Diisobutylaluminum 2,6-Di-*t*-butyl-4-methylphenoxide. Novel Stereoselective Reducing Agent for Prostaglandin Synthesis[1)]

Sadahiko IGUCHI, Hisao NAKAI, Masaki HAYASHI,* Hisashi YAMAMOTO,† and Keiji MARUOKA†

(Received January 12, 1981)

In an effort to explore the selective reducing agents suitable for prostaglandin synthesis, diisobutylaluminum 2,6-di-*t*-butyl-4-methylphenoxide (**1**) is found to be among the best. Reduction of the C-15 ketone with **1** in toluene at −78 °C produced the desired 15*S*-alcohol in 95% yield with 92% stereoselectivity. The present procedure is suitable for the synthesis of prostaglandin derivatives and related polyfunctional natural products as shown in the conversion of PGE_2 methyl ester to $PGF_{2\alpha}$ methyl ester in 95% yield and 100% selectivity.

One major problem encountered in the synthesis of prostaglandins[2)] is stereoselective construction of the functional groups present in these molecules. Three of the four chiral centers of prostaglandin E_2, those at position 8, 11, and 12, are mutually *trans* and are relatively easily established. Stereochemical control of the fourth center at C-15, however, placed in a conformationally mobile side chain, and at a considerable distance from influence of the ring, poses a much more difficult problem. For example, introduction of the lower side-chain and establishment of the *trans*-C-13-ene unit are readily accomplished by simple Wadsworth-Emmons' reaction. The successive zinc borohydride or Meerwein-Ponndorf-Verley reduction of the resulting α,β-unsaturated ketone produced a 1 : 1 mixture of 15*S* and 15*R* allylic alcohols.

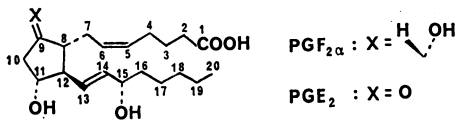

Fig. 1.

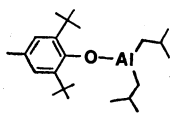
So far tremendous efforts have been devoted to solve this problem, and 15*S*/15*R* ratio of 92% was recorded in the reduction of the enone having a *p*-phenylphenylcarbamoyl protecting group at C-11 using a bulky trialkylhydroborate reagent at −130 °C.[3)] This result was explained on the basis that at low temperature the molecule is frozen into a conformation wherein the *p*-phenylphenylcarbamoyl group is lined up with the enone side-chain, effectively screening one side of the molecule. The hydride then attacks from the opposite side of the molecule, but can give rise to the desired 15*S* alcohol only if the enone is in a *S-cis* conformation.

Very recently an interesting asymmetric reduction of this enone with special binaphthol modified aluminum hydride reagent was reported.[4)] With this optically active reagent at −100 °C, 99.5% stereoisomeric purity was achieved.

Our interest has been focused on the stereoselective approach to the reduction of the C-9 and C-15 ketones in prostaglandins[5)] using the more practical reagent under mild reaction conditions. Diisobutylaluminum 2,6-di-*t*-butyl-4-methylphenoxide (**1**)[6)] has solved this problem practically, and has been found to be among the best selective reducing agent for the control of the stereochemistry at C-15.

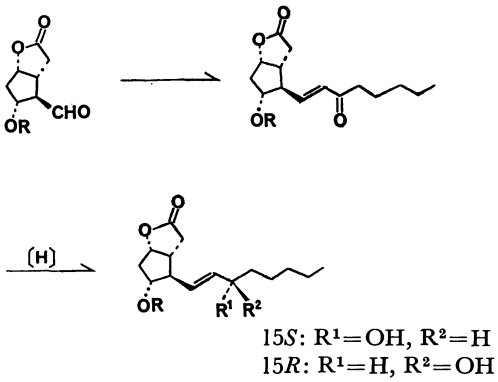


1

Fig. 2.

Results and Discussion

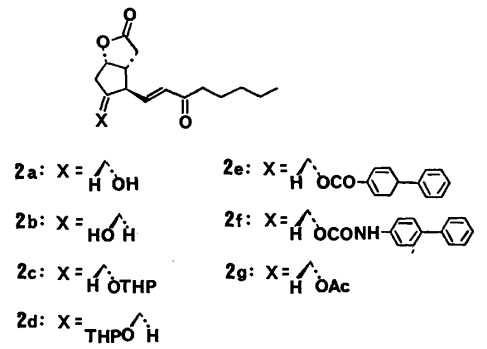
A solution of diisobutylaluminum 2,6-di-*t*-butyl-4-methylphenoxide (**1**) can be prepared from diisobutylaluminum hydride (DIBAH) in toluene and 2,6-di-*t*-butyl-4-methylphenol (molar ratio 1 : 1 to 1 : 2)[7)] in toluene at 0 °C for 1 h. Reduction of the C-11 hydroxy enone **2a** with the reagent **1** (10 equiv.) in toluene was



Scheme 1.

complete at −78 °C for 2 h, then at −40 °C for 1 h. The reaction mixture was then poured onto diluted hydrochloric acid and extracted with ethyl acetate. Short-path chromatographic separation to remove the recovered phenol gave allylic alcohol **3a** in 95% yield. The ratio of 15*S* to 15*R* isomers in several runs was 92/8 by high pressure liquid chromatographic analysis. When the aluminum reagent **1** was decreased to 3 equiv, the reaction proceeded slowly under the reaction conditions described above to give **3a** in 85% yield with the similar stereoselectivity (15*S*/15*R*=92/8).

The enone unit exists in both the *S-cis* and *S-trans* conformations, and the hydride attack can occur from either direction to give the 15*S* or 15*R* configuration. Therefore, reduction of the enone with sodium borohydride or zinc borohydride produced a 1 : 1 mixture



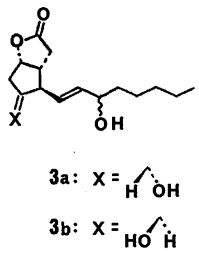


Fig. 3.

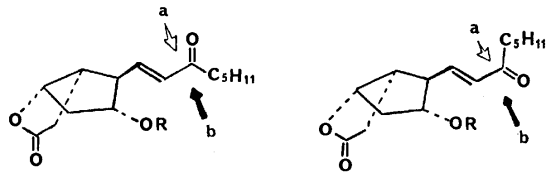

S-cis enone form *S-trans* enone form

Fig. 4.

of epimeric 15*S* and 15*R* alcohols. As previously reported, the examination of Corey-Pauling-Koltun models showed that van der Waals contact of the *p*-biphenylyl group in **2f** and the enone unit is indeed most favored when the enone is in the *S-cis* conformation. Clearly, the *p*-biphenylyl group must not only block approach from axis b but also stabilize the *S-cis* enone conformation in order to direct the formation of 15*S* alcohol. The present high stereoselectivity shown especially in **2a** can be attributed to the significant frontal steric bulk of the reagent **1** and at the same time to the substantial screening effect of *S-cis* enone chain to inhibit the α-approach of the reagent. Thus, the excess aluminum reagent, which is strongly coordinated at the C-11 hydroxyl function appears to play an important role as an exogeneous directing group to block the approach from axis b as well as to maintain *S-cis* enone conformation.

On the basis of this hypothesis, we examined the reduction of the THP ethers **2c** and **2d** using the reagent **1** under the standard conditions. It was thought that moderate selectivity for formation of 15*S* alcohol should be observed in these cases, since the aluminum reagent may be coordinated with ethers rather weakly.[6,8] The substrates and the observed 15*S*/15*R* ratios are shown in Table 1. In contrast to the high stereoselectivity in the

a) The ratio was determined by the isolation of each isomer using the usual silica-gel column chromatography. b) The ratio was determined by high pressure liquid chromatography. c) To a solution of the aluminum reagent in toluene cooled at −78 °C was added a solution of the enone in toluene and then the temperature was raised gradually to −20 °C over 2 h. d) The reaction conditions were −78 °C for 2 h, and then −40 °C for 1 h.

reduction of hydroxy ketones, the *p*-phenylbenzoyl ester **2e**[9] and the acetate **2g** afforded the corresponding alcohols without any stereoselectivity (15*S*/15*R*=1/1).

Although the reduction of the hydroxy enone **2a** with the lactone unit using the reagent **1** was complete within 2 h at −78 °C, the reduction of hydroxy enones

having α-chains proceeded considerably slowly at −78 °C to afford a trace of the product in 4 h. Therefore, the reaction mixture was warmed gradually to −20 °C over 2 h to produce 15α-allylic alcohols with moderate stereoselectivity as shown in Table 2. Presumably, in the reduction of the C-11 hydroxy enones with α-chains the *S-cis* enone conformation would be maintained at −78 °C by van der Waals contact of O-Al-OPh group and the enone moiety. However due to the steric hindrance of α-chains, the hydride attack along axis a would be unfavorable. At −20 °C, the stereoselectivity for formation of 15α-allylic alcohols is somewhat lost, since the *S-cis* enone conformation would not be stabilized at this temperature.

The stereoselectivity in the reduction of **7** was significantly influenced by the equivalent of the aluminum reagent **1**, as listed in Table 3. The best result was obtained using more than 10 equiv. of the aluminum reagent **1**. Surprisingly, with 2 equiv. of **1**, the 15*R* alcohol was produced predominantly. These results might be attributed to the relatively weak coordination of the reagent **1** to C-11 THP ether and then the direct attack of the coordinated aluminum reagent **1** to the substrate from the front side of the molecule (axis b). This is in sharp contrast with the reduction of **2a**, in which the stereoselectivity is essentially independent of the equivalent of **1** as described previously.

The substituent effect of the aryl group in the aluminum reagents upon the stereoselectivity of allylic alcohols was investigated using the enone **2c** and various diisobutylaluminum phenoxides in toluene. Under the similar reaction conditions, the use of 2,6-di-*t*-butylphenoxides gave higher stereoselectivity compared to other phenoxides in shorter reaction time (Table 5).

The significance of the frontal steric effect by the use of the aluminum reagent **1** was further demonstrated. Reduction of prostaglandin E with sodium borohydride or zinc borohydride proceeds in a nonstereoselective manner to give a mixture of C-9α and C-9β hydroxy compounds[10] with somewhat higher yield of the C-9β hydroxy isomer. Owing to the lack of the stereochemical control in this transformation, the design of chemical synthesis of these substances was extremely limited: the protected prostaglandin F_α derivative (*e.g.* **4**) may be prepared first, and oxidized to prostaglandin E derivative. Recently, some bulky trialkylhydroborate reagents[5] have been employed successfully for the reduction of prostaglandin E to prostaglandin F_α. Our aluminum reagent **1** can be also effective for the preparation of prostaglandin F_α with excellent stereoselectivity. Thus, reaction of prostaglandin E_2 methyl ester (**5a**) with **1** in toluene at −78 °C for 2 h produced prostaglandin

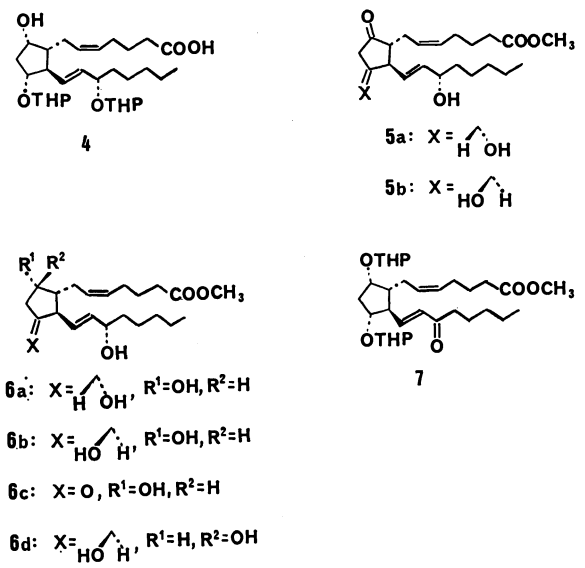

Fig. 5.

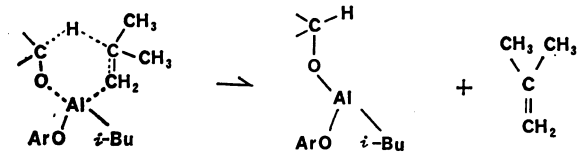
$F_{2\alpha}$ methyl ester (**6a**) cleanly in 95% yield with 100% selectivity. Furthermore, treatment of the C-11 epimeric prostaglandin E_2 methyl ester (**5b**) or prostaglandin D_2 methyl ester (**6c**) using **1** afforded the C-11 epimeric prostaglandin $F_{2\alpha}$ methyl ester (**6b**) with 76% or 98% selectivity.[11,12]

The generality of the new reagent **1** was examined using a simple hydroxy ketone and cyclic ketones with alkyl chains on the ring. Thus, treatment of 4-hydroxy-3-methyl-2-butanone with **1** at −78 °C gave a mixture of *erythro*- and *threo*-2-methyl-1,3-butanediols (ratio, 2 : 1) in 96% yield. Moreover, reduction of 4-*t*-butylcyclohexanone or 2-methylcyclohexanone with **1** at −78 °C furnished 4-*t*-butylcyclohexanol (84% yield; *cis*/*trans* ratio, 28 : 72) or 2-methylcyclohexanol (85% yield; *cis*/*trans* ratio, 75 : 25), respectively. The results of this investigation clearly reveal that unlike in the reduction of prostaglandin derivatives, the aluminum reagent **1** showed no remarkable stereoselectivity in the case of the simple unhindered hydroxy ketone. Therefore, the conformation of substrates also appears to be highly important to achieve the favorable frontal steric effect. It is also evident from the results that the reactivity of **1** is totally different from that of the usual bulky metal hydrides (*e.g.* Selectrides), which gave the less stable (*cis*) isomer predominantly in the reduction of cyclic ketones with an alkyl chain.[13]

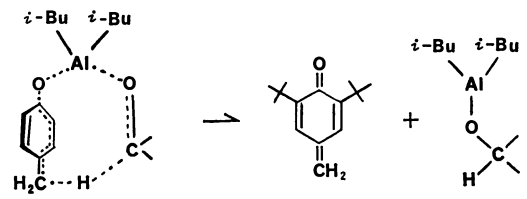
A plausible mechanism for the reduction of ketones with **1** involves an initial coordination of the trivalent aluminum reagent to the carbonyl group, followed by an intramolecular hydride transfer from the β-carbon of the isobutyl group as shown in Scheme 2. Such a mechanism seems to be analogous to those in reductions



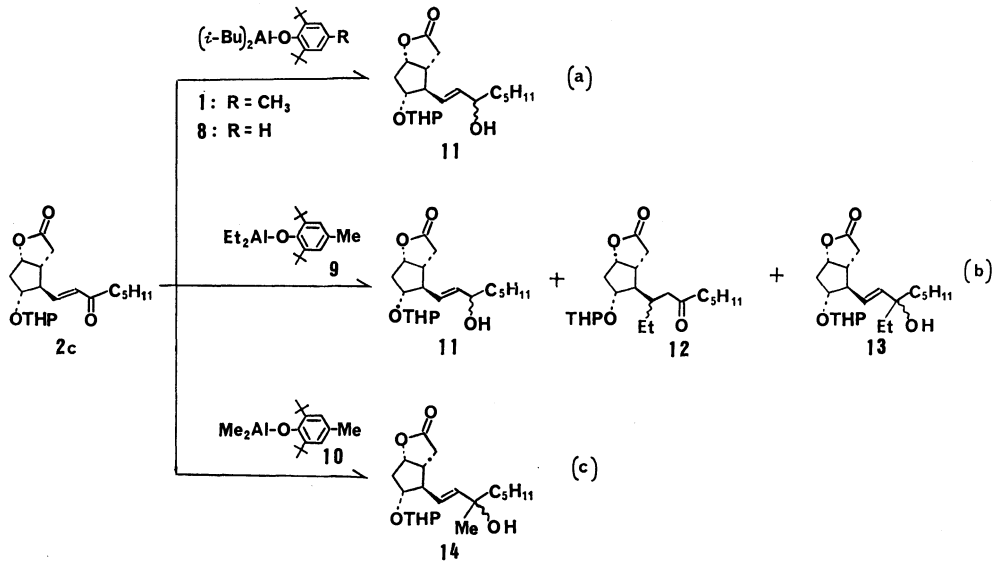
Scheme 2.

with Grignard reagents,[14,15] dialkylmagnesium compounds,[15] and triisobutylaluminum.[16] Therefore, in the reduction of α,β-unsaturated ketones only 1,2-reduction products can be obtained *via* the six-membered transition state. This is in sharp contrast with the reduction of enones using the bulky aluminum hydride reagents,[17] which afforded conjugate addition products predominantly.

Another mechanism may be considered for the



Scheme 3.



Scheme 4.

reduction with **1**, in which the actual hydride source of the reagent **1** is derived from the methyl group of phenoxide. This possibility was ruled out by the following experimental results. Scheme 4 represents the results obtained for the reduction of **2c** with several aluminum phenoxides. Since the reduction with diisobutylaluminum 2,6-di-*t*-butylphenoxide (**8**) afforded the same result as obtained with **1**, the methyl group of the reagent **1** is not necessary for reduction (Eq. a). The use of diethylaluminum 2,6-di-*t*-butyl-4-methylphenoxide (**9**) (Eq. b) produced three kinds of products: **11** (reduction product), **12** (Michael adduct to the enone **2c**), and **13** (ethylation product). In the reaction with dimethylaluminum 2,6-di-*t*-butyl-4-methylphenoxide (**10**), only the methylation product **14** was formed (Eq. c). It is evident from these results (Eqs. b and c) that at least a β-hydrogen of alkyl group of dialkylaluminum phenoxides is indispensable for reduction. Based on the above consideration we conclude that the mechanism shown in Scheme 2 is a most plausible one.

The reduction process which is described herein should be extremely useful for complex or polyfunctional molecules. The new aluminum reagent **1** for the reduction of ketone group of prostaglandins is characterized by the following features. (a) Yields are high and selectivities are unique. (b) No side reaction occurs. (c) Diisobutylaluminum hydride and 2,6-di-*t*-butyl-4-methylphenol are commercially available and inexpensive. (d) This reagent is stable and can be stocked. (e) There is no neccessity for protecting the C-11 hydroxy group with the special hindered function. (f) The process is operationally simple and can be done on a large scale.

Experimental

^{1}H NMR spectra were taken on a JEOL PMX-60 or a Varian XL-100 spectrometer in $CDCl_3$. Chemical shifts are reported as parts per million relative to TMS as the internal standard. The infrared spectra were recorded on a Hitachi EPI-G2 model. The mass spectra were obtained on a JMS-OlSG double focussing mass spectrometer. Molecular ion peaks of some compounds were too weak to be detected because of their low volatility, and in these cases the molecular weights were determined by their dehydration peaks.

For TLC analysis throughout this work, Merck TLC plates (Kieselgel 60 F_{254}, pre-coated, layer thickness 0.2 mm) were used. Column chromatography was carried out on silica gel (Merck, particle size 0.063—0.20 mm) or using Lobar Prepacked Column (Merck, silica gel). The isomeric ratio of the products was determined by high pressure liquid chromatography using a JASCO TRI ROTAR instrument equipped with a Waters μ-Porasil and a refractive index detector or a UV index detector.

Unless otherwise specified, all reactions were carried out under an atmosphere of argon.

*Preparation of Diisobutylaluminum 2,6-Di-*t*-butyl-4-methylphenoxide (**1**).* Diisobutylaluminum hydride in toluene (1.76 M (1 M=1 mol dm^{-3}), 21.7 ml, 38.2 mmol) was added slowly at 4 °C over 20 min to a solution of 2,6-di-*t*-butyl-4-methylphenol (16.81 g, 76.4 mmol) in toluene (180 ml) with the vigorous hydrogen gas evolution. During this operation, *ca.* 1 equiv. of hydrogen gas was collected. Strring was continued at 4 °C for 1 h. The reagent, thus prepared, was directly used for the following reduction, and is stable enough to be stored under argon at 0 °C for several weeks.

Reduction of Carbonyl Compounds. Method A: A solution of a carbonyl compound in toluene was added slowly below −60 °C to a solution of the aluminum reagent **1** (10 equiv.) in toluene. The mixture turned into orange. Further stirring was continued at −78 °C for 2 h, then at −40 °C for 1 h. The mixture was poured onto cold 1 M hydrochloric acid (*ca.* total volume of the reaction mixture), and extracted with ethyl acetate. The combined extracts were washed with aq sodium hydrogencarbonate, followed by brine, dried over magnesium sulfate, and concentrated by the evaporator. The residue was applied to column chromatography on silica gel with dichloromethane to separate 2,6-di-*t*-butyl-4-methylphenol, then with ethyl acetate to elute a mixture of 15*S* and 15*R* alcohols. The ratio of 15*S* and 15*R* isomers was determined Lobar Pre-packed Column (Merck) or high pressure liquid chromatographic analysis.

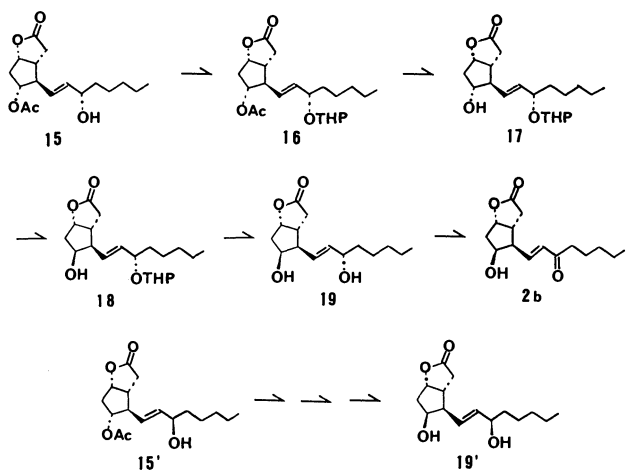
Method B: The reaction was carried out starting from −78 °C according to the method A. After addition of a carbonyl compound, the cooling bath was removed. The reaction mixture was allowed to warm to −10——20 °C over 2 h, stirred at this temperature for 30 min, and worked up as described above.

*Reduction of (1*S*, 5*R*, 6*R*, 7*R*)-7-Hydroxy-6-[(*E*)-3-oxo-1-octenyl]-2-oxabicyclo[3.3.0]octan-3-one (**2a**).* Reduction of **2a** (1.016 g, 3.82 mmol) with 2,6-di-*t*-butyl-4-methylphenol (16.81 g, 76.4 mmol) and DIBAH (25 g/100 ml in toluene; 21.7 ml, 38.2 mmol) was carried out using the method A to give a mixture of 15*S* and 15*R* isomers (0.964 g, 95% yield): TLC, R_f 0.229 for 15*S* isomer, 0.289 for 15*R* isomer (AcOEt–benzene, 2 : 1, 2 developments).[18] The ratio of 15*S* and 15*R* isomers was 92 : 8 by HPLC analysis (μ-Porasil, refractive index, AcOEt). Lobar Pre-packed Column chromatography on silica gel (Merck, size C, AcOEt–benzene, 4 : 1) separated the 15*S* isomer (833 mg) and the 15*R* isomer (72.3 mg): 15*S*: IR (film) 3400, 2950, 2850, 1770, 980 cm^{-1}; ^{1}H NMR δ 5.22—5.81 (2H, m, olefinic H), 4.55—5.02 (1H, m, C_1–H), 3.52—4.36 (2H, m, C<u>H</u>–OH), 0.87 (3H, t, CH_3); MS *m/e* 268 (M^+), 250 (M^+-H_2O), 232 (M^+-2H_2O); high resolution MS *m/e* 250.159 (dehydration peak, calcd for $C_{15}H_{22}O_3$, 250.157). The IR, ^{1}H NMR and MS spectra of the 15*R* isomer were identical with those of the 15*S* isomer: 15*R*: high resolution MS *m/e* 250.159 (dehydration peak, calcd for $C_{15}H_{22}O_3$, 250.157).

The reaction using the method B gave the similar results.

*Reduction of (1*S*, 5*R*, 6*R*, 7*S*)-7-Hydroxy-6-[(*E*)-3-oxo-1-octenyl]-2-oxabicyclo[3.3.0]octan-3-one (**2b**).* Reaction of the enone **2b** (50 mg, 0.188 mmol) and the aluminum reagent **1** in toluene (9 ml, 1.88 mmol) was carried out according to the method A to afford a mixture of 15*S* and 15*R* isomers (47 mg, 94% yield) after short column chromatography: IR (film) 3400, 2950, 2850, 1770, 980 cm^{-1}; ^{1}H NMR δ 5.66—5.89 (2H, m, olefinic H), 4.90—5.23 (1H, m, C_1–H), 4.20—4.42 (1H, m, $C_{3'}$–H), 3.91—4.20 (1H, m, C_7–H), 0.89 (3H, t, CH_3); high resolution MS *m/e* 268.165 (calcd for $C_{15}H_{24}O_4$, 268.168). HPLC analysis showed the ratio of 15*S* and 15*R* isomers to be 85 : 15 : TLC, R_f, 0.420 for the 15*S* isomer, 0.374 for the 15*R* isomer (ether–EtOH, 100 : 1, 3 developments). These R_f values were identical with those by the $NaBH_4$ reduction of **2b**. The configuration of two isomers was determined by comparison with the authentic samples, which were prepared as shown in Scheme A.

*Synthesis of (1*S*, 5*R*, 6*R*, 7*S*)-7-Hydroxy-6-[(1*E*, 3*S*)-3-hydroxy-1-ocetenyl]-2-oxabicyclo[3.3.0]octan-3-one (**19**).* A mix-



Scheme A.

ture of **15** (10 g, 32.3 mmol),[18] 2,3-dihydropyran (5.9 ml 64.5 mmol), and *p*-toluenesulfonic acid (60 mg) in dichloromethane (100 ml) was stirred in a water bath for 20 min. The reaction was terminated by the addition of pyridine (20 drops). Dilution with ethyl acetate (500 ml), washing with aq sodium hydrogencarbonate, followed by brine, being dried over magnesium sulfate, and concentration of the extracts left the residue, which was dissolved in methanol (120 ml) and stirred at 25 °C for 15 min after addition of anhydrous potassium carbonate (5.348 g). The solution was then acidified to pH 4 by the addition of acetic acid, diluted with ethyl acetate (500 ml), and washed with aq sodium hydrogencarbonate, then brine. Being dried over magnesium sulfate, and purification of the concentrated product by column chromatography (silica gel, 360 g; AcOEt–benzene, 1 : 1) gave **17** (10.846 g, 96% yield): TLC, R_f 0.273 (benzene–AcOEt, 2 : 1, 2 developments); IR (film) 3450, 2950, 2850, 1780, 980 cm^{-1}; ^1H NMR δ 5.25—5.65 (2H, m, olefinic H), 4.70—5.15 (1H, m, C_1–H), 4.61 (1H, br s, OCHO), 3.00—4.20 (4H, m, C_7, $C_{3'}$–H, OCH_2), 0.90 (3H, t, CH_3); MS *m/e* 352 (M^+), 334 (M^+-H_2O), 268 (M^+—DHP), 243 (M^+—OTHP—H_2O), 250 (M^+—HOTHP). The alcohol **17** (5.00 g, 14.2 mmol) in dry THF (70 ml) was treated with triphenylphosphine (7.443 g, 28.4 mmol) and benzoic acid (3.465 g, 28.4 mmol). Diethyl azodiformate (4.941 g, 28.4 mmol) in THF (10 ml) was then added slowly. The whole mixture was stirred at 25 °C for 30 min, and concentrated under reduced pressure. The residue, thus obtained, was dissolved in methanol (100 ml), treated with anhydrous potassium carbonate (3.919 g, 14.2 mmol) at 25 °C and stirred at 40—50 °C for 30 min. The mixture was cooled to 25 °C, acidified to pH 4 with acetic acid, diluted with ethyl acetate (500 ml), washed with aq sodium hydrogencarbonate followed by brine, dried over magnesium sulfate, and concentrated. Purification of the residue by column chromatography (silica gel, 150 g; cyclohexane–AcOEt, 2 : 1, then 1 : 1) gave **18** (4.689 g, 97% yield): TLC, R_f 0.357 (benzene–AcOEt, 2 : 1, 2 developments). The IR, ^1H NMR, and MS spectra of **18** were identical with those of **17**. The alcohol **18** (1.026 g) was dissolved in 65% acetic acid (30 ml) and THF (3 ml). The resulting mixture was stirred at 50 °C for 1 h, poured onto iced water (150 ml), and extracted with ethyl acetate. Concentration of the extracts left the residue, which was purified by column chromatography (silica gel, 30 g; AcOEt–cyclohexane, 2 : 1) to give **19** (664 mg, 85% yield): IR (film) 3600, 3450, 1760, 975 cm^{-1}; ^1H NMR δ 5.40—5.97 (2H, m, olefinic H), 4.98—5.25 (1H, m, C_1–H), 3.99—4.22 (2H, m, C_7, $C_{3'}$–H), 0.90 (3H, t, CH_3); MS *m/e* 268 (M^+), 250 (M^+-H_2O), 232 (M^+-2H_2O), high resolution MS *m/e* 268.165 (calcd for $C_{15}H_{24}O_4$, 268.167).

Synthesis of (1S, 5R, 6R, 7S)-7-Hydroxy-6-[(E)-3-oxo-1-octenyl]-2-oxabicyclo[3.3.0]octan-3-one (19'). The title compound (275 mg) was prepared starting from **15'** (633 mg)[17] according to the procedure described above. The IR, ^1H NMR, and MS spectra of **19'** were similar to those of **19**: high resolution MS *m/e* 268.165 (calcd for $C_{15}H_{24}O_4$, 268.167).

Reduction of (1S, 5R, 6R, 7R)-7-(Tetrahydro-2-pyranyloxy)-6-[(E)-3-oxo-1-octenyl]-2-oxabicyclo[3.3.0]octan-3-one (2c). Reduction of the enone **2c** (500 mg, 1.43 mmol) with the aluminum reagent **1** (14.3 mmol) in toluene (48 ml) using the method B gave a mixture of 15*S* and 15*R* isomers (490 mg, 98% yield): TLC, R_f 0.418 for the major product, 0.345 for the minor product (ether, 2 developments). The R_f values of these isomers were identical with those of the reduction product of **2c** with sodium borohydride. Column chromatography (silica gel, 40 g; ether–hexane–AcOEt, 2 : 1 : 1) separated the more polar isomer (92 mg), the less polar isomer (97 mg), and these mixture (199 mg). The two isomers gave the similar spectral data: IR (film) 3450, 1770, 975 cm^{-1}; ^1H NMR δ 5.10—5.17 (2H, m, olefinic H), 4.77—5.11 (1H, m, C_1–H), 4.64 (1H, br s, OCHO), 3.64—4.25 (4H, m, C_7, $C_{3'}$–H, OCH_2), 0.91 (3H, t, CH_3); MS *m/e* 352 (M^+), 334 (M^+-H_2O), 268 (M^+—DHP); high resolution MS *m/e* 334.215 (dehydration peak, calcd for $C_{20}H_{30}O_4$, 334.214). The two isomers were separately converted by the hydrolysis of the THP group (aq 65% AcOH, 40—45 °C, 2 h) into the corresponding diols, which were compared with the authentic samples[18] by TLC. The less polar isomer (major component) was the 15*S* alcohol. The ratio of 15*S* to 15*R* was 66 : 34 by HPLC analysis (μ-Porasil, refractive index, AcOEt–CH_2Cl_2, 1 : 1).

Reduction of (1S, 5R, 6R, 7S)-7-(Tetrahydro-2-pyranyloxy)-6-[(E)-3-oxo-1-octenyl]-2-oxabicyclo[3.3.0]octan-3-one (2d). Reduction of **2d** (101 mg, 0.289 mmol) with the aluminum reagent **1** (2.89 mmol) in toluene (20 ml) by the method B furnished a mixture of 15*S* and 15*R* isomers (90 mg, 90% yield). Hydrolysis of the THP group in these isomers gave the diols, which was characterized as described in the reduction of **2b**. IR, ^1H NMR, and MS spectra of the diols were identical with those of the reduction products of **2b**. HPLC analysis showed the ratio of 15*S* to 15*R* isomers to be 79 : 21.

Reduction of (1S, 5R, 6R, 7R)-7-(p-Phenylbenzoyloxy)-6-[(E)-3-oxo-1-octenyl]-2-oxabicyclo[3.3.0]octan-3-one (2e). Reduction of **2e** (89 mg, 0.201 mmol) with the aluminum reagent **1** (2.01 mmol) in toluene (15 ml) using the method B afforded a mixture of 15*S* and 15*R* isomers (82 mg, 93% yield): TLC, R_f 0.546, 0.452 (2-butanone–benzene, 15 : 85). Column chromatography of the mixture (42 mg) on silica gel (2-butanone–benzene, 10 : 90) separated the less polar isomer (13 mg), the more polar isomer (11 mg), and a mixture of these isomers (17 mg). The two isomers gave the similar ^1H NMR spectra: δ 7.23—8.09 (9H, m, Phenyl H), 5.23—5.42 (1H, m, C_7–H), 4.89—5.10 (1H, m, C_1–H), 5.35—5.65 (2H, m, olefinic H), 3.80—4.20 (1H, m, $C_{3'}$–H), 0.90 (3H, t, CH_3). The products by hydrolysis of the *p*-phenylbenzoyl group (1 equiv. of K_2CO_3 in MeOH, 25 °C for 2 h) was identical with the reduction products of **2a** by TLC. HPLC analysis (μ-Porasil, UV index 254 nm, hexane–AcOEt, 1 : 1) indicated the ratio of 15*S*/15*R* isomers to be 1 : 1.

Reduction of (1S, 5R, 6R, 7R)-7-Acetoxy-6-[(E)-3-oxo-1-octenyl]-2-oxabicyclo[3.3.0]octan-3-one (2g). Reduction of **2g** (195 mg, 0.635 mmol) with the aluminum reagent **1** (6.35 mmol) in toluene (30 ml) according to the method A produced

a mixture of 15*S* and 15*R* isomers (177 mg, 91% yield): TLC, R_f 0.523, 0.424 (ether, 2 developments). Comparison of the R_f values with those of the authentic sample[18] showed the less polar isomer to be the 15*S* alcohol. The mixture (100 mg), obtained above, was applied to column chromatography (silica gel, 20 g; ether–AcOEt–cyclohexane, 2 : 1 : 1) to furnish the less polar isomer (33 mg), the more polar isomer (23 mg), and their mixture (35 mg). Both isomers had the similar spectroscopic properties (IR, ^{1}H NMR, and MS), which were identical with those of the authentic sample: IR (film) 3450, 2950, 2850, 1780, 1760, 1250, 975 cm^{-1}; ^{1}H NMR δ 5.55—5.77 (2H, m, olefinic H), 4.86—5.23 (2H, m, C_{11}, C_7–H), 3.90—4.21 (1H, m, $C_{3'}$–H), 2.01 (3H, s, $CH_3C{=}O$), 0.90 (3H, t, CH_3); MS *m/e* 310 (M^+), 292 (M^+-H_2O), 250 (M^+-CH_3COOH); high resolution MS *m/e* 310.178 for the 15*S* isomer, 310.179 for the 15*R* isomer (calcd for $C_{17}H_{26}O_5$, 310.178). The ratio of 15*S*/15*R* isomers was 1 : 1 by HPLC analysis (μ-Porasil, refractive index, hexane–AcOEt, 1 : 1).

In the reduction products of enones with α-side chains using the aluminum reagent **1**, every less polar isomer correspond to the 15*R* alcohol. This was based on the transformation of both isomers into the end products, followed by the results of their biological activity. The 15*R* isomer had little activity.

Reduction of (5Z, 13E, 17R)-9α-Acetoxy-11α-(tetrahydro-2-pyranyloxy)-15-oxo-17-methyl-20-chloroprosta-5,13-dienoic Acid Methyl Ester. Reduction of the enone (1.8 g, 3.33 mmol) with the aluminum reagent **1** (33.3 mmol) in toluene (65 ml) using the method B produced a mixture of 15*R* and 15*S* isomers (1.71 g, 95% yield): TLC, R_f 0.42 for the 15*R* isomer, 0.31 for the 15*S* isomer (CH_2Cl_2–AcOEt, 4 : 1). Column chromatography (silica gel, 200 g; CH_2Cl_2–AcOEt, 5 : 1) separated the 15*R* isomer (295 mg) and the 15*S* isomer (1.346 g). Both isomers had the similar spectroscopic properties: IR (film) 3450, 2950, 2850, 1740, 980 cm^{-1}; ^{1}H NMR δ 4.80—5.93 (5H, m, olefinic H, and C_9–H), 4.52—4.55 (1H, m, OCHO), 3.63 (3H, s, $COOCH_3$), 3.50 (2H, t, CH_2Cl), 2.06 (3H, s, CH_3COO), 0.95 (3H, d, C_{17}–CH_3); MS *m/e* 524 (M^+-H_2O), 380 ($524-OCH_3-DHP$); high resolution MS *m/e* 524.290 for the 15*R* isomer, 524.291 for the 15*S* isomer (dehydration peak, calcd for $C_{29}H_{45}O_6Cl$, 524.290).

Reduction of (13E)-9α-Acetoxy-11α-hydroxy-15-oxoprost-13-enoic Acid Methyl Ester. Reduction of the enone (410 mg, 1.001 mmol) with the aluminum reagent **1** (10.01 mmol) in toluene (40 ml) using the method B afforded a mixture of 15*S* and 15*R* isomers (389 mg, 95% yield): TLC, R_f 0.46 for the 15*R* isomer, 0.26 for the 15*S* isomer (benzene–AcOEt, 1 : 2). Separation of the mixture (389 mg) by column chromatography (silica gel, 40 g; benzene–AcOEt, 1 : 1) gave the 15*R* isomer (299 mg) and the 15*S* isomer (65.8 mg). IR, ^{1}H NMR, and MS spectra of both isomers were identical: IR (film) 3450, 2950, 2850, 1740, 1250, 980 cm^{-1}; ^{1}H NMR δ 5.30—5.76 (2H, m, olefinic H), 4.92—5.30 (1H, m, C_9–H), 3.11 — 4.34(5H, m, C_{11}, C_{15}–H and $COOCH_3$), 2.31—2.82 [2H, br s, OH (disappearance in D_2O)], 2.05 (3H, s, CH_3COO), 0.90 (3H, t, C_{20}–H); MS *m/e* 394 (M^+-H_2O), 381 (M^+-OCH_3), 376 (M^+-2H_2O), 363 ($M^+-H_2O-OCH_3$), 334 (M^+-H_2O-AcOH); high resolution MS *m/e* 394.272 for both isomers (dehydration peak, calcd for $C_{23}H_{38}O_5$, 394.272). The 15*S* isomer was converted by treatment with potassium carbonate (1 equiv.) in MeOH at 45 °C for 2 h into the methyl ester of prostaglandin $F_{1\alpha}$ ($PGF_{1\alpha}$). The R_f value of this ester was in agreement with that of the authentic sample.

Reduction of (5Z, 13E)-9α-Acetoxy-11α-hydroxy-15-oxo-16-(3-chlorophenoxy)-17,18,19,20-tetranorprosta-5,13-dienoic Acid Methyl Ester. Reduction of the enone (388 mg, 0.812 mmol) with the aluminum reagent **1** (8.12 mmol) in toluene (20 ml) by the method B furnished a mixture of 15*R* and 15*S* isomers (329 mg): TLC, R_f 0.44 for the 15*R* isomer, 0.22 for the 15*S* isomer (benzene–AcOEt, 1 : 2). HPLC analysis (μ-Porasil, UV index 273 nm, CH_2Cl_2–AcOEt, 20 : 1) showed the ratio of 15*S*/15*R* to be 86 : 14. The mixture of 15*R* and 15*S* isomers: IR (film) 3450, 2950, 2850, 1740, 1600, 1450, 980, 780 cm^{-1}; ^{1}H NMR δ 6.70—7.22 (4H, m, phenyl H), 5.22—5.76 (4H, m, olefinic H), 5.05—5.23 (1H, m, C_9–H), 4.00—4.31 (1H, m, C_{15}–H), 3.55—4.00 (6H, m, C_{11}–H, CH_2OAr, and $COOCH_3$), 2.05 (3H, s, CH_3COO); MS *m/e* 462 (M^+-H_2O), 449 (M^+-OMe), 444 (M^+-2H_2O), 402 (M^+-H_2O-AcOH).

Reduction of (13E)-2-Phenylseleno-9α-acetoxy-11α-(tetrahydro-2-pyranyloxy)-15-oxo-16,16-dimethylprost-13-enoic Acid Methyl Ester. Reduction of the enone (448 mg, 0.644 mmol) with the aluminum reagent **1** (6.44 mmol) in toluene (20 ml) according to the method B afforded a mixture of 15*S* and 15*R* isomers (417 mg, 93% yield): TLC, homogeneous (CH_2Cl_2–AcOEt, 4 : 1). The ratio of 15*S*/15*R* was 87 : 13 by HPLC analysis (μ-Porasil, UV index 273 nm, CH_2Cl_2–AcOEt, 3 : 1). The mixture of 15*S* and 15*R* isomers: IR (film) 3400, 2950, 2850, 1740, 1580, 1440, 975, 790, 760 cm^{-1}; ^{1}H NMR δ 7.20—7.70 (5H, m, phenyl H), 5.50—5.72 (2H, m, olefinic H), 5.00—5.20 (1H, m, C_9–H), 4.50—4.70 (1H, m, OCHO), 3.62 (3H, s, $COOCH_3$), 2.05 (3H, s, CH_3COO), 0.80, 0.90, 0.91 (9H, s, s, t, CH_3); MS *m/e* 661 (M^+-H_2O), 648 (M^+-OMe), 619 (M^+-AcOH), 577 (M^+-H_2O-DHP).

Reduction of (5Z, 13E)-9α,11α-Bis(tetrahydro-2-pyranyloxy)-15-oxoprosta-5,13-dienoic Acid Methyl Ester (7). Reduction of the enone **7** (145 mg, 0.272 mmol) with aluminum reagent **1** (2.71 mmol) in toluene (5 ml) using the method B produced a mixture of 15*S* and 15*R* isomers (129 mg, 89% yield): TLC, R_f, 0.476 for the 15*R* isomer, 0.285 for the 15*S* isomer (benzene–AcOEt, 2 : 1). HPLC analysis (μ-Porasil, refractive index, CH_2Cl_2–AcOEt, 1 : 1) indicated the ratio of 15*R*/15*S* to be 74 : 26. Column chromatography (silica gel, 9 g; CH_2Cl_2–AcOEt, 7 : 1) separated the 15*S* isomer (96 mg) and 15*R* isomer (32 mg), which gave the similar spectral data: IR (film) 3450, 2950, 2850, 1740, 970 cm^{-1}; ^{1}H NMR δ 5.23—5.75 (4H, m, olefinic H), 4.50—4.83 (2H, m, OCHO), 3.30—4.20 (10H, m, s,$COOCH_3$, C_9 C_{11}, C_{15}–H, OCH_2), 0.90 (3H, t, CH_3); MS *m/e* 451 (M^+-THP), 434 ($M^+-HOTHP$), 332 ($M^+-2HOTHP$). Hydrolysis of the THP groups (65% aq AcOH, 40—45 °C for 2 h) in each isomer gave the corresponding triols. Their R_f values ($CHCl_3$–THF–AcOH, 10 : 2 : 1 or AcOEt) were identical with those of authentic samples ($PGF_{2\alpha}$ and its epimer).

Similarly, the enone **7** was reduced with 2, 5, and 20 equiv. of **1**, and their results are shown in Table 3.

Reduction of 2c with Various Diisobutylaluminum Phenoxides. The enone **2c** was reduced with various diisobutylaluminum phenoxides, which were prepared under the similar conditions as described for the synthesis of **1**. The reduction conditions are indicated in Table 5. The ratio of 15*S*/15*R* was determined by HPLC analysis (μ-Porasil, refractive index, CH_2Cl_2–AcOEt, 1 : 1).

Reduction of 2c with Diethylaluminum 2,6-Di-t-butyl-4-methylphenoxide (9). Triethylaluminum (2.71 mmol) in hexane was added dropwise at 0 °C to 2,6-di-*t*-butyl-4-methylphenol (715 mg, 3.25 mmol) in toluene (10 ml) under nitrogen. Stirring was continued at 0 °C for 30 min, then at 25 °C for 30 min. The solution was cooled to −78 °C, and the enone **2c** (210 mg, 0.600 mmol) in toluene (2 ml) was added dropwise at this temperature. Further stirring was carried out at −70 °C for 1 h, from −70 °C to 0 °C over 5 h, and at 25 °C for 1 h. The reaction was quenched by the addition of saturated

sodium hydrogentartarate. The crude product was extracted with ether, dried over $MgSO_4$, concentrated, and purified by column chromatography (silica gel, 5 g; CH_2Cl_2–cyclohexane, 1 : 1, then only AcOEt) to give a mixture of **11**, **12**, and **13**: TLC, R_f 0.727 for **2c**, 0.454 for **11**, and **13**, 0.808 for **12** (ether, 2 developments). Further purification by column chromatography (silica gel, 10 g; ether) afforded a mixture of **11** and **13** (105 mg), and **12** (32 mg): the mixture of **11** and **13**: IR (film) 3450, 1780, 1180, 980 cm^{-1}; ^1H NMR δ 5.30—5.55 (2H, m, olefinic H), 4.81—5.03 (1H, m, C_9–H), 4.61—4.70 (1H, m, OCHO), 3.02—4.05 (4H, m, C_{11},C_{15}–H, OCH_2), 0.90 (3H, t, CH_3); MS *m/e* 352 (M^+ of **11** $-H_2O$), 278 (M^+ of **13**—HOTHP), 250 (352—HOTHP): **12**: IR (film) 1780, 1720, 980 cm^{-1}; ^1H NMR δ 4.40—5.00 (2H,m, C_9–H, OCHO), 3.10—4.20 (3H, m, C_{11}–H, OCH_2), 0.90 (6H, t, CH_3); MS *m/e* 380 (M^+), 295 (M^+—THP).

Reduction of **2c** *with Dimethylaluminum 2,6-Di-t-butyl-4-methylphenoxide (***10***).* Trimethylaluminum (2.71 mmol) in hexane was added dropwise at 0 °C to a solution of 2,6-di-*t*-butyl-4-methylphenol (715 mg, 3.25 mmol) in toluene (10 ml) under nitrogen. Stirring was continued at 0 °C for 30 min, then at 25 °C for 30 min. The solution was cooled to −78 °C, and the enone **2c** (210 mg, 0.600 mmol) in toluene (2 ml) was added slowly over 5 min at this temperature. The whole mixture was stirred at −70 °C for 1 h, and warmed up to −5 °C over 2 h. The cooling bath was then removed and further stirring was carried out overnight. The reaction was terminated with saturated sodium hydrogentartarate. Extraction with ether, being dried over $MgSO_4$, concentration, and purification of the crude product by column chromatography (silica gel, 5 g; CH_2Cl_2–cyclohexane, 1 : 1, then only AcOEt) afforded the methylation product **14** with the recovery of **2c**: TLC, R_f 0.727 for **2c**, 0.461 for **14** (ether, 2 developments). Repurification by column chromatography (silica gel, 6 g; ether) furnished **2c** (50 mg) and **14** (100 mg): **14**: IR (film) 3450, 1770, 980 cm^{-1}; ^1H NMR δ 5.40—5.56 (2H, m, olefinic H), 4.75—5.00 (1H, m, C_9–H), 4.55—4.73 (1H, m, OCHO), 1.19 (3H, s, CH_3), 0.89 (3H, t, CH_3); MS *m/e* 366 (M^+), 348 (M^+ $-H_2O$), 264 (M^+ —HOTHP); high resolution MS *m/e* 366.242 (calcd for $C_{21}H_{34}O_5$, 366.241).

*Reduction of Prostaglandin E_2 Methyl Ester (***5a***).* A solution of the ester **5a** (104 mg, 0.284 mmol) in toluene (1 ml) was added slowly over 5 min to a solution of **1** (2.84 mmol) in toluene (15 ml) at −78 °C. The resulting mixture was stirred at −78 °C for 2 h, warmed up to −20 °C over 1 h, and again stirred at −20 °C for 30 min. The reaction mixture was poured onto cold 1 M hydrochloric acid (20 ml) and ethyl acetate (20 ml). The aqueous layer was extracted with ethyl acetate twice. The combined organic layers were washed successively with 1 M hydrochloric acid once, aq sodium hydrogencarbonate twice, then brine once, and dried over $MgSO_4$. Evaporation of the solvent, followed by purification of the residue by column chromatography (silica gel, 10 g; CH_2Cl_2, then AcOEt) gave $PGF_{2\alpha}$ methyl ester (**6a**) (99 mg, 95% yield): TLC, R_f 0.562 (homogeneous, AcOEt, 2 developments), which was in agreement with that of the authentic sample; boric acid impregnated TLC,[19] R_f 0.785 (homogeneous, AcOEt, 2 developments); IR (film) 3400, 2950, 2850, 1720, 1250, 975 cm^{-1}; ^1H NMR δ 5.22—5.65 (4H, m, olefinic H), 3.70—4.30 (3H, m, C_9, C_{11}, C_{15}–H), 3.66 (3H, s, $COOCH_3$), 0.90 (3H, t, CH_3); MS *m/e* 350 (M^+ $-H_2O$), 332 (M^+-2H_2O), 319 (M^+-H_2O-OMe), 314 (M^+-2H_2O), 301 (M^+ $-2H_2O-OMe$); high resolution MS *m/e* 350.244 (dehydration peak, calcd for $C_{21}H_{34}O_4$, 350.246). $PGF_{2\beta}$ methyl ester [TLC, R_f 0.424; boric acid impregnated TLC, R_f 0.462 (AcOEt, 2 developments)] was not detected in the reaction mixture.

*Synthesis of 11-Epiprostaglandin E_2 Methyl Ester (***5b***).* The ester **5b** was prepared starting from the diol **19** using the Corey method:[17] IR (film) 3400, 2950, 2850, 1740, 980 cm^{-1}; ^1H NMR δ 5.59—5.82 (2H, m, *trans* olefinic H), 5.26—5.45 (2H, m, *cis* olefinic H), 4.25—4.45 (1H, m, C_{11}–H), 3.92—4.15 (1H, m, C_{15}–H), 3.65 (3H, s, $COOCH_3$), 0.90 (3H, t, CH_3); MS *m/e* 348 (M^+-H_2O), 335 (M^+—OMe), 330 (M^+-2H_2O), 317 (M^+-H_2O-OMe); high resolution MS *m/e* 348.230 (dehydration peak, calcd for $C_{21}H_{32}O_4$, 348.230).

Reduction of **5b**. Reduction of the ester **5b** (200 mg, 0.546 mmol) with the aluminum reagent **1** (5.46 mmol) in toluene (30 ml) according to the method for reduction of **5a** afforded a mixture of 11-*epi*-$PGF_{2\alpha}$ methyl ester (**6b**) (major product) and 11-*epi*-$PGF_{2\beta}$ methyl ester (**6d**) (minor product) (188 mg, 94% yield): boric acid impregnated TLC, R_f 0.380 for **6b**, 0.565 for **6d** (AcOEt, 2 developments). These R_f values were in agreement with those of the reduction product from **5b** using $NaBH_4$.[20] Regular silica gel TLC plate showed a single spot with ethyl acetate (2 developments). The mixture of **6b** and **6d**: IR ($CHCl_3$) 3600, 3400, 1730, 980 cm^{-1}; ^1H NMR δ 5.48—5.72 (2H, m, *trans* olefinic H), 5.20—5.48 (2H, m, *cis* olefinic H), 3.82—4.43 (3H, m, C_9, C_{11}, C_{15}–H), 3.68 (3H, s, $COOCH_3$), 2.90—3.55 [3H, brs, OH disappearance in D_2O)], 0.89 (3H, t, CH_3): MS *m/e* 350 (M^+ $-H_2O$), 332 (M^+-2H_2O), 314 (M^+-3H_2O), 319 (M^+ $-H_2O-OMe$); high resolution MS *m/e* 350.243 (dehydration peak, calcd for $C_{21}H_{34}O_4$, 350.246). The ratio of **6b**/**6d** was determined by the conversion of **6b** and **6d** to the acids (2 M KOH–MeOH, 1 : 1, 25 °C for 2 h), then to the phenacyl esters (α,*p*-Dibromoacetophenone, Et_3N, CH_3CN, 25 °C for 3 min), followed by the HPLC analysis of these esters (μ-Porasil, UV index 264 nm, AcOEt–hexane, 4 : 1) to be 76 : 24.

*Reduction of Prostaglandin D_2 Methyl Ester (***6c***).* Reduction of **6c** (53 mg, 0.145 mmol) with the aluminum reagent **1** (1.61 mmol) in toluene (5 ml) using the method for the reduction of **5a** produced a mixture of 11-*epi*-$PGF_{2\alpha}$ methyl ester (**6b**) (major product) and $PGF_{2\beta}$ methyl ester (**6a**) (minor product) (49 mg, 92% yield): TLC, homogeneous; boric acid impregnated TLC, R_f 0.381 for **6b**, 0.501 for **6a** (AcOEt, 2 developments). The R_f values for **6b** and **6a** were completely identical with those for the reduction product of **5b**, and for the authentic $PGF_{2\alpha}$ methyl ester, respectively. The ratio of **6b**/**6a** (98/2) was determined, as described above, by the conversion of **6b** and **6a** into the corresponding phenacyl esters, followed by their HPLC analysis (μ-Porasil, UV index 264 nm, AcOEt–hexane, 4 : 1). The mixture of **6b** and **6a**: IR ($CHCl_3$) 3600, 3450, 1730, 980 cm^{-1}; ^1H NMR δ 5.50—5.69 (2H, m, *trans* olefinic H), 5.20—5.50 (2H, m, *cis* olefinic H), 3.96—4.46 (3H, C_9, C_{11}, C_{15}–H), 3.66 (3H, s, $COOCH_3$), 0.89 (3H, t, CH_3); MS *m/e* 350 (M^+-H_2O), 332 (M^+ $-2H_2O$), 319 (M^+-H_2O-OMe), 314 (M^+-3H_2O); high resolution MS *m/e* 350.246 (dehydration peak, calcd for $C_{21}H_{34}O_4$, 350.246).

Reduction of 4-Hydroxy-3-methyl-2-butanone. A solution of 4-hydroxy-3-methyl-2-butanone (500 mg, 4.90 mmol) in toluene (5 ml), which was cooled below −60 °C, was added dropwise to the aluminum reagent **1** (49 mmol) in toluene (100 ml) at −78 °C. The resulting mixture was stirred at −78 °C for 4 h, warmed up to −20 °C for 1 h, and again stirred at −20 °C for 30 min. The reaction mixture was poured onto 0.1 M hydrochloric acid (20 ml). Removal of the white solid by filtration, washing of the filtrate with brine, being dried over $MgSO_4$, and evaporation of the solvent left the crude oil, which was purified by column chromatography (silica gel, 150 g; CH_2Cl_2, then AcOEt) to furnish a

mixture of *erythro*- and *threo*-2-methyl-1,3-butanediol (480 mg, 96% yield): ^{1}H NMR (CD_3OD) δ 3.40—3.91 (3H, m, CH_2–O, CH–O), 1.41—1.70 (1H, m, CH_3–C<u>H</u>), 1.14, 1.16 (3H, two d, J=6.5 Hz, C_4–H), 0.87, 0.92 (3H, two d, J=7.0 Hz, C_2–CH_3); MS *m/e* 105 ($M^+ + 1$), 89 ($M^+ - CH_3$), 86 ($M^+ - H_2O$). The ratio of the peaks at δ 1.16 and 1.14 (or δ 0.92 and 0.87) was 2 : 1. The authentic *erythro* form[21] showed the peaks for 2 methyl groups at δ 1.16 (d, J=6.5 Hz) and 0.92 (d, J=7.0 Hz). Furthermore, the ^{1}H NMR analysis of the reduction product in the presence of the authentic *erythro* form showed the larger peaks at δ 1.16 and 0.92. Therefore, the ratio of *erythro* to *threo* form would be 2 : 1.

Reduction of 4-t-Butylcyclohexanone. A solution of 4-*t*-butylcyclohexanone (154 mg, 1 mmol) in toluene (2 ml) was added dropwise to the aluminum reagent **1** (10 mmol) in toluene (18 ml) at −78 °C. Stirring was continued at −78 °C for 4 h. Then the mixture was poured onto ice, and diluted with 1 M hydrochloric acid (75 ml). Extraction with ether, washing of the extracts with brine, being dried over $MgSO_4$, and concentration of the solvent left the crude oil, which was purified by column chromatography on silica gel (CH_2Cl_2, then CH_2Cl_2–AcOEt, 6 : 1) to afford the less polar isomer (37 mg, 24% yield) and the more polar isomer (94 mg, 60% yield) as white crystals: TLC, R_f 0.50 for the less polar isomer, 0.38 for the more polar isomer (AcOEt–CH_2Cl_2, 1 : 5). These R_f values were identical with those of the authentic samples (predominantly *cis*), which was prepared by the reduction of 4-*t*-butylcyclohexanone with L-Selectride in tetrahydrofuran at −78 °C.[22] The TLC analysis showed that the less polar isomer corresponded to the *cis* form, and therefore, the ratio of *cis*-/*trans*-4-*t*-butylcyclohexanol was 28 : 72. *cis*-4-*t*-Butyl-cyclohexanol: IR ($CHCl_3$) 3470, 1480, 1449, 1392, 1222, 1135, 1106, 949 cm^{-1}; ^{1}H NMR δ 3.93—4.18 (1H, m, CH–O), 1.14—2.04 (10H, m, aliphatic CH, OH), 0.87 (9H, s, *t*-Bu); MS *m/e* 156 (M^+), 141 ($M^+ - CH_3$), 138 ($M^+ - H_2O$), 123 ($M^+ - H_2O - CH_3$), 99 ($M^+ - t$-Bu); high resolution MS *m/e* 156.158 (calcd for $C_{10}H_{20}O$, 156.151). *trans*-4-*t*-Butylcyclohexanol: IR ($CHCl_3$) 3457, 1461, 1373, 1112, 1059, 978 cm^{-1}; ^{1}H NMR δ 3.29—3.80 (1H, m, CH–O), 0.80—2.23 (10H, m, aliphatic CH, OH), 0.83 (9H, s, *t*-Bu); MS *m/e* 138 ($M^+ - H_2O$), 123 ($M^+ - H_2O - CH_3$), 99 ($M^+ - t$-Bu), 81 ($M^+ - t$-Bu $- H_2O$).

Reduction of 2-Methylcyclohexanone. A solution of 2-methylcyclohexanone (112 mg, 1 mmol) in toluene (2 ml) was added dropwise to the aluminum reagent **1** (10 mmol) in toluene (18 ml) at −78 °C. Stirring was continued at −78 °C for 3.5 h, then at −20 °C for 3.5 h. The mixture was poured onto ice and diluted with 1 M hydrochloric acid (75 ml). Extraction with ether, washing of the extracts with brine, and purification of the concentrated crude product by column chromatography on silica gel (CH_2Cl_2, then ether) gave a mixture of *cis*- and *trans*-2-methylcyclohexanol (97 mg, 85% yield) as a colorless oil: IR ($CHCl_3$) 3490, 1452, 1378, 1220, 1123, 965 cm^{-1}; ^{1}H NMR δ 2.83—3.30, 3.63—3.97 (1H, m, CH–O), 1.10—2.12 (9H, m, aliphatic CH), 0.83—1.10 (3H, two d, CH_3); MS *m/e* 96 ($M^+ - H_2O$), 81 ($M^+ - H_2O - CH_3$). The ^{1}H NMR spectrum showed the ratio of the *cis* to *trans* isomers to be 75 : 25. This analysis was determined by an absorption due to the α-proton peak (C<u>H</u>–OH) of the hydroxyl group at δ 3.63—3.97 and 2.83—3.30.[23]

Photo-induced Radical Rearrangements of Hypoiodite of *N*-Acetyljervine and the Related *C*-nor-*D*-Homosteroid in the Presence of Mercury(II) Oxide and Iodine[1]

Hiroshi SUGINOME,*,** Kimitoshi KATO, and Tadashi MASAMUNE
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 3, 1981)

Irradiation of the hypoiodite of *N*-acetyljervine in benzene containing mercury(II) oxide and iodine gave a mixture of products. The major product was *N*-acetyl-11-oxojerva-5,12(13)-dien-3β-yl *N*-acetyl-*A*-homo-4-oxa-11-oxojerva-5,12(13)-dien-3α-yl ether (**4**) (25%). Four minor products, *N*-acetyl-2-iodo-11-oxo-*A*-nor-2,3-secojerva-5,12(13)-dien-3-yl formate, *N*-acetyl-3α,5-epoxy-6α-iodo-*A*-homo-4-oxa-5α-jerva-5,12(13)-dien-11-one, *N*-acetyl-4-oxajerva-5,12(13)-dien-11-one, and *N*-acetyl-4-oxa-*A*-homojerva-5,12(13)-diene-3,11-dione, were also isolated. Irradiation of the hypoiodite of 3β-hydroxy-17-ethyletiojerv-5-ene-11,20-dione also gave a dimer corresponding to **4**. The formation of **4** as the major product contrasts with the result of the corresponding reaction of cholesterol.

It has been shown that hypoiodites generated from a variety of steroidal alcohols undergo heat- or light-induced reaction to give products originating through alkoxy radical intermediates.[2,3] Mercuric oxide–iodine reagent has been shown to be an effective reagent for the formation of hypoiodites from steroidal alcohols.[4]

In previous papers,[5–7] we described the results of investigations of the photo- and thermally-induced rearrangements of hypoiodites of cholesterol and several related 5-cholesten-3-ols substituted with methyl groups on their C-3 and C-4 positions in the presence of mercury(II) oxide and iodine. It has been found that 3α,5-epoxy-*A*-homo-4-oxa-5α-cholestanes (type A) carrying α- or β-oriented iodine on their C-6 positions or 3α,5-epoxy-*A*-homo-4-oxa-5α-cholest-6-enes (type B) are usually formed when the reactions are induced by irradiation, although their yields varied widely; these products are usually accompanied by seco-iodide of type (C). It has also been found that methyl substituents on their C-3 or C-4 positions affect the relative yields of oxabicyclic compounds (type A) appreciably and that the presence of *gem* dimethyl group on the C-4 position results in the formation of 3-oxa-5-cholestenes (type D) with the loss of one carbon atom.[5,7] The products from thermally-induced reactions were almost parallel, but the thermally-induced reaction of cholesterol hypoiodite gave a novel dimeric product of type (E) as the major product.[5]

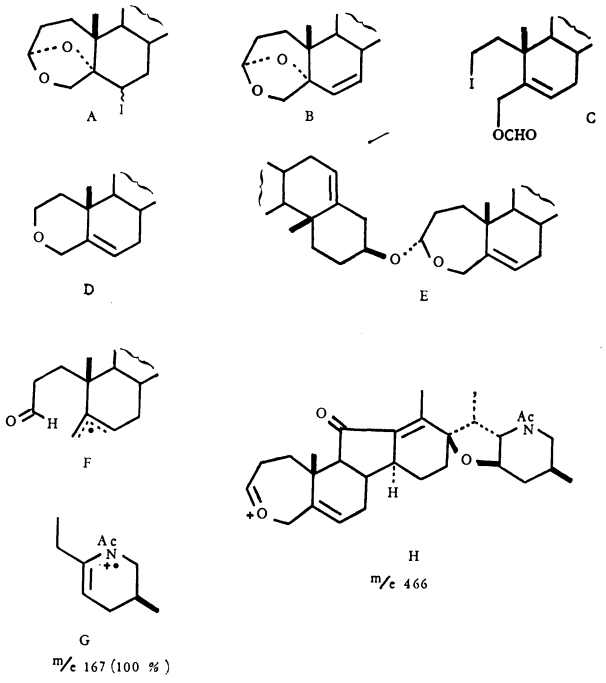
The pathways of the rearrangements which can explain the stereochemistry of these products have been advanced in the previous papers.[5–7] All the above products are formed from an allyl radical intermediate (F) derived from β-scission of the corresponding 3β-oxyl radicals.

In this paper, we report the results of the photo-induced reaction of hypoiodite of *C*-nor-*D*-homosteroid-5-en-3β-ols in which their C-ring is 5-membered instead of 6-membered as in normal steroids.

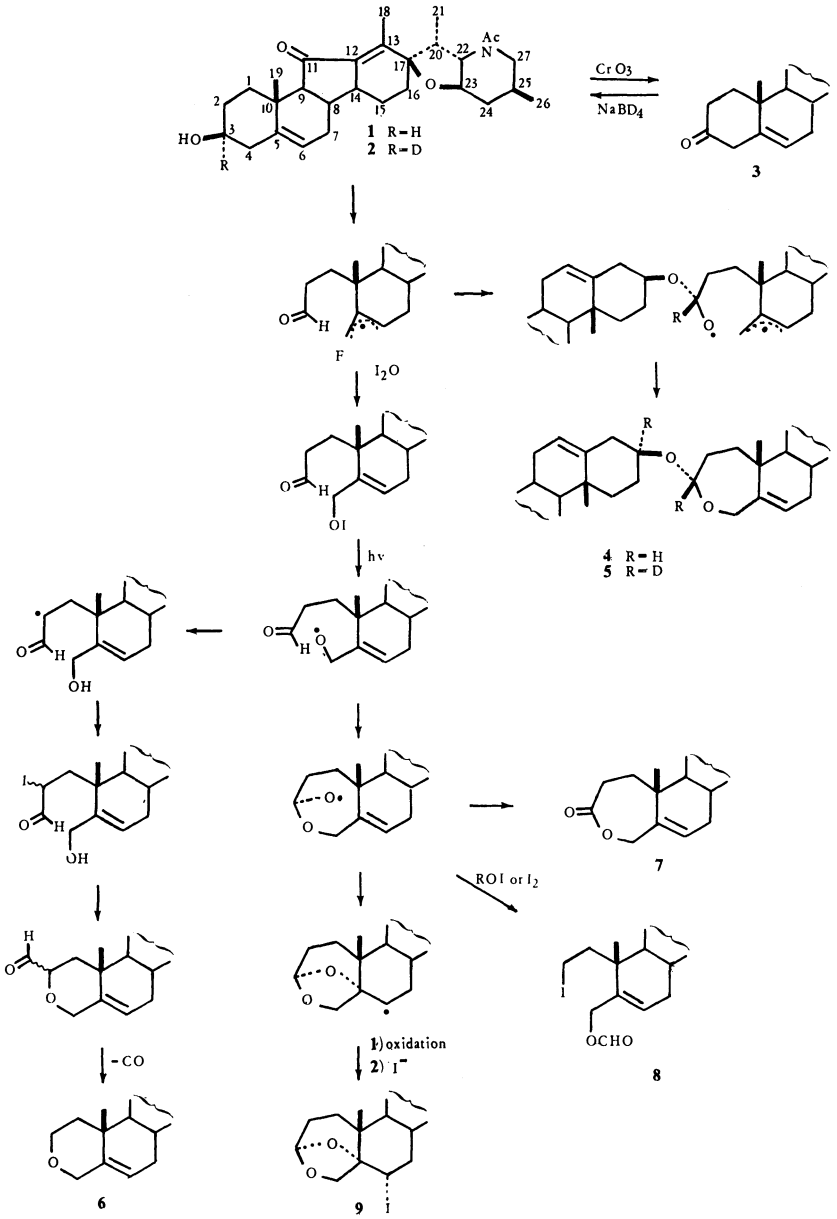
Results and Discussion

N-Acetyljervine (**1**)[8] and 3β-hydroxy-17α-ethyletiojerv-5-ene-11,20-dione (**11**)[9] were chosen as the substrates. The photo-induced reactions were conducted under the conditions reported previously;[5–7] irradiation of *N*-acetyljervine (**1**) in benzene containing mercury(II) oxide and iodine (*ca.* 3 mol equiv. each) with a 100-W high pressure mercury arc for 12 h under an atmosphere of nitrogen gave a mixture of products, from which five crystalline products (**8**) (5%), (**9**) (2%), (**6**) (1%), (**7**) (1%), and (**4**) (25%) in order of their mobility, were isolated by preparative TLC (Scheme 1). The noted yields of the products are those in pure crystalline states; thus the actual yield of each product is higher than those described above. The structures of all these products were deduced by the analysis of their spectra. The mass, IR, UV, and ^{1}H NMR spectra showed that the C, D, and heterocyclic rings in jervine were intact in all the five products.

The structure of the crystalline product (**8**) carrying iodine, which was the most mobile on the TLC plate, was proved to be *N*-acetyl-3-iodo-11-oxo-*A*-nor-2,3-secojerva-5,12(13)-dien-3-yl formate[10] by the following spectral evidence. Although the mass spectrum showed



** Present address: Organic Chemistry Laboratory, Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060.



Scheme 1.

no molecular ion peak, the elemental analysis was in accord with the molecular formula $C_{29}H_{40}NO_5I$. A formate structure analogous to the formate[2] obtained from the hypoiodite of cholesterol was suggested by the presence of the 1H singlet at τ 1.91 in the ^1H NMR spectrum. The olefinic proton at the C-6 was present at τ 4.06 as a one-proton diffused doublet with J=4.5 Hz and the allylic C-3 methylene protons appeared as a broad singlet at τ 5.40 ($W_{1/2}$=5 Hz). The IR spectrum was also in agreement with the assigned structure. The pathway to this formate has already been discussed for the formation of an analogous formate from cholesterol in the previous paper.[5]

The crystalline product (**9**) carrying iodine was proved to be *N*-acetyl-3α,5-epoxy-6α-iodo-*A*-homo-4-oxa-5α-jerva-5,12(13)-dien-11-one[7] (**9**) from the following evidence: the molecular formula $C_{29}H_{40}NO_5I$ was determined by mass spectrometry (*m/e* 609, M^+) and elemental analysis. The ^1H NMR spectrum showed a broad one-proton singlet at τ 4.48, a one-proton double doublet at τ 5.55 with J=4.5 and 12.3 Hz, and an AB quartet at τ 5.84 and 6.24 with J=7.6 Hz. These signals were assigned to the 3β-H, the 6β-H, and the C-4a-methylene protons and were entirely analogous to those arising from the corresponding protons of 3α,5-epoxy-6β-iodo-*A*-homo-4-oxa-5α-cholestane[5] with respect to their chemical shifts and the coupling constants. The IR spectrum was also in accord with the assigned structure.

The molecular formula of the third TLC mobile crystalline product (**6**) was determined to be $C_{28}H_{39}NO_4$ by high resolution mass spectrometry. The structure was proved to be N-acetyl-4-oxajerva-5,12(13)-dien-11-one.[10] The ^1H NMR spectrum showed a one-proton doublet at τ 4.57 and a superimposed nine-proton multiplet (τ 5.81—7.20). The former is assigned to the olefinic 6-H and the latter is assigned to superimposed signals arising from the C-2-methylene protons, C-4-

methylene protons, 9α-H, 22β-H, 23α-H, and C-27-methylene protons. The shape of the multiplet signals is almost identical with that obtained by superimposing the signals due to 22-H, 23-H, C-27-methylene protons, and 9-H in the spectrum of *N*-acetyljervine and those due to C-2-methylene protons and C-4-methylene protons of 3-oxacholest-5-ene.[5] The IR spectrum was also in agreement with the assigned structure.

The molecular formula of the fourth TLC mobile crystalline product (**7**) was confirmed to be $C_{29}H_{39}NO_5$ by high resolution mass spectrometry. The results of the IR and NMR spectra were consistent with the structure, *N*-acetyl-4-oxa-*A*-homo-jerva-5,12(13)-diene-3,11-dione. In the IR spectrum, a new band arising from an unstrained lactone carbonyl band is present at 1737 cm^{-1}, together with the band due to the α,β-unsaturated carbonyl. In the ^1H NMR spectrum two doublets, at τ 5.36 and 5.84, and a one-proton doublet at τ 4.21 assigned to the C-4a methylene protons and the 6-H could be seen.

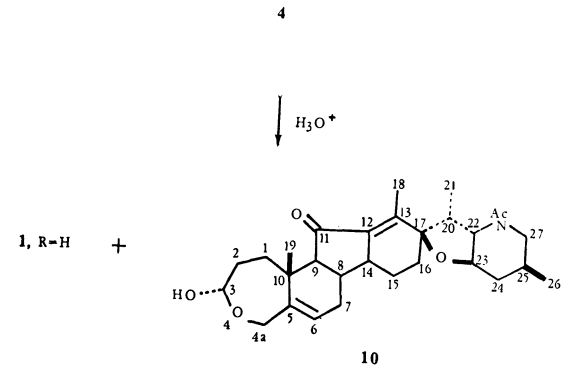
Finally, the structure of the most polar product (**4**), obtained in highest yield in this reaction, was deduced to be *N*-acetyl-11-oxojerv-5,12(13)-dien-3β-yl *N*-acetyl-*A*-homo-4-oxa-11-oxojerva-5-en-3α-yl ether, which was analogous to cholest-5-en-3β-yl *A*-homo-4-oxacholest-5-en-3α-yl ether obtained from thermal decomposition of cholesterol hypoiodite, on the basis of the spectroscopic, especially ^1H NMR spectral evidence. The molecular formula, $C_{58}H_{80}N_2O_8$, was deduced by the osmometric molecular weight determination[1] and the elemental analysis. The molecular weight was further confirmed by FD mass spectrometry, which showed the $M^+ + 1$ ion at *m/e* 933. The IR, UV, and ^1H NMR spectra proved that the C, D, and the heterocyclic ring portions of the starting jervine molecule were unchanged in this compound, as described earlier.

