

in agreement with the general order reported by Knaak *et al.*[2] The nonideality of the N-I transition curve is very remarkable in the ENS–AA system (see Fig. 1c). The transition at 50 mol% of AA deviates by about 16 °C from the line joining the transition temperatures of the component compounds. The degree of nonideality of the transition curve, which is the extent of the induction of liquid crystal at 50 mol% of AA, occurs in the following order:

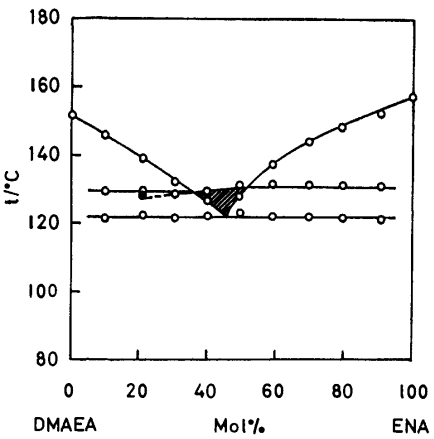

Fig. 2. Phase diagram of the 4-(dimethylamino)-4′-ethoxyazobenzene–4-ethoxy-4′-nitroazobenzene system. In the hatched area, the nematic liquid crystal is stable as a single phase.

$$ENS \simeq (NO_2, EtO) > (EtO, NO_2) > ENA.$$

The attractive interaction with AA is probably of the electron donor-acceptor type, as will be discussed later.

Systems with the Azobenzenes. The phase diagram of the DMAEA–ENA system is of the eutectic type, as is shown in Fig. 2. The eutectic point is found at 122 °C and 46 mol% of ENA. A nematic liquid crystal remains a single phase in the composition range from 36 to 52 mol% of ENA. The maximum transition temperature is 131.5 °C, observed at 60 mol%. Equilibrium diagrams such as the above have been reported by Lohar for the systems consisting of two Schiff bases: namely, (MeO, EtO) mixed with (NO_2, EtO), (Me_2N, EtO), or (MeCO, Me).[8] In his first system, the N-I transition curve is markedly convex upwards, suggesting the electron donor-acceptor interaction between the molecules of different kinds. On the other hand, the observed transitions vary more or less linearly with the composition in the remaining two systems. As the eutectic point is lowered with respect to the curve connecting the latent transition temperatures of the component compounds, a nematic liquid crystal is observable in these mixtures. Because of the strong tendency of the azobenzenes to crystallize, the transition curve observed in Fig. 2 is so short that one cannot say whether it is straight or curved. Considering the latent N-I transition temperatures given in Table 1, one can conclude that the nematic liquid crystal is induced as much as 18 °C by mixing. If there were no stability enhancement, the liquid crystal in this system would be metastable in the entire composition range.

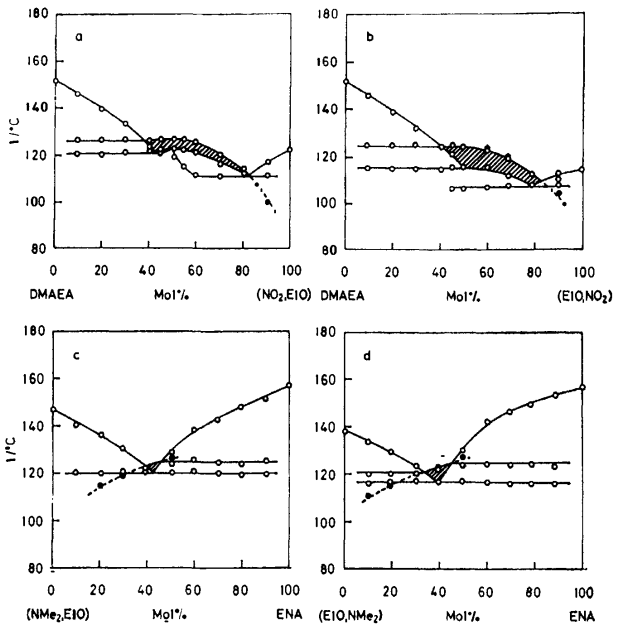

Fig. 3. Phase diagrams of (a) the 4-(dimethylamino)-4′-ethoxyazobenzene–*N*-(4-nitrobenzylidene)-4-ethoxyaniline, (b) 4-(dimethylamino)-4′-ethoxyazobenzene–*N*-(4-ethoxybenzylidene)-4-nitroaniline, (c) *N*-[4-(dimethylamino) benzylidene]-4-ethoxyaniline–4-ethoxy-4′-nitroazobenzene, and (d) *N*-(4-ethoxybenzylidene)-4-(dimethylamino)aniline–4-ethoxy-4′-nitroazobenzene systems. As to the hatched area, see the caption of Fig. 2.

The combination of DMAEA with (NO_2, EtO) or (EtO, NO_2) gives the diagram shown as Fig. 3a or b. The former system involves a congruently melting 1 : 1 molecular complex. The eutectic points are at 120.5°C and 42.5 mol% and at 111 °C and 82 mol% of the Schiff base. The molecular complex melts at 123 °C. The nematic liquid crystal appears as a stable single phase in the hatched area above the freezing point curve of the molecular complex. The area covers the composition range from 38 to 83 mol% of (NO_2, EtO). The maximum N-I transition temperature is located at 127 °C and 50 mol%. This temperature is higher by 26 °C than the mean value of the latent transition temperatures of the component compounds.

As is shown in Fig. 3b, a molecular complex is also formed in the system with (EtO, NO_2), but it is obviously less stable than that mentioned above. A peritectic point appears at 115 °C and 50 mol% and a eutectic point at 107 °C and 79 mol% of (EtO, NO_2). At the former temperature, the molecular complex decomposes, leaving the solid azobenzene and the melt of a 1 : 1 mole ratio. The composition of the solid molecular complex is not 1 : 1 mole ratio but possibly 3 : 2 or 2 : 1. A single phase nematic liquid crystal appears in the composition range from 41 to 83 mol% of the Schiff base. The maximum temperature is 124 °C. The extent of the induction is estimated to be 21 °C.

The (Me_2N, EtO)–ENA and (EtO, Me_2N)–ENA systems yield no solid molecular complex (see Figs. 3c and d). The eutectic points are located at 120 °C and 42.5 mol% and at 117 °C and 39 mol% of ENA respectively. The nematic liquid crystal is stable as a single phase in a very limited area. In the former system, the composition range is only from 39 to 46 mol% and in the latter from 33 to 45 mol% of ENA. The N-I transitions at 50 mol% occur at 126 and 127 °C respectively. The stability of the liquid crystal is enhanced by 22 °C in the former system and by 21 °C in the latter. These values are a little bit larger than the 18 °C found with the system comprising only the azobenzenes. In Fig. 3c, a horizontal transition line is supposed to exist; this extends from the point of intersection between the N-I transition curve and the freezing point curve of the Schiff base. However, no peak due to this transition could be recorded because of overlapping with a much larger peak at the eutectic temperature.

Systems with 4-Ethoxy-4′-nitrostilbene. When the stilbene is the acceptor in binary systems, a stable 2 : 3 molecular complex is formed in all the examined systems and no liquid crystal is observable (see Figs. 4a, b, and c). The regions of existence of the solid molecular complexes (the composition difference between the two eutectic points) are as follows: 69 mol% with DMAEA, 74.5 mol% with (Me_2N, EtO), and 82 mol% with (EtO, Me_2N). The stability of solid molecular complex may be considered to increase in this order. While the stilbene is yellow and (Me_2N, EtO) is pale yellow, the molecular complex is orange, suggesting the appearance of a charge-transfer absorption band. On the other hand, the color change by the molecular complex formation is hardly noticeable when the orange-colored

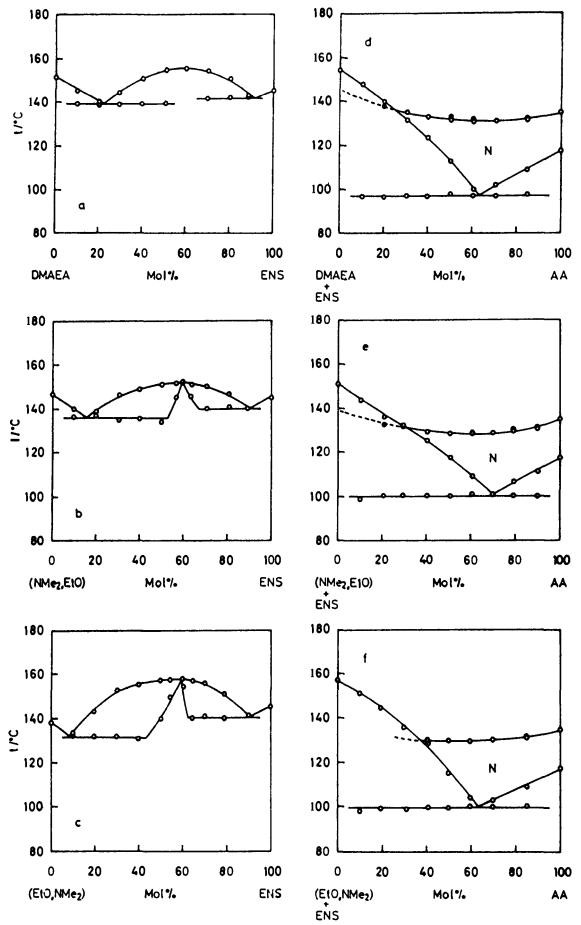

Fig. 4. Phase diagrams of (a) the 4-(dimethylamino)-4′-ethoxyazobenzene–4-ethoxy-4′-nitrostilbene, (b) *N*-[4-(dimethylamino)benzylidene]-4-ethoxyaniline–4-ethoxy-4′-nitrostilbene, and (c) *N*-(4-ethoxybenzylidene)-4-(dimethylamino)aniline–4-ethoxy-4′-nitrostilbene systems, (d) the system consisting of azoxydianisole and the equimolar mixture of 4-(dimethylamino)-4′-ethoxyazobenzene and 4-ethoxy-4′-nitrostilbene, (e) the system consisting of azoxydianisole and the equimolar mixture of *N*-[4-(dimethylamino)benzylidene]-4-ethoxyaniline and 4-ethoxy-4′-nitrostilbene, and (f) the system consisting of azoxydianisole and the equimolar mixture of *N*-(4-ethoxybenzylidene(-4-(dimethylamino)-aniline and 4-ethoxy-4′-nitrostilbene.

azobenzene is one of the components.

It seemed highly likely that the transition of the melt to a metastable nematic liquid crystal is overshadowed by the strong tendency to form a solid molecular complex; therefore, a study on the phase diagram of pseudo-binary system comprising AA and the mixture of the component compounds was undertaken. We employed equimolar mixtures instead of the solid molecular complexes because the nematic liquid crystal of the former composition is expected to be more stabilized than that of the latter composition. Such features are exemplified by the DMAEA–(EtO, NO_2) system presented in Fig. 3b. The diagrams of the pseudo-binary systems are displayed in Figs, 4d, e, and f. The latent induction of nematic liquid crystals is clearly proved in all three. The N-I transition temperature in the mixture of DMAEA and ENS is estimated by the extrapolation of the transition curve to 0 mol% of AA to be 145 °C. The deviation from the mean value of the latent transition temperatures of DMAEA and ENS is 29 °C. The induction of a nematic liquid crystal is even larger in the (Me_2N, EtO)–ENS and (EtO, Me_2N)–ENS systems: namely, 33 and 32 °C respectively.

The N-I transition temperature at 50 mol% and the extent of the induction are summarized in Table 2. For a given electron donor, the temperature varies with electron acceptor in the following order:

$$\text{ENS} > \text{ENA} > (NO_2, \text{EtO}) > (\text{EtO}, NO_2).$$

With a given acceptor, DMAEA gives a higher transition temperature than the Schiff bases do. These results conform to the order of the latent N-I transition temperatures of the component compounds; therefore, they conform also to the order of central double bond linkages reported by Knaak *et al.*[2] Of as great importance as the N-I transition temperatures, however, are the extents of the induction of nematic liquid crystals. In contrast to the transition temperature themselves, the extents of the induction are found more pronounced with the Schiff bases than with the azobenzenes: that is,

$$(Me_2N, \text{EtO}) \simeq (\text{EtO}, Me_2N) > \text{DMAEA}.$$

As to the electron acceptors, the order is consistently

$$\text{ENS} > (NO_2, \text{EtO}) > (\text{EtO}, NO_2) > \text{ENA}.$$

The coincidence between the latter series and the order of the induction of nematic liquid crystals in the systems with AA supports our proposition that AA acts as an electron donor in the examined mixtures. In summary, the order of the induction efficiency of central double bond linkages may be

$$\text{-CH=CH-} > \text{-CH=N-} > \text{-N=N-}.$$

It must be emphasized that the above order agrees

Table 2. Nematic liquid crystal-isotropic liquid transition temperature at 50 mol% and the deviation from the mean value of the transition temperatures of the component compounds
(The latter values are in parentheses)

Acceptor	Donor			
	DMAEA	(Me_2N, EtO)	(EtO, Me_2N)	AA
ENA	131 (18)	126 (22)	127 (21)	129 (6.5)
ENS	145 (29)	139 (33)	140 (32)	141 (16)
(NO_2,EtO)	127 (26)	123 (32)[a]	124 (31)[a]	125.5 (15.5)
(EtO, NO_2)	124 (21)	121 (27)[a]	119 (23)[a]	121.5 (9)

a) Taken from Ref. 1.

with that of the tendency of formation of solid molecular complexes in the systems studied here. As we see in Fig. 4, a stable molecular complex is formed in all the systems containing ENS as one of the components. Comparison of Fig. 2 with Figs. 3a and b undoubtedly leads to the conclusion that the tendency to form a solid molecular complex is higher with the Schiff base than with the azobenzene. Indeed, examining the effect of terminal alkoxyl groups in Schiff base molecules, we have found that the extent of the induction of nematic liquid crystals in binary systems is qualitatively related to the tendency of formation of solid molecular complexes.[1)]

The authors wish to express their sincere thanks to Mr. Nobuhiko Miyajima for the preparation of some component compounds. The present work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, and Culture (No. 543001).

Molecular Structure of Bromotrichloromethane as Determined by Gas Electron Diffraction

Shigehiro KONAKA,* Kiyo YAMAGATA, and Masao KIMURA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 18, 1980)

The molecular structure of $CBrCl_3$ has been determined by gas electron diffraction to be as follows: r_g(C–Cl) = $1.765_4(1_7)$ Å, r_g(C–Br) = 1.944(4) Å, and $\angle$ClCCl = $109.7_4(1_3)°$.† The mean amplitudes have been fixed at the calculated values in the data analysis. The result has been compared with the structures of related halomethanes.

The molecular structures of halomethanes have been investigated extensively,[1] but modern structural data are relatively few for halomethanes containing different halogen atoms.[2] Recently, precise structures of HCBrClF,[3] CF_3Cl,[4] CF_3Br, and CF_3I[4,5] have been reported. The C–F bond lengths of CF_3X molecules decrease with increasing electronegativity of atom X(X=H, I, Br, Cl, and F),[4] while the bond angles show only a slight and unsystematic change in value from H to F.[5] A more distinct change in value of bond angles is found for CCl_3X molecules (X=H, Cl, and F).[2] The molecular structure of bromotrichloromethane was determined only by the visual method of gas electron diffraction;[6,7] no accurate geometry of $CBrCl_3$ is available. The present study has been undertaken to supplement the structural data of halomethanes and to compare the structure of $CBrCl_3$ with the geometries of related halomethanes.

Experimental

A sample with the stated purity of at least 99% was obtained from Nakarai Chemical Co., Ltd. and used without further purification. Diffraction patterns were recorded on Kodak electron image plates using an electron diffraction unit[8] equipped with an r^3-sector at two camera distances, 109.3 and 244.3 mm. Experimental conditions were as follows: accelerating voltage, about 39 kV; sample pressure, 20 Torr; vacuum pressure during experiment, $(5-9)\times10^{-5}$ Torr; nozzle temperature, about 18 °C; beam currents, 0.15 and 0.23 μA; exposure times, about 3 and 1 min for the short and long camera distances respectively. The electron wave length was determined from the diffraction patterns of carbon disulfide taken in the same sequence of exposures. The drift of the accelerating voltage was monitored throughout the experiments by measuring the voltage drop of the standard resistance in a high-voltage source.[9] The drift of the wave length during each experimental sequence was confirmed to be less than 0.01%. The number of plates used for data analysis was four and five for the short and long camera distances respectively.

Calculation of Mean Amplitudes

A radial distribution curve obtained from long camera data is shown in Fig. 1. The overlap of C–Cl and C–Br peaks and that of Cl···Cl and Cl···Br peaks indicate difficulty in the precise determination of experimental mean amplitudes. In the data analysis, the mean amplitudes were fixed at the calculated values. Quadratic force constants are needed for the calculation of the mean amplitudes. Zietlow *et al.* reported a quadratic force field for $CBrCl_3$ based on the fundamental frequencies observed for the liquid phase.[10] Recently Clark *et al.*[11] reported the fundamental frequencies for the gas phase which are significantly different from those for the liquid. The force field given by Zietlow

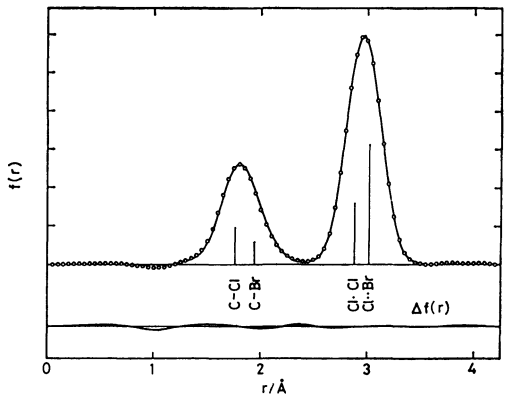

Fig. 1. Experimental (open circles) and theoretical (solid curve) radial distribution curves for $CBrCl_3$; $\Delta f(r) = f(r)^{obsd} - f(r)^{calcd}$. A damping factor, $\exp(-0.0075\,s^2)$, was used.

δr_{cent}	3	6	5	8

a) Calculated at 291 K.

et al. was then modified in the present study to reproduce the gas-phase frequencies. The force constants thus obtained in the symmetry coordinates are listed in Table 1 together with Zietlow's values rewritten in the symmetry coordinates. Although there is some arbitrariness in the choice of the force field, the above force constants are sufficient for our purpose, since the mean amplitudes are not sensitive to force constants chosen as long as they reproduce the vibrational frequencies correctly.[13] In Table 2 are listed the calculated values of the mean amplitudes, along with the stretchings due to the perpendicular thermal vibration and the centrifugal stretchings δr_{cent} to be used for shrinkage correction.[14,15]

Data Analysis

Optical densities measured at an interval of 1/3 mm on each photographic plate were converted to intensities.[9] The intensities were corrected for the imperfection of the sector shape and leveled by the theoretical background. Reduced molecular scattering intensities, $sM(s)$, were obtained by drawing a smooth background through the leveled intensities, then the background was revised by applying the non-negativity criterion to radial distribution curves calculated from $sM(s)$ and the drawing procedure was repeated. Data from the two camera distances covered the s-ranges of 2.8 and 17.4 $Å^{-1}$ and 6.0 and 37.4 $Å^{-1}$. The elastic and inelastic scattering factors were taken from the literature.[16] The asymmetry parameters, κ, for C–Cl and C–Br were estimated from the formula[17]

$$\kappa \simeq \frac{a}{6} l^4,$$

where the Morse parameter, a, was assumed to be 2 $Å^{-1}$. The asymmetry parameters for the non-bonded atom pairs were assumed to be zero. The parameters adjusted by the least-squares analysis of $sM(s)$ constrained to C_{3v} symmetry were r_a(C–Cl), r_a(C–Br), ∠ClCBr, and the index of resolution.[18] A conventional diagonal weight matrix was used.[9]

The observed values of $sM(s)$ and the best fit curve for one plate from each camera distance are shown in Fig. 2.[19] The parameter values obtained from each camera-distance data are listed in Table 3; these data converted to the thermal average structure are listed in Table 4 together with the weighted averages. The limits of error for the parameter values were estimated from 2.6 times the larger of the random standard deviations, σ_1 and σ_2, and the systematic errors. The errors in the scale factor were estimated to be 0.05% and 0.06% for the short and long camera distance data respectively. The systematic errors originating from the uncertainties of the anharmonicity parameters and those of correction values for the sector shape were also taken into consideration.[9] Other details of the analytical procedures are described elsewhere.[9] The experimental errors are smaller for the long distance data than for the short distance data. The agreement between the two data is satisfactory. The weighted average is given as the final result of the present work.

a) The numbers in parentheses represent the estimated limits of error attached to the last significant digits. b) Bond angles defined in the r_a structure.

Discussion

The bond lengths of $CBrCl_3$ are compared with those of tetrahalomethanes in Fig. 3. Only modern structural data are collected here. The data for CF_3X(X=Cl, Br, I) and CF_4 are taken from Typke *et al.*[4] and Fink *et al.*'s[21] papers respectively and those for $CFCl_3$ from the Landolt-Börnstein table.[2] The structures of CCl_4 and CBr_4 have been determined in our laboratory.[22,23] Carbon-halogen bond lengths, r(C–W), in tetrahalomethanes, CWXYZ, are plotted against the sums of electronegativity values†† for the other halogen atoms, X, Y, and Z. In general, the carbon-halogen bond length decreases with an increase in the sum of the electronegativity values. This trend is in accordance with a prediction given by the valence-shell electron-pair repulsion (VSEPR) theory.[25] According to this theory, replacement of neighboring atoms by more electronegative ones shortens the bond length of interest. However, the trend of change in bond lengths is reversed to that expected by the VSEPR theory for CBr_4 and $CBrCl_3$ and for $CBrCl_3$ and CCl_4. This shows that factors governing the geometry of halomethanes are not so simple as those for most inorganic molecules.

The values of ∠ClCCl for related halomethanes are compared in Table 5. As stated before, the bond angle of the CCl_3 group changes considerably with substituents in contrast with that of the CF_3 group. It is noted that the ClCCl angle of $CBrCl_3$ is slightly larger than the tetrahedral angle. This is also inconsistent with the VSEPR theory.

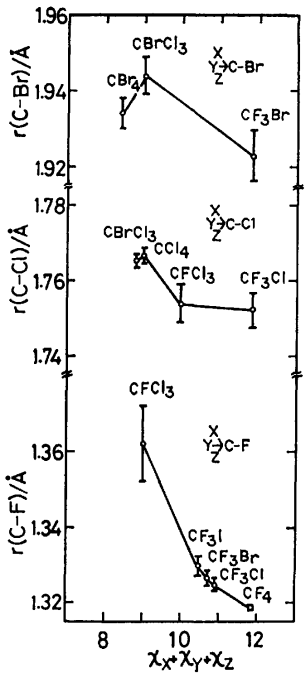

Fig. 3. Plots of carbon-halogen bond lengths of tetrahalomethanes *versus* the sums of electronegativities of adjacent halogen atoms.

†† Electronegativities were taken from Ref. 24.

Table 5. Comparison of ∠ClCCl (in degrees)

	Obsd	Calcd[a]	Calcd[b]
CCl_4	109.5	109.5	109.5
$CBrCl_3$	$109.7_4(1_3)$	110.4	110.5
$CFCl_3$	111(1)[c]	111.4	111.5
$CHCl_3$	111.3(2)[c]	112.0	112.0

a) Molecular mechanics calculation given in Ref. 26 b) Given by molecular mechanics calculation with experimental bond lengths. c) Taken from Ref. 2.

Dashevskii calculated the bond angles of halomethanes by means of molecular mechanics.[26] As shown in Table 5, column 3, his results are in fair agreement with the experimental values. In his calculation, the nonbonded atom potential of a 6-exp type was adopted and the same elastic constant was used for all the bond angles, while the bond lengths were fixed at the following values: C–H 1.10, C–F 1.34, C–Cl 1.77 and C–Br 1.93 Å. The experimental bond lengths differ from the assumed values by as much as 0.02 Å and accordingly a different choice of bond lengths may change the result. Thus, the bond angles were recalculated with the experimental bond lengths, but the change is small, as is shown in Table 5, column 4. The agreement between calculation and experiment suggests that the steric effect is an important factor governing the bond angles of trichloromethanes.

The authors wish to thank Dr. Koichi Tamagawa for his helpful discussions. The numerical computations were carried out on a HITAC M180 of the Hokkaido University Computing Center.

UV Absorption Studies of the Pyrolysis of Butane in Shock Waves

Tohru KOIKE* and Kihei MORINAGA

Department of Chemistry, National Defense Academy, Hashirimizu, Yokosuka 239

(Received December 19, 1980)

The UV absorption measurements at 216 nm were carried out for three shock-heated mixtures, 1, 2, and 2.8% n-C_4H_{10} diluted in Ar, in the temperature range of 1290—1610 K and at about half atmospheric pressures. From the initial absorption rise, which can be attributed to the CH_3 growth, the rate constant of the reaction, n-$C_4H_{10}=CH_3+n$-C_3H_7, was evaluated as $k_2=8.9\times10^{13}\exp(-71.9\,\text{kcal}/RT)$ (s^{-1}). A computer modeling using a 44-reaction mechanism including the k_2 value so evaluated could reproduce the absorption early in the reaction and in the temperature range of 1420—1610 K with a reasonable value.

The pyrolysis of butane has mainly been studied at lower temperatures using a flow tube[1-3] and a wall-less reactor.[4] The basic idea for the pyrolysis at low temperatures is almost established, and the features of the reaction are explainable through a free-radical mechanism of the Rice-Herzfeld type.[3,4]

At high temperatures, however, only a few studies of the pyrolysis have been reported.[5-7] Recently, shock-tube studies using TOF mass spectroscopy for the pyrolysis have been carried out and the observed concentration profiles of several species have been subjected to a computer modeling.[7] The results of the computer modeling at high temperatures were not as satisfactory as those in the low temperature region where the modeling results tolerably concurred with the observed profiles.[8,9]

The pyrolysis of n-C_4H_{10} has two channels for the initiation reaction:

$$n\text{-}C_4H_{10} = 2C_2H_5, \quad (1)$$

$$n\text{-}C_4H_{10} = CH_3 + n\text{-}C_3H_7. \quad (2)$$

Because of the fall-off effect, the rate constants of these unimolecular reactions at high temperatures may not accord with the values obtained by extrapolations of the rate constants at low temperatures. Therefore, it is desirable to measure the k values directly; this may be one of the most important steps in clarifying the reaction mechanism of the n-C_4H_{10} pyrolysis at high temperatures.

Recently, the absorption measurement at 216 nm of the CH_3 profile has been proved to be a useful method for studying the alkane pyrolysis. However, the measurement has thus far been applied only to the CH_4 and C_2H_6 pyrolysis[10] and the CH_3 recombination.[11]

In this study, we will estimate the k value of Reaction (2) by measuring the absorption profile at 216 nm in the n-C_4H_{10} pyrolysis. The k_2 value thus obtained is incorporated into a reaction mechanism of the pyrolysis, and the absorption profile at the early stage of the reaction is elucidated by computer modeling.

Experimental

The shock tube and the optical system used in this study have been described in a preceding paper.[12] The D_2-lamp of 30 W used before was replaced by a 200 W high-power one (Hanau, D200F) so as to gain much larger signals.

The gases used were 99.8% pure n-C_4H_{10} purchased from the Takachiho Co. and 99.999% pure Ar from the Nippon Sanso Co. The test gas compositions, n-C_4H_{10}/Ar, were 1/99, 2/98, and 2.8/97.2, while the starting pressure of the test gas was always 20 Torr (1 Torr=133.322 Pa). It was confirmed that no emission from the shocked test gas was observed.

The computer modeling for the observed absorption profiles was done using the flow model of the laminar-boundary-layer growth with limiting separation.[13]

Results and Discussion

A sample oscillogram of 216 nm light attenuation through the shocked gas is shown in Fig. 1. This oscillogram is a typical one for the present studies; *i.e.*, the absorption increases gradually right after the shock arrival at the observation window. Since no absorption has been reported for CH_4 and C_2H_6 at 216 nm,[14] n-C_4H_{10} was also expected to have no absorption band in this wavelength region.

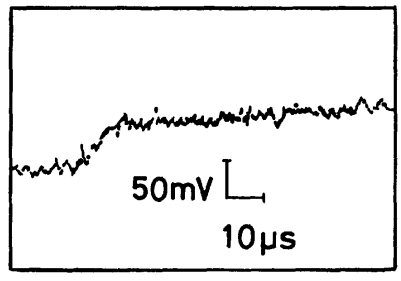

Fig. 1. A representative oscillogram for 2% n-C_4H_{10} in Ar mixture, $P_1=20$ Torr, and $T_2=1436$ K.

The absorption measurement of C_2H_5 in this wavelength range has been reported;[15] the absorptivity at 216 nm is at least 30 times smaller than that of CH_3. The effect of n-C_3H_7 on the measured absorption was assumed to be negligibly small. The validity of this assumption will be confirmed below by a computer modeling; the steady [n-C_3H_7] modeled is about 4 orders of magnitude less than the [CH_3]. Therefore, it is reasonable to assume that the absorption early in the reaction is entirely due to CH_3.

The primary reactions of the CH_3 radical at the early stage of the reaction are:

$$CH_3 + n\text{-}C_4H_{10} = CH_4 + n\text{-}C_4H_9, \quad (5)$$

$$= CH_4 + s\text{-}C_4H_9, \quad (6)$$

$$s\text{-}C_4H_9 = CH_3 + C_3H_6, \quad (11)$$

$$n\text{-}C_3H_7 = CH_3 + C_2H_4. \quad (24)$$

The methyl radical produced by Reaction 2 decreases as a result of metathetical reactions (5) and (6). The unimolecular decompositions of the radicals thus produced, Reactions 11 and 24, also give CH_3. At a very early time in the reaction, for example, lab. time of 0.2 μs, only Reactions 2 and 24 are important for evaluating the CH_3 profile; this can be confirmed by comparing the value of the rate of each reaction obtained by the computer modeling to be discussed later. The steady state assumption for n-C_3H_7 leads to the following expression of CH_3 production:

$$k_2 = (\mathrm{d}[CH_3]/\mathrm{d}t)_{t\to 0}/(2[n\text{-}C_4H_{10}]_0)$$

where t=particle time and $[n\text{-}C_4H_{10}]_0$ is the shock-front concentration of n-C_4H_{10}. To evaluate the k_2 value using the above equation, it is necessary to estimate the absorptivity of CH_3, which correlates the measured absorption to $[CH_3]$. We adopted the absorptivities reported by Tsuboi[10] and Glänzer *et al.*[11]

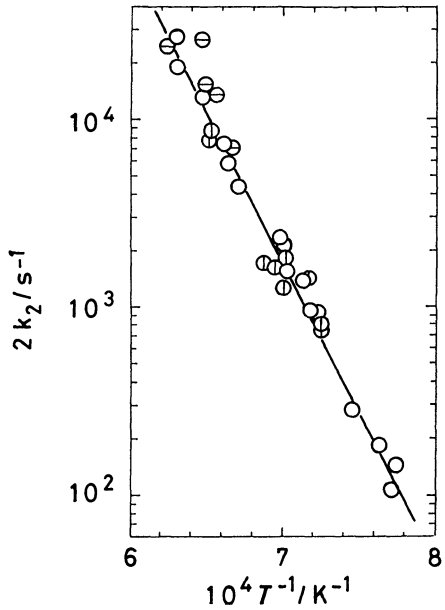

Fig. 2. Arrhenius plots for k_2. The symbols used are as follows.
⊖: For 1% n-C_4H_{10} in Ar, ⓘ: for 2% n-C_4H_{10} in Ar, and ○: for 2.8% n-C_4H_{10} in Ar.
The line shows a least squares fitting for the data points.

The k_2 values thus obtained are shown *vs.* $10^4/T$ in Fig. 2. A least-squares calculation for the relation provided the following Arrhenius expression:

$$k_2 = 8.9\times 10^{13} \exp(-71.9\ \mathrm{kcal}/RT) \quad (s^{-1}).$$
$$(1\ \mathrm{kcal} = 4.184\ \mathrm{kJ})$$

The rate constants of the metathetical reactions are reported to show deviations from the Arrhenius plots, and the actual values of the rate constants at high temperatures are larger than those extrapolated from the k values measured at low temperatures.[2] It is also well known that the k value of the metathetical reaction decreases with an increase in the structual complexity of the radicals accompanying the reaction.[3] At an early time in the n-C_4H_{10} pyrolysis, [H] is much smaller than $[CH_3]$ and $[C_2H_5]$. Therefore, it is expected that the value of k[R], where k and [R] are the rate constant and the concentration of the radical in the metathetical reaction respectively, will change depending on both the temperature and the reaction time. As for the unimolecular decompositions of the radical, the rate constant may be in the fall-off range under the present experimental conditions.

To elucidate the roles of these metathetical reactions and unimolecular decompositions of the radicals in the n-C_4H_{10} pyrolysis, a computer modeling was carried out for the initial stage of the reaction. The absorption at the lab. time of 10 μs, A_{10}, defined as $A_{10}=\ln(I_0/I_{10})$ where I_0 and I_{10} are the incident-light intensity and the transmitted intensity at the time respectively, is calculated and plotted in Fig. 3.

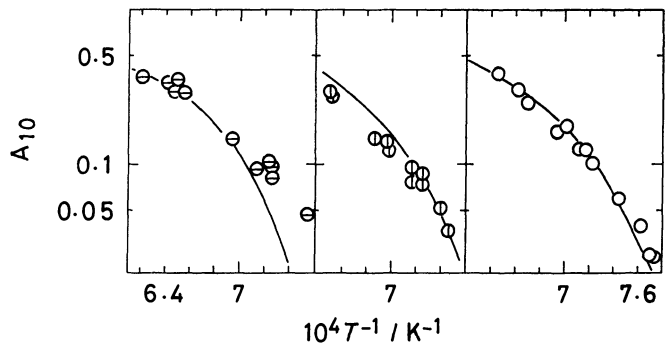

Fig. 3. The relation between A_{10} and $10^4/T$.
The symbols used are the same as those in Fig. 2.
The lines show modeled A_{10} for the three mixtures.

Table 1 shows the final reaction mechanism of the n-C_4H_{10} pyrolysis assumed in this study. The reaction mechanism consists of 44 reactions with the maximum value of the rate larger than 10^{-7} (mol cm^{-3} s^{-1}) during the initial reaction period (10 μs). The rate constant of each reaction was taken from several sources except in a few cases. The k_{-1} value, the rate constant of the reverse reaction (−1), was estimated from the geometric mean rule using the following equation:

$$k_{-1} = k_{18}^2/(4k_{-31}[M]).$$

The k_{-31} value was evaluated from $k_{-31}=k_{31}/K_{31}$, where K_{31} is the equilibrium constant and [M]=density. The k values of the metathetical reactions, (3)—(8), were taken from those in the proposed reaction mechanism.[2,3] Each butyl radical has two channels for the decomposition. One of them is to H and butene, Reactions 9 and 10. The others are Reactions 11 and 12, which obey the β-bond breaking rule;[16] n-C_4H_9 decomposes to C_2H_4 and C_2H_5 and s-C_4H_9 to CH_3 and C_3H_6. Reactions 13—17 are primary steps in the butene pyrolysis. The k values adopted for Reactions 9—14 and 17 are those reported for the high pressure limit. Since these radical decompositions are expected to have different sensitivity spectra for the modeled A_{10} value, while their k values could be corrected for the fall-off with a similar factor, we left the k values of radical decompositions at the values shown in Table 1. In the reactions of the C_3 species, 18—30, their k values are taken mainly from

those determined in the C_3H_8 pyrolysis study in shock waves.[17] The k values of Reactions 31—40 are also taken form those derived in the C_2H_6 pyrolysis study in shock waves.[18] In Reactions 31—40, the k values of the two channels of CH_3+CH_3 into C_2H_5+H and $C_2H_4+H_2$ were determined recently.[10,19] Thus, the reaction mechanism in Table 1 has three channels for CH_3+CH_3, Reactions, —31, 34, and 35. The dispropor-

tionations, (41)—(43), which have only a minor effect on the modeling results, were included and their k values were assumed to be around 10^{11}; the ratios, k_{-1}/k_{42} and k_{18}/k_{41}, are expected to be larger than 1.[20] In comparison with the reaction mechanisms of the C_2H_6 and C_3H_8 previously reported,[17,18] it is characteristic of the 44-reaction mechanism that the isomerization reaction of C_4H_9, Reaction 44, is included.[21]

Our original computer program was devised to calculate the concentration of each species. To compare directly the computer modeling results with the A_{10} values shown in Fig. 3, the concentration of each species was converted to the absorption, A, in the program according to this equation:

$$A = \sum A_i = \sum C_i a_i d,$$

where A_i, C_i, and a_i are the absorption, the concentration, and the absorptivity of a species subscribed i respectively, and where d=optical path length (=7.2 cm). At 216 nm, the species which have large absorptivities are CH_3, C_3H_6, C_2H_4, and C_2H_2. The absorptivity of CH_3 was taken from the values previously reported[10,11] and was expressed by a 4th-order polynominal fit for the temperature. The absorptivity of the other three species were measured from the absorption at the shock front for mixtures diluted in Ar.[12,22] The following expressions of the absorptivity-temperature relation, together with that for CH_3, were incorporated in the computer program:

$$\log a(C_2H_4) = -3430/T + 6.66,^{12}$$
$$\log a(C_2H_2) = -1829/T + 5.88,^{12}$$
$$\log a(C_3H_6) = -3662/T + 8.15.^{22}$$

The lines in Fig. 3 show the A_{10} values for the three mixtures modeled using the reaction mechanism shown in Table 1. We noticed the following disagreements in the two mixtures, though the lines almost went through the data points. In the 1% mixture, the modeled A_{10} value is smaller than the measured value at temperatures lower than 1400 K. The effect of the secondary reactions on the A_{10} value may be negligibly small under the present experimental conditions. Therefore, it is probable that the k_1 and/or k_2 values used are not appropriate to the modeling of the A_{10} value at these low temperatures. The k_2 values shown in Fig. 2 seem to be on a straight line at temperatures as low as 1290 K. However, the light attenuations due to the absorption measured at these low temperatures are small, and the k_2 value evaluated may have much larger data-reading errors than those at high temperatures. As for the k_1 value used, it can be adjusted so as to reproduce the experimental A_{10} value. No further fitting of the modeled A_{10} value to the measured value by adjusting these k values was done because Reactions (1) and (2) have a similar sensitivity for the A_{10}. In the 2% mixture, the modeled A_{10} is slightly larger than the measured one at high temperatures. However, we do not have any clear-cut explanations for the disagreement because almost the same sensitivity spectra were obtained for the 2 and 2.8% mixtures; a nice agreement between the two values is shown in Fig. 3 for the 2.8% mixture.

In the 2.8% mixture, the contributions to the modeled absorption are CH_3; 90%, C_3H_6; 6%, and C_2H_4; 3% at 1300 K and CH_3; 60%, C_3H_6; 27%, and C_2H_4; 12% at 1550 K, and it is found that the effect of C_2H_2 on the A_{10} value is negligible under the present experimental conditions. Thus, it is clear that, with an increase in the temperature, the products by the pyrolysis have much influence on the A_{10} value.

No further modeling for the reported experimental results[5-7] and for the absorption after 10 μs measured in this study were done. Propylene is one of the primary products in the n-C_4H_{10} pyrolysis, but the reaction mechanism of the C_3H_6 pyrolysis at high temperature has not yet been determined.[23] The reaction mechanism proposed by Burcat[24] is not satisfactory in explaining the experimental results measured by means of a 3.39-μm He-Ne laser absorption; that experiment was carried out under conditions similar to the present ones.[23] Since C_3H_6 is subjected to further decomposition as the reaction proceeds at these high temperatures, the ambiguity of the reaction mechanism may give an erroneous result for the modeled product distribution. Moreover, preliminary experimental results[22] by means of the absorption at 216 nm indicate that a large absorption by an unidentified product was measured in the C_3H_6 pyrolysis.

The Determination of the Chemical Diffusion Coefficient of n-Type AgBr by Means of a D.c. Polarization Cell

Jun SASAKI,* Junichiro MIZUSAKI,* Shigeru YAMAUCHI, and Kazuo FUEKI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 23, 1980)

The electronic conductivity of AgBr and the chemical diffusion coefficient of n-type AgBr were measured by means of a d.c. polarization cell, ⊖ Ag/AgBr/inert electrode ⊕, in the temperature range from 325 °C to 400 °C. In order to suppress the electrolysis of AgBr, a platinum plate was used instead of carbon as the inert anode. The chemical diffusion coefficient, $\tilde{D}$, was determined by two methods. One was the intermediate probe method (IP method) whereby the relaxation of the voltage between the Ag reversible electrode and the Pt intermediate probe, inserted into the middle of AgBr, was followed after an abrupt change in the polarization voltage. The other was the open-circuit method (OC method) whereby the terminal voltage of the cell was followed after the circuit of the cell had been opened. The electronic conductivity in the steady state was independent of the nature of the inert electrodes (Pt or C), provided that the inert electrode was completely sealed. However, it took more time for the cell with a carbon electrode to reach the steady state than that with a platinum one. The chemical diffusion coefficient, $\tilde{D}$, determined by the IP method for the Ag/AgBr/Pt cell agreed with that for the Ag/AgBr/C cell. The chemical diffusion coefficient, $\tilde{D}$, determined by the OC method for the Ag/AgBr/Pt cell agreed with that obtained by the IP method. The chemical diffusion coefficients determined by these methods were expressed by

$$\tilde{D} = 3.0 \times 10^3 \exp\left(\frac{-89.0\ \mathrm{kJ\ mol^{-1}}}{RT}\right) / \mathrm{cm^2\ s^{-1}}.$$

No chemical diffusion coefficient can be obtained by the OC method for the Ag/AgBr/C cell, because of the slow diffusion of the Br_2 gas produced by the electrolysis of AgBr from the carbon electrode.

Since the application of the d.c. polarization technique to the investigation of solid ionic conductors by Hebb[1] and Wagner,[2] the method has been used widely to determine the electronic conductivities or chemical diffusion coefficients of halides of silver and copper.[3–19] Mizusaki *et al.*,[7–10] for instance, investigated silver halides by using the following cell:

$$\mathrm{Ag/AgX(X = Cl, Br, I)/C.} \qquad (1)$$

Using the improved cell configuration shown in Fig. 1(a) (A-type cell), they found several important facts as follows:

(i) One can determine the chemical potential profile in AgX under d.c. polarization by measuring the voltage between the Ag electrode and the Pt probes inserted into AgX. The chemical potential profile obtained experimentally agrees with that expected from Wagner's theory.[2]

(ii) In order to obtain the electronic conductivity, the inert electrode (ion-blocking electrode) must be completely sealed.

(iii) The chemical diffusion coefficient, $\tilde{D}$, in AgX can be determined from the relaxation of the voltage between the Ag electrode and the Pt probe inserted into AgX after an abrupt change in the voltage applied to the cell.

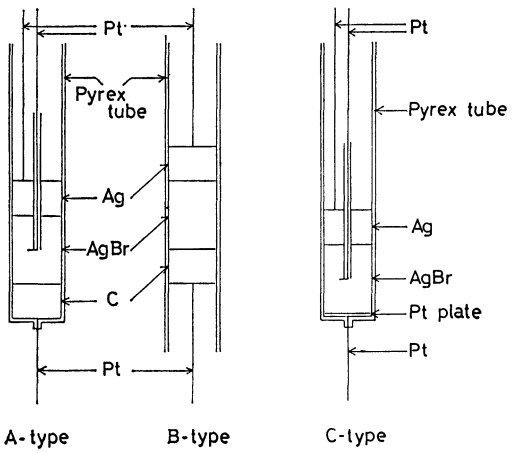

Fig. 1. Configurations of d.c. polarization cell.

The methods for the determination of the chemical diffusion coefficient by using the d.c. polarization cell[6,9,11–17] were classified as follows:

(i)[6,11–15] The method whereby the current is measured with the passage of time after the abrupt change in the polarization potential applied to the cell. (voltage step-transient current method; TC method).

(ii)[9] The method whereby the potential difference between the reversible (reference) electrode and the probe inserted into the sample is measured with the passage of time after a change in the polarization potential (voltage step-intermediate probe method; IP method).

(iii)[16,17] The method whereby the voltage of the cell is followed after the cell circuit has been opened (open circuit method; OC method).

Raleigh[18,19] measured the time change in the current by the TC method using the Ag/AgBr/Pt (or C) cell; he found that the current-time curve involved several time constants. The current was interpreted by the super-imposition of the current due to the charging of the double layer of the AgBr/Pt interface, the current due to the redistribution of electronic carriers within AgBr (chemical diffusion), and the electrolytic current of AgBr. It seems to be difficult, however, to measure these currents separately. Therefore, the TC method is not appropriate for determining the chemical diffusion coefficient.

The IP method has the advantage of measuring the

change in the chemical potential profile directly. However, the influence of the electronic current flowing during the relaxation on the mass transfer caused by the chemical diffusion is not clear. From this point of view, the OC method is considered to be superior to the IP method, because the transient current does not flow during the chemical relaxation.

Weiss[16] determined $\tilde{D}$ in AgBr by means of the OC method using the cell shown in Fig. 1(b) (B-type cell). Since the carbon electrode was exposed to the inert atmosphere, it was doubtful that the decay of the open-circuit voltage gave the correct value of $\tilde{D}$.[9] Even if an A-type cell is used, the Br_2 gas produced by the electrolysis of AgBr diffuses and is absorbed by the carbon electrode. Therefore, the decay of the open-circuit voltage may be supposed not to correspond to the chemical diffusion in AgBr because of the influence of the slow diffusion of Br_2 gas in the carbon electrode. In order to eliminate the influence of Br_2-gas diffusion in the carbon electrode, platinum should be used instead of carbon as follows:

$$\ominus \text{ Ag/AgBr/Pt } \oplus. \qquad \text{(II)}$$

Moreover, the cell configuration shown in Fig. 1(c) (C-type cell) should be used.

The present work aims to determine the electronic conductivity by the d.c. polarization method, and $\tilde{D}$ by means of the IP method and the OC method.

Experimental

Circuit and Measurement Procedure. Figure 2 shows a schematic diagram of the experimental circuit. The polarization voltage was applied by means of a potentiostat. The current was determined by measuring the *IR* drop which appeared between the two ends of a standard resistance, R_s, connected with the cell in series. The potential difference $E(X=L/2)$ between the Ag electrode and Pt probe inserted into AgBr and the open-circulit voltage were recorded by means of a voltage follower with high input impedance.

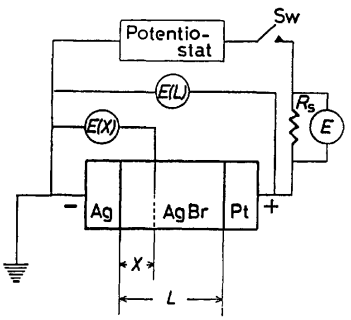

Fig. 2. Schematic diagram of experimental circuit.

IP Method: After the steady state under the applied voltage, E_1, had been attained, a second voltage, E_2, was suddenly applied to the cell by means of a function generator. The time changs in $E(X=L/2)$ and the current were recorded.

OC Method: After the steady state under the applied voltage, $E(L)$, has been attained, the circuit was opened and the time change in $E(L)$ was recorded.

The experiment was carried out in the temperature range from 325 to 400 °C. A polarization voltage below 300 mV was applied. Under these experimental conditions, the electronic conduction of AgBr was of the n-type.

Samples and Cell Configurations. Rod-like single crystals of AgBr were prepared from the powder material of a 99.999% purity by means of the Bridgman method. The rod thus obtained was cut into disks 10 mm in diameter.

Figure 3 shows the construction of the cell. The surface of a platinum plate with platinum-lead wire was polished with 1 μm of alumina abrasive powder and then cleaned with an alkali cleaning solution. The platinum plate was then carefully sealed in a Pyrex tube so that no vacant spaces remained between the Pyrex tube and the platinum plate.

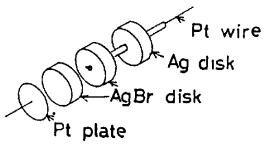

Fig. 3. Cell and samples.

Two AgBr disks of the same size were prepared. A hole 1.2 mm in diameter was drilled in the center of one AgBr disk for inserting the Pt probe. A platinum wire was insulated by means of a mullite tube 1.2 mm in diameter, its tip placed at the center of the interface of two AgBr disks. The surface of each AgBr disk was polished with 1 μm of alumina abrasive powder and cleaned by the use of an ultrasonic cleaner. The cell was constructed in a Pyrex tube 10 mm in inner diameter and was pressed with a slight pressure so that the side surface of the AgBr disk was assured of a good contact with the inside wall of the Pyrex tube as a result of the plastic deformation of AgBr at high temperatures. Thus, a good sealing of the ion-blocking electrode could be obtained.

In the present study, two types of cells, the A-type cell and the C-type cell shown in Fig. 1, were employed. The A-type cell was constructed in a way essentially similar to the C-type cell.

Results and Discussion

Electronic Conductivity. Under the steady state of d.c. polarization, the electronic current flowing in the cell (I) or (II) is represented by:[2,8,10]

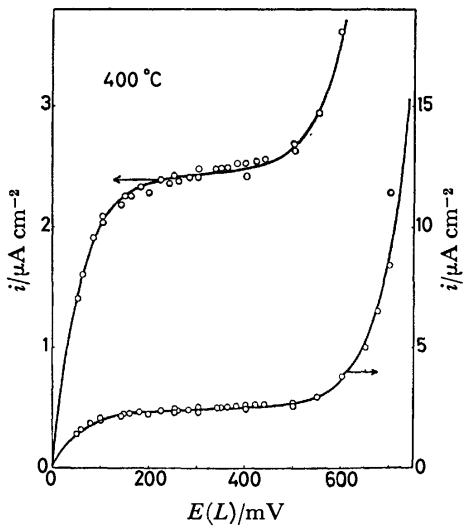

Fig. 4. Plot of i *vs.* $E(L)$ for C-type cell.

$$\frac{iFL}{RT} = \sigma_e^\circ\left[1 - \exp\left(-\frac{E(L)F}{RT}\right)\right] + \sigma_h^\circ\left[\exp\left(\frac{E(L)F}{RT}\right) - 1\right], \quad (1)$$

where L is the thickness of the electrolyte, $E(L)$ is the applied voltage, i is the current density, and σ_e° and σ_h° are the electronic conductivities due to electrons and holes in AgBr in equilibrium with Ag respectively.

Figure 4 shows the plots of i *vs.* $E(L)$ for the C-type cell at 400 °C. By dividing both sides of Eq. 1 by $\exp(E(L)F/RT)-1$, we obtain:[20]

$$\frac{iFL}{RT}\frac{1}{\exp\left(\frac{E(L)F}{RT}\right) - 1} = \sigma_e^\circ \exp\left(-\frac{E(L)F}{RT}\right) + \sigma_h^\circ. \quad (2)$$

From the gradient of the plot of Eq. 2, σ_e° can be determined. Similarly, σ_h° can be determined from the gradient of the plot of the following equation:[20]

$$\frac{iFL}{RT}\frac{1}{1 - \exp\left(-\frac{E(L)F}{RT}\right)} = \sigma_e^\circ + \sigma_h^\circ \exp\left(\frac{E(L)F}{RT}\right). \quad (3)$$

Figure 5 shows the plot of Eq. 2, with a good linear relationship. From the slope of the plot, σ_e° was determined. Similarly, σ_h° was determined from the plot of Eq. 3.

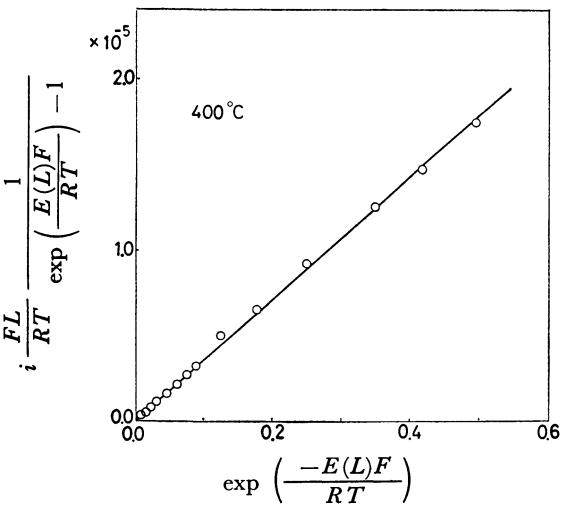

Fig. 5. Plot of $i\frac{FL}{RT}\frac{1}{\exp\left(\frac{E(L)F}{RT}\right)-1}$ *vs.* $\exp\left(\frac{-E(L)F}{RT}\right)$ for C-type cell.

According to Mizusaki *et al.*,[8,10] we can calculate σ_e and σ_h as functions of the chemical potential of bromine. The results are shown in Fig. 6. The broken line indicates the results obtained by Mizusaki *et al.*[8] using the A-type cell. The two sets of results are in good agreement, within the limit of experimental error.

The chemical potential profiles under a steady state were also measured for the C-type cell. The results were in good agreement with those obtained by Mizusaki *et al.*[7] Therefore, it may be concluded that the chemical potential profiles can be well interpreted on the basis

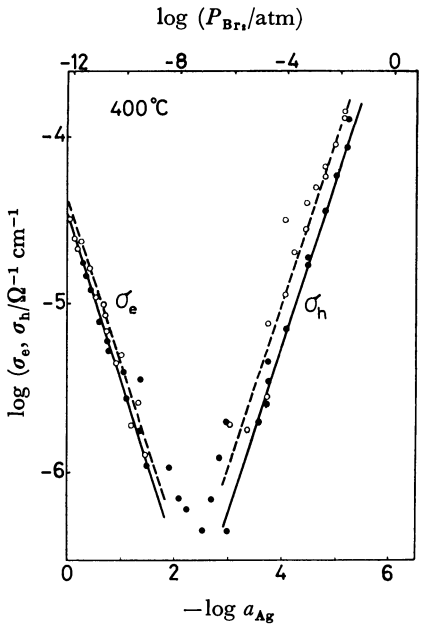

Fig. 6. Plots of σ_e and σ_h *vs.* $-\log a_{Ag}$ for A and C-type cell.
----: Mizusaki *et al.*[8] (A-type cell), ——: this work (C-type cell).

of Wagner's theory[2] and that the same results are obtained under a steady state, whether an A-type cell or a C-type cell is used.

Chemical Diffusion Coefficient. Unlike aqueous electrolyte solutions, solid electrolytes have an electronic conductivity more or less. Therefore, they should be dealt with by the theory on mixed conductors.

According to Ilschner,[3] silver bromide shows n-type conduction under a low polarization potential and at the temperatures studied. Therefore, the silver bromide can be represented by $Ag_{1+\delta}Br$ ($\delta>0$). Mizusaki *et al.*[7] found that δ in silver bromide is distributed linearly under a steady state, as is schematically shown in Fig. 7 (a). The distribution of δ is represented by the following equation:

$$\frac{\delta(X) - \delta^\circ}{\delta(L) - \delta^\circ} = \frac{X}{L}, \quad (4)$$

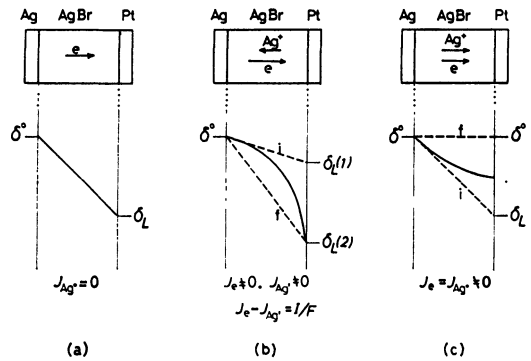

Fig. 7. Schematic diagram of δ profiles.
(a): Steady state, (b): voltage step, (c): open circuit.
i: Initial steady state, t: transient state, f: final steady state.

where $\delta(X)$ denotes δ in $Ag_{1+\delta}Br$ at the distance, X, from the Ag/AgBr interface, L is the thickness of the silver bromide sample, and δ° is δ in $Ag_{1+\delta}Br$ equilibrated with Ag.

Voltage-step Method: After the steady state has been attained under the voltage applied, $E_1(L)$, a second voltage, $E_2(L)$, larger than $E_1(L)$ is abruptly applied to the cell. The chemical potential of silver at the AgBr/inert electrode is immediately fixed to that corresponding to $E_2(L)$. The gradient of the electrical field is compensated for quickly by the motion of the major carrier Ag^+ ions, and the electrochemical potential of the Ag^+ ion becomes uniform throughout the silver bromide. The profile of δ in $Ag_{1+\delta}Br$ changes with the time as is schematically shown in Fig. 7(b). The relaxation process (redistribution of δ) proceeds by means of the counter diffusion of Ag^+ ions and electrons, and the rate is determined exclusively by the diffusion of excess silver atoms. Therefore, the relaxation of δ can be expressed by this equation:

$$\frac{\partial\delta}{\partial t} = \tilde{D}\frac{\partial^2\delta}{\partial X^2}, \tag{5}$$

where $\tilde{D}$ denotes the chemical diffusion coefficient in n-type AgBr. The chemical diffusion coefficient, $\tilde{D}$, is determined by solving Eq. 5 analytically with the following boundary conditions:

$$\frac{\delta(X,0)-\delta^\circ}{\delta(L,0)-\delta^\circ} = \frac{X}{L} \qquad t=0, \tag{6}$$

$$\delta(L,t) = \delta^\circ \exp\left(-\frac{E_1(L)F}{RT}\right) \qquad t<0, \tag{7}$$

$$\delta(L,t) = \delta^\circ \exp\left(-\frac{E_2(L)F}{RT}\right) \qquad t\geqslant 0, \tag{8}$$

$$\delta(0,t) = \delta^\circ, \tag{9}$$

where $\delta(X,t)$ denotes the value of δ at a position X apart from the Ag/AgBr interface and at a time t. When t is sufficiently large, the solution of Eq. 5 at $X=L/2$ is:[9]

$$\frac{\delta(L/2,\infty)-\delta(L/2,t)}{\delta(L/2,\infty)-\delta(L/2.0)} = \frac{4}{\pi}\exp\left(-\frac{D\pi^2 t}{L^2}\right). \tag{10}$$

The nonstoichiometry $\delta(X)$ is related to $E(X)$ by means of this equation:

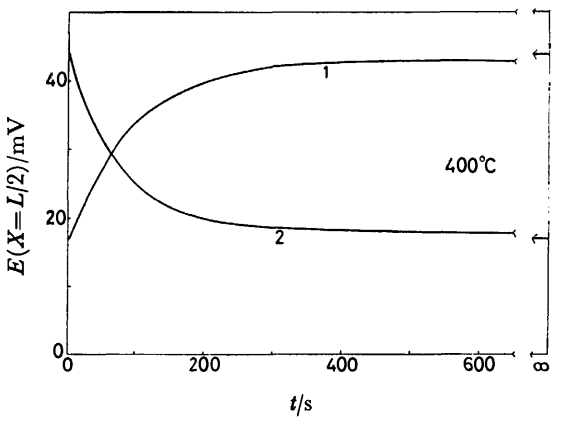

Fig. 8. Time change of $E(L/2)$ for C-type cell.
1: $E(L)$, 40 mV 200 mV, 2: $E(L)$, 200 mV 40 mV.

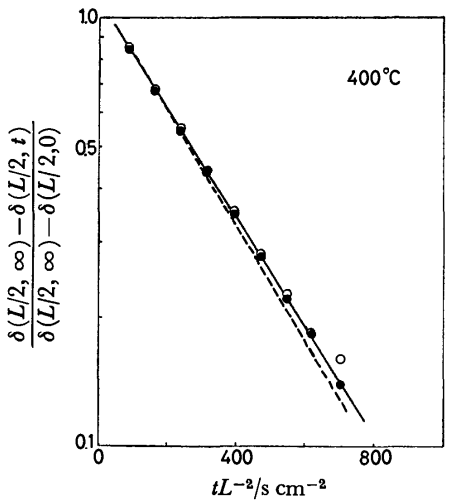

Fig. 9. Plots of $\frac{\delta(L/2,\infty)-\delta(L/2,t)}{\delta(L/2,\infty)-\delta(L/2,0)}$ *vs.* tL^{-2}.
●: $E(L)$, 40 mV→200 mV, ○: $E(L)$, 200 mV→40 mV, ——: this work (C-type cell), -----: Mizusaki *et al.*[9] (A-type cell).

$$\delta(X) = \delta^\circ \exp\left(-\frac{E(X)F}{RT}\right). \tag{11}$$

The time change in $\delta(L/2)$ is calculated from the change in $E(L/2)$.

Figure 8 shows the time change in $E(L/2)$ for the C-type cell. $\tilde{D}$ is determined from the slope of the plot of $\log[\{\delta(L/2,\infty)-\delta(L/2,t)\}/\{\delta(L/2,\infty)-\delta(L/2,0)\}]$ *vs.* tL^{-2}. Figure 9 shows the plot. In the figure, the results of the A-type cell are also given. A good agreement is seen between the $\tilde{D}$ values obtained using both types of cells. The results clearly indicate that the IP method gives the same $\tilde{D}$ values, regardless of the nature of the inert electrode.

Open-circuit Method: In the case of the voltage-step method, the electronic current is driven not by the electrical field, but by the concentration gradient of the electrons. The ionic current due to silver ions is not equal to the electronic current ($J_e - J_{Ag^+} \neq 0$) during the relaxation, as is shown in Fig. 7(b). The difference is observed as the current flowing in the external circuit, and it does not correspond to the flux of mass transport due to the relaxation.

In the case of the OC method, the relaxation proceeeds by means of the ambipolar diffusion of silver ions and electrons, because no net current flows in the external circuit. Therefore, the same diffusion situation as in the metal oxidation is set up in this method.

By solving Eq. 5 with the following boundary conditions:

$$\frac{\delta(X,0)-\delta^\circ}{\delta(L,0)-\delta^\circ} = \frac{X}{L} \qquad t=0 \tag{12}$$

$$\frac{\partial(L,t)}{\partial X} = 0 \qquad t<0 \tag{13}$$

$$\delta(0,t) = \delta^\circ \qquad t\geqslant 0 \tag{14}$$

we obtain:

$$\frac{\delta^\circ - \delta(L,t)}{\delta^\circ - \delta(L,0)} = \frac{8}{\pi^2}\exp\left(\frac{\tilde{D}\pi^2 t}{4L^2}\right) \quad (15)$$

for a sufficiently large t. The time change in $\delta(L,t)$ is calculated from $E(L,t)$ by using Eq. 11.

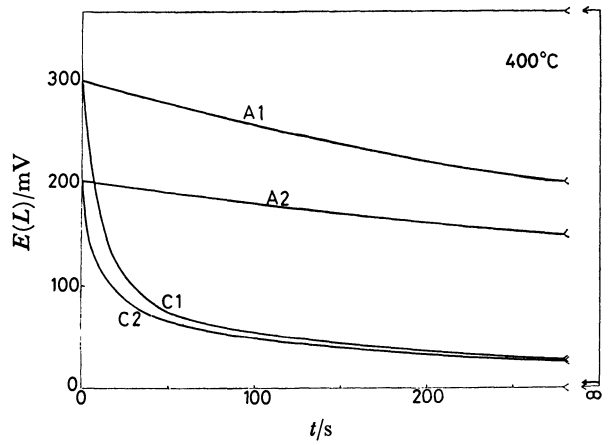

Fig. 10. Time change of $E(L)$ for A and C-type cell.
A1: $E(L)=300$ mV (A-type cell), A2: $E(L)=200$ mV (A-type cell), C1: $E(L)=300$ mV (C-type cell), C2: $E(L)=200$ mV (C-type cell).

Accordingly, $\tilde{D}$ is determined from the slopes of the plot of $\log[\{\delta^\circ-\delta(L,t)\}/\{\delta^\circ-\delta(L,0)\}]$ *vs.* tL^{-2}. Figure 10 shows the time change in the open-circuit voltage $E(L,t)$. As can be seen from the figure, the decay of $E(L,t)$ for the A-type cell is very slow and the reproducibility is poor. On the other hand, the time change in $E(L,t)$ for the C-type cell is reproducible.

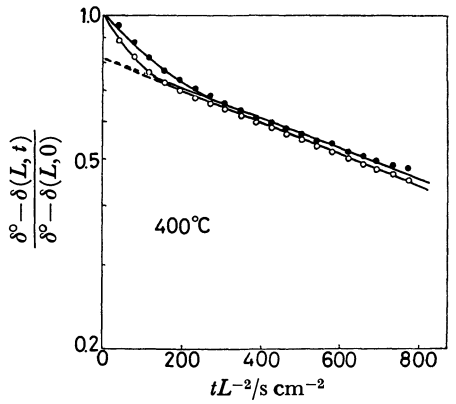

Fig. 11. Plots of $\frac{\delta^\circ-\delta(L,t)}{\delta^\circ-\delta(L,0)}$ *vs.* tL^{-2} for C-type cell.
●: $E(L,0)=300$ mV, ○: $E(L,0)=200$ mV.

Figure 11 gives the plots for determining $\tilde{D}$. This figure shows that $\tilde{D}$ is independent of the voltage applied before opening the circuit. Therefore, $\tilde{D}$ in n-type AgBr may be supposed to be independent of δ. From the decay in $E(L,t)$ for the A-type cell, we can not determine the $\tilde{D}$, for the plot of $\log[\{\delta^\circ-\delta(L,t)\}/\{\delta^\circ-\delta(L,0)\}]$ *vs.* tL^{-2} is curved.

Figure 12 shows the plots of $\log[\{\delta^\circ-\delta(L,t)\}/\{\delta^\circ-\delta(L,0)\}]$ *vs.* tL^{-2} for the C-type cell. As can be seen from the figure, $\tilde{D}$ is independent of the thickness of AgBr. Therefore, it may be concluded that the decay of $E(L,t)$ for the cell is due to the relaxation of δ within AgBr.

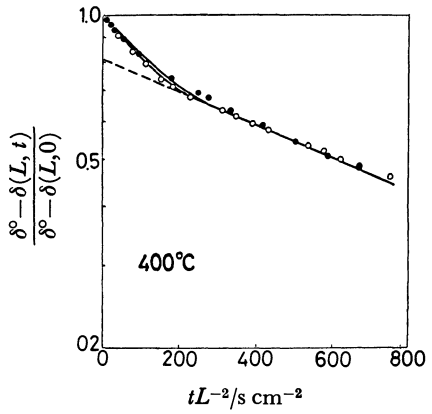

Fig. 12. Plots of $\frac{\delta^\circ-\delta(L,t)}{\delta^\circ-\delta(L,0)}$ *vs.* tL^{-2} for C-type cell.
●: $L=0.84$ cm, ○: $L=0.51$ cm.

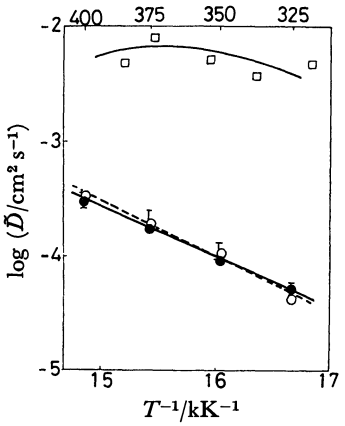

Fig. 13. Arrhenius plots of $\tilde{D}$.
□: B-type cell be Weiss[16] (OC method), I : A-type cell by Mizusaki *et al.*[9] (IP method), —●—: C-type cell in this work (IP method), --○--: C-type cell in this work (OC method).

Figure 13 gives the Arrhenius plot for $\tilde{D}$ of n-type AgBr. The chemical diffusion coefficient, $\tilde{D}$, determined by the IP method using the A and C-type cells and that determined by the OC method using the C-type cell are in good agreement. Therefore, the electronic current driven by the concentration gradient does not affect the mass transfer due to the chemical relaxation. However, $\tilde{D}$ can not be determined by the OC method when the A-type cell is used. This may be due to the diffusion and absorption of the Br_2 gas produced by the electrolysis of AgBr in the carbon electrode.

Weiss'[16] data obtained by the OC method using the B-type cell is one order of magnitude larger than the other data. In his experiment, the carbon electrode was exposed to an inert atmosphere, and bromine gas was supposed to be liberated at the AgBr/C interface by the electrolysis of AgBr. Therefore, larger $\tilde{D}$ values were obtained.

From these results, it seems that the OC method can be used provided that the inert electrode does not absorb or does not react with the electrolysis product. Platinum and gold seem to be appropriate as inert electrodes for the OC method. However, at a high polarization potential (for example, above 777 mV for Ag/AgBr/Pt cell at 400 °C), platinum bromide are produced at the AgBr/Pt interface.[21] Although gold does not react with bromine at a high polarization potential, the formation of a solid solution with AgBr must be taken into account.

Visible Light-induced Oxidation of Ascorbic Acid and Formation of Hydrogen Peroxide

Yoshimi KURIMURA,* Hiroshi YOKOTA, and Yuko MURAKI
Department of Chemistry, Ibaraki University, Mito 310
(Received December 23, 1980)

Photosensitized oxidation of ascorbic acid and the formation of hydrogen peroxide using tris(2,2'-bipyridine)-ruthenium(II), $Ru(bpy)_3^{2+}$, proceed simultaneously in oxygen containing an aqueous solution of ascorbic acid with the illumination of visible light. The mechanism of the reaction has been suggested from the rate dependence on the solute concentrations and from quenching experiments. The charge separation could be achieved as the result of scavenging $Ru(bpy)_3^{3+}$, which is formed by the reaction of the lowest excited state species of $Ru(bpy)_3^{2+}$ with O_2.

The luminescence quenching of $Ru(bpy)_3^{2+}$ by various substances is a subject of much current interest.[1-12] The lowest excited state of $Ru(bpy)_3^{2+}$, $*Ru(bpy)_3^{2+}$, is able to react with an electron-transfer reagent.[13,14] The oxidative and reductive quenchings of $Ru(bpy)_3^{2+}$ give $Ru(bpy)_3^{3+}$ as a strong oxidant and $Ru(bpy)_3^{+}$ as a strong reductant, respectively. In most photosystems the utilization of the redox properties of photo-generated $Ru(bpy)_3^{3+}$ or $Ru(bpy)_3^{+}$ is prevented because of fast back-electron-transfer reactions.[12]

The ability of $*Ru(bpy)_3^{2+}$ to act as an electron donor or acceptor has been utilized in several prototype models of solar energy conversion.[15-18] Hydrogen evolution by water splitting with the irradiation of visible light has been extensively studied.[19,20] However, relatively little attention has been paid to the productions of superoxide ion,[21,22] and hydrogen peroxide[22] in the reaction of $*Ru(bpy)_3^{2+}$ with molecular oxygen. The reductions of O_2 to O_2^- and H_2O_2 are both up-hill reactions, *e. g.*, the standard free energy changes for the production of O_2^- and H_2O_2 from O_2 are 129 kJ mol^{-1} ($E_0'(O_2/O_2^-) = -0.32$ V)[23] and 274 kJ mol^{-1} ($E_0(O_2/H_2O_2) = -0.68$ V),[23] respectively. The excited state of $Ru(bpy)_3^{2+}$ is rapidly quenched by O_2 to produce O_2^-: the quenching rate constants obtained were 3.3×10^9 M^{-1} s^{-1} [24] and 3.7×10^9 M^{-1} s^{-1} [25] (1 M = 1 mol dm^{-3}) in neutral aqueous solution and 3.0×10^9 M^{-1} s^{-1} in 0.5 M HCl.[22] Fast back-reaction of the $Ru(bpy)_3^{3+}$ with O_2^-, however, occurs and the production of hydrogen peroxide could not be observed in the $Ru(bpy)_3^{2+}/O_2$ system.

We found that hydrogen peroxide was formed in the solution containing oxygen, using ascorbate ion as a scavenger of $Ru(bpy)_3^{3+}$. So we have investigated the mechanism of visible-light induced formation of hydrogen peroxide in the $Ru(bpy)_3^{2+}$/ascorbic acid/O_2 system.

Experimental

$[Ru(bpy)_3]Cl_2\cdot6H_2O$ was prepared according to the literature method[26] and recrystallized twice from water. Ascorbic acid from Kanto Kagaku was used without further purification.

The ionic strength of the irradiated samples were maintained at 0.2 by sodium chloride. The hydrogen ion concentration was adjusted by acetate buffers. An oxygen- or air-saturated aqueous solution containing $Ru(bpy)_3^{2+}$ and ascorbic acid in a cylindrical glass cell (40-mm diameter and 15-mm thickness) with a glass cap was liluminated by a 150 W tungsten lamp with a UV cut-off filter (Kenko, Skylight L-40, UV) at 25±0.2 °C.

The irradiation sample (2 ml) was poured into a column (10-mm diameter and 30-mm length) of cation-exchange resins (Dowex 50 W, X-8, 100—200 mesh, the hydrogen form), followed by washing with water. The concentrations of hydrogen peroxide[27] and dehydroascorbic acid[28] in the eluant were determined by a colorimetric method. The absorption spectra were observed with a Hitachi Model 320 spectrophotometer.

The quenching experiments were carried out by using a Shimadzu Model RF-500 spectrofluorometer at 25±0.1 °C. For the luminescence experiments, the excitation was carried out at 455 nm. If necessary, dissolved oxygen in the samples was removed by flushing nitrogen gas, which was passed through an alkanine pyrogallol solution. The concentration of the dissolved oxygen in the solutions was adjusted by saturations of air and pure oxygen under atmospheric pressure at 25±0.2 °C.

Results

In the air- and oxygen-saturated solutions containing $Ru(bpy)_3^{2+}$ and ascorbic acid (AH_2) at pH 3.1—5.5, the formation reaction of hydrogen peroxide and the oxidation reaction of ascorbic acid proceeded simultaneously with the illumination of visible light, while the absorption spectrum of the solution in the visible

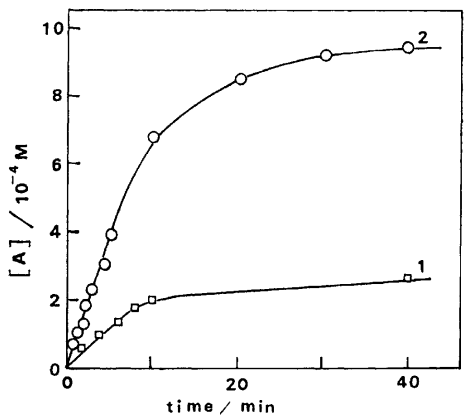

Fig. 1. Plots of [A] *vs.* time in $Ru(bpy)_3^{2+}/AH_2$ solutions at pH 4.6 and 25 °C.
$[Ru(bpy)_3^{2+}] = 1.0\times10^{-4}$ M, $[AH_2]_T = 1.0\times10^{-3}$ M,
1: air-saturated solution, 2: O_2-saturated solution.

region was unchanged during 1 h illumination. These results show that the $Ru(bpy)_3^{2+}$ photosensitized production of hydrogen peroxide occurs in the $Ru(bpy)_3^{2+}/AH_2/O_2$ system.

The plots of the concentration of dehydroascorbic acid (A) against the illumination time in oxygen-saturated and air-saturated solutions are shown in Fig. 1. The oxidation rates of ascorbic acid to dehydroascorbic acid, d[A]/dt, were determined from the slopes of [A] *vs.* time plots. The saturation of [A] *vs.* time curves is seen in Fig. 1 as the result of consumption of the dissolved oxygen in the solutions.

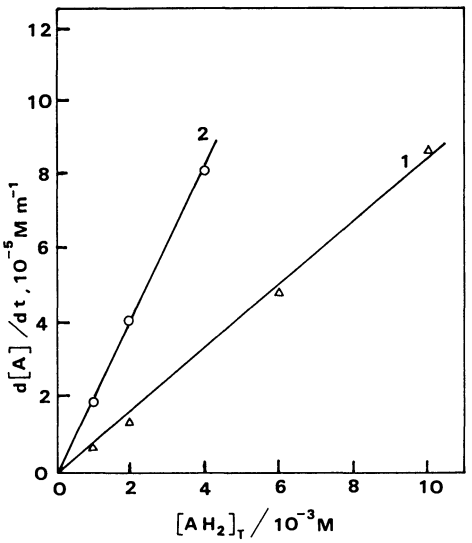

Fig. 2. Dependence of rate on ascorbic acid concentration in air-saturated (1) and O_2-saturated (2) solutions at pH 4.6 and 25 °C.
$[Ru(bpy)_3^{2+}]=1.0\times10^{-4}$ M.

The dependence of the rate on the total concentration of ascorbic acid, $[AH_2]_T$, is shown in Fig. 2. The oxidation rate of ascorbic acid was found to be proportional to the ascorbic acid concentration in the lower concentration region of the acid at a given pH.

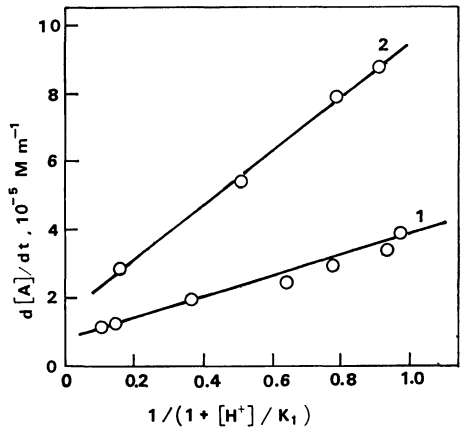

Fig. 3. Plots of d[A]/dt *vs.* $1/(1+[H^+]/K_1)$ in air-saturated (1) and O_2-saturated (2) solutions at 25 °C.
$[Ru(bpy)_3^{2+}]=1.0\times10^{-4}$ M, $[AH_2]_T=1.0\times10^{-3}$ M.

In Fig. 3 the rates are plotted as a function of $1/(1+K_1/[H^+])$ where K_1 is the dissociation constant of Reaction 1: the value of $1/(1+K_1/[H^+])$ is proportional to the concentration of ascorbate monoanion, $[AH^-]$. Under the conditions employed, Reaction 2 can be neglected. The acid dissociation constants of

$$AH_2 \overset{K_1}{\rightleftharpoons} AH^- + H^+ \quad (1)$$

$$AH^- \overset{K_2}{\rightleftharpoons} A^{2-} + H^+ \quad (2)$$

Reactions 1 and 2 are reported to be $K_1=9.16\times10^{-5}$ M and $K_2=4.57\times10^{-12}$ M at 25 °C, respectively.[29]

The rate is also dependent on the concentration of the dissolved oxygen: the ratios of the rates in the oxygen-saturated and air-saturated solutions range from 2.4 to 2.6 (Fig. 3).

The values of product distribution, $[H_2O_2]/[A]$, in the illuminated solutions under various conditions are shown in Table 1. This table shows that the observed $[H_2O_2]/[A]$ ratio are around 0.6.

Table 1. Product distributions in the irradiated solutions[a]

pH	$\frac{[H_2O_2]}{10^{-4}\,M}$	$\frac{[A]}{10^{-4}\,M}$	$\frac{[H_2O_2]}{[A]}$	Sat. gas
3.5[b]	1.86	2.68	0.69	Air
3.6[c]	1.14	1.79	0.64	Air
4.5[c]	1.66	2.61	0.64	Air
5.4[c]	1.32	2.13	0.62	Air
3.3[c]	4.18	8.34	0.50	Oxygen
4.1[e]	4.20	7.99	0.53	Oxygen
4.6[c]	5.68	9.85	0.58	Oxygen
5.0[c]	4.88	8.23	0.59	Oxygen

a) 1.0×10^{-3} M AH_2, 1.0×10^{-4} M $Ru(bpy)_3^{2+}$, μ= 0.2, 25 °C. b) Illumination time 25 min. c) Illumination time 10 min. d) Illumination time 60 min. e) Illumination time 30 min.

By the determination of the concentration of ascorbic acid or hydrogen peroxide in the solutions at pH 5.5 and 25 °C, it was observed that a) the oxidation reaction of ascorbic acid by dissolved oxygen in the O_2-saturated solution can be neglected compared with the photosensitized oxidation of ascorbic acid and b) no appreciable

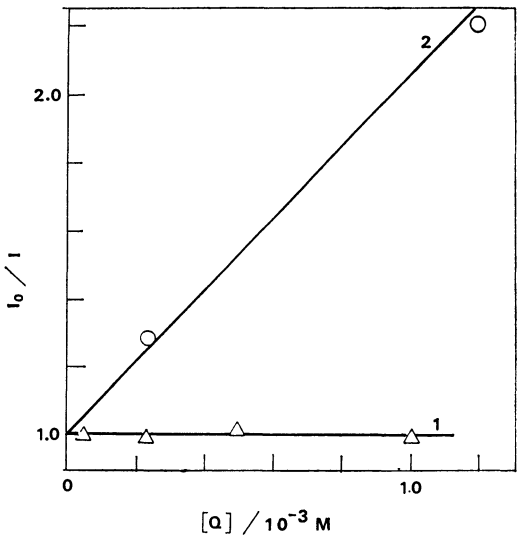

Fig. 4. Stern-Volmer plots at pH 4.6 and 25 °C.

decomposition of hydrogen peroxide occurred during 30 min illumination of an oxygen-saturated solution containing 2.0×10^{-4} M $Ru(bpy)_3^{2+}$ and 1.0×10^{-3} M H_2O_2.

The luminescence quenching studies were carried out in $Ru(bpy)_3^{2+}/O_2$ and deaerated $Ru(bpy)_3^{2+}$/ascorbic acid solutions at pH 4.6. The Stern-Volmer plots for these systems are shown in Fig. 4. From the results shown in this figure, we conclude that the predominant species that reacts with $*Ru(bpy)_3^{2+}$ is the dissolved oxygen. The Stern-Volmer constant estimated from slope 2 in Fig. 4 was 1900 M^{-1} and the quenching rate constant, k_q, for $*Ru(bpy)_3^{2+}$ by O_2 was 3.2×10^9 $M^{-1}\,s^{-1}$ at 25 °C, since the excited state life time of $*Ru(bpy)_3^{2+}$ is known to be 6.0×10^{-7} s.[30]

Discussion

The rate profiles shown in Figs. 1 to 3 indicate that the rates depend on the concentrations of ascorbic acid and O_2 and that the reactive species of the acid is the ascorbate anion, AH^-. The results of the quenching experiments (Fig. 4) show that the reaction of $*Ru(bpy)_3^{2+}$ with AH^- can be ignored compared with that of $*Ru(bpy)_3^{2+}$ with O_2 under the conditions employed.

The proposed reaction mechanism responsible for the experimental results is given by Reactions 3 to 13.

$$Ru(bpy)_3^{2+} \xrightarrow{h\nu} *Ru(bpy)_3^{2+} \quad (3)$$

The $*Ru(bpy)_3^{2+}$ reacts with O_2 to give a superoxide ion. At low pH the superoxide ion becomes an HO_2 radical. The scavanging reaction of $Ru(bpy)_3^{3+}$ by ascorbate anion competes for the back-electron-transfer reaction.

$$*Ru(bpy)_3^{2+} + O_2 \longrightarrow Ru(bpy)_3^{3+} + O_2^- \quad (4)$$

$$O_2^- + H^+ \rightleftharpoons HO_2 \qquad pK\,4.8^{31} \quad (5)$$

$$Ru(bpy)_3^{3+} + AH^- \rightleftharpoons Ru(bpy)_3^{2+} + AH\cdot \quad (6)$$

$$Ru(bpy)_3^{3+} + O_2^-(\text{or } HO_2) \longrightarrow Ru(bpy)_3^{2+} + O_2(\text{or } O_2 + H^+), \quad (7)$$

where AH· is the ascorbic acid radical. The superoxide ion and HO_2 radical oxidize the ascorbic acid.[29] When the concentration of ascorbic acid is low, the disproportionation reactions of O_2^- and HO_2 occur.[32,33] The HO_2 radical is, presumably, decomposed by Reactions 12 and 13.[29] The rate constant of Reaction 13 was estimated to be 8×10^7 $M^{-1}\,s^{-1}$ in the pH range 2.5—4.0.[34]

$$AH^- + O_2^- + 2H^+ \longrightarrow AH\cdot + H_2O_2 \quad (8)$$

$$AH_2 + HO_2 \rightleftharpoons AH\cdot + H_2O_2 \quad (9)$$

$$O_2^- + O_2^- + 2H^+ \longrightarrow H_2O_2 + O_2 \quad (10)$$

$$HO_2 + HO_2 \longrightarrow H_2O_2 + O_2 \quad (11)$$

$$AH\cdot + O_2 \longrightarrow A + HO_2 \quad (12)$$

$$AH\cdot + AH\cdot \longrightarrow A + AH_2 \quad (13)$$

The rate constants for the forward reaction, k_{14} (Eq. 14), and backward reaction, k_{15} (Eq. 15), were determined by means of flash photolysis by Creutz and Sutin[35] to be $k_{14}=2\times10^7$ $M^{-1}\,s^{-1}$ and $k_{15}=1\times10^9$ $M^{-1}\,s^{-1}$ at 25 °C.

$$*Ru(bpy)_3^{2+} + AH^- \xrightarrow{k_{14}} Ru(bpy)_3^{3+} + AH\cdot \quad (14)$$

$$Ru(bpy)_3^{2+}\,AH\cdot \xrightarrow{k_{15}} Ru(bpy)_3^{3+} + AH^- \quad (15)$$

By assuming the competition between Reactions 4 and 14 the fraction of $*Ru(bpy)_3^{2+}$ molecules scavenged by AH^-, f, is given by:

$$f=\frac{1}{1+k_4[O_2]/k_{14}[AH^-]}. \quad (16)$$

Using $k_4=3.2\times10^9$ $M^{-1}\,s^{-1}$ and $k_{14}=2\times10^7$ $M^{-1}\,s^{-1}$,[34] we can derive $f<0.03$ in the air-saturated solution and $f<0.006$ in the O_2-saturated solution under the conditions employed. The results seem to support the contention that the reaction of $*Ru(bpy)_3^{2+}$ with AH^- could be essentially ignored.

The luminescence quenching efficiency of $*Ru(bpy)_3^{2+}$ by O_2 and thus the rate would increase with an increase in the concentration of O_2. The ratio of the amounts of $*Ru(bpy)_3^{2+}$ being oxidized to $Ru(bpy)_3^{3+}$ by Reaction 4 in the oxygen- and air-saturated solutions would correspond to $(I_0-I_{O_2})/(I_0-I_{air})$ where I_0, I_{O_2}, and I_{air} are the relative luminescence intensities in the deaerated, oxygen-saturated, and air-saturated $Ru(bpy)_3^{2+}$ solutions, respectively. The ratio was estimated to be about 2.8 from the results shown in Fig. 4. The ratio of the rates in O_2-saturated and air-saturated solutions, $(d[A]/dt)_{O_2}/(d[A]/dt)_{air}=2.6$, is essentially in agreement with the value of $(I_0-I_{O_2})/(I_0-I_{air})$.

Dependence of the rate on $[AH_2]_T$ (Fig. 3) would account for the competition between Reactions 6 and 7 for $Ru(bpy)_3^{3+}$. A linear dependence of the rate on $[AH_2]_T$ at lower $[AH_2]_T$ indicates that the rate of Reaction 7 increases almost linearly with $[AH^-]$. The relatively small increase in the rate in the higher concentration region of ascorbic acid is attributable to that $k_7[O_2^-]$ or $k_7'[HO_2]$, where k_7 and k_7' are the rate constants of $Ru(bpy)_3^{3+}$ with O_2^- and $Ru(bpy)_3^{3+}$ with HO_2 respectively, is not so much different from $k_8[AH^-]$. When the concentration of the ascorbic acid becomes high enough for scavenging $Ru(bpy)_3^{3+}$, the rate would not depend on $[AH_2]_T$ any longer.

According to Reactions 3 to 13, the stoichiometric ratio of $[H_2O_2]/[A]$ should be about unity, whereas the observed product distributions (Table 1) show that the ratio was 0.5—0.7. This lower value of the observed ratio is probably attributable to the chain decomposition reaction of H_2O_2.[32] Such cahin reactions would occur when the concentration of H_2O_2 becomes high enough for HO_2 to react with H_2O_2 instead of with ascorbic

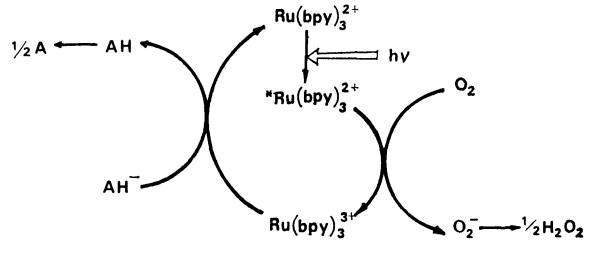

Fig. 5. Schematic representation of the photosensitized reaction.

acid (Eqs. 8 and 9) or with itself (Eqs. 10 and 11).

$$HO_2 + H_2O_2 \longrightarrow H_2O + O_2 + OH \quad (17)$$

$$H_2O_2 + OH \longrightarrow H_2O + HO_2 \quad (18)$$

Similar chain decomposition reactions would occur for O_2^- instead of HO_2. The reactions of OH radical with ascorbic acid and $Ru(bpy)_3^{2+}$ have to be considered.

The main features of the $Ru(bpy)_3^{2+}$ photosensitized reaction are illustrated schematically in Fig. 5. The ratio of the rate of the electron-transfer reaction (Eq. 4) to that of the back-electron-transfer reaction (Eq. 7) would determine the efficiency of the charge-separation of the reaction of $Ru(bpy)_3^{2+}$ with O_2 and thus that of the photosensitized reaction under study.

An Electron Spin Resonance Study of the Phosphorescent Triplet State of Poly(vinylnaphthalene)s

Jiro HIGUCHI,* Mikio YAGI, Juichiro SAITO, and Midori TAKANASHI

Department of Chemistry, Faculty of Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240

(Received February 14, 1981)

The electron spin resonance (ESR) of poly(1-vinylnaphthalene) and poly(2-vinylnaphthalene) in their phosphorescent triplet states is studied in glassy solutions and in plastic hosts. The zero-field splitting parameters thus obtained are discussed in comparison with those of 1- and 2-methylnaphthalene. Through the ESR measurement, the possibility of detecting the triplet energy transfer through the naphthyl groups is examined.

The lowest triplet state of vinyl polymers with aromatic groups attached has been investigated mainly in connection with their intramolecular energy transfer through aromatic chromophores, by measuring the delayed fluorescence and phosphorescence spectra at low temperatures.[1] Nevertheless, comparatively little attention has been paid to studies of their electron spin resonance (ESR), especially for synthetic polymers. If the naphthyl groups are attached to polymeric chains, their fairly strong phosphorescent ESR signals may be expected to be observed in rigid glasses, judging from those of the naphthalene molecule. In the present work, therefore, ESR studies of poly(1-vinylnaphthalene) (P1-VN) and poly(2-vinylnaphthalene) (P2-VN) in their lowest triplet states are taken up as typical examples of such works.

Experimental

The P1-VN and P2-VN were purchased from Polysciences, Inc., and were purified repeatedly by dissolving in tetrahydrofuran and by precipitation with methanol (after a purification, the molecular weights of P1-VN and P2-VN were $M_w=3.4\times10^3$ and $M_n=2.0\times10^3$, and $M_w=1.93\times10^4$ and $M_n=9.2\times10^3$, respectively). The 1-methylnaphthalene (1-MN) and 2-methylnaphthalene (2-MN) were obtained from Tokyo Kasei Co. and were used without further purification, because the ESR signals of the other molecules could not be detected. The ESR spectra were observed in 2-methyltetrahydrofuran (MTHF) glasses. As the plastic host of these polymers, stretched atactic polystyrene (PS) film was used, because it is very hard for isotactic PS to form transparent films from either a toluene or a 1,3,5-trimethylbenzene solution. By evaporating the toluene from a solution containing a 50 : 1 (*w*/*w*) mixture of PS and a sample in a glass vessel on a hot plate, a transparent film was obtained on the glass. Then the film was stretched at 80 °C. The films thus obtained had about 200% of stretch in the stretched direction.

The details of the ESR experiment are exactly the same as in our previous works,[2,3] except for the use of an additional apparatus of JES-UCT-2AX variable-temperature adapter and a JES-VT-3 variable-temperature controller when the measurements were carried out at temperatures above 77 K.

Results and Discussion

In comparison with the ESR spectrum of the naphthalene molecule, the line shapes for P1-VN and P2-VN resemble each other closely, but their intensities are relatively weak in MTHF glasses at 77 K. The zero-field splitting (ZFS) parameters obtained under the same conditions are listed in Table 1. For the naphthalene molecule, the coordinate axes were taken as follows: the x axis is parallel to the longest direction of the molecule, and the y axis is perpendicular to it in the molecular plane, while the z axis is perpendicular to the molecular plane. The directions of the magnetic principal axes of the PVN and MN molecules were assumed not to deviate largely from those of the naphthalene molecule, although they could not be determined in the present work. The results for the ZFS parameters may be summarized as follows: for naphthalene and 1- and 2-MN, the present values are slightly different from those obtained in EPA glasses by Yamanashi and Bowers.[5] (1) The D and $|E|$ values of 1-MN are both smaller than the respective values of 2-MN, although such a relation is completely reversed in the latter work. (2) Similarly, the D and $|E|$ values of P1-VN are both smaller than the corresponding values of P2-VN. (3) Each D value of these polymers is smaller than that of the corresponding MN, while such differences are hardly found at all for the E values.