In the downfield region of the ^1H NMR spectrum, four signals (each one-proton) are present; these signals appeared at τ 4.45 (broad singlet), 4.69 (broad singlet), 5.12 (triplet, J=5.3 Hz) and 5.68 (doublet, J=13.5 Hz). These signals were assigned to those arising from 6-H of the *N*-acetyl-11-oxojerva-5,12(13)-dien-3β-yl portion, 6-H of the *A*-homo-4-oxa-11-oxojerva-5,12(13)-dien-3α-yl portion, and the 3β-H and 4a-H signals of *A*-homo-4-oxa-11-oxojerva-5,12(13)-dien-3α-yl portion on the basis of spin-decoupling experiments, deuterium labeling, acidic hydrolysis, and comparison of the spectrum with that of cholest-5-en-3β-yl *A*-homo-4-oxacholest-5-en-3α-yl ether.[5]

Decoupling experiments showed that the two signals at τ 4.45 and 4.69 collapsed into two clear singlets on irradiation at τ 7.5, while the triplet at τ 5.10 is only partially decoupled. The behavior of these two signals in the spin-decoupling is similar to those of C-6 olefinic proton of Δ^5-steroids. The diffused triplet at τ 5.10 was also partially decoupled to a broad singlet ($W_{1/2}$=7.0 Hz) on irradiation at τ 8.3. On the basis of an experiment which used 3α-deuterio-*N*-acetyljervine (**2**), this signal was confirmed to arise from C-3α-H of *N*-acetyljervine. 3α-Deuterio-*N*-acetyljervine (**2**) was prepared by reduction of *N*-acetyljerva-5,12(13)-diene-3,11-dione, which was prepared by the Jones oxidation of *N*-acetyljervine with $NaBD_4$. 3α-Deuterio-*N*-acetyljervine in benzene containing mercury(II) oxide and iodine was subjected to the photolysis to give a product (**5**) carrying deuterium. The ^1H NMR spectrum of **5** shows the absence of the triplet at τ 5.10 which was in the spectrum of product (**4**), proving that the triplet originated from 3α-H of the starting jervine.

The doublet at τ 5.68 in **4** was found to be a part of an AB quartet, and another doublet of the AB system superimposed with other signals was found at τ 6.48. On irradiation of the center of the doublet at τ 6.48, the doublet at τ 5.68 collapsed to a singlet. The irradiation at the center of the doublet at τ 5.68 caused a collapse of the doublet at τ 6.48 to a singlet without any change of the signal shapes at τ 4.45, 4.69 and 5.10. This AB quartet was thus assigned to an isolated C-4a methylene protons of *A*-homo-4-oxacholest-5-en-3α-yl portion.

The dimeric structure assigned to compound (**4**) was further confirmed by its acidic hydrolysis (Scheme 2).



Scheme 2.

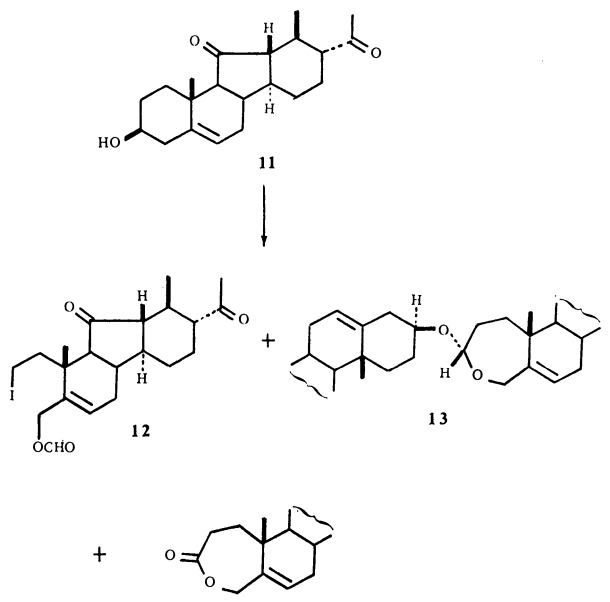
Hydrolysis of either **4** or **5** in THF containing dilute hydrochloric acid at room temperature gave only two products. As expected from the assigned structure, one of the products was found to be identical with *N*-acetyljervine (**1**) or 3α-deuterio-*N*-acetyljervine (**2**) by direct comparisons. All the spectra on the other product **10** were consistent with that of *N*-acetyl-*A*-homo-4-oxa-11-oxojerva-5,12(13)-dien-3α-ol or its 3β-deuterio compound. The MS spectrum showed the molecular ion at *m/e* 483. The IR spectrum shows the presence of a hydroxy and an α,β-unsaturated carbonyl. The ^1H NMR spectrum shows two one-proton signals at τ 4.41 and 4.86 and an AB quartet at τ 5.59 and 6.41, with J=13.3 Hz, together with a set of signals arising from the B, C and heterocyclic rings of jervine. The series of signals in the downfield region shows a remarkable similarity to the signals of compound **4** with respect to the chemical shifts and behavior in spin-decoupling. However, the spectrum shows the absence of a signal corresponding to the ones at τ 4.69 in the spectrum of compound **4**, proving that it originated from the *N*-acetyl-11-oxojerva-5,12(13)-dien-3β-yl portion.

All the foregoing results can be reconciled to the assigned structure **4**. It is noted that the signals arising from the *N*-acetyl, 18-H, 19-H, 21-H, and 26-H of the *N*-acetyl-11-oxojerva-5,12(13)-dien-3β-yl portion in the ^1H NMR spectrum were superimposed with those due

to the corresponding protons of the *N*-acetyl-*A*-homo-4-oxa-11-oxojerv-5-en-3α-yl portion.

The electron impact mass spectrum of compound **4** showed no peak above *m/e* 500 and showed weak peaks at *m/e* 465, 466, 467, and a base peak at *m/e* 167. The structures of the species of *m/e* 167 and 466 may be assigned to (G)[11] and (H). The ^{13}C FT NMR spectrum, with the aid of the off-resonance spectrum of **4**, fully supported the assigned formula. With the exceptions of the C-17 and the C-17′, the NAc and the N′Ac, and C-23 and C-23′, which appeared as the superimposed singlets at τ 172.97, 85.42, and 72.68 ppm, all the sp^2 carbon atoms and oxygen-bearing carbon atoms appeared as a pair of signals. Their assignments are as follows: C-11–CO and C-11′–CO (δ 206.65 ppm), C-5 and C-5′ (145.79 and 146.28), C-13 and C-13′ (142.46 and 144.22), C-6 and C-6′ (120.67 and 125.95), and C-3 of oxepane ring (99.08) and C-3′ (75.72).

To compare these results with those from a simpler *C*-nor-*D*-homosteroid, hypoiodite of 3β-hydroxy-17α-ethyletiojerv-5-ene-11,20-dione (**11**)[9] was subjected to the photolysis in the presence of mercury(II) oxide and iodine under the conditions described for *N*-acetyljervine hypoiodite. The results were found to be almost parallel to the case of *N*-acetyljervine (Scheme 3).



Scheme 3.

From a mixture of the products a formate (**12**), a dimer (**13**), and a lactone (**14**) were isolated in 32, 26, and 9% yields. The structures of these products were deduced by spectrometry in a manner analogous to the case of the products from *N*-acetyljervine. The results of the analysis of the spectra on each product are described in the experimental section, but the results of the electron impact mass spectrum of dimer **13** are only mentioned here. In contrast to the mass spectrum of dimer **4**, in which no molecular ion peak was present and the intensity of a fragment ion (H) was only 0.4%, that of dimer **13** showed the molecular ion peak at *m/e* 658 and the fragment ion of *m/e* 329 corresponding to the fragment (H) is the base peak. These results further supports the structure given to the product **4**. In this photolysis, two minor products (corresponding to **6** and **9**) were almost certainly present in the product mixture, but we failed to isolate these compounds in the pure forms. All the types of products, with the exceptions of lactone **7** and dimers **4** and **13**, obtained in this experiment were those already obtained in the photo-induced rearrangement of cholesterol[5] and the related 5-choleten-3-ols.[6,7] Changing the C-ring from 6-membered[5] to 5-membered, however, introduces appreciable variations in the products and their yields: dimeric acetal **4** was obtained as the major product, whereas no compound of this type was formed in the photo-induced reaction of cholesterol.[5] On the other hand, oxabicyclic compound **9** was formed in only a very minor amount although it is one of the major products in the corresponding reaction of cholesterol.[5] Unlike the cholesterol case,[5] we failed to isolate an oxabicyclic compound carrying β-oriented iodine.

The paths to dimeric acetal **4**, 4-oxa compound **6**, formate **8** and oxabicyclic compound **9** were already discussed in the previous papers.[5–7] All these products are derived from an allyl radical (F) formed by a β-scission of the 3β-oxyl radical. The Scheme 1 shows these pathways, including a path for the formation of lactone (**7**), the isolation of which in the present experiment strengthened the validity of our proposed pathways.[5] Although a further study is required for fuller understanding of origins of the variations in the products and their relative yields observed for *C*-nor-*D*-homosteroids and steroids,[5] one of the important factors would be slight changes in the geometries between groups or atoms introduced to the vicinity of the reaction center of the intermediary allyl radical. The change would affect the subtle balance between rates of intra- and intermolecular processes and would bring about appreciable differences in the products and their yields.

Experimental

For instruments used and general procedure see Ref. 2. Low resolution mass spectra of compounds, **2**, **3**, **7**—**9**, and **13** (70 eV), high resolution mass spectra of **2**, **3**, **7**, **9**, and FD mass spectra of **4**, and **5** were measured by Miss Yuko Chiba of the Faculty of Agriculture of this university. Low resolution mass spectra of compounds, **10**, **12**, and **14** (70 eV) were measured by the staff of Faculty of Pharmaceutical Sciences of this university. ^{13}C FT NMR spectra (25.1 MHz, solvent $CDCl_3$: TMS as internal reference) were determined by JEOL Ltd., Tokyo.

Irradiation of N-*Acetyljervine Hypoiodite in the Presence of Mercury(II) Oxide and Iodine.* *N*-Acetyljervine (**1**) (806 mg), mercury(II) oxide (763 mg), and iodine (1.346 g) in benzene (60 ml) in Pyrex vessel were irradiated for 12 h with a 100-W high pressure mercury arc under a nitrogen atmosphere. After the solution was filtered, the filtrate was evaporated to give a residue which was dissolved in chloroform. The chloroform solution was washed with 5% sodium thiosulfate solution and water (twice), and dried over anhydrous sodium sulfate. After the usual work-up, the residue was subjected to preparative TLC (SiO_2) with a chloroform–diethyl ether (10 : 1). Five products: **8**, **9**, **6**, **7**, and **4**, in order of their increasing mobility in TLC, were obtained. The product **8**, which was

the most mobile on the TLC plate, was recrystallized from ethanol to yield crystals (52 mg), mp 159—160.5 °C. The Beilstein test was positive. Found: C, 56.77; H, 6.64; N, 2.37%. Calcd for $C_{29}H_{40}NO_5I$: C, 57.12; H, 6.62; N, 2.30%. IR, 1719 and 1672 (α,β-unsaturated carbonyl), 1751 (formate carbonyl), 1627 (*N*-acetyl), 1176 (formate C=O), 895, and 840 cm^{-1}; NMR, τ 1.91 (1H, s, formate), 4.06 (1H, d, J=4.5 Hz, 6-H), 5.40 (2H, s, $W_{1/2}$=5 Hz, CH_2–OCHO), 7.75 (3H, s, 18-H), 7.90 (3H, s, N-Ac), 9.95 (3H, d, J=6, 21-H), 8.99 (3H, s, 19-H), and 9.13 (3H, d, J=7.5 Hz, 26-H); MS, *m/e* (rel intensity), 435 (1.9), 156 (100), and 114 (27.7).

Product **7** was recrystallized from acetone to yield crystals (21 mg), mp 218—220 °C. The Beilstein test gave a postive result. Found: C, 57.30; H, 6.69; N, 2.68%. Calcd for $C_{29}H_{40}NO_5I$: C, 57.12; H, 6.62; N, 2.30%. IR, 1710 and 1655 (α,β-unsaturated carbonyl), 1628 (*N*-acetyl), 1112 (C–O), 928, 910, and 890 cm^{-1}; NMR, τ 4.48 (1H, broad s, $W_{1/2}$= 3.9 Hz, 3-H), 5.55 (1H, dd, J=4.5 and 12.3 Hz, 6β-H), 5.84 and 6.25 (each 1H, AB quartet, J=7.6 Hz), 7.77 (3H, s, 18-H), 7.91 (3H, s, N-Ac), 8.96 (3H, d, J=6.3 Hz, 21-H), 9.08 (3H, s, 19-H), and 9.13 (3H, d, 26-H); MS, *m/e* (rel intensity), 609 (M^+ 0.4), 482 (M^+-I, 0.7), 167 (100), 152 (8.7), 74 (14.7), 59 (26.9), 45 (17.4), and 43 (8.4).

Product **6** was recrystallized from diethyl ether to yield crystals (8 mg), mp 165—167 °C. Found: C, 73.82; H, 8.73; N, 2.98%; M^+*m/e* 453.2842. Calcd for $C_{28}H_{39}NO_4$: C, 74.17; H, 8.67; N, 3.10%; M^+453.2877. IR, 1712 and 1671 (α,β-unsaturated carbonyl), 1624 (*N*-acetyl), 1262, 1100, and 904 cm^{-1}; NMR, τ 4.57 (1H, d, J=3.0 Hz, 6-H), 5.81—7.20 (9H, m, 2-H, 4-H, 9α-H, 22β-H, 23α-H, and 27-H), 7.77 (3H, s, 18-H), 7.92 (3H, s, N-Ac), 8.89 (3H, s, 19-H), 8.97 (3H, d, J=6.6 Hz, 21-H), and 9.14 (3H, d, J=7.5 Hz, 26-H); MS, *m/e* (rel intensity),453 (M^+, 0.5), 167 (100), and 152 (15.4).

Product **7** was recrystallized from diethyl ether to yield crystals (8 mg) mp 258—260 °C. Found: 481.2800. Calcd for $C_{29}H_{39}NO_5$: M, 481.2826. IR 1737 (7-membered lactone), 1712, and 1633, shoulder (α,β-unsaturated carbonyl), 1624 (*N*-acetyl), 1277, and 1028 cm^{-1}; NMR, τ 4.21 (1H, d, J= 3.0 Hz, 6-H), 5.36 and 5.84 (each 1H, AB quartet, J=13.5 Hz, 4a-H), 7.78 (3H, s, 18-H), 7.94 (3H, s, N-Ac), 8.94 (3H, s, 19-H), 8.97 (3H, d, J=6.6 Hz, 21-H), and 9.15 (3H, d, J= 6.9 Hz, 26-H); MS, *m/e* (rel intensity), 481 (M^+, 0.6), 167 (100), and 152 (14.7%).

Product **4** was recrystallized from acetone to yield crystals (201 mg), mp 216—218 °C. Found: C, 74.32; H, 8.80; N, 2.82. Calcd for $C_{58}H_{80}N_2O_8$: C, 74.64; H, 8.64; N, 3.00%. FD MS, (rel intensity), *m/e* 933 (M^++1, 100), 932 (43.4), 931 (26.9), 918 (M^+-CH_3, 21.0), and 777 (17.2); MS, (rel intensity), 467 (0.5), 466 (0.4), 465 (0.7), 330 (4.9), 167 (100), and 151 (10.6); IR, 1713 and 1633 (α,β-unsaturated carbonyl), 1659 (*N*-acetyl), 1094, 1074, 1032, and 762 cm^{-1}; NMR, τ 4.45 (1H, broad, s, 6-H of *N*-acetyl-11-oxojerva-5,12(13)-dien-3β-yl portion), 4.69 (1H, broad, s, 6-H of *A*-homo-4-oxa-11-oxojerva-5,12(13)-dien-3α-yl portion), 5.12 (1H, t, J=5.3 Hz, 3β-H of *A*-homo-4-oxa portion), 5.68 and 6.48 (each 1H, AB quartet, J=13.5 Hz, 4a-H of *A*-homo-4-oxa-11-oxojerva-5,12(13)-dien-3α-yl portion), 7.75 (6H, s, 18- and 18′-H), 7.92 (6H, s, *N*-acetyl and *N*′-acetyl), 8.97 (6H, d, J=6.6 Hz, 21-H and 21′-H), 9.00 (6-H, s, 19-H and 19′-H) and 9.14 (6H, d, J=7.5 Hz, 26-H and 26′-H).

Hydrolysis of N-*Acetyl-11-oxojerva-5,12(13)-dien-3β-yl* A-*Homo-4-oxa-11-oxojerva-5,12(13)-dien-3α-yl Ether with Aqueous Methanolic Hydrochloric Acid.* A suspension of the dimer (100 mg) in methanol (30 ml) containing concd hydrochloric acid (1 ml) was stirred at room temperature. The crystals gradually dissolved over a period of 1 h. The solution was stirred at room temperature for four more hours. After the addition of water, methanol was removed at room temperature and solution was extracted with chloroform. The chloroform solution was washed with aq sodium carbonate solution, washed with water, and dried over anhydrous sodium sulfate. The usual work-up of the solution left a residue which showed two spots on a TLC plate (SiO_2) (a 8:1 mixture of chloroform–acetone). The product was subjected to preparative TLC to give two products. The more TLC mobile product (39 mg) was recrystallized from acetone to yield a compound which was identical with *N*-acetyljervine. The less TLC mobile amorphous product (45 mg) could not be induced to crystallise. IR, 3380 (OH), 1706, and 1620, broad, (α,β-unsaturated carbonyl and *N*-acetyl), 1100, 1056, and 1025 cm^{-1}; NMR, τ 4.41 (1H, d, J=3.9 Hz), 4.86 (1H, t, J=6 Hz), 5.59 and 6.41 (each 1H, AB quartet, J=13.3 Hz, 4a-H), 7.76 (3H, s, 18-H), 7.91 (3H, s, N-Ac), 8.96 (3H, d, J=6.6 Hz, 21-H), 9.01 (3H, s, 19-H), and 9.14 (3H, d, J=7.2 Hz, 26-H); MS, *m/e* 483 (M^+).

Oxidation of N-*Acetyljervine with Jones Reagent.* To *N*-acetyljervine (652 mg) in acetone (40 ml) there was added Jones reagent dropwise until the solution turned brown. The solution was stirred for a few min. On addition of water (250 ml), crude 3-ketone crystallized out from the solution. The crystals were collected by filtration, washed with water and recrystallized from acetone to yield 255 mg of pure 3-ketone **3**, mp 172.5—174.5 °C. Found: *m/e* 465.2860. Calcd for $C_{29}H_{39}NO_4$: M, 465.2877. IR, 1714, 1640 (shoulder) and 1627 cm^{-1}(six-membered ring ketone, and α,β-unsaturated carbonyl), 1244, 1148, and 1096 cm^{-1}; NMR, τ 4.63 (1H, broad, s, 6-H), 7.73 (3H, s, 18-H), 7.91 (3H, s, NAc), 8.93 (3H, s, 19-H), 8.93 (3H, d, J=6.6 Hz, 21-H), and 9.12 (3H, d, J=7.2 Hz, 26-H); MS, *m/e* (rel intensity), 465 (M^+, 0.7), 167 (100), 152 (15.5), and 43 (14.4).

*Preparation of 3α-Deuterio-*N-*acetyljervine (2).* The 3-ketone (202 mg) in ethanol (40 ml) containing sodium borodeuteride (148 mg) was stirred for 50 min. After the addition of water, the solvent was evaporated and the residue was dissolved in chloroform. The chloroform solution was washed with water and dried over anhydrous sodium sulfate. The usual work-up of the solution gave a product which was recrystallized from acetone–diethyl ether to yield 3β-ol, **2**, mp 224.5—226.5 °C. Found: *m/e* 468.3086. Calcd for $C_{29}H_{40}DNO_4$: M, 468.3097. IR, 3407 (OH), 1712 and 1649 (α,β-unsaturated carbonyl), 1628 (NAc), and 960 cm^{-1}; NMR, τ 4.64 (1H, d, J=4.5 Hz, 6-H), 7.76 (3H, s, 18-H), 8.91 (3H, s, N-Ac), 8.96 (3H, d, J=6.6 Hz, 21-H), 9.00 (3H, s, 19-H), and 9.13 (3H, d, J=7.5 Hz); MS, *m/e* (rel intensity) 468 (M^+, 0.6), 167 (100), and 152 (8.7).

*The Irradiation of 3α-Deuterio-*N-*acetyljervine Hypoiodite in the Presence of Mercury(II) Oxide and Iodine.* 3α-Deuterio-*N*-acetyljervine (147 mg), mercury(II) oxide (157 mg), and iodine (243 mg) in benzene (30 ml) in a Pyrex vessel were irradiated for 26.5 h as in the case of *N*-acetyljervine. The usual work-up of the reaction product gave a product which was subjected to preparative TLC (SiO_2) with a 7 : 1 mixture of chloroform and acetone. The crude product (58 mg) was recrystallized from diethyl ether to yield a pure dimer incorporating deuterium. It had a mp of 220—222 °C. FD-MS, *m/e* (rel intensity), 936 (M^++D, 78.2), 935 [$(M+H)^+$, 100], 934 (M^+, 91.1), 878 (20.8), and 769 (16.5): IR, 1713 and 1633 (α,β-unsaturated carbonyl), 1659 (*N*-acetyl), 1104, 1065, and 1039 cm^{-1}; the NMR spectrum was identical with that of the corresponding dimer from *N*-acetyljervine, with the exception of the absence of a 1H triplet at τ 5.12.

*The Irradiation of 3β-Hydroxy-17α-ethyletiojerv-5-ene-11,20-dione (**11**) in Benzene Containing Mercury(II) Oxide and Iodine.* 3β-Hydroxy-17α-ethyletiojerv-5-ene-11,20-dione (**11**) (300 mg) in benzene (51 ml) containing mercury(II) oxide (581 mg) and iodine (695 mg) was irradiated for 5 h at room temperature under an argon atmosphere while stirring. The reaction mixture was worked up as usual. The product was a complex mixture and showed a pattern of spots on TLC similar to a mixture from *N*-acetyljervine. The product was subjected to preparative TLC (chloroform–acetone, 20 : 1) to give six fractions (A–F in the order of decreasing mobility). The most mobile product A (100 mg) was an amorphous formate **12**. IR ($CDCl_3$), 1724 (broad, formyl carbonyl, 11-carbonyl and 20-carbonyl) and 1162 cm^{-1} (formyl C–O); NMR, τ1.89 (1H, s, OCHO), 4.03 (1H, d, J=5.4 Hz, 6-H), 5.39 (2H, broad s, $W_{1/2}$=3.6 Hz, C-3 methylene), 6.93 (2H, m, C-2 methylene), 7.84 (3H, s, 17α-acetyl), 8.82 (3H, d, J=6.0 Hz, 18-H), and 8.94 (3H, s, 19-H). MS, *m/e* 469 (M^+). The fractions B (44 mg) and C (14 mg) were a mixture. The fraction D (57 mg) was crystals; they were identified to be a dimeric acetal **13**. After recrystallization from acetone it had a mp of 250—253 °C. Found: *m/e* 658.4229. Calcd for $C_{42}H_{58}O_6$: M, 658.4232. IR, 1727 (11-carbonyl), 1703 (20-carbonyl), and 1034 cm^{-1} (C–O); NMR, 4.39 (1H, d, J= 4.5,6- H of *A*-homo-17α-ethyletiojerv-5-ene-11,20-dion-3α-yl portion) 4.65 (1H, d, J=4.5, 6-H of 17α-ethyletiojerv-5-ene-11,20-dion-3β-yl portion, 5.14 (1H, t, J=6 Hz, 3β-H of *A*-homo-17α-ethyletiojerv-5-ene-11,20-dion-3α-yl portion), 5.75 and 6.50 (each 1H, d, J=12.8 Hz, 4a-methylene of *A*-homo-17α-ethyletiojerv-5-ene-11,20-dion-3α-yl portion), 7.85 (6H, s, two acetyls), 8.79 (3H, d, J=6.0 Hz, 18-H), 8.83 (3H, d, J=6.0 Hz, 18′-H), and 8.97 (6H, s, superimposed 19-H). MS (rel intensity), *m/e* 658 (M^+, 0.4), 347 (1.6), 346 (1.5), 329 (100), 312 (46.8), 311 (29.2), and 269 (31.2).

The fraction E (20 mg) was *A*-homo-4-oxa-17α-ethyletiojerv-5-ene-3,11,20-trione (**14**). IR ($CHCl_3$) 3440 (hydroxy), 1735 (11-carbonyl and lactone), and 1705 (20-carbonyl); NMR, τ 4.6 (1H, d, J=4.5 Hz, 6-H), 5.27 and 5.72 (each 1H, d, J= 13.5 Hz, 4a-H), 7.83 (3H, s, 21-H), 8.81 (3H, d, J=6.0 Hz, 18-H), and 8.87 (3H, s, 19-H). MS, *m/e* 342 (M^+).

The authors are grateful to Mrs. Satoko Araki and Mrs. Tomoko Okayama for the measurements of the ^1H NMR spectra and the spin decoupling experiments.

Studies of Reactions of Amines with Sulfur Trioxide. VI.[1] Thermal Reactions of Anilinium, Dimethylanilinium, and Trimethylanilinium Salts of Butylamidosulfuric Acid

Fujio KANETANI* and Hachiro YAMAGUCHI

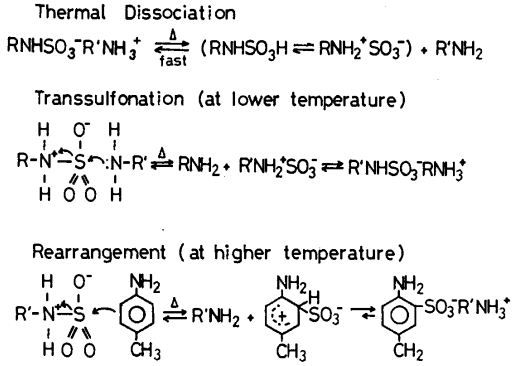
Department of Applied Chemistry, Hiroshima University, Senda-machi, Naka-ku, Hiroshima 730

(Received March 20, 1981)

When the title compounds were heated in an evacuated reaction vessel, both transsulfonation and rearrangement occurred. At lower temperatures (80—120 °C) the corresponding phenylamidosulfates and sulfophenylamidosulfates (*transsulfonation products*) were the main products. Increasing temperature led to the formation of ring mono- and disulfonates (*rearrangement products*) at the expense of the transsulfonation products. The sulfonate group always migrated to the *ortho* and/or *para* position(s) to the amino group. In no case was any *meta*-product detected. There was no significant difference in the ease of transsulfonation among the anilinium salts studied except 2,6-dimethyl- and 2,4,6-trimethylanilinium salts. On the other hand, the ease of rearrangement and the orientation of ring sulfonation depended strongly on the structure of the substrate anilines. The thermal reactions of 2,4,6-trimethylanilinium butylamidosulfate produced (2,4,6-trimethylphenylimido)bis(sulfate) in addition to (2,4,6-trimethylphenylamido)sulfate. This is the first isolation of an arylimidobis(sulfate) from such reactions. Mechanisms of the transsulfonation and the rearrangement have been discussed.

Considerable attention has been paid to the chemistry of amidosulfuric acid and its *N*-substituted derivatives in recent years.[2] In particular, rearrangement of arylamidosulfuric acids ($ArNHSO_3H$) to the corresponding ring-sulfonated anilines is of great interest from both mechanistic and preparative viewpoints, because arylamidosulfuric acids have been postulated as intermediates in the sulfonation of aromatic amines with sulfuric acid[3] as well as in the "baking" process.[4-6]

Accordingly we studied the thermal reactions of amine salts of *N*-substituted amidosulfuric acids ($RNHSO_3^-R'NH_3^+$; R=*n*-Bu or *p*-$CH_3C_6H_4$, R'=*n*-Bu or *p*-$CH_3C_6H_4$) and showed[1] that: (1) at lower temperatures (80—120 °C) (4-methylphenylamido)sulfate and 4-methylaniline-*N*,2-disulfonate (transsulfonation products) are the main products; (2) at higher temperatures (120—180 °C) 4-methylaniline-2-sulfonate and 4-methylaniline-2,6-disulfonate (rearrangement products) predominate; and (3) the ease of both transsulfonation and rearrangement[7] depends on the basicity of both the parent amine (RNH_2) and the salt-forming amine ($R'NH_2$). On the basis of these results we proposed a tentative mechanism involving a preequilibrium thermal dissociation into the free acid ($RNHSO_3H$) and the salt-forming amine ($R'NH_2$) followed by a rate-determining nucleophilic attack by $R'NH_2$ on the tetracoordinate sulfur atom of the zwitterionic amidosulfuric acid ($RNH_2^+SO_3^-$) (Scheme 1).



Scheme 1.

In order to obtain a better picture of the mechanism of thermal reaction, we studied the substituent effects both on the ease of transsulfonation and rearrangement and on the orientation of ring sulfonation in a series of methyl-substituted anilinium salts of butylamidosulfuric acid (*n*-$BuNHSO_3^-ArNH_3^+$).

Results and Discussion

Anilinium Butylamidosulfate (1). The thermal reaction of **1** at 100 °C for 8 h produced phenylamidosulfate (**2**) in an 85% yield. Aniline-*N*,4-disulfonate (**3**)[8] was also formed at the temperatures ranging 100—140 °C (Fig. 1). The structure of this new compound, **3**,[9] was unequivocally established by acid hydrolysis; namely, a sulfo-amidosulfate fraction from the reaction of **1** at 115 °C for 8 h gave aniline-4-sulfonic acid on acid hydrolysis. No isomeric aniline-*N*,2-disulfonate (which should give aniline-2-sulfonic

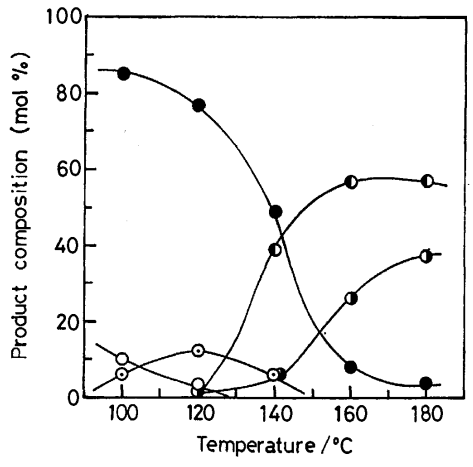


Fig. 1. Thermal reaction of anilinium butylamidosulfate. Reaction time 8 h.
○: *n*-$C_4H_9NHSO_3^-$, ●: $C_6H_5NHSO_3^-$, ◐: $NH_2C_6H_4SO_3^-$, ⊙: $C_6H_4(NHSO_3^-)(SO_3^-)$, ◑: $NH_2C_6H_3(SO_3^-)_2$.

acid on the hydrolysis) was detected on TLC.

The thermal reaction of **1** at 160 °C for 8 h gave a mixture of aniline-2- (**4**) and 4-sulfonate (**5**) (57%)[10] and aniline-2,4-disulfonate (+2,6-disulfonate) (26%);[11] neither **2** nor **3** was detected in the product.

In no run was any evidence obtained for the formation of aniline-3-sulfonic acid (*meta*-compound).

2,3-Dimethylanilinium Butylamidosulfate (6). Thermal reaction of **6** (120 °C, 8 h) gave (2,3-dimethylphenylamido)sulfate (**7**) in an 85% yield (Table 1). The amount of *N*,ring-disulfonate(s) (**8**) was negligibly small. The reaction at 140 °C for 8 h gave a mixture of **7** (13%), **8** (11%), 2,3-dimethylaniline-4-sulfonate (**9**) (27%), 2,3-dimethylaniline-6-sulfonate (**10**) (12%), and 2,3-dimethylaniline-4,6-disulfonate (**11**) (33%).[12]

Reaction of **6** at 160 °C for 8 h produced a mixture of **9** (5%), **10** (32%), and **11** (56%). The structure of **9** was established by direct comparison of its IR spectrum, R_f value (TLC), and melting point with those of an authentic sample prepared umambiguously (see Experimental section).

It is interesting to note here that increasing reaction temperature tends to increase the ratio of **10** : **9** (0.52 : 1 at 140 °C and 1.82 : 1 at 160 °C, respectively[13]).

2,4-Dimethylanilinium Butylamidosulfate (12). The reaction of **12** at 120 °C for 8 h gave (2,4-dimethylphenylamido)sulfate (**13**) in a 93% yield. 2,4-Dimethylaniline-6-sulfonate (**14**)[14] and 2,4-dimethylaniline-*N*,6-disulfonate (**15**) were also formed in small amounts. On the other hand, the thermal reaction of **12** at 160 °C for 8 h gave **14** in a 74% yield, together with **13** and **15**.

2,5-Dimethylanilinium Butylamidosulfate (16). The reaction of **16** at 100 °C for 8 h gave (2,5-dimethylphenylamido)sulfate (**17**) in a 91% yield. In contrast, the reaction at 120 °C for 8 h produced 2,5-dimethylaniline-4-sulfonate (**18**) (43.5%), and 2,5-dimethylaniline-*N*,4-disulfonate (**19**) (16%), together with **17** (32%). The reaction of **16** at 160 °C for 8 h yielded **18** predominantly; isomeric 2,5-dimethylaniline-6-sulfonate was formed in a small quantity (TLC). It should be noted that most of **19** remained unchanged and no trace of 2,5-dimethylaniline-4,6-disulfonate (**20**) was detected even at 160 °C. This fact indicates that the introduction of a sulfonate group into the 6 position of **18** is highly sterically hindered. This position is flanked by an amino and a methyl groups. Moreover, a buttressing effect of both 2-methyl and 4-sulfonate groups is operative (see also under the headings "3,5-dimethylanilinium butylamidosulfate" and "2,4,5-trimethylanilinium butylamidosulfate").

2,6-Dimethylanilinium Butylamidosulfate (21). In marked contrast with any other anilinium salt studied, **21** was thermally very unstable and showed a great tendency to dissociate into 2,6-dimethylaniline and butylamidosulfuric acid (even at room temperature).[15] Evidently this tendency is ascribable to B strain arising from the salt formation.[16]

It is to be expected that transsulfonation of **21** occurs much more readily than that of the other anilinium salts studied, because the transsulfonation of $RNHSO_3^-R'NH_3^+$ is believed to involve a preequilibrium thermal dissociation into the reacting species ($RNH_2^+SO_3^-$) and the substrate amine ($R'NH_2$) followed by a rate-determining transfer of a sulfonate group from $RNH_2^+SO_3^-$ to $R'NH_2$.[1] In fact, heating at 110 °C for as short as 30 min brought about *ca.* 90% transsulfonation.[17] The reaction for 2 h at the same temperature gave a mixture of (2,6-dimethylphenylamido)sulfate (**22**) (66%), 2,6-dimethylaniline-*N*,4-disulfonate (**23**) (21%), 2,6-dimethylaniline-4-sulfonate (**24**) (7%), and as little as 6% of the starting salt **21**. Heating at 110 °C for 8 h gave **24** in a 44% yield, in addition to **22** (38%) and **23** (15%).

When **21** was heated at 160 °C for 8 h, **24** was produced in a 90% yield. **22** disappeared almost completely (only a trace on TLC). No *meta*-isomer, 2,6-dimethylaniline-3-sulfonate, was detected.

Nitration of 2,6-dimethylaniline (**25**) and its *N*-acetyl derivative (**26**) with nitric acid or with mixed acid is known to occur exclusively at the *meta* position.[18] This anomalous behavior has been attributed to the steric inhibition of resonance.[19] The situation, however, is more complex, because bromination of **25** both in hydrobromic acid and in glacial acetic acid and chlorination of **25** in glacial acetic acid have been reported to give the 4-substituted compounds.[20] Bromination of **26** in hydrobromic acid leads to the formation of the 3-bromo derivative, whereas the bromination in glacial acetic acid gives a mixture of the 3- and the 4-isomers.[20]

These facts led us to examine the orientation of sulfonation of **25**. Our experiments showed that the "baking" of 2,6-dimethylanilinium hydrogensulfate in *o*-dichlorobenzene[21] yields **24** as the sole product, while the sulfonation with 25% oleum gave the *meta*-isomer (**27**) as the main product and, in addition, minor amounts of **24** and (a) disulfonic acid(s). **27** was also produced by reaction of **26** with $ClSO_3H$[22] and subsequent hydrolysis of the acetyl group.

The structure of **24** was established both by direct comparison with an authentic material prepared from 2-nitro-4,6-dimethylaniline and by chemical conversion of **24** to 3,5-dimethylbenzenesulfonic acid (see Experimental section).

Unlike the other *N*,ring-disulfonates, **23** failed to give the bis(tetraphenylphosphonium) salt; therefore, **23** was isolated and characterized as the dipotassium salt (Table 5). Its structure was proved by acid hydrolysis to **24**.

3,4-Dimethylanilinium Butylamidosulfate (28). Thermal reaction of **28** at 120 °C for 8 h gave (3,4-dimethylphenylamido)sulfate (**29**) in an 85% yield. Additionally, 3,4-dimethylaniline-*N*,6-disulfonate (**30**) (18%) was formed. No 3,4-dimethylaniline-6-sulfonate (**31**) was detected (TLC).

On the other hand, the reaction at 160 °C for 8 h produced **31** in a high yield. **29** and **30** were also formed in small amounts. No isomeric 3,4-dimethylaniline-2-sulfonate was found in the product.

3,5-Dimethylanilinium Butylamidosulfate (32). When heated at 110 °C for 8 h, anilinium salt **32** readily underwent transsulfonation to give (3,5-dimethylphenylamido)sulfate (**33**) in a 77% yield, but the subsequent rearrangement of **33** to 3,5-dimethylaniline-2-sulfonate (**34**) proceeded with difficulty and incom-

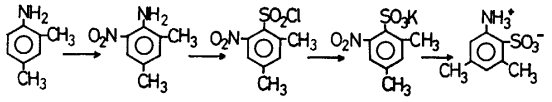
pletely (see Fig. 2). Even after heating of **32** at 180 °C for 8 h, **33** was the main product (54%); 3,5-dimethylaniline-2-sulfonate (**34**) (14%), 3,5-dimethylaniline-*N*,2-disulfonate (**35**) (22%), and 3,5-dimethylaniline-2,6-(?)-disulfonate (a trace amount) were the minor products. The reaction at 200 °C gave rise to considerable decomposition.

It is particularly noteworthy that the sulfonation occurred almost exclusively at the *ortho* position, the *para*-isomer, 3,5-dimethylaniline-4-sulfonate (**36**) being formed in trace amounts.[23)]

These results show that the transfer of the sulfonate group to the aromatic ring is very subject to steric hindrance. Such preferential or exclusive sulfonation at a less hindered *ortho*- or *para*-position (as observed with **16**, **28**, **32**, and **37**) may be explained in terms of the steric requirements of the attacking species.[24)]

To determine the position of the sulfonate group in **34** we carried out the deamination of **34**; thus, diazotization followed by reduction with $NaBH_4$ in methanol gave *m*-xylene-4-sulfonic acid. The structure of **34** was proved additionally by direct comparison with a sample prepared *via* an unambiguous route outlined below:



The structure of **35** was confirmed by acid hydrolysis to **34**.

A fourth component was isolated chromatographically in only a trace. This substance, which had the smallest R_f value on TLC, seemed to be 3,5-dimethylaniline-*N*,4-disulfonate, because this compound underwent hydrolysis on heating with dil HCl to give a spot corresponding to **36**.

2,4,5-Trimethylanilinium Butylamidosulfate (37). This salt, when heated at 130 °C for 4 h, yielded (2,4,5-trimethylphenylamido)sulfate (**38**) in an almost quantitative yield. 2,4,5-Trimethylaniline has one available position *ortho* to the amino group. This position, however, is highly sterically hindered by 1-amino and 5-methyl substituents. In addition there seems to be a "buttressing" effect of 2- and 4-methyl substituents.

In accord with this view, **38** rearranged to 2,4,5-trimethylaniline-6-sulfonate (**39**) with muth difficulty; thus, the thermal reaction of **37** at 160 °C for 8 h gave a mixture of the starting salt **37** (10.5%), **38** (80%), and **39** (9.4%).[25)] There was no evidence of the formation of either (2,4,5-trimethylphenylimido)bis(sulfate) or 2,4,5-trimethylaniline-*N*,6-disulfonate.

2,4,6-Trimethylanilinium Butylamidosulfate (40). This salt had some tendency to dissociate to 2,4,6-trimethylaniline (**41**) and butylamidosulfuric acid (**42**) at room temperature; consequently, **40** readily underwent transsulfonation to give (2,4,6-trimethylphenylamido)sulfate (**43**). Since **41** has no reactive site in the ring, any ring-sulfonated product cannot be formed. Deficiency of substrate amine **41** in the reaction mixture (caused by condensation of **41** on the cool wall of the reaction vessel) led to the formation of a new compound, (2,4,6-trimethylphenylimido)bis(sulfate) (**44**) in yields of 19—23% (Table 1). This is the first example of isolation of an arylimidobis(sulfate) from such reactions. **44** could also be obtained in an almost quantitative yield by fusion of an equimolar mixture of butylammonium (2,4,6-trimethylphenylamido)sulfate **43** and **42** (Scheme 2).[26]

44

Scheme 2.

When the thermal reaction of **40** was carried out in **41** or 1,3,5-trimethylbenzene as reaction medium, the formation of **44** was suppressed.

Mechanistic Considerations. The thermal reactions of amine salts of amidosulfuric acids ($\text{RNHSO}_3^-\text{R'NH}_3^+$) are characterized by the initial thermal dissociation into the free acid (RNHSO_3H) and the salt-forming base (R'NH_2).[27] The degree of dissociation, of course, depends greatly on the basicity of R'NH_2; a decrease in the basicity of R'NH_2 favors the dissociation (Scheme 1).

Transsulfonation. There was no significant difference in the rate of transsulfonation among the anilinium salts examined except 2,6-dimethylanilinium and 2,4,6-trimethylanilinium butylamidosulfates. Evidently, in these two cases relief of B strain favors the dissociation.

It has been proved that free amidosulfuric acids exist as zwitterions ($\text{RNH}_2^+\text{SO}_3^-$) at least in the solid state;[2,28] the zwitterionic form is believed to be the reactive species.[1,2]

There are two possible mechanisms for the transfer of a sulfonate group from the zwitterionic amidosulfuric acid to the substrate amine. One involves rate-determining thermal cleavage of the N–S bond to give the parent amine and SO_3 (Eq. 1), followed by an electrophilic attack of SO_3 on the substrate (Eq. 2). The other involves a bimolecular nucleophilic substitution at the tetracoordinate sulfur atom (Eq. 3).

It should be noted that the transsulfonation occurs in the molten state (*viz.*, non-solvolytic conditions) at such low temperatures that the zwitterion, $n\text{-BuNH}_2^+\text{SO}_3^-$, is quite stable. As an example may be cited the fact that the transsulfonation of 2,6-dimethylanilinium butylamidosulfate (**21**) proceeds very rapidly at 110 °C (90% conversion of **21** occurred in 30 min at this temperature). The *gas-phase* reaction between sulfur trioxide and an amine such as trimethylamine is very exothermic.[29] These two facts suggest that, under "*non-solvolytic*" conditions, the dissociative process may be unlikely, whereas the latter process involving synchronous bond-forming and bond-breaking in the transition state is much more likely from the energetical point of view. It has been reported that *N*-substituted amidosulfate salts undergo acid-catalyzed hydrolysis mostly by an A-2 type mechanism (involving a bimolecular nucleophilic attack of water in the transition state) (Eq. 4).[2] It has also been suggested that the catalytic sulfation of 1-hexadecanol with amidosulfuric acid in the presence of DMF may involve the formation of a DMF–SO_3 complex by an S_N2 mechanism (Eq. 5).[30] Further, the rates of sulfation of eleven alcohols with $n\text{-Bu}_3\text{N}^+\text{–SO}_3^-$ have been measured and an S_N2-type mechanism has been proposed (Eq. 6).[31]

Rearrangement. There are at least three possible mechanisms to be considered for the rearrangement.[32]

(a) Intramolecular Pathway: Any mechanism which does not involve the N–S bond cleavage before a ring-sulfonation, encounters geometrical difficulties; that is, direct transfer of the sulfonate group from the amino nitrogen to the *para*-position of the ring is improbable because of the large distance which would have to be

spanned in the transition state.[33]

In order to account for the intramolecularity of the nitramine rearrangement, Dewar has proposed a π-complex mechanism involving initial cleavage of the N-NO_2 bond, followed by a series of 1,2-shifts *via* π-complex intermediates.[34] The very ready rearrangement of butylammonium (2,6-dimethylphenylamido)-sulfate (**22**) to 2,6-dimethylaniline-4-sulfonate (**24**) could not be accounted for by this scheme, because the migration of the sulfonate group passing through the ring to the *para*-position should be highly sterically hindered (Fig. 3).

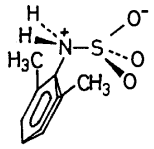

Fig. 3. (2,6-Dimethylphenylamido)sulfuric acid zwitterion.

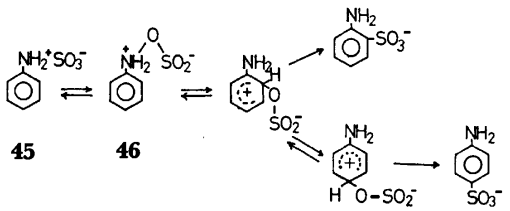
Hughes and coworkers proposed the "cartwheel" mechanism in order to explain the intramolecular migration of the nitro group from the amino nitrogen to the *para*-position in the ring.[35] If a similar mechanism were to operate, the amidosulfuric acid rearrangement could be written as follows:



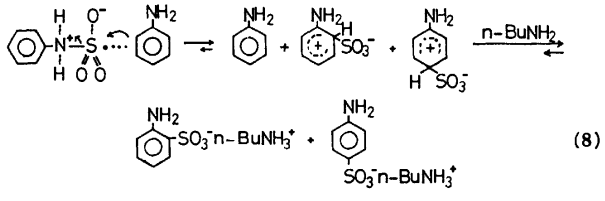
45 **46**

This mechanism seems unlikely from the following reasons. First, there is neither evidence nor analogy for such initial isomerization of **45** to *N*-phenylhydroxylamine-*O*-sulfite (sulfitoamine), **46**.[36] Secondly, **46**, a postulated intermediate in the reaction of *N*-phenylhydroxylamine with SO_2, has neither been isolated nor characterized.

It should be noted that the formation of disulfonated products does not eliminate the possibility of an intramolecular process, because a sulfonate group exchange between an arylamidosulfate and an aniline occurs very rapidly in the presence of the anilinium chloride (Eq. 7).[37]

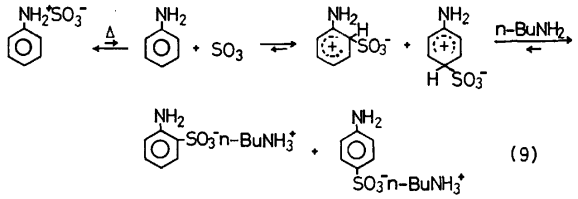
$$ArNHSO_3^- + Ar'NH_2 \overset{H^+}{\rightleftharpoons} ArNH_2 + Ar'NHSO_3^- \quad (7)$$

(b) S_N2*-type Intermolecular Pathway*: A second possible mechanism is an S_N2-type intermolecular pathway involving a nucleophilic attack by a substrate amine at the tetracoordinate sulfur atom of the zwitterion (ligand-exchange) to form (a) σ-complex(es) leading to *ortho* and/or *para* sulfonates (Eq. 8).



(8)

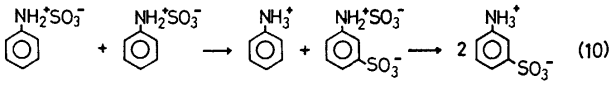
(c) S_N1*-type Intermolecular Pathways*: A third possible mechanism is an S_N1-type intermolecular process, which involves a unimolecular thermal cleavage of the zwitterion, $ArNH_2^+$–SO_3^-, to the substrate aromatic amine ($ArNH_2$) and SO_3 molecule. The latter species attacks at the *ortho*- and/or *para*-position(s) in the substrate (Eq. 9).



(9)

It is well known that, in marked contrast with amidosulfuric acid itself and its *N*-alkyl derivatives, arylamidosulfuric acids are very unstable and have a great tendency to undergo a hydrolytic and thermolytic N–S bond cleavage.[38] Further, it should be emphasized that (a) the composition of the product formed in the rearrangement of anilinium butylamidosulfate (160 °C, 8 h) closely resembled that of the product obtained by heating free phenylamidosulfuric acid, $C_6H_5NH_2^+SO_3^-$, in dioxane at 100 °C for 30 min (in the solid state)[28] and (b) in no case was any *meta*-sulfonated product detected.

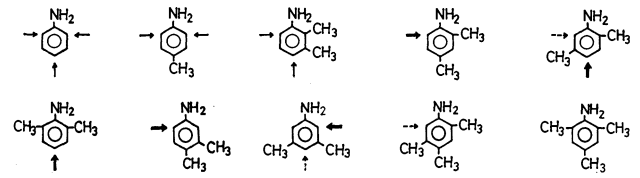
These facts support the S_N1-type intermolecular mechanism (Eq.9). A mechanism whereby the sulfonate group is transferred directly from the amino nitrogen to the *ortho*- and/or *para*-position(s) of another molecule (Eq. 10) is excluded. If this mechanism were operative, one would expect *meta* substitution (positively charged nitrogen).[3]



(10)

We suggested previously[1] that the transsulfonation and the rearrangement may occur concurrently. However, in the present study we have found that the former process proceeds much more rapidly than the latter; therefore, it seems more likely that both processes proceed consecutively.

Orientation of Ring Sulfonation. In marked contrast to the transsulfonation, the rearrangement was very subject to steric hindrance; *viz.*, both the ease and the orientation of the rearrangement were governed by steric factors. Relief of the steric strain around the amido-nitrogen markedly accelerated the rearrangement as observed with 2,6-dimethylanilinium butylamidosulfate. Two methyl substituents *ortho* to the reactive site hindered the introduction of a sulfonate group as observed typically with 3,5-dimethylanilinium butylamidosulfate. Moreover, a buttressing effect of 2- and 4-methyl substituents may operate. Thus, 2,4,5-trimethylanilinium butylamidosulfate underwent transsulfonation as rapidly as the other anilinium salts, but the subsequent rearrangement was very much retarded. The absence of 3,4-dimethylaniline-2-sulfonate in the



→ indicates the position where sulfonation occurs.
➡ indicates the position where sulfonation occurs (almost) exclusively.
⇢ indicates the position where sulfonation occurs to only a small extent.

Fig. 4. The orientation of ring sulfonation.

product of the rearrangement of 3,4-dimethylanilinium butylamidosulfate is also ascribable to this effect.

Formation of N, *Ring-disulfonates.* Deficiency of the substrate aniline caused by the partial condensation of the dissociated amine on the cool part of the reaction vessel gave rise to the formation of disulfonates compounds. Thus, the thermal reaction of **1** gave aniline-*N*,4- (**3**) and 2,4-disulfonates in addition to aniline-2- and 4-sulfonates and phenylamidosulfate (Fig. 1). No trace of the *N*,2-disulfonate was found in the product mixture. In contrast, the same reaction of **32** yielded 3,5-dimethylaniline-*N*,2-disulfonate (**35**), together with (3,5-dimethylphenylamido)sulfate and 3,5-dimethylaniline-2-sulfonate. 4-Sulfonate (**36**) and *N*,4-disulfonate (**47**) were formed in only traces.

There are three possible pathways to an *N*,ring-disulfonate: (1) *N*-sulfonation of a ring monosulfonate (route a); (2) ring sulfonation of an arylamidosulfate (route b); (3) rearrangement of an arylimidobis(sulfate) (route c) which could be formed by the *N*-sulfonation of the corresponding arylamidosulfate (Scheme 3).

The results described above can best be interpreted in terms of route a. The exclusive formation of **3** is accounted for by the preferential *N*-sulfonation of aniline-4-sulfonate. The *N*-sulfonation of aniline-2-sulfonate must be sterically unfavored. If route b were to be followed, **47** should be formed instead of **35**. Formation of **36** and **47** in only traces supports pathway b. Route c is unlikely, because this route is sterically unfavorable as compared with route a.

Scheme 3.

Experimental

General experimental details have been described previously.[1]

Material. *Anilinium Salts of Butylamidosulfuric Acid (**42**)*: These compounds were prepared simply by neutralization of the free acid (**42**) with an appropriate aniline in methanol.[1]

2,6-Dimethylanilinium and 2,4,6-trimethylanilinium salts were prepared as follows and immediately used for the reactions: a large excess of the aniline was added to a methanol solution of **42**; the mixture was evaporated *in vacuo* to give a slurry of the salt. This was filtered, washed with benzene, and dried in a desiccator (Table 2).

Isolation and Identification of the Reaction Products. For details see Ref. 1. *Amidosulfates* were isolated by liquid chromatography (cellulose Whatman CF-11, dioxane-H_2O 4 : 1) or by extraction with EtOH of the product mixtures obtained (as the sodium salts) from the reactions at lower temperatures. The crude amidosulfates thus obtained were readily purified and characterized as the tetraphenylphosphonium salts (Table 3).

a) See footnote a) to Table 3. b) Dipotassium salt. c) Absorptions due to the tetraphenylphosphonium cation are omitted.

Amino-monosulfonic acids were easily isolated by treatment with hydrochloric acid of the sodium salt mixtures obtained from the reactions at higher temperature. These acids were characterized as the hexylammonium or butylammonium salts (Table 4).

Sulfo-amidosulfates (*N*, ring-disulfonates) were isolated by liquid chromatography or by fractional precipitation with $(C_6H_5)_4PCl$ from the disulfonate fractions (obtained as the insoluble residues of the foregoing ethanol extraction). The tetraphenylphosphonium amidosulfates were more soluble in acetone than the bis(tetraphenylphosphonium) *N*, ring-disulfonates; hence, the former salts can readily be removed by washing the precipitate with a small volume of acetone. Disodium 2,6-dimethylaniline-*N*,4-disulfonate could not be converted to the corresponding bis(phosphonium)salt by the double-decomposition method (Table 5).

(2,4,6-Trimethylphenylimido)bis(sulfate) was isolated by liquid chromatography. Isolation was also achieved as follows: the product from the reaction of **40** (2 mmol, 120 °C, 8 h) was dissolved in water and the solution was passed through a column of Dowex 50W (K^+ form). The eluate was evaporated to dryness and the residue was extracted three times with 99.5% ethanol. The residual solid [composed of potassium (2,4,6-trimethylphenylamido)sulfate and dipotassium (2,4,6-trimethylphenylimido)bis(sulfate)] was then dissolved in water (3 ml) containing a few drops of aqueous KOH; to this solution was added 60 ml of hot ethanol with vigorous stirring. The mixture was filtered immediately and the filtrate was left at room temperature overnight. The precipitate was collected by filtration; for further purification this was dissolved in hot water containing a few drops of aqueous KOH, and reprecipitated with hot ethanol, giving the pure *imidobis(sulfate)* as colorless needles (Table 4).

Confirmation of the Structures of the Products Isolated from the Thermal Reactions. Deamination of 2,6-Dimethylaniline-4-sulfonic Acid: The aminosulfonic acid [obtained from the thermal reaction (160 °C, 5 h) of **22**] was deaminated by diazotization followed by reduction with $NaBH_4$ in MeOH (5—10 °C, 5 h),[39] yielding *m*-xylene-5-sulfonic acid; this was converted to the sulfonamide, mp 133—134 °C (lit,[40] 133—134 °C), mixed mp 132—133.5 °C.[41]

Deamination of 3,5-Dimethylaniline-2-sulfonic Acid: The aminosulfonic acid isolated from the thermal reaction (180 °C, 8 h) of **33** was deaminated in the same way as described above. The product was identical with authentic *m*-xylene-4-sulfonic acid;[42] its anilinium salt melted at 203—204 °C (lit,[40] 197—199 °C); mixed mp 202.5—203.5 °C; IR: 1551, 1194 (SO_3^-), 1168, 1089 (SO_3^-), 1018, 833 (2H), 746 (5H), and 680 (5H) cm^{-1}.

Proof of the Constitutions of Aniline-N,4-disulfonate and 3,5-Dimethylaniline-N,2-disulfonate. Disodium aniline-*N*,ring-disulfonate [obtained from the thermal reaction of **2** (110 °C, 8 h)] was hydrolyzed by refluxing for 30 min with dil HCl. After cooling, the mixture was neutralized with $Ba(OH)_2$, filtered, and the filtrate was passed through a column of Amberlite IR-120B (H^+ form). The effluent was evaporated to dryness and the residual solid washed in a minimum quantity of ethanol. The product thus obtained gave a single spot on TLC. Its R_f value and IR spectrum were entirely in agreement with those of authentic aniline-4-sulfonic acid.

In the same manner, acid hydrolysis of disodium 3,5-dimethylaniline-*N*,ring-disulfonate gave 3,5-dimethylaniline-2-sulfonic acid, deamination of which yielded *m*-xylene-4-sulfonic acid.

Preparation of Authentic Compounds. (1) 2,3-Dimethylaniline-4-sulfonic Acid:[43] *Nitration of 2,3-Dimethylacetanilide*:[44,45] To a stirred solution of 2,3-dimethylacetanilide (mp 130—131 °C) (8.0 g) in concd H_2SO_4 (20 ml) was added HNO_3 (d 1.42; 3.3 ml) at 5—10 °C over a period of half an hour. The mixture was poured into ice water (250 ml) and the precipitate was filtered, washed, and dried.

2,3-Dimethyl-4-nitroaniline:[44] The foregoing nitroacetanilide was hydrolyzed by refluxing for 1 h with 60% sulfuric acid (100 ml). The product (6.91 g) was chromatographed on silica gel by use of CCl_4–acetone (15 : 1 v/v) as an eluent. The 4-nitro compound thus obtained was recrystallized from CCl_4; the pure product (2.48 g) melted at 114—115 °C (lit,[46] 115.5—116.5 °C).

2,3-Dimethyl-4-nitro-1-benzenesulfonic Acid: 2,3-Dimethyl-4-nitroaniline (2.2 g) was diazotized in the usual way and the excess of nitrous acid was destroyed with NH_2SO_3H. The mixture was poured in one portion into a cold, saturated solution of SO_2 (8.7 g) in CH_3COOH to which a solution of $CuCl_2$ (0.37 g) in water (0.80 ml) had been added. The

temperature was raised gradually to 40 °C. The mixture was stirred for 1 h at this temperature, then poured into water (150 ml), and neutralized carefully with a $NaHCO_3$ solution; the oily layer was extracted twice with benzene and the extract was washed with aqueous $NaHCO_3$, dried, and concentrated *in vacuo* to give the crude sulfonyl chloride. A mixture of the sulfonyl chloride, 50% aq MeOH (15 ml), and Na_2CO_3 (0.60 g) was boiled for 1 h. The reaction mixture was evaporated and the residual solid was dissolved in water (10 ml), filtered, and evaporated to dryness. The residue was again dissolved in methanol (35 ml). After filtration, the filtrate was concentrated to give the *sodium nitro-sulfonate*. IR: 1517 (NO_2), 1356 (NO_2), 1178 (SO_3^-) 1067 (SO_3^-), 1039, 828(2H), 802, and 663 (SO_3^-) cm^{-1}; *S*-(1-naphthylmethyl)isothiouronium salt, mp 222—222.5 °C.

2,3-Dimethylaniline-4-sulfonic Acid: The crude nitrosulfonate was reduced with activated iron powder (2.5 g). Work-up in the usual way gave the pure *sulfonic acid* as needles; IR: 1503, 1206 (SO_3), 1082, 1052 (SO_3), 818 (2H), and 695 cm^{-1}. Found: S, 14.58%. Calcd for $C_8H_{11}NO_3S \cdot H_2O$: S, 14.62%. The *hexylammonium salt* (from EtOH–AcOEt 1 : 2) melted at 138.5—139.5 °C. Found: S, 10.51%. Calcd for $C_{14}H_{26}N_2O_3S$: S, 10.60%.

(2) 2,5-Dimethylaniline-4-sulfonic Acid: Treatment of 2,5-dimethylacetanilide (mp 138—139 °C, 1.0 g) with $ClSO_3H$ (4.2 ml) (80 °C, 1 h)[47] and subsequent recrystallization from C_6H_6–AcOEt(1 : 1) gave N-*acetyl-2,5-dimethylaniline-4-sulfonyl chloride* (0.55 g); mp 159—160 °C (lit, [47]160 °C), IR: 1660 (CO), 1560 (NH_3^+), 1360 (SO_2), 1275, 1121 (SO_2), 895 (1H), and 829 cm^{-1}.

A mixture of the sulfonyl chloride (0.30 g), ethanol (1 ml), and concd HCl (5 ml) was refluxed for 1h. After cooling the *sulfonic acid* was collected and recrystallized from H_2O. IR: 1219, 1083, 1055, 900, and 873 cm^{-1}. Its *hexylammonium salt* melted at 178.5—179.5 °C. Found: S, 10.52%. Calcd for $C_{14}H_{26}O_3N_2S$: S, 10.60%. The sulfonic acid was converted to its sodium salt, which was then refluxed for 1 h with Ac_2O in pyridine to give the N-*acetyl derivative*. Its p-*toluidinium salt* melted at 232—233 °C. The same *N*-acetylated sulfonic acid was also prepared according to Junghahn's procedure.[48]

(3) 2,6-Dimethylaniline-3-sulfonic Acid: This acid was prepared by two methods.

(a) Sulfonation of 2,6-Dimethylaniline with Oleum: To 25% oleum (32 ml) was added, drop by drop, 2,6-dimethylaniline (5.1 ml) and the mixture was heated for 4 h at 80—90 °C. The reaction mixture was poured on cracked ice and neutralized with $BaCO_3$. After removal of $BaSO_4$ the filtrate was concentrated and treated with concd HCl (5 ml), giving the 3-sulfonic acid in a 30% yield. IR: 1607, 1185 (SO_3^-), 1044 (SO_3^-), 822 (2H), 741, and 694 cm^{-1}.

(b) Chlorosulfonylation of 2,6-Dimethylacetanilide.[49] To ice-cooled $ClSO_3H$ (18.69 g) was added the acetanilide (3.00 g) with stirring. The mixture was stirred at 5 °C for 15 min, then at 25 °C for 1 h, and finally at 40 °C for 10 min, and poured on cracked ice, yielding the *sulfonyl chloride*. IR: 3290 (NH), 1665 (CO), 1505, 1367 (SO_2), 1202, 1168 (SO_2), and 814 (2H) cm^{-1}. The sulfonyl chloride was treated with concd ammonia, giving N-*acetyl-2,6-dimethylbenzene-3-sulfonamide*. Recrystallization from water gave the pure sulfonamide; mp 263—264 °C. IR: 3345 (NH), 3235 (NH), 1638 (CO), 1327 (SO_2), 1120 (SO_2), and 810 (2H) cm^{-1}. The foregoing sulfonyl chloride was heated under reflux with concd HCl for 1 h to give the *3-sulfonic acid*.

(4) 2,6-Dimethylaniline-4-sulfonic Acid: This acid was prepared by "baking" 2,6-dimethylanilinium hydrogensulfate in *o*-dichlorobenzene (180 °C, 6 h).[21,51] No isomeric 3-sulfonic acid was detected. IR: 1618, 1529, 1438, 1222, 1190, 1154, 1111, 1045 (SO_3^-), 883 (1H), and 723 cm^{-1}.

(5) 3,4-Dimethylaniline-6-sulfonic Acid: This acid was prepared in a 76% yield by baking 3,4-dimethylanilinium hydrogensulfate in *o*-dichlorobenzene (171—175 °C, 3 h).[43,51,52] IR: 1603, 1553, 1502, 1258, 1167 (SO_3^-), 1048 (SO_3^-), 880 (1H), 787, 732, and 660 cm^{-1}.

(6) 3,5-Dimethylaniline-2-sulfonic Acid: This compound was prepared by three different methods.[43] *(a) Synthesis* via *2,4-Dimethyl-6-nitroaniline*: The procedure was almost the same as that for the synthesis of 2,3-dimethylaniline-4-sulfonic acid. 2,4-Dimethyl-6-nitroacetanilide, mp 171.5—172.8 °C (from H_2O) (lit,[53] 172 °C); 2,4-dimethyl-6-nitroaniline, mp 67—68 °C (from CCl_4) (lit,[54] 67—68 °C); potassium 4,6-dimethyl-2-nitrobenzene-1-sulfonate, IR; 1529 (NO_2), 1377 (NO_2), 1208 (SO_3^-), 1093, 1032 (SO_3^-), 852 (1H), and 773 cm^{-1}; 3,5-dimethylaniline-2-sulfonic acid (from H_2O), IR: 1200 (SO_3^-), 1162, 1123, 1087, 1015 (SO_3^-), 866 (1H), and 683 (SO_3^-) cm^{-1}; p-*toluidinium* N-*acetyl-3,5-dimethylaniline-2-sulfonate* melted at 180.5—181.5 °C (from H_2O), IR; 1662 (CO), 1580 (amide), 1322, 1184 (SO_3^-), 1082, 1017 (SO_3^-), 858 (1H), and 806 (2H). *(b) Sulfonation of 3,5-Dimethylaniline with 100% Sulfuric Acid*: Sulfonation of 3,5-dimethylaniline (2.5 g) with 100% H_2SO_4 (3.0 g) (170 °C, 1 h) gave almost exclusively the *2-sulfonic acid* (TLC, IR).[55] *(c) Sulfonation of 3,5-Dimethylaniline with Chlorosulfuric Acid*: Sulfonation of 3,5-dimethylaniline (2.0 g) with $ClSO_3H$ (3.25 g) in 1,1,2,2-tetrachloroethane (150 °C, 45 min)[56] also gave the *2-sulfonic acid* as the main product, together with the 4-sulfonic and 2,6-(?)-disulfonic acids.

(7) 3,5-Dimethylaniline-4-sulfonic Acid: This acid was prepared by chlorosulfonation of 3,5-dimethylacetanilide.[57] The sulfonyl chloride obtained was moderately soluble in water unlike the normal sulfonyl chlorides and considerably susceptible to hydrolysis. Accordingly, this chloride was immediately converted to the corresponding *sulfonamide*, which melted at 230—231 °C after repeated crystallization from dil alcohol. IR: 3245 (NH), 1660 (C=O), 1593 (NH), 1543, 1319 (SO_2), 1150 (SO_2), 872, 850, and 740 cm^{-1}.

The sulfonyl chloride was subjected to hydrolysis with aqueous K_2CO_3 (100 °C, 1 h), followed by acidification to give the *4-sulfonic acid*. IR: 1476, 1242 (SO_3^-), 1148, 1118, 1080, 1003 (SO_3^-), 860 (1H), and 680 (SO_3^-) cm^{-1}; the butylammonium salt melted at 168.5—170 °C.

*Formation of (2,4,6-Trimethylphenylimido)bis(sulfate) (**44**) by Reaction of (2,4,6-Trimethylphenylamido)sulfate (**43**) with Butylamidosulfuric Acid (**42**).* An intimate mixture of **43** (0.56 g) and **42** (0.30 g) was heated at 120 °C for 4 h in an evacuated tube; the product was dissolved in aqueous KOH. The solution was evaporated to dryness; the residual solid was dissolved in hot water (8 ml) containing two drops of aqueous KOH. This solution was added, with vigorous stirring, to boiling 99.5% ethanol (100 ml). The precipitated crystals were collected, and dried. Its IR spectrum was completely in accord with that of the material isolated from the thermal reaction of **40**.

22) British Patent 1027060; *Chem. Abstr.*, **65**, 10905h (1966).
23) Sulfonation of 3,5-dimethylaniline with 100% H_2SO_4 and with $ClSO_3H$ also gave the 2-sulfonic acid almost exclusively (see Experimental section). A similar *ortho*-sulfonation of 3,5-dimethylphenol has been reported (F. Raschig, D. R. P. 283306; *Chem. Zentral.*, **1915 I**, 926).
24) Nitration of 3,5-dimethylaniline with mixed acid has been reported to give the 2- and 4-nitro compounds in yields of 55 and 24%, respectively [B. M. Wepster and P. E. Verkade, *Recl. Trav. Chim. Pays-Bas*, **68**, 88 (1949)]. Further, nitration of 3,5-dimethylanisole with nitric acid in $HClO_4$ has been reported to give *ca.* 1 : 1 mixtures of the 2- and 4-nitro isomers [R. B. Moodie, K. Schofield, and P. N. Thomas, *J. Chem. Soc., Perkin Trans. 2*, **1978**, 318]). In the present rearrangement the reacting species is probably SO_3, which is much larger than the species, NO_2^+, involved in nitration.
25) Paal and Hubalek have reported that (2,4,5-trimethylphenylamido)sulfuric acid as well as its ammonium salt did not rearrange to **39** at the temperatures up to 250 °C [C. Paal and M. Hubalek, *Ber.*, **50**, 1110 (1917).]. To the contrary a German patent claims that **39** is obtained by treatment of 2,4,5-trimethylaniline with an equimolar amount of $ClSO_3H$ in *o*-dichlorobenzene [I. G. Farbenindustrie A–G., DRP 541258; *Chem. Zentral.*, **1931 II**, 2057; *Chem. Abstr.*, **26**, 1942 (1932).]. It has been reported that *N*-bromo-2,4,5-trichloroacetanilide does not undergo the Orton rearrangement [M. J. S. Dewar and J. M. W. Scott, *J. Chem. Soc.*, **1957**, 1445.].
26) Diammonium imidobis (sulfate) is readily prepared by fusion of $NH_2SO_3NH_4$ or of an equimolar mixture of NH_3^+-SO_3^- and $NH_2SO_3NH_4$ [H.H. Sisler and L. F. Audrieth, *Inorg. Synth.*, Vol. II, 179 (1946)].
27) In the present experiment all of the anilinium salts melted in a few minutes at the reaction temperatures. Immediately after the reaction had started, the substrate amine ($ArNH_2$) was released and refluxed briskly. This refluxing subsided in 20—30 min.

X-Ray Crystallographic Studies on the Structure of Alnuserrudiolone Isolated from the Male Flowers of *Alnus serrulatoides*

Toshifumi HIRATA, Tadashi AOKI, and Takayuki SUGA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received March 23, 1981)

The structure of alnuserrudiolone was corroborated to be (12*R*,20*S*)-12,20-dihydroxy-24-methylenedammaran-3-one by the X-ray crystallography together with the ^{13}C NMR and the high resolution mass spectral measurements.

In connection with biochemical and physiological studies of pollination,[1] we investigated chemical constituents of the male flowers of *Alnus serrulatoides* CALL. (Japanese name: Kawara-hannoki) and reported the isolation and the structure elucidation of new C_{31} dammarane-type triterpenoids, alnuserol,[2] alnuseric acid,[3] and alnuselide.[3] In advance of these reports, the isolation of a new C_{31} dammarane-type triterpenoid, alnuserrudiolone, had been communicated, and structure (**1**) had been proposed to this triterpenoid on the basis of chemical and spectroscopic studies.[4] The structure has a feature of C_{31} dammarane-type triterpenoid having an acyclic side chain, in contrast to the above-described triterpenoids with the side chain including a tetrahydrofuran ring. It is, however, considered essential to establish the skeletal structure of **1**, because **1** has not been yet related to any compound having the well-defined structure. We, therefore, studied the structure of alnuserrudiolone by the X-ray crystallographic method together with the ^{13}C NMR and the high resolution mass spectral measurements.

2: R_1=H_2, R_2=O

4: R_1=H_2, R_2= 
Results and Discussion

The male flowers of *Alnus serrulatoides* CALL. grown naturally on a river side were collected just before the flowering and immersed in acetone. An ether-soluble fraction of the acetone extract was subjected to chromatography using silica gel to give the sample of alnuserrudiolone (**1**), which showed completely the same physical (mp and optical rotation), spectral (IR, ^1H NMR, MS, and ORD) properties, and chemical behaviors as described previously.[4]

The acyclic side chain and functional groups characteristic of the previously-proposed structure (**1**) were first corroborated by measurement of ^{13}C NMR and high resolution mass spectra. Comparison of the ^{13}C NMR chemical shifts of **1** with those of the dammarane-type derivatives[2,5] indicated that **1** possesses a dammarane-type skeleton with a carbonyl group at the 3-position (δ_c 217.8), a secondary hydroxyl group on C-12 (δ_c 70.5), and a tertiary hydroxyl group on C-20 (δ_c 73.6). The last two signals showed that the chirality at C-12 and C-20 is *R* and *S*, respectively.[5] On the other hand, the signals at δ_c 156.5 and 106.2 indicated the presence of an acyclic side chain with a terminal methylene on C-24. This was further supported by the high resolution mass spectrum, which exhibited ions characteristic of such an acyclic side chain at *m/z* 141.1280 and 123.1279,[4,6,7] together with an ion derived from the 3-keto dammarane-type skeleton at *m/z* 205.1603.[6]

a) $B_{eq}=8\pi^2(U_1+U_2+U_3)/3$, where U_1, U_2, and U_3 are the principal components by U matrix.

The structure (**1**) for alnuserrudiolone was finally established by X-ray crystallography of a 3-deoxo-12-keto derivative (**2**) and a 31-bromo derivative (**3**) derived from **1**, because a good single crystal of **1** is not available. Huang-Minlon reduction of **1** gave a 3-deoxo compound (**4**), which could be converted to the 3-deoxo-12-keto derivative (**2**) by the Jones oxidation. The structure of **2** was determined by the direct method using MULTAN[8] and refined by full-matrix least-squares techniques to R=0.105 for 1876 reflections. Final atomic coordinates, bond lengths, and bond angles are given in Tables 1—3. A perspective view of the molecule of **2** is shown in Fig. 1. Since the ORD and the CD curves of **2** exhibited a negative Cotton effect similar to that of 3β-acetoxy-20-hydroxydammaran-12-one,[9,10] the absolute configuration is as given in **2**.

Bromination of **1** was carried out with pyridinium tribromide[11] with a view to preparing the bromo derivative of **1** for an X-ray crystallographic study. However, when **1** was treated with the above reagent,

the bromination took place with the cyclization of the acyclic side chain of **1**. The presence of the brominated side chain including a tetrahydrofuran ring was evidenced by the high resolution mass spectrum, which exhibited ions at m/z 491.2332, 489.2344, and 139.1104. The ^{13}C NMR signals at δ_c 88.2, 87.5, and 32.9 also demonstrated the presence of the tetrahydrofuran ring[2,3] with a bromomethyl group on C-24. On the other hand, comparison of the high resolution mass and the ^{13}C NMR spectra of the bromo derivative (**3**) with those

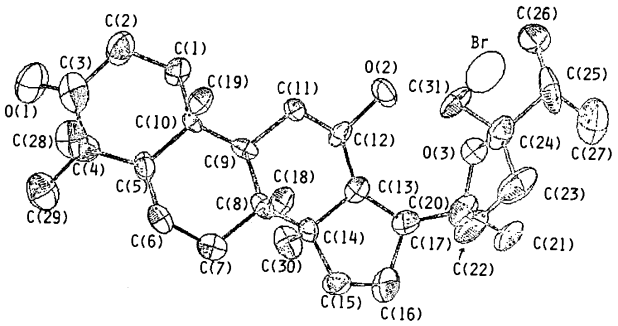

Fig. 2. Perspective view of **3**.

of **1** suggested that **3** possesses the same tetracyclic skeleton as **1**. Further, the bromo derivative (**3**) was confirmed to be convertible into **1** in a quantitative yield by treatment with zinc dust in acetic acid. The structural elucidation of **3** was carried out by X-ray crystallography using the heavy atom method. Refinement by least-squares calculation gave a final R value of 0.075 for 1707 reflections. Final atomic coordinates, bond lengths, and bond angles are shown in Tables 4—6. A perspective view of the molecule of **3** is shown in Fig. 2. The ORD and CD curves of **3** exhibited a positive Cotton effect, which indicated the absolute configuration to be as shown in **3**.

From the spectroscopic evidence of **1** and the X-ray crystallographic results of **2** and **3** derived from **1**, it has now been established that alnuserrudiolone is (12*R*,20*S*)-12,20-dihydroxy-24-methylenedammaran-3-one (**1**).

Experimental

The ^{1}H NMR spectra were taken on a Varian T-60 spectrometer using TMS as an internal standard. The ^{13}C NMR spectra were obtained on a JEOL JNM FX-60 (15.1 MHz) and a Hitachi R-42 FT NMR (22.6 MHz) spectrometers (δ_{TMS}=0). The ORD and the CD curves were taken on a JASCO ORD/UV-5 spectropolarimeter, equipped with a circular dichroism attachment, at 25 °C. The X-ray intensity data were collected on a syntex R3 and a Rigaku AFC-5 diffractometers using graphite-monochromated radiation.

Extraction and Isolation. The male flowers (10.3 kg) of *Alnus serrulatoides* Call. Grown naturally on a river side in the suburbs of Hiroshima city were collected just before the flowering in December, 1975. The flowers, after minced mechanically, were immersed in acetone (54 l) at room temp for 2 months. Removal of the solvent from the acetone solution gave a viscous sirup, which was extracted with ether (500 ml×5) to give a viscous oil (66.0 g). A part (7.0 g) of the viscous oil was subjected to centrifugal chromatography using silica gel (160 g) and a hexane–EtOAc mixture with EtOAc increasing 0 to 100% as a solvent, and then to preparative TLC (silica gel GF_{254}; 0.75 mm thick) with hexane–EtOAc (7 : 3 v/v) to give alnuserrudiolone (**1**) (1.27 g; R_f 0.20).

Alnuserrudiolone (1). Mp 174—175 °C; $[\alpha]_D^{25}$ +50.7° (c 0.61, $CHCl_3$); IR (0.005 M,† CCl_4) ν_{max} 3613 (free OH), 3432 (intramolecularly hydrogen-bonded OH), 1708 (C=O), 3082 and 1638 cm^{-1} (>C=CH$_2$); ^{1}H NMR ($CDCl_3$) δ=0.90—

† 1 M=1 mol dm^{-3}.

Huang-Minlon Reduction of 1. A mixture of **1** (200 mg), hydrazine hydrate (3 ml), and diethylene glycol (30 ml) was refluxed for 2 h to give a 3-deoxo compound (**4**) (157 mg): mp 167—168 °C; $[\alpha]_D^{25}$ +10.7° (*c* 0.56, $CHCl_3$); IR (0.0004 M, CCl_4) ν_{max} 3649, 3431 (OH), and 3081 cm^{-1} (>C=CH$_2$); ^{1}H NMR ($CDCl_3$) δ=3.64 (1H, br, >CH–OH), 4.73 (2H,br, >C=CH$_2$).

Found: C, 81.35; H, 12.16%. Calcd for $C_{31}H_{54}O_2$: C, 81.16; H, 11.87%.

Jones Oxidation of 4. The Jones reagent[12] (2 ml) was added to a solution of **4** (150 mg) in acetone (30 ml), followed by stirring for 1 h at 5 °C, to yield a 3-deoxo-12-keto derivative (**2**) (114 mg): mp 195—197 °C; $[\alpha]_D^{25}$ +44.3° (*c* 0.70, $CHCl_3$); IR (0.0002 M, CCl_4) ν_{max} 3652, 3452 (OH), 1702, 1689 (C=O), and 3083 cm^{-1} (>C=CH$_2$); ^{1}H NMR ($CDCl_3$) δ=4.73 (2H, br, >C=CH$_2$); MS (70 eV) *m/z* (rel. int.) 456 (M^+, 16), 438 (M−H_2O, 55), 359 (88), 315 (49), 191 (85), 141 (44), 124 (100), 123 (73); ORD (*c* 0.23, dioxane) $[\phi]_{600}$ +97°, $[\phi]_{589}$ +97°, $[\phi]_{309}$ −1069°, $[\phi]_{295}$ 0°, $[\phi]_{260}$ +3645°; CD (*c* 0.22, dioxane) $[\theta]_{318}$ 0, $[\theta]_{287}$ −1980, $[\theta]_{244}$ 0.

Found: C, 81.48; H, 11.30%. Calcd for $C_{31}H_{52}O_2$: C, 81.52; H, 11.48%.

Conversion of 1 to a Bromo Derivative (3). Pyridinium tribromide (264 mg)[11] was added to a warmed solution (55 °C) of **1** (300 mg) in EtOH (7.7 ml) and then the mixture was stirred for 1 min. After removal of the solvent, the reaction mixture was subjected to preparative TLC [silica gel GF_{254}; EtOAc–hexane (3 : 7 v/v); developed continuously for 3 h] to give a bromo derivative (**3**) (146 mg): mp 174—176 °C; $[\alpha]_D^{25}$ +33.5° (*c* 0.82, $CHCl_3$); IR (Nujol) ν_{max} 3329 (OH) and 1731 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=3.53 (2H, d, *J*=2.5 Hz, –CH_2Br); ^{13}C NMR ($CDCl_3$) δ_c=217.8 (d, C-3), 88.2 (s, C-24), 87.5 (s, C-20), 70.6 (s, C-12), 32.9 (t, C-31), 28.6 (q, Me), 26.7 (q, Me), 21.0 (q, Me), 18.0 (q, Me×2), 17.3 (q, Me), 16.2 (q, Me), 15.4 (q, Me); MS (70 eV) *m/z* 491.2332 (Calcd for $C_{28}H_{42}O_2Br$: 491.2347), 489.2344 ($C_{28}H_{42}O_2Br$: 489.2367), 205.1571 ($C_{14}H_{21}O$: 205.1591), 139.1104 ($C_9H_{15}O$: 139.1122), 43.0539 (C_3H_7: 43.0547); ORD (*c* 0.38, dioxane) $[\phi]_{600}$ +204°, $[\phi]_{589}$ +204°, $[\phi]_{317}$ +1750°, $[\phi]_{312}$ +1640°, $[\phi]_{308}$ +1714°, $[\phi]_{292}$ 0°, $[\phi]_{276}$ −985°, $[\phi]_{246}$ −79°; CD (*c* 0.38, dioxane) $[\theta]_{320}$ 0, $[\theta]_{292}$ +1224, $[\theta]_{264}$ 0.

Found: C, 67.24; H, 9.46%. Calcd for $C_{31}H_{51}O_3Br$: C, 67.60; H, 9.43%.

Conversion of 3 to 1. A suspension of **3** (8 mg) and Zn powder (5 mg) in ether (3 ml) and acetic acid (0.5 ml) was refluxed for 3 h at room temp. The reaction mixture was diluted with water and extracted with ether to give a crude product (6 mg), which was then purified by preparative TLC [silica gel GF_{254}; EtOAc–hexane (3 : 7 v/v)] to afford alnuserrudiolone (**1**) (mp 171—173 °C; direct comparison with mixed mp, ^{1}H NMR, and MS).

X-Ray Crystallographic Analyses. (i) 3-Deoxo-12-keto Derivative (2). The crystal used was about 0.7 mm×0.5 mm×0.05 mm in size. Cell dimensions were obtained by least-squares calculations from 2θ values of 15 well-centered, resolved Cu $K\alpha$ diffraction peaks. Crystal data: monoclinic, space group $P2_1$, two molecules per unit cell with dimensions a=7.629(5), b=10.438(5), c=17.714(6) Å, β=90.84(4)°; U=1410.4 Å^3; D_c=1.08 g cm^{-3}; D_m=1.12 g cm^{-3}; μ(Cu $K\alpha$)=4.30 cm^{-1}. A total of 2506 reflections were collected on an automatic four-circle diffractometer by the 2θ-ω scan method (θ_{max}=70°); 1876 reflections with intensities greater than 2.0 times the standard deviations were used in the structure determination. The phases of 456 strong reflections with $|E|>1.30$ were determined by the direct method, by the use of the program MULTAN.[8] The *E* map for the best solution yielded positions for all non-hydrogen atoms. The structure was refined by full-matrix least-squares methods. Anisotropic refinement for carbon and oxygen atoms reduced the *R* index to 0.105.

(ii) 3l-Bromo Derivative (3). The crystal used was about 0.2 mm×0.3 mm×0.6 mm in size. Cell dimensions were obtained by least-squares calculations from 2θ values of 14 well-centered, resolved Mo $K\alpha$ diffraction peaks. Crystal data: orthorhombic, space group $P2_12_12_1$, four molecules per unit cell with dimensions a=7.991(3), b=11.610(9), c=31.214(21) Å; U=2898.2 Å^3; D_c=1.26 g cm^{-3}; D_m=1.21 g cm^{-3}; μ(Mo $K\alpha$)=15.3 cm^{-1}. A total of 2702 reflections were collected by using the ω-scan technique (θ_{max}=60°); 1707 reflections with intensities greater than 1.96 times the standard deviations were used in the structure determination. The bromine atom position was obtained from a Patterson function, and then the positions of oxygen and carbon atoms were determined by difference-Fourier syntheses. A least-squares refinement using anisotropic temperature factors for bromine, carbon, and oxygen atoms and isotropic ones for hydrogen atoms reduced the *R* index to 0.075.

The complete F_o-F_c data and the tables of anisotropic thermal parameters for **2** and **3** are deposited as Document No. 8151, respectively, at the Office of the Editor of the Bulletin of the Chemical Society of Japan.

The authors thank Mr. Akio Wada of JASCO Instruments Co. Ltd. for useful advice for the X-ray crystallographic analyses and JEOL Co. Ltd. for obtaining the ^{13}C NMR spectra. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 354189 (1978, to T.A.) from the Ministry of Education, Science and Culture and Matsunaga Science Foundation in 1977 (to T.H.).

Intramolecular Interactions between a Group Bearing *n*-Electrons and a CH_2-X Where X is an Electronegative Group[1)]

Giichi Izumi, Gaku Yamamoto, and Michinori Ōki*

(Received April 17, 1981)

Conformational equilibrium of 9-(2-acyloxyethyl)-1,4-dimethoxytriptycenes in chloroform-*d* suggests that the stability of the $\pm sc$ conformation increases as the electronegativity of the acyl group increases. The results together with other pertinent data are discussed from the stand point that there is an attractive interaction between the acyloxymethyl and the methoxyl groups in proximity. Reflecting its high ionization potential, the chloro group in 1-position showed no stabilization of the $\pm sc$ conformation, although mass spectra and some chemical properties indicate that there is an interaction between the chloro group and highly electronegative CH_2X group. A possible correlation of these results with the incipient transition state for S_N2 reactions is suggested.

During the course of investigations on the reactivity-conformation correlations, we have encountered a striking difference in reactivities of 1,2,3,4-tetrachloro-9-(2-chloro-1,1-dimethylethyl)triptycene rotamers: the $\pm sc$ conformation reacted in the presence of titanium tetrachloride to afford Friedel-Crafts cyclization products, whereas the *ap* conformation remained intact under the conditions.[2)] The results suggest that there may be a kind of interaction between the CH_2–Cl group in the substituent at the bridgehead and the chloro group in the peri-position: the peri-chloro group stabilizes the transition state by delocalizing the partially developed positive charge on the carbon atom of the CH_2–Cl group. Although this phenomenon is concerned with the transition state of the reaction, the ground state of the molecule may be stabilized as well if we consider a charge-transfer interaction between the *n*-electrons of the chloro group and the σ^* orbital of the CH_2–Cl group.

Since we have succeeded in detecting the attractive interactions of *n*-electron-phenyl[3)] and *n*-electron-carbonyl[4)] in triptycene systems by looking at the population ratios of rotamers, we thought the same technique may be applied to the present case to diagnose the presence or absence of the interaction involving the CH_2–Cl group and a group carrying a lone pair of electrons. At the outset, it was thought that the attractive interaction could easily be observed if the group in 1-position of the triptycene system had a low ionization potential. Thus we first attempted to synthesize 9-(2-chloroethyl)-1,4-dimethoxytriptycene from the corresponding alcohol and thionyl chloride and observed that the treatment afforded only a cyclized product:[5)] it seemed that the interaction between a CH_2–Cl (or possibly the corresponding ion pairs) and a methoxyl group in this system was so strong that it caused a reaction. The results suggest that if we wish to find interactions instead of reactions, we should use a combination of a weaker electron acceptor than the CH_2–Cl group and a methoxyl group or that of CH_2–Cl group and a weaker electron donor than the methoxyl. Our choice was acyloxymethyl groups instead of the CH_2–Cl in combination with the methoxyl because the electronegativities and consequently the electron-accepting power of the former group can be easily modified by changing the acyl group. This paper reports the results of such investigations together with those of the interaction between a chloro group and a CH_2–X where X is either a chloro or a *p*-toluenesulfonyloxyl group.

Syntheses of the compounds were straightforward. 9-(Formylmethyl)-1,4-dimethoxytriptycene or 1,2,3,4-tetrachloro-9-(formylmethyl)triptycene was reduced to the corresponding alcohol (**1** and **11**). They were converted to esters by ordinary methods or to chloride by treatment with thionyl chloride.

Experimental

^1H NMR spectra were measured on a Hitachi R-20B spectrometer equipped with a temperature variation accessory. The temperature was read by the chemical shift differences of methanol protons. High resolution mass spectra were recorded on a JEOL JMS-D300 spectrometer.

*9-(2-Hydroxyethyl)-1,4-dimethoxytriptycene (**1**).* To a boiling solution of 1.3 g (3.7 mmol) of 9-(formylmethyl)-1,4-dimethoxytriptycene[4)] in 20 mL of dichloromethane and 20 mL of methanol, 0.5 g (13 mmol) of sodium tetrahydridoborate in 20 mL of methanol was added in 15 min. The mixture was heated for additional 30 min and evaporated. The residue was treated with dilute hydrochloric acid and extracted with dichloromethane. The alcohol, mp 220.8—221.5 °C, was obtained in 95% yield. Found: C, 80.30; H, 6.01%. Calcd for $C_{24}H_{22}O_3$: C, 80.42; H, 6.19%. ^1H NMR ($CDCl_3$, δ): 2.00 (1H, m), 3.50 (2H, t, J=7 Hz), 3.68 (3H, s), 3.77 (3H, s), 4.20 (2H, t, J=7 Hz), 5.88 (1H, s), 6.50 (2H, s), 6.80—7.70 (8H, m).

*1,2,3,4-Tetrachloro-9-(2-hydroxyethyl)triptycene (**11**),* mp 251—252 °C, was similarly prepared by sodium tetrahydridoborate

reduction of 1,2,3,4-tetrachloro-9-(formylmethyl)triptycene.[4] High resolution MS (M^+): 433.9798, 435.9763, 437.9694, and 439.9718. $C_{22}H_{14}OCl_4$ requires 433.9799, 435.9770, 437.9740, and 439.9708. The intensities of these observed M^+ peaks agreed well with those calculated from the natural abundance of ^{35}Cl and ^{37}Cl.

1,4-Dimethoxy-9-(2-methoxyethyl)triptycene (2). To a solution of 0.5 g (1.4 mmol) of 9-(2-hydroxyethyl)-1,4-dimethoxytriptycene (**1**) in 30 mL of tetrahydrofuran, was added 0.2 g (8 mmol) of sodium hydride which had been washed with hexane. The mixture was stirred for 1 h and then 0.5 mL (0.8 mmol) of methyl iodide was added to the mixture. Stirring was continued in a sealed system for 24 h and the solvent was evaporated. The residue was treated with dilute hydrochloric acid and extracted with dichloromethane. Evaporation of the solvent followed by recrystallization of the residue from benzene–hexane afforded the desired compound, mp 226—227 °C, in 92% yield. Found: C, 80.91; H, 6.66%. Calcd for $C_{25}H_{24}O_3$: C, 80.62; H, 6.49%. ^1H NMR ($CDCl_3$, δ): 3.45 (3H, s), 3.66 (3H, s), 3.74 (3H, s), *ca.* 3.5 (2H), 3.98 (2H, br t), 5.88 (1H, s), 6.46 (2H, s), 6.80—7.70 (8H, m).

Esters of 9-(2-Hydroxyethyl)-1,4-dimethoxytriptycene. A general procedure is given for acetylation. The other compounds were similarly prepared from the alcohol and acyl chloride except trifluoroacetate, in the preparation of which the acid anhydride was used.

A mixture of 0.6 g of the alcohol and 0.2 mL of acetyl chloride in 3 mL of pyridine was shaken for 5 min. To the mixture were added 30 mL of dichloromethane and dilute hydrochloric acid. The organic layer afforded, after chromatography on silica gel (benzene–hexane), the acetate (**3**), mp 167—168 °C, in 82% yield. Found: C, 77.77; H, 5.94%. Calcd for $C_{26}H_{24}O_4$: C, 77.98; H, 6.04%. ^1H NMR ($CDCl_3$, δ): 2.21 (3H, s), 3.56 (2H, br t, J=7 Hz), 3.70 (3H, s), 3.77 (3H, s), 4.78 (2H, t, J=7 Hz), 5.88 (1H, s), 6.50 (2H, s), 6.90—7.70 (8H, m).

Benzoate (4), mp 170.4—171.2 °C. Found: C, 80.56; H, 5.52%. Calcd for $C_{31}H_{26}O_4$: C, 80.50; H, 5.67%. ^1H NMR ($CDCl_3$, δ): 3.71 (3H, s), 3.79 (3H, s), 3.50—4.00 (2H), 5.07 (2H, t, J=7 Hz), 5.90 (1H, s), 6.51 (2H, s), 6.90—7.70 (11H, m), 8.10—8.30 (2H, m).

p-*Methoxybenzoate (5)*, mp 192.5—193.0 °C. Found: C, 77.86; H, 5.53%. Calcd for $C_{32}H_{28}O_5$: C, 78.03; H, 5.73%. ^1H NMR ($CDCl_3$, δ): 3.73 (3H, s), 3.80 (3H, s), 3.89 (3H, s), 3.50—4.00 (2H), 5.02 (2H, t, J=7 Hz), 5.90 (1H, s), 6.52 (2H, s), 6.90—7.70 (10H, m), 8.19 (2H, d, J=9 Hz).

p-*Nitrobenzoate (6)*, mp 254—255 °C. Found: C, 73.52; H, 4.71; N, 2.58%. Calcd for $C_{31}H_{25}NO_6$: C, 73.36; H, 4.97; N, 2.76%. This compound was so scarcely soluble in chloroform-*d* that the NMR measurement was not carried out.

Chloroacetate (7), mp 166—167 °C. Found: C, 71.80; H, 5.33; Cl, 8.15%. Calcd for $C_{26}H_{23}O_4Cl$: C, 71.69; H, 5.30; Cl, 8.10%. ^1H NMR ($CDCl_3$, δ): 3.56 (2H, br t, J=7 Hz), 3.71 (3H, s), 3.79 (3H, s), 4.20 (2H, s), 4.90 (2H, t, J=7 Hz), 5.88 (1H, s), 6.50 (2H, s), 6.90—7.60 (8H, m).

Dichloroacetate (8), mp 166.5—167.0 °C. Found: C, 66.39; H, 4.75; Cl, 14.97%. Calcd for $C_{26}H_{22}O_4Cl_2$: C, 66.53; H, 4.72; Cl, 15.11%. ^1H NMR ($CDCl_3$, δ): 3.60 (2H, br t), 3.72 (3H, s), 3.79 (3H, s), 5.00 (2H, t, J=6.5 Hz), 5.90 (1H, s), 6.62 (2H, s), 6.90—7.60 (8H, m).

Trichloroacetate (9), mp 178—179 °C. High resolution MS (M^+): 502.0485, 504.0471, 506.0357, and 508.0418. $C_{26}H_{21}O_4Cl_3$ requires 502.0507, 504.0477, 506.0448, and 508.0418. The observed intensities of the molecular ions agreed well with those calculated from the natural abundance of ^{35}Cl and ^{37}Cl. The base peak was 326.1292 to indicate that the loss of a trichloroacetoxyl and a methyl group occurred. ^1H NMR ($CDCl_3$, δ): 3.72 (3H, s), 3.80 (3H, s), *ca.* 3.75 (2H), 5.08 (2H, t, J=6.5 Hz), 5.90 (1H, s), 6.53 (2H, s), 6.90—7.60 (8H, m).

Trifluoroacetate (10), mp 170.0—170.3 °C. Found: C, 68.94; H, 4.86%. Calcd for $C_{26}H_{21}O_4F_3$: C, 68.72; H, 4.66%. ^1H NMR ($CDCl_3$, δ): 3.60 (2H, br t, J=6.5 Hz), 3.70 (3H, s), 3.79 (3H, s), 5.08 (2H, t, J=6.5 Hz), 5.85 (1H, s), 6.52 (2H, s), 6.90—7.60 (8H, m).

9-(2-Acetoxyethyl)-1,2,3,4-tetrachlorotriptycene (12), mp 192—193 °C, was similarly prepared from the corresponding alcohol (**11**). Found: C, 60.40; H, 3.58%. Calcd for $C_{24}H_{16}O_2Cl_4$: C, 60.28; H, 3.37%. ^1H NMR ($CDCl_3$, δ): 2.23 (3H, s), 3.86 (2H, t, J=7 Hz), 4.61 (2H, t, J=7 Hz), 6.01 (1H, s), 7.00—7.70 (8H, m).

1,2,3,4-Tetrachloro-9-(2-chloroethyl)triptycene (13). A solution of 0.1 g of the alcohol (**11**) in 30 mL of dichloromethane and 0.2 mL of thionyl chloride were stirred at 0 °C for 30 min and then refluxed for 30 min. The mixture was mixed with dilute aqueous sodium hydroxide and shaken. Evaporation of the organic layer followed by recrystallization of the residue from tetrahydrofuran–hexane afforded the desired material, mp 270—271 °C, in 93% yield. High resolution MS gave M^+ peaks at 451.9515, 453.9501, 455.9610, and 457.9221. Peaks corresponding to the loss of a hydrogen chloride and a chlorine were observed. The intensity ratios were in agreement with the calculated from the natural abundance of ^{35}Cl and ^{37}Cl. $C_{22}H_{13}Cl_5$ requires 451.9445, 453.9431, 455.9401, and 457.9372. ^1H NMR ($CDCl_3$, δ): 3.91 (2H, br t, J=6.5 Hz), 4.51 (2H, br t, J=6.5 Hz), 6.03 (1H, s), 6.90—7.70 (8H, m).

1,2,3,4-Tetrachloro-9-[2-(p-tolylsulfonyloxy)ethyl]triptycene (14). A mixture of 0.1 g of the alcohol (**11**), 10 mL of pyridine and 0.1 g of *p*-toluenesulfonyl chloride was stirred at room temperature for 24 h. The mixture was shaken with 40 mL of dichloromethane and dilute hydrochloric acid. The desired product was rather labile and hydrolyzed to the starting material on standing and on chromatography. ^1H NMR ($CDCl_3$, δ): 2.45 (3H, s), 3.88 (2H, t, J=7 Hz), 4.60 (2H, t, J=7 Hz), 5.99 (1H, s), 6.90—7.60 (10H, m), 7.88 (2H, d, J=8 Hz).

Deuterated Compounds. 9-Allyl-1,4-di(methoxy-d_3)triptycene was prepared as described elsewhere[5] from the Diels-Alder adduct between 9-allylanthracene and *p*-benzoquinone and di(methyl-d_3) sulfate. It was ozonized as reported to produce 9-(formylmethyl)-1,4-di(methoxy-d_3)triptycene which was reduced with sodium tetrahydridoborate. The alcohol (**1**-d_6) thus obtained was transformed into esters as described above.

The ^1H NMR spectrum of a chloroform-*d* solution of the acetate at −55 °C showed an AB quartet (δ 3.08 and 3.74, J=15 Hz) and a singlet (δ 3.74), whose relative intensities were 2.1±0.4, on irradiation at δ 4.76 corresponding to $AcOCH_2$ protons. Under the same conditions, the peak at δ 6.50 split into two peaks (δ 6.48 and 6.58). The intensity ratio (the low field peak over the high field peak) was 1.6±0.2.

The ^1H NMR spectrum of the trifluoroacetate at −50 °C gave the following data. 9-CH_2: quartet δ 3.28 and 3.82, J=15 Hz; singlet δ 3.74; intensity ratio (quartet/singlet) 2.9±0.8. Dimethoxybenzo protons: δ 6.51 and 6.42; intensity ratio (low/high) 3.1±0.3.

Results and Discussion

Determination of Conformations and Population Ratios.

Since the compounds studied here all carry a CH_2 group at the bridgehead of the triptycene skeleton, it should exhibit, in principle, a set of AB quartet if it is the $\pm sc$ conformation and a singlet if it is the *ap*. In practice, however, the determination of conformation poses difficult questions. Firstly, since the CH_2 (α) group at the bridgehead is connected to another CH_2 (β) group, it is necessary for seeing clearly a set of AB quartet and a singlet to irradiate the β-CH_2 protons for decoupling. Then, if the chemical shifts of these two methylene protons are very close, the α-CH_2 protons are partially saturated to make it difficult to obtain good data for the intensity. Secondly, the compounds carrying methoxyl groups give the methoxyl signals in the range of those due to α-CH_2 to cause heavy overlaps. And finally irradiation of β-CH_2 protons may not cause saturation completely because of its range.

These difficult situations were overcome by the following procedures. Since the overlap of the α-CH_2 signals can be avoided by deuterating the methoxyl groups, we first synthesized two triptycenes (acetate and trifluoroacetate) carrying the fully deuterated methoxyl groups in 1,4-positions. Their population ratios were observed by irradiating the β-CH_2 protons. We found that the population ratios obtained by integrating the AB quartet and the singlet due to $\pm sc$ and *ap* conformations, respectively, involve rather large errors but are in agreement with those obtained by integrating singlets which are formed by splitting of the signal at δ 6.5, if we assume that the signal at a higher magnetic field is due to the *ap* form and that at a lower field to the $\pm sc$ form. The protons which give a signal at δ 6.5 at room temperature are assigned to the aromatic protons of the dimethoxybenzeno bridge from the electronic density considerations. Since the splitting of the signal at δ 6.5 is definitely caused by freezing of the conformations, it is reasonable to assume that the intensities of these signals reflect conformational populations. Since the correspondence of the higher field signal to the population of the *ap* conformation and that of a lower field signal to the $\pm sc$ were unaltered in the cases examined, we may assume that the tendency is common in the series examined here, although the exact cause for the chemical shifts is unknown. As discussed later, this assumption afforded reasonable data about the conformational populations.

Conformational Equilibria. The population ratios of conformers of 1,4-dimethoxytriptycenes are listed in Table 1 together with pK_a values of the corresponding acids. Since the population ratio $\pm sc/ap$ of 9-ethyl-1,4-dimethoxytriptycene is known to be 1.0,[6] we cannot take the appearance of the $\pm sc$ conformer as evidence for the presence of attractive interactions as are the other cases.[4] Thus we take the 9-(2-methoxyethyl) compound (**2**) as a reference. This compound exhibits a low $\pm sc/ap$ value which is close to that of 9-ethyl-1,4-dimethoxytriptycene and can be taken that the attractive interaction between the methoxymethyl and the methoxyl groups is absent because of the low electron-accepting power of the former: thus this much of population ratio is expected in the absence of the attractive interaction.

Table 1. Populations ratios ($\pm sc/ap$) of 9-(2-acyloxy- or alkoxyethyl)-1,4-dimethoxytriptycene and pK_a's of the corresponding acids

Acyl (or Alkyl) group (R)	$\pm sc/ap$	Temp/°C	pK_a of ROH[7]
CH_3	0.7	−50	14.4
CH_3CO	1.5	−45	4.76
C_6H_5CO	1.7	−50	4.20
p-$CH_3OC_6H_4CO$	1.7	−50	4.47
$ClCH_2CO$	2.0	−45	2.86
Cl_2CHCO	2.5	−45	1.26
Cl_3CCO	3.0	−50	0.65
F_3CCO	3.0	−50	0.23

Inspection of the data in Table 1 reveals that all the compounds examined here exhibit larger $\pm sc/ap$ values than that of the 9-(2-methoxyethyl) compound (**2**). The results cannot be attributed to the electric effect although it was the case for some carbonyl-substituted triptycenes.[4] Although the conformation of the acyloxyl group is not well known, the important contribution for the interaction with the dipole of the peri-methoxyl group should be given by the CH_2–O group. Then the $\pm sc$ form is considered to be more polar since the two dipoles are arranged in a closer proximity: there cannot be an important compensation by solvent molecules. Therefore, if it is the electric nature which dominates as a factor in controlling the population, the $\pm sc$ form should be disfavored in nonpolar solvents such as chloroform. The difference between the methoxy (**2**) and acyloxy compounds cannot be accommodated by the steric repulsion either, because the steric sizes are, by and large, the same among the conformers examined.

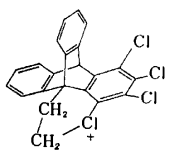
The favoredness of the $\pm sc$ conformation relative to the *ap*, when an electronegative acyl group is introduced, should be attributed to the increased stability of the $\pm sc$ conformation, because no instability factor associated with the *ap* form is apparent. The results correspond to the fact that the acyloxyl group is more electronegative than the methoxyl and consequently the former group is more electron-accepting. pK_a values of carboxylic acids are associated with the electronegativities of the acyl group.[8] The fact that, among carboxylic esters, the larger is the pK_a of the corresponding acid, the smaller is the $\pm sc/ap$ value, although a minor change in pK_a does not seem to affect the $\pm sc/ap$ value to a significant extent, clearly shows that the attracting interaction is occurring between the acyloxymethyl group and the methoxyl group. The nature of the interaction is of the charge-transfer type, the acyloxymethyl group acting as an electron acceptor and the methoxyl group as an electron-donor.

Since the acyloxymethyl group should possess at least two low-lying vacant orbitals, it may be worthwhile to discuss the orbitals involved in the interaction here. Our choice is the σ^* orbital, which involves mainly the CH_2–O group, that is responsible to the interaction. It may be argued that the π^* orbital of the carbonyl group is responsible because of its electron-accepting ability. Indeed, the C–T interaction involving the carbonyl moiety is well documented.[4,9] However, we rule out

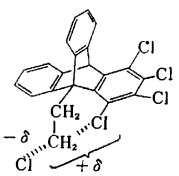
this possibility for the following reasons. The first is the fact that if the interaction between the carbonyl of the acyl group and the methoxyl had occurred, the ring formed there must be 8-membered. This kind of interaction is usually very unfavorable because of the decrease in entropy. It is especially so if we consider the weakness of the interaction discussed here. The second is indirect but is more convincing. Namely the attempt at synthesizing the tosylate of 9-(2-hydroxyethyl)-1,4-dimethoxytriptycene ended in the formation of a cyclic ether.[5] In this case, the result is best accommodated by assuming that the interaction between the SO_3–CH_2 and the methoxyl groups was so strong that it resulted in a reaction. Several phenomena related to this may be cited: that is the reactivities of 9-(2-chloroethyl) compound (**13**) which will be discussed later in this paper, where it becomes apparent that an interaction between a CH_2–Cl and a chloro group can take place. Finally the behavior of the trichloroacetate (**9**) may be taken into consideration. An attempted purification of the compound on a TLC plate which was inpregnated strongly activated silica gel ended in failure because a part of the compound reacted to give a cyclized compound, 6-methoxy-7,11b-*o*-benzeno-7,11b-dihydronaphtho[1,2,3-*de*]chromene.[5] The results together with the fact that the loss of a trichloroacetoxyl and a methyl groups was observed in the MS support the idea that it is the trichloroacetoxy-CH_2 group that is interacting with the methoxyl group in the peri-position. These considerations lead to a conclusion that σ^* orbital of the CH_2–O group is responsible to the interaction.

In contrast to the population ratios of the 1,4-dimethoxytriptycenes, 9-(2-acetoxyethyl)-1,2,3,4-tetrachlorotriptycene (**12**) showed the sole presence of the *ap* form at −50 °C. It was not possible to obtain a $\pm sc/ap$ ratio of 1,2,3,4-tetrachloro-9-(2-chloroethyl)-triptycene (**13**), since the NMR signals of α-CH_2 and β-CH_2 in this compound were too closely located to perform a decoupling experiment. 1,2,3,4-Tetrachloro-9-[2-(*p*-tolylsulfonyloxy)ethyl]triptycene (**14**) did show a sign of the presence of the $\pm sc$ form but the $\pm sc/ap$ value was practically zero. These results indicate that, being a weak electron-donor than a methoxyl group,[10] the chloro group is not a good enough electron-donor for the detectable interaction: that is best illustrated by the fact that compound **14** was prepared at room temperature in contrast to the facile cyclization of 1,4-dimethoxy-9-[2-(*p*-tolylsulfonyloxy)ethyl]triptycene.[5] The size of the chloro group is also responsible to the absence of the interaction.

Although the interaction between the CH_2–X and the chloro groups in compounds **12**, **13**, and **14** was not spectroscopically detectable, the chemical properties of the latter two compounds do indicate the presence of such an interaction. The CH_2–Cl compound (**13**) afforded 1,2,3,4-tetrachloro-9-(2-hydroxyethyl)triptycene (**11**) on chromatography on silica gel. Namely, the hydrolysis of the CH_2–Cl group in **13** is very easy. Probably the stabilization of a chloronium cation (**15**)[11] or the incipient transition state (**16**) for the formation of the chloronium cation is responsible to the phenomenon. A similar situation is found for the tosylate (**14**) as well: chromatography of this compound on silica gel or standing a solution of **14** in tetrahydrofuran–hexane in atmosphere caused hydrolysis to afford **11**. Fragmentation of **13** in mass spectroscopy is a further support to the above discussion: those corresponding to the chloronium ion (**15**) and to the loss of a hydrogen chloride molecule were observed as strong peaks, whereas the molecular ion peaks were rather weak in this compound.



15



16

Establishing that there is an attractive interaction between the CH_2–Cl and the chloro group, we can now discuss the population ratios of 1,2,3,4-tetrachloro-9-(2-chloro-1,1-dimethylethyl)triptycene and 1,2,3,4-tetrachloro-9-(2-chloro-1-chloromethyl-1-methylethyl)triptycene.[12] As were discussed elsewhere,[13] the $\pm sc/ap$ ratio of 1,2,3,4-tetrachloro-9-(2-phenyl-1,1-dimethylethyl)triptycene is 0.48.[14] Being larger than a methyl, the chloromethyl group in 9-(2-chloro-1,1-dimethylethyl)- and 9-(2-chloro-1-chloromethyl-1-methylethyl)-1,2,3,4-tetrachlorotriptycenes should disfavor conformations in which the chloromethyl group is close to the peri-chloro group. In practice, however, the *ap* form of the latter which has two chloromethyl groups flanking the peri-chloro is unusually favored: $\pm sc/ap$ for the former is 0.96 and that for the latter is 1.80. We may attribute this anomaly to the attractive interaction between the CH_2–Cl and the chloro group.

Incipient Transition State for S_N2 *Reactions.* The above discussions reveal that the interaction as depicted by **16** is important. Then it implies that the molecules investigated here present models for the incipient transition state for S_N2 reactions. Here the peri-chloro or peri-methoxyl group acts as a nucleophile and the chloro or acyloxyl group in the 9-substituent as the leaving group in S_N2 reactions. This view is in conformity with the idea that pK_a values of acids corresponding to the leaving groups parallel with the leaving ability.[15] As we predicted before, the triptycene system has proved to be a good one in finding weak interactions which are otherwise not detectable. Dunitz *et al.* were able to show that the intramolecular nucleophile-carbonyl interaction could be taken as models for the nucleophilic addition to the carbonyl group.[16] We now add that the intramolecular interaction between a chloro or a methoxyl group and a CH_2–X group where X is an electronegative group can be considered as models for the incipient transition state of S_N2 reactions.

S_N2 reactions had originally been considered that it involves a single transition state.[17] However, data are accumulating for these days which suggest that S_N2 reactions may involve multisteps. Sneen *et al.* postulated that S_N2 reactions involve prior ionization from product distributions and rates of reaction studied as a function

of nucleophile concentration in competitive substitutions by solvent and nucleophile.[18] Ion cyclotron resonance study by Brauman and coworkers revealed that organic halides form complexes with nucleophiles before reaching the transition state for the S_N2 reactions.[19] Roberts *et al.*, using high-pressure mass spectrometry, have shown that various alkyl halides form complexes with nucleophiles.[20] Hayami and his coworkers have shown that a mixture of an organic halide and a nucleophile shows a definite shift in ^1H NMR spectroscopy and attributed this phenomenon to the formation of a hydrogen bond.[21] Since our system is a primary halide or a primary alkyl ester, the phenomenon may be attributed to the hydrogen bonding as well. However, we take the fact shown by Roberts *et al.* that even *t*-butyl bromide or carbon tetrachloride can form a complex significant. We prefer to state that, during the course of S_N2 reactions, there is a point which is stable due to interactions between *n*-electrons of a nucleophile and the σ^* orbital of a substrate.

We wish to acknowledge the receipt of a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture which made this work possible.

(Received April 22, 1981)

A new method is described for protein sequence analysis. The principle is realized as follows: 1) determination by field-desorption mass spectrometry of the molecular weights of the constituents in peptide mixtures prepared from a polypeptide or protein by specific cleavage methods, 2) quantitation of the 3-phenyl-2-thiohydantoin derivatives of amino acids liberated successively from the constituent peptides in 1) by Edman-degradation, and 3) determination of amino acid sequences with a computer from the data obtained in 1) and 2). The method was applied to sequence determination of a polypeptide of unknown structure, the *N*-terminal BrCN fragment of *Streptomyces erythraeus* lysozyme.

The Edman method[1] is widely used for sequencing of polypeptides and proteins, making it possible to determine their partial or even almost complete sequences by cleavage and identification of the *N*-terminal amino acid residue in each degradation reaction. Recently, we[2-4] reported a new method for sequencing of peptide mixtures that cannot be achieved by Edman-degradation alone, by a combination of Edman-degradation and field-desorption mass spectrometry.[5] The principle of the method is based on the determination of the molecular weights of peptides and peptide fragments degraded by the Edman method in a mixture by the field-desorption ionization technique and calculation of possible mass differences before and after degradation. We also reported that when preparations of peptide mixtures are obtained from a polypeptide by two or more kinds of specific cleavage methods, the sequence of the polypeptide can be examined using the computer program "PROSEQ,"[6] the data for which consist of the molecular weights and partial amino acid sequences, determined by the method[2-4] described above, of constituent peptides in mixtures.

More recently, some of the authors and others[7,8] developed another method for sequencing of polypeptides and proteins. The procedure consists of the following steps: 1) determination by the field-desorption ionization technique of the molecular weights of peptides in mixtures, which are prepared from a polypeptide by two or more kinds of specific cleavage methods, and their peptide fragments obtained after one-cycle of degradation, 2) estimation of the 3-phenyl-2-thiohydantoin derivatives of amino acids released successively from peptides in mixtures, prepared in 1), by Edman-degradation, and 3) deduction of amino acid sequences from the data obtained in 1) and 2) using the computer program "PROSEQ2."[8] The program "PROSEQ2" uses the data on the 3-phenyl-2-thiohydantoin amino acids released from peptide mixtures in each cycle of Edman-degradation in place of those on partial amino acid sequences of constituent peptides used in "PROSEQ1." We named the procedure the "IPR-sequencing method." To appreciate the utility of the procedure, the sequence of a polypeptide of unknown structure was examined.

In this paper we report in detail the sequence determination of the *N*-terminal BrCN fragment of *Streptomyces erythraeus* lysozyme[9] (SE lysozyme) of unknown sequence, which consists of 55 amino acid residues with an Ala residue at the *N*-terminus,[10] by the procedure. The amino acid sequence of this polypeptide was determined from data on peptides prepared by tryptic and chymotryptic digestion.

Materials and Methods

The *N*-terminal BrCN fragment of SE lysozyme was isolated as described elsewhere.[10] Trypsin treated with L-(1-tosylamino-2-phenylethyl) chloromethyl ketone was purchased from Worthington Biochemical Corp. (USA) and chymotrypsin treated with L-(1-tosylamino-5-aminopentyl) chloromethyl ketone from Sigma Chemical Co. (USA). [Gly[1]]-ACTH-(1—18)-NH_2[11] was obtained from Shionogi Research Laboratory, Shionogi and Co., Ltd. (Osaka), by courtesy of Dr. K. Inouye. H-Val-Tyr-Ile-His-Pro-Phe-OH was synthesized by a conventional method in this laboratory. Reagents for Edman-degradation were obtained from Wako Pure Chemical Ind. Ltd. (Osaka). The solvents used were redistilled. All other reagents were reagent grade and were used without further purification.

BrCN Cleavage. A peptide was dissolved at a concentration of 1% (w/v) and in a ratio of its Met residue to BrCN of 50/1 (mol/mol) in 70% formic acid.[12] The solution was stood for 20 h at 25 °C, diluted with distilled water and lyophilized repeatedly.

Enzymic Digestion. The *N*-terminal BrCN fragment (0.7 mg (110 nmol) and 1.0 mg (160 nmol)) of SE lysozyme were digested with trypsin and chymotrypsin, respectively, at a substrate concentration of 1% (w/v) and in a ratio of substrate to enzyme at 50/1 (w/w) in 1% NH_4HCO_3 at pH 8.0 for 4 h at 37 °C, and the digests were lyophilized immediately after the reaction.

Field-desorption Mass Spectra. Field-desorption

mass spectra were measured with a second-order double focusing mass spectrometer[13] with a mono field-desorption ion source, equipped with a data processor (JEOL JMA-2000 mass data analysis system). Mass assignment was made using polypropylene glycol as a standard.[14] Silicon emitters[15] grown on a tungsten wire were used for measurements of field-desorption mass spectra. The lyophilized material of sample peptides was dissolved in a mixture of pyridine and water (1/1, v/v) and the solution (1—2 μl containing 1—2 μg of sample peptides) was loaded by the syringe technique[16] on the emitter. The conditions for measurement of field-desorption mass spectra were as described.[15]

Edman-degradation. Degradations were performed manually as described[1,4] using the following buffer solutions: a) a mixture of pyridine and water (1/1, v/v), pH 9.35; b) a mixture of pyridine and water (1/1, v/v), adjusted to pH 9.5 by adding *N*-methylmorpholine; c) a mixture of pyridine and water (1/1, v/v), adjusted to pH 9.5 by adding 30% aq trimethylamine and glacial acetic acid, and d) a mixture of pyridine and water (1/1, v/v), adjusted to pH 9.5 by adding *N,N*-dimethylallylamine and trifluoroacetic acid.[1] The resultant 3-phenyl-2-thiohydantoin derivatives of amino acids were subjected to high-performance liquid chromatography, and the remaining peptides in the water layer were subjected to field-desorption mass spectrometry.

High-performance Liquid Chromatography (HPLC). HPLC was performed on a Zorbax ODS column (4.6 mm × 25 cm) (Dupont) in a high-performance liquid chromatograph (Shimadzu HPLC LC-3A equipped with a data processor chromatopac C-R1A), for the quantitation of the 3-phenyl-2-thiohydantoin derivatives of amino acids released from sample peptides by Edman-degradation. Samples were dissolved in methanol and introduced into the sample holder. The solvent employed for chromatography was a mixture of CH_3CN and 0.01 M NaOAc (pH 4.5) (42/58, v/v).[17] Chromatography was performed at 62 °C at a flow rate of 1.0 ml/min for samples from the organic phase and at 2.0 ml/min for those from the aqueous phase.

Computer Calculation. The computer programs "PROSEQ1"[6] and "PROSEQ2"[8] were used for deducing the major portions of the sequences or the complete sequences of the polypeptide from the data on the peptides obtained by digestions of the polypeptide with trypsin and chymotrypsin. Calculations were carried out in the ACOS 700 computer of the Crystallographic Research Center (Institute for Protein Research, Osaka University).

Results and Discussion

Mass Spectra of Peptides Containing Homoserine Residues at the C-*Terminus.* The cleavage of a polypeptide or protein containing a Met residue(s) by BrCN[12] gives a peptide fragment(s) containing a homoserine residue at its (their) *C*-terminus and the *C*-terminal fragment of the original polypeptide or protein, as *N*-terminal BrCN fragments. Therefore, in this experiment,

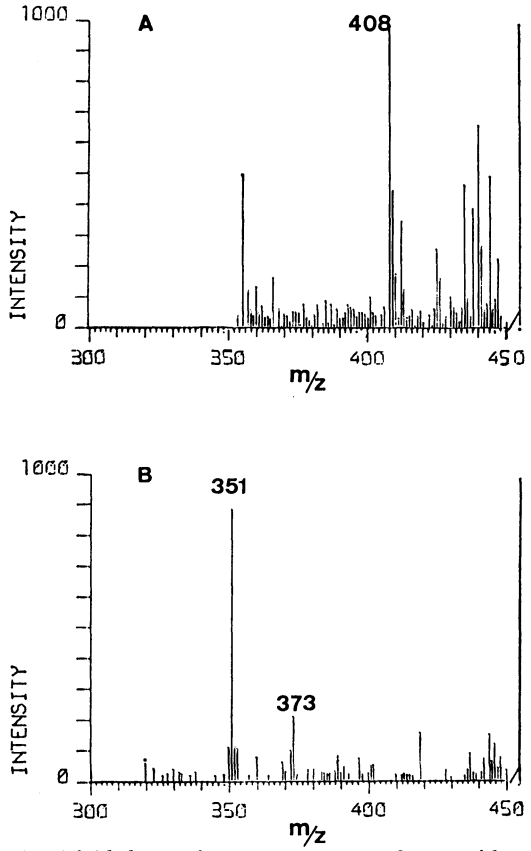

Fig. 1. Field-desorption mass spectra of a peptide mixture (A) prepared by cleavage of [Gly¹]-ACTH-(1—18)-NH_2 with BrCN and its one-step degraded peptide fragments (B). Spectra are shown in the range from 300 to 450 atomic mass units.

it was necessary to obtain information on whether peptides containing a homoserine residue at their *C*-termini give mass peaks with mass values of homoserine-peptides or those of homoserine-lactone peptides in mass spectra. As examples, we measured the field-desorption mass spectra of a peptide mixture obtained by cleavage with BrCN of [Gly¹]-ACTH-(1—18)-NH_2[11] containing a Met residue at the 5th position from the *N*-terminus and its peptide fragments prepared after one-cycle of Edman-degradation, as shown in Figs. 1A and 1B. The mass peaks of the peptide containing a homoserine residue in the mixture and its peptide fragment after Edman-degradation were observed at m/z=408 and 351, respectively, which corresponded to mass values of peptides containing homoserine lactones. However, when the peptides were measured after being kept for a long time, they gave mass values of homoserines opened at the *C*-terminal lactone rings. Generally, free "underivatized" peptides give mass peaks as quasi-molecular ions ($[M+H]^+$).[18,19] It is unknown whether peptides at their *C*-termini containing homoserine-lactones are observed as molecular ions $[M]^+$ or as quasi-molecular ions ($[M+H]^+$). The mass values (m/z=408 and 351) of the peptides containing homoserine residues observed above are responsible for the molecular ions. However, these mass values may be observed with a discrepancy of 1 atomic mass unit, because the mass peak at m/z=373 shown in Fig. 1B

is considered to be ($[M+Na]^+$) derived probably from 351 by addition of Na. This problem remains to be investigated further.

Edman-degradation and Field-desorption Mass Spectra. In our procedure of sequence determination, it was desirable to measure the mass spectra of peptides kept in the buffer solution for Edman-degradation. Therefore, we attempted to measure the mass spectra of several peptides in various buffer solutions. First we measured the mass spectra of peptides dissolved in a buffer solution containing *N,N*-dimethylallylamine as a base,[1] which is generally used in the coupling reaction of peptides with phenyl isothiocyanate in the Edman method. However, in this buffer the mass peaks could not be observed with high intensities in the spectra. The same phenomena were observed when some peptides were treated by the Edman method in the buffer solution and applied to the emitter. However, intense mass peaks could be obtained when the peptides were degraded in a mixture of pyridine and water without *N,N*-dimethylallylamine.[2,4]

Then we measured the mass spectra of a model peptide (H–Val–Tyr–Ile–His–Pro–Phe–OH) and its peptide fragments degraded successively under various conditions, as described in the Experimental section. Examples are illustrated in Figs. 2A and 2B. The model peptide and its peptide fragment gave mass peaks at $m/z=775$ and 676, respectively, with high intensities in all the buffer solutions examined except that containing *N,N*-dimethylallylamine. It was made not clear why the spectrum could not be obtained with high intensity in buffer solution with *N,N*-dimethylallylamine as base.

On the other hand, the 3-phenyl-2-thiohydantoin

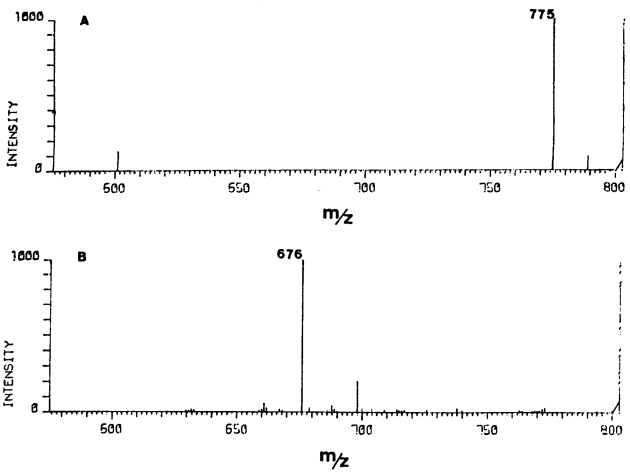

Fig. 2. Field-desorption mass spectra of H–Val–Tyr–Ile–His–Pro–Phe–OH (A) dissolved in a buffer solution containing *N*-methylmorpholine as a base (see text) and its peptide fragment (B) after one-cycle of degradation in the buffer solution.

derivatives of amino acids released from the model peptide in the degradation were quantitated by HPLC. The recoveries were similar in the all buffer solutions, but results seemed best in buffer solution containing *N*-methylmorpholine (data not shown), so, we used this buffer solution in Edman-degradation of the unknown polypeptide, as described below.

Mass Spectra of Tryptic and Chymotryptic Peptides of the N-Terminal BrCN Fragment of SE Lysozyme. We used trypsin and chymotrypsin, which specifically cleave different peptide bonds to each other, as methods for cleavage of the *N*-terminal BrCN fragment of SE

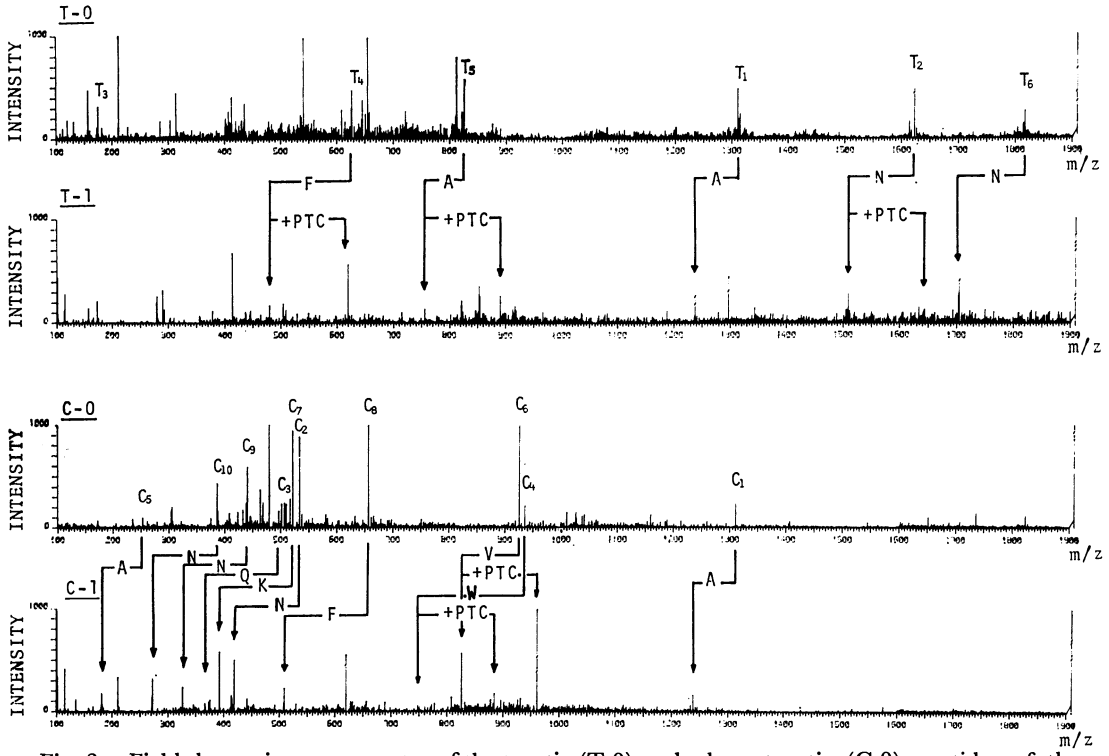

Fig. 3. Field-desorption mass spectra of the tryptic (T-0) and chymotryptic (C-0) peptides of the *N*-terminal BrCN fragment of SE lysozyme and their peptide fragments (T-1 and C-1) after one-step of degradation.

lysozyme. The tryptic and chymotryptic peptides and their peptide fragments obtained after the first-cycle of Edman-degradation gave the field-desorption mass spectra illustrated in Fig. 3. The spectra of the tryptic peptides and their degraded peptide fragments were simple, suggesting that the original polypeptide was specifically cleaved by this enzyme since it has only 3 Lys and 2 Arg residues. On the other hand, the spectra of the chymotryptic peptides and their degraded peptide fragments should be rather complicated, because the polypeptide contains many aromatic amino acid residues (6 Tyr, 3 Trp, and 2 Phe residues), which are susceptible to chymotryptic digestion. In fact, chymotryptic peptides and their degraded peptide fragments gave rather complicated spectra in the mass region up to 600 atomic mass units, as shown in Fig. 3. All the possible mass differences before and after the first-cycle of Edman-degradation of the tryptic and chymotryptic peptides were examined by the collation to the 3-phenyl-2-thiohydantoin derivatives of amino acids released in the degradation (Tables 1 and 2), as described previously.[2,4] In this case, the mass spectra were examined for mass peaks of $[M+Na]^+$, $[M+H-H_2O]^+$ and multiply charged ions $[M+2H]^{2+}$, *etc.*, which are occasionally observed with quasi-molecular ions $[M+H]^+$ in free "underivatized" peptides. Furthermore, the presence of peptides containing a Lys residue, giving mass peaks in the spectra with mass values that increased by addition of the phenylthiocarbamoyl group (135) after Edman-degradation,[4] was examined. The results revealed possible mass peaks of peptides obtained from the original polypeptide by enzymic digestion; namely, six tryptic peptides with R, F, A, and N[20] as *N*-termini and ten chymotryptic peptides with A, N, K, Q, F, W, and V as *N*-termini, as illustrated in Fig. 3. It was also found that the mass peaks at m/z=627, 826, and 1623 in tryptic peptides and at m/z=925 and 935 in chymotryptic peptides each contain a Lys residue. These findings are compatible with the presence of 3 Lys residues in the original polypeptide.

The molecular weight of the polypeptide was assumed to be within the range of 6280 and 6293 from the amino acid composition,[10] as described in Fig. 6, because Asp and Asn and Glu and Gln are quantitated together on amino acid analysis of acid hydrolysates of peptides and proteins. This molecular weight was compared with the sum of the molecular weights of the tryptic and chymotryptic peptides, which were obtained from the mass peaks in Fig. 3. The molecular weight of each peptide was obtained by subtracting one proton from the mass value of each peptide, because the mass peaks of free "underivatized" peptides are generally observed as quasi-molecular ions ($[M+H]^+$). Consequently, the tryptic peptides were assumed to be composed of peptides with mass values at m/z=175(R) : T_3, 627(F) : T_4, 826(A) : T_5, 1310(A) : T_1, 1623(N) : T_2 and 1818(N) : T_6 (amino acid residues in parentheses indicate the *N*-terminal amino acid residue of each peptide and T stands for tryptic peptide). Thus, the sum of the molecular weights of these six tryptic peptides was calculated as 6283. On the other hand, the chymotryptic peptides were suggested to be 253(A) : C_5, 386(N) : C_{10}, 440(N) : C_9, 496(Q) : C_3, 521(K) : C_7, 533(N) : C_2, 656(F) : C_8, 925(V) : C_6, 935(W) : C_4 and 1310(A) : C_1 (C stands for chymotryptic peptide). The peptide with a mass value of m/z=496 was assumed to have Q as the *N*-terminal residue, because the intense mass peaks at 479 and 501 were considered to be derived from a peptide with a mass value of m/z=496 by elimination of NH_3 during Edman-degradation or measurements of mass spectra and to correspond to $[M+H-NH_3]^+$ and $[M+Na-NH_3]^+$, respectively. Therefore, another peptide with the same mass difference (128) before and after the first-cycle of Edman-degradation as that of the peptide (m/z=496) and with a mass value at m/z=521 was expected to have *K* as the *N*-terminal residue, because one Lys residue, having the same residual weight (128) as that of Q, was observed in the 3-phenyl-2-thiohydantoin derivatives of amino acids released in the first-cycle of degradation, as shown in Table 2. The sum of the molecular weights of the chymotryptic peptides was calculated as 6283, and thus, completely coincided with that of the tryptic peptides and was definitely within the range (6280—6293) of the expected molecular weight of the polypeptide. Thus, the mass peaks of the tryptic and chymotryptic peptides

Numerals are recoveries (nmol) from the *N*-terminal BrCN fragment (110 nmol). Ten % of the peptide fractions were removed for mass measurements before the 1st, 2nd and 3rd cycles of degradation. Thr was estimated in addition to *Δ*-Thr. The separations of Asn and Gln and Ser-derivatives and of Ala and Tyr-derivatives were not satisfactory in some cases. In these cases (*), recoveries were estimated as those of the main component. t means the presence of a trace of material.

Numerals are recoveries (nmol) from the *N*-terminal BrCN fragment (160 nmol). Ten % of the peptide fractions were removed for mass measurements before the 1st, 2nd, and 3rd cycles of degradation. Thr was estimated in addition to *Δ*-Thr. The separations of Asn and Gln and Ser-derivatives and of Ala and Tyr-derivatives were not satisfactory in some cases. In these cases (*), recoveries were estimated as those of the main component. t means the presence of a trace of material.

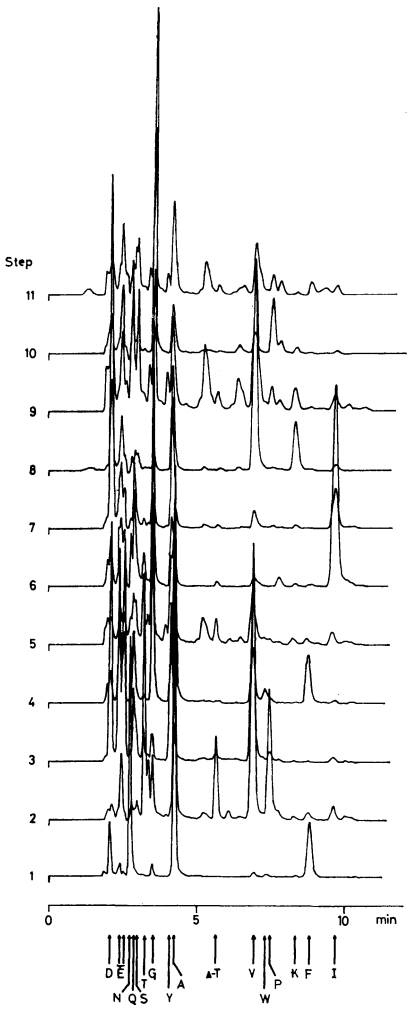

Fig. 4. High-performance liquid chromatograms of the 3-phenyl-2-thiohydantoin derivatives of amino acids released successively in the organic phase from the tryptic peptides of the *N*-terminal BrCN fragment of SE lysozyme. Numerals indicate the cycle of Edman-degradation. For conditions see text.

seemed to be selected correctly.

High-performance Liquid Chromatography of the 3-Phenyl-2-thiohydantoin Derivatives of Amino Acids Released from Tryptic and Chymotryptic Peptides. The 3-phenyl-2-thiohydantoin derivatives of amino acids released from peptide mixtures by Edman-degradation were quantitated using HPLC.[17] The chromatograms of the 3-phenyl-2-thiohydantoin derivatives of amino acids released from tryptic and chymotryptic peptides are illustrated in Figs. 4 and 5, respectively. The recoveries in each cycle of Edman-degradation are summarized in Tables 1 and 2. From these values, the kind and ratio of the 3-phenyl-2-thiohydantoin derivatives of amino acids released from the tryptic and chymotryptic peptides in each cycle of degradation were selected as interger values within the limits between possible maxima and minima, as described in Fig. 6, although the composition of the 3-phenyl-2-thiohydantoin derivatives of amino acids released were rather complicated. In these cases, the specificity of the enzymes used and the expected number of peptides in mixtures were considered. Furthermore, the fact that the recoveries of 3-phenyl-2-thiohydantoin derivatives of amino acids from larger peptides or Arg-containing peptides are generally better than those from smaller peptides was taken into consideration.

In this experiment, the 3-phenyl-2-thiohydantoin derivative of tryptophan was recovered with difficulty, because Edman-degradation was performed manually. Moreover, the 3-phenyl-2-thiohydantoin derivatives of homoserine and its lactone were not detected on the chromatograms.

Sequence Deduction with a Computer Program. The amino acid sequence of the *N*-terminal BrCN fragment of SE lysozyme was examined using the computer program "PROSEQ2,"[8] which was designed for deducing sequences of polypeptides or proteins from the molecular weights of the constituent peptides prepared from the polypeptides or proteins by two or more kinds of specific cleavage methods, the *N*-terminal amino acid residues or partial sequences of the constituent peptides and the 3-phenyl-2-thiohydantoin derivatives of amino acids released from the constituent peptides by successive degradation. The input data were as described in Fig. 6 and A and U (U denotes an Hse residue in this paper) as *N*- and *C*-terminal residues of the original

polypeptide,[10] respectively. There was only one output sequence, and it was complete as seen in Fig. 6. The results show that the procedure described above is applicable as a method for peptide or protein sequence analysis, and compares favorably with other methods,[1,21] although there may be no problem in sequencing a peptide as long as the *N*-terminal BrCN fragment tested with an automated sequencer.[22]

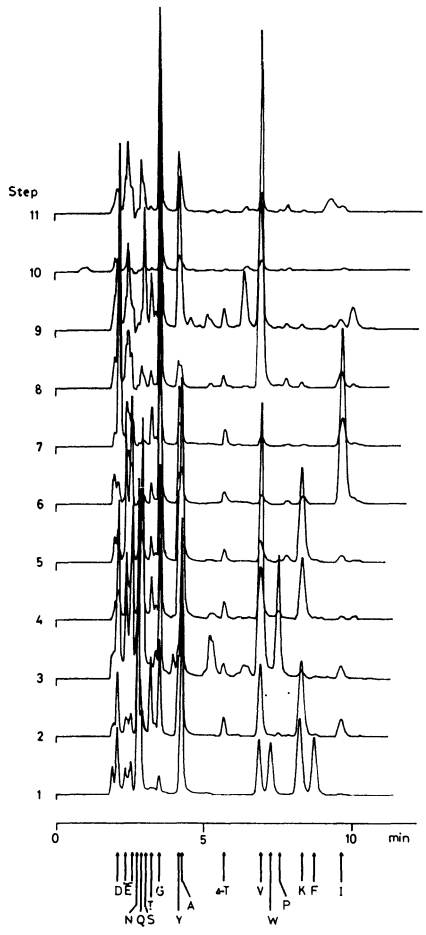

Fig. 5. High-performance liquid chromatograms of the 3-phenyl-2-thiohydantoin derivatives of amino acids released successively in the organic phase from the chymotryptic peptides of the *N*-terminal BrCN fragment of SE lysozyme. Numerals indicate the cycle of Edman-degradation. For conditions see text.

We express our sincere thanks to Professors Y. Izumi (Institute for Protein Research, Osaka University), H. Matsuda (College of General Education, Osaka University) and T. Ikenaka (Faculty of Science, Osaka University) for much helpful discussion and encouragement throughout this work.

Synthesis and Properties of O^6-Substituted Guanosine Derivatives

Hristo Petrov DASKALOV, Mitsuo SEKINE, and Tsujiaki HATA*

Department of Life Chemistry, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received April 27, 1981)

Reactions of 2′,3′,5′-tri-*O*-acetyl-N^2-protected or unprotected guanosine derivatives with phosphoryl, phosphinothioyl, arylsulfonyl, and silyl halides in dichloromethane gave the corresponding O^6-substituted guanosine derivatives in good yields. In these reactions, 4-(dimethylamino)pyridine (DMAP) was found to be very effective catalyst. The physical data of these products and their stabilities under acidic and basic conditions were described in detail. Selective detritylation of O^6-arylsulfonyl-N^2-tritylguanosine derivatives was accomplished by treatment with 80% acetic acid. It was found that O^6-dibutylphosphinothioyl derivatives were relatively stable under conditions where acetyl group was predominantly removed.

In recent years, introduction of new methodologies into nucleotide chemistry has facilitated dramatically the synthesis of oligonucleotides.[1] The modern phase of chemical synthesis of oligonucleotides rests mainly on the development of new types of condensing agents[2] and protecting groups[3] and the application of rapid purification and separation procedures.[4] For example, several (arylsulfonyl)azoles[2] have proved to be the most promising condensing agents since the reaction time for the condensation is being outstandingly shortened and the yields of oligomers are usually high. Narang[5] and Itakura[6] have recently showed rapid and practical methods for the synthesis of oligodeoxyribonucleotides demonstrating its successful application to the chemical synthesis of the fragments of the double stranded bioactive genes of lactose operator,[5a] human hormones,[6a,b] and insulin.[5b,c,6c,d] Ohtsuka and Ikehara[7] have also reported the utility of arenesulfonyl azoles in "unit-type" synthesis involving the total synthesis of $tRNA^{fMet}$. These new synthetic devices seem to be accepted satisfactorily. However, it appears that the preparation of guanosine-containing oligomers by the improved phosphotriester approach involves still synthetic problems, especially, on the aspect of the coupling yields. This problem is more severe in the case of the ribo-series. Several years ago, Reese[8-10] reported that guanosine derivatives were sulfonylated at the O^6-position of guanine moiety with arenesulfonyl chlorides in pyridine. It suggests strongly that during the elongation of oligonucleotide chains such unavoidable side reactions might occur at the O^6-position of guanosine. Indeed, we have met similar troubles owing to these side reactions in the synthesis of a guanosine monomer (as a unit nucleotide) and guanosine-rich oligomers. In connection with our project in oligoribonucleotide synthesis we have needed a highly lipophilic guanosine derivative capable for elaboration of a phosphate group at the 5′-ribose hydroxyl. Consequently, the coupling reaction between N^2-tritylguanosine and cyclohexylammonium *S,S*-bis(4-methoxyphenyl) phosphorodithioate (MPT) was performed by use of 2,4,6-triisopropylbenzenesulfonyl chloride (TPS) (TPS–MPT reaction) according to the established procedure.[11]

However, the desired 5′-*O*-phosphorylated product was not obtained and some unidentified by-products were formed. Careful investigation of the TPS–MPT reaction on more simplified (*i.e.*, fully protected) guanosine derivatives such as 2′,3′,5′-tri-*O*-acetyl-N^2-trityl-guanosine (**1**) and 2′,3′,5′-tri-*O*-acetyl-N^2-benzoylguanosine (**2**) has revealed that O^6-substitution reactions of the above mentioned compounds occured easily under similar conditions. This led us to study extensively the protection of the O^6-position of guanosine residue, which would give some insight on the oligonucleotide synthesis.

In this paper, we wish to report the facile phosphorylation, sulfonylation, silylation of the O^6-position of guanosine derivatives and the properties of the O^6-substituted guanosine derivatives in detail.[12] During this work, we dealed mainly with N^2-tritylguanosine derivatives since the trityl group has proved to be useful and promising protecting group of the 2-amino group of guanine moiety because of its stability and great lipophilicity.