These relations can reasonably be explained in terms of the spin distributions of these molecules, except for the E values described in (3). That is, since, in the naphthalene molecule, the spin density at the 2 position of the carbon atom is smaller than that at the 1 position, the spin delocalization from the naphthyl group in 2-naphthyl substituents is smaller than that in 1-

a) Observed in MTHF glasses at 77 K. b) $D^*=(D^2+3E^2)^{1/2}$. c) Obtained from the observed resonance field of the $\Delta m=\pm2$ transition with Kottis-Lefebvre's correction.[4]

naphthyl ones. Also, such spin delocalization may generally be larger for P1- and P2-VN than for the corresponding MN molecule. The above elucidation is actually based on the hyperconjugation-type consideration. On the other hand, the results of (3) may possibly be interpreted as being caused by the influence of the triplet-energy transfer which occurs slightly through the naphthyl groups at 77 K. The intramolecular triplet-energy transfer through naphthyl groups has been demonstrated by Cozzens and Fox for P1-VN in a THF: diethyl ether (1 : 1) glass at 77 K through the measurements of the delayed fluorescence due to triplet-triplet annihilation.[6] In P1- and P2-VN, therefore, the triplet exciton may mainly move along the polymer chain if the normal axes of naphthyl groups are locally aligned on this direction. In that case, only the D value of PVN slightly decreases from that of the corresponding MN, while the E value is hardly changed.

Until now, the intramolecular triplet-energy transfer through naphthyl groups has been optically studied in P1-VN[6-8] and P2-VN.[8-11] In the present work, the possibility of detecting such a triplet exciton was examined from the change in the ESR line shapes at different temperatures where the rates of triplet-energy transfer may be appreciably changed. Generally, the use of glassy solutions does not permit the detection of the phosphorescent ESR signals at temperatures where the host glass is not rigid. For observing the line shapes over a fairly wide range of temperature, therefore, a stretched PS film was used as a host.

The ZFS parameters obtained in the PS films at 77 K are slightly smaller than those in MTHF glasses, although the line shapes become rather broad. With a rise in the temperature, the intensity of each peak with the $\Delta m=\pm 1$ transition decreases and the line shapes become broad. The peak intensities for P2-VN are quite weak as compared with those of P1-VN. Therefore, further experiments were carried out for only P1-VN and its reference compound of 1-MN. The signals of the $\Delta m=\pm 1$ transition observed at 77 K barely showed a little anisotropy due to the directions of the stretched film against the applied magnetic field. Because of the lowering of the peak intensities, it may be impossible to deduce some meaningful information from its detection at higher temperatures. Actually, its Z peaks could not be detected near 160 K.

On the other hand, it is possible to detect the triplet ESR signal of P1-VN with the $\Delta m=\pm 2$ transition with an appreciable deformation of line shape at a temperature not higher than 160 K. Figure 1 shows the ESR spectra of the $\Delta m=\pm 2$ transition for P1-VN and 1-MN in stretched PS films at 77 K and 160 K. It may be noted here that these samples all contain roughly the same amount of naphthyl groups. For P1-VN, the line shape observed at 160 K becomes fairly broad as compared with that at 77 K, while that of 1-MN is hardly changed over the temperature range studied. This may suggest that some intramolecular triplet-energy transfer through naphthyl groups in the same polymer chain occurs for P1-VN, for the distances between adjacent naphthyl groups along a polymer chain are fairly small as compared with those of separated molecules. Such a consideration may generally support the interpretation of observation (3) described above. At 160 K, the D^* values of P1-VN and 1-MN were also obtained according to Kottis-Lefebvre's correction.[4] They are each 0.002 cm^{-1} smaller than that of the corresponding molecule observed at 77 K. In addition to the effect of triplet-energy transfer in P1-VN, the lowering of D^* values may be partly attributed to the motion of naphthyl groups in the host polymer.[12]

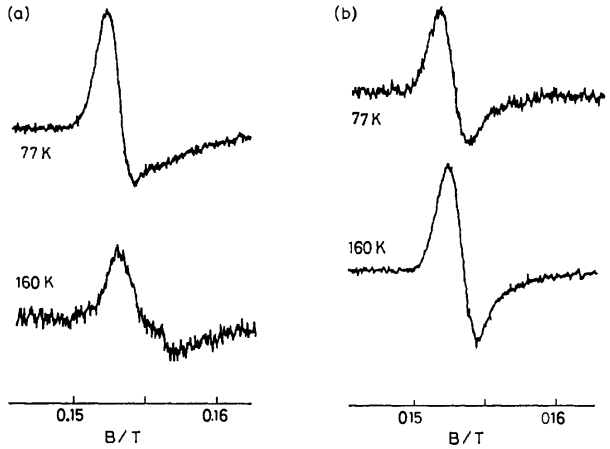

Fig. 1. ESR spectra of the $\Delta m=\pm 2$ transitions for the phosphorescent triplet states of poly(1-vinylnaphthalene) (a) and 1-methylnaphthalene (b) in stretched polystyrene films.

Several years ago, Avakian *et al.*[9] studied the magnetic-field modulation of delayed fluorescence for P2-VN in a THF: diethyl ether (1 : 1) glass at 77 K. In comparison with the fluorescence intensity calculated by assuming that the D value is nearly equal to that of naphthalene and $E=0$, they deduced tendencies for the normal axes of naphthyl groups to be locally aligned approximately parallel to one another and for the naphthyl planes to have orientations tending to an average of the in-plane components. The last part of their assumption is evidently different from our value of $E\neq 0$. Compared with the present results, their interpretation may overestimate the triplet-energy transfer for P2-VN at 77 K, although the steric hindrance between the naphthyl group and the polymer chain is rather small as compared with the case of P1-VN.

In the present work, the host polymer consists of stretched atactic PS films without perfect ordering. Although the isotactic polymers were used, PS and P1-VN have different molecular symmetries, with threefold and fourfold screw axes respectively.[13,14] Therefore, the present selection of guest and host polymers may not always be suitable if we are to expect even the partial ordering of guest molecules. Under these circumstances, a more detailed analysis of the observed spectra could not actually be carried out. Also, the characterization of the molecular weight or polymerization degree of the polymers may possibly be meaningless unless the aforementioned points are improved.

The authors wish to thank Professor Minoru Kinoshita, The University of Tokyo, for his helpful

discussions, and Dr. Shimpei Hashimoto, Japan Synthetic Rubber Co., Ltd., for his kind communications. They also wish to thank Professor Shigeo Tazuke and Mr. Sumio Okano, Tokyo Institute of Technology, for their measurements of the molecular weight of PVN, and Dr. Takashi Nogami, Osaka University, for donating the Pl-VN at the preliminary step of the present work. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 347005 from the Ministry of Education, Science and Culture.

(Received November 19, 1980)

The crystal structures of $Na_2[Mo_2O_4(R\text{-pdta})]\cdot 3H_2O$ (**1**), $Na_2[Mo_2O_3S(R\text{-pdta})]\cdot 4H_2O$ (**2**), and $Na_2[Mo_2O_2S_2(R\text{-pdta})]\cdot 4H_2O$ (**3**) have been determined from diffractometer data collected by the use of Mo $K\alpha$ radiation. The structures of **1**, **2**, and **3** were refined by the least-squares method to R 0.064, 0.040, and 0.058 for 1370, 2794, and 2141 nonzero reflections respectively. Each Mo^V ion has a distorted octahedral coordination, and the two coordination octahedra share a common edge to form a binuclear complex. Two terminal oxo ligands are *cis* to the bridging oxide or sulfide. The R-pdta^{4-} ligand bridges two Mo^V ions, yielding a Mo–N–CH_2–CH(CH_3)–N–Mo ring with an equatorial methyl group, the N and carboxyl O atoms occupying the axial (*trans* to the terminal O) and equatorial positions respectively. A specific distortion of the donor-atom disposition is observed, which is represented as the twist (Δ) of the terminal O–O edges in the O(L$_b$)Mo(L$_b$)Mo portion about the axis passing through the mid-points of the O–O edges (Δ denotes the absolute disposition of two skew edges or bonds), and as the twist (Δ) of Mo–N bonds about the Mo–Mo axis. The O=Mo bonds of the O=Mo–Mo=O segment in **1** twist in Δ, but those in **2** and **3** are virtually parallel. The distortion of donor-atom disposition is discussed on the basis of the strain due to chelate-ring formation.

Few studies have been reported on the structure-circular dichroism (CD) correlation for molybdenum complexes, despite the rapid and extensive development of molybdenum chemistry.[1] Four of the present authors (K. Z. S., Y. S., S. O., and K. S.) have previously measured the CD spectra of a number of the binuclear Mo(V) complexes in solution and in crystalline state and have found, from a comparison of the spectral features with the X-ray structure, that the signs of the CD bands in the 26000—33000 cm^{-1} region are related to the distortion of the two coordination polyhedra about the Mo–Mo axis.[2] The present work has been conducted to provide structural data for this investigation. The structural details of $Na_2[Mo_2O_4(R\text{-pdta})]\cdot 3H_2O$ (**1**), $Na_2[Mo_2O_3S(R\text{-pdta})]\cdot 4H_2O$ (**2**), and $Na_2[Mo_2O_2S_2(R\text{-pdta})]\cdot 4H_2O$ (**3**) (R-pdta^{4-}, (R)-propylenediaminetetraacetate) will now be reported, thus providing the first example of the crystal structure of a complete series of binuclear Mo(V) complexes with three kinds of bridging structures and a common ligand.

Experimental

The preparation of the compounds was described elsewhere.[2] All three compounds are red-brown in color. The crystal data are shown in Table 1, where the experimental details are also given. The Laue symmetries and approximate unit-cell dimensions were determined from Weissenberg photographs. The cell dimensions were refined by the least-squares analyses of 15, 31, and 24θ values, as measured on a Philips four-circle diffractometer, for **1**, **2**, and **3** respectively.

The intensities were measured on the diffractometer using graphite-monochromated Mo $K\alpha$ radiation, and corrected for the Lp factor, but not for absorption. The backgrounds were measured on each side of the scan range. The intensities of three standard reflections were monitored every 4 h for each of the three compounds, but they showed no appreciable decay.

The crystal structure was solved by the heavy-atom technique. The positional and thermal parameters were refined by the least-squares method. The minimized function was $\sum w(F_o-|F_c|)^2$. Weights were assigned as $w=p$ for $F_o<F_{min}$, $w=1.0$ for $F_{min}\leq F_o\leq F_{max}$, and $w=(F_{max}/F_o)^2$ for $F_o>F_{max}$. The p, F_{max}, and F_{max} for each compound are as follows:

	p	F_{min}	F_{max}
1	0.1	16.9	42.3
2	0.6	7.8	31.2
3	0.7	9.5	35.6

No attempt was made to locate the H atoms. The atomic scattering factors, with corrections for anomalous dispersions of Mo^0 and S, were taken from Ref. 3. The absolute crystal structure was determined on the basis of the configuration of the asymmetric carbon atom. The atomic coordinate are given in Table 2. The F_o-F_c table and the anisotropic thermal parameters for heavy atoms are preserved by the Chemical Society of Japan (Document No. 8136). All computations were performed by means of a FACOM 230-60 computer at Osaka City University using programs in the UNICS.[4]

Results and Discussion

Crystal Structure. Figures 1 and 2 show the crystal structures of **1** and **2**. Compound **3** is isostructural with **2**. In **2** and **3** the complex anion is surrounded by 6 Na^+ ions, which are in contact with the O(O=C) atoms of the COO portions at distances of 2.30—2.55 Å. Although the cation disposition around the complex anion in **1** is somewhat different from those in **2** and **3**, the 6 Na^+ ions also lie in the vicinities of the O(O=C) atoms.

a) Equivalent isotropic mean-square amplitude.

Although no H atoms were located in the structure analyses, some possible hydrogen bonds, inferred from the interatomic distances and angles, are listed in Table 3. All the H atoms of $O_w(1)$, $O_w(2)$, and $O_w(3)$ in **2** and **3**, and those of $O_w(2)$ and $O_w(3)$ in **1**, seem to participate in O–H···O(carboxylate) hydrogen bonding, while one of the H atoms of $O_w(4)$ in **2** and **3** and that of $O_w(1)$ in **1** do not seem to be involved in the hydrogen bonding.

The O atom of Mo=O is generally distant from the Na^+ ions. The $O_w(1)$ atoms in **2** and **3** are located at distances of 3.04(1) and 3.00(2) Å respectively from O(1)(O=Mo), and one of the H atoms of $O_w(1)$ seems to be in contact with the O(1). The O(1) in **2** and **3** also has a short contact with the $C(2)H_2$ group of the adjacent anion at $(x, 1+y, z)$, the O(1)···C(2) distances being 3.17(2) and 3.08(3) Å respectively. However, the O(1)···H(CH_2) distances, calculated on the assumption of C–H=1.05 Å, are 2.57 and 2.70 Å even in **3**. No such contacts are found in **1**.

In **1**—**3**, however, there are no remarkable short distances indicative of a strong interaction; accordingly, the interatomic interaction seems to produce no significant deformation of the complex anion.

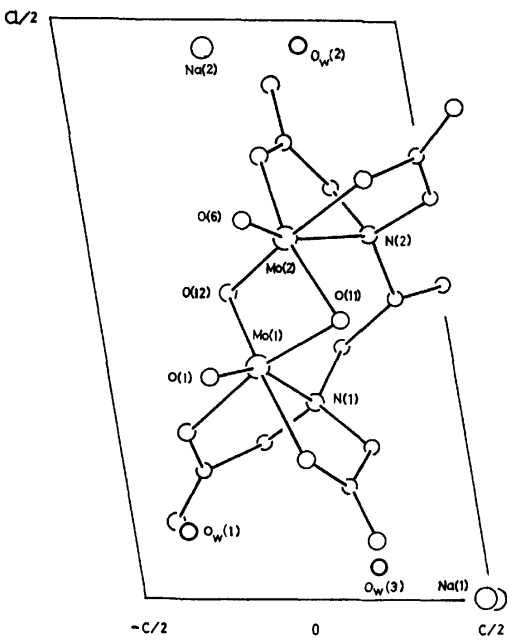

Fig. 1. The crystal structure of $Na_2[Mo_2O_4(R\text{-pdta})]\cdot 3H_2O$ viewed down the b axis.

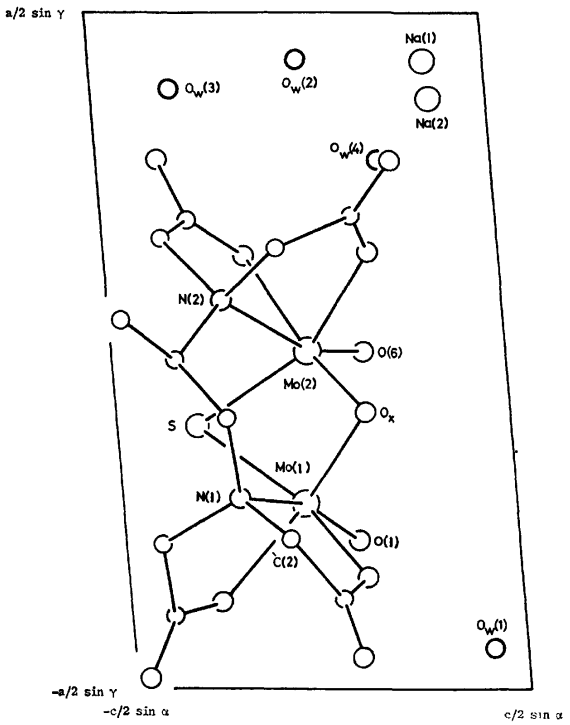

Fig. 2. The crystal structure of $Na_2[Mo_2O_3S(R\text{-pdta})]\cdot 4H_2O$ viewed down the b axis.

Structure of the Binuclear Complex Anion. Figure 3 shows a perspective view of the binuclear complex anion in **1**. As the three complex anions have configurations similar to one another, a common atom numbering was used for all three, as is shown in figure, except for the bridging atoms. The projections and elevations of the anions are given in Fig. 4. Table 3 lists the interatomic distances and bond angles. The corresponding bond lengths agree well within the experimental

a) $L_b(1)$ and $L_b(2)$stand for O(11) and O(12) in **1**, S and O_x in **2**, and for S(2) and S(1) in **3**.

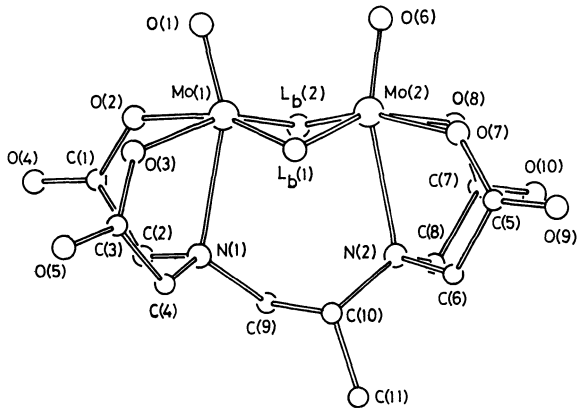

Fig. 3. A perspective view of $[Mo_2O_4(R\text{-pdta})]^{2-}$ anion with atom numbering. The same numbering is used for $[Mo_2O_3S(R\text{-pdta})]^{2-}$ and $[Mo_2O_2S_2(R\text{-pdta})]^{2-}$ anions. The $L_b(1)$ and $L_b(2)$ stand for O(11) and O(12) in $[Mo_2O_4(R\text{-pdta})]^{2-}$, S and O_x in $[Mo_2O_3S(R\text{-pdta})]^{2-}$, and S(2) and S(1) in $[Mo_2O_2S_2(R\text{-pdta})]^{2-}$.

error in the three complexes, except for those in which L_b atoms are concerned (L_b, bridging ligand).

Structure of the $Mo_2O_2L_{b2}$ Core: The geometry and dimensions of $Mo_2O_2L_{b2}$ core are not much different from those of the corresponding core in the other binuclear Mo(V) complexes.[5,6] Each Mo atom has a very distorted octahedral coordination. The deviation of the Mo atom from the mean plane defined by two O(carboxylate) and two L_b atoms is in the range of 0.35—0.37 Å, irrespective of the kind of bridging ligand (Table 4).

The Mo–Mo distance increases in the order of **1**, **2**, and **3**. The distance in **1** is slightly shorter than those so far found in Mo_2O_4 cores (2.541—2.580 Å),[5] while that in **2** is comparable to that in $[Mo_2O_3S(S_2CNPr_2)_2]$ (2.673(3) Å).[7] The Mo–Mo bond in **3** is comparable in length to that in $Cs_2[Mo_2O_2S_2(edta)]\cdot 2H_2O$ (2.799 (1) Å),[8] but shorter than those in the other complexes with a $Mo_2O_2S_2$ core.[6] Although the Mo–Mo=O(1) and Mo–Mo=O(6) bond angles in **2** and **3** are nearly equal, they are significantly different from each other in **1**.

The Mo–S bond length in **3** ranges from 2.299 to 2.331(3) Å. The Mo–S(1) distances are longer than the Mo–S(2) distances; concomitantly, the Mo–S(2)–Mo angle is 1.0° larger than the Mo–S(1)–Mo angle. However, the average value of the Mo–S bond length (2.312 Å) is comparable to that of the edta complex (2.294(1) Å).[8] The Mo–S–Mo angle in **2** is smaller by *ca.* 5° than any of the corresponding angles in the $Mo_2O_2S_2$ cores of other complexes.[6] The Mo–O–Mo angles in **1** are normal and close to those in $[Mo_2O_4(H_2PO_2)_2(bpy)_2]$ (82.5°, 82.9(5)°),[9] but the Mo–O–Mo angle in **2** is greater by 4° than those in **1**. The two L_b–Mo–L_b angles in each complex agree well with each other, and increase in the order of **1**, **2**, and **3**.

The interplanar angle between the two MoL_{b2} planes is 145.4° in **1**, comparable to that in the bpy complex (143°),[9] but smaller than that in $Na_2[Mo_2O_4(R\text{-cys})_2]\cdot 5H_2O$ (151°).[10] The angle increases with the elongation of the Mo–Mo bond (Table 4), and that in **3** is nearly equal to that in the edta complex (152.3°).[8] The two Mo=O bonds in **1** are twisted in a Δ configuration with an O=Mo–Mo=O torsion angle of 5.4(8)°, whereas those in **2** and **3** are virtually parallel (Δ or Λ is used to designate the chirality of two skew edges or bonds, according to the definition given in our previous paper[2]).

Structure of the Chelate Ring: The Mo(1)–N bond in

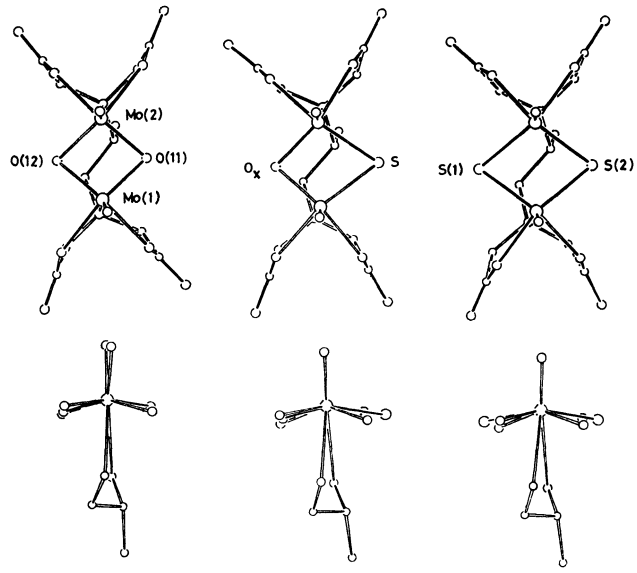

Fig. 4. The projection (top) on [O(2), O(3), O(7), O(8)] plane and the elevation (bottom) viewed along Mo(1)→Mo(2) vector, for each of the three complex anions: $[Mo_2O_4(R\text{-pdta})]^{2-}$ (left), $[Mo_2O_3S(R\text{-pdta})]^{2-}$ (middle), and $[Mo_2O_2S_2(R\text{-pdta})]^{2-}$ (right). The glycinato rings are not drawn in the elevation for clarity. The Mo–L_b bond is shown by solid line in the elevation.

a) The sign of the torsion angle in the A–B–C–D segment is negative if the direction of the rotation which superimposes the A–B bond on the C–D bond is counterclockwise.

every pdta complex is significantly shorter than the Mo(2)–N bond, whose N atom is nearer to the methyl group than that of the Mo(1)–N. The Mo–Mo–N bond angle decreases in the sequence of **1**, **2**, and **3**. The decrement along the sequence is 3.9° in Mo(2)–Mo(1)–N, but 2.1° in Mo(1)–Mo(2)–N; the replacement of the bridging ligands has a greater influence on the Mo–Mo–N bond angle containing an N atom more distant from the methyl group.

The propylenediamine portion of the ligand takes a λ gauche conformation. The methyl group is equatorial with respect to the 6-membered Mo(1)–N(1)–C(9)–C(10)–N(2)–Mo(2) ring. The N···N distance and N–C–C–N torsion angle are in the 3.46—3.51 Å and 94—98° range respectively, and are thus relatively insensitive to the kind of bridging ligand. The torsion angle is much larger than that in the usual 5-membered chelate ring of propylenediamine.[11] The N–Mo–Mo–N frame is not planar, but the two terminal bonds are twisted in a Δ configuration (Fig. 4) and the torsion angle ranges from 5.4° in **1** to 10.8° in **3**. The bond angles in the 6-membered ring indicate the presence of considerable strain: the Mo–N–C and N–C–C angles are considerably larger than the tetrahedral angle and rather near to the trigonal one, except for the C(9)–C(10)–N(2) angle. The methyl group is in short contact with the C(6)H_2 and C(8)H_2 groups. The mean value of the C(11)···C(6) distance is 0.1 Å shorter than that of C(11)···C(8).

The O(carboxylate)–Mo–O(carboxylate) angle diminishes along the 1-2-3 sequence. This arises from the repulsion between the ligating carboxylate O atoms and the bridging atoms, as is indicated by the contact distances of O···O_b (2.74—2.88 Å) and O···S (2.954—3.176 Å).

The Mo–N–C–C–O glycinato rings have a highly puckered structure. The two rings, linked to a common Mo, have an enantiomeric conformation. The glycinato ring has some strain, as is indicated by the bond angle. The Mo(2)–O(8)–C(7) angles are larger than 126°, while the Mo(2)–O(7)–C(5), Mo(1)–O(2)–C(1), and Mo(1)–O(3)–C(3) angles are 122—126°. The C(2)–C(1)–O(2) angles (113—116°) are significantly smaller than 120°, though the other C–C–O(carboxylate) angles

are 116—119°. The N(1)–C(2)–C(1) and N(2)–C(6)–C(5) angles show a significant deviation from 109.5°, but N(1)–C(4)–C(3) and N(2)–C(8)–C(7) do not. All the other bond angles are normal.

As has been described above, there is a slight but significant difference between the corresponding bond lengths and angles around the two Mo's in the dimer. The difference is systematic for the three complexes, despite the difference in crystal packing. This inequivalence of the Mo's is thought to result from the methyl group disposed unsymmetrically in relation to the Mo(1) and Mo(2).

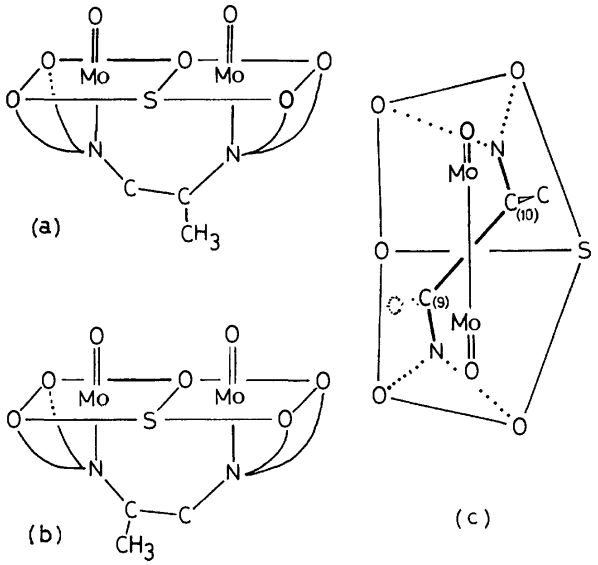

Fig. 5. The two isomers for $[Mo_2O_3S(R\text{-pdta})]^{2-}$ anion. (a) Isomer (1), (b) isomer (2), and (c) the projection of the isomer (1) showing schematically the disposition of the ethylenediamine moiety relative to the Mo_2O_3S core (the methyl carbon shown by dotted letter corresponds to that in the approximated structure of the isomer (2)).

Geometrical Isomerism of $[Mo_2O_3S(R\text{-pdta})]^{2-}$. Figures 5(a) and (b) show two geometrical isomers for this anion. The structure shown in Fig. 4 (middle) corresponds to the (1) isomer, which was selectively obtained by the method of preparation described in Ref. 2. The (1) isomer differs from (2) in the disposition of the methyl group with respect to the Mo_2O_3S core. The structure of the (2) isomer may be approximated by a structure obtained by exchanging C(10)–CH_3 for equatorial C(9)–H in the (1) isomer. Figure 5(c) shows schematically the projection of the (1) isomer. The atom arrangement is unsymmetric with respect to the Mo–Mo line because of the difference between the Mo–O_b and Mo–S distances; accordingly, the ligating $pdta^{4-}$ is bent out of the Mo–Mo line. This gives rise to a difference between the conformational energies of the (1) and (2) isomers. In the approximated structure for the (2) isomer, the $CH_3\cdots C(2)$ and $CH_3\cdots C(4)$ contact distances are estimated to be 2.72 and 2.91 Å respectively. These values are significantly smaller than those of the corresponding short contacts in the (1) isomer, although the atom overcrowding in the approximated structure may be alleviated to some extent in the actual structure of the (2) isomer. Such an unfavorable ligand structure may be responsible for low abundance of the (2) isomer in solution.

Distortion of Donor-atom Disposition. The CD signs of the binuclear Mo(V) complexes of the dissymmetric ligand in the 26000—33000 cm^{-1} region are not directly related to the configuration of asymmetric carbon in the ligand.[2] A closer investigation of the X-ray structures of the eight dissymmetric Mo(V) complexes led us to the conclusion that the asymmetric factor responsible for the sign of the crystalline CD spectra in this region is, in the first approximation, the dissymmetric distortion of the donor-atom disposition. The distortion can be represented by; i) a twist of the X–Y and X′–Y′ edges about the axis parallel to the Mo–Mo axis (Fig. 6), ii) a twist of Mo=O_t and Mo=O'_t about the Mo–Mo axis, and iii) a twist of Mo–Z and Mo–Z′ about the Mo–Mo axis. The third twist is thought to be less important for the optical activity in view of the fact that the Mo–Z(Z′) distance is longer than the other Mo–donor distances in the dimer.[2]

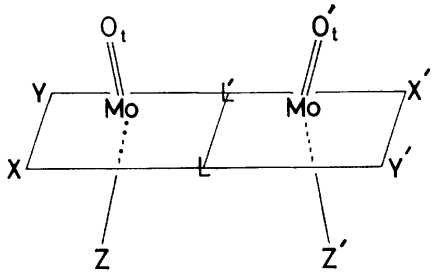

Fig. 6. The idealized corrdination framework for the binuclear Mo(V) complex.

Such a distortion should arise from the strain characteristic of the coordinating ligand. If there were no chelate rings, 2 Mo, O_t, O'_t, Z, and Z′ would lie on one plane[12] (Fig. 6). When the donor atoms of *R*-$pdta^{4-}$ occupy the X, Y, Z, X′, Y′, and Z′ coordination sites, the *R*-propylenediamine moiety takes a λ skew conformation to make C–CH_3 equatorial; accordingly the $N\langle^{C}_{C}C$ portion cannot be symmetric with respect to the [2Mo,O_t,O'_t,Z,Z′] plane of the idealized coordination framework (Fig. 6). Each NC_3 portion rotates counterclockwise about the Mo→N vector, from the symmetric position with respect to the [2Mo,O_t,O'_t,Z,Z′] plane until the N–C–C–N torsion angle becomes 94—98° as in the structures of **1**—**3**. Such a rotation brings about the upper shift of Y(Y′) and the down shift of X(X′), making the X–Y edge (X′–Y′) slant against L–L′ in the Δ configuration. The strain in the glycinato and *R*-propylenediamine rings may be alleviated by the displacement of the N atoms from the [2Mo,O_t,O'_t,Z,Z′] plane, thus twisting the N–Mo–Mo–N in the Δ configuration.

The O(1)···O(2) and O(6)···O(7) distances in the three complexes are shorter than the O(1)···O(3) and O(6)···O(8) distances (Table 5). The former distances

are in the 2.67—2.72 Å range, and thus substantially invariable for all three complexes. This indicates that the O(1) and O(6) atoms are in short contact with the O(2) and O(7) atoms respectively; hence, the direction of the Mo=O(1) and Mo=O(6) bonds depends on the positions of the O(2) and O(7) atoms. Since the ligation of R-pdta^{4-} displaces the X and Y by 0.09—0.16 Å from the [X,Y,L,L'] plane of the idealized framework (Table 4), the O_t moves so as to keep the contact distance constant, resulting in the Δ twist of the O=Mo–Mo=O segment. The displacements of O'_t, X', and Y' from the idealized positions are similar to those of the unprimed sites and give rise to the enlargement of the O=Mo–Mo=O torsion angle.

The Mo=O bonds are virtually parallel to each other in **2** and **3**. The Mo–Mo distance and the interplanar angle between the [Mo,L_b(1),L_b(2)] planes in these complexes are significantly larger than the corresponding ones in **1**, while the N···N distance, the Mo–Mo=O bond angle, and the deviation of Mo from the equatorial plane are not different from those in **1**. On the basis of these structural features, the idealized framework for **3** can be derived from that for **1** in the following way; i) the elongation of the Mo–Mo, $O_t\cdots O'_t$, X···Y', and Y···X' distances by 0.28 Å along the Mo–Mo axis, followed by ii) the enlargement of the [Mo,L,L'] interplanar angle by 8.0°. In the derived framework, X and Y (as well as X' and Y') are calculated to lie 0.13 Å below the equatorial plane of the intermediate framework obtained by the i) operation. However, the Y(Y') shifts 0.14 Å (average) upward upon the ligation of R-pdta^{4-} (Table 4). Consequently, the atom at the Y(Y') site may be regarded as lying on the equatorial plane of the intermediate framework, in contact with $O_t(O'_t)$ without repelling it, thus making the Mo=O_t bonds nearly parallel to each other in **3**. The inherent low symmetry of the Mo_2O_3S core may have some additional influence on the donor-atom disposition in **2**.

That the twist in the O=Mo–Mo=O segment is solely found in **1**, but not in **2** and **3**, weakens the basis of the interpretation of the twist. However, the interpretation is substantiated by the following analysis of the twist of O=Mo–Mo=O in $[Mo_2O_2S_2(S\text{-hist})_2]\cdot 1.5H_2O$[13] (**4**) (hist$^-$=histidinate), $Na_2[Mo_2O_4(R\text{-cys})_2]\cdot 5H_2O$[10] (**5**), and $Na_2[Mo_2O_2S_2(R\text{-cys})_2]\cdot 2H_2O$[14] (**6**) (cys^{2-}= cysteinate), which were utilized for the investigation of the CD-structure correlation in the Mo(V) dimer.[2] These complexes have a common framework (shown in Fig. 7) and have no bridge like that of the propylenediamine moiety in **1**—**3**. The torsion angle and the

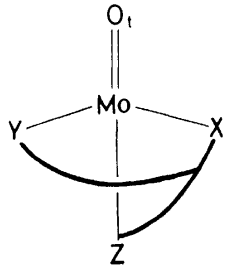

Fig. 7. A sketch of chelate ring in the half of the Mo(V) dimer with terdentate S-hist$^-$ or R-cys^{2-} ligand.

configuration of the distortion were described in Ref. 2 (torsion angle in O_t=Mo–Mo=O'_t (θ_1) and that for the X–Y and Y'–X' edges (ξ) in the respective complexes are as follows: **4** θ_1=2.5°(Δ), ξ=4.5°(Δ); **5** θ_1=4.0°(Δ), ξ=0.1°(Δ); **6** θ_1=4.7°(Δ), ξ=0.2°(Δ); the ξ values for **5** and **6** are meaningless in view of the experimental errors).

Each of the **4**—**6** complexes has an approximate twofold axis passing the mid-point between the Mo's across the XYX'Y' plane. Figure 7 shows a sketch of this type of complex as viewed along the Mo–Mo axis. The three ligating atoms, S, N, and O of R-cys^{2-}, and N(ring), N, and O of S-hist$^-$, are located in a clockwise fashion in this order (Y, X, and Z) when the Mo atom is looked at from the asymmetric carbon of the coordinating R-cys^{2-} and S-hist$^-$. The chelate ring spanning X and Z sites is 5-membered, irrespective of the kind of ligand. Table 5 lists the distances between O_t and atoms at the X and Y sites. These distances are somewhat shorter than those to be expected from the van der Waals radii of the two atoms; therefore, the O_t atom must be in contact with atoms at the X and Y sites. The formation of a 5-membered ring between X and Z shifts X toward Z and makes O_t distant from X. In order to make the interatomic interaction optimal, O_t shifts toward X, and in turn Y approaches O_t. Such shifts lead to, as a whole, a rotation of the O_tXY triangle about its center. The rotations of the O_tXY and O'_tX'Y' triangles compatible with the symmetry of the dimer must have resulted in the twist in O_t=Mo–Mo=O'_t, as well as in that of the X–Y and Y'–X' edges. Since Mo–S(Y) is *ca.* 0.3 Å longer than Mo–N(X), the rotation of Mo–Y(S) and that of Mo–X'(N) in opposite directions about the Mo–Mo axis, giving a torsion angle of 4—5° in O_t=Mo–Mo=O'_t, seems to give the negligible twist of the X–Y and Y'–X' edges in **5** and **6**.

The distortion of the coordination framework in the binuclear Mo(V) complexes, **1**—**6**, is thus explainable

on the basis of the strain due to chelate-ring formation. The *Λ* twist in **1** and the negligible twist in **2** and **3** for the O=Mo–Mo=O segment may be taken to be intrinsic for the respective complex, and not ascribable to crystal packing.

Studies on Characteristics of Electron Capture Responses. V. Estimation of Electron Attachment Mechanisms from Carrier Gas Flow-rate Dependence of Electron Capture Coefficients

Masahiro TAKEUCHI

Tokyo Metropolitan Research Laboratory of Public Health, Hyakunincho, Shinjuku-ku, Tokyo 160

(Received December 6, 1980)

The electron capture coefficients, K, defined by Wentworth *et al.* were measured for several samples in various carrier gas flow-rates, F, by a pulse sampled electron capture detector (ECD). The carrier gas flow-rate dependence of K, *i.e.*, the plot of K *versus* F, is discussed from the viewpoint of the kinetic theory. The results reveal that the flow-rate dependence of K can be used for estimating the electron attachment mechanisms.

In their early studies on the responses of the ECD, Wentworth *et al.*[1-4] theorized about the electron attachment mechanisms on the basis of kinetic derivations using steady-state approximations. According to their theory, the electron attachment phenomena can be classified into four different mechanisms which can be determined from the temperature dependence of K, *i. e.*, the plot of $\ln KT^{3/2}$ *versus* $1/T$.

The author reported[5] that the carrier gas flow-rate dependence of K[6] was also closely related to the electron attachment mechanisms: The values of K for samples undergoing a non-dissociative electron capture reaction were little affected by the flow-rate, those for samples undergoing a dissociative electron capture reaction increased significantly with increasing the flow-rate, and those for samples undergoing an electron capture reaction through an anion radical intermediate were little affected with the flow-rate at lower temperatures, but the values increased gradually with increasing the flow-rate at higher temperatures. In the present paper, these relations have been discussed from the viewpoint of the kinetic theory proposed by Wentworth *et al.*

Experimental

Apparatus and Samples. A Shimadzu GC-5A gas chromatograph equipped with a pulse sampled ECD was used. The ECD was of co-axial geometry and contained a 10 mCi ^{63}Ni radioactive source. Pulses were supplied with a DuMont 404 pulse generator. The pulse conditions were set up as follows in order to collect all of the electrons formed during a pulse period and to assure a steady-state for kinetic equations derived from the reactions postulated within the ECD: the pulse period, 2000 μs; the pulse width, 2.0 μs; the pulse amplitude, 30 V. An analog device was used for the calculation of K from the equation:

$$Kn = \frac{F}{S}\int \frac{I_b - I_e}{I_e}\,dX, \qquad (1)$$

where n is the number of moles injected, F is the carrier gas flow-rate in l/min, S is the chart speed in cm/min, X is the chart distance in cm, I_b is the base current due to pure carrier gas, and I_e is the current in the presence of electron capturing vapor. Practically, K was obtained from the slope of the n *versus* peak area plot under constant conditions of F and S, and corrected in the same manner as in the proceeding paper.[5] The carrier gas used (Nihon Sanso, A Grade) was specified to contain more than 99.9995% of nitrogen and less than 0.5 ppm of oxygen. Before being introduced into the system, the gas was passed through a Molecular Sieve 13X filter and an oxygen scrubber (Alltech, Oxy-Trap). The flow-rate was measured at the exit end of the system with a bubble flow meter and a stopwatch. Peak areas were calculated with a Spectra-Physics Autolab System IV integrator. Two different kinds of chromatographic columns were used. One was a 1 m×3 mm i.d. glass column packed with 2% Silicone OV-17 on Chromosorb W (80—100 mesh), and the other was a 1 m×3 mm i.d. glass column packed with 2% Silicone OV-275 on Chromosorb W (60—80 mesh). The ECD temperature was measured with a thermometer inserted into the detector oven rather than with the thermocouple provided.

The samples used in the present study were commercially available reagents. Solutions of the samples were prepared to give suitable peak heights, *i.e.*, $(I_b - I_e)/I_e = 1$—4.[7]

Results and Discussion

Figures 1, 2, and 3 show the flow-rate dependences of K for nitrobenzene, acetophenone, and Aldrin. The flow-rate dependences of K for these samples are quite different. The values of K for nitrobenzene are constant, *i. e.*, not affected with the flow-rate at all, those for acetophenone decrease in nearly inverse proportion to the increase of the flow-rate, and those for Aldrin increase in nearly direct proportion to the increase of the flow-rate. The differences among these samples are explained below.

According to Wentworth *et al.*,[2] K is represented in the form of Eq. 2 by using the rate constants attached to Eqs. 3—6:

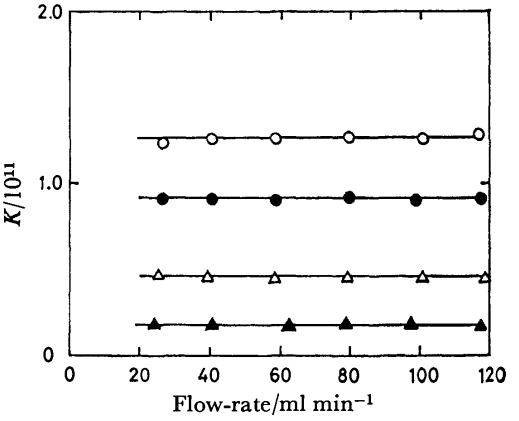

Fig. 1. Carrier gas flow-rate dependence of K for nitrobenzene at 200 °C (○), 240 °C (●), 280 °C (△), and 320 °C (▲).

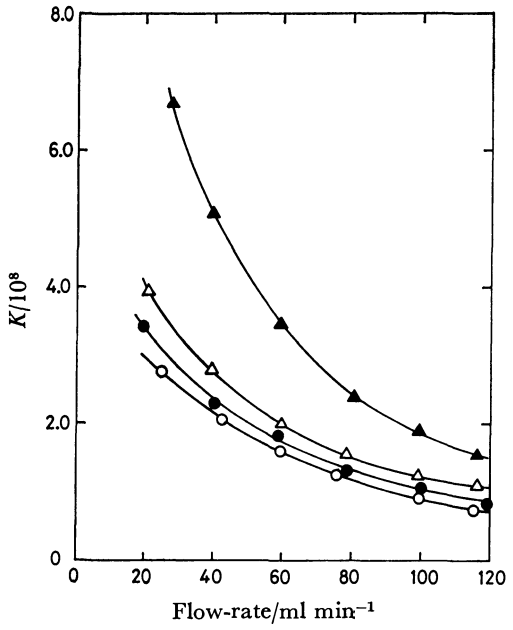

Fig. 2. Carrier gas flow-rate dependence of K for acetophenone at 200 °C (○), 240 °C (●), 280 °C (△), and 320 °C (▲).

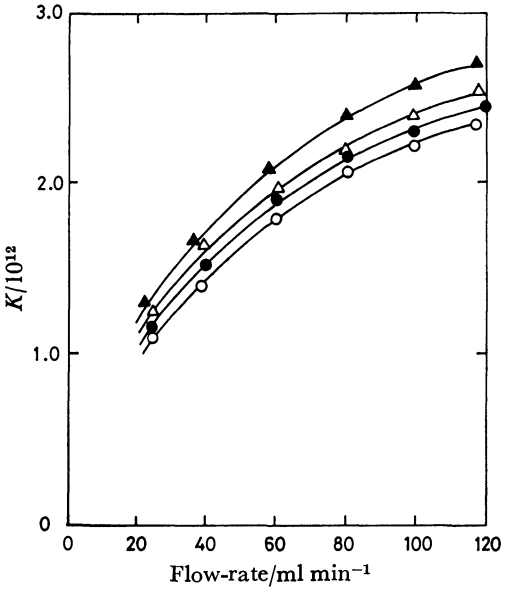

Fig. 3. Carrier gas flow-rate dependence of K for Aldrin at 200 °C (○), 240 °C (●), 280 °C (△), and 320 °C (▲).

$$K = \frac{k_{12}}{k_N + k_R} + \frac{k_1 k_2}{(k_N + k_R)\Sigma k} + \frac{(k_{N1} + k_{R1})k_1}{(k_N + k_R)\Sigma k}, \quad (2)$$

where $k_N+k_R=k'_N[P^+]+k'_R[R\cdot]$, $k_{N1}+k_{R1}=k'_{R1}[P^+]+k_{R1}[R\cdot]$,
and $\Sigma k=k_{-1}+k_2+k_{N1}+k_{R1}$.

$$AB + e^- \xrightarrow{k_{12}} A\cdot + B^- \quad (3)$$

$$AB + e^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} AB^- \xrightarrow{k_{N1}+k_{R1}} AB \quad (4)$$

$$AB^- \xrightarrow{k_2} A\cdot + B^-$$

$$P^+ + e^- \xrightarrow{k'_N} R\cdot \quad (5)$$

$$R\cdot + e^- \xrightarrow{k'_R} R^-, \quad (6)$$

where AB is an electron capturing molecule, AB^- is a negative ion, A· and B^- are fragments of dissociation, and P^+ and R· are symbols to designate any of the positive ions and radicals.

It can be seen that K is a sum of three terms, and that the first term of Eq. 2 corresponds to the situation in which Eq. 3 predominates. Such a situation, however, is considered to be the same as the situation where $k_2 \gg k_{-1}+k_{N1}+k_{R1}$ is satisfied in Eq. 4 to which the second and the third terms in Eq. 2 correspond. Consequently, the first term of Eq. 2 can be abbreviated.

Hence,

$$K = \frac{k_1(k_2 + k_{N1} + k_{R1})}{(k_N + k_R)\Sigma k}. \quad (7)$$

Equation 7 can be further simplified as follows, according to the relative magnitude of each rate constant in Σk.

(I) When $k_{N1}+k_{R1} \gg k_{-1}+k_2$, the expression for K becomes

$$K = \frac{k_1}{k_N + k_R}. \quad (8)$$

In this situation, K is not affected by the flow-rate. In other words, K for a given sample is constant at any flow-rate. A typical sample belonging to this group is nitrobenzene (Fig. 1).

(II) When $k_{-1} \gg k_2+k_{N1}+k_{R1}$, the expression for K becomes

$$K = \frac{k_2 + k_{N1} + k_{R1}}{k_N + k_R} \times \frac{k_1}{k_{-1}}. \quad (9)$$

The part of k_1/k_{-1} of Eq. 9 is equal to the equilibrium constant, K_{eq}, of the reaction between AB and an electron in Eq. 4. The concentration of AB^- is negligible in comparison with that of AB in Eq. 4, since K_{eq} is very small in this situation. Therefore, K_{eq} is expressed in the form of Eq. 10 by using the ionization efficiency, p, and the initial concentration of AB, a:

$$K_{eq} = \frac{k_1}{k_{-1}} = \frac{[AB^-]}{[AB][e^-]} = \frac{p}{a(1-p)}. \quad (10)$$

On the other hand, p is expressed in the form of Eq. 11:[8]

$$p = \frac{c}{c + F}, \quad (11)$$

where c is a constant, and F is the carrier gas flow-rate. Combination of Eqs. 10 and 11 gives

$$K_{eq} = \frac{k_1}{k_{-1}} = \frac{c}{a} \times \frac{1}{F}. \quad (12)$$

Equation 12 means that K_{eq} is in inverse proportion to the carrier gas flow-rate. Therefore, if the part of $(k_2+k_{N1}+k_{R1})/(k_N+k_R)$ is not affected by the carrier gas flow-rate, K expressed by Eq. 9 will also be in inverse proportion to the flow-rate. A typical sample satisfying Situation II is acetophenone (Fig. 2). Another sample belonging to this group was benzonitrile. The flow-rate dependence of K for benzonitrile was similar to that for acetophenone.

(III) When $k_2 \gg k_{-1}+k_{N1}+k_{R1}$, the expression for K becomes

$$K = \frac{k_1}{k_N + k_R}.$$

The values of K in this situation are expected to be constant in any flow-rate, since K is expressed in the same form as in Situation I. In practice, however, K is approximately proportional to the flow-rate. This is because a molecule AB dissociates spontaneously to give A· and B^- on entering into the ECD. Under such a situation, the ECD is considered to be coulometric in response and to act as a mass-sensitive detector.[9-11] Therefore, the values of K calculated from Eq. 1, which is derived by assuming that the ECD is concentration-sensitive,[9,10] are not kept constant but become proportional to the flow-rate. Aldrin is a typical sample which satisfies Situation III (Fig. 3). In fact, Aldrin has a very small activation energy for dissociation, which is calculated from the slope of the ln $KT^{3/2}$ *versus* $1/T$ plot shown in Fig. 4 and the gas constant ($-\text{slope} \times R$). Consequently, all of the molecules of Aldrin dissociate within the ECD. Therefore, it is reasonable that the ECD acts as a mass-sensitive device rather than a concentration-sensitive one, for detection of Aldrin. Other samples belonging to this group were *p,p'*-DDE, *p,p'*-DDT, and γ-BHC. Their flow-rate dependences of K were similar to that for Aldrin.

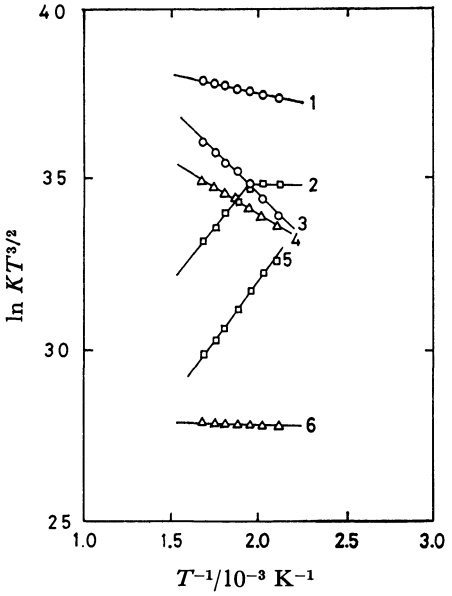

Fig. 4. Temperature dependence of K for Aldrin (1), nitrobenzene (2), 1,2,4-trichlorobenzene (3), dodecyl bromide (4), azulene (5), and acetophenone (6).

On the basis of the flow-rate dependence of K for the three situations described above, those shown in Fig. 5—7 can be considered as follows:

In the case of azulene (Fig. 5), the values of K are not affected at all by the flow-rate at lower temperatures, but decrease slightly with increasing the flow-rate at higher temperatures. Therefore, it is likely that $k_{N1}+k_{R1} \gg k_{-1}+k_2$, *i. e.*, Situation I, is satisfied at lower temperatures, but $k_{-1}+k_2$ becomes almost equal to $k_{N1}+k_{R1}$ at higher temperatures, since k_{-1} becomes larger with the rise of temperature. Although acetophenone,

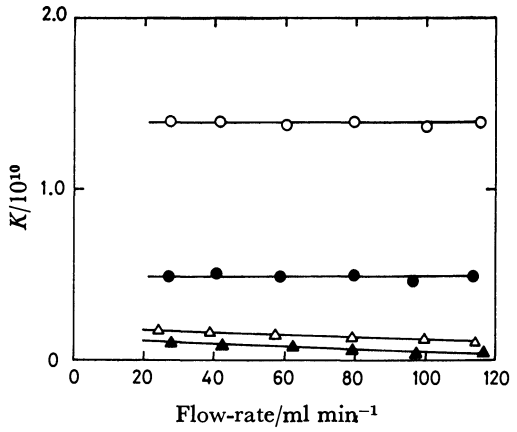

Fig. 5. Carrier gas flow-rate dependence of K for azulene at 200 °C (○), 240 °C (●), 280 °C (△), and 320 °C (▲).

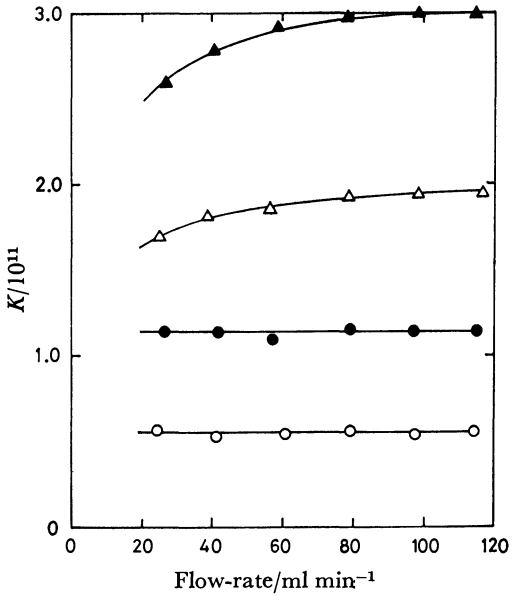

Fig. 6. Carrier gas flow-rate dependence of K for 1,2,4-trichlorobenzene at 200 °C (○), 240 °C (●), 280 °C (△), and 320 °C (▲).

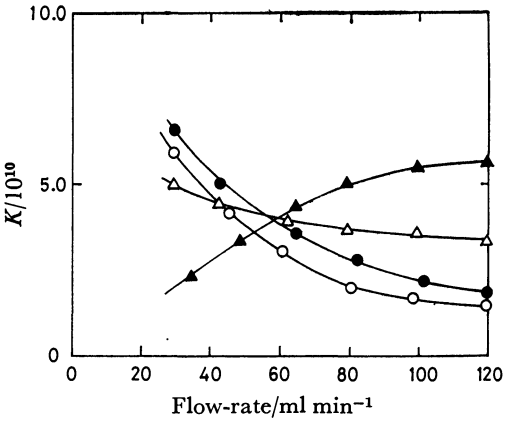

Fig. 7. Carrier gas flow-rate dependence of K for dodecyl bromide at 200 °C (○), 240 °C (●), 280 °C (△), and 320 °C (▲).

nitrobenzene, and azulene are all regarded as non-dissociative samples from the plots of ln $KT^{3/2}$ *versus* $1/T$, *i. e.*, a positive slope at higher temperatures and/or a negative slope nearly zero at lower temperatures (Fig. 4), the flow-rate dependences of K show that they are not necessarily in the same situation. This is owing to the difference of the electron affinities: 5.5, 14.7, and 15.2 kcal/mol, for benzonitrile, azulene, and nitrobenzene, respectively.[4,12]

In the case of 1,2,4-trichlorobenzene (Fig. 6), the values of K are constant at lower temperatures, but increased gradually with increasing the flow-rate at higher temperatures. Therefore, the electron capture reaction of 1,2,4-trichlorobenzene occurs non-dissociatively under Situation I, *i. e.*, $k_{N1}+k_{R1} \gg k_{-1}+k_2$, at lower temperatures, but dissociatively under Situation III, *i. e.*, $k_2 \gg k_{-1}+k_{N1}+k_{R1}$, at higher temperatures. Although 1,2,4-trichlorobenzene apparently belongs to the dissociative sample, considering the plot of ln $KT^{3/2}$ *versus* $1/T$ (Fig. 4), it is really a sample which dissociates through an anion radical intermediate.[5,12-14]

In the case of dodecyl bromide (Fig. 7), which is regarded as one of the dissociative samples from the negative slope of the ln $KT^{3/2}$ *versus* $1/T$ plot, the values of K decrease with increasing the flow-rate at lower temperatures, but increase at higher temperatures. This flow-rate dependence of K suggests that the electron capture reaction of dodecyl bromide occurs under Situation II, *i. e.*, $k_{-1} \gg k_2+k_{N1}+k_{R1}$, at lower temperatures, but occurs under Situation III, *i. e.*, $k_2 \gg k_{-1}+k_{N1}+k_{R1}$, at higher temperatures. The change from Situation II to III with the rise of temperature reveals that the dissociative electron capture reaction of dodecyl bromide proceeds by a mechanism similar to bimolecular nucleophilic substitution (S_N2), as shown in Fig. 8. This mechanism is supported by Kojima *et al.*,[15] who have concluded on the basis of the activation energy that the electron capture reaction of alkyl halide is a kind of S_N2.

Conclusion

The carrier gas flow-rate dependence of K was considered from the viewpoint of the kinetic theory proposed by Wentworth *et al.* The results revealed that the electron capture reaction could be divided into three situations by the relative magnitude of the rate constants of elementary reactions postulated within the ECD, and that each situation is related to the carrier gas flow-rate:

(I) When $k_{N1}+k_{R1} \gg k_{-1}+k_2$, K is not affected by the flow-rate.

(II) When $k_{-1} \gg k_2+k_{N1}+k_{R1}$, K is inversely proportional to the flow-rate.

(III) When $k_2 \gg k_{-1}+k_{N1}+k_{R1}$, K is approximately proportional to the flow-rate.

The author wishes to express his thanks to Emeritus Professor Shun Araki and Professor Shigetaka Suzuki, Tokyo Metropolitan University, for their encouragement and advice.

Kinetic Studies of Fast Equilibrium by Means of High-performance Liquid Chromatography. II. Ligand Exchange of *N,N*-Disubstituted Dithiocarbamate Chelates of Ni(II)

Masataka MORIYASU* and Yohei HASHIMOTO

Kobe Women's College of Pharmacy, Motoyamakita-machi, Higashinada-ku, Kobe 658

(Received December 11, 1980)

The equilibrium of the ligand exchange of labile Ni(II) dialkyldithiocarbamate chelates ($MA_2+B \rightleftharpoons MAB+A$, $MAB+B \rightleftharpoons MB_2+A$, $K_1=[MAB][A]/[MA_2][B]$, $K_2=[MB_2][A]/[MAB][B]$) has been investigated by means of high-perfromance liquid chromatography, two solutions of MA_2 and B being mixed and then equilibrated. The equilibrium constants, K_1 and K_2, have been determined by measuring the concentrations of each complex, including the kinetically unstable ternary complex in the equilibrium state. The ratio of the stability constants of the two Ni(II) chelates, which is equal to K_1K_2, has been calculated. The following series of increasing stability constants has been found for the alkyl substituents in chloroform; tetramethylene<dimethyl<pentamethylene<diethyl<hexamethylene<dipropyl<dibutyl. The rate of ligand exchange has been investigated by mixing very dilute MA_2 and B and by injecting the mixture into HPLC after the lapse of a certain time. The rate of ligand exchange is slow when low initial concentrations of MA_2 and B are chosen. The rate of ligand exchange is more than ten times faster than that of ternary complex formation.

In our previous studies[1,2] the equilibrium of the labile ternary-complex formation of *N,N*-disubstituted dithiocarbamate chelates of Ni(II) and Cu(II) was investigated by means of high-performance liquid chromatography (HPLC). The labile ternary complex, which is formed by mixing two solutions of the corresponding binary complexes, undergoes disproportionation as soon as it is separated from binary complexes in the column. The separation process of HPLC is so rapid that it might compete with the progress of disproportionation during the course of chromatography. In HPLC there are some factors serving to retard disproportionation in the column: (1) Each species is diluted rapidly in the column, suppressing the disproportionation which can be anticipated to occur by means of the bimolecular collisional process of two binary complexes. (2) The rate of disproprotionation can be controlled by a suitable choice of initial concentrations of two binary complexes, disproprotionation being slow when the initial concentrations are low. (3) The control of the column temperature will be effective, disproportionation being retarded when the column temperature is kept low. By the combination of these factors, disproportionation during chromatography is retarded effectively, and chromatograms obtained directly indicate the concentrations of each species before chromatography. Thus, it becomes possible to trace quite fast bimolecular reactions by means of HPLC. In our previou studies, the equilibrium constants and rate constants of labile ternary complex formation of *N,N*-disubstituted dithiocarbamate chelates of Ni(II) and Cu(II) were determined in this way. The present article shows that HPLC can also be applied to the kinetic investigation of ligand exchange in solution. We have chosen Ni(II) chelates because the rate of the ligand exchange of Ni(II) chelates is moderately fast and so the determination of the kinetic characteristics can be carried out by means of HPLC.

Experimental

Reagents. Sodium salts of *N,N*-disubstituted dithiocarbamates were prepared and purified as has been reported previously.[2] Diethylammonium salt of diethyldithiocarbamic acid was purchased commercially (Nakarai Chemicals, Ltd.). Dipropylammonium salt of dipropyldithiocarbamic acid was prepared as follows. In a 500-cm^3 of flask, 0.2 mol of dipropylamine dissolved in 100 cm^3 of hexane was placed. The flask was cooled in an ice bath, and then 0.1 mol of carbon disulfide in 100 cm^3 of hexane was stirred in, drop by drop. A voluminous white product was gradually precipitated. After having been washed with hexane, the product was dried in a vacuum desiccator. This product was found to be >98% pure when the content was determined to be Ni(II) chelates by colorimetry. It was used without further purification, because recrystallization from water gave worse results as a result of the formation of disulfide compounds (mainly *N,N,N',N'*-tetrapropylthiuram disulfide) on heating.

The concentration of the Ni(II) standard solution (0.01 mol dm^{-3} $NiCl_2$) was determined to be Ni(II) diethyldithiocarbamate by colorimetry. All the solvent used for the eluent were saturated with water before use, as had been reported previously.[2]

Apparatus. The apparatus used in this study was identical with that used in our previous reports.[1-3]

Procedure. The metal chelates were prepared by mixing the Ni(II) standard solution and the sodium salts of the corresponding dialkyldithiocarbamic acids. The metal chelates produced were extracted with chloroform under the condition of a complete extraction (pH 4.0 acetate buffer). The chloroform layer was washed with a 1% sodium hydrocarbonate solution four times to remove the residual free ligands in chloroform. Thus, solutions of each metal chelate (0.5 to 1.0×10^{-3} mol dm^{-3}) were prepared. These solutions were stable for at least three weaks when stored in a refrigerator. Solutions of dialkylammonium salts of dialkyldithiocarbamic acids were prepared by dissolving the corresponding salts in chloroform. These solutions were newly prepared before use, for they were not very stable and disulfide-degradation compounds were gradually produced on storage. The contents of these solutions were determined after the formation of Ni(II) chelates as will be shown in the following section.

For the determination of the equilibrium constants and rate constants, each solution was thermostated at 25 °C. All the measurements were carried out at least three times.

Theoretical

HPLC Analysis of Equilibrium of Ternary-complex Formation. The HPLC method for the analysis of a fast equilibrium in solution is, in principle, a conventional one. When two labile binary complexes, MA_2 and MB_2, are mixed in the absence of excess free ligands, the following ternary-complex formation will be equilibrated promptly.

$$MA_2 + MB_2 \underset{k_-}{\overset{k}{\rightleftharpoons}} 2MAB, \quad (1)$$

$$K = [MAB]^2/[MA_2][MB_2]. \quad (2)$$

When the separation speed of HPLC is so fast that the disproportionation of the kinetically unstable ternary complex MAB is negligible during the course of chromatography, K can be determined by measuring the peak heights of each chelate that appears on the chromatograms.

The rate constants, k and k_-, will be determined as follows assuming a simple bimolecular rate equation. When two dilute solutions of MA_2 and MB_2 are mixed, a ternary complex, MAB, is gradually produced according to the following equation:

$$\frac{d[MAB]}{dt} = k[MA_2][MB_2] - k_-[MAB]^2. \quad (3)$$

Taking the initial concentrations of MA_2 and MB_2 to be a_0 and b_0 respectively, we obtain:

$$\frac{dx}{dt} = k(a_0-x/2)(b_0-x/2)-k_-x^2$$

$$= -(kx^2/4)(4/K-1) - (kx/2)(a_0+b_0)+a_0b_0k, \quad (4)$$

where x is the concentration of MAB. We obtain the following equations by integrating Eq. 4:

$$k = -[2/(a_0+b_0)t] \ln [1-(a_0+b_0)x/2a_0b_0], \quad (5)$$
$$(K=4.0)$$

$$k = (2/m_0t)\left[\ln \frac{\left(\frac{a_0+b_0+m_0}{1-K/4}-x\right)}{\left(\frac{a_0+b_0-m_0}{1-K/4}-x\right)} + \ln\left(\frac{a_0+b_0-m_0}{a_0+b_0+m_0}\right)\right], \quad (6)$$
$$(K\neq 4.0)$$

where $m_0=\sqrt{(a_0+b_0)^2-4a_0b_0(1-4/K)}$. Thus, the two rate constants k and k_- can be determined from Eqs. 5 and 6.

HPLC Analysis of the Equilibrium of Ligand Exchange and Determination of the Relative Stability Constants of Metal Chelates. When the free ligand B is added to a solution containing only one kind of binary complex, MA_2, the following ligand exchange will occur in the mixture:

$$MA_2 + B \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} MAB + A, \quad (7)$$

$$MAB + B \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} MB_2 + A, \quad (8)$$

$$K_1 = [MAB][A]/[MA_2][B], \quad (9)$$

$$K_2 = [MB_2][A]/[MAB][B]. \quad (10)$$

From Eqs. 2, 9, and 10, it follows that:

$$K_1/K_2 = [MAB]^2/[MA_2][MB_2] = K. \quad (11)$$

The product of the two equilibrium constants, K_1K_2, is the ratio of the stability constants of the two binary complexes as is shown below:

$$K_1K_2 = [MB_2][A]^2/[MA_2][B]^2 = \beta_{MB_2}/\beta_{MA_2}, \quad (12)$$

$$\beta_{MA_2} = [MA_2]/[M][A]^2, \quad (13)$$

$$\beta_{MB_2} = [MB_2]/[M][B]^2. \quad (14)$$

These equilibrium constants will be determined if the equilibrium concentrations of each species are determined by HPLC. The rate constants of the ligand exchange can also be obtained by observing the change in the chromatogram patterns after mixing two solutions of MA_2 and B. It should be noted here that, being different from equilibrium constants, the two rate constants k_1 and k_2 vary independently of each other. This complicates the determination of these characteristics. When the initial concentration of MA_2 ($=a$) is much larger than that of B($=b$), the formation of MB_2 in the equilibrium state can be neglected. In this case, we can neglect the equilibrium shown in Eq. 8, and the following equation is obtained if the rate of ligand exchange can be expressed by a simple bimolecular-rate equation including $[MA_2]$ and [B]:

$$\frac{dx}{dt} = k_1(a-x)(b-x)-k_{-1}x^2$$

$$= k_1(1-1/K_1)x^2 - (a+b)k_1x + abk_1. \quad (15)$$

Equation 15 can then be integrated to give:

$$k_1 = -[1/(a+b)t]\ln[1-(a+b)x/ab] \quad K_1=1.0, \quad (16)$$

$$k_1 = (1/mt)\left[\ln \frac{\left(\frac{a+b+m}{2(1-1/K_1)}-x\right)}{\left(\frac{a+b-m}{2(1-1/K_1)}-x\right)} + \ln\left(\frac{a+b-m}{a+b+m}\right)\right], \quad (17)$$
$$K_1\neq 1.0$$

where $m=\sqrt{(a+b)^2-4ab(1-1/K_1)}$.

Results and Discussion

Equilibrium Constants of Ligand Exchange and the Relative Stability of Ni(II) Chelates. Some examples of chromatograms for determining the equilibrium constants, K_1 and K_2, are shown in Fig. 1. Here, for A and B we have chosen $(CH_2)_6NCSS^-$ and $(C_3H_7)_2NCSS^-$ respectively. Standard solutions of MA_2 and MB_2 were diluted with chloroform to various concentrations, and 5-μl portions of these solutions were injected into the column (Figs. 1(a) and (b)). Linear calibration graphs were obtained for MA_2 and MB_2 within a wide range of sample amounts. Then solutions of MA_2 and MB_2 were mixed so that the initial concentrations were equivalent ($=a_0$). In the mixture, the ternary-complex MAB was gradually formed, and after it had stood for some time, equilibrium was attained. The equilibrium concentrations of MA_2, MB_2, and MAB are $a_0/2$, $a_0/2$, and a_0 respectively, because the ternary-complex formation in this case is known to be controlled by a statistical factor ($K=4.0$).[1,2] Then the equilibrated solution was diluted to various concentrations, and these portions were injected into the column (Fig. 1(c)). Calibration graphs of MAB, which were also linear, were obtained in this way.

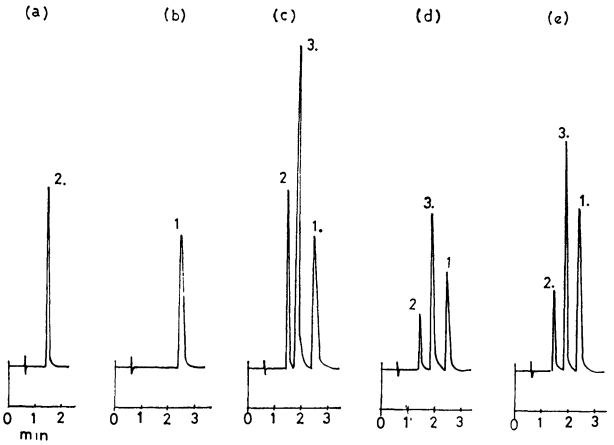

Fig. 1. Chromatogram patterns of the mixture of Ni-$[(CH_2)_6NCSS]_2$ and $(C_3H_7)_2NCSS^-$.
Column: Shodex silipak (4 mm × 15 cm). Eluent: hexane: ethyl acetate = 100 : 8 (water saturated). Flow rate: 2.5 cm³/min. Detector: 325 nm. Sample size: 5 μl. Sample: (a) 0.25 mmol dm^{-3} $Ni[(C_3H_7)_2NCSS]_2$ (=NiB_2) in chloroform; (b) 0.25 mmol dm^{-3} $Ni[(CH_2)_6NCSS]_2$ (=NiA_2) in chloroform; (c) 0.50 mmol dm^{-3} NiA_2+0.50 mmol dm^{-3} NiB_2 in chloroform. Equilibrium concentrations of NiA_2, NiB_2, and NiAB were 0.25, 0.25, and 0.50 mmol dm^{-3}, respectively;[2] (d) 0.50 mmol dm^{-3} NiA_2+b ($=0.58_0$) mmol dm^{-3} B in chloroform. Equibrium concentrations of NiA_2, NiB_2, and NiAB were determined to be 0.18_5, 0.077_3, and 0.24_4 mmol dm^{-3}, respectively. Total concentration of Ni(II) was calculated to be 0.50_5 mmol dm^{-3}. (a=0.50 mmol dm^{-3}); (e) Solution of (d) and aqueous $NiCl_2$ solution were mixed, and the mixture was shaken vigorously for about 20 s. After standing for some time the chloroform layer was supplied to HPLC. Equilibrium concentrations of NiA_2, NiB_2, and NiAB were 0.31_0 0.11_1, and 0.35_8 mmol dm^3, respectively. Thus concentration of b was calculated to be $0.11_1\times2+0.35_8=0.58_0$ mmol dm^{-3}. Total concentration of A was $0.31_0\times2+0.35_8=0.97_8$ ($2a$=1.00 mmol dm^{-3}).
1: NiA_2, 2: NiB_2, 3: NiAB.

Two solutions of MA_2 and B, whose initial concentrations were a and b, were then mixed at 25 °C. When a and b were relatively large (about 1×10^{-3} mol dm^{-3}), the equilibrium of ligand exchange occurred almost instantaneously after mixing. The equilibrated solution was divided into two parts, and a 5-μl portion of one part (Soln A) was supplied to HPLC (Fig. 1(d). Peaks corresponding to MA_2, MB_2 and MAB appeared on the chromatograms. Since free dithiocarbamates have no absorption at 325 nm, peaks of the free ligands, A and B, did not appear on the chromatograms. Injection into the column should be carried out within 10 min after mixing, otherwise, some errors were observed due to the gradual decomposition of the free ligands (probably attributable to the formation of disulfide compounds). The total concentration of Ni(II) of MA_2, MB_2, and MAB in the equilibrium state was equal to the initial concentration of MA_2($=a$), within the limit of experimental error as is shown in Fig. 1. Thus, the concentrations of MA_2, MB_2, and MAB in the equilibrium state were determined. The concentration of the free ligand A was calculated by means of this equation: $[A]=2a-2[MA_2]-[MAB]$. The concentration of the free ligand B was determined as follows: to the residual part of the equilibrated solution mentioned above, an aqueous nickel chloride solution was added, after with the mixture was shaken vigorously for about 20 s. Thus, free ligand residing in chloroform reacted with Ni(II) to form metal chelates, which were then extracted into chloroform quantitatively. Then the solution (Soln B) was supplied to HPLC (Fig. 1(e)). The total concentration of B was thus determined, and the concentration of [B] in Eqs. 9 and 10 was calculated. Here, the total concentration of the A ligand in Soln B should be equal to $2a$: this was confirmed as is shown in Fig. 1(e). Now, since the concentrations of [MA_2], [MB_2], [MAB], [A], and [B] in Eqs. 9 and 10 were determined, K_1 and K_2, and, therefore, K and K' could be calculated.

With similar procedures, the K_1 and K_2 for the system composed of other Ni(II) dialkyldithiocarbamates and dipropylammonium salt of dipropyldithiocarbamic acid were determined. The results are summarized in Table 1. The K_1/K_2 ratio, which are equal to the equilibrium constants of ternary-complex formation, were always

B: $(C_3H_7)_2NCSS^-$, in chloroform, 25 °C, Chromatographic conditions: column: Shodex silipak (4 mm × 15 cm), eluent: hexane: ethyl acetate (water saturated) = 100 : 15(A), 100 : 8 (B), 100 : 3.5(C), flow rate: 2.5 cm³/min, detector: 325 nm, sample size: 5 μl.

equal to 4 within the limit of experimental error, as was predicted by the results of our previous reports.[1,2] The ratios of the stability constants ($\beta_{MB_2}/\beta_{MA_2}=K_1K_2$) shown in Table 1 suggest that the following order of increasing stability constants was found for alkyl substituents: tetramethylene<dimethyl<pentamethylene<diethyl<hexamethylene<dipropyl<dibutyl. It is well known that the introduction of an alkyl group into chelate reagents has a tendency to stabilize the chelates formed, because the alkyl group shows electron-donating effect, and therefore, the acidity of the chelate reagents is decreased. It seems that the present results can be well interpreted in terms of such electron-donating effects of the alkyl group. The stability constants of dithiocarbamate chelates, including Ni(II) chelates, were investigated by Scharfe *et al.*,[4] and the following order of increasing stability constants was indicated for Ni(II) chelates: diethyl<tetramethylene<pentamethylene<hexamethylene. The discrepancy between their results and the present one with respect to the relationship between cyclic and acyclic alkyl substituents might be interpreted in terms of the difference in the solvent. Janssen[5] scrutinized the stability constants of Cu(II) dialkyldithiocarbamate chelates in a mixed solution of water : ethanol by the spectroscopic method. His results on the order of stability constants as to alkyl substituents were identical with those of our present work.

Rate of Ligand Exchange. There remains some difficulties in the determination of the rate constants of ligand exchange. (1) When the concentrations of MA_2 and B were relatively large, ligand exchange was equilibrated instantaneously after mixing. In order to decrease the rate of ligand exchange enough for determination by HPLC, the initial concentrations of MA_2 and B should be chosen so as to be of the order 10^{-6} mol dm^{-3}, close to the detection limit of the UV detector. (2) If the concentrations of MA_2 and B were chosen to be close to each other, the two steps of ligand exchange shown in Eqs. 7 and 8 should occur simultaneously. This will complicate the determination of the rate constants because k_1 and k_2 vary independently. Therefore, the two solutions of MA_2 and B should be mixed so that only the first step of ligand exchange occurs predominantly ($[MA_2]\gg[B]$). Too much excess of MA_2, however, is not favorable because the rate of ligand exchange increases with the increase of $[MA_2]$. Thus, the concentration range of a and b suitable for kinetic study is narrow, and a large error is inevitable.

For the determination of the rate constants of ligand exchange, two dilute solutions of $Ni[(C_2H_5)_2NCSS]_2$ (=MA_2) and $(C_3H_7)_2NCSSC_3H_7NH$ (=B), were mixed at 25 °C. The mixed solution was left to stand for 15 s, 35 s, 2 min, and 5 min, and then a portion of the mixture was submitted to HPLC. Figure 2 illustrates the change in the chromatograms. Measurements for each were made four times. With the lapse of time, the peak of MAB rose, while that of MA_2 fell. Since the initial concentration of MA_2 was chosen to be considerably larger than that of B, the peak of MB_2 did not appear on the chromatograms, the second step of ligand exchange shown in Eq. 8 being negligible.

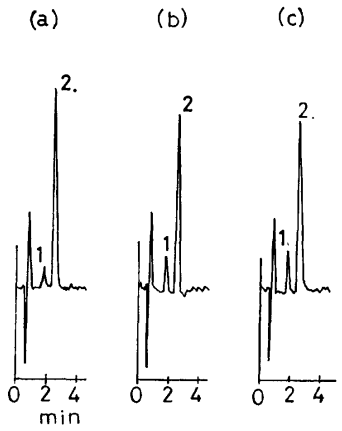

Fig.. 2 Change of chromatogram patterns by ligand exchange. Column: Shodex silipak (4 mm × 15 cm). Eluent: hexane : ethyl acetate=100 : 8 (water saturated). Flow rate: 2.5 cm^3/min. Detector: 325 nm. Sample size: 200 μl (in chloroform: ethyl acetate: hexane=1 : 1 : 8). Sample: 5.0×10^{-6} mol dm^{-3} $Ni[(C_2H_5)_2NCSS]_2$ (=MA_2)+7.9×10^{-7} mmol dm^{-3} $(C_3H_7)_2NCSS^-$ (=B). (a) After mixing 15 s, (b) 35 s, (c) 3 min (equilibrium).
1: NiAB, 2: NiA_2.

The equilibrium was attained within 2 min, as shown by the fact that the chromatograms of the solutions after mixing for 2 and 5 min were identical. The time required to attain equilibrium was approximately inversely proportional to the product of the initial concentrations of MA_2 and B. From these results, the rate constants k_1 and k_{-1} in Eq. 7 can be calculated in terms of Eq. 17 if ligand exchange occurs by means of a bimolecular process. The simple bimolecular mechanism in ligand exchange does not seem to be conclusively proved, however, because of the relatively large experimental error and also because of the following reason. The kinetic study of the ligand exchange of square-planer Pt(II) complexes has been investigated by many workers, and it has been established that the ligand exchange of monodentate ligand proceeds by means of a two-path mechanism, including a five-coordinate intermediate[6] in an aqueous solution. In such cases, the rate of ligand exchange, R, is expressed by the following two-term rate law: ($MA_3X+Y\rightarrow MA_3Y+X$, $R=k[MA_3X]+k'[MA_3X][Y]$). A similar mechanism has been suggested for Ni(II) complexes.[7] Therefore, it seems probable that the rate of ligand exchange of Ni(II) dithiocarbamates might be expressed by a similar two-term rate law, though the present experiments were carried out in a nonaqueous solvent and the ligands involved were bidentate. It can be safely concluded at present that the bimolecular collisional process is predominant, even though the rate equation of ligand exchange is expressed by a two-term rate law or other more complicated equations.[8] If we assume that the simple bimolecular process is valid, the rate constants, k_1 and k_{-1}, in Fig. 2 can be calculated in terms of Eq. 17, because all the variables, K_1, a, b, and x, are known. Thus, k_1 and k_{-1} were calculated to be $(8.3\pm2.4)\times10^3$ mol dm^{-3} s^{-1} and $(2.4\pm0.7)\times10^3$ mol dm^{-3} s^{-1} respectively. The rate constant of ternary-

complex formation between $Ni[(C_2H_5)_2NCSS]_2$ and $Ni[(C_3H_7)_2NCSS]_2$ is $(2.4\pm0.2)\times10^2$ mol dm^{-3} s^{-1}, as was shown in our previous report.[2] The present results show that the rate of ligand exchange is more than ten times faster than that of ternary-complex formation. Considering that the ligand exchange of Ni(II) chelates is so fast that equilibrium is attained promptly at room temperature,[9] the present results seem reasonable.

Electrode Kinetics of the Redox Couples of Co(III/II) Complexes with Ethylenediamine-*N*-acetate, Iminodiacetate, and Diethylenetriamine

Takeo Ohsaka, Noboru Oyama, Shuichiro Yamaguchi, and Hiroaki Matsuda*

Department of Electronic Chemistry, Graduate School at Nagatsuta, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received December 27, 1980)

The electrochemical kinetic parameters of $Co(edma)_2^{+/0}$ (edma: ethylenediamine-*N*-acetate), $Co(ida)_2^{-/2-}$ iminodiacetate), $Co(dien)_2^{3+/2+}$ (dien: diethylenetriamine), $Co(1,2\text{-pn})_3^{3+/2+}$ (1,2-pn: 1,2-propanediamine), and $Co(gly)_3^{0/1-}$ (gly: glycinate) redox couples were determined by d.c. and normal pulse polarographic measurements as well as galvanostatic double pulse measurements. A difference in the evaluated kinetic parameters for the geometric isomers, *trans*(*O*)- and *cis*(*O*)-$Co(edma)_2^{+/0}$ and *trans*(*N*)- and *cis*(*N*)-$Co(ida)_2^{-/2-}$ couples, was recognized. The values of the standard rate constant for the bis forms with dien, edma, and ida were reduced with increase in the number of replacement of amino groups in dien by carboxyl groups. The standard rate constants of the redox couples of Co(III/II) complexes with a series of bi- and tridentate polyamines and aminocarboxylates increase in proportion to the number of nitrogen donor atoms involved in the ligands.

The relationship between the structure of metal complexes and their electrochemical reactivity has been the research subject of electrochemists for the past three decades.[1] Attempts were made to correlate the structure of Co(III) complexes with their polarographic half-wave potentials or to their reduction rates. The Co(III) complexes with a wide variety of unidentate ligands and their geometric isomers with mixed ligands were used for this purpose.

As regards Co(III) complexes with multidentate ligands, however, only a few papers have been reported. Bond *et al.*[2] found that the half-wave potentials for the reduction of three geometric isomers of $Co(dien)_2^{3+}$ (dien=diethylenetriamine) in acetone solvent slightly differ from each other. Gouzerh[3] reported that the half-wave potentials of *cis*(*N*)- and *trans*(*N*)-$Co(ida)_2^{-/2-}$ (ida=iminodiacetate) redox couples are 0.16 and 0.05 V *vs.* SCE, respectively. Recently, Rader and Mcmillin[4] proposed that the electrolytic reductions of *cis*(*N*)- and *trans*(*N*)-$Co(ida)_2^-$ isomers are reversible and irreversible, respectively, and that the *cis*(*N*) configuration is favored in the Co(II) system. However, no attempt has been made to evaluate the electrochemical kinetic parameters. Systematic examination of the redox behavior of a series of similar metal complexes containing multidentate ligands has not been reported so far.

We have attempted to measure the electrochemical kinetic parameters of $Co(dien)_2^{3+/2+}$, $Co(edma)_2^{+/0}$ (edma=ethylenediamine-*N*-acetate) and $Co(ida)_2^{-/2-}$ redox couples. Discussion was made on the relative effects of amino and carboxyl groups on the electrode kinetics, where dien, edma, and ida are chosen as typical tridentate ligands, which make the five-membered chelate ring with metal ion and contain the amino, imino, and/or carboxyl groups as the donating groups. The difference in the redox behavior of the geometric isomers was also examined. In order to confirm the results obtained for tridentate ligands we have determined the kinetic parameters of $Co(1,2\text{-pn})_3^{3+/2+}$ (1,2-pn=1,2-propanediamine) and $Co(gly)_3^{0/1-}$ (gly=glycinate) redox couples.

Experimental

Reagents. *trans*-(*O*)-$Co(edma)_2^+$ and *cis*(*O*)-$Co(edma)_2^+$ were prepared according to the method of Fujii *et al.*[5] *cis*-Complexes obtained, however, contained an appreciable amount of *trans*-form. A *trans*-form free product was obtained by the following procedure utilizing the fact that the *trans*-form is soluble in a concentrated sodium perchlorate solution but not the *cis*-form: the initial product was dissolved in a saturated $NaClO_4$ solution, and the *cis*-complex precipitated was filtered, decanted with cold water and methanol, and dried. *cis*(*N*)-$Co(ida)_2^-$,[6] *trans*(*N*)-$Co(ida)_2^-$,[6] $Co(dien)_2^{3+}$,[7] $Co(1,2\text{-pn})_3^{3+}$,[8] *mer*-$Co(gly)_3^0$,[9] and *fac*-$Co(gly)_3^0$,[9] were synthesized by the standard procedures, where the following abbreviations were used: edma, $NH_2CH_2CH_2NHCH_2COO^-$; ida, $NH(CH_2COO^-)_2$; dien, $NH_2CH_2CH_2NHCH_2CH_2NH_2$; 1,2-pn, $NH_2CH_2CH(CH_3)NH_2$; gly, $NH_2CH_2COO^-$. Results of the elementary analysis for each species are as follows:

trans(*O*)-$[Co(edma)_2]Cl\cdot 2H_2O$	Found (%)	H(6.27), C(26.39), N(15 35), Cl(9.96),
	Calcd (%)	H(6.08), C(26.32), N(15.36), Cl(9.72)

	Calcd	H(4.72), C(24.09), N(14.04)

Ethylenediamine-*N*-acetic acid dihydrochloride dihydrate (Hedma·2HCl·2H_2O), diethylenetriamine (dien), and iminodiacetic acid were prepared and/or purified by the methods described in the previous paper.[10] 1,2-Propanediamine diperchlorate was prepared from perchloric acid and 1,2-propanediamine and then purified by recrystallization three times from water. Other chemicals were of reagent grade. All solutions were prepared with triply distilled water.

Apparatus. An apparatus containing d.c. and pulse polarographic modes constructed in our laboratory was employed, the polarograms being recorded with a X-Y recorder (Riken Denshi Co., Model F-42Cp, Tokyo). The electrolytic cell was designed to measure pH values accurately.[10] A digital pH/mV meter (Orion Research, Model 801) and a glass electrode (Beckman, No. 40495) were used for pH measurements. The dropping mercury electrode (DME) with the following characteristics was used: flow rate of mercury $m=0.45$ mg s^{-1}, the drop time $\tau=4.5$ s at the height of mercury head $h=72.0$ cm in 1 M $NaClO_4$ solution (1 M= 1 mol dm^{-3}). The test solution was deaerated with argon gas before each measurement of the current-voltage curves. All measurements were performed in a paraffin oil thermostat at 25.0±0.1 °C. Potentials were measured and recorded with respect to a saturated calomel reference electrode (SCE).

Results

D.c. and Normal Pulse Polarographic Measurements of trans*(O)- and* cis*(O)-Co(edma)$_2^{+/0}$ Couples.* A solution in which the bis-form of Co(II) complexes with respect to edma is predominantly present was used for the sake of convenience. The mechanism of the electrode processes might be as follows:

$$\begin{array}{ccc} cis(O)\text{-Co(edma)}_2^{+} & \underset{\alpha_c(cis),\ k_0(cis)}{\overset{+e}{\rightleftharpoons}} & cis(O)\text{-Co(edma)}_2^{0} \\ \Big\updownarrow & & \Big\updownarrow \\ trans(O)\text{-Co(edma)}_2^{+} & \underset{\alpha_c(trans),\ k_0(trans)}{\overset{+e}{\rightleftharpoons}} & trans(O)\text{-Co(edma)}_2^{0}, \end{array} \quad (1)$$

where α_c denotes the cathodic transfer coefficient and k_0 the standard rate constant of the charge transfer process.

D.c. polarographic current-potential curves of *cis(O)*- and *trans(O)*-Co(edma)$_2^+$ in 1.0 M NaCl solution were measured in the pH range 8.3—9.7 and the quasi-reversible one-electron reduction waves with diffusion-controlled limiting currents were observed for both species. The reversible half-wave potential $E_{1/2}^r$ was determined by means of extrapolation,[11] the values obtained being given in Table 1. The difference in the values of $E_{1/2}^r$ of the *cis*- and the *trans*-forms exceeds 10 mV, being independent of the drop time in the range 3—6 s. This suggests that within the d.c. polarographic time scale the Co(II) species produced by the reduction at the electrode remain in the same geometric form as the Co(III) species, although the Co(II) species are labile, and the standard potential of the *cis*-Co(III/II) couple is *ca.* 10 mV more negative than that of *trans*-Co(III/II) couple. Thus in the analysis of d.c. and pulse polarographic waves it is not necessary to consider any effects of geometric configuration changes at the state of Co(II) complex.

The electrochemical kinetic parameters were evaluated from the analysis of normal pulse polarograms.

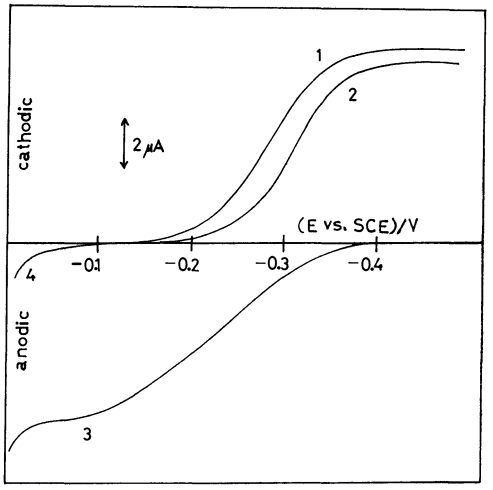

Fig. 1. Typical normal pulse polarograms of the Co(edma)$_2^{+/0}$ couple in 1.0 M NaCl solution.
(1): Reduction wave of 1.0 mM *trans* (*O*)-Co(edma)$_2^+$, (2): reduction wave of 1.0 mM *cis*(*O*)-Co(edma)$_2^+$, (3): oxidation wave of 1.0 mM Co(edma)$_2^0$, (4): residual current.
Concentration of Hedma=20 mM, pH=8.3 and sampling time $\tau_s=34.5$ ms.

Figure 1 shows typical normal pulse polarograms for the reduction of the *cis(O)*- and the *trans(O)*-Co(edma)$_2^+$ complexes as well as the oxidation of Co(edma)$_2^0$ complex. The half-wave potential of reduction waves shifted to cathodic direction with decreasing sampling time, τ_s, and their limiting current was diffusion-controlled, as proved from the fact that the product of the limiting current and $\tau_s^{1/2}$ is always constant.

The current-potential relationship for normal pulse polarograms of the simple electrode process, Ox+$ne \rightleftarrows$ Red, is given by[12]

$$E = E^* - \frac{2.303RT}{\alpha_c nF} \log \left\{ x \left[\frac{1.75 + x^2(1+\exp\zeta)^2}{1 - x(1+\exp\zeta)} \right]^{1/2} \right\} \quad (2)$$

with

$$E^* = E_{1/2}^r + \frac{2.303RT}{\alpha_c nF} \log \left\{ \frac{4}{\sqrt{3}} \frac{k_0\sqrt{\tau_s}}{\sqrt{D}} \right\}, \quad (3)$$

$$x = i/(i_d)_{Cott}, \quad (4)$$

$$\zeta = (nF/RT)(E - E_{1/2}^r), \quad (5)$$

$$D = D_{Ox}^{1-\alpha_c} D_{Red}^{\alpha_c}, \quad (6)$$

where $(i_d)_{Cott}$ denotes the diffusion current expressed by the Cottrel equation, i the normal pulse polarographic current, E the electrode potential, τ_s the sampling time, D_{Ox} and D_{Red} are the diffusion coefficients of Ox and Red, respectively, the other symbols having their usual meanings. The log-plots of the normal pulse polarograms, in which the log-term on r.h.s. of Eq. 2 is plotted against E, gave straight lines for the reduction of *cis(O)*- and *trans(O)*-Co(edma)$_2^+$ (Fig. 2). The straight lines have constant slopes for the *cis(O)*- and *trans(O)*-species, respectively, within experimental errors. The cathodic transfer coefficients were evaluated from their reciprocal slopes. The value of E^* was obtained from the intersects of these lines with the zero-line. The plots of E^* against log τ_s, shown in Fig. 3, give straight lines, their slopes also enabling us to evaluate the transfer

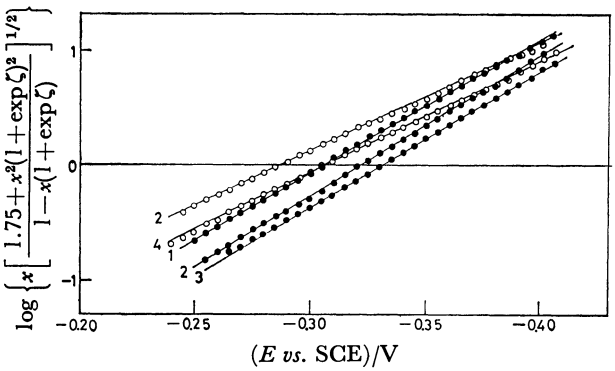

Fig. 2. Representative results for the plots of $\log\left[x\left\{\frac{1.75+x^2(1+\exp\zeta)^2}{1-x(1+\exp\zeta)}\right\}^{1/2}\right]$ *vs.* E for the reduction of 1.0 mM *cis*(*O*)- and *trans*(*O*)-Co(edma)$_2^+$.
(●): *cis*(*O*)-Species and (○): *trans*(*O*)-species. Sampling time τ_s=(1) 24.1 ms, (2) 8.7 ms, (3) 5.9 ms, and (4) 3.1 ms. Other conditions are same as in Fig. 1.