Results and Discussion

O^6-Substitution Reaction of Guanosine Derivatives. At first, pyridine was chosen as a solvent for the above mentioned O^6-substitution reaction, since it was the common solvent used for the TPS–MPT reaction. By use of pyridine, however, unsatisfactory results were obtained for O^6-sulfonylation and O^6-phosphorylation of N^2-substituted 2′,3′,5′-tri-*O*-acetylguanosines. Another disadvantage was difficult work-up procedure which allowed isolation of the O^6-substituted derivatives only in low yields. On the other hand, excellent results were obtained, when the reaction was carried out in the presence of a catalytic amount of 4-(dimethylamino)-pyridine (DMAP)[13,14] in dichloromethane. It can be

Other physical data (^{1}H NMR and elemental analysis) are given as follows: **7c**: ^{1}H NMR ($CDCl_3$): δ 1.18 (9H, s, $(CH_3)_3C$), 1.93 (3H, s, 5′-acetyl protons), 2.06 (6H, br. s, 2′- and 3′-acetyl protons), 5.06—5.53 (3H, m, ribose protons), 5.63 (3H, br. s, ribose protons), 7.10 (15 H, br. s, ArH), 7.17—7.83 (11H, Ph_2Si and H-8); Found: C, 69.07; H, 5.80; N, 7.47%. Calcd for $C_{51}H_{51}N_5O_8Si$: C, 68.82; H, 5.78; N, 7.87%. a) Benzene–ethyl acetate (4 : 1, v/v). b) Compound **7a** was too unstable to characterize its properties (see the text). c) It was not possible, according to the techniques developed in this report, to isolate **7b** in pure form. Therefore, no elemental analysis, precise, UV, ^{1}H NMR data are given here. R_f value for **7b** should be accepted with some reservation due to partial decomposition of **7b** during TLC. d) The yield of **7b** was *ca.* 90—95% (determined by the amount of triethylammonium hydrochloride and ^{1}H NMR appearance of the partially purified product; see General Procedure B.

emphasized that O^6-substitution reactions took place by use of appropriate sulfonyl and phosphoryl halides in the presence of DMAP and the reactions were very clean and the results were also satisfactory. The reaction conditions and the results are summarized in Tables 1—3.

Concerning the reaction rate of O^6-substitution reaction, it depended on the lipophilicity of the guanosine derivatives. For instance, compound **1** containing trityl group was more reactive than 2′,3′,5′-tri-*O*-acetylguanosine (**3**) having no trityl group, while **1** entered in O^6-substitutions a little faster than **2**. As one could easily see from Tables 1—3, electronic and steric effects in the O^6-substitution reactions have apparently a little influence on the reaction rates.

The successful isolation of this type of guanosine derivatives (**4** and **5**) is of great interest since O^6-phosphorylated species have been discussed as by-products in the synthesis of oligonucleotides involving guanosines but they have never been characterized.

On the other hand, two kinds of phosphinothioyl halides, *i.e.*, dibutylphosphinothioyl bromide and diphenylphosphinothioyl chloride, were employed in place of the phosphoryl halides in order to introduce phosphinothioyl groups into the O^6-position of guanosine derivatives. As a consequence, the corresponding O^6-phosphinothioylated guanosine derivatives (**6a** and **6b**) were successfully obtained in 98 and 60% yields, respectively.

Furthermore, this DMAP/Et_3N/CH_2Cl_2 system could be also extended to the O^6-silylation. We examined the DMAP-catalyzed silylation of **1** using trimethylsilyl chloride, *t*-butyldimethylsilyl chloride, and *t*-butyldiphenylsilyl chloride. The superiority of DMAP/Et_3N/CH_2Cl_2 system was also confirmed in this case by comparison with the conventional system (imidazole/*N*,*N*-dimethylformamide/silyl chloride[15)]). Thus, the *t*-butyldiphenylsilyl derivative (**7c**) was successfully isolated in an excellent yield of 98%. However, in the case of the trimethylsilylation, it was impossible to isolate the silylated product (**7a**) and even to detect it on the TLC plate. Very rapid decomposition of **7a**

to the starting material was observed. However, indirect evidence of the O^6-silylation was supported by the fact that a stoichiometric amount of triethylamine hydrochloride was obtained from the reaction mixture. When t-butyldimethylsilyl chloride was used for the silylation, it was possible to detect the corresponding silylated product (**7b**) by TLC and to separate it as a material which was contaminated with DMAP and traces of triethylammonium chloride (see Procedure B in Experimental Section).

Stability of the O^6*-Substituted Guanosine Derivatives.* Since it was quite important for our synthetic purpose, we undertook a careful examination of the stability of the above mentioned compounds (**4**—**10**) either during work-up procedure, in solid state, or in several acidic and basic mediums. Consequently, their stabilities have varied in a quite wide range. The summary of the results is given below (for further details see Table 6 and Experimental Section). In connection with their stability in solid state, we have found that N^2-unsubstituted guanosine derivatives were unstable and after two months at room temperature a significant decomposition has been observed.

It was proved also that an introduction of the bulky substituents near O^6-oxygen of the O^6-substituted guanosines increases their stability both during work-up and in the solid state. Thus, in the O^6-sulfonylated derivatives of **3** the order of stability in the solid state was **10a**>**10b**>**10c**. On the other hand, in O^6-phosphorylation of **1**, it was found that the O^6-diethylphosphoryl derivative (**4a**) was not stable enoguh to be isolated in pure form, while the O^6-diisopropylphosphoryl compound (**4b**) could be isolated, although the yield was relatively low (*ca.* 30%).

Because of the circumstances under which this study was undertaken we have been in keen interest for lability of the substituent on O^6-guanosine oxygen, especially, in different basic mediums. Our principal goal is to obtain O^6- and N^2-disubstituted guanosines so that we can call them "fully protected" selectively in the guanine part. As a consequence, we tried to check the stability of O^6-substituted 2′,3′,5′-tri-O-acetyl-N^2-tritylguanosines in more detail. It was found that most of substituents of O^6-guanosine oxygen were too unstable in several alkaline mediums to serve as protecting groups for O^6-position of the compounds involved. The O^6-sulfonylated derivatives (**8**—**10**) were particularly susceptible to nucleophilic substitution at C^6 carbon. A similar reaction of 2′,3′,5′-tri-O-acetyl-O^6-mesitylsulfonylguanosine (**10b**) has been described by Reese.[9] Unfortunately, it was not possible to find a suitable reagent which would attack preferably ribose acetoxyl groups, but not the C^6-carbon in the guanine moiety.

In order to gain information on the possibility of using O^6-substituents as protecting groups some data on their stability in acidic mediums were also required. We have found that, as a rule, they were quite labile under acidic conditions (see Table 6). It was, however, possible to find removal conditions of trityl group selectively from 2′,3′,5′-tri-O-acetyl-O^6-sulfonyl-N^2-tritylguanosine (**8a**—**c**) where the sulfonyl groups remained intact to afford **10a**—**c** in almost quantitative yields. On

TABLE 6. REMOVAL OF THE PROTECTING GROUPS OF SOME O^6-SULFONYLATED PHOSPHORYLATED, OR SILYLATED COMPOUNDS IN ACIDIC OR BASIC MEDIUMS

Compound	Acidic or basic medium[a)]	Time/h	Product
8a	80% acetic acid in dioxane–water (4 : 1, v/v)	1.0	**10a**

7c		24	**11**
6a	*t*-butylamine in methanol–dichloromethane[d)]	6.0	**12** and **13**[e)]
6a	butylamine in dichloromethane	48	no reaction
6a	*t*-butylamine in methanol	0.25	**12** and **13**[f)]

a) All operations were carried out at room temperature, if not otherwise stated. b) The TLC ($CHCl_3$– MeOH, 9 : 1, v/v) of the reaction mixture after 2 h showed that at least 4 products were formed (no starting material remained). No attempts were made to identify these compounds, but at least for one of them it could be judged (from R_f value) that it was N^2-tritylguanosine. c) In 5% methanolic ammonia a similar reaction took place. d) This was one of the best solvent systems which have been tested for aminolysis of **6a**. The reaction was sufficiently slow for isolation of monoacetyl- and deacetylated products of **6a**. e) See Experimental section. f) See the text.

the other hand, simultaneous removal of both trityl and arylsulfonyl groups could be accomplished by employing 60% formic acid (see Table 6).

The O^6-phosphorylated guanosine derivatives (**4** and **5**) were also quite labile in basic mediums, and the O^6–P bond was cleaved easily in either aqueous or anhydrous solvents to give rise to N^2-tritylguanosine (**11**) as a principal reaction product.

For aminolysis of 2′,3′,5′-tri-*O*-acetyl-O^6-dibutylphosphinothioyl-N^2-tritylguanosine (**6a**), ammonia, *t*-butylamine, and butylamine in different solvent systems were tested. It was found that both ammonia (in methanol) and butylamine (in methanol–dichloromethane) had given unsatisfactory results. The aminolysis was too fast and O^6-dibutylphosphinothioyl group was cleaved considerably. On the contrary, *t*-butylamine [in methanol and especially in methanol–chloroform (or dichloromethane)] had given good results both in terms of aminolysis reaction and stability of the O^6-dibutylphosphinothioyl group. The aminolysis with *t*-butylamine appeared to be very sensitive to the solvent system. For instance, there was no reaction between **6a** and *t*-butylamine in solvents such as dichloromethane, 2-propanol, and chloroform, while the reaction was very fast in methanol (only 15 min was enough for disappearance of **6a**) and relatively slow in ethanol. Thus, it was shown that the dibutylphosphinothioyl group was relatively stable during the aminolysis of the corresponding guanosine derivatives with *t*-butylamine. On the other hand, an easy cleavage of the group was detected in acidic mediums (for example, 80% acetic acid) to give **3**. Therefore, it seems to us that the dibutylphosphinothioyl group (BPT) is useful for O^6-protection of guanosine derivatives, because it has the following useful features; 1) ribose acetyl groups undergo more rapid aminolysis by *t*-butylamine than the O^6-BPT group; 2) it is possible to cleave easily O^6-BPT groups in either acidic or appropriate basic mediums; 3) the corresponding O^6-phosphinothioyl compounds could be obtained conveniently in high yields; 4) compounds **6a**—**c** are stable in solid state at room temperature for a long period of time and in aqueous pyridine for one day and can survive TLC or other purification procedures; 5) O^6-dibutylphosphinothioyl derivatives of N^2-tritylguanosine can be detected easily on TLC plates because of their characteristic blue fluorescence at 254 nm; 6) compounds **6**, **12**, or **13** have very characteristic UV spectra (see the later section); 7) butyl groups are easily detectable by ^1H NMR and it might be useful in nucleotide synthesis, because no significant signals appeared in that region.

Diphenylphosphinothioyl group showed similar properties to the BPT group but the introduction of the former to the O^6-imidoyl group was performed only in moderate yields and it does not have blue fluorescence like BPT-containing compounds.

Thus, as a result of this investigation, it seems that the BPT group might be useful for protection of the O^6-oxygen of guanosine. It could be a valuable starting point for designing similar and even better groups. Further efforts toward this goal are now in progress in our laboratory.

Solubility of O^6*-Substituted Guanosine Derivatives.* It is well documented by Guschlbauer that guanosine forms rigidly stable hydrogen bonded complexes of cyclic structure.[16)] This greatly diminishes the solubility of the molecule in many organic solvents and makes it impossible to perform some interesting synthetic transformations. Generally, in the oligonucleotide synthesis, the longer the chain of an oligonucleotide is, the poorer its solubility is so that the R_f becomes low and the separation of the oligonucleotide from other polar by-products is difficult. Therefore, from the two points of the prevention of the side reactions at the O^6-position of guanine moiety and the enhance of the solubility of guanosine derivatives, introduction of a protecting group into the O^6-imidoyl group seems to be important. The solubility of the O^6-substituted guanosine derivatives obtained in the present works increases dramatically in several organic solvents. For example, the *t*-butyldiphenylsilylated derivative (**7c**) is freely soluble in ether and fairly even in hexane. The high solubility of the O^6-substituted guanosine derivatives is seen from the R_f values described in Tables 1—3 and 7.

UV and ^1H *NMR Spectra of* O^6*-Substituted Guanosine Derivatives.* All O^6-substituted guanosines have similar UV spectra which are quite different from the corresponding UV spectral data of O^6-unsubstituted derivatives. All O^6-substituted compounds have a

Table 7. Some physical data for O^6-dibutylphosphinothioyl-N^2-tritylguanosine (**12**) and 5′-O-acetyl-O^6-dibutylphosphinothioyl-N^2-tritylguanosine (**13**)

a) Benzene–ethyl acetate (4 : 1, v/v).

maximum at 290—305 nm (ε=6000—9000) which is not characteristic of guanosine-type derivatives. In the case of the O^6-sulfonylated compounds this maximum lies between 300—305 nm, while the corresponding O^6-silylated and phosphinothioylated derivatives have their higher wavelength maximum at 290 and 300 nm, respectively.

^{1}H NMR spectra of O^6-substituted guanosines also have some very characteristic features. For instance, all O^6-substituted N^2-tritylguanosines have a moderately broad singlet around δ 6.0—6.5 (due to N^2-proton)[9] which disappears after D_2O exchange. Also all O^6-substituted 2′,3′,5′-tri-O-acetyl-N^2-tritylguanosines have their ribose protons split in two three protons groups, one located as a characteristic multiplet around δ 5.0—5.6 and the other as a broad singlet around δ 4.2. Resonance positions of trityl, acetyl, and H-8 protons are also of great value, but usually their chemical shift on NMR scale does not depend so crucially on O^6-substitution pattern. In the case of O^6-substituted 2′,3′,5′-tri-O-acetyl-N^2-benzoyl (or unsubstituted) derivatives the same pattern of resonance for the ribose protons was observed.

In conclusion, preparative new findings on the O^6-substitution reactions of guanosine derivatives have been obtained by use of 4-(dimethylamino)pyridine as a catalyst. All O^6-substituted guanosine compounds are highly soluble in many nonpolar organic solvents. It might be due to the cleavage of hydrogen bond between N^1 and O^6 by the introduction of the O^6-substituent. The O^6-dibutylphosphinothioyl derivatives are promising synthetic intermediates of guanosine compounds in nucleotide chemistry, because of some useful characteristics of the BPT group.

From the synthetic point of view in oligonucleotide synthesis, it is highly likely that coupling agents such as arenesulfonyl chlorides or azoles and phosphorylating species activated by the coupling agents attack the O^6-imidoyl group of guanine residue during the desired internucleotidic bond formation. This seems to be the reason why yields of the coupling reactions of oligonucleotides containing guanosine residue are remarkable unsatisfactory.

Experimental

Proton nuclear magnetic resonance spectra (60 MHz) were taken on a Hitachi Model R-24 spectrometer and are reported in parts per million from internal tetramethylsilane on the δ scale (δ=0). Ultraviolet spectra were recorded on a Hitachi Model 124 spectrophotometer. Elemental analyses were performed by the Microanalytical Laboratory, Tokyo Institute of Technology, at Nagatsuta. All solvents were distilled prior to use. Dichloromethane and pyridine were dried over 3A molecular sieves and calcium hydride, respectively. t-Butyldiphenylsilyl chloride,[17] diphenylphosphinothioyl chloride,[18] and dibutylphosphinothioyl bromide[19] were prepared according to the literature procedures.

General Procedure for O^6-*Sulfonylation, Silylation, or Phosphorylation of* N^2-*Substituted*[a] *or Unsubstituted 2′,3′,5′-Tri*-O-*acetylguanosines (Procedure A).* Two mmol of N^2-substituted or unsubstituted 2′,3′,5′-tri-O-acetylguanosine and 0.12 mmol of DMAP were dissolved[b] in 20 ml of dichloromethane and then to this solution were added successively 3.3 ml of triethylamine and 2.94 mmol of the corresponding sulfonyl, silyl, or phosphoryl halide.[c] After stirring of the homogeneous solution[d] for several hours,[e] the solvent was evaporated at 30 °C. The crystalline residue was redissolved[f] in 4 ml of dichloromethane and purified by column chromatography on silica gel. Elution was performed with benzene–ethyl acetate. Yields of the products are listed in Tables 1—3.

a) N^2-Substituent refers to trityl, benzoyl, or hydrogen. For a specific compound details are given in Tables 1—3.

b) In the case of 2′,3′,5′-tri-O-acetylguanosine, it was not possible to dissolve completely the guanosine derivative before addition of the corresponding sulfonylating, phosphorylating, or silylating reagent.

c) The corresponding silyl chloride (2.4 mmol) was used in the case of O^6-silylation reaction.

d) In the case of 2′,3′,5′-tri-O-acetylguanosine the reaction mixture became homogeneous after 30 min.

e) The reaction times for each individual compound are listed in Tables 1—3.

f) In some cases it was not possible to dissolve completely the white solid residue in 4 ml of dichloromethane. This did not, however, hamper the purification because it was possible to apply this suspension to the silica-gel column.

General Procedure for Partial Purification (Removal of Triethylammonium Chloride) of O^6-*Substituted* N^2-*Substituted or Unsubstituted 2′,3′,5′-Tri*-O-*acetylguanosines (Procedure B).* The general procedure A was followed until the solid residue was obtained after evaporation of the solvent. Then the solid was suspended

in 20 ml of dry ether, stirred for 10 min. and the white precipitate of triethylamine hydrochloride was filtered. The O^6-substituted-N^2-substituted or unsubstituted 2′,3′,5′-tri-*O*-acetylguanosine was in the filtrate together with DMAP and the excess of the corresponding sulfonylating, silylating, or phosphorylating agent. This procedure is especially useful for a quick confirmation that the reaction between guanosine derivative and the corresponding O^6-substitution reagent takes place. It is supported by the formation of triethylamine hydrochloride.

General Procedure for Aminolysis of Compounds 4—8 (Procedure C). O^6-Sulfonylated, O^6-phosphorylated, or O^6-silylated N^2-substituted 2′,3′,5′-tri-*O*-acetylguanosine (0.26 mmol) was dissolved in 1 ml of the corresponding organic solvent (dichloromethane, chloroform, methanol, ethanol, 2-propanol, or mixtures of two of them) and 2.8 mmol of the amine (ammonia, *t*-butylamine, or butylamine) in 2 mL of the above mentioned solvent was added at once. The course of the reaction was monitored by TLC (chloroform–methanol, 9 : 1, v/v). In the case of 2′,3′,5′-tri-*O*-acetyl-O^6-dibutylphosphinothioyl-N^2-tritylguanosine (**6a**: 1.59 mmol), *t*-butylamine (16.4 mmol) in methanol (12 ml) were stirred for 15 min at room temperature. The organic solvent was evaporated at 25 °C and the solid residue was chromatographed on silica gel with benzene–ethyl acetate to give **12** and **13** as white foams in 50 and 10% yields, respectively. In Table 7 the data are given for compounds **12** and **13**.

General Procedure for Acid Hydrolysis of O^6*-Sulfonylated 2′,3′,5′-Tri-*O*-acetyl-*N^2*-tritylguanosines to* O^6*-Sulfonylated 2′,3′,5′-Tri-*O*-acetylguanosines (Procedure D).* 2′,3′,5′-Tri-*O*-acethyl-O^6-arylsulfonyl-N^2-tritylguanosine[g] (0.1 mmol) was dissolved in 1 ml of 80% acetic acid in dioxane–water (4 : 1, v/v).[h] After 1 h water (4 ml) was added to the homogeneous reaction mixture and the resulting suspension was extracted with dichloromethane (3 × 2 ml). The combined dichloromethane solutions were washed with water (2 × 2 ml), dried over anhydrous sodium sulfate and evaporated at 25 °C. The remaining residue was redissolved in a small amount of dichloromethane and purified by column chromatography on silica gel (2 g). Benzene was used as the first eluent for removal of triphenylmethanol (about 10 ml of the eluate were collected) and the desired O^6-sulfonylated 2′,3′,5′-tri-*O*-acetylguanosine was eluted by ethyl acetate. The yield was nearly quantitative. The results are summarized in Table 6. All obtained 2′,3′,5′-tri-*O*-acetyl-O^6-(arylsulfonyl)guanosines (see Table 6) were proved to be identified (^{1}H NMR, R_f values, and UV spectra) with the corresponding 2′,3′,5′-tri-*O*-acetyl-O^6-(arylsulfonyl)guanosine obtained from direct O^6-sulfonylation of 2′,3′,5′-tri-*O*-acetylguanosine (see Table 1).

[g] Compounds **8a**—**c** were subjected to this reaction.

[h] No reaction took place in the absence of water.

*General Procedure for Conversion of 2′,3′,5′-Tri-*O*-acetyl-*O^6*-arylsulfonyl-*N^2*-tritylguanosines to 2′,3′,5′-Tri-*O*-acetylguanosine (Procedure E).* 2′,3′,5′-Tri-*O*-acetyl-O^6-arylsulfonyl-N^2-tritylguanosine (0.1 mmol) was suspended in 70% aqueous formic acid (2 ml) and stirred at room temperature for 30 min. The white precipitate of tritylcarbinol was filtered off and the colorless filtrate was poured into 8 ml of water and extracted with chloroform (3 × 2 ml). After evaporation of the chloroform at 30 °C the remaining residue was chromatographed on silica gel (2 g) with chloroform–methanol to give the desired 2′,3′,5′-tri-*O*-acetylguanosine (**11**). The yield of **11** was nearly quantitative in each experiment.

*2′,3′,5′-Tri-*O*-acetyl-*N^2*-tritylguanosine (1)* 2′,3′,5′-Tri-*O*-acetyguanosine (26.35 g, 64 mmol) was suspended in 400 ml of dry pyridine and heated at 100 °C and 53.9 g (0.193 mmol) of trityl chloride was added. After stirring at 100 °C for 6 h, the reaction mixture was poured into 1.5 l of water and extracted with dichloromethane (3 × 400 ml). The organic solvent was then removed by evaporation and the remaining oily residue was subjected to coevaporation with benzene (2 × 150 ml) for removal of the traces of pyridine. After that the dark brown oil (sometime it could crystallize) was suspended and stirred in 500 ml of ether for 1 h at room temperature. The resulting yellow precipitate was filtered off. After drying at 40 °C *in vacuo*, the crude 2′,3′,5′-tri-*O*-acetyl-N^2-tritylguanosine was dissolved in 90 ml of dichloromethane–methanol (9 : 1, v/v) and was purified by column chromatography on silica gel (60 g) by using dichloromethane–methanol as eluent. After evaporation of the eluate, the resulting light yellow solid was dissolved in 1.6 l of boiling methanol. The hot solution was filtered and the filtrate was concentrated by evaporation until 800 ml of methanol remained. External cooling (10—15 °C) was applied and after stirring of the suspension for 3 h the purified 2′,3′,5′-tri-*O*-acetyl-N^2-tritylguanosine was filtered and washed with a small amount of methanol. The yield was usually 70—80%.

We express great thanks to Prof. Hisashi Takei Tokyo Institute of Technology, for his kind gift of DMAP.

Reaction of Hexafluoropropene Dimers with Organomagnesium and -lithium Reagents

Nobuo Ishikawa,* Sigmund Butler, and Masamichi Maruta
Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 20, 1981)

Nucleophilic reactions of *F*-2-methyl-2-pentene (**1**) and (*E*)-*F*-4-methyl-2-pentene (**2**), the dimers of hexafluoropropene, with organomagnesium and -lithium reagents were investigated. The reaction of **1** proceeded readily, giving two alkyl- or aryl-substituted polyfluoroalkenes which resulted from α- and γ-fluorine elimination, respectively. Only phenyllithium reacted with **2**, giving also α- and γ-fluorine eliminated phenylpolyfluoroalkenes. The reaction mechanism of γ-elimination was postulated in relation to the electropositive property of the organo group and to Mg–F or Li–F bond formation.

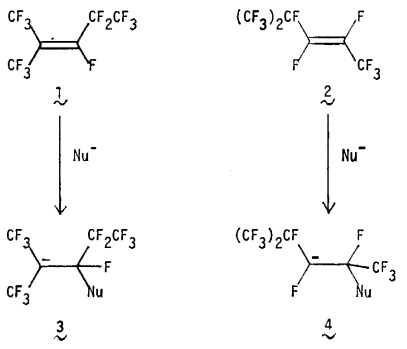
In our continuing studies on the chemistry of hexafluoropropene oligomers,[1] we have reported a number of reactions of the oligomers with various nucleophiles except those with C-nucleophiles such as organomagnesium or organolithium reagents. Although some reactions between terminal perfluoroalkenes and organometallic reagents of this type have been investigated,[2] none of reports on those of non-cyclized inner perfluoroalkenes have appeared in the literature.

In this paper we wish to reveal an interesting behavior of the dimers of hexafluoropropene, a typical inner perfluoroalkene, towards organomagnesium and organolithium reagents.

Results and Discussion

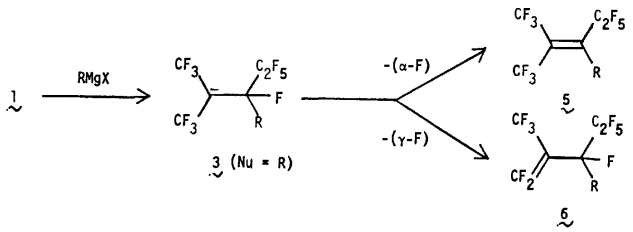
It is well known that two kinds of perfluoroalkenes are obtained by the anionic dimerization of hexafluoropropene:[1] *F*-2-methyl-2-pentene (**1**) and (*E*)-*F*-4-methyl-2-pentene (**2**).

The perfluoroalkene **1** is thermodynamically more stable than the other isomer **2**, and, nevertheless, **1** is much more reactive to O-, N- and S-nucleophiles than **2**.[3] This is ascribed to the higher stability of the carbanion (**3**) formed from **1** and a nucleophile, compared with the carbanion (**4**) derived from **2**, owing to the two electron-withdrawing trifluoromethyl groups attached to the anionic carbon atom.[3]

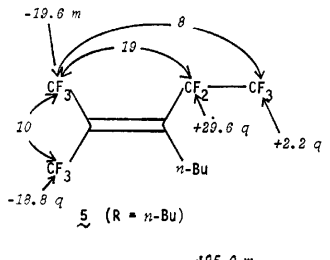


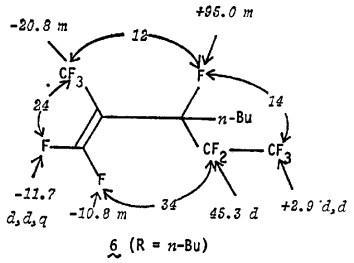
In a course of studies on the reactions of these dimers with organo-magnesium and -lithium reagents, we observed a similar tendency. The reaction of **1** was instantaneous and highly exothermic for all Grignard reagents except aryl one, while the less reactive isomer **2** with Grignard reagents, for example butylmagnesium bromide, did not produce any significant amount of products.

The products obtained by the reactions between **1** and alkylmagnesium halides were, however, always a mixture of two isomeric compounds which resulted from α- and γ-elimination of a fluoride ion from the intermediate carbanion **3** (Nu=R).



All the reactions were carried out in diethyl ether using about twice molar amounts of the Grignard reagents to ensure fast reaction. Although the two isomeric compounds in the products were not separable, the combined yield was over 70% (from ^{19}F NMR), and the structure of each isomer was readily established by careful checking of the ^{19}F NMR spectra. For example, the chemical shifts and coupling constants for the compound **5** and **6** (R=*n*-Bu) were as follows:†





† All the ^{19}F chemical shifts throughout this article are shown in δ ppm upfield from external CF_3CO_2H. The coupling constants are given in Hz.

Table 1. Reaction of *F*-2-methyl-2-pentene (**1**) with Grignard reagents

$$(CF_3)_2C{=}CFCF_2CF_3 \xrightarrow[Et_2O]{RMgX} (CF_3)_2C{=}C(R)CF_2CF_3 + CF_2{=}C(CF_3)CF(R)CF_2CF_3$$

a) Deviation in the range of ±3 °C was allowed. b) Based on the ^{19}F NMR signal intensities unless otherwise noted.
c) Isolated yield. d) 1 mmHg≈133.322 Pa.

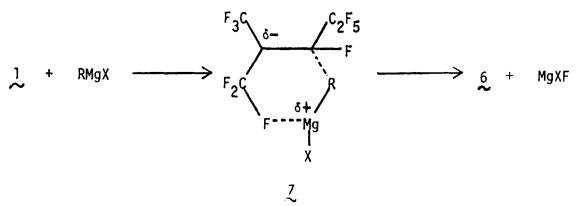
Although no evidence was found for isomerization of **6** into thermodynamically more stable **5** in the reaction system, and also in the post-treatment of the reaction mixture, the conversion was ascertained by the ^{19}F NMR to be realized readily by adding triethylamine in a polar solvent such as acetonitrile or *N*,*N*-dimethylformamide within 5 min, assisting confirmation of the structures.

The ratios of isomeric products in reaction mixtures, **6** *vs.* **5** or γ-elimination *vs.* α-elimination varied with the organo group of the reagents, reaction temperature, and other reaction conditions.

Thus, from Table 1, the order of percentage for γ-elimination forming **6** in ethereal solution was *i*-Pr> $PhCH_2$≫*n*-alkyl>aryl which is correlated to the relative reactivities of Grignard reagents, *i*-Pr>*s*-Bu>$PhCH_2$> *n*-alkyl.[4,5] Also the reactivity of Grignard reagents is correlated to the electropositivity of their identifying organo group[6] and, in fact, the order listed above shows a general, if imperfect, similarity to that of the electropositivities of organo groups, *i.e.* $PhCH_2$>*i*-Pr>*n*-alkyl>aryl.[7]

Regarding the mechanism of the reaction of **1** with Grignard reagents, α-elimination of a fluoride ion from the carbanion **3** resulting in a substituted product **5** is quite natural, and this type of reaction is frequently observed in the normal reactions of **1** with O- and N-nucleophiles.[1]

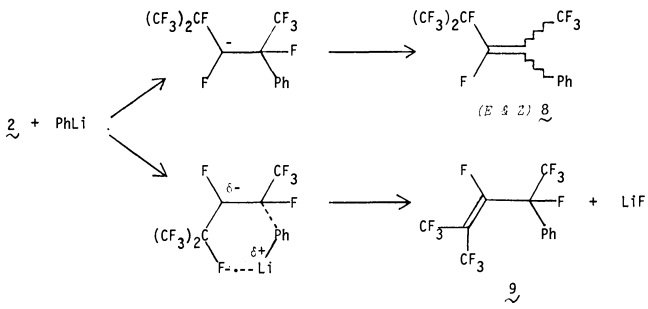
However, the formation of the rather unstable terminal alkene **6** resulted from γ-elimination is unusual. The elimination of a fluoride ion from the terminal trifluoromethyl group should be assisted by an electron donating group on one side and a fluoride ion-pulling group on another side. Thus we postulate that the magnesium behaves as a strong fluoride ion acceptor, as it can occupy a very close position to the fluorine atoms of CF_3, and as the Mg–F bond is thermodynamically very strong (462 kJ mol^{-1}).[8]



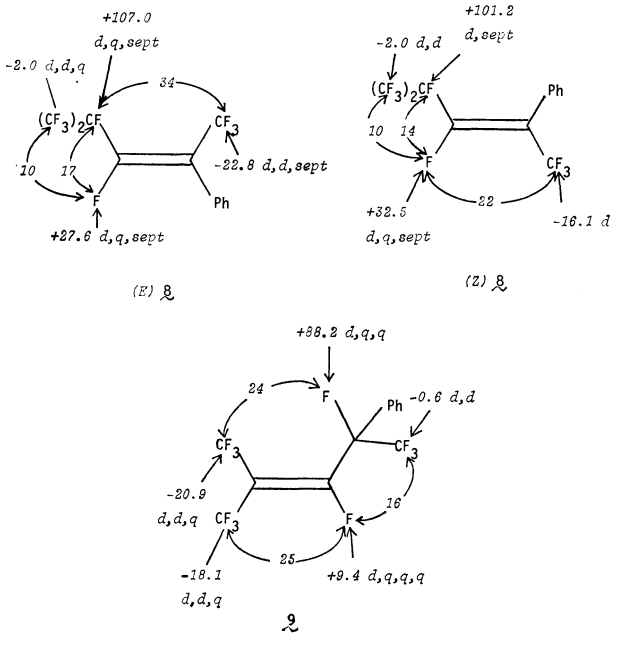
This kind of γ-elimination has been also observed in the reactions of **1** with thiols[9] and with ortho-difunctional benzenes.[10] The experimental fact mentioned above revealed that the more electropositive the organo group of the Grignard reagent is, the more γ-elimination becomes dominant. This is quite reasonable because an electropositive group will make the electron density more localized on a $^-C(CF_3)$ group, and will make magnesium more "metallic," and both effects will

render it easy to release a fluoride ion from the trifluoromethyl group. This assumption would be also supported by the difference in values **6**/**5** for RMgBr and RMgI. The more metallic organomagnesium bromide slightly prefers γ-elimination than organomagnesium iodide does. However, a fluoride ion elimination from a trifluoromethyl group is a process demanding higher energy because of a stronger carbon-fluorine bond in CF_3. So that it is natural that the reactions at higher temperatures enhanced the γ-elimination.

Similar reactions of another dimer, (*E*)-*F*-4-methyl-2-pentene, **2**, were sluggish and practically no products were formed with Grignard reagents. Phenyllithium, however, reacted with **2** and gave a significant amount of γ-elimination product (**9**) together with normal α-elimination product (**8**) in a ratio **9**/**8**=0.6.



This value seems rather high because probability of γ-elimination for **2** should be one sixth of that for **1**. However, it should be understandable by considering that the Li–F bond is very strong (577 kJ mol^{-1})[8] and the tertiary fluorine atom would be released easily to give a stable perfluoro inner alkene. The structures of these isomers were also established by careful cheking of the ^{19}F NMR spectra for the mixture though it was unable to separate them from each other. The ratio of **8** to **9** was 5 : 3, of which **8** containing (*E*) and (*Z*) form (1 : 6.5). The chemical shifts and coupling constants were assigned to all fluorine atoms of the isomers as above:



Experimental

Grignard Reactions of F-2-Methyl-2-pentene (1). Grignard reagents were prepared in a dried apparatus with air replaced by argon. Magnesium turnings and mild heating were used to initiate the reaction; in no case were chemical initiators necessary. The Grignard reagents in diethyl ether were very clear, almost colorless solution, except for aryl reagents which were dark brown. After formation of the Grignard reagent, the solution was brought to a specified temperature, and **1** was added with magnetic stirring. The addition was highly exothermic, and vigorous shaking of the bath was required to keep the temperature under control. Addition of the requisite amount of perfluoroalkene generally took about 5 min, after which the mixture was quenched by 2% HCl. Typical procedures are as follows.

Determination of Isomer Ratio. To the Grignard reagent prepared from magnesium turning (0.28 g, 11.5 mmol) and propyl bromide (1.51 g, 12.3 mmol) in dry diethyl ether (9 ml) was added **1** (purity over 95%, 1.62 g, 5.13 mmol) over 10 min at 0±3 °C. After stirring for 50 min at that temperature, the remaining Grignard reagent was quenched by the addition of dilute hydrochloric acid (2%, 2 ml). To the homogeneous ethereal solution, fluorobenzene (0.3784 g, 3.94 mmol) was added as internal standard. The ^{19}F NMR spectrum for this solution showed that the ratio of **6** to **5** (R=Pr) was 1.4, in a combined yield of 78%.

Isolation. To the Grignard reagent prepared from magnesium turning (2.65 g, 110 mmol) and octyl bromide (17.3 g, 90 mmol) in dry diethyl ether (55 ml) was added **1** (13 g, 41 mmol) at 0 °C. After 30 min the reaction was quenched by the addition of dilute hydrochloric acid (2%, 10 ml). The mixture was extracted with ether, washed with brine and dried over $MgSO_4$. After removing the solvent, distillation gave a mixture (15.2 g) of **5** and **6** (R=*n*-C_8H_{17}). The yield was 89%.

Isomerization of 6 to 5. To a mixture of **5** and **6** (R=alkyl) was added an approximately equal volume amount of acetonitrile in an NMR tube. It was ascertained by ^{19}F NMR that no isomerization occurred until a drop of triethylamine was added, upon which complete conversion of **6** to **5** occurred with 1 or 2 min. *N,N*-Dimethylformamide in the presence of triethylamine also effected the isomerization of **6** to **5** quantitatively.

Reaction with Phenyllithium. Into a solution of **1** (3.00 g, 10.0 mmol) in dry diethyl ether (20 ml), a solution of phenyllithium in diethyl ether (1.3 M (1 M=1 mol dm^{-3}), 10 ml) was dropped under nitrogen atmosphere at −60 °C, controlling the temperature with Dry Ice–acetone bath. The reaction mixture was stirred for 2 h allowing the temperature to rise up to room temperature. After additional stirring for 1 h at room temperature, the reaction was quenched by the addition of dilute hydrochloric acid and ethereal layer was washed with water and dried over $MgSO_4$. The solvent was removed and the residue was subjected to distillation *in vacuo* yielding a mixture of **5** and **6** (R=Ph) (2.25 g, 63%, **6**/**5**=0.16), bp 101—103 °C/97 mmHg. Found: C, 40.42; H, 1.47%. Calcd for $C_{12}H_5F_{11}$: C, 40.24; H, 1.41%.

In a similar manner, **2** (3.00 g, 10.0 mmol) and phenyllithium–diethyl ether solution (1.0 M, 20 ml) were allowed to react for 1 h at −70 °C. The reaction mixture was worked up as mentioned above and distillation under reduced pressure gave a mixture of **8** and **9** (2.80 g, 78%, **9**/**8**=0.6, (*Z*)**8**/(*E*)**8**=

6.5), bp 98—102 °C/115 mmHg. Found:C,40.04; H,1.48%. Calcd for $C_{12}H_5F_{11}$: C, 40.24; H, 1.41%.

A Synthesis of Human Proinsulin C-Peptide[1)]

Ken'ichi IGANO, Yuriko MINOTANI, Nobuo YOSHIDA, Masao KONO, and Ken INOUYE*

Shionogi Research Laboratories, Shionogi and Co., Ltd., Fukushima-ku, Osaka 553

(Received December 6, 1980)

A peptide corresponding to the thirty-one amino acid sequence of human proinsulin C-peptide (positions 33—63 of proinsulin) was synthesized by the solid-phase method. The product was purified consecutively by gel filtration, DEAE-cellulose chromatography, and high-performance liquid chromatography (HPLC). The purified material behaved as a single component in reversed-phase HPLC, gave correct amino acid ratios, and was not distinguished from natural human C-peptide in terms of immunoreactivity and chromatographic behaviors. The $\alpha \rightarrow \beta$ transpeptidation at the Asp–Leu sequence, possible to occur associated with the HF cleavage, was studied using model peptides to demonstrate that the formation of β-peptide was 3—4% regardless of whether the β-carboxylic acid is free or protected as a benzyl ester.

Proinsulin synthesized in the β cells of the pancreas is transferred to the Golgi apparatus, where this precursor is degraded into insulin and C-peptide by certain proteolytic processes and both are released into the circulation.[2,3)]

The measurement of the concentration of C-peptide in peripheral venous plasma is of increasing importance for estimating the endogenous function of the pancreas, particularly in patients receiving insulin therapy. For this purpose Melani *et al.* first established a radioimmunoassay system using natural human C-peptide.[3)] However, the use of natural peptide is extremely limited and in addition human C-peptide can not be substituted by the animal peptides because C-peptides are highly species-specific in their primary structure. The chemical synthesis is thus the only means to meet the requirement for this peptide.

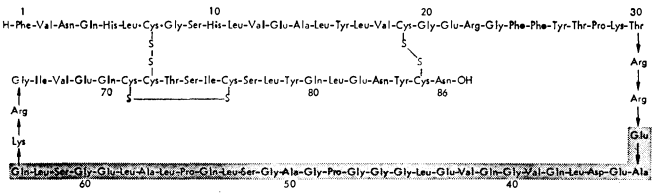

Fig. 1. Primary structure of human proinsulin.[4a)]
The shadowed portion indicates the region of C-peptide.

Human C-peptide (Fig. 1)[4)] is a thirty-one amino acid peptide corresponding to positions 33—63 of human proinsulin and contains none of aromatic amino acids, basic amino acids, and sulfur-containing amino acids. The synthesis by the conventional solution method has already been done by Naithani *et al.*,[5,6)] Geiger *et al.*,[7)] and Yanaihara *et al.*[8)] Yanaihara *et al.*[9)] also synthesized a derivative of human connecting peptide (Arg–Arg–C-peptide–Lys–Arg, positions 31—65 of proinsulin). These synthetic products were used in establishment of the radioimmunoassay system for C-peptide.[7,10,11)] The present paper describes our synthesis of human C-peptide by the solid-phase method.[12)] Synthesis of as large a peptide as C-peptide, particularly by the solid-phase technique, often presents considerable difficulty because it usually affords a highly heterogeneous product. Recently, however, HPLC has become a powerful tool for separation of closely related polypeptides[13,14)] including synthetic corticotropins and semisynthetic insulins.[14)] In the present synthesis of C-peptide also, reversed-phase HPLC played a major role in purification and characterization of the product.

Results and Discussion

The $\alpha \rightarrow \beta$ Rearrangement at the Aspartic Acid Residue. Human C-peptide contains a single Asp residue in position 36 (as numbered for proinsulin sequence) within the sequence Glu–Asp–Leu–Gln. It has been of special concern, particularly in the solid-phase synthesis, that Asp(OBzl)–Ser(Bzl)[15)] and Asp(OBzl)–Gly[16,17)] sequences are highly susceptible to cyclic imide formation when treated with HBr in TFA or with HF. The aspartimide formed is subject to nucleophilic attack at either carbonyl to give a mixture of α-Asp and β-Asp peptides. It is known, however, that Asp–Ser(Bzl) or Asp–Gly sequences containing a free β-COOH have little tendency to undergo this $\alpha \rightarrow \beta$ rearrangement.[15,18)] Thus, Yang and Merrifield[19)] proposed the use of the Pac group for temporary protection of the β-COOH. The Pac can be removed selectively after the completion of peptide synthesis but before the HF cleavage. This rearrangement is also known with other Asp peptides.[20)] Therefore, we tried to estimate the occurrence of the rearrangement in the present synthesis of C-peptide using Boc–Glu(OBzl)–Asp(OR)–Leu–Gly–OBzl (**1**: R=Bzl, **2**: R=H, **3**: R=Pac) as model compounds. The authentic samples of α-peptide, H–Glu–Asp(OH)–Leu–Gly–OH (**18**), and β-peptide, H–Glu–Asp(Leu–Gly–OH)–OH (**23**), were synthesized as illustrated in Fig. 2. They were well distinguished from each other and could, therefore, be determined easily on an amino acid analyzer.

The model compounds **1**—**3** were treated with HF–anisole in the usual manner and the product was

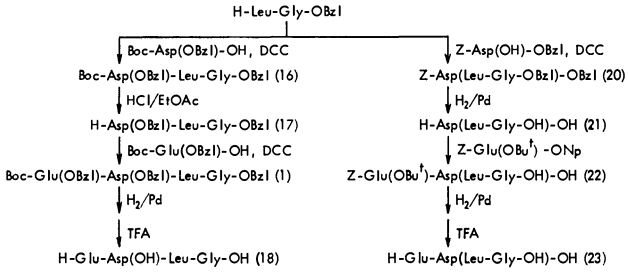

Fig. 2. Synthesis of model peptides.

Table 1. The $\alpha \rightarrow \beta$ rearrangement of aspartyl peptides, as examined with model compounds Boc–Glu(OBzl)–Asp(OR)–Leu–Gly–OBzl[a)]

R	Percent formation of	
	α-Peptide	β-Peptide
Bzl	96.9	3.1
H	95.9	4.1
Pac	49.4	50.6

subjected to an amino acid analyzer before and after treatment with triethylamine. Before the base treatment β-peptide was not found in the product, but the chromatogram showed the presence of an unknown material. When treated with base, β-peptide became detectable, while the unknown peak had disappeared completely, indicating the latter to be an aspartimide, H–Glu–Asp> Leu–Gly–OH, the intermediate to β-peptide. The results are summarized in Table 1. The data show that compound **1** is not more susceptible to the α→β rearrangement than compound **2**, indicating that in compound **1** the rate of cyclization is much slower than the rate of cleavage of the benzyl ester, that is, the protecting group is removed first, then cyclization occurs very slowly as in compound **2**. Since the Asp(OBzl)–Leu sequence was thus found not to be more susceptible than the Asp–Leu sequence, which gave 4% of β-peptide under the conditions used, we decided to use the benzyl ester as a protecting group of Asp-36 in the present synthesis of C-peptide.

Compound **3** containing a β-Pac ester has a great tendency to undergo rearrangement as shown in Table 1. Therefore, the β-Pac ester has to be removed completely prior to the HF cleavage,[19)] or otherwise its incomplete removal will lead to ready formation of β-peptide.

Solid-phase Synthesis of Human C-Peptide. The synthesis was started with the introduction of Boc–Gln to the solid support using perhydrodibenzo-18-crown-6 as catalyst according to Roeske and Gesellchen.[22)] The resulting Boc–Gln-resin had a substitution of 0.35 mmol Gln/g. A 2.5-g portion (0.87 mmol) of the resin was placed in a peptide synthesizer and subjected to cycles of synthesis according to the procedure outlined in Table 2. The amino acid residues were introduced stepwise except for positions 50—51, 44—49, and 38—40, which were introduced by using Boc–Ala–Gly–OH (**4**), Boc–Leu–Gly–Gly–Gly–Pro–Gly–OH (**5**), and Boc–Gln–Val–Gly–OH (**6**), respectively.

The α-amino function was temporarily blocked by the Boc group and the side chain functional groups of Asp, Glu, and Ser were protected by the benzyl group. The Boc group was removed with TFA–CH_2Cl_2 (1 : 1 by vol).[23)] The coupling reactions were mediated by DCC throughout except for glutamines which were incorporated by the active ester method using Boc–Gln–ONp with DMF as solvent (steps 11—13 in Table 2).

The DCC couplings were performed with 3 equiv of reactants (reactons) (6 equiv in the case of Boc–Pro or Boc–Val) at room temperature for 2 h, while the active ester couplings were carried out for 16 h with 6 equiv of Boc–Gln–ONp. All the coupling reactions were performed twice by repeating steps 11—20 and the second coupling reaction was followed by acetylation with acetic anhydride to block any remaining amino function

Table 2. Schedule for solid-phase synthesis of peptide

Step	Operation and reagent[a)]	Number of operation	Mixing time (min)
1	50% TFA in CH_2Cl_2, 15 ml	1	3
2	50% TFA in CH_2Cl_2, 15 ml	1	20
3	CH_2Cl_2, 15ml	2	3
4	2-Propanol, 15 ml	2	3
5	CH_2Cl_2, 15 ml	3	3
6	5% DIEA in CH_2Cl_2, 15 ml	2	3
7	Repeat step 3		
8	Repeat step 4		
9	Repeat step 5		
10	Monitoring[b)]		
11	Boc–amino acid or Boc–peptide (3 equiv.)[c)] in CH_2Cl_2, 6 ml[d)]		
12	CH_2Cl_2 rinse, 6 ml		
13	DCC (3 equiv.) in CH_2Cl_2, 6 ml		120

8	CH_2Cl_2, 15 ml	3	3

a) The washings collected in steps 5—8 are combined and subjected, after appropriate dilution with 95% ethanol, to manual measurement of absorption at 358 nm. The procedure basically follows Gisin's.[24)]

completely (steps 33—42).

The progress of solid-phase synthesis was monitored by the picrate method,[24] which determines resin-bound free amino group by picric acid salt formation. The determination was carried out, according to the procedure shown in Table 3, after every reaction of the deprotection, couplings, and acetylation. Only when a Gln came to the N-terminal, the determination after deprotection was omitted to prevent the chain termination by possible formation of the pyrrolidone ring. The picric acid bound to the resin was displaced by DIEA and measured on a spectrophotometer based on the molar absorptivity of 16100 at 358 nm.[24] The results are shown in Fig. 3. The total free amino group, as determined after deprotection, decreased progressively from 0.87 mmol for Gln-63 to 0.32 mmol for Ala-34 at an average rate of 4.5% per cycle.

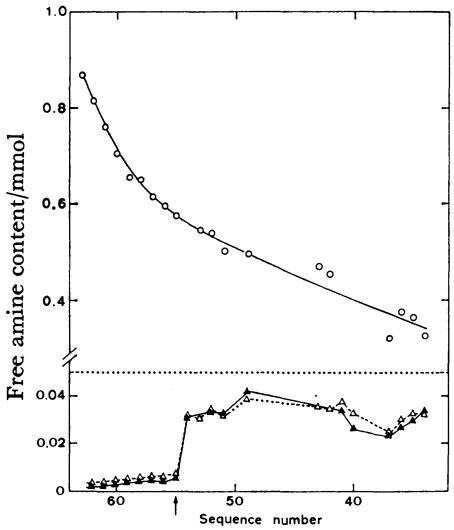

Fig. 3. Progress of solid-phase synthesis of human C-peptide as monitored by the picrate method.[24]
○—○: After deprotection (step 10 in Table 2), △---△: after 1st coupling (step 21 in Table 2), ▲—▲: after acetylation (step 43 in Table 2). Note that the scale is different between the upper part and the lower part of the ordinate. Sequence number (abscissa) represents position in the human proinsulin sequence. Positions 51—50, 49—44, and 40—38 were introduced as fragments. Glutamine residues occupy positions 54, 41, and 38, where the determination after deprotection (step 10 in Table 2) was eliminated. The arrow indicates the position of Pro-55. For details see text.

The free amino group was also determined after both first and second couplings. The values for the two determinations were nearly identical and were little affected by the subsequent acetylation, indicating that the reaction had been achieved satisfactorily by a single coupling operation. Therefore, the second coupling and acetylation might not be essential in the present synthesis. It is worthy of note that the picrate value showed a sudden rise by 0.02—0.03 mmol when Boc-Gln was introduced next to Pro-55. Schou *et al.*[25] suggested that an N-alkylation takes place between Pro and surplus chloromethyl group on the resin to form a tertiary amine. Such amine may be a cause for the apparent increase in free amino group which is seen in Fig. 3.

The protected peptide-resin obtained was found to contain 0.49 mmol of peptide, as calculated from the content of Leu. This value is significantly higher than the picrate value (0.32 mmol) obtained for Ala-34. The big difference might be a reflection of the accumulation of incomplete couplings not easily detectable by the picrate method.

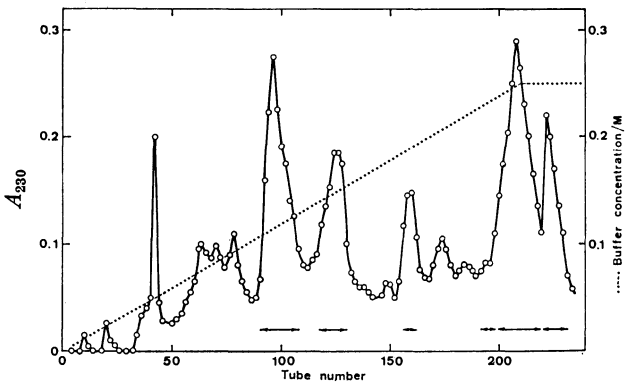

Fig. 4. Fractionation of crude human C-peptide preparation on DEAE-cellulose column.
Material: solid-phase synthetic product (gel-filtered through a Sephadex G-50 column), 237 mg; column: Whatman DE-52, 2.2×33 cm; eluent: 0—0.25 M NH_4HCO_3 (3000 ml) with a linear concentration gradient; fractionation: 14 ml/tube. Fractions, as indicated by the horizontal arrows, were collected.

The peptide-resin was deprotected with HF–anisole in the usual manner[21] and the resulting crude product was gel-filtered first and then subjected to DEAE-cellulose chromatography (Fig. 4). The fractions indicated by the horizontal arrows were collected and lyophilized. Tubes 199—220 and 221—234 had virtually the same and the simplest HPLC profile consisting of one major (**b**) and three minor components (**a**, **c**, and **d**) (Fig. 6A). These fractions were also shown to resemble human C-peptide more closely than any other fractions in the amino acid ratios. The combined amount of tubes 199—234 represented 25% of the crude product. Rechromatography of this preparation on a DEAE-cellulose column afforded a major peak (tubes 174—200, Fig. 5), from which a preparation containing components **a** and **b** but not **c** and **d** was obtained (Fig. 6B). For final purification, this was subjected to HPLC under conditions similar to those used for analytical HPLC. The eluate corresponding to component **b** was collected and desalted by gel filtration. The resulting preparation was shown to be fairly homogeneous by the criteria of HPLC (Fig. 6D) and TLC. The amino acid composition was consistent with that expected for human C-peptide and the optical rotation was identical with those reported in the literature.[5,6] Components **a**, **c**, and **d** have remained unidentified.

The synthetic peptide thus obtained was then compared with natural C-peptide preparations in order to establish their identity. For this purpose C-peptide was isolated from human urine and purified to a single

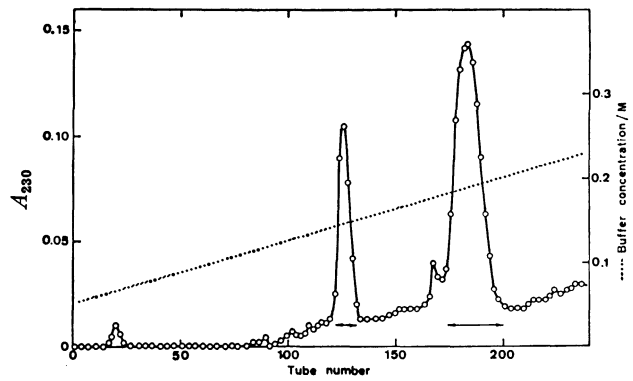

Fig. 5. Rechromatography of synthetic human C-peptide. Material: preparation from tubes 199—234 in Fig. 4, 21.3 mg; column: Whatman DE-52, 1.74×33 cm; eluent: 0.05—0.25 M NH_4HCO_3 (2000 ml) with a linear concentration gradient; fractionation: 6 ml/tube. Fractions, as indicated by the horizontal arrows, were collected.

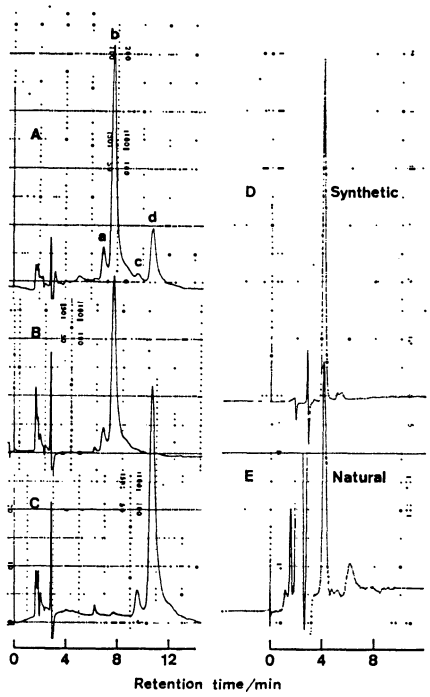

Fig. 6. HPLC of human C-peptide preparations.
A, tubes 199—220 in Fig. 4; B, tubes 174—200 in Fig. 5; C, tubes 122—132 in Fig. 5; D, synthetic C-peptide (component **b**, isolated by HPLC from tubes 174—200 in Fig. 5); E, natural C-peptide isolated from human urine. Peaks seen in E, but not in D, are those derived from a phosphate buffer used as solvent of natural C-peptide. HPLC conditions: column, Nucleosil $5C_{18}$, 0.4×25 cm; eluant, 0.1 M sodium phosphate (pH 7.0)–CH_3CN (79 : 21 by vol), 1 ml/min; detection, at 220 nm (0.04 AUFS).

component. This preparation contained all the constituent amino acids of human C-peptide in correct ratios. The isolation and purification of this urinary C-peptide will be described elsewhere. The identical HPLC profiles of the synthetic and natural preparations are shown in Fig. 6. Comparison between these two

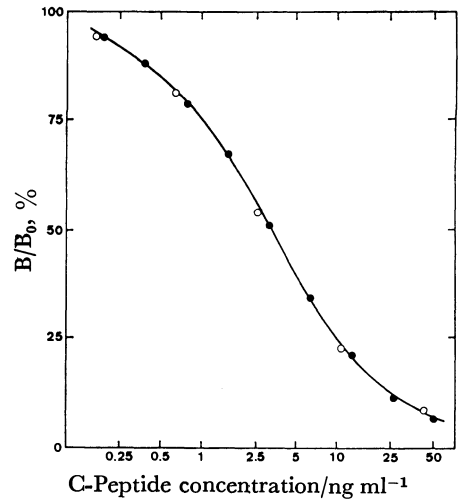

Fig. 7. Radioimmunoassay of human C-peptide preparations.
●—●: Synthetic C-peptide (component **b**), ○—○: natural C-peptide isolated from human urine. The assay was performed using a C-peptide assay system described elsewhere.[26]

preparations was also made in terms of the ability to displace [^{125}I]iodotyrosylated C-peptide specifically bound to the antibodies using a radioimmunoassay system developed by Kono *et al.*[26] As illustrated in Fig. 7, the displacement curves of the synthetic and natural preparations are perfectly superimposable. The identical results were also obtained in the radioimmunoassay performed with human pancreatic C-peptide as reference (data not shown).

These observations permit us to conclude that the synthetic peptide prepared in the present work is identical to human C-peptide.

Experimental

Protected amino acid derivatives, DCC, TFA, and chloromethylated copoly(styrene–2%-divinylbenzene) resin (200—400 mesh, 0.73 mmol Cl/g) were obtained from Protein Research Foundation, Osaka. DIEA (Aldrich) was distilled before use (bp 129—129.5 °C). Other reagents and solvents were of reagent grade and used without further purification. All melting points are uncorrected. TLC was performed on precoated silica gel plates (Kieselgel $60F_{254}$, Merck), unless otherwise specified, with the following solvent systems (ratios by vol): A, $CHCl_3$–MeOH (9 : 1); B, $CHCl_3$–MeOH (8 : 2); C, $CHCl_3$–MeOH–AcOH (90 : 10 : 3); D, $CHCl_3$–MeOH–AcOH (80 : 20 : 3); E, EtOAc–AcOH–H_2O (4 : 1 : 1); F, EtOAc–AcOH–H_2O (3 : 1 : 1). For detection the plate developed was sprayed with concd HCl, heated at 150 °C, and then sprayed with 0.2% ninhydrin in H_2O-saturated *n*-BuOH. Silica gel used for column chromatography was Kieselgel 60 (Merck). Amino acid analyses were performed on a Hitachi amino acid analyzer KLA-5 equipped with a Shimadzu data processor Chromatopac-ElA. Acid hydrolysis of peptide-resin samples was carried out in sealed evacuated tubes with concd HCl–propionic acid (1 : 1 by vol)[27] at 110 °C for 20 h. The hydrolysis of free peptides was carried out with 6 M HCl under similar conditions. Digestion with leucine aminopeptidase (Worthington) was performed as described by Hofmann *et al.*[28] in a substrate-enzyme ratio

of 10 (by wt). For HPLC a Waters Associates Model 6000A solvent delivery system, equipped with a Waters U6K injector, and a Japan Spectroscopic UVIDEC-100-II variable-wavelength UV detector were used throughout.

Peptide Synthesizer. A microcomputer-controlled semiautomated peptide synthesizer was designed and constructed in these Laboratories. The whole design basically followed that of Brunfeldt[29] except for the reaction vessel and its shaking device, which are rather similar to those of Merrifield's instrument.[30] The apparatus performed all the operations required for introduction of at least one amino acid residue or equivalent according to the schedule shown in Table 2. Although the apparatus is not equipped with any monitoring system, it performed transfer of reagents and solvents, for monitoring by the picrate method,[24] along the reservoir-reaction vessel-collecting bottle line. The spectrophotometric determination of the displaced picric acid was carried out manually.

Solid-phase Synthesis of Human C-Peptide. Neutralization of Boc–Gln–OH (2.1 g, 8.5 mmol) with KOH in 60% EtOH yielded Boc–Gln–OK, which was dried over P_2O_5 and then dissolved in DMF (100 ml). To this were added perhydrodibenzo-18-crown-6 (3.21 g, 8.6 mmol)[22] and chloromethylated copoly(styrene–2%-divinylbenzene) resin (10 g, 0.73 mmol Cl/g) and the mixture was gently stirred at 50 °C for 18 h. The Boc–Gln–resin thus obtained was filtered off, washed with DMF (30 ml×3), 75% DMF (30 ml×3), water (30 ml×2) and EtOH (30 ml×4) and dried over P_2O_5 *in vacuo* (11.2 g); Gln content: 0.35 mmol/g resin.

The Boc–Gln–resin (2.5 g, 0.87 mmol Gln) was placed in the peptide synthesizer and the synthesis was performed at room temperature according to the procedure shown in Table 2. On completion of the synthetic cycles the protected peptide-resin obtained was dried over P_2O_5 *in vacuo* (3.61 g).

A 1.08-g sample of the protected peptide-resin was treated with HF (7 ml) at −3—0 °C for 60 min in the presence of anisole (3 ml). After evaporation of the HF at the same temperature, the residue was triturated with EtOAc and the supernatant was discarded by decantation. The residue was washed with EtOAc two more times and then extracted with 0.05 M NH_4HCO_3. Lyophilization of the extract gave 320 mg of crude product.

The crude material (305 mg) was subjected to gel filtration on a column (3.3×91 cm) of Sephadex G-50 (superfine) with 0.05 M NH_4HCO_3 as eluent. Fractions (7.5 ml/tube) collected were monitored by absorbance at 230 nm and by TLC on a cellulose plate (Cellulose F_{254}, Merck) with *n*-BuOH–AcOH–pyridine–H_2O (30 : 6 : 20 : 24) as solvent. Tubes 40—83, which showed similar TLC patterns, were pooled and lyophilized (237 mg). This material was then fractionated on a DEAE-cellulose column (Whatman DE-52), as shown in Fig. 4, to give tubes 90—108 (40 mg), 118—130 (22 mg), 156—161 (11 mg), 191—198 (7 mg), 199—220 (60 mg), and 221—234 (17 mg). Amino acid ratios in acid hydrolysate of tubes 199—220: Asp 1.0 (1), Ser 1.8 (2), Glu 7.1 (8), Pro 2.5 (2), Gly 6.9 (7), Ala 3.0 (3), Val 1.9 (2), Leu 6.0 (6) (theoretical values for human C-peptide are given in parentheses).

Tubes 199—220 and 221—234 were combined and its small portion (21.3 mg) was rechromatographed on a DE-52 column (Fig. 5). The major peak at tubes 174—200 afforded 13.8 mg of peptide upon lyophilization. This was then subjected in ten separate portions (1.4 mg each) to HPLC on a column of Nucleosil $5C_{18}$ (1.0×30 cm) with a mixture of 0.01 M sodium phosphate buffer (pH 7.1) and CH_3CN (84.5 : 15.5 by vol) as eluent. The flow rate was 6 ml/min. The eluete corresponding to a major peak, as monitored by absorbance at 220 nm, was collected. Evaporation of the solvent gave a residue, which was desalted by gel filtration on a column (2.4×120 cm) of Sephadex G-25 (medium) with 5 mM NH_4HCO_3 as eluent. The peptide emerged was lyophilized and dried over P_2O_5; 7.6 mg (9% based on crude deprotection product), $[\alpha]_D^{26}$ −95.4±6.2° (*c* 0.2, 0.05 M NH_4HCO_3). Lit: $[\alpha]_D^{22}$ −95.4° (*c* 0.3, 0.05 M NH_4HCO_3),[5] $[\alpha]_D^{23}$ −96.2° (*c* 0.4, 0.05 M NH_4HCO_3),[6] $[\alpha]_D^{22}$ −92.3° (*c* 0.3, 0.1 M NH_3aq),[7] $[\alpha]_D^{20}$ −103.2° (*c* 1.00, 50% AcOH).[9] Amino acid ratios in acid hydrolysate: Asp 1.04 (1), Ser 1.88 (2), Glu 7.90 (8), Pro 2.24 (2), Gly 7.01 (7), Ala 3.09 (3), Val 1.95 (2), Leu 6.00 (6). TLC (cellulose): homogeneous in *n*-BuOH–AcOH–pyridine–H_2O (30 : 6 : 20 : 24). For HPLC see Fig. 6.

Synthesis of C-Peptide Fragments. *Boc–Ala–Gly–OBzl (**7**)*: Coupling of Boc–Ala–OH and H–Gly–OBzl (free base) with DCC in CH_2Cl_2 yielded compound **7**; 92%, mp 85—85.5 °C, $[\alpha]_D^{24.5}$ −28.1±0.7° (*c* 1.0, MeOH). Lit:[31] mp 83—84 °C, $[\alpha]_D^{20}$ −23.9° (*c* 1.0, $CHCl_3$). TLC: homogeneous in system C.

*Boc–Ala–Gly–OH (**4**)*: Catalytic hydrogenolysis of **7** gave **4** in 83% yield; mp 82—86 °C, $[\alpha]_D^{23.5}$ −25.1±0.6° (*c* 1.0, MeOH). Lit:[32] mp 78—80 °C, $[\alpha]_D$ −23° (MeOH). TLC: homogeneous in system C.

*Boc–Pro–Gly–OBzl (**8**)*: Coupling of Boc–Pro–OSu with H–Gly–OBzl (free base) in DMF yielded **8**; 88%, mp 71 °C, $[\alpha]_D^{25}$ −64.3±1° (*c* 1.0, MeOH). Lit:[33] mp 68—70 °C. TLC: homogeneous in system B.

*Boc–Gly–Pro–Gly–OBzl (**9**)*: Treatment of **8** with 1 M HCl in AcOH yielded H–Pro–Gly–OBzl·HCl, which was coupled with Boc–Gly–OSu in DMF in the presence of Et_3N to give **9**; 78%, mp 150—151 °C, $[\alpha]_D^{24}$ −81.3±1.6° (*c* 1.0, MeOH). Lit:[33] mp 145—147 °C. TLC: homogeneous in system B.

*Boc–Leu–Gly–Gly–OH (**10**)*: Coupling of Boc–Leu–OSu with H–Gly–Gly–OH (solubilized by Triton B) in DMF gave **10** as hygroscopic amorphous powder; 82%, $[\alpha]_D^{27}$ −8.1±0.5° (*c* 1.0, MeOH). TLC: homogeneous in system D. Found: C, 50.92; H, 7.74; N, 11.02%. Calcd for $C_{15}H_{27}N_3O_6\cdot 0.5H_2O$: C, 50.84; H, 7.96; N, 11.86%.

*Boc–Leu–Gly–Gly–NHNH$_2$ (**11**)*: Coupling of Boc–Leu–OSu with H–Gly–Gly–OBzl gave Boc–Leu–Gly–Gly–OBzl, from which compound **11** was derived by hydrazinolysis; 81%, $[\alpha]_D^{24}$ −8.3±0.5° (*c* 1.0, MeOH). TLC: homogeneous in system B. Found: C, 49.51; H, 7.83; N, 19.08%. Calcd for $C_{15}H_{29}N_5O_5\cdot 0.5H_2O$: C, 48.90; H, 8.21; N, 19.01%.

*Boc–Leu–Gly–Gly–Gly–Pro–Gly–OBzl (**12**)*: Treatment of **9** with 1 M HCl in EtOAc gave H–Gly–Pro–Gly–OBzl·HCl, which was coupled to **10** with DCC–HOSu[34] in DMF in the presence of Et_3N to yield **12** as amorphous solid; 87%, $[\alpha]_D^{24}$ −56.6±1.0° (*c* 1.0, MeOH). TLC: homogeneous in system B. Found: C, 56.61; H, 7.52; N, 12.56%. Calcd for $C_{31}H_{46}N_6O_9$: C, 56.78; H, 7.22; N, 12.81%.

Coupling of H–Gly–Pro–Gly–OBzl with the azide derived from **11** by the treatment with isopentyl nitrite[35] also produced **12** in 96% yield; $[\alpha]_D^{24.5}$ −57.0±0.9° (*c* 1.0, MeOH).

*Boc–Leu–Gly–Gly–Gly–Pro–Gly–OH (**5**)*: Catalytic hydrogenolysis of **12** in AcOH gave **5** as amorphous solid; 96%, $[\alpha]_D^{24.5}$ −55.9±1.0° (*c* 1.0, MeOH). TLC: homogeneous in system E. Found: C, 51.72; H. 7.18; N, 14.93%. Calcd for $C_{24}H_{40}N_6O_9$: C, 51.79; H, 7.24; N, 15.10%.

*Boc–Val–Gly–OBzl (**13**)*: Coupling of Boc–Val–OH and H–Gly–OBzl with DCC yielded **13**; 76%, mp 73—75 °C, $[\alpha]_D^{24}$ −27.1±0.7° (*c* 1.0, MeOH). Lit: mp 63—69 °C;[36] mp 74.5—76.5 °C, $[\alpha]_D^{20}$ −8.3° (*c* 2.0, DMF).[37] TLC: homogeneous in system A.

Boc-Gln-Val-Gly-OBzl (14): Treatment of **13** with TFA yielded H-Val-Gly-OBzl·TFA, which was coupled with Boc-Gln-ONp in DMF in the presence of DIEA to give **14**; 61%, mp 208—209 °C, $[\alpha]_D^{23}$ −47.9±1.3° (*c* 1.0, MeOH). TLC: homogeneous in system D. Found: C, 58.56; H, 7.10; N, 11.36%. Calcd for $C_{24}H_{36}N_4O_7$: C, 58.52; H, 7.34; N, 11.37%.

Boc-Gln-Val-Gly-OH (6): Catalytic hydrogenolysis of **14** in AcOH yielded **6** as amorphous solid; 76%, $[\alpha]_D^{26}$ −45.6 ±1.5° (*c* 0.5, MeOH). TLC: homogeneous in system F. Found: C, 50.47; H, 7.68; N, 13.76%. Calcd for $C_{17}H_{30}N_4O_7$: C, 50.47; H, 7.51; N, 13.92%.

Synthesis of Model Peptides. H-Leu-Gly-OBzl·HCOOH (15): Coupling of Boc-Leu-OH and H-Gly-OBzl with DCC followed by treatment with HCOOH for 5 h yielded **15**; 74%, mp 93—94 °C, $[\alpha]_D^{22.5}$ +7.4±0.5° (*c* 1.0, MeOH). Lit:[39] mp 92.5—93.5 °C, $[\alpha]_D^{20}$ +5.0° (*c* 1.0, MeOH). TLC: homogeneous in system E.

Boc-Asp(OBzl)-Leu-Gly-OBzl (16): Coupling of Boc-Asp-(OBzl)-OH and H-Leu-Gly-OBzl (free base derived from **15**) with DCC yielded **16**; 80%, mp 111—115 °C, $[\alpha]_D^{23}$ −38.6±0.8° (*c* 1.0, MeOH). TLC: homogeneous in system A. Found: C, 63.88; H, 7.19; N, 7.10%. Calcd for $C_{31}H_{41}N_3O_8$: C, 63.79; H, 7.08; N, 7.19%.

H-Asp(OBzl)-Leu-Gly-OBzl·HCl (17): Treatment of **16** with 1 M HCl in EtOAc produced **17**; 91%, mp 172—174 °C, $[\alpha]_D^{23}$ −19.7 ±0.6°, (*c* 1.0, MeOH). TLC: homogeneous in system B. Found: C, 59.83; H, 6.61; N, 8.10; Cl, 6.96%. Calcd for $C_{26}H_{33}N_3O_6$·HCl: C, 60.05; H, 6.59; N, 8.08; Cl, 6.82%.

Boc-Glu(OBzl)-Asp(OBzl)-Leu-Gly-OBzl (1): Boc-Glu-(OBzl)-OH and **17** were coupled with DCC in CH_2Cl_2 in the presence of DIEA to give compound **1** as amorphous solid after purification on a silica gel column with EtOAc–hexane (1 : 1) as solvent; 62%, $[\alpha]_D^{23}$ −30.1±0.7° (*c* 1.0, MeOH). TLC: homogeneous in system B. Found: C, 64.04; H, 6.80; N, 6.92%. Calcd for $C_{43}H_{54}N_4O_{11}$: C, 64.32; H, 6.78; N, 6.98%.

H-Glu-Asp-Leu-Gly-OH (18): Catalytic hydrogenolysis followed by treatment with TFA of compound **1** produced the TFA salt of **18**. This was treated with Amberlite CG-400 (acetate form) with 1 M AcOH as solvent. The resulting solution was lyophilized and the residue was subjected to chromatography on a column (1.2×29 cm) of DEAE-cellulose (Whatman DE-52) using an NH_4HCO_3 buffer (pH 7.8, 2000 ml) with a linear concentration gradient of 0—0.2 M. The fractions (10 ml/tube) were monitored by absorbance at 230 nm and those corresponding to a major peak were pooled and lyophilized. The resulting material was desalted by gel filtration on a Sephadex G-10 column with 0.1 M AcOH as eluent. A pure preparation of **18** was obtained as colorless powder upon lyophilization; 88%, $[\alpha]_D^{24}$ −36.2±1.4° (*c* 0.5, H_2O). TLC: homogeneous in system F. Found: C, 44.42; H, 6.82; N, 12.18%. Calcd for $C_{17}H_{28}N_4O_9\cdot 1.5H_2O$: C, 44.44; H, 6.80; N, 12.19%. Amino acid ratios in: acid hydrolysate: Asp 1.03 (1), Glu 1.03 (1), Gly 0.96 (1), Leu 1.00 (1); leucine aminopeptidase digest: Asp 0.97 (1), Glu 0.98 (1), Gly 0.97 (1), Leu 1.00 (1).

Z-Asp(OH)-OBzl (19): The Cs salt of Z-Asp(OBu^t)-OH was allowed to react with benzyl bromide at 25 °C for 3 d. The resulting Z-Asp(OBu^t)-OBzl was treated with 1 M HCl in EtOAc to give **19**; 39%, mp 83—84 °C, $[\alpha]_D^{25}$ −18.1±0.6° (*c* 1.0, MeOH). Lit:[40] mp 82—85 °C, $[\alpha]_D^{25}$ −15.3° (*c* 1.60, EtOH). TLC: homogeneous in system B.

Z-Asp(Leu-Gly-OBzl)-OBzl (20): Compound **19** and H-Leu-Gly-OBzl (free base derived from **15**) were coupled with DCC to yield **20**; 74%, mp 150 °C, $[\alpha]_D^{25}$ −35.2±0.8° (*c* 1.0, MeOH). TLC: homogeneous in system B. Found: C, 66.22; H, 6.53; N, 7.01%. Calcd for $C_{34}H_{39}N_3O_8$: C, 66.11; H, 6.63; N, 6.80%.

H-Asp(Leu-Gly-OH)-OH (21): Crystalline **21** was obtained from **20** by catalytic hydrogenolysis in AcOH; 93%, mp 236—237 °C dec, $[\alpha]_D^{26}$ −30.0±0.7° (*c* 1.0, H_2O). Found: C, 47.42; H, 7.09; N, 13.52%. Calcd for $C_{12}H_{21}N_3O_6$: C, 47.52; H, 6.98; N, 13.85%.

Z-Glu(OBu^t)-Asp(Leu-Gly-OH)-OH (22): Compound **21** was coupled with Z-Glu(OBu^t)-ONp in DMF in the presence of DIEA to give **22** as amorphous solid; 89%, $[\alpha]_D^{24}$ −24.9 ±0.6° (*c* 1.0, MeOH). TLC: homogeneous in system E. Found: C, 54.98; H, 6.88; N, 8.64%. Calcd for $C_{29}H_{42}N_4O_{11}\cdot 0.5H_2O$: C, 55.14; H, 6.86; N, 8.87%.

H-Glu-Asp(Leu-Gly-OH)-OH (23): Catalytic hydrogenolysis and subsequent treatment with TFA of **22** yielded **23**, which was purified in the same manner as described for **18**; 86%, $[\alpha]_D^{24.5}$ −8.0±0.5° (*c* 1.0, H_2O). TLC: homogeneous in system E. Found: C, 43.99; H, 6.71; N, 11.73%. Calcd for $C_{17}H_{28}N_4O_9\cdot 2H_2O$: C, 43.59; H, 6.89; N, 11.96%.

Boc-Asp(OPac)-Leu-Gly-OBzl (24): Boc-Asp(OPac)-OH derived from the dicyclohexylamine salt[19] and H-Leu-Gly-OBzl derived from **15** were coupled with DCC to give **24**; 84%, mp 233—233.5 °C, $[\alpha]_D^{22}$ −36.5±0.8° (*c* 1.0, MeOH). TLC: homogeneous in system B. Found: C, 62.89; H, 6.91; N, 6.78%. Calcd for $C_{32}H_{41}N_3O_9$: C, 62.83; H, 6.76; N, 6.78%.

H-Asp(OPac)-Leu-Gly-OBzl·HCl (25): Treatment of **24** with M HCl in EtOAc yielded **25**; 90%, mp 79—80 °C, $[\alpha]_D^{23}$ −7.4±0.5° (*c* 1.0, MeOH). TLC: homogeneous in system D. Found: C, 58.93; H, 6.17; N, 7.65; Cl, 6.55%. Calcd for $C_{27}H_{33}N_3O_7$·HCl: C, 59.17; H, 6.25; N, 7.67; Cl ,6.47%.

Boc-Glu(OBzl)-Asp(OPac)-Leu-Gly-OBzl (3): Coupling of Boc-Glu(OBzl)-OH and H-Asp(OPac)-Leu-Gly-OBzl (free base derived from **25**) with DCC yielded **3**, which was purified on a silica gel column with 20—30% EtOAc in CH_2Cl_2 as solvent; 68%, mp 142—143.5 °C, $[\alpha]_D^{23}$ −31.6 ±0.7° (*c* 1.0, MeOH). TLC: homogeneous in system B. Found: C, 63.33; H, 6.55; N, 6.91%. Calcd for $C_{44}H_{54}N_4O_{12}$: C, 63.60; H, 6.55; N, 6.74%.

Boc-Glu(OBzl)-Asp(OH)-Leu-Gly-OBzl (2): Compound **3** was treated with Zn in AcOH at 25 °C overnight to give the Zn salt of **2** as amorphous solid. TLC: almost homogeneous in system C. Found: C, 51.88; H, 6.25; N, 7.01%. Calcd for $C_{36}H_{47}N_4O_{11}Zn$: C, 50.95; H, 6.10; N, 7.21%.

The α→β Rearrangement of Aspartyl Peptides. The model compound (**1**, **2**, or **3**; 108 mg) was treated with HF (2 ml) in the presence of anisole (0.3 ml) at 0 °C for 60 min. The HF was evaporated at 0 °C *in vacuo* and the residue was dissolved in water. The solution was washed twice with Et_2O and then lyophilized (80 mg). A 30-mg portion of this product was dissolved in 1% Et_3N (5 ml) and the solution was kept at 37 °C for 16 h, after which the solvent was removed by lyophilization. The resulting material was subjected to determination on an amino acid analyzer. The contents of α-peptide [H-Glu-Asp(OH)-Leu-Gly-OH] and β-peptide [H-Glu-Asp(Leu-Gly-OH)-OH] were calculated with the authentic samples (**18** and **23**) as reference. The α-peptide and β-peptide had retention times of 103 and 91 min, respectively, and the ninhydrin color intensity of β-peptide was found to be 0.96 relative to that of α-peptide under the following conditions: column, Hitachi Custom No. 2613, 0.9× 55 cm; buffer, 0.2 M sodium citrate (pH 3.25), 30 ml/h; temp, 55 °C. The results are shown in Table 1.

The peptide synthesizer used in the present work was

constructed in these Laboratories in collaboration with Drs. Hiroshi Hakata and Tetsuo Takahashi and their groups including Nobuhiko Imamura, Masayoshi Shudou, Masamitsu Nakanishi, and Hiroyuki Miyamoto. Their valuable contributions are gratefully acknowledged. Thanks are also due to Dr. Tadashi Okabayashi, these Laboratories, for his advice and encouragement.

(Received January 29, 1981)

Optically active alkyl cobalt complexes, $CH_3CHXCo(Hdmg)_2$·Base [X=$COOCH_3$ or CN; Base=(*R*)- or (*S*)-1-phenylethylamine, H_2O, pyridine, or (1*R*,2*S*)-1,2-diphenyl-2-aminoethanol; Hdmg=dimethylglyoximate-(1-)], have been prepared, and their spectroscopic and chiroptical data are given. The rotational contribution of the chiral alkyl moiety was shown to be considerably greater than that of the chiral amine moiety. This suggests that the rotational sign (in the longer-wave length region of about 546 to 589 nm) may be useful for deducing the chirality of the alkyl moiety.

Transition-metal alkyl complexes are important intermediates in various catalytic reactions. The reactions with chiral alkyl transition metal complexes can provide a clearer description of the elementary process of catalytic reactions, especially catalytic asymmetric reactions. Studies on the mechanism of asymmetric hydrogenation catalyzed by the bis-(dimethylglyoximato)cobalt(II)–chiral amino alcohol system[1-5] prompted us to prepare optically pure (alkyl)bis(dimethylglyoximato)cobalt complexes which have chirality at the carbon coordinated directly to cobalt.

Two approaches are, in principle, possible in the preparation of such a complex. One is based on the stereospecific displacement of a labile group or atom of chiral-carbon compounds with metal complexes (1).[6] Another method is the resolution of diastereomeric complexes with a chiral ligand (L_1*) other than the alkyl group, followed by the displacement of the chiral ligand L_1* with an achiral ligand (L_2) (2). The optical purity gained by the former approach is completely dependent on the degree of stereospecificity of the reaction applied; also, there is no guarantee that the same stereospecificity will be afforded as in a model reaction. In fact, (−)-1-methylheptyl bromide ($[\alpha]_D$ −29°) reacts with bis(dimethylglyoximato)cobalt (I) anion to give bis(dimethylglyoximato)(1-methylheptyl)(pyridine)cobalt(III) of $[\alpha]_D$ +50°,[6a] while we could not detect the optical activity of the alkyl complex produced in a similar reaction with optically pure methyl 2-bromopropanoate. Therefore, the latter method (2) is considered to be favorable for obtaining optically pure alkyl complexes.

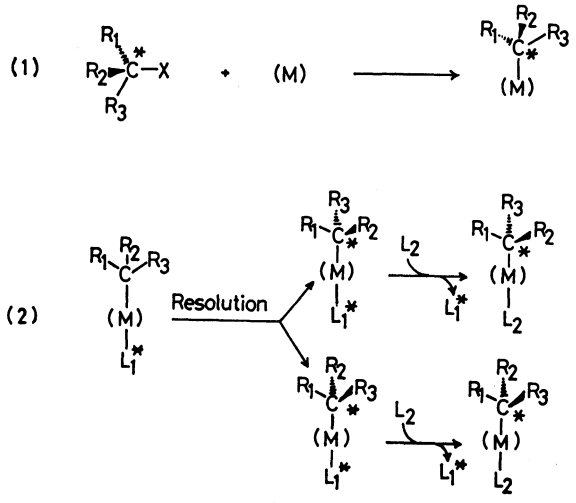

Fig. 1.

We wish here to report preparations and properties of some optically pure (alkyl)bis(dimethylglyoximato)-cobalt complexes.

Results and Discussion

Bis(dimethylglyoximato)cobalt(II) was allowed to react with methyl acrylate or acrylonitrile in methanol under weakly acidic conditions under a hydrogen atmos-

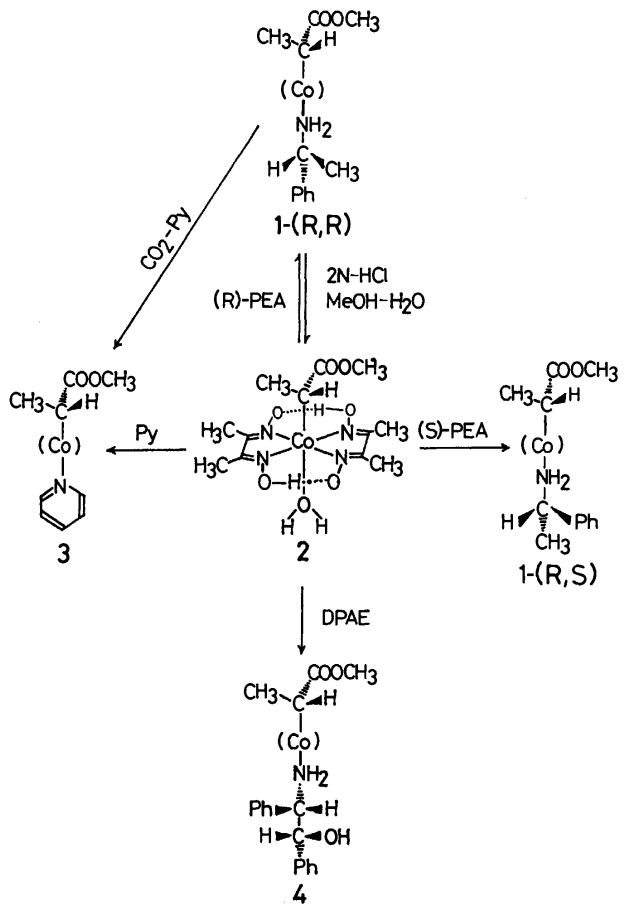

Fig. 3.

phere.[7] After neutralization, (*R*)- or (*S*)-1-phenylethylamine was added to give diastereomeric alkyl complexes with a chiral axial base (**1** or **5**; see Fig. 2). The repeated recrystallization of **1** from a mixture of methanol and water gave $(+)_{578}$-bis(dimethylglyoximato)[1-(methoxycarbonyl)ethyl]cobalt(III), **1**-(*R*,*R*), with $[\alpha]_{578}$ +211.3°. (*S*)-1-Phenylethylamine coordinated 1-cyanoethyl cobalt complexes were resolved into two diastereomers, **5**-(*R*,*S*) ($[\alpha]_{578}$ +55.85°) and **5**-(*S*,*S*) ($[\alpha]_{578}$ −60.13°). By the use of (*R*)-1-phenylethylamine, the enantiomer of the former, **5**-(*S*,*R*), was also obtained ($[\alpha]_{578}$ −55.6°).

The absolute configurations of cobalt-alkyl moieties of dextrorotating $(+)_{578}$-bis(dimethylglyoximato)-[1-(methoxycarbonyl)ethyl][(*R*)-1-phenylethylamine]-cobalt(III), dextrorotating $(+)_{578}$- and levorotating $(-)_{578}$-1-cyanoethylbis(dimethylglyoximato)[(*S*)-1-phenylethylamine]cobalt(III) were determined by the X-ray method to be (*R*), (*R*), and (*S*) respectively.[8–10]

The ^{1}H NMR spectra and main bands of the IR spectra of diastereomeric pairs of 1-(methoxycarbonyl)-ethyl and 1-cyanoethyl complexes are shown in Tables 1 and 2.

A diastereomeric difference appears in the ^{1}H NMR signals of the proton on the carbon attached to cobalt: the HC–Co proton signal of the *R*–*S* complex (**1**-(*R*,*S*), **5**-(*R*,*S*)) appears in a somewhat higher field (0.02 ppm) than that of the corresponding *R*–*R* or *S*–*S* complex (**1**-(*R*,*R*) or **5**-(*S*,*S*)). The absorption bands due to the asymmetric stretching vibration of $-NH_2$ of the *R*–*R* or *S*–*S* complex appear at a higher frequency than that of the diastereomer, the *R*–*S* complex, while the other absorption bands are almost identical.

Aquabis(dimethylglyoximato)[(*R*)-1-(methoxycarbonyl)ethyl] cobalt(III) was obtained in about a 60% yield by treating **1**-(*R*,*R*) with 2 mol dm^{-3} hydrochloric acid in aqueous methanol. The aqua ligand is so labile in this complex that the aqua complex is a useful intermediate in exchanging the axial ligand. Thus, the pyridine, (1*R*,2*S*)-1,2-diphenyl-2-aminoethanol, and (*S*)-1-phenylethylamine coordinated complexes were easily derived only by evaporating a methanol solution of an equimolar amount of the aqua complex and the axial base desired (Fig. 3). The pyridine complex (**3**) was also obtained in one step by treating **1**-(*R*,*R*) with CO_2

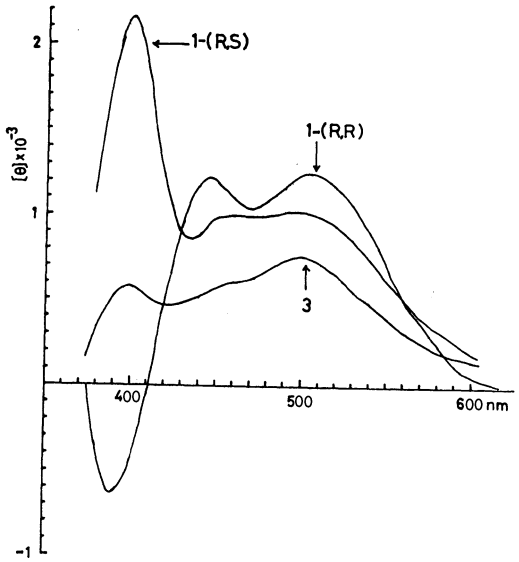

Fig. 4. CD spectra of 10^{-3} mol dm^{-3} dichloromethane solution of **1**-(*R*,*R*), **1**-(*R*,*S*), and **3**.

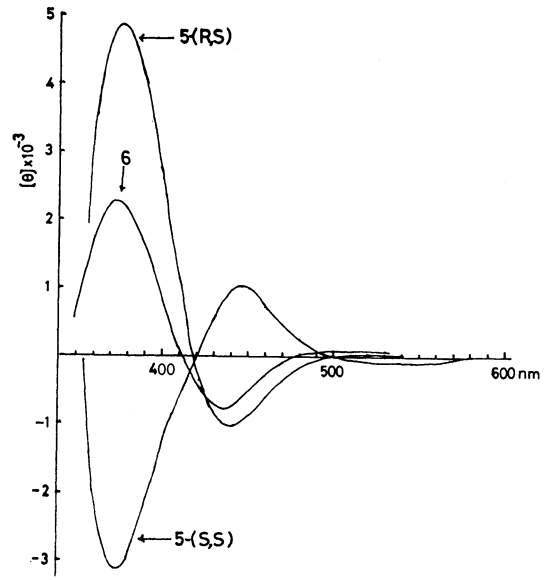

Fig. 5. CD spectra of 10^{-3} mol dm^{-3} dichloromethane solution of **5**-(*R*,*S*), **5**-(*S*,*S*), and **6**.

Table 3. Specific and molecular rotation of 1-substituted ethyl cobaloximes, CH_3CHX–$Co(Hdmg)_2$-base, and their configurations at α-carbon

	X	Axial base	Conf. at α-carbon	$[\alpha]_{578}^{RT}$	$[\phi]_{578}^{RT}$ [d]
1-(*RR*)	$COOCH_3$	(*R*)-1-PEA[a]	*R*[c]	+211($CHCl_3$)	+1051
1-(*RS*)	$COOCH_3$	(*S*)-1-PEA	*R*	+161($CHCl_3$)	+801
2	$COOCH_3$	H_2O	*R*	+160(MeOH)	+631
3	$COOCH_3$	Pyridine	*R*	+167($CHCl_3$)	+760
4	$COOCH_3$	(1*R*,2*S*)-DPAE[b]	*R*	+143($CHCl_3$)	+843
5-(*RS*)	CN	(*S*)-1-PEA	*R*[c]	+55.85($CHCl_3$)	+259
5-(*SR*)	CN	(*R*)-1-PEA	*S*[c]	−55.6($CHCl_3$)	−258
5-(*SS*)	CN	(*S*)-1-PEA	*S*[c]	−60.13($CHCl_3$)	−279
6	CN	Pyridine	*R*	+52.2($CHCl_3$)	+220

a) 1-PEA: 1-phenylethylamine. b) (1*R*,2*S*)-DPAE: (1*R*,2*S*)-1,2-diphenyl-2-aminoethanol. c) These configurations were determined by the X-ray method.[3-5] d) Molecular rotation.

Table 4. Estimation of partial contribution of alkyl and amine parts for molecular rotation of diastereomeric 1-substituted ethyl-(1-phenylethylamine)cobaloximes

Alkyl		Base	Parial contribution	
Substituent	Configuration		$[\phi_{alkyl}]_{578}$	$[\phi_{amine}]_{578}$
$COOCH_3$	*R*	(*R*)-1-PEA[a]	+925.9	+125.1
$COOCH_3$	*R*	(*S*)-1-PEA[a]	+925.9	−125.1
CN	*R*	(*S*)-1-PEA	+269.3	−9.9
CN	*S*	(*S*)-1-PEA	−269.3	−9.9

a) (*R*)-1-PEA: (*R*)-1-phenylethylamine.

and pyridine. 1-Cyanoethyl complex, **6**, was obtained by the same procedure. The structures of these complexes were characterized by IR, ^1H NMR, and/or elemental analyses.

No substantial racemization occurs during the ligand-exchange process: optical rotation did not decrease during 12 h under the conditions applied in ligand exchange, and the (*R*)-1-phenylethylamine complex, **1**-(*R*,*R*), regained through the aqua complex showed almost the same optical rotation ($[\alpha]_{578}$ +210°) as the original one.

The CD spectra of chiral 1-cyanoethyl and 1-(methoxycarbonyl)ethyl complexes are shown in Figs. 4 and 5 respectively. (*R*)-1-Cyanoethyl complexes (**5**-(*R*,*S*), **6**) have clear negative and positive Cotton effects at about 440 and 375 nm respectively; the (*S*)-1-cyanoethyl complex (**5**-(*S*,*S*)) also has clear but reverse Cotton effects at the corresponding wave lengths. However, the (*R*)-1-(methoxycarbonyl)ethyl complexes (**1**-(*R*,*R*), **1**-(*R*,*S*), **3**) give broad positive spectra, ranging from 600 to 400 nm, and the CD peak around 380 nm is greatly influenced by the chiral amine moiety rather than by the chiral alkyl. Thus, the configuration of the alkyl part can not simply be deduced from the sign of the Cotton effect.

The specific rotations and molecular rotations of the chiral alkyl-cobalt complexes prepared here are listed in Table 3. As may be seen from Table 3, the (*R*)-1-substituted alkyl complex and the (*S*)-1-substituted alkyl complex causes positive and negative rotation respectively. If the contribution from a chiral distortion of the inplane ligand is negligible, the molecular rotation of diastereomeric complex will be expressed by the sum of the partial contributions of the alkyl part ($[\phi_{alkyl}]$)

and the amine part ($[\Phi_{amine}]$):

$$[\Phi] = [\Phi_{alkyl}] + [\Phi_{amine}]. \quad (1)$$

The $[\Phi_{alkyl}]$ and $[\Phi_{amine}]$ values of the diastereomers are calculated (Table 4). From Table 4 it can be said that the partial contribution of the alkyl part is considerably greater than that of the amine part, and the calculated values of the partial contribution of the alkyl part, $[\Phi_{alkyl}]$, are comparatively near to the molecular rotations of the corresponding pyridine complex, **3** or **6**, which has no chirality on the axial base. Thus, the rotational sign (in the longer-wavelength region of about 546 to 589 nm) can be useful for deducing the configuration of the 1-substituted alkyl metal complexes. Further studies on this respect are now under way.

Experimental

The IR spectra were recorded on a JASCO A-3 spectrometer. The NMR spectra were obtained on a JEOL JNM-PS-100 spectrometer, using TMS as the internal standard. The optical rotations were measured on a Perkin-Elmer 241 polarimeter and a Carl Zeiss photoelectric precision polarimeter. The circular dichroism spectra were recorded on a JASCO J-40C spectrometer.

Bis(dimethylglyoximato) [(R)-*1-(methoxycarbonyl) ethyl*] [(R)-*1-phenylethylamine*]*cobalt(III)*, (**1**-(R,R)). To a methanol (100 cm³) solution of $Co(OCOCH_3)_2 \cdot 4H_2O$ (50 g) was added a hot solution of dimethylglyoxime (47 g) in methanol (400 cm³) under a nitrogen atomosphere with stirring. The solution was stirred for 5—10 min. The reaction vessel was then connected to a hydrogen-gas burret. 22.5 cm³ of methyl acrylate was added to the reaction vessel by means of a syringe. The reaction mixture was then stirred under a hydrogen atmosphere. After a theoretical amount of hydrogen had been absorbed, the reaction mixture was neutralized by an aqueous solution of sodium hydroxide (16 g) on cooling. To the resulting solution, 25.5 cm³ of *R*(+)-1-phenylethylamine ($[\alpha]_D^{23}$ +38°) was added. The products were extracted with dichloromethane (2 dm³) and washed several times with water. The dichloromethane solution was dried over anhydrous sodium sulfate and concentrated *in vacuo* to give a crystalline mass. The crude product was dissolved in methanol (370 cm³) at room temerature. The solution was filtered, and then, to the filtrate, water (445 cm³) was added gradually by means of a syringe on warming (30—35 °C). The solution was left standing overnight at room temperature. The dark red crystals thus deposited were collected by filtration; 25.4 g (1C-I). 1C-I (25.4 g) was recrystallized from methanol (240 cm³) and water (288 cm³) to give 15 g of crystals (1C-II), $[\alpha]_{578}$ +195.5° (*c* 0.404, chloroform). The recrystallization of 1C-II (14.9 g) from methanol (144 cm³) and water (156 cm³) gave 10.4 g of crystals (1C-III), $[\alpha]_{578}$ +211.3°, $[\alpha]_{546}$ +233,4° (*c* 0.407, chloroform). Found: C, 48.34; H, 6.33; N, 14.39%. Calcd for $C_{20}H_{32}N_5O_6Co$: C, 48.29; H, 6.48; N, 14.08%.

Aquabis(dimethylglyoximato) [(R)-*1-(methoxycarbonyl) ethyl*]*cobalt(III)*, (**2**). To a methanol (20 cm³) solution of 4.5 g of **1**-(*R*, *R*) was added 2 mol dm⁻³ hydrochloric acid (9 cm³), after which the solution was left standing for 2 h, and then 9 cm³ of 6 mol dm⁻³ hydrochloric acid was added. The resulting complexes were extracted with three 100-cm³ portions of dichloromethane. The extract was neutralized by adding an excess of solid potassium carbonate and 1 cm³ of water. After 10 min, the dichloromethane solution was concentrated under a reduced pressure to give a crystalline mass. The crude product was dissolved in acetone (10 cm³). In a few minutes crystals appeared which were collected by filtration; 1.7 g (48%). These are satisfactory enough for further syntheses. From the above filtrate another crop (0.9 g) of crystals was obtained by concentrating it, followed by treating the residue with acetone. The product was further purified by silica-gel column chromatography (Kiesel gel 60, Merck), using acetone–benzene as the eluent. Fractions giving a single spot on TLC [R_f 0.45, acetone (2)/benzene(1)] were collected and concentrated under reduced pressure to give a thick paste, which was then crystallized on addition of acetone. $[\alpha]_{578}$ +160° (*c* 0.206, methanol); IR(KBr): 3400 (OH), 1670 (ester), 1565 cm⁻¹ (C=N); ¹H NMR (D_2O): δ 0.05 (d, 3H, $\underline{CH_3}CHCo$), 2.28 and 2.29 (CH_3 of Hdmg), 3.38 (s, 3H, $-COOCH_3$), 4.75 (broad, HOD); Found: C, 37.05; H, 5.89; N, 14.50%. Calcd for $C_{12}H_{23}N_4O_7Co$: C, 36.56; H, 5.88; N, 14.21%.

Bis(dimethylglyoximato)[(R)-*1-(methoxycarbonyl)ethyl*]*(pyridine)-cobalt(III)*, (**3**). *Method (A)*: 2.7 g of bis(dimethylglyoximato)[(*R*)-1-(methoxycarbonyl)ethyl][(*R*)-1-phenylethylamine]cobalt(III) ($[\alpha]_{578}$ +209°) was dissolved in methanol (30 cm³), and pyridine (1.5 cm³) was then added. Carbon dioxide was bubbled through the solution for 20 min, and then 15 cm³ of water were added. The bubbling was continued for another 10 min. The reaction mixture was extracted with 200—250 cm³ of benzene and washed several times with water. The benzene layer was dried over anhydrous sodium sulfate and concentrated under reduced pressure to give a yellow crystalline powder; 2.14 g (87%). The crude product (1 g) was recrystallized from methanol (15 cm³) and water (25 cm³) to give leaflets (0.46 g), $[\alpha]_{578}$ +167°, $[\alpha]_{546}$ +198° (*c* 0.408, chloroform). The IR and ¹H NMR spectra were identical with those of the racemic compound.

Method (B): 8 g of bis(dimethylglyoximato)[(*R*)-1-(methoxycarbonyl)ethyl][(*R*)-1-phenylethylamine]cobalt(III) ($[\alpha]_{578}$ +196°) was dissolved in methanol (35 cm³), and then 12 cm³ of 2 mol dm⁻³ hydrochloric acid were added. After 1 h, pyridine (2.5 cm³) was added to the solution. The resulting solution was left standing for another 30 min, extracted with 200 cm³ of dichloromethane, and then washed with water. The dichloromethane layer was dried over anhydrous sodium sulfate and concentrated under reduced pressure to give a yellow crystalline powder; 7 g (96%). The IR and ¹H NMR spectra were identical with those of the racemic compound.

Mutarotation of Compound 3 in Methanol–Water: To a methanol (5 cm³) solution of the pyridine complex **3** (0.0303 g, 0.09 mmol) were added water (5 cm³) and pyridine (0.021 g, 0.27 mmol). The optical rotational change of the above solution was followed. The change was very slow (see below):

Time/h	α_{578}/°
0.0	+0.31
0.5	+0.31
12.0	+0.30
20.0	+0.28
111.0	+0.175

Bis(dimethylglyoximato) [(R)-*1-(methoxycarbonyl) ethyl*] [(S)-*1-phenylethylamine*]*cobalt(III)*, (**1**-(R,S)). 300 mg (0.76 mmol) of the *R*(+)-aqua complex (**2**) and 93 mg (0.76 mmol) of (*S*)-(−)-1-phenylethylamine were dissolved in methanol. The solution was concentrated *in vacuo* to dryness. The procedure was repeated three times. The IR and ¹H NMR spectra were shown in Tables 1 and 2. $[\alpha]_{578}^{21}$ +161°, $[\alpha]_{546}^{21}$

+186° (*c* 0.404, chloroform); Found: C, 47.97; H, 6.64; N, 13.93%. Calcd for $C_{20}H_{32}N_5O_6Co$: C, 48.29; H, 6.48; N, 14.08%.

Bis(dimethylglyoximato) [(R)-*1*-(*methoxycarbonyl*)*ethyl*] [(*1R*,-*2S*)-*1,2-diphenyl-2-aminoethanol*]*cobalt(III)*, (*4*). 250 mg (0.63 mmol) of the *R*(+)-aqua complex (**2**) and 135 mg (0.63 mmol) of (1*R*, 2*S*)-1,2-diphenyl-2-aminoethanol were dissolved in methanol. The solution was concentrated *in vacuo* to dryness. The procedure was repeated three times. ^{1}H NMR ($CDCl_3$): δ 0.25 (d, 3H, $C\underline{H}_3CHCOOCH_3$), 1.95 and 1.98 ($CH_3$(Hdmg) and $CH_3C\underline{H}Co$), 3.34 (s, 3H, $COOC\underline{H}_3$), 4.46 (d, 1H, $\underline{H}COH$), 6.84 (broad m, NH_2), 7.22 (m, 10H, Ph). $[\alpha]_{578}$ +143.3°, $[\alpha]_{546}$ +190° (*c* 0.30, chloroform).

[(R)-*1-Cyanoethyl*]*bis*(*dimethylglyoximato*) [(S)-*1*-*phenylethylamine*]*cobalt(III)*, (*5*-(R,S)), and [(S)-*1-Cyanoethyl*]*bis*(*dimethylglyoximato*)[(S)-*1-phenylethylamine*]*cobalt(III)*, (*5*-(S,S)). Acrylonitrile (8 cm^3) was added to a methanolic solution of bis(dimethylglyoximato)cobalt (II), prepared from Co $(OCOCH_3)_2 \cdot 4H_2O$ (25 g) and dimethylglyoxime (23.5 g) in methanol (250 cm^3). The reaction mixture was stirred under a hydrogen atmosphere at room temperature. After a theoretical amount of hydrogen had been absorbed, an aqueous solution of sodium hydroxide (8 g) and 13 cm^3 of (*S*)-1-phenylethylamine ($[\alpha]_D$ −39°) were successively added to the cooled reaction mixture. The resulting complexes were extracted with dichloromethane (1.5 dm^3) and washed several times with water. The dichloromethane solution was dried over anhydrous sodium sulfate and then concentrated under reduced pressure to give a crude product. It was dissolved in 150 cm^3 of methanol at room temperature. The solution was filtered, and 140 cm^3 of water were added by means of a syringe on warming (30—35 °C). The solution was then left standing overnight at room temperature. Dark red crystals deposited were collected by filtration; 26.7 g (5C-I), $[\alpha]_{578}$ +2°. 5C-I (25.3 g) was recrystallized from methanol (290 cm^3) and water (350 cm^3) to give 12.3 g of crystals (5C-II); $[\alpha]_{578}$ +32° (*c* 0.5, chloroform). 5C-II (11 g) was again recrystallized from methanol (140 cm^3) and water (200 cm^3) to give 6.68 g of crystals (5C-III); $[\alpha]_{578}$ +48.5°. 5C-III (6.68 g) was recrystallized from methanol (94 cm^3) and water (106 cm^3) to give 4.5 g of crystals (5C-IV); $[\alpha]_{578}$ +55.5° and $[\alpha]_{546}$ +60.5° (*c* 0.2, chloroform). Another experiment gave a constant rotation of $[\alpha]_{578}^{23}$ +55.85°, $[\alpha]_{546}^{23}$ +60.10°(*c* 0.188, chloroform). Found: C, 49.05; H, 6.45; N, 18.18%. Calcd for $C_{19}H_{29}N_6O_4Co$: C, 49.13; H, 6.29; N, 18.09%. From filtrates of 5C-I and 5C-II, 10 g of crystals (5F-I) ($[\alpha]_{578}$ −15.3°) and 2.5 g of crystals (5F-II) ($[\alpha]_{578}$ −47.7°) were obtained respectively. The repeated recrystallization of 5F-II (2 g) from methanol/water (1.2/1) gave 0.275 g of crystals with a constant rotation; $[\alpha]_{578}^{23.5}$ −60.13°, $[\alpha]_{546}^{23.5}$ −64.56° (*c* 0.158, chloroform). Found: C, 48.16; H, 6.34; N, 17.81%. Calcd for $C_{19}H_{29}N_6O_4Co$: C, 49.13; H, 6.29; N, 18.09%.

[(R)-*1-Cyanoethyl*]*bis*(*dimethylglyoximato*)(*pyridine*)*cobalt(III)*, (*6*). Pyridine (0.42 cm^3, 5.2 mmol) and water (6 cm^3) were added to a solution of [(*R*)-1-cyanoethyl]bis(dimethylglyoximato) [(*S*)-1-phenylethylamine]cobalt (III), **5**-(*R*,*S*), (0.8 g, 1.7 mmol) in methanol (12 cm^3). Carbon dioxide was bubbled through the solution for 20 min at room temperature. The reaction mixture was then extracted with benzene (200 cm^3) and washed several times with water. The benzene layer was dried over anhydrous sodium sulfate and concentrated *in vacuo* to give 0.65 g of a crude product (89%). The crude product (0.65 g) was recrystallized from methanol (19 cm^3) and water (35 cm^3) to give orange leaflets (0.08 g), $[\alpha]_{578}^{22}$ +52.2°, $[\alpha]_{546}^{22}$ +59.2° (*c* 0.157, chloroform). The IR and ^{1}H NMR spectra were identical with those of the racemic compound.

The authors wish to express their thanks to Mr. Hitoshi Matsumoto and Mr. Yuzuru Ishida for their NMR measurements.

One-step Oxidation of Olefins into α-Phenylseleno Carbonyl Compounds[1]

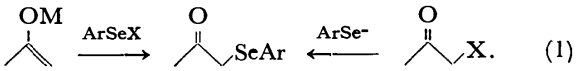
Makoto SHIMIZU and Isao KUWAJIMA*

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 14, 1981)

Oxidation of olefins has been examined with the following three types of reagents; (i) $(C_6H_5Se)_2$–Br_2–$(Bu_3Sn)_2O$, (ii) $(C_6H_5Se)_2$–*t*-BuOOH, and (iii) $(C_6H_5Se)_2$–$(C_6H_5SeO)_2O$, and the corresponding α-phenylseleno carbonyl compounds have been obtained directly from the olefins.

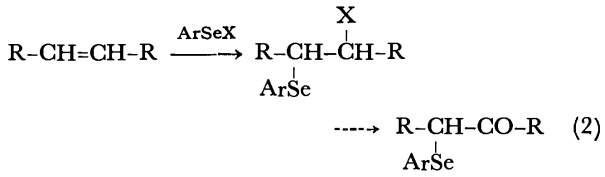
Recent developments in organoselenium chemistry[2] have brought about a wide range of synthetic utilities of α-phenylseleno carbonyl compounds. They have been used for regioselective introduction of various functional groups, especially for that of unsaturation *via* well established *syn*-elimination process.[2] For their preparation, both electrophilic and uncleophilic organoselenium reagents are usually available as shown below:[3]



(1)

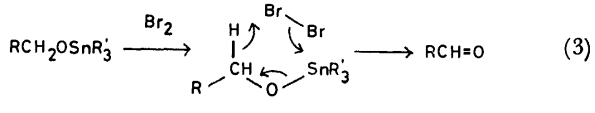
However, no simple and reliable route to α-phenylseleno carbonyl compounds from both internal and terminal olefins has been developed until now,[4] although olefinic compounds are in general readily accessible *via* a number of established synthetic procedures.

Electrophilic 1,2-addition of PhSeX species constitutes a potential methodology for the introduction of double functionalities into carbon-carbon double bonds.[2] It is expected that during this process if CH–X group is converted into a carbonyl simultaneously, α-phenylseleno carbonyl compounds may be produced directly from olefins (Eq. 2). In this paper, we describe an efficient approach for one-step oxoselenenylation reaction of olefins to afford α-phenylseleno carbonyl compounds.



(2)

Oxidation of Olefins with $(C_6H_5Se)_2$–Br_2–$(Bu_3Sn_2)O$. Trialkylstannyl ethers are well known to be transformed into carbonyl compounds on treatment with bromine or *N*-chlorosuccinimide (NCS)[5] as shown in the following equation. In a related reaction, a formation of a



(3)

$$Bu_3SnOSnBu_3 \xrightarrow{Br_2} Bu_3SnOBr + Bu_3SnBr \quad (4)$$

hypohalite species, Bu_3SnOBr, is postulated through the reaction of hexabutyldistannoxane with bromine.[6] In a similar way, a formation of "$C_6H_5SeOSnBu_3$" **1** is expected on treatment of hexabutyldistannoxane with benzeneselenenyl bromide. Like other electrophilic species such as ArSeCl, ArSeBr, ArSeOAc, *etc.*,[2] **1** appears to behave as an electrophile to attack a C=C bond to form β-(phenylseleno)alkyl tributylstannyl ether **2** which may be converted to the corresponding α-phenylseleno carbonyl compounds **3** as usual with stannyl ethers. Treatment of styrene with diphenyl

$$Bu_3SnOSnBu_3 \xrightarrow{C_6H_5SeBr} \underset{\mathbf{1}}{Bu_3SnOSeC_6H_5} + Bu_3SnBr \quad (5)$$

$$RCH{=}CH_2 \xrightarrow{\mathbf{1}} \underset{\mathbf{2}}{RCH(OSnBu_3)-CH_2SeC_6H_5} \longrightarrow \underset{\mathbf{3}}{R\text{-}CO\text{-}CH_2SeC_6H_5} \quad (6)$$

diselenide (0.55 equiv.), bromine (0.50 equiv.), and hexabutyldistannoxane (1.0 equiv.) indeed afforded α-(phenylseleno)acetophenone in 38% yield. An optimum result was obtained when the reaction was performed with 2.2 equiv. of diphenyl diselenide, 2.1 equiv. of bromine, and 2.2 equiv. of hexabutyldistannoxane in refluxing chloroform for 2 h. Various olefins were also

$$C_6H_5CH{=}CH_2 \xrightarrow{(C_6H_5Se)_2,\ Br_2,\ (Bu_3Sn)_2O} C_6H_5CO\text{-}CH_2SeC_6H_5 \quad (7)$$

converted to the corresponding α-phenylseleno carbonyl compounds **3** in good yields by this procedure. The results are shown in Table 1.

Styrene gave a single regioisomer, whereas other terminal olefins usually afforded a mixture of α-phenylseleno ketones and α-phenylseleno aldehydes. Their ratios are dependent on the reaction conditions, especially on the solvent. Electron-deficient olefins such as vinyl bromide or α,β-unsaturated esters are almost inert to this oxidation reaction. The major drawbacks of this procedure are relatively troublesome work-up for removal of organotin moieties and lack of regioselectivity. To eliminate these disadvantages, other methods were investigated, especially for improvement of regioselectivity in the oxoselenenylation reactions.

Oxidation of Olefins with $(C_6H_5Se)_2$–t-BuOOH or $(C_6H_5Se)_2$–$(C_6H_5SeO)_2O$. It has been described that allylic alcohols are oxidized with benzeneselenenyl bromide and silver acetate to give α,β-unsaturated carbonyl compounds.[7] More recently, oxidation of aldehyde hydrazones with benzeneseleninic anhydride was reported,[8] which proceeded presumably *via* an intermediacy of selenenate esters. These examples indicate that alkyl selenenates appear to undergo fragmentation readily to afford carbonyl compounds and selenols.[9]

Benzeneselenenic anhydride "$C_6H_5SeOSeC_6H_5$" **4**, a rare class of compound, is expected to add to olefins to form alkyl selenenates **5** in a similar manner with other kinds of electrophilic organoselenium species,[2] and the resulting selenenate esters **5** may decompose to

a) Reactions were performed on a 1 mmol scale with olefin : $(C_6H_5Se)_2$: Br_2 : $(Bu_3Sn)_2O$ = 1.0 : 2.0 : 2.0 : 2.0. b) Isolated yield. c) Olefin: $(C_6H_5Se)_2$: Br_2 : $(Bu_3Sn)_2O$ = 1.0 : 4.0 : 4.0 : 4.0. d) 2-Cyclododecenone was also formed in 20% yield.

give α-phenylseleno carbonyl compounds.

Woodbridge reported that the oxidation of diphenyl diselenide with ozone afforded benzeneseleninic anhydride,[10] presumably *via* an intermediate of benzeneselenenic anhydride **4**. We have examined the olefin oxidation under the expectation that the oxidation of diphenyl diselenide with *t*-butyl hydroperoxide may produce benzeneselenenic anhydride **4**.

$$(C_6H_5Se)_2 + t\text{-BuOOH} \longrightarrow \underset{\mathbf{4}}{\text{“}C_6H_5SeOSeC_6H_5\text{”}} + t\text{-BuOH} \quad (8)$$

Treatment of styrene with diphenyl diselenide (1.5 equiv.) and *t*-butyl hydroperoxide (2.0 equiv.) gave rise to α-(phenylseleno)acetophenone (48%) with 1-*t*-butoxy-1-phenyl-2-(phenylseleno)ethane (38%). The latter product was certainly produced *via* oxyselenenylation with $C_6H_5Se^+$ species and *t*-butyl alcohol formed from *t*-butyl hydroperoxide during the oxidation. The incorporation of *t*-butyl alcohol could be avoided by the removal of *t*-butyl alcohol after the oxidation of the diselenide with the peroxide followed by the addition of an olefin to the resulting solution. The optimum

$$C_6H_5CH{=}CH_2 \xrightarrow{\mathbf{4}} C_6H_5CO\text{–}CH_2SeC_6H_5 \quad (9)$$

conditions were examined about the reaction of styrene.

The results shown in Table 2 indicate that the use of *ca.* 2 equiv. of reagents leads to the optimum yield and a slightly higher reaction temperature is required for the completion of the reaction when compared with the previous system.

Displacement of *t*-butyl hydroperoxide to other oxidants did not lead to the satisfactory result. Oxidation of diphenyl diselenide with pyridinium chlorochromate (PCC), active manganese dioxide, or Jones reagent followed by the addition of styrene to the oxidation product gave only a trace amount of α-(phenylseleno)acetophenone.[11]

A remarkable result was obtained when styrene was treated with diphenyl diselenide (1.4 equiv.) and benzeneseleninic anhydride (0.7 equiv.) as oxidant in refluxing carbon tetrachloride. By this system, α-(phenylseleno)acetophenone was obtained in 77% yield. Generation of benzeneselenenic anhydride **4** may occur *via* disproportionation reaction of diphenyl diselenide and benzeneseleninic anhydride, and it seems to be this species which acts as an electrophile toward olefins to form selenenate ester intermediates.

$$2(C_6H_5Se)_2 + (C_6H_5SeO)_2O \longrightarrow 3\underset{\mathbf{4}}{\text{“}C_6H_5SeOSeC_6H_5\text{”}}$$

$$\xrightarrow{C_6H_5CH=CH_2} C_6H_5CO\text{–}CH_2SeC_6H_5 \quad (10)$$

a) Reactions were perormed in refluxing carbon tetrachloride. Yields were determined by NMR using a calibrated internal standard. b) Isolated yield.

Oxidation of Terminal Olefins. Oxidation of terminal olefins with $(C_6H_5Se)_2$–Br_2–$(Bu_3Sn)_2O$ system usually produces a mixture of α-phenylseleno ketones and aldehydes. The regioselectivity on the oxidation of terminal olefins with **4** was proved to be highly dependent on the reaction solvent. Predominant formation of α-phenylseleno ketones was observed in DMSO solvent, whereas the ratio of α-phenylseleno aldehydes increased in toluene, acetonitrile, sulfolane, and nitromethane. This tendency is explained in terms of the stabilization of the seleniranium intermediate which has often been involved in the addition process of ArSeX to olefins.[12]

Raucher has examined the addition of benzeneselenen-

		56[c]

a) Reactions were performed in refluxing benzene with olefin: $(C_6H_5Se)_2$: *t*-BuOOH = 1.0 : 4.4 : 4.4 or olefin: $(C_6H_5Se)_2$: $(C_6H_5SeO)_2O$ = 1.0 : 2.8 : 1.4. b) Cyclododecenone was formed in 15% yield. c) Reported by Smith III, Nicolaou *et al.*, see Ref. 18.

yl bromide to terminal olefins and has observed the following regioselectivity: under thermodynamically controlled conditions, olefin-PhSeX adducts undergo equilibration to form Markownikoff type adducts predominantly, while under kinetically controlled conditions, the formation of *anti*-Markownikoff adducts are favored.[13] In this regard, in DMSO, oxygen atom on sulfoxide appears to associate with the seleniranium ion and stabilize it, which results in the equilibration of this intermediate to afford the Markownikoff adduct predominantly.

One disadvantage of this oxidation lies in the insolubility of olefins in this solvent, and for reproducible results the use of an excess reagent is required. DMSO–toluene solvent system has found a complemental use for insoluble olefins, although regioselectivity has been somewhat decreased.

We may exclude a possibility for the role of DMSO as oxidant by the following observations. It is well known that olefin–PhSeX adducts are very susceptible to solvolysis.[14] The reaction of these adducts with DMSO,

$$C_8H_{17}CH{=}CH_2 \xrightarrow[DMSO]{C_6H_5SeBr} C_8H_{17}{-}CO{-}CH_2SeC_6H_5 + C_8H_{17}CH(OH){-}CH_2SeC_6H_5 \quad (11)$$

Et_3N: 3% 6%

$AgBF_4$, EtN_3: 14% 80%

however, did not practically proceed. Even in the presence of silver tetrafluoroborate, a phenylseleno ketone was obtained in only low yield. These strongly suggest inefficiency of DMSO as an oxidant in the present system.

Displacement of diphenyl diselenide did not noticeably improve product distribution.

$$C_8H_{17}CH{=}CH_2 \xrightarrow[toluene]{\text{"ArSeOSeAr"}} C_8H_{17}CO{-}CH_2SeAr + C_8H_{17}CH(SeAr){-}CH{=}O \quad (12)$$

Ar: C_6H_5 58:42

$2,4,6\text{-}(CH_3)_3C_6H_2$ 69:31

Oxidation of Internal Olefins. By the procedures reported so far, oxidation of internal olefins to α-phenylseleno ketones appears to be quite difficult. For

example, treatment of (*E*)-3-hexene and (*E*)-6-dodecene with PhSeBr–$AgPF_6$–DMSO–Et_3N produced the corresponding β-hydroxy selenides in *ca.* 60% yield,[4b] whiles terminal olefins gave phenylselenomethyl ketones. The procedure developed by Tsuji *et al.*[4a] does not appear to be applicable to internal olefins due to a facile *syn*-elimination of the resulting selenoxides, although this point has not been tested. By the present method, internal olefins were smoothly oxidized to α-phenylseleno ketones in good yields. The results are listed in Table 4.

$$R\text{-}CH{=}CH\text{-}R \xrightarrow{\mathbf{4}} R\text{-}CO\text{-}\underset{\displaystyle SeC_6H_5}{\underset{|}{CH}}\text{-}R \qquad (13)$$

In general, however, internal olefins are less reactive than terminal ones even under the present oxidation conditions, and good conversion of the starting olefins calls for the use of *ca.* 4.4 equiv. of the reagent.

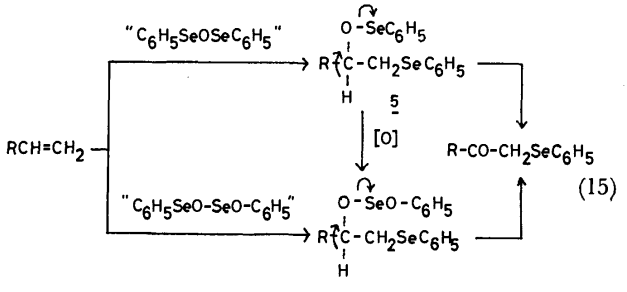
The difference of the reactivity of C=C bonds in a polyene has been studied by van Tamelen and Sharpless using addition reaction of a hypohalite.[15] More recently, Krief *et al.*[16] examined the reactivity of dienes bearing an internal and a terminal C=C bonds toward methane- and benzeneselenenyl bromide, and they observed selective addition to the terminal olefin. In the present oxidation, a terminal olefin was selectively oxidized to the corresponding α-phenylseleno ketone. For example, when an equimolar mixture of ethyl 10-undecenoate and cyclododecene was treated with diphenyl diselenide (2.8 equiv.) and benzeneseleninic anhydride (1.4 equiv.) in DMSO at 110 °C for 30 min, a mixture of ethyl 10-oxo-11-phenylselenoundecanoate and ethyl 11-oxo-10-phenylselenoundecanoate (92 : 8) was obtained in 64% yield with the recovered cyclododecene (90%). It is expected that the present system will find applications in selective oxidation of polyenes.

Reaction Mechanism. Sharpless and Reich have suggested a "Conproportionation" reaction between diphenyl diselenide and benzeneseleninic acid to yield benzeneselenenic acid as a reactive species to olefinic bonds.[17] Smith III and Nicolaou have also described

$$(C_6H_5Se)_2 + C_6H_5\overset{\displaystyle O}{\overset{\|}{S}}e\text{-}OH + H_2O \longrightarrow 3\text{“}C_6H_5SeOH\text{”} \qquad (14)$$

a cyclization reaction of dienes using this kind of species.[18]

We propose here a generation of benzeneselenenic anhydride **4** from both of the systems, which acts as a reactive species. However, it is not very clear whether the introduction of carbonyl proceeds *via* a selenenate ester or not. One possible alternative seems to be the involvement of the fragmentation of a seleninate ester



(15)

via addition of "$C_6H_5SeOSe(=O)C_6H_5$" species or oxidation of a selenenate ester intermediate. In regard to the reports dealing with fragmentation of seleninate esters proposed by Barton *et al.*,[19] we can not exclude the possibility of seleninates as the intermediates in this oxidation process.

Experimental

All reactions involving air- or moisture-sensitive compounds were performed under either argon or ultra-grade nitrogen atmosphere. NMR spectra were taken on a Hitachi R-24B spectrometer and chemical shifts are recorded in parts per million downfield from internal tetramethylsilane. IR spectra were taken on a Hitachi EPI- G3 or 260-10 spectrometer, and mass spectra on a Hitachi RMU-7M or RMU-6C spectrometer at 70 eV ionizing irradiation. Analytical gas liquid chromatography was performed on a Hitachi 063 or 163 instrument. Microanalyses were performed on a Perkin Elmer 240 instrument. Melting points which were taken in open capillaries and boiling points were uncorrected.

Diphenyl diselenide, bis(*p*-chlorophenyl) diselenide, and bis(2,4,6-trimethylphenyl) diselenide were prepared by the procedure reported by Sharpless and Reich.[3c,17] Benzeneseleninic anhydride was prepared according to the procedure of Woodbridge,[10] and was stored over P_2O_5.

Oxidation of Styrene with $(C_6H_5Se)_2$–Br_2–$(Bu_3Sn)_2O$. To a solution of diphenyl diselenide (686 mg, 2.2 mmol) and hexabutyldistannoxane (1.31 g, 2.2 mmol) in 3 ml of chloroform were added a carbon tetrachloride solution of bromine (1.55 ml of 1.35 M (1 M = 1 mol dm^{-3}) solution, 2.10 mmol) and then a solution of styrene (104 mg, 1.0 mmol) in 2 ml of chloroform. After stirring for 2 h under refluxing, the brown colored mixture was washed with 5% aq NaOH, and satd aq NaCl. The organic layer was dried over $MgSO_4$, concentrated, and purified by silica gel column chromatography followed by bulb-to-bulb distillation to afford α-(phenylseleno)acetophenone (204 mg,74%). Bp 150—160 °C/0.15 mmHg;[20] IR (neat): 1665 cm^{-1}; NMR ($CDCl_3$): δ 4.13 (s, 2H), 7.13—7.63 (m, 8H), 7.73—7.97 (m, 2H); MS:[21] *m/e* (%) 276 (M^+, 16), 105 (100), 77 (20), 52 (13); Found: C, 61.37; H, 4.62%. Calcd for $C_{14}H_{12}OSe$:C, 61.10; H, 4.40%.

Oxidation of 1-Decene with $(C_6H_5Se)_2$–Br_2–$(Bu_3Sn)_2O$. To a solution of diphenyl diselenide (686 mg, 2.2 mmol) and hexabutyldistannoxane (1.31 g, 2.2 mmol) in 5 ml of carbon tetrachloride in the presence of molecular sieves 3A (1 g) were added a carbon tetrachloride solution of bromine (1.3 ml of 1.64 M solution, 2.1 mmol) and then a solution of 1-decene (140 mg, 1.0 mmol) in 5 ml of carbon tetrachloride, and the mixture was heated to refluxing for 7 h. After a usual work-up, the crude oil was purified by silica gel column chromatography to give diphenyl diselenide (437 mg), 1-phenylseleno-2-decanone (143 mg, 46%), and 2-p henylselenodecanal(68 mg, 22%). *1-Phenylseleno-2-decanone*, Bp 168 °C/0.3 mmHg;[20] Mp 39—40 °C (hexane); IR (KBr): 1692 cm^{-1}; NMR (CCl_4): δ 0.60—1.90 (m, 15H), 2.50 (t, J=7.0 Hz, 2H), 3.47 (s, 2H), 6.70—7.60 (m, 5H); MS[21] *m/e* (%) 321 (M^+, 5), 155 (6), 141 (6), 77 (20), 57 (69), 43 (100); Found: C, 61.66; H, 7.68%. Calcd for $C_{19}H_{28}O_3Se$: C, 59.52; H, 7.36%.

2-Phenylselenocyclododecanone. The reaction was carried out with cyclododecene (84 mg, 0.5 mmol) using diphenyl diselenide (2.2 equiv.), bromine (2.1 equiv.), and hexabutyldistannoxane (2.2 equiv.) in refluxing benzene for 8 h. Purification of the reaction mixture by silica gel column chromatography gave 2-cyclododecenone (18 mg, 20%) and the title compound (87 mg, 52%). Bp 148—152 °C/0.06 mmHg;[20] IR (neat): 1685 cm^{-1}; NMR (CCl_4): δ 0.70—2.35 (m, 18H), 2.53 (unresolved dd, J= 10.0 and 6.0 Hz, 2H), 3.90 (dd, J= 5.0 and 8.0 Hz, 1H), 7.10—7.60 (m, 5H); MS:[21] *m/e* (%) 338 (M^+, 2), 181 (6), 157 (28), 83 (61), 55 (100).

3-Oxo-3-phenyl-2-phenylselenopropyl Acetate. IR (neat): 1740, 1680 cm^{-1}; NMR (CCl_4): δ 1.90 (s, 3H), 4.40—4.90 (m, 3H), 7.10—7.55 (m, 8H), 7.75—8.00 (m, 2H); MS:[21] *m/e* (%) 348 (M^+, 8), 289 (90), 271 (7), 191 (40), 105 (100), 77 (45), 59 (88), 43 (40).

1-Phenylseleno-2-phenyl-2-propanol. Bp 127—130 °C/0.4 mmHg;[20] IR (neat): 3440 cm^{-1}; NMR (CCl_4): δ 1.57 (s, 3H), 2.80 (brs, 1H, disappeared on D_2O exchange), 3.38 (d, J= 6.0 Hz, 1H), 3.40 (d, J=6.0 Hz, 2H), 7.00—7.50 (m, 12H); MS:[21] *m/e* (%) 274 ($M^+ - 18$, 5), 172 (18), 117 (70), 115 (100), 77 (80).

Oxidation of Styrene with $(C_6H_5Se)_2$–t-BuOOH (General Procedure). To a solution of diphenyl diselenide (628 mg, 2 mmol) in 5 ml of carbon tetrachloride were added molecular sieves 3A (2 g) and a solution of 70% *t*-butyl hydroperoxide (256 mg, 2.0 mmol) in 5 ml of carbon tetrachloride, and the mixture was heated to refluxing for 1 h. Then all the solvent as well as *t*-butyl alcohol was removed *in vacuo*, and a solution of styrene (104 mg, 1.0 mmol) in 5 ml of carbon tetrachloride was added to the resulting pale yellow solid. After stirring for 1 h under refluxing, the reaction mixture was washed with satd aq NaCl and dried over $MgSO_4$. Removal of the solvent gave a brown oil, which was purified by silica gel column chromatography to give α-(phenylseleno)acetophenone (238 mg, 87%) and diphenyl diselenide (414 mg).

Oxidation with $(C_6H_5Se)_2$–$(C_6H_5SeO)_2O$ (General Procedure). To a solution of diphenyl diselenide (437 mg, 1.4 mmol) and benzeneseleninic anhydride (252 mg, 0.7 mmol) in 5 ml of the solvent were added an olefin (1 mmol) in 5 ml of solvent and molecular sieves 3A (2 g), and the mixture was stirred under refluxing until the starting olefin was all consumed. The resulting reaction mixture was worked up and purified as described above.

Oxidation of 1-Decene. 1-Decene (70 mg, 0.5 mmol) was oxidized with diphenyl diselenide (686 mg, 2.2 mmol) and *t*-butyl hydroperoxide (282 mg of 70% solution, 2.2 mmol) in DMSO at 110 °C for 1 h. A mixture (108 mg, 70%) of 2-phenylselenodecanal and 1-phenylseleno-2-decanone was obtained. The isomeric ratio was determined to be 9 : 91 by NMR analysis. Further purification gave both samples which exhibit similar spectroscopic properties to ones prepared previously.

Oxidation of Ethyl 10-Undecenoate. Ethyl 10-undecenoate (106 mg, 0.5 mmol) was oxidized with diphenyl diselenide (686 mg, 2.2 mmol) and 70% *t*-butyl hydroperoxide (282 mg, 2.2 mmol) in 10 ml of DMSO at 110 °C for 1.5 h. A mixture (134 mg, 70%) of ethyl 10-oxo-11-phenylselenoundecanoate and ethyl 11-oxo-10-phenylselenoundecanoate was obtained, and their ratio was determined to be 94 : 6 by NMR analysis. Separation of the mixture gave pure samples which exhibit similar spectroscopic properties to ones prepared previously.

Oxidation of 1-Dodecene. 1-Dodecene (84 mg, 0.5 mmol) was oxidized by the same procedure. A mixture of 1-phenylseleno-2-dodecanone and 2-phenylselenododecanal was obtained, and their ratio was determined to be 93 : 7 by NMR analysis. Separation of the mixture gave pure samples. *1-Phenylseleno-2-dodecanone*, IR (neat): 1705 cm^{-1}: NMR (CCl_4): δ 0.70—2.00 (m, 19H), 2.60 (t, J=7.0 Hz, 2H), 3.57 (s, 2H), 7.30—7.90 (m, 5H); MS:[21] *m/e* (%) 340 (M^+, 71), 172 (89), 15; (32), 133 (29), 109 (54), 95 (39), 91 (57), 85 (54), 77 (25), 71 (57), 57 (100). *2-Phenylselenododecanal*, IR (neat): 1705 cm^{-1}; NMR (CCl_4): δ 0.70—2.00 (m, 21H), 3.3—3.9 (m,1H), 7.40—7.90 (m, 5H), 9.50 (d, J=3.0 Hz, 1H).

3-Oxo-3-phenyl-2-phenylselenopropyl Acetate. Cinnamyl acetate (88 mg, 0.5 mmol) was oxidized by a similar procedure in benzene (5 ml) for 4 h, and the title compound (144 mg, 83%) was obtained as an oil. IR (neat): 1740, 1680 cm^{-1}; NMR (CCl_4): δ 1.90 (s, 3H), 4.40—4.90 (m, 3H), 7.10—7.55 (m, 8H), 7.75—8.00 (m, 2H); Found: C, 58.92; H, 4.78%. Calcd for $C_{17}H_{16}O_3Se$: C, 58.80; H, 4.64%.

2-Phenylselenocyclododecanone. Cyclododecene (91 mg, 0.5 mmol) was oxidized in a similar procedure in refluxing benzene for 3 h, and the title compound (118 mg, 67%) and 2-cyclododecenone (14 mg, 15%) were obtained.

1,4-Bis(benzyloxy)-3-phenylseleno-2-butanone. (*E*)-1,4-Bis-(benzyloxy)-2-butene (120 mg, 0.5 mmol) was oxidized in a similar procedure in refluxing benzene for 4.5 h, and the title compound (166 mg, 81%) was obtained. IR (neat): 3100, 1710, 1100, 750 cm^{-1}; NMR (CCl_4): δ 3.90—4.17 (m, 3H), 4.37 (d, J=5.0 Hz, 4H), 7.00—7.53 (m, 5H). Further deselenenylation with benzenethiol (0.15 ml) and triethylamine (1.0 ml) gave analytically pure deselenenylated product, 1,4-bis(benzyloxy)-2-butanone. IR (neat): 3100, 1705 cm^{-1}; NMR (CCl_4): δ 2.71 (t, J=7.0 Hz, 2H), 3.60 (t, J=7.0 Hz, 2H), 3.90 (s, 2H), 4.07 (s, 2H), 4.74 (s, 2H), 7.20 (s, 10H); Found: C, 76.19; H, 7.14%. Calcd for $C_{18}H_{20}O_3$: C, 76.037; H, 7.09%.

Oxidation of Ethyl 10-Undecenoate in the Presence of Cyclododecene. To a mixture of diphenyl diselenide (437 mg, 1.4 mmol) and benzeneseleninic anhydride (252 mg, 0.7 mmol) were added a solution of cyclododecene (83 mg, 0.5 mmol) and ethyl 10-undecenoate (106 mg, 0.5 mmol) in DMSO (10 ml) and then molecular sieves 3A (2 g). After stirring for 30 min at 110 °C, the reaction mixture was washed with satd aq NaCl and was extracted with ether. Cyclododecanone (91 mg) was added to the reaction mixture as an internal standard, and the resulting solution was examined by GLPC to give an indication that cyclododecene was recovered in 90%. Purification of the mixture by silica gel column chromatography afforded a mixture of ethyl 10-oxo-11-phenylselenoundecanoate and ethyl 11-oxo-10-phenylselenoundecanoate (123 mg, 64%). The ratio of the seleno ketone *vs.* the seleno aldehyde was determined to be 92 : 8 by NMR analysis.

The Characterization of a Novel Metathesis Catalyst, β-Titanium Oxide-supported Molybdenum Oxide

Katsumi TANAKA, Koshiro MIYAHARA,* and Ken-ichi TANAKA**
Research Institute for Catalysis, Hokkaido University, Sapporo 060
***Faculty of Engineering, Hokkaido University, Sapporo 060*
(Received December 17, 1980)

The results of the X-ray photoelectron spectroscopy of a novel metathesis catalyst, MoO_x/β-TiO_2, are discussed with reference to its catalytic behavior. It is concluded that the active center for the metathesis reaction of olefin is the molybdenum ion with an oxidation higher than +4 on the average, and that the hydrogen scrambling of olefin during the metathesis is caused by the OH group on the TiO_2 surface. During the preparation of this catalyst, the decomposition of titanic acid to TiO_2 is found to be accelerated by MoO_3; a similar thing can be seen of the reduction of MoO_3 to zero-valent molybdenum by TiO_2.

Many active catalysts, homogeneous and heterogeneous, have been developed[1] for the olefin-metathesis reaction, and its mechanism has been investigated since 1964;[2] the simultaneous hydrogen scrambling of olefin has been an intricate problem. We ourselves have reported a novel solid catalyst, MoO_x/β-TiO_2 (x= 2.3—2.9), on which the metathesis reaction of olefin proceeds with a negligible extent of hydrogen scrambling of olefin.[3] When alumina and zirconia are used as catalyst supports, the hydrogen scrambling of olefin surpasses the metathesis.[4] In this paper, this novel catalyst was characterized, mainly by using X-ray photoelectron spectroscopy.

Experimental

The catalyst was prepared by impregnating a powder of β-titanic acid with an aqueous solution of ammonium molybdate and then dried at 120 °C. The sample (*ca.* 0.3 g) was oxidized with O_2 and evacuated at 500 °C in a conventional circulation apparatus with a volume of *ca.* 350 cm^3. Preceding the metathesis reaction, the following pretreatments of the catalyst were performed: it was reduced with hydrogen at 500 °C for 1 h and preconditioned by performing on it a reaction of N_2O (*ca.* 40 Pa) with H_2 (*ca.* 100 Pa) at 200 °C for 1 h.[4,5] By this pretreatment, the catalyst surface was controlled to give a characteristic activity for metathesis reaction; *i.e.*, it was active for metathesis, but had a negligible extent of hydrogen scrambling as well as of the isomerization of olefin.[4]

A mixture (1 : 1) of propene and [D_6]propene (CH_2=$CHCH_3$ and CD_2=$CDCD_3$) or *cis*-2-butene and [D_8]*cis*-2-butene was admitted at room temperature onto the catalyst at a total pressure of *ca.* 6×10^3 Pa, and its catalytic activities for the productive and degenerative metathesis, as well as for the hydrogen scrambling of olefin, were studied. The analysis of the products was carried out by GC, and the deuterated isomers separated by GC were analyzed by means of a mass spectrometer with low isonization voltages. The reagents used were of a chemically pure grade.

The X-ray photoelectron spectra of the catalyst were obtained by means of an ESCA-3 apparatus of the Vacuum Generator Co. The untreated samples prepared from ammonia molybdate and β-titanic acid were pressed on a sample hoder of the ESCA-3 apparatus and treated in a side chamber under conditions similar to those used in the catalyst pretreatments. The binding energies of Mo(3d) and Ti(2p) electrons were corrected using a reference of 530 eV for the ls electron from oxygen of oxide; this value is common for a variety of metal oxides.[6]

Results

The catalytic properties of 6.7 wt% MoO_3/TiO_2 change with the extent of reduction, as is shown in Fig. 1,[4] in which the extent of reduction (x in MoO_x) was estimated from the amount of hydrogen consumed in the reduction of an oxidized catalyst sample at 500 °C for 1 h. It was found that the molybdenum oxide supported on titanium oxide was finally reduced to the zero-valent state, although Ti^{3+} could not be detected by ESR during the reduction of the catalyst.[5]

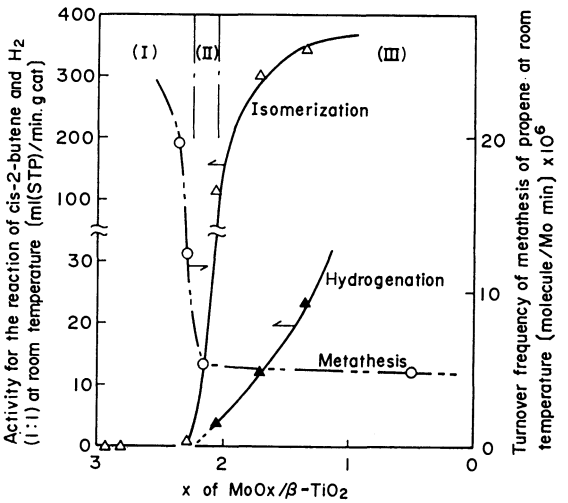

Fig. 1. Characteristic profile of the catalytic activity of MoO_x/β-TiO_2 for reactions of olefins at room temperature.

Only oxidation of olefin was caused by a catalyst, MoO_x/β-TiO_2, with an x value larger than 2.9. However, the catalyst of x=2.3—2.9, State I, gave preferentially olefin metathesis with little hydrogen scrambling of the olefins. As a result, a mixture of propene and [D_6]propene yielded mainly [D_2] and [D_4]propene by degenerative metathesis, and [D_0], [D_2], and [D_4]ethylene by productive metathesis, respectively. In contrast to the State I surface, the catalyst of x=2.0—2.3, State II, is active for the isomerization of olefin in the presence of hydrogen. The more reduced surface, described by State III, of a

catalyst with x value less than 2.0 can catalyze the isomerization in the absence of hydrogen. Such an isomerization caused by a process other than metathesis can be followed by interconversion between 1-butene and 2-butene.[7] The hydrogenation of olefin is also brought about over the catalyst surfaces of States II and III. A more reduced surface has a higher activity for hydrogenation. We found that a State I or II surface can be prepared from a reduced catalyst by carrying out on it the reaction of N_2O with H_2 at 200 °C or with CO at room temperature for 1 h.

Figure 2 shows the amount of hydrogen consumption in the reduction of oxidized catalyst samples at 500 °C for 1 h, in which the stoichiometric reduction of MoO_3 is brought about if the catalyst samples are loaded with less than *ca.* 10 wt% of MoO_3.

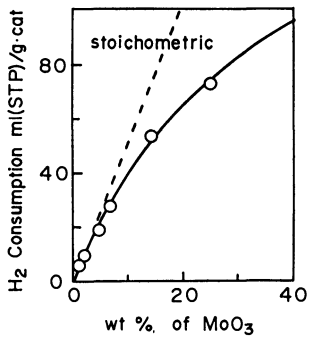

Fig. 2. Amounts of H_2 consumed in reduction of MoO_3/β-TiO_2 catalysts loaded with different amounts of MoO_3 at 500 °C for 1 h.

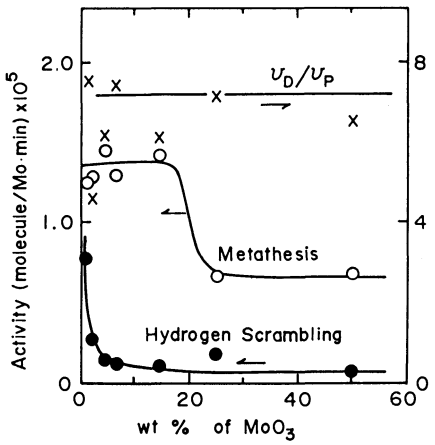

Fig. 3. Catalytic activity changes of MoO_x/β-TiO_2 (x= 2.3—2.9) depending on the amount of loaded MoO_3.

Figure 3 shows the specific activities for a metathesis reaction and for a simultaneous hydrogen scrambling of olefin over catalysts with various wt% MoO_3, where the catalysts were prepared by oxidation, and the reduction at 500 °C, followed by the reaction of N_2O with H_2 at 200 °C for 1 h and its evacuation at 500 °C. The ratio of a productive metathesis to a degenerative one is plotted in Fig. 3. The turnover frequency in this figure is evaluated by assuming that all the molybdenum loaded on TiO_2 is active for the reactions. Up to *ca.* 15 wt% MoO_3, the turnover frequency of metathesis is nearly constant,while that of hydrogen scrambling decreases steeply.

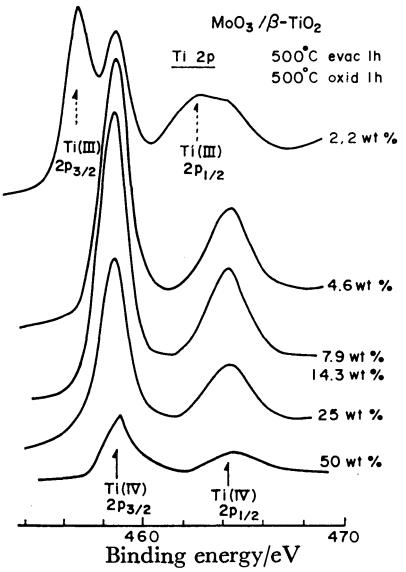

Fig. 4. XPS spectra of Ti(2p) electrons from surfaces of MoO_3/β-TiO_2 with different amounts of loaded MoO_3.

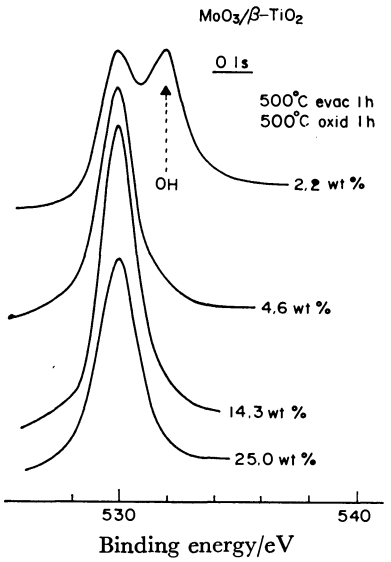

Fig. 5. XPS spectra of O(1s) electrons from surfaces of MoO_3/β-TiO_2 with different amounts of loaded MoO_3.