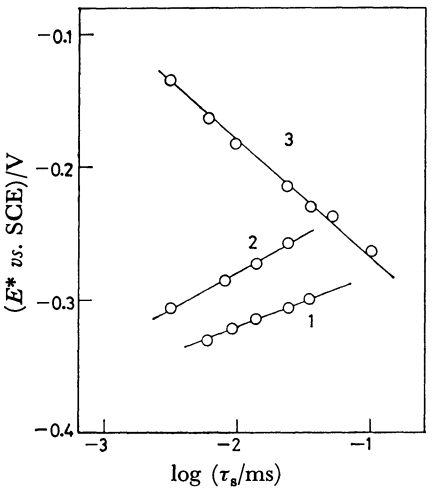

Fig. 3. Plots of E^* against log τ_s for the Co(edma)$_2^{+/0}$ couple.
(1): Reduction of *cis*(*O*)-Co(edma)$_2^+$, (2): reduction of *trans*(*O*)-Co(edma)$_2^+$, and (3): oxidation of Co(edma)$_2^0$. Other conditions are the same as in Fig. 1.

coefficients, as can be seen from Eq. 3. The cathodic transfer coefficients evaluated from the reciprocal slopes of the plots given in Figs. 2 and 3 are in good agreement with each other; they are 0.70 and 0.57 for the *cis*- and the *trans*-forms, respectively. The standard rate constants of charge transfer processes, k_0, were evaluated by means of Eq. 3. The values obtained are given in Table 1, where the values of diffusion coefficients used (6.2×10^{-6} and 7.3×10^{-6} cm^2 s^{-1} for the *cis*- and *trans*-forms, respectively) were obtained from the cathodic limiting currents of d.c. polarograms by using the Ilkovic equation or from those of normal pulse polarograms by using the Cottrell equation. We find that the standard rate constants for the reduction of the Co(III) complexes are in the order: *trans*(*O*)>*cis*(*O*).

The d.c. polarogram for the oxidation of the Co(edma)$_2^0$ complex shows the quasi-reversible nature (Fig. 4), its reversible half-wave potential being obtained as 0.281 ± 0.001 V *vs.* SCE by means of extrapolation.[11]

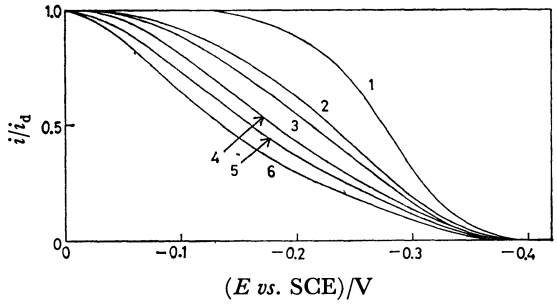

Fig. 4. Normalized d.c. and normal pulse polarograms for the oxidation of Co(edma)$_2^0$ in 1.0 M NaCl solution.
(1) D. c. polarogram at the drop time τ=4.0 s, (2) normal pulse polarograms at the sampling time τ_s= 52.4 ms, (3) 24.1 ms, (4) 8.7 ms, (5) 5.9 ms, and (6) 3.1 ms. Other conditions are the same as in Fig. 1.

The half-wave potential of the normal pulse polarograms shifts to the anodic direction as the sampling time is reduced (Fig. 4), their limiting current being diffusion-controlled. At the sampling times below 30 ms the limiting currents of the oxidation wave start to overlap with the dissolution-wave of mercury. Thus, the current was measured as the difference between the total current and the residual current as measured in the solution containing no Co(II) ion at the same potential. The relevant electrochemical kinetic parameters for the oxidation of the Co(edma)$_2^0$ complex were evaluated according to the same procedure as mentioned for the reduction of Co(III) complex and are summarized in Table 1, where the value of diffusion coefficient used was 5.9×10^{-6} cm^2 s^{-1}.

At present we have no means to decide what form of the geometrical isomer of Co(edma)$_2^0$ complex is predominantly present in the bulk of solution. However, the following indicates that the predominant species at equilibrium is the *cis*(*O*)-form: (1) The value of the reversible half-wave potential obtained from the d.c. polarographic oxidation wave is in good agreement with that of the reduction wave of *cis*(*O*)-Co(edma)$_2^+$ complex, and (2) agreement between the standard rate constants determined from the oxidation wave of Co(II) complex and the reduction wave for the *cis*(*O*)-form of Co(III)

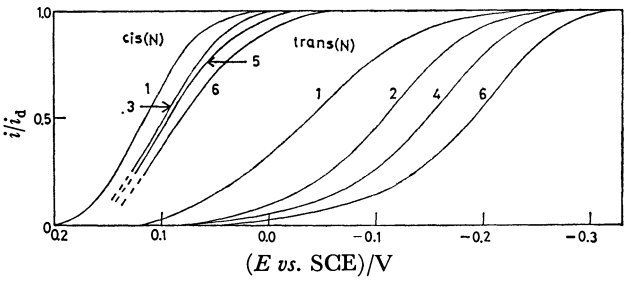

Fig. 5. Normalized d.c. and normal pulse polarograms for the reduction of 1.0 mM *cis*(*N*)-Co(ida)$_2^-$ in 1.0 M KNO_3 solution.
(1) D. c. polarogram at τ=4.2 s, (2) normal pulse polarograms at τ_s=75.0 ms, (3) 24.1 ms, (4) 14.0 ms, (5) 8.7 ms, and (6) 3.1 ms. Concentration of H_2ida= 10 mM and pH=8.3.

complex is quite good, the sum of their transfer coefficients being equal to unity.

D.c. and Normal Pulse Polarographic Measurements of trans-*(*N*)- and* cis*(*N*)-Co(ida)$_2^{-/2-}$ Couples.* Figure 5 shows the d.c. and normal pulse polarograms for reduction of *trans(N)*- and *cis(N)*-Co(ida)$_2^-$ complexes under the conditions in which the bis-species exists predominantly in the state of Co(II). In the case of the *cis*-species the current was measured carefully as the difference between the total and residual currents since the reduction current of the complex at the foot of the wave overlapped with the dissolution current of mercury. The log-plot of d.c. polarogram for the *cis*-species give a straight line with the reciprocal slope of 58 mV, corresponding to the reversible wave, whereas the log-plot of the *trans*-species indicates that the electrode reaction is quasi-reversible (close to irreversible) (Fig. 6).

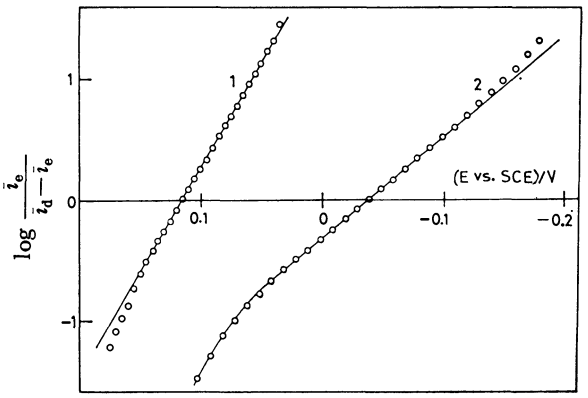

Fig. 6. D. c. polarographic log-plots for the reduction of *cis(N)*- and *trans(N)*-Co(ida)$_2^-$.
(1): *cis(N)* and (2) *trans(N)*.

In order to evaluate the kinetic parameters of reduction for the Co(III) complex, it is necessary to know the isomer form of Co(II) complex produced by reduction. Rader and Mcmillin[4] proposed that the reduced product of *trans(N)*-Co(ida)$_2^-$ isomerizes to the corresponding *cis*-isomer and that *cis(N)*-Co(ida)$_2^-$ is formed at the electrode upon reoxidation, as judged from the assignment of UV-vis. absorption spectra of bulk electrolysis product. They also stated that the isomerization reaction may proceed rapidly. However, our detailed examination of the isomerization kinetics using the anodic normal pulse measurements with cathodic pre-electrolysis of the *cis(N)*- and *trans(N)*-Co(ida)$_2^-$ gave no support for the *rapid* isomerization. The overlap of the polarogram of anodic reaction for the Co(II) species with the dissolution current of mercury was a main obstacle against detailed analysis. That the formation of the *cis*-form does not proceed in a quantitative way within d.c. and pulse polarographic timescales is suggested also by the disagreement between the reversible half-wave potentials for the reduction of the *cis*- and *trans*-Co(III) complexes (Table 1). At any rate, the *cis(N)*-configuration is favored at equilibrium for the state of Co(II).[4] Therefore, *cis(N)*-Co(ida)$_2^-$ keeps preferably the *cis(N)*-configuration after being reduced at the electrode, whereas the reduced product of *trans(N)*-Co(ida)$_2^-$ may gradually be isomerized to the *cis(N)*-form. Even if the isomerization process might proceed rapidly, the electrochemical kinetic parameters of *trans(N)*-Co(ida)$_2^-$ can be evaluated with sufficient accuracy, since the electrode reaction of *trans(N)*-form is d.c. polarographically quasi-reversibe (close to irreversible) and thus pulse-polarographically irreversible, so that the potential-shift due to the follow-up isomerization reaction may be negligibly small.

The kinetic parameters of the *cis(N)*- and *trans(N)*-Co(ida)$_2^-$ complexes were evaluated by means of the same method as described in the previous section. The reduction half-wave potentials for the *cis*- and *trans*-forms shifted to cathodic direction as the sampling time was reduced (Fig. 5) and their limiting currents were diffusion-controlled.

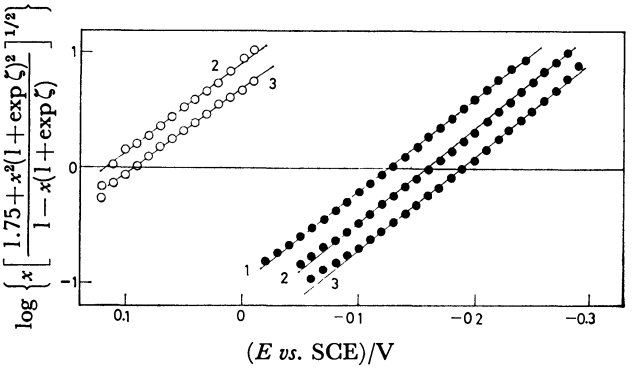

Fig. 7. Representative plots of $\log\left[x\left\{\frac{1.75+x^2(1+\exp\zeta)^2}{1-x(1+\exp\zeta)}\right\}^{1/2}\right]$ *vs.* E for the reduction of 1.0 mM *cis(N)*- and *trans(N)*-Co(ida)$_2^-$.
(○): *cis(O)*-Species and (●): *trans(O)*-species.
τ_s=(1) 34.0 ms, (2) 8.7 ms, and (3) 3.1 ms. Other conditions are the same as in Fig. 5.

The log-plots afford a set of straight lines at the different sampling times (Fig. 7). The cathodic transfer coefficients were obtained from the reciprocal slopes of these lines as follows: $\alpha_c(trans)=0.47\pm0.02$ and $\alpha_c(cis)=0.46\pm0.04$. The standard rate constants evaluated from the values of E^* are summarized in Table 1. Magnitude difference in these two values amounts to several tens. The diffusion coefficients used to evaluate the kinetic parameters were 5.6×10^{-6} and 6.8×10^{-6} cm^2 s^{-1} for the *cis*- and *trans*-forms, respectively, as determined from cathodic limiting currents of normal pulse polarograms.

Galvanostatic Double Pulse Measurements of Co(dien)$_2^{3+/2+}$ Couples. Although the Co(dien)$_2^{3+}$ complex has three geometric isomers, meridional(*mer*), symmetrical facial(*s-fac*), and unsymmetrical facial(*u-fac*), the *mer*-Co(dien)$_2^{3+}$ species which can easily be synthesized was chosen as a typical species of the Co(III) complex with polyamine ligand. D.c. polarographic reduction wave showed a reversible nature and its half-wave potential was constant at −0.448 V *vs.* SCE in the presence of a large excess of dien at pH above 8.5. The rate of charge transfer processes for the Co(dien)$_2^{3+/2+}$ couple was very rapid, so that their kinetic parameters

could not be evaluated even by the normal pulse polarographic technique. We therefore used the galvanostatic double pulse method with polarographic generation of reactant(g.d.p.p. method),[13] which has been recognized to be one of the most powerful techniques for very fast charge transfer processes. The analysis of experimental results was performed by using Eqs. 16 and 18 of Ref. 13. The experimental plots of the overpotential η_h *vs.* square root of the first pulse width $\sqrt{t_1}$ and of the exchange current density i_0 *vs.* applied d.c. potential E are shown in Figs. 8 and 9, respectively, in accordance with Eqs. 16 and 18 of Ref. 13, respectively. The theoretical slope was calculated by use of the diffusion coefficient of 4.4×10^{-6} cm^2 s^{-1} obtained from the d.c. polarographic limiting current (Fig. 8). The standard rate constant and the cathodic transfer coefficient obtained are given in Table 1.

Electrochemical Kinetic Parameters of Co(1,2-pn)$_3^{3+/2+}$ and mer-*Co(gly)$_3^{0/1-}$ Couples.* For the sake of comparison, the kinetic parameters for the reduction of the Co(1,2-pn)$_3^{3+}$ complex were also evaluated by the g.d.p.p. measurement (Table 1). The Co(1,2-pn)$_3^{3+}$ has two geometric isomers, *mer* and *fac*, with respect to methyl group but the product synthesized according to Ref. 8

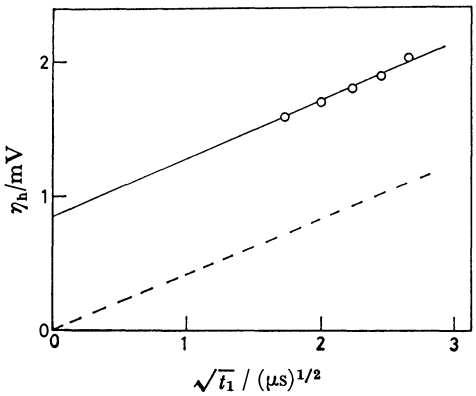

Fig. 8. A plot of the overpotential η_h *vs.* square root of first-pulse width $\sqrt{t_1}$ at the reversible half-wave potential of the *mer*-Co(dien)$_2^{3+/2+}$ couple in the g.d.p.p. measurement.
Solution composition: 1.0 mM *mer*-Co(dien)$_2^{3+}$, 0.10 M dien and 1.0 M $NaClO_4$ (pH=10.7). The dotted line indicates the theoretical slope.

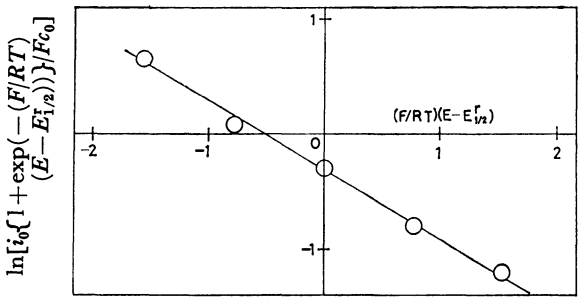

Fig. 9. A plot of ln $[i_0\{1+\exp(-(F/RT)(E-E^r_{1/2}))\}/Fc_0]$ *vs.* $(F/RT)(E-E^r_{1/2})$ for the Co(dien)$_2^{3+/2+}$ couple.

may be a mixture of two isomers. However, d.c. polarogram of the reduction of the synthesized complex showed only a single reversible reduction wave at −0.465 V *vs.* SCE. We thus used the synthesized product recrystallized without separation of the isomers.

In contrast to the electrochemical behavior of the polyamine complexes, the rate of reduction of *mer*-Co(gly)$_3^0$ was very slow and the reduction wave was d.c. polarographically irreversible. Thus, the log-plot of normal pulse polarograms gave only the cathodic transfer coefficient and the cathodic rate constant at $E=0$, *i. e.*, at the potential of SCE. According to Hin-Fat and Higginson,[17] the standard potential of the Co(gly)$_3^{0/1-}$ couple is -0.06 ± 0.01 V *vs.* SCE. If we use this value, we can calculate the standard rate constant of this couple, which is also given in Table 1 together with the cathodic rate constant at $E=0$.

No electrochemical measurements for *fac*-Co(gly)$_3^{0/1-}$ couple were performed since the *fac*-Co(gly)$_3^0$ species is insoluble in aqueous solutions containing 1 M supporting electrolytes.

Discussion

On the basis of the kinetic parameters summarized in Table 1, we can find some correlation between the electrochemical reactivity of Co(III/II) complexes and their structure.

(1) For the reduction of Co(III) complexes, six coordination sites of which are occupied by amines of similar ligands, the standard rate constant, k_0, increases

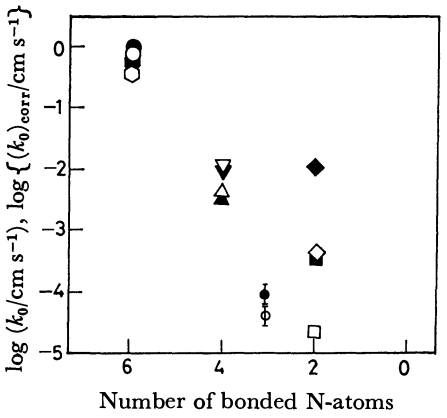

Fig. 10. Correlation between the standard rate constants and the number of bonded nitrogen donor atoms.
(●, ○): *mer*-Co(dien)$_2^{3+/2+}$, (⬢, ⬡): Co(1,2-pn)$_3^{3+/2+}$, (▼, ▽): *trans*(*O*)-Co(edma)$_2^{+/0}$, (▲, △): *cis*(*O*)-Co(edma)$_2^{+/0}$, (◆, ◇): *cis*(*N*)-Co(ida)$_2^{-/2-}$, (■, □): *trans*(*N*)-Co(ida)$_2^{-/2-}$, and (⧫, ⧫): *mer*-Co(gly)$_3^{0/1-}$.
The solid and open symbols denote the measured values, k_0, and the values corrected by the Frumkin theory, $(k_0)_{corr}$, respectively.

in the order: Co(dien)$_2^{3+/2+}$>Co(1,2-pn)$_3^{3+/2+}$, Co(en)$_3^{3+/2+}$ (en: ethylenediamine)[14]>Co(NH$_3$)$_6^{3+/2+}$.[15,16] This order is the same as that of the number of coordination sites involved in the ligand, *i. e.*, tridentate> bidentate>unidentate.

(2) Increase in the number of replacement of amino groups in dien by carboxyl groups reduces the values of k_0. The values of k_0 increase in the order: Co(dien)$_2^{3+/2+}$ >Co(edma)$_2^{+/0}$>Co(ida)$_2^{-/2-}$ (Fig. 10). The complex species studied have a different number of charges, the difference between their reversible half-wave potentials amounting to *ca.* 500 mV, so that the ϕ_2-potential at the outer Helmholtz plane may affect the kinetics of electrode reactions concerned. The open symbols in Fig. 10 express the values of the standard rate constant corrected for the double layer effect by means of the Frumkin theory,[18] in which the values of ϕ_2 were taken from Russell's Tables.[19] We find that for the present series of the redox couples of Co(III/II) complexes with bi- and tridentate polyamines and aminocarboxylates the logarithms of the corrected values, $(k_0)_{corr}$, increase

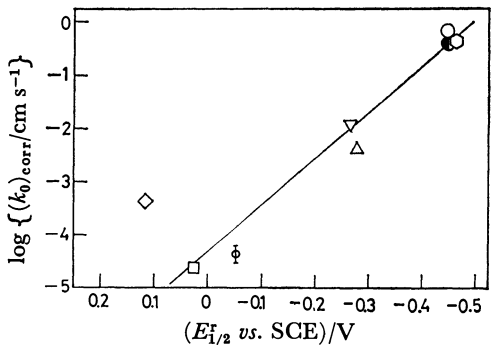

Fig. 11. Linear relationship between $\log(k_0)_{corr}$ and $E_{1/2}^r$.
(◐): Co(en)$_3^{3+/2+}$. Other symbols are the same as in Fig. 10.

in proportion to the number of nitrogen donor atoms involved in the ligand.

(3) Oyama *et al.*[20-22] showed that the linear relation between the logarithms of cathodic rate constants and the corresponding standard potentials holds for the Cd(II) and Pb(II) complexes with EDTA and related compounds. It is of interest to see if such a correlation prevails for the present series of Co(III/II) redox couples. Log $(k_0)_{corr}$ is plotted against the reversible half-wave potential $E_{1/2}^r$ in Fig. 11. We see linear correlation, except for the *cis*(*N*)-Co(ida)$_2^{-/2-}$ couple whose reversible half-wave potential is unusually positive. As can be seen from Table 1, the values of $E_{1/2}^r$ are also proportional to the number of the nitrogen donor atoms involved in the ligand, so that the linear correlation given in Fig. 11 could be attributed to that of Fig. 10.

(4) The difference of the kinetic parameters for the geometric isomers is obvious from the data in Table 1.

The authors wish to express their sincere thanks to Prof. S. Aoyagui and Dr. H. Mizota for allowing them to use their apparatus for the g.d.p.p. method. This work was partially supported by a Grant-in-Aid for Scientific Research No. 247065 from the Ministry of Education, Science and Culture.

An Alternative Display of Potentiostatic Measurements. I. Instrumental Design and Verification of Modified Pulse Polarograph

Yoshikiyo KATO,* Yoshio ANZAI,† Akifumi YAMADA, and Nobuyuki TANAKA
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received January 5, 1981)

A modified instrument for the potentiostatic method (modified pulse polarograph) has been developed, which uses techniques of the time-to-voltage converter. The modified pulse mode and the modified differential pulse mode have been tested as tools for quantitative analysis. The determination of kinetic parameters of electrode reactions is presented, together with the characteristics of the modified pulse polarograph.

Modern polarographic methods, especially normal and differential pulse techniques, have been widely used in trace analysis.[1-23] An advantage of using commercial instruments of pulse polarography is in the high signal-to-noise ratio (S/N): the averaging of current signal is synchronized to the a.c. power line. Although signal averagings of this type produce high S/N ratio, available sampling times are restricted, and current-potential curves are slightly distorted.[7]

Recently, the authors have developed a new polarographic technique. The method records the time instead of current or potential and has been successfully introduced in constant-current electrolysis.[24-26] The measurement and the recording of the time have been carried out by the time-to-voltage converter. Introduction of the time-to-voltage converter produces high S/N ratios without sacrifice of the frequency response of the data sampling circuit.

Previously, the authors reported a modified potentiostatic method. This method is based on the measurement of time required to reach a constant sampling current in the potentiostatic method.[27,28] The fundamental concept and the determination of kinetic parameters were reported. However, the complete system has not been developed. The measurement of time was carried out descretely, using a comparator and a digital counter.[27]

In this report, instrumental designs of a modified pulse polarograph, characteristics of modified pulse polarography (MPP), and some applications in the electrode kinetics are presented. The use of the time-to-voltage converter is indispensable to realize the full advantages of the modified potentiostatic method. The development of the modified pulse polarograph simplified the measurement of the instantaneous time-potential-current relation without limitations of sampling time and without distortion of data, attempts at the modified differential pulse polarography (MDPP) are also reported.

Experimental

A three-electrode cell equipped with a saturated calomel reference electrode (SCE: Yanagimoto MR-P_2-05-1), a platinum wire electrode (counter electrode) and a dropping mercury electrode (DME: Yanagimoto Type-C) was used; synchronization of DME was done by a electro-mechanical knocker (Fuso Solenoid).

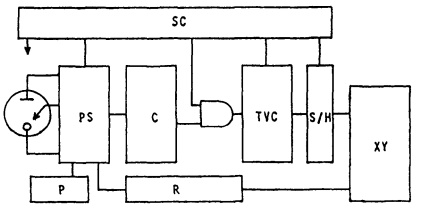

Fig. 1. The block diagram of the modified pulse polarograph. (PS: potentiostat, C: comparator, TVC: time-to-voltage converter, S/H: sample and hold circuit, P: potentiometer, R: ramp generator, SC: sequence controller, XY: x-y recorder).

$[Co(NH_3)_6]Cl_3$ was prepared according to the literature[29] and identified by elemental analysis. The solution was deaerated with pure nitrogen and kept under nitrogen atmosphere. The temperature of the solution was kept constant at 25.0±0.1 °C. All solutions were prepared in twice distilled water; all chemicals were analytical grade.

Apparatus

A new modified pulse polarograph was designed for this study. The polarograms were recorded with this instrument using a Rikadenshi RW-11 x-y recorder. The block diagram and the electronic circuit of the modified pulse polarograph are shown in Figs. 1 and 2. The modified pulse polarograph is constructed with a three-electrode-type potentiostat (PS), comparator (C), time-to-voltage converter (TVC), sample-and-hold

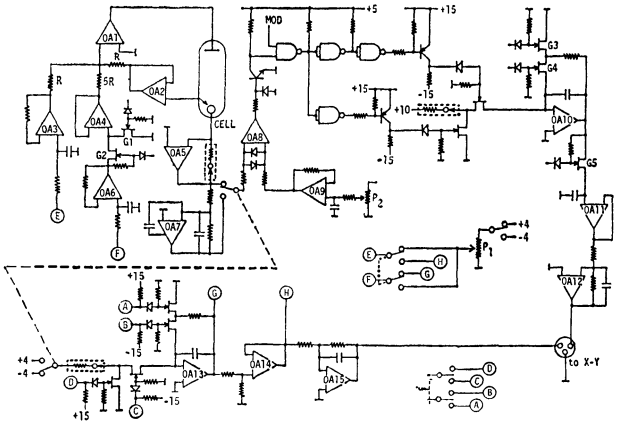

Fig. 2. The electronic circuit of the modified pulse polarograph.

† Present address: Kikakushitsu Kikakuka, Nihon Recruit Center, 8-4-17, Ginza, Chuo-ku, Tokyo 104.

circuit (S/H), and ramp generator (R). The procedure for measurements is controlled by a sequence controller (SC). When a mercury drop begins to grow, it is held at the initial potential E_i set by the potentiometer P_1 (In differential mode, the drop is held at the potential set by the ramp generater.). After the lapse of a preset time period t_w(0.5—11 s), the sequence controller turns the gate G1 off and the gate G2 on. The potentiostat is then connected to the ramp generator, which provides the step voltage ΔE (In the differential mode the step voltage ΔE is provided by the potentiometer P_1.). Simultaneously, the time-to-voltage converter is turned to the ready state by gates G-3 and G-4.

The current signal resulting from potential relaxation (E_i to $E_i+\Delta E$) is fed to a high-speed comparator OA-8. The slice level of the comparator (*i. e.* the constant sampling current, i_s) is set by the potentiometer P_2. The output of the comparater is connected to the gates of the time-to-voltage converter. After 1 s of t_w, the gates G-1 and G-2 are turned to the former state and the DME knocker is started. Simultaneously, gate G-5 stores the output of the TVC in the sample-and-hold circuit (OA-11). Then, gates G-3 and G-4 reset the TVC. The measurement cycle is completed and the sequence is repeated. The values of t are displayed on an x-y recorder as a function of E. The time chart and the relationships between control signals and FET gates are shown in Fig. 3.

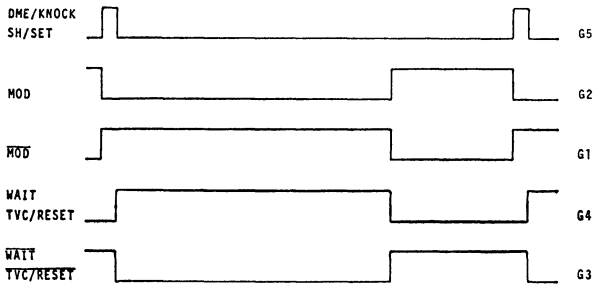

Fig. 3. The time chart of the control sequences and their connection with FET-gates.

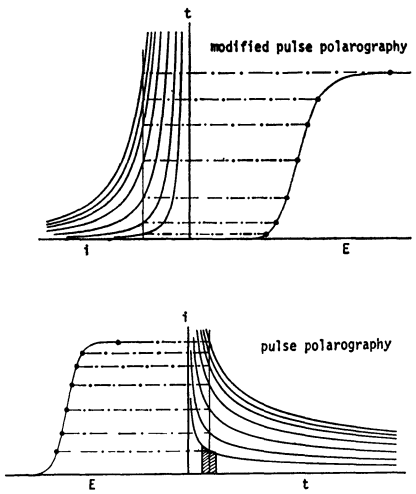

Fig. 4. The relations of current-time curves and the modified pulse and/or the normal pulse polarogram.

The principle of MPP is schematically shown in Fig. 4 together with that of pulse polarography. In MPP, the time required to reach a constant sampling current i_s in potentiostatic measurements is recorded versus the potential. Therefore, the modified pulse polarogram gives the instantaneous time-potential-current relation. On the other hand, in the pulse polarography, the average current in the sampling period is recorded *versus* the potential.

Results and Discussion

System Evaluation. To evaluate the function of the system, modified pulse polarograms of a reversible and an irreversible electrode reactions were measured. Potential-time relations of reversible and irreversible electrode processes were also tested for the case of cathodic reduction, when only the oxidant is present in the solution.

Reversible Case: The potential-time relationships of modified pulse mode are given by

$$E = E_o - \frac{RT}{(\alpha_a+\alpha_c)nF} \ln \sqrt{\frac{D_O}{D_R}} + \frac{RT}{(\alpha_a+\alpha_c)} \ln \frac{\sqrt{t_{diff}}-\sqrt{t}}{\sqrt{t}}, \quad (1)$$

for a reversible electrode process.[27,28] Here E is the electrode potential; E_o, the formal potential; α the transfer coefficient; D, the diffusion coefficient; t, the time; t_{diff}, the time at potentials controlled by diffusion; and R, T and F have their usual meanings. The subscripts a and c indicate the anodic and the cathodic processes, and O and R the oxidant and the reductant.

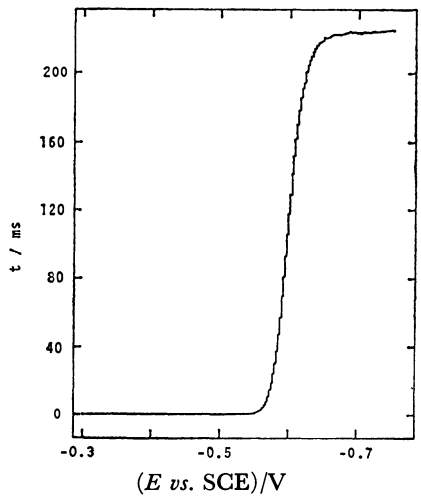

Fig. 5. An example of modified pulse polarogram. (1 mM $Cd(NO_3)_2$†† in 1 M $NaNO_3$ containing 2 μM LEO, i_s=10 μA, t_w=2 s, m=1.063 mg s^{-1}).

The modified pulse polarogram of cadmium ion is shown in Fig. 5 as an example of a reversible process. Equation 1 shows the linear relation between E and $\ln\{(\sqrt{t_{diff}}-\sqrt{t})/\sqrt{t}\}$. Such plots of the Cd(II)/Cd(Hg) system are shown in Fig. 6. The data points lie very close to the least-square line drawn through them. Furthermore, the slope of the least-square line is almost

†† 1 M=1 mol dm^{-3}.

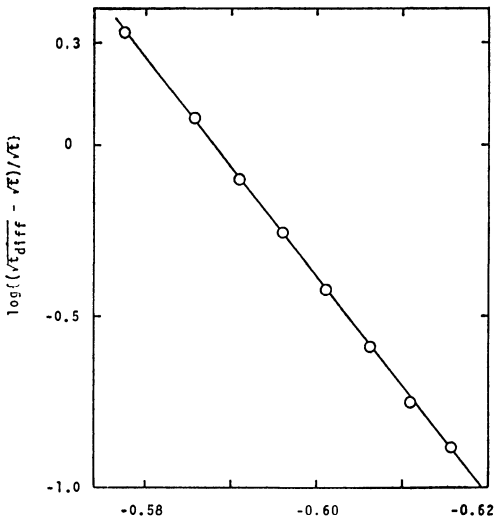

Fig. 6. The plots of $\log\{(\sqrt{t_{diff}}-\sqrt{t})/\sqrt{t}\}$ *vs.* E. (1 mM $Cd(NO_3)_2$ in 1 M $NaNO_3$ containing 2 μM LEO $i_s=30$ μA, $t_w=4$ s, $m=0.6656$ mg s^{-1}).

equal to RT/nF.

The time at potentials controlled by diffusion, t_{diff}, is represented as

$$\sqrt{t_{diff}} = \frac{nFA\sqrt{D_O}c_O^\circ}{\sqrt{\pi}\,i_d} \qquad (2)$$

for both the reversible and the irreversible processes, where A is the electrode area at t_w; c_O°, the concentration of the bulk of the solution and i_d, the diffusion current.

Equation 2 shows the linear relation between $\sqrt{t_{diff}}$ and c_O° or $1/i_d$. In this report, the time data are corrected for the effect of the expansion of DME during measurements. The correcting factor of the time data is

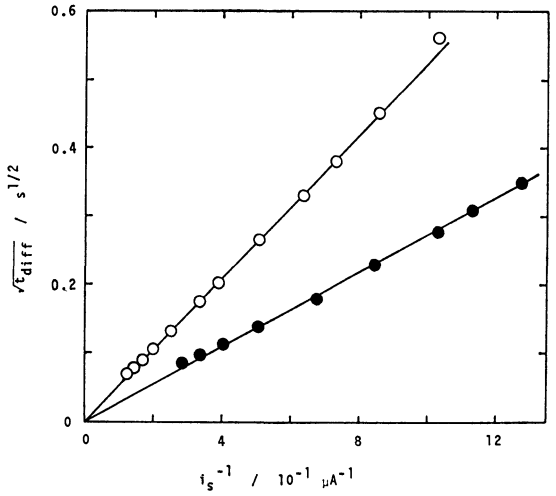

Fig. 8. The plots of $\sqrt{t_{diff}}$ *vs.* reciprocal of i_d. (○: 0.8 mM $Cd(NO_3)_2$ in 1 M $NaNO_3$, $t_w=4$ s, $m=0.6656$ mg s^{-1}; ●: 1 mM $[Co(NH_3)_6]Cl_3$ in 0.9 M $NaNO_3$ containing 0.1 M acetate buffer (pH 5.0) and 2 μM LEO, $t_w=3$ s, $m=1.05$ mg s^{-1}).

$1/(1-t/t_w)^{2/3}$ which is the reciprocal of relative surface area at t_w+t. The linear relations between $\sqrt{t_{diff}}$ and c_O° or reciprocal of i_d were tested for the reduction of Cd(II) and $[Co(NH_3)_6]^{3+}$. The plots of $\sqrt{t_{diff}}$ *versus* c_O° and $\sqrt{t_{diff}}$ *versus* $1/i_d$ are shown in Figs. 7 and 8, respectively. Those plots gave excellent linear relations up to 300 ms of the t_{diff} values, indicating that the instrument works satisfactorily.

Irreversible Case: The potential time relations for an irreversible electrode process are given by[27,28]

$$E = E_o + \frac{RT}{2\alpha_c nF}\ln\frac{16t_{diff}(k_s)^2}{3D_O} - \frac{RT}{2\alpha_c nF}\ln\frac{1.75+t/t_{diff}}{1-\sqrt{t}/\sqrt{t_{diff}}}, \qquad (3)$$

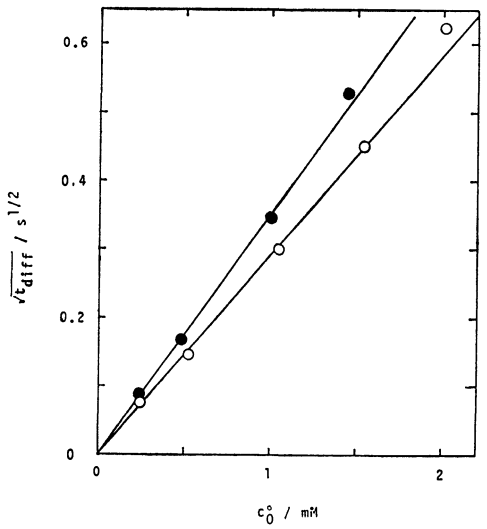

Fig. 7. The plots of $\sqrt{t_{diff}}$ *vs.* the bulk concentration. (●: $[Co(NH_3)_6]Cl_3$ in 0.9 M $NaNO_3$ containing 0.1 M acetate buffer (pH 5.0) and 2 μM LEO, $i_s=8$ μA, $t_w=3$ s, $m=1.05$ mg s^{-1}; ○: $Cd(NO_3)_2$ in 1 M $NaNO_3$ containing 2 μM LEO, $i_s=15$ μA, $t_w=2$ s, $m=0.6656$ mg s^{-1}).

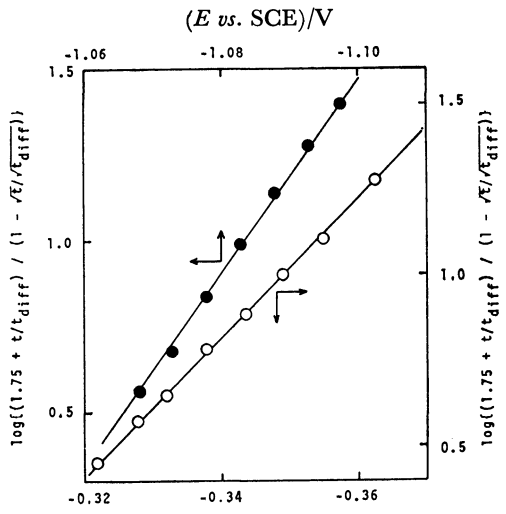

Fig. 9. The plots of $\log\{(1.75+t/t_{diff})/(1-\sqrt{t}/\sqrt{t_{diff}})\}$ *vs.* E. (○: 1 mM $[Co(NH_3)_6]Cl_3$ in 0.9 M $NaNO_3$ containing 0.1 M acetate buffer (pH 5.0) and 2 μM LEO, $i_s=8$ μA; ●: 1 mM $NiCl_2$ in 0.1 M KCl containing 2 μM LEO, $i_s=18$ μA; $t_w=3$ s, $m=1.05$ mg s^{-1}).

where, k_s is the formal standard rate constant. The linear relation of E and $\ln\{(1.75+t/t_{diff})/(1-\sqrt{t}/\sqrt{t_{diff}})\}$ has been tested for the reduction waves of $[Co(NH_3)_6]^{3+}$ and Ni(II). These plots, shown in Fig. 9, gave good linear relations.

The above mentioned results of the system evaluation for reversible and irreversible cases were quite satisfactory. The logarithmic plots shown in Fig. 6 can be utilized for the diagnostic criteria of reversibility. The working curve, $\sqrt{t_{diff}}$ *versus* c_0°, will give a fundamental concept of quantitative analysis.

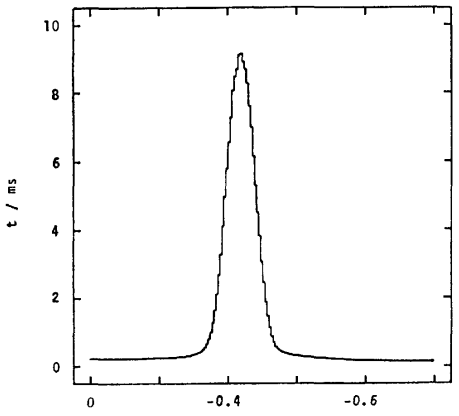

Fig. 10. A display of modified differential pulse polarogram of 600 μM $TlNO_3$ in 1 M KNO_3. (i_s=3.0 μA, t_w=6 s, m=0.539 mg s^{-1}, ΔE=100 mV).

Modified Differential Pulse Polarography. A new method, modified differential pulse polarography, has been successfully introduced. The measurement is carried out by measuring the time required to reach a constant sampling current; the principle of electrolytic method of MDPP is similar to that of the differential pulse polarography. Characteristics of modified differential pulse polarogram were studied using Tl(I)/Tl(Hg) and Cd(II)/Cd(Hg) systems. Figure 10 shows a modified differential pulse polarogram of 600 μM $TlNO_3$ in 1 M KNO_3. The slope of the log-log plots of peak-height and bulk concentration was 2.0. The empirical relation between the peak height t_p of modified differential pulse polarogram and the bulk concentration can be written as

$$\sqrt{t_p} = p \cdot c_0^\circ. \quad (4)$$

Here, p is the proportionality constant. The plots of

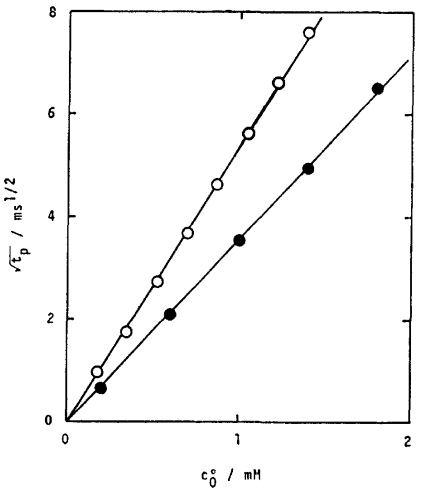

Fig. 11. The plots of $\sqrt{t_p}$ *vs.* the bulk concentration. (●: $TlNO_3$ in 1 M $NaNO_3$, t_w=6 s, ΔE=100 mV, ○: $Cd(NO_3)_2$ in 1 M $NaNO_3$, t_w=6 s, ΔE=100 mV, m=0.539 mg s^{-1}).

$\sqrt{t_p}$ *vs.* c_0° of Tl(I)/Tl(Hg) and Cd(II)/Cd(Hg) systems are shown in Fig. 11. The data points gave a good straight line which through the origin. These plots can be utilized as the working curve of quantitative analysis.

The theoretical treatment of modified differential pulse polarography will be discussed elsewhere.

Application to the Determination of Kinetic Parameters. Kinetic parameters of electrode reactions can be determined from the following relations:[27,28]

$$\frac{\sqrt{t}}{\sqrt{t_{diff}}} \frac{1+\sqrt{D_O/D_R}\gamma}{1-(c_R^\circ/c_O^\circ)\gamma} = \sqrt{\pi}\lambda\sqrt{t}\exp(\lambda^2 t)\mathrm{erfc}(\lambda\sqrt{t}), \quad (5)$$

$$\gamma = \frac{k_a}{k_c} = \exp[(\alpha_a+\alpha_c)(E-E_o)nF/RT], \quad (6)$$

$$k_c = \frac{\sqrt{D_O}}{1+\sqrt{D_O/D_R}\gamma}. \quad (8)$$

Introducing the values of $\alpha_c+\alpha_a$ and E_o from the references,[27,28] the value of γ in Eq. 6 can be calculated. Since the value of $\sqrt{t/t_{diff}}$ is measurable, the left hand side of Eq. 5 is calculated from experimental data. Then, the parameter λ can be obtained at various potentials. In these calculations, the function $\phi(\lambda\sqrt{t})$ and the inverse function of $\phi(\lambda\sqrt{t})$ can be calculated by a computer.[30,31]

The rate constants k_a and k_c are calculated from

Table 1. Kinetic parameters of electrode reactions obtained at 25.0 °C

(E_o *vs.* SCE)/V	α_c	α_a	k_s/cm s^{-1}	Ref.
$Zn(NO_3)_2$ in 0.3 M $NaNO_3$ +1 mM $HClO_4$+2 μ M LEO				
−0.999	0.31	0.63	8.4×10^{-3}	This work
−0.998	0.32	0.62	8.7×10^{-3}	27, 28
$Cu(NO_3)_2$ in 1 M $NaNO_3$+5 mM HNO_3+0.001% PAA				
0.022	0.23	0.73	2.2×10^{-2}	This work
0.022	0.24	0.73	2.9×10^{-2}	27, 28
$[Co(NH_3)_6]Cl_3$ in 0.9 M $NaNO_3$+0.1 M acetate buffer				
−0.250	0.58	0.42	1.5×10^{-3}	This work
−0.249	0.71	0.29	1.9×10^{-3}	27, 28

Eqs. 6 and 7 using the value of λ obtained above. The kinetic parameters are determined from the relations

$$k_a = k_s \exp\left\{\frac{\alpha_a nF}{RT}(E-E_0)\right\}, \quad (8)$$

$$k_c = k_s \exp\left\{\frac{-\alpha_c nF}{RT}(E-E_0)\right\}, \quad (9)$$

using a least square method.[27,28,30,31] Kinetic parameters of the electrode reactions of Cu^{2+}, Zn^{2+}, and $[Co(NH_3)_6]^{3+}$ were determined. The obtained values of k_s, E_0, and α_c are listed together with literature values in Table 1. The results are in good agreement with the literature values.

In conclusion, it should be mentioned that the modified pulse polarograph developed has advantages in the easy measurement of the instantaneous potential-current-time relationship.

The research was carried out by a Grant-in-Aid from the Ministry of Education, Science and Culture. A part of the work was supported by Scientific Grant No. 472570091668.

The authors wish to thank Mr. Tokio Ohoto for his help throughout the experiment.

(Received January 24, 1981)

The sorption behavior of low molecular weight organic vapors on β-cyclodextrin polyurethane resins was estimated from desorption or breakthrough experiments and compared with that on the commercially available resins. Temperature-programmed desorption patterns show that the β-cyclodextrin resins interact strongly with benzene vapor in a nitrogen or air stream. This strong interaction presumably results from the hydrophobic interaction of benzene with the β-cyclodextrin cavity. From the breakthrough experiments using the gas stripping method, it was found that the resin prepared by reacting β-cyclodextrin with 1,3-bis(isocyanatomethyl)cyclohexane, β-H6XDI-P-6.0-M, retains the polar volatile organic compounds more than Amberlite XAD-7 does.

Because of the relatively low concentrations of organic contaminants in ambient air or in water, most methods for the measurement of these contaminants require a concentration step before the actual analysis.[1-3] Several commercially available porous polymer beads (*i. e.*, Tenax GC,[4,5] Porapak Q,[6] and Amberlite XAD-2[7]) and graphitized carbon black[8] are used widely to collect organic contaminants. The polarity of monomers brings about some selectivity[9] in sorbing organic compounds to the porous polymer beads: the more polar the monomer is, the more strongly the polymer beads interact with polar organic compounds. A series of the Amberlite XAD resins, for example, are capable of collecting a variety of organic compounds. The Amberlite XAD resins and related ones are hydrophobic in nature and have energetically homogeneous sorption sites. Therefore, the selectivity of these resins in collecting organic compounds cannot be expected to be strong. In order to strengthen the selectivity mentioned above, it is necessary to introduce specific sorption sites into a resin.

We are interested in finding organic sorbents that will be able to collect organic compounds in environments selectively. It is well known that cyclodextrins form stable inclusion complexes with specific organic compounds. The polyurethane resins containing cyclodextrin units were prepared by cross-linking cyclodextrins with diisocyanates.[10] The interactions of these polyurethane resins with low molecular weight organic vapors were investigated by gas chromatography in a dry nitrogen carrier gas. It was found that the cyclodextrin resins exhibit large retention times for the compounds containing π-electrons or hetero atoms (such as benzene, pyridine, and ethyl methyl ketone).

In this work, the preliminary sorption behavior of β-cyclodextrin polyurethane resins is investigated and compared with that of Porapak Q, Tenax GC, or Amberlite XAD-7 in order to evaluate the possibility of using these cyclodextrin resins as sorbents to collect organic vapors. The isothermal and temperature-programmed desorption patterns and the breakthrough times were studied for several low molecular weight organic compounds.

Experimental

Materials. β-Cyclodextrin was obtained from Hayashibara Biochemical Laboratories, 1,3-bis(isocyanatomethyl)-cyclohexane and 1,3-bis(isocyanatomethyl)benzene from Takeda Chemical Industries, and all other chemicals from Wako.

The preparation of β-cyclodextrin polyurethane resins was described in detail in our previous paper.[10] The β-cyclodextrin polyurethane resins obtained were granulated to a particle size of 177—250 μm with an agate mortar, sieved, and used as sorbents.

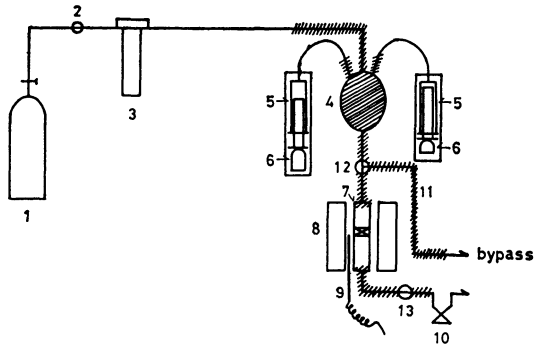

Fig. 1. Apparatus for adsorption behavior studies.
1: Nitrogen gas cylinder, 2: bellows valve, 3: flow meter, 4: mixing vessel, 5: syringe, 6: syringe drive, 7: adsorption tube, 8: furnace, 9: thermocouple, 10: gas sampler, 11: heater, 12: 3-way cock, 13: 2-way cock.

Apparatus. The apparatus utilized for the studies of adsorption behavior of the resins is shown schematically in Fig. 1. This apparatus was constructed in our laboratory and equipped with an automatic temperature-programming device. The nitrogen stream flowing through the path was controlled to 100 ml/min by a bellows valve. The flow rate was measured with an orifice flow meter. One or two adsorbates (model organic compounds) were introduced into an adsorption tube at a known, continuous, reproducible rate using one or more syringe pumps (Adzuma Model MF-2). As the adsorbate(s) vaporized from the syringe tip(s) inserted into the mixing vessel (60 ml) heated with a heater, it was swept into the flowing nitrogen stream. Thus, a constant stream containing the gaseous adsorbate(s) with a constant concentration was provided; the stream was introduced into the glass adsorption tube (25×2 cm i.d.) with a sintered glass filter. Each resin (*ca.* 2 g) was dry-packed into the tube and preconditioned at 180 °C for 1 h in a pure nitrogen stream at 100 ml/min. The nitrogen gas containing the adsorbate(s) was collected in a gas sampler (1.2—1.5 ml), and the concentration of adsorbate(s) was determined by gas chromatography with a thermal conductivity detector (Shimadzu Model

GC-3BT gas chromatograph). The chromatographic column packed with Porapak Q (2 m×3 mm i.d.) or with 10% DNP on Chromosorb W (3 m×3 mm i.d.) was used.

After the resin in the tube was equilibrated with the adsorbate(s)-nitrogen mixture at 102 °C, the asdorbate(s) vapor was completely removed from the mixing vessel through a 3-way cock (by-pass). Then, the 3-way cock was positioned again so that the pure nitrogen stream (at 100 ml/min) passed through the adsorption tube, and the adsorbate(s) taken up by the resin was desorbed at 102 °C for 2 h. Then, the desorption temperature was programmed at 3.1 °C/min to 170 °C. The desorbed adsorbate(s)-nitrogen mixture was periodically collected in a gas sampler and analyzed by gas chromatography.

The measurements of breakthrough time were carried out by replacing nitrogen gas cylinder in Fig. 1 with an air bag containing the adsorbate(s) and by directly introducing the sample gas in the air bag with a pump into a FID (flame ionization detector in a Shimadzu Model GC-3BF gas chromatograph) through the adsorption tube. The sample-air flow rate was 20 ml/min and the resin weight in the tube was 1 g.

The total adsorption capacities of adsorbates on the resins were measured with a Shimadzu Model ADS-1B sorptograph with the automatic temperature-programming device connected to a Shimadzu Model GC-3BT gas chromatograph.

All chromatograms were recorded on a Shimadzu Model R-101 recorder; peak areas were measured by a Shimadzu Chromatopac E-1A integrator.

Results and Discussion

Preliminary Uptake Studies. Initially, the total amounts of organic vapors taken up by the resins were estimated from the desorption peak area measured with the sorptograph. As listed in Table 1, the β-cyclodextrin polyurethane resin, β-HDI-P-5.5-M, gives larger uptake values for the organic vapors than the polyurethane resin containing no cyclodextrin units, BDOL-HDI-P-M, does. This result suggests that the β-cyclodextrin units in the resin interact strongly with the organic vapors.

The amount of benzene vapor taken up by each resin was compared. Porapak Q has the greatest uptake of benzene at 55 °C. On the other hand, at 150 °C Porapak Q takes up less than the resins containing β-cyclodextrin units do. The uptake amount of benzene for the β-cyclodextrin resin at 55 °C varies apparently with the diisocyanate used. The amount of benzene taken up by each β-cyclodextrin resin decreases with increasing adsorption temperature and reaches a constant, nearly equal value at 150 °C; this result strongly suggests that the β-cyclodextrin cavities in the resins take part in the adsorption of benzene molecules.

Sorption Behavior of β-Cyclodextrin Polyurethane Resins for Benzene Vapor. As one approach to the actual application of the β-cyclodextrin resins, it is of value to investigate their sorption behavior for one given organic vapor (benzene in this work) co-existing with another one. The resin was equilibrated with the 0.004% benzene–0.055% cyclohexane–nitrogen flow at 102 °C. After benzene and cyclohexane which had been taken up were desorbed for 2 h by the pure nitrogen stream at the same temperature, the desorption temperature was programmed at 3.1 °C/min to 170 °C. Figure 2

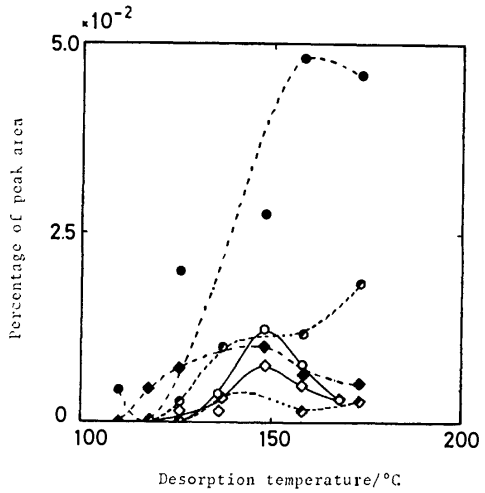

Fig. 2. Desorption of benzene and cyclohexane on β-cyclodextrin polyurethane resins.

0.004% benzene–0.055% cyclohexane–N_2.

shows the temperature-programmed desorption patterns thus obtained. The amount of benzene desorbed is larger than that of cyclohexane. Considering that there is a much lower concentration of benzene than of cyclohexane in the benzene–cyclohexane–nitrogen flow, we interpret these results as indicating that the β-cyclodextrin resins collect the benzene vapor much better than the cyclohexane one. β-XDI-P-5.8-A gives desorption patterns different from those on either β-HDI-P-5.5-A or β-H6XDI-P-6.0-M; this is presumably due to the lower thermal stability of β-XDI-P-5.8-A. Thermally, the β-H6XDI-P-6.0-M resin is the most stable of the three β-cyclodextrin resins. Therefore,

Table 1. Total adsorption capacities for organic vapors

Resin	mg Benzene/g Resin		mg Cyclohexane/g Resin		mg Ethyl alcohol/g Resin	
	55 °C	150 °C	55 °C	150 °C	55 °C	150 °C

β-XDI-P-5.8-A	58	27				
BDOL-HDI-P-M	48	5	38	1	21	0.5
Tenax GC	59	1				
Porapak Q	213	18				

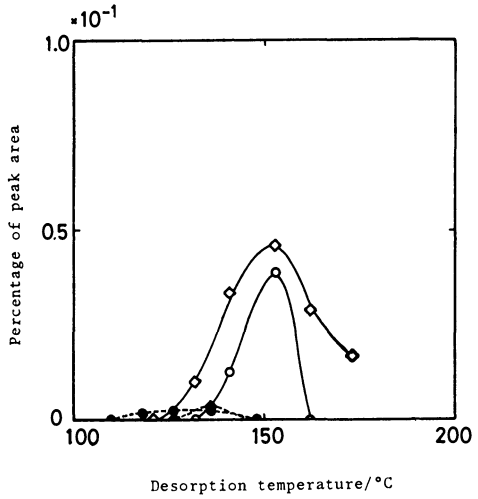

Fig. 3. Desorption of benzene and ethyl methyl ketone on β-H6XDI-P-6.0-M and Porapak Q.
——: β-H6XDI-P-6.0-M, ----: Posapak Q. ○●: Benzene, ◇◆: ethyl methyl ketone.
0.013% benzene–0.12% ethyl methyl ketone–N_2 (β-H6XDI-P-6.0-M), 0.016% benzene–0.074% ethyl methyl ketone–N_2 (Porapak Q).

β-H6XDI-P-6.0-M was investigated in further experiments.

Figure 3 shows the temperature-programmed desorption peaks of benzene and ethyl methyl ketone on both β-H6XDI-P-6.0-M and Porapak Q. β-H6XDI-P-6.0-M gives large peaks of benzene and ethyl methyl ketone. Considering the concentrations of both adsorbates, the benzene peak area is very large compared with that of ethyl methyl ketone. On the other hand, Porapak Q gives only small peaks of both adsorbates; BDOL-HDI-P-M shows no desorption peaks at all in the temperature-programmed experiments.

It is interesting to investigate whether one adsorbate on the resin is replaced by the other or not. Figure 4 clearly shows that ethyl methyl ketone on β-H6XDI-P-6.0-M is replaced by benzene. First, the 0.16% ethyl methyl ketone–nitrogen flow was passed for 1 h through the tube containing the resin to saturate the adsorption sites completely with ethyl methyl ketone; next, the 0.006% benzene–0.06% ethyl methyl ketone–nitrogen flow was passed for 3 h. A large desorption peak of benzene appears when the desorption temperature is programmed at 3.1 °C/min from 102 °C. Similarly, the 0.08% benzene–nitrogen flow was passed for 1 h and then the 0.5% benzene–0.05% ethyl methyl ketone–nitrogen flow was passed for 3 h. The desorption peak of ethyl methyl ketone is minute in comparison with that of benzene.

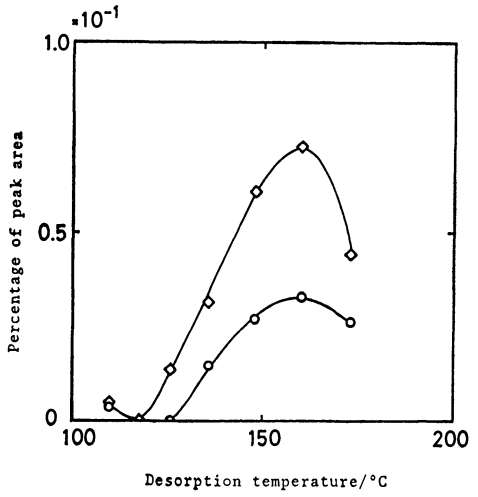

Fig. 4. Replacement of ethyl methyl ketone with benzene on β-H6XDI-P-6.0-M.
○: Benzene, ◇: ethyl methyl ketone.
Adsorption system: 0.16% ethyl methyl ketone–N_2 (1 h), 0.06% ethyl methyl ketone–0.006% benzene–N_2 (3 h).

These results strongly suggest that the β-cyclodextrin polyurethane resin is selectively adsorptive for benzene vapor. Both desorption peaks have the maxima at *ca.* 150 °C; this result supports the contention that the cyclodextrin cavities in the resin take part in the interaction with the adsorbate molecules, as described previously.[10]

Breakthrough Studies. All the experiments cited to this point were carried out with samples prepared by introducing one or two organic compounds into a dry nitrogen flow. Practical samples, however, will contain many different compounds including water. It is thus especially important to study the effect of co-existing water.

First, the 0.4% benzene–air stream containing 0.4% ethyl methyl ketone or 1.76% water as a concomitant was used to obtain the breakthrough profiles for β-H6XDI-P-6.0-M. Co-existing water or ethyl methyl ketone does not affect the breakthrough time (26 min). In the case of 0.4% ethyl methyl ketone–air stream, the breakthrough time is 66 min. It decreases to 45 min, when 0.04% benzene is added to the 0.4% ethyl methyl ketone–air stream. This result is reasonably interpreted as follows. Ethyl methyl ketone is adsorbed on the β-cyclodextrin resin by both the hydrophobic and hydrogen-bonding interactions, while benzene is taken up almost by the hydrophobic one. This is supported by the fact that BDOL-HDI-P-M interacts strongly with the compounds capable of forming hydrogen-bonding.[10] The decrease in the breakthrough time with increasing benzene concentration in the ethyl methyl ketone–air stream seems to result from the strong, selective occupation of the hydrophobic adsorption sites by benzene.

Second, the mixing vessel in Fig. 1 was replaced with a gas stripping vessel in order to perform the breakthrough experiments by a gas stripping method; this is generally a highly sensitive method for collecting volatile organic compounds in water.[11] A stream of nitrogen at 50 ml/min stripped 150 ml of sample solution at 25 °C. After the concentration of stripped organic compound in the gas coming out of the vessel reached a constant value, the sorption tube containing 2 g of a resin was connected to the stripping vessel, and the breakthrough curve was obtained by flame ionization gas chromatography. The breakthrough profiles were well-defined S-shaped curves.

Table 2 shows the breakthrough times on β-H6XDI-

Table 2. Breakthrough times (min) on β-H6XDI-P-6.0-M and amberlite XAD-7

P-6.0-M and Amberlite XAD-7 at sorption temperatures of 50 and 100 °C. At both temperatures, β-H6XDI-P-6.0-M gives a larger breakthrough time for each polar solute expect for benzene than XAD-7 does, while the reverse is observed for nonpolar benzene at 50 °C. The greater retention of the polar compounds on β-H6XDI-P-6.0-M presumably results from the much stronger affinity of this resin for water: the distribution of the polar compounds into the water layer retained on β-H6XDI-P-6.0-M plays an important role in their greater retention, compared with the XAD-7 resin. It is unusual that benzene breakthrough on β-H6XDI-P-6.0-M varies little with the sorption temperature in the range of 50—100 °C. Supposedly, a large amount of water on the resin surface also brings about the small breakthrough time of 12 min for benzene at 50 °C: nonpolar benzene must penetrate through the water layer to reach the hydrophobic sorption site of the resin. Amberlite XAD-7, on the other hand, is hydrophobic in nature and retains much less water than β-H6XDI-P-6.0-M does. Therefore, nonpolar benzene is taken up more strongly by the XAD-7 resin.

In summary, it is found from this preliminary work that the β-cyclodextrin polyurethane resins exhibit a strong interaction with benzene vapor in the nitrogen or air stream. Also, in the gas stripping method, the β-H6XDI-P-6.0-M resin retains the polar volatile organic compounds more greatly than Amberlite XAD-7 (used widely to collect them) does; this results indicates the possibility of using the β-cyclodextrin polyurethane resins as sorbents to collect polar volatile organic compounds.

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

The Oxidation Products of Tetracyanoferrate(II) Chelates with Optically Active 1,2-Diamines : Tetracyano(1,2-diamine)ferrate(III)s and Tetracyano(1,2-diimine)ferrate(II)s

(Received January 31, 1981)

Optically active diamagnetic title complexes were oxidized with hydrogen peroxide under acidic and basic aqueous conditions. The corresponding low-spin tetracyano(diamine)ferrate(III) complexes with (*R*)-1,2-propanediamine, (1*R*,2*R*)-1,2-cyclopentanediamine, and (1*R*,2*R*)-1,2-cyclohexanediamine as diamines formed under acidic conditions and were characterized with several spectral measurements including the CD spectra. Each CD spectrum showed a moderate positive Cotton effect at *ca.* 24700 cm^{-1} and was assigned to a d-d transition. However a ligand oxidation took place, yielding tetracyano(1,2-diimine)ferrate(II) complexes under neutral and basic conditions; their electronic and ^{1}H- and ^{13}C-NMR spectra are also reported.

Diamagnetic and low-spin Fe^{II} and Fe^{III} complexes with a simple ligand system have been scarcely investigated. Tetracyanoferrate(II) chelates of 1,2-diamines are diamagnetic as a result of the strong ligand field produced by cyano groups and have been well characterized.[1,2] The diamagnetic complexes are oxidized with various oxidizing agents to yield metal-oxidized tetracyano(1,2-diamine)ferrate(III) and ligand-oxidized tetracyano(1,2-diimine)ferrate(II) depending on the reaction conditions.[1] Optically active Fe^{III} chelates can be expected to be prepared from the corresponding Fe^{II} chelates with optically active diamines, such as (*R*)-1,2-propanediamine(*R*-pn), (1*R*,2*R*)-1,2-cyclopentanediamine(*R*-cptn), and (1*R*,2*R*)-1,2-cyclohexanediamine(*R*-chxn), under acidic conditions. The chemistry of cyanoammineferrate(III)s has not been fully investigated except for pentacyanoferrate(III)s.[3] Their electronic spectra are still ambiguous because of their many allowed electronic transitions. Hexacyanoferrate(III) and several pentacyano complexes with OH_2, NH_3, $As(C_6H_5)_3$, NCS^-, and $P(C_6H_5)_3$ have been investigated with magnetic circular dichroism spectra as well as electronic spectra.[4] The CD spectra of tetracyano(*R*-diamine)ferrate(III)s will provide unique information on the nature of the electronic transitions.

The other product is ligand-oxidized tetracyano(1,2-diimine)ferrate(II); it has been characterized by visible and ^{1}H-NMR spectroscopies.[1] The diimines examined up to the present bear substituents at the nitrogen atoms(*e. g.*, 1,10-phenanthroline and *N,N'*-dimethyl-2,3-butanediimine), but this dehydrogenation yields diimines which have no substituents at the nitrogens. The dehydrogenation of amines coordinated to transition-metal ions has been reported with Cu^{II},[5] Ni^{II},[6] Ru^{II},[7] Co^{II},[8] and Fe^{II},[9] and it is generally accepted that a higher oxidation state of transition-metal ions is responsible for the reaction.[10] Tetracyano(1,2-ethanediamine)ferrate(III) undergoes a spontaneous metal reduction, yielding a mixture of ligand-oxidized and ligand-intact Fe^{II} chelates, in basic solutions.

This paper will deal with the preparation and some spectral properties of these complexes.

Experimental

Materials. 1,4-Dimethyl-1,4-diazabicyclo[2,2,2]octanediium diiodide(dimethyldabconium iodide) was prepared according to the method of Oae *et al.*[11] $Na_2[Fe(CN)_4(R\text{-pn})]\cdot 0.5NaClO_4\cdot 0.5H_2O$,[2] $Na_2[Fe(CN)_4(R\text{-cptn})]\cdot 0.5NaClO_4\cdot 0.5H_2O$,[12] and $Na_2[Fe(CN)_4(R\text{-chxn})]\cdot 0.5NaClO_4\cdot 0.5H_2O$[2] were prepared according to the methods reported previously. $Na[Fe(CN)_4(en)]\cdot 3H_2O$ and dimethyldabconium tetracyano(1,2-ethanediimine)ferrate(II) were prepared according to the method of Goedken.[1] *cis*-1,2-Cyclohexanediamine was separated from a commercially available mixture of 1,2-cyclohexanediamines(Tokyo Kasei) according to the method of Kidani and Saito.[13]

Preparation of Complexes. *Na[Fe(CN)$_4$(R-pn)]·H$_2$O.* The corresponding diamagnetic Fe^{II} chelate, $Na_2[Fe(CN)_4(R\text{-pn})]\cdot 0.5NaClO_4\cdot 0.5H_2O$ (3.5 g, 0.01 mol), was dissolved in a mixture of acetic acid (1 cm^3), ethanol (20 cm^3), and water (6 cm^3) at 0 °C. Into the mixture, 30% aqueous hydrogen peroxide (1.5 cm^3) was then stirred in small portions. The resultant mixture was filtered after 5 min at 0 °C to remove the undissolved green materials. Ethanol (20 cm^3) and ether were added to the filtrate until the solution became turbid. The mixture was then allowed to stand in a refrigerator overnight. The pale yellow crystals thus separated were collected on a filter, washed with absolute ethanol and subsequently with ether, and dried *in vacuo*. Yield, 2.3 g (84%). Found: C, 30.16; H, 4.47; N, 30.43%. Calcd for $Na[Fe(CN)_4(C_3H_{10}N_2)]\cdot H_2O$: C, 30.55; H, 5.10; N, 30.56%.

Na[Fe(CN)$_4$(R-cptn)]·2H$_2$O. In a mixture of acetic acid (1 cm^3) and ethanol (10 cm^3), $Na_2[Fe(CN)_4(R\text{-cptn})]\cdot 0.5NaClO_4\cdot 0.5H_2O$ (1.5 g, 4 mmol) was suspended: after the mixture had been cooled to 0 °C, 2 M (1 M=1 mol dm^{-3}) perchloric acid (2 cm^3) and water (1 cm^3) were added to dissolve the complex. A portion of aqueous hydrogen peroxide (30%, 0.3 cm^3) was then stirred into the mixture. To the resultant mixture, ether (3 cm^3) was added, and the mixture was filtered at 0 °C. A mixture of ethanol (10 cm^3) and ether (10 cm^3) was added to the filtrate, and the mixture was allowed to stand at −15 °C overnight. The separated crystals were collected on a filter, washed with ether, and dried *in vacuo*. Yield, 1.5 g (quantitative).

This substance was dissolved in a mixture of 2 M $HClO_4$ (0.65 cm^3) and ethanol (5.35 cm^3) at 0 °C, after which the mixture was filtered. Ether (5 cm^3) was added, and the mixture was allowed to stand overnight at −15 °C. The crystals thus separated were collected on a filter, washed with ether, and dried *in vacuo*. Yield, 160 mg (12%).

Found: C, 34.41; H, 5.31; N, 26.41%. Calcd for $Na[Fe(CN)_4(C_5H_{12}N_2)]\cdot 2H_2O$: C, 33.87; H, 5.05; N, 26.34%.

$Na[Fe(CN)_4$(R-chxn)$]\cdot 3H_2O$. Into a solution of $Na_2[Fe(CN)_4(R\text{-chxn})]\cdot 0.5NaClO_4\cdot 0.5H_2O$ (3.0 g, 7.7 mmol) in a mixture of acetic acid (3 cm³), ethanol (30 cm³), and water (3 cm³) in an ice–water bath, 15% aqueous hydrogen peroxide (6 cm³) was stirred, drop by drop, at 0 °C. A mixture of methanol (10 cm³), acetic acid (4 cm³), and ether (30 cm³) was added to the yellow mixture until the mixture became turbid. The mixture then allowed to stand at −15 °C overnight. The yellow crystals thus separated were collected on a filter, washed with ice-cold ethanol and subsequently with ether, and stored *in vacuo*. Yield, 2.0 g (74%).

These were recrystallized by adding ether to a solution of the crude product in a mixture of acetic acid, water, and ethanol (1:2:15) until the solution became turbid. This procedure was carried out at 0 °C. The pale yellow needles thus separated were collected on a filter, washed with ethanol and subsequently with ether, and dried *in vacuo*. Found: C, 34.45; H, 5.62; N, 23.60%. Calcd for $Na[Fe(CN)_4(C_6H_{14}N_2)]\cdot 3H_2O$: C, 34.04; H, 5.62; N, 23.60%.

*Sodium Tetracyano(*cis-*1,2-cyclohexanediamine)ferrate(II) Dihydrate.* A methanol solution (40 cm³) of *cis*-1,2-cyclohexanediamine(*cis*-chxn) (22.8 g, 0.2 mol) was vigorously stirred into a methanol solution (200 cm³) of iron(II) perchlorate hexahydrate (35.2 g, 0.098 mol) under nitrogen at 0 °C, followed by the addition of aqueous sodium cyanide (19.1 g, 0.39 mol) in 80 cm³ of water. The resultant yellow brown solution was concentrated to near dryness under reduced pressure below 40 °C. To the oily residue, ethanol (200 cm³) was added, and a yellow precipitate was collected on a filter, washed with ethanol and subsequently with ether, and dried *in vacuo*. Found: C, 34.20; H, 4.36; N, 23.84%. Calcd for $Na_2[Fe(CN)_4(C_6H_{14}N_2)]\cdot 2H_2O$: C, 33.72; H, 5.09; N, 23.59%.

$Na[Fe(CN)_4$(cis-chxn)$]\cdot 0.5NaClO_4\cdot H_2O$. In a mixture of concentrated $HClO_4$ (3 cm³), methanol (20 cm³), and water (4 cm³), $Na_2[Fe(CN)_4(cis\text{-chxn})]\cdot 2H_2O$ (3.9 g, 0.011 mol) was dissolved, and the mixture was cooled to 0 °C. Concentrated aqueous hydrogen peroxide (30%, 1.4 cm³) was then stirred, drop by drop, into the mixture. A mixture of 1-propanol (40 cm³) and diisopropyl ether (20 cm³) was added to the mixture. The crystals thus separated were collected on a filter. Yield, 3.9 g (70%).

The crude product was dissolved in a mixture of 2 M $HClO_4$ (3 cm³) and ethanol (20 cm³), and the undissolved materials were filtered off. A mixture of ethanol (35 cm³) and diisopropyl ether (25 cm³) was added, and the mixture was allowed to stand at −15 °C overnight. The crystals thus separated were collected on a filter, washed with ether, and dried *in vacuo*. Found: C, 31.77; H, 4.83; N, 21.55%. Calcd for $Na[Fe(CN)_4(C_6H_{14}N_2)]\cdot 0.5NaClO_4\cdot H_2O$: C, 31.91; H, 4.29; N, 22.33%.

Dimethyldabconium Tetracyano(1,2-propanediimine)ferrate(II) Trihydrate, $[C_8H_{18}N_2][Fe(CN)_4$(o-pn)$]\cdot 3H_2O$. The designations of the diimines formed by dehydrogenation are abbreviated by adding the prefix *o-* to the corresponding diamines, as is shown in Table 1 (*vide infra*). Into an aqueous solution of $Na_2[Fe(CN)_4(R\text{-pn})]\cdot 0.5NaClO_4\cdot 5H_2O$ (2.25 g, 6.5 mmol) in 10 cm³ of water, 2 M hydrogen peroxide (18 cm³) was stirred, drop by drop, at 40 °C. The resultant deep red solution was concentrated with a rotatory evaporator. A red residue was dissolved in 10 cm³ of water, and dimethyldabconium iodide (2.6 g) was added to the solution. Ethanol (200 cm³) was added until the solution became turbid, after which the mixture was allowed to stand in a refrigerator overnight. The red crystals thus separated were collected on a filter and washed with ethanol and subsequently with ether. Found: C, 42.03; H, 6.44; N, 26.69%. Calcd for $[C_8H_{18}N_2][Fe(CN)_4(C_3H_6N_2)]\cdot 3H_2O$: C, 42.26; H, 7.09; N, 26.29%.

Dimethyldabconium Tetracyano(1,2-cyclopentanediimine)ferrate(II) Hemi(sodium perchlorate), $[C_8H_{18}N_2][Fe(CN)_4$(o-cptn)$]\text{-}0.5NaClO_4$. Into an aqueous solution of $Na_2[Fe(CN)_4(R\text{-cptn})]\cdot 0.5NaClO_4\cdot 0.5H_2O$ (1.0 g, 2.7 mmol) in 10 cm³ of water, 1 M hydrogen peroxide (17 cm³) was stirred, drop by drop, at 40 °C, the pH of the mixture being kept at 10.5 by adding 1 M aqueous NaOH. The resultant intense red solution was concentrated with a rotatory evaporator. The red residue was dissolved in 4 cm³ of water, and the mixture was filtered to remove brown precipitates. To the filtrate, dimethyldabconium iodide (1.0 g) was added, and then ethanol (6 cm³) was added. The blue precipitates thus separated were removed by filtration, and another 30-cm³ portion of ethanol was added to the filtrate. The mixture was allowed to stand in a refrigerator overnight. The purple crystals thus separated were collected on a filter and washed with ethanol and subsequently with ether. Found: C, 43.88; H, 6.00; N, 24.17%. Calcd for $[C_8H_{18}N_2][Fe(CN)_4(C_5H_8N_2)]\cdot 0.5NaClO_4$: C, 44.43; H, 5.70; N, 24.39%.

Dimethyldabconium Tetracyano(1,2-cyclohexanediimine)ferrate(II) Tetrahydrate, $[C_8H_{18}N_2][Fe(CN)_4$(o-chxn)$]\cdot 4H_2O$. To an aqueous solution of $Na_2[Fe(CN)_4(R\text{-chxn})]\cdot 0.5NaClO_4\cdot 0.5H_2O$ (2.0 g, 5.06 mmol) in 10 cm³ of water, 2 M hydrogen peroxide (20 cm³) was added, drop by drop, at 48 °C. The resultant intensely red solution was concentrated with a rotatory evaporator. The red residue was dissolved in 8 cm³ of water, after which dimethyldabconium iodide (2 g) and then ethanol (18 cm³) were added. The red crystals thus separated were collected on a filter and washed with ethanol and subsequently with ether.

The crude product was dissolved in 3 cm³ of water, and a 30-cm³ portion of absolute ethanol was added. The red crystals thus separated were collected and dried *in vacuo*. Found: C, 44.63; H, 7.25; N, 23.30%. Calcd for $[C_8H_{18}N_2][Fe(CN)_4(C_6H_{10}N_2)]\cdot 4H_2O$: C, 44.63; H, 7.49; N, 22.13%.

Physical Measurements. The electronic spectra of 10^{-3} M hydrochloric acid solutions of tetracyano(diamine)ferrate(III)s and aqueous solutions of Fe^{II} complexes were recorded with a Shimadzu UV-210A spectrophotometer. The CD spectra were measured with a JASCO J-40 recording polarimeter. The ^{1}H-NMR were recorded with a JEOL JNM-MH-100 spectrometer using D_2O solutions and sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as the internal standard. The ^{13}C-NMR were recorded with a JEOL FX-100 spectrometer using a D_2O solution and dioxane as the internal standard (67.4 ppm). The infrared spectra were measured with a JASCO IRA-2 spectrophotometer using Nujol mulls. The magnetic susceptibilities were measured with a Shimadzu magnetic balance.

Results and Discussion

Tetracyano(*cis*-1,2-cyclohexanediamine)ferrate(II) showed a typical electronic spectrum of tetracyano(1,2-diamine)ferrate(II) chelates:[2] $\tilde{\nu}_{max}(\varepsilon_{max})$=25400(439), 31800(*ca.* 450), 43100(8600), and 46200 cm^{-1}(9430).

Tetracyano(1,2-diamine)ferrate(III) Chelates. Diamagnetic tetracyano(1,2-diamine)ferrate(II) chelates with C-substituted 1,2-diamines, *R*-pn, *R*-cptn, *R*-chxn, and *cis*-chxn, yield two types of oxidation products with hydrogen peroxide, depending on the acidity of the reaction medium, as tetracyano(1,2-ethanediamine)-

ferrate(II).[1]

In an acidic solution, oxidation took place at the central metal ion, yielding the corresponding Fe^{III} chelates at 0 °C. The chelates with *R*-pn, *R*-cptn, and *R*-chxn were prepared with acetic acid as an acid, but that with *cis*-chxn was prepared with perchloric acid as an acid because a successive oxidation to the diimine chelate occurred with acetic acid. These were isolated as sodium salts in pale yellow crystals. These complexes tend to undergo disproportionation at room temperature with atmospheric moisture and so were kept in a refrigerator under a vacuum. The magnetic susceptibilities of the crystals were measured with a magnetic balance by means of the Faraday method at room temperature. The values of the mole magnetic moments were 2.3, 2.4, and 2.4 BM for the *R*-pn, *R*-cptn, and *R*-chxn respectively. These values are in accordance with the low-spin Fe^{III} complexes. These complexes are stable in an acidic solution. The IR spectra contained sharp C≡N stretchings at 2120 cm^{-1}, higher by 80 cm^{-1} than those of the corresponding Fe^{II} chelates.[2] The higher wave numbers of the C≡N stretching absorptions are compatible with the smaller contribution of the back donation from Fe^{III} to coordinated C≡N than from Fe^{II}. The IR absorptions are almost the same as those of the corresponding Co^{III} chelates, as is shown in Fig. 1. These complexes exhibit well-separated ^1H- and ^{13}C-NMR: preliminary results have previously reported.[14] The results are consistent with the bidentate coordination of these diamines.

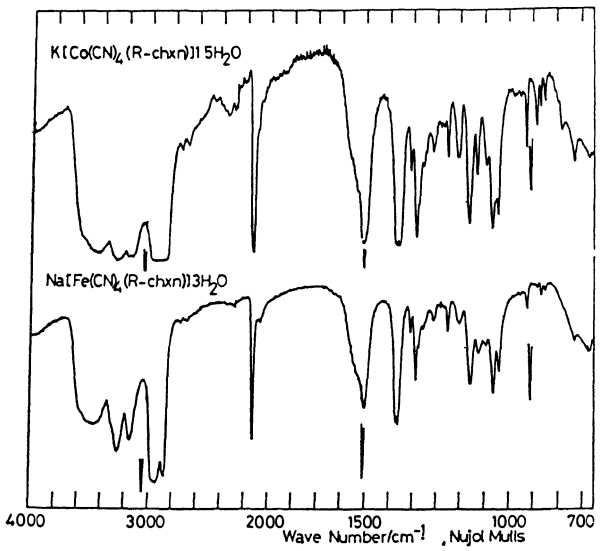

Fig. 1. Infrared spectrum of $K[Co(CN)_4(R\text{-chxn})]\cdot 1.5H_2O$[2] and $Na[Fe(CN)_4(R\text{-chxn})]\cdot 3H_2O$.

The electronic and CD spectra of these complexes in 10^{-3} M HCl are shown in Fig. 2. The CD spectra of these chelates are similar to each other and reflect the conformation of five-membered chelate rings, because the diamines may be expected to coordinate in the λ conformation. These optically active diamines, *R*-pn, *R*-cptn, and *R*-chxn, have been reported to coordinate to Fe^{II}, forming chelate rings of the λ conformation.[2,12]

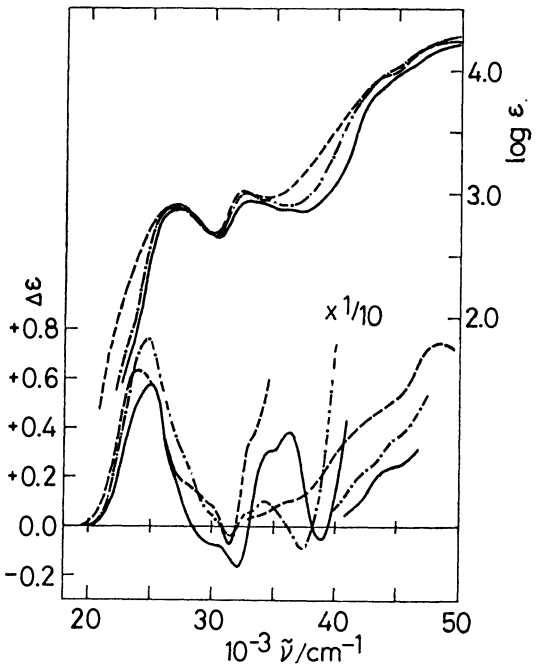

Fig. 2. Electronic and CD spectra of $[Fe(CN)_4(diamine)]^-$ in 10^{-3} M hydrochloric acid. diamine: *R*-pn, ——; *R*-cptn, – – –; *R*-chxn, -·-·-.

A large number of measurements and interpretations of the electronic spectra of $[Fe(CN)_6]^{3-}$ and several pentacyanoferrate(III) complexes have been reported.[4] The electronic configurations of these complexes are low-spin d^5, *i. e.*, $(t_{2g})^5$. The electronic transitions of these complexes are expected to arise from (i) ligand-to-metal charge transfer (LMCT), (ii) metal-to-ligand charge transfer (MLCT), and (iii) d-d transition. McCaffery and Gale assigned electronic absorptions with the aid of the magnetic circular dichroism spectra.[4] The absorptions with d-d transitions are partially hidden by LMCT bands, but are located at 29800, $E_g''(^2T_{2g})\rightarrow U_g'(^2T_{1g})$, 30200$\rightarrow E_g''(^2A_{2g})$, and 33200 $cm^{-1}\rightarrow U_g'(^2E_g)$. The remaining bands below 40000 cm^{-1} originate from LMCT, 25500($^2T_{2g}\rightarrow{}^2T_{1u}(\pi)$), 32700($\rightarrow{}^2T_{2u}(\pi)$), and 40000 cm^{-1} ($\rightarrow{}^2T_{2u}(\sigma)$). They also measured several pentacyanoferrate(III) complexes, but did not assign the d-d transitions. Furthermore, complexes with ligands which have lone pairs of relatively high energies, such as triphenylphosphine and azido, show intense absorptions in the visible region. These absorptions are assigned to the LMCT bands arising from the ligand σ bond to the t_{2g} orbital. From this band, the energy difference between the ligand lone pair and the metal t_{2g} orbital are estimated: *e. g.*, 26600 cm^{-1} for NH_3.

The electronic transitions of $Na[Fe(CN)_4(R\text{-diamine})]^-$ are composed of d-d, LMCT, and MLCT transitions. The electronic spectra show moderate bands at 27000 and 30000—35000 cm^{-1} of ε of *ca.* 800. In this region, d-d and LMCT bands are to be expected if the LMCT band of $NH_3\rightarrow t_{2g}$ retains its energy. The maxima of the electronic spectra in the visible region, 27000 cm^{-1}, seem to arise from CT bands, for the molar-absorption coefficient of 800 is large for a d-d transition. The maxima of the CD spectra are located

at *ca.* 24700 cm^{-1} and correspond to a shoulder of each absorption spectrum. The corresponding d-d transitions of $Na_2[Fe(CN)_4(R\text{-diamine})]^{2-}$ have a minor negative component at 23300 and a positive component at 26000 cm^{-1} for the *R*-pn and the *R*-chxn complexes and a positive component at 25200 cm^{-1} for the *R*-cptn complex. The magnitudes of the major CD components decreased in the order of; *R*-cptn>*R*-chxn>*R*-pn as the ligands. The analogous CD components have been observed for isoelectronic Co^{III} chelates at 25000 and 28700 cm^{-1} for *R*-pn and *R*-chxn as *R*-diamines.[2] The wave numbers and magnitudes of the positive CD components for $[Fe(CN)_4(R\text{-diamine})]^-$ suggest that this component corresponds to the d-d transitions. Two transitions are expected for the first absorption band ($^2T_{2g}\rightarrow{}^2T_{1g}$ parentage) of the $(t_{2g})^5$ configuration, but the energy difference between these bands should be smaller than for the $(t_{2g})^6$ configuration because the interelectron repulsion in the highest t_{2g} orbitals is absent for the d^5 configuration. The minor components appearing in diamagnetic Fe^{II} and Co^{III} chelates will be hidden for the d^5 configuration.

At least four CD components are observed in the region between 31000 and 38000 cm^{-1}. These CD components exhibit similar features for the *R*-pn and *R*-chxn complexes: *i. e.*, negative, positive, positive, and negative components in the order of their energies, and they resemble the MCD components of $[Fe(CN)_6]^{3-}$.[4] The probable origin of these CD components is the charge transfer from the coordinated C≡N to the t_{2g} orbital. Each CD component of the *R*-chxn chelate appears at an energy lower by 2000 cm^{-1} than the corresponding component of the *R*-pn chelate. Since the absolute energy level of coordineated C≡N is expected to be little affected by the structure of 1,2-diamine, this difference represents the difference in energy levels in the t_{2g} orbitals of these Fe^{III} chelates. The large fixed ligand, *R*-chxn, tends to lower d-orbitals. Large positive CD components dominate in the region between 33000 and 37000 cm^{-1} for the *R*-cptn chelate. Similar enhancements of positive CD components in the region of charge-transfer bands have been observed for dianionobis[(1*R*,2*R*)-1,2-cyclopentanediamine]cobalt(III) complexes;[12] they may be due to the strained structure of this ligand.

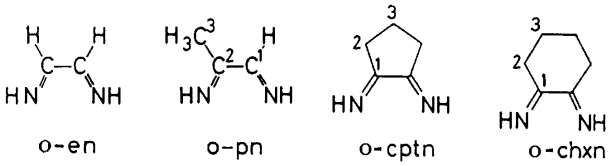
The remaining electronic bands and CD components, which appear at energies higher than 40000 cm^{-1}, have large absorption coefficients and large CD magnitudes. Two electronic bands and at least three CD components are recognized. MLCT bands are to be expected in this region. Positive CD components appear for $[Fe(CN)_4(R\text{-diamine})]^{2-}$ and $[Co(CN)_4(R\text{-diamine})]^-$ with *R*-pn and *R*-chxn. The invariance of the signs of the CD components on a change in the central metal ions suggests that these bands may be ascribed to the charge transfer from coordinated amine to e_g orbitals; the dependency of the magnitude of the CD components on the structure of 1,2-diamines supports this assignment.

Tetracyano(1,2-diimine)ferrate(II) Chelates. In a neutral or basic solution, the yellow solution of tetracyano(*R*-diamine)ferrate(II) turned an intense red on the addition of a slight excess of hydrogen peroxide at 40 to 50 °C. Tetracyano(1,2-diimine)ferrate(II)s were isolated as dimethyldabconium salts. This cation is almost the same size as the chelate anions, has a bivalent charge, and facilitates the crystallization of soluble-complex anions.[15] The structural identifications are confirmed by the electronic spectra and the ^1H- and ^{13}C-NMR spectra. Each ^1H- and ^{13}C-signal appeared in the normal region for the D_2O solution, indicating that these complexes are diamagnetic Fe^{II} complexes. The results are shown in Table 1, along with the abbreviations and structures of the 1,2-diimines.

Table 1. ^1H- and ^{13}C-NMR of $[Fe(CN)_4(1,2\text{-diimine})]^{2-}$ in D_2O and abbreviations of 1,2-diimines

1,2-Diimine	^1H-Chemical shift[a]/ppm	^{13}C-Chemical shift[b]/ppm
o-en	8.50[c]	166.8
o-pn	8.42,2.48	**1**,[d] 169.1; **2**, 175.1; **3**, 22.3
o-cptn	**2**, 2.71; **3**, 2.35	**1**, 185.6; **2**, 31.5; **3**, 25.3
o-chxn	**2**, 2.90; **3**, 1.87	**1**, 176.8; **2**, 33.8; **3**, 22.6

a) DSS=0.00 ppm. b) Dioxane=67.4 ppm. c) Ref. 1. d) The number denotes the assignment of the corresponding nucleus shown in the structure below.



More reliable identifications can be obtained on the basis of the ^{13}C-NMR spectra. The parent material, $[Fe(CN)_4(o\text{-en})]^{2-}$, showed a single resonance at 166.8 ppm. All the 1,2-diimine chelates studied showed signals in the region between 166 and 186 ppm. These are assigned to azomethine carbons. The chemical shifts of the *o*-pn and *o*-chxn chelates showed that an alkyl substituent at the azomethine carbon cause a downfield shift of 9 ppm. The azomethine carbon of the *o*-cptn chelate resonates at a magnetic field lower by 8.8 ppm than that of the *o*-chxn chelate. The steric effect of the cyclopentane ring exerted on the chelate ring causes it to deform from a plane structure, and the conjugation of the diimine is reduced.