Figures 4 and 5 show the XPS spectra of Ti(2p) and O(1s) of oxidized samples with various wt% MoO_3. The XPS peak areas of Mo(3d), Ti(2p), and O(1s), observed as measures of the surface concentrations of these components, are plotted in Fig. 6 against the loaded amounts of MoO_3.

Discussion

The activity for metathesis reaction increases proportionally to the amount of loaded MoO_3 up to *ca.* 15 wt%, as can be seen from the constant turnover frequency for metathesis shown in Fig. 3. This result implies that molybdenum is dispersed rather homogeneously on the

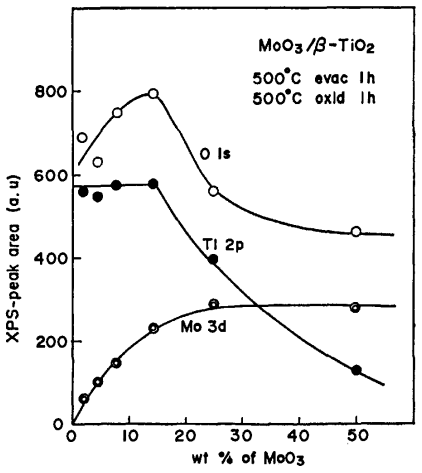

Fig. 6. Changes of XPS-peak areas of Mo(3d), Ti(2p), and O(1s) electrons from the surfaces of MoO_3/β-TiO_2 catalysts with different amounts of loaded MoO_3.

catalyst surface when the loaded MoO_3 is less than *ca.* 15 wt%. The valence state of the molybdenum ion is quite sensitive to a metathesis reaction, as is shown in Fig. 1, and a characteristic activity for metathesis reaction appears only in the range of $x=2.3$—2.9 of MoO_x/TiO_2. In contrast to the result of Iwasawa *et al.*,[8] the activity for metathesis reaction became higher when the average oxidation state was slightly higher than Mo^{4+}.

It was confirmed[7] that, in the hydrogen scrambing of olefin, the relative contribution of *n*- and *s*-alkyl species to the catalyst of State II is quite similar to that of the MoS_2 catalyst.[9] With the MoS_2 catalyst, the selectivity for isomerization and hydrogenation of olefin has been found to be sensitive to the degree of the coordinative unsaturation of the central Mo ion.[9]

The turnover frequency for a metathesis reaction decreases with an increase in the loaded amount of MoO_3 above *ca.* 20 wt%, as can be seen in Fig. 3, while the ratio of the degenerative metathesis to the productive one, v_D/v_P, is constant, irrespective of the loaded amount of MoO_3. These results imply that the active sites on MoO_x/TiO_2 are not influenced by the loaded amount of MoO_3. In contrast to this, the turnover frequency for the simultaneous hydrogen scrambling of olefin is quite sensitive to the amount of MoO_3 loaded on TiO_2. It was found that the O(1s) peak at 531.5 eV in the XPS spectra, which may be attributed to the OH group,[10] was observed in the present experiments only on a catalyst with 2.2 wt% MoO_3 (Fig. 5), and the hydrogen scrambling might be caused by this OH group on the TiO_2 surface.

As is shown in Fig. 6, the XPS peak area of Ti(2p) decreases steeply, while that of Mo(3d) increases to a plateau, with an increase in the loaded amount of MoO_3 above *ca.* 20 wt%. The samples subjected to XPS measurements were completely oxidized, so that this catalyst may be different from the catalyst used for the metathesis reaction. Titanium oxide is not influenced by the pretreatment of the catalysts, and the reproducible results shown in Fig. 2 were obtained. This fact may indicate that the distribution of the molybdenum ion on the catalyst surface is not changed by this pretreatment. The results given in Fig. 6 suggest that MoO_3 loaded with more than *ca.* 20 wt% causes its aggregation on the TiO_2 surface and is more difficult to be reduced by hydrogen, as is shown in Fig. 2. As a result, the specific activity for the metathesis reaction decreases with an increase in the loaded amount of MoO_3, as is shown in Fig. 3.

Figures 4 and 5 show the XPS spectra of a sample of 2.2 wt% MoO_3. It is interesting that the sample loaded with MoO_3 less than 4.6 wt% gives the exceptional peaks of the Ti^{3+} ion and the O(1s) peak of the OH group. This fact indicates that the decomposition of titanic acid to TiO_2 is accelerated by MoO_3 loaded more than 4.6 wt%. Furthermore, it has been reported[11] that the reduction of MoO_3/TiO_2 was far faster than those of MoO_3 supported on SiO_2, MgO, ThO_2, *etc.* It was found in this work that MoO_3 loaded on TiO_2 with *ca.* 10 wt% or less could be reduced to nearly the zero-valent state of molybdenum with hydrogen at 500 °C for 1 h, while MoO_3 loaded by an amount of more than 10 wt% was hard to be reduced to zero valence. This result is in contrast to the MoO_3 loaded on alumina, which is difficult to be reduced to a state lower than Mo^{4+}.[12] It may be concluded that a special interaction between molybdenum oxide and titanium oxide can keep the valence state of the molybdenum ion suitable for metatheses, while the coordinative unsaturation of oxygen on the molybdenum ion may be more important in hydrogenation and/or isomerization reactions, such as in the case of the MoS_2 catalyst.[7,9]

By referring to the results shown in Figs. 2, 3, and 6, we see that the catalyst of 6.7 wt% MoO_3, used by chance,[3,4,7] is one of the most effective catalysts for the selective metathesis of olefin, causing a negligible simultaneous hydrogen scrambling of olefin.

The present work was supported in part by a Grant-in-Aid for Scientific Research, No. 343001, from the Ministry of Education, Science and Culture and also by a grant from the Mitsubishi Foundation, 1979. We are much indebted to Professor Isamu Toyoshima ofthe Research Institute for Catalysis, Hokkaido University, for his valuable discussions of the XPS spectra.

Magnetic Interaction in Solvent-free DPPH and DPPH-Solvent Complexes

Teruaki FUJITO†

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 19, 1980)

Magnetic interaction in solvent-free DPPH and DPPH–solvent complexes has been studied by means of measurements of the magnetic susceptibility, the proton magnetic resonance, and the low-field ESR at very low temperatures. The susceptibility of solvent-free DPPH shows a round maximum at 11 K, and then it decreases with a lowering of the temperature, no ordered state being observed. The DPPH–benzene (1 : 1) complex shows a round maximum of susceptibility at 0.65 K and antiferromagnetic ordering at about 0.40 K. The DPPH–CCl_4 (4 : 1) complex shows a curious temperature dependence of the susceptibility, which is interpreted in terms of a two-magnetic sublattice model; one sublattice is in the singlet spin state, while the other is in the paramagnetic state at low temperatures except below 0.45 K. Pair interaction is dominant both solvent-free DPPH and in solvent complexes of DPPH. A theoretical approach to the ordered state of DPPH–benzene is given by taking the inter-pair interaction into account.

Recently many studies have been made of the magnetic properties of some organic stable free radicals, such as 4-hydroxy-2,2,6,6-tetramethyl-1-piperidinoxyl (TANOL), diphenyl nitroxide (DPNO) and 1,3-bis-(biphenyl-2,2′-diyl)-2-phenylallyl (BDPA).[1,2] It has been found that the linear-chain interaction is dominant in these radicals. 2,2-Diphenyl-1-picrylhydrazyl (DPPH) is a well known, stable, organic free radicals, and its magnetic properties have been investigated by many workers using various techniques.[3-5] However, the results obtained by different workers have not been consistent with each other. For example, the results of NMR by Karimov and Schegolev[5] were different from those reported by Anderson, Pake, and Tuttle.[4] In 1965, Weil and Anderson[6] reported that there are three different crystal forms for the group of solvent-free DPPH and DPPH-solvent complexes (this group will be abbreviated as DPPHs hereafter). Subsequent X-ray investigations by Williams showed that there are indeed three types of crystal structures for DPPHs.[7] Hence, the complication of the magnetic properties of DPPHs is probably due to the differences in the crystal structures of the samples used by different workers. In order to understand the magnetism of DPPHs, it is, therefore, important to examine the relation between magnetism and crystal structure.

Previously, we measured the magnetic susceptibilities of several DPPHs samples obtained by recrystallization from different solvents.[8] The results showed that the magnetic susceptibilities are also classified into three types in accordance with the structure types reported by Williams. In this paper, the author will report the results of powder-magnetic-susceptibility, NMR, and ESR measurements of DPPH recrystallized from ether (hereafter abbreviated as free DPPH), DPPH–benzene (1 : 1) complex (DPPH–Bz), and DPPH–CCl_4 (4 : 1) complex (DPPH–1/4CCl_4), in addition to the single-crystal-susceptibility measurements of DPPH–Bz; he will also discuss the types of magnetic interactions existing in the different types of crystals.

Here let us review the crystal structure of DPPHs before we proceed to the analysis of the magnetic properties. In the free DPPH, DPPH molecules are more closely packed (d=1.485) than in any other crystals of DPPH–solvent complexes. The crystal parameters of the free DPPH have been reported, but their precise structure has not yet been established. The crystal structure of DPPH–Bz, on the other hand, was precisely determined.[7] In this case, DPPH molecules align face-to-face to form a chain along the a-axis (Fig. 1a). A DPPH molecule at site "A" is 0.776 nm from the adjacent DPPH molecule at the same site along the a-axis. The DPPH molecules at site "B" are in a similar situation. The DPPH molecules at site "A" and site "B" make an alternative array. The nearest distance between the centers of their N–N bonds is about 0.85 nm. Two phenyl rings, the α phenyl of A_0 and the β phenyl of B_0 in Fig. 1b, however, have the nearest carbon-carbon distance of 0.372 nm. Recently, the crystal structure of the DPPH-acetone (4 : 1) complex, considered to be very similar to that of DPPH–

$1/4CCl_4$, was reported by Kiers *et al.*[9] This crystal has a hole with a diameter of at least 0.6 nm, which an acetone molecule possibly occupies, and four DPPH molecules in a unit cell ($z=4$). The four DPPH molecules are located in two different crystallographic sites. Two of the four DPPH molecules in the unit cell are related to each other by an inversion center and are close together, with a distance of only 0.595 nm between the centers of their N–N bonds. These molecules surround the hole mentioned above, so that the molecules have a relatively large freedom of motion. On the other hand, the other two molecules are separated by a distance of 0.692 nm between the centers of their N–N bonds. However, the nearest two phenyl rings of the latter lie parallel to each other at a carbon distance of 0.393 nm. Solvent–acetone molecules are randomly distributed in the holes which make channels along the c-axis. The number of the acetone molecules is about one-fourth that of the DPPH molecules.

These DPPHs show different magnetic properties. The susceptibility of DPPH–Bz and free DPPH were explained by a pair model of localized spins (localized model).[8,10,11] The DPPH–$1/4CCl_4$ complex shows a curious magnetic susceptibility which gives two Weiss constants, θ_{high} (above 30 K) and θ_{low} (below 4.2 K). The spin concentration in the low-temperature region (below 4.2 K) is half of that in the high-temperature region (above 30 K). In order to interpret this phenomenon, Duffy and Strandberg[3] proposed a "two-sublattice model," one featuring the coexistence of strong and weak pair interactions between the electron spins localized on the DPPH molecules in the crystal. On the other hand, Fedders and Kommandeur[12] applied a "narrow-band model" to explain the magnetic susceptibility of the DPPH complexes. They assumed a delocalization of unpaired electrons throughout the crystal, resulting in the formation of an energy band of the electrons.

In this paper, the present author tries to answer the following questions on the basis of the results of his magnetic measurements: (1) Which models are suitable to explain the magnetic behavior of the DPPHs crystals? (2) What types of magnetic interactions are dominant in these crystals? (3) How do the solvent molecules affect the magnetic properties of the DPPH–solvent complexes?

Experimental

The samples were prepared by the oxidation of 2,2-diphenyl-1-picryl-hydrazine($DPPH_2$) with PbO_2 in extra pure diethyl ether, benzene, carbon tetrachloride, carbon disulfide, or chloroform solutions; they were then recrystallized several times using the same solvents. It was confirmed by the elementary analyses and preliminary X-ray analyses that the free DPPH and DPPH–solvent complexes can be classified into three groups with the different, definite crystal structures (I, III, and DPPH–Bz) reported in Williams' paper.[7] Free DPPH has the same crystal structures as that of DPPH(I), while DPPH–Bz has the crystal structure identified by him. The crystal parameters of the complexes of DPPH with CS_2, CCl_4, and $CHCl_3$ are very close to those of DPPH(III) in Williams' paper[7] and those of DPPH(IIIa) in Kiers' paper.[9]

Magnetic-susceptibility(χ) measurements of polycrystalline samples were carried out with a magnetic torsion balance at temperatures between 1.2 K and 4.2 K and with a bridge method at the temperatures obtained by the adiabatic demagnetization described below. The measurement of the anisotropy of the magnetic susceptibility in DPPH–Bz was carried out in order to determine the phase-transition temperature (T_N) to an antiferromagnetic state using a single crystal of 1.34g in the adiabatic-demagnetization temperature region. Single crystals of free DPPH and DPPH–$1/4CCl_4$ were too small for us to measure the anisotropy of χ. The data obtained by the torsion balance above 1.7 K have been corrected for diamagnetism by the use of Pascal's constants. The data at the adiabatic-demagnetization temperatures were fitted to the data measured by the torsion balance at 4.22 K. The adiabatic demagnetization was carried out following the standard method. Samples were mixed with a high-vacuum diffusion oil and Apiezone-N-grease, and placed in contact with a coolant of chromium potassium alum (Cr–K–Alum) through 3000 Cu-formal wires. The temperatures were determined from the paramagnetic susceptibility of Cr–K–Alum to temperature measurement; this substance was thermally linked by copper wires to the samples. The temperature gradient between the sample and the coolant was calibrated by comparing the susceptibility of the coolant with that of Cr–K–Alum mixed with diamagnetic $DPPH_2$ at the same position. The temperatures, T^*, thus obtained were corrected to thermodynamic ones, T, by the use of T^*-*vs.*-T table.[13]

In order to study the paramagnetic shift, ^{1}H-NMR resonance (PMR) measurements were performed on powder samples (*ca.* 1 g), using Robinson and Pound-Knight-Watkins-type spectrometers operating at 12—40 MHz in the tempera-

ture range of 1.3—77 K. Low-field ESR measurements were carried out with a Kushida-type spectrometer[14] with 80 Hz field modulation to confirm the presence of the antiferromagnetic state and T_N. The sample cell for low-field ESR in the adiabatic-demagnetization-temperature region is shown in Fig. 2. The field-modulation power and radio-frequency power were minimized to prevent sample heating.

Results

Magnetic Susceptibility. The data were analyzed with the isolated-pair model and also the interacting-pair model to be discussed later. The susceptibility in the isolated-pair model[15] is accurately given by:

$$\chi = \frac{N'g^2\beta^2S(S+1)}{3kT}\frac{1}{1+1/3\exp(\delta/kT)}, \quad (1)$$

where $\delta=2|J|$ and where N' is the number of spin pairs with $S=1$, which is half the Avogadro number. Here, δ means the singlet-triplet energy separation for the electron-spin pairs. The exponential function in Eq. 1 can be expanded in the series of δ/kT; the high-temperature approximation for Eq. 1 is given as follows:

$$\chi = \frac{N'g^2\beta^2S(S+1)}{4k(T+\delta/4k)} = \frac{C'}{T+\theta'}, \quad (2)$$

where $C'=N'g^2\beta^2S(S+1)/4k$ and $\theta'=\delta/4k$. Thus, the susceptibility in the pair model shows the same form as that of the Curie-Weiss law at high temperatures where $T\gg\delta/k$. Figure 3 shows the molar susceptibilities of DPPHs, with the theoretical curves calculated using Eq. 1.

Free DPPH: Free DPPH showed a magnetic behavior which can be well explained by the pair model with $\delta/k=17.6$ K at temperatures down to 5 K. In the temperature region between 1.8 and 2.5 K, on the other hand, a paramagnetic contribution to the susceptibility corresponding to a spin concentration of 2.5% was observed (see Fig. 3). From the comparison with

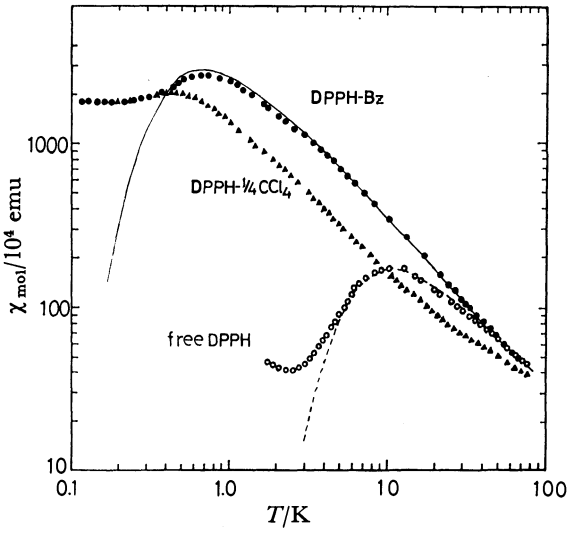

Fig. 3. Powder magnetic susceptibilities of free DPPH and DPPH solvent complexes, where 1 χ_{mol} (emu)= 4 $\pi\chi_{mol}$ (SI). Solid line : pair model curve with $\delta/k=$ 1.04 K. Dotted line : pair model curve with $\delta/k=$ 17.6 K.

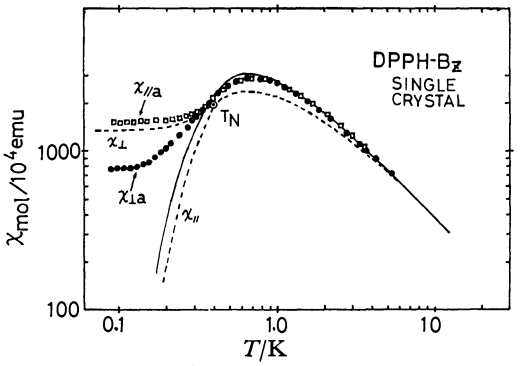

Fig. 4. Anisotropy of the magnetic susceptibility of DPPH–Bz single crystal. Solid line represents the pair model curve with $\delta/k=1.04$ K, and dotted line is the interacting-pair model for $\kappa=1.3$ (Ohya's model). $\chi_{//}$ and $\chi_{\perp}$ denote the susceptibilities parallel and perpendicular to the easy axis, respectively.

the paramagnetic shifts in the PMR spectra described below, it is concluded that the susceptibility increase below 2.5 K is due to an isolated paramagnetic "impurity."

DPPH–Bz: The susceptibility of DPPH–Bz reached a maximum χ_{max} at about 0.65 K and remained constant below 0.3 K. The data above 0.40 K are better fitted to the pair model with $\delta/k=1.04$ K than to other models, such as the linear-chain model. Figure 4 shows the anisotropy of the susceptibility in a DPPH–Bz single crystal. The squares (□) and filled circles (●) in the figure indicate the observed susceptibility along the a-axis ($\chi_{//a}$) and the directions perpendicular to the a-axis ($\chi_{\perp a}$) respectively; they show the anisotropy of the susceptibility below 0.40 K. These data suggest an antiferromagnetic ordering at about 0.40 K in the DPPH–Bz.

DPPH–1/4CCl_4: This sample is characterized by two Weiss constants, $\theta_{high}=-26$ K and $\theta_{low}=-0.3$ K, in the temperature ranges above 30 K and below 4.2 K respectively, which were obtained from a comparison of the experimental susceptibility and the Curie-Weiss law in Eq. 2. The spin concentration, C, in the low-temperature region (below 4.2 K) is about half the high-temperature one (above 30 K). In the intermediate region (4.2—30 K), θ and C gradually changed. The susceptibility increased with a lowering of the temperature from 1.7 K down to 0.45 K and remained constant below 0.45 K. The constant susceptibility, probably due to spin ordering below 0.45 K, had a value similar to that of the DPPH–Bz complex. In the high-temperature region (above 30 K), the best fit for the pair model is obtained by assuming δ/k(high)= 96 K. The remaining unpaired spins at temperatures between 4.2 and 0.45 K show an ordinary paramagnetic behavior, following the Curie-Weiss law with the Weiss constant $\theta=-0.3$ K.

A summary of the susceptibility data is given in Table 1, where C is the spin concentration obtained by comparing the observed and theoretical Curie constants.

Proton Magnetic Resonance. In the case of the powder samples, the PMR line-width (ΔH_i) is proportional to both the resonance field for the i-th proton, H_i,

TABLE 1. SUMMARY OF THE MAGNETIC SUSCEPTIBILITY DATA

Sample	T_{max} [a] / K	χ_{max} [b]	C	θ / K	δ / kK	$\lvert J\rvert$ / kK	T_N / K

and the magnetic susceptibility, χ, because of the proton-electron dipolar interaction. The paramagnetic shift (δH_i) is also proportional to χ and H_i, as is given by:

$$\delta H_i = H_i - H_0 = -\frac{a_i \chi H_i}{g_N \beta_N}, \quad (3)$$

where H_0 is the resonance field for the free proton and where a_i is the hyperfine constant of the i-th proton. For $T \gg \delta/k$, this equation can be approximated as:

$$\delta H_i \cong \frac{-5.2 \nu_i a_i}{T+\theta} \quad (4)$$

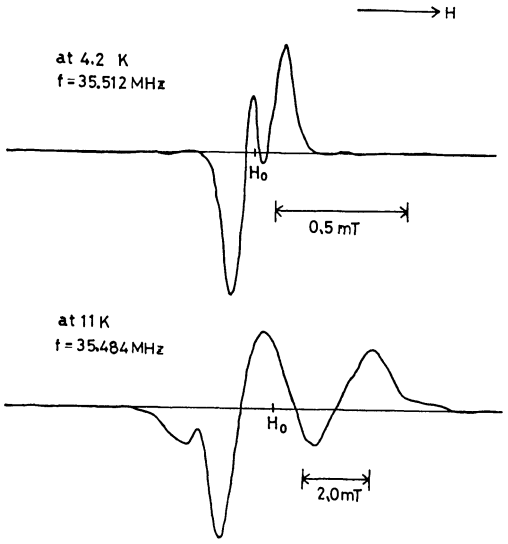

Fig. 5. PMR spectra of free DPPH at low temperatures.

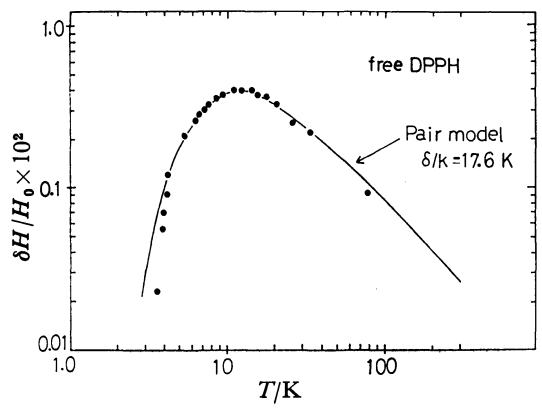

Fig. 6. Temperature dependence of the relative paramagnetic shift of free DPPH.

where ν_i is the observed resonance frequency in MHz and where $2\pi\nu_i = \gamma_N H_i$. Therefore, one can determine χ and the microscopic behavior of the compounds by measuring the temperature dependence of δH_i and ΔH_i.

Free DPPH: Figure 5 shows the PMR-derivative spectra of free DPPH at 4.2 and 11 K. At about 11 K, where the susceptibility shows χ_{max}, four lines were resolved, the ratio of the integrated line intensities being 2 : 4 : 3 : 3. It should be noted that the unshifted line does not appear at these temperatures. The distance between the inner two lines of the spectra, δH, has the same temperature dependence as that of the observed susceptibility, and agrees well with that predicted by the pair model with $\delta/k = 17.6$ K (Fig. 6). The pair-model curve in Fig. 6 was fitted to the experimental results so that its maximum value coincided with the experimental one at 11 K. In spite of an increase in the static magnetic susceptibility below 2.5 K, the spectra did not show any shifted lines down to 1.2 K, as in Verlinden's work.[16] It can be easily deduced from Eq. 3 that the disappearance of the shift leads to the decrease in χ. Therefore, the susceptibility increase below 2.5 K shown in Fig. 3 is due to isolated paramagnetic "impurity" spins, the concentration being about 2.5%.

DPPH-Bz: The PMR spectra of DPPH-Bz show five lines at 4.2 K, as given in a previous paper.[4] The intensity ratio of the five lines is about 2 : 4 : 6 : 3 : 3. This ratio is consistent with the number of protons at five different positions in DPPH-Bz: *i.e.*, two protons in metapicryl, four protons in metaphenyl, six protons in benzene, three protons at the ortho and para positions in α phenyl, and three protons at the ortho and para positions in β phenyl.[17] When the reciprocal of the paramagnetic shifts, δH_i, is plotted as a function of the temperature, the Weiss constant of $\theta = -0.5$ K is obtained by extrapolation to the absolute zero degree. This θ value is in good agreement with that obtained from the susceptibility measurements. As the temperature is lowered or frequency is increased, the shifted lines become broader and split further. The broadening of the lines is roughly proportional to χ. The central line due to benzene protons is easily saturated at 1.5 K, because the spin-lattice relaxation time, T_1, of the diamagnetic benzene protons is longer than those of the paramagnetic DPPH protons.

DPPH-1/4CCl_4: The PMR spectra of DPPH-1/4CCl_4 below 20 K showed a strong unshifted line which is easily saturated at 1.5 K, in addition to four weak, shifted lines (two high-field and two low-field shifted lines), as was shown in Karimov's paper.[5] Above 20 K,

four shifted lines coalesced into a broad central line. The intensity ratio of the unshifted central line to the sum of the four shifted lines at 18.082 MHz was determined to be 2.5 : 1 from the PMR absorption spectra at 4.2 K. The intensity of the central line increased as the frequency became higher. The unshifted line can be attributed not to the protons of the DPPH molecule in the paramagnetic state, but to the protons of DPPH in the singlet state.[16] The relative shift for this sample is somewhat larger than that for DPPH–Bz. The following results were obtained from the reciprocal plot of the paramagnetic shift *versus* the temperature. In the lower temperature region (below 4.2 K), the Weiss constant $\theta_{low}=-0.2$ K is in agreement with that obtained from the susceptibility measurement.

Low-field ESR. In order to confirm the long-range ordering observed by the anisotropy of χ for DPPH–Bz, low-field ESR measurements were carried out at 74.4 MHz in the range from 0.27 K to 4.2 K. The derivative spectra are shown in Fig. 7. The $g=2$ signal intensity decreased rapidly below 0.6 K. The line-width, ΔH_{pp}, increased with a lowering of the temperature and then diverged between 0.46 and 0.42 K. (Fig. 8) Below 0.42 K, the $g=2$ resonance became very small, and the $g=4$ resonance due to forbidden dipolar transition became dominant.[18] The rapid increase in the line-width observed in the paramagnetic region near 0.42 K is interpreted as follows: the critical fluctuation sets in the spin system and makes the exchange correlation time, τ_e, long[19] thus reducing the extent of exchange narrowing of the ESR line-width. Then, long-range ordering occurs at about 0.40 K. The transition temperature to the antiferromagnetic state (0.43 ± 0.03 K) is consistent with that determined from the magnetic-susceptibility measurements for a single-crystal sample.

Discussion

Magnetic Interaction in the Paramagnetic State. From the results of the magnetic susceptibility shown in Fig. 3, it can easily be understood that, in the DPPH–solvent complexes, solvent molecules play an important part in constructing a spatial configuration of the magnetic moments. Different solvents form free DPPH and different solvent complexes with certain crystal structures. Therefore, the type and the intensity of magnetic interaction depend on the solvent used for preparing the crystal.

In the free DPPH, DPPH molecules are most closely packed in the crystal ($d=1.485$). The susceptibility results show that every two molecules make pairs with a strong antiferromagnetic exchange interaction ($J/k=-8.8$ K) and fall into a singlet ground state at low temperatures below about 3 K. The results of the paramagnetic shift in PMR spectra support this model. No fall in the PMR intensity was observed in the free DPPH below 3 K, at which point the paramagnetic shift lines are coalesced into an unshifted single line, while a sudden decrease in PMR intensity was observed in the BDPA and TANOL radicals in the vicinity of their antiferromagnetic transition.[20,21] In the low-field ESR measurements, a maximum of the line-width was observed in DPPH–Bz near the Néel temperature, while no such maximum was observed in the free DPPH. From these results, one can conclude that the magnetic properties of the free DPPH are characterized by the isolated-pair model.

In the case of DPPH–Bz, the powder magnetic susceptibility in Fig. 3 and that as well as the heat capacity measured by Duffy *et al.*[11] show that the pair interaction is rather dominant in this crystal. The pair interaction, however, does not lead to any long-range ordering. Therefore, some inter-pair exchange interaction must be taken into account in order to explain the antiferromagnetic ordering. Duffy *et al.* proposed the exchange paths for DPPH–Bz described below in order to explain the magnetic susceptibility in the paramagnetic region: DPPH molecules which are 0.776 nm apart from each other along the a-axis are considered to form a chain along this axis from the crystallographic point of view (Fig. 1a), suggesting the existence of linear-chain-type interaction along this axis.

In a DPPH molecule, the unpaired electron is not localized on a N–N bond, about 30% of it being distributed on the phenyl and picryl rings.[22] Therefore, the exchange interaction between the unpaired electron on Site "A" and on Site "B" will take place dominantly through the overlap of the $2p\pi$-orbitals on the adjacent α and β phenyl rings. (Fig. 1b) This interpretation is reasonable if we take the crystal structure into account. However, their heat capacity and susceptibility measurements were limited to the paramagnetic region, and there was no mention of the antiferromagnetic transition. Below we will discuss the phase transition using the interacting-pair model based on the interpretation of the exchange path mentioned above.

DPPH–1/4CCl_4 shows more complicated magnetic behavior. The magnetic susceptibility results have been explained by both the two-sublattice model and the narrow-band model. However, the PMR spectra can be analyzed in terms of the coexistence of weakly and strongly coupled spin pairs, supporting the two-sublattice model proposed by Duffy *et al.* This excludes the narrow-band model. The following exchange mechanism is suggested from the point of view of the two-sublattice model. DPPH–1/4CCl_4 has one CCl_4 molecule and four DPPH molecules in a unit cell. The two DPPH molecules are close together (0.595 nm) and are mutually coupled with a strong exchange interaction. They form singlet spin pairs at higher temperatures compared with free DPPH. On the other hand, the other two weakly coupled DPPH molecules (0.692 nm apart) interact with each other with some weak exchange interactions through both paths between nearest N–N bonds and between nearest phenyl rings, which may trigger an antiferromagnetic ordering of unpaired spins below 0.9 K.[23]

Phase Transition to Antiferromagnetic State. An antiferromagnetic ordering of DPPH–Bz was suggested by Prokhorov and Fedrov from the disappearance of the low-field ESR signal near 0.18 K.[24] In the present work, the low-field ESR signal disappeared at 0.43 ± 0.03 K, below which point the magnetic susceptibility of a powder sample approaches a finite constant value with a decrease in the temperature. In addition, the single crystal shows magnetic anisotropy below 0.40 K, as is shown in Fig. 4. All of these data support the appearance of an antiferromagnetic ordering about 0.40 K. The Néel temperature, T_N, is higher than that given by Prokhorov and Fedrov. As has been described already, the paramagnetic susceptibility of DPPH–Bz is rather well described by the isolated-pair model, although linear-chain interaction can be expected to be dominant from its crystallographic data. Duffy, Strandburg, and Deck reported the susceptibility and heat capacity of DPPH–Bz from 0.4 K up to room temperature, but neither the linear-chain model nor the quadratic-net Heisenberg model gives a satisfactory explanation of their data. The pair interaction, J, however, cannot cause a long-range ordering. Therefore, in order to explain the long-range ordering of a spin-pair system, inter-pair interaction must be considered. We try to explain the long-range ordering temperature and the magnetic behavior, in both paramagnetic and antiferromagnetic regions, by using the following model as a first-order approximation. This model is a modified version of Oguchi's "improved molecular field theory of the antiferromagnet,"[25] the details of which were recently described by Ohya-Nishiguchi.[26]

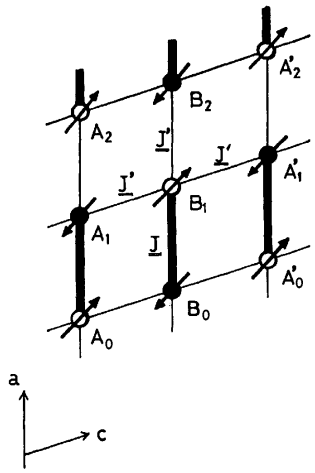

Fig. 9. Interacting-pair model for DPPH–Bz. The positions of DPPH molecules are projected in the ac-plane. J and J' represent intra-pair and averaged inter-pair interactions, respectively.

Assuming a spin pair i-j with intra-pair exchange interaction, J, having other exchange interactions with their neighboring spin pairs, averaged as $J'(|J'|<|J|)$, as is shown in Fig. 9. J' is treated as a kind of molecular field. For such a spin system, a two-body Hamiltonian is given by the following equation:

$$\begin{aligned} \mathcal{H} &= 2|J|(\boldsymbol{S}_i\cdot\boldsymbol{S}_j) + aS_i^z + bS_j^z \\ a &= 2|J'|Z'(-\langle S^z\rangle+\langle\delta S^z\rangle) - g\mu H^z \\ b &= 2|J'|Z'(\langle S^z\rangle+\langle\delta S^z\rangle) - g\mu H^z, \end{aligned} \tag{4}$$

where Z' is the number of the nearest interaction paths of i-spin with all neighboring spins except the j-spin and is equal to three in the case of Fig. 9. Calculation using Eq. 4 gives the following paramagnetic susceptibility, χ_{para}, and Néel temperature, T_N. The susceptibility of the antiferromagnetic region is discussed in Ohya-Nishiguchi's paper:[26]

$$\chi_{para} = \frac{N/2(g\mu)^2}{\kappa|J|+kT\left(1+\exp(|J|/kT)\times\dfrac{\cosh(|J|/kT)}{\cosh(g\mu H/kT)}\right)} \tag{5}$$

$$\exp(-|J|/kT_N)+\cosh(|J|/kT_N) = \kappa\times\sinh(|J|/kT_N), \tag{6}$$

where $\kappa=Z'\times|J'|/|J|$. In the case of $\kappa=0$, χ_{para} is equal to the pair-model susceptibility of Eq. 1. From Eq. 5, it can be seen that χ depends also on the external field, H. At 4.22 K, such a field effect is negligibly small, *i.e.*, $\chi(0)/\chi(0.829\text{ T})=0.98$. By taking the field effect into account, the susceptibility data obtained by the ballistic method in a zero external field were fitted to that obtained by means of a torsion balance in the field of 0.829 T at 4.22 K. A comparison of the theoretical values with the experimental ones shows that the $T_N/T(\chi_{max})$ ratio is best fitted to the experimental one, 0.6, which results in the value of $\kappa=1.3$. The theoretical susceptibility for the case of a single crystal obtained by Ohya-Nishiguchi's model is represented by a dotted

line in Fig. 4 in the case of $\kappa=1.3$; it is qualitatively well fitted to the experimental susceptibility. Using the value of $\kappa=1.3$, the inter-pair interaction $|J'|$ is estimated to be $0.43|J|$ for $Z'=3$ in the case of Fig. 9, while $|J'|=0.26|J|$ is obtained for the case of $Z'=5$ proposed by Duffy *et al.*, who take the other interaction paths into account, also.[11] In both cases, the inter-pair interaction is not so small compared with the intra-pair one.

In conclusion, a spin with antiferromagnetic interaction with a nearest-neighbor spin in free DPPH makes a singlet spin-pair as a ground state. However, in the case of DPPH–Bz spin-pairs interact with each other by means of second-exchange interaction, J', and an antiferromagnetic ordering takes place at a temperature of about 0.40 K. It is difficult, at present, to say definitely what kind of magnetic structure exists in DPPH–1/4CCl_4, but it is most likely that DPPH–1/4CCl_4 is the case of the coexistence of isolated pairs and mutually interacting pairs.

The author is greatly indebted to Professor Yasuo Deguchi for his continuous help and encouragement. Thanks are also due to Dr. Hiroaki Ohya-Nishiguchi, and Professor Noboru Hirota for their helpful advice and discussions, and to Dr. Toshiaki Enoki and Mr. Toshio Yoshioka for their collaboration. He also wishes to express his appreciation to Professor Ikuji Tsujikawa and Dr. Hanako Kobayashi for their courtesy in carring out the adiabatic demagnetization experiments and for their helpful discussions.

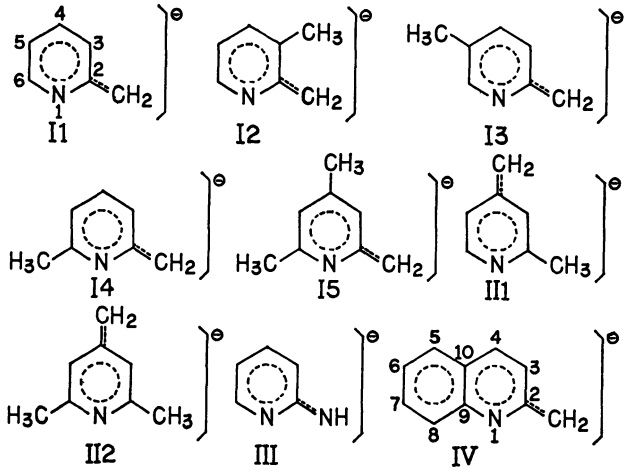
(Received December 24, 1980)

The ^{7}Li and ^{13}C NMR spectra have been observed for picolyl-type anions with lithium as a counter ion in polar solvents. With reference to the observed chemical shifts, it is concluded that these lithium salts are present in THF as tight ion pairs in which the anion-cation interaction takes place mainly at the ring nitrogen. Thus, the picolyl-type anions are characterized by their ion-pair structures.

In the previous reports on picolyl(pyridylmethyl)-type delocalized anions, the following points of interest were disclosed for I—IV (shown below) in polar solvents:[1,3] (1) The methylene carbon in I is virtually sp^2-hybridized; (2) for II, the observed ^{13}C chemical shifts are linearly related to the calculated π-electron densities; and (3) II—IV can be regarded as delocalized anions with the same significance as I. In order to delineate the nature of interaction between the picolyl-type anions under discussion and the lithium ion, the ^{7}Li, ^{13}C, and ^{1}H resonances of these ionic species have been investigated in polar solvents. The anions prepared are numbered as follows:



Experimental

The procedures used in this study are similar to those described in previous reports.[1,3] All the anions were produced by reacting methyl-substituted pyridines, 2-methylquinoline, and 2-aminopyridine with butyllithium.

The ^{7}Li and ^{13}C NMR spectra were measured on a Varian FT 80A spectrometer installed at the Institute for Molecular Science, operating in the FT mode at 30.913 and 20.000 MHz respectively. The measuring temperatures and sample concentrations were 36—37 °C and 0.8—1.3 mol dm^{-3}. The lithium chemical shifts were expressed relative to that for aqueous LiCl (0.5 mol dm^{-3}), used as an external reference. The carbon chemical shifts were evaluated with the solvent peaks used as an internal reference. The more shielded peaks of diethyl ether (DEE), tetrahydrofuran (THF), 1,2-dimethoxyethane (DME), the most shielded peak of tetraglyme (TG), and the peak of hexamethylphosphoric triamide (HMPA) were taken to be 17.1, 26.4, 58.8, 58.6, and 37.0 ppm from TMS respectively.

The PPP and CNDO/2 MO calculations for the 2- and 4-pyridylmethyl (picolyl) anions[4] were carried out using the Okitac-4300C and Hitac-8450 computer systems installed at The Industrial Technology Center of Mie Prefecture and at the Nagoya Institute of Technology respectively, using the same procedure as that described in the preceding paper.[1] The bond lengths between the methylene and 2-carbons and between the methylene and 4-carbons were set at 1.39 Å in the calculations.

Results and Discussion

Some typical spectra of the anions with lithium as a counter ion are shown in Figs. 1 and 2. The ^{7}Li and ^{13}C chemical-shift data are given in Tables 1 and 2 respectively.

Table 1. The lithium chemical shifts for the anions, in ppm[a]

Anion	Solvent	
I1	DEE	−0.52
	THF	−0.29
	DME	−0.62
	TG	−0.26
	HMPA	−0.05
I1′[b]	THF	−0.01
I1″[b]	THF	−0.26
I1‴[b]	THF	−0.40
I2	THF	−0.24
I3	THF	−0.34
I4	THF	−0.30
I5[c]	DEE	−0.10
II1	THF	−0.22
II2	THF	−0.03
	HMPA	−0.08
III	THF	1.08
	HMPA	0.78
IV	THF	−0.08
	HMPA	−0.10

a) Errors are estimated to be within ±0.05 ppm. b) In proportions of starting materials, 2-methylpyridine : butyllithium = 1.77 : 1, 1.31 : 1, and 0.58 : 1 for I1′, I1″, and I1‴ respectively. c) Contaminated with a small amount of II2.

Table 2. The carbon chemical shifts of the anions, in ppm[a)]

Anion	Solvent	Assignment										
		2-C	3-C	4-C	5-C	6-C	7-C	8-C	9-C	10-C	CH_2	CH_3
I1	DEE	165.5	118.8	134.7	102.0	149.8					57.5	
	THF	164.2	116.1	131.6	97.3	148.7					57.0	
	DME	163.5	115.7	131.3	96.2	148.8					58.0	
	TG	161.9	114.8	130.5	94.1	149.0					61.5	
	HMPA	161.3	113.6	129.8	92.2	149.8					62.6[b)]	
I2	THF	163.2	119.4	130.7	97.2	146.7					56.2	21.0
I3	THF	164.1	116.6	134.2	104.6	147.1					54.2	18.1
I4	THF	166.0	112.7	132.6	97.3	155.7					54.1	24.6
I5	DEE	169.1	114.2	144.7	104.7	156.8					52.9	22.6
												25.5
II1	THF	149.7	107.9	150.0	107.9	143.7					64.9	24.4
II2	THF	150.2	106.4	151.9	106.4	150.2					62.2	24.3
	HMPA	150.1	105.2	150.5	105.2	150.1					62.2	24.8
III	THF	174.2	113.3	136.3	104.7	148.1						
	HMPA	173.2	112.2	134.4	101.0	148.6						
IV	THF	159.0	126.0	128.6	126.3	111.8	128.2	117.7	155.8	122.7	70.2	
	HMPA	159.0	125.0	127.9	125.5	108.7	127.7	119.0	156.5	121.9	70.7	

a) Errors are estimated to be within ± 0.3 ppm. b) This value should be adopted, though it is somewhat different from the corresponding CH_2 value in Table 2 of Ref. 1.

NMR Spectra of the Anions with Lithium as a Counter Ion.[5)]
^{7}Li Spectra: A typical spectrum is shown in Fig. 1. With changes in the anion, the solvent, the concentration, and the temperature, the chemical shifts and/or linewidths varied. In the case of 2-pyridylmethyllithium (I1),[6)] the variation in the chemical shift was 0.24 ppm, and the linewidth increased about 6.5 times (*i.e.*, from about 14 to 90 Hz), with a change in solvent from THF to HMPA.

^{13}C Spectra: The signals were assigned by comparison with the ^{1}H spectra and by confirmation of a quarternary carbon by means of the off-resonance decoupling method. The 2- and 4-pyridylmethyl anions with lithium as a counter ion, produced from methyl-substituted pyridines by the action of butyllithium, were distinguishable by a difference in spectral pattern, as is shown in Fig. 2.

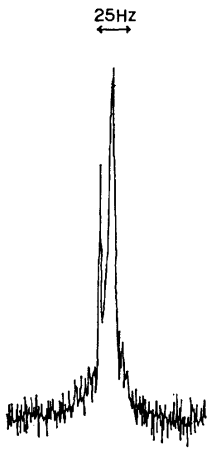


Fig. 1. ^{7}Li spectrum for I1 in THF. The less shielded peak is due to the signal of aqueous LiCl used as an external reference.

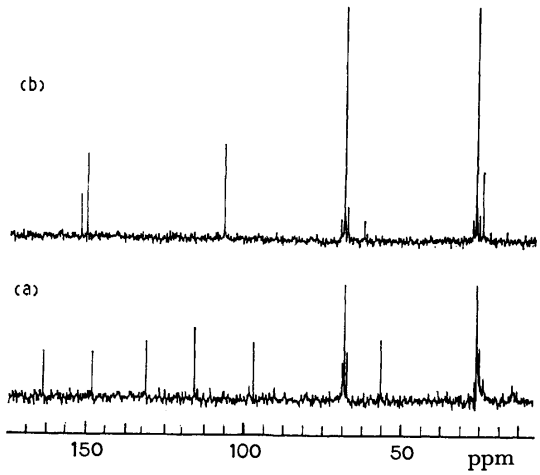

Fig. 2. ^{13}C spectra of pyridylmethyl anions in THF; (a) I1 and (b) II2.

Types and Structures of Ion Pairs Formed. In the ^{7}Li NMR spectra for I—IV, the signals appear at higher fields than those of typical alkyllithium compounds (*i.e.*, 1—2 ppm in ether, triethylamine, and cyclopentane)[7)] and at lower fields than those of typical aromatic lithium salts present in THF as primarily loose (or solvent-separated) ion pairs, such as fluorenyl-, 1,3-diphenylallyl-, triphenylmethyl-, and cyclononatetraenyllithium (*i.e.*, -1——-2 ppm in THF).[8)] These ^{7}Li spectra may indicate that the ionic natures of lithium salts of I—IV are different from those of the alkyllithiums and the loose ion pairs. As has already been reported,[9)] phenylmethyl-(benzyl-), 1-phenylallyl-, cyclopentadienyl-, and indenyllithium exist as tight (or contact) ion pairs in THF. The signals of phenylmethyl- (*i.e.*, -0.12 ppm in THF) and 1-phenylallyllithium (*i.e.*, -0.71) are found within a range (-1—1

ppm) similar to those for I—IV, but those of cyclopentadienyl-(*i.e.*, −8.37) and indenyllithium (*i.e.*, −6.12) show an upfield shift of more than 6 ppm from I—IV.[8,10] This large difference reflects the specific location of the counter ion in relation to the anion in a tight ion pair. Consequently, if I—IV form tight ion pairs with lithium cations, the cations are not situated so as to be strongly subject to the diamagnetic shielding of the induced ring current.[11]

The dependence of the lithium chemical shift with a solvent for the I1, II2, III, and IV given in Table 1 is relatively small. The lithium shift for I1 in DME is 0.33 ppm upfield from the THF value. This variation is similar to those for typical tight ion pairs, but is not large enough to indicate primarily loose ion pairs in THF and DME. An 1 ppm or greater difference between THF and DME should be observed for primarily loose ion pairs.[8]

The carbon chemical shifts of I1, II2, III, and IV in various solvents are given in Table 2. As can be seen from the table, the effect of a change in solvent is large on the carbon shifts of I1. The 5-carbon shift, being a well-defined index of electron delocalization,[1] appears in a higher field with the change to a more polar solvent in this order: DEE, THF, DME, TG, and HMPA; it is about 5 and 10 ppm upfield in HMPA from the THF and DEE values respectively. The same tendency is observed with the proton chemical shifts.[1,3,12] This upfield shift is induced by a change in the ion-pair equilibrium toward loose ion pairs or an increase in the external solvation of tight ion pairs.[13] Generally, the same overall trends for the carbon and proton shifts are observed on a lowering of the temperature as on an increase in the solvating ability of the solvent. The 5-proton shifts of I1 in THF and DME show a relatively large temperature dependence, but the magnitude of the upfield shift induced by changing the temperature from 40 °C to −30 °C in DME is slightly larger than that in THF.[1,3] The temperature dependence of the 5-proton shifts of I1 and I2 in DME is shown in Fig. 3. The shift of I1 at −60 °C is about 0.25 ppm upfield from the 40 °C value, but it is still about 0.2 ppm downfield from that at room temperature in HMPA, favoring loose ion pairs in comparison with DME. In addition, the two curves depicted in this figure cannot be claimed to be the remarkable sigmoid curves, which imply a change in the ion-pair equilibrium toward loose ion pairs in this temperature range.[13] Consequently, in THF and DEE, which favor tight ion pairs in comparison with DME at room temperature, the significant upfield shift induced by the change in solvent from DEE to THF can be accounted for by an increase in the external solvation of tight ion pairs. These results on the lithium and carbon shifts in various solvents and the proton shifts at various temperatures lead to the conclusion that I1 forms a tight ion pair with a lithium cation in THF, and that, therefore, so do I2—IV.

At concentrations in the range of 0.5—2.0 mol dm^{-3}, the variation in the lithium shifts for I1 in THF is negligibly small, but the linewidth at the half-peak height varies from 21 to 8 Hz. At 0.8—1.2 mol dm^{-3}, the variations for I1 in DME, and for I4 and III1 in THF are less than 0.05 ppm. Thus, no meaningful difference in lithium shift for I1 is observed on a change in the concentration in discrete solvents. Consequently, it is reasonable to assume that either the state of association does not change in this concentration range or that the effect of association is not important in determining the lithium shifts.[8]

The lithium shifts for I1′—I1‴ contaminated with an excess of the starting materials in THF are given in Table 1. With an increase in the proportion of 2-methylpyridine relative to butyllithium, the lithium signal is shifted to a lower field, and the linewidth becomes broader. In view of these shifts, the effect of contamination is negligibly small for the lithium salts prepared in this study. Further, when lowered to −76 °C, the peak for I1′ and I1″ is split into two, but not so for I1‴, as is shown in Fig. 4. The ratio of the two peak areas for I1′ is roughly 1.8 : 1, while that for I1″ is 0.22 : 1. One of the two peaks for I1′ and I1″ appears at about 1.35ppm, and the other, at −0.1—−0.2 ppm. It seems that the less and more shielded peaks with respect to inorganic lithium are attributable to

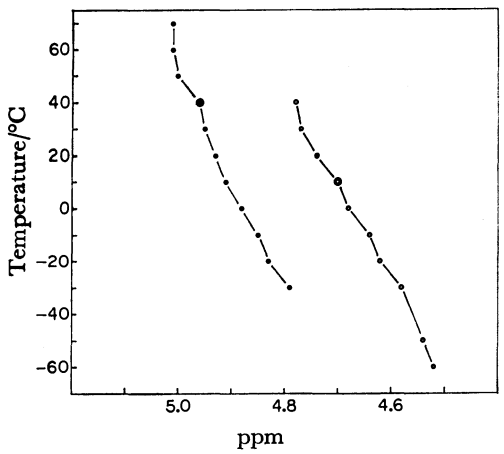

Fig. 3. Temperature dependence of the 5-proton chemical shifts of I1 and I2. ○: I1 in DME, ●: I2 in DME, and ◎: coalescence temperature of the two methylene proton peaks of I1, and ⊙: I2 in DME.

the 2-pyridylmethyllithium–2-methylpyridine complex formed and to 2-pyridylmethyllithium respectively.

Turning now to the comparison of 2-pyridylmethyllithium (I1) with phenylmethyl alkali compounds, especially with phenylmethyllithium in THF, we note first that the preparation of I1 is indeed easy, and that I1 is thermodynamically very stable in THF and DME.[3] Secondly, it is apparent that phenylmethylpotassium is much more ionic than phenylmethyllithium in THF.[10,14,15] The ^{1}H and ^{13}C spectra of phenylmethylpotassium in THF are similar to those of I1 in DME, except for the positions bonded to the ring nitrogen, *i.e.*, the 2- and 6-positions. With the procedure reported for naphthylmethyl alkalis present as tight ion pairs in THF at room temperature,[16] the proton chemical shifts, calculated on the basis of the assumption that the cation radius for the phenylmethyl anion can be infinitely large (that is, that the phenylmethyl anion may form a loose ion pair or free ions with the cation), would be about 5.2, 5.7, and 4.2 ppm for the *o*-(3-), *m*-(4-), and *p*-(5-)protons respectively. These values are comparable to values of 5.16, 5.68, and 4.33 ppm for I1 in HMPA.[1] The π-electron densities, calculated using the PPP MO method, at the 3-, 4-, and 5-positions in the phenylmethyl anion are also comparable to those in I1. These suggest that I1 may be present as a loose ion pair in HMPA. Thirdly, we recall that the methylene carbon in I1 is virtually sp^2-hybridized.[3] Fourthly, an *o*-position in I1 is a nitrogen atom. The excess charge density, calculated using the PPP and CNDO/2 MO methods, at the *o*-nitrogen (ring nitrogen) is comparable to that at the methylene carbon. Thus, I1 has some different features as compared with phenylmethyllithium, apparently caused by the effect of *o*-nitrogen, but it seems to be monomeric in polar solvents, much like to phenylmethyl and naphthylmethyl alkalis.[16,17] Therefore, when I1 is present as a tight ion pair in THF, either the methylene carbon or the ring nitrogen can be regarded as the site where the anion-cation interaction mainly takes place.

A good correlation has been obtained between the carbon chemical shifts and the π-electron densities calculated using the PPP and CNDO/2 MO methods for the 2-pyridylmethyl anions I and 4-anions II. The relationship given in Fig. 5 shows that the π-electron densities at the carbons in both 2-anion I1 and 4-anion

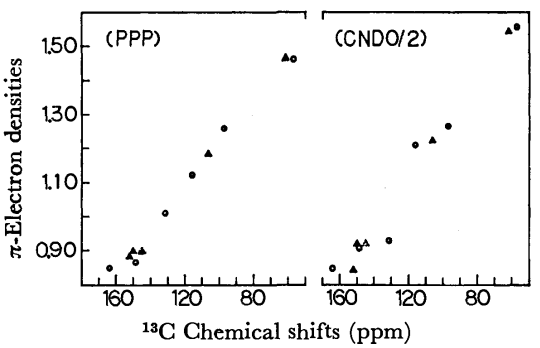

Fig. 5. π-Electron densities *vs.* ^{13}C chemical shifts.
○:I1, △: II2 in THF, and ⛬: 2- and 6-C corrected for effect of methyl group by reducing 5 ppm in II2.

II2 can be evaluated from the carbon chemical shifts using an identical scale. In addition, as is shown in Table 1, the lithium-shift difference between lithium salts of the 2-anions I and the 4-anions II is less than 0.31 ppm in THF; especially, that between I2 and III is negligibly small. These imply that both have essentially the same ion-pair structure in THF. However, it was previously reported that 2,4-dimethylpyridine and 2,4,6-trimethylpyridine underwent deprotonation to give 2-anions such as I, and that isomerization took place from the 2- to the thermodynamically more stable 4-anions II.[3] The lithium salts of the 4-anions II are indeed surprisingly stable, for about 30—40% of these lithium salts in TG could still be detected in the ^{1}H spectra after the samples had stood for 1 h at 100 °C, while the lithium salts of the 2-anions I completely changed to the corresponding methyl-substituted pyridines in TG. In view of these experimental facts, it is not reasonable to assume that the anion-cation interaction takes place mainly at the methylene carbon in lithium salts of the 2-anions I and the 4-anions II present as tight ion pairs in THF, for this assumption would predict a primarily loose ion-pair structure for both lithium salts I—II. Therefore, in both lithium salts I and II and, furthermore, in III—IV, the ring nitrogen can be regarded as the site where the anion-cation interaction mainly takes place.

It is concluded that I—IV are present in THF as tight ion pairs in which the anion-cation interaction takes place mainly at the ring nitrogen. Thus, the picolyl-type anions with lithium as a counter ion are characterized by their ion-pair structures.

This work was supported by the Joint Studies Program (1978—1979) of the Institute for Molecular Science.

The Binding of Sodium Dodecyl Sulfate to Lysozyme in Aqueous Solutions

Kohsuke FUKUSHIMA,* Yoshio MURATA, Nagamune NISHIKIDO,
Gohsuke SUGIHARA, and Mitsuru TANAKA
Department of Chemistry, Faculty of Science, Fukuoka University, Fukuoka 814-01
(Received January 16, 1981)

The binding mode of sodium dodecyl sulfate to lysozyme and the accompanying structural change of lysozyme by binding have been investigated by means of the binding isotherm, the precipitation curve, and the CD spectra in pure water, NaCl, and borate buffer solutions. The precipitation phenomena could be explained in terms of the neutralization of the net charge of lysozyme due to dodecyl sulfate-ion binding. The analysis of the binding isotherms by the use of the BET equation gave the site number of the first layer corresponding to the positively charged residues at the pH studied. The conformational change from the β-structure to the α-helix has been observed in the second-layer binding. The environmental change of the side-chain residues has also been observed.

It has been well known that the denaturation of protein is caused or influenced by many factors, such as heat, the pH, and the addition of inorganic or organic substances.[1] Above all, it is interesting that most ionic surfactants behave uniquely as strong denaturants for proteins.[1-3] The addition of a surfactant to a protein solution causes a drastic change in the conformation of protein. Even in a very low surfactant concentration (far below the critical micelle concentration, CMC), the protein is denatured by surfactant molecules. For instance, the extent of the conformational change of serum albumin increases with the surfactant concentration, but it reaches a certain limit at a concentration close to 10^{-5} mol dm^{-3}.[4]

With respect to the hen egg-white lysozyme, an X-ray study revealed that the lysozyme is a rigid and stable enzyme.[5] In the range of physiological pH values, the lysozyme does not show any detectable change in its structure up to 77 °C, and at the physiological temperature no detectable change in the structure was observed with a pH change from 1.2 to 11.3. The stability of lysozyme has been attributed to the four disulfide bonds besides hydrogen bonds and hydrophobic interactions among the 129 amino-acid residues. Thus, it is supposed that the lysozyme molecule may be comparatively resistant to the addition of a surfactant.

The precipitation and the inactivation of the enzyme occurred when a surfactant mixture of sodium dodecyl sulfate (SDS) and sodium tetradecyl sulfate (STS) was added to the lysozyme. The mixing ratio of SDS to STS was 80 to 20.[6] In the past, these phenomena were interpreted in terms of the weight-mixing ratio of surfactant to protein. However, these experimental results should be interpreted with reference to binding isotherms.

In a study of the binding of SDS to various proteins including lysozyme, it was found that as much SDS bound to a protein as the weight of the protein itself,[7] and it was suggested, from the solubilizing ability of the SDS–protein complex for water-insoluble dye, that SDS formed a so-called hemimicelle containing a polypeptide as a core. We are interested in what type of hemimicelle is formed in the lysozyme–SDS system. Fortunately, the structure of lysozyme has been well defined, so that lysozyme may give some detailed information about the interaction.

In this work, the binding of SDS to lysozyme, and the precipitation and structural change upon binding are investigated as a function of the concentrations of SDS and the added NaCl, and the pH by means of circular dichroism (CD) measurement and potentiometry.

Experimental

Materials. Hen egg-white lysozyme (6 times recrystallized) was purchased from the Seikagaku Kogyo Co., Ltd., and was used without further purification. The SDS was synthesized from the purified 1-dodecanol according to the literature.[8] The product was purified by recrystallizing it three times from ethanol. The CMC of the SDS was determined by electric-conductivity measurements. The value of 8.28×10^{-3} mol dm^{-3} at 25 °C was consistent with that in the literature.[9] There was no minimum in the plot of the surface tension *vs.* the concentration. All the inorganic salts (Nakarai Chemical Co., Ltd.) were of a special grade and were used without further purification.

Precipitation Measurements. An aqueous solution of lysozyme and one of the SDS solution were mixed in a test tube, and then water was added to make a 25-ml solution. Throughout the series of experiments, the concentration of lysozyme in the test tube was kept constant. After the samples had been allowed to stand at 25 °C for over 20 h, the precipitates were separated through a membrane filter (pore size, 0.1 μm; Toyo Roshi, Co., Ltd.) The concentration of lysozyme in the filtrate was determined spectrophotometrically at 280 nm (Model 323 of Hitachi Mfg. Co.) using the molar extinction coefficient of 36500 for lysozyme.[10] The amount of protein precipitated was evaluated by comparing the absorbance of the filtrate with that of the reference solution without SDS.

Binding Isotherms. The binding isotherms of SDS to lysozyme were constructed by the determination of the equilibrium SDS concentration by means of potentiometry.[11] The electromotive force (emf) of the cell with a liquid membrane was measured by means of a digital multimeter(Takeda Riken TR 6856). The temperature of the solution in the cell was kept within 25 ± 1 °C using a thermostated water bath. The corresponding calibration curves of emf for SDS in pure water, NaCl, and buffer solutions showed a good linearity and gave a slope consistent with the Nernstian response (59.4 ± 0.5 mV per decade of change in SDS at 25 °C). After the mixed solutions of lysozyme and SDS had been allowed to stand for 1 d at 25 °C, the emf was measured. The concentration of lysozyme in the sample solution was constant (2×10^{-5} mol dm^{-3}) throughout the series of experiments. The coexistence of lysozyme in the solution has been reasonably assumed not to affect the response for the DS^- ion, and so the

change of emf should be ascribable specifically to the change in the free-DS^--ion concentration in solution.

The average number of SDS molecules ($\bar{\nu}$) bound to a lysozyme molecule can be given as:

$$\bar{\nu} = (C_t - C_e)/C_l, \quad (1)$$

where C_t is the total SDS concentration, C_e is the equilibrium SDS concentration, as determined from the curve of emf *vs.* the concentration, and C_l is the lysozyme concentration.

Circular Dichroism (CD). The CD spectra in the ranges of 240—200 nm and 320—270 nm were measured by the use of a spectropolarimeter (JASCO-A40) under nitrogen flush. Calibration was made with a D-10-camphorsulfonic acid solution. The path length of the cell used was 10 mm. The temperature was controlled at 25±0.1 °C by circulating thermostated water through the cell.

The CD spectra were obtained by accumulating 4 times for 240—200 nm and 8 times for 320—270 nm, with a microproccessor equipped with a spectropolarimeter, and their mean values were recorded. The data were expressed in terms of the mean residue ellipiticity.

All samples were equilibrated in a water bath at 25 °C for 1 d, and then the CD spectra were measured. The concentrations of lysozyme were 1.2×10^{-6} mol dm^{-3} and 2.7×10^{-5} mol dm^{-3} in the ranges of 240—200 nm and 320—270 nm respectively.

Results

Figure 1 shows the binding isotherm of SDS to lysozyme as well as the precipitation curve at two lysozyme concentration in pure water. The $\bar{\nu}$ was calculated according to Eq. 1. In the lower equilibrium concentration (4×10^{-5}—9×10^{-4} mol dm^{-3} SDS), the $\bar{\nu}$ is about 10, while in the range higher than 9×10^{-4} mol dm^{-3} the $\bar{\nu}$ gradually rises to about 20, and then it reaches a certain limit of measurement, *i.e.*, the upper limit of the linearity in the calibration curve of emf.

The shape of the precipitation curve of lysozyme depends on the lysozyme concentration when the total concentration of SDS, C_t, is taken as the abscissa. However, the data can be replotted against the equilibrium SDS concentration, C_e, which is calculated by using the binding isotherm. As is shown in Fig. 1, the precipitation curves at two different lysozyme concentrations coincide with each other when C_e at equilibrium is taken as the abscissa. It can be seen from Fig. 1 that the amount of the precipitate increases parallel with the binding, and thereafter it is kept constant (*i.e.*, the lysozyme is almost completely precipitated) when $\bar{\nu}$ is about 10. In the range of the binding number of 10, the lysozyme keeps being precipitated almost completely. With an increase in $\bar{\nu}$ from 10 to 20, the precipitation curve goes down to zero.

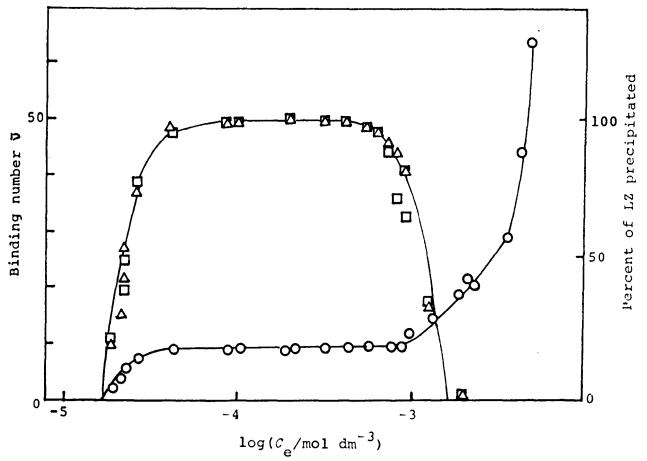

Fig. 1. The binding isotherm of SDS (○) and precipitation curve of lysozyme (LZ) in pure water (pH 5.8) at 25 °C. △: Lysozyme concentration 3.76×10^{-5} mol dm^{-3}, □: lysozyme concentration 2.19×10^{-5} mol dm^{-3}.

For the NaCl solution system whose ionic strength is 0.1, as may be seen in Fig. 2, the binding isotherm begins to rise at $C_e=1\times10^{-4}$ mol dm^{-3}. The region where the binding number is kept at 10 is very narrow as compared with Fig. 1. After reaching a $\bar{\nu}$ value of about 13, the binding isotherm is characterized by a sharp uprise. The precipitation (nearly 100%) is seen in the same manner as in a pure water system when $\bar{\nu}$ is also about 10. With an increase in $\bar{\nu}$ from 10 to 20, the amount of precipitate also goes down to zero. The region of the maximum precipitation is narrow, corresponding to the narrowness of the region where $\bar{\nu}=10$.

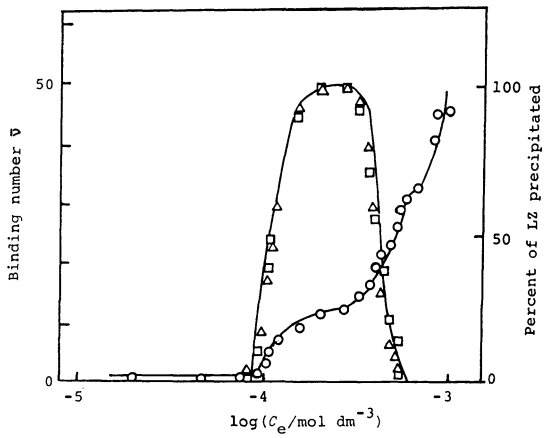

Fig. 2. The binding isotherm of SDS (○) and precipitation curve of lysozyme in NaCl solution (pH 5.8) at 25 °C. △: Lysozyme concentration 4.20×10^{-5} mol dm^{-3}, □: lysozyme concentration 2.56×10^{-5} mol dm^{-3}.

Figure 3 shows the binding isotherm and the precipitation curves in a borate buffer system, the pH and the ionic strength of which are 9.2 and 0.1 respectively. The binding isotherm shows a gradual rise in the range of 1×10^{-4}—1×10^{-3} mol dm^{-3} SDS up to the binding number of 35, and then it shows an abrupt increase up to 55, which seems to be followed by a levelling-off tendency near the CMC. Each precipitation curve has a maximum at $\bar{\nu}=9$. In this case, 100% precipitation does not occur, and the amount of the precipitate depends on the lysozyme concentration, unlike the case in Figs. 1 and 2.

The α-helix, β-structure, and random coil of proteins each have their own characteristic SDS spectra. The CD spectra of synthetic polypeptides are changed by various factors, such as the pH, the solvent, the temperature, and the addition of a surfactant, and have been used as the criteria of the α-helix, the β-structure, and the random coil.[12-15] However, the magnitudes of the CD spectra do vary among different helical, β-structured, and random-coiled polypeptides. In this work, we

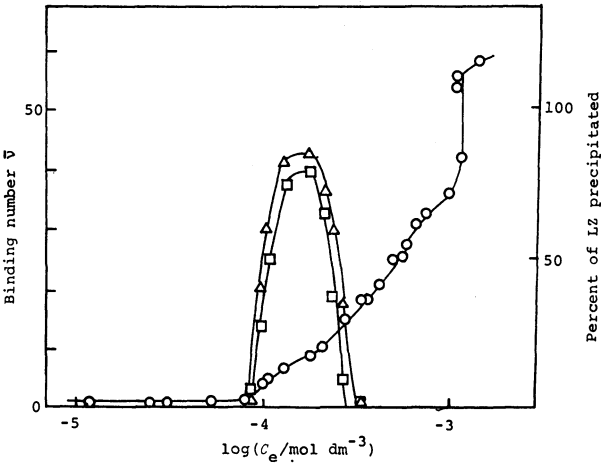

Fig. 3. The binding isotherm of SDS (○) and precipitation curves of lysozyme in borate-buffer solution (pH 9.2) at 25 °C. △: Lysozyme concentration 3.95×10^{-5} mol dm^{-3}, □: lysozyme concentration 2.70×10^{-5} mol dm^{-3}.

applied the criteria of the α-helix, the β-structure, and the random coil, which had been deduced from the CD spectra of 5 proteins (myoglobin, lysozyme, lactate dehydrogenase, papain, and ribonuclease) as analysed by means of X-rays.[16] The optical activity of the above three conformations is assumed to be additive and can be expressed as described below.

At any wavelength, λ,[16]

$$[\theta]_\lambda = f_H X_{H,\lambda} + f_B X_{B,\lambda} + f_R X_{R,\lambda}, \quad (2)$$

where $f_H+f_B+f_R=1$. $[\theta]$ is the mean residue ellipticity. The f is the fraction of each conformation in a protein molecule. The $X_{H,\lambda}$, $X_{B,\lambda}$, and $X_{R,\lambda}$ are the mean ellipticities for the helix (H), the β-structure (B), and the random coil (R) at a certain wavelength λ, respectively. The f_H, f_B, and f_R were determined by fitting the CD spectra of lysozyme to Eq. 2. The calculation by Eq. 2 was made by the least-squares method at 3 nm intervals from 240 to 200 nm. Figure 4a shows the typical CD spectra of lysozyme alone and those of lysozyme saturated with SDS in a pure-water system. The results calculated for lysozyme alone are consistent with those deduced from X-ray study.[5] In Fig. 5, we can see the correlation of the binding isotherm with the fraction of each conformation in the borate-buffer system. Below the concentration at which SDS binding begins to occur, none of the content of the conformations was affected by adding SDS. The dashed line shows the precipitation region where CD spectra can not be observed. The fractions of the α-helix and the β-structure change above the concentration where the redissolution of lysozyme takes place. With an increase in $\bar{\nu}$, the fraction of the α-helix increases, but that of the β-structure decreases. The fraction of the random coil is almost constant over the whole range of equilibrium concentrations of SDS. Similar results were also obtained in pure-water and NaCl-solution systems.

The typical near-ultraviolet CD spectra of lysozyme alone and that saturated with SDS in a pure-water system are shown in Fig. 4b. The change in the CD spectra in the near-ultraviolet region is more drastic than

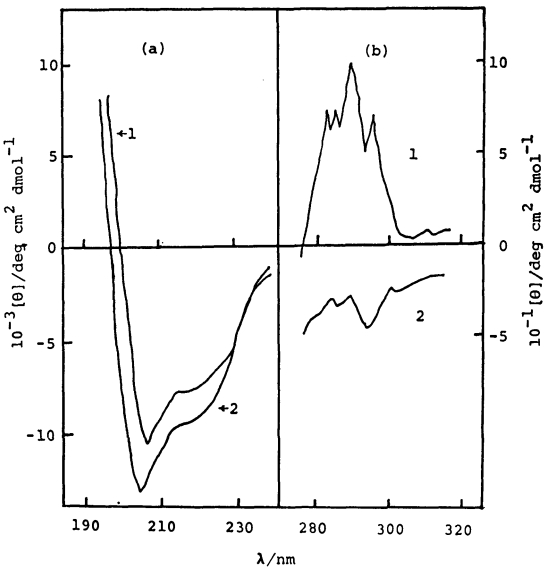

Fig. 4. The effect of the addition of SDS on CD spectrum of lysozyme (1) in pure water, (2) in SDS solution 1.03×10^{-2} mol dm^{-3}.

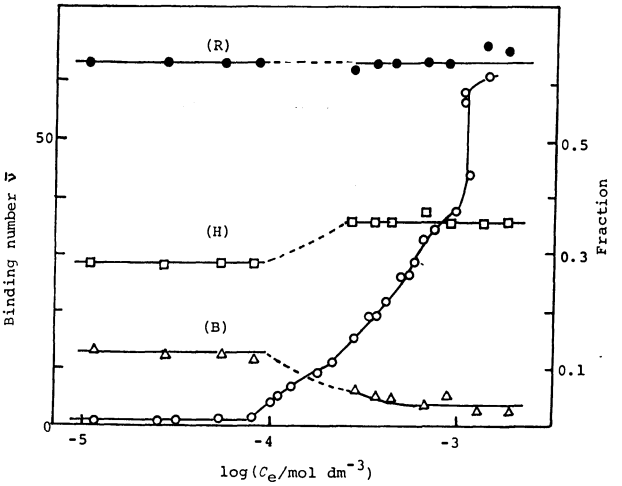

Fig. 5. The correlation of binding isotherm with the fraction of three conformations in borate-buffer solution. (H), (B), and (R) indicate the fractions of α-helix, β-structure, and random coil, respectively.

that in the far-ultraviolet region. Figure 6 shows the binding isotherm and the corresponding change in $[\theta]$ at 294 nm in a NaCl solution. The $[\theta]_{294}$ of the redissolved lysozyme solution is negative in contrast with that of a lysozyme solution without binding. In both pure-water and borate-buffer solutions, the corresponding plots showed the same tendency as that in a NaCl solution.