The electronic spectra of Fe^{II} complexes with 1,2-diimines have been studied extensively, and a characteristic intense band between 450 and 600 nm has been assigned to an electron-transfer band($t_{2g}\rightarrow$ligand).[16] The tetracyano(1,2-diimine)ferrate(II) has simple structures for the Fe^{II} 1,2-diimine chromophore. The electronic spectra of $[Fe(CN)_4(o\text{-pn})]^{2-}$, $[Fe(CN)_4(o\text{-chxn})]^{2-}$, and $[Fe(CN)_4(o\text{-cptn})]^{2-}$ in water are shown

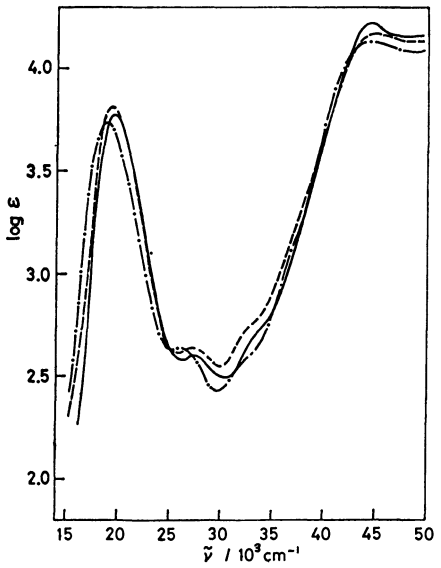


Fig. 3. Electronic spectra of $[Fe(CN)_4(diimine)]^{2-}$ in water.
Diimine: *o*-pn, ——; *o*-cptn, —·—; *o*-chxn, – – –.

in Fig. 3. A sharp absorption appeared at 19400 and at 18700 cm^{-1} for the former two and the latter complexes respectively. Weak absorptions at 30300 and 33300 cm^{-1} are assigned to d-d transitions, based on the results of tris(1,2-diimine)iron(II).[17] The first absorption band ($^1A_{1g} \rightarrow {}^1T_{1g}$) moved to an energy higher by 4700 cm^{-1} than that for $[Fe(CN)_4(diamine)]^{2-}$. This is in agreement with the difference in the spectrochemical series between 1,2-diimine and 1,2-diamine.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Kinetics of the Oxidation of Ethylenediaminetetraacetato and *N*-(2-Hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetato Complexes of Cobalt(II) by Hydrogen Peroxide in Aqueous Acidic Medium

Pradyot BANERJEE* and Mahesh P. PUJARI

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Jadavpur, Calcutta-700 032, India

(Received August 15, 1980)

Kinetics of the oxidation of Co(II) complexes, $Co(edta)^{2-}$ and $Co(hedta)^{-}$ [H_4edta=ethylenediaminetetraacetic acid and H_3hedta=*N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid] have been studied in aqueous acidic medium (pH 3.6—4.8) at 30—60 °C. The reactions were shown to exhibit second-order kinetics, first-order in each of the reactants. In the pH range studied, the rates of reaction showed inverse $[H^+]$ dependence which could be accounted for in terms of the acid-base equilibrium $H_2O_2 \overset{K_a}{\rightleftharpoons} HO_2^- + H^+$. Applying the limiting conditions $[H^+] \gg K_a$, $[H_2O_2] \gg [HO_2^-]$, the rate-law is given by $d[Co^{III}\text{-}L]/dt = 2\{k_{H_2O_2} + k_{HO_2^-} K_a [H^+]^{-1}\} [Co^{II}\text{-}L] [H_2O_2]$ where L denotes the general form of the ligand in either case. At 30 °C (*I*, 0.5 mol dm^{-3}), values obtained are $k_{H_2O_2} = (5.6 \pm 0.3) \times 10^{-5}$ mol^{-1} dm^3 s^{-1}, $k_{HO_2^-} = (5.4 \pm 0.3) \times 10^2$ mol^{-1} dm^3 s^{-1} for the $Co(edta)^{2-}$ complex and $k_{H_2O_2} = (4.5 \pm 0.4) \times 10^{-5}$ mol^{-1} dm^3 s^{-1}, $k_{HO_2^-} = (5.1 \pm 0.5) \times 10^2$ mol^{-1} dm^3 s^{-1} for the $Co(hedta)^{-}$ complex. The corresponding activation parameters are $\Delta H^* = (71 \pm 8)$ kJ mol^{-1}, $\Delta S^* = -(92 \pm 23)$ J K^{-1} mol^{-1} ($Co(edta)^{2-}$ system) and $\Delta H^* = (89 \pm 2)$ kJ mol^{-1} and $\Delta S^* = -(36 \pm 4)$ J K^{-1} mol^{-1} ($Co(hedta)^{-}$ system).

Redox reactions of hydrogen peroxide have been studied earlier by a number of workers.[1] In view of the resemblance of hydrogen peroxide reactions with the biologically relevant reactions of catalase and peroxidase,[2,3] peroxide reactions are of topical interest. The present kinetic study of the oxidation reactions of $Co^{II}(edta)^{2-}$ and $Co^{II}(hedta)^{-}$[H_4edta= ethylenediaminetetraacetic acid and H_3hedta=*N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid] with hydrogen peroxide was carried out because of the general interest in redox reactions of hydrogen peroxide, and also due to the fact that marked differences in the reactivity between various coordination complexes with hydrogen peroxide are generally observed.

Experimental

Materials. The Co^{II}–edta solution was prepared by adding a little excess (≈10%) of the requisite amount of Na_2H_2edta to the Co(II) solution. Preparation of Co^{II}–hedta and buffers has been described elsewhere.[4] Stabilizer-free hydrogen peroxide (BDH) was distilled under vacuum, and its concentration was checked by titration with standard $KMnO_4$. Ionic strength of the solutions were adjusted with KNO_3. All chemicals were of reagent grade.

Measurements. pH measurements were done with a Beckman digital pH meter (4500) and a Pye-Unicam recording spectrophotometer (SP8-150) was used for the measurements of absorption spectra. Kinetics were followed on a Hilger Uvispek machine as mentioned earlier.[4]

Results

Kinetics of the Oxidation of Co^{II}–edta and Co^{II}–hedta with H_2O_2. When aqueous solutions of the Co(II) complexes were mixed with that of hydrogen peroxide, intense coloration developed slowly. No rapid reaction as revealed by spectral features was observed.

The stoichiometry of the reactions corresponding to the slow change was determined as follows. Solutions containing the Co(II) complexes of concentration greater than twice the concentration of hydrogen peroxide (in each case) were kept at 50 °C for 24 h, and the amounts of Co(III) product formed were estimated from the ε_{max} values at 380 and 535 nm for the Co^{III}–edta complex, and at 380 and 550 nm for Co^{III}–hedta complex. One mole of the oxidant was consumed per two moles of the Co(II) complexes. Under our experimental conditions (pH 3.6—4.8), Co(III) complexes are formed quantitatively. Spectral data reveal that the product of oxidation for the Co^{II}–hedta complex is not the sexidentate species Co(hedta), but the quinquedentate species, $Co(hedta)H_2O$. Earlier studies[4] carried out by us on the oxidation of Co^{II}–hedta by peroxodisulfate ion show the formation of the identical species. Sulfab[5] also claims the formation of the quinquedentate species in course of the oxidation studies of Co^{II}–hedta with periodate in the pH range 4.0—4.8. Kinetics of both the reaction systems were studied at 30—60 °C using large excess of hydrogen peroxide over the Co(II) complexes. The conventional first-order plots log $(A_\infty - A_t)$ *vs.* time(t) are linear for at least three half-lives of the reactions. This shows that the oxidation reactions are first-order dependent on the Co(II) complex concentration. Plots of k_{obsd} *vs.* $[H_2O_2]$ gave good straight lines passing through zero. This shows that the reactions are also first-order with respect to the oxidant (Fig. 1). The rate-law for the oxidation of Co^{II}–edta and Co^{II}–hedta by H_2O_2 is thus represented by Eq. 1:

$$\frac{d[Co^{III}\text{-}L]}{dt} = 2k[Co^{II}\text{-}L][H_2O_2], \quad (1)$$

where L is the abbreviated form of the ligand in each case (the charges for the complexes have been omitted for brevity) and k is the second-order rate constant. Values of k determined from the slopes of plots of the type shown in Fig. 1 for both the systems are shown in Table 1. ΔH^* and ΔS^* values obtained from least-squares fit to Eyring equation are also shown in Table 1.

The effect of pH on the redox reactions was also

investigated in the range 3.6—4.8 (at a fixed peroxide concentration). Both the complexes exhibited an inverse $[H^+]$ dependence which indicates the occurrence of an acid-base equilibrium. It is well-known that hydrogen peroxide is a weak acid, dissociation of which is governed by an equilibrium of the type,

$$H_2O_2 \overset{K_a}{\rightleftharpoons} HO_2^- + H^+. \quad (2)$$

($K_a = 2.6\times10^{-12}$ mol dm^{-3} at 30 °C[6])

Under the present conditions of kinetic study where $[H^+] \gg K_a$, the predominant reacting species is obviously molecular hydrogen peroxide ($[HO_2^-] \ll [H_2O_2]$). The second-order rate constant (defined by $k_{obsd}/2[H_2O_2]$) is therefore given by:

$$k = k_{H_2O_2} + k_{HO_2^-}K_a[H^+]^{-1}, \quad (3)$$

where $k_{H_2O_2}$ and $k_{HO_2^-}$ denote the rate contributions due to hydrogen peroxide and hydrogen peroxide ion respectively. Values of $k_{H_2O_2}$ and $k_{HO_2^-}$ can be extracted from plots of k *vs.* $K_a[H^+]^{-1}$. Such plots (at 30 °C) gave excellent linearity with slopes and intercepts (Fig. 2), and the computed values are listed in Table 2. The reactivity of HO_2^- is $\approx 10^7$ times

higher than that of H_2O_2 in either case.

Discussion

In most of the reactions of hydrogen peroxide studied earlier one-electron oxidation and formation of radicals are observed.[7] On the basis of our experimental data, it is quite reasonable to believe that the present reaction systems follow the general scheme (Eqs. 4—6) in which H_2O_2 and HO_2^- are both involved in bimolecular rate-determining steps with $Co^{II}L$,

$$Co^{II}L + H_2O_2 \xrightarrow[k_{H_2O_2}]{\text{slow}} Co^{III}L + OH^- + OH\cdot, \quad (4)$$

$$Co^{II}L + OH\cdot \xrightarrow{\text{fast}} Co^{III}L + OH^-, \quad (5)$$

$$Co^{II}L + HO_2^- \xrightarrow{k_{HO_2^-}} \text{Products}. \quad (6)$$

The free radical mechanism, namely (4)—(5) is well supported by experimental evidences gathered over the last few years[8-10] (specially using the ESR technique[1]). The electron transfer step expressed in Eq. 6 could be followed by a precursor equilibrium between the substrate and HO_2^-. The criterion for such an equilibrium under the present conditions must be that it is significantly small. Furthermore, the equilibrium must be obtained fairly rapidly compared to the intramolecular electron transfer step, else saturation of the pseudo-first-order rate constant would have been observed at high concentration of hydrogen peroxide. Sutin[11] has also put forward evidence for an HO_2^- path in course of kinetic studies of the reaction of chromium(II) cyanide complexes with hydrogen peroxide in aqueous solution. The rate-determining intramolecular electron transfer is preceded by an association step as:

$$Cr(CN)_5H_2O^{3-} + HO_2^- \overset{K_a}{\rightleftharpoons} [\text{Complex}]^{3-} + CN^-, \quad (7)$$

$$[\text{Complex}]^{3-} \xrightarrow{k} \text{Products}. \quad (8)$$

Yalman[12] has studied the electron transfer reaction of Co^{II}–edta with hydrogen peroxide in the pH range 6.5—8.5 by manometric, spectrophotometric, and polarographic techniques. A peroxodicobalt(III, III) intermediate, (edta)CoOOCo(edta)$^{4-}$ having an intense band in the ultraviolet region is claimed to be formed, the formation of which is supported by polarographic measurements. In the present study where the pH has been kept below 4.8, no spectral evidence could be gathered for the formation of any intermediate species. However, our earlier studies[4] on the electron transfer reaction of Co^{II}–hedta with peroxodisulfate ion present the opportunity for detection of an intermediate which is believed to be a mononuclear Co^{III} complex containing the oxidant (in part) in the inner-sphere.

The reactivity of the two complexes towards peroxide oxidation is more or less the same (the Co^{II}–edta complex reacting little faster than the Co^{II}–hedta complex). However, a fairly large difference in the entropy of activation (Table 1) is found for the two reaction systems which may originate from the difference in charge on the Co(II) complexes. Positively charged complexes reacting with HO_2^- are expected to have the least negative entropies of activation due to charge neutralization in the transition state leading to desolvation. Neutral and negatively charged complexes will have more negative entropies because of developing charge in the transition state.[13] The activation energies for these reactions are considerably lower than the value of 140 kJ required for the symmetrical fission of the peroxide bond[1] and may be rationalized as a stabilization of the activated complexes caused by partial transfer of electrons from the metal ion to a 'generating' hydroxyl radical ion.

Circular Dichroism of Chromium(III) Complexes. VI. Preparation, Optical Resolution, and Circular Dichroism Spectra of (Amino acidato)bis(ethylenediamine)chromium(III) Complexes

Sumio KAIZAKI* and Mieko ITO

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630

(Received November 7, 1980)

Three (amino acidato)bis(ethylenediamine)chromium(III) complexes were prepared and resolved into their optically active isomers, their absorption and circular dichroism spectra being measured in the spin-forbidden and spin-allowed d-d transition regions. The amino acids used were glycine, L-alanine, and L-phenylalanine, the latter two yielding pairs of diastereomeric, not enantiomeric, isomers in their complexes. The configurational and vicinal CD curves were obtained from the observed CD of each pair of diastereomers. The additivity of configurational and vicinal contributions to the optical activity in the whole region of the d-d transitions was substantiated. The configurational and vicinal CD peaks in the spin-forbidden band region were assigned in connection with those in the first spin-allowed band region.

In contrast to the large number of corresponding Co(III) complexes, only a limited number of Cr(III) complexes containing optically active amino acid chelates are known.[1-3] No complex such as $[Cr(am)(N)_4]^{2+}$ (am=amino acid anion) has been prepared, but this type of Cr(III) complex is fundamental for spectroscopic and stereochemical studies on (amino acidato) chromium(III) complexes as for analogous Co(III) complexes on the basis of their chiro-optical spectra.[4-7] With use of two ethylenediamines as $(N)_4$ ligands, circular dichroism(CD) spectra of the complexes with optically active amino acids might be separated into the configurational contribution due to the chiral arrangement of three chelate rings around a central Cr(III) ion and the vicinal one due to the chirality around optically active amino acidato ligands as in Co(III) complexes.[5-7] For such Cr(III) complexes, the vicinal CD curves in the spin-forbidden transitions might reveal the split components of the excited states as found for the CD in the first band region of Co(III) complexes.[5-7] The electronic doublet states would be clarified for the Cr(III) complexes of the present type as has been revealed for the so-called praseo type complexes[8] and in more detail than for the tris-chelate complexes.[9]

This paper deals with the preparation and optical resolution of $[Cr(am)(en)_2]^{2+}$, where am refers to glycine anion(gly), L-alanine anion(L-ala), and L-phenylalanine anion(L-phala), and with their absorption and CD spectra in the d-d transition region. The absolute configuration and additivity of the configurational and vicinal CD curves of these complexes are discussed. The configurational and vicinal CD peaks in the spin-forbidden transition region are elucidated in relation with those in the first spin-allowed transition region by means of the relations[8-9] between the rotational strengths for the spin-forbidden transitions and those for the first spin-allowed transitions.

Experimental

Preparation of the Complexes. *1)* *$[Cr(gly)(en)_2]Cl_2 \cdot 0.5H_2O$*: A solution of 1.0 g of *cis*-$[CrCl_2(en)_2]Cl \cdot H_2O$ in 4 cm^3 of water was heated at 80 °C. To the resulting red solution in which the species may be *cis*-$[CrCl(en)_2(H_2O)]^{2+}$ was added 0.3 g of glycine at room temperature. After the pH of the mixture had been adjusted to 8—9 with a 2 mol dm^{-3} potassium hydroxide solution, the solution was warmed at 35 °C for a few hours; when the coloration of the solution turned reddish orange. To this was added a large excess of potassium iodide. On cooling the solution in an ice bath, orange powder was precipitated. This was filtered and washed with methanol and ether. Another crop of the crude complex was obtained from the filtrate by adding methanol. The crude product was purified as follows. An aqueous solution of the obtained powder was poured into an SP-Sephadex C-25 column (ϕ3.5 cm×30 cm), and the adsorbed complex was eluted with a 0.2 mol dm^{-3} sodium chloride solution at 5 °C in the dark. A yellow orange eluate showing absorption maxima at 478 nm and 359.5 nm was collected. The eluate was reloaded on a short column of SP-Sephadex C-25 after dilution with cold water at 5 °C, and the adsorbed complex on the Sephadex was washed thoroughly with a 0.05 mol dm^{-3} lithium chloride solution. After elution of the adsorbed complex with a 3 mol dm^{-3} lithium chloride solution, the concentrated solution obtained was evaporated to dryness by means of freeze drying. The orange powder contaminated with a large amount of lithium chloride was dissolved completely in a small amount of ethanol. A large excess of ether was added, yellow orange powder being obtained. This was filtered and washed thoroughly with ethanol. Pure chloride was obtained by recrystallization from cold water and ethanol. Found: C, 20.94; H, 6.74; N, 20.60%. Calcd for $[Cr(gly)(en)_2]Cl_2 \cdot 0.5H_2O$: C, 20.75; H, 6.67; N, 20.57%.

2) *$(+)_{589}$- and $(-)_{589}$-$[Cr(gly)(en)_2]^{2+}$*: An aqueous solution of $[Cr(gly)(en)_2]Cl_2 \cdot 0.5H_2O$ was adsorbed on an SP-Sephadex C-25 column, and the charged complex was eluted with a 0.1 mol dm^{-3} aqueous solution of sodium $(+)_{589}$-tartratoantimonate(III) at a rate of 0.3 cm^3/min at 5 °C in the dark. Equal amounts of two bands, $(+)_{589}$- and $(-)_{589}$-isomers, were eluted separately. Each eluate was reloaded on a short column of SP-Sephadex C-25 after dilution with cold water. Each adsorbed complex was eluted with a 3 mol dm^{-3} lithium chloride solution, the eluates being stored for CD measurements. Isolation of these complexes was unsuccessful. Based on the quantitative analysis of the Cr^{3+} content in these solutions, the absorption spectra of the concentrated solutions coincided in position and intensity with those of the unresolved $[Cr(gly)(en)_2]Cl_2 \cdot 0.5H_2O$ in water.

3) *$(\Delta\Lambda)$-$[Cr(L\text{-}ala)(en)_2]^{2+}$*: This complex ion was prepared by the same method as for the glycinato complex in *1)*. However, it was not isolated owing to decomposition during the course of isolation.

4) $(+)_{589}$- *and* $(-)_{589}$-*[Cr(L-ala)(en)$_2$]$^{2+}$*: After the reaction of *cis*-[$CrCl_2(en)_2$]$Cl\cdot H_2O$ with L-alanine in water as described in *1)*, the mixture was poured into an SP-Sephadex C-25 column (ϕ4 cm×50 cm). The adsorbed band was eluted with a 0.2 mol dm^{-3} sodium chloride solution at 5 °C in the dark. Of six separate bands, the fourth eluted yellow orange band showed a similar absorption spectrum to that of [Cr(gly)$(en)_2$]$^{2+}$. The dilute aqueous solution of this eluate was resorbed on a column of SP-Sephadex C-25 and the adsorbed complex was resolved into diastereomers by elution with a 0.1 mol dm^{-3} aqueous solution of sodium $(+)_{589}$-tartratoantimonato(III) at a rate of 0.3 cm^3/min at 5 °C in the dark. Two bands were separated: the first and the second bands being $(+)_{589}$- and $(-)_{589}$-diastereomers, respectively. $(+)_{589}$- and $(-)_{589}$-isomers are found to be formed in the ratio 48:52. Each eluate was concentrated by the same procedure as given in *2)*.

5) $(\Delta\Lambda)$-*[Cr(L-phala)(en)$_2$]I_2*: The iodide of this complex was obtained as needle-like crystals by the same method as for the glycinato complex. Recrystallization was carried out from a small amount of water and methanol. Found: C, 26.28; H, 4.52; N, 11.73%. Calcd for [Cr(L-phala)-$(en)_2]I_2$: C, 26.46; H, 4.44; N, 11.87%.

6) $(+)_{589}$- *and* $(-)_{589}$-*[Cr(L-phala)(en)$_2$]$^{2+}$*: Two diastereomers of the L-phenylalaninato complex were obtained by SP-Sephadex column chromatography of the mixture after the reaction as in the case of the L-alaninato complexes in *4)*. The faster and slower eluates of two separate bands were $(+)_{589}$- and $(-)_{589}$-isomers, respectively, their formation ratio being *ca.* 3 : 2.

Measurements. Absorption spectra were obtained on a Shimadzu UV-200S spectrophotometer, and CD spectra on a JASCO MOE-1 spectropolarimeter. The quantitative absorption spectra of the unresolved glycinato and L-phenylalaninato complexes were measured on the basis of their elemental analytical results. The molar absorption coefficients of the L-alaninato complex were determined on the basis of quantitative analysis of the Cr^{3+} content in sample solutions, since this complex could not be isolated. The values of the molar absorption coefficients (ε=86.06 mol^{-1} dm^3 cm^{-1} at 478 nm and ε=71.68 mol^{-1} dm^3 cm^{-1} at 359.5 nm) obtained by this method seem reasonable in comparison with those of the other amino acidato complexes: ε=87.05 at 478 nm and 76.65 mol^{-1} dm^3 cm^{-1} at 359.5 nm for the glycinato complex, and ε=86.72 at 478 nm and 72.42 mol^{-1} dm^3 cm^{-1} at 359.5 nm for the L-phenylalaninato complex. The CD measurements of the present optically active complexes were performed by using the sample solutions in *ca.* 2 mol dm^{-3} lithium chloride solutions in which the Cr^{3+} content was determined by quantitative analysis and/or the molar absorption coefficients of the first absorption band. In the latter case, it is assumed that each diastereomer of the L-alaninato and L-phenylalaninato complexes has equal molar absorption coefficients, since those of diastereomers of [Co$(ox)_2$(L-ala)]$^{2-}$, [7] [Co$(mal)_2$(L-phala)]$^{2-}$, [7] and [Cr-(L-ala)$(en)_2]^{2+}$ [5] have been found to be equal.

Chemical Analysis. Chromium content was determined by spectrophotometric analysis of CrO_4^{2-} at 372 nm after oxidation of the complexes with hot alkaline hydrogen peroxide.

Results and Discussion

Absorption and Circular Dichroism Spectra. The first and second absorption band maxima of the three amino acidato complexes coincide with each other (Fig. 1). The positions agree with those predicted from the rule of average environment[10] or Yamatera's rule[11] by using the first and second band positions for $[Cr(en)_3]^{3+}$ and $[Cr(ox)_3]^{3-}$.

The CD spectra of the complexes give only one component in the first band region and two components with opposite signs in the second band region (Figs. 1 and 2). The CD intensities of these complexes are comparable to those of tris-chelate

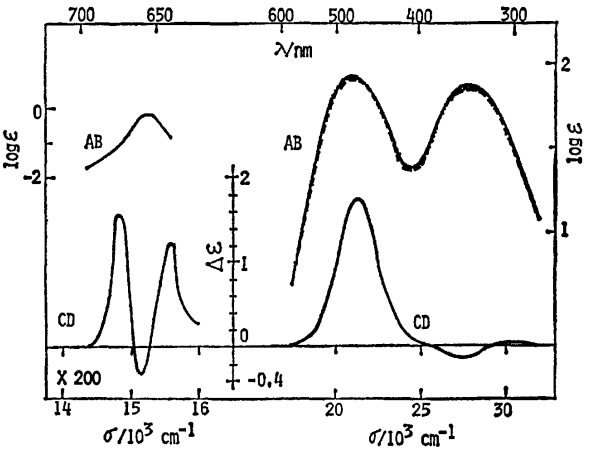

Fig. 1. Absorption curves (upper) of [Cr(gly)$(en)_2]^{2+}$ (——), [Cr(L-ala)$(en)_2]^{2+}$ (----), and [Cr(L-phala)-$(en)_2]^{2+}$ (·····); observed CD curves (lower) of $(+)_{589}$-[Cr(gly)$(en)_2]^{2+}$.

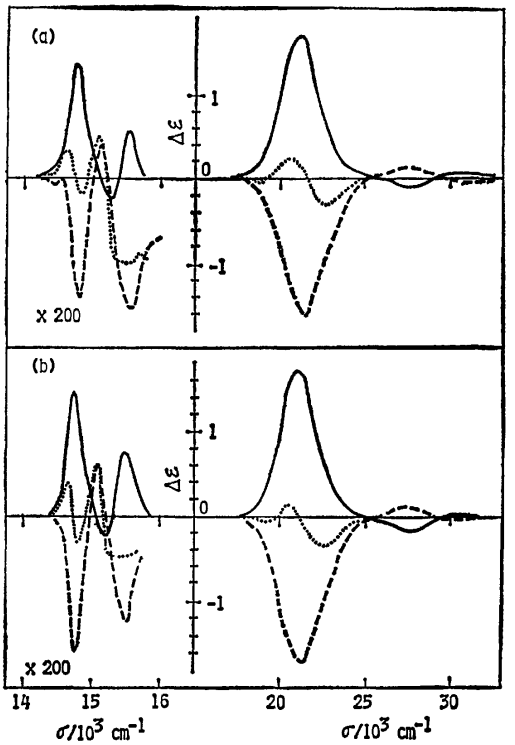

Fig. 2. (a) CD curves of $(+)_{589}$-[Cr(L-ala)$(en)_2]^{2+}$ (——) and $(-)_{589}$-[Cr(L-ala)$(en)_2]^{2+}$ (----), and calculated vicinal CD curve ($2\Delta\varepsilon$(L)) of [Cr(L-ala)-$(en)_2]^{2+}$ (·····). (b) CD curves of $(+)_{589}$-[Cr(L-phala)$(en)_2]^{2+}$ (——) and $(-)_{589}$-[Cr(L-phala)$(en)_2]^{2+}$ (----), and calculated vicinal CD curve ($2\Delta\varepsilon$(L)) of [Cr(L-phala)$(en)_2]^{2+}$ (·····).

complexes such as $(+)_{589}$-$[Cr(en)_3]^{3+}$ and $(+)_{589}$-$[Cr(ox)(en)_2]^{+}$.[9] This confirms the chelation of amino acidato ligands in the complexes. Since the faster eluted $(+)_{589}$-isomers of these complexes exhibit a positive CD band in the first band region, they are assigned to a Λ absolute configuration. Thus, the slower eluted $(-)_{589}$-isomers with a negative CD band in this region take a Λ configuration. The elution order is the same as that found for the corresponding Co(III) complex with glycine anion.[12] A preliminary experiment of the optical resolution for the trimethylenediamine complex, $[Cr(gly)(tn)_2]^{2+}$, indicates that the faster eluted band on SP-Sephadex column chromatography exhibits a negative CD band in the first band region and is assigned to a Λ configuration. The inversion of the elution order for the ethylenediamine and trimethylenediamine complexes is also found for the corresponding Co(III) complexes.[12b]

It has been revealed for several Co(III) complexes[5-7] that the configurational and vicinal contributions are separable and almost additive on the CD curves in the spin-allowed d-d absorption band region. However, there is no application of the additivity rule to the CD of chromium(III) complexes in both the spin-forbidden and spin-allowed band regions. The vicinal CD due to one coordinated optically active amino acidato ligand, $\Delta\varepsilon$(L), and the configurational CD, $\Delta\varepsilon(\Lambda)$ or $\Delta\varepsilon(\Lambda)$, have been calculated by applying the following relations to the observed CD curves, $\Delta\varepsilon(\Lambda_L)$ and $\Delta\varepsilon(\Lambda_L)$, of Λ- and Λ-$[Cr(am)(en)_2]^{2+}$.

$$\Delta\varepsilon(\text{L}) = 1/2\{\Delta\varepsilon(\Lambda_L) + \Delta\varepsilon(\Lambda_L)\}$$
$$\Delta\varepsilon(\Lambda) = 1/2\{\Delta\varepsilon(\Lambda_L) - \Delta\varepsilon(\Lambda_L)\}$$
$$\Delta\varepsilon(\Lambda) + \Delta\varepsilon(\Lambda) = 0$$

The calculated configurational curves from the CD data of each diastereomer of the L-alaninato and L-phenylalaninato complexes agree with the observed curve of the glycinato complex, $(+)_{589}$-$[Cr(gly)(en)_2]^{2+}$, in the lower frequency spin-forbidden band region as well as in the first and second spin-allowed band regions (Fig. 3). The configurational CD in the spin-forbidden band region is similar in appearance to that of $(+)_{589}$-$[Cr(en)_3]^{3+}$,[9] but the half-bandwidths of the complexes are approximately twice as wide as that of $(+)_{589}$-$[Cr(en)_3]^{3+}$.[9] Assuming pseudo D_3 symmetry for the present complexes as for $[Cr(ox)(en)_2]^{+}$,[9] one positive configurational CD component in the first spin-allowed band region is due to the $^4E(^4T_{2g})$ state. Then, three CD peaks of the configurational curves in the spin-forbidden band region are assigned to the $^2E(^2E_g)$, $^2A_2(^2T_{1g})$, and $^2E(^2T_{1g})$ states from the lower frequency side according to the theoretical relation of the rotational strengths for these d-d transitions.[9]

The calculated vicinal CD curves of the L-alaninato and L-phenylalaninato complexes in the first band region give three components, (−), (+), and (−) from the lower frequency side (Fig. 2). This CD

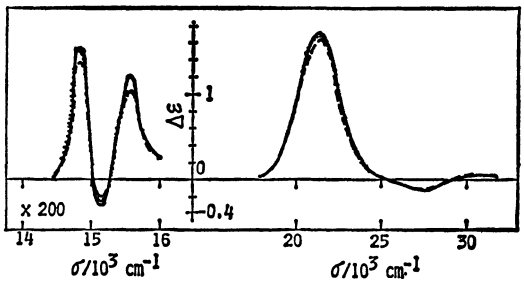

Fig. 3. Calculated configurational CD curves of [Cr(L-ala)$(en)_2]^{2+}$ (----) and $[Cr(L\text{-phala})(en)_2]^{2+}$ (……), and observed CD curve of $(+)_{589}$-$[Cr(gly)(en)_2]^{2+}$ (——).

a) CD intensities are multiplied by 10^3.

behavior is similar to that of the corresponding Co(III) complexes[5] except their CD intensities. In the spin-forbidden band region, the vicinal CD curves exhibit four components with alternate signs; (+), (−), (+), and (−) from the lower frequency side. The intensity ratios between the configurational and vicinal CD components in the first spin-allowed band region are found to be almost equal to those between the configurational and vicinal CD ones on the lowest frequency side of the spin-forbidden band region (Table 1). This suggests that the intensity borrowing mechanism of the spin-forbidden transitions *via* spin-orbit coupling for the rotational strengths due to the vicinal effect is also operative and valid as in the case of the configurational effect. Of the four vicinal CD components in the spin-forbidden band region, two components on the lower frequency side, (+) and (−), are covered under the band envelope of the configurational CD component on the lowest frequency side in this region; *e.g.*, (+) one for $(+)_{589}$-$[Cr(gly)(en)_2]^{2+}$ (Fig. 2). Thus, the two peaks correspond to the splitting components of the configurational CD peak, which was previously assigned to the $^2E(^2E_g)$ state. The remaining vicinal components, (+) and (−), might correspond to the central $^2A_2(^2T_{1g})$ and the highest frequency $^2E(^2T_{1g})$ configurational CD bands, respectively, in view of the positions of their CD peaks. The large splitting interval of *ca.* 250 cm^{-1} obtained for the $^2E(^2E_g)$ state is comparable to those observed for such tetragonal complexes as $[CrX(NH_3)_5]^{n+}$ type.[13] The splitting interval of the $^2E(^2E_g)$ state for tris(ethylenediamine)chromium(III) complex has been found to be *ca.* 18 cm^{-1}.[14] Assuming that the present complexes belong effectively to holohedrized tetragonal (D_4) symmetry,[15] two vicinal CD peaks on the lower frequency side of the first band, (−) and (+), might be due to the splitting components of the ^4E state, and the remaining negative highest frequency peak to the $^4B_2$ one. The total rotational strength for the $^4E \leftarrow {}^4B_1$ transition in a tetragonal (D_4) field seems to be given by the sum of those for two individual transitions in a lower symmetry field. Thus, the signs of the rotational strengths for the $^4E \leftarrow$ and $^4B_2 \leftarrow {}^4B_1$ transitions are positive and negative, respectively, since the positive component of the ^4E state is much larger than the negative one (Fig. 2 and Table 1). On the basis of the theoretical relation between the rotational strengths for the spin-allowed and magnetic dipole allowed transitions and those for the spin-forbidden transitions of tetragonal Cr(III) complexes (Ref. 8, Table 2 third column), four vicinal CD peaks in the spin-forbidden band region are assigned as follows. Since the rotational strengths for the $^2A_1$, $^2A_2 \leftarrow {}^4B_1$ transitions should have the same signs as those for the $^4E \leftarrow {}^4B_1$ transition, two positive peaks are assigned to the $^2A_1$ and $^2A_2$ states from the lower frequency side. Two remaining negative peaks might be due to the $^2B_1$ and ^2E one from the lower frequency side, the rotational strengths of which are expected to have the same signs as those of the $^4B_2$ state (Table 1). It seems plausible that the orbitally nondegenerate $^2A_2(D_4)$ and the degenerate $^2E(D_4)$ components for the vicinal CD correspond to the nondegenerate $^2A_2(D_3)$ and degenerate $^2E(D_3)$ ones for the configurational CD, respectively.

The authors wish to thank Prof. Yoichi Shimura, Osaka University, and members of his laboratory for their aid in obtaining the circular dichroism spectra. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture. Some preliminary work was carried out by Miss Misako Nishio.

(Received August 5, 1980)

Acylcarnitine chlorides form micelles in water and polyprotic solvents such as glycerol, ethylene glycol; 1,3-propanediol and 1,4-butanediol. The effect of the acyl chain on the formation of micelles was studied for compounds with chain lengths of 2 to 16 carbon atoms. The critical micellar concentration in glycerol was determined at 25 °C by means of difference spectroscopy using phenol as a probe. The acylcarnitine chlorides with chains containing less than 8 C atoms do not form micelles in glycerol. The critical micellar concentration varies from 0.060 mol dm^{-3} for octanoylcarnitine to 0.011 mol dm^{-3} for palmitoylcarnitine. The free energy of micellization, ΔG°_{mic}, varies linearly with chain length in the range of -6.95 kJ mol^{-1} to -11.2 kJ mol^{-1}. The "hydrophobic" or "solvophobic" effect was more pronounced in water than in glycerol and the free energy change per metylene group was -2.89 kJ mol^{-1} and -0.75 kJ mol^{-1}, respectively. The formation of micelles of acylcarnitine chlorides in glycerol is important in terms of the metabolism of fatty acids and their transport across biological membranes.

The principal pathway for the oxidation of fatty acids is generally considered to be β-oxidation. Several enzymes, known collectively as the fatty acid oxidase complex, are found in the mitochondrion closely associated with the enzymes of the respiratory chain. These catalyze the oxidation of fatty acids to acetyl-S-CoA, the system being coupled with the phosphorylation of ADP to ATP. Although the oxidation of fatty acids occurs inside the mitochondrion, the long chain fatty acids in the cytoplasm cannot pass through the mitochondrial membrane, unless they are enzymatically combined with carnitine to form a fattyacylcarnitine complex.

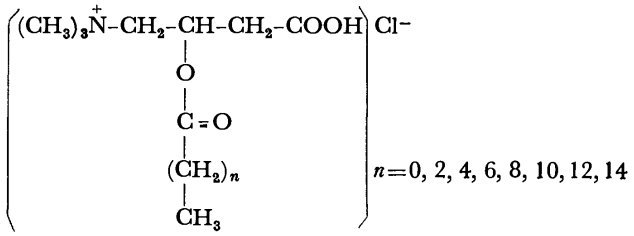
Long chain acylcarnitines are known to form micelles in water.[1,2] The critical micellar concentration (CMC) decreases by an order of magnitude as the alkyl chain length increases by units of two carbon atoms. The aggregation number of long chain acylcarnitines in water slightly increases concomitant with the increment in alkyl chain length.

In comparison with the amount of work done on the properties of surface active agents in water, the chemistry of surfactants in mixed aqueous solvents and nonaqueous solvents is a rather limited field. As part of a systematic study of the process of micellization[3-5] and the use of micelles as simple membrane models,[6] we have decided to search for micelle formation also in nonaqueous protic solvents such as glycerol, ethylene glycol; 1,2-propanediol and 1,4-butanediol. These solvents are very much like water and are known to form micelles with the nonionic detergent polyethylene glycol *p-t*-nonylphenyl ether, NPE_9 (Igepal CO-630) with an average of nine oxyethylene residues in the poly(oxyethylene) chain. The critical micellar concentration of Igepal CO-630 varies from 1.01×10^{-6} mol dm^{-3} in water to 1.55×10^{-2} mol dm^{-3} in 1,4-butanediol and the free energy of micellization, ΔG°_{mic}, ranges from -34.3 to -10.5 kJ mol^{-1} for the same solvents.[7] In general, the process of micellization appears to be thermodynamically favored and is similar to micelle formation in water. The main interaction responsible for micellization is of a hydrophobic type, not unique to water, but found in many other solvents. It is most pronounced in water and glycerol. This interaction is often given by the name "solvophobic" and its exact nature is hard to explain in terms of hydrogen bonding, OH groups, dielectric constant or other parameters.

Glycerol and ethylene glycol form intra- and intermolecular hydrogen bonds,[8,9] although they are much less strong than those in water. Both have been used widely in protein conformation studies and as simple membrane simulators. These dense liquids approximate portions of membranes in terms of the anhydrous environment that they provide. Glycerol has been applied as a viscous agent in the construction of a medium having a viscosity closer to the intracellular environment in the study of the allosteric enzyme glycogen phosphorylase b.[10] Reactivation effects by glycerol and ethylene glycol of inactivated δ-aminolevulic acid synthetase were observed. It was suggested that the protein conformation around the pyridoxal 5'-phosphate binding site of synthetase was stabilized by the polyprotic alcohols.[11]

Materials and Methods

Acylcarnitine chlorides have the generalized structure given below. The compounds studied ranged from acetylcarnitine chloride (n=0) to palmitoylcarnitine chloride (n=14) and differed in the chain



length of the fatty acid by units of two carbon atoms. They were prepared in our laboratory according to the method of Ziegler, Bruckner and Binon.[12] The synthesis essentially involved the preparation of the acyl chlorides from the corresponding acids by means of thionyl chloride, followed by reaction of the acyl

chloride with carnitine employing trichloroacetic acid as the solvent. The acylcarnitines were subsequently recrystallized from isopropyl alcohol and dried over P_2O_5 under high vacuum. Acetyl chloride and trichloroacetic acid (reagent grade) were obtained from Allied Chemical Company. Butanoic, hexanoic, octanoic, decanoic, lauric, myristic, palmitic acid, and *dl*-carnitine hydrochloride were of the highest quality available and were purchased from Aldrich Chemical Co. Thionyl chloride and phenol were of reagent grade and were supplied by Fisher Scientific Co. Glycerol (reagent grade) was purchased from Eastman Organic Chemicals and used without any further purification.

In the original experiments, the CMC was determined by surface tensiometry and only lauroylcarnitine chloride was used. The surface tension measurements were performed at 25 °C with a Du Nouy Tensiometer Model No. 70547 or a Fisher Surface Tensiomat Model 21. Both instruments were calibrated before use. Solutions of lauroylcarnitine chloride in glycerol ranging 1×10^{-9} to 0.1 mol dm^{-3} were prepared. Ten milliliter aliquots of solution in a glass dish with a diameter of 6 cm were used for the measurements. The first determination in a given series was the measurement of the surface tension of deionized distilled water, followed by pure glycerol at 25 °C. Subsequent measurements were of the various surfactant solutions in order of increasing concentration. By plotting the surface tension versus the concentration or the logarithm of the concentration of the surfactant solution, a curve with a sharp initial drop and subsequent levelling off was obtained. The first concentration at which the levelling off took place was taken as the critical micellar concentration.[3,4] Typical results obtained are illustrated in Fig. 1.

Because of the experimental difficulties encountered in the measurement of the surface tension of the viscous glycerol solutions, an alternate method using phenol as a probe for micelle formation was employed for the determination of the CMC. This is essentially a difference spectrophotometric technique developed by Ray and Némethy[13,14] The absolute absorption spectrum of 5.0×10^{-4} mol dm^{-3} phenol in glycerol was recorded with a Beckman Model 24 Spectrophotometer. Phenol has a well-defined λ_{max} at 272 nm. The difference spectra were determined with the same intrument using an expanded absorbance scale (0—0.1, 0—0.25, or 0—0.5). A solution of 5.0×10^{-4} mol dm^{-3} phenol in glycerol was placed in the reference cuvette. The sample cuvette contained a solution of the same concentration of phenol in glycerol and varying amounts of the corresponding acylcarnitine chloride. The spectra of the solutions were measured from 240 to 350 nm. The difference absorption spectra were determined for all the acylcarnitine chlorides mentioned above, namely, acetyl-, butyryl-, hexanoyl-, octanoyl-, decanoyl-, lauroyl-, myristoyl-, and palmitoylcarnitine chloride.

In general fifteen to twenty solutions of the surfactants were measured. These solutions were prepared by diluting stock solutions of acylcarnitines containing 5.0×10^{-4} mol dm^{-3} phenol in glycerol with glycerol containing the same amount of phenol. All the spectra were determined at 25 °C. A plot of the change in absorption at 272 nm, ΔA, *versus* the concentration or the logarithm of the concentration of surfactant gave a curve with a definite break at the CMC. Linear plots were taken as an indication that micelle formation did not take place. Figure 2 gives some typical experimental results obtained for lauroylcarnitine chloride.

Results and Discussion

A summary of the critical micellar concentrations and the free energies of micellization of acylcarnitine chlorides is given in Table 1. As can be seen, octanoylcarnitine chloride is the shortest acylcarnitine that forms micelles in glycerol. The value obtained for the CMC of lauroylcarnitine chloride by surface tension measurements was also 0.030 mol dm^{-3} and thus the agreement between the two different techniques was within experimental error. The CMC decreases with increasing carbon chain length, but the effect is much less pronounced in glycerol than in water.

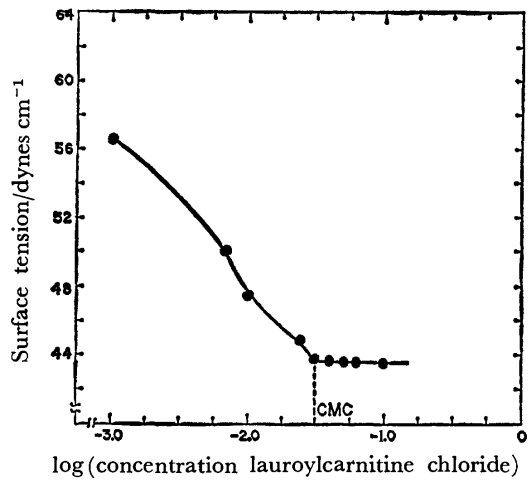


Fig. 1. Plot of surface tension *versus* the logarithm of the concentration of lauroylcarnitine chloride in glycerol at 25 °C.

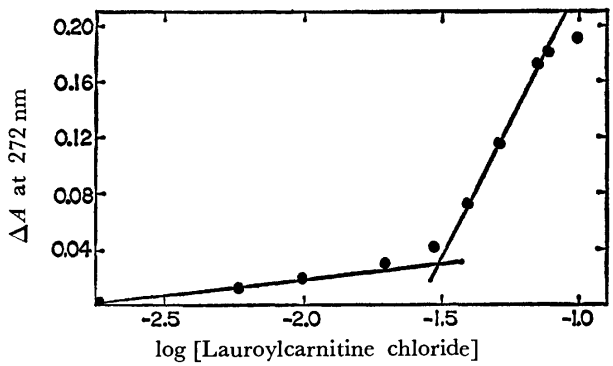

Fig. 2. Dependence of absorbance difference (ΔA) of phenol on the logarithm of the concentration of lauroylcarnitine chloride in glycerol at 25 °C.

Table 1. Critical micellar concentration and free energy of micellization for acylcarnitine chlorides in glycerol at 25 °C

Acylcarnitine chloride	Critical micellar concentration / mol dm^{-3}	ΔG°_m / kJ mol^{-1}
Acetyl-	None	—
Butyryl-	None	—
Hexanoyl-	None	—
Octanoyl-	0.060	−6.95
Decanoyl-	0.050	−7.45
Lauroyl-	0.030	−8.66
Myristoyl-	0.020	−9.67
Palmitoyl-	0.011	−11.2

The formation of normal micelles in nonaqueous polar solvents is of particular interest because in addition to providing novel insights into the process of micellization, it may lead to a better understanding of the interactions that take place between surfactant molecules and the solvent. For micelles in water, the process of micellization is generally explained by means of the hydrophobic interactions between the surfactant and water. "Hydrophobic interactions" is in many ways a convenient term that is used to describe an entire array of inter- and intramolecular interactions involved in micellization and in a certain way the term disguises our ignorance about the actual molecular dynamic processes that take place.

In general, the formation of micelles in water is assumed to take place by the association of the hydrophobic parts of the surfactant molecules and the repulsion of water of solvation from their immediate environment. The thermodynamics of micelle formation has been discussed and treated extensively in the literature.[15,16] One approach assumes that the process of micellization involves the formation of a distinct micellar phase at the CMC and that the concentration of monomers in solution is constant, once micelles are formed. Then, the standard free energy of micellization, ΔG°_{mic}, is given by Eq. 1 to a good

$$\Delta G^\circ_{mic} = RT \ln \mathrm{CMC} \quad (1)$$

approximation. If one postulates that the aggregation number and the degree of ionization of the surfactant are temperature independent, the standard enthalpy (ΔH°_{mic}) and entropy (ΔS°_{mic}) can be evaluated by the temperature dependence of the CMC and the relationship given by Eq. 2.

$$\Delta G^\circ_{mic} = \Delta H^\circ_{mic} - T\Delta S^\circ_{mic} \quad (2)$$

The over-all process of micellization involves a decrease in the free energy of the system. According to Eq. 2, ΔG°_{mic} is the result of enthalpy and entropy contributions. For aqueous solutions, micellization is generally regarded as an entropy directed process and the preponderant contribution of the entropy term is explained by the disordering of the water structure and the breakup of the "Frank-Evans microcrystals" by the surfactant molecules.

The type of interactions involved in the formation of micelles in polar solvents other than water are called "solvophobic." The understanding of "solvophobic interactions" and micellization in nonaqueous media is considerably more nebulous. The driving force for micellization is less for such systems and the more positive ΔG°_m is usually believed to be primarily due to a decrease of the entropic contribution.[7,18] Few solvent systems are as highly ordered and as strongly hydrogen-bonded as water.

As has already been mentioned, the study of nonaqueous micellar systems is of importance also in terms of the understanding of membranes. In fact, the first dynamic membrane model, precursor of the current fluid mosaic or liquid crystal model, was a micelle.[17] In the over-all analysis of solvent-surfactant interactions it is desirable to sort out hydrogen bonding, solvation and the "solvophobic effect." However, the understanding and clear differentiation of these processes in certain systems may prove to be quite a formidable task.

We have attempted to quantify the solvophobic effect in water and glycerol by varying the chain length of the acylcarnitine surfactants. The free energies of micellization of these surfactants at 25 °C have been calculated for water and glycerol and are shown in Fig. 3. The values for water have been calculated from the experimental results of Yalkowsky and Zografi.[1] A simple analysis of the results indicates that the formation of micelles of acylcarnitine chlorides is thermodynamically more favored in water than in glycerol.

The change in ΔG°_{mic} for a given solvent as a function of chain length provides information about the nature of the interaction of the $-CH_2-$ groups with the given solvent and can be interpreted as the solvophobic effect. One can quantify such an interaction by determining the slope of the plots of ΔG°_{mic} *versus* chain length. Large breaks or deviations from linearity in such plots should be indicative of unusual interactions. The data in Fig. 3 illustrates a linear behavior for both solvents, but the slope is considerably steeper for water than for glycerol. The free energy

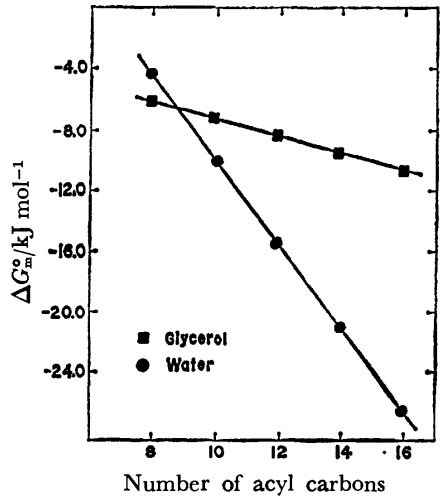

Fig. 3. Dependence of the free energy of micellization (ΔG°_m) on the acyl chain length of acylcarnitine chlorides in water and glycerol at 25 °C.

change per methylene group in water is -2.89 kJ mol^{-1} and in glycerol is -0.75 kJ/mol. The value obtained for water is in agreement with that commonly reported in the literature,[16] while the result for glycerol agrees well with -0.75 kJ mol^{-1} determined by Ray and Némethy for the polyether NPE_9 in ethylene glycol.[18] The solvophobic effect is thus considerably more pronounced in water and shows about the same change in going from water to glycerol and from water to ethylene glycol.

Preliminary experiments performed in our laboratory indicate that lauroylcarnitine chloride forms micelles also in ethylene glycol; 1,3-propanediol and 1,4-butanediol. All these solvents are similar to water in the sense that they form hydrogen bonds and are polar in nature. Glycerol and ethylene glycol form intra and inter hydrogen bonds, although they are much less strong than those in water.[8,9]

The experimental results clearly indicate that the long chain acylcarnitine chlorides, *i.e.*, octanoyl-, decanoyl-, lauroyl-, myristoyl-, and palmitoylcarnitine chloride form micelles in glycerol in addition to water. The shorter chain acylcarnitines do not form micellar aggregates in either of the two solvents. The results may be of biochemical interest for several reasons. It is well known that short chain fatty acids move freely in non-complexed form across membranes. Longer fatty acids, on the other hand, are known to cross the mitochondrial membrane in the form of acylcarnitine complexes. Glycerol has been widely used in protein conformation studies and as a simple membrane simulator. Its viscous nature and anhydrous environment may approximate portions of membranes.[19,20] In addition, the relationship between micelles and the liquid crystal membrane model has already been pointed out. The present work has shown that long chain alkanoylcarnitines form charged colloidal aggregates or micelles in an anhydrous environment akin to that of biological membranes. It would appear reasonable to suggest that micelles may play a role in the transport of long chain acylcarnitines across membranes.

Peroxomonophosphoric Acid Oxidations. VI.[1] Kinetics and Mechanism of Oxidation of 3-Aminopyridine

Surendra Nath MAHAPATRO, Abhina Kumar PANDA, and Ganesh Prasad PANIGRAHI*

Department of Chemistry, Berhampur University-760007, Orissa, India

(Received October 3, 1980)

The oxidation of 3-aminopyridine to 3,3′-azoxypyridine by peroxomonophosphoric acid (PMPA) is a total second order reaction: first order each in peroxomonophosphoric acid and 3-aminopyridine at constant acidity. The observed pH-rate profile has been rationalized invoking various PMPA species, protonated and unprotonated forms of 3-aminopyridine as the reactive species and their reactivities have been estimated. Interestingly, 2-aminopyridine is not oxidized in the pH-range where the oxidation of 3-aminopyridine is facile.

The oxidation of primary aromatic amines by peroxidic reagents have received considerable attention.[2,3] A general feature of these oxidations is the formation of a tetrahedral intermediate involving nucleophilic attack by the amine lone pair on the electrophilic peroxo bond which undergoes oxidative decomposition to phenylhydroxylamine. Further oxidation of the hydroxylamine derivative leads to nitroso and eventually to the nitro group (Eq. 1).

$$Ar\text{-}NH_2 \rightarrow Ar\text{-}NHOH \rightarrow Ar\text{-}NO \rightarrow Ar\text{-}NO_2 \quad (1)$$

Bimolecular condensation between the products and unreacted amine may also lead to azoxy and azo compounds (Eqs. 2a and 2b).

$$Ar\text{-}NHOH + Ar\text{-}NO \rightarrow Ar\text{-}\overset{\overset{O}{\uparrow}}{N}{=}N\text{-}Ar \quad (2a)$$

$$Ar\text{-}N{=}O + Ar\text{-}NH_2 \rightarrow Ar\text{-}N{=}N\text{-}Ar \quad (2b)$$

We have recently reported that in the oxidation of anthranilic acid,[1] Eq. 2a is the major route leading to 2,2′-azoxybenzenedicarboxylic acid.

In our search for similar systems, we have found that 3-aminopyridine is oxidized to 3,3′-azoxypyridine essentially in quantitative yields.[4] Interestingly 2-aminopyridine did not undergo any oxidation in the pH range where the oxidation of 3-aminopyridine was facile. We wish to report the salient kinetic features of this oxidation.

Experimental

PMPA was prepared by the acid hydrolysis of $K_4P_2O_8$[5-8] (Eq. 3).

$$H_4P_2O_8 + H_2O \rightarrow H_3PO_5 + H_3PO_4 \quad (3)$$

The rate of hydrolysis Eq. 3 is about two orders of magnitude higher than the hydrolysis of H_3PO_5 to H_2O_2 (Eq. 4).

$$H_3PO_5 + H_2O \rightarrow H_2O_2 + H_3PO_4 \quad (4)$$

In the entire range of this study, the total amount of H_2O_2 was never more than 2% and H_2O_2 under our experimental conditions did not oxidize 3-aminopyridine in independent runs.

$NaClO_4$ was used to maintain constant ionic strength. $HClO_4$ (Baker analyzed 60%), KH_2PO_4, Na_2HPO_4, NaOH, potassium hydrogen phthalate were used to maintain pH which was measured using a Systronics digital pH-meter 335. 3-Aminopyridine (Aldrich 99%) was recrystallized from ethanol mp 157 °C (lit, 158 °C). The kinetics was followed by measuring the rate of disappearance of PMPA which was estimated by iodometry at pH 4—5 with a drop of ammonium molybdate solution.[1] All the reported rate constants, computed by the usual method, are reproducible to within ±5%. k_{obsd} (second order rate constant) is calculated by dividing pseudo-first order rate constant with respect to PMPA disappearance by the substrate concentration. Least squares analysis of the rate laws were done by a DCM Microsystem 1121.

Stoichiometry. A clean stoichiometry of 3-aminopyridine: PMPA (1:1.5) was observed at several pH's in the range 0—7. 3,3′-Azoxypyridine has been characterized as the only product of this oxidation and has already been reported.[4]

Results and Discussion

The oxidation of 3-aminopyridine by peroxomonophosphoric acid (PMPA) in aqueous acid medium at 308 K with different initial concentrations of PMPA and 3-aminopyridine (Table 1) enabled us to write the rate equation at constant acidity;

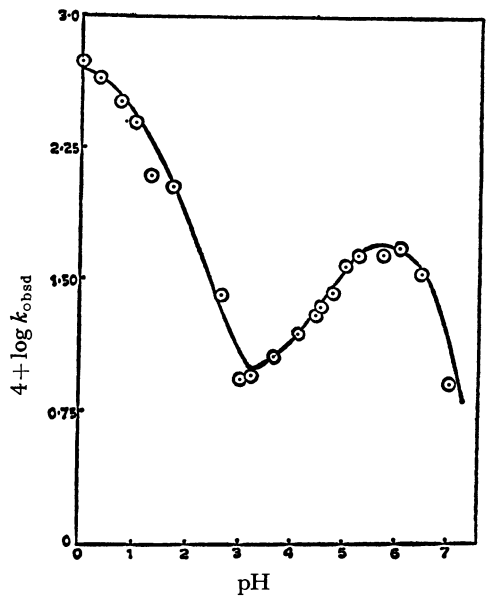

Fig. 1. Plot of log k_{obsd} *vs.* pH.
⊙: Experimental points. —: Theoretical line.

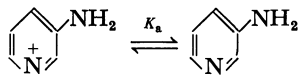
$$\text{Rate} = k_{obsd}[\text{3-Aminopyridine}]_t[\text{PMPA}]_t,$$

where k_{obsd} is the second order rate constant and 't' denotes total concentration.

The influence of acidity on the oxidation rate are presented in Table 2 and shown in Fig. 1 (log k_{obsd} *versus* pH). The pH-rate profile clearly reflects the involvement of various PMPA species and protonated and unprotonated forms of 3-aminopyridine (Eqs. 5, 6, and 7).

$$H_3PO_5 \overset{K_1}{\rightleftharpoons} H_2PO_5^- + H^+, \quad K_1 = 8.0 \times 10^{-2} \qquad (5)^{8)}$$

$$H_2PO_5^- \overset{K_2}{\rightleftharpoons} HPO_5^{2-} + H^+, \quad K_2 = 4.2 \times 10^{-6} \qquad (6)^{8)}$$



$$\overset{K_a}{\rightleftharpoons} + H^+, \quad K_a = 1.047 \times 10^{-6} \qquad (7)^{3)}$$

(BH$^+$) (B)

Reaction in the pH Range 0—3. In the pH range 0—3, the rate of oxidation goes on decreasing with the increase in pH *i.e.* with the decreasing electrophilic character of PMPA species.[9] The pK_a of 3-aminopyridine (5.98) suggests that whole of 3-aminopyridine (B) exists as BH$^+$ and PMPA exists as H_3PO_5 and $H_2PO_5^-$ in this pH range. Hence, the steps of the oxidation can be written as

$$BH^+ + H_3PO_5 \xrightarrow{k_1} \text{Products} \qquad (8)$$

$$BH^+ + H_2PO_5^- \xrightarrow{k_2} \text{Products}. \qquad (9)$$

Hence,

$$\text{Rate} = -\frac{d[\text{PMPA}]_t}{dt} = k_1[BH^+][H_3PO_5] + k_2[BH^+][H_2PO_5^-]. \qquad (9a)$$

But

$$[PMPA]_t = [H_3PO_5] + [H_2PO_5^-]. \quad (9b)$$

From Eqs. 9b and 5, we get

$$[H_3PO_5] = \frac{[H^+]}{K_1+[H^+]}[PMPA]_t \quad (9c)$$

and

$$[H_2PO_5^-] = \frac{K_1}{K_1+[H^+]}[PMPA]_t. \quad (9d)$$

Substituting Eqs. 9c and 9d in Eq. 9a, we get

$$-\frac{d[PMPA]_t}{dt} = \frac{k_1[H^+]+k_2K_1}{K_1+[H^+]}[BH^+][PMPA]_t, \quad (9e)$$

where

$$k_{obsd} = \frac{k_1[H^+]+k_2K_1}{K_1+[H^+]}. \quad (10)$$

Least squares analysis of the above equation gave us the values of k_1 and k_2 which are collected in Table 3. The correspondence between the k_{obsd} and k_{cald} based on the values of k_1 and k_2 is very good (Fig. 1).

TABLE 3. RATE CONSTANTS IN $dm^3\,mol^{-1}\,s^{-1}\times10^2$

k_1	k_2	k_3	$\left(\frac{k_4K_a}{K_2}+k_5\right)$	$\approx k_4$	k_6
5.28	0.068	0.098	4.50	18	0.05

Reaction in the pH Range 3—7. In this pH region, a bell shaped curve is observed. PMPA exists as $H_2PO_5^-$ and HPO_5^{2-} and 3-aminopyridine exists as BH^+ and B.

Therefore, the reaction steps are postulated as

$$BH^+ + H_2PO_5^- \xrightarrow{k_3} \text{Products} \quad (11)$$

$$B + H_2PO_5^- \xrightarrow{k_4} \text{Products} \quad (12)$$

$$BH^+ + HPO_5^{2-} \xrightarrow{k_5} \text{Products} \quad (13)$$

$$B + HPO_5^{2-} \xrightarrow{k_6} \text{Products}. \quad (14)$$

Equations 11—14 lead us to the rate law

$$-\frac{d[PMPA]_t}{dt} = k_3[BH^+][H_2PO_5^-] + k_4[B][H_2PO_5^-] + k_5[BH^+][HPO_5^{2-}] + k_6[B][HPO_5^{2-}]. \quad (14a)$$

But $$[B]_t = [BH^+] + [B]. \quad (14b)$$

From Eqs. 7 and 14b, we get

$$[BH^+] = \frac{[H^+]}{K_a+[H^+]}[B]_t \quad (14c)$$

and

$$[B] = \frac{K_a}{K_a+[H^+]}[B]_t. \quad (14d)$$

Now,

$$[PMPA]_t = [H_2PO_5^-] + [HPO_5^{2-}]. \quad (14e)$$

From Eqs. 6 and 14e, we get

$$[H_2PO_5^-] = \frac{[H^+]}{K_2+[H^+]}[PMPA]_t \quad (14f)$$

and

$$[HPO_5^{2-}] = \frac{K_2}{K_2+[H^+]}[PMPA]_t. \quad (14g)$$

Substituting Eqs. 14c, 14d, 14f, and 14g in 14a, we get

$$-\frac{d[PMPA]_t}{dt} = \frac{k_3[H^+]^2+\left(\frac{k_4K_a}{K_2}+k_5\right)K_2[H^+]+k_6K_aK_2}{(K_a+[H^+])(K_2+[H^+])} \times [B]_t[PMPA]_t, \quad (14h)$$

where

$$k_{obsd} = \frac{k_3[H^+]^2+\left(\frac{k_4K_a}{K_2}+k_5\right)K_2[H^+]+k_6K_aK_2}{(K_a+[H^+])(K_2+[H^+])}. \quad (15)$$

A least squares analysis of Eq. 15 was done and values of k_3, (k_4K_a/K_2+k_5) and k_6 were obtained (Table 3). These values were used to obtain k_{calcd} which showed excellent agreement with experimental points (Fig. 1).

It is gratifying that the values of k_2 (Eq. 9) and k_3 (Eq. 11), obtained by two different rate expressions Eq. 10 and Eq. 15 are of the same order of magnitude and provide credence to the steps envisaged.

Activation Energy and Entropy. The second order rate constants at 308, 313, 318, and 323 K and at $[H^+]=0.05$ mol dm^{-3} were 1.28×10^{-2}, 1.63×10^{-2}, 2.18×10^{-2}, and 2.73×10^{-2} $dm^3\,mol^{-1}\,s^{-1}$ respectively. The energy of activation from a plot of log k_{obsd} against $1/T$ was 41.8 kJ mol^{-1}. ΔH^* and ΔS^* were estimated to be 39.5 kJ mol^{-1} and -153 J K^{-1} mol^{-1} respectively.

Mechanism. That the rate limiting step involves nucleophilic attack of the amino nitrogen on the electrophilic peroxo oxygen is evident from the following facts.

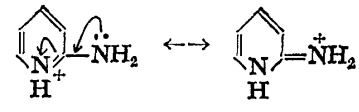
(1) No oxidation is observed above pH 7. The order of decreasing electrophilicity of the various PMPA species is $H_3PO_5>H_2PO_5^->HPO_5^{2-}>PO_5^{3-}$. At pH $\approx$7 HPO_5^{2-} is about 90%.

(2) The insensitivity of the rates to added acrylamide, Cu^{2+}, Ag^+ points to the polar nature of these oxidations without the mediation of free radical intermediates.

(3) The reactivity of H_3PO_5 (k_1) is about two orders of magnitude higher than that of $H_2PO_5^-$ (k_2), Table 3.

(4) The facile oxidation of 3-aminopyridine stands in sharp contrast to the total unreactivity of 2-aminopyridine. The reason most probably lies in the nucleophilicity of the $-NH_2$ nitrogen. The 3-NH_2 group is not conjugated with the pyridine nitrogen and thus the nitrogen lone pair is not delocalized into the heterocyclic ring.

Thus the nucleophilicity of the NH_2 group in 3-aminopyridine is fully alive. In 2-aminopyridine there are contributing structures like



and this reduces the nucleophilicity of 2-NH_2 group to a great extent.[3] In the pH range 0—5 the pyridine nitrogen is protonated which enhances the meso-

meric interaction of the $-NH_2$ group. Above pH 5, we have both B and BH^+ and B is decidedly more nucleophilic than BH^+. We have seen a very slow oxidation of 2-aminopyridine above pH 5.

In the oxidation of anthranilic acid,[1] it is the unprotonated amine which is the reactive species as the rate decreased at higher acidities. The oxidation of 3-aminopyridine provides altogether a different situation. The pK_a of 3-aminopyridine is 5.98 and this refers to the protonation of the tertiary pyridine nitrogen and the 3-NH_2 group is unprotonated. One could in principle protonate it and this obviously requires still higher acidities than presently used in this kinetic study. Our pH-rate profile at still higher acidities could possibly have shown such a decreasing trend which is a reflection of the 3-NH_2 protonation. But our attempts to see that presented serious experimental problems in the estimation of PMPA iodometrically.

Reactivity of Amine and Peroxo Acid.

1) It is seen that the reactivity of H_3PO_5 is two orders of magnitude higher than that of $H_2PO_5^-$ which has been attributed to electrophilicity difference.

2) The peak in the pH region 3—7 is significant which calls for an explanation. In this range, 3-aminopyridine exists as B and BH^+. In BH^+ the tertiary nitrogen becomes tetrahedral on protonation, the delocalized positive charge experiences a field effect due to the NH_2 lone pair which makes the NH_2 of BH^+ less nucleophilic than that of B.

3) The value of (k_4K_a/K_2+k_5) is of the order of 10^{-2}, and k_5 should be very less than k_6 as explained above.

Hence, $(k_4K_a/K_2+k_5)\approx k_4K_a/K_2$.

Using values of K_a, K_2, a rough estimate of k_4 has been obtained (Table 3). Thus it is seen that B is about two orders of magnitude higher in reactivity than BH^+.

Electrochemical Formation of 1,3,5-Trinaphthylbenzene Tri- and Tetraanions

Tetsuo SAJI* and Shigeru AOYAGUI

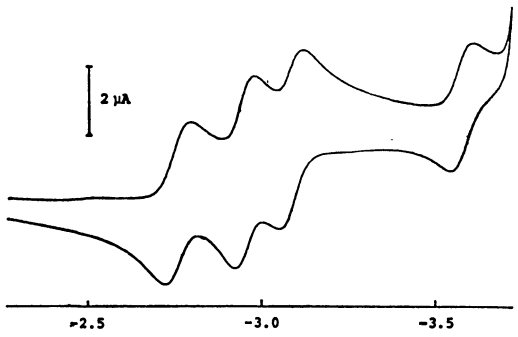
Department of Electronic Chemistry, Graduate School at Nagatsuta, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received January 20, 1981)

Synopsis. Each of the cyclic voltammograms of tri(1-naphthyl)benzene and tri(2-naphthyl)benzene in 1,2-dimethoxyethane at −50 °C exhibits four reversible one-electron reduction steps; this may be evidence for the successive formation of the mono-, di-, tri-, and tetraanions of these hydrocarbons. The degeneracy of their π^*-orbitals can account for the formation of the tri- and tetraanions.

We reported recently a well-defined cyclic voltammogram for the reduction of decacyclene in 1,2-dimethoxyethane (DME).[1] It exhibited four reversible one-electron steps, showing a successive formation of the mono-, di-, tri-, and tetraanions of considerable stability. The formation of the tetraanion was ascribed to the lowest π^*-orbitals of decacyclene degenerating two-fold due to the molecular symmetry of C_{3h}. The only hydrocarbon tetraanions ever reported except decacyclene^{4-} have been bicyclooctatetraene^{4-} [2] and benzo[1,2: 4,5]dicyclooctane^{4-}.[3] This note deals with the voltammograms of trianphthylbenzenes, which provide further examples of hydrocarbon tetraanions.

1,3,5-Tri(1-naphthyl)benzene (I) and 1,3,5-tri(2-naphthyl)benzene (II) were prepared by the trimerization of acetylnaphthalene[4] and identified on the basis of the melting point and IR spectrum.



[*E vs.* (Ag/AgNO$_3$)]/V

Fig. 1. Cyclic voltammogram of 0.5 mmol dm^{-3} 1,3,5-tri(β-naphthyl)benzene in 0.2 mol dm^{-1} TBAP–DME at −50 °C. Scan rate 0.1 V s^{-1}.

Figure 1 shows a cyclic voltammogram for 0.5 mmol dm^{-3} of II in 0.2 mol dm^{-3} tetrabutylammonium perchlorate (TBAP)–DME obtained with a scan rate of 0.1 V s^{-1} at −50 °C. It exhibits four reduction steps. They were all reversible one-electron transfer steps, according to the reversibility criteria of the peak separation and the peak current ratio. The ultimate current rise overlapped the reversal peak of the fourth step at −40 °C and 0.1 V s^{-1}; this step was not observed at all at room temperature and 0.1 V s^{-1}, while the first three steps remained reversible. Similar voltammograms were obtained for I. Table 1 lists the reversible half-wave potentials and the peak separations for these compounds, together with the first reduction half-wave potential for naphthalene obtained under the same experimental conditions. The residual resistance of the solution between the reference electrode and the working electrode due to incomplete compensation of the ohmic resistance may account for the peak separations greater than the theoretical separation, 43 mV at −50 °C.

A SCF MO calculation of the π-orbital energies of these substances was made by assuming that the angle between the molecular planes of naphthalene and benzene was 26° for I and 20° for II.[5] Thus the lowest π^*-orbital is two-fold degenerate and the next higher orbital differs from it by only 0.2 eV in II and 0.1 eV in I; a similar situation exists in tris(2,2′-bipyridine) complexes of transition metals[6] of D_{3d} molecular symmetry. If these orbitals are three-fold degenerate, the appearance of the voltammograms for the trinaphthylbenzenes would be very similar to that for tris(bipyridine) complexes. Comparison may better be made with the voltammogram of tris(4,7-diphenyl-1,10-phenanthroline)iron(II),[7] which exhibits two sets of three neighbouring reduction steps; these results lead to the supposition that the penta- and hexaanions of the trinaphthylbenzenes may be formed at potentials between −3.7 and −4 V *vs.* Ag/AgNO$_3$, though such highly negative potentials could not be realized.

The half-wave potentials of the first steps of tri-

The Measurement of the Solubility of Metallic Mercury in Hydrocarbons by Means of the Cold-vapor Atomic Absorption Method

Shoichi Okouchi* and Sokichi Sasaki

Chemical Laboratory, Faculty of Engineering, Hosei University, Kajino, Koganei, Tokyo 184

(Received April 24, 1980)

Synopsis. The metallic mercury solubility in hydrocarbons (pentane, hexane, heptane, and octane) was determined in the temperature range from 5 to 40 °C by the cold-vapor atomic absorption method. The results, for pentane at 25 °C, were found to agree well with Kuntz's result obtained by means of the ultraviolet absorption method, while those for hexane, heptane, and octane were found to agree well with Spencer's results, which were obtained using a radioactivetracer technique in the above temperature range. The liquid-liquid distribution constant for metallic mercury between the above hydrocarbons and water was measured at 25 °C, and in each case was found to be equal to the ratio of the independent solubility in the hydrocarbon and in water.

The solubility of metallic mercury in water has been studied by many researchers. Early measurements of the solubility of mercury were made by means of the amalgamation[1] or electrodeposition[2] of the dissolved mercury. More recently, the measurements have been made using the radioactive tracer Hg^{203},[3,4] atomic absorption spectrometry,[5,6] and neutron-activation analysis.[7] Mercury solubility in hydrocarbons was studied by Spencer[4] and by Kuntz.[8] Spencer determined the solubility of mercury in hexane, heptane, and octane using a radioactive technique in the temperature range from 0 to 40 °C. Kuntz determined the solubility of mercury in pentane at 25 °C by combining optical data with a known mercury-solubility value.

In this work the mercury solubility in the above hydrocarbons was determined by the cold-vapor atomic absorption method. The liquid-liquid distribution constant of metallic mercury between these hydrocarbons and water was also investigated.

Experimental

All the chemicals used were of an analytical reagent grade. The hydrocarbon solvents (pentane, hexane, heptane, and octane) were purified by passing them through activated alumina, and by distilling. The metallic mercury was purified in the usual manner.[5]

The solubility experiments were conducted by shaking each hydrocarbon solvent with a drop of metallic mercury in a constant-temperature water bath, controlled to within ±0.1 °C. It was found that the mercury concentration was constant after about 24 h of shaking and thereafter remained constant over a period of several days. A solution of 0.5 cm^3 equilibrated was analyzed by the cold-vapor atomic absorption method, consisting of tin(II) chloride reduction, nitrogen bubbling (at a flow rate of 1.5 $dm^3\ min^{-1}$), and passing through a magnesium-perchlorate tube for mercury-vapor drying. The mercury concentration was determined from the area under the atomic absorption peak at 253.7 nm. A calibration curve was constructed by analysing a series of standard solutions from 0.1 to 1.5 ng of mercury in 100 cm^3 of water with the addition of 0.5 cm^3 of hydrocarbon. No effects of the amount of hydrocarbon added in the range from 0.1 to 1.0 cm^3 and of the type of the hydrocarbon on the calibration curve were seen. Also, Fujii[9] has reported on the basis of the cold-vapor atomic absorption method, that these hydrocarbons have no effect on mercury analysis. Experiments were carried out in the temperature range from 5 to 40 °C.

Measurements of the liquid-liquid distribution constant of metallic mercury between the hydrocarbons and water were made by dissolving metallic mercury in the hydrocarbon solvents, shaking these solutions at 25 °C with distilled water containing 0.001 mol of phosphinic acid[3] in order to prevent mercury oxidation, and determining the mercury concentrations of both phases.

Results and Discussion

The temperature dependence of the mercury solubility in each hydrocarbon is shown in Fig. 1. The constants, A and B, that were found to satisfy Eq. 1 are shown in Table 1.

$$\text{Log } X = A \text{ Log } T + B, \qquad (1)$$

where X is the mole fraction of the solute and where T is the absolute temperature. The results for pentane at 25 °C were found to agree well with Kuntz's result,[8]

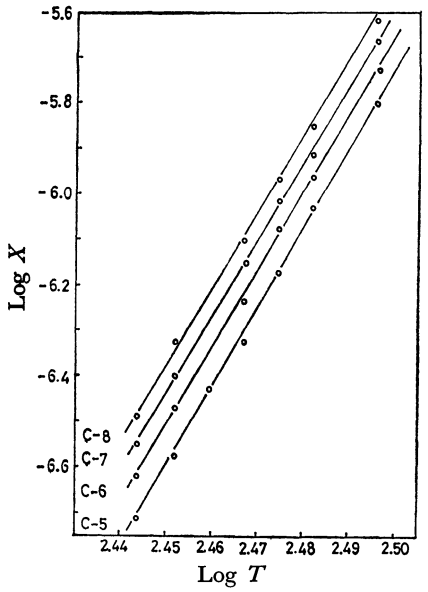

Fig. 1. Temperature dependence of the mercury solubility in hydrocarbons.
C-5: Pentane, C-6: hexane, C-7: heptane, C-8: octane.

Table 1. Constants of Eq. 1

Solvent	A	B
Pentane	17.375	−49.169
Hexane	17.111	−48.432
Heptane	17.250	−48.705
Octane	16.500	−46.800

which was obtained using the ultraviolet-absorption measurements at 256.0 nm, while for hexane, heptane, and octane the results agreed well with those of Spencer,[4] which were obtained using the radioactive tracer Hg^{203} in the temperature range from 5 to 40 °C. The mercury solubility in these hydrocarbons was estimated using the Hildebrand equation for regular solutions.[10] The agreement between the values calculated from the equation and the experimental measurements was a good approximation by an order of magnitude except in the case of water.

The liquid-liquid distribution constant for metallic mercury between each hydrocarbon and water is shown in Table 2. The distribution constant, K, is expressed by Eq. 2:

$$K = [Hg]_{aq}/[Hg]_{hc}, \quad (2)$$

where $[Hg]_{aq}$ and $[Hg]_{hc}$ are the mercury concentrations in the aqueous solution and in the hydrocarbon respectively. Table 2 shows the K values from this work in the first column and those from Moser's work[3] in the second column. The third column shows the values calculated from the ratio of the mercury solubility in the hydrocarbon and water at 25 °C. The mercury solubility in the water used was found to be $(3.0\pm0.1)\times10^{-7}$ mol dm^{-3} at 25 °C in this work, in good agreement with the results of Glew[5] and Enat.[6] The distribution constant was found to be equal to the ratio of the independent mercury solubility in the hydrocarbon and in water.

Table 2. Distribution constants, K, at 25 °C

	Measured	Reference[3]	Calculated

Catalysis by Alkaline Earth Metal Oxides. II. The Mechanism of Ethylene Hydrogenation on Magnesium Oxides

Makoto TEZUKA, Yasunobu INOUE,* and Iwao YASUMORI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 4, 1980)

Synopsis. The kinetic study of ethylene hydrogenation on a thermally activated MgO was carried out. The slow step of the reaction changed from the irreversible addition of a hydrogen atom to adsorbed ethylene in the lower temperature range(373—423 K) to the hydrogenation of an ethyl radical in the higher temperature range (523—673 K).

In a previous paper, we reported the mechanism of ethylene hydrogenation on a thermally activated CaO.[1] The maximum in the reaction rate appeared around a reaction temperature of 340 K. Above this temperature, the kinetic behavior of the reaction resembled those on such transition metals as Ni, Fe, and Pd, whereas, below the temperature, they were rather similar to those on oxides, *e.g.*, ZnO[2] and Cr_2O_3.[3]

Tanabe and his co-workers[4] found that a pretreatment of MgO *in vacuo* at temperatures higher than 1200 K generated the catalytic activity for the hydrogenation of olefins and dienes. In order to establish catalysis by alkaline earth metal oxides, it would be constructive to extend the research into ethylene hydrogenation to other alkaline earth metal oxides. Thus, we undertook the present study to see whether or not the kinetic features described above exist on MgO and then to compare them with the previous results for CaO.

Experimental

Magnesium oxide catalysts were prepared by decomposing $Mg(OH)_2$ of an extra pure grade *in vacuo*. The DTA spectra of $Mg(OH)_2$ showed an endothermic peak in the temperature range of 590—720 K, which was due to H_2O evolution upon the structural rearrangement from trigonal to cubic; this indicated the development of the crystallite structure of MgO by treatment above this temperature range. The oxide thus obtained was subjected to evacuation at 1273 K for 2 h at a pressure lower than 2×10^{-6} Torr (1 Torr=133.3 Pa). Emission spectral analysis showed that the oxide contained Cu (<0.5 ppm), Fe(<0.1), Mn(<10), Si(<80), and Ca(<0.5). The surface area of MgO after the treatment was 118 $m^2\ g^{-1}$. The apparatus, procedure, and reactant gases used were the same as those reported previously.[1] Ethane was the sole product under the present experimental conditions. The repetition of kinetic runs at 523 K decreased the catalytic activity to less than 50% of the initial value, but subsequent evacuation at 1273 K for 2 h recovered the deactivated activity to the original level.

Results and Discussion

As is shown in Fig. 1, the Arrhenius plot of the rate of ethylene hydrogenation on MgO gave rise to a maximum at around 490 K, and the activation energy, E_a, was determined to be 28.5 kJ mol^{-1} in the lower temperature range (373—423 K) and −36.8 kJ mol^{-1} in the higher temperature range (523—673 K). The reaction orders with respect to the pressure of hydrogen, P_h, and ethylene, P_e, were both 1.0 at 623 K, whereas the latter value decreased to nearly zero at 393 K. These variations were similar to those for the same reaction on CaO,[1] but the hydrogen order, 1.0, in the lower temperature range was different from 0.7. Table 1 shows the deuterium distributions in the reaction of ethylene with D_2. At 623 K and in conversions of 28 to 42%, there existed highly-exchanged ethylene ranging from $[D_1]$ to $[D_4]$, and the gaseous composition of H_2, HD, and D_2 nearly reached equilibrium. Ethane contained species from $[D_0]$ to $[D_4]$; the fraction

P_D=20 Torr, P_e=10 Torr.

of ethane [D_2] amounted to about 65%. On the other hand, at 393 K and in similar conversions, small amounts of the deuterium-exchanged ethylene and HD were produced in the gas phase, whereas the fraction of ethane [D_2] was as high as 85%. No isotopic-exchange reaction between ethane and D_2 occurred up to 623 K.

The wide deuterium distributions in the higher temperature range indicated that the hydrogenation proceeds *via* the pathway described by the associative mechanism and that the reaction between the hydrogen atom and the ethyl radical was the rate-determining step, as has been proposed in the case of CaO.[1] Thus, we are able to employ the rate equation obtained before:

$$V_e^h = k_4 K_h K_3 K_e P_h P_e = k^h P_h P_e, \quad (1)$$

where k_4 is the rate constant of the reaction in the rate-determining step. K_e and K_h are the equilibrium constants for the adsorption of ethylene and hydrogen respectively, while K_3 is the equilibrium constant for the surface reaction between the hydrogen atom and the adsorbed ethylene to form the ethyl radical and its reverse reaction. Equation 1 is in agreement with the experimental rate equation.

The drastic fall in the catalytic activity during the course of a reaction at a higher temperature is probably due to the formation of strongly bound surface ethylene species, since the pre-exposure of a fresh catalyst to 10 Torr of ethylene at 523 K caused a decrease in the activity to as low as 15%. The species appears to remain after evacuation at the reaction temperature, but to be removed by evacuation at 1273 K. An analogous poisoning species, presumably polymerized ethylene, was observed in the ethylene hydrogenation on ZnO at 383—673 K.[5]

The reaction in the lower-temperature range provided very small amounts of the deuterium-exchanged ethylene and HD (with scarcely any H_2) in the gas phase, and resulted in the selective formation of ethane-[D_2](≈85%). These findings indicate that the irreversible addition of a hydrogen atom to adsorbed ethylene is a slow step compared to the other steps. When one assumes that the hydrogen atoms adsorbed in a randomly-mixed state participate in the hydrogenation, the reaction order in P_h fails to become larger than 0.5; this contradicts the observed value, 1.0. However, the assumption that the reactive surface hydrogen is a pair of hydrogen atoms on an isolated site leads to the following rate equation:[1]

$$V_e^1 = \frac{k^1 K_e K_h P_h P_e}{(1+K_e P_e + K_h P_h)^2}, \quad (2)$$

where k^1 is the rate constant of the reaction between the hydrogen and adsorbed ethylene. This equation was transformed into the equations having a linear relationship between the $\sqrt{P_e/V_e^1}$ term and P_e or between the $\sqrt{P_h/V_e^1}$ term and P_h in the same way as has been described previously.[1] Figure 2 demonstrates the linearity in their relationships, which gives evidence for the validity of Eq. 2 and, hence, the mechanism proposed. The reaction of 1,3-butadiene with D_2 on MgO was proposed to proceed *via* the attack of a heterolytically split hydrogen atom on the adsorbed butadiene on the isolated sites;[6] this gives support to the assumption employed in deriving Eq. 2. The slightly higher kinetic order in P_h for the ethylene hydorgenation on MgO than for that on CaO suggested the weaker adsorption of hydrogen, in comparison with the ethylene adsorption, on the former oxide.

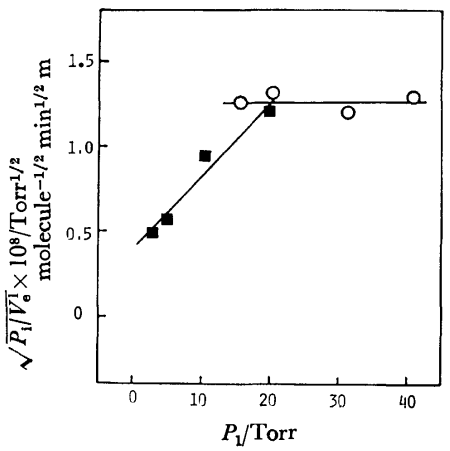

Fig. 2. Plots of $\sqrt{P_1/V_e^1}$ *vs.* P_1.
Reaction temp=393 K, ○: $P_1=P_h$(P_e=10 Torr), ■: $P_1=P_e$(P_h=20 Torr).

There existed a general similarity in the reaction behavior of the ethylene hydrogenation on MgO and CaO; it appears to arise from the common nature of these oxide surfaces. A study of the surface state of thermally-treated alkaline earth metal oxides is in progress using X-ray photoelectron spectroscopy.

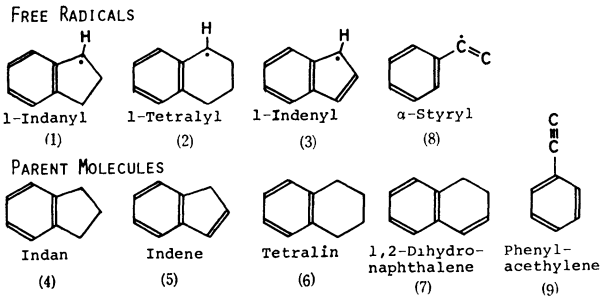
Electronic Spectra of Some Aromatic Free Radicals

Tatsuo IZUMIDA, Kunihiko INOUE, Shoji NODA,* and Hiroshi YOSHIDA
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received December 22, 1980)

Synopsis. Electronic spectra are reported for 1-indanyl, 1-tetralyl, and 1-indenyl radicals generated photolytically or radiolytically in rigid matrices; the former two radicals show spectral features similar to those of benzyl radical, whereas the latter radical has a different spectrum because of its non-alternant π electron system.

Aromatic hydrocarbon radicals have been attracting interest as possible intermediates in such reactions as radiolysis of aromatic hydrocarbons,[1] soot formation from combustion,[2] and coal liquefaction.[3] However, there have been very few reports on the observation of the fluorescence spectra of the aromatic free radicals, except for benzyl radical and its methylsubstituted derivatives.[4] We report here for the first time the electronic spectra of 1-indanyl (**1**), 1-tetralyl (1,2,3,4-tetrahydro-1-naphtyl, **2**), and 1-indenyl (**3**) radicals generated photolytically or radiolytically from indan (**4**), indene (**5**), tetralin (1,2,3,4-tetrahydronaphthalene, **6**), and 1,2-dihydronaphthalene (**7**). The electronic spectra will be discussed for α-styryl radical (**8**) generated from phenylacetylene (**9**) also.



Experimental

4, **5**, **6**, and **9** were vacuum-distilled before use. **7** from Tokyo Kasei Co. (GR grade) and spectrograde ethanol (EtOH) were used as received. 3-Methylhexane (3MHx) was purified as described elsewhere.[5] Solutions of the parent aromatic compounds (about 10 mmol·dm^{-3}) in EtOH or 3MHx were thoroughly degassed by freeze-pump-thaw cycles and sealed in quartz sample tubes (0.4 cm diameter) for optical emission and ESR measurements and in a quartz flat cell (optical path-length of 0.2 cm) for optical absorption measurements. The sample solutions were irradiated at 77 K either with γ-rays from a ^{60}Co source to a dose of 2×10^5 rad or with UV light from a high pressure mercury lamp. Optical emission and excitation spectra of the irradiated samples were recorded with a Hitachi MPF-2A fluorescence spectrophotometer at 77 K. Occasionally, optical absorption and ESR spectra were examined with a Shimadzu MPS-5000 spectrophotometer and a Varian E-109 ESR spectrometer.

Results and Discussion

1-Indanyl and 1-Tetralyl Radicals. The UV-irradiation of **4** and **6** in nonpolar 3MHx matrix gave the emission and excitation spectra shown in Figs. 1A and B. The spectra comprise three excitation bands in visible wavelength region (400—490 nm), near-UV region (300—350 nm), and far-UV region (250—300 nm). The visible excitation band is a mirror image with the emission band. The spectra are attributed to 1-indanyl (**1**) or 1-tetralyl (**2**) radical generated by the photoinduced C–H bond scission in the corresponding parent molecule.

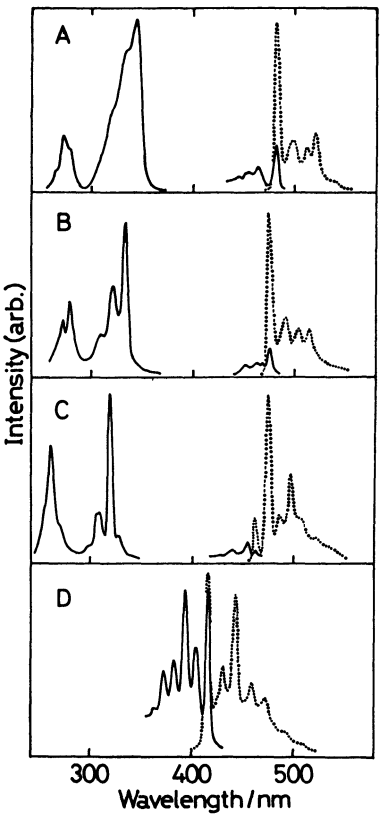


Fig. 1. Emission (·····) and excitation (——) spectra of 1-indanyl (A), 1-tetralyl (B), benzyl (C) and 1-indenyl (D) radicals in 3MHx matrix at 77 K.

When **5** or **7** was γ-irradiated in a polar protic matrix of EtOH, the spectra were essentially the same as Figs. 1A or B. The previous study on the proton transfer to styrene anion gave similar results.[6] These spectra are attributed to **1** or **2**, which result from the electron capture of **5** or **7** followed by the proton transfer from matrix EtOH. The formation of the molecular anions of **5** and **7** was proven by the observation of their absorption spectra which were obtained by γ-irradiating the polar aprotic matrices of 2-methyltetrahydrofuran (MTHF) with **5** and **7**. The absorption spectra of the molecular anions consist of two broad peaks (λ_{max} of 400 and 710 nm for **5**, and 400 and 600 nm for **7**), which are readily bleached with light from an incandescent lamp.

The emission and excitation spectra of benzyl radical generated by UV-irradiation of toluene in the 3MHx matrix are shown for comparison in Fig. 1C. Three excitation bands in the visible, near-UV, and far-UV regions have been assigned to the transitions to $^2A_2$, $^2A_2$, and $^2B_2$ excited states from the $^2B_2$ ground state in the π electron system with C_{2v} symmetry.[7] Both the **1** and **2** radicals, which have the same π electron system, show similar features of the electronic spectra, though a red-shift of the spectra and the removal of the forbidden character of the lowest $^2B_2$—$^2B_2$ transition[8] (comparatively intense 0-0 vibration bands in the visible emission and excitation bands) possibly results from a deviation of the symmetry from C_{2v}. The larger shift observed for **1** may be due to a more constrained structure due to its five-membered ring.

1-Indenyl Radical. The UV-irradiation of **5** in the 3MHx matrix gave two set of emission and excitation spectra generally overlapping each other. The one set was apparently due to **1** mentioned above. The other set could be separated, as shown in Fig. 1D, from the spectra due to **1** by choosing proper wavelengths for excitation and observation. The ESR signal of the same irradiated sample showed a three-line spectrum with a hyperfine separation of 1.2 mT superimposed on a broad spectrum due to 3-methylhexyl radicals and probably due to **1**. The three-line spectrum is assigned to 1-indenyl (**3**) radical on the basis of the hyperfine coupling constants reported by Livingston *et al.*[9] This ESR spectrum and the spectra shown in Fig. 1D slowly disappeared at 77 K, while the emission and excitation spectra of **1** remained unchanged.

The above observations lead to the assignment that the spectra of Fig. 1D is due to **3**. The band origin lies at 415 nm, appreciably shorter than that for benzyl, **1**, and **2** radicals. **3** has a non-alternant π electron system, and it has been suggested that the transition energy to the first excited state is larger.[10] The excited **5** undergoes both the scission of C–H bond giving **3** and the abstraction of H giving **1**; it is not known whether the precursor states for these reactions are the same or not.

α-Styryl Radical. The γ-irradiation of **9** in the MTHF matrix gave the absorption spectrum with maxima at 370 and 533 nm due to the molecular anion of **9**. The irradiation in the EtOH matrix gave the absorption spectrum comprising a visible band with the band origin at 480 nm and a near-UV band with the maximum at 320 nm (no far-UV band could be observed, because of the intense overlapping absorption of the parent molecule). The same near-UV band has been reported previously by Shida and Hamill.[11] This absorption spectrum is very probably due to α-styryl (**8**) radical, because it indicates a π electron system similar to that of benzyl radical.[12] **8** can be generated by the proton transfer to the molecular anion of **9** in the EtOH matrix.

The emission and excitation spectra of **8** were difficult to detect: a weak emission from the irradiated EtOH matrix with **9** was mostly due to α-methylbenzyl radical,[13] probably from impurity styrene contained in **9**. It is unknown why the fluorescence efficiency of **8** is very low compared to that of benzyl radicals, in spite of the fact that both radicals have a similar π electron system. In contrast to the present result, Brocklehurst *et al.* have observed an intense green thermoluminescence spectrum with the band origin at 474 nm upon melting the methylcyclohexane–isopentane mixed solvent containing **9** after γ-irradiating it at 77 K; they have tentatively assigned this luminescence spectrum to **8**.[14]

X-Ray Photoelectron Spectroscopic Studies of SbSI

Isao IKEMOTO

Research Center for Spectrochemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received January 21, 1981)

Synopsis. The binding energies of the core electron peaks suggest that SbSI has more ionic character than covalent character. The valence band spectrum was compared with the calculated density of states. XPS spectra of low temperature ferroelectric phase could not be obtained due to the inhomogeneous spontaneous polarization.

SbSI is the first substance which has been found to be ferroelectrics[1] with semiconductive and photoconductive properties.[2,3] It has a Curie point at 22 °C where it shows first-order phase transition between the high temperature paraelectric phase and the low temperature ferroelectric phase. The crystal structures of the both phases have been analyzed and it has been found that the atomic arrangement is nearly consistent with an ionic model of $Sb^{3+}S^{2-}I^{-}$.[4] However rather short distances among electronegative ions such as sulfurs and iodines suggest that there are tendencies of covalent bond formation.[4] The electronic band structures of SbSI have been calculated using CNDO approximation[5,6] and pseudo-potential method[7] for the ionic and/or covalent models. However more experiments are necessary for more precise calculations.