Discussion

The solubility of protein in an aqueous solution is on a critical balance between the net charge and the hydrophobicity. The net charge effect on the solubility of protein is typically demonstrated in the case of the precipitation at the isoelectric point. As is shown in Figs. 1—3, the binding number which gives the maximum

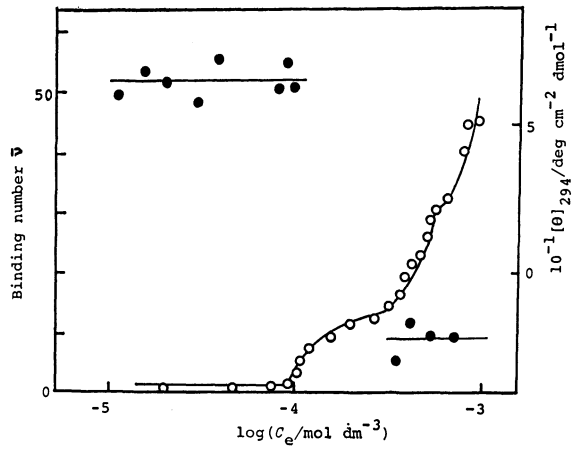

Fig. 6. The change of $[\theta]_{294}$ due to SDS binding in NaCl solution. (○): Binding isotherm, (●): $[\theta]_{294}$.

precipitation is about 10 in each case. If the change in the net charge of lysozyme caused by the binding of DS^- ion can be estimated, it must give a means of interpreting the precipitation.

The lysozyme molecule has ionizable residues (*i.e.*, 6 Lys's, 11 Arg's, and 1 His) as basic amino acid residues and 7 Asp's and 2 Glu's as acidic residues. At the pH's studied (pH 5.8 for pure water and a NaCl solution; pH 9.2 for a borate buffer solution), Lys and Arg are positively ionized, since their pK values on lysozyme are within the ranges of 10.3—10.6 and 12.7—13.3[17] respectively. This means that the lysozyme molecule has 17 positive charges. On the other hand, the negatively ionized residues are 7 Asp's and one Glu^7 in pure water and the NaCl solution system, since their pK values are within the ranges of 3.0—4.7 and 2.7—4.7[15] respectively. In the borate buffer solution of pH 9.2, Glu^{35}, whose pK is between 6 and 6.5,[17] is also ionized besides 7 Asp's and one Glu^7. Therefore, the value of the net charge of lysozyme is +9 in the solutions with and without NaCl (+17−8=+9) and +8 in the borate-buffer solution (+17−9=+8). The number of binding which gives the maximum precipitation seems to be consistent with the number of negative ions necessary to neutralize the net charge of lysozyme. Here, we have assumed that, in the competitive binding to lysozyme, the DS^- ion is much superior to its co-ion, Cl^-, because there exists a hydrophobic interaction between DS^- and lysozyme.

The binding of the DS^- ion introduces the hydrophobicity to the lysozyme (LZ) surface in addition to the neutralization of the positive charges, since DS^- consists of both ionic and hydrophobic parts. Once the DS^- ions have neutralized the net positive charge, the solubility of the LZ^+–DS^- complex will depend on the hydrophobicity of the complex itself. The number of DS^- neutralizing the net charge (+8) in a borate-buffer solution is smaller than those (+9) in pure water or a NaCl solution. Therefore, a number of DS^- ions necessary for the complete neutralization of lysozyme in the borate-buffer solution is one less than in pure water or the NaCl solution; *i.e.*, the surface of the LZ^+–DS^- complex with a zero net charge is less hydrophobic in the borate-buffer solution. This causes less precipitation than in pure water or the NaCl solution. On the other hand, Sophianopoulos and Van Holde have suggested that the lysozyme is in equilibrium with the dimer in alkaline pH.[18] If the dimerization was caused by the aggregation of the hydrophobic part of the lysozyme, the reduction of the hydrophobic area by dimerization would lead to the easy dissolution of lysozyme.

As is shown in Figs. 1—3, each isotherm has two or more steps. This means that there exist two or more kinds of mechanisms in the binding. It is well-known that the BET equation is applicable to the analysis of such a type of binding isotherm. According to Hill,[19] the statistical expression for the BET equation is given as:

$$\frac{\bar{N}}{M} = \frac{q_1\lambda}{(1-q_2\lambda+q_1\lambda)(1-q_2\lambda)}, \tag{3}$$

where $\bar{N}$ is the average number of molecules bound to protein; M, the number of sites; q_1, the partition function for the molecule in the first layer; q_2, the partition function for the molecule in the second and higher layers, and λ, the absolute activity of the free molecule in equilibrium with the bound molecule. Equation 3 is then rewritten as:

$$\frac{\bar{N}}{M} = \frac{KX}{(1-X+KX)(1-X)}, \tag{4}$$

where

$$K = q_1/q_2, \text{ and } X = q_2\lambda. \tag{5}$$

The chemical potential of SDS in solution, μ_{sol}, can be written, using the concentration, C, as:

$$\mu_{sol} = \mu^\ominus + kT\ln(C/\mathrm{CMC}), \tag{6}$$

where $\mu^\ominus$ is the chemical potential of SDS at CMC. From Eqs. 5 and 6, we obtain:

$$X = q_2 \exp(\mu^\ominus/kT) \times \frac{C}{\mathrm{CMC}}. \tag{7}$$

By analogy with the adsorption of vapor on an absorbent, we can consider that, as the SDS concentration increases, the amount of the binding species increases, especially on the hydrophobic surface of the lysozyme–DS complex, where the DS^- ion is concentrated. In a bulk solution, a subsequent increase in SDS causes micelle formation, and simultaneously the amount of DS^- per site, $\bar{N}/M$, rises abruptly. We assume that $\bar{N}/M \to \infty$ when $C \to$ CMC; thus, $\bar{N}/M \to \infty$ means that $X \to 1$, as is known from Eq. 4. Therefore, from Eqs. 6 and 7 we may obtain $q_2\exp(\mu^\ominus/kT)=1$, and then;

$$X = \frac{C}{\mathrm{CMC}}. \tag{8}$$

Using Eq. 8, Eq. 4 may be rewritten as follows:

$$\frac{C}{\bar{N}(\mathrm{CMC}-C)} = \frac{1}{MK} + \frac{K-1}{MK} \times \frac{C}{\mathrm{CMC}}. \tag{9}$$

Thus, if the BET equation reproduces the data, the plot of $C/\bar{N}(\mathrm{CMC}-C)$ against C/CMC will be linear, while M and K may be obtained from the slope and the intercept of the line. The plots of $C/\bar{N}(\mathrm{CMC}-C)$ against C/CMC for the pure-water, NaCl, and borate-buffer solution systems are given in Fig. 7. The slopes and the intercepts give values of $M=18$ and $K=10$

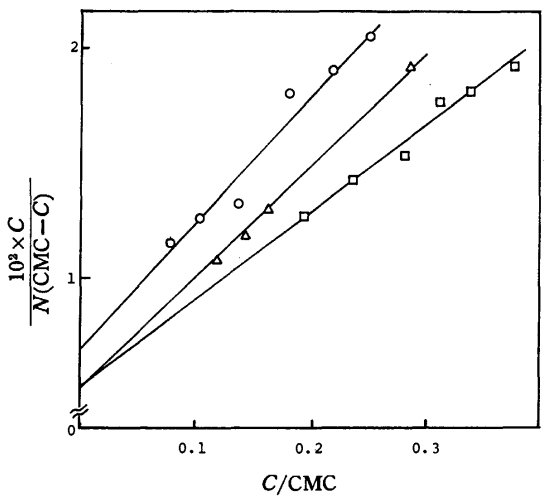

Fig. 7. BET plots for SDS binding on lysozyme in pure water (△), NaCl solution (○), and borate-buffer solution (□).

for the pure-water system, $M=16$ and $K=9$ for the NaCl-solution system, and $M=21$ and $K=11$ for the borate-buffer solution system. According to the BET theory, M is the number of sites, *i.e.*, the number of molecules forming the first layer. As has been mentioned above, the number of positively charged residues of lysozyme is 17 in the pH range studied. The values of M for both the pure-water and NaCl-solution systems are in fair agreement with the number of positively charged residues, but the value of $M=21$ for the borate-buffer system is somewhat large. This aspect of the borate-buffer system is attributable to the dimerization of lysozyme in an alkaline pH.[18]

Recalling that the precipitation is interpreted in terms of the neutralization of the net charge, and that the site number corresponds to the number of positively charged residues, the driving force for the binding of SDS to the first layer may be mainly attributed to the electrostatic interaction with the positively charged residues of lysozyme. The hydrocarbon tail of DS^- of the first layer can be expected to interact with the hydrophobic portion of the lysozyme surface, in addition to the ion-pairing of the head with the positively charged residue of lysozyme. Consideration by photo of the space-filling molecular models of lysozyme and SDS leads us to consider that the surface of lysozyme can be roughly covered with 17 DS^- ions, corresponding to the site number of the first layer, if they lay on lysozyme. This implies that mutual hydrophobic interaction between DS^-'s can be expected for the subsequent binding over the first layer. The subsequent binding is reflected in the sharp uprise of the binding isotherms. This mechanism is supported by the fact that the equilibrium SDS concentration at which the binding isotherms rise sharply is lower in NaCl and borate-buffer solution than in the pure-water solution, as in the case of the salt effect on the micelle formation.

The change in the secondary structure of lysozyme is caused by binding above an SDS concentration where the binding of SDS to the second layer begins to occur in each case. With an increase in the binding number, the helical content increases, but the β-structure decreases; later both reach constant values. An increase in the helical content of lysozyme in an aqueous solution containing more than 60% (v/v) of ethanol, methanol, and 2-propanol has been reported by Ikeda and Hamaguchi.[20] The increase in the helical content with the binding of SDS may be related to their finding that a development of the hydrophobic environment enhances the helical conformation. The tendency for the fraction of each conformation to reach a constant value indicates that the environment of lysozyme is no longer changed above a certain limit of the binding number of SDS, at which the surface of lysozyme is completely covered.

Taking into account the constant fraction of the random coil, it seems that the β-helix transition is induced partly by binding ($\bar{\nu}>10$). Hayakawa *et al.* have reported the β-helix transition of poly (L-lysine) upon the addition of sodium 1-octanesulfonate.[21] With respect to the surfactant-concentration dependence of the secondary structure, the renin substrate has been investigated by Yang and Wu.[22] At a low SDS concentration, the renin substrate shows the characteristic CD spectrum of β-structure, but at a high SDS concentration it shows the characteristic CD spectrum of the α-helix with double minima. These results surpport the idea that the β-structure of lysozyme changes to the α-helix above a certain SDS concentration.

The CD bands in the region between 275 and 300 nm originate in Trp and Tyr. The drastic change from the positive CD spectrum to the negative one upon binding, as is shown in Fig. 4b, means that the environment of these residues is largely altered.

Ikeda and Hamaguchi have demonstrated that the positive CD spectrum of lysozyme in the range from 275 to 300 nm is enhanced by the addition of alcohols (methanol, ethanol, and 2-propanol), but in a concentration of alcohols above 60% (v/v) it begins to decrease, finally becoming a negative CD spectrum. A similar decreasing tendency of the CD spectrum of lysozyme has been observed in the case of the oxidation of Trp's by *N*-bromosuccinimide.[20] These findings mean that Trp gives a clue to the CD spectrum in the range from 275 to 300 nm. The effect of the polarity of a solvent on the CD spectrum of amino-acid derivatives has been examined by Shiraki.[23] He showed that the positive CD spectrum of *N*-acetyltryptophan amide in water changed to a negative one in dioxane, and so he suggested that the sign of the CD spectrum of Trp residues in protein may be changed by the change in their surroundings. It seems reasonable that the reduction of the positive CD spectrum of lysozyme is attributable to the enhancement of the hydrophobic nature of surroundings of Trp on the binding SDS. Thus, the idea that lysozyme is covered with DS^- ions clustering like a micelle can explain the present CD spectrum obtained experimentally.

The present work has been performed within a research program sponsored by The Institute for Advanced Research, Fukuoka University. The authors are grateful to Professor Keishiro Shirahama, Saga

Univ., Professor Iwao Satake, Kagoshima Univ., and Professor Eiji Kimoto, Fukuoka Univ., for encouragement and help.

Dissociation of Micelles and Intermicellar Concentrations of Aqueous Solutions of Calcium and Sodium Decyl Sulfates

Masakatsu KOSHINUMA

Laboratory of Chemistry, Faculty of Education, Chiba University, Chiba 260

(Received January 26, 1981)

Activities of the surfactant ions and the counterions were calculated from the electromotive forces of concentration cell with ion-exchange membranes for the aqueous solutions of calcium ($Ca(DeS)_2$) and sodium (NaDeS) decyl sulfates. Moreover, the mean activities and the activity coefficients were obtained. From these activities, the valence effects of the counterions on the dissolved state of micellar solutions were studied. The following results were obtained: (1) The mean activities were not constant, but increased with the increase in the concentration of the two surfactants above the CMC; the slope of curve of the mean activity for $Ca(DeS)_2$ against its concentration was smaller than that for NaDeS. (2) The CMCs were 6.4 for $Ca(DeS)_2$ and 32.8 mmol dm^{-3} for NaDeS, respectively. (3) For the mechanism of micelle formation, the phase separation model was set up in both cases. (4) From this model, the degrees of dissociation of the micelles were calculated as 0.12 for $Ca(DeS)_2$ and 0.28 for NaDeS, respectively. (5) The intermicellar concentrations of the Ca^{2+}, the Na^+, and the decyl sulfate (DeS^-) ions were calculated; those of the counterions increased but those of the DeS^- ions decreased with the increase in their surfactant concentrations. Moreover, those of the DeS^- for $Ca(DeS)_2$ changed slowly while those for NaDeS changed steeply.

The dissolved state properties of surfactant solutions, *e.g.* the dissociation of micelles, a critical micellar concentration (CMC), effects of addition of electrolytes on the CMC and dissociation, theories and mechanisms of micelle formation, have been studied by many investigators in terms of surfactant concentrations but in disregard of the activity coefficients.[1] Taking surface energy of micelles into account, Hall and Pethica have proposed recently a detailed theory of micelle formation.[2] But on the other hand, from an experimental point of view, the activities of the surfactant ion and the counterion, being in equilibrium with the micelle, are necessary to investigate the dissolved state of micellar solution. This is because the micellar properties and validity of these theories can not be discussed without any assumption until the activities are obtained. Recently, correct measurements of activity for ionic surfactants by use of solid[3–6] or liquid[7–11] ion-exchange membranes have been reported. From these results for sodium alkyl sulfates, the following new knowledge has been obtained.[4–6] With an increase in the surfactant concentration, (1) the mean activity and the mean intermicellar concentration of the surfactant above the CMC increased; (2) the activity of the surfactant ion decreased, (3) while that of the counterion increased. (4) The activity of the surfactant ion above the CMC was approaching a constant when much more electrolyte was added into the surfactant solution.[10] (5) Depression of the surface tension above the CMC could be explained by the change of the mean activity.[4,5]

It has been well known that the bivalent-metal ions affected the dissolved state of a micellar solution. Some reports on the activities for monovalent-metal alkyl sulfates are available, but those for bivalent- and polyvalent-metal alkyl sulfates are few.[11] In the present paper, effects of valence in the counterions on the dissolved state are studied on the basis of the activities which are calculated from the membrane potentials developed across the ion-exchange membranes. Among these effects, we discuss the dissociation of micelles, the mechanism of micelle formation, and the intermicellar concentrations in the aqueous solutions of calcium ($Ca(DeS)_2$) and sodium (NaDeS) decyl sulfates.

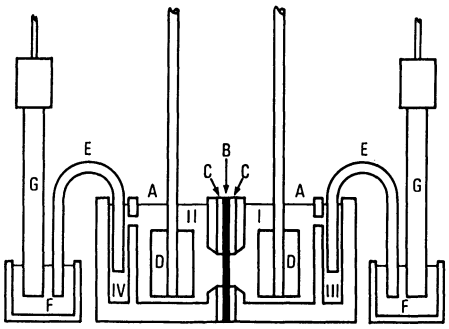

Fig. 1. Apparatus of surfactant concentration cell. A: Cell and solutions; (I) standard solution, (II), sample solution, and (III), (IV), compartments of bridge inserted. B: Anion or cation-exchange membrane. C: Silicon rubber washer. D: Stirrer. E: Agar bridge (2 M NH_4NO_3, 2% agar). F: Saturated KCl solution. G: Reference electrode.

Experimental

In order to obtain good stability and reproducibility in the measurement of electromotive force (EMF), the cell shown in Fig. 1 was used. The cell consisted of four compartments. A standard solution was poured into I and a sample solution into II. The compartments III and IV were connected to them through small holes to avoid any contamination of KCl by agar bridges into it, because EMF was greatly affected by such contamination. The solutions in I and II were gently stirred by means of stirrers, D, rotating at a constant velocity (130 rmp). The EMF developed across a solid ion-exchange membrane, B, was measured at 30 ± 1 °C by means of an electrometer (Keithley, model 610C) through agar bridges (2 M NH_4NO_3, 2%-agar), E, and reference electrodes (Orion, model 90-01), G, and was recorded with time. The EMF was determined as an extraporated value at the time zero since it changed during the first 5 min and then decreased very slowly with time after it had passed a flat region. The solutions of 5.0 and 1.0 mmol dm^{-3} for $Ca(DeS)_2$, and 10.0 and 2.0 mmol

dm^{-3} for NaDeS were used as the standard solutions. Other experimental conditions and procedures were the same as in a previous paper.[5]

Results and Discussion

Single Ionic Activities and Mean Activities. The EMFs developing in the concentration cell of surfactant solution were measured for the two surfactants. The experimental values of the Ca^{2+} ion, E_{Ca}, and of the decyl sulfate (DeS^-) ion, E_{DeS}, are plotted against the concentration of $Ca(DeS)_2$ in Fig. 2 and those of the Na^+ ion, E_{Na}, and of the DeS^- ion, E_{DeS}, against the concentration of NaDeS in Fig. 3. According to Nernst's equation, the single ionic activities are given by

$$\left.\begin{aligned} E_{Ca} &= -(2.303RT/2F)\log(a_{Ca}/a_{OCa}) \\ E_{Na} &= -(2.303RT/F)\log(a_{Na}/a_{ONa}) \\ E_{DeS} &= (2.303RT/F)\log(a_{DeS}/a_{ODeS}), \end{aligned}\right\} \quad (1)$$

where R, T, and F are the gas constant, the absolute temperature, and the Faraday constant, respectively. The activities of the Ca^{2+}, the Na^+, and the DeS^- ions in the sample solutions are represented as a_{Ca}, a_{Na}, and a_{DeS}; those of the corresponding ions in the standard solutions as a_{OCa}, a_{ONa}, and a_{ODeS}. Their values, which were determined in the same way as in the previous paper,[5,6] are listed in Table 1. The activities of the individual ions for $Ca(DeS)_2$, having been calculated by Eq. 1, are shown in Fig. 4 and for NaDeS in Fig. 5. All the activities increased linearly with the increase in the surfactant concentration up to the CMC; after that concentration, those of the DeS^- ions in the two surfactant solutions decreased, while those of the Ca^{2+} and the Na^+ ions increased monotonously. It is also notable that the changes of activity of the Ca^{2+} and the DeS^- ions with the concentration of $Ca(DeS)_2$ are smaller than those of the Na^+ and the DeS^- ions of NaDeS. This finding comes mainly from the difference in the valence between the counterions and will be discussed later in connection with the dissociation of micelle and the intermicellar concentration. The mean activities calculated from the single ionic activities according to the usual definition are shown in Fig. 6; the values of the CMC, which were determined from the breaking points in their curves, are listed in Table 2 and agreed with those reported in the literature.[11,12] Below the CMC, the slope of the curve (mean activity coefficient) for $Ca(DeS)_2$ was smaller than that of NaDeS. This result can be explained by the difference

a) The value was obtained as an extrapolated one by means of the reference(Y. Moroi, K. Motomura, and R. Matuura, *J. Colloid Interface Sci.*, **46**, 111 (1974).), when $K_g=0.95$ and $\sigma=8.64\times10^4$ were used. b) Cobalt dodecyl sulfate.

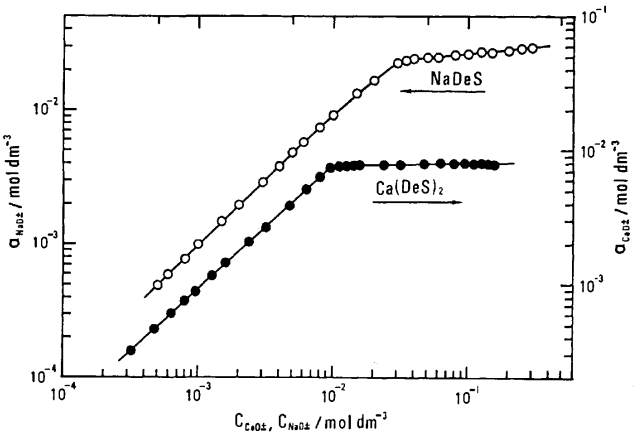

Fig. 6. Mean activities of $Ca(DeS)_2$ and NaDeS against their mean concentrations.

in the valence of the counterions, like that considered in simple electrolytes. In spite of the decrease in the activities of the DeS^- ion above the CMC (shown in Figs. 4 and 5), the mean activities of $Ca(DeS)_2$ and NaDeS did not remain constant, but increased gradually with the increase in their concentrations owing to a large increase in the activities of the corresponding counterions compensating completely for the decrease in the activities of the DeS^- ions. Figure 6 and K in Table 1, which will be defined by Eq. 2, show clearly that the mean activity of NaDeS above the CMC changes with the concentrations steeper than that of $Ca(DeS)_2$, but the activity of the DeS^- ion decreases slowly in comparison with that of NaDeS (Fig. 4). This is because the increase in the activity of the Na^+ ion was much larger than that in the activity of the Ca^{2+} ion. The mean activity coefficients of these surfactants within the concentration ranges illustrated are given by the following formula,[4-6] except for that of NaDeS below the CMC:

$$\log f_\pm = -(K\log C_\pm + L), \qquad (2)$$

where $f_\pm$ and $C_\pm$ denote the mean activity coefficient and the mean concentration of the surfactant, respectively. The constants of K and L are tabulated in Table 1. The activity coefficient of NaDeS solution below its CMC is expressed empirically and satisfactorily by

$$\log f_\pm = -(K\log C_\pm + L) - MC_\pm^2, \qquad (3)$$

where M is a constant and also shown in Table 1.

Formation and Dissociation of Micelles. Various mechanisms of micelle formation have been proposed, but little satisfactory experimental investigation has yet been reported. Recently the mechanism and the dissociation of micelles have been discussed by use of the activity only on 1-1 electrolytic surfactants, such as sodium dodecyl sulfate[4] or sodium tetradecyl sulfate.[5,6] But they should be also focussed on the micelles of 2-1 electrolytic surfactants such as $Ca(DeS)_2$ in connection with the valence effect of counterions. If a micelle of $Ca(DeS)_2$ is composed of $p$$DeS^-$ ions and $q$$Ca^{2+}$ ions which are always in equilibrium with the micelle, the micelle formation is expressed by

$$p\mathrm{DeS}^- + q\mathrm{Ca}^{2+} \rightleftarrows \mathrm{Ca}_q\mathrm{DeS}_p^{-(p-2q)}.$$

According to the mass action theory,[13-15]

$$a_M/(a_{DeS}{}^p\cdot a_{Ca}{}^q) = \text{const}$$

holds, where a_M denotes the activity of micelle. Then,

$$p\log a_{DeS} + q\log a_{Ca} \neq \text{const} \qquad (4)$$

is obtained. On the other hand, according to the phase separation theory,[15-17] in which a_M is assumed to be constant, the micelle formation is expressed by

$$a_{DeS}{}^p\cdot a_{Ca}{}^q = K_{CaD},$$

therefore, $$p\log a_{DeS} + q\log a_{Ca} = K_{CaD} \qquad (5)$$

holds, where K_{CaD} is a constant. We can test which mechanism of the two is applicable, by plotting $\log a_{DeS}$ against $\log a_{Ca}$. Figure 7 shows two linear relationships for $Ca(DeS)_2$ and NaDeS. Therefore, the phase separation theory is also a more probable mechanism for the micelle formation of $Ca(DeS)_2$, as in the cases of 1-1 electrolytic surfactants.[4-6] The degrees of counterion attachment, $r=-q/p$, for $Ca(DeS)_2$(r_{Ca}) and NaDeS (r_{Na}) were obtained from each slope of the straight lines, and the constants were also calculated independl-

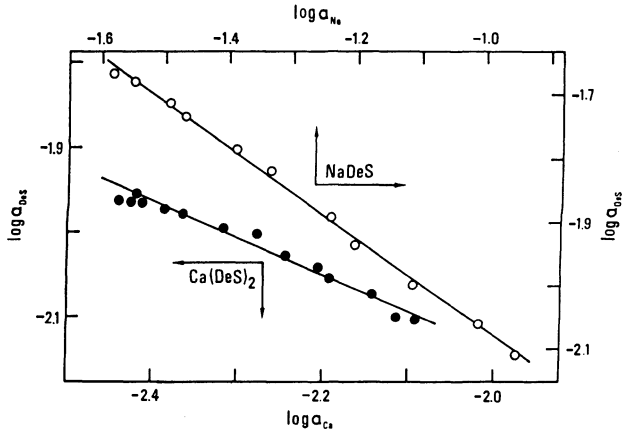

Fig. 7. Curves of log a_{Ca} and log a_{Na} against log a_{DeS} above their CMCs.

ently. The degrees of dissociation of micelles, therefore, are given as $1-2r_{Ca}$ and $1-r_{Na}$. Table 2 shows these values together with those reported.[10-12,18] It is found that the dissociation of $Ca(DeS)_2$ micelles was less than a half of that of NaDeS micelles. This finding can be explained by the idea that the Ca^{2+} ions remain rather near the surface of micelles because of the stronger coulombic interaction of the Ca^{2+} ion than that of the Na^+ ion; as the result of this, the micelle has a smaller dissociation. The observed degree of dissociation of $Ca(DeS)_2$ micelle can not be compared with ones reported in the literature, because there were few found. But the value, being slightly larger than that of bivalent-metal dodecyl sulfate as shown in Table 2, seems reasonable, because the shielding effect resulting from the high intermicellar concentration of $Ca(DeS)_2$ must lessen the counterion binding. The values for the NaDeS micelle in Table 2 scatter, but this discrepancy comes from the differences in the methods of measurement and in the assumptions made in the calculation. The value in the present study is reliable since it is almost free from assumption or approximations.

The smaller increase in the activity of the Ca^{2+} ion than in the Na^+ ion with the increasing concentrations of their surfactants above the CMCs observed already in Figs. 4 and 5 can be directly ascribed to the smaller degree of dissociation of the $Ca(DeS)_2$ micelle; in other words, the activity of Ca^{2+} ion varies with the increase in the intermicellar concentration of the Ca^{2+} ion which will be calculated later. Moreover, the mean activity of $Ca(DeS)_2$ is given by

$$a_{CaD\pm} = (a_{DeS}{}^2 \cdot a_{Ca})^{1/3} \tag{6}$$

according to the definition. If Eq. 5 is introduced into Eq. 6,

$$a_{CaD\pm} = (K_{CaD})^{2/3} \cdot a_{Ca}{}^{(1-2r_{Ca})/3} \tag{7}$$

is obtained. For NaDeS,

$$a_{NaD\pm} = (K_{NaD})^{1/2} \cdot a_{Na}{}^{(1-r_{Na})/2}, \tag{8}$$

where $a_{CaD\pm}$ and $a_{NaD\pm}$ denote the mean activities of $Ca(DeS)_2$ and NaDeS, respectively. The slope of the curves of mean activity are also given by

$$\left.\begin{aligned} \mathrm{d}\ln a_{CaD\pm}/\mathrm{d}\ln C_\pm &= [(1-2r_{Ca})/3]\cdot \mathrm{d}\ln a_{Ca}/\mathrm{d}\ln C_\pm, \\ \mathrm{d}\ln a_{NaD\pm}/\mathrm{d}\ln C_\pm &= [(1-r_{Na})/2]\cdot \mathrm{d}\ln a_{Na}/\mathrm{d}\ln C_\pm \end{aligned}\right\} \tag{9}$$

which are equal to the osmotic coefficients of their solutions.[4] As a_{Ca} and a_{Na} (shown in Figs. 4 and 5) increase, the gradual increases in their mean activities with the increasing concentration of their surfactants in Fig. 6 can be explained by Eqs. 7 and 8. Their increments are mainly restricted by the terms of $(1-2r_{Ca})/3$ and $(1-r_{Na})/2$ in Eq. 9. Therefore, the increment of $a_{CaD\pm}$ becomes smaller than that of $a_{NaD\pm}$. The osmotic coefficient of $Ca(DeS)_2$ was 0.03 and that of NaDeS was 0.10, which almost agreed with 0.07 of sodium dodecyl sulfate.[4]

Calculation of the Intermicellar Concentrations. From the definition, a_{Ca} and a_{DeS} above the CMC are expressed

$$a_{Ca} = f_{Ca} \cdot C_{Ca} \text{ and } a_{DeS} = f_{DeS} \cdot C_{DeS} \tag{10}$$

where f_{Ca}, f_{DeS}, C_{Ca}, and C_{DeS} are the activity coefficients and the intermicellar concentrations of Ca^{2+} and DeS^- ions, respectively. According to Eq. 6,

$$a_{CaD\pm} = f_{CaD\pm} \cdot C_{CaD\pm} \tag{11}$$

holds, where

$$f_{CaD\pm} = (f_{Ca} \cdot f_{DeS}{}^2)^{1/3} \tag{12}$$

and

$$C_{CaD\pm} = (C_{Ca} \cdot C_{DeS}{}^2)^{1/3} \tag{13}$$

are the mean activity coefficient and the mean intermicellar concentration, respectively. If micelles have no effect upon the relation between the mean activity and the mean intermicellar concentration, namely if the

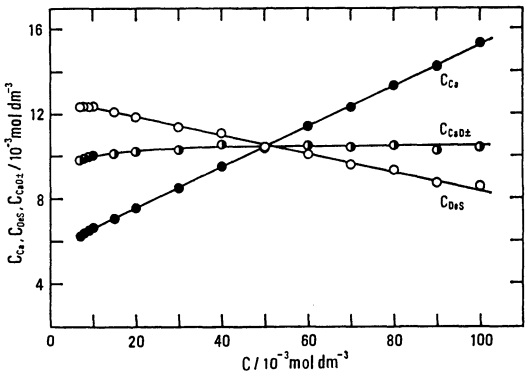

Fig. 8. Intermicellar concentrations of the Ca^{2+} and the DeS^- ions and intermicellar mean concentration against concentration of $Ca(DeS)_2$.

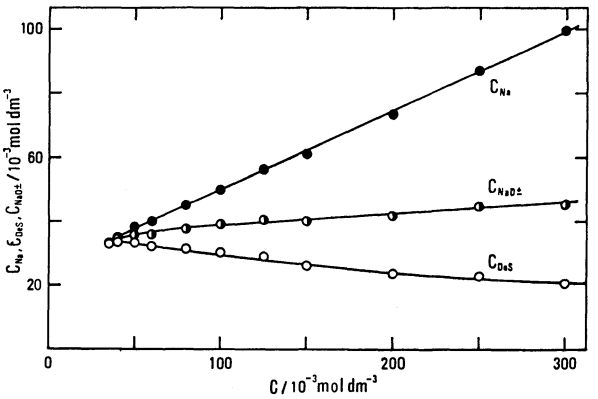

Fig. 9. Intermicellar concentrations of the Na^+ and the DeS^- ions and intermicellar mean concentration against concentration of NaDeS.

The values were calculated by use of $K=0.301$ and $L=0.591$ in Eq. 2 which was set up satisfactorily within the range of concentration from 10.0 to 30.0 mmol dm^{-3} in stead of Eq. 3.

mean activity coefficient shows the same behavior as just below the CMC, then Eq. 2 holds above the CMC. Moreover, the conditions of electrical neutrality hold

$$C_{Ca} = [(2C - C_{DeS})(1 - 2r_{Ca}) + C_{DeS}]/2, \quad (14)$$

where C is the concentration of $Ca(DeS)_2$. Substituting Eqs. 2, 6, 11, 12, and 13 into Eq. 14 yields

$$r_{Ca}C_{DeS}^3 + (1 - 2r_{Ca})C \cdot C_{DeS}^2 - 1000^{(L+\log a_{CaD_\pm})/(1-K)} = 0. \quad (15)$$

As a solution of Eq. 15, C_{DeS} is obtained, and then C_{Ca} is found by substituting C_{DeS} into Eq. 14. With respect to NaDeS, the intermicellar concentrations are given in a manner similar to that of $Ca(DeS)_2$.[4,6]

$$\left.\begin{aligned} C_{DeS} &= -(1 - r_{Na})(C/2r_{Na}) + (1/2r_{Na}) \\ &\quad \times [(1 - r_{Na})^2 \cdot C^2 + 4r_{Na}C_{NaD_\pm}^2]^{1/2} \\ C_{Na} &= -(1 - r_{Na})(C/2) - (1/2) \\ &\quad \times [(1 - r_{Na})^2 \cdot C^2 + 4r_{Na}C_{NaD_\pm}^2]^{1/2} \\ C_{NaD_\pm} &= 100^{(L+\log a_{NaD_\pm})/(1-K)} \end{aligned}\right\} \quad (16)$$

Figures 8 and 9 show the calculated results, which are essentially similar in the two surfactants: namely, the intermicellar mean concentrations and the intermicellar concentrations of counterions increase, while those of the DeS^- ion decrease monotonously. But the increment and the decrement of $Ca(DeS)_2$ with the increasing concentration are smaller than those of NaDeS.

A Conductance Study of Alkali Metal Ion-18-Crown-6 Complexes in *N,N*-Dimethylformamide

Yasuyuki TAKEDA

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received February 5, 1981)

The formation constants, K_{ML}^+, for 1 : 1 complexes of 18-crown-6 (18C6) with alkali metal ions (Na^+, K^+, Rb^+, and Cs^+) and the limiting ionic molar conductivities, λ°, of the complexed cations in *N,N*-dimethylformamide have been determined conductometrically at 25 °C. The K_{ML}^+ sequences of the alkali metal ions with 18C6 are $K^+ > Rb^+ > Cs^+ > Na^+$. The stabilities and selectivities on complexation are governed by the solvent medium and the relative sizes of the cation and the 18C6 cavity. The λ° values of the 18C6 complexes with the alkali metal ions are all approximately equal except for Cs^+, suggesting that, in the cases of Na^+, K^+, and Rb^+, the charge of the alkali metal ion trapped in the 18C6 cavity is effectively screened by 18C6, while this is not true in the case of Cs^+. The ratio of the size of the alkali metal ion to that of the 18C6 cavity appears to be an important factor in determining the magnitude of λ° for alkali metal ion–18C6 complexes.

Complexation reactions of 18-crown-6 (18C6) with alkali metal ions in various solvents have been investigated from the thermodynamic point of view by several different methods, *e.g.* conductance,[1,2] calorimetry,[3,4] potentiometry,[5,6] and spectroscopy.[7,8] The stabilities and selectivities on complexation are governed by the solvent medium and the relative sizes of the cation and the 18C6 cavity.

In the present study, the formation constants for 1 : 1 complexes of 18C6 with alkali metal ions and the limiting ionic molar conductivities of the alkali metal ion–18C6 complexes in *N,N*-dimethylformamide (DMF) have been determined conductometrically at 25 °C; the complex-formation constants have been compared with those in other solvents in order to clarify the factors influencing the magnitude of the complex-formation constant; on the basis of the data for the limiting ionic molar conductivities of the alkali metal ion–18C6 complexes, the behavior of the complexes in DMF has been discussed.

Experimental

Materials. 18C6 (Nisso Co., Ltd.) was recrystallized from acetonitrile and, prior to use, dried at 70 °C in a vacuum oven. The rubidium and caesium perchlorates were prepared by adding an equimolar perchloric acid solution to aqueous solutions of rubidium and caesium chlorides respectively. The lithium, sodium, and potassium perchlorates were purchased commercially. All the perchlorates were recrystallized from water four times and, prior to use, dried at 150 °C in a vacuum oven. The DMF was distilled twice under nitrogen at approx. 12 mmHg.† The middle 70% of the distillate was used. The water content of the finally purified DMF, as determined by Karl Fischer titration, was less than 0.01%. The conductivity of the final product was less than 1×10^{-7} Ω^{-1} cm^{-1}.

Apparatus and Procedure. The conductance measurements were conducted on a Yanagimoto conductivity apparatus, model MY-7, in a water bath thermostated at 25.00± 0.01 °C. Three cells were used with cell constants of 0.05971, 0.09393, and 0.09776 cm^{-1}.

The experimental procedure to obtain the formation constants and the limiting ionic molar conductivities of 18C6 complexes with alkali metal ions was just the same as that described in a previous paper.[2]

† 1 mmHg≈133.322 Pa.

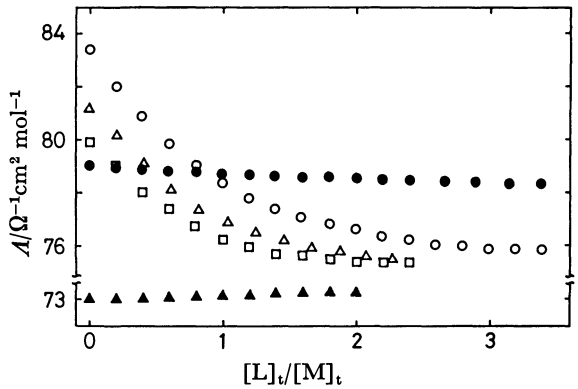

Fig. 1. Λ *vs.* $[L]_t/[M]_t$ curves for 18C6–alkali metal perchlorate systems in DMF at 25 °C.
▲: Li^+, ●: Na^+, □: K^+, △: Rb^+, ○: Cs^+, $[M]_t=5\times10^{-4}$ M.

Results

The molar conductivity, Λ, *vs.* $[L]_t/[M]_t$ plots in DMF at 25 °C are given in Fig. 1, where $[L]_t$ and $[M]_t$ are the total concentrations of 18C6 and the alkali metal ion respectively. The Λ *vs.* $[L]_t/[M]_t$ plots show a decrease in Λ with an increase in the 18C6 concentration, except for Li^+. In the case of Li^+, a very small increase in Λ is found with an increase in the 18C6 concentration. However, since the change in Λ is very small, the conductometric determination of the complex formation constant is impossible. It is assumed that the association between the cation and the perchlorate ion in DMF is negligible under these highly dilute experimental conditions and that, in this work, 18C6 forms the 1 : 1 complexes with the alkali metal ions in DMF. Since the 18C6 concentration was kept low ($<2.0\times10^{-3}$ M; 1 M=1 mol dm^{-3}) during these experiments, corrections for viscosity changes were neglected. The procedure for obtaining the complex-formation constant, K_{ML}^+, and the limiting ionic molar conductivity, λ°, of the alkali metal ion-18C6 complex was just the same as that described in a previous paper.[2] M^+ and L denote the alkali metal ion and 18C6 respectively. The log K_{ML}^+ and the λ° values of the alkali metal ion–18C6 complexes are listed in Tables 1 and 2, together

Discussion

As can be seen from Table 1, in the case of each crown ether-solvent system, except for Na^+, the more closely the alkali metal ion fits into the crown ether cavity (18C6 cavity radius: 1.3—1.6 Å[9]), the more stable is the alkali metal ion–crown ether complex. Of all the alkali metal ion–18C6 complexes in the same solvent, the log K_{ML}^+ value of the Na^+–18C6 complex is the second largest for acetonitrile (AN) and propylene carbonate (PC); however, it is the smallest for H_2O, CH_3OH, DMF, and DMSO. The log K_{ML}^+ value of the Na^+–dibenzo-18-crown-6 (DB18C6) complex is the largest for AN and PC, and the second largest for H_2O, CH_3OH, DMF, and DMSO. The difference in the log K_{ML}^+ values of Na^+ and K^+ with 18C6 about the same solvent is larger for H_2O, CH_3OH, DMF, and DMSO than for AN and PC. The difference in the log K_{ML}^+ values of Na^+ and Rb^+ with DB18C6 in relation to the same solvent is larger for AN and PC than for H_2O, CH_3OH, DMF, and DMSO; the same tendency is observed for the Na^+ and Cs^+ with the DB18C6 system. A possible interpretation for this is that, in every one of these solvents, Na^+ is the most strongly solvated of all the alkali metal ions (Na^+, K^+, Rb^+, and Cs^+), and that the differences in the free energies of the solvation of Na^+ and K^+, Na^+ and Rb^+, and Na^+ and Cs^+ are much smaller for AN and PC than for the others.[5]

The strength of the interaction of the alkali metal ion with the donor oxygen atoms of the crown ether is due to the basicity of the donor oxygen atoms. Since the aromatic ether oxygen atom is less basic than the aliphatic one, and since DB18C6 has four aromatic ether oxygen atoms, the stability of the DB18C6 complex with the same alkali metal ion may be lower than that of the 18C6 complex. For the same solvent, the log K_{ML}^+ value of the DB18C6 complex with the same alkali metal ion is smaller than that of the 18C6 complex except in the case of Na^+, which is consistent with this expectation; however, the log K_{ML}^+ value of the Na^+–DB18C6 complex is large for AN, H_2O, and DMSO, and nearly identical for PC, CH_3OH, and DMF, compared with 18C6 (Table 1). This result is unexpected. Because the charge density of Na^+ is the largest of all the alkali metal ions (Na^+, K^+, Rb^+, and Cs^+), Na^+ may attract the donor oxygen atoms of the crown ether much more strongly than the others. Thus, when a complexation reaction occurs between a flexible crown ether and the alkali metal ion, the greatest ligand-ring conformational change may be observed in the case of Na^+. Consequently, since 18C6 is more flexible than DB18C6, the 18C6 complex with Na^+ may be entropy destabilized much more than the DB18C6 complex, resulting in the small or nearly the same log K_{ML}^+ value of the Na^+–18C6 complex compared with DB18C6. This explanation may be supported by the following data. The values of the enthalpy (ΔH/kJ mol^{-1}) and entropy changes (ΔS/J K^{-1} mol^{-1}) in methanol are −35.0 and −34 for the Na^+–18C6 system,[4] −31.3 and −18.8 for the Na^+–DB18C6 system,[10] −56.13 and −72.4 for the K^+–18C6 system,[4] and −40.1 and −36.7 for the K^+–DB18C6 system[10] respectively. The reason why, in each case of Na^+ and K^+, the $-\Delta H$ value of DB18C6 is small and the $-\Delta S$ value of DB18C6 is very small compared with 18C6 may be largely due to the four aromatic ether oxygen atoms and the more rigid structure of DB18C6 respectively. Compared to DB18C6, the greater stability of the K^+–18C6 complex entirely depends on the much larger $-\Delta H$ value of the K^+–18C6 complex. However, in the case of Na^+, compared to DB18C6, the larger $-\Delta H$ value of 18C6 is greatly canceled by the much more unfavorable ΔS value of 18C6, resulting in the smaller log K_{ML}^+ value of 18C6. For H_2O, CH_3OH, DMF, and DMSO, the log K_{ML}^+ value of Na^+ with DB18C6 is the second largest; however, that with 18C6 is the smallest of all the alkali metal ions. Similarly, for AN and PC, that with DB18C6 is the largest; however, that with 18C6 is the second largest (Table 1). This may indicate that, from DB18C6 to 18C6, the Na^+ complex is much more entropy destabilized than the other alkali metal ion complexes because the structure of 18C6 is more flexible than that of DB18C6.

The solvation power sequences of the solvents for the same alkali metal ion are as follows:

Na^+: PC<AN<CH_3OH<H_2O<DMF<DMSO,

K^+: CH_3OH<PC<AN<H_2O<DMF<DMSO,

Rb^+: CH_3OH<PC<AN<H_2O<DMF<DMSO,

Cs^+: $CH_3OH < PC < AN < H_2O < DMF < DMSO$.[5]

The solvation power sequences of the aprotic solvents for the same alkali metal ion are PC<AN≪DMF<DMSO,[5] while, for both 18C6 and DB18C6, the log $K_{ML}{}^+$ value sequences of the aprotic solvents about the same alkali metal ion are completely the reverse except that, for the Cs^+–DB18C6 system, the log $K_{ML}{}^+$ value of AN is larger than that of PC (Table 1). For the aprotic solvents, between the group of PC and AN, and that of DMF and DMSO, there is a very great difference in the solvation power for the same alkali metal ion, and also a large difference in the log $K_{ML}{}^+$ value with regard to the same alkali metal ion in every system except for the Cs^+–18C6 system. These results indicate that, for the same alkali metal ion, the solvation power of the aprotic solvent is a very important factor in determining the $K_{ML}{}^+$-value sequences of the aprotic solvents for both 18C6 and DB18C6. For both 18C6 and DB18C6, the log $K_{ML}{}^+$ value of CH_3OH about the same alkali metal ion gains in ranking in these solvents with an increase in the size of the alkali metal ion. This may reflect the fact that, of all the solvents, the solvation power of CH_3OH for Na^+ is the third smallest, while those for K^+, Rb^+, and Cs^+ are the smallest. It is interesting that, although the solvation power of H_2O for the same alkali metal ion is the third largest of all the solvents, the log $K_{ML}{}^+$ value of H_2O is the smallest for every alkali metal ion–crown ether system (Table 1).

Table 2. ($\lambda^\circ/\Omega^{-1}\,cm^2\,mol^{-1}$) values of alkali metal ion–18C6 complexes, alkali metal ions, and a perchlorate ion in DMF at 25 °C

Ion	$\lambda^\circ/\Omega^{-1}\,cm^2\,mol^{-1}$	
		M^+–18C6
Na^+	29.7_9	24
K^+	30.6_7	$24._6$
Rb^+	32.4_3	$24._3$
Cs^+	34.7_2	$23._4$
$ClO_4{}^-$	52.8_3	

Table 2 shows that the λ° value of the alkali metal ion-18C6 complex is much smaller than that of the corresponding alkali metal ion, indicating that the alkali metal ion–18C6 complex is much bulkier than the corresponding alkali metal ion in DMF. The λ° values of the 18C6 complexes with the alkali metal ions are approximately equal except for Cs^+ (Table 2). From the data, it appears that, in the cases of Na^+, K^+, and Rb^+, the charge of the alkali metal ion trapped in the 18C6 cavity is effectively screened by the 18C6 and that the 18C6 complexes with the alkali metal ions are nearly equal to each other in size in DMF. Since Cs^+, whose size is larger than the cavity size of 18C6, cannot get into the plane of the oxygen atoms of 18C6, Cs^+ may protrude from the plane of 18C6. Thus, the exposed part of Cs^+ in the 18C6 complex may strongly interact with the DMF molecules. This may be the reason why the λ° value of the Cs^+–18C6 complex is smaller than those of the others. Judging from the above observations, the ratio of the size of the alkali metal ion to that of the 18C6 cavity appears to be an important factor in determining the magnitude of λ° for alkali metal ion–18C6 complexes.

Table 3. Stokes' radii, R_s, and crystal ionic radii, R_c, of alkali metal ion–18C6 complexes (Å)

Cation	R_c/Å	R_s/Å	
		DMF	PC[2]
Na^+	4.8	4.3	3.8_0
K^+	4.9	4.1_8	3.6_3
Rb^+	4.9	4.2_3	3.6_5
Cs^+	4.9	4.4_0	3.6_9

The crystal ionic radii, $R_C(ML^+)$, of the alkali metal ion–18C6 complexes may be approximately evaluated from the crystal ionic radii, $R_C(M^+)$, of the alkali metal ions held in the 18C6 cavity and from the 18C6 volume, V:

$$R_c(ML^+) = \{R_c(M^+)^3 + 3V/4\pi\}^{1/3}.$$

V may be approximated by summing the van der Waals volumes of the atoms or groups forming 18C6. The $R_c(ML^+)$ values are given in Table 3, together with the Stokes' radii, $R_s(ML^+)$, of the alkali metal ion–18C6 complexes calculated from this equation: $R_s(ML^+) = 0.819/\eta_0\lambda^\circ$, where η_0 is the viscosity of the pure solvent. For the same alkali metal ion–18C6 complex, the R_s value of DMF, whose dielectric constant (36.71 at 25 °C[11]) is smaller than PC (64.4 at 25 °C[11]), is larger than that of PC. The crystal ionic radii of the alkali metal ion–18C6 complexes are nearly equal to that of a tetrabutylammonium ion (4.94 Å[12]) (Table 3). The λ° values of the alkali metal ion–18C6 complexes are, however, smaller than that of the tetrabutylammonium ion (26.9[13]) (Table 2). This is the same tendency as that found in the alkali metal ion–18C6 complex–PC system.[2] Since, in the case of the tetrabutylammonium ion, four butyl groups effectively shield the surface charge of the central nitrogen atom, while, in the case of the alkali metal ion–18C6 complex, solvent contacts with the alkali metal ion trapped in the 18C6 cavity are still possible in the direction perpendicular to the plane of 18C6, the alkali metal ion–18C6 complex would much more strongly undergo specific solvation than the tetrabutylammonium ion. This may be the reason why the λ° value of the alkali metal ion–18C6 complex is smaller than that of the tetrabutylammonium ion for both DMF and PC.

Liquid Crystal Formation in Binary Systems. IV.[1] Induction of Smectic Phases in Mixtures of *N*-(*p*-Nitrobenzylidene)-*p*-aminoazobenzene and Various Electron Donors of the Type *N*-(*p*-Substituted Benzylidene)-*p*-aminoazobenzene

Minoru FUKUI and Yoshio MATSUNAGA*

(Received February 5, 1981)

A study of the phase diagrams of binary systems consisting of nematogenic *N*-(*p*-nitrobenzylidene)-*p*-aminoazobenzene and various electron donors of the type *N*-(*p*-*X*-benzylidene)-*p*-aminoazobenzene revealed the induction of a smectic A phase in the cases where X=MeO, EtO, *n*-PrO, Me_2N, and Et_2N and of a smectic B phase as well in the cases where X=EtO and *n*-PrO. The extent of thermal stability enhancement of the smectic A phase is larger with non-nematogenic dialkylamino derivatives than with nematogenic alkoxy derivatives; this supports our postulate that the smectic phases are stabilized by the intermolecular interaction of the electron donor-acceptor type. The induction of smectic A phases was shown also in all the combinations of the *p'*-ethoxy derivatives, including the cases where X=H, Me, and Ph.

We reported earlier that nematic and smectic liquid crystals can be induced by mixing the *p*-dimethylamino and *p*-nitro derivatives of *N*-benzylideneaniline, which are both potentially mesogenic.[2] The induction of the mesophases in these binary systems was attributed to the stabilization of the parallel molecular arrangement by the interaction of the electron donor-acceptor type. In order to seek further correlation between the donor-acceptor interaction and the formation of smectic liquid crystals, we have applied the phase diagram approach to mixtures of nematogenic *N*-(*p*-nitrobenzylidene)-*p*-aminoazobenzene and various electron donors of the type *N*-(*p*-*X*-benzylidene)-*p*-aminoazobenzene. The latter compounds themselves are nematogenic or non-nematogenic depending upon the substituent X. The following substituents were selected purely from the standpoint of the electron-donor strength: H, Me, MeO, EtO, *n*-PrO (hereafter abbreviated PrO), Me_2N, and Et_2N. As the nature of each of these terminal substituents is so different, the influence on the thermal stability of mesophases of the component compounds may be quite variable. In addition, we worked on mixtures of the *p'*-ethoxy derivatives.

The appearance of a smectic phase has been noted by several research groups with a number of binary systems in which either one or both of the components are capable of giving nematic mesophases.[3-8] For instance, Schroeder and Schroeder have found the formation of a smectic phase in the system comprised of nematogenic 4,4'-bis(hexyloxy)azoxybenzene and non-nematogenic *N*-(*p*-methoxybenzylidene)-*p*-nitroaniline.[3] Engelen *et al.* have examined about thirty combinations and concluded that mixtures of terminal nonpolar and terminal polar nematogens usually induce a smectic phase of the type A.[5] While the nematogens with only alkyl and alkoxyl groups are considered to be nonpolar, the cyano and nitro derivatives are polar. A paper of Domon and Billard published a year later has referred to about ten systems which comprise two different nonpolar nematogens and yield smectic phases.[7] The donor-acceptor systems examined in our previous work consist of only polar components and markedly differ from theirs. Thus, it seems difficult to explain the role of terminal substituents and their dipole moments in the induction of smectic phases in binary mixtures. Recently, Sharma *et al.* have reported their work on the electron donor-acceptor complexes formed by two mesogenic component compounds and noted that the formation of smectic A phase is favored by such an interaction.[8] Their donor compounds are 4,4'-bis(alkylamino)biphenyls and the acceptors are various compounds carrying nitro, cyano, and/or carbonyl groups.

Experimental

Materials. The condensation reaction between *p*-X-substituted benzaldehyde and *p*-aminoazobenzene yields *N*-(*p*-X-benzylidene)-*p*-aminoazobenzene, as reported by Vorländer and Schuster.[9] The *p'*-ethoxy derivatives were similarly prepared. Hereafter, the component compounds are represented by their terminal substituents: that is, [X, H] in the first series and [X, EtO] in the second series. *p*-Amino-*p'*-ethoxyazobenzene needed for the latter series was prepared by the rearrangement of *p*-ethoxydiazoaminobenzene obtained by the coupling of benzenediazonium chloride with *p*-phenetidine.[10] Binary mixtures in known proportions were melted in small test tubes, shaken well to ensure homogeneity, and then rapidly cooled.

Measurements. The calorimetric curves were recorded on a Rigaku Denki differential scanning calorimeter, Model 8001 SL/C, during the processes of heating and cooling. The heating rate in the present work was 5 °C min^{-1}. The liquid crystals were identified by examining their texture with the aid of a polarizing microscope and/or by studying the continuous miscibility with a reference mesogen.

Results and Discussion

The [H, H] and [Me, H]–[NO_2, H] Systems. The acceptor compound [NO_2, H] has a nematic phase stable between 181 and 228 °C. The combination with non-mesogenic [H, H] yields no smectic phase (see Fig. 1a). A eutectic point is located at 122.5 °C and 14.5 mol% of [NO_2, H] and a peritectic point at 161 °C and 81 mol%.

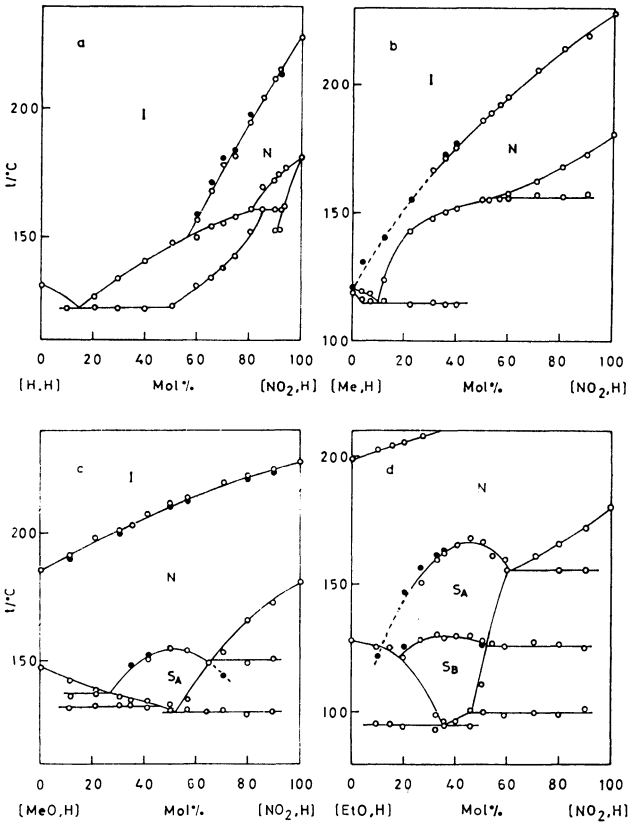

Fig. 1. Phase diagrams of (a) the *N*-benzylidene-*p*-aminoazobenzene–*N*-(*p*-nitrobenzylidene)-*p*-aminoazobenzene, (b) *N*-(*p*-methylbenzylidene)-*p*-aminoazobenzene–*N*-(*p*-nitrobenzylidene)-*p*-aminoazobenzene, (c) *N*-(*p*-methoxybenzylidene)-*p*-aminoazobenzene–*N*-(*p*-nitrobenzylidene)-*p*-aminoazobenzene, and (d) *N*-(*p*-ethoxybenzylidene)-*p*-aminoazobenzene–*N*-(*p*-nitrobenzylidene)-*p*-aminoazobenzene systems. The open and shaded circles are transitions observed in the processes of heating and cooling respectively.

The nematic liquid crystal-isotropic liquid (N-I) transition curve is met by the freezing point curve at 150 °C and 56.5 mol%. The extrapolation of the N-I transition curve, which is almost straight, to 0 mol% of the acceptor indicates that [H, H] has a latent N-I transition temperature around 50 °C. This temperature is far below its melting point, 131 °C.[9]

The compound [Me, H] exhibits a nematic phase stable between 118.5 and 120.5 °C. This temperature range is so narrow that the N-I transition is not detectable on the calorimetric curve recorded in the process of heating; however, the transition is well established in the process of cooling because of the delayed solidification. The N-I transition curve in the [Me, H]–[NO_2, H] system is slightly convex upwards (see Fig. 1b). A eutectic point is found at 114.5 °C and 10 mol% of [NO_2, H]. As the phase change at the former temperature is detected only below 50 mol%, the solid molecular compound melting incongruently at 156 °C may be of a 1 : 1 mole ratio. No smectic phase is induced in this system.

The [MeO, H], [EtO, H], and [PrO, H]–[NO_2, H] Systems. The donor [MeO, H] is nematogenic.[9] The liquid crystal is stable between 147.5 and 185.5 °C. The system [MeO, H]–[NO_2, H] gives a eutectic point located at 130 °C and 52 mol% of the acceptor. The N-I transition curve is convex upwards but only slightly. A smectic liquid crystal of the type A is induced and the maximum temperature of 154.5 °C is at 50 mol% (see Fig. 1c). The smectic liquid crystal-nematic liquid crystal (S-N) transition curve intersects the freezing point curve of the donor component at 137.5 °C and 27 mol% and that of the acceptor component at 150 °C and 65 mol%. The extrapolation of the S-N transition curve to 0 mol% gives a latent S_A-N transition temperature of donor at about 90 °C, while the extrapolation to 100 mol% yields a temperature of about 100 °C. Thus, the smectic phase is stabilized as much as 60 °C by the interaction between these two mesogens.

The nematic phase of [EtO, H] covers the temperature range from 128 to 199 °C. The system with [NO_2, H] shows a eutectic point at 95 °C and 36 mol% of [NO_2, H] and a peritectic point at 100 °C and 47 mol% (see Fig. 1d). There seems to be a solid molecular compound at 50 mol% with an incongruent melting point. Not only a smectic A phase but also a smectic B phase can be observed in this system. The maximum temperature of the former phase is about 167 °C and of the latter about 130 °C. The extrapolation of each transition curve to 0 mol% suggests that the donor has latent S_A-N and S_B-S_A transition temperatures at about 95 and 90 °C respectively. The existence of these two transitions has been confirmed by a study of the phase diagram of the system [EtO, H]–[NoO, H], *N*-(*p*-nonyloxybenzylidene)-*p*-aminoazobenzene. The reference compound gives a smectic B phase stable between 109.5 and 126 °C and a smectic A phase stable between 126 and 156 °C, in agreement with the data reported by Demus and Sackmann.[11] The freezing point curve of [EtO, H] is met by the S_A-N transition curve at 114 °C and 31 mol% of [NoO, H] and by the S_B-S_A transition curve at 105 °C and 44 mol% (see Fig. 2a). While the S_A-N transition curve above 31 mol% is convex upwards, the curve below this composition appears concave upwards. The extrapolation yields the latent transition temperatures of 95 and 89 °C which agree well with those suggested above. The latent S_B-S_A transition expected to be around 95 °C for [NO_2, H] is also supported by the phase diagram of the system with the same reference mesogen (see Fig. 2b). Here, the S_A-N transition curve is markedly convex upwards, as has been noted with the shorter alkoxy derivatives (see Figs. 1c and 1d). Passing the maximum at 177 °C and 60 mol% of [NoO, H], the transition curve is met by the freezing point curve of [NO_2, H] at 157.5 °C and 37 mol%. In contrast to the S_A-N transition curve, the curve separating the smectic A and B phases is slightly concave upwards. The intersection with the freezing point curve is found at 112 °C and 58 mol%. Consequently, the extents of stabilization of the smectic A and B phases in the [EtO, H]–[NO_2, H] system are estimated to be about 70 and 38 °C respectively.

With the [MeO, H]–[EtO, H] system, we have confirmed the ideal linear relationship of N-I transition

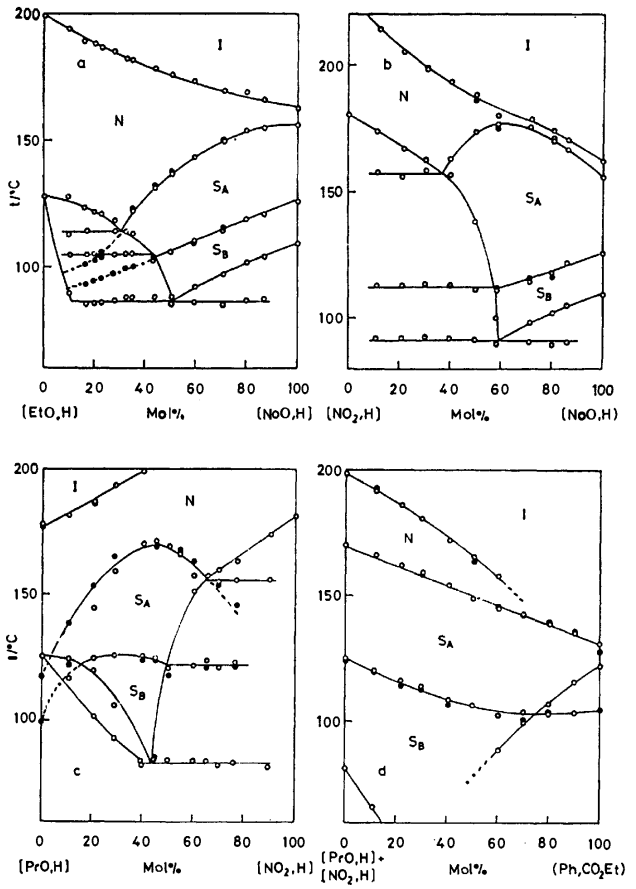

Fig. 2. Phase diagrams of (a) the *N*-(*p*-ethoxybenzylidene)-*p*-aminoazobenzene–*N*-(*p*-nonyloxybenzylidene)-*p*-aminoazobenzene, (b) *N*-(*p*-nitrobenzylidene)-*p*-aminoazobenzene–*N*-(*p*-nonyloxybenzylidene)-*p*-aminoazobenzene, and (c) *N*-(*p*-propoxybenzylidene)-*p*-aminoazobenzene–*N*-(*p*-nitrobenzylidene) -*p*-aminoazobenzene systems and (d) the system consisting of *N*-(*p*-phenylbenzylidene)-*p*-(ethoxycarbonyl)aniline and the 6 : 4 mixture of *N*-(*p*-propoxybenzylidene)-*p*-aminoazobenzene and *N*-(*p*-nitrobenzylidene)-*p*-aminoazobenzene. As to the open and shaded circles, see the caption of Fig. 1.

temperatures in the absence of a particular interaction. The single eutectic point is located at 115 °C and 56 mol% of [EtO, H]. It is rather surprising to see that solid [EtO, H] can dissolve [MeO, H] up to 30 mol%. On the other hand, the solubility of [EtO, H] into solid [MeO, H] is less than 10 mol%.

The nematic phase of [PrO, H] makes an appearance at 125 °C and is stable up to 178 °C. This donor has metastable smectic A and B phases: that is, the supercooled nematic phase is transformed into a smectic A phase at 117 °C and then into a smectic B phase at 99 °C. When mixed with [NO_2, H], a eutectic point appears at 83 °C and 44 mol% of the acceptor (see Fig. 2c). The smectic A phase has a region of existence from 4 to 65 mol% and the smectic B phase from 15 to 50 mol%. The upper temperature limit of the former mesophase is located at about 170 °C, which is higher by 62 °C than the straight line joining the S_A-N transition temperatures of the components. When the composition is lower than 30 mol%, the S_A-N transition temperatures recorded in the process of heating were found to deviate significantly from those recorded in the process of cooling. The curve was drawn on the basis of the latter points which are in conformity with the transition temperature of pure [PrO, H]. In contrast to the smectic A phase, the maximum deviation from the ideal linear relationship in the smectic B phase apparently occurs at a composition far from a 1 : 1 mole ratio. This phase at 30 mol% is stabilized by about 28 °C.

The induced smectic A and B phases could be identified by their characteristic fan-shaped texture. In addition, the classification has been confirmed by the selective miscibility with the smectic A phase of *N*-(*p*-phenylbenzylidene) -*p*- (ethoxycarbonyl) aniline (Ph,

CO_2Et) which is stable between 121.6 and 131 °C.[12] Fig. 2d presents the diagram of the pseudo-binary system consisting of a mixture of [PrO, H] and [NO_2, H] at 40 mol% and the reference compound. The diagram is of the eutectic type. The N-I transition curve is slightly convex upwards and the nematic phase is not observable above 70 mol% of (Ph, CO_2Et). Doubtlessly the mesophases induced in the mixture at high temperatures form an uninterrupted series of mixed crystals with the smectic A phase of the reference compound. Another smectic phase appearing enantiotropically in the mixtures at lower temperatures is identical with the metastable smectic phase of (Ph, CO_2Et). The latter was classified into type B on the basis of its miscibility behavior with [NoO, H].

The smectic B phase could be found also in the system comprising a 1 : 1 mixture of [MeO, H] and [NO_2, H] and the reference mesogen. The phase is stable in the composition range from 5 to 68 mol% of (Ph, CO_2Et). The extrapolation of the transition curve to 0 mol% gives a temperature only a few degrees below the eutectic temperature of the [MeO, H]–[NO_2, H] system.

The [Me_2N, H] and [Et_2N, H]–[NO_2, H] Systems. The donor [Me_2N, H] is non-mesogenic. A eutectic point is located at 142 °C and 75.5 mol% of [NO_2, H]. A peritectic point appears at 146 °C and 59 mol% because of the formation of an incongruently-melting molecular compound, possibly of a 1 : 1 mole ratio. The mixtures give rise to a smectic A phase, as is shown in Fig. 3a. The induced S_A-N transition curve is met by the freezing point curve of the donor component at 152 °C and 48 mol% and by that of the acceptor component at 166 °C and 87 mol%. The maximum may be located around 190 °C in the composition range between 60 and 70 mol%. The steep slope on the donor-rich side suggests that the latent S_A-N transition temperature of [Me_2N, H] is very low. This may be the reason why the maximum of the transition curve is found at an acceptor-rich composition. As this temperature is higher by 90 °C than the estimated S_A-N transition temperature of [NO_2, H], the extent of the stabilization of the smectic phase certainly exceeds 100 °C.

Replacement of a dimethylamino group by a diethyl-

amino group in the donor compound seems to lower markedly the latent N-I transition temperature. As is shown in Fig. 3b, the N-I transitions lie on an approximately straight line in the diagram. The extrapolation to 0 mol% of [NO_2, H] yields −12 °C. The line intersects the induced S_A-N transition curve at 167 °C and 72 mol%. The maximum temperature of the smectic A phase is found at 168 °C near 75 mol%. The extent of induction is at least 90 °C, because the latent S_A-N transition of [Et_2N, H] is expected to be lower than the latent N-I transition. It must be noted that the smectic A phase induced over the range of composition below 72 mol% is thermally more stable than the nematic phase. At 83 mol% and 164.5 °C, the S_A-N transition curve is met by the freezing point curve of the acceptor.

In summary, the maximum temperature of the induced smectic A phase in the present series decreases in the following order: [Me_2N, H]>[PrO, H]>[EtO, H]≃[Et_2N, H]>[MeO, H]. Even though these results arise from the complex interplay of different molecular parameters determining the thermal stability of smectic phases, the extents of the stability enhancement with more electron-donating dialkylamino derivatives are clearly larger than those with less electron-donating alkoxy derivatives, 60—70 °C, supporting our postulate that the ordered arrangement of molecules characteristic of smectic phases can be achieved by the interaction of the electron donor-acceptor type. In the latter derivatives, the sequence of the extents is [EtO, H]>[PrO, H]≃[MeO, H]. It must be emphasized that the maximum deviation of the nematic phases from the ideal linear relationship is merely several degrees in the above-mentioned systems. Moreover, the induction of the smectic A phases is about twice as large as that of the smectic B phases when observable. As no smectic phase could be found in the [H, H] and [Me, H]–[NO_2, H] systems, we decided to take up the second series, mixtures of the *p'*-ethoxy derivatives. The unsubstituted compound [H, EtO] is an isomer of [EtO, H] and has been found to be nematogenic by the work of Vorländer.[10]

The [H, EtO] and [Me, EtO]–[NO_2, EtO] Systems. The compound [H, EtO] melts at 136 °C and has an enantiotropic nematic range up to 204 °C. The range is shifted upwards by several degrees compared with that of the isomeric [EtO, H]. When this donor is mixed with nematogenic [NO_2, EtO], a smectic A phase is produced in the composition range from 50 to 88 mol% of the acceptor (see Fig. 4a). At the latter composition, the induced S_A-N transition curve intersects the freezing point curve of the acceptor. The extrapolation of this transition curve to 100 mol% suggests that the acceptor has the latent transition temperature at about 155 °C. The smectic phase shows the maximum temperature of about 178 °C at 75 mol%. It must be added that the latent S_A-N transition temperature of pure [H, EtO] is apparently much lower than that of [EtO, H], which is located at 95 °C. This combination produces a congruently melting molecular compound, presumably at 33 mol%. Eutectic points are located at 118 °C and 22.5 mol% and at 127 °C and 47 mol%. The acceptor compound [NO_2, EtO] is transformed from a solid to a nematic liquid crystal at 177.5 °C.

Phase diagrams of (a) the *N*-[*p*-(dimethylamino)-benzylidene] - *p*-aminoazobenzene–*N* - (*p* - nitrobenzylidene)-*p*-aminoazobenzene and (b) *N*-[*p*-(diethylamino)benzylidene]-*p*-aminoazobenzene–*N*-(*p*-nitrobenzylidene)-*p*-aminoazobenzene systems. As to the open and shaded circles, see the caption of Fig. 1.

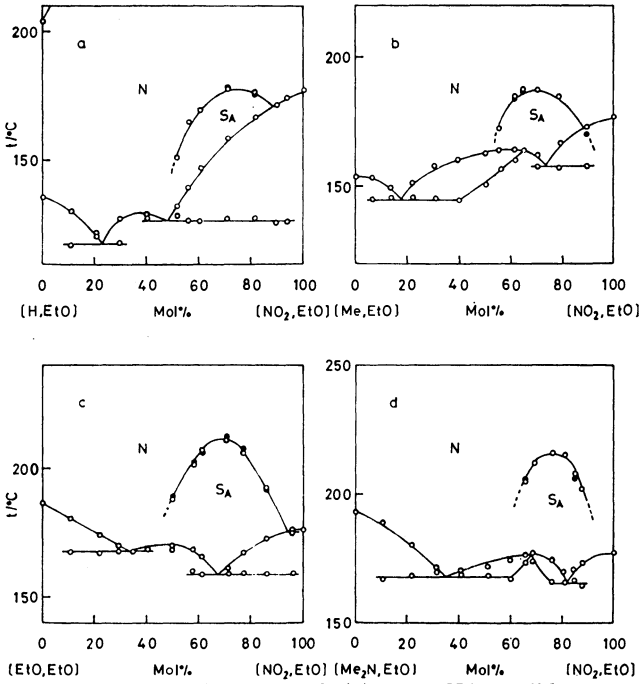

Fig. 4. Phase diagrams of (a) the *N*-benzylidene-*p*-amino-*p'*-ethoxyazobenzene–*N*- (*p*-nitrobenzylidene)-*p*-amino-*p'*-ethoxyazobenzene, (b) *N*-(*p*-methylbenzylidene)-*p*-amino-*p'*-ethoxyazobenzene–*N*-(*p*-nitrobenzylidene)-*p*-amino-*p'*-ethoxyazobenzene, (c) *N*-(*p*-ethoxybenzylidene)-*p*-amino-*p'*-ethoxyazobenzene–*N*-(*p*-nitrobenzylidene)-*p*-amino-*p'*-ethoxyazobenzene, and (d) *N*-[*p*-(dimethylamino)benzylidene]-*p*-amino-*p'*-ethoxyazobenzene–*N*-(*p*-nitrobenzylidene)-*p*-amino-*p'*-ethoxyazobenzene systems. As to the open and shaded circles, see the caption of Fig. 1.