We measured X-ray photoelectron (XPS) spectra of SbSI and deduced bonding system in SbSI using the binding energies of the core electron peaks. We also compared the XPS valence band with the calculated density of states.[7]

Experimental

X-Ray photoelectron spectra were recorded with a McPherson ESCA 36 Electron Spectrometer, employing Al $K\alpha$ radiation (1486.6 eV). SbSI was kindly supplied by Professor Hideaki Chihara of Osaka University. Samples were single crystals, needle-like along the c axis, but they are not large enough for the measurement. Powdered samples were directly mounted onto Al or Pb plates. Binding energies of photoelectron peaks were calibrated by using the Au $4f_{7/2}$ peak (84.0 eV) of a thin gold film deposited on the sample surface. For the measurement of low temperature ferroelectric phase, samples were cooled with a Dry Ice–ethanol mixture or ice–water mixture.

Results and Discussion

High Temperature Paraelectric Phase. The binding energies of the various core electron peaks are shown in Table 1 with those of related compounds.

The binding energies of iodine peaks in SbSI agree with the corresponding binding energies of iodine peaks in KI. The binding energies of Sb peaks in SbSI are almost same with those of Sb peaks in Sb_2S_3. The binding energy of S peak in SbSI is 1.8 eV smaller than that of S peak in sulfur, and comparing it with the data by Siegbahn *et al.*[8] the state of S in SbSI seems to be S^{2-}. These results show that SbSI has more ionic character than covalent character.

The XPS valence band spectrum of SbSI is shown in Fig. 1 with the density of states obtained by band structure calculation using pseudopotential method.[7] In the calculated density of states, the valence bands separated into five groups and these are interpreted as

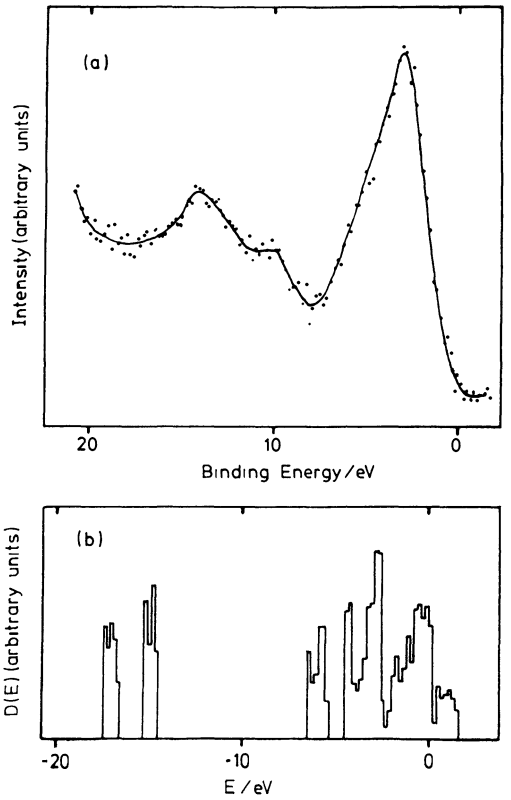

Fig. 1. (a) XPS valence band spectra of SbSI. (b) Calculated density of states of the energy bands of SbSI in the paraelectric phase.[7]

Table 1. Binding energies/eV of SbSI and related compounds

	SbSI	KI	Thiourea	Sulfur	Sb_2S_3[a]	Sb_2S_5[a]
I $3d_{3/2}$	630.3	630.4				
I $3d_{5/2}$	618.8	618.9				
Sb $3d_{3/2}$	538.9				539.0	538.7
Sb $3d_{5/2}$	529.5				529.7	529.4
S 2p	161.2		162.0	163.0		

a) Data from Ref. 9.

the 5s-like bands of I atoms, the 3s-like bands of S atoms, the 5s-like bands of Sb atoms, the 5p-like bands of I atoms, and the 3p-like bands of S atoms as the energy increases. In the XPS spectrum of the valence band region, there are two main bands. On the higher binding energy band, there is a shoulder on the lower binding energy side. The overall shape corresponds well to the calculated density of states, but in the latter the distribution of the density of states is rather broader and the separation between two main bands is also larger than the observed one. Calculated intensities of the bands are rather different from the observed ones, but the difference of the cross section of various levels in XPS must be considered. SbSI has very complicated structure. Therefore, the calculated density of states seems to correspond to the observed XPS valence band rather well.

Low Temperature Ferroelectric Phase. XPS spectra of the ferroelectric phase show very anomalous behavior. When the samples were cooled through the Curie point, each core electron peak showed large shift, sometimes split into two or three peaks or gave a very broad peak. This behavior is similar to that due to large and inhomogeneous charging effect and the reproducible spectra could not be obtained. However when the samples were heated through the Curie point, the normal reproducible spectra of the paraelectric phase could be obtained. Several experiments under various conditions suggested that these behaviors could be explained by the spontaneous polarization which was characteristic of the ferroelectricity. Since samples are powder, the spontaneous polarization is not homogeneous throughout sample surface, then the spectra show the same behavior as that due to the charging effect. Anyway these anomalous behaviors of the XPS spectra are due to the ferroelectric property of SbSI and single crystals must be used to get the true spectra.

The author wishes to express his thanks to Professor Haruo Kuroda, the University of Tokyo for his helpful discussions and Professor Hideaki Chihara for kindly supplying the samples.

Highly Active Aluminas for Isomerization of 1-Butene and Hydrogen Exchanges between Ethylene or Cyclopropane and Deuterium

Masahiro UTIYAMA, Hideshi HATTORI, and Kozo TANABE*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 25, 1981)

Synopsis. Among eleven kinds of aluminas, alumina V prepared from aluminium sulfate with urea exhibited a pronounced activity for the isomerization of 1-butene, while alumina III or II prepared from aluminium nitrate with ammonia or urea showed the highest activities for the exchange reactions between ethylene or cyclopropane and deuterium, respectively.

Alumina is one of the most interesting and useful oxide catalysts for hydrocarbon reactions. The exchange reaction of deuterium between CH_4 and D_2 is known to take place easily over alumina even at room temperature,[1,2] but not over the other oxides such as MgO, CaO, SrO, BaO, La_2O_3, CeO_2, Pr_2O_3, Tb_2O_3, TiO_2, ZnO, and WO_3 below 300 °C of reaction temperature,[3] indicating an anomalously high catalytic activity of alumina compared with the other oxides. However, the catalytic properties of various aluminas for the exchange reaction have been found to change remarkably depending on the preparation method.[4] In order to examine how the activity of alumina is affected by the preparation method and to know what kinds of aluminas are best for particular hydrocarbon reactions, eleven kinds alumina catalysts were prepared by different methods and subjected to the activity test.

Experimental

Various aluminas were prepared from various aluminium compounds by different methods as shown in Table 1. In the case of hydrolysis with ammonia or urea, the final pH was adjusted to 7—8. Precipitation with urea was carried out at ≈90 °C, precipitates of hydroxides being formed gradually in 4 h. Details of precipitation with urea were described previously.[5] The hydroxides of Al_2O_3 V and VI were washed with distilled water until sulfate ions were not detected with barium chloride in the washings. The hydroxide of Al_2O_3 XI was washed with 30 L of distilled water. The hydroxide of Al_2O_3 VII, VIII, and X were washed with 6 L of distilled water. In the latter case, halogen ions remained in the washings. The hydroxides were dried at 120 °C for 20 h and calcined in air at 550 °C. The aluminas which were evacuated at 600 °C for 3 h were used as catalysts. Surface area was determined by applying the BET method to the adsorption isotherm of nitrogen at −196 °C. The structure of aluminas was determined from the powder patterns obtained with a Rigaku Denki Giger flex X-ray diffractometer using filtered Cu K_α radiation.

The exchange reactions between ethylene or cyclopropane and deuterium were carried out at room temperature in a closed recirculation reactor that had a total volume of *ca.* 400 ml. A mixture of 5 Torr of each hydrocarbon and 40 Torr (1 Torr = 133.322 Pa) of D_2 was used. The reaction products were analyzed by a mass spectrometer (Hitachi M-52 type), parent peaks of $m/e=28$—32 and $m/e=42$—48 being used for deuterated ethylene and cyclopropane, respectively. The catalytic activity was expressed by K_ϕ % per unit surface area of catalyst in thefollowing equation.[3]

$$d\phi/dt = K_\phi(\phi_\infty - \phi)/\phi_\infty WS,$$

where ϕ represents the average number of D atoms in 100 molecules of each hydrocarbon in time t, ϕ_∞ for $t=\infty$, W the weight of catalyst, and S specific surface area.

Isomerization of 1-butene was carried out at room temperature in the same reactor as above with 70 Torr of 1-butene. For analysis of the butenes, a 5-m column packed with VZ-7 and thermostated at 0 °C was used. Initial rates of the formation of 2-butenes were taken as the catalytic activity.

Results

Catalytic activities of various aluminas are shown in Table 2, where the activity for the exchange of methane with deuterium was cited from the literature.[4] Al_2O_3 VII which showed the highest activity for the exchange reaction of methane with deuterium did not show high activities for the exchange reaction between ethylene or cyclopropane and D_2 and was almost inactive for the

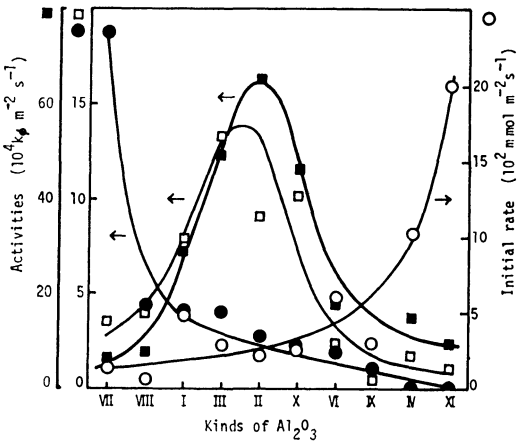

Fig. 1. Activities of various kinds of Al_2O_3 for hydrocarbon reactions. ●; CH_4–D_2, □; C_2H_4–D_2, ■; C_3H_6–D_2, ○; isomerization of 1-butene (Kinds of Al_2O_3 were arranged in decreasing order of the activity for the exchange reaction of CH_4 with D_2).

isomerization of 1-butene. The aluminas which showed the highest activities for the exchange of D_2 with ethylene or cyclopropane and the isomerization of 1-butene were Al_2O_3 III, Al_2O_3 II, and Al_2O_3 V, respectively. Al_2O_3 V exhibited a pronounced activity for the isomerization, but was completely inactive for the exchange reactions. In the case of Al_2O_3 V, the ratio of *cis*-2-butene to *trans*-2-butene is very low (0.8) compared with that of other aluminas. This suggests that the acid sites play an important role for the isomerization of 1-butene.[6] For the exchange reaction of methane with deuterium, the proton abstraction from methane by basic sites is reported to be important.[3,7] However, the activity per unit basic sites of alkaline earth oxides whose basic strength is higher than that of alumina is much lower than that of alumina.[3] The *cis*/*trans* ratio which is sometimes used as an indication of basic property of catalyst[8,9] does not correlate with the exchange activity. Thus, besides basic sites, acidic sites are considered to be important as active sites for exchange reaction to stabilize carbanion intermediates formed by proton abstraction. In the present work, we demonstrate highly active aluminas for the exchange and isomerization reactions and emphasize that the activity of alumina is remarkably controlled by the preparation method.

In order to characterize the activities of various aluminas, the activities for four hydrocarbon reactions were plotted against the eleven kinds of alumina which are arranged in the order of activity for the exchange between methane and deuterium in Fig. 1. The higher the activity for the exchange of methane with deuterium, the lower the activity for the isomerization of 1-butene. On the other hand, the aluminas which are less active for the above two reactions showed the maximum activities for the exchange reaction between ethylene or cyclopropane and deuterium.

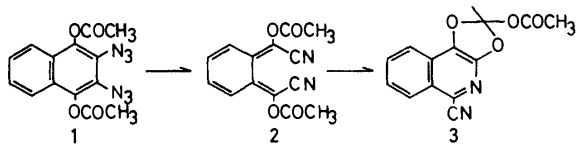
(Received November 19, 1980)

Synopsis. The crystal of the title compound is triclinic, with a space group of $P\bar{1}$ and with two molecules per unit cell with dimensions of $a=8.317$ (2), $b=11.191$ (1), $c=7.731$ (1)Å, $\alpha=105.91$ (1), $\beta=103.76$ (2), and $\gamma=102.60$ (1)°. The fused isoquinoline and dioxolane rings lie on nearly the same plane; the non-hydrogen atoms of the acetoxyl and methyl groups make another plane. These two planes make an angle of 92.0° with each other.

In a series of photolyses of organic azides, it has been reported that 1,4-diacetoxy-2,3-diazidonaphthalene (**1**) gave efficiently an unexpected photoproduct (**3**) *via* α,α′-dicyano-*o*-quinodimethan (**2**) by prolonged photo-irradiation at 77 K in a rigid medium.[1] The structure



1 2 3

of the product was studied spectroscopically, but could not be established exclusively. The compound, obtained in the form of single crystals, was then submitted to X-ray analysis.

Experimental

Single crystals of the compound were grown by the slow evaporation of an ethanol–dichloromethane solution at room temperature. They were yellow plates tabular on (100), elongated in the *c* direction. The lattice constants were obtained by a least-squares fit of 2θ values of 15 reflections measured on a Rigaku automated four-circle diffractometer.

Crystal Data. $C_{14}H_{10}H_2O_4$, MW=270.24, Mp=146 °C (dec), triclinic, $P\bar{1}$, $a=8.137$ (2), $b=11.191$ (1), $c=7.731$ (1)Å, $\alpha=105.91$ (1), $\beta=103.76$ (2), $\gamma=102.60$ (1)°, $V=640.5$ Å^3, $Z=2$, $d_{obsd}=1.41$, $d_{calcd}=1.402$ g cm^{-3}, μ (for Cu $K\alpha$)=8.95 cm^{-1}.

The intensity data were collected from a crystal having dimensions of $0.3\times0.4\times0.3$ mm. The intensities were recorded in the 2θ-ω scan mode with a speed of 10° (ω) min^{-1} and the range of $(1.0+0.142\tan\theta)$° (ω), graphite-monochromated Cu $K\alpha$ radiation being used. 2270 independent reflections with $2\theta\leq135$° were obtained, of which 2208 were non-zero reflections. The intensities of three reference reflections, periodically remeasured, decreased gradually during data collection. The intensity data were corrected for crystal deterioration and for Lorentz and polarization effects, but no absorption correction was applied.

Structure Determination and Refinement

The structure was solved by the direct method with the MULTAN 78 program,[2] refined by the block-diadonal least-squares procedure with the HBLS V program.[3] In the refinement, the function minimized was $\sum\omega(|F_o|-|F_c|)^2$ with the weight scheme of $\omega=k$ for $F_o=0$, and $\omega=(\sigma^2(F_o)+a|F_o|+b|F_o|^2)^{-1}$ for $F_o\neq0$, where $\sigma(F_o)$ is the standard deviation based on the counting statistics. The final refinement ($k=7.28$, $a=-0.666$, and $b=0.025$) led to the *R*-index ($\sum||F_o|-|F_c||/\sum|F_o|$) of 0.0624 for all the reflections and 0.0610 for the non-zero reflections. The scattering factors were taken from the International Tables for X-Ray Crystallography.[4] The final atomic parameters for the non-hydrogen atoms are given in Table 1.[5]

a) The equivalent isotropic temperature factor defined by W. C. Hamilton (*Acta Crystallogr.*, **12**, 609 (1959)).

Results and Discussion

The bond lengths and angles are shown in Fig. 1, together with the atomic symbols.

All the atoms of the fused heterocyclic ring lie on the same plane; the average deviation of the thirteen ring atoms from the plane is 0.008 Å, with the maximum deviation of 0.017 Å for C(8). The C(11) and N(2) atoms of the cyano group deviate from this plane by 0.069 and 0.118 Å respectively. The non-hydrogen atoms of the acetoxyl and methyl groups bonded to the dioxolane ring also make a plane; the average displace-

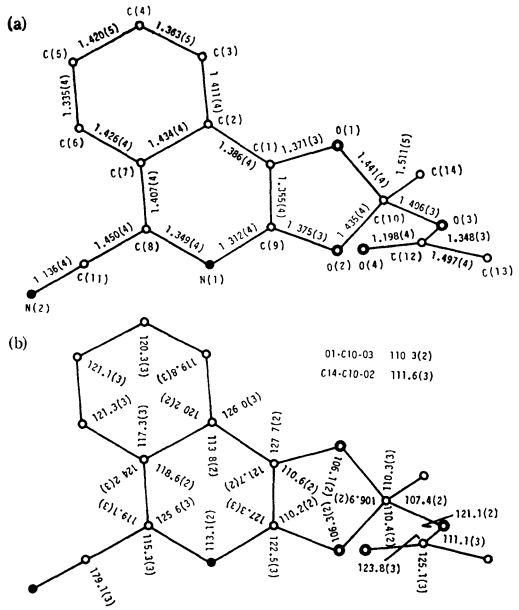

Fig. 1. a) Bond lengths (l/Å) and b) bond angles (ϕ/°) of the compound.

ment of the atoms from the mean plane is 0.030 Å, with the maximum deviation of 0.059 Å for C(13). These two mean planes make an angle of 92.0° with each other.

All the bond lengths and angles are normal. The O(1)–C(10) and O(2)–C(10) bond lengths in the dioxolane ring are in good agreement with the accepted value for the C–O single bond[6] and can well be compared with the corresponding values for the isolated dioxolane ring in 4′-methylsulfonylspiro[1,3-dioxolane-2,4′-piperidine].[7] The somewhat short O(1)–C(1) and O(2)–C(9) lengths can be explained partly in terms of the conjugation of the dioxolane oxygen atoms with the isoquinoline nucleus.

The arrangement of the molecules in the crystals is shown in Fig. 2. The fused heterocyclic rings, approximately parallel to (001), are stacked at intervals of

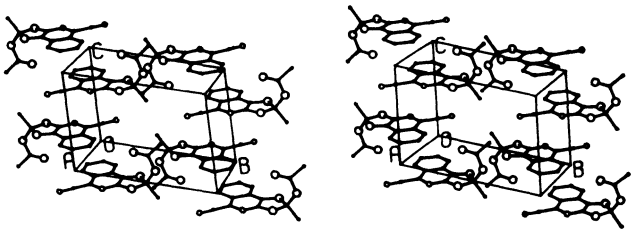

Fig. 2. The arrangement of the molecules in the crystal drawn by the plotter program PLUTO.[8]

3.5 Å along the c axis. The cyano groups of the two molecules around a center of symmetry are antiparallel to each other, leading to favourable dipole-dipole interaction. There are no abnormally short intermolecular contacts.

On the Additivity of Molar Volume and Refractivity of Molten $Ca(NO_3)_2 \cdot 3.18H_2O$–KSCN System

Sheik Mahiuddin and Kochi Ismail*

Department of Chemistry, North-Eastern Hill University, Laitumkhrah, Shillong-793 003, India

(Received May 17, 1980)

Synopsis. Densities and refractive indices of $Ca(NO_3)_2 \cdot 3.18H_2O$–KSCN melts have been measured as functions of temperature and composition. Densities, molar volumes, and refractive indices show linear dependence on temperature. Molar volume, intrinsic volume, molar refractivity, and the product of refractive index and molar volume show additivity within ±2% error. The molten $Ca(NO_3)_2 \cdot 3.18H_2O$–KSCN system at ambient temperatures appears to behave like an ideal mixture of molten $Ca(NO_3)_2 \cdot 3.18H_2O$ and supercooled KSCN melt.

Earlier, we have reported the densities, viscosities, and equivalent conductances of molten $Ca(NO_3)_2 \cdot 3.99H_2O$–KSCN systems.[1] In that paper,[1] although we have mentioned about an interesting feature of this system, *i. e.*, its ideal behavior with respect to molar volume, our major emphasis was on the non-Arrhenius temperature dependence of viscosities and equivalent conductances. In order to understand more about the ideal behavior of such a binary system we have reported here the densities and refractive indices of molten $Ca(NO_3)_2 \cdot 3.18H_2O$–KSCN systems as functions of temperature and composition.

Experimental

Reagent grade calcium nitrate tetrahydrate, mp 43.5 °C, was used in the molten state. The exact number of moles of water per mole of calcium nitrate has been determined through EDTA titration method and is found to be 3.18. Potassium thiocyanate was recrystallized twice from double-distilled water. Preparation of samples of $Ca(NO_3)_2 \cdot 3.18H_2O$–KSCN and their density measurements were made as described earlier.[1] The refractive index (±0.1%) measurements were made corresponding to sodium light using the Abbe refractometer.

Results and Discussion

The molar volumes (V) of $Ca(NO_3)_2 \cdot 3.18H_2O$–KSCN melts are calculated from their measured densities and are represented in Table 1 in the form of a linear function

$$V = V_o' + b'T, \tag{1}$$

where V_o' and b' are constants at a particular concentration. As the system under study has an inherent tendency to supercool the temperature dependence of molar volume may also be represented as

$$V = V_o + b'(T - T_o), \tag{2}$$

where T_o is the ideal glass transition temperature and V_o is the intrinsic volume. Comparison of Eqs. 1 and 2 gives that

$$V_o' = V_o - b'T_o. \tag{3}$$

From Fig. 1a it may be noticed that both V_o' and b' vary linearly with mole fraction of KSCN, x_2. Presuming that V_o and T_o vary linearly with concentration,[1] Eq. 3 becomes on substituting the linear concentration dependences of all the terms

$$m_1 = m_2 - m_3T_{o1} + b_1'm_4 - m_3m_4x_2, \tag{4}$$

where m_1, m_2, m_3, and m_4 are the respective slopes of linear variations of V_o', V_o, b', and T_o with x_2. T_{o1} and b_1' are the values of T_o and b', respectively for pure $Ca(NO_3)_2 \cdot 3.18H_2O$ melt. From Eq. 4 it may be understood that the observed constancy of m_1 appears to be explainable only when T_o becomes almost independent of solute concentration. In such

Parameters for Eq. 6 (k_1 and k_2) are within the parantheses. a) $\sigma_1 = [\Sigma(V_{obsd} - V_{calcd})^2/N]^{1/2}$ and $\sigma_2 = \Sigma(n_{obsd} - n_{calcd})^2/N]^{1/2}$, N is the number of the data points. b) Intrinsic volume, $V_0 = V_o' + 206b'$. c) Data from Refs. 6 and 7.

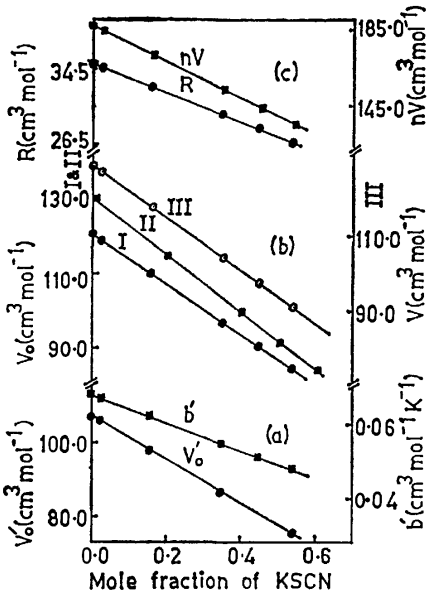

Fig. 1. Variations of (a) V_o' and b', (b) V_o (I-present work; II-Ref 1) and V (at 323 K), and (c) molar refractivity (R) and nV (at 323 K) with concentration for molten $Ca(NO_3)_2 \cdot 3.18H_2O$–KSCN systems.

a case $m_4 \approx 0$ and Eq. 4 reduces to

$$m_1 = m_2 - m_3 T_{o1}. \quad (5)$$

With the knowledge of the reported[1-3] values of T_o for calcium nitrate tetrahydrate, the T_o value for $Ca(NO_3)_2 \cdot 3.18H_2O$ may be considered as nearly equal to 206 K. Substituting this value for T_{o1} and also the values of $m_1 = 59.1$ cm^3 mol^{-1} and $m_3 = 0.037$ cm^3 mol^{-1} K^{-1} obtained from Fig. 1a in Eq. 5, the value of m_2 may be determined which is found to be 66.7 cm^3 mol^{-1}. This value of m_2 is also in agreement with the observed value of the slope of the plot of V_o versus concentration (Fig. 1b), the value of V_o (Table 1) being obtained from Eq. 3 after keeping T_o as 206 K. It is worthy to note that the present extrapolated value of $V_o = 54.0$ cm^3 mol^{-1} for pure KSCN coincides with the value obtained in a similar manner using computed values of V_o from the transport property data of $Ca(NO_3)_2 \cdot 3.99H_2O$–KSCN melts[1] (Fig. 1b). Such an agreement in the V_o value of pure KSCN estimated independently from the molar volume and transport property data appears to envisage that the assumption made regarding the concentration independent nature of T_o is justifiable. Accordingly, the T_o value of pure KSCN may be considered as nearly the same as that of $Ca(NO_3)_2 \cdot 3.18H_2O$ which we have taken as 206 K. This value is closely comparable with the value 203 K for T_o of KSCN computed from its electrical conductance data.[4] Moreover, it has been found that the concentration dependence of V_o predominantly governs the variation of V with x_2 for the $Ca(NO_3)_2 \cdot 3.18H_2O$–KSCN melts. As reported earlier[1] V is found to be additive within ±2% error. The molar volumes of pure KSCN at low temperatures required for testing the additivity of V are estimated from the same linear function for its density above the melting point.[5]

The measured refractive indices (n) of the systems under study also show a linear dependence on temperature. In this case, however, the least-squares fitted values of the intercepts and slopes do not vary linearly with x_2. Therefore, the composition dependence of refractive index has been described in terms of molar refractivity. Molar refractivities show negligible dependence on temperature but vary linearly with x_2 as illustrated with an isotherm at 323 K in Fig. 1c. It may be noted that the extrapolated value of molar refractivity (19.5 cm^3) for pure KSCN at 323 K coincides within ±2% with the value (19.11 cm^3) calculated from the refractive index and density values for molten KSCN obtained after extrapolating the high temperature data[5,6] to 323 K. Therefore, in a mixture of $Ca(NO_3)_2 \cdot 3.18H_2O$ and KSCN the formation of complex ions does not appear to take place.

Furthermore, an attempt to fit the n data to the Gladstone-Dale (G-D) equation,[7] $n = 1 + k/V$, has revealed that the present data fit into a slightly modified G-D equation of the form

$$n = k_1 + k_2/V. \quad (6)$$

The least-squares fitted values of the constants k_1 and k_2 are given in Table 1. Rearranging Eq. 6 and then by substituting the additive behavior of molar volume on the right hand side of the rearranged expression, we obtain

$$nV = A - Bx_2, \quad (7)$$

where $A = n_1V_1$ and $B = n_1V_1 - n_2V_2$. The terms with suffix 1 correspond to $Ca(NO_3)_2 \cdot 3.18H_2O$ and those with 2 to KSCN. In obtaining Eq. 7 k_1 and k_2 are considered to be independent of concentration. The least-squares fitted values of k_1 and k_2 (Table 1), on the other hand, are not exactly independent of concentration, but vary in a non-linear fashion. However, such changes in k_1 and k_2 do not seem to produce much deviation from Eq. 7 as apparent from the linearity of the plot of nV *versus* x_2 (Fig. 1c). It has also been found that the least-squares fitting of nV into Eq. 7 is reasonably good. Therefore, the applicability of the modified G-D equation seems to account for the observed additive nature of the product nV within ±2%.

The financial help from the university to one of us (S.M.) is gratefully acknowledged.

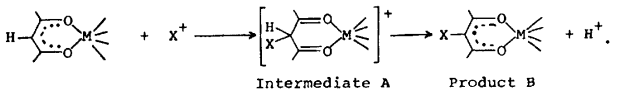
(Received October 28, 1980)

Synopsis. [Ni(tfac$_2$en)] reacted with NXS (*N*-chloro- or *N*-bromosuccinimide) in an alcoholic solvent to give the halogenated complexes at the γ-carbon atoms. The reaction intermediate was successfully isolated and was characterized by the use of the ^{1}H-NMR, IR, and AB spectra.

It is well known that the γ-protons of metal β-diketonates[1] and their Schiff-base derivatives[2,3] can be replaced by halogen atoms by the use of NXS. These halogenations have been regarded as examples of the electrophilic substitution reaction of the γ-protons with X^+, and the following reaction mechanism has been proposed:[1]



Intermediate A Product B

However, there have been few detailed studies of the reaction mechanism.[4,5]

In the course of our study[6] for the halogenation of Ni(II) complexes of *N,N'*-ethylenebis(β-oxo imine) in an alcoholic solvent, we found that the titled complex, abbreviated as [Ni(tfac$_2$en)],[7] gives a pretty stable reaction intermediate.

Experimental

Chlorination. A methanol solution (100 cm^3) of NCS (1.3 g) was added to a slurry of [Ni(tfac$_2$en)][8] (1.0 g) in methanol (200 cm^3). The mixture was stirred for 10 min at 35 °C to give a homogenious red solution. It was then concentrated to about 30 cm^3 under reduced pressure below 35 °C. When the solution was allowed to stand for 1 h, red crystals were separated out, and were washed with cold methanol. Yield, about 21%. Found: C, 32.04; H, 3.48; N, 5.48%. Calcd for $NiC_{14}H_{18}N_2O_4F_6Cl_2$: C, 32.21, H, 3.48; N, 5.37%. (Complex I).

On the other hand, the red solution obtained above was heated on a water bath for 30 min and then concentrated to about 100 cm^3. When water was added to the solution, a light-green precipitate was separated out. It was subsequently recrystallized from methanol. Yield, about 40%. Found: C, 31.48; H, 2.39; N, 6.24%. Calcd for $NiC_{12}H_{10}N_2O_2F_6Cl_2$: C, 31.48; H, 2.21; N, 6.12%. (Complex II).

When Complex I was allowed to stand in the atomosphere, it gradually decomposed to [Ni(tfac$_2$en)] in the solid state. When water was added to a methanol or DMSO solution of Complex I, it decomposed rapidly to give [Ni(tfac$_2$en)]. However, when the methanol solution of Complex I was heated at about 90 °C, it decomposed to form Complex II.

Bromination. The brominated complexes were obtained by using NBS by a method similar to that for the chloronation. From the red reaction mixture, reddish crystals were separated out in about a 30% yeild. Found: C, 27.38; H, 2.79; N, 4.66%. Calcd for $NiC_{14}H_{18}N_2O_4F_6Br_2$: C, 27.53; H, 2.98; N, 4.59%. (Complex III). When ethanol was used as the solvent, reddish crystals were obtained in about a 60% yield. Found: C, 29.91; H, 3.27; N, 4.52%. Calcd for $NiC_{16}H_{22}N_2O_4F_6Br_2$: C, 30.08; H, 3.48; N, 4.39%. (Complex IV).

When the red reaction mixture was treated by a method similar to that employed for the red solution with NCS, light-green crystals were obtained in about a 80% yield. Found: C, 26.53; H, 1.95; N, 5.33%. Calcd for $NiC_{12}H_{10}N_2O_2F_6Br_2$: C, 26.36; H, 1.95; N, 5.31%. (Complex V).

Results and Discussion

The characterization data are listed in Table 1. It is well known that *N,N'*-ethylenebis(β-oxo iminato)-nickel(II) complexes are diamagnetic and take a square planar structure. Since Complexes II and V are also diamagnetic and show AB spectra similar to that of [Ni(tfac$_2$en)], it is evident that Complexes II and V take the planar structure. In the ^{1}H-NMR spectra of Complexes II and V, no signal which corresponds to the γ-proton is observed. Accordingly, it is clear that they are the halogen-substituted complexes at the γ-carbon atoms. The two strong IR bands at 1500—1600 cm^{-1} for [Ni(tfac$_2$en)] shift to a somewhat lower energy site in Complexes II and V.

Further, the π-π^* transitions at 26.3—28.0 kcm^{-1} for [Ni(tfac$_2$en)] also shift to a somewhat lower energy site in the halogenated complexes II and V. These lower energy shifts of the IR and AB spectra are characteristic of the halogenated complexes at the γ-carbon atom.[1,3,4,9]

Complexes I, III, and IV are also diamagnetic and show the d-d transitions at about 20.8 kcm^{-1} which is characteristic of the square planar Ni(II) complexes. In their ^{1}H-NMR spectra, the signal of the γ-proton is observed at about 4.7 ppm; this position is at a somewhat higher field as compared with that of [Ni(tfac$_2$en)]. This higher field shift may be due to the saturation of the γ-carbon atom upon the addition of the halogen atom to it. Further, Complexes I, III, and IV exhibit the signals corresponding to methoxyl or ethoxyl groups. These groups are thought to be attached to the carbon atom, where the CF_3 group is bonded, and they may stabilize the halogenated intermediate like A. This is because it has been shown for the (trifluoroacetylacetonato)antimony(V)-complex that the complex reacts with water to give a complex in which the hydroxyl group is attached at the carbon atom, where the CF_3 group is bonded, and in which two protons are attached at the γ-carbon atom.[10] The proposed structure for Complexes I, III, and IV is shown in Fig. 1. (Intermediate II). Complexes I, III, and IV exhibit a broad IR band at about 1660 cm^{-1} which can be assigned to the $\nu_{C=N}$ of the C=N group with no conjugation.[11] The π-π^* transitions of these complexes are observed at a higher energy site than those of complexes II and V. This higher energy shift supports the idea that Complexes I, III, and IV take a structure in which the C=N groups do not conjugate with the other group, as is shown in Fig. 1.

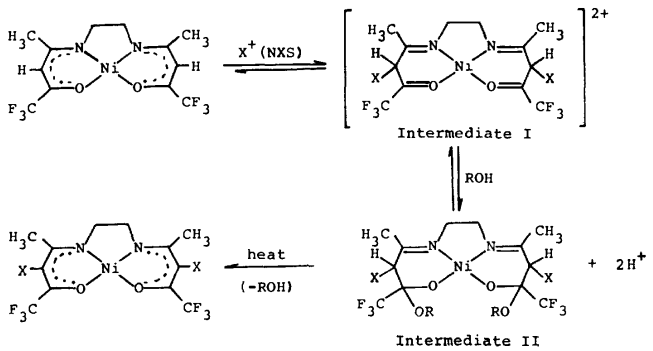

Fig. 1. The reaction scheme and the proposed structure of the reaction intermediate.

The proposed reaction mechanism is also shown in Fig. 1. Since the haloganation of [Ni(tfac$_2$en)] with NXS has also taken place in the presence of 2,6-di-*t*-butylphenol, a kind of radical scavenger, the reaction of NXS can be regarded as the electrophilic attack of the X^+ ion, which is formed by the ionic dissociation of NXS, on the γ-carbon atoms of [Ni(tfac$_2$en)]. Thus, in the first step of the reaction, Intermediate I in Fig. 1 should be formed. This Intermediate I has two positive charges. Further, the electron-withdrawing CF_3 group is attached. Therefore, the carbon atom, where CF_3 group is bonded, should be quite electron-deficient. Therefore, the attack of the alcoholic solvent may occur at the carbon atom to produce Intermediate II. As has been mentioned in the Experimental section, Complexes I, III, and IV decompose to give not only Complexes II or V but also [Ni(tfac$_2$en)]. This fact means that the reverse reaction from Intermediate II to [Ni(tfac$_2$en)] is possible. When water is added to the methanol solutions of Complexes II or IV, [Ni(tfac$_2$en)] is formed quite rapidly. Probably, in the presence of water, the elimination of alcohol from Intermediate II readily occurs upon the attack of the proton which is formed by the dissociation of water to give Intermediate I, and then [Ni(tfac$_2$en)].

The haloganation occurred also in a chloroform solvent. In that case, [Ni(tfac$_2$en)] (reddish brown) turned brown at the initial stage of the reaction, and then it turned to a brownish green with heating. The brown material could not be isolated well. However, when methanol was added to the brown solution, the solution turned to red, and reddish crystals, which correspond to Complex I, could be isolated from the solution. These facts suggest that the brown material may correspond to Intermediate I.

It should be noted that trifluoroacetylacetone, its metal complexes, and its Schiff base ligand itself are not halogenated by NXS.

Ligand Dissociation Rate Constants of Tris(4,4′-dimethyl-2,2′-bipyridine)chromium(II) and Tris(5,5′-dimethyl-2,2′-bipyridine)chromium(II) Complexes

Kunio NAKANO, Yoshio NARUSAWA,* and Hiroyuki MOROI

Department of Chemistry, College of Science, Rikkyo University (St. Paul's University), Nishi-Ikebukuro, Toshima-ku, Tokyo 171

(Received December 3, 1980)

Synopsis. Ligand dissociations of tris(4,4′-Me_2bpy)- and tris(5,5′-Me_2bpy)chromium(II) complexes** have been studied by scavenging the ligand with zinc ion according to a stopped-flow method.

The ligand dissociation of $[Cr(bpy)_3]^{2+}$ was first studied by a redox reaction between $[Cr(bpy)_3]^{2+}$ and $[Co(PO_4)(NH_3)_5]$ using a stopped-flow method[1] and subsequently by d.c. polarography,[2,3] while that for a heterogeneous system was studied cyclic voltammetrically.[4,5] Reports were given on the ligand dissociation rate constants obtained from the studies of the oxidation of $[Cr(bpy)_3]^{2+}$ or $[Cr(phen)_3]^{2+}$ with $[Co(NH_3)_6]^{3+}$ by the stopped-flow method.[6,7] Since all the results were obtained by indirect methods, attempts were made to obtain the ligand dissociation rate constants of $[Cr(bpy)_3]^{2+}$ and $[Cr(phen)_3]^{2+}$ directly by the stopped-flow method.[8] Although the ligand dissociation rate constants for a few complexes of 1,10-phenanthroline derivatives ($[Cr(5\text{-Me(phen)})_3]^{2+}$, $[Cr(5\text{-Cl(phen)})_3]^{2+}$ and $[Cr(5\text{-Br(phen)})_3]^{2+}$)*** were measured cyclic voltammetrically,[5] no paper has appeared so far on chromium(II) complexes of 2,2′-bipyridine derivatives. We have studied the ligand dissociations of $[Cr(4,4'\text{-}Me_2bpy)_3]^{2+}$ and $[Cr(5,5'\text{-}Me_2bpy)_3]^{2+}$, and obtained their kinetic and activation parameters.

Experimental

Apparatus. The stopped-flow apparatus for kinetic measurements was the same as reported.[7] Ultraviolet and visible absorption spectra were measured with a Hitachi recording spectrophotometer Type EPS-3T using a quartz cell of 1.0 mm optical path.

Reagents. 4,4′-Me_2bpy and 5,5′-Me_2bpy were synthesized according to the procedure of Sasse and Whittle.[9] The synthesized ligands 4,4′-Me_2bpy and 5,5′-Me_2bpy were checked spectrophotometrically. High purity nitrogen was used after further purification with activated copper columns. All other chemicals were of GR grade and used without purification.

Measurements of Absorption Spectra. The absorption spectra of *ca.* 2 mmol dm^{-3} aqueous solutions of $[Cr(4,4'\text{-}Me_2bpy)_3]^{2+}$ and $[Cr(5,5'\text{-}Me_2bpy)_3]^{2+}$ were measured. Preparation of the sample solution using a vacuum line was carried out as reported previously.[7] Since 4,4′-Me_2bpy and 5,5′-Me_2bpy were hardly soluble in water, not being able to give solutions of the desired concentration, suspensions of these ligands were used. Chromium (II) complex solutions were obtained by mixing anhydrous chromium(II) chloride with their respective suspensions. Absorption spectra of these complexes were measured and found to agree with those reported.[10]

Kinetic Measurements. A solution of $[Cr(4,4'\text{-}Me_2bpy)_3]^{2+}$ or $[Cr(5,5'\text{-}Me_2bpy)_3]^{2+}$ and a zinc chloride solution were mixed with the stopped-flow apparatus, the concentrations of chromium(II) complexes and zinc ion being 2.0 mmol dm^{-3} and 50 mmol dm^{-3}, respectively. The ionic strength for each solution was adjusted to 0.20 mol dm^{-3} by addition of sodium chloride, the pH being adjusted to 5.3 with an acetic acid–sodium acetate buffer solution. Kinetic measurements were performed by observing the absorbance change of the starting chromium(II) complex with time after mixing the solution of the chromium(II) complex with excess zinc ion used as a scavenger. The wavelengths were fixed at 571 nm for $[Cr(4,4'\text{-}Me_2bpy)_3]^{2+}$ and 565 nm for $[Cr(5,5'\text{-}Me_2bpy)_3]^{2+}$. The temperatures for the kinetic measurements were in the range 20—45 °C, the respective temperature being kept constant within ±0.1 °C.

Reaction Analysis. Reaction curves, absorbance *vs.* time, were analyzed by means of

$$\ln[(A_t-A_\infty)/(A_0-A_\infty)] = k_{obsd}\,t, \qquad (1)$$

where A_0, A_t, and A_∞ denote the absorbance of the solution at time $t=0$, t and ∞, respectively, and k_{obsd} is the apparent first-order rate constant.

Results and Discussion

Plots of $\log(A_t-A_\infty)$ *vs.* t show linearity over the whole range of the reaction curves, indicating that the reaction is of first-order type.

The following succesive equilibria seem to hold for both the complex of 4,4′-Me_2bpy and that of 5,5′-Me_2bpy:

Table 1. Rate constants for the ligand dissociation of Cr(II) complexes[a]

Complex	Temp/°C	k_{obsd}/s^{-1}[b]
$[Cr(4,4'\text{-}Me_2bpy)_3]^{2+}$	20.0	0.644±0.005 (7)
	25.0	1.17 ±0.02 (6)
	30.0	2.05 ±0.03 (6)
	35.0	3.60 ±0.04 (8)
	40.0	5.93 ±0.06 (7)
	45.0	9.68 ±0.12 (5)
$[Cr(5,5'\text{-}Me_2bpy)_3]^{2+}$	20.0	0.338±0.002 (6)
	25.0	0.663±0.002 (6)

$[Cr(5,5'\text{-}Me_2bpy)_3]^{2+}$	0.663±0.002	89.9±1.0	53.5±4.0	b)

a) Values at 25.0 °C. b) This work.

$$[Cr(LL)_3]^{2+}+2H_2O \rightleftharpoons [Cr(H_2O)_2(LL)_2]^{2+}+LL, \quad (2)$$

$$[Cr(H_2O)_2(LL)_2]^{2+}+2H_2O \rightleftharpoons [Cr(H_2O)_4(LL)]^{2+}+LL, \quad (3)$$

$$[Cr(H_2O)_4(LL)]^{2+}+2H_2O \rightleftharpoons [Cr(H_2O)_6]^{2+}+LL, \quad (4)$$

where LL denotes 4,4'-Me_2bpy and 5,5'-Me_2bpy. Since zinc ion rapidly scavenges the free ligand,[11] no reverse reactions need be considered for the equilibria under excess zinc ion. Thus, the ligand dissociation of this system could be observed. The kinetic measurements of the present experiment satisfy the above conditions. Since the molar extinction coefficient of the bis complex is considered to be small, in analogy to $[Cr(bpy)_3]^{2+}$,† the dissociation of the tris to the bis complex can be determined. A first-order reaction was observed over the whole range of each reaction curve, and thus the determination of the first step (Eq. 2) is considered to be rate-determining. It is evident that the observed rate constant k_{obst} represents the rate constant for the ligand dissociation of the tris to bis complex.

The rate constants obtained under various temperatures are given in Table 1, and kinetic and activation parameters in Table 2, along with the previous data.[8] The ligand dissociation rate constants of $[Cr(4,4'\text{-}Me_2bpy)_3]^{2+}$ and $[Cr(5,5'\text{-}Me_2bpy)_3]^{2+}$ are greater than those of $[Cr(bpy)_3]^{2+}$. This seems to correspond to greater rates of $[Cr(5\text{-}Me(phen))_3]^{2+}$, $[Cr(5\text{-}Cl(phen))_3]^{2+}$ and $[Cr(5\text{-}Br(phen))_3]^{2+}$ as compared with $[Cr(phen)_3]^{2+}$.[5] The values of activation entropy ΔS^* for $[Cr(bpy)_3]^{2+}$, $[Cr(phen)_3]^{2+}$, and $[Cr(4,4'\text{-}Me_2bpy)_3]^{2+}$ are *ca.* 30 J K^{-1} mol^{-1}, whereas that for $[Cr(5,5'\text{-}Me_2bpy)_3]^{2+}$ is far greater. The positive activation entropy suggests that the ligand dissociation of the present system proceeds *via* the dissociative mechanism,[12] while the greater value of ΔS^* for $[Cr(5,5'\text{-}Me_2bpy)_3]^{2+}$ suggests the possibility of a different dissociative mechanism.

† In the case of $[Cr(bpy)_3]^{2+}$,[8] the absorbance at the starting point of the reaction is estimated to be 0.833 (concentration, 0.96 mmol dm^{-3}; molar extinction coefficient, 4340 dm^3 mol^{-1} cm^{-1}; cell length, 2 mm). If most of the tris complex was consumed for the formation of the bis complex during the dead-time, the initial absorbance observed would be less than 0.154, since the molar extinction coefficient of the bis complex is 803 dm^3 mol^{-1} cm^{-1}.[8] However, in a typical case, the absorbance for the first observable reaction signal was 0.624, the reaction curve approaching zero. The first-order plot fell on a straight line over the whole range observed. The reaction seems to correspond to the dissociation of the tris to the bis complex, and this step is regarded to be rate-determining.

The authors wish to thank Mr. Teruo Nagaoka and Miss Misa Okamoto for their assistance in absorption spectral measurements, Dr. Yoshio Koike, Kanagawa University, for the samples of 4,4'-dimethyl-2,2'-bipyridine and 5,5'-dimethyl-2,2'-bipyridine, and Prof. Tatsuo Matsuura, Institute for Atomic Energy, Rikkyo University, for use of the stopped-flow apparatus.

Solubility Phase Diagram Containing Racemic Compound of Bis(ethylenediamine)oxalatocobalt(III) Oxalate

Akira FUYUHIRO,* Kazuaki YAMANARI, and Yoichi SHIMURA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received December 20, 1980)

Synopsis. Solubility of *Λ*- and *rac*-$[Co(ox)(en)_2](C_2O_4)_{0.5}$ was measured in water at 5—60 °C, the solubility isotherm of the ternary system, *Λ*-$[Co(ox)(en)_2](C_2O_4)_{0.5}$–*Δ*-$[Co(ox)(en)_2](C_2O_4)_{0.5}$–$H_2O$, being determined at 25 °C. It was found that the oxalate is not spontaneously resolvable and forms the racemic compound, *Λ*-$[Co(ox)(en)_2]$·*Δ*-$[Co(ox)(en)_2](C_2O_4)$·nH_2O.

In 1968 Yamasaki *et al.* reported the spontaneous resolution of bis(ethylenediamine)oxalatocobalt(III) oxalate, $[Co(ox)(en)_2]_2(C_2O_4)\cdot 8H_2O$, which shows hemihedral facets in the crystals.[1] However, the result seemed doubtful considering their method for preparing the oxalate, *i. e.* by the reaction, *trans*-$[CoCl_2(en)_2]Cl + 2H_2C_2O_4 \rightarrow [Co(ox)(en)_2]^+ + 3Cl^- + 4H^+ + C_2O_4^{2-}$. The crystals obtained seem to be chloride known to be spontaneously resolvable, since the solubility of *rac*-$[Co(ox)(en)_2](C_2O_4)_{0.5}$ ($m=0.369$ mol kg^{-1}) is larger than that of *rac*-$[Co(ox)(en)_2]Cl$ ($m=0.118$ mol kg^{-1}) at 25 °C and the molar ratio of counter ions, $Cl^-/(C_2O_4)_{0.5}^-$, is 3/2 even disregarding the association of H^+ and $C_2O_4^{2-}$. Chloride was obtained in our experiments. The hemihedrally distinguishable crystals obtained by Yamasaki *et al.* seem to be $[Co(ox)(en)_2]Cl\cdot 4H_2O$.

In order to confirm whether the spontaneous resolution of oxalate occurs or not, the optically active and the racemic oxalates were prepared and their solubilities in binary and ternary systems were measured.

Experimental

Materials. *$[Co(ox)(en)_2](C_2O_4)_{0.5}\cdot nH_2O$*: The *Λ*-, *Δ*-, and *rac*-$[Co(ox)(en)_2](C_2O_4)_{0.5}\cdot nH_2O$ were obtained from the corresponding chloride and $Ag_2(C_2O_4)$. Found: C, 21.20; H, 6.38; N, 14.09%. Calcd for *Λ*-$[Co(ox)(en)_2](C_2O_4)_{0.5}\cdot 4.5H_2O$: C, 21.44; H, 6.42; N, 14.28%. Found: C, 21.24; H, 6.44; N, 14.13%. Calcd for *Δ*-$[Co(ox)(en)_2](C_2O_4)_{0.5}\cdot 4.5H_2O$: C, 21.44; H, 6.42; N, 14.28%. Found: C, 23.01; H, 5.93; N, 15.33%. Calcd for *rac*-$[Co(ox)(en)_2](C_2O_4)_{0.5}\cdot 3H_2O$: C, 23.02; H, 6.07; N, 15.34%.

Measurements. Solubility in water was determined in molality.[2] The solid phases were identified from elemental analysis, absorption and CD spectra. Optical densities were measured with a JASCO UVIDEC-1 spectrophotometer and CD with a JASCO MOE-1 spectropolarimeter.

Results and Discussion

Binary System. The solubility of *Λ*- and *rac*-$[Co(ox)(en)_2](C_2O_4)_{0.5}$ is given in Table 1. The solubility ratio of racemate/*Λ*-salt is 0.720(5 °C) or 0.340(60 °C). If spontaneous resolution takes place, the ratio should exceed *ca.* $2^{2/3}=1.59$ expected in this type of electrolyte.[3] Thus, the present salt is not spontaneously resolvable. The solubility curve of *Λ*-salt shows an inflection at *ca.* 38 °C, at which the solid phase changes from (4.5—5)-hydrate(below 38 °C) to monohydrate(above 38 °C). However, the trihydrated racemic salt shows no solid phase change at 5—60 °C. This also confirms that the racemic salt exists as a racemic compound.

E_2	0.06 (±0.01)	1.11 (±0.01)	Δ+*rac*
B		1.07 (±0.01)	Δ

a) Values in parentheses are estimated errors and calculated from twice the standard deviations of measurements repeated 5—11 times.

$(C_2O_4)\cdot 6H_2O$=*rac*-[Co(ox)(en)$_2$]$(C_2O_4)_{0.5}\cdot 3H_2O$, whose region spreads widely ($E_1E_3E_2$). It is evident that no spontaneous resolution occurs.[4] Points E_1 and E_2 are the invariant points where two solids (active and racemic salts) coexist.

DTA Analyses. Differential thermal analysis (DTA) of the optically active and the racemic oxalate was carried out under suspended conditions in water at *ca.* 0—100 °C,[5] providing one peak in heating process for each salt. The peak for the optically active salt (38 °C) corresponds to the transition observed in the binary solubility. The racemic salt shows a peak at *ca.* 74 °C at which the solid phase changes from trihydrate-(below 74 °C) to 0.5-hydrate(above 74 °C). However, the transition of racemate does not correspond to the change from the racemic compound to a racemic mixture, because the extrapolated solubility ratio at 74 °C (*ca.* 0.37) in Table 1 does not exceed 1.59, and the active and the racemic salts have different numbers of water of crystallization.

Thus, the optically active oxalate can not be obtained from the racemic solution of [Co(ox)(en)$_2$]$(C_2O_4)_{0.5}$ in equilibrium, *viz.*, the salt is not spontaneously resolvable.

Extraction of Lead(II) in Aqueous Thiocyanate-Perchlorate Solutions wtih Trioctylphosphine Oxide in Hexane and with 4-Methyl-2-pentanone

Satoshi KUSAKABE and Tatsuya SEKINE*

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received December 26, 1980)

Synopsis. The stability of lead(II) thiocyanate complexes and the extraction behavior of lead(II) in 1 mol dm^{-3} Na(SCN, ClO_4) were studied. By an extraction method with thenoyltrifluoroacetone, $\log\beta_1=0.49$ was obtained for $PbSCN^+$. The extraction was poor with 4-methyl-2-pentanone but effective with trioctylphosphine oxide in hexane. Not only $Pb(SCN)_2$ but also $Pb(SCN)(ClO_4)$ and $Pb(ClO_4)_2$ were extracted into both of the solvents.

The complex formation equilibria of lead(II) in aqueous 1 mol dm^{-3} Na(SCN,ClO_4) solutions were determined by an extraction method with thenoyltrifluoroacetone (TTA). The extraction equilibria of this metal ion from these ionic media into 4-methyl-2-pentanone (MIBK) and hexane containing trioctylphosphine oxide (TOPO) were studied as follows.

Experimental and Statistical

All of the reagents used were of a reagent grade. Sodium perchlorate was recrystallized from water. The solutions of sodium thiocyanate and sodium perchlorate were standardized by gravimetry. The extractants, TTA and TOPO, were obtained from Dojindo Laboratories in Kumamoto. TOPO and MIBK were purified as described previously.[1,2] A carbon tetrachloride solution containing 0.1 mol dm^{-3} TTA, hexane solutions containing TOPO at various concentrations and MIBK were used as the organic solutions.

All of the experiments were carried out in a thermostated room at 25 °C in a manner essentially similar to that described previously[3] except that the initial metal concentration was 1×10^{-4} mol dm^{-3} and that the metal concentration in the two phases was determined by an atomic absorption method.

In the present paper, the chemical species in the organic phase are denoted by the subscript "org," while the lack of any subscript denotes those in the aqueous phase. The distribution ratio is defined as $D=[Pb(II)]_{org}/[Pb(II)]$. The total concentration of lead(II) in aqueous solution containing thiocyanate ions can be described as:

$$[Pb(II)] = [Pb^{2+}](1 + \sum\beta_i[SCN^-]^i), \quad (1)$$

where β_i is the stability constant of the "i-th" complex.

The TTA extraction can be written as:

$$Pb^{2+} + 2Htta_{(org)} \rightleftarrows Pb(tta)_{2(org)} + 2H^+$$

$$K_{TTA,0} = D_0[H^+]^2[Htta]_{org}^{-2}, \quad (2)$$

where D_0 is the distribution ratio in the absence of thiocyanate ions. If the concentration of TTA in the organic phase and of the hydrogen-ion in the aqueous phase are kept constant, the following equation can be obtained:

$$D/D_0 = 1/(1+\sum\beta_i[SCN^-]^i). \quad (3)$$

The MIBK extraction can be treated as follows. Since it was found that only the $PbSCN^+$ species was the complex in the aqueous phase and that $[Pb(II)]_{org}=[Pb(ClO_4)_2]_{org}+[Pb(SCN)(ClO_4)]_{org}+[Pb(SCN)_2]_{org}$, the distribution ratio is written as:

$$D = (K_{MIBK,0}[ClO_4^-]^2 + K_{MIBK,1}[SCN^-][ClO_4^-] + K_{MIBK,2}[SCN^-]^2)/(1+\beta_1[SCN^-]), \quad (4)$$

where

$$K_{MIBK,n} = [Pb(SCN)_n(ClO_4)_{2-n}]_{org}/([Pb^{2+}][SCN^-]^n[ClO_4^-]^{2-n}). \quad (5)$$

The TOPO(L) extraction was as follows.

$$[Pb(II)]_{org}=[Pb(ClO_4)_2L_4]_{org}+[Pb(SCN)(ClO_4)L_4]_{org}+[Pb(SCN)(ClO_4)L_3]_{org}+[Pb(SCN)_2L_3]_{org}$$

$$D=(K_{ex0,4}[ClO_4^-]^2[L]_{org}^4+K_{ex1,4}[SCN^-][ClO_4^-][L]_{org}^4+K_{ex1,3}[SCN^-][ClO_4^-][L]_{org}^3+K_{ex2,3}[SCN^-]^2[L]_{org}^3)/(1+\beta_1[SCN^-]) \quad (6)$$

where

$$K_{exn,m} = \frac{[Pb(SCN)_n(ClO_4)_{2-n}L_m]_{org}}{[Pb^{2+}][SCN^-]^n[ClO_4^-]^{2-n}[L]_{org}^m} \quad (7)$$

The data were treated by a least squares program in order to find the values of the constant which give the best fit.

Results and Discussion

From the extraction of lead(II) with TTA, the value of $K_{TTA,0}$ in Eq. 2 was obtained to be $10^{-10.60}$. This was valid up to $-\log[H^+]$ 4.0. Figure 1 shows the decrease in the TTA extraction as a function of the thiocyanate concentration in the aqueous phase. By the least squares treatment, the data were found to be explained by assuming only the $PbSCN^+$ species. The value of β_1 determined was $10^{0.49}$.

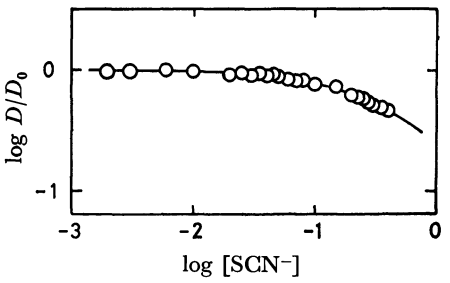

Fig. 1. Decrease in the lead (II) extraction with TTA *vs.* the aqueous thiocyanate concentration. Org. phase; CCl_4 containing 0.1 mol dm^{-3} TTA. Aq. phase; 1 mol dm^{-3} Na (SCN, ClO_4). The solid curve gives; $\log D/D_0=-\log(1+10^{0.49}[SCN^-])$.

The results of the extraction of lead(II) into MIBK are shown by Fig. 2. The extraction constants obtained by the least squares calculation on the basis of Eq. 4 using $\beta_1=10^{0.49}$ are listed in Table 1. The curve is calculated from these constants and Eq. 4.

Figure 2 also shows the extraction curves of lead(II) with TOPO in hexane. The value of $K_{ex0,4}$ was obtained separately from the extraction data from 1 mol dm^{-3} sodium perchlorate solutions as $10^{6.92}$. Using the above β_1 and $K_{ex0,4}$ values, the values of the extraction constants

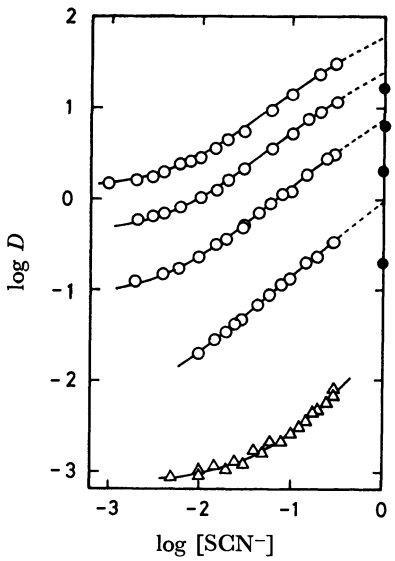

Fig. 2. Extraction curves of lead (II) with 4-methyl-2-pentanone (△) and triocylphosphine oxide in hexane (○) from 1 mol dm^{-3} Na (SCN, ClO_4) solutions. The concentration of TOPO in the organic phase is 0.02, 0.015, 0.01, and 0.005 mol dm^{-3} from top to bottom. The solid curves are calculated ones by means of Eqs. 4 and 6 using the constants in Table 1. The closed circles at 1 mol dm^{-3} thiocyanate indicate the values obtained experimentally (see text).

TABLE 1. SUMMARY OF THE EQUILIBRIUM CONSTANTS[a),b)]

MIBK		TOPO in hexane	
$\log K_{MIBK,0}$	−3.11	$\log K_{ex,0,4}$	6.92
$\log K_{MIBK,1}$	−1.68	$\log K_{ex,1,4}$	8.81
$\log K_{MIBK,2}$	−1.03	$\log K_{ex,1,3}$	6.96
		$\log K_{ex,2,3}$	7.48

a) Stability constant of aqueous complex, $\log \beta_1 = 0.49$.
b) Extraction constant of $Pb(ClO_4)_2$, $Pb(SCN)(ClO_4)_2$, and $Pb(SCN)_2$ species; *cf.* Eqs. 5 and 7.

were determined by means of Eq. 6 also by the least squares method. The best-fit constants are shown in Table 1.

The stability constants of lead(II) thiocyanate have been reported as $\log \beta_1 = 0.20$ and $\log \beta_2 = 0.90$ in 1 mol dm^{-3} $Na(SCN,ClO_4)$[4] and $\log \beta_1 = 0.54$, $\log \beta_2 = 0.88$, $\log \beta_3 \simeq -1$, and $\log \beta_4 = 0.85$ in 2 mol dm^{-3} $Na(SCN, ClO_4)$[5] solutions at 25 °C by polarography. The present β_1 is similar to these literature values, though no higher complexes were found in the present study. The value of β_1 of this metal ion is lower than that for several bivalent transition metals,[6-8] cadmium,[6] mercury(II),[2] and zinc(II).[3]

The MIBK extraction of lead(II) from thiocyanate solutions is poorer than zinc(II),[3] cobalt(II),[7] and mercury(II)[2] but better than nickel(II).[8] The MIBK extraction of lead(II) from 1 mol dm^{-3} $Na(SCN,ClO_4)$ was calculated to be mainly due to $Pb(ClO_4)_2$ and $Pb(SCN)(ClO_4)$ species; the contribution of the $Pb(SCN)_2$ species is rather small up to 0.3 mol dm^{-3} thiocyanate.

It was calculated that under the conditions in Fig. 2, the $Pb(SCN)_2(TOPO)_3$ species is not dominant in the organic phase even at 0.3 mol dm^{-3} thiocyanate. This is due to the instability of the metal thiocyanate and also the high extractability of the lead(II) perchlorate and the mixed thiocyanate. The extraction from sodium thiocyanate solutions containing no perchlorate was poorer than the calculated values, as indicated in Fig. 2. This is due to changes in the activity coefficients of chemical species by the replacement of the anion in the aqueous phase.

The extraction constant of the mixed thiocyanate, $K_{ex1,3}$, is not very much different from that of the dithiocyanate, $K_{ex2,3}$, in Table 1. This evidence, that the extraction of $Pb(SCN)_2$ is rather similar to $Pb(SCN)(ClO_4)$, seems to indicate that the interactions of the second thiocyanate ion with the metal ion are not so strong in the $Pb(SCN)_2$ species. This instability of the dithiocyanate complex should be the reason for its high solvation number, three; it seems to be rather common that if the di-complex of a bivalent metal ion is stable it tends to be extracted as a disolvate.[2,9]

Isotope Effects in the *p*-Tolylation of Pyridine

Takeshige NAKABAYASHI,* Toyokazu HORII, Shunichi KAWAMURA, and Yasuo ABE
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka 593

(Received October 11, 1980)

Synopsis. *p*-Toluoyl peroxide, *p*-iodotoluene, and di-*p*-tolyl sulfone, sulfoxide, and sulfide were photolyzed in an equimolar pyridine–pyridine-d_5 mixture to give rise to isomeric *p*-tolylpyridines (α, β, and γ) and their deuterated compounds. Isotopic distribution ratios (Y_H/Y_D) in the isomeric products were determined to be slightly larger than unity.

Vidal and coworkers[1] reported that in the phenylation of 4-methylpyridine with benzoyl peroxide (BPO), the deuterium isotope effect (K_H/K_D) at 2-position of the substrate was somewhat large, 3.7, though that at 3-position was 1.0. In order to check the generality of this tendency, isotope effects in arylation of pyridine with various aryl radical sources were determined. We have found previously[2] that *p*-toluoyl peroxide and *p*-iodotoluene, as well as di-*p*-tolyl sulfone, sulfoxide, and sulfide, are photolyzed in pyridine to afford isomeric *p*-tolylpyridines (α, β, and γ, respectively). Here, the isotope effects at the three nuclear positions of pyridine in the free-radical *p*-tolylation with these radical precursors were determined from the isotope distribution ratios (Y_H/Y_D) in the reaction products. The results are summarized in Table 1.

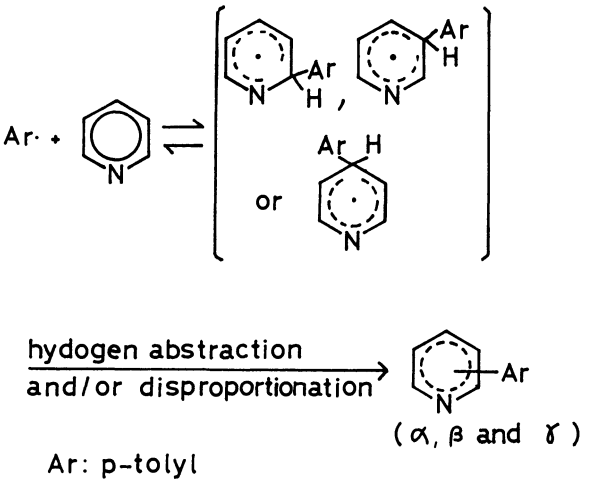
TABLE 1. ISOTOPIC DISTRIBUTION RATIOS (Y_H/Y_D)[a] IN ISOMERIC *p*-TOLYLPYRIDINES PRODUCED IN THE REACTION

Run No.	Compound[b]	*p*-Tolylpyridines		
		α	β	γ
0.015 mol dm^{-3} Solution				
1	$ArSO_2Ar$	1.06	1.15	1.09
2	ArSOAr	1.08	1.20	1.05
3	ArSAr	1.05	1.35	1.12
4	$(ArCO_2)_2$	1.26	1.27	1.10
5	ArI	1.06	1.19	1.17
0.15 mol dm^{-3} Solution				
1′	$ArSO_2Ar$	1.09	1.14	1.08
2′	ArSOAr	1.05	1.18	1.07
3′	ArSAr	1.14	1.45	1.11
4′	$(ArCO_2)_2$	1.30	1.30	1.13
5′	ArI	1.06	1.12	1.12

a) Experimental error is ± 0.05. b) Ar is *p*-tolyl.

As shown in Table 1, only small isotope effects (<1.5) were observed for *p*-tolylation of all positions of pyridine; no case was found in which 2-arylation showed a larger isotope effect than 3-arylation. The difference with the result by Vidal *et al.*[1] appears to depend on the radical sources.

Eliel and coworkers[3] reported that, in the phenylation of benzene-d_6 with the phenyl radical generated from BPO, the isotope effects ($K_H/K_D=1.0$—6.6) vary with the concentrations of BPO used in the reaction. As Table shows, however, the values of Y_H/Y_D in the present reactions were independent of the concentrations of the radical sources used under our conditions.



On the basis of the mechanism[3-5] proposed for homolytic arylations of aromatic compounds, it seems reasonable to consider that the product isotope effect is observed in either of the following cases: (1) reversal of the addition of *p*-tolyl radicals on pyridine, or (2), disproportionation and combination between *p*-tolyldihydropyridyl radicals takes place in competition with the production of the *p*-tolylpyridines. In order to check the reversibility of addition of *p*-tolyl radicals to pyridine, the peroxide and the iodide were allowed to react with a small excess of an equimolar pyridine–pyridine-d_5 mixture, and isotopic compositions of the recovered pyridine were compared with those of the starting one. The data in Table 2 reveal that the recovered pyridine was completely unchanged in its isotopic composition within the experimental errors. This finding implies that the values of Y_H/Y_D larger slightly than unity are due to disproportionation and combination between the dihydropyridyl radicals; the disproportionation and combination compete with the hydrogen abstraction from the radical to yield the *p*-tolylpyridines.

TABLE 2. ISOTOPIC COMPOSITIONS OF STARTING[a] AND RECOVERED PYRIDINE-PYRIDINE-d_5 MIXTURE

Run No.[b]	Compound[c]	Pyridine, (% in mol)	Pyridine-d_5, (% in mol)
1	$(ArCO_2)_2$	48.72(48.72)	51.28(51.28)
2	ArI	48.88(48.93)	51.02(51.07)

a) The figures in parentheses indicate those for starting materials. b) In run 1, refluxed for 6 h at boiling point of pyridine. c) Ar is *p*-tolyl.

Table 1 indicates that the values of Y_H/Y_D change with the radical sources to some extent and that in most runs, the values of Y_H/Y_D of β-(*p*-tolyl)pyridines are somewhat larger than those of α- and γ-compounds. The reason for these tendencies is not clear at present.

Experimental

Materials. Commercial available di-*p*-tolyl sulfone and sulfoxide and *p*-iodotoluene were purified by recrystallization and employed for the reaction. *p*-Toluoyl peroxide and authentic *p*-tolylpyridines (α, β, and γ) were prepared and purified by the method[2] reported previously. Di-*p*-tolyl sulfide was prepared by the literature method[6] from reduction of the corresponding sulfoxide with trichlosilane and recrystallized from ethanol (mp 58.5 °C). Pyridine–pyridine-d_5 (isotope purity 99%) were purchased from E. Merck, Darmstadt, and used for the reaction without further purification.

General Procedure for Photolysis of Radical Sources in Pyridine–Pyridine-d_5 *Mixture.* The procedure for the sulfone is described here as a typical run. An equimolar pyridine–pyridine-d_5 mixture was prepared and its isotopic content was determined by GC-MS analysis. In the case of 0.15 mol dm^{-3} solution, 0.3 mmol (74.1 mg) of the sulfone was dissolved in 2 ml of the pyridine mixture. Each solution was placed in a Pyrex cylinder, degassed five times, sealed, and irradiated for 200 h at room temperature with a 400 W medium-pressure mercury arc lamp. After evaporating the excess pyridine under a reduced pressure, the residue was subjected to preparative GLC to collect a mixture of isomeric *p*-tolylpyridines produced. The preparative GLC was done on a 3 mm × 2 m stainless steel column packed with 3% OV-17 on Chromosorb GAW (DMCS), using a JEOL Chromatograph JGC-650. Three isomeric *p*-tolylpyridines were then fractionated from the mixture on a preparative HPLC with THF–hexane (1 : 9 in volume) as a solvent. The instrument used was a Waters Model 6000 A High-Pressure Liquid Chromatograph equipped with a 4 mm × 30 cm column packed with μ-porasil. Each isomeric *p*-tolylpyridine thus separated was identified by comparison of its retention time with that of authentic specimen, and its deuterium content was determined by GC-MS analysis at 70 eV using a Shimadzu-LKB 9000 Gas Chromatograph-Mass Spectrometer equipped with a 3 mm × 2 m glass column packed with 0.5% OV-17 on Chromosorb GAW (DMCS). The values of Y_H/Y_D of isomeric *p*-tolylpyridines were calculated from its parent peak ratios (I_{169}/I_{173}). The parent peak ratios were determined by repeated scans of a range of $m/e=160$ to $m/e=185$. It was ascertained that the parent peak ratios did not change when ionization potentials were changed from 20 to 70 eV.

Isotopic Compositions of Starting and Recovered Pyridine–Pyridine-d_5 *Mixture.* *p*-Toluoyl peroxide (1.35 g, 5 mmol) was added to an equimolar pyridine–pyridine-d_5 (1 g, 12.5 mmol) mixture. The mixture was refluxed at the boiling point of pyridine until evolution of CO_2 gas ceased. The unchanged pyridine was recovered by distillation and subjected to GC-MS analysis by using a small glass vessel in place of the OV-17 column. Its isotopic composition was calculated from the parent peak rations (I_{79}/I_{84}) by the technique mentioned above. *p*-Iodotoluene (2.18 g, 10 mmol) was dissolved in 1 g (12.5 mmol) of the equimolar pyridine–pyridine-d_5 mixture. The solution was placed in a small Pyrex cylinder, degassed, and irradiated for 200 h at room temperature with a 400 W medium-pressure mercury arc lamp. After irradiation, the unchanged pyridine was recovered by distillation and analyzed on the GC-MS. Its isotopic composition was calculated in the way described above. After irradiation for 200 h, GLC analysis indicated that 50% of the initially charged iodide remained unchanged.

A Convenient Synthesis of Azuleno[2,1-*b*]thiophene

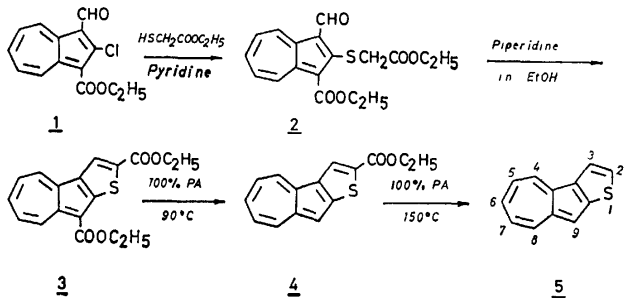
Kameji YAMANE,* Kunihide FUJIMORI,* and Toru TAKEUCHI
Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390
(Received December 2, 1980)

Synopsis. Azuleno[2,1-*b*]thiophene and its derivatives were prepared from ethyl 2-chloro-3-formylazulene-1-carboxylate and ethyl mercaptoacetate in a few steps.

Azuleno[2,1-*b*]thiophene, which is a polycyclic aromatic compound containing a heterocycle, is of interest in its physical properties and chemical behavior. The compound and related compounds have so far been prepared by reaction of diethyl 2-chloroazulene-1,3-dicarboxylate with ethyl mercaptoacetate, followed by cyclization, methylation, hydrolysis, decarboxylation, reduction, and dehydration.[1]

We now wish to report a convenient synthesis of the title compound and its derivatives.

When ethyl 2-ethoxycarbonylmethylthio-3-formylazulene-1-carboxylate (**2**) prepared by the reaction of ethyl 2-chloro-3-formylazulene-1-carboxylate (**1**)[2] with ethyl mercaptoacetate was heated with piperidine in EtOH, cyclization occurred to afford the diethyl azuleno[2,1-*b*]thiophene-2,9-dicarboxylate (**3**) in good yield. The conversion of **2** to **3** could also be carried out with basic activated alumina. The compound **3**, on treatment with 100% phosphoric acid at 90 °C, gave ethyl azuleno[2,1-*b*]thiophene-2-carboxylate (**4**). When the ester (**4**) was heated at 150 °C in 100% phosphoric acid, deethoxycarbonylation occurred to give azuleno[2,1-*b*]thiophene (**5**). The compound **5** was also obtained from **4** as follows. Compound **4** was hydrolyzed in ethanolic KOH and the resulting carboxylic acid was heated at 170—180 °C under reduced pressure (2 mmHg†) to yield **5**.



1 2 3 4 5

The spectral data of **2**, **3**, **4**, and **5** are shown in the experimental section.

The NMR vicinal coupling constants indicate that 7-membered rings of **3**, **4**, and **5** exhibit some bond length alternation, similar to the results for benz[*a*]azulene;[3] this behavior is characteristic of polyenes. (Table 1).

TABLE 1. NMR VICINAL COUPLING CONSTANTS OF **3**, **4**, AND **5**

Compound	J_{45}/Hz	J_{78}/Hz	ΔJ/Hz
3	9.0	10.2	1.2
4	9.0	10.2	1.2
5	8.5	10.0	1.5

† 1 mmHg=133.322 Pa.

Experimental

All melting points are uncorrected.

Ethyl 2-Ethoxy Carbonylmethylthio-3-formylazulene-1-carboxylate (**2**). A mixture of ethyl 2-chloro-3-formylazulene-1-carboxylate (51.8 mg), ethyl mercaptoacetate (60 mg), and pyridine (3 ml) was heated at 100 °C on an oil bath for 15 min. After cooling, the reaction mixture was poured into water, acidified with 2 mol dm^{-1} sulfuric acid, and extracted with chloroform. The chloroform layer was dried over anhydrous sodium sulfate and evaporated under reduced pressure. The residue was chromatographed on a silica-gel column with benzene–chloroform (1 : 1). The red effluent was freed from solvent to give **2** (52.4 mg, 76.7%) as red oil, which was used for the next step without further purification.

^{1}H NMR ($CDCl_3$) δ ppm: 1.09 (3H, t, J=7.5 Hz, $SCH_2COOCH_2C\underline{H}_3$), 1.50 (3H, t, J=7.5 Hz, $COOCH_2C\underline{H}_3$), 3.37 (2H, s, $SC\underline{H}_2COOCH_2CH_3$), 4.02 (2H, q, J=7.5 Hz, $SCH_2COOC\underline{H}_2CH_3$), 4.51 (2H, q, J=7.5 Hz, $COOC\underline{H}_2CH_3$), 7.8—8.0 (3H, m, H-5,6,7), 9.4—9.7 (1H, m, H-8 or H-4), 9.8—10.0 (1H, m, H-4 or H-8).

IR ($CDCl_3$): 2992, 1734, 1696, 1652, 1441, 1403, 1195, 647 cm^{-1}.

*Diethyl Azuleno[2,1-*b*]thiophene-2,9-dicarboxylate* (**3**). *a*): Three drops of piperidine were added to a solution of **2** (177.3 mg) in ethanol (17 ml). The mixture was refluxed for 1 h. The reaction mixture was freed from solvent and the residue was chromatographed on a silica-gel column with chloroform. The yellowish brown effluent was evaporated under reduced pressure. The residue was recrystallized from cyclohexane to give **4** (155.6 mg, 92.6%) as yellowish brown needles; mp 136—137 °C.

IR (KBr): 2989, 1695, 1249, 779, 727 cm^{-1}.

ES λ_{max} in cyclohexane ,nm (log ε): 215 (4.27), 252 (4.31), 321 (4.74), 337 (4.80), 348 (4.08), 386 (3.62), 402 (3.80), 409 (3.70), 428 (4.01), 574 (2.45).

^{1}H NMR ($CDCl_3$) δ ppm: 1.44 (3H, t, J=7.0 Hz, 2-$COOCH_2C\underline{H}_3$), 1.51 (3H, t, J=7.0 Hz, 9-$COOCH_2C\underline{H}_3$), 4.40 (2H, q, J=7.0 Hz, 2-$COOC\underline{H}_2CH_3$), 4.43 (2H, q, J=7.0 Hz, 9-$COOC\underline{H}_2CH_3$), 7.2—7.9 (3H, m, H-5,6,7), 8.19 (1H, s, H-3), 8.39 (1H, d, J=9.0 Hz, H-4), 9.43 (1H, d, J=10.2 Hz, H-8).

^{13}C NMR ($CDCl_3$) δ ppm: 14.5 (q), 14.6 (q), 60.3 (t), 61.2 (t), 109.3 (s), 124.6 (d), 128.4 (d), 129.5 (d), 133.6 (d), 133.9 (s), 134.0 (s), 136.4 (d), 137.0 (s), 138.1 (d), 145.2 (s), 153.9 (s), 163.2 (s), 164.1 (s).

Found: C, 65.92; H, 4.85; S, 10.02%. Calcd for $C_{18}H_{16}O_4S$: C, 65.84; H, 4.91; S, 9.76%.

b): Compound **2** (29.9 mg) was dissolved in chloroform and adsorbed on a basic alumina column. After standing overnight, the reaction mixture was eluted with chloroform. From the yellowish brown effluent, **3** was obtained as yellowish brown needles (16 mg, 56.4%); mp 136—137 °C. The IR spectrum was identical with that of a sample prepared by Method *a*) and the mixed melting point was not depressed.

*Ethyl Azuleno[2,1-*b*]thiophene-2-carboxylate* (**4**). A mixture of bis (ethoxycarbonyl) compound (**3**) (121.4 mg) and 100% phosphoric acid (5 ml) was heated at 90 °C for 1 h. After cooling, the reaction mixture was poured into water and extracted with chloroform. The extract was dried, freed

from solvent, and the residue was chromatographed on silica gel. Elution with benzene gave bluish green plates (90 mg, 94.4%); mp 86.5—87.5 °C, which were recrystallized from cyclohexane.

IR (KBr): 2985, 1695, 1510, 1253, 1243, 719 cm^{-1}.

ES λ max in cyclohexane nm (log ε): 216 (4.06), 236 (4.21), 319 (4.82), 332 (4.98), 358 (3.86), 363 (3.56), 376 (3.83), 396 (4.01), 407 (3.65), 420 (4.04), 599 (2.88).

^{1}H NMR ($CDCl_3$) δ ppm: 1.43 (3H, t, J=7.0 Hz, $COOCH_2\underline{CH_3}$), 4.40 (2H, q, J=7.0 Hz, $COO\underline{CH_2}CH_3$), 7.0—7.7 (4H, m, H-5,6,7,9), 8.14 (1H, d, J=10.2 Hz, H-8), 8.33 (1H, dm, J=9.0 Hz, H-4), 8.39 (1H, s, H-3).

^{13}C NMR ($CDCl_3$) δ ppm: 14.5 (q), 61.1 (t), 109.9 (d), 124.5 (d), 125.0 (d), 125.3 (d), 131.5 (d), 132.4 (s), 134.7 (s), 135.8 (d), 135.8 (s), 136.3 (d), 143.8 (s), 152.5 (s), 163.4 (s).

Found: C, 70.25; H, 4.79; S, 12.56%. Calcd for $C_{15}H_{12}O_2S$: C, 70.29; H, 4.72; S, 12.51%.

Azuleno[2,1-b]thiophene (5). *a)*: A mixture of **4** (25 mg) and 100% phosphoric acid was heated at 150 °C for 2 h. After cooling, the reaction mixture was diluted with water and extracted with chloroform. The extract was dried, evaporated under reduced pressure, and the residue was chromatographed on alumina column. From benzene effluent, **5** was obtained as bluish green plates (12 mg, 66.8%); mp 173—174 °C, which were recrystallized from ethanol. The UV spectrum was identical with that of azuleno[2,1-*b*]-thiophene prepared by Matsui *et al.*[1]

^{1}H NMR ($CDCl_3$) δ ppm: 6.9—7.6 (3H, m, H-5,6,7), 7.47 (1H, s, H-9), 7.32 (1H, d, J=5.4 Hz, H-3), 7.69 (1H, d, J=5.4 Hz, H-2), 8.20 (1H, d, J=10.0 Hz, H-8), 8.39 (1H, d, J=8.5 Hz, H-4).

^{13}C NMR ($CDCl_3$) δ ppm: 109.4 (d), 118.6 (d), 122.5 (d), 123.4 (d), 125.5 (d), 131.1 (d), 132.5 (s), 135.7 (d), 136.9 (s), 141.7 (s), 149.7 (s).

b): A mixture of **4** (202 mg), ethanol, and 20% potassium hydroxide aqueous solution was refluxed for 30 min. After removal of the solvent, water was added to the residue. When the solution was made acid with 2 mol dm^{-3} sulfuric acid, a green precipitate separated out. The precipitate was filtered off, washed with a small amount of ethanol to give azuleno-[2,1-*b*]thiophene-2-carboxylic acid as green powder (173 mg, 96.5%); this was used for the next step without further purification.

The carboxylic acid obtained above was heated under reduced pressure (2 mmHg) in a sublimation aparatus. The bluish green crystals was sublimed at 170—180 °C. Recrystallization from ethanol gave bluish green plates (18 mg, 46.1%); mp 173—174 °C. The IR spectrum was identical with that of the sample obtained by Method *a)*, and the mixed melting point was not depressed.

A New Synthetic Route to Electrophilic Cyclopropane Derivatives from Olefins

Nariyoshi KAWABATA,* Shinji YANO, Jiro HASHIMOTO, and Jun-ichi YOSHIDA

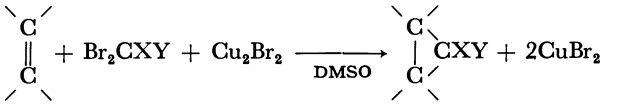
Department of Chemistry, Faculty of Polytechnic Science, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received January 12, 1981)

Synopsis. 1,1-Bis(alkoxycarbonyl)-, 1-alkoxycarbonyl-1-cyano-, and 1,1-dicyanocyclopropane derivatives were obtained in 10—99% yields by the reaction of $Br_2C(COOR)_2$, $Br_2C(CN)(COOR)$, and $KBr[Br_2C(CN)_2]_4$, respectively, with olefins and Cu_2Br_2 in dimethyl sulfoxide (DMSO).

Recently cyclopropane derivatives activated by two electron-withdrawing substituents such as COOR, COR, and CN at geminal position were found to be useful intermediates in organic synthesis.[1] A number of methods exist for the preparation of these electrophilic cyclopropanes.[2] This paper describes a new synthetic route to electrophilic cyclopropane derivatives from olefins by the reaction with organic *gem*-dihalide and Cu_2Br_2 in dimethyl sulfoxide (DMSO).

The reaction of $Br_2C(COOEt)_2$, $Br_2C(CN)(COOEt)$, and $KBr[Br_2C(CN)_2]_4$ with Cu_2Br_2 in the presence of olefins gave the corresponding 1,1-bis(ethoxycarbonyl)-, 1-cyano-1-ethoxycarbonyl-, and 1,1-dicyanocyclopropane derivatives, respectively, in good yields. Some experimental results are given in Table 1. All products were identified by comparison of their ^1H NMR and IR spectra with those of authentic samples, or showed satisfactory analytical data and expected spectra. GLC analysis of the reaction mixture showed that no isomeric olefins were formed.



(X, Y=COOEt, CN)

During the course of reaction Cu_2Br_2 was converted into $CuBr_2$, which was isolated as a coordinated complex with two molecules of DMSO, and identified by comparison of its spectral data with those of an authentic

material.[3]

The new reaction is useful for the synthesis of electrophilic cyclopropane derivatives from olefins (Table 1). The reaction with $Br_2C(COOEt)_2$ gave cyclopropane derivatives in a non-stereospecific way. A *ca.* 1 : 9 mixture of cis and trans isomers of the corresponding cyclopropane derivatives was obtained from both *cis*- and *trans*-β-methylstyrene. No isomerization of *cis*- and *trans*-β-methylstyrene or of *cis*- and *trans*-1,1-bis-(ethoxycarbonyl)-2-methyl-3-phenylcyclopropane was observed under the experimental conditions. The relative reactivity of substituted styrenes in the reaction with $Br_2C(COOEt)_2$ gave a Hammett ρ-value of −0.1. Thus the reaction was concluded to be weakly electrophilic.

In the reaction with $Br_2C(CN)(COOEt)$, two stereoisomers of the cyclopropane derivatives were obtained from styrene and acrylonitrile, the *E* to *Z* isomer ratio being 92 : 8 and 60 : 40, respectively. The relative configuration was determined on the basis of their ^1H NMR spectra. The *E* : *Z* isomer ratios seemed to reflect the thermodynamic stability of the product. However, GLC analysis of the reaction mixture showed only one peak in the cases with cyclooctene and 1-octene. ^1H NMR spectra of the isolated cyclopropane derivatives did not clearly indicate the presence of stereoisomers.

Experimental

Microanalyses were performed at the Elementary Analyses Center of Kyoto University. ^1H NMR spectra were recorded on a Varian Model T-60A spectrometer in CCl_4 or $CDCl_3$ using Me_4Si as an internal standard. IR spectra were recorded on a Hitachi Model 215 grating spectrophtometer, or a Japan Spectroscopic Co. Model DS-402G spectrophotometer. Mass spectra were obtained on a Hitachi Model RMU-6 mass spectrometer, or on a Japan Electron Optics Lab. Model JMS D-300 mass spectrometer at an ionization potential of 24 eV. GLC analyses were carried out on a Shimadzu GC-4B or GC-4C gas chromatograph.

Materials. $Br_2C(COOEt)_2$,[4] $Br_2C(CN)(COOEt)$,[5] and $KBr[Br_2C(CN)_2]_4$[6] were prepared according to the methods reported. *cis*- and *trans*-β-Methylstyrene, *p*-methylstyrene, *p*-chlorostyrene were prepared as reported.[2] DMSO was purified by distillation under reduced pressure.

Procedure. Olefin, organic *gem*-dihalide and Cu_2Br_2 were allowed to react in DMSO at the prescribed temperature with stirring for 2 h. After the reaction, the organic materials were extracted by hexane, benzene, or ethyl acetate from the reaction mixture. Yields were determined by GLC analysis of the organic layer, and the products were isolated by collection from the organic layer by GLC and analyzed. Some 1,1-dicyanocyclopropane derivatives were thermally unstable. In these cases, products were isolated by column chromatography, yields being determined by means of isolation. Results are given in Table 1.

1,1-Bis(ethoxycarbonyl)cyclopropane derivatives were identified by comparison of their spectral data with those of authentic samples.[2] Spectral data of (*E*)- and (*Z*)-1-cyano-1-ethoxycarbonyl-2-phenylcyclopropane were identical with those of authentic substances.[7] Spectral data of 1,1-dicyano-2-phenylcyclopropane were identical with those of an authentic sample.[8,9] Spectral and elementary analyses of the other electrophilic cyclopropane derivatives are given below.

1,2-Dicyano-1-(ethoxycarbonyl)cyclopropane. n_D^{30} 1.4644. Found: C, 58.37; H, 4.87; N, 16.81%. Calcd for $C_8H_8N_2O_2$: C, 58.53; H, 4.91; N, 17.06%. (Received January 30, 1981)

Synopsis. Palladium complex-catalyzed elimination of acetic acid from (2*E*,4*E*)-2,4-hexadienyl acetate and (2*E*, 4*E*, 6*E*)-2,4,6-octatrienyl acetate afforded, respectively, the title conjugated polyenes stereoselectively.

Recently, a simple preparative method for terminal conjugated dienes by palladium complex-catalyzed elimination of acetic acid and phenol from easily available allylic acetates and phenyl ethers, has been developed in this laboratory[1] and by Trost *et al.*[2]

The elimination reaction can be explained *via* the formation of a π-allylic palladium complex by oxidative addition of allylic compounds to Pd(0) species. Elimination of acetic acid or phenol is nonstereoselective insofar as each hydrogen α to the π-allylic system in the complex is eliminated, resulting in the formation of a mixture of (*E*)- and (*Z*)-isomers for simple 1,3-dienes.

This method may be of synthetic value for conjugated polyenes as well, especially if stereochemical limitation can be obviated. We wish to present a stereoselective preparation of (*E*)-1,3,5-hexatriene and (3*E*,5*E*)-1,3,5,7-octatetraene by way of the palladium complex-catalyzed elimination. Pyrolytic routes to these polyenes hitherto reported are usually nonstereoselective.

(2*E*,4*E*)-2,4-Hexadienyl acetate (**1**), derived from commercial (2*E*,4*E*)-2,4-hexadien-1-ol (isomeric purity >98%), was heated at reflux in toluene with palladium(II) acetate (1.0 mol%) and excess triphenylphosphine. 1,3,5-Hexatriene[3,4] was obtained by fractional distillation in 87% yield prior to the distillation of acetic acid eliminated. GLC analysis showed the triene to consist of (*E*)- and (*Z*)-isomers at least in a ratio of 97 : 3. IR spectrum of the product indicated characteristic bands of the (*E*)-isomer.

The Diels-Alder adduct of (*E*)-1,3,5-hexatriene with maleic anhydride was prepared for further structural characterization. ^{13}C NMR data for the adduct, 3-vinyl-1,2,3,6-tetrahydrophthalic anhydride[4] (Table 1) indicate high diastereomeric purity which should arise from (*E*)-triene.

On the other hand, the same procedure as above with use of 1-vinyl-3-butenyl acetate (**2**) afforded the triene in 67% yield. GLC analysis revealed isomeric hexatrienes in the ratio 80 : 20. The (*E*)-isomer as a major component was confirmed by IR spectrum. Nonstereoselective elimination of acetic acid from **2** was found to take place. ^{13}C NMR data of the Diels-Alder adduct obtained with this sample are also given in Table 1. Three pairs of signals, which are unambiguously assigned to C_4, C_5, and C_8, respectively, stem from the adduct of the (*Z*)-triene in addition to that of the (*E*)-isomer.

It is noteworthy that the formal 1,ω-elimination of acetic acid from **1** took place as readily as 1,2-elimination to give (*E*)-hexatriene stereoselectively, whereas the 1,2-elimination from **2** gave an *E*/*Z* mixture. The results are related to the fact that the intermediate π-allylic palladium(II) complexes are apt to take *syn* configuration.

As an extension, (2*E*,4*E*,6*E*)-2,4,6-octatrienyl acetate (**3**) was prepared by the Wittig reaction of (ethoxycarbonylmethylene)triphenylphosphorane with (2*E*,4*E*)-2,4-hexadienal followed by lithium aluminium hydride reduction and acetylation. The trienyl acetate **3** was subjected to palladium complex-catalyzed elimination of acetic acid to give white, waxy crystalline (3*E*,5*E*)-1,3,5,7-octatetraene[5] in 48% yield. IR spectrum of the product indicated the *trans* structure.

Experimental

Materials. (2*E*, 4*E*)-2,4-Hexadienyl acetate (**1**)[6] was prepared by acetylation of commercial (2*E*, 4*E*)-2,4-hexadien-1-ol (6.00 g, 60 mmol) with acetic anhydride (11.4 mL, 120 mmol) and excess pyridine in 82% yield, bp 83—84 °C/19 Torr (1 Torr=133.322 Pa). GLC (PEG 20 M 3 m, at 160 °C) analysis indicated the isomeric purity to be >98%.

1-Vinyl-3-butenyl acetate (**2**) was prepared by the method

reported,[3] bp 56—57 °C/18 Torr.

(2E, 4E, 6E)-2,4,6-Octatrienyl Acetate (3). (i) A mixture of (ethoxycarbonylmethylene)triphenylphosphorane (2.93 g, 8.4 mmol) and freshly distilled (2*E*, 4*E*)-2,4-hexadienal (0.81 g, 8.4 mmol) dissolved in dry benzene (20 mL) was heated under argon atmosphere at 60 °C for 3.5 h. Evaporation of the reaction mixture and trituration of the residue with ether follwed by filtration were repeated three times to give phosphine oxide in 98% combined yield. The final filtrate was evaporated to dryness to give crude waxy ethyl (2*E*, 4*E*, 6*E*)-2,4,6-octatrienoate,[7] 1.30 g (93%). (ii) Lithium aluminium hydride reduction of the ester (1.22 g, 7.3 mmol) and acetylation of the resulting crude 2,4,6-octatrien-1-ol[5c] by the conventional procedure yielded **3**, 0.75 g (67%): bp 86—87 °C/3 Torr; ^{1}H NMR (CCl_4) δ 1.76 (t, J=5.6 Hz, MeCH=), 1.96 (s, MeCO), 4.45 (d, J=5.8 Hz, CH_2O), and 5.4—6.3 (m, olefinic protons); IR (neat) 1740 and 1240 cm^{-1}. GLC (PEG 20 M 3 m, at 180 °C) analysis of **3** appeared to cause significant decomposition.

Palladium Complex-catalyzed Elimination from Allylic Acetates. A typical procedure is as follows. A mixture of **1** (5.61 g, 40 mmol), palladium(II) acetate (91 mg, 0.4 mmol), and triphenylphsophine (1.05 g, 4.0 mmol) dissolved in dry toluene (30 mL) was heated at reflux under argon atmosphere. Low-boiling substances formed soon were fractionated through a column packed with glass helices (8×200 mm) until an azeotropic mixture of acetic acid with toluene was distilled. The distillate (bp 78—90 °C) was fractionated again to give a colorless oil, bp 80—83 °C (lit,[3] bp 80.5 °C), 2.42 g (95% purity by NMR, 87% yield) contaminated with a small amount of toluene and acetic acid. GLC (UCON 3 m, at 45 °C) analysis of the triene indicated that a principal peak is accompanied by a small peak, with a little longer retention time, in a ratio of 97 : 3. IR (neat): Characteristic bands of (*E*)-1,3,5-hexatriene are at 1430, 1010, and 940 cm^{-1}; lit,[8] 1429, 1011, and 941 cm^{-1}.

Similarly, 1,3,5-hexatriene was obtained by use of **2** (4.20 g, 30 mmol), bp 78—83 °C, 1.60 g (67%). GLC analysis of the product indicated that the isomeric composition is 4 : 1: IR (neat) 1430, 1010, and 940 cm^{-1} for the (*E*)-isomer, and 1450, 985, and 820 cm^{-1} for the (*Z*)-isomer; lit,[8] 1451, 987, and 818 cm^{-1}.

The acetate **3** (1.05 g, 6.3 mmol) was similarly heated in diethylene glycol diethyl ether (8 mL) in the presence of palladium(II) acetate (1 mol%) with added triphenylphosphine. Fractional distillation under reduced pressure (113 Torr) gave white, way crystalline (3*E*, 5*E*)-1,3,5,7-octatetraene, 0.33 g (48%), bp 89—93 °C/113 Torr, mp 50 °C; ^{1}H NMR (CCl_4) δ 4.90—5.30 (m, 4H) and 6.13 (br s, 6H); IR (CCl_4) 1010 and 900 cm^{-1} for the (*E*, *E*)-configuration.[5b] Octatetraene is rather unstable in the air, giving an insoluble polymeric material.

Diels-Alder Reaction. A mixture of (*E*)-1,3,5-hexatriene (1.40 g, crude fraction, 85% purity) and excess maleic anhydride (3.92 g, 40 mmol) in dioxane (10 mL) was stirred at room temperature for 3 d. After removal of the solvent under reduced pressure, the residue was chromatographed (silica gel, hexane–ethyl acetate, 10 : 1) to give 3-vinyl-1,2,3,6-tetrahydrophthalic anhydride[4] (1.18 g, 40%).

In the case of an isomeric mixture of (*E*)- and (*Z*)-hexatriene obtained by the elimination of **2** (1.12 g, 8.0 mmol), the crude fraction was heated at 60 °C for 2 d with maleic anhydride (2.94 g, 30 mmol) in dioxane under argon. Chromatographic purification as above gave the adduct (0.54 g, 38%).

^{13}C NMR ($CDCl_3$) data for the purified adducts are given in Table 1. Diels-Alder reaction of the tetraene with excess maleic anhydride in toluene at 60 °C under argon afforded a white powder after chromatographic purification in low yield, mp 136—139 °C (lit,[5a] 238—242 °C). No useful assignment of ^{13}C NMR data for the adduct could be made.

The authors thank Mr. Y. Nakamura for ^{13}C NMR measurements and Mr. Y. Kimura for assisting in the experimental work.

Studies on Biologically Active Pteridines. VII.[1] Absolute Configuration of (−)-6-Methyltetrahydropterin Produced by Enzymic Reduction

Sadao MATSUURA* and Takashi SUGIMOTO

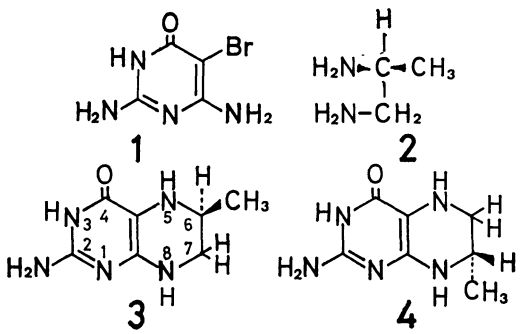
Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received February 19, 1981)

Synopsis. The C-6 configuration of (−)-6-methyltetrahydropterin, produced by enzymic reduction of the 7,8-dihydro precursor, is shown to be *S* by a synthesis. Condensation of 2,4-diamino-5-bromo-6-hydroxypyrimidine with (*S*)-1,2-propanediamine gave (*S*)-6-methyltetrahydropterin. Examination of CD spectra of the 6-methyltetrahydropterins from the two origins led to the above conclusion.

The reduction of 7,8-dihydrobiopterin and 7,8-dihydro-6-methylpterin to the 5,6,7,8-tetrahydro derivatives by the action of dihydrofolate reductase is stereospecific and the (−)-tetrahydropterins thus produced are shown to possess the same configuration at the C-6 chiral center.[2,3] (−)-Tetrahydrobiopterin is the natural cofactor for aromatic amino acid hydroxylases, whereas the C-6 diastereoisomeric (+)-tetrahydrobiopterin shows different cofactor characteristics.[3-5] Because of the indispensable contribution of (−)-tetrahydrobiopterin to the biosynthesis of neurotransmitting serotonin and dopamine, the determination of the C-6 configuration is highly desired and has been studied in several ways.[2,3,6,7] In these studies, the C-6 configuration of the enzymically reduced (−)-6-methyltetrahydropterin was shown to be *S* (and then, by analogy, that of (−)-tetrahydrobiopterin to be *R*), by comparison with a tetrahydroquinoxaline or by transformation into a tetrahydrolumazine or a piperazine. This paper describes a straightforward proof for the C-6 configuration of (−)-6-methyltetrahydropterin as *S* by its synthesis.

Since N-5 unsubstituted tetrahydropterins are notoriously unstable to air oxidation, we first attempted to synthesize a N-5 alkylated derivative of 6-methyltetrahydropterin, such as 5,6,8-trimethyl- or 5,8-dibenzyl-6-methyl-tetrahydropterin. In contrast to the ready formation of 5,8-dimethyl-5,6,7,8-tetrahydropterin[8] by condensation of 2,4-diamino-5-bromo-6-hydroxypyrimidine (**1**) with 1,2-bis(methylamino)ethane, an analogous condensation of **1** with 1,2-bis(methylamino)propane or 1,2-bis(benzylamino)ethane gave a very complex mixture, from which we could detect no tetrahydropterins. Heating of **1** with (*S*)-1,2-propanediamine (**2**) at about 115 °C, however, gave 6- and 7-methylpterins as predominant products. These compounds were



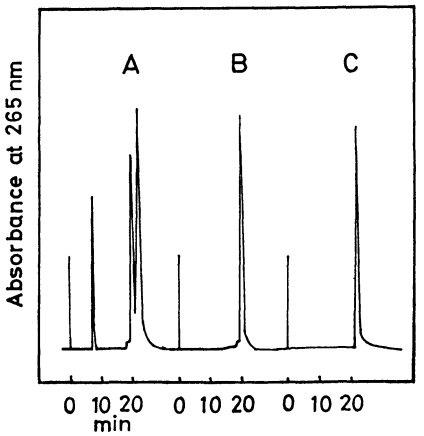


Fig. 1. HPLC of a reaction mixture after CM-Sephadex column separation (A), and authentic (*RS*)-6-methyl- (B) and (*RS*)-7-methyl-tetrahydropterin (C). Column: Whatman Partisil-10 SCX (8.0 mm×250 mm). Eluant, 30 mM† aqueous $NH_4H_2PO_4$ adjusted to pH 3.0 with H_3PO_4. Flow rate 4.0 ml/min.

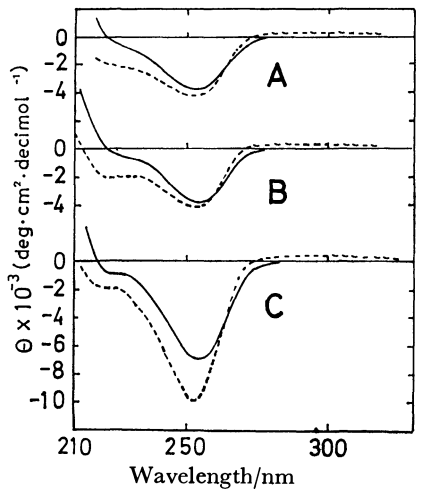

Fig. 2. CD spectra of the enzymically reduced tetrahydro-6-methylpterin[2] (A), synthetic (*S*)-6-methyl- (B), and (*S*)-7-methyl-tetrahydropterin (C). The data were obtained at pH 3.0 (——, monocation) and at H_0 −1.0 (——, dication).

undoubtedly produced by oxidation of the initially formed (*S*)-6-methyl- and (*S*)-7-methyl-5,6,7,8-tetrahydropterins by atmospheric oxygen. This oxidation could be prevented effectively when the condensation was carried out under hydrogen atmosphere. The 6- and 7-methyltetrahydropterins were isolated as a mixture (15% yield, estimated from UV spectra) by chromatography on a Florisil column and subsequently

† 1 M=1 mol dm^{-3}.

on a CM-Sephadex column. Separation of 6- and 7-methyltetrahydropterin from each other was achieved by means of HPLC on a preparative Partisil-10 SCX column (8 mm×250 mm) using an ammonium phosphate buffer (30 mM, pH 3.0) as the solvent. Under the conditions, (*S*)-6-methyl-5,6,7,8-tetrahydropterin (**3**) was eluted a little, but sufficiently, faster than the isomeric (*S*)-7-methyltetrahydropterin (**4**) as shown in Fig. 1. The structure of these compounds were confirmed by comparing their chromatograms (HPLC) and UV spectra with those of the authentic racemates.[9,10]

The CD spectra of (*S*)-6-methyltetrahydropterin (**3**) were found superimposable with those of the enzymatically reduced (−)-6-methyltetrahydropterin[2] as shown in Fig. 2 at two different pH values, *i. e.* pH 3.0 (monocation) and H_0 −1.0 (dication). (*S*)-7-Methyltetrahydropterin (**4**) also showed a negative Cotton effect in CD spectra (Fig. 2) with a trough at a wavelength slightly longer than the isomer (**3**).

The results described here clearly prove that the C-6 configuration of (−)-6-methyltetrahydropterin is *S*, and accordingly that of (−)-tetrahydrobiopterin is *R*, which is consistent with the previous conclusions.[2,3,6,7]

Experimental

The UV spectra were measured on a Shimadzu UV-300 spectrometer, and the CD spectra on a JASCO J-40A recording spectropolarimeter equipped with a JASCO J-PRY data processor. The high-performance liquid chromatography was carried out using a JASCO TRI ROTAR on a Partisil-10 SCX column (8.0 mm×250 mm), which was eluted with a 30 mM ammonium phosphate (pH 3.0) buffer (flow rate 4.0 ml/min) and detected on a JASCO UVIDEC 100-II spectrometer. The retention time was determined by means of a SYSTEM INSTRUMENTS model 500E integrator.

(S)-6-Methyl-5,6,7,8-tetrahydropterin (3) and the *(S)-7-Methyl Isomer (4)*. A mixture of 2,4-diamino-5-bromo-6-hydroxypyrimidine[11] (1.0 g), (*S*)-1,2-propanediamine[12] (4.0 g), and acetic acid (0.7 g) was heated at 115 °C under hydrogen atmosphere for 7 h. The excess amine was removed by distillation under diminished pressure. The residue was dissolved in water (5 ml) and made acid with acetic acid. The solution was fractionated on a Florisil column (20 mm× 80 mm), eluted by 0.3 M acetic acid. The eluate was concentrated to about 10 ml and then passed through a CM-Sephadex column (20 mm×250 mm). The column was washed with water (1000 ml). The tetrahydropterins were eluted gradiently by 0—0.1 M hydrochloric acid (100 ml). The yield of the tetrahydropterins, as a mixture, was estimated to be 15% from the UV absorbance at 265 nm of the pooled eluate. The eluate was concentrated to about 6 ml under reduced pressure. A 0.5 ml aliquot of the concentrate was injected to a preparative Partisil-10 SCX column (8 mm×250 mm) and eluted with the above mentioned ammonium phosphate buffer (4.0 ml/min) to give (*S*)-6-methyltetrahydropterin (retention time 21.5 min) and the (*S*)-7-methyl isomer (retention time 22.7 min). The pooled eluates of each fraction were used for measuring the UV and CD spectra.

Preparation of Aryl Hydrazonates and 1,2-Diacylhydrazines by Phase Transfer Catalysis

Ahmad Sami SHAWALI,* Hamdi Mahmoud HASSANEEN,† Richard PAGNI,† and Mourad Sherif SHERIF

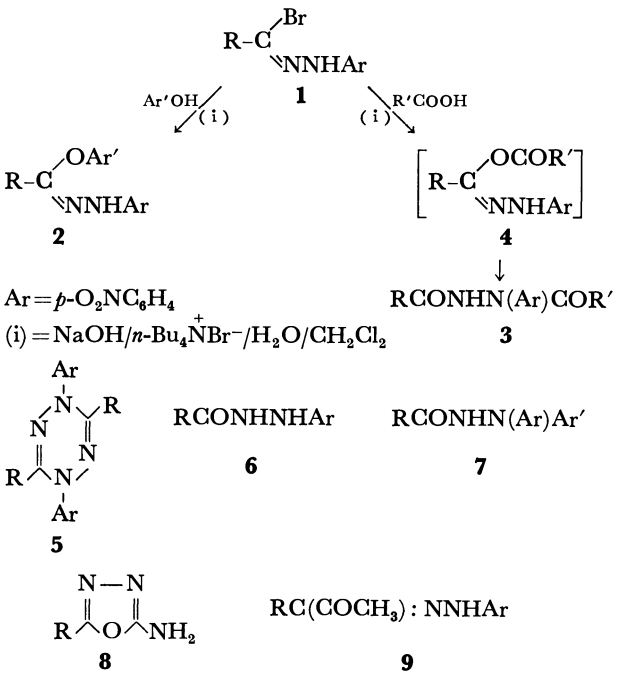
Department of Chemistry, Faculty of Science, University of Cairo, Giza, Egypt

†*Department of Chemistry, The University of Tennessee, Knoxville, Tennessee 37916, U.S.A.*

(Received October 21, 1980)

Synopsis. A series of aryl hydrazonates has been prepared in excellent yield (>90%) by phase-transfer-catalysis technique from the corresponding phenol and hydrazonoyl bromides in dichloromethane in the presence of tetrabutylammonium iodide. 1,2-Diacyl derivatives of arylhydrazines were also prepared by the same technique using carboxylic acids in place of phenols.

Recently the phase-transfer-catalysis as a synthetic tool has attracted the attention of several investigators.[1,2] We have extended the application of this technique to the preparation of aryl hydrazonates (**2**) and 1,2-diacylhydrazines (**3**) by the reaction of hydrazonoyl bromides (**1**) with phenols and carboxylic acids, respectively. In both cases tetrabutylammonium iodide was used as the phase transfer catalyst (Scheme 1). Both esters **2** and hydrazides **3** with ortho halogen atom in the *N*-aryl moiety proved useful in synthesis of 4*H*-1,3,4-benzoxadiazine derivatives.[3] The results are given herewith.



Scheme 1.

Results and Discussion

Treatment of **1** and phenol or naphthol with tetrabutylammonium iodide and sodium hydroxide in dichloromethane at room temperature affords the corresponding aryl hydrazonates (**2**) in 91—96% yields. Previously reported aryl hydrazonates were prepared by treating hydrazonoyl halides (**1**) with sodium phenolates in ethanol[4] or in benzene.[5,6] Alternatively, a mixture of hydrazonoyl halide (**1**) and phenol is treated with triethylamine in benzene[6,7] to give **2**. Reaction of **1** with phenol in the presence of sodium acetate was reported to give **3** (R'=CH_3) instead of **2**.[8] The yield of **2** prepared by either of the foregoing procedures did not exceed 65%. The phase transfer catalysis method described here seems to be more convenient and leads to excellent yields of **2**, eliminating the formation of tetrazines (**5**) or hydrazides (**6**) as competing reaction products. The structures of the esters prepared (Table 1) were confirmed by elemental analysis and spectral data. For example,

TABLE 1. ARYL HYDRAZONATES, **2**

the infrared spectra of **2** reveal, in each case, two characteristic bands near 1255 and 1070 cm^{-1} assignable to an aryl ether linkage. Their electronic absorption spectra in ethanol are of typical hydrazones. The structures of **2** were also substantiated by the identification of 1,1-diaryl-2-acylhydrazines (**7**) obtained by thermolysis of **2** in xylene.[4,7]

1,2-Diacylhydrazines (**3**) (R′=CH_3) are usually prepared by treatment of hydrazonoyl halides (**1**) with sodium acetate in acetic acid or in water.[9–11] However, this method leads in some cases to hydrolysis product **6** or intramolecular nucleophilic substitution products, for example **8**.[12,13] Ciusa and Mega[14] claimed the formation of **9** by treatment of **1** (R=C_6H_5, Ar=2-Br, 4-$NO_2C_6H_4$) with sodium acetate. We have found that treatment of a mixture of **1** and carboxylic acid with tetrabutylammonium iodide and sodium hydroxide in dichloromethane at room temperature eliminates all such side reactions, giving **3** in yields higher than 93%. In this reaction, the initially formed hydrazonoyl carboxylate **4** undergoes a rapid 1,3-acyl migration to give **3**.[15] All compounds in series **3** exhibit in their infrared spectra two CO bands near 1675 and 1685 cm^{-1} and an NH band near 3250 cm^{-1}. The new 1,2-diacyl-1-aryl hydrazines (**3**) prepared by phase transfer catalysis method are given in Table 2.

Experimental

All melting points are uncorrected. Microanalyses were performed at Galbraith Laboratories, Inc., Knoxville, Tennessee, U. S. A. The IR and UV spectra were recorded on Pye-Unicam spectrophotometers, models SP1000 and SP8000, respectively.

Aldehyde *p*-nitrophenylhydrazones were converted into the corresponding hydrazonoyl bromides (**1**) by reaction with bromine in glacial acetic acid.[4]

Aryl Hydrazonates. As a general procedure a solution of hydrazonoyl bromide (1.6 mmol) in dichloromethane (15 ml) is added to a rapidly stirred solution of the appropriate phenol (2.1 mmol), sodium hydroxide (0.082 g, 2.1 mmol) and tetrabutylammonium iodide (0.022 g, 0.06 mmol) in water (15 ml). The mixture was stirred at room temperature for 1 h and then diluted with chloroform (25 ml). The organic layer was separated and washed successively with 5% sodium hydroxide solution and water, dried with anhydrous sodium sulfate. The solvent was removed and the residue was triturated with methanol. The crude solid formed was collected and crystallized from acetic acid or ethanol to give the corresponding aryl hydrazonates (Table 1).

1,2-Diacyl-1-(p-nitrophenyl)hydrazines (3). General Method: To a rapidly stirred solution of carboxylic acid (1.4 mmol), sodium hydroxide (0.055 g, 1.4 mmol), and tetrabutylammonium iodide (0.011 g, 0.03 mmol) in water (15 ml) was added the appropriate hydrazonoyl bromide (1.3 mmol) in dichloromethane (15 ml) and the mixture was stirred at room temperature for 1 h. The mixture was diluted with chloroform (30 ml) and the organic layer separated, dried with anhydrous sodium sulfate, and evaporated. The crude product was collected, washed with water and crystallized from acetic acid, to give hydrazides **3** in 93—97% yields (Table 2).

The Reaction of Dibenzylthiocarbamoyl Chloride with Sodium Nitrite

Masayuki NAKAJIMA, Rose Ann HERGET, and Jean-Pierre ANSELME*

Department of Chemistry, University of Massachusetts at Boston, Harbor Campus, Boston, MA 02125, U.S.A.

(Received November 12, 1980)

Synopsis. The reaction of dibenzylthiocarbamoyl chloride with sodium nitrite in acetonitrile at room temperature yields *N*-nitrosodibenzylamine, dibenzylcarbamoyl chloride, bis(dibenzylcarbamoyl) disulfide, benzaldehyde, and benzyl isothiocyanate; possible mechanisms for the formation of these products are suggested.

The quantitative formation of *N*-nitrosodibenzylamine (**4**) from the nitrosative decarboxylation of dibenzylcarbamoyl chloride (**5**) with sodium nitrite in acetonitrile was recently reported.[1] In the interest of exploring the use of related systems for the formation of nitrogen-nitrogen bonds, the study of the action of sodium nitrite in dibenzylthiocarbamoyl chloride (**1**) was undertaken.

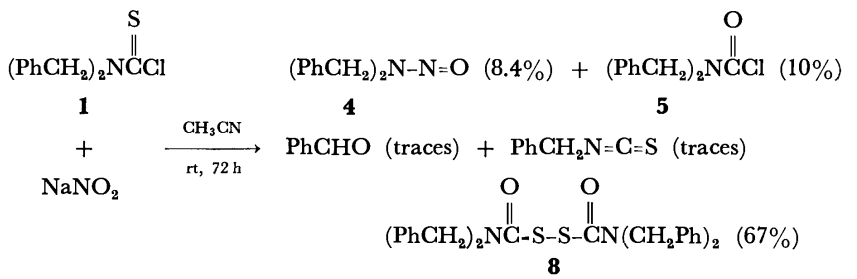
Although the NMR spectrum of the reaction mixture of equimolar amounts of **1** and sodium nitrite in dry acetonitrile indicated that the reaction was not as clean as that of **5** with sodium nitrite,[1] the presence of benzaldehyde and *N*-nitrosodibenzylamine (**4**) in the crude reaction mixture was established; beside carbonyl bands at 1645, 1675, 1695 cm^{-1}, the IR spectrum displayed absorptions at 2180—2100 cm^{-1} which suggested the presence of a compound with a cumulative bond system. Chromatography of the mixture on silica gel led to the isolation and characterization on benzaldehyde, *N*-nitrosodibenzylamine, dibenzylcarbamoyl chloride (**5**) and the compound which displayed the absorption at 2180—2100 cm^{-1}; in addition an unknown soild, mp 132.5—133 °C, was isolated; its elemental analysis indicated the empirical formula to be $C_{15}H_{14}NOS$; the presence of a carbonyl group,[2] its NMR and mass spectra,[3] established the structure of bis(dibenzylcarbamoyl) disulfide (**8**). The compound displaying the strong absorption at 2180—2100 cm^{-1} was shown to be benzyl isothiocyanate (**6**) by comparison with an authentic sample.[4] Once the identity of the products was established, the reaction was repeated and the yield of each product (except for **8** which was isolated and weighed) was determined by the integration of the NMR spectrum of the crude reaction product.

The formation of **8** may be understood in terms of an oxygen to sulfur migration of the nitroso group of **2**, followed by the loss of nitrogen monoxide from **3** and generation of the carbamoylthio radical (**7**) which could then dimerize to **8**. Although *N*-nitrosodibenzylamine (**4**) may be formed by loss of COS from **2** as anticipated, it could also arise from the action of nitrite ion on **3** and on **5**.[1] However, control experiments showed that **8** did not react either with chloride or nitrite ions. A reaction run with a 1.4 excess of sodium nitrite for four days showed a dramatic increase in the yield of **4** (39%) with a concurrent decrease in the yield of **8** (43%); the yield of **5** was unchanged. The same reaction carried out overnight gave **8** as the major product (63%) with **4** and **5** being formed in only minor amounts. Similarly the formation of **5** could be rationalized by displacement of chloride ion on **3**. Although direct displacement of nitrite ion on **1** may account for the formation of benzyl isothiocyanate (Scheme 2, path a), an alternate path involves **2** as the intermediate which undergoes an internal displacement *via* a six-membered ring transition state leading to benzyl isothiocyanate (**6**) and benzyl nitrite (Scheme 2, path b); the latter compound is known to decompose to benzaldehyde;[5] authentic benzyl nitrite reacted with chloride ion to give benzaldehyde. Scheme 3 summarizes the possible paths leading to the observed products.

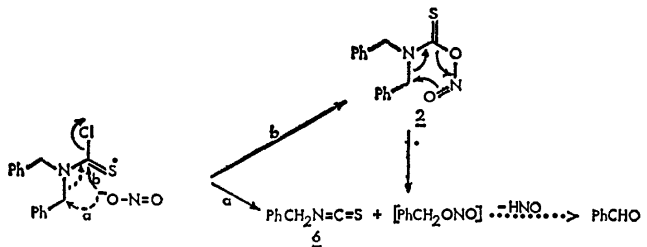
Experimental

All mps and bps are uncorrected. Infrared spectra were obtained on a Perkin-Elmer Infracord and NMR spectra were determined on CCl_4 or $CDCl_3$ on a R-24 Hitachi-Perkin Elmer Spectrometer using TMS as an internal standard. Mass spectra were obtained at Chemical Spectrometry Laboratory of Massachusetts Institute of Technology and taken on Varian Mat 44 mass spectrometer. A low energy (50 eV) spectrum was obtained on a Hitachi-Perkin Elmer mass spectrometer model RMU-6L.

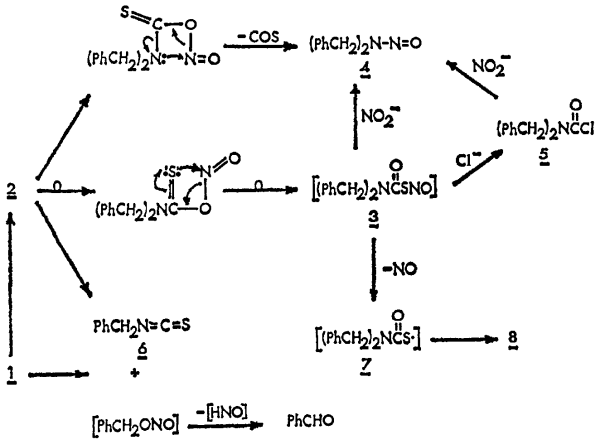
Dibenzylthiocarbamoyl Chloride (1). To a solution of 85% (w/w) thiophosgene (10.5 g, 77 mmol) in anhydrous ether (75 ml) at −5 °C, was added a solution of dibenzylamine (30.5 g, 155 mmol) in anhydrous ether (75 ml) with a mechanical stirring. An additional 50 ml of anhydrous ether was added, and the mixture was stirred at ambient temperature overnight. The precipitated dibenzylamine hydrochloride was collected, and the filtrate was evaported to dryness at room temperature *in vacuo*. The solid residue



Scheme 1.



Scheme 2.



Scheme 3.

was crystallized from chloroform–ligroin mixture to yield 10.6 g (53%) of **1**, mp 43—45 °C, lit,[6] mp 49 °C.

Reactions of ***1*** *with Sodium Nitrite.* A mixture of dibenzylthiocarbamoyl chloride (3.2 g, 12 mmol) and sodium nitrite (1.0 g, 14.5 mmol) in dry acetonitrile (40 ml) was stirred overnight in a flask covered with aluminum foil and connected to a gas bubbler. The insoluble inorganic material was filtered, and the acetonitrile solution was evaporated *in vacuo* to leave a residue, which was deposited on a preparative column chromatography (silica gel mesh 60—200, g). Elution with a mixture of benzene and hexanes (1:2 v/v, 150 ml) gave benzyl isothiocyanate (20 mg) whose IR and NMR spectra were superimposable upon those of an authentic sample.[4,7] Further elution (200 ml) afforded dibenzylcarbamoyl chloride (566 mg, 2.2 mmol, 19%), identical to an authentic sample.[1] Continued elution with the same mixture (100 ml) and with a mixture of benzene and hexanes (1:1 v/v, 100 ml) yielded *N*-nitrosodibenzylamine (**4**, 425 mg, 1.9 mmol, 16%) and trace amounts of benzaldehyde; their structures were established by their spectra data and by addition of authentic samples to the NMR samples. Elution with benzene–hexane (1:1 v/v, 100 ml) and with benzene (200 ml) gave crude bis(dibenzylcarbamoyl) disulfide (797 mg, 1.6 mmol, 31%) mp 130—131.5 °C. The crude disulfide was recrystallized from dichloromethane–hexane mixture to afford colorless crystals, mp 132.5—133 °C. IR (KBr): 1675 cm^{-1} (>C=O); NMR ($CDCl_3$): δ 7.30 (s, ArH, 20H), δ 4.60 (s, $PhCH_2$ 8H); mass spectrum [*m/e*, (relative intensity)]: 512 (very weak),[3] 256 (0.05), 224 (6), 196 (0.3), 91 (100). Found: C, 70.38; H, 5.75; N, 5.33 S, 12.46. Calcd for $C_{30}H_{28}N_2O_2S_2$: C, 70.28; H, 5.50; N, 5.47; S, 12.51.

The reaction was repeated using 11.7 mmol of **1** and 11.7 mmol of sodium nitrite. After overnight stirring, the acetonitrile was evaporated *in vacuo* to leave a solid residue which was stirred with a mixture (20 ml) of ether and petroleum ether (1:3 v/v). The insoluble solid left after the first extraction was stirred with dichloromethane (25 ml×2). Evaporation of dichloromethane from the second extract gave bis(dibenzylcarbamoyl) disulfide (1.97 g, 3.8 mmol, 65%). Evaporation of the solvents from the first extract gave a residue (0.7 g), which was chromatographed on silica gel (mesh 60—200, 20 g). Elution with benzene–hexane mixture (1:1 v/v, 150 ml) gave a mixture of dibenzylcarbamoyl chloride (1.2 mmol, 10%) and *N*-nitrosodibenzylamine (0.1 mmol, 0.8%) whose molar ratio was estimated by the NMR integration under benzyl protons. Continued elution with the same mixture (150 ml) yielded *N*-nitrosodibenzylamine (0.9 mmol, 7.7%). Elution with benzene (200 ml) afforded bis(dibenzylcarbamoyl) disulfide (38 mg, 0.07 mmol, 1.2%).

The same reaction was carried out using 6.2 mmol of dibenzylthiocarbamoyl chloride and 8.7 mmol of sodium nitrite for 4 d. The acetonitrile was evaporated under reduced pressure to give a solid residue. The solid was stirred with ether (25 ml), and the solid left after the first extraction was stirred with dichloromethane (25 ml×2). Evaporation of dichloromethane from the second extract afforded bis(dibenzylcarbamoyl) disulfide (411 mg, 0.8 mmol, 26%). Evaporation of ether from the first extract gave a residue (1.06 g) which was stirred with a mixture (25 ml) of petroleum ether and ether (2:1 v/v) to leave a mixture (322 mg) of the disulfide (0.48 mmol, 15.5%) and *N*-nitrosodibenzylamine (0.34 mmol, 5.5%). The extract was concentrated under reduced pressure to yield a mixture of dibenzylcarbamoyl chloride (0.6 mmol, 10%) and *N*-nitrosodibenzylamine (2.1 mmol, 33%) whose molar ratio was estimated by the NMR integration under benzyl protons.

Control Experiments. Reaction of Bis(dibenzylcarbamoyl) Disulfide with Sodium Chloride: A mixture of the disulfide (200 mg) and sodium chloride (1.0 g) in a mixture of acetonitrile (20 ml) and dichloromethane (5 ml) was stirred at room temperature overnight. Inorganic material was filtered, and filtrate was concentrated on a rotary evaporator to give a quantitative recovery of the disulfide.

Reaction of Bis(dibenzylcarbamoyl) Disulfide with Sodium Nitrite: A mixture of the disulfide (76 mg) and sodium nitrite (1.0 g) in acetonitrile (30 ml) was stirred at room temperature for 3 d. The mixture was filtered, and washed with dichloromethane (50 ml). The acetonitrile filtrate and the dichloromethane solution were combined and concentrated under reduced pressure to afford the unreacted disulfide (66 mg) in 86% recovery.

Properties of Polyelectrolyte Complexes Consisting of [2-(Diethylamino)-ethyl]dextran Hydrochloride, Carboxymethyldextran, and Sodium Dextran Sulfate for Clot Formation *in Vitro*

Yasuo KIKUCHI* and Koji SHIMIZU

Faculty of Engineering, Ōita University, 700-Dannoharu, Ōita 870

(Received July 29, 1980)

Synopsis. A polyelectrolyte complex (PEC) prepared at higher hydrogen ion concentration enhanced the coagulation of blood, whereas PEC prepared at lower hydrogen ion concentration prevented coagulation of blood. This difference sholud be attributed to the difference in the molecular structures of the PEC prepared.

The mixing of oppositely charged polyelectrolytes in solution leads to the formation of a complex.[1] Many reports[2,3] have dealts with the polyelectrolyte interaction between polysaccharides, or between polysaccharide and synthetic macromolecules and their properties. The biomedical characteristics are important in relation to biological systems, membranes, and industrial applications.[4]

We have reported the novel chemical reaction, structure, and properties of polyelectrolyte complexes containing three materials,[5-7] and the clot formation of these polyelectrolyte complex *in vitro*.[5,6] This note deals with the attractive results for clot formation *in vitro* of the novel polyelectrolyte complexes (PEC) consisting of three materials, which have been reported in a previous paper.[7]

Experimental

The materials of [2-(diethylamino)ethyl]dextran hydrochloride (EA), sodium dextran sulfate (DS), and sodium carboxymethyldextran (CMD) and the general experimental procedures, the apparatus and the chemical analyses were the same as those described in the previous paper.[7]

ACD blood samples of O and A type were provided from the Red Cross Hospital Blood Center, Japan and kept in a thermostat at 4—6 °C. The storage time of 0 type ACD blood was 10 d; that of A type ACD blood was 5 d. The ACD blood was prepared by adding the blood to an anticoagulant citrate dextrose solution consisting of sodium citrate, citric acid and dextrose. The blood test was carried out according to the procedure of Imai and Nose[8]: a polymer blend of 80 mg PEC and 320 mg poly (vinyl chloride) in 1-C and 1-D (Table 1 in ref. 8) was pressed (8.5 t/4.9 cm^2) under vacuum for 5 min to make a sample tablet; in series 2—5, the PEC of 5 mg was coated on a sample tablet by pressing (8 t/4.9 cm^2) under vacuum for 5 min after 400 mg poly (vinyl chloride) was pressed (2 t/4.9 cm^2) for 15 s under vacuum.

Experimental conditions and yields in the preparation of PEC, and elementary analyses and composition of PEC, are given in Tables 1 and 2 of the previous paper.[7] As seen in these tables, the hydrogen ion concentration and the mole ratio of mixture solution (DS+CMD) to EA solution in the reaction mixture both played important roles in changing the ratio of the mixture solution to that of EA in the PEC produced. However, all the PEC were found to consist of the three materials, EA, CMD, and DS, by IR spectra, even though precipitates did not form in the reaction mixtures of EA and CMD at higher hydrogen ion concentration of the reaction system (pH$<$2).

The IR spectra and content in CMD of PEC were described in the previous paper.[7] That is, the localized interactions between -OH and $-OSO_3H$ groups in the 1, 2, and 3 series would result from the formation of $-SO_3H$ groups. In other words, the long chains on the three materials having the same dextran ring and the intermolecular hydrogen bonds between OH groups for PEC may be broken at high hydrogen ion concentraiton and consequently bonds will form between $-OSO_3H$ and -OH groups. Furthermore, the carboxy groups in the PEC of 1, 2, and 3 series existed as undissociated -COOH. Actually, the PEC in 4 and 5 series differed appreciably from the PEC in 1 and 2 series in such properties as sulfur content, solubility, and color reaction with Toluidine Blue, as described previously. From those results, the structures of PEC were estimated as follows: the PEC prepared at higher hydrogen ion concentration consisted of both COOH groups and a great number of $-OSO_3H$ groups (4%$>$1%$>$ pH 2 HCl solution of reaction system); the molecular weight of the PEC prepared became smaller because of the breaking of long chains of the materials; those prepared at pH 6.5 or 11.0 were not composed of the -COOH and $-OSO_3H$ groups in PEC; and in addition, the content of CMD in PEC became greater with an increase in hydrogen ion concentration.

The results in three-component solvents show that there is a small region in the solvent composition field where the complex remain in solution to yield a homogenous, transparent, viscous syrup. Phase diagrams were not obtained in the PEC

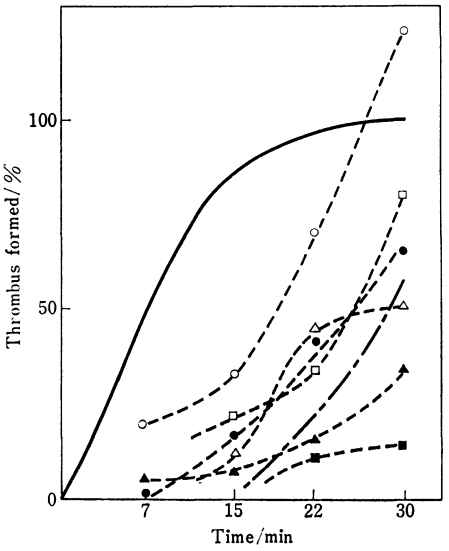

Fig. 1. Percentage of the thrombus formed on polyelectrolyte complexes compared with that on glass after a lapse of 30 min as a criterion.
Storage time of 0 type blood: 10 d, ——: glass, — - —: poly (vinyl chloride). ···□···: 1-C, ···○···: 1-D, ···●···: 2-D, ···▲···: 3-D, ···■···: 4-D, ···△···: 5-C. Sample codes 1-C, 1-D, 2-D, 3-D, 4-D, and 5-C correspond to those in Table 1 in the previous paper.

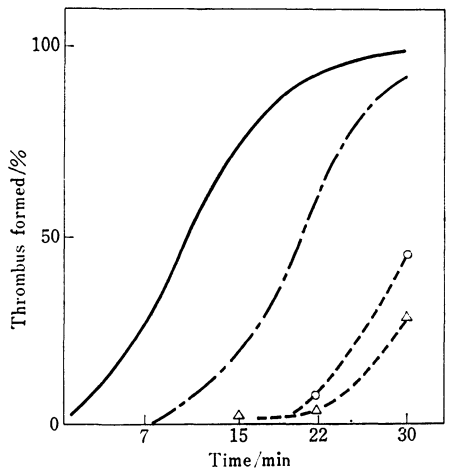

Fig. 2. Percentage of the thrombus formed on polyelectrolyte complexes compared with that on glass after a lapse of 30 min as a criterion.
Storage time of A type blood: 5 d, ——: glass, — — —: poly (vinyl chloride). ···○···: 3-C, ···△···: 5-D. Sample codes 3-C and 5-D correspond to those in Table 1 in the previous paper.

except for 1-C and 1-D, but the PEC in 2-D dissolved partially in the three-component solvent metnioned above. The experimental results in which the PEC in 1 series or 2 series dissolved or partially dissolved in the three-component solvent, and also the colored reaction with Toluidine Blue[7] in PEC, strongly support the difference in the molecular structure according to the experimental conditions of hydrogen ion concentration mentioned above.

Blood tests were performed on PEC (1-C, 1-D, 2-D, 3-C, 3-D, 4-D, 5-C, 5-D) listed in the previous paper[7] by measuring gravimetrically[8] the amount of thrombus formed at appropriate time intervals, after adding $CaCl_2$ solution (0.1 M, 0.02 ml;= 1 mol dm^{-3}) to ACD blood (0.2 ml, O or A type, storage time: 10 or 5 d) which had been in contact with test samples. The blood clotting test by coating on PEC tablet could not be performed on the PEC prepared in 4% hydrochloric acid solution (1-C, 1-D) because of the soaking of blood into the tablet. Therefore, tests were performed on a tablet of polymer blend of PEC and poly(vinyl chloride). A firm clot did not form even after 10 min with PEC of 3, 4, or 5 series except with 1-C, 1-D, and 2-D complexes. It may be noted that the PEC in 3,4, and 5 series suppressed the coagulation of blood considerably. On the other hand, the PEC in 1 series somewhat enhanced the coagulation of blood, as seen in Figs. 1 and 2, considering the amount of poly(vinyl chloride) in a tablet was 4 times as much as the PEC and the amounts of thrombus were larger than that formed on poly (vinyl chloride) tablets. Moreover, it was found that the quantities of the clot on the PEC tablet formed in high hydrogen ion concentration are somewhat greater than those on that formed in lower hydrogen ion concentration, although the contents of DS of PEC in 1, 2, and 3 series were greater than those in 4 and 5 series. Similarly, these experimental results strongly support the difference in molecular structure according to the experimental conditions of hydrogen ion concentration mentioned above. Thus, it has been well confirmed by the experimental results that the difference in the character of coagulation of blood should be attributed to the difference in the molecular structure of PEC prepared as mentioned above.

The likely mechanism of enhancement of coagulation appears to be the following: the factors of coagulation in blood were activated by the interactions of -COOH and $-OSO_3H$ groups with blood in PEC. On the other hand, as seen in the colorimetric reaction of Toluidine Blue, the mechanism of suppression of coagulation may be related to the possibility that negative charges such as $-COO^-$ and $-SO_3^-$ groups exist actively on the surface of PEC.[9]

Finally, it is concluded that the preparation of the described PEC offers an important reservoir of materials whose properties may be tailored according to each requirement.

Stabilization of Normal Methyl Radicals after γ-Radiolysis at 300 K

Duro A. ODUWOLE* and Barrie WISEALL†

Department of Chemistry, Queen Mary College, Mile End Road, London, El 4NS, England

†*Department of Chemistry, City of London Polytechnic, Jewry Street, London, EC3 2EY, England*

(Received September 16, 1980)

Synopsis. Radiolytically produced normal methyl radicals are stabilized on solid surfaces at room temperature for the first time. The remarkable stability of this species on basic and neutral alumina surfaces at 300 K and in the presence of oxygen makes this system potentially useful as an intermediate in organic synthesis.

Since Turkevich and Fujita[1] first published the stabilization of normal methyl radicals (Me_n, $a \simeq 2.3$ mT) on porous Vycor glass, there have been several investigations of this system.[2-5] Such studies have shown that unlike the photolytically produced Me_n radical, the Me_n radical produced radiolytically at liquid nitrogen temperatures is neither observed at room temperature nor is the radical observed directly after radiolysis at room temperature. No suggestion has been put forward to explain this anomaly. In the course of our studies on the radiolysis of adsorbed species on alumina surfaces we succeeded in stabilizing Me_n radicals directly after radiolysis of adsorbed methyl iodide on basic and neutral alumina at 300 K. The line widths, hyperfine splitting and g values are $\simeq 0.10$ mT, 2.25 ± 0.005 mT and 2.0021 ± 0.0002 respectively, in good agreement with known data for the photolytically produced radical stabilized on other adsorbents.

Chromatographic grades aluminium oxides obtained from Hopkin and William (codes 128400-active basic, 128700-active neutral and 1287.50-acidic), Merck (codes 1076-basic, 1077-neutral and 1078-acidic) British Drug House (code 15139-neutral) and Woelm of Germany (code W200-basic) were used in this investigation; all were specified as γ-alumina and Brockmann activity=1. These oxides were initially heated in oxygen at 680 K and then under vacuum at $\simeq$900 K for 5 h. The samples were given an approximate 2% surface coating of methyl iodide at room temperature and sealed in vitreosil/pyrex ESR cells as generally described by other workers.[1-4] Surfaces given larger MeI coverages gave an unstable broad ESR signal (on radiolysis) having a line width of $\simeq 1.5$ mT and a mean life time of $\simeq 2$ h at room temperature. Samples were mixed thoroughly and were normally given a γ-dose of 250 krad, at room temperature, from a ^{60}Co source, although a dose of 100 krad produced signals having an adequate signal to noise ratio. Irradiation induced defects in the cells were flame annealed from the cavity section before transferring the sample. ESR measurements were made on a Decca X-3 spectrometer, all the hyperfine components of the spectrum being measured with respect to line widths, splittings and intensities.

The Me_n radical thus formed on basic and neutral alumina surfaces was found to be remarkably stable over several months at room temperature and we were able to study its reactivity towards various additives (Table 1). The results are contrary to those observed by Turkevich and Fujita[1] who found that the Me_n radical produced by photolysis of methyl iodide adsorbed on porous Vycor glass at room temperature reacted very rapidly with oxygen and hydrogen.

The decay of the Me_n radical *in vacuo* as a function of temperature (Fig. 1), shows a cascade effect at each temperature with an initial relatively rapid decay followed by a levelling off to a value dependent on the temperature. This result suggests that there is a continuum of activation energies for decay rather than the discrete activation energies proposed by Joppien and Willard.[3] This interpretation is in accord with that of Fujimoto *et al.*[2] who observed such a cascade effect in the decay of photolytically produced Me_n radicals on porous Vycor glass above 77 K.

Measurements of the line widths at liquid nitrogen temperatures showed a generalised broadening effect

Table 1. The effect of additives on the yield of Me_n radicals formed by radiolysis of adsorbed methyl iodide on basic-Al_2O_3 at 300 K

Additive	Me_n Signal intensity/%[c]	
	a)	b)
Oxygen	95	96
Hydrogen	74	81
Water vapour[d]	13	72

a) Additive present during radiolysis. b) Additive introduced after radiolysis. c) Yield of unadulterated sample *in vacuo*=100%. d) These measurements were made at 260 K to compensate for the dielectric loss of H_2O.

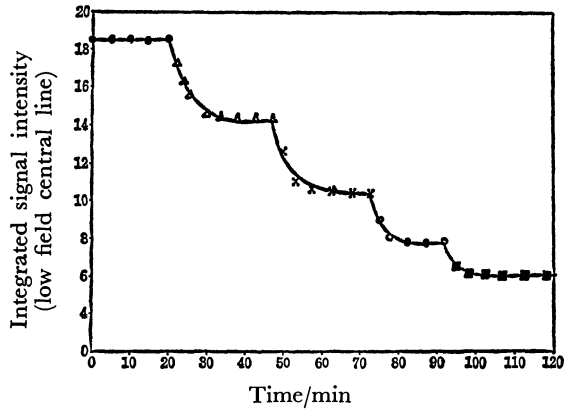

Fig. 1. The decay at elevated temperatures of Me_n radicals radiolytically produced on basic-Al_2O_3 at 300 K.
●: 293 K, △: 323 K, ×: 373 K, ○: 423 K, ■: 473 K.

(of all the component lines) to a value of $\simeq$2.5 mT, suggesting that unlike the Me_n radical trapped on silica gel[5,6] and on porous Vycor glass,[1] the species on alumina is immobilised on the surface.

Failure to observe the radical at room temperature on acidic alumina and other acidic surfaces such as silica gel and porous Vycor glass, suggests that the radical is perturbed under these conditions. Although it is believed that the acidity of the latter surfaces is very much weaker than that of γ-alumina, significantly increased acidity of these surfaces as a result of exposure to ionizing radiation has been reported previously.[7] This irradiation induced acidity may well preclude the stabilization of Me_n radical. A study of these surfaces by the present authors[8] shows that an irradiation induced defect interacts with Me_n radicals stabilized on them at liquid nitrogen temperature to produce line broadening and other secondary effects, and persists to above 300 K; this has a g value of 2.0022 ± 0.0001, suggesting that it may be due to trapped electrons. The absence of such a defect signal on the alumina surfaces would enhance stabilization of the radical.

The above results, showing the remarkable stability of radiolytically produced Me_n radical on alumina surfaces at room temperature and in oxygen, make this system potentially useful as an intermediate in organic synthesis. A more detailed study of the site or mechanism of stabilization of this species and of the effect of other additives on yield is in progress.

PTFE-bonded Raney Nickel Hydrogen Electrodes in Alkaline Fuel Cells

Tadao KENJO

Department of Applied Science for Energy, Faculty of Engineering, Muroran Institute of Technology, Mizumoto-cho, Muroran 050

(Received September 3, 1980)

Polytetrafluoroethylene (PTFE)-bonded Raney nickel hydrogen electrodes have been prepared and their polarizations have been measured at 62 °C, using 6 M KOH (1 M=1 mol dm^{-3}) as an electrolyte. The electrodes were reproducible in polarization characteristics from electrode to electrode. The polarization resistance was found to be 0.29 Ω cm^2 for the electrode loaded with a 48-mg cm^{-2} catalyst. The limiting current density was 600 mA cm^{-2} for the electrode loaded with a 45.4-mg cm^{-2} catalyst. The influences of the pressure of the press machine and of the PTFE content on the polarizations have been investigated. The polarization resistance decreases with the catalyst loading in the manner to be expected from the reaction mechanism of the gas diffusion through electrolyte film. An experimental evidence for this reaction mechanism has been obtained by measuring the polarization of an electrode of a triple-layered structure containing a silver powder layer.

In most of the Raney nickel electrodes that have thus far been studied, electrolyte penetration into the electrode pores is prevented by the gas pressure applied on the pores from the other side of electrode. To attain a delicate balance between the gas pressure and the capillary force over the whole working area of electrode, a very good uniformity in the pore-size distribution and a careful gas-pressure control are required. Unless the pore sizes are uniform, the hydrogen gas is wasted by bubbling through the large pores, or the working area of catalytic surface is lost by the electrolyte drowning of the small pores. Although the amount of gas wasted by bubbling can be reduced by using a double-layered sintered nickel matrix[1,2] or a finely porous and wettable diaphragm,[3,4] the pore-size uniformity and the control of the gas pressure are still required.

On the other hand, electrodes water-proofed by a repellancy agent do not require such a rigorous pore-size uniformity or such a careful pressure control. However, this type of electrode has rarely been applied to Raney catalysts because the water-proofed metal electrodes have readily suffered from electrolyte drowning at a very low load current and their electrode characteristics have been quite unreproducible.[5]

Polytetrafluoroethylene (PTFE) is the repellancy agent used most frequently because of its good stabilities against heat and electrolytes. The PTFE particles are apt to cross-link with each other when they are milled with the catalyst powder for mixing. The fraction of cross-linked PTFE particles resulting from the mixing process seems to increase with the mixing time and the temperature. The repellancy of electrode and the area of the catalytic surface covered by PTFE, which essentially influence the polarization characteristics, depend not only upon the content of PTFE added, but also upon its cross-linkage. Thus, the polarization characteristics vary with the mixing condition. This is a reason why the PTFE-bonded electrodes are liable to be poorly reproducible. In the present study, the mixing time and the temperature have been kept constant so as to minimize the fluctuations in the polarization data.

The Raney nickel catalysts can be depyrophorized through a slow surface oxidation in air and can be reactivated by a reduction in the hydrogen atmosphere.[6] This permits the Raney catalysts to be handled safely in air for the electrode processing.

Experimental

Preparation of the Catalysts. A melt possessing a mass fraction of 40% Ni (99.95% purity) and 60% Al (99.99% purity) was prepared by means of an induction furnace using an alumina crucible. To avoid the separation of the nickel, the melt was quenched by pouring it into an iron cylinder. The ingot thus obtained was crushed and powdered in a mill to a particle size of less than 37 μm.

The aluminium was leached with a 6 M KOH solution at 40 °C. The Raney nickel thus obtained was washed with water and methyl alcohol alternatively.

Preparation of the Electrodes. A weighed amount of a PTFE dispersion (D-1, Daikin Industrial Company) containing 60% PTFE was added to the Raney catalyst. When the mixture was milled under blowing with a hair-dryer at the room temperature of 20±2 °C for 1 h, it became a paste. This paste was calender-rolled by hand into sheets using spacers 0.1—0.2 mm thick. After having been dried in air overnight, the sheets were boiled in acetone for 2 h to remove the surfactant which had been originally contained in the PTFE dispersion. These sheets were then used as catalyst layers.

Gas-side layers were used to stop the leakage of electrolytes that might occur through the large pores in the catalyst layers. They were prepared by using nickel black powder bound with the PTFE dispersion. Nickel black powder, which had been obtained by heating nickel formate in a hydrogen atmosphere at 250 °C, was milled with the PTFE dispersion in a way similar to that used in the case of Raney nickel. The nickel black sheets obtained by calender-rolling were attached to a stainless steel screen (100 mesh) from both sides and pressed at 200 kg cm^{-2}. The gas-side layer was heated in a nitrogen atmosphere at 380 °C for 15 min to sinter the PTFE particles and to remove the surfactant. The catalyst layers were then attached to the gas-side layer by pressing at pressures ranging from 200 kg cm^{-2} to 1200 kg cm^{-2}. The double-layered electrode thus obtained was heated at 150 °C in a hydrogen atmosphere for 1 h to activate the catalyst.

Measurement of Polarization. The geometrical working area of the electrodes was 7 cm^2. The electrolyte used was a 6 M KOH solution, and it was circulated at a rate of 5 ml min^{-1}. The electrolyte temperature was 62±0.5 °C. The IR voltage drop was eliminated by the current-interruption method.[7]

Results and Discussion

Figure 1 shows plots of the polarization, η, *vs.* the current density, i, for various catalyst loadings. Since they are almost linear up to a polarization of 20 mV, the polarization resistance, ω, which corresponds to the slope can be used as an electrode characteristic. The polarization resistance for the electrode loaded with a 48-mg cm^{-2} catalyst is found to be 0.29 Ω cm^2. It can be compared to the value of 0.31 Ω cm^2 given by Sturm for the supported Raney-Ni-Ti electrodes operated at 60 °C and at a loading of 100 mg cm^{-2}.[8]

The controllable electrode parameters in the present electrode preparation are the PTFE content, the pressure of the press machine, and the catalyst loading. When they are kept constant and a Raney nickel prepared under fixed experimental conditions is used, the performance of electrode should be reproduced. In the present preparative method, however, the thickness of the catalyst layers, which is proportional to the catalyst loading, is scattered from layer to layer beyond the limit required to obtain constant polarization data. To test the reproducibility of performance, therefore, the scattering of data due to the variation in the catalyst loading must be taken into account.

As will be discussed in a later section, the reciprocal polarization resistance, ω^{-1}, for the thin electrode is proportional to the catalyst loading, since the reaction mechanism can be regarded as that of the gas diffusion through the electrolyte film; the current density at a given polarization is proportional to the catalyst loading. The polarization data, therefore, can be normalized to a loading of 1 g cm^{-2} by dividing i by the loading weight in unit of gram. Figure 2 shows the plots thus normalized for various loadings; i_N in the figure refers to the current density divided by the loading. The plots all fall on essentially the same curve. This proves that the electrodes yield reproducible polarization data.

Figure 3 shows the polarization curves as a function of the PTFE content, indicating that the polarization resistance increases with the PTFE content. This is due to an increase in the area of catalytic surface

covered by PTFE.

The pressure of the press machine influences the performance, as is shown in Fig. 4; no significant differences can be observed between the plots in the low-pressure region, and at 1260 kg cm^{-2} the plots deviate markedly. This discrete change is probably due to the calender-rolling, which compacts the catalyst layers as tightly as if they were pressed by the press machine at 842 kg cm^{-2}.

A test piece of electrode was prepared under the preparative conditions of PTFE content=10% and the pressure of press machine=421 kg cm^{-2}. The polarization curve is shown in Fig. 5. A limiting current density of 600 mA cm^{-2} is thus obtained.

Two different mechanisms have been proposed for the porous electrode reactions: a three-phase-boundary zone mechanism and one of the gas diffusion through the electrolyte film.[9] They are two extreme models with regard to the way of the electrolyte penetration into the pores. The first mechanism is based on the assumption that the electrolyte fills the pores up to the boundaries where the gas, electrolyte, and catalyst encounter each other; they are known as the three-phase-boundaries. Most of the load is sustained by the reaction occurring in the very narrow three-phase-boundary zones. It is less likely that the dried area in the pores contributes to sustaining the load by supplying the activated species toward the boundaries through surface diffusion. Hence, one can expect from this model that the polarization resistance is almost independent of the catalyst loading.

The feature of the second mechanism is that the whole catalytic surface of the pores is covered by thin electrolyte films. These films are thin enough to permit the gas molecules to diffuse. The gas molecules are dissolved into the films, and the electrode reaction takes place at the electrolyte-catalyst interface. The whole catalytic surface participates in the electrode reaction. This contrasts with the three-phase-boundary mechanism. The area of the catalytic surface can be enhanced by increasing the catalyst loading. Thus, one can expect that the polarization decreases with the catalyst loading. On the basis of this model, Mund has expressed the polarization resistance, ω, as a function of the catalyst loading, d, in this form;[10]

$$\omega = \sqrt{\rho k}\cdot\coth\sqrt{\rho d^2/k}, \qquad (1)$$

where ρ is the electrolyte resistivity in the catalyst layers, and k, the polarization resistance of the catalysts. When the electrode is so thin that the polarization due to the electrolyte resistivity and the gas diffusibility can be neglected, Eq. 1 can be approximated as $\omega^{-1}\propto d$. This is the case described in the section on the reproducibility test. Figure 6 gives the plots of ω^{-1} *vs.* d for the present electrodes. The plots fall on a curve that is expected from Eq. 1, suggesting that the second mechanism is valid. However, the values for ρ and k are unknown, and a small possibility still remains of the mechanism of the three-phase-boundary zone holding. Further experiments, therefore, are required to judge which mechanism is valid.

For this purpose an electrode of a triple-layered structure containing a sheet of PTFE-bonded silver powder sandwiched by two sheets of a Raney-nickel layer has been prepared. The aim of this electrode is to prevent the activated species in the gas-side layer from diffusing on the surface toward the electrolyte-side layer. The diffusibility of the activated species on the silver surface is probably very small, since the silver powder used is almost inactive as a hydrogen catalyst, as is shown in Fig. 7 (△). Hence, the activated species formed in either of the Raney nickel sheets will not be able to traverse the silver sheet. The three-phase-boundary, if it is the correct mechanism, can be expected to be located in the gas-side Raney nickel layer. In the three-phase-boundary mechanism, the surface diffusion is the only way for the gas-side layer to contribute to sustaining the load. That is prevented by the silver sheet, so that if the

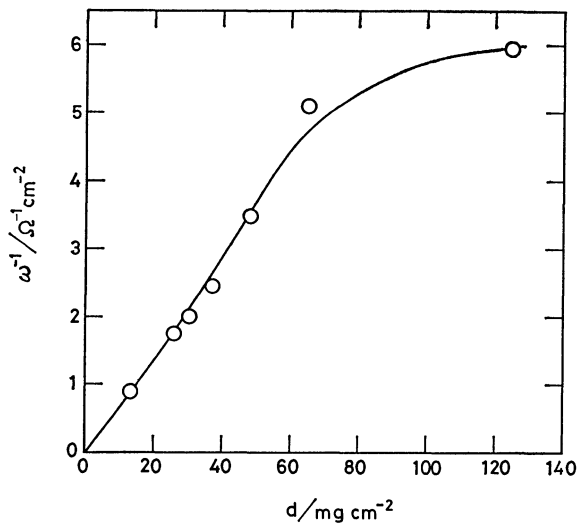

Fig. 6. Reciprocal polarization resistance as a function of catalyst loading at a PTFE content of 10%.

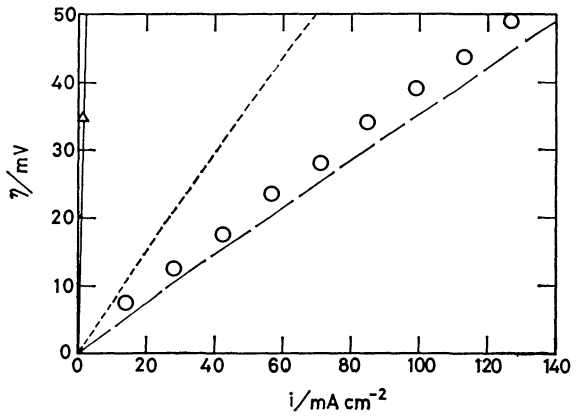

Fig. 7. Polarizations of the triple-layered electrode containing silver catalyst layer.
----: Calculated from the model of three-phase-boundary zone, — — —: calculated from the model of gas diffusion through the electrolyte film, ○: observed, △: electrode loaded with silver catalyst alone.

three-phase-boundary mechanism is valid, this electrode will be as polarized as if it is loaded with the electrolyte-side layer alone.

In the second model, the electrolyte films extend over all three layers so that the two Raney nickel sheets are connected to each other in ionic contact through the films in the silver layer. Therefore, the gas-side catalyst layer shares the load current with the electrolyte-side layer. Thus, the polarization in this case can be expected to be equal to that for a loading of both Raney nickel layers.

The polarization expected for each case can be calculated by using the polarization data in Fig. 2 and the loadings of the electrolyte-side and gas-side layers used. The dotted line and the broken line in Fig. 7 were calculated on the basis of the mechanisms of the three-phase-boundary zone and the electrolyte film respectively. The polarization data observed are closer to the broken line, suggesting that the electrolyte film is more probable.

Another piece of experimental evidence for the electrolyte penetration has been obtained by inserting pieces of filter paper between the layers. The electrode used for this experiment consists of three sheets of Raney nickel layers and a gas-side layer. Three pieces of filter paper were inserted, piece by piece, between adjacent layers. After the measurement of the polarization was over, the filter paper inserted was tested by phenolphthalein to see if it had been wetted by the KOH solution. All the test pieces were found to have been wetted. This experiment indicates that the electrolyte penetrates through all the catalyst layers.

These two experiments lead to the conclusion that the mechanism of the gas diffusion through electrolyte film is valid for the PTFE-bonded Raney nickel electrodes. The role of PTFE is to thin the electrolyte film sufficiently for the diffusion of gas molecules rather than to prevent the electrolyte penetration into the pores.

The present work was partially supported by a Grant-in-Aid from the Saneyoshi Foundation.

Isomorphism in the High-temperature Forms of Molecular Complexes between Aromatic Hydrocarbons and Various Electron Acceptors Arising from Molecular Motion

Tamotsu INABE, Yoshio MATSUNAGA,* and Mikiko NANBA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received January 12, 1981)

In addition to the six crystalline pyrene complexes reported earlier, the high-temperature forms of the following nineteen 1:1 molecular complexes have been found to be isomorphous to each other; the pyrene complexes with 1,3,5-trinitrobenzene, 2,4,6-trinitrophenol, 4-nitrophthalic anhydride, pyromellitic dianhydride, 5-nitrobenzofuroxan, 4,6-dinitrobenzofuroxan, and benzotrifuroxan, the fluoranthene complexes with 2,4-dinitrophenol, 1,3,5-trinitrobenzene, 2,4,6-trinitrochlorobenzene, 2,4,6-trinitrophenol, 2,4,6-trinitrotoluene, 4-nitrophthalic anhydride, pyromellitic dianhydride, 4,6-dinitrobenzofuroxan, and benzotrifuroxan, and the phenanthrene complexes with 1,3,5-trinitrobenzene, 2,4,6-trinitrophenol, and 4,6-dinitrobenzofuroxan. Furthermore, metastable isomorphous forms were obtained in the process of the solidification of the melt of the following three complexes: fluoranthene-5-nitrobenzofuroxan, phenanthrene-2,4,6-trinitrotoluene, and phenanthrene-4-nitrophthalic anhydride. Rather large entropies of the transitions to these unique high-temperature forms, up to 57 J mol^{-1} K^{-1}, are often comparable with the entropies of melting, 46—67 J mol^{-1} K^{-1}. The isomorphism in these twenty-eight complexes is demonstrated by essentially identical and very simple X-ray diffraction patterns and/or by the formation of continuous solid solutions between pairs of these forms. A trigonal lattice is proposed as the probable structure of these high-temperature forms. A broad-line ^1H NMR study clearly showed that the unusual features of these isomorphous forms are mostly associated with the onset of a large degree of molecular motion at the transition temperatures.

We reported earlier that the crystalline pyrene complexes with 2,4-dinitrofluorobenzene, 2,4-dinitrochlorobenzene, 2,4-dinitrophenol, 2,4-dinitrotoluene, and 2,4,6-trinitrochlorobenzene exhibit polymorphic transitions and become isomorphous to each other above the transition temperatures.[1] Isomorphism in molecular complexes is not unknown; however, the cases so far reported are limited to the complexes of closely related component compounds. For example, the 1,3,5-trinitrobenzene and 2,4,6-trinitrophenol complexes of naphthalene, pyrene, and fluoranthene have each been shown to be isomorphous by Herbstein and Kaftory.[2] This relationship has been established for the crystals stable at room temperature. The phenomenon found by us is apparently different from this kind of isomorphism. Except for the 2,4-dinitrochlorobenzene complex, the transitions are associated with rather large enthalpy and entropy changes: 12—18 kJ mol^{-1} and 37—50 J mol^{-1} K^{-1}, which are of the same order of magnitude as the corresponding values of melting: 18—25 kJ mol^{-1} and 50—59 J mol^{-1} K^{-1} respectively. On the basis of these thermodynamic data, we speculated that the specific interaction between the hydrocarbon molecule and the substituent on the acceptor molecule disappears because of the dynamical averaging of the interaction by a large degree of thermal motion in the high-temperature forms. Later, the onset of such a molecular motion was firmly established by the drastic decreases in the second moments in broad-line ^1H NMR spectra at the transition temperatures.[3] Moreover, the 2,4,6-trinitrotoluene complex was added to the list of this interesting class of molecular complexes. Continuing the search for such complexes, nineteen more complexes have been found to behave similarly. All the complexes studied before are composed of pyrene and one of the derivatives of *m*-dinitrobenzene or 1,3,5-trinitrobenzene; however, we have now succeeded in finding complexes containing hydrocarbons other than pyrene, such as phenanthrene-2,4,6-trinitrophenol and fluoranthene-1,3,5-trinitrobenzene, and also complexes containing an acceptor bearing no nitro group, such as pyrene-pyromellitic dianhydride and fluoranthene-benzotrifuroxan. Thus, the appearance of this kind of isomorphism needs neither a common-component compound nor a close similarity between components. The present paper gives an account of an examination of the thermodynamic data of the transition and melting, the X-ray diffraction pattern, the solid-solution formation, and the broad-line ^1H NMR study of the newly found complexes.

Experimental

Materials. The donors employed were pyrene (Py), fluoranthene (Fl), and phenanthrene (Ph), while the acceptors were 2,4-dinitrophenol (DNP), 1,3,5-trinitrobenzene (TNB), 2,4,6-trinitrochlorobenzene (TNC), 2,4,6-trinitrophenol (TNP), 2,4,6-trinitrotoluene (TNT), 4-nitrophthalic anhydride (NPA), pyromellitic dianhydride (PMDA), 5-nitrobenzofuroxan (NBF), 4,6-dinitrobenzofuroxan (DNBF), and benzotrifuroxan (BTF). Their structural formulas are presented in Fig. 1. The Py, Eastman white label, was recrystallized from xylene. The Ph, Eastman white label, was boiled with maleic anhydride in xylene to remove any anthracene.[4] TNB was prepared, starting from TNT, through 2,4,6-trinitrobenzoic acid.[5] The TNT, Eastman yellow label, was purified by recrystallization from ethanol. The NPA and PMDA were sublimed in a vacuum just before use. The NBF, DNBF, and BTF were prepared following the procedures reported by Bailey and Case.[6] The other reagents obtained from commercial sources were employed without further purification. The complexes were crystallized by mixing the component compounds dissolved in appropriate solvents or by melting mixtures of equimolar amounts of the component compounds.

Measurements. Calorimetric, X-ray, and NMR measurements were carried out as described in our previous

papers.[1,3] Density measurements of four complexes with transition temperatures lower than 60 °C were made using Gay-Lussac pycnometers. A small amount of a detergent had to be added to the water employed as the immersion fluid in order to wet the crystals. Air bubbles trapped by the crystals were eliminated by repeated evacuations and then by leaving the pycnometers overnight under reduced pressure.

Results and Discussion

Thermodynamic Data. The complexes which become isomorphous upon transitions, including the six Py complexes found previously, are summarized in Fig. 1. Solid circles indicate that enantiotropic transitions are observable. On the other hand, broken circles show that the high-temperature forms of these complexes are metastable, as will be described later.

The transition temperatures, melting points, and associated enthalpies and entropies are collected in Table 1. Not only the six Py complexes reported previously by us, but also some other complexes are known to exhibit polymorphic transitions. Casellato *et al.* have located the transitions in the Py–TNB complex at 129 and 215.5 °C with enthalpies of 2.4 and 1.9 kJ mol^{-1} respectively, and the melting point, at 253.3 °C with an enthalpy of 38.5 kJ mol^{-1}.[7] Except for the first transition temperature, our results are in fair agreement with theirs. The transitions in the Py–TNP complex have been reported to occur at 170 and 183.4 °C, with enthalpies of 2.9 and 1.2 kJ mol^{-1} respectively, by Farrell *et al.*[8] The melting point reported by them is 233.4 °C, and the enthalpy is 32.6 kJ mol^{-1}. All our temperatures for this complex are located lower than theirs by about 5 °C. Casellato *et al.* have observed three modifications of the Py–NPA complex.[9] According to them, the I modification crystallized from a solution is transformed into the III modification at 122 °C with an enthalpy of 18 kJ mol^{-1}. The transformation into the III modification from the II obtained by cooling from the melt occurs at 105 °C. The enthalpy of the latter transition was reported to be 11 kJ mol^{-1}. Our enthalpy of the transition at 112.5 °C is a little larger than the former one reported by Casellato *et al.*, but our transition temperature is appreciably lower than theirs. We occasionally observed an additional endothermic peak at 108 °C with samples crystallized from some solvents. This peak could be detected only in the first run of the calorimetric measurements. The Py–NPA complex has been reported to melt at 179.5 °C, with an enthalpy of 24 kJ mol^{-1}, in agreement with our observation. The thermodynamic data for the Py–PMDA complex have been presented by Pelizza *et al.*; the enthalpy for the transition at 174.3 °C is 29 kJ mol^{-1}, while that of the melting at 290.4 °C is 72 kJ mol^{-1}.[10] Our enthalpy values are barely over 40 percent of theirs.

The Fl–TNP complex has been studied by Farrell *et al.*[8] The reported transition temperature, 92.4 °C, and the enthalpy, 13.8 kJ mol^{-1}, agree well with our values. The melting point has been found at 189.2 °C, and the enthalpy, at 24.7 kJ mol^{-1}. The latter is a little larger than the present value.

The Ph–TNB complex has been reported by Kofler to exhibit a transition at 149 °C.[11] Casellato *et al.* have located it at 148.2 °C, with an enthalpy of 12 kJ mol^{-1}, while they located the melting point at 164.6 °C, with an enthalpy of 27 kJ mol^{-1}.[7] Our results in Table 1 generally agree with their values. The transition in the Ph–TNP complex has been noted also by Kofler at 106 °C.[11] The enthalpy has been estimated to be 13 kJ mol^{-1} by one of the present authors, together with an additional transition at 77 °C associated with an enthalpy of 4.6 kJ mol^{-1}.[12,13] Our new determinations well reproduced the previous results. According to Casellato *et al.*, the Ph–NPA complex melts at 96 °C, with an enthalpy of 29 kJ mol^{-1}.[9] Our results are in good agreement with theirs.

With the exception of several complexes, the entropy of transition into the unique high-temperature form is fairly large, up to 57 J mol^{-1} K^{-1}. These values are often comparable with the entropies of melting of these complexes, 46—67 J mol^{-1} K^{-1}. As the sum of all entropies of transition and melting may be supposed to be correlated with the molecular structure, it may agree with the entropy of melting of a complex which is structurally related to the present one but which does not exhibit polymorphic transitions. For example, we observed 102 J mol^{-1} K^{-1} for the Fl–DNT complex, 100 J mol^{-1} K^{-1} for the Fl-3-nitrophthalic anhydride complex, and 101 J mol^{-1} K^{-1} for the 1,10-phenanthroline–TNB complex. These values are reassuringly similar to the sum of the entropies of transition and melting of the present complexes: *e.g.*, 104 J mol^{-1} K^{-1} of the Py–DNF complex. If the latter value is appreciably smaller than the former, the occurrence of low-temperature transitions may be predictable for such a complex.

The ordinary samples of the Fl–NBF, Ph–TNT, and Ph–NPA complexes exhibit no polymorphic transition; however, the metastable high-temperature form appears when the melt is solidified. As the monotropic transition from the supercooled metastable form to the stable one is well separated from the solidification, the enthalpy and entropy associated with the melting of the metastable form could be measured. a) Taken from Ref. 1. b) Taken from Ref. 3. c) The values are reproducible within 5% when the enthalpies are in the order of 10 kJ mol^{-1}. The errors are twice as large if the enthalpies are about 1 kJ mol^{-1}.

1, the thermodynamic data for the melting of these three complexes are for the stable forms. It is noteworthy that the entropy values of melting, 80 J mol^{-1} K^{-1} for the Fl–NBF, 75 J mol^{-1} K^{-1} for the Ph–TNT, and 78 J mol^{-1} K^{-1} for the Ph–NPA, are definitely larger than those of any other complexes in the table. The enthalpy and entropy associated with the monotropic transition given in Table 1 were estimated by taking the difference between the value for the melting of the stable form and that for the melting of the metastable form.

X-Ray Diffraction Patterns. In Fig. 2, the X-ray diffraction patterns observed at room temperature and above the transition temperature using filtered copper radiation are schematically presented for eight representative complexes. Reflecting the special natures of the donor and acceptor molecules, the room-temperature patterns are not simple and are markedly different from each other. However, the diffraction patterns are remarkably simplified upon the transition. Three or four lines are observable with the high-temperature forms: a strong line appearing between $2\theta_1=11$ and 12°, a weak one near $2\theta_2=20°$, and another strong one between $2\theta_4=26$ and 27°. The patterns of the Ph–TNP complex in its three forms were previously recorded by Koizumi and Matsunaga.[13] It was emphasized that the pattern given by the high-temperature form is very simple.

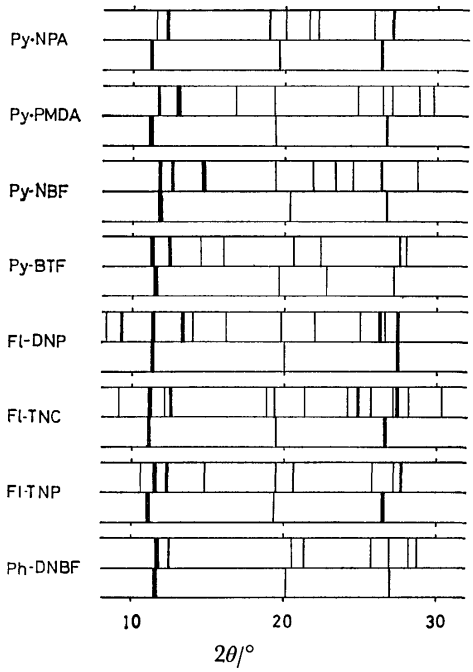

Fig. 2. X-Ray (Cu $K\alpha$ radiation) diffraction patterns of the molecular complexes. The upper pattern for each complex was recorded at room temperature and the lower one above the transition temperature.

Only three lines were found in it, in accordance with the present complexes. For some complexes, a very weak line is detectable near $2\theta_3=23°$, as is exemplified by the Py–BTF complex (see Fig. 2). The general features described here are in good agreement with those obtained for the six Py complexes studied before.

A comparison of the spacings, d_1, d_2, and d_3, which are inversely proportional to $\sin\theta_1$, $\sin\theta_2$, and $\sin\theta_3$ respectively, shows that

$$1/d_1 : 1/d_2 : 1/d_3 = 1 : \sqrt{3} : 2$$

within the limits of error of measurements, for all the complexes examined. On the other hand, the d_4 spacing is not in any simple ratio with the others. This remarkably simple ratio suggests that the lattice in the high-temperature form is hexagonal or trigonal.

With the hope of limiting further the probable structures, the density measurements were carried out for the Py–DNC, Py–DNT, Py–TNT, and Fl–TNC complexes, which can be transformed into the high-temperature forms below 60 °C. The densities measured within a few degrees below and above the transition temperature are summarized in Table 2. Trial

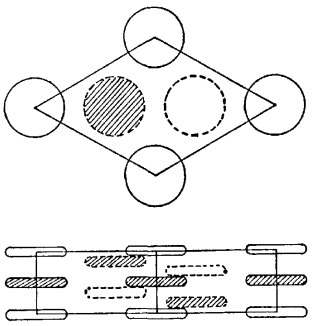

Fig. 3. Proposed structure for the isomorphous high-temperature forms. The molecules located at 000, 2/3 1/3 1/3, and 1/3 2/3 2/3 are different from those located at 0 0 1/2, 2/3 1/3 5/6, and 1/3 2/3 1/6.

shows that the trigonal lattice presented in Fig. 3 well explains the X-ray diffraction patterns and the observed densities and so seems probable. As this lattice must be common to all the complexes listed in Table 1, the shape of the component molecules is entirely ignored in this figure. The indices assigned to the above-mentioned four lines are (110), (300), (220), and (102). Table 2 records also the estimated unit-cell dimensions and the calculated densities. Three molecules of each component are in the cell shown in Fig. 3. The donor and acceptor molecules are stacked alternatively in infinite columns in parallel with the c-axis. The stacking angle may be nil, as the mean separation between the molecular planes is expected to be about 3.5 Å.

Solid-solution Formation. The complete miscibility of a pair of the complexes is a severe test for the isomorphism. To be isomorphous, the high-temperature forms must have the same space group and the same number of molecules per unit cell.[14] The additional requirement to be miscible in all proportions is that the difference in the unit-cell sizes not be too great. The room-temperature forms of the Py–TNB and Py–TNP complexes have been reported to be isomorphous ($P\bar{1}$ and $Z=2$) by Herbstein and Kaftory.[2] Two enantiotropic transitions in the range from room temperature to the melting point are observed with both the complexes: 138 and 216 °C with the TNB complex and 164.5 and 178 °C with the TNP complex. The phase diagram of the pseudo-binary system comprising these two Py complexes given in Fig. 4 clearly shows that each pair of the polymorphs of these two complexes are completely miscible. The combination of the Fl–TNB and Fl–

TABLE 2. DENSITIES MEASURED WITHIN A FEW DEGREES BELOW AND ABOVE THE TRANSITION TEMPERATURE, AND UNIT-CELL DIMENSIONS AND CALCULATED DENSITY OF THE HIGH-TEMPERATURE FORM

Molecular complex	Density / g cm^{-3}		Unit-cell dimensions		Calcd density / g cm^{-3}
	Below Tp	Above Tp	a/Å	c/Å	
Py-DNC	1.414	1.396	15.31	6.99	1.42

Fl-TNC	1.506	1.449	15.80	6.94	1.49

TNP complexes gives similar results. The room-temperature forms are monoclinic ($P2_1/c$, $Z=4$), and the following unit-cell dimensions have been given by Herbstein and Kaftory: $a=8.48$, $b=7.27$, $c=30.35$ Å, $\beta=96°$ for the Fl–TNB complex, and $a=8.68$, $b=7.27$, $c=31.0$ Å, $\beta=96°$ for the Fl–TNP complex, fulfilling the conditions cited above.

The diagrams for the following six systems are illustrated in Fig. 5: Py–(NPA, DNF), Py–(DNF, TNT), (Py, Fl)–TNT, Fl–(TNT, TNP), (Fl, Ph)–TNP, and Ph–(TNP, TNB). These systems were selected so that the two molecular complexes share either a hydrocarbon or an acceptor. Moreover, the neighboring systems share one of the molecular complexes. In all the diagrams, the freezing points of mixtures lie between the melting points of the pure molecular complexes. These results undoubtedly indicate that the solid miscibility between the high-temperature forms is unlimited in all the systems shown in Fig. 5. Thus, we are quite certain that the high-temperature form of the Py–NPA is isomorphous with that of the Fl–TNT complex and also with that of the Ph–TNB complex. Besides the Fl–TNP complex described above, the room-temperature form of the Ph–TNB complex is known to be monoclinic ($P2_1/c$, $Z=4$), and that of the Ph–TNP complex, to be triclinic (P1 or $P\bar{1}$, $Z=2$).[2] Accordingly, a eutectoid system is produced by these two complexes, and the diagram is split by a miscibility gap at room temperature. It may be noticed from Fig. 5 that the formation of substitutional solid solutions based on the parent-complex lattices occurs extensively. The solubility of the Ph–TNP complex into the Ph–TNB complex lattice exceeds 60 mol%, while that in the inverse direction is merely about 20 mol%. The most striking example is found in the diagram involving the Fl–TNT and Fl–TNP complexes, which gives a peritectoid system. The Fl–TNT complex can dissolve the Fl–TNP complex over 80 mol%, and the width of the miscibility gap in this system is as narrow as 3 mol%.

As the high-temperature forms of the Py–DNT and Fl–TNT complexes are isomorphous to each other, the pseudo-binary system gives a continuous solid solution (see Fig. 6). However, it must be noted that the composition of the solid solution is unusually different from the composition of the liquid solution in equilibrium. The equimolar mixture of these two complexes is equally considered to be an equimolar mixture of the Py–TNT and Fl–DNT complexes. As there is no unique high-temperature form appearing in the Fl–DNT complex, the miscibility gap should exist somewhere in the system consisting of the Py–TNT and Fl–DNT complexes. As expected, the diagram of the latter pseudo-binary system (shown in Fig. 6) has a gap extending from 60 to 90 mol% of the Fl–DNT complex. The large temperature difference between the solidus and liquidus near 50 mol% in the other pair of the complexes apparently arises from the wide miscibility gap located close to this composition. Results similar to those presented above may be anticipated for the system consisting of the Fl–TNT and Ph–TNP complexes because of the absence of a transition in the combination of Ph and TNT. Unexpectedly, however, the solidus and liquidus are not so separated as those in the system

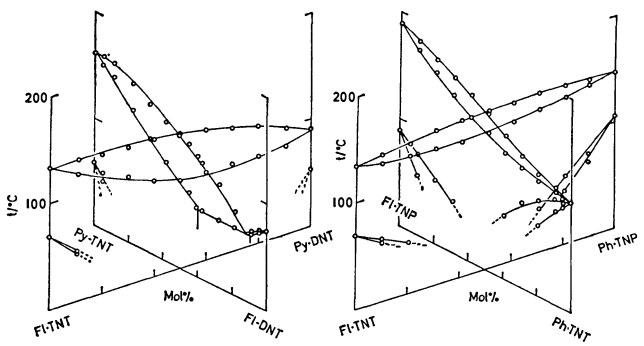

Fig. 6. Phase diagrams for the (Py, Fl)–(DNT, TNT) and (Fl, Ph)–(TNP, TNT) systems.

consisting of the Py–DNT and Fl–TNT complexes. The study of the system of the Fl–TNP and Ph–TNT complexes has revealed the formation of a continuous solid solution (see Fig. 6). The appearance of this phase must be due to the coincidence between the transition and melting points in the latter complex. The metastable polymorphs have also been found for the Fl–NBF and Ph–NPA complexes and have been demonstrated to be completely miscible at high temperatures with the Fl–TNT and Fl–NPA complex respectively (see Fig. 7).

Broad-line ^1H NMR. The second moment, the mean-square width of the resonance line, of the ^1H NMR spectrum is shown in Fig. 8 as a function of the temperature for each of the seven Py complexes. Py is known to have an intramolecular second moment of 3.43 G^2.[15] All the complexes studied here show evidence of molecular motion in the solid state, as indicated by a decrease in the moment. In the case of the TNB complex, the transition to the unique isomorphous form is located at 216 °C, well above the range measurable with our spectrometer. The second moment decreases gradually up to 138 °C and then more sharply above this temperature (see Fig. 8a). The value in the phase stable between 138 and 216 °C is as small as 1 G^2, indicating that some fast motional process exists before the transition to the isomorphous form. This observation is consistent with the small enthalpy and entropy values for the second transition. Similar small changes in the second moment are found for the TNP and DNBF complexes, in which the enthalpy and entropy of the transitions are also comparatively small. There is a large, abrupt drop in the second moment at the transition to the high-temperature forms of the other four complexes, reflecting a significantly larger enthalpy and entropy of the transition.

The PMDA complex is the only one among the complexes studied here for which the crystal structure has been determined. Herbstein and Snyman have made an intensive and comprehensive study of the structure at 110 and 300 K.[16] The NMR spectrum has been measured, and the nature of the molecular motions has been discussed by Fyfe.[15] Our results are essentially the same as his (see Fig. 8d). The moment observed at low temperatures compares very well with 4.8 G^2, the theoretical value for the rigid lattice calculated by means of Van Vleck's formula using the atomic coordinates of the X-ray determination. The reduction in the second moment to 2.3 G^2 by 130 °C has been interpreted by Fyfe in terms of the complete reorientation of the hydrocarbon molecules in their molecular planes. Furthermore, Dunn *et al.* have reported on heat-capacity measurements in the range from 10 to 323 K and have established the growth of orientational disorder over a very considerable temperature range.[17] Unfortunately, the transition located at 170 °C was covered by neither of these works.

Figure 9 shows the second moments of the nine Fl complexes. The intramolecular moment is esti-

mated to be 2.88 G^2 using the atomic coordinates previously reported by Herbstein and Kaftory.[2] The change upon the transition into the isomorphous high-temperature form is drastic except for the BTF complex. In this complex, the reduction occurs by the transition at 83 °C rather than by that at 86.5 °C. The fact that the enthalpy of the former transition is about four times that of the latter may account for this result. The moment is generally not very temperature-dependent below the transition. There is no distinct reduction in the second moment by passing through the transition at 82 °C in the DNBF complex (see Fig. 9h).

The temperature variation in the second moment in the three Ph complexes is shown in Fig. 10. The moment drops abruptly and substantially upon the transition into the isomorphous form, but gradually at the other transitions in the TNP and DNBF complexes. Thus, the thermodynamic transition to the isomorphous form is, in general, accompanied by the abrupt reduction of the second moment. Such a coincidence implies that the molecules are moving fast on an NMR time-scale (40 MHz) above the transition temperature. Although the transition at 105.5 °C in the DNBF complex has a larger enthalpy than that at 121 °C, the change in the second moment is smaller and more gradual, suggesting that the motion initiated by the transition at 105.5 °C is not fast on an NMR time-scale. While the intramolecular moment of the hydrocarbon is calculated to be 4.12 G^2 on the basis of the molecular structure determined by Trotter,[18] the observed moment in the isomorphous form is less than 1 G^2 in every complex. Therefore, the flat hydrocarbon molecules in this phase seem to have a considerable freedom of rotation. The large entropy associated with the transition supports also the onset of such a large degree of molecular motion.

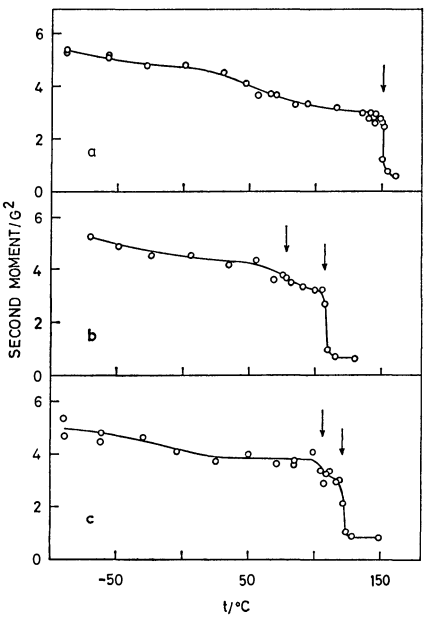

Fig. 10. Second moment values of the proton resonance for the phenanthrene complexes with a) TNB, b) TNP, and c) DNBF. The vertical arrows indicate the thermodynamic transition temperatures.

Benzene is an example which shows line narrowing due to rotation about a single axis.[19] The second moment has been reported to show a slow decrease beginning at about 100 K and ending at about 120 K. Above this temperature, the moment is 0.76 G^2. The entropy of melting is 35.3 J mol^{-1} K^{-1}.[20] Twice this value may be compared with those of our complexes: 46—67 J mol^{-1} K^{-1}. One should remember that this quantity is a measure of the difference in organization between the solid and the melt. As the association of the hydrocarbon and acceptor molecules is likely in the molten complexes,[21] one cannot conclude, on the basis of these entropies, that the acceptor molecules are also mobile in the high-temperature forms. At any rate, the number of hydrogen atoms on the acceptor molecules is so small that the contribution to the second moment may be expected to be appreciably smaller than that due to the hydrocarbon molecules.

General Remarks. The molecular rotation certainly forms an important part of the mechanism for isomorphism reported here. In this connection, the present complexes bear some similarity to plastic crystals, which are composed of globularly shaped molecules. Plastic crystals are of a cubic habit. The transition entropy to this phase is high (about 40 J mol^{-1} K^{-1}) compared with that for melting (less than 20 J mol^{-1} K^{-1}). The largest transition entropy in our complexes to be compared is 59/2 J mol^{-1} K^{-1} for the metastable form of the Fl–NBF complex, while the largest entropy of melting is 67/2 J mol^{-1} K^{-1} for the Py–TNB complex. Clearly, the motion of the flat component molecules in the present complexes is generally more restricted than that of the spherical molecules in plastic crystals; nevertheless, some translational disorder might be also conceivable for the former crystals such as has been reported for the latter.[22] The reactivity for donor- or acceptor-exchange in solids is currently under investigation below and above the transition temperature in order to search for such indications.

The sections of the van der Waals repulsion envelopes of the Py and Fl molecules are drawn in Fig. 11 as Al-Mahdi and Ubbelohde did for a number of aromatic molecules.[23] The two are found to be sufficiently similar and to fit in essentially the same circle. The envelope of the Ph molecule is, of course,

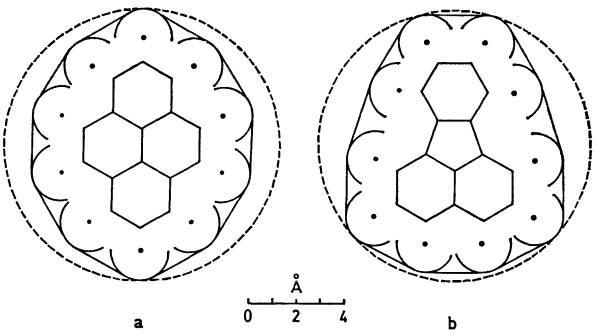

Fig. 11. Sections of van der Waals repulsion envelopes of the pyrene and fluoranthene molecules.

not very different from that of the Py molecule, but of a lower symmetry. If the molecules are rotating in their planes, the columns in the solid complexes of these three hydrocarbons would have cross sections very much alike and would produce unit-cell dimensions close to one another. The ease of the rotation seems to depend on comparatively small differences in the structure of the component molecules. The results summarized in Fig. 1 indicate that the rotation occurs most easily for the Py molecule with a higher symmetry and a little bit less easily for the Fl molecule. In the case of the Ph molecule, the shape of which is farther from a circle than the other two, the rotation is allowed only in limited complexes.

It is apparent that the lattice symmetry proposed in Fig. 3 is incompatible with the symmetry of the constituent molecules. This discrepancy provides one of the reasons for concluding that the molecules, even if not literally rotating, are disordered in orientation. The trigonal lattice is not entirely new for molecular complexes. Some years ago, Dahl found that the crystals of the hexamethylbenzene–hexafluorobenzene (1:1) complex are trigonal ($R\bar{3}m$) at room temperature and are transformed into a triclinic form ($P\bar{1}$) when cooled below 0 °C.[24,25] The lattice constants for the former form are $a=14.596\pm0.012$ Å and $c=7.124\pm0.007$ Å, fairly close to those given in Table 2. The donor and acceptor molecules are stacked alternatively in columns, with some disorder in the stacking sequence, in the trigonal form. No indication has been noted of such a disorder in the low-temperature form.[25] On the basis of thermal-vibration ellipsoids, Dahl postulated that rotation occurs for the hexamethylbenzene molecule not only in the trigonal form, but also in the triclinic form. We have examined the ^1H and ^{19}F NMR spectra of this complex. The second moment in the former spectrum is 11.3 G^2 at −142 °C and gradually decreases to 1.8 G^2 by −65 °C. Similarly, the moment in the latter spectrum shows a decrease from 1.2 to 0.65 G^2 in the same temperature range. The enthalpy associated with the transition located at about −25 °C is as small as 0.7 kJ mol^{-1}; therefore, no change in the second moment may be expected upon this transition.

The proposed lattice suggests that the stacking column acquires an effectively circular cylindrical symmetry. As the minimum distance between the sites for donor and acceptor molecules located in neighboring columns is less than the average of two molecular diameters, the molecules have no room to rotate freely and a change in the orientation requires correlated movements of interlocking molecules. For example, the distance is about 8.9 Å, and the average molecular diameter is about 10.6 Å, in the Py–DNC complex. The ratio of these two quantities, 0.84, fits nicely into the range of the minimum distance between molecular centers divided by the maximum diameter of the molecule, which is found for plastic crystals consisting of globular molecules, 0.81—0.94.[26]

In conclusion, it may be added that the electron acceptors in our complexes are relatively weak ones. The complexes are yellow to orange, and the mean separations between molecular planes are comparatively large, about 3.5 Å. Attempts to find isomorphous high-temperature forms with deeply colored complexes have not met with any success.

The authors wish to express their sincere thanks to Mr. Nobuhiko Miyajima for the preparation of some acceptor compounds; to Mr. Eiji Ochi for recording some X-ray diffraction patterns, and to Dr. Akio Furusaki for his helpful comments on the probable structure of the high-temperature forms. The present work was partly supported by a Grant-in-Aid for Scientific Research No. 543001 from the Ministry of Education, Science and Culture.

Formation of H(n=4) and CH($A^2\Delta$) by the Electron Impact Dissociation of Benzene, Pyridine, and Pyrazine

Ikuo Tokue* and Masami Ikarashi

Department of Chemistry, Faculty of Science, Niigata University, Ikarashi, Niigata 950-21

(Received January 16, 1981)

Benzene, pyridine, and pyrazine were excited by electron impact (0—70 eV) under low pressure conditions. In the wavelength region of 250—510 nm, emissions from H, CH, C_2, and CN (except for benzene) fragments were observed. Formations of H(n=4) and CH($A^2\Delta$) from benzene, pyridine, and pyrazine were investigated. The appearance potentials for the hydrogen Balmer β emission were determined to be 19.5±1.0 eV in benzene, 19.7±1.0 eV in pyridine, and 19.6±1.0 eV in pyrazine. The appearance potentials for the CH(A-X) emission were also determined to be 12.7±1.0 and 21.4±1.0 eV in benzene, 20.1±1.0 eV in pyridine, and 18.5±1.0 eV in pyrazine. No emissions from the excited parent species of pyridine and pyrazine were observed.

When a relatively large molecule is excited by electron impact, photoemission from small fragments is observed more easily than that from the parent molecule. This is probably because the parent molecule has many degrees of freedom of motion and non-radiative processes become important. However, aromatic molecules are one of the exceptions, where excited parent species give intense fluorescence upon electron impact. The fluorescence ($S_1 \rightarrow S_0$) from benzene by electron impact has been studied extensively.[1-4] On the other hand, nitrogen-heterocycles in the vapor phase hardly emit radiation,[5,6] because radiationless processes among excited states are particularly efficient.

As stressed by Platzman[7] for benzene, neutral excited states having excitation energy in excess of its ionization play an important role in the formation of neutral fragments. Recently, emissions for these neutral fragments from benzene have been studied.[8-10] However, as for large nitrogen-heterocycles such as pyridine and pyrazine, very little is known at this time about the fragments and the mechanism of fragmentation from the excited parent species by electron impact.[11]

The fragmentation of molecules by electron impact has been studied by mass spectrometry, but the information thus obtained has been restricted to relatively large ionic fragments; furthermore, only little has been known about the excited states leading to the ionization.

In the present paper the emission spectra of the fragments produced by electron impact dissociation of benzene, pyridine, and pyrazine are assigned and the appearance potentials for the fragments are determined.

Experimental

Figure 1 shows a schematic drawing of the apparatus, which consists of an electron source, a collision chamber and an optical detection system. The electron source and the collision chamber are evacuated by an oil diffusion pump to about 0.27 mPa, as measured by an ionization gauge. The negative potential from 0 to 70 eV was applied to a tungsten filament (0.1 mm diameter) heated by 3 V d.c. Electrons accelerated and focused by three electrodes were introduced into the collision chamber through an aperture (3 mm diameter). The maximum beam current measured at a Faraday cage (g) was about 0.8 mA at 70 eV. For measurement of the excitation functions electron-beam currents ranging from 10 μA at the threshold to 60 μA at higher energies were used.

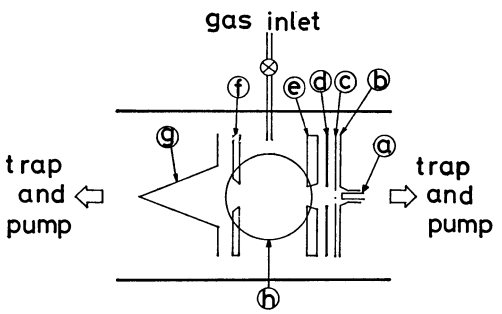

Fig. 1. Schematic diagram of the collision chamber and the electron gun.
a: Tungsten filament, b: repeller electrode, c, d, e, and f: electrodes, g: Faraday cage, h: quartz window.

The sample gases were fed into the collision chamber through a nozzle (1 mm diameter) at a constant pressure controlled by the temperature of the sample holder and a variable leak valve. The sample pressures during the emission measurements, as measured by an ionization gauge, were 5—40 mPa.

A 30 cm Czerny-Turner scanning monochromator equipped with a 1200 Gr/mm grating blazed at 300 nm, an HTV R585 photomultiplier, and an HTV C1230 photon-counter were used. With a slit-width of 200 μm spectral resolution of 0.6 nm (FWHM) was obtained and was used for measurement of the excitation function.

The energy scale for the incident electrons was calibrated using the excitation functions for the (0, 0) band of the N_2-($C^3\Pi$-$B^3\Pi$) emission by Finn *et al.*[12] and the (0, 0) band of the N_2^+($B^2\Sigma$-$X^2\Sigma$) emission by Borst and Zipf.[13] About 5% of nitrogen gas was mixed with the sample gas and their excitation functions were measured simultaneously. A slight discrepancy was observed in the steepness of the excitation function for the N_2(C-B) emission in the threshold region (Fig. 2); it is probably because of the energy spread of about 2 eV in the present experiment.

The samples of benzene, pyridine, and pyrazine were of guaranteed grade from Nakarai Chemicals. Pyridine was fractionally distilled over sodium hydroxide under a stream of nitrogen.[6] Pyrazine was recrystallized from its diethyl ether solution.[14] The samples were degassed by several freeze-pump-thaw cycles just before use.

Results and Discussion

Emission Spectra. The observed emission spectra by electron impact on benzene are similar to those reported by Smith[1] and Ogawa *et al.*[9] Figure 3 shows the emission spectra obtained from pyridine and pyrazine in the region of 250—510 nm at electron energy of 70 eV. Many sharp bands in these spectra were assigned to the following fragment species; the hydrogen Balmer series (n=4—10→2), the CH($A^2\Delta$-$X^2\Pi$), the C_2($A^3\Pi$-$X^3\Pi$), and the CN($B^2\Sigma$-$X^2\Sigma$) bands.

The photoemission intensities of the hydrogen Balmer β (H_β) and the CH($A^2\Delta$-$X^2\Pi$) band from benzene, pyridine, and pyrazine, and the CN($B^2\Sigma$-$X^2\Sigma$) band from pyridine and pyrazine were found to be proportional to the electron-beam current up to 0.5 mA. In the measurement of the excitation functions, the gas density of the parent molecule in the column of electron-beam (0.4 cm^3) is estimated to be less than 3×10^{12} molecule/cm^3 and is two orders of magnitude lower than the electron density in the collision region, 6×10^{14} electron/s, for a beam current of about 0.1 mA. Such a low gas density was necessary because low-energy electrons formed by ionization can reach the electron collector and affect the Faraday cage current.

Therefore, the H and CH species from benzene, pyridine and pyrazine seem to be formed by fragmentation *via* a single collision, and two-step collisions of the electron with the sample molecule and intermolecular quenching processes seem to be negligible.

As for pyrazine, fluorescence and phosphorescence[15] were expected especially near the excitation threshold. Neverthless, no emission from the parent species was observed even at the sample pressure as high as 47 mPa.

Excitation Functions and Appearance Potentials. Figures 4 and 5 show the excitation functions for the H_β and CH(A-X) emissions from benzene, pyridine, and pyrazine near their thresholds. The electron energy scale for each experiment was calibrated using the well-known thresholds for the N_2(C-B) and N_2^+(B-X) emissions which lie close in energy to the thresholds for the H_β and the CH(A-X) emissions. Although each excitation function near the threshold is broadened by the electron energy distribution of about 2 eV (FWHM), the appearance potential in each excitation function is determined using a linear extrapolation (see Figs. 4 and 5). We estimate that

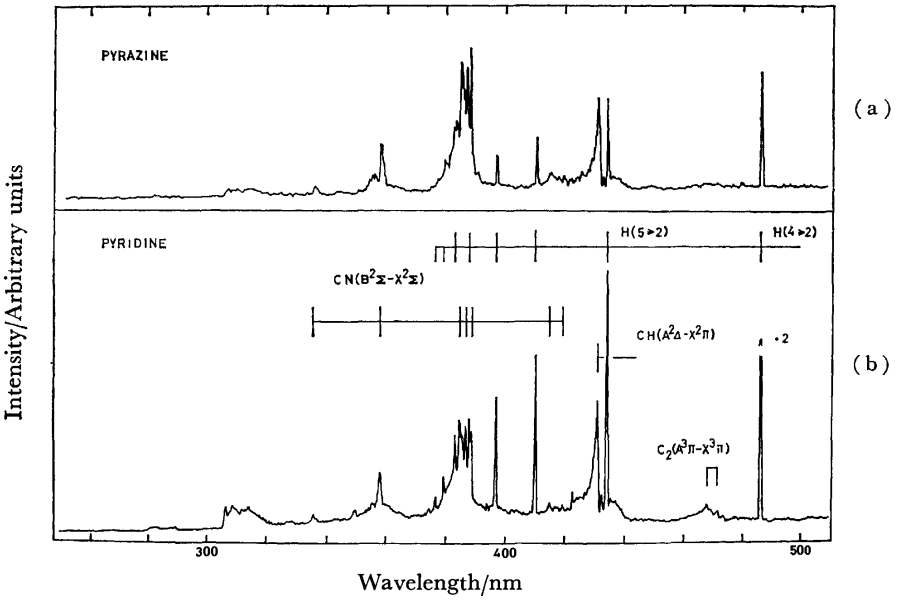

Fig. 3. Emission spectra by electron impact at 70 eV and 0.5 mA. The fragment emission peaks observed are assigned except for the broad peaks near 310 nm. (a): Pyrazine at 16 mPa. (b): Pyridine at 19 mPa.

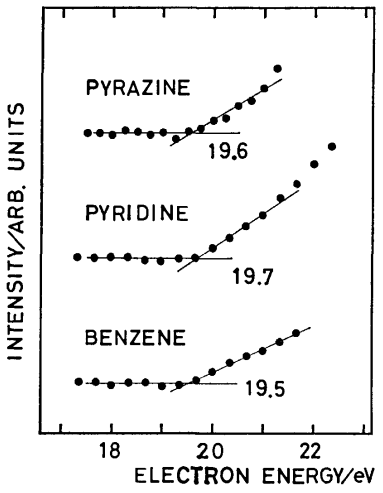

Fig. 4. The excitation functions for H_β from benzene, pyridine, and pyrazine near the thresholds. Typical data are presented. The standard deviation is about twice as large as the diameter of the circles.

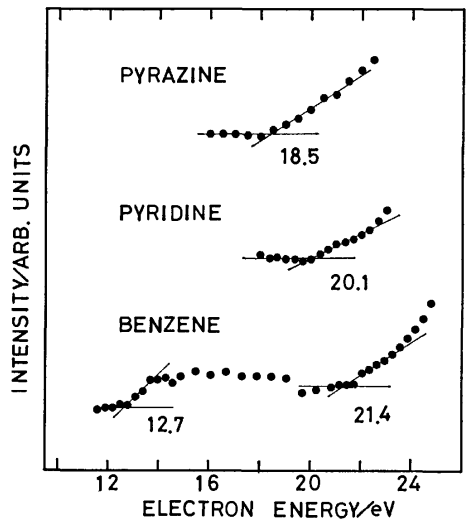

Fig. 5. Same as Fig. 4 for the CH(A-X) emission. The standard deviation is nearly as large as the diameter of the circles.

this calibration is accurate to 1 eV[16] and the random error of each calibrated appearance potential is about 0.4 eV. The appearance potentials thus determined for the H_β and the CH(A-X) emissions are summarized in Table 1 in comparison with previous work.[10]

Formation of H(n=4). The onset for H_β from benzene is found at 19.5±1.0 eV: this value agrees well with 19.3±1.0 eV reported by Beenakker and de Heer.[10] The absence of structure near the threshold indicates that only one state or at most a few states of benzene are involved in the formation of excited hydrogen atoms. By comparison of the observed threshold energy with the dissociation energy of the C–H bond, 4.87 eV,[17] and the excitation energy of H(n=4), 12.7 eV, the following dissociation process, which is reported by Beenakker and de Heer,[10] seems to play an important role in the formation of excited hydrogen atoms.

Table 1. Appearance potentials for the H_β and the $CH(A^2\Delta\text{-}X^2\Pi)$ emissions determined from their excitation functions (in eV)

	H_β		$CH(A^2\Delta\text{-}X^2\Pi)$	
	This work	Beenakker *et al.*[a]	This work	Beenakker *et al.*[a]
Benzene	19.5±1.0	19.3±1.0	12.7±1.0	15.0±1.0
			21.4±1.0	
				29 ±1
Pyridine	19.7±1.0		20.1±1.0	
Pyrazine	19.6±1.0		18.5±1.0	

a) Ref. 10.

$$C_6H_6(19.5\,eV) \longrightarrow C_6H_5(X^2\tilde{A}_1) + H(n=4) + 1.9 \pm 1.0\,eV$$

The onsets for H_β from pyridine and pyrazine are observed at 19.7±1.0 and 19.6±1.0 eV, respectively. A similar consideration on the energy balance with the dissociation energy of the C–H bond, 4.87 eV,[17] because the dissociation energy of the C–H bond of pyridine and pyrazine are not known, leads to the following processes

$$C_5H_5N(19.7\,eV) \longrightarrow C_5H_4N(X) + H(n=4) + 2.1 \pm 1.0\,eV$$

and

$$C_4H_4N_2(19.6\,eV) \longrightarrow C_4H_3N_2(X) + H(n=4) + 2.0 \pm 1.0\,eV.$$

Formation of CH(A). The excitation function for the CH(A-X) emission from benzene indicates some structure and a shallow dip near 20 eV. Hence, several states of benzene seem to be involved in the formation of CH(A), and further, the formation of CH(A) seems to compete with other processes: probably ion formations. The onsets for the CH(A-X) emission from benzene are observed at 12.7±1.0 and 21.4±1.0 eV; the first value is lower than 15.0±1.0 eV obtained by Beenakker and de Heer.[10] The second value, 21.4 eV, is even lower than 29±1 eV reported by Beenakker and de Heer.[10] Comparing the observed excitation function for the CH(A-X) emission with theirs, we conclude that the structure leading to this second appearance potential is different from that reported by Beenakker and de Heer.

Dissociation processes leading to the formation of CH(A) from benzene are still uncertain. Neverthless, if one assumes that the threshold energy consists of the difference between heats of formation of benzene and products[18–20] and the electronic energy of CH(A),[21] the following dissociation processes are considered to occur. Heats of formation and bond dis-

$$C_6H_6 \longrightarrow \text{  } + CH(A^2\Delta) \qquad 14.3\,eV \quad (1)$$

$$\longrightarrow \text{  } + C_2H_2(\tilde{X}) + CH(A^2\Delta) \qquad 22.9\,eV \quad (2)$$

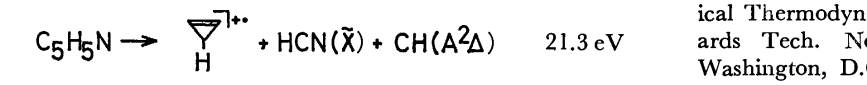
TABLE 2. HEATS OF FORMATION AND BOND DISSOCIATION ENERGIES USED FOR THE CALCULATION OF THRESHOLD ENERGIES

Species	ΔH_f° / kJ mol^{-1}	Ref.	D(R-H) / eV	Ref.
Benzene	82.89±0.54	18	4.87	17
Pyridine	144.56±0.5	18	4.87[a]	
Cyclopentadiene	130.25	18	4.87[a]	
C_2H_2	227.29	19		
HCN	135.5	19		
CH	592.5	19		
$C_3H_3^+$ (Cyclopropenyl ion)	1196.6 ±8[b]	20		

a) The value in benzene is used. b) This is the value of $C_4H_4^+$ (cyclobutadienyl) ion because the formation processes of $C_3H_3^+$ and $C_4H_4^+$ have identical thermochemical thresholds.[20]

sociation energies used for the calculation of the thresholds are summarized in Table 2. Process (1) seems to play an important role in the formation of CH(A) near the first threshold. Dissociation into more than two neutral fragments may happen at an intermediate energy region, 14—22 eV, because $C_4H_4^+$, $C_4H_3^+$, $C_4H_2^+$, and $C_3H_3^+$ ions from benzene are relatively abundant;[22,23] furthermore, dissociations producing only neutral fragments such as CH(A) proceed via so-called super-excited states competing with these ion formations. Process (2) including an ionic byproduct seems to play an important role in the formation of CH(A) near the second threshold. Some processes including $C_5H_5^+$ ion seems to be unimportant because $C_5H_5^+$ ion appears only very weakly or is not observed.[20,22]

The appearance potentials for CH(A) from pyridine and pyrazine are determined to be 20.1±1.0 and 18.5±1.0 eV, respectively. The absence of structures near the thresholds indicates that only one state or at most a few states of pyridine and pyrazine are involved in the formation of CH(A). On the basis of a similar consideration (see Table 2), the following dissociation process from pyridine is considered to occur because $C_3H_3^+$ (cyclopropenyl) ion is relatively abundant in photo-ionization mass spectrometry of pyridine.[20,24] It is impossible to derive dissociation processes from pyrazine because the relevant dissociation energies are not known. Neverthless, processes forming CH(A) from pyrazine presumably include the formation of an ionic fragment and may correspond to the dissociation processes forming CH(A) from benzene with the second threshold and pyridine.



In summary, the appearance potentials for H_β from benzene, pyridine, and pyrazine are nearly equal and H(n=4) may dissociate by a similar mechanism. The two appearance potentials for CH(A) from benzene are found from the structures in the excitation function for the CH(A-X) emission, while no corresponding structures exist near the thresholds of the excitation functions for the CH(A-X) emission from pyridine and pyrazine.

We wish to thank Prof. Kozo Kuchitsu of the University of Tokyo for many valuable comments on the manuscript and useful discussions.

Formation of Electron-Donor-Acceptor Complex and 1,4-Cycloadduct of Tetracyanoethylene with Styrene and Its α- or β-Substituted Derivatives

Yasuhiro Uosaki, Masaru Nakahara,* and Jiro Osugi

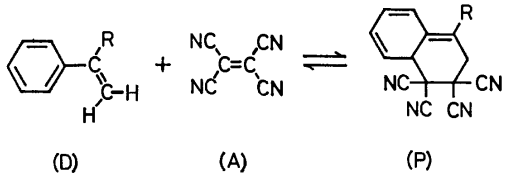
Department of Chemistry, Faculty of Science, Kyoto University, Oiwake-cho, Kitashirakawa, Sakyo-ku, Kyoto 606

(Received February 9, 1981)

EDA-complex formation and 1,4-cycloaddition of tetracyanoethylene (TCNE) with styrene, α-methylstyrene, 1,1-diphenylethylene, *cis*-stilbene, and *trans*-stilbene were studied spectrophotometrically in chloroform at 25 °C. Formation constants of the EDA complexes were found to be in the order, *trans*-stilbene > styrene > α-methylstyrene > *cis*-stilbene > 1,1-diphenylethylene. The difference in the formation constants was discussed in terms of both electronic and steric effects of the donors studied. α-Methylstyrene and 1,1-diphenylethylene underwent thermal cycloaddition to TCNE faster than styrene. It is suggested that some charge separation took place in the transition state. The fact that *trans*- and *cis*-stilbenes do not react with TCNE was explained in terms of the difference in stability of the 1,4-cycloadducts estimated from the 1,4-bislocalization energy obtained by Dewar's perturbation molecular orbital method.

The nature of tetracyanoethylene (TCNE) as a strong acceptor causes a few typical cycloaddition reactions with π-electron donors as well as the EDA (electron-donor-acceptor)-complex formation.[1] When TCNE is mixed with benzene derivatives, electron-rich olefins, and conjugated dienes, it usually yields the EDA complexes only, cyclobutane derivatives (1,2-cycloadducts), and cyclohexene derivatives (1,4-cycloadducts), respectively, under mild conditions.

Styrene has been considered to be nonreactive toward TCNE under mild conditions, although benzylidenemalononitrile and a cycloadduct consisting of two molecules of styrene and one molecule of TCNE were obtained by refluxing in xylene.[2] Recently, however, it was found by the high-pressure quenching method that styrene and its derivatives(D) undergo reversible cycloaddition to TCNE(A) to afford the 1,4-cycloadduct(P) besides the EDA complex.[3,4] The 1,4-cycloaddition reaction illustrated below is of



(D) (A) (P)

interest. Styrenes serve as a diene, losing their aromaticity, while they act as a dienophile in the Diels-Alder reaction with anthracenes.[5] In order to get insight into the mechanism of the reaction, a detailed kinetic study has been carried out. It was not clarified in the previous work[4] why neither *cis*- nor *trans*-stilbene provides the 1,4-cycloadduct, despite the fact that ionization potentials of these molecules are lower than those of other styrenes which give the cycloadduct. An interpretation for the unexpected result is given herewith in view of the molecular orbital theory.

The formation constant and molar absorption coefficient of the EDA complex between TCNE and styrene were determined[6-9] without taking into consideration the coexistence of the 1,4-cycloadduct confirmed previously.[3,4] Reliable values of these parameters were obtained in the present study taking into account the 1,4-cycloadduct. Discussion is given on the factors determining the stability of the EDA complexes between TCNE and styrene and its derivatives.

Experimental

Electron donors and TCNE were purified by the method reported.[4] Chloroform as a solvent was purified by the standard method. The boiling points and melting points of all the reagents agree with the values reported.

Stock solutions of the donors and the acceptor were prepared immediately before use. Electronic absorption spectra and their time dependences for kinetic studies were measured with a Shimadzu UV-200S spectrophotometer. Thermostatted water (25 °C) was circulated around a quartz cell and donor and acceptor reservoirs. The temperature was regulated within ±0.1 °C. Under the conditions where the concentration (mol dm^{-3}) of the donor is in large excess, reaction rates were determined by following the increase in the absorbance around 320 nm due to the 1,4-cycloadduct, and equilibrium studies by observing the charge-transfer (CT) band at a longer wavelength. The absorbance due to the EDA complex decreased to a stationary value (not zero) with time except in the case of stilbenes. The time at half-mixing of donor and acceptor solutions was taken as time zero when we get an absorbance of the EDA complex at time zero by extrapolation.

Results and Discussion

EDA Complexes of TCNE with Various Styrene Derivatives. When α-methylstyrene is mixed with TCNE in chloroform, absorption bands due to the EDA complex instantaneously appear in the visible region (Fig. 1b). Similar absorption spectra can be observed in solutions of TCNE and other styrene derivatives. The donor and TCNE have no absorption in this region. The wavelength of the maximum absorption(λ_{max}) is slightly larger in chloroform than that in dichloromethane (Table 1).

The plot of transition energies ($h\nu_{CT}$) of a series of EDA complexes with a fixed acceptor against ionization potential (I_p) of donors generally shows a

Table 1. Spectroscopic properties and formation constants of EDA complexes between TCNE and various styrene derivatives in $CHCl_3$ at 25 °C

linear relationship.[1b] This was also found to be the case in this study:

$$h\nu_{CT}/\text{eV} = 0.873(I_p/\text{eV}) - 4.89 \quad \text{(in } CHCl_3\text{)} \quad (1)$$

$$h\nu_{CT}/\text{eV} = 0.847(I_p/\text{eV}) - 4.63 \quad \text{(in } CH_2Cl_2\text{)}. \quad (2)$$

The gradients obtained for the TCNE–styrene derivative systems are nearly the same as those obtained for other TCNE–aromatic hydrocarbon systems in the corresponding solvents.[1b] The fact that the gradient is not very far from unity suggests that the resonance interaction between the donors and acceptor is weak; the EDA complexes we have examined are weak ones.

The formation constant(K_c) and molar absorption coefficient (ε_{max}) of the EDA complex at λ_{max} are determined by the Scott equation,[10]

$$\frac{[D]_0[A]_0 l}{A_0} = \frac{1}{K_c\varepsilon_{max}} + \frac{[D]_0}{\varepsilon_{max}}, \quad (3)$$

where $[D]_0$ and $[A]_0$ are the initial concentrations of the donor and acceptor, respectively, A_0 is the absorbance of the EDA complex at λ_{max} at time zero, ε_{max} the molar absorption coefficient at λ_{max}, and l the path length (10 mm). Figure 2 shows a plot of the left-hand side of Eq. 3 against $[D]_0$ for α-methylstyrene–TCNE system. Applying the least-squares method to linear plots like this, we obtain values of K_c and ε_{max} of the complexes as in Table 1, the K_c values being in the sequence, *trans*-stilbene>styrene> α-methylstyrene > *cis*-stilbene > 1,1-diphenylethylene. The sequence of the TCNE complexes is similar to that of the 1,3,5-trinitrobenzene complexes, except for the case of *cis*-stilbene.[11]

In the case of planar molecules like styrene and *trans*-stilbene, the sequence is in accord with the trend that the lower the ionization potential of the electron donors, the larger the formation constant. The trend has been derived theoretically by assuming that CT forces mainly contribute to the stabilization energy of the EDA complex.[9,12] On the other hand, in the case of nonplanar molecules like α-methylstyrene, 1,1-diphenylethylene, and *cis*-stilbene, the result is not in accord with the general trend. Since these three nonplanar styrenes have dihedral angles, *ca.* 30—40°,[13,14] the configuration of the complexes is considered to differ a great deal from that of planar-styrene complexes. The nonplanarity of the electron donors interferes approach of the planar TCNE molecule as a factor of steric hindrance, which is responsible for the formation constant smaller than that expected simply from the electronic effect.

Kinetics of 1,4-Cycloaddition. The absorption band around 320 nm due to the 1,4-cycloadduct increases and the CT-absorption band decreases with time, and finally, they reach stationary values (Fig. 1a). Since the EDA-complex formation and 1,4-cycloaddition take place reversibly, the following reaction scheme in which both reactions proceed successively can be assumed:[15]

$$D + A \overset{K_c}{\rightleftharpoons} \text{EDA complex} \overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} P \quad (4)$$

where k_1 and k_{-1} are the rate constants of the forward and backward reactions, respectively. Let us carry out a kinetic analysis of the reaction according to Eq. 4. When $[D]_0 \gg [A]_0$, the rate equation for the increase of the 1,4-cycloadduct is

$$\frac{d[P]}{dt} = a - k_{obsd}[P], \quad (5)$$

where the square brackets denote the concentration, t time,

$$a = \frac{k_1 K_c [D]_0 [A]_0}{1 + K_c [D]_0} = k_1 [EDA]_0, \quad (6)$$

and

$$k_{obsd} = \frac{k_1 K_c [D]_0}{1 + K_c [D]_0} + k_{-1}. \quad (7)$$

Integration of Eq. 5 gives the expression for [P] as

$$[P] = \frac{k_1 [EDA]_0 \{1 - \exp(-k_{obsd} t)\}}{k_{obsd}}, \quad (8)$$

since [P]=0 at time zero. Pseudo-first-order rate constant, k_{obsd}, was determined by the Guggenheim plot. Plots of k_{obsd} *vs.* $K_c[D]_0/(1+K_c[D]_0)$ for the styrene- and α-methylstyrene–TCNE systems afford good straight lines as shown in Fig. 3. Values of k_1 and k_{-1} obtained from plots of this kind are given in Table 2, together with those of equilibrium constant between the 1,4-cycloadduct and EDA complex, $K_1(\equiv k_1/k_{-1})$, and overall equilibrium constant $K(\equiv K_c K_1)$. We see from Eq. 7 that the product $k_1 K_c$ is overall second-order rate constant from the reactants to the 1,4-cycloadduct. Table 2 shows that the effect of substitution at the α-position by methyl or phenyl group on $k_1 K_c$ is substantially large, the methyl or phenyl substitution enhancing the reactivity by factors of *ca.* 70 and *ca.* 50, respectively. Though most 1,4-cycloadditions are considered to proceed *via* concerted mechanism, the enhancement of the reaction is too large for a concerted mechanism.[16] Similar enhancement has been observed for 1,2-cycloaddition of TCNE to enol or enethiol ethers in which a dipolar intermediate is considered to be involved.[17,18] Thus the α-substitution effect suggests that some charge separation develops in the transition state of the 1,4-cycloaddition. The marked dependence of the rate on solvent polarity supports this idea.[19]

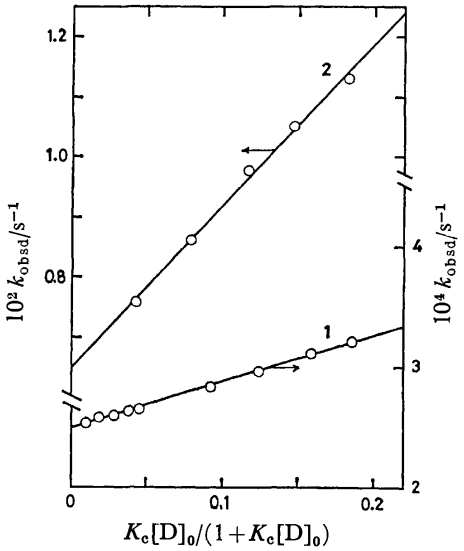

Fig. 3. Plots of k_{obsd} against $K_c[D]_0/(1+K_c[D]_0)$ in $CHCl_3$ at 25 °C.
1: Styrene–TCNE, 2: α-methylstyrene–TCNE.

Equilibria Including 1,4-Cycloadduct. At the stationary state, *i.e.*, $t=\infty$, we obtain

$$[P]_e = \frac{k_1 [EDA]_0}{k_{obsd}}, \quad (9)$$

where $[P]_e$ is the concentration of the 1,4-cycloadduct at the stationary state. By means of the definition $K_1=[P]_e/[EDA]_e$ and Eqs. 6, 7, and 9, we have

$$[EDA]_e = \frac{K_c [D]_0 [A]_0}{1 + (1+K_1) K_c [D]_0}. \quad (10)$$

This can be rewritten as

$$\frac{[D]_0 [A]_0 l}{A_e} = \frac{1}{K_c \varepsilon_{max}} + \frac{(1+K_1)[D]_0}{\varepsilon_{max}}, \quad (11)$$

by means of Beer's relation $[EDA]_e = A_e/\varepsilon_{max}\, l$, where A_e is the absorbance of the EDA complex at λ_{max} at the stationary state. A plot of the left-hand side of Eq. 11 against $[D]_0$ in the α-methylstyrene–TCNE system is also shown in Fig. 2. The two kinds of plots corresponding to Eqs. 3 and 11 should have the same intercept; this is actually the case. The equilibrium constant K_1 is determined from Eq. 11 and the slope of the line 2 in Fig. 2. The value of K_1 obtained from the equilibrium measurement is in accord with that obtained kinetically $(K_1 \equiv k_1/k_{-1})$ within experimental error (Table 2). The agreement indicates that the present analysis is self-consistent.

We can obtain from Eq. 8 a reliable value of the molar absorption coefficient (ε_{320}) of the 1,4-cycloadduct at 320 nm. The values of $\varepsilon_{320}/mol^{-1}\,dm^3\,cm^{-1}$ are $(7.7\pm0.1)\times10^3$, $(5.1\pm0.3)\times10^3$, and $(4.0\pm0.2)\times$

Table 2. Rate and equilibrium constants of the 1,4-cycloaddition between TCNE and various styrene derivatives in $CHCl_3$ at 25 °C

Donor	$10^3 k_1/s^{-1}$	$10^3 k_{-1}/s^{-1}$	K_1	$K/mol^{-1}\,dm^3$
Styrene	0.380±0.012	0.250±0.001	1.52±0.05	0.71±0.04
α-Methylstyrene	26.8±0.6	6.50±0.09	4.12±0.15 (4.29±0.15)[a]	1.80±0.12
1,1-Diphenylethylene	28.9±2.5	8.21±0.12	3.51±0.35	1.07±0.15

a) From the equilibrium measurement.

10^3 for the styrene, α-methylstyrene, and 1,1-diphenylethylene adducts, respectively. The value of ε_{320} for the styrene adduct is slightly larger than that obtained in dichloromethane ($(5.5\pm0.1)\times10^3$).[4] The difference arises from the change of solvents and the neglect of the presence of the EDA complex in the previous treatment.

Tonchéva *et al.* determined K_c and ε_{max} of the TCNE complexes with styrene and α-methylstyrene in 1,2-dichloroethane at 20 °C without noticing the 1,4-cycloadduct, and reported 645 as ε_{max} for styrene and 200 for α-methylstyrene.[7] These values are too small for the TCNE complexes with aromatic hydrocarbons.[1b] The stationary state reaches within 10 minutes in the case of α-methylstyrene–TCNE in chloroform (Table 2). In a more polar solvent, 1,2-dichloroethane, the stationary state is attained faster. The ε_{max} is considered to be $\varepsilon_{max}/(1+K_1)$; ε_{max} and K_1 are shown to be $(3.33\pm0.16)\times10^3$ mol^{-1} dm^3 cm^{-1} and 13.8 under the same condition.[19]

Reactivity of Styrenes. The reactivity of dienes toward TCNE generally increases with the decrease in its ionization potentials, though it is not the diene having lower ionization potential that shows high reactivity in the Diels-Alder reaction. This is also the case for the reaction we examined. Although *trans*- and *cis*-stilbenes have lower ionization potentials than other styrene derivatives, the stilbenes react with TCNE to form only the EDA complex, showing no further reaction such as 1,4-cycloaddition.

The reactivity of styrenes toward TCNE can be examined by the method described by Mok and Nye;[20] the energy of the transition state is considered to depend on the FMO (frontier molecular orbital) interaction energy between reactants and on the stability of the product. The FMO treatment predicts that a diene of lower ionization potential is more reactive on the assumption that other interactions (*e.g.*, van der Waals interactions) are constant within a series of dienes. Since this is contradictory to the experimental results, we should examine the stability of the product. The 1,4-bislocalization energy calculated from Dewar's perturbation molecular orbital method is of great use for a comparison of the stability of the adducts.[21] The 1,4-bislocalization energies computed for three styrenes are given in Table 3, where *para*-localization energies by Brown[22] are included for comparison. It turns out that both parameters have nearly the same value for the donors. We see from the definition of localization energy that a diene of a smaller localization energy, *i.e.*, smaller coefficient of the localization energy, reacts with TCNE to form a stable adduct. For the discussion of reactive sites,[22] the critical value of the localization energy divided by the resonance integral (β) is taken as 3.6 below which reaction takes place. Stilbenes have a larger value than this corresponding to the fact that they are nonreactive toward TCNE (Table 3).

Table 3. 1,4-Bislocalization and *para*-localization energies of three styrenes

Donor	1,4-Bislocalization energy/β	*Para*-localization energy[a]/β
Styrene	3.51	3.44
1,1-Diphenylethylene	3.26	3.34
Stilbene	3.84	3.89

Determination of Local Structure and Moving Unit Formed in Binary Solution of *t*-Butyl Alcohol and Water

Nobuyuki Ito,† Tadashi Kato, and Tsunetake Fujiyama*

Institute for Molecular Science, Myodaiji, Okazaki 444

† *Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158*

(Received February 18, 1981)

The concentration dependences of the mutual diffusion coefficients at 24, 37, and 63 °C were observed for a binary solution of *t*-butyl alcohol (TBA) and water by the use of the light scattering method. The observed concentration dependences of the mutual diffusion coefficients were explained well by postulating the existence of a "moving unit"—a group of molecules which move together for a time much longer than the velocity correlation time. The structure of the moving units which are formed in the solution are $(H_2O)_{11}$TBA at 24 °C and $(H_2O)_{20}$TBA at 63 °C in the concentration range of $0<x_{TBA}<0.1$, where x_{TBA} is the mole fraction of TBA. Taking into account the local structures, which had been determined from the concentration dependences of the mean-square concentration fluctuation values, we could conclude that water molecules form a polyhedron which encages a TBA molecule and that these cages then gather together to form an aggregate. It is essential that these polyhedra do not share their faces with each other in the aggregate. It was also concluded that the number of cages which form an aggregate increases with an increase in the temperature. This suggests the existence of a pseudo-critical temperature for this system. That is to say, the TBA–water solution can separate into two phases under high pressures, a TBA-rich phase and a water-rich phase, in the latter of which almost all the molecules form polyhedra.

In our previous reports,[1,2] the mean-square concentration fluctuation observed by means of the light scattering spectra for TBA–water solution has been reported. From a quantitative analysis of the concentration fluctuation, it has been shown that the local structure of the type $g[(H_2O)_i$TBA$]$ exists in the solution. As the number ratio of TBA to water for this local structure was close to that of the solid clathrate hydrate of TBA,[3] we proposed that this local structure can be a clathrate hydrate-like structure.

It has been established, in the solid clathrate hydrate, that water molecules form polyhedra, each of which encages a guest molecule and that the several polyhedra share one of their faces (we will call this an "associated polyhedron" hereafter). We are interested in whether or not the same sort of associated polyhedra can be formed even in the solution phase, because we can draw another picture for the local structure formed in the solution phase. That is, the polyhedra gather together to form an aggregate without sharing faces with each other (we call this an "aggregated polyhedron" hereafter). The observation of the mean-square concentration fluctuation does not afford information which is accurate enough to judge which picture is correct, that is, whether "associated polyhedron" or "aggregated polyhedron." In addition to the mean-square concentration fluctuation, we have to know the life-time of the local structure in order to solve this problem.[4]

Recently, we have emphasized the importance of the concept of a "moving unit" — a group of molecules which move together for a time much longer than the velocity correlation time — in order to obtain information about the life-time of local structures. A moving unit can be determined by expressing the mutual diffusion coefficient theoretically in terms of the self-diffusion coefficients and the number of moving units.[5,6]

In the present study, we will discuss the above problem on the basis of an analysis of the mutual diffusion coefficients which are obtained from the correlation function of the electric field of Rayleigh light. It will be shown that the aggregated polyhedron picture is preferrable to the associated polyhedron picture. This conclusion will lead us to emphasize the fact that the mixing state of the TBA and water system is governed by a moving unit of the type $(H_2O)_i$TBA. We will also discuss the temperature effect on the mixing state on the basis of the "aggregated polyhedron" picture. It will be suggested that a binary solution of TBA and water may be separated into two phases under high pressure, a TBA-rich phase and a water-rich phase, in the latter of which almost all the water molecules form polyhedra.

Experimental

The light scattering spectrometer used in the present study was designed and constructed in our laboratory. The light source was an Argon ion laser (Spectra-Physics, model 165-09) which produced 0.1—1 W power at 488 nm. The scattering angle, θ, was defined by two pinholes approximately 50 cm apart and 0.5 mm in diameter. The laser beam was focused into a rectangular cell with a path length of 1.5 cm. A scattered light and a local oscillator beam (scattered from the cell walls) were collected onto the surface of a photomultiplier tube (HTV R-374). The photo current was amplified by a factor of about 400 by means of a preamplifier and autocorrelated by a 400-channel correlation and probability analyzer (KANOMAX SAI-43A). The computed time auto-correlation function of the photocurrent was recorded on an X-Y recorder. At the same time, the auto-correlation function was transferred in a digital form from the correlator to a micro-computor (SHARP Mz-80C).

In our previous study,[7] a spectrum analyzer (Takeda Riken, TR-4120S) was used instead of a signal correlator. The signal correlator is superior to the spectrum analyzer for the observation of the current fluctuation in the low-

frequency range (DC≈kHz) in the following respects. First the rate of data collection with the signal correlator is higher than that with the spectrum analyzer by a factor of more than 10^2. Second, we can compare the precision of the data sampling interval, τ. For the signal correlator used in the present work, the precision of τ is about 10^{-4} for the frequency range of DC≈50 kHz. In the case of the spectrum analyzer, on the other hand, the corresponding precision can be estimated from the precision of the observed frequency, $|\Delta f/f|$, because the $|\Delta\tau/\tau| = |\Delta f/f|$ relation holds between these two kinds of precision. The precision of the observed frequency is about 10^{-4} at 50 kHz and about 10^{-2} at 500 Hz. Thus, the signal correlator is more appropriate for the observation of the current fluctuation of the low-frequency signal (DC≈50 kHz). The characteristic frequency of the concentration fluctuation appears in this frequency range.

The time-correlation function of the electric field of Rayleigh light was observed at the temperatures of 24, 37, and 63 °C, with a temperature constancy of ±0.5 °C.

t-Butyl alcohol purchased from the Katayama Chemical Industries Co., Ltd., was used without further purification. Water was distilled after being passed through an ion-exchange resin. The binary mixture of TBA–water was made dust-free by the use of a Nuclepore filter with a pore size of 0.1 μm.

Results and Discussion

Light Scattering Measurement and Mutual Diffusion Coefficient. The time-correlation function of the electric field of the Rayleigh light isotropically scattered from a binary solution is composed approximately from two exponential functions.[8] One corresponds to the scattering due to entropy fluctuation, and the other, to that due to concentration fluctuation. Since the relaxation of the latter is slower than that of the former by a factor of 10^2, these two exponential curves can be identified separately. The correlation function for the concentration fluctuation is expressed as:

$$\frac{\langle \Delta c(\boldsymbol{q}, t)\Delta c(\boldsymbol{q}, 0)\rangle}{\langle \Delta c(\boldsymbol{q}, 0)^2\rangle} = \exp(-q^2Dt) \tag{1}$$

$$\Delta c(\boldsymbol{q}, t) = \int_V (c(\boldsymbol{r}, t) - \langle c\rangle)e^{i\boldsymbol{q}\cdot\boldsymbol{r}}d^3\boldsymbol{r}, \tag{2}$$

where $c(\boldsymbol{r}, t)$ is the concentration at the point $\boldsymbol{r}$ at time t in the scattering volume, V, and where the pointed bracket represents an equilibrium ensemble average. Therefore, we can obtain the mutual diffusion coefficient, D, from the relaxation time of the time correlation function, $\tau_c \equiv 1/q^2D$.

Figure 1 shows a typical example of the observed photocurrent-correlation function, $\langle i(t)i(0)\rangle$, which corresponds to the correlation function of the scattered electric field. The observed correlation function was well expressed by a single exponential function. By plotting $1/\tau_c$ against q^2, the theoretical prediction of the linear dependence of $1/\tau_c$ on q^2 was confirmed. The mutual diffusion coefficients thus obtained are plotted against the mole fraction of TBA in Fig. 2.

The mutual diffusion coefficient for a binary solution composed of A and B components, D, is expressed in terms of the velocity correlation function as:[5]

$$D = QL \tag{3}$$

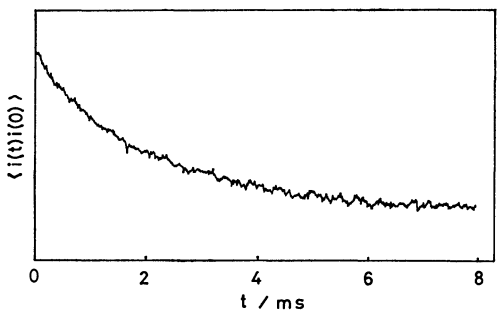

Fig. 1. Typical light scattering photocurrent autocorrelation function observed for TBA–water solution (x_{TBA}=0.13, θ=9.62°).

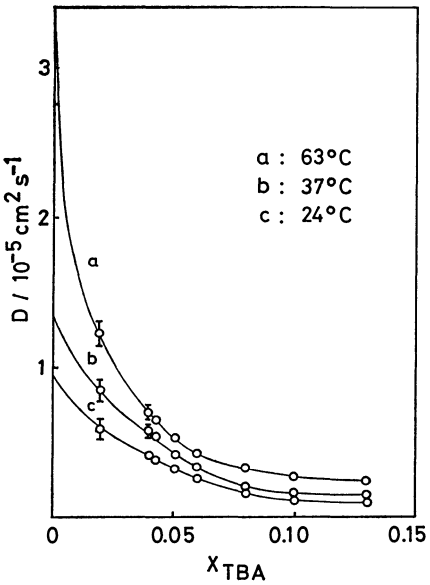

Fig. 2. Concentration dependence of the mutual diffusion coefficient for TBA–water solution at different temperatures.

$$L = L^\circ + (n_A+n_B)x_Ax_B(V_{aa'}+V_{bb'}-2V_{ab}) \quad (a\neq a',\ b\neq b') \tag{4}$$

with

$$Q \equiv x_Ax_B/N\langle(\Delta x_A)^2\rangle \tag{5}$$

$$L^\circ = x_AD_B + x_BD_A \tag{6}$$

$$V_{ij} \equiv \frac{1}{3}\int_0^\infty \langle \boldsymbol{v}_i(t)\boldsymbol{v}_j(0)\rangle dt \quad (i, j=a, a', b, \text{ or } b'), \tag{7}$$

where $\boldsymbol{v}_a(t)$ and $\boldsymbol{v}_b(t)$ are the velocities of an a-th molecule of A and a b-th molecule of B respectively. x_A and x_B are the mole fraction of A and B, and n_A and n_B are the number of A and B molecules respectively. D_A and D_B are the self-diffusion coefficients of the A and B molecules respectively. L is called a kinetic diffusion coefficient. Figure 3 shows the concentration dependence of L for the water(A) and TBA(B) system, where Q is obtained from the observed mean-square concentration fluctuation, $N\langle(\Delta x_A)^2\rangle$, of Fig. 4.[9]

In order to calculate the L° value, the D_A and D_B values must be observed. Figure 5 shows the observed concentration dependences of D_A and D_B which

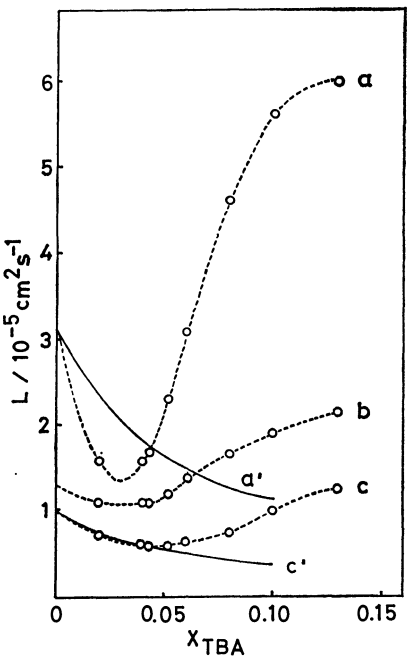

Fig. 3. Concentration dependence of L (curves a, b, and c) and L° (curves a′ and c′); a, a′: 63 °C, b: 37 °C, c, c′: 24 °C (see Eqs. 4—6).

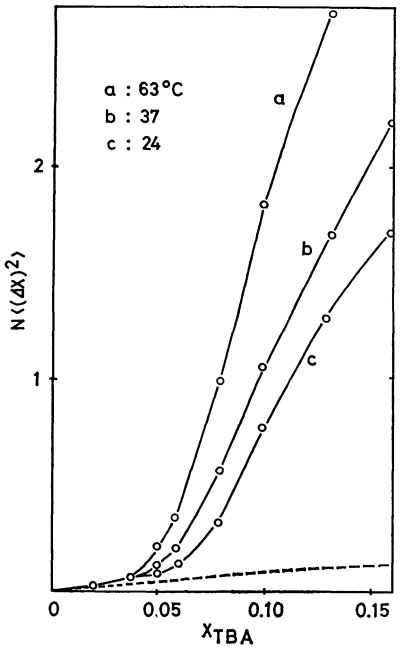

Fig. 4. Concentration dependence of the mean-square concentration fluctuation for TBA–water solution at different temperatures.[2] The dashed line corresponds to the concentration fluctuation expected for an ideal binary solution.

are found in the literature.[10,11] Using these values, we have calculated the D_A and D_B values at 24 and 63 °C according to the following procedure. The temperature dependences of the self-diffusion coefficients, D_s, of pure water (0—55 °C) and TBA for a dilute aqueous solution (4—37 °C) have been reported.[12,13] The plots of $\ln D_s$ against $1/T$ are adequately approximated by straight lines, where T is

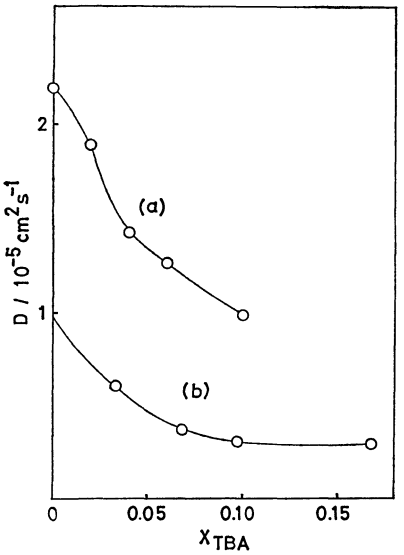

Fig. 5. Concentration dependence of the self-diffusion coefficients of: (a) water at 21 °C, (b) TBA at 25 °C.

the absolute temperature. If we assume that the temperature dependence of the self-diffusion coefficient is independent of the concentration, the D_s values at other temperatures can be estimated from these linear relations.

The concentration dependence of $L°$ thus obtained for 24 and 63 °C are shown in Fig. 3. It may be seen from the figure that $(L\text{-}L°)$ increases with the increase in the temperature in the concentration range of $0.05 < x_{TBA}$. This result indicates that the velocity correlation within the same species is larger for the higher temperature (see Eq. 4).

Analysis of Kinetic Diffusion Coefficient L. In the preceding report,[6] we have obtained the following expression for the kinetic diffusion coefficient, L, for the system composed of the moving units of the A_r, B_s, and gA_lB types:

$$L = M - x_{A_lB} H D_{gA_lB} \tag{8a}$$

and;

$$M = r x_B D_A + s x_A D_B \tag{8b}$$

$$H = l[2g - (x_B/x_A)(gl - r)] - (x_A/x_B)(g - s) \tag{8c}$$

$$x_{A_lB} = (1/2l)\left[x_A + l x_B - \{(x_A + l x_B)^2 - \frac{4Kl}{K+1} x_A x_B\}^{1/2}\right] \tag{8d}$$

$$K = (n_{A_lB}/N')/(n_{A_l}/N')(n_{B_1}/N') \tag{8e}$$

$$N' = n_{A_l} + n_{A_lB} + n_{B_1}, \tag{8f}$$

where D_{gA_lB} is the self-diffusion coefficient of the moving unit, gA_lB. In that preceding report, though, the value of D_{gA_lB} could not be determined uniquely.[6] In the present study, we have determined the parameters included in Eq. 8 in the following way. Table 1 shows the self-diffusion coefficients of pure liquids and the self-diffusion coefficients at an infinite dilution. It may be seen from the table that the ratio of the two diffusion coefficients corresponding to the two different solutes is almost the same for the three solvents. For example, the ratios of the self-diffusion coefficients of acetone and carbon tetrachloride are

Table 1. Self-diffusion coefficients of a few organic substances at an infinite dilution (25 °C)

Solute	Solvent		
	Acetone	Benzene	Carbon tetrachloride
Acetone	4.8* [a]	2.8[b]	1.7[e]
Benzene	4.3[b]	2.2* [a]	1.5[e]
Carbon tetrachloride	3.6[c]	2.0[d]	1.4* [f]

almost equal (1.33 in acetone, 1.4 in benzene, and 1.21 in carbon tetrachloride). This fact suggests that the ratio of the self-diffusion coefficients of two different species coexisting in a certain medium is almost constant, even if the physical properties of the medium are changed. Thus, we may assume that the magnitude of D_{gA_lB} is proportional to that of D_{A_r} or D_{B_s}; that is,

$$D_{gA_lB} = D_{B_s}/k_B \tag{9a}$$

or

$$D_{gA_lB} = D_{A_r}/k_A, \tag{9b}$$

where k_A and k_B are constans. On the other hand, the D_A and D_B self-diffusion coefficients have been expressed as:[6]

$$D_A = \frac{(x_A - lx_{A_lB})}{x_A} D_{A_r} + \frac{lx_{A_lB}}{x_A} D_{gA_lB} \tag{10a}$$

$$D_B = \frac{(x_B - x_{A_lB})}{x_B} D_{B_s} + \frac{x_{A_lB}}{x_B} D_{gA_lB}. \tag{10b}$$

By substituting Eqs. 9a and 9b into Eqs. 10b and 10a respectively, we can obtain the expression of D_{gA_lB} in terms of D_A and D_B as:

$$D_{gA_lB} = \frac{x_B}{k_B(x_B - x_{A_lB}) + x_{A_lB}} D_B \tag{11a}$$

or

$$D_{gA_lB} = \frac{x_A}{k_A(x_A - lx_{A_lB}) + lx_{A_lB}} D_A. \tag{11b}$$

By substituting Eq. 11a or 11b into Eq. 8a, we can calculate L by the use of D_A and D_B. In order to obtain the parameters, K, l, r, s, q, and k_A (or k_B), the least-squares method was used.[14] There is no strong reason for having which equation, Eq. 9a or 9b, is more appropriate. However, the better fit between the observed and the theoretical values for the concentration dependences of L could be obtained when we employed Eq. 9a.

Figure 6 shows the concentration dependences of the observed (dots) and the calculated (solid line)

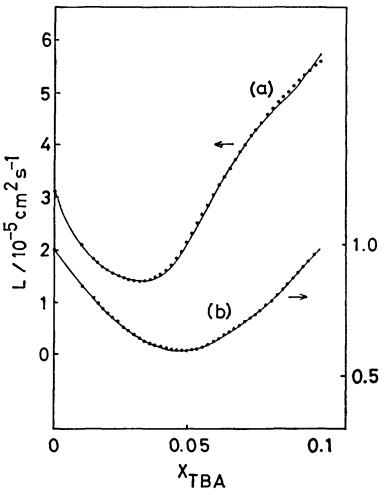

Fig. 6. The observed L values (·····) and the best fit curve (——) calculated from Eqs. 8 and 11a: (a) 63 °C, (b) 24 °C.

L values. For 24 °C, the best-fit parameters are: $K=39.0\pm7.7$, $l=11.1\pm0.3$, $r=6.0\pm0.8$, $s=4.0\pm1.2$, $g=0.9\pm0.03$, and $k_B=2.1\pm1.5$. These results show that the moving units of the $(H_2O)_{11}TBA$, $(H_2O)_6$, and $(TBA)_4$ types coexist in the concentration range of $0<x_{TBA}<0.1$ at 24 °C. For 63 °C, the best-fit parameters are $K=51.0\pm7.1$, $l=20.2\pm0.6$, $r=9.7\pm1.8$, $s=15.6\pm2.3$, $g=0.8\pm0.03$, and $k_B=0.3\pm0.09$. These results indicate the coexistence of the moving units of the $(H_2O)_{20}TBA$, $(H_2O)_{10}$, and $(TBA)_{16}$ types at 63 °C. The value of k_B at 63 °C is much smaller than that at 24 °C. This result seems quite reasonable, because these relations hold;

$$D_{(H_2O)_{11}TBA} \simeq \frac{1}{2} D_{(TBA)_4}$$

and

$$D_{(H_2O)_{20}TBA} \simeq 3D_{(TBA)_{16}}.$$

A self-diffusion coefficient should increase with the decrease in a molecular weight.

Life-time of Local Structure and Mixing State of TBA–Water Solution. In the study of the mean-square concentration fluctuation for the TBA–water system, the existence of local structure of the $g[(H_2O)_lTBA]$, $(H_2O)_r$, and $(TBA)_s$ types has been suggested. In order to compare this result (local structure) with the present result (moving unit), the values of g, l, and s are summarized in Table 2. Hereafter, g, l, r, and s will refer to the parameters related with the local structure, while g^d, l^d, r^d, and s^d will refer to the corresponding parameters related with the moving unit.

In the preceding report,[6] the g^d value was found to be 2—4 at 24 °C when the l^d value was fixed at 20. Based upon this result, we considered that the local structure obtained from the mean-square concentration fluctuation study can also be a moving unit. However, the estimation of the g^d value corresponding to an l^d value other than 20 has not been done. In the present study, the parameter values have been determined uniquely without fixing the

Table 2. The parameter values which characterize the sizes of the local structures and the moving units

Moving unit:

T/°C	l^d	g^d	s^d	r^d
24	11	1	3—5	5—7
63	19—21	1	13—18	8—11

Local structure (data from Ref. 2):

T/°C	l	g[a)]		s	r[b)]
		$x<x^s$	$x^s<x$		
24	15—19	2—3	4—8	4—16	—
63	21—25	2—3	12—22	2—20	—

a) $x^s=0.05$ (mole fraction of TBA). b) The r-value could not be determined uniquely, for the $N\langle(\Delta x)^2\rangle$ value was insensitive to the r-value (see Ref. 2).

l^d value. Therefore, we will be discuss about the moving unit in more detail in comparison with the local structure.

The number ratios of TBA to water molecules which form a moving unit, $g^d[(H_2O)_{l^d}TBA]$, are 1:11 and 1:20 at 24 and 63 °C respectively. It has been known that TBA molecules form a solid clathrate hydrate of the "17 hydrate" structure with water molecules.[3] In this solid clathrate hydrate, the water molecules form polyhedra, each of which encages a guest molecule. As the number ratio of TBA to water molecules in the moving unit is colse to that in the solid clathrate hydrate (1:17), the moving unit is considered to have a polyhedron-like structure.

It can also be seen from Table 2 that the g^d and l^d value are smaller than the g and l values respectively. This difference may be explained as follows. A moving unit is defined as a group of molecules which move together for a time much longer than the velocity-correlation time (10^{-13}—10^{-12} s), while a local structure is defined as an averaged local configuration of molecules, without considering its life-time. If the life-time of the local structure of the $g[(H_2O)_lTBA]$ type is as long as that of the moving unit, the g^d and l^d values should be equal to the g and l values respectively. As g^d and l^d are different from g and l, we can conclude that the life-time of the local structure of the $g[(H_2O)_lTBA]$ type is shorter than that of the moving unit of the $(H_2O)_{l^d}TBA$. In other words, the moving unit is relatively stable. As the g^d value is about 1 in the concentration range of $0<x_{TBA}<0.1$, the local structure determined from the mean-square concentration fluctuation study (*i.e.*, $g[(H_2O)_lTBA]$) can be an aggregate of the moving units of the $(H_2O)_{l^d}TBA$ type. The difference between the local structure and the moving unit has already been pointed out in a previous study of the methanol–carbon tetrachloride system and of the ethanol–carbon tetrachloride system.[5]

Now we can answer the question raised in the introductory paragraph. The above results show that the translational motions of the polyhedra which form a local structure, $g[(H_2O)_lTBA]$, are mutually independent. If an "associated polyhedron" is formed in the solution, the motions of the component polyhedra may be considered to be mutually correlated, because the polyhedra share their faces with each other. Thus, the "aggregated polyhedron" is the more appropriate picture for the mixing state of the TBA–water solution.

The above conclusion is schematically visualized in Fig. 7. In the concentration range of $0<x_{TBA}<0.05$, the water molecules form a polyhedron which encages a TBA molecule and the aggregate of a few polyhedra is dispersed in water. In the concentration range of $0.05<x_{TBA}<0.1$, the aggregate of 4—8 polyhedra is dispersed in TBA. The aggregate of the polyhedra grow larger with the increase in the number of the moving units, $(H_2O)_{l^d}TBA$, formed in the solution.

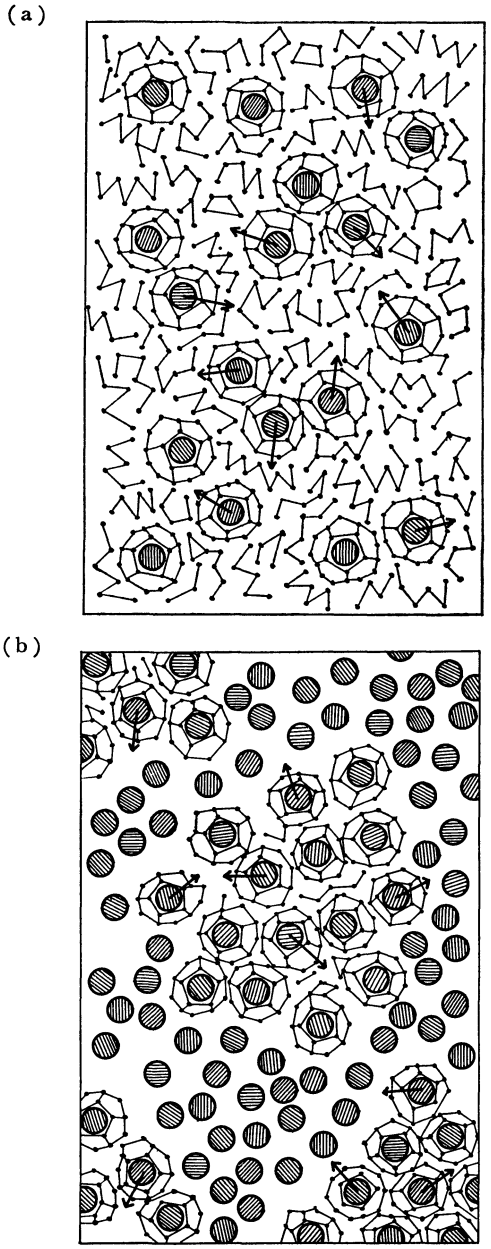

Fig. 8. Mixing state of TBA–water solution for: (a) $x_{TBA} \simeq 0.02$, (b) $x_{TBA} \simeq 0.09$ (schematic) at 63 °C. (●) and (▨) represent a water and a TBA molecule, respectively.

Temperature Effect on Mixing State. Next we will discuss the temperature effect on the mixing state of the TBA–water solution. As can be seen from Table 2, the g and l values increase with the increase of the temperature from 24 °C to 63 °C. The simultaneous increase in g and l brings about rapid increase in the total number of molecules which take part in the formation of the local structure of the $g[(H_2O)_l$-TBA] type. The increase in the l value shows that the number ratio of water to TBA molecules increases with the increase in the temperature. It can also be seen from Table 2 that the l^d value increases with the increase in the temperature, indicating that the polyhedron formed by water molecules becomes larger with an increasing temperature. It is important to emphasize that the g^d value is about 1 at both 24 °C and 63 °C, indicating that the moving unit of the $(H_2O)_{l^d}$TBA type is a relatively stable unit and that these moving units gather together to form a local structure. These situations are visualized in Fig. 8, where the state of mixing at 63 °C is schematically drawn. When we drew Figs. 7 and 8, paying particular attention to the magnitudes of $x_{A_{l^d}B}/x_B$ and $l^d x_{A_{l^d}B}/x_A$, which can be calucluated from Eq. 8d. The former is the number ratio of the moving unit, $(H_2O)_{l^d}$TBA, to all the TBA molecules in the system. The latter is the number ratio of the water molecules which take part in the formation of the moving unit, $(H_2O)_{l^d}$TBA, to all the water molecules in the system. In Figs. 7 and 8, arrows are attached to moving units in order to demonstrate that these units can move independently of one another.

In our previous report,[2] we suggested the existence of a pseudo-critical point for this system. If we compare Fig. 7 with Fig. 8, we can see that the state of mixing at 63 °C ($0.05 < x_{TBA} < 0.1$) is very near to the phase separation into two phases: a water-rich phase and a TBA-rich phase. Moreover, all the water molecules in the water-rich phase may be expected to take part in the formation of polyhedra. Though the phase separation has not been observed at atmospheric pressure for this system, we will probably be able to see this sort of phase separation if we can elevate the temperature of this system under high pressure.

Determination of Thermodynamic Properties of Boehmite from its Solubility Data in NaOH Solutions[1)]

Byong-Tae CHANG

Department of Chemistry, Faculty of Science, Korea University, Kodaira, Tokyo 187

(Received February 13, 1981)

Thermodynamic properties of boehmite in alkaline pH range are determined by applying the extended Debye-Hückel theory to its solubility data in NaOH solutions. When $\log(K_s/a_w^2)$, where $K_s=m_H m_{Al}$ and a_w is the activity of the water in NaOH solutions, is plotted against a Debye-Hückel function of ionic strength(I), $I^{1/2}/(1+B_t a_1 I^{1/2})$, at a given temperature, the curve approaches gradually the theoretical Debye-Hückel limiting slope($2A_t$) with decrease in the ionic strength, and at high ionic strength it deviates positively from the straight line. Under the assumption of the same ionic size parameters for OH^- and $Al(OH)_4^-$ ions, the ionic solubility product, $K_s^\circ=a_H a_{Al}/a_w^2$, for boehmite is given by following equations in the temperature range from 80 to 250 °C: $\log K_s^\circ=-2663/T-5.71$ (Case 1) or $\log K_s^\circ=-2764/T-5.45$ (Case 2). From a comparison of the temperature dependences of K_s° for boehmite and gibbsite, a transition temperature between the two alumina hydrates was calculated to be 60±3 °C.

Thermodynamics of Al_2O_3–Na_2O–H_2O system is very important not only for alumina production by the Bayer process, but also for understanding corrosion and passivation of aluminium in water and aqueous geochemistry of aluminous minerals.[2-8)] In the previous paper,[1)] based on the Debye-Hückel theory, a more reasonable method was presented in order to determine thermodynamic properties of alumina hydrates from their solubility data, and was applied to the solubility data of gibbsite, one of alumina trihydrates, in NaOH solutions with success.

The purpose of this paper is to evaluate several thermodynamic properties of boehmite, one of alumina monohydrates, by applying the similar procedure to solubility data of boehmite in NaOH solutions at temperatures up to 300 °C.[2,9)] This problem may be also interesting as a study on the thermodynamics and the Debye-Hückel theory of high temperature aqueous solutions.[10,11)]

Theoretical

One can express a dissolution process of alumina monohydrate and the dissociation of water as follows:

$$AlOOH(s) + 2H_2O(1) = Al(OH)_4^-(1) + H^+(1), \quad (1)$$

$$K_s^\circ = a_{Al}a_H/a_w^2 = K_s\gamma_1^2/a_w^2, \quad (2)$$

$$H_2O(1) = H^+(1) + OH^-(1), \quad (3)$$

$$K_w^\circ = a_H a_{OH}/a_w = K_w\gamma_2^2/a_w, \quad (4)$$

where $K_s=m_{Al}m_H$, $K_w=m_H m_{OH}$, m_i the molality of species i, $\gamma_1^2=\gamma_{Al}\gamma_H$, $\gamma_2^2=\gamma_H\gamma_{OH}$, and a_w the activity of the water in the molar fraction unit. From Eqs. 2 and 4 we can derive a general equation for the alumina monohydrate, introducing a new function, $f(I)$, of ionic strength (I):

$$f(I) = \log(m_{Al}/m_{OH}) + \log(K_w^\circ/a_w)$$
$$= \log K_s^\circ + 2\log(\gamma_2/\gamma_1). \quad (5)$$

It should be noted that, in the case of the monohydrate, $f(I)$ involves a term of a_w, differing from the case of the trihydrate. Evaluation of the a_w values at a given temperature and pressure of sodium aluminate and hydroxide solutions, therefore, become much important together with the solubility data. Russell *et al.* have used the a_w values of corresponding NaOH solutions at 25 °C for the sodium aluminate and hydroxide solutions up to 170 °C without any correction.[2)] Dibrov *et al.* studied in detail the saturated vapor pressure exerted by the sodium aluminate and hydroxide solutions in the wide range of temperatures and concentrations.[12)] In this paper, the a_w values at a given temperature and concentration were calculated by using the vapor pressure data by Dibrov and virial coefficients, B′ and C′ of H_2O(g) by Kell,[13)] that is,

$$a_w = f_1/f_o = \gamma_1^v P_1/\gamma_o^v P_o, \quad (6)$$

$$RT\ln(f_1/P_1) = RT\ln\gamma_1^v = B'P_1 + C'P_1^2, \quad (7)$$

where f_1 and γ_1^v are the fugacity and activity coefficient of H_2O(g), respectively, and a subscript "o" means the pure water.

Figure 1 gives the relationships between $f(I)$ and I obtained from Eq. 5, using the solubility data of boehmite reported by Russell (80—170 °C)[2)] and Bernshtein (250 and 300 °C),[9)] and the a_w values calculated by Eqs. 6 and 7. The K_w° values were quoted from Refs. 14 and 15.

On the other hand, using the following extended

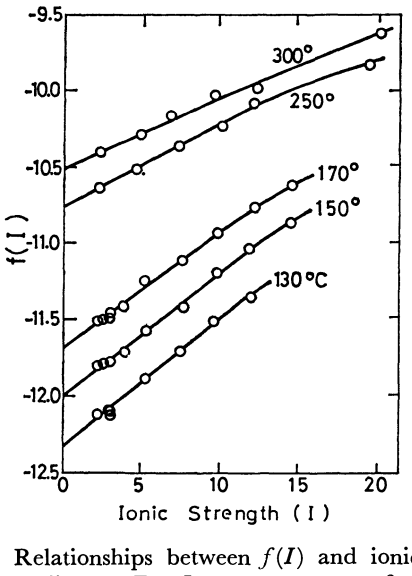

Fig. 1. Relationships between $f(I)$ and ionic strength (I) according to Eq. 5 at temperatures from 130 to 300 °C.

Debye-Hückel equation,

$$\log \gamma_i = -A_t I^{1/2}/(1+B_t a_i I^{1/2}) - c_i I - d_i I^2, \quad (8)$$

the function, $f(I)$, can be expressed by

$$f(I) = \log K_s^\circ + 2A_t I^{1/2}[1/(1+B_t a_1 I^{1/2}) - 1/(1+B_t a_2 I^{1/2})] + CI + DI^2, \quad (9)$$

where A_t is the theoretical Debye-Hückel limiting slope, and B_t, a_1, c_1, d_1, $C=2(c_1-c_2)$ and $D=2(d_1-d_2)$ are adjustable parameters. The problem is to decide the five parameters in Eq. 9 to get the best fit for the data given in Fig. 1.

Results and Discussion

The Case of the Same Ionic Size Parameters. Setting up the same ionic size parameters, that is, $a_1=a_2$, as did May[8] and Smith,[16] Eq. 9 can be simplified into a following equation;

$$f(I) = \log K_s^\circ + CI + DI^2. \quad (10)$$

Table 1 gives the values of $\log K_s^\circ$, C, and D obtained by the least squares method for Eq. 10 in the whole range of ionic strengths (Case 1). Moreover, as being obvious from Fig. 1, there are good linear relationships between $f(I)$ and the ionic strength in the range of low ionic strengths below *ca.* 10, *i.e.*,

$$f(I) = \log K_s^\circ + CI. \quad (11)$$

Table 1 also gives the values of $\log K_s^\circ$ and C for Eq. 11 (Case 2).

Figures 2 and 3 show variations of $\log K_s^\circ$ with the temperature in the case of 1 and 2, respectively. We can observe linear relationships between $\log K_s^\circ$ and $1/T$ in the range of temperature from 80 to 250 °C, which are given by following equations:

$$\log K_s^\circ = -2663/T - 5.71 \text{ (Case 1)}, \quad (12)$$

$$\log K_s^\circ = -2764/T - 5.45 \text{ (Case 2)}. \quad (13)$$

According to Eq. 12 or 13, the value of $\log K_s^\circ$ at 25 °C becomes −14.65 or −14.73, being a little larger than that for gibbsite, −15.18.[1] From the values of $\log K_s^\circ$ at 25 °C for gibbsite and boehmite, the standard Gibbs free energy of following reactions can be calculated as follows:

$$Al(OH)_3 + H_2O = Al(OH)_4^- + H^+, \quad \Delta G_{298}^\circ = 86.61 \text{ kJ}, \quad (14)$$

$$AlOOH + 2H_2O = Al(OH)_4^- + H^+, \quad \Delta G_{298}^\circ = 83.82 \pm 0.23 \text{ kJ}. \quad (15)$$

From the above two equations,

$$Al(OH)_3 = AlOOH + H_2O, \quad \Delta G_{298}^\circ = 2.79 \pm 0.23 \text{ kJ}. \quad (16)$$

This means that gibbsite is more thermodynamically

stable than boehmite at 25 °C and 1 atm. From a comparison of the temperature dependences of K_s° for gibbsite and boehmite, a transition temperature between the two alumina hydrates was found to be 60±3 °C. Based on the ΔG_f° value of −915.0 kJ/mol selected as a standard Gibbs free energy of formation for boehmite by Parks,[5] ΔG_f° value for $Al(OH)_4^-$ ion was obtained to be −1305.6 kJ/mol, which agrees well with the value of −1302.5 kJ/mol obtained in the case of gibbsite. A heat of Reaction 1 is equal to be 51.9±0.8 kJ between 80 and 250 °C, using Eqs. 12 and 13.

For a reaction of boehmite with OH^- ion,

$$AlOOH(s) + OH^-(1) + H_2O(1) = Al(OH)_4^-(1) \quad (17$$

$$K_r^\circ = a_{Al}/a_{OH}a_w \quad (18)$$

using Eqs. 2 and 4, K_r° is given by

$$K_r^\circ = K_s^\circ/K_w^\circ. \quad (19)$$

Table 1, and Figs. 2 and 3 also show the values of $\log K_r^\circ$ at various temperatures. They can be expressed approximately as a function of the temperature as follows;

$$\log K_r^\circ = 2217/T + 17.32 \log T - 51.10 \quad \text{(Case 1)}, \quad (20)$$

$$\log K_r^\circ = 1066/T + 11.58 \log T - 33.24 \quad \text{(Case 2)}. \quad (21)$$

It should be noted that the values of C, which usually reflect interactions between ions and solvent, have the magnitude of nearly 0.05 commonly for boehmite and gibbsite[1] in a wide temperature range.

The Case of Different Ionic Size Parameters. In order to evaluate an effect of difference in the ionic size parameters, a_1 and a_2, on magnitudes of K_s°, we assumed conveniently $c_2=0$ and $d_2=0$ for the dissociation of water as well as did in the previous paper.[1] Then, from Eqs. 4 and 8,

$$\log (K_w/a_w) = \log K_w^\circ + 2A_tI^{1/2}/(1+B_ta_2I^{1/2}) \quad (22)$$

using $K_s=m_Hm_{Al}=K_w(m_{Al}/m_{OH})$ and Eq. 22,

$$\log (K_s/a_w^2) = \log (K_w^\circ/a_w) + \log (m_{Al}/m_{OH}) + 2A_tI^{1/2}/(1+B_ta_2I^{1/2}). \quad (23)$$

At a given temperature, K_w°, A_t, and B_t are constant, and so the values of $\log (K_s/a_w^2)$ depend upon (m_{Al}/m_{OH}), a_w, a_2, and I. Figure 4 gives plots of $\log(K_s/a_w^2)$ and $I^{1/2}/(1+1.59I^{1/2})$ at 150 °C with a_1=4.5 Å and various values of a_2 from 3.5 to 6.0 Å. It is obvious from Fig. 4 that the values of $\log (K_s/a_w^2)$ and $\log K_s^\circ$ increase with decrease in the a_2 value.

On the other hand, from Eqs. 2 and 8,

$$\log (K_s/a_w^2) = \log K_s^\circ + 2A_tI^{1/2}/(1+B_ta_1I^{1/2}) + 2c_1I + 2d_1I^2. \quad (24)$$

Figure 4 also shows that the curves approach gradually the theoretical slope, $2A_t=1.38$, as the ionic strength decreases, and deviate positively from the straight line in the range of high ionic strength owing to the last two terms in Eq. 24. The similar tendency was observed at different temperatures up to 300 °C, for example, as shown in Fig. 5. Furthermore, such behaviors are consistent with those of gibbsite in NaOH solutions. Therefore, plots of $\log (K_s/a_w^2)$ *vs.* $I^{1/2}/(1+B_ta_1I^{1/2})$ consist of the straight line in low I range and the positive deviation in high I range, and the latter may be attributed to the formation of complex ion(s) such as $Al_2O(OH)_6^{2-}$ and/or the dehydration of $Al(OH)_4^-$ to $AlO(OH)_2^-$ and AlO_2^- ions.[12] It should be noted that the sodium aluminate and hydroxide solutions show the same behavior according to the extended Debye-Hückel expression in the wide range of temperatures from 40 to 300 °C for the both solid phases of gibbsite and boehmite.

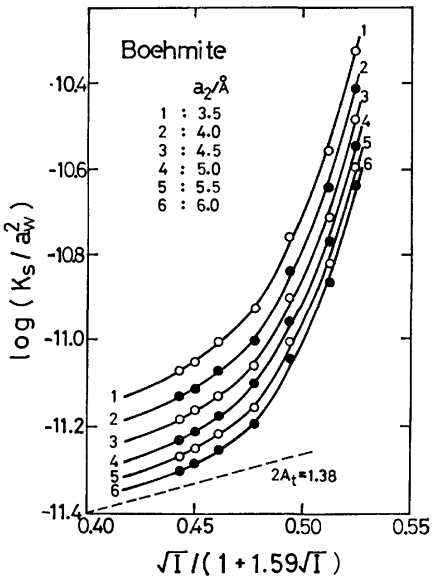

Fig. 4. Plots of $\log(K_s/a_w^2)$ *vs.* $I^{1/2}/(1+1.59I^{1/2})$ at various values of a_2 in the case of a_1=4.5 Å and 150 °C.

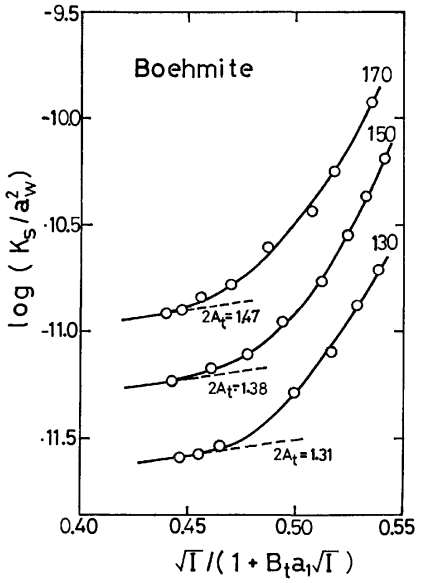

Fig. 5. Plots of $\log(K_s/a_w^2)$ *vs.* $I^{1/2}/(1+B_ta_1I^{1/2})$ at temperatures of 130, 150, and 170 °C in the case of a_1= 4.5 Å and a_2=5.0 Å. A value of B_ta_1 is equal to 1.57, 1.59, and 1.61 at 130, 150, and 170 °C, respectively.

Pressure and Temperature Dependence of NMR Spin-lattice Relaxation in Plastic 2,2-Dimethylpropanoic Acid

Tooru HASEBE,*,† (the late) Gen SODA, and Hideaki CHIHARA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560

(Received February 23, 1981)

Proton spin-lattice relaxation time T_1 of 2,2-dimethylpropanoic acid in its plastic phase was measured at 10 MHz up to 120 MPa between 268 K and 330 K. A minimum in T_1 appears in the low-pressure region which is due to overall reorientation of molecules. The T_1 minimum value decreases as the pressure increases in a way different from simple-minded prediction. The activation volume, 25 ± 3 cm^3 mol^{-1}, is twice as large as in other plastic crystals when normalized by the molar volume. The pressure dependence of the activation enthalpy is also about twice as large. These can be rationalized by considering associated dimers as the reorienting unit. The phase diagram is given and the volume changes associated with the transition and with the fusion were derived (15.6 and 5.86 cm^3/mol of dimer).

2,2-Dimethylpropanoic acid $(CH_3)_3CCOOH$ has been investigated by various techniques[1—16] because it is a unique plastic crystal having a very small entropy of fusion 6.5 J K^{-1} mol^{-1} (309.7 K) in spite of the molecular polarity.

The NMR studies established the nature of the spin-lattice relaxation in solid as well as in liquid state. Thus, in the low-temperature brittle phase both methyl and t-butyl reorientations are responsible for the T_1 minimum, in the high-temperature plastic phase the overall molecular tumbling governs T_1, and in the liquid phase the self-diffusion is the dominant relaxation mechanism.

Since our previous analysis[7] of T_1 results in the plastic phase was not correct, we decided to carry out additional experiments, particularly about the effect of external pressure on T_1 in the plastic phase. The present paper reports such experimental results and proposes that the dynamical unit for molecular tumbling is probably an associated dimer.

Experimental

Material and T_1 Measurements. 2,2-Dimethylpropanoic acid (reagent grade) from Tokyo Kasei Kogyo Co., Ltd. was subjected to dehydration using Molecular Sieve 4A, vacuum distillation, and degassing by repeated freeze-pump-thaw cycles and then transferred into the pressure vessel *via* a specially designed adapter which will be described.

Proton spin-lattice relaxation time was measured using π-τ-$\pi/2$ pulse sequences with an operating frequency of 10.0 MHz. The working pressure and temperature ranges over which T_1 was measured were between the saturated vapor pressure of the sample and 120 MPa and between 268 K and 330 K, respectively.

Pressure Vessel and Its Operation. Figure 1 is a schematic drawing of the high-pressure NMR vessel (hereafter referred to as the vessel). The vessel was machined from non-magnetic beryllium-copper alloy (Cu 97.57%, Be 1.86%, Co 0.27%, Fe 0.16%, and Ni 0.01%) and was annealed at 570 K for three hours after machining. The ratio of the outside to the inside diameter was nowhere less than 1.9. Hermetic closure of electrical leads was made by using phosphor bronze of cone shape (Fig. 1B) insulated from the body of the vessel with Epoxy putty XD 580 (Japan Ciba-Geigy Co.). At other places (j, k, and l for the lead-wire housing and e and f for the piston), three washers of Teflon, Be–Cu alloy, and lead metal were used in turn from inside to outside to secure pressure-tightness.

The working pressure gauge was a length of manganin wire (B. S. #38) wound round a Teflon bobbin (q) and annealed at 390 K for 17 h *in vacuo*. The gauge was calibrated against the standard Heise gauge up to 200 MPa at the High Pressure Laboratory, Faculty of Engineering Science, Osaka University after several cycles of pressurizing and releasing. The gauge reading was reversible above 100 MPa but showed a small hysteresis effect at lower pressures. The temperature dependence of the electrical resistance was also measured at 0.1 MPa; at other pressures

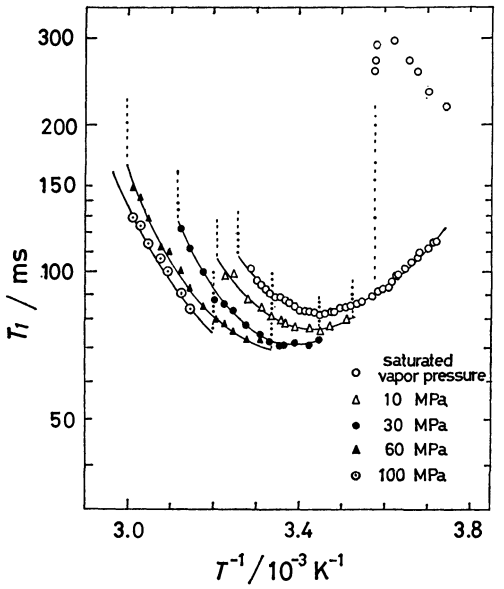

Fig. 3. Temperature dependence of T_1 at various pressures.

we used the pressure coefficient values reported by Wang.[17] The overall uncertainty of the pressure values in the present study was estimated as ± 1.4 MPa.

The temperature of the specimen was controlled by non-inductive winding of KARMA heater (h) (B. S. #36, Driver Harris Co.) and cold nitrogen stream evaporated from the bottom of the Dewar flask in which the vessel was placed. The electrical current through the heater was controlled automatically with a Chromel-P/Constantan thermocouple attached to the outer surface of the vessel as the temperature sensor.

Figure 2 shows the connecting device for distilling the specimen from outside into the vessel. The plunger and the screwed cap (a and b of Fig. 1A) were removed from the top of the vessel and then the body was attached to the connecting device from below (g of Fig. 2). The plug was pulled up with movable supporters b and c to connect the inside of the vessel to the outside vacuum/purification line. The system was made vacuum-tight with a number of fluoride rubber O rings as shown in Fig. 2. When distillation of the specimen is over, the piston (e) was dropped into the vessel using the rods a, b, and c, the vessel was taken off the connecting device, and piston/plunger was pressed and clamped. Because the plastic phase of 2,2-dimethylpropanoic acid is extremely soft for a crystal, we may safely assume that the pressure applied is hydrostatic.

Results and Discussion

Spin-lattice Relaxation Time. The results of experimental determination of T_1 under various pressures are given in Fig. 3. The upper and lower bounds of the existence of the plastic phase of 2,2-dimethylpropanoic acid are indicated by vertical broken lines. The curves in Fig. 3 do not correspond to the results of a continuous run under a given pressure, except the one at the saturated vapor pressure of the specimen, because the pressure inside the vessel changed when the specimen temperature changed. Therefore, the primary results were rearranged to show, in Fig. 3, the temperature dependence of T_1 under a constant pressure. It is seen that the plastic phase is readily undercooled down to about 269 K ($1/T = 3.72 \times 10^{-3}$ K^{-1}), some 10 K below the transition point, giving smooth extrapolation of the T_1 curve under the ordinary pressure.

There is a distinct minimum of T_1 in the plastic phase which has been substantiated as caused by reorientational motion of molecules.[6,7,13] The relaxation rate T_1^{-1} can be expressed in terms of the correlation time τ and the part of second moment M_2 modulated by such molecular motion;[18]

$$T_1^{-1} = C[\{\omega\tau/(1+\omega^2\tau^2)\} + \{4\omega\tau/(1+4\omega^2\tau^2)\}], \quad (1)$$

where

$$C = (2/3)\gamma^2\{M_2(\text{intra}) + M_2(\text{inter})\}, \quad (2)$$

and γ is the gyromagnetic ratio of the proton. The T_1 minimum tends to move to higher temperatures as the pressure is increased although more slowly than the movement of the phase boundaries. Also the minimum value of T_1 decreases as the pressure is increased. This indicates that M_2, particularly M_2-(inter), increases its magnitude upon compression. In the case of fast isotropic reorientation of molecules, M_2(inter), for the fcc lattice is given by

$$M_2(\text{inter}) = 4.14 \times 10^{-2} N_0 a^{-6}, \quad (3)$$

where N_0 is the number of protons per molecule and a is the lattice constant in the units of nanometer. Since M_2(inter) depends on the inverse sixth power of intermolecular proton-proton distances, we would expect that T_1^{-1}(max) changes linearly with the inverse square of the crystal volume. Thus, T_1^{-1}(max) is plotted against $(V_0/V)^2$ in Fig. 4, where V_0 is the crystal volume at the saturated vapor pressure. The volume at other pressures were determined from the distance of travel of the piston plunger into the pressure vessel by compression. The compression was ap-

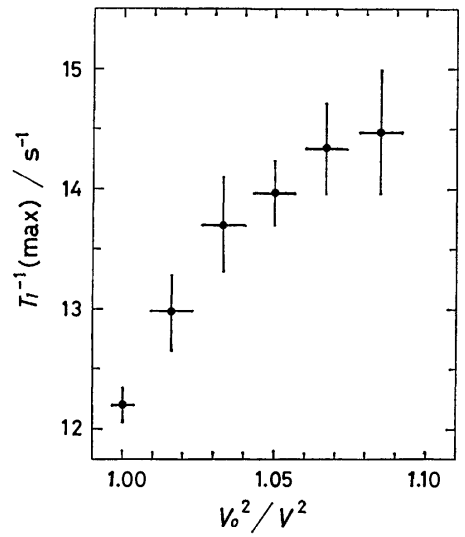

Fig. 4. T_1^{-1}(max) against the square of reduced crystal volume, V_0/V.

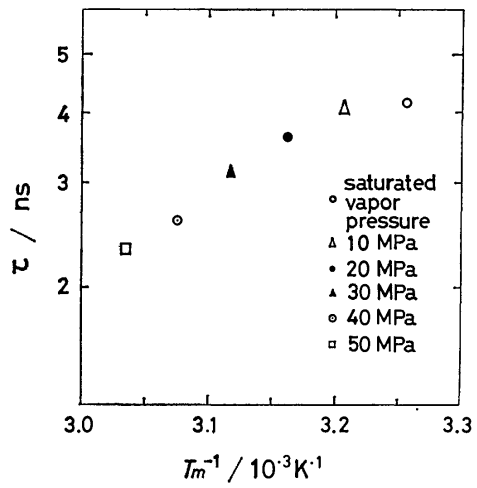

Fig. 5. The correlation time of the overall molecular reorientation at the melting points under different pressures.

parently linear in the pressure increase within the experimental error and it was approximately described by a constant isothermal compressibility $(8\pm2)\times 10^{-4}$ MPa^{-1}. It is seen that T_1^{-1}(max) is not linear in $(V_0/V)^2$ contrary to expectation. The reason is not apparent at present although it is possible that the pressure range studied was not wide enough to cause such a significant volume change that a very meaningful analysis could be made.

The T_1 curves in Fig. 3 were fitted to Eq. 1 assuming the Arrhenius type of activation process

$$\tau = \tau_0 \exp(\Delta G^*/RT), \quad (4)$$

where ΔG^*, the Gibbs energy of activation, is defined by

$$\Delta G^* = \Delta H^* - T\Delta S^*. \quad (5)$$

Since the volume of activation ΔV^* is given by

$$\Delta V^* = (\partial \Delta G^*/\partial P)_T, \quad (6)$$

values of τ derived from the curve fitting may be used to obtain ΔV^* and ΔH^* through the relations,

$$\Delta V^* = RT(\partial \ln \tau/\partial P)_T, \quad (7)$$

and

$$\Delta H^* = R\{\partial \ln \tau/\partial(1/T)\}_P. \quad (8)$$

The value of ΔV^* thus derived was 25 ± 3 cm^3 mol^{-1} between 290 K and 305 K. The magnitude of uncertainty attached to this derived quantity did not permit determination of its dependence on temperature.

The ratio of the volume of activation to the molar volume, $\Delta V^*/V_m$, is 0.24±0.03, considerably larger than for other plastic crystals. Thus, in the case of 2-methyl-2-nitropropane, it is 0.07.[19] In fact, values between 0.04 and 0.08 are more common for this quantity if ΔV^* corresponds to activation of molecular reorientation. Now, if one considers that the plastic phase of 2,2-dimethylpropanoic acid consists of dimeric units in which the two acid molecules are associated with a pair of hydrogen bonds, the ratio $\Delta V^*/V_m$ to be compared would be 0.12 rather than 0.24. However, this value is larger yet than the values for overall molecular reorientation in other plastic organic materials; *e.g.* in cases[20,21] of norbornane, cyclohexane, and 2,2,3,3-tetramethylbutane, they are 0.04, 0.07, and 0.07—0.09, respectively.

The activation enthalpy, ΔH^*, and the value of τ_0 for the overall molecular reorientation under some typical pressure conditions are listed in Table 1. The value of ΔH^* is also much larger than other typical plastic crystals; even a molecule as large as adamantane has a value of only 15 kJ mol^{-1}.[22] The ΔH^* exhibits a pressure dependence with the best slope 0.13 kJ MPa^{-1} mol^{-1} between the saturated vapor pressure of the sample and 50MPa. The slope is also very much larger than the case of adamantane (0.0069 kJ MPa^{-1} mol^{-1}).

Figure 5 shows the correlation time, τ, of the overall molecular reorientation at the melting points under different pressures. In contrast to the behavior of the correlation time for self-diffusion, which assumes

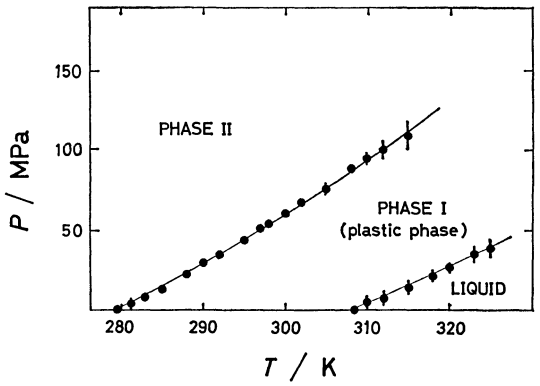

Fig. 6. Phase diagram of 2,2-dimethylpropanoic acid.

an almost constant value at melting points, the correlation time for reorientation decreases as the melting occurs at higher temperatures. This suggests the reorientational motion is not the direct trigger of the fusion phenomenon.

To summarize this subsection, the characteristic quantities, *i.e.* the volume and the enthalpy, of activation for overall molecular reorientation are about twice as large as those for other typical plastic crystals. However, these magnitude can be rationalized if one takes a dimer as the dynamical unit of motion. The molecule would then be not very spherical in shape, which fact explains why T_1 minima can be observed in the temperature region in which the plastic phase exists. This fact also corresponds to much longer correlation time in the plastic solid at its melting points.

Phase Diagram. Figure 6 is the phase diagram obtained by determining the temperature of phase changes from the jumps of the T_1 values. The average slopes of the boundary curves are

$$dP/dT = 3.26 \text{ MPa K}^{-1} \text{ (transition)}$$
$$= 2.22 \text{ MPa K}^{-1} \text{ (fusion)}$$

and show that the two curves become separated further as the pressure increases. The volume changes at these transition points were calculated by use of Clapeyron-Clausius equation from the entropy changes, 25.5 and 6.5 J K^{-1} mol^{-1} at the transition and the melting point, respectively. These were 7.82 and 2.93 cm^3 mol^{-1}, respectively, or 15.6 and 5.86 cm^3/mol of dimer.

It is interesting to note that application of external pressure displaces the region of the existence of the plastic crystal to a higher temperature whereas the T_1 minimum moves more slowly with the result of a shorter correlation time at a higher pressure. This means that although the compression should slow down molecular reorientation, additional thermal energy more than compensates the effect.

The authors would like to express their gratitude to late Professor Naoto Kawai and Dr. Akifumi Onodera for help in developing the high pressure apparatus used in the present study.

Mechanochemical Change in the Solid State and the Solubility of Amobarbital

Akiko IKEKAWA* and Sohachiro HAYAKAWA**

Faculty of Pharmaceutical Sciences, Showa University, Hatanodai, Shinagawa-ku, Tokyo 142

***Department of Applied Physics, Faculty of Science, Tokyo Institute of Technology, Oh-okayama, Meguro-ku, Tokyo 152*

(Received February 23, 1981)

Influence of ball-milling on the X-ray diffraction pattern, the thermal properties, the IR spectra, the particle size distribution and the solubility of amobarbital was investigated. The fraction of crystal I decreased, and the fraction of crystal III and the amorphous part increased at the first stage of ball-milling. The heat of fusion decreased slightly by ball-milling, which was considered to be due to the increase in the fraction of the amorphous part. The melting point lowered by 1—3 °C and the NH and CO absorptions in the IR spectra were influenced by ball-milling, which was considered to be due to the transformation of crystal I into crystal III. The particle size decreased at the first stage of ball-milling. It was considered that the transformation of crystal I into crystal III was remarkable when the particles were broken. The solubility of amobarbital in the KH_2PO_4–Na_2HPO_4 buffer solution with pH of 6.0 increased by ball-milling, which was considered to be due to the increase in the fraction of the amorphous part and crystal III.

The solubility of the slightly soluble powders in the amorphous state is higher than the solubility in the crystal state.[1] The solubility of the powders in the metastable crystal form is also higher than the solubility in the stable crystal form.[2] The solubility of fine particles is larger than the solubility of large particles, as the surface energy of fine particles is larger than the energy of the large particles.[3]

As reported previously, the solubility of amobarbital (5-ethyl-5-isopentylbarbituric acid) increased, the X-ray diffraction intensities decreased and the melting point lowered by the mechanical treatment with the diluent, such as methylcellulose.[4,5] In this paper, amobarbital was ball-milled without the diluent and influence of ball-milling on the physical and chemical properties was investigated in order to clarify the mechanism of solubilization by the mechanical treatment.

Experimental

Commercial powders of amobarbital was of guaranteed grade purchased from Nihon Shinyaku Co. Ten g of the commercial powders was ball-milled under the conditions as referred to the previous paper.[5] Powder II was obtained by recrystallization of amobarbital from the 25 v/v % aqueous ethanol solution, and powder I was obtained by heating powder II at 150 °C for 1 h.[6] Powder III was obtained by freeze-drying the aqueous solution of amobarbital.

The X-ray diffraction measurement was carried out by a JEOL X-ray diffractometer (Model 7E). The differential thermal analysis was made by a thermal analyser (Model DT-20B) of Shimazu Seisakusho. The heat of fusion of amobarbital was measured by a differential scanning calorimeter (Model SC-20) of Shimadzu Seisakusho, using indium as a standard substance. Infrared (IR) spectra of the samples were measured by the Nujol method with a JASCO diffraction granting infrared spectrometer (Model A-2).

The sample was added to the 0.1 w/v % sodium dodecyl sulfate solution saturated with amobarbital in each of the samples, as the solubility varied by ball-milling. The suspension was stirred intensely for 2 min, and irradiated with the supersonic waves for a min. Then, the size distribution of the particles was measured with a micron photosizer (Model SKN 500) of Seishin Kigyo Co. Solubility of amobarbital from various samples in the KH_2PO_4–Na_2HPO_4 buffer solution (pH 6.0, ionic strength 0.08) at 30 °C was obtained from the absorbance at 238 nm as described in the previous paper.[4]

Results and Discussion

X-Ray Diffraction. Mesley reported two polymorphs for amobarbital, that is, crystal II obtained by recrystallization from a 25 v/v % aqueous ethanol solution and crystal I obtained by heating crystal II at 150 °C.[6] It is considered that powder I is composed of crystal I by Mesley and the amorphous part, and that powder II is composed of crystal II by Mesley and the amorphous part. As shown in Fig. 1, the X-ray diffraction pattern for the commercial powders before ball-milling was identical with the pattern for powder I, and the pattern for the ball-milled powders was identical with the pattern for powder III. The pattern for powder III was different from the patterns for powder I and II. The similar pattern as for powder III was obtained for the powders obtained by condensing the vapor from the solution of the fused amobarbital on a cold glassy wall. The pattern for powder III was identical with the pattern for amobarbital crystallized from diethyl ether by Williams.[7] In this paper, the polymorph in powder III is called crystal III. Vizzini *et al.* obtained single crystals of two kinds of polymorphs, I and II, from the same aqueous ethanol solution by slow evaporation at room temperature. They confirmed that the crystal morphology of these two forms were in agreement with those previously reported by Williams. They also found that the melting point of crystal I was lower than the point of crystal II by 4—6 °C.[8] As shown later in this paper, the melting point of powder III was lower than the point of powder I by 2—4 °C, though powder II was transformed into powder I at 150 °C. It is considered that crystal I by Vizzini is identical with crystal III in this paper.

The crystallinity of various kinds of amobaribtal, x_{cr}, was obtained by the Ruland's method.[9] The results are shown in Table 1.

a) bt is the ball-milling time.

Hermans *et al.* considered that the coherent scattering was due to the crystal part and that the non-coherent scattering was due to both of the crystal part and the amorphous part. On the basis of this consideration, they obtained the crystallinity of the cellulose fibers.[10] A glassy state was obtained by the rapid cooling of the solution of the fused hexobarbital or phenobarbital, though the state was not obtained for amobarbital. The intensity of the non-coherent scattering for the glassy state of hexobarbital was identical with the intensity for phenobarbital. The mean value of the intensity for these samples was taken as the intensity for the glassy state of amobarbital, assuming that the intensity was independent of the kind of the barbituric acid derivatives. It was confirmed that the kind of the polymorph did not influence the parameters for determining the crystallinity by the Hermans' method, from the results for the glassy state, powder I and III using the values of x_{cr}. The values of the crystallinity by the Hermans' method, x_{cr}', are tabulated in Table 1.

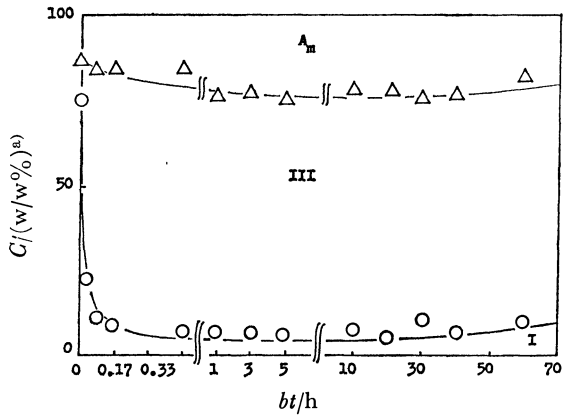

Fig. 2. Influence of ball-milling on the solid state of amobarbital.
○: The content of crystal I, △: the content of the crystal part, I: crystal I, III: crystal III, A_m: amorphous part. a) C is the composition.

The ratio of the intensity of the diffraction lines between 12.4° and 12.7° of 2θ to the intensity between 16.0° and 16.7° of 2θ, R_x, was larger for powder III than for powder I. From the data of R_x and x_{cr} for powder I and III, the fraction of crystal I, III and the amorphous part were obtained for the commercial powders before and after ball-milling. The results are shown in Fig. 2. The fraction of crystal I decreased and that of crystal III increased at the first stage, and the ratio between the fractions was constant after ball-milling for more than 10 min. The fraction of the amorphous part increased at the first stage, but the fraction was approximately constant after ball-milling for more than 1 h.

Thermal Analysis. The melting point of amobarbital lowered by 1—3 °C by ball-milling, as shown in Fig. 3. This phenomenon was already observed after ball-milling for 5 min. The melting point of powder III, 152—154 °C, was 2—4 °C lower than the point of powder I. The lowering of the melting point of amobarbital by ball-milling is considered to be due to the transformation of crystal I into crystal III.

As shown in Table 2, the heat of fusion, ΔH_{obsd}, for powder I and II was larger than the heat for the other samples. It was also shown that ΔH_{obsd} for the commercial powders decreased slightly by ball-milling by the t-test at the probability level of 0.05 and at the freedom of 29. Equation 1 was assumed to be applied, where x_I, x_{III}, and x_a were the fractions of crystal I, III, and the amorphous part and ΔH_I, ΔH_{III}, and ΔH_a were the heat of fusion of crystal

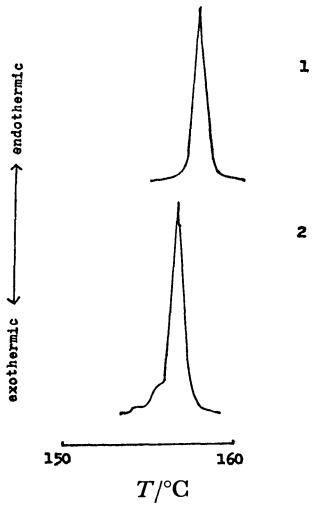

Fig. 3. Influence of ball-milling on DTA thermograms of amobarbital.

Table 2. Heat of fusion of various kinds of amobarbital

Sample	$\Delta H_{obsd} \pm \sigma_H$[a] kcal/mol
Powder I	7.0±0.3
Powder II	6.7±0.4
Powder III	6.1±0.5
Commercial powders	6.2±0.5
Commercial powders ball-milled for 60 h	5.7±0.6

a) σ_H is the standard deviation.

I, III, and the amorphous part, respectively.

$$\Delta H_{obsd} = x_I \Delta H_I + x_{III} \Delta H_{III} + x_a \Delta H_a \quad (1)$$

The values of ΔH_I, ΔH_{III}, and ΔH_a, 7.0, 6.9, and 1.2 kcal/mol, respectively were obtained from the data of ΔH_{obsd} and x_{cr} for powder I, the commercial powders before ball-milling and the powders after ball-milling for 60 h. The slight decrease in the heat of fusion of amobarbital by ball-milling is probably due to the decrease in the crystallinity.

IR Spectra. The following facts are confirmed from the study on the IR spectra of various kinds of barbituric acid derivatives by Mesley[6] and the study on the interaction of barbituric acid derivatives with polyethylene glycol by Chang *et al.*[11] The ν-NH absorption band is observed at 3600—3000 cm^{-1} region. The absorption for free NH in the solid state is observed at 3340—3310 cm^{-1} and shifts to the lower frequency by hydrogen bonding. The CO absorption at 1800—1600 cm^{-1} shifts to the lower frequency by hydrogen bonding. The highest frequency band at 1750 cm^{-1} is due to the CO in the 2-position and the other bands are due to the CO in the 4- and 6-position in the spectra of amobarbital. The δ'-NH absorption band at 900—750 cm^{-1} shifts to the higher frequency by hydrogen bonding.

Figure 4 shows the IR spectra of various kinds of amobarbital. In Table 3, $R_{\nu,\nu'}$ is the ratio of the

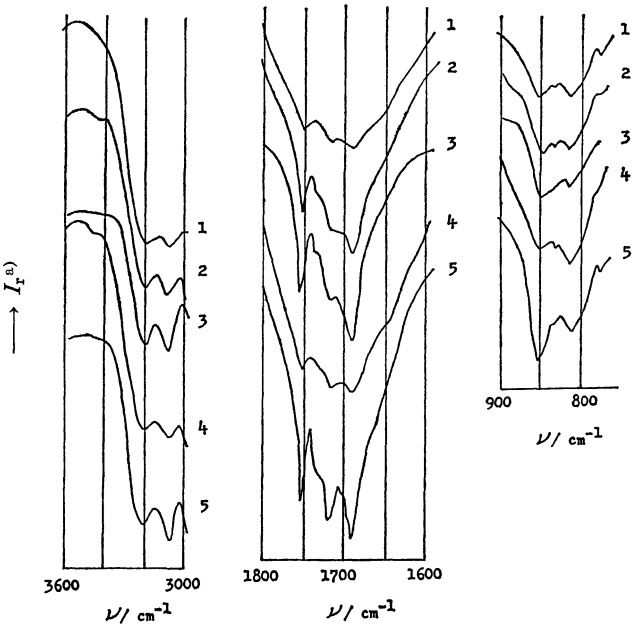

Fig. 4. IR spectra of various kinds of amobarbital powders.

absorbance at wave number ν to the absorbance at ν' obtained by assuming that the percent transmission at 3450, 2000, 1000, and 700 cm^{-1} are 100. As shown in Fig. 4 and Table 3, the IR spectra of the commercial powders before ball-milling were similar to those of powder I and the spectra of the ball-milled powders were similar to the spectra of powder III. Figure 5 shows the variation in the values of $R_{\nu,\nu'}$ with ball-milling. $R_{\nu,\nu'}$ varied remarkably at the first stage of ball-milling, but the values were nearly constant after ball-milling for more than 10 min. It is considered from the above findings that the variation in the IR spectra of amobarbital with ball-milling is due to the increase in the fraction of the part of

Table 3. Numerical values of $R_{\nu,\nu'} \pm \sigma_R$[a] for various kinds of amobarbital

ν/cm^{-1}	3085	1690	850
ν'/cm^{-1}	3210	1750	815

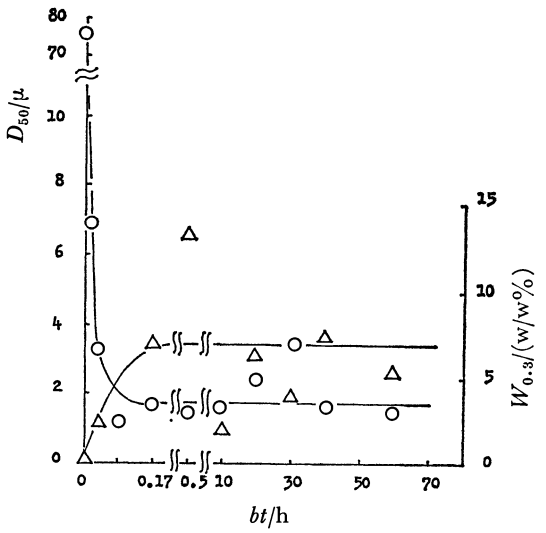

Fig. 6. Decrease in the particle size of amobarbital by ball-milling.
○: D_{50}, △: $W_{0.3}$.

the strong hydrogen bonding between NH and CO, which is probably related to the transformation of crystal I into crystal III.

Particle Size. Figure 6 shows the variation of the particle size of amobarbital with ball-milling. In Fig. 6, D_{50} is the median diameter by weight base and $W_{0.3}$ is the weight fraction of the particles smaller than 0.3 μ in diameter. The value of D_{50} decreased and the value of $W_{0.3}$ increased at the first stage of ball-milling, and these values were nearly constant after ball-milling for more than 10 min. Variation of these values with ball-milling was parallel to the variation of the X-ray diffraction pattern, the IR spectra and the melting point. It is considered that the transformation of crystal I into crystal III is remarkable when the particles are broken.

Solubility. The solubility of amobarbital in the KH_2PO_4–Na_2HPO_4 buffer solution with pH of 6.0 at 30 °C was investigated. The concentration of amobarbital in the filtrate of the suspension in the buffer solution increased at the first stage of dissolution, but the concentration was nearly constant for the dissolution time between 10 min and 2 h. In Fig. 7, c_{2h} is the concentration after shaking for 2 h from the time of the preparation. As shown in Fig. 7 and Table 4, c_{2h} increased by ball-milling.

In the previous paper, the solubility of amobarbital was influenced little by ball-milling with dextran or dextrose, but the solubility increased by 20—30% by ball-milling with methylcellulose only for 10 min.[4] The value of D_{50} for amobarbital ball-milled with methylcellulose for 10 min was larger than the values for amobarbital ball-milled with dextran or dextrose. This finding shows that the decrease in the particle size is not the main factor for the increase in the solubility of amobarbital by ball-milling.

Table 4. Solubility of amobarbital in the KH_2PO_4–Na_2HPO_4 buffer solution in pH of 6.0 at 30 °C

Sample	$c_{2h} \pm \sigma_c$[a] mg/100 ml
Powder I	58.4±1.9
Powder II	64.6±1.6
Powder III	67.4±0.6
Commercial powders	63.4±0.6
Commercial powders ball-milled for 20 h	67.1±1.1
Commercial powders ball-milled for 60 h	65.7±1.1

a) σ_c is the standard deviation.

The variation in c_{2h} with ball-milling was parallel to the variation in the fraction of the amorphous part. Table 4 shows the numerical values of c_{2h} for various samples. The value for the commercial powders before ball-milling was nearly identical with the value for powder I and the value for the ball-milled powders was similar to the value for powder III. If the solid state is equilibrated with the state of solution and ΔH_{obsd} is constant near the melting point, Eq. 2 is applied, where X_2^s is the mole fraction of the solute, R is the gas constant, T is the absolute temperature at the equilibrated state, T_f is the melting point of the solute by absolute temperature and γ is the activity coefficient of the solute.

$$\ln X_2^s = -\frac{\Delta H_{obsd}}{R}\left(\frac{1}{T}-\frac{1}{T_f}\right) - \ln \gamma \qquad (2)$$

The increase in the solubility of amobarbital in the buffer solution by ball-milling can be calculated from Eq. 2, if γ is influenced little by ball-milling. Using the data of ΔH_{obsd} in Table 2 and setting the lowering of the melting point by ball-milling to be 1 °C, the solubility of the ball-milled powders was calculated to be 1.2 times the solubility of the commercial powders, if the solid state obtained by ball-milling was equilibrated with the state of solution. The ratio of

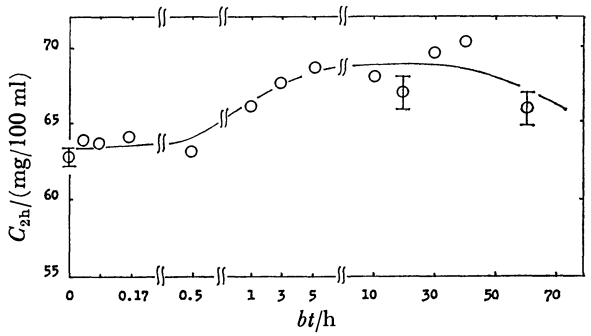

Fig. 7. Influence of ball-milling on solubility of amobarbital in the KH_2PO_4–Na_2HPO_4 buffer solution at 30 °C.

c_{2h} for the ball-milled powders to the value for the commercial powders before ball-milling was approximately 1.1, as shown in Table 4. The above findings show that the increase in the solubility of amobarbital by ball-milling is due to the increase in the fraction of the amorphous part and to the transformation of crystal I into crystal III.

The authors are grateful to Mrs. Mayumi Tobe, one of the members of the Analytical Center of Showa University, for the measurement of the IR spectra.

Effect of Surfactant Micelles on the Rate of Reaction of Tetranitromethane with Hydroxide Ion

Tsuyoshi HARADA, Nagamune NISHIKIDO, Yoshikiyo MOROI,* and Ryohei MATUURA
Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812

(Received March 2, 1981)

The rates of trinitromethanide anion formation by the reaction of tetranitormethane with hydroxide ion were measured in the presence of anionic, cationic and nonionic surfactant micelles in aqueous solutions. Using the analytical approach which takes into consideration the distribution of hydrophobic reactants among micelles,[1] k_1 (a second-order rate constant on micelles associated with one reactant molecule) and K_1/N(K_1: an association constant of the reactant with micelles having no reactant, N: an aggregation number of surfactant molecule in a micelle) were estimated. The anionic surfactant exhibited no effect on the reaction rate. In the case of cationic surfactants, both k_1 and K_1 values increased not only with alkyl chain length but also with hydrophobicity of the surfactants. In the case of nonionic surfactants, an increase of alkyl chain length with a given oxyethylene unit resulted in an increase in the k_1 values, while an increase of oxyethylene group with the fixed alkyl chain length resulted in an appearance of the maximum k_1 value. From temperature dependence of the reaction rate, a stabilization of the activated complex could be explained by an electrostatic interaction of the complex with the charged micellar surface. It was also found from the analytical approach that the distribution of tetranitromethane among micelles used in the present experiment could be approximated by the Poisson distribution.

Surfactant molecules aggregate to form micelles in aqueous solution above a narrow concentration range which is called the critical micelle concentration (CMC).[2] The hydrophobic groups of surfactant form a core of micelle which is liquid hydrocarbon like in character, while the hydrated polar groups constitute an outer shell of micelle and contact with water. Physico-chemical properties of the micelle-bulk interface and an interior of micelles have been really interested not only from the colloid chemistry itself but also from an application of micelles to other fields of chemistry. Especially, the application to a medium or catalyst for organic reactions has been undertaken since the pioneering work by Duynstee and Grundwald in 1959.[3] Then, for more than a decade many studies have been reported on micelle-catalyzed reactions.[4]

The reactions of tri- and tetranitromethane with hydroxide ion were minutely investigated in both aqueous[5–7] and micellar[8] solutions. However, there have been few systematic studies of the effect of surfactant structures, particularly of nonionic surfactant, on the reaction rate. In the present study, the rates of trinitromethanide anion formation by the reaction of tetranitromethane with hydroxide ion were measured in the presence of various surfactants in aqueous solutions. Hereupon, the dependence of the reaction rate on surfactant structure was systematically investigated. Furthermore, in order to find the relationship of stability of the activated complex with kinds of surfactant structures, a temperature effect on the rate was pursued. In addition, the distribution of tetranitromethane among micelles was also examined by applying the random, Poisson, and Gaussian distributions.

Experimental

Materials. Tetranitromethane (TNM) supplied from Tokyo Kasei Ind. was washed three to five times with 0.8 mol dm^{-3}-H_2SO_4, and subsequently five times with double-distilled water. TNM was recrystallized from water below 10 °C and the supernatant was discarded. After these treatments, no absorption of trinitromethanide anion was found at 350 nm in an aqueous solution of TNM. Anionic surfactant, sodium dodecyl sulfate SDS, was synthesized and purified according to the procedure described previously.[9] Cationic surfactants (decyltrimethylammonium chloride DeTAC, dodecyltrimethylammonium chloride DoTAC, hexadecyltrimethylammonium chloride HTAC, hexadecyltrimethylammonium bromide HTAB, *N*-hexadecylpyridinium chloride HPC, benzylhexadecyldimethylammonium chloride BHAC (all obtained from Tokyo Kasei Ind.)) were recrystallized three times from acetone–ethanol mixture in which the volume fraction of ethanol was below 0.1. Hexadecyltrimethylammonium nitrate HTAN was prepared by refluxing HTAB with an excess of silver nitrate in anhydrous methanol for several hours, and the precipitated silver salts were removed by filtration. The above procedure was repeated twice. The HTAN thus prepared was recrystallized three times from acetone. For all cationic surfactants, small amount of residual solvents on recrystallization were eliminated by heating at 100 °C under reduced pressure for more than ten hours. They were always kept in a desiccator because of their hygroscopicity. All nonionic surfactants, poly(oxyethylene) alkyl ether C_mE_n were a gift from Kao Soap Co. and were used without further purification.[10] The details of these surfactants are given in Table 1 together with their CMCs in pure water and in the reaction systems, which were determined by the plots of surface tension against concentrations. Inorganic salts of reagent grade used for adjusting pH, commercial NH_4Cl, NH_4NO_3, and NH_4Br, were purified by recrystallization from water before use.

Method. The reaction of TNM with hydroxide ion was started by injecting an aliquot of aqueous solution of TNM into alkaline surfactant solutions. The reaction rates were followed spectrophotometrically (Beckman-Toshiba DSB-80) by measuring the rate of trinitromethane anion formation at 350 nm ($\varepsilon\{C(NO_2)_3^-\} = 1.34\times10^4$ dm^3 mol^{-1} cm^{-1}).[8] The temperature was controlled at 30±0.1 °C by circulating water through the equipment. The initial concentration of TNM (*ca.* 5×10^{-5} mol dm^{-3}) in the individual run was estimated from the optical density at 350 nm at infinite time. The pseudo first-order rate constant k^{obsd} was determined from the slope of linear plots of $\log(OD_\infty - OD_t)$ against time in the usual manner, where OD_∞ and OD_t represent the optical density due to trinitromethanide anion at infinite time and time t, repectively. The adjustment of pH was made using an NH_3–NH_4^+ buffer whose

ionic strength was maintained at 0.03; NH_4Cl–aqueous ammonia for anionic and nonionic surfactant solutions, and NH_4X–aqueous ammonia for the micellar solutions of cationic surfactant whose gegenion is X. The pH of the reacting solutions was confirmed not to be changed before and after the reaction.

Results and Discussion

The reaction of TNM with hydroxide ion is represented by:[6]

$$C(NO_2)_4 + OH^- \xrightarrow{k} C(NO_2)_3^- + HNO_3, \quad (1)$$

where k is the second-order rate constant. The reaction rate is expressed by:

$$-[C(NO_2)_4]/dt = k[C(NO_2)_4][OH^-]. \quad (2)$$

Since the pH in each solution is kept constant in an alkaline side by a given buffer, $[OH^-]$ remains constant during the course of reactions. Thus, the reaction obeys the following pseudo first-order kinetics:

$$-d[C(NO_2)_4]/dt = k^{obsd}[C(NO_2)_4] \quad (3)$$

and

$$k = k^{obsd}/[OH^-]. \quad (4)$$

From Eq. 3 we obtain the following relation:

$$OD_\infty - OD_t \propto [C(NO_2)_4]_t = [C(NO_2)_4]_0 \exp(-k^{obsd}t), \quad (5)$$

where $[C(NO_2)_4]_0$ and $[C(NO_2)_4]_t$ represent the concentration of TNM at $t=0$ and t, respectively. The rate constant k^{obsd} increases linearly with hydroxide ion concentration and the linearity is very good. Then, the second-order rate constant k is determined from the slope of linear plots of k^{obsd} against $[OH^-]$ whose linearity is good. The second-order rate constant k thus obtained in the absence of surfactant at 30 °C was calculated to be 0.38 dm^3 mol^{-1} s^{-1}, which seems reasonable compared with 0.52 dm^3 mol^{-1} s^{-1} at 30 °C and at ionic strength of 0.1[8] and with 0.65 dm^3 mol^{-1} s^{-1} at 30 °C and at ionic strength 1.0.[7]

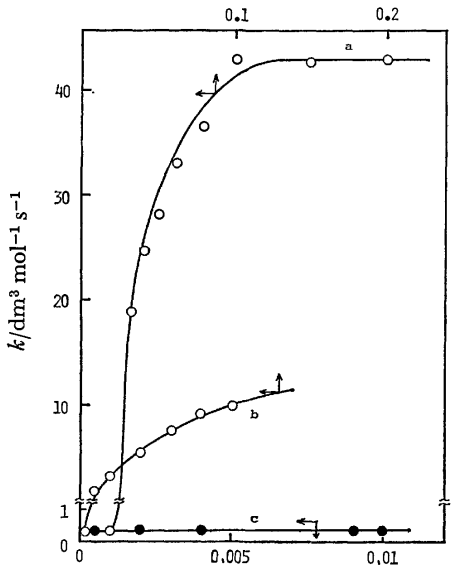

Fig. 1. Effect of surfactant type on the second-order rate constant(k). The variation of k values with surfactant concentrations.
a): DoTAC, b): $C_{12}E_6$, c): SDS.

In the first place, the effect of structure of surfactant on the reaction rate was examined using C_{12} surfactants, DoTAC, SDS, and $C_{12}E_6$ (Fig. 1). SDS had no effect on the reaction rate, while DoTAC and $C_{12}E_6$ brought about an increase in the rate constant with increasing their concentrations.[11–15] From these results, it can be considered that the increase in k

values in the presence of cationic micelles of DoTAC is attributable mainly to the concentration of hydroxide ion in the vicinity of cationic head groups of micelle.

Secondly, in order to understand the above differences on account of surfactant types, further analysis was made using the following reaction mechanism. The reactions take place both in a bulk solution and in micelles. The apparent increase in reaction rate above CMC is mainly due to the presence of micelles. For simplifying the reaction systems, the following assumptions are made; 1) the reactants associate with micelles to form some distribution among micelles and 2) the rate of the association which is of millisecond order is much faster than those of the reactions in both bulk and micellar phases which are of second order. With these assumptions the following reaction scheme which was adopted in the preceeding paper[1] is used to study the present reaction system:

$$\begin{array}{lll} M + R \overset{K_1}{\rightleftharpoons} MR_1 \xrightarrow[OH^-]{k_1} P & & \\ \quad k_b \downarrow OH^- & MR_1 + R \overset{K_2}{\rightleftharpoons} MR_2 \xrightarrow[OH^-]{k_2} P + MR_1 & \\ \quad P & \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots & (6) \\ & MR_{n-1} + R \overset{K_n}{\rightleftharpoons} MR_n \xrightarrow[OH^-]{k_n} P + MR_{n-1}. & \end{array}$$

In the above scheme, M, R, MR_i, and P represent micelle, monomer reactant(TNM), micelle with i reactant molecules, and product(trinitromethanide anion), respectively. K_i is the association constant of monomer reactant with MR_{i-1} micelle, and k_b and k_i are the second-order rate constant in the bulk solution and on the MR_i micelle, respectively. The apparent second-order rate constant for the reaction of TNM with hydroxide ion, k^{app}, is represented in the following way:

$$-d[R_t]/dt = k^{app}[R_t][OH^-]$$
$$= \{k_b[R] + \sum_{i=1}^{n} k_i[MR_i]\}[OH^-], \quad (7)$$

where k^{app} is $k^{obsd}/[OH^-]$ and $[R_t]$ represents the total equivalent concentration of reactant and is given by:

$$[R_t] = [R] + \sum_{i=1}^{n} i[MR_i]. \quad (8)$$

On the other hand, the total micellar concentration $[M_t]$ can be expressed by the following equation:

$$[M_t] = (C_t - CMC)/N, \quad (9)$$

where C_t and N represent the total equivalent surfactant concentration and an aggregation number per micelle, respectively. Eq. 10 or 11 results from the Poisson distribution of reactants,[1]

$$\frac{1}{k^{app}-k_b} = \frac{1}{k_1-k_b} + \frac{N}{K_1(k_1-k_b)} \times \frac{1}{C_t-CMC}, \quad (10)$$

$$\frac{k^{app}-k_b}{k_1-k^{app}} = \frac{K_1}{N} \times (C_t-CMC). \quad (11)$$

In this case the plots of $1/(k^{app}-k_b)$ against $1/(C_t-CMC)$ should be linear, and k_1 and k_1/N values can be determined from the intercept and the slope. At the same time some information on reactant distribution among micelles could be also obtained.[1] The

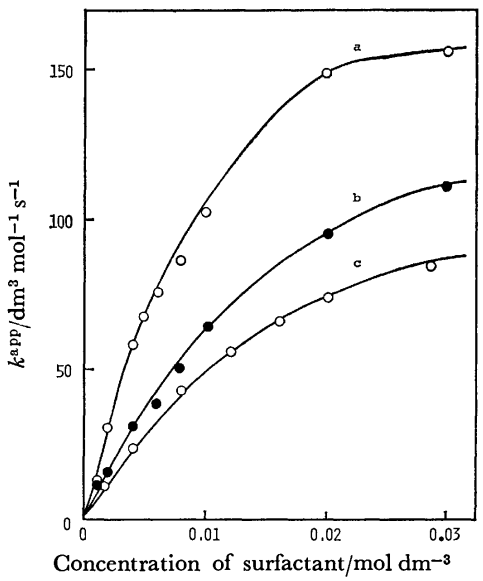

Fig. 2. Effect of the kind of counterion of the cationic surfactants (HTAC(a), HTAB(b), and HTAN(c)) on the apparent second-order rate constant(k^{app}). Plots of k^{app} against the surfactant concentrations.

k_1 values thus obtained are given in Table 2. From the consideration described in the preceeding paper, it can be said that the k_1 value of DoTAC is much larger than that of $C_{12}E_6$ and the reactant distribution is very likely to be the Poisson distribution. Further discussion will be given more in detail in the following sections which describe the effect of the cationic and nonionic surfactants and the temperature effect on the reaction rates.

(1) The Reaction Rates in the Presence of Cationic Surfactants: The k^{app} *vs.* concentration relationship of HTAN, HTAB, and HTAC micelles are plotted in

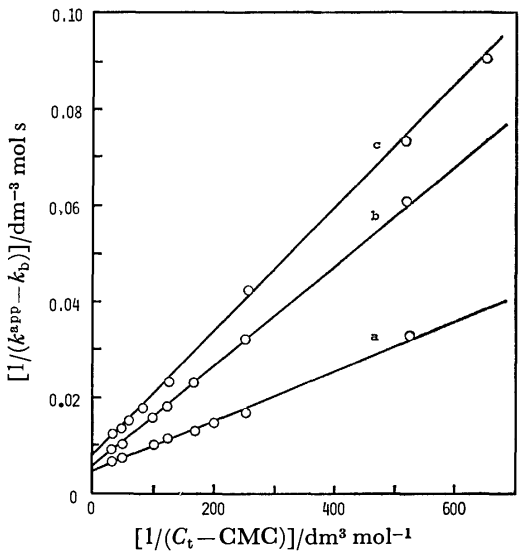

Fig. 3. Determination of the k_1 and K_1/N values from the linearity plots of $1/(k^{app}-k_b)$ against $1/(C_t-CMC)$.
a): HTAC, b): HTAB, c): HTAN.

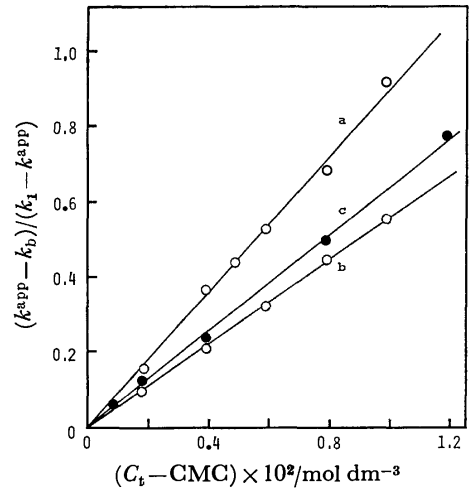

Fig. 4. Determination of the K_1/N vaules from the linearity plots of $(k^{app}-k_b)/(k_1-k^{app})$ against (C_t-CMC).
a): HTAC, b): HTAB, c): HTAN.

Fig. 2 where some differences owing to counterions are clear. In order to make clear a reason for these differences and to take an insight into the reactant distribution, another plots are given in Fig. 3, relating $1/(k^{app}-k_b)$ to $1/(C_t-CMC)$. Judging from the linearity of these plots shown in Fig. 3, the Poisson distribution is well applicable to these reaction systems within experimental error. The k_1 and K_1/N values obtained in this way are given in Table 2. Equation 11 predicts that the plots of $(k^{app}-k_b)/(k_1-k^{app})$ against C_t should be linear and also determine k_1/N values (Fig. 4). The disadvantage of using Eq. 11 is due to a large uncertainty in the value of either numerator or denomenator when k^{app} is nearly equal to k_b or k_1; thus, the useful values are limited to the region of marked increase in k^{app} values. The values of k_1 and K_1/N thus obtained characterize the properties of each micelle.

The k_1 values decrease in the order HTAC>HTAB>HTAN. In these reaction systems, hydroxide ions compete with the surfactant counterions in approaching to charged micellar surface through the electrostatic interaction. In regard to the counterions of surfactants, the hydration radius of the ions decreases in the order $Cl^->Br^->NO^-_3$. That is, the strength of their electrostatic attraction with the charged micelle increases in the order $Cl^-<Br^-<NO^-_3$, which reflects the CMC order (Table 1). In other words, the stronger their electrostatic attraction, the less the electrostatic surface potential of micellar surface. Therefore, it is reasonable to say that the counterions interfere with approach of hydroxide ions to the micellar surface in the order HTAC<HTAB<HTAN. On the other hand, the values of K_1/N decrease slightly in the order HTAC>HTAN>HTAB. For CMC decreases in the order HTAC>HTAB>HTAN, the aggregation number of the micelles may slightly increase in the order HTAC<HTAB<HTAN. Therefore, the large difference is not found in the K_1 values of these cationic surfactants. The K_1 values are about $4—6\times 10^3\ dm^3\ mol^{-1}$.

Next, the effect of the cationic surfactant micelles with different alkyl chain lengths but with the same head group, DeTAC, DoTAC, and HTAC, is examined in order to see the effect of the aggregation number of micelle. The k_1 values (Table 2) increase with increasing alkyl chain length of the surfactants, *i.e.*, with increasing aggregation number of micelle. This increase in the order is mainly due to the increase in electrical surface potential of the micelle in the above order which can be reasoned by analogy of anionic surfactant micelles[16] and partially due to an increase of hydrophobicity of palisade layer of micelle in the above order. Thus, the hydroxide ion concentration of vicinity of the micellar surface is expected to increase with increasing the aggreagation number. The large difference in the k_1 values, however, can not be explained only with the difference in surface potential of the micelles.[16] This must be considered in relation with the K_1/N values. The K_1/N values, on the other hand, increase in the order DeTAC<DoTAC<HTAC, notwithstanding the same order in the aggregation number (*ca.* 36, 50, and 80 for DeTABr, DoTABr, and HTABr, respectively,[17] and these values do not change so much by replacing Br^- by Cl^-; 38 for DoTAC[18]). This means that the K_1 value of TNM for HTAC micelles is about 20 times as large as that of DeTAC. Such a large difference is likely to come from a difference of the location of TNM in the micelles. The roughly estimated K_1 values are given in Table 2. Smaller aggregation number of micelle results in looser palisade layer of micelle, and the hydrophobic reactant is in an innermore part of micelle. Therefore, the effective area for the reactant to sit in micelle becomes less for shorter chain surfactant, which corresponds to a smaller K_1 value. On the other hand, the HTAC micelles have a larger aggregation number as well as a more rigid palisade layer, and the location of TNM must be an outer part of the micelles. This results in a closer contact between TNM and OH^-

ion, a higher value of k_1. The larger effective area thus available for the reactant location leads to larger K_1 value. Thus, the large difference in k_1 values between DeTAC and HTAC results from not only the difference in micellar surface potential term but also the difference of the location of TNM in the micelles.

Finally, in order to confirm the above consideration concerning location site of reactants in micelles, the effect of difference of ionic head groups on the reaction rates was examined using HTAC, HPC, and BHAC micelles. Almost the same aggregation number of HTAC and HPC can be deduced from their CMC values (87 for HPBr). The samller k_1 value of HPC, however, results from a large distance between solubilized TNM and OH^- ion in HPC micelles due to interposition of pyridine ring between them. In the case of BHAC micelle both k_1 and K_1/N values are larger than those of the other micelles in spite of the smaller CMC. This result rests on a more hydrophobic nature of outermost part of the micelle. Therefore, the probability for TNM to sit on an outer part of the micelle increases; this should be the main reason for their increase in BHAC micelles.

From these results, we would like to stress that the reaction rate increase in the presence of cationic surfactant micelles is owing mainly to the hydroxide ion concentration near the cationic micellar surface and that the location of reactants in micelle has a strong influence on the reaction rate.

(2) The Reaction Rates in the Presence of Nonionic Surfactants. As is shown in Fig. 1, the nonionic surfactant also increases the reaction rate. Then, in the first place, an effect of alkylchain length on the reaction rate was examined using the surfactants of C_8E_6, $C_{10}E_6$, and $C_{12}E_6$. The k_1 values increase with increasing alkyl-chain length of the nonionic surfactants, or with increasing aggregation number of micelle, in a similar way as the case of cationic surfactants. On the other hand, the K_1/N values decrease with increasing alkyl-chain length. In the case of nonionic surfactants, the aggregation number of micelle in pure water (30, 100, and 460 at 30 °C for C_8E_6, $C_{10}E_6$, and $C_{12}E_6$, respectively[19]) will remain almost unchanged in the buffer solution of such low ionic strength as 0.03.[19] The roughly estimated K_1 values of these surfactants using the above aggregation number are given in Table 2, too. Contrary to the order of the K_1/N values, the K_1 values thus obtained increase with increasing alkyl-chain length of the surfactants. This increase can also be understood from the view point of an available area of the reactant solubilized. From comparison between cationic and nonionic surfactants with an identical alkylchain length, *e.g.* $C_{10}E_6$ and DeTAC or $C_{12}E_6$ and DoTAC, the k_1 values of the cationic surfactants are almost three times as large as those of nonionic surfactants. On the contrary, the K_1 values of the nonionic surfactants are almost four times as large as those of cationic surfactants, which means that the oxyethylene groups connected with alkyl chain probably constitute a palisade layer of the micelles where the hydrophobic reactant locates.[20] This leads to larger available area in the nonionic surfactant micelles than in the cationic micelles.

TABLE 3. RATE PARAMETERS FOR THE REACTION OF TNM WITH HYDROXIDE ION

Surfactant	ΔG^* / kJ mol^{-1}	ΔH^* / kJ mol^{-1}	ΔS^* / J mol^{-1} K^{-1}
None	76.9	65.6	−37.2
DeTAC	66.5	60.2	−20.9
DoTAC	64.8	59.8	−16.7
HTAC	61.9	57.7	−13.8

Next, to see the effect of an oxyethylene chain length the reaction rates were measured in the presence of nonionic surfactants containing different numbers of oxyethylene unit but with the fixed alkyl-chain length, $C_{12}E_6$, $C_{12}E_{10}$, $C_{12}E_{15}$, $C_{12}E_{20}$, and $C_{12}E_{29}$. The k_1 and K_1/N values obtained from the linearity plots are summarized in Table 2. Concerning the decrease in k_1 values with an increase in oxyethylene unit more than ten, it can be expected that the location of TNM goes into an innermore part of the micelles owing to not only loosening of the palisade layer but also their smaller aggregation number with increasing oxyethylene group. Consequently, a separation between TNM and OH^- comes to increase with an increase in oxyethylene unit. Regarding the K_1/N values, on the other hand, even if the decrease in aggregation number of the micelles with increase of oxyethylene group is taken into account (460, 180, 120, 80, and 60 at 30 °C for $C_{12}E_6$, $C_{12}E_{10}$, $C_{12}E_{15}$, $C_{12}E_{20}$, and $C_{12}E_{29}$, respectively, which were estimated by an interpolation or extrapolation from the aggregation numbers in the literature[19]), the K_1 value of $C_{12}E_6$ is almost five times as large as that of $C_{12}E_{29}$. The roughly estimated K_1 values are given in Table 2. This decrease in K_1 values with increasing oxyethylene group is also likely to result from the loose palisade layer caused by less aggregation number with increase of oxyethylene goup. That is, the area for TNM to sit becomes less with increase of the group. The identical explanation should be applicable to the reaction rates on both cationic and nonionic surfactant micelles.

Concerning the distribution of TNM among micelles, the Poisson distribution could be well approximated for both cationic and nonionic surfactant micelles. Namely, regardless of the kinds of surfactants used, the linearity of the plots of $1/(k^{app}-k_b)$ against $1/(C_t-\mathrm{CMC})$ is very good. We may conclude at this point that the Poisson distribution of TNM among micelles can be applied to the present cationic and nonionic surfactant micelles. In other words, the assumption used for this treatment is suitable for these systems.

(3) Temperature Effect on the Reaction Rates. Finally, a dependency of the reaction rates on temperature was examined both in the absence and presence of micelles. The reaction rates were measured over the temperature range of 20—40 °C, and the surfactants used were DeTAC, DoTAC, and HTAC. The reaction rate determination in the presence of these sur-

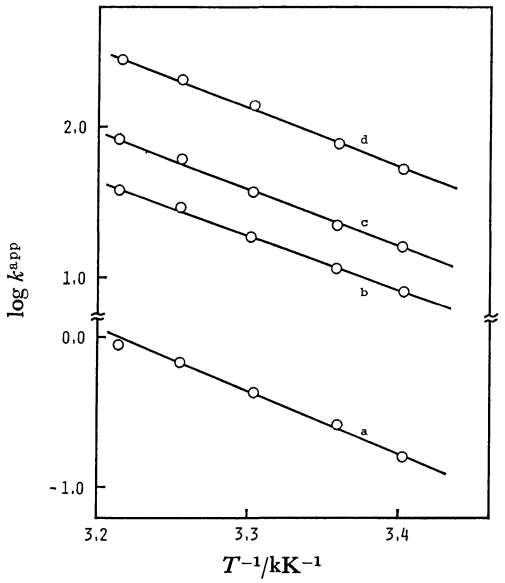

Fig. 5. Arrhenius plots for the reaction of TNM with hydroxide ion.
a): No micelles, b): DeTAC 0.3 mol dm^{-3}, c): DoTAC 0.2 mol dm^{-3}, d): HTAC 0.03 mol dm^{-3}.

factants were made at the higher surfactant concentrations where the second-order rate constant k^{app} is almost equal to the rate constant k_1. The plots of $\log k^{app}$ against $1/T$ gives a straight line as shown in Fig. 5, and then the activation energy E_a can be calculated by the Arrhenius equation. The ΔG^* and ΔH^* values decrease and ΔS^* values increase in the presence of these micelles compared with those in the absence of micelles (Table 3). The transition state of the reaction of TNM with hydroxide ion is represented by:[6]

$$C(NO_2)_4 + OH^- \rightleftharpoons [(NO_2)_3C\text{-}\overset{+}{N}\overset{O^-}{\underset{O}{\diagdown\diagup}}\cdots\cdots OH^-]^- \longrightarrow C(NO_2)_3^- + HNO_3. \quad (12)$$

Therefore, the transition state having a negative charge is electrostatically stabilized by the cationic micelles. In any event, the drastic change of ΔG^* and ΔH^* values could not be found even in the presence of the cationic micelles. This means that the increase in the rate constant in the presence of cationic micelles can be attributed mainly to a local concentration increase of another reactant OH^- ions around the micelles and that the reaction mechanism is not changed much by the presence of these micelles.

Pressure Effect on Rate Constants of Proton-transfer Reactions from 2,4,6-Trinitrotoluene to *N,N,N',N'*-Tetramethylguanidine and 1,8-Diazabicyclo[5.4.0]undec-7-ene in Acetonitrile and Dichloromethane

Naoki Sugimoto, Muneo Sasaki,* and Jiro Osugi
Department of Chemistry, Faculty of Science, Kyoto University, Oiwake-cho, Kitashirakawa, Sakyo-ku, Kyoto 606
(Received March 2, 1981)

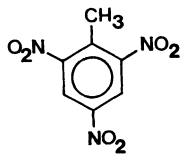
Influence of pressure on the rate constants of the proton-transfer reactions between title compounds was studied in acetonitrile and dichloromethane at 25 °C up to 1000 bar by means of a high-pressure stopped-flow method. In the reaction of 2,4,6-trinitrotoluene (TNT) with *N,N,N',N'*-tetramethylguanidine, the volume of activation for the forward reaction ΔV_f^* is -12.7 ± 1.0 cm^3 mol^{-1} in acetonitrile and -19.0 ± 1.5 cm^3 mol^{-1} in dichloromethane. In the reaction of TNT with 1,8-diazabicyclo[5.4.0]undec-7-ene, ΔV_f^* is -9.0 ± 1.0 cm^3 mol^{-1} in acetonitrile and -10.8 ± 1.0 cm^3 mol^{-1} in dichloromethane. These results are discussed in comparison with other proton-transfer reactions.

Proton-transfer reaction in solution has been extensively studied from the theoretical and phenomenological viewpoints.[1-3] Some proton-transfer reactions also have attracted much interest because of occurrence of appreciable tunneling effect.[4] It is known that the proton-transfer reaction between 4-nitrophenylnitromethane (4NPNM) and a base such as amine[4,5] or alkoxide ion,[6] proceeds in a simple way.[7] In the case of the reaction of 2,4,6-trinitrotoluene (TNT) with ethoxide ion in ethanol, two colored compounds are formed.[8] At high concentrations of TNT($\approx10^{-3}$ M; 1 M=1 mol dm^{-3}) and ethoxide ion($\approx10^{-1}$ M) a brown species is formed, which is elucidated to be a type of Meisenheimer complex by Bernasconi.[9] On the other hand at low concentrations of TNT($\approx10^{-5}$ M) and ethoxide ion($\approx10^{-3}$ M), 2,4,6-trinitrobenzyl anion (TNT^-; $\lambda_{max}=514$ nm) is mainly produced by a proton abstraction from the methyl group of TNT.[8,10] Since the reaction with a nonionic base is expected to shift in favor of the proton-transferred state compared with the case of an ionic base, Pruszynski *et al.*[11] have studied the reaction between TNT and *N,N,N',N'*-tetramethylguanidine (TMG) in aprotic solvents, namely acetonitrile and benzonitrile. The reaction in both solvents produces a purple solution due to ion-pair which has the absorption maxima similar to those observed for the reaction of TNT with ethoxide ion in ethanol. Further, they have investigated this reaction in DMF solvent and discussed the relation between kinetic isotope effects and steric effects of solvent.[12]

If we can obtain some informations on the effective mass or volume change accompanied with the proton-transfer reaction, the behavior of the solvent in the vicinity of the reactive site will be made clear. The volume of activation is well known to be a more easily interpretable quantity than the entropy or the energy of activation.[13] There are several works of high-pressure effects on the slow proton-transfer reactions.[14] However, as technical difficulty has restricted the high-pressure investigation on a reaction faster than several seconds, there are only a few reports on high-pressure effects on the fast proton-transfer reactions.[15,16] We reported previously[16] that the proton/deuteron-transfer reactions of 4NPNM+TMG in toluene and dichloromethane were accelerated at high pressure and the kinetic isotope rate ratio reduced from 11.9 at 1 bar to 9.3 at 1000 bar in toluene while it almost unchanged in dichloromethane(10.7±0.2).

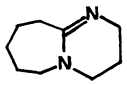
In this paper we investigate the proton-transfer reactions between TNT(AH) and TMG(B) in acetonitrile and dichloromethane solvents by means of a high-pressure stopped-flow method up to 1000 bar at 25 °C. The reaction between TNT and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in both solvents is also studied. Such a base was chosen for the reasons that (a) the base nitrogen atom was not protonated in the free base,[7] (b) it was a strong base favorable to proton-transfer reaction, and (c) it was a cyclic amidine suitable for the study of the steric effect.

$$AH + B \underset{k_b}{\overset{k_f}{\rightleftharpoons}} [A]^-[BH]^+_{\text{ion pair}} \quad (1)$$



TNT

TMG



DBU

Experimental

Materials. 2,4,6-Trinitrotoluene (TNT) was purified by repeated crystallization from ethanol with charcoal; mp 81 °C. The purity of TNT was examined by NMR spectrum (methyl protons $\delta=2.75$, benzene ring protons $\delta=8.92$ in the ratio 3:2). *N,N,N',N'*-Tetramethylguanidine (TMG, Nakarai Chemicals Co. Ltd.) was dried with potassium hydroxide and then distilled under a nitrogen atmosphere; bp 161 °C (lit, 161 °C). 1,8-Diazabicyclo[5.4.0]-undec-7-ene(DBU, Nakarai Chemicals Co. Ltd., spectrograde reagent) was dried with potassium hydroxide and then distilled under reduced pressure. The pure DBU was identified by NMR spectrum. Acetonitrile was purified by the method of O'Donell[17] and then distilled over phosphorus pentaoxide; bp 82 °C. Dichloromethane was dried with calcium hydride and then distilled; bp 39.5—40 °C.

Apparatus and Procedure. Absorption spectra were determined by a Shimadzu UV-200S spectrophotometer. Kinetic measurements at 1 bar (1 bar=10^5 Pa) were carried out by a Union Giken RA-401 stopped-flow apparatus. In all measurements at 1 bar, the temperature was kept at 25.0±0.1 °C by circulating thermostated water. At

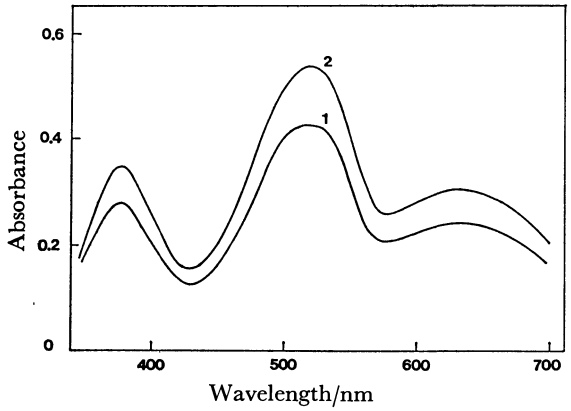


Fig. 1. Visible spectra of the product of the TNT+TMG reaction (1) and of the TNT+DBU reaction (2) in acetonitrile.

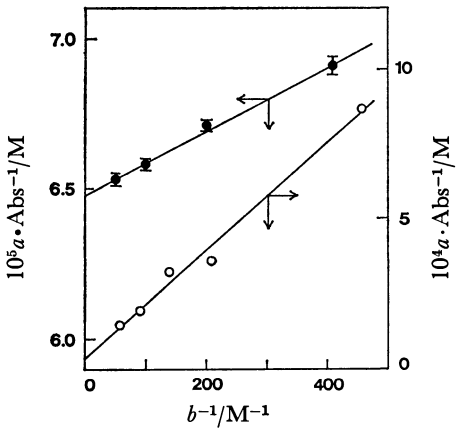

Fig. 2. Plots of a/Abs against reciprocal of DBU concentration in acetonitrile (open circles) and dichloromethane (closed circles) at 25 °C.

high pressure the reaction was followed by means of a high-pressure stopped-flow apparatus; the details were described elsewhere.[18] In high-pressure measurements the temperature was kept at 25.0±0.5 °C by circulating thermostated fluid around the high-pressure vessels.

The following weighed-in concentrations of solutions at 1 bar were freshly prepared every day before use: TNT 0.02—0.03 mM, TMG 2—10 mM in acetonitrile and TNT 0.1—0.3 mM, TMG 5—100 mM in dichloromethane; TNT 0.02—0.06 mM, DBU 2—13 mM in acetonitrile and TNT 0.04—0.08 mM, DBU 3—18 mM in dichloromethane.

The rate of the proton-transfer reactions of TNT with TMG and DBU was determined by monitoring the change of the absorption with time at 520 nm in acetonitrile and at 530 nm in dichloromethane. The increase of the absorbance obeyed first-order kinetics when the base (TMG, DBU) existed in large excess over TNT. The observed rate constant k_{obsd} was determined by the least-squares fitting to the Guggenheim plot.

Results

The reactions of TNT with TMG and DBU within the range of present experimental concentrations give the purple anion. The possibility of reactions other than the proton-transfer was ruled out with reference to the careful examinations of Pruszynski *et al.*[11] and

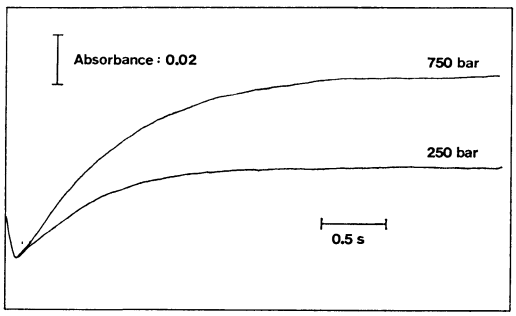

Fig. 3. Typical stopped-flow traces of the TNT+DBU reaction in dichloromethane at 25 °C. The absorbance change was monitored at 530 nm: [TNT]= 3.4×10^{-5} M, [DBU]=2.40×10^{-3} M at 1 bar.

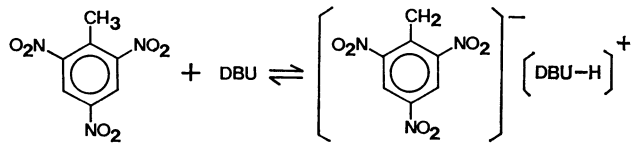
Jarczewski *et al.*[12] The absorption maxima for the ion-pair produced by a proton-transfer from the methyl group of TNT to TMG are around 375, 530, 635 nm in dichloromethane and identical to those observed in acetonitrile (378, 520, 635 nm). The reaction mixtures between TNT and DBU show the absorption maxima at around 375, 530, 635 nm in dichloromethane and 378, 520, 635 nm in acetonitrile; they are very similar to those observed in the reaction between TNT and TMG (Fig. 1), while each reactant is transparent in the visible region.

The equilibrium constant of the TNT+DBU reaction was determined at 25 °C and 1 bar according to the Benesi-Hildebrand equation (2).[19] In this equation, [a] is the initial concentration of TNT, [b] that of the base, K the equilibrium constant, ε the molar absorption coefficient, Abs the absorbance at 520 nm in acetonitrile and 530 nm in dichloromethane at the equilibration. The fact that the plot of Eq. 2 gives a very good straight line as shown in Fig. 2 supports that the product is not separate ions but a contact one, namely ion-pair. Otherwise the plot would be significantly curved and the following would be valid:

$$\frac{[a]}{Abs} = \frac{1}{K\varepsilon}\frac{1}{[b]} + \frac{1}{\varepsilon} \quad (2)$$

$$\frac{[a]}{Abs} = \frac{1}{K\varepsilon^2}\frac{Abs}{[b]} + \frac{1}{\varepsilon}. \quad (3)$$

Therefore, it is concluded that the reaction path between TNT and DBU is simple and the same as that between TNT and TMG as described below.



(4)

In Fig. 3 are shown some representative traces of the increase of absorption with time. The stopped-flow trace at each pressure obeyed a first-order kinetic equation. The plot of k_{obsd} against TMG or DBU concentration [b] is of a straight line at each pressure (Figs. 4 and 5), in agreement with Eq. 5.

$$k_{obsd} = k_f[b] + k_b \quad (5)$$

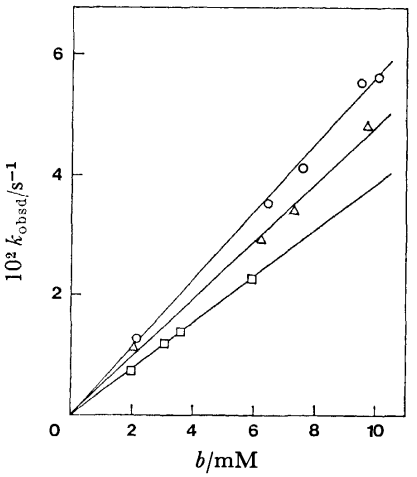


Fig. 4. Dependence of k_{obsd} on TMG concentration in acetonitrile at 25 °C.
□: 1 bar, △: 500 bar, ○: 1000 bar.

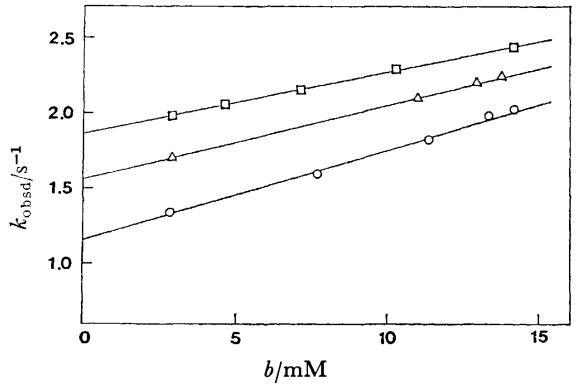

Fig. 5. Dependence of k_{obsd} on DBU concentration in dichloromethane at 25 °C.
□: 1 bar, △: 500 bar, ○: 1000 bar.

In the equation, k_f and k_b are the forward and backward rate constants of the proton-transfer reactions. Since molar concentration unit is convenient to compare the rate constants at various conditions, we corrected the weighed-in concentration at 1 bar for the compression of each solvent to know [b] of molar unit at high pressure. In the plots of Figs. 4 and 5, compression was taken into account on the basis of data of Srinivasan *et al.*[20] for acetonitrile and of Newitt *et al.*[21] for dichloromethane. Thus the values of k_f and k_b were determined from the dependence of k_{obsd} on TMG and DBU concentration by a least-squares method. The values of k_f are given in Table 1. The values of k_b in dichloromethane are given in Table 2, but in acetonitrile they are too small to be reliable and are not recorded. The equilibrium constants K are also evaluated and listed in Table 2.

The volume of activation ΔV^* for either k_f or k_b was determined by

$$\left(\frac{\partial \ln k}{\partial p}\right)_T = -\frac{\Delta V^*}{RT} + \Delta n^* \kappa, \qquad (6)$$

where, κ is the compressibility of the solvent, Δn^* the difference of the number of molecules from the initial to the transition state, T the absolute temperature, and R the gas constant. In the present reaction, the value of Δn^* is -1 for the forward reaction and zero for the backward one. The value of κ at 25 °C were calculated from the literatures.[20,21] The plots of $\ln k_f$ against pressure were almost linear for both systems and both solvents (Figs. 6 and 7). The values of ΔV_f^* are given in Table 3 together with ΔV_b^*.

Discussion

Equilibrium and Rate Constants at Atmospheric Pressure. In the reaction between TNT and ethoxide ion, Buncel *et al.*[10] found that when first-order rate constants k_{obsd} were plotted against ethoxide ion concentration it was slightly curved. The analysis of these results led them to the conclusion that the brown species other than TNT^- was formed. However, in the reaction between TNT and TMG, Pruszynski *et al.*[11] obtained a linear relation obeying Eq. 5 in both acetonitrile and benzonitrile. In our experiments also, the plots of k_{obsd} against TMG and DBU concentration [b] gave a straight line in acetonitrile and dichloromethane. The equilibrium constants obtained by rate constant ratio $K(=k_f/k_b)$ are well in accord with the direct determination after equilibration by Eq. 2 (Table 2), which strengthens the reliability of the determined rate constants.

The rate constant k_f of TNT+TMG reaction at 25 °C and 1 bar is 3.84±0.05 $M^{-1}\,s^{-1}$ in acetonitrile, which is almost equal to Pruszynski's value (k_f= 4.04±0.12 $M^{-1}\,s^{-1}$), and 3.13±0.07 $M^{-1}\,s^{-1}$ in dichlo-

romethane. In the reaction between TNT and DBU, the value of k_f is 204±4 M^{-1} s^{-1} in acetonitrile and 41.8±0.8 M^{-1} s^{-1} in dichloromethane. In both reactions, the rate constants of the forward reaction in acetonitrile (dielectric constant; ε=36) are larger than those in dichloromethane (ε=8.9). These kinetic behaviors are in accord with the view that each reaction involves the formation of a polar transition state since the polar transition state is, in general, more stabilized in the higher polarity of solvent. Further, the kinetic results for TNT may be compared with those reported for the corresponding reaction of 4NPNM with TMG and DBU.[4,22] The forward rate constant k_f of the reaction of 4NPNM at 25 °C in toluene is larger for DBU (k_f=2.7×10^5 M^{-1} s^{-1}) than for TMG (k_f=2.29×10^3 M^{-1} s^{-1}) by a factor of about 120. While in our results k_f of the reaction of TNT is larger for DBU than for TMG by a factor of about 55 in acetonitrile and 15 in dichloromethane. Thus the explanation on the difference in solvent sensitivity between TMG and DBU is, even qualitatively controversial at present, but it is clear that 4NPNM releases the α-proton more easily than TNT irrespective of solvent or base.

Judging from the results of the reaction with 4NPNM,[22] DBU is a much stronger base: the equilibrium constant K at 25 °C is about 100 times larger than for *N,N*-diethylpentanamidine and about 70 times larger than for *N,N*-diethyldecanamidine. As found in Table 2, K between TNT and DBU is larger than between TNT and TMG: DBU is a much stronger base than TMG especially in less polar solvent. Between TNT and DBU, K at 25 °C and 1 bar is 6070±600 M^{-1} in acetonitrile and 24±5 M^{-1} in dichloromethane (from kinetic measurements, $K=k_f/k_b$ is 5200±400 and 22±4 M^{-1}, respectively). Therefore, the stability of the ion-pair in acetonitrile is higher than that in dichloromethane.

Pressure Effects on Reaction Rates. The volume of activation ΔV^* of chemical reactions in solution are recognized to give very important information about the reaction mechanism and the role of the solvent during activation.[23] ΔV^* mainly consists of two major contributions, one due to the structural change of activation (ΔV_{str}^*), and the other due to the solvation change (ΔV_{solv}^*) on going from the initial to the transition state.[24] In the case of the bond-forming process, ΔV_{str}^* would be negative. When electronic charge is generated during activation, ΔV_{solv}^* will also be negative. The proton-transfer reaction from TNT to TMG and DBU conforms to the above case; in fact, our data result is the negative values of the volume of activation. The volume of activation of the forward reaction ΔV_f^* of TNT+TMG reaction is −12.7±1.0 cm^3 mol^{-1} in acetonitrile and −19.0±1.0 cm^3 mol^{-1} in dichloromethane, and then ΔV_f^* of TNT+DBU reaction is −9.0±1.0, −10.8±1.0 cm^3 mol^{-1}, respectively. Absolute value of ΔV_f^* for TNT+TMG reaction in dichloromethane is a little larger than that of 4NPNM+TMG reaction (−15.3±1.5 cm^3 mol^{-1})[16a] and that of 4NPNM+TMG-d_2 (−14.6±1.7 cm^3 mol^{-1}).[16b]

On the basis of Kirkwood's theory,[25] Eqs. 7 and 8 hold for k and ΔV^*, respectively;

$$\ln k = \ln k_0 + (N_0\Sigma\mu^2/a^3)q, \quad (7)$$

$$\Delta V^* = \Delta V_0^* - (N_0\Sigma\mu^2/a^3)(\partial q/\partial p)_T, \quad (8)$$

where $q=(\varepsilon-1)/(2\varepsilon+1)$, μ and a are dipole moment and radius, respectively, $\sum\mu^2/a^3$ the difference between the initial state and the transition state, and N_0 Avogadro's number. Since the reaction studied here proceeds through a highly polar transition state, the term $\sum\mu^2/a^3$ is expected to be positive. In many cases, though not generally, the larger the q value (the higher dielectric constant) the smaller the $(\partial q/\partial p)_T$ term. Thus, our results that the forward reaction proceeds faster and ΔV_f^* is less negative in the more polar solvent will be qualitatively explained by the above electrostatic solvation-model of an ionogenic reaction: similar tendency is found in many Menschutkin reactions.[26] Hence it is likely that even in the solvent of low polarity such as dichloromethane solvation in the proximity of reaction center, more or less, takes places.

Absolute values of ΔV_f^* for DBU are larger than those for TMG in both solvents. This may be attributed to the steric effect of DBU, that is, the nonplanar seven-membered ring of DBU will prevent solvation in the vicinity of reaction center. ΔV_f^* values in dichloromethane are considerably less negative compared with the volume change of reaction $\Delta V^\circ(=\Delta V_f^*-\Delta V_b^*)$ (Table 3). The transition state is therefore not as highly ionic as the ion-pair.

Further studies of the rate and its kinetic isotope effect in many solvents and other systems at high pressure will reveal the behavior of the solvent in the vicinity of reaction site.

The authors are grateful to Mr. Fujitugu Amita for maintenance of the high-pressure stopped-flow apparatus. The present work was supported by a Grant-in-Aid for Scientific Research No. 454123 from the Ministry of Education, Science and Culture.

Raman Spectra of a Compound under Inversion Motions. II. *N*-Methylpiperazine

Kunio FUKUSHIMA* and Hiromichi TAKAHASHI

Department of Chemistry, Faculty of Science, Shizuoka University, 836 Oya, Shizuoka 422

(Received March 13, 1981)

Raman spectra of *N*-methylpiperazine in proton donors and acceptors were measured. Forms of stable conformers in the donors and the acceptors were studied by comparison of the Raman spectra and normal vibration calculations. A conformational change of the molecule in the donors was found, suggesting the change of valence state of nitrogen atom, which is caused by hydrogen bonding.

One of the present authors reported[1] the conformational change of *N,N'*-dimethylpiperazine, which might be ascribed to suppression of inversion motion at nitrogen by hydrogen bonding. In the present study, the effect of hydrogen bonding on molecular conformation of *N*-methylpiperazine molecule, which has two nitrogen atoms, one bonded by a light atom and the other bonded by a heavier group, was investigated in order to compare the effect by hydrogen bonding on the valence state of nitrogen atoms in different situations.

Experimental

Commercial *N*-methylpiperazine (grade GR, Tokyo Kasei Chemicals Co., Ltd.) distilled under vacuum was used. Raman spectra were measured with a Model R-800T Raman Spectrophotometer (Japan Spectroscopic Co., Ltd.) under excitation with a Spectra Physics argon ion laser (model 165) using 514.5 nm line (300 mW). Depolarization ratio was measured by use of a system consisting of a half-wave plate, a lens and a polarizer. Measured depolarization ratio of the Raman bands of carbon tetrachloride at 459 cm^{-1} (A_1 species) and at 218 cm^{-1} (E species) were 0.007 ± 0.001 and 0.75 ± 0.01, respectively. Liquid samples at room temperature were measured with 0.3 ml Raman cells, while crystal at low temperature was measured with an Oxford-type cryostatt and liquid nitrogen. The experimental results are shown in Tables 1—2 and Figs. 1—2.

Results and Discussion

In the following discussion, refer to Tables 1—2 and Figs. 1—2.

Raman Spectrum Change Associated with Hydrogen Bonding. The three Raman bands of pure liquid at 615 cm^{-1}, 608 cm^{-1}, and 587 cm^{-1} reduce their frequencies by *N*-deuteration as shown in the spectrum of heavy water solution. On the other hand, the band at 339 cm^{-1} shifts to 330 cm^{-1} by an apparently small frequency decrease as the result of both decrease of frequency on *N*-deuteration and increase of frequency by hydration. On the basis of the frequency changes, they are ascribed to the vibrations of –NH– group. Among them, the band at 615 cm^{-1} reduces its intensity both in the benzene and the acetone solutions, where concentration of the species hydrogen-bonded to the nitrogen atom in the group decreases. Therefore, it is assigned to the species, which is hydrogen-bonded to the nitrogen atom, though which might be hydrogen-bonding to other molecule. On the other hand, the band at 587 cm^{-1} increases its intensity in the solutions, being assigned to the species, which is not hydrogen-bonded to the nitrogen atom.

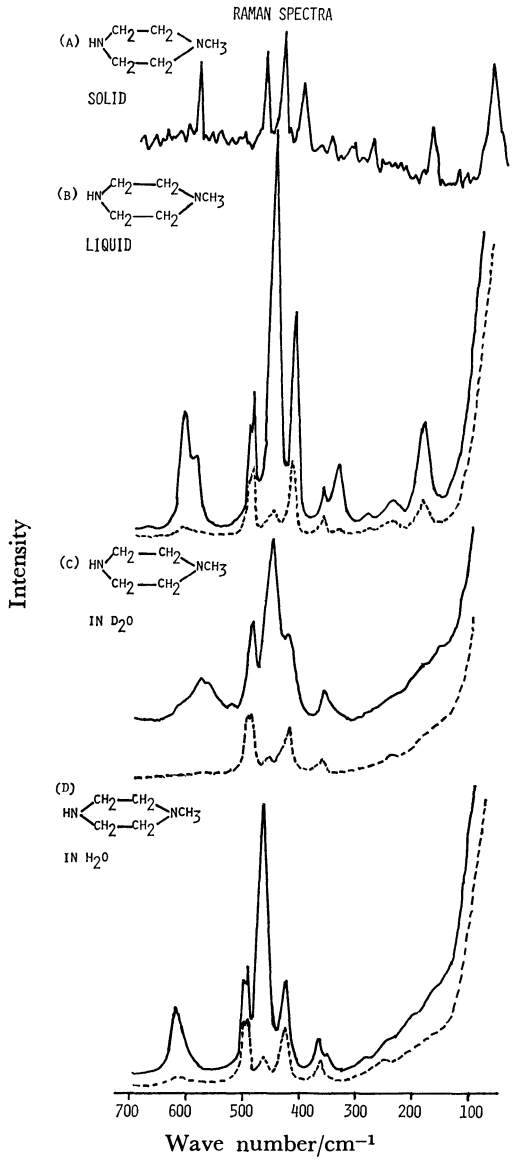

Fig. 1. Raman spectra of *N*-methylpiperazine. (A): Solid at −63 °C, (B): liquid at room temperature, (C): heavy water solution (mole fraction=0.335), (D): aqueous solution (mole fraction=0.335) Solid line: $I_{//}$, dotted line: $I_{\perp}$.

Intensity of the band at 608 cm^{-1} decreases in the acetone solution, in which the species hydrogen-bonding to acetone molecule but not hydrogen-bonded to its nitrogen atom increases. Therefore, it is assigned to the species which is hydrogen-bonded to its nitrogen, but is not hydrogen-bonding to other

molecule. In the aqueous solution, the band at 587 cm^{-1} becomes weaker, and the band at 615 cm^{-1} becomes intense, so being the case for the methanol solution. Intensity of the band at 339 cm^{-1} increases in the benzene and the acetone solutions, while it decreases in the aqueous and the methanol solutions. So, the band is assigned to a vibration of –NH– group of the species, which is not hydrogen-bonded to nitrogen atom. In the latter solutions, frequency of the band increases to 363 cm^{-1} on hydrogen bonding to nitrogen atom.

These changes indicate that the bands at 587 cm^{-1} and 339 cm^{-1} arising from non-bonded –NH– group increase their frequencies to 615 cm^{-1} or 608 cm^{-1} and 363 cm^{-1} by being hydrogen-bonded to the nitrogen atom.

Frequencies of the bands of pure liquid at 453 cm^{-1}, 440 cm^{-1}, and 363 cm^{-1}, do not change much on *N*-deuteration. The band at 440 cm^{-1} increases its intensity in the benzene and the acetone solutions, while its intensity decreases in the aqueous and the methanol solutions. Therefore, it is attributed to the species which is not hydrogen-bonded to the nitrogen atom of –N(CH_3)– group. The other two bands at 453 cm^{-1} and 363 cm^{-1}, which are intense in the aqueous and the methanol solutions, are attributed to the species hydrogen bonded to the nitrogen atom of –N(CH_3)– group, although the latter band might be overlapped by a band of non-bonded species. Based on these changes, it is concluded that the band at 440 cm^{-1} of non-bonded –N(CH_3)– group increases its frequency to 453 cm^{-1} on the hydrogen bond for-

Frequency change associated with hydrogen bonding to nitrogen atom in the case of –NH– group ((615−587)/587=0.048, (608−587)/587=0.036; (363−339)/339=0.071) is larger than that of –N(CH_3)– group ((453−440)/440=0.030).

Comparison of the Bands of Non-bonded Species with Normal Vibration Calculation and the Bands of the Solid. The results of normal vibration calculation according to Wilson's GF matrix method[2] by use of the modified Urey-Bradley force field and the force constants in Table 3 are shown in Table 2, compared with the observed frequencies of the non-bonded species. The observed frequencies agree well to the calculated frequencies of ee form or e(CH_3)a(H) (e: equatorial, a: axial), but they are not consistent with those of aa form or a(CH_3)e(H) form. Therefore, it is probable that molecular form of non-bonded species is close to ee form or e(CH_3)a(H) form. As valence state of nitrogen atom is almost sp^3 in the species hydrogen-bonded to the nitrogen atom, the observed frequencies in Table 2 are considered to be due to the molecular form, which is close to but not the same as the form having sp^3 valence state of nitrogen atom. In the solid state, species having similar molecular form persists as frequencies of the non-bonded species are somewhat close to those in the spectrum of the solid in the region below 700 cm^{-1}. From the above discussion, it is concluded that in the liquid state non-bonded *N*-methylpiperazine molecules are in one form close to ee or e(CH_3)a(H) form and that some of normal frequencies of –NH– or –N(CH_3)– group of the form are affected very much by hydrogen bonding to the nitrogen atom of –NH– or –N(CH_3)– group. The frequency changes on hydrogen bonding cannot be explained as the conformational change, ee or e(CH_3)a(H)→aa or a(CH_3)e(H), because the frequency of the polarized band at 339 cm^{-1} decreases and those of the bands at 363 cm^{-1}, 417 cm^{-1}, 440 cm^{-1}, and 587 cm^{-1} all increase in the case of the conformational change, while the observed change is contradictory to the change as shown in Table 2. Therefore, the change may be ascribed to change of valence state of nitrogen atom from the state for the ground state of the normal vibration associated with inversion coordinate to sp^3 type in hydrogen-bonded nitrogen atom.

Interpretation of the Spectrum Change Associated with Hydrogen Bonding. According to the normal vibration calculation, the Raman bands at 339 cm^{-1}, 440 cm^{-1}, and 587 cm^{-1}, which are affected much by hydrogen bonding, correspond to the vibrations to which the symmetrical skeletal deformation modes (A′ species) contribute to a great deal. These modes are related to the coordinates of inversions, ring inversion and inversion at nitrogen. It has been reported for 1,4-dimethylpiperazine and other compounds that rate of inversion at nitrogen is much faster than that of ring inversion and also that the activation energy for inversion at nitrogen of 1,4-dimethylpiperazine is a rather small value of 14 kJ mol^{-1}.[3] Therefore, the potential barrier for inversion at nitrogen is expected to be lower than that for ring inversion. When *N*-methylpiperazine is hydrogen-bonded, inversion at nitrogen may be suppressed and the molecule is likely to be primarily under ring inversion. In that situation, the potential is different from that of inversion motion including inversion at nitrogen especially in the height of potential barrier and the anharmonicity. The change of shape of the potential by hydrogen bonding necessarily accompanies the change of energy levels of normal vibrations associated with inversion coordinates as well as the change of molecular structure for the vibrational ground state. Thus, for the vibrations, to which inversion coordinates contribute, the energy difference between ground state (v=0) and the first excited state (v=1) become different between non-bonded molecule and hydrogen-bonded molecule. The Raman shift frequencies which we observe are related to the transition from the ground state to the first excited state, and therefore, they change considerably by the change of the energy difference of the energy levels.

Difference of frequency change associated with hydrogen bonding to nitrogen atom suggests that potential barrier of inversion at nitrogen of –NH– group is different from that of –N(CH_3)– group.

(Received March 25, 1981)

The glass transition temperature (T_g) is measured as a function of pressure up to 200 MPa for the aqueous Li, Na, K, Rb, and Cs acetate solutions. The effects of cation radius on the glass transition of these solutions are discussed and some attempts are made to correlate T_g (and associated properties) with r (cation radius).

Glass transition is characterized by a heat absorbing inflection in a DTA trace and affected by many factors.[1] In recent glass formation studies,[2,3] it is shown that glass transition temperature (T_g) is a good diagnostic parameter to represent thermodynamic and transport properties of a supercooled liquid and glass system. In contrast to silicate and borate systems,[4] glass formation studies of aqueous solutions have been still scarce.

As aqueous electrolyte solutions in high concentrations are a very complicated system, defying any simple theoretical treatment, it is of importance, as a first step, to investigate the effects of various factors affecting the magnitude of T_g. Ionic radius of ions (r) is of course an important factor in transport and thermodynamic properties of aqueous solutions.[5] Alkali ions are simple in structure and essentially ionic so that aqueous solutions of alkali salts are a suitable target if only they are glass-forming. It is expected that the effect of pressure on T_g can be an auxilliary diagnostic tool to clarify the structure and thermodynamic properties of concentrated aqueous solutions.

In this work, we have measured the glass transition temperatures of aqueous alkali acetate solutions as a function of pressure and discussed the effects of pressure and cation radius on the glass transition of the solutions.

Experimental

Aqueous solutions of alkali acetates were prepared by dissolving guaranteed grade alkali acetates in distilled water. The concentration was all set to be $R=10$ (R=mol of water/mol of salt). The high pressure DTA cell is essentially the same one as used in the measurements of homogeneous nucleation temperature of emulsified aqueous solutions and water.[6] The sample container used for the high pressure experiment was a 1 mm inner-diameter capillary glass cell, in which an aliquot of sample solution was filled and an alumel-cromel thermocouple junction (Omega-clad 0.02 inch o.d. thermocouples) was inserted. As a pressure transmitting fluid and the reference material, a 1:1 mixture of methylcyclopentane and methylcyclohexane was used because of its low vitrification temperature (below −150 °C at atmospheric pressure).

Vitrification of the sample solution was made at pressure of about 30 MPa by plunging the high pressure cell directly into liquid nitrogen. The overall cooling rate was about 200 K/min. Then the differential and temperature emf's were recorded at a heating rate of about 5 K/min in the temperature range where the glass transition took place Immediately after observing the glass transition, pressure was increased by 20—30 MPa and then the high pressure cell was cooled to liquid nitrogen temperature. This process was repeated up to pressure about 200 MPa.

T_g at atmospheric pressure was also measured with a simple DTA method. The reference material in this case was benzene. Vitrification of the sample solution in a 2 mm diameter Pyrex glass cell was carried out by immersing the cell in liquid nitrogen. The overall cooling rate in this case was about 10^3 K/min. The DTA trace was recorded at a heating rate of about 5 K/min.

Results and Discussion

The T_g values obtained at normal pressure are shown in Fig. 1 together with two insets in which a typical DTA trace and the (T_c/T_g) *vs.* $1/r$ plot are presented (T_c: crystallization temperature). As is already pointed out,[6] T_g for the sodium acetate solution is the maximum among all alkali acetate solutions.

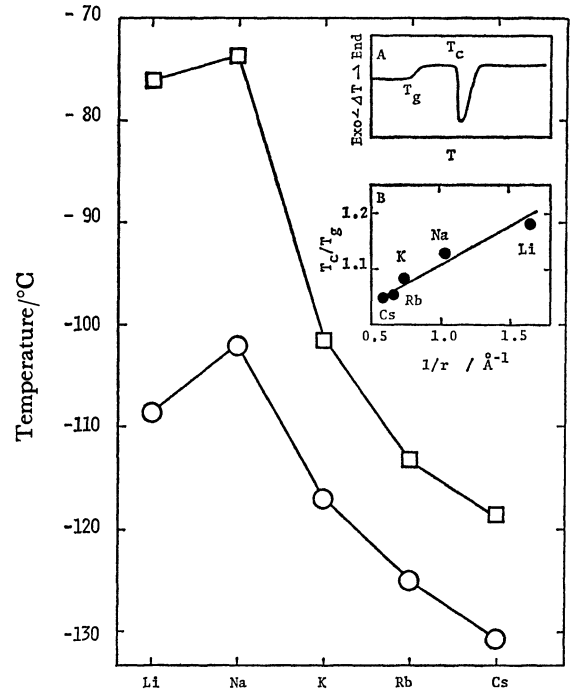

Fig. 1. Glass transition temperature (T_g) and crystallization temperature (T_c) of aqueous alkali acetate solution.
○: Glass transition temperature, □: crystallization temperature. The inset A shows a schematic DTA trace of a glassy sample. The inset B shows the correlation of T_c/T_g with $1/r$.

As acetate anions in these aqueous solutions are common, variation of T_g with a solute can be ascribed to cationic effect. A general trend is the decrease of T_g with the increase in cation radius and is in parallel with the observations for aqueous solutions of lanthanoid chlorides and perchlorates.[7] Kanno and Akama[7] have recently shown that T_g of aqueous rare earth chloride and perchlorate solutions is sensitive to an inner-sphere hydration number of cations. This clearly indicates that the inner-sphere hydration number of cations is one of the key parameters for the magnitude of T_g in aqueous solution. While a smaller ion is expected to have a small number of near neighbor water molecules on account of its small size, it has a greater polarizing power than a larger one, thus accomodating a larger total hydration sphere.[8] As the glass transition takes place at a temperature above which there are relatively rapid translational motions of ions (molecules),[9] a higher T_g is expected for a solution in which ions have a larger hydration sphere. Therefore, the trend of the T_g increase with decreasing ionic radius in these solutions is very reasonable.

The apparent deviation of T_g for the lithium acetate solution from the above-mentioned general trend deserves a special attention because the total hydration sphere of lithium ion should be the largest among all alkali ions. From X-ray diffraction studies of aqueous LiCl and NaCl solutions, the inner-sphere hydration numbers of Li^+ and Na^+ ions are determined to be four although there remains some uncertainty in the case of Na^+ ion.[10] Consequently it is difficult to ascribe the anomalous T_g behavior of the lithium acetate solution to the difference of the inner-sphere hydration number between Li^+ and Na^+.

A plausible explanation, though tentative at the moment, may be resorted to the fact that the electropositivity of lithium ion is rather weak among alkali ions.[11] The lithium ion-water interaction is claimed to be partially covalent.[12] This is simply exemplified by Samoilov's positive and negative hydration concept[13]: the hydration of K^+, Rb^+, and Cs^+ is classified as negative (structure breaker), Na^+ is almost on the borderline between positive and negative hydration and Li^+ is strongly positive (structure marker) in hydration. From T_g's of a vapor-deposited amorphous ice[14,15] and binary mixtures of water and organic compounds,[16] the glass transition temperature of a bulk glassy water is expected to be very near -139 °C. Accordingly, the structure making effect of Li^+ ions should act T_g of a lithium salt solution to become nearer to T_g of a bulk water.

In contrast to the above irregularity, the linear relation between T_c/T_g and $1/r$, shown in the inset of Fig. 1, is interesting. The transport properties of supercooled liquids are well described by the Vogel-Tammann type equation[17]

$$\rho = \rho_0 \exp\left\{\frac{B}{(T-T_0)}\right\}, \qquad (1)$$

where ρ is the transport property such as viscosity, electrical conductivity of supercooled liquid, T_0 is the temperature below which the liquid contains no free volume and is considered to be near T_g, and

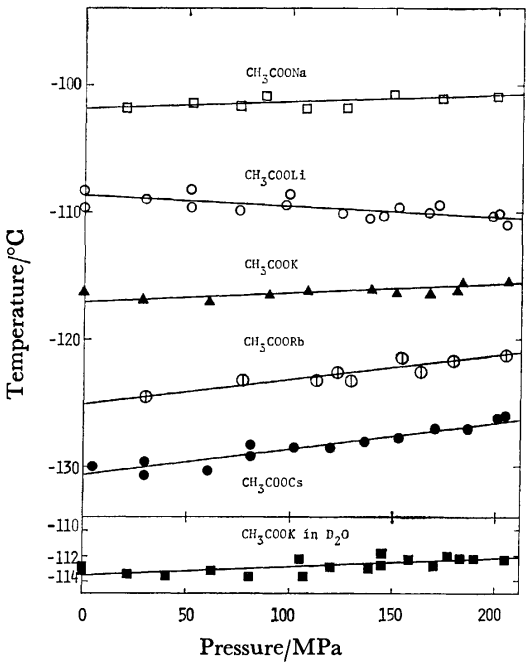

Fig. 2. Pressure dependence of T_g for aqueous alkali acetate solutions ($R=10$).
The (dT_g/dP) values are, CH_3COOLi: -0.85; CH_3COONa: 0.55; CH_3COOK: 0.70; CH_3COORb: 1.91; CH_3COOCs: 2.07; CH_3COOK in D_2O: 0.66 K/kbar (or $\times 10^{-2}$ K/MPa). The estimated error for each (dT_g/dP) is about ± 0.30 K/kbar.

ρ_0 and B are constants. Replacing T_0 with T_g and rearranging Eq. 1, we obtain

$$T_c - T_g \simeq B/\ln(\rho_c/\rho_0), \qquad (2)$$

where ρ_c is ρ at T_c. Therefore, knowing that T_c is one of the corresponding states, the linear relation between T_c/T_g and $1/r$ demonstrates that the transport properties such as viscosity and conductivity of supercooled aqueous alkali acetate solutions are well correlated with ionic radius of alkali ions.

The T_g data at high pressures are presented in Fig. 2. The results for the CH_3COOK solution in D_2O are shown in the bottom inset of Fig. 2. A remarkable point is that the (dT_g/dP) value increases in the order $Li^+<Na^+<K^+<Rb^+<Cs^+$. Another is the negative pressure dependence of T_g for the lithium acetate solution. The latter point is already pointed out by William and Angell.[18] They interpreted this negative pressure dependence as evidence for the failure of the free volume theory for transport properties of liquid. The (dT_g/dP) value obtained in this work is $-0.8_5\pm0.3$ K/kbar (1 kbar=100 MPa), in fair agreement with the value $(-0.6_4\pm0.3)$ by William and Angell.[18]

The (dT_g/dP) *vs.* $1/r$ plot is shown in Fig. 3. We again obtain an approximately linear relation between (dT_g/dP) and $1/r$. Although the glass transition is not an equilibrium phase transition and is still controversial whether it is a kind of second order transition or a kinetic phenomenon due to slow relaxation,[19-21] the applicability of the following thermodynamic relations is often noted at the glass transition[9,22]

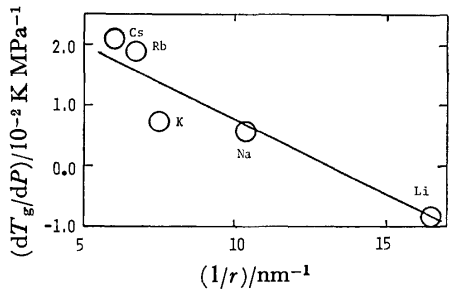

Fig. 3. Correlation of (dT_g/dP) with ionic radius of alkali ion.

$$\frac{dT_g}{dP} \simeq V_g T_g \frac{\Delta\alpha}{\Delta C_p}$$
$$\frac{dT_g}{dP} \simeq \frac{\Delta\kappa}{\Delta\alpha},$$

where $\Delta\alpha$, ΔC_p, and $\Delta\kappa$ are the changes in volume expansion coefficient, constant pressure heat capacity and isothermal compressibility at T_g, and V_g is molar volume of glass. Without experimental data for $\Delta\alpha$, ΔC_p, $\Delta\kappa$, and V_g, it is difficult to single out the factor responsible for the order of the (dT_g/dP) values in alkali acetate solutions. However, knowing that T_g is in the order $Na^+>Li^+>K^+>Rb^+>Cs^+$ and $\Delta\alpha$ can not be a major cause, we infer that V_g and $\Delta\kappa$(or one of them) should be the major factors for the magnitude order of (dT_g/dP) in alkali acetate solutions. This is partially supported by the fact that the partial molal volume of alkali metal ion in an aqueous solution increases in the order $Na^+<Li^+<K^+<Rb^+<Cs^+$ [5] (Note: $T_g(Li)V_{Li}<T_g(Na)V_{Na}$, V_a: partial molal volume for ion **a**) and that it is closely connected with ionic radius of ion. Clearly more data are needed before we can give a more clear-cut interpretation about the sequence of the (dT_g/dP) values.

Finally it is worth mentioning about the isotope effect on T_g at high pressures. The pressure dependence of T_g for the potassium acetate solution in D_2O ($R=10$) is shown in the inset of Fig. 2. The least-square best fit yields $0.6_6\pm0.3$ K/kbar for the slope (dT_g/dP) of the D_2O solution, which is almost identical to the value for the H_2O solution ($dT_g/dP=0.7_0\pm0.3$ K/kbar). This feature is very similar to the isotope effect of melting temperature of water along the melting curve. The difference of melting temperature between H_2O and D_2O is 3.82 °C at normal pressure and changes little with pressure up to 200 MPa.[23]