The compound [Me, EtO] is nematogenic and melts at 154 °C. The mixtures with [NO_2, EtO] in the composition range from 55 to 90 mol% of [NO_2, EtO] yield a smectic A phase (see Fig. 4b). The maximum temperature of 188 °C is found at 70 mol%. The molecular compound formed in this system has a 1 : 2

mole ratio and melts congruently at 164 °C. Eutectic points are located at 145 °C and 18 mol% and at 158 °C and 74 mol%.

The [MeO, EtO], [EtO, EtO], and [PrO, EtO]–[NO_2, EtO] Systems. All the donor compounds are nematogenic. The donor [MeO, EtO] melts at 161 °C. When mixed with [NO_2, EtO], a smectic A phase is induced in the composition range from 55 to 88 mol%. The S_A-N transition curve has a maximum at 192 °C and 73 mol% and is met at 88 mol% by the freezing point curve of the acceptor. As the donor molecule has electron donating groups at the *p* and *p'* positions, the molecular complex formed in the smectic phase may be, at least, partly of a 1 : 2 mole ratio. A solid molecular compound is found at a 1 : 2 mole ratio and is stable up to its melting point, 164 °C. A eutectic point on the donor-rich side is located at 161 °C and about 48 mol%; therefore, the freezing point curve below this point is flat. Another eutectic point is found at 158 °C and 74 mol%.

The phase diagram of the [EtO, EtO]–[NO_2, EtO] system is presented in Fig. 4c. The donor compound has a nematic phase stable above 186 °C. The smectic mesophase appears in the range from 50 to 93 mol% of the acceptor. The upper temperature limit of the mixture's smectic range is found at 211.5 °C and 68 mol%. The equimolar solid molecular compound formed by the present combination melts at 170 °C. Eutectic points are located at 168 °C and 32 mol% and at 159 °C and 67 mol%.

The diagram of the [PrO, EtO]–[NO_2, EtO] system bears a similarity to the afore-mentioned one. The nematogenic [PrO, EtO] melts at 167 °C. The induced smectic A mesophase can be seen in the composition range from 45 to 90 mol%. The maximum in smectic phase stability occurs at 226 °C and 65 mol%. The intersection between the S_A-N transition curve and the freezing point curve on the acceptor-rich side may be at 176 °C and 93 mol%. The 1 : 1 molecular compound melts at 165°C. As this melting point and the eutectic temperature are not distinguishable from each other, the latter location could not be determined. Another eutectic point is at 150 °C and 67 mol%.

The [Me_2N, EtO], [Et_2N, EtO], and [Ph, EtO]–[NO_2, EtO] Systems. Contrary to [Me_2N, H], the donor [Me_2N, EtO] gives a stable nematic liquid crystal above 193 °C. As is shown in Fig. 4d, a smectic A phase is induced in the mixtures with [NO_2, EtO]. The maximum for the S_A-N transition is located at about 216 °C and 75 mol%. This combination yields a 1 : 2 molecular compound with a congruent melting point of 177.5 °C. Two eutectic points are at 168 °C and 35 mol% and at 165 °C and 82 mol%.

The compound [Et_2N, EtO] has a nematic range from 159.5 to 198.5 °C. The reduction of the enantiotropic N-I transition temperature by replacement of a dimethylamino group with a diethylamino group is in accordance with the trend suggested for the latent N-I transitions in [Me_2N, H] and [Et_2N, H]. The induced smectic A phase in the system with [NO_2, EtO] covers a wide composition range. One end of the S_A-N transition curve is the intersection with the freezing point curve of the donor located at 144 °C and 29 mol% and the other is the intersection with the freezing point curve of the acceptor, possibly around 98 mol%. The maximum temperature of 239 °C is found at about 77 mol%. The solid 1 : 2 molecular compound in this system is of lower stability and ceases to exist stably at 146 °C, producing a peritectic point at 64 mol%. The eutectic is at 138.5 °C and 34 mol%.

In addition to the above-mentioned systems, the phase diagram has been prepared for the combination of [Ph, EtO] and [NO_2, EtO]. The donor [Ph, EtO] is transformed from a solid to a nematic liquid crystal at 199 °C. The diagram has a eutectic point at 159 °C and 64 mol%. In this system too, only a smectic A phase is induced. The S_A-N transition curve recorded in the range from 30 to 90 mol% reaches its maximum at 234 °C and 54 mol%. The smooth extrapolation to 0 mol% suggests that the donor has the latent transition a little below 150 °C. The extent of induction may be about 90 °C.

As described above, the smectic A phases induced in the second series are found to exhibit maxima beyond 50 mol% of [NO_2, EtO]. Except for the last donor, the latent S_A-N transition temperatures are expected to be considerably lower than that of the acceptor. The large mole percentages at the upper temperature limits may be ascribed to the low latent transition temperatures of the donor compounds and also to the formation of 1 : 2 molecular complexes. The observed upper temperature limits of the induced mesophases give the following sequence of the donors:

[Et_2N, EtO]>[Ph, EtO]>[PrO, EtO]>[Me_2N, EtO]>
[EtO, EtO]>[MeO, EtO]>[Me, EtO]>[H, EtO].

The extent of induction may be concluded to be less only when both the temperature limit and the composition are lower. Judging by such a condition, the donors may be partially arranged in order of their decreasing ability of inducing a smectic A phase: namely,

[Me_2N, EtO]>[MeO, EtO]>[Me, EtO],
[Et_2N, EtO]>[PrO, EtO],
[Me_2N, EtO]>[EtO, EtO], and
[Me_2N, EtO]>[H, EtO].

A plausible explanation for these features is that the stabilization is provided by the intermolecular electron donor-acceptor interaction.

No smectic B phase could be observed in the second series. As the molecular compounds found in this series are more stable than those in the first series, the freezing point may be too high to allow the observation of the S_B-S_A transition. This assumption has been supported by a study on the system consisting of a 3 : 7 mixture of [Me, EtO] and [NO_2, EtO] and the reference compound [NoO, H]. The composition of the mixture has been chosen to correspond to the upper temperature limit of the induced smectic A phase (see Fig. 4b). The diagram shown in Fig. 5 strongly suggests that the mixture has a latent S_B-S_A transition located around 120 °C, which is not very different from the transitions exhibited by mixtures of [EtO, H] and [NO_2, H]. The

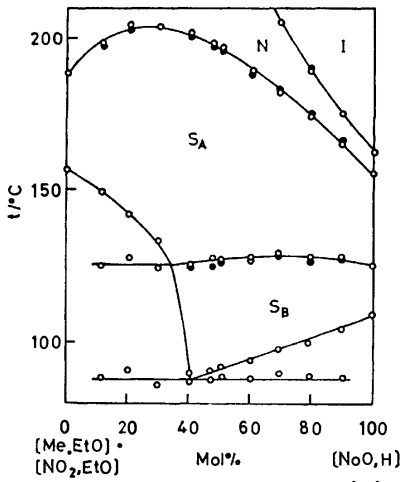

Fig. 5. Phase diagram of the system consisting of *N*-(*p*-nonyloxybenzylidene)-*p*-aminoazobenzene and the 3 : 7 mixture of *N*-(*p*-methylbenzylidene)-*p*-amino-*p'*-ethoxyazobenzene and *N*-(*p*-nitrobenzylidene)-*p*-amino-*p'*-ethoxyazobenzene. As to the open and shaded circles, see the caption of Fig. 1.

S_A-N transition curve is appreciably convex upwards and the maximum is located at about 25 mol% of [NoO, H]. These results imply that [NoO, H] is a better electron donor than [Me, EtO] is.

The present work was partly supported by a Grant-in-Aid for Scientific Research No. 543001 from the Ministry of Education, Science and Culture.

The Temperature Dependence of the Localization and Scavenging of Electrons in a Glassy 2-Methyltetrahydrofuran Matrix

Masato YOSHIZAKI, Masaaki OGASAWARA,* and Hiroshi YOSHIDA
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060
(Received February 21, 1981)

The nature and behavior of localized electrons in a γ-irradiated 2-methyltetrahydrofuran matrix were studied at 4 and 77 K by optical absorption measurements. Electrons localized in shallow traps generated at 4 K in a neat matrix showed one broad peak with ε_{max} of 1.2×10^4 mol^{-1} dm^3 cm^{-1} at 1490 nm. The yield was 1.9 (for 100 eV energy absorbed). This yield is less than the yield of electrons localized in deep traps at 77 K, 2.6. With an increasing concentration of biphenyl added to the matrix, the localized electrons were completely transformed into biphenyl anions. The scavenging efficiency was twice as high at 4 K as at 77 K. These results indicated that the electron scavenging took place by tunneling of the once localized electrons.

Glassy 2-methyltetrahydrofuran (MTHF) is a rigid organic matrix in which the nature and behavior of radiation-generated localized electrons at 77 K have been extensively studied by means of optical absorption and electron spin resonance (ESR) measurements.[1] The temperature dependence of an electron scavenging reaction in this glassy matrix was first studied by Higashimura and two of the present authors (M. O. and H. Y.). They used the 4 K γ-irradiation technique combined with the ESR method. From the observed temperature dependence it was inferred that the scavenging efficiency of biphenyl was higher by about a factor of four at 4 K than at 77 K. This was attributed to a temperature-dependent competition among localization, charge recombination, and scavenging of electrons.[2] In this early study, however, the ESR measurements were made after warming of the samples to 77 K, so that ambiguity caused by the effect of warming could not be avoided. Hase *et al.* have tried to study the relaxation of electrons localized in the MTHF matrix by a 4 K irradiation-optical absorption method, but the spectrum of localized electrons obtained prior to their relaxation was not clear enough, mainly because of the efficient electron-scavenging at 4 K by impurities contained in the sample.[3] Hager and Willard have studied the relaxation of localized electrons in this matrix by generating them photolytically in the temperature range 10—97 K.[4]

Owing to the recent progress in pulse radiolysis studies at low temperatures, electron tunneling from localized states to scavenger molecules has become the prevailing interpretation of the mechanism for electron scavenging reactions in rigid matrices.[5] In this respect, we thought it was necessary to re-examine the temperature dependence of the electron scavenging in the MTHF matrix in a more quantitative way and also to examine the absorption spectrum of the localized electrons before their relaxation.

Experimental

MTHF was washed with an aqueous NaOH solution, distilled over Na metal, and dried with a Na–K alloy. Solutions of zone-refined biphenyl in MTHF were degassed with freeze-pump-thaw cycles, sealed in Suprasil quartz cells (0.2 cm optical path) under a vacuum of 10^{-5} Torr,† frozen in liquid nitrogen into the glassy state, and transferred into a liquid helium cryostat. In order to avoid breakage of the cells in liquid helium, the glass in the cells was usually made moderately cracked by introducing a tiny piece of quartz.

The samples were irradiated with ^{60}Co γ-rays at a dose rate of 6.24×10^{18} eV g^{-1} h^{-1} at 77 K (in the cryostat filled with liquid nitrogen) or at 4 K, and subjected to optical absorption measurements at the irradiation temperatures with a Shimadzu MPS-5000 spectrophotometer. Post-irradiation annealing of the samples irradiated at 4 K was carried out by transferring them into liquid nitrogen, keeping them there for ten minutes, and transferring them back into the liquid helium cryostat again. All measurements and the handling of the samples were carried out in complete darkness. The absorption spectra were corrected for the background absorption recorded before the irradiation.

Results and Discussion

Spectra of Localized Electrons. The absorption spectrum due to localized electrons in neat MTHF irradiated at 4 K initially showed a broad single peak at 1490 nm and a long absorption tail to the high energy side as shown in Fig. 1. Annealing at 77 K changed the spectral shape; it became red-shifted and double-peaked at 1150 and 1300 nm. Such a spectral change has been observed previously and was attributed to the rearrangement of MTHF molecules around electron

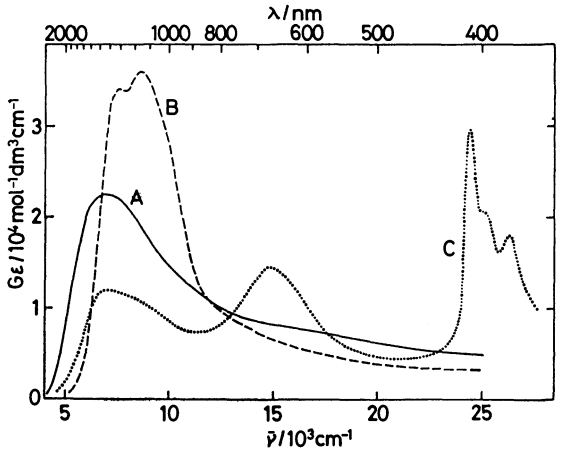

Fig. 1. Absorption spectra obtained from γ-irradiated MTHF at 4 K (A) in the absence and (C) presence of biphenyl. The spectrum B was obtained from γ-irradiated neat MTHF at 4 K after annealing the sample at 77 K for 10 min.

† 1 Torr≈133. 322 Pa.

traps.[3,4,6] The possibility that the spectral change is due to a redistribution of the electrons into deeper traps, as is the case for aqueous glasses[7] and (partly) for alcoholic glasses,[8] cannot yet be discarded however. Irrespective of the mechanism responsible for the spectral change, the localization of the electrons becomes deeper when the samples are annealed at 77 K. The spectral shape after the annealing is almost the same as that recorded from MTHF irradiated at 77 K.

The intensity increase at the absorption maximum during annealing seems to be complemented by a disappearance of the low-energy part of the absorption and an intensity decrease of the high-energy absorption tail. This kind of spectral change is theoretically expected from an effective deepening of electron traps on the basis of the cavity model.[9] Assuming no loss of electrons during annealing, the molar absorptivity at the absorption maximum, ε_{max}, of the electrons localized in shallow traps at 4 K is calculated to be 1.2×10^4 mol^{-1} dm^3 cm^{-1} at 1490 nm, based on the reported ε_{max} value, 1.9×10^4 mol^{-1} dm^3 cm^{-1} for the electrons localized in deep traps generated at 77 K.[10] It turns out that the yield (for 100 eV energy absorbed, *G*-value) of the localized electrons at 4 K is 1.9, which is significantly lower than the *G*-value at 77 K, 2.6.[11] This result is consistent with the previous finding[2] that the *G*-value at 4 K is 75% of that at 77 K in MTHF and is similar to the temperature-dependence of the *G*-values observed in glassy alkanes by steady-state measurements.[12] Klassen *et al.*,[13] however, have claimed, based on their pulse radiolysis study, that the apparent difference in the *G*-value is due to rapid decay of a fraction of localized electrons immediately after their formation. This is more significant at 4 K than at 77 K.

In the presence of a small amount of biphenyl in MTHF, the optical absorption signal recorded after the irradiation at 4 K is comprised of the spectrum due to localized electrons and that due to biphenyl molecular anions as is shown in Fig. 1C. Although the high-energy absorption tail of the electron spectrum could not be examined in detail because it was overlapped by the anion spectrum peaks at 395, 408, and 650 nm, the low-energy side of the electron spectrum is efficiently depleted. This depletion can probably be attributed to the selective scavenging by biphenyl of the localized electrons. In contrast, the electron spectrum at 77 K is depleted homogeneously by the addition of biphenyl. The heterogeneous depletion of electron spectra at 4 K has also been demonstrated for glassy ethanol.[14,15]

Electron Scavenging of Biphenyl. The yields of localized electrons and biphenyl anions were determined for 4 K and 77 K-irradiations as a function of the biphenyl concentration by graphically decomposing the recorded absorption curves into their component spectra. They are shown in Fig. 2. The electron yield at 77 K was determined from the absorption peak height at 1150 nm, while that at 4 K was estimated from the spectral intensity integrated down to 400 nm (below this wavelength, free radicals from MTHF contribute to the optical absorption[16]) to minimize the effect of the heterogeneous spectral depletion. The anion yield

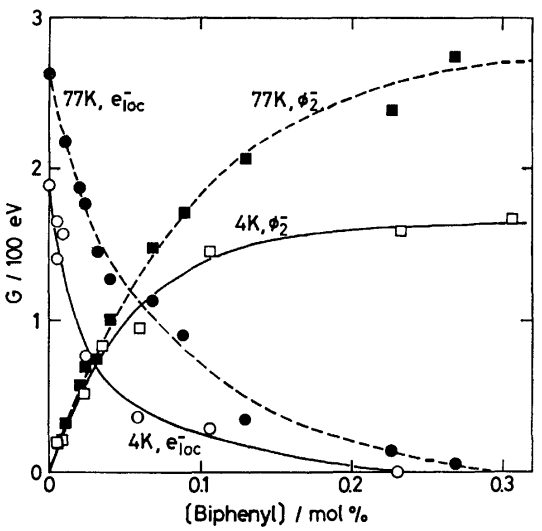

Fig. 2. Effect of biphenyl concentration on the yield of the localized electron, e^-_{loc}, and biphenyl anion, ϕ^-_2, in γ-irradiated MTHF at 4 and 77 K.

at 4 and 77 K was determined by using the ε_{max} at 408 nm measured at 77 K, 3.9×10^4 mol^{-1} dm^3 cm^{-1}, reported by Shida,[10] as the present study has shown ε_{max} to be independent of the temperature.

The plateau value of the anion yield at 77 K for high biphenyl concentrations agrees with the electron yield in the absence of the scavenger at the same temperature. The plateau value at 4 K is 1.7, which appears to be a little lower than the initial electron yield of 1.9. However, this small difference may be the result of the uncertainty in the ε_{max} value for the localized electrons at 4 K. If one assumes a partial disappearance of 10% of the localized electrons in the MTHF during annealing, then the ε_{max} value will be 1.1×10^4 mol^{-1} dm^3 cm^{-1} instead of 1.2×10^4 mol^{-1} dm^3 cm^{-1}, and agreement at 4 K will be attained between the yields of the localized electrons and the anions. Within the uncertainty of the present experiments, it can be concluded that the yield of scavengeable electrons is equal to the yield of stably localized electrons in the absence of the scavenger. The yield of such electrons is appreciably lower at 4 K than at 77 K.

Figure 2 also indicates the temperature dependence of the electron scavenging efficiency. The efficiency can be estimated from the reciprocal of that biphenyl concentration at which the electron yield is halved or from that where the anion yield is half of its plateau value. Biphenyl is about twice as efficient at 4 K as at 77 K in scavenging electrons. This temperature dependence is less significant but qualitatively consistent with the previous result obtained by ESR for the biphenyl–MTHF system.[2] When the concentration of added biphenyl exceeded 1 mol%, the *G*-value of the anion was found to decrease slowly at both 4 and 77 K. The reason for this is probably complicated.

Localization and Tunneling of Electrons. The temperature dependence of the electron yield combined with the complete conversion into biphenyl anions at a high enough biphenyl concentration naturally leads to the conclusion that at first the electrons are localized

in traps in the matrix; subsequently they are transferred to the scavenger molecules. If one assumes that the electrons are scavenged before localization, the observed temperature dependence of the electron yield can only be interpreted by the rather improbable hypothesis that the *G*-value of ionization is lower at 4 K than at 77 K, *i.e.*, that the *W*-value in the MTHF matrix is dependent on temperature. Otherwise, the plateau *G*-value of the anion should have been independent of temperature, as the electrons must be scavenged completely by biphenyl at sufficiently high concentrations.

The low *G*-value of localized electrons at 4 K is interpreted as a competition between electron localization and charge recombination. The former process will become less dominating at a lower temperature because of weaker interactions between the excess electron and the motions of the matrix molecules, so that the electron has a greater chance of encountering positive ions as its migration path is longer before being localized. An alternative interpretation is that a large fraction of the localized electrons have disappeared at low temperature before the steady-state measurements took place. This is the result of charge recombination by electron tunneling which competes with the slow relaxation of the localized electrons. This interpretation, however, seems unlikely as it predicts that the *G*-value of scavengeable electrons (the plateau *G*-value of the anions) is independent of temperature.

The transfer of the localized electrons to scavenger molecules has generally been explained by a tunneling mechanism.[5] The observed dependence of the electron and anion yields on the scavenger concentration is replotted in Fig. 3; this shows the survival probability of the localized electrons to decrease exponentially, consistent with the tunneling mechanism. The tunneling transfer of electrons in the MTHF matrix is also suggested by the previous observation that the rate of decay of the localized electrons by charge recombination deviates from an Arrhenius-type dependence in the low temperature region and is almost independent of temperature below 77 K.[17]

The slopes of the straight lines in Fig. 3 again indicate that the efficiency of scavenging of the localized electrons is about twice as high at 4 K as at 77 K. This

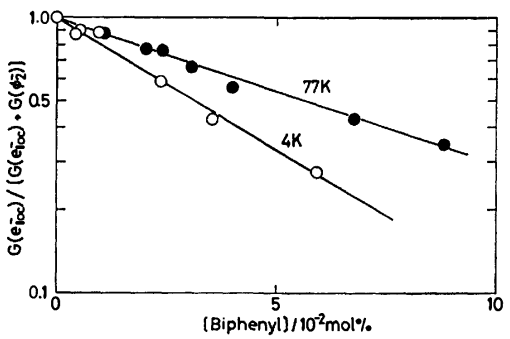

Fig. 3. Survival probability of the localized electron as a function of biphenyl concentration at 4 and 77 K.

temperature dependence can be understood qualitatively by taking into account that the height of the potential barrier to tunnel through is effectively lower for the electrons localized in shallow traps at 4 K than the ones in deep traps at 77 K. Unfortunately direct calculation of the tunneling probability is difficult or even impossible for the present case. The discrete electron energy pectrum of the chemical product of the scavenging reaction is unknown, so that the energy difference between electron-donating levels and electron-accepting levels can not be properly expressed in the calculation of the tunneling probability. Efficient scavenging of electrons localized in shallow traps has been reported also in glassy ethanol by using benzyl chloride[14] and toluene[15] as scavengers.

A part of this work was carried out in the Research Reactor Institute, Kyoto University. The authors wish to thanks Prof. Takenobu Higashimura for giving opportunity to use the experimental facilities.

Adsorption Behavior of N-Containing Heterocycles at a Mercury/Water Interface

Osamu IKEDA,* Fumio GOTO, and Hideo TAMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

(Received March 11, 1981)

Adsorption behavior of 1-methylimidazole and 1-methylbenzimidazole at a mercury/water interface were investigated by electrocapillary measurement. These heterocycles showed a horizontal orientation at lower surface excesses, but at higher surface excesses a vertical one complicated by the presence of the horizontal one. In positive surface charge density, 1-methylbenzimidazole showed an anomalous behavior in which the potential drops across the inner layer, $\Delta_2^M\phi$ does not change with adsorption through the displacement of the water molecules on the electrode. The analysis of the electrosorption valency indicated the absence of a partial charge transfer between the electrode and the adsorbate. This anomalous behavior was interpreted by the compensation effect between the polarization of the water molecules due to the permanent dipoles and that of the 1-methylbenzimidazole molecules due to the dipoles induced in the electric field.

It has been observed that organic compounds with π-electron system show unique adsorption behavior, compared to the compounds lacking π-electron system. Gerovich *et al.*[1-4] studied adsorption of nonpolar organic compounds with π-electrons, such as benzene, anthracene, phenanthrene and chrysene, and found that the adsorbability of these compounds at positive surface charges increases with an increase in the number of benzene ring in the molecule and at the same time the potential of zero charge (p.z.c) shifts toward the negative potentials. They considered that these characteristics are due to a strong interaction between π-electrons and the positive charges. Similar consideration has also been given by Blomgren and Bockris,[5] and Conway and Barradas.[6,7] Damaskin *et al.* studied adsorption of aniline molecules[8] and anilinium cations[9] by the differential capacity measurement. They found that the capacity-potential curves at highly positive potentials measured in pure electrolyte solution and solution containing aniline or anilinium cation approximately coincide, and that the anode peak is caused by the reorientation process not the adsorption-desorption process. These results were explained as following: the aniline and the anilinium cations lie horizontally on the electrode surface with the positive charges and constitute a kind of extension of the metallic surface toward the solution; the double layer capacity changed very slightly.

Thereafter, the negative shift of the p.z.c due to adsorption of organic compounds with π-electron system has been attributed to the extension of the metallic surface[10] or the partial charge transfer.[11] However, the partial electron transfer from the adsorbed molecules to the electrode should increase the negative charge on the electrode, and as the result, the p.z.c seems to shift toward the positive direction. The possibility of this partial charge transfer was discussed in this study.

Furthermore, in the previous report[12] in which the adsorption behaviors of various N-containing heterocycles were studied, it was pointed out that imidazole adsorbed through aggregates due to intermolecular association,[13] because it did not take a vertical orientation owing to the large dipole moment.[14] It was also found that on positive surface charges the potential drop across the inner layer $\Delta_2^M\phi$ was not changed with adsorption of imidazole. This anomalous behavior was considered to result from an interaction between positive charges on the electrode and the aggregates at the outer layer without displacement of the water molecules adsorbed. In order to clarify the above two phenomena, namely the formation of aggregates and the anomalous adsorption behavior of a constant $\Delta_2^M\phi$, 1-methylimidazole (1-MI) without a possibility of intermolecular association,[15] and 1-methylbenzimidazole (1-MBI) with larger π-electron system were chosen, and their adsorption behavior at the mercury/water interface was studied. Besides the above two compounds which are classified into π-excessive heterocycles, quinoxaline, which is a π-deficient heterocycle, was also studied, but the adsorption equilibrium was not observed in the measurement of interfacial tension.

Experimental

All chemicals were analytical grade materials. 1-Methylimidazole (1-MI) was purified by distillation in a vacuum. 1-Methylbenzimidazole (1-MBI) was prepared by the methylation of benzimidazole,[16] and recrystallized twice from petroleum ether. Mercury was purified by treatment with dilute nitric acid, then triply distilled in vacuum. Nitrogen gas, after passing through a purification line, was used for deaeration of the solution. As the supporting electrolyte 0.099 M (1 M = 1 mol dm^{-3}) $NaClO_4$ containing 0.001 M NaOH was prepared from triply distilled water, and treated with purified active charcoal before use. The 0.001 M NaOH was used to depress the ionization of the adsorbates.

Adsorption behavior of 1-MI and 1-MBI was estimated from the analysis of the electrocapillary curves, which were measured by the maximum bubble pressure method.[17,18] The interfacial tension was measured at 50 mV intervals, except for positive and negative extrema where 25 mV intervals were chosen. The error of the measurement was ± 0.1 mN m^{-1} near the electrocapillary maximum, and ± 0.3 mN m^{-1} at positive and negative extrema. The measurement was carried out in a water bath thermostated at 25 ± 0.1 °C, and the potentials were measured against a normal calomel electrode (NCE).

Most of the parameters essential to adsorption were derived by analyzing the electrocapillary curves with a computer program. In the analysis, no corrections were made for the medium effect on the activity coefficient of the supporting electrolyte[19,20] and the activity coefficient of the adsorbate.[21]

Results and Discussion

Electrocapillary Curves. The electrocapillary data for 1-methylimidazole (1-MI) and 1-methylbenzimidazole (1-MBI) are summarized in Table 1. The interfacial tension, γ for 1-MBI dropped gradually with an increase in the concentration, C_{org}. However, such a change was not observed in quinoxaline (QX). Figure 1 shows the plot of γ at -0.5 V against log C_{org} with respect to 1-MBI and QX. The surface excess, Γ can be obtained by a differentiation of the above plot

$$(\partial\gamma/\partial \ln C_{org})_E = -RT\Gamma. \quad (1)$$

The interfacial tension for QX was nearly constant up to 1 mM, but fell abruptly beyond 2 mM, and then gradually at more than 5 mM. The surface excess obtained from the constant slope at higher concentrations is considered to be a saturated value of the surface excess, Γ_s. These values were 3.4×10^{-10} mol cm^{-2} for 1-MBI and 2.9×10^{-10} mol cm^{-1} for QX, which are in fair agreement with 2.9—3.0×10^{-10} mol cm^{-2} estimated from the projected areas assuming a horizontal orientation for both compounds, though somewhat large with 1-MBI.

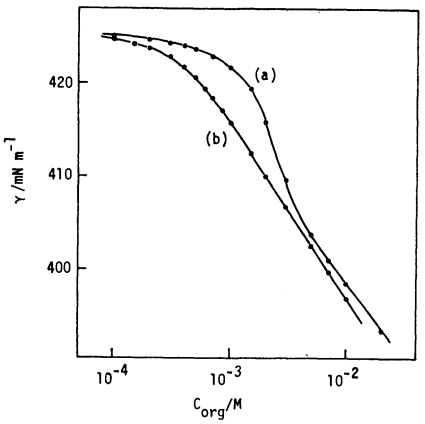

Fig. 1. Plot of γ at -0.5 V against log C_{org} for quinoxaline (a) and 1-methylbenzimidazole (b).

The relation for QX in Fig. 1 is similar to that in the presence of a diffusion limit, which was observed in the interfacial tension measurement due to drop time.[22] However, the concentration of 10^{-3} M where γ changes abruptly, is considered to be higher than that of 10^{-4} M observed for the diffusion limit. Probably, micelle formation[23] or polymeric aggregate formation due to an interaction with water molecules seems to be the cause.

Evaluation of Γ_s. The valuation of Γ_s is necessary to elucidate the adsorption state qualitatively. When adsorption can be described by a Langmuir isotherm, Γ_s is evaluated from the slope of the plot of x/Γ against x, where x is the molar fraction. If this is not the case, Γ_s can be evaluated simply from the extrapolation of the plot of $1/C_{org}$ against $1/\Gamma$ to $1/C_{org}=0$. From the nature of this plot, Γ_s obtained in this way reflects Γ_s at higher surface excesses. Therefore, the validity of the Γ_s at Γ_s should be confirmed by a fit to the isotherm molecular model.

The values of Γ_s evaluated by the above simple method are shown in Fig. 2 for 1-MI and 1-MBI. Various orientation parameters expected for 1-MI and 1-MBI were estimated using the CPK molecular model; these are shown in Fig. 3 for 1-MI and in Fig. 4 for

1-MBI. The paramenters obtained for a horizontal and a vertical orientation are summarized in Table 2.

Surface Excess. Figures 5 and 6 show the relations between Γ and surface change density σ with respect to 1-MI and 1-MBI, respectively. The broken line in Fig. 5 is the result for 0.2 M imidazole[12] obtained previously. Adsorption behavior of 1-MI is somewhat similar to that of imidazole at positive charges, but at negative charges it is quite different. From the results in Fig. 2 and Table 2, 1-MI is considered to take a horizontal orientation at lower surface excesses, but change to a vertical orientation at higher surface excesses, owing to the large dipole moment[24] and the absence of the intermolecular association.[15]

The difference in the adsorption behavior of imidazole and 1-MI supports the previous consideration[12] that imidazole adsorbs in an aggregate form. On the other hand, the adsorbability of 1-MBI is similar to that of imidazole, as can be seen from Fig. 6. This result also supports the formation of aggregate for imidazole, whose structure resembles that of 1-MBI with a large π-electron system and planarity.

Potential Drop across the Inner Layer, $\Delta_2^M\phi$. Figures 7 and 8 show the relations between $\Delta_2^M\phi$ at constant charge and Γ, with respect to 1-MI and 1-MBI, respectively. The values of $\Delta_2^M\phi$ were determined by the following equation

$$\Delta_2^M\phi = E - E_z - \phi_2, \qquad (2)$$

where E is the measured potential against NCE, E_z is the potential of zero charge obtained in the electrolyte without specific adsorption of ions (−0.472 V *vs.* NCE[25]), and ϕ_2 is the potential drop ascross the diffuse layer, which was determined using the Gouy-Chapman theory.[26]

The results in Fig. 7 also show that 1-MI changes its orientation from horizontal to vertical above a certain value of Γ. The change in the slope indicates that 1-MI at negative charges takes a vertical orientation with the positive pole of the dipole toward the electrode, but at positive charges it takes a vertical orientation with the

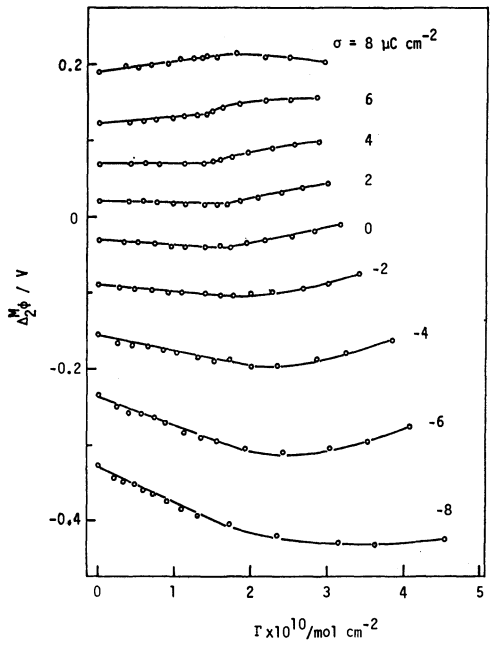

Fig. 7. Change in $\Delta_2^M\phi$ due to adsorption of 1-methylimidazole. Charge densities are indicated by each line.

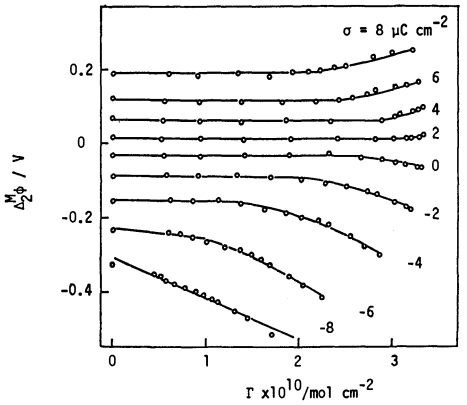

Fig. 8. Change in $\Delta_2^M\phi$ due to adsorption of 1-methylbenzimidazole. Charge densities are indicated by each line.

negative pole of the dipole towards the solution side.

The results in Fig. 8 show the presence of the region where $\Delta_2^M\phi$ does not change due to adsorption of 1-MBI, especially in $\sigma \geq -2\ \mu C\ cm^{-2}$. This is similar to the results obtained in imidazole.[12] In general, organic compounds without a net dipole moment, such as pyrazine, exhibit a constant $\Delta_2^M\phi$ around $\sigma = -4\ \mu C\ cm^{-2}$,[27] where the orientation of water molecules on the electrode becomes most disordered, they show linear lines with a positive or negative slope at more positive or negative charges than -2——$4\ \mu C\ cm^{-2}$, respectively. An example is shown in Fig. 9 for pyrazine. This was obtained in the previous experiment[12] and was nearly same as that reported by Conway *et al.*[28]

The anomalous adsorption behavior of 1-MBI appears to result from an adsorption without displacement of the adsorbed water molecules. However, such an adsorption seems to be unreasonable, because

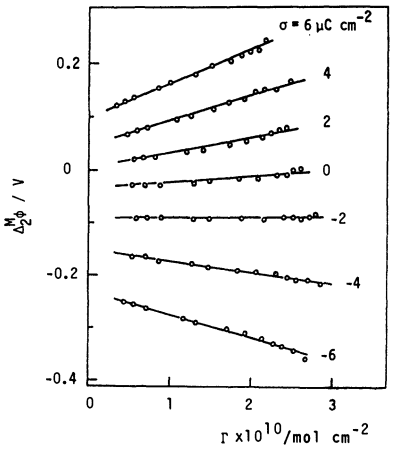

Fig. 9. Change in $\Delta_2^M\phi$ due to adsorption of pyrazine. Charge densities are indicated by each line.

adsorption due to the displacement of water actually occurs at fairly negative charges, as can be seen from Fig. 8; generally organic compounds without a net dipole moment adsorb strongly at low electric fields. This behavior of 1-MBI will be discussed precisely in the following sections.

The constancy of $\Delta_2^M\phi$ disappeared at higher surface excesses. The cause is not clear at the present time. However, note the following: (1) Γ_s of 1-MBI at the holizontal orientation was estimated from the projected area to be 3.0×10^{-10} mol cm^{-2}, which is somewhat smaller than that of 3.4×10^{-10} mol cm^{-2} determined from the experiment. A vertical orientation contributing to a change in $\Delta_2^M\phi$ through the dipole moment will be mixed with the horizontal orientation at higher surface excesses. (2) Specifically adsorbed perchlorate ions will be desorbed at higher surface excesses.

The Adsorption Isotherm and Free Energy of Adsorption. The determination of the adsorption isotherm and the free energy of adsorption at infinite dilution, $\Delta\bar{G}^\circ$, was carried out in the region where the change in the orientation was considered to be negligible, namely at lower surface excesses for 1-MI and that showed a constant $\Delta_2^M\phi$ for 1-MBI.

By examining a fit to various isotherms, 1-MI and 1-MBI were found to obey the Langmuir (Fig. 10) and the Frumkin isotherm (Fig. 11) with $\Gamma_s = 3.0\times10^{-10}$

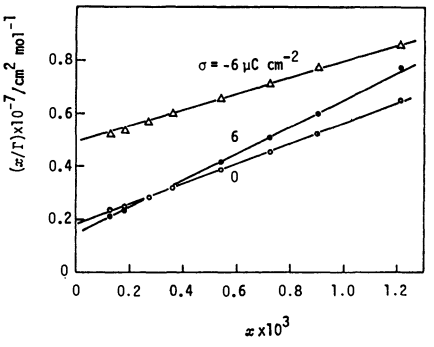

Fig. 10. Test of the Langmuir isotherm for adsorption of 1-methylimidazole at various charge densities. Charges are indicated by each line.

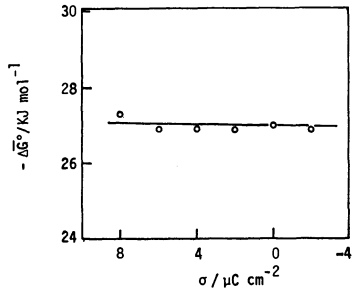

Fig. 13. Variation of $\Delta\bar{G}^\circ$ for 1-methylbenzimidazole due to surface charge density.

mol cm^{-2} and the interaction parameter $2a=2.5$, respectively.

Γ_s and $\Delta\bar{G}^\circ$ obtained for 1-MI are shown in Fig. 12. $-\Delta\bar{G}^\circ$ was increased with an increase in the surface charge, and the maximum was observed at highly positive charges. This behavior is typical to that of organic compounds with π-electrons. On the other hand, $\Delta\bar{G}^\circ$ for 1-MBI was charge independent, as shown in Fig. 13. If the isotherms are congruent to charge the slopes of linear lines in Fig. 8 are related to the change in $\Delta\bar{G}^\circ$ due to surface charge[29]

$$(\partial\Delta_2^M\phi/\partial\theta) = -RT\Gamma_s(\partial \ln\beta/\partial\sigma), \quad (3)$$

where $\beta=\exp(-\Delta\bar{G}^\circ/RT)$. Since both $(\partial\Delta_2^M\phi/\partial\theta)$ and $(\partial\ln\beta/\partial\sigma)$ are nearly zero, Eq. 3 is set up for adsorption of 1-MBI. This indicates that the experimental results are reliable and the final picture is consistent.

Quantitative Interpretation of Adsorption. From the fit to the adsorption isotherm, the horizontal orientation was approximately confirmed for both 1-MI and 1-MBI at lower surface excesses. Further to verify this, evaluation of the dipole moment at the adsorbed state was made at $\sigma=0$ μC cm^{-2}, to simplify the calculation.

In general, if the adsorption of an organic compound is charge congruent, the change in $\Delta_2^M\phi$ can be described by the following equation[30]

$$\Delta(\Delta_2^M\phi)/\theta = (\Gamma_sP_1/\varepsilon_1-\Gamma_snP_0/\varepsilon_0) + \sigma(1/C_1-1/C_0), \quad (4)$$

where P, ε, and C are the effective normal dipole moment, the permittivity of the inner layer and the inner layer capacity, respectively, n is the number of water molecules displaced by adsorption of one adsorbate molecule, and subscripts 1 and 0 denote the surface layer saturated with the adsorbate and water. The potential drop due to water dipoles, Δg^w_{dipole} can be represented by Eq. 5

$$\Delta g^w_{dipole} = -\Gamma_snP_0/\varepsilon_0. \quad (5)$$

The ε_1 can be obtained from C_1 using the relation, $C_1=\varepsilon_1/d_1$, where d_1 is the thickness of the adsorption layer. Further, the values of C_1 can be obtained by the extrapolation of the linear relation between $1/C^i$ and Γ at $\sigma=0$ μC cm^{-2}, as shown in Fig. 14, to the corresponding to Γ_s. They were 32.5 μF cm^{-2} for 1-MI and 40.0 μF cm^{-2} for 1-MBI.

One can obtain 30 mV as Δg^w_{dipole} at $\sigma=0$ μC cm^{-2} from Bockris and Habib's water adsorption model,[31] and 3.4 Å as d_1 from Table 2, and -20 mV for 1-MI and -13 mV for 1-MBI as $\Delta(\Delta_2^M\phi)/\theta$ from Figs. 7 and 8. By introducing the above values into Eq. 4, the effective normal dipole moment at $\sigma=0$ μC cm^{-2}, P_1 was found to be -1.1 Debye for 1-MI and -1.0 Debye for 1-MBI. The negative value of P_1 means an orientation with the negative pole of the dipole of the adsorbate toward the electrode. However, the above values seem to be too large, compared with the value

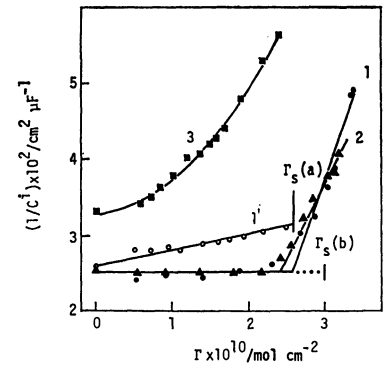

Fig. 14. Plot of $1/C^i$ against Γ at various charge densities. Open and closed symbols correspond to 1-methylimidazole and 1-methylbenzimidazole, respectively. Charge density in μC cm^{-2}: (1) and (1′) 0, (2) 6 and (3) -6. Γ_s (a) and Γ_s (b) represent Γ_s of 1-methylimidazole and 1-methylbenzimidazole at the horizontal orientation, respectively.

expected for the horizontal orientation, $P_1=0$ Debye, The cause of the large negative values is probably the presence of the specifically adsorbed perchlorate anions, which contribute to the negative dipole moment. Therefore, the effect of the specific adsorption of perchlorate anion was taken into consideration in the calculation of the true P_1. In this calculation, the data obtained by Payne[32] in the mixed solution of 0.1 M NH_4ClO_4 and 0.9 M NH_4F was used. The procedures are as follows: (i) If the specific adsorption of ClO_4^- is deducted, $\Delta_2^M\phi$ shifts towards a positive direction by 31 mV, which is the difference between $\Delta_2^M\phi$ at $\sigma=0$ μC cm^{-2} in the base solution of 0.099 M $NaClO_4$+ 0.001 M NaOH, -0.031 V and that in the 0.1 M NaF,[33] 0 V. (ii) In the absence of the specific adsorption of ClO_4^-, true surface charge density at -0.504 V. which is the p.z.c for the base solution, can be estimated to be -0.64 μC cm^{-2} from the result on 0.1 M NaF,[33] then Δg^{w}_{dipole} at that charge amounts to 24 mV.[31] (iii) True value of C_1, C_1^t is given by the following relation derived using the data of Payne[32]

$$1/C_1^t = 1/C_1^a + 4.73\times10^{-3}, \quad (6)$$

where C_1^a is the apparent value of C_1 in the presence of specifically adsorbed perchlorate ions. After the above treatment, the true P_1 was calculated to be -0.2 Debye for 1-MI and -0.1 Debye for 1-MBI. These values are reasonable for the horizontal orientation.

Electrosorption Valency.[11] It was discussed on the basis of the electrosorption valency whether the constancy of $\Delta_2^M\phi$ observed clearly in 1-MBI results from a partial charge transfer or not. Figure 15 shows a change in σ at constant $\Delta_2^M\phi$ due to adsorption of 1-MBI. The electrosorption valency, r is defined by Eq. 7

$$r = (1/F)(\partial\sigma/\partial\Gamma)_{\Delta_2^M\phi}, \quad (7)$$

where F is the Faraday constant. Further, r at $\Delta_2^M\phi=0$, r_N is represented by Eq. 8 with respect to neutral organic compounds

$$r_N = -\lambda(1-g) + K^{ad} - nK^w, \quad (8)$$

where λ is the partial charge transfer coefficient, g is the geometric factor defined as $(X_o-X_a)/X_0$, X_o, and X_a are the distance of the outer Helmholtz plane and the adsorption plane from the electrode, respectively, K_{ad} and K_w are the dipole terms of the adsorbate and water, and n is the same as used in Eq. 4. The value of r is plotted as a function of $\Delta_2^M\phi$ in Fig. 16, from which r_N was estimated to be 0.0035.

As can be seen from Fig. 14, and as Eq. 4 and the result in Fig. 8 predict, C_1 and C_0 for 1-MBI are nearly equal in the region where the constancy of $\Delta_2^M\phi$ is observed. This implies compensation between $(\Gamma_s P_1/\varepsilon_1)$ and $(-\Gamma_s n P_0/\varepsilon_0)$. Therefore, $(K_{ad}-nK_w)$ in Eq. 8 becomes also zero. If X_o and X_a can be represented by the sum of d_1 and the ionic radius of Na^+(0.96 Å), and the half of d_1, respectively, g is calculated to be 0.61. Finally one obtains λ near 0.01. However, this value is too small to be considered a partial charge transfer between the electrode and the adsorbed 1-MBI molecules.

What is the compensation between $(\Gamma_s P_1/\varepsilon_1)$ and $(-\Gamma_s n P_0/\varepsilon_0)$? If this effect results from a partial charge transfer, it corresponds to the increased negative dipole moment or charge in 1-MBI. That means the partial electron transfer from the electrode to the adsorbed 1-MBI molecules. Since the compensation is observed even at fairly positive charges, the above deduction is hard to accept. The most reasonable consideration will be an electronic polarization effect. Thus, the dipole moment of 1-MBI induced in the electric field compensates for the dipole moment of the water molecules displaced. Further, this effect is valid at positive charges and seems to disappear at highly negative electric field because of increased repulsion between π-electrons and the negative charges on the electrode surface.

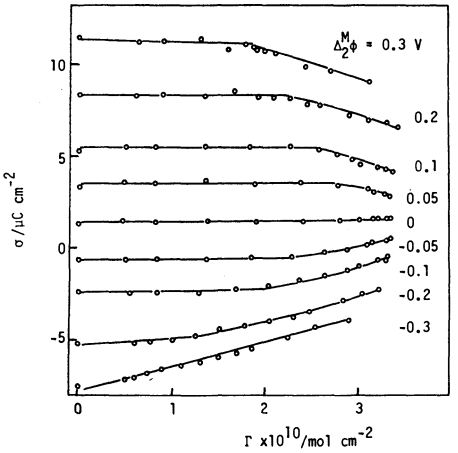

Fig. 15. Change in σ at constant $\Delta_2^M\phi$ due to adsorption of 1-methylbenzimidazole. The values of $\Delta_2^M\phi$ are indicated by each line.

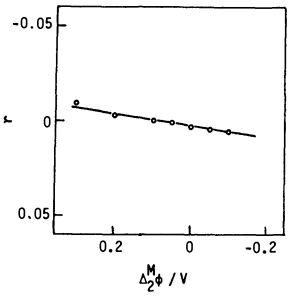

Fig. 16. Variation of electrosorption valency due to $\Delta_2^M\phi$.

The compensation effect observed in this study correlates with the constant adsorbability in positive charges. Such an adsorbability was clearly observed for heterocycles classified into π-excessive type, for example 1-MI and 1-MBI in this study, and imidazole and pyrazole,[12] but not so clearly observed for those classified into π-deficient type, for example pyrazine, pyrimidine and pyridazine.[12] These results are also considered to support the compensation effect observed in 1-MBI which has easily polarizable π-electrons. Recently, King *et al.*[34] explained the enormous intensity enhancement observed for Raman scattering from pyridine adsorbed on the electrode on the basis of a classical electrostatic theory, namely electronic polarization.

"Macromolecular Ion Flotation" of MnO_4^- by Combined Use of Macromolecular Anion and Cationic Surfactant

Tsunetaka SASAKI,* Kiyoo MATSUBARA, and Ikuko MACHIDA

Department of Chemistry, Faculty of Science, Tokai University, 1117 Kitakaname, Hiratsuka 259-12

(Received March 26, 1981)

MnO_4^- ions in aqueous solution were subjected to macromolecular ion flotation, a process of flotation applied for an aqueous solution containing organic or inorganic ions to be floated, macromolecular ions including macroscopic or colloidal particles with an ion exchange capacity and polymer ions, and oppositely charged ionic surfactant. The macromolecular anions examined were basic aluminum chloride, polyaluminum chloride, carboxymethylcellulose, sodium polyacrylate, sodium alginate, potassium poly(vinyl sulfate), sodium hexametaphosphate, polyphosphoric acid, polyacrylic acid, bentonite, and sodium metasilicate. As a cationic surfactant, hexadecyltrimethylammonium chloride was used. All the above substances are effective for the MnO_4^- ion flotation, whereas low molecular substances such as Na_3PO_4 are ineffective, when used with the cationic surfactant. Molecular models of sublate formed during the macromolecular ion flotation are proposed.

In our prevous papers,[1-2] we have confirmed that combined use of macromolecular or polymer anions, such as bentonite and silicate ions, with a cationic surfactant is effective for the flotation of both organic and inorganic anions and cations. The purpose of the present investigation is to examine whether or not macromolecular anions, including both macroscopic or colloidal particles with cation exchange capacity and polymer anions, are in general effective for ion flotation when used in combination with a cationic surfactant.

MnO_4^- ions were adopted as the ions to be subjected to flotation. The macromolecular ions tested were aluminum chloride ($AlCl_3$) and polyaluminum chloride ($PAlCl_3$) in basic solution, carboxymethylcellulose (CMC), sodium polyacrylate (NaPA), sodium alginate (NaAlg), potassium poly(vinyl sulfate) (KPVS), sodium hexametaphosphate (NaHMP), polyphosphoric acid (PPA), polyacrylic acid (PAA), bentonite (Bt), and sodium metasilicate (NaMS); NaHMP and PPA, not high molecules, were adopted since they behave similarly to high polymer ions with respect to the flotation. The cationic surfactant tested was hexadecyltrimethylammonium chloride (HTAC) which had shown good floatability for both anions and cations.

Experimental

Materials. Commercial products of pure grade were used for $AlCl_3$ ($AlCl_3 \cdot 6H_2O$), $PAlCl_3$ ($AlCl_3 \cdot nAl_2O_3$, Al_2O_3 content 30 wt%), CMC (dp, 700—850), NaPA (dp, 22000—66000), NaAlg (relative viscosity, 15.67 at 30 °C), KPVS (dp, 1500), NaHMP ($[NaPO_3]_6$), PPA ($P_6O_4H_{13}$), PAA (dp, 8000—12000), Bt (montmorillonite), NaMS ($Na_2SiO_3 \cdot 9H_2O$), trisodium phosphate (TNaP), and potassium permanganate.

Measurement. The concentration of silicate ions was measured colorimetrically at the wavelength 450 nm[3] from the color developed by adding an aqueous solution of ammonium molybdate to a sample liquor. The concentration of permanganate ions was determined by the usual titrimetric method using a solution of sodium oxalate. The concentration of each of the remainder was determined by dissolving its known amount of dried substance in water; concentration of $PAlCl_3$ could not be determined accurately due to its Al_2O_3 content indicated 30 wt%, being qualitative.

The solution to be subjected to flotation processing was prepared to contain MnO_4^- ions at a constant concentration around 1.6×10^{-4} mol dm^{-3}, proper amounts of one or some macromolecular ions and HTAC, a small amount of NaPA if necessay, and HCl or NaOH for pH control when needed. A volume (12 cm^3 for the systems of Table 1 and 10 cm^3 for the other systems) of the solution thus prepared was put into a stoppered test tube, 1.6 cm in inner diameter and 19 cm in engths, equipped with a stop cock at its bottom. It was slowly mixed and kept standing for 1 min, then vigorously shaken by hand to float MnO_4^- ions. After 5 min of standing, the lower portion was taken out and its MnO_4^- concentration was measured by use of a Shimazu Model Spectronic-20 spectrophotometer at wavelength 525 nm; the specific absorbance had been confirmed to be independent of the pH range 1—11 at this wavelength. The floatability of MnO_4^- ions was calculated from the difference between concentrations before and after the flotation processing on MnO_4^- ions.

Results and Discussion

Table 1 shows results of preliminary measurements on the MnO_4^- ion flotation by the combined use of macromolecular ions and HTAC. In these measurements, the concentration of MnO_4^- ions was kept constant at 1.59×10^{-4} mol dm^{-3} in average. The concentrations of macromolecular ions and HTAC are not necessarily for the optimum flotation condition; Table 1 is compiled

Table 1. Macromolecular ion flotation of MnO_4^-

Macromolecule		HTAC	NaPA	pH	Floatability/%
Substance	Concn / ppm	Concn / ppm	Concn / ppm		
$AlCl_3$	996	55	1.67	9.8[a]	87
$PAlCl_3$	548	55	1.67	9.8[a]	88
CMC	666	833	—	6.3	100
NaPA	388	809	—	1.5[b]	98
NaAlg	1667	2447	—	6.8	98
KPVS	898	1691	—	1.1[b]	100
NaHMP	2196	3306	—	1.5[b]	100
PPA	10670	826	—	1.3	99
PAA	4514	1664	—	2.3	90
Bt	5839	662	—	8.8	100
NaMS	1314	500	—	11.2	98

merely to show a possibility of effective ion flotatition of MnO_4^- by combined use of macromolecular anions and cationic surfactant. As seen from Table 1, many macromolecular anions, when used with HTAC, are effective for the flotation of MnO_4^- ions, whereas low molecular electrolytes were found ineffective for that flotation, as exemplified by as low a floatability as 46% which TNaP showed at pH 1.1 (not indicated in Table 1). On the basis of this finding, the present authors propose the term "Macromolecular ion flotation" for such flotations as are effected by use of macromolecular or polymer ions and ionic surfactants both carrying charges opposite to each other; the present investigation has dealt with a case of combination of macromolecular anions with an cationic surfactant and the preceding paper[4] reported a case of effective use of poly(ethyleneimine) (cationic macromolecule) and sodium dodecyl sulfate (anionic surfactant).

For several systems in Table 1, flotation of MnO_4^- ions was studied in dedail by varying the ratio of macromolecular anions to HTAC and their total amount while the concentration of MnO_4^- ions was kept constant. The results obtained are shown in Figs. 1 to 5 for NaHMP+HTAC+HCl, Bt+HTAC, NaPA+HTAC+HCl, NaAlg+HTAC, and CMC+HTAC systems, respectively, each of which was treated similarly

to the NaMS+HTAC system already reported.[1] In each solution studied, the concentration of MnO_4^- ions and pH are given in the caption of each figure. In these diagrams, the floatability of the system is greater than 95% in the areas inside the curves. Thus we can confirm wide ranges of composition to be effective for ion flotation for the systems of Figs. 1 and 3, while we note narrow vertical ranges of the effective ion flotation, and only a small region for the system of Fig. 4. For the cases of Figs. 2 and 5, a nearly constant weight ratio of macromolecular ions to surfactant may be expected for the sublate composition, similarly to the case of NaMS+HTAC system already reported.[1]

To get the pH dependence of flotation efficiency of MnO_4^- ions, a study was made on the systems of NaMS+HTAC,** NaAlg+HTAC, NaPA+HTAC+HCl, and NaHMP+HTAC. The initial pH of solution was controlled by addition of HCl or NaOH. The results are shown in Figs. 6 to 9, where as a whole, floatabilities are seen to exceed 90% over a wide pH range, especially in acidic regions for the NaPA and NaHMP systems, attaining nearly 100%.

It is confirmed from the above results that the composition and total concentration of the set of macromolecular ions and surfactant as well as the pH of solution are important factors affecting the floatabiitly

** The corresponding composition diagram has been shown in the preceding paper.[1]

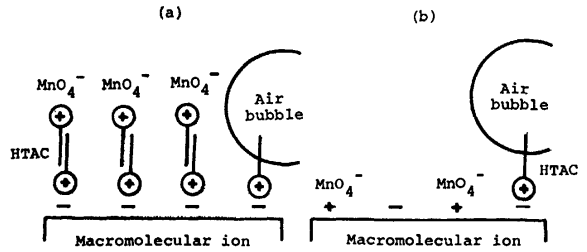

Fig. 10. Sublate structures of MnO_4^-+macromolecular ion+HTAC.
(a): The case of macromolecular anion, (b): the case of macromolecular ampholyte.

of MnO_4^- ions. In addition, it is noted that, although the NaPA+HTAC+HCl system is capable of effective MnO_4^- flotation in an acidic region, the system PAA with HTAC is not so effective at pH 2.3 as shown in Table 1. The reason is not clear at present, but it may be due to the different order of adding the flotation reagent, namely, in the former case, PAA is formed by the acidification after the reaction of NaPA with HTAC, while in the latter case, PAA is added without NaPA and this makes difficult the attachment of hexadecyltrimethylammonium ion to polyacrylate chain. These phenomena are similar to those observed in the case[1] of MnO_4^- ion flotation by NaMS and HTAC where the order of adding NaMS and HTAC sensitively affects the floatability.

A probable model of MnO_4^- sublate is given in Fig. 10a, which has already been proposed in the case of macromolecular anions.[1] On the other hand, for the case of ampholyte polymers like $AlCl_3$ and $PAlCl_3$ in alkaline solution, the model shown in Fig. 10b is applicable since it is in conformity with the observation, given in Table 1, that HTAC in less quantity than in the case of other macromolecular anions is capable of resulting in effective MnO_4^- flotation.

Corrosion Inhibition and Adsorption Behavior of Some Thioamides on Mild Steel in Sulfuric Acid

Badr G. Ateya,*,† B. E. El-Anadouli, and F. M. A. El-Nizamy
Chemistry Department, Faculty of Science, Cairo University, Cairo, Egypt
(Received June 20, 1980)

The objective of this work was to evalulate the effect of changing functional and structural groups on the protection efficiency imparted by the various inhibitor molecules. It was found that the molecules which include a thiocarbonyl group *e.g.* thiourea (TU), thioacetamide (TA), and thiosemicarbazide (TSC) exhibited much higher protection efficiencies than the corresponding compounds which do not *e.g.* semicarbazide, guanidine, and aminoguanidine. Furthermore, it made only little difference whether the thiocarbonyl group was attached to two amino groups as in thiourea, an amino and a methyl group as in thioacetamide or an amino and a methyl group as in thioacetamide above certain concentrations both TU and TA lose their efficiency and eventually become corrosion promotors. The adsorption behavior of TU and TA was quist complicated whereas that of TSC points towards complete coverage at high concentrations. The differences in behaviour between TSC, TU, and TA have been explained on the basis of delocalization or resonance stabilization energy.

The use of organic compounds as inhibitors for the aqueous corrosion of metals dates back several hundred years. A large number of such compounds has been developed to suit various applications. The diversity of these compounds and their applications, as well as the sheer volume of the pertinent literature, are quite evident in a classical review in the corrosion handbook[1] which was published in 1947.

This area is still attracting considerable attention in efforts to obtain more efficient inhibitors and to further the understanding of the mechanisms involved in the corrosion and inhibition processes. The work published in the last thirty years is quite extensive and is directed more towards understanding the effect of inhibitors on the kinetics of the half-cell reactions. Some of this work has already been reviewed.[2-4]

The relationship between the structure of the inhibitor molecule and its efficiency has been the subject of several investigations.[5-16] On the other hand, much less attention has been paid to the dependence of the protection efficiency on the size and the electronic distribution in the inhibitor molecule. This is an important question especially for sulfur-containing compounds *e. g.* thioamides (–CS–NH_2), many of which have been found to be good inhibitors. In this connection, several questions may be asked, for example; what is the effect on the protection efficiency of replacing the amino group of thiourea by a methyl group ? or upon replacing the thiocarbamoyl group $\diagdown\!\!\!\!\diagup C{=}S$ by either a carbonyl or carbonimidoyl group $\diagdown\!\!\!\!\diagup C{=}NH$? What is the effect of the above changes on the degree of surface converage and the mechanism of adsorption? The objective of this work is to answer some of the above questions by experimental measurements.

Experimental

The system chosen for this study is the acid corrosion of mild steel. Several organic compounds have been chosen for the purpose of this work. Table 1 lists these compounds. The main criterion for their selection was to provide a number of variables *e. g.* effect of a $\diagdown\!\!\!\!\diagup C{=}S$ as against $\diagdown\!\!\!\!\diagup C{=}NH$ or $\diagdown\!\!\!\!\diagup C{=}O$ substitution of an $-NH_2$ by a $-CH_3$ group or by the hydra zino group $-NH\cdot NH_2$.

Table 1. Molecular structures and abbreviations of the inhibitors used

Compound	Abbreviation	Molecular formula
Thiourea	TU	$H_2N-\overset{\overset{S}{\|}}{C}-NH_2$
Thioacetamide	TA	$CH_3-\overset{\overset{S}{\|}}{C}-NH_2$
Thiosemiearbazide	TSC	$NH_2-NH-\overset{\overset{S}{\|}}{C}-NH_2$
Semicarbazide	SC	$NH_2-NH-\overset{\overset{O}{\|}}{C}-NH_2$
Urea	U	$H_2N-\overset{\overset{O}{\|}}{C}-NH_2$
Guanidine	G	$H_2N-\overset{\overset{NH}{\|}}{C}-NH_2$
Aminoguanidine	AG	$H_2N-NH-\overset{\overset{NH}{\|}}{C}-NH_2$

The experimental approach taken here was to evaluate the effect of the inhibitors on the overall corrosion rate, and on the rate of the hydrogen evolution reaction (h.e.r.) at different inhibitor concentrations. This was done using the steady state galvanostatic technique. From these results, the protection efficiency of the inhibitor and the degree of coverage of the metal surface was calculated. Details of the experimental procedure, cell design, electrode preparation, pre-electrolysis....*etc.* were given elsewhere.[17] The composition of the mild steel electrode was 0.08% C, 0.44% Mn, and trace amounts of both S and P. The temperature was adjusted to 30±0.1 °C using an air thermostat. The electrolyte was 1.0 mol dm^{-3} H_2SO_4. The compounds used as inhibitors were of the highest purity available.

Results and Discussion

Effect of Inhibitor Concentration. Figures 1a, 1b, and 1c show the effect of the concentrations of TSC,

† Present address: Faculty of Science, University of the United Arab Emirates, Al-Ain, Abu Dhabi, United Arab Emirates.

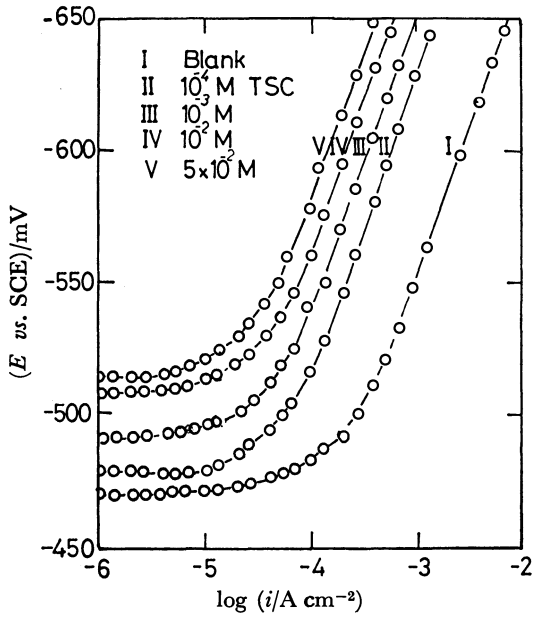

Fig. 1a. Effect of the concentration of thiosemicarbazide on the cathodic polarization curves of mild steel in 10 mol dm^{-3} H_2SO_4 at 30 °C.

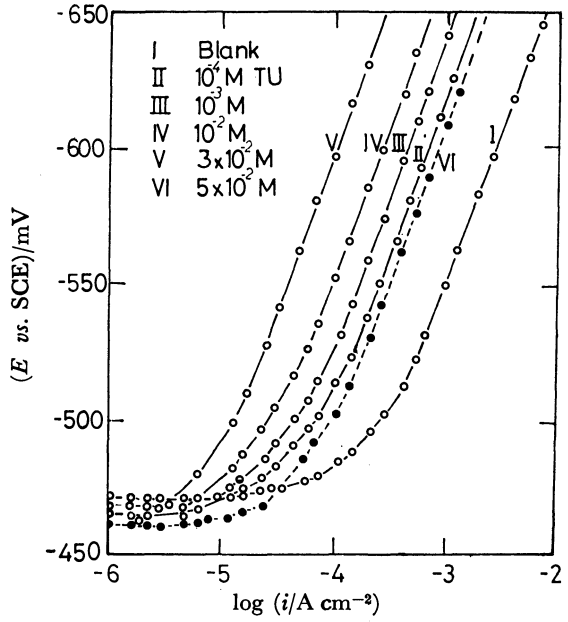

Fig. 1b. Effect of the concentration of thiourea on the cathodic polarization curves of mild steel in 1.0 mol dm^{-3} H_2SO_4 at 30 °C.

TU, and TA on the current-potential relations of hydrogen evolution on mild steel in 1.0 mol dm^{-3} H_2SO_4 at 30 °C. Clearly the concentrations of TSC, TU, and TA have a strong effect on the current-potential relations. Thus as their concentrations increase, it is seen that:

1) In case of TSC, the electrode potential at low current densities and the corrosion potential were shifted in the cathodic direction by about 10 to 40 mV, while in the cases of both TU and TA, the shifts were smaller in magnitude and in the anodic direction.

2) They caused large bodily shifts of the Tafel lines

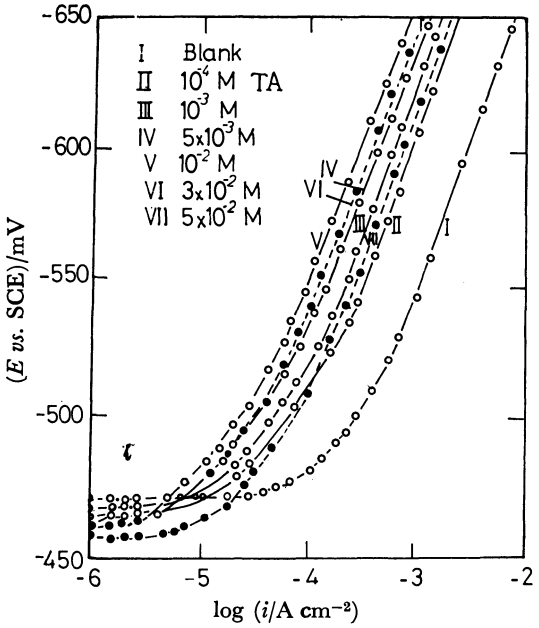

Fig. 1c. Effect of the concentration of thioacetamide on the cathodic polarization curves of mild steel in 1.0 mol dm^{-3} H_2SO_4 at 30 °C.

in the cathodic direction. In the case of TSC, the Tafel lines were shifted by 70 to 140 mV depending on the TSC concentration over the entire range. In the case of TU and TA, the magnitude of this shift also depended on their concentrations, only up to a critical value above which TU and TA became much less efficient (see below).

3) The Tafel slopes were approximately constant independent of inhibitor concentration.

The above two effects (2 and 3) indicate that TSC, TU, and TA have significant inhibiting effects on the hydrogen evolution reaction. From the Tafel slope, the transfer coefficient of the hydrogen evolution reaction is calculated to be $\beta=0.51$ which agrees with the generally accepted values.[18,19] The constancy of the cathodic transfer coefficient β in the presence and in the absence of the inhibitors indicates that their adsorption in the double layer does not change the mechanism of the hydrogen evolution reaction even though they significantly reduce its rate. This suggests that these inhibitors operate *via* a blocking adsorption mechanism.

It is recognized that the inhibitors which shift the entire current-potential curves in the cathodic direction are cathodic inhibitors, while those which shift them in the anodic direction are anodic inhibitors.[20] On the other hand, the inhibitors of the type of the mixed control shift the cathodic Tafel lines towards more cathodic potentials and the current-potential curves near the free corrosion potential towards less cathodic potentials. On the basis, TSC is characterized as a purely cathodic inhibitor while TU and TA exhibit dual inhibiting action, *i. e.* they inhibit both the cathodic and the anodic reactions, although to varying degrees.

Adsorption Behavior. The degree of surface coverage can be calculated from the currents obtained at constant potential in presence (i_2) and in absence (i_1) of inhibitor.[21,22] Thus

$$\theta = 1 - i_2/i_1. \quad (1)$$

Alternatively, the degree of coverage can be obtained at constant current.[23,24] Thus

$$\theta = 1 \exp(\beta\Delta\varepsilon/b), \quad (2)$$

where B is the transfer coefficient, $\Delta E = E_{inh} - E_{blank}$ is the difference between the electrode potential in the inhibited solution and that in the blank solution, and $b = RT/F$. Under the present conditions, Eqs. 1 and 2 gave virtually identical results.

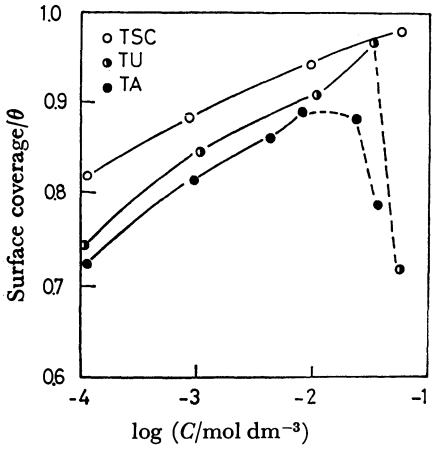

Fig. 2. Effect of inhibitor concentration on the surface coverage at 30 °C for mild steel in 1.0 mol dm^{-3} H_2SO_4.

Figure 2 shows the effect of inhibitor concentrations on coverage of the electrode surface. TSC is the only compound which displays a simple behavior over the tested concentration range. Its behavior points to the tendency to form a monolayer of adsorbed TSC. Both TU and TA undergo an apparent loss in the degree of surface coverage above certain concentrations. It is evident that at a certain inhibitor concentration, the tendency for adsorption is in the order TSC>TU>TA (see below).

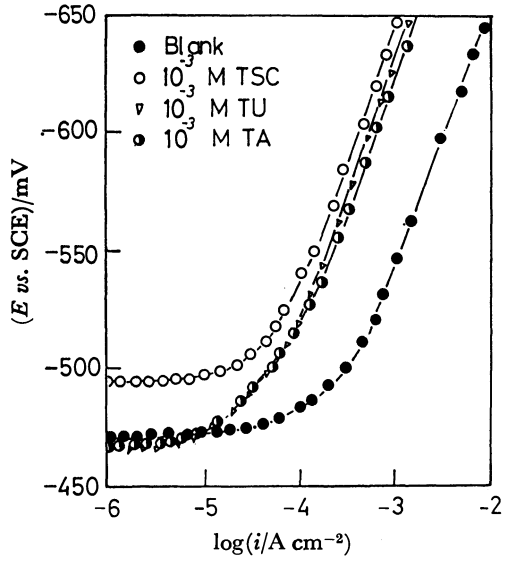

Fig. 3. Effect of the structure of molecules on the cathodic polarization curves of mild steel in 1.0 mol dm^{-3} H_2SO_4.

Effect of the Structure of the Inhibitor Molecule. Figure 3 shows a comparison of the cathodic polarization relations in the presence of TSC, TU, and TA at a concentration of 10^{-3} mol dm^{-3}. Clearly the differences among these compounds are not too large. The inhibiting effect of these compounds on the h.e.r. is in the order TSC>TU>TA as evident by the extent of the shift in Tafel lines in the cathodic direction. Alternatively, Fig. 4 shows the effect of the functional group on the current-potential relations for TSC, SC, and AG at a concentration of 10^{-2} mol dm^{-3}. Clearly aminoguanindine (AG) is a slightly better inhibitor than SC but TSC is far more efficient than both. The above evidence indicates that the inhibiting action of the compounds is mainly imparted by the thiocarbonyl group.

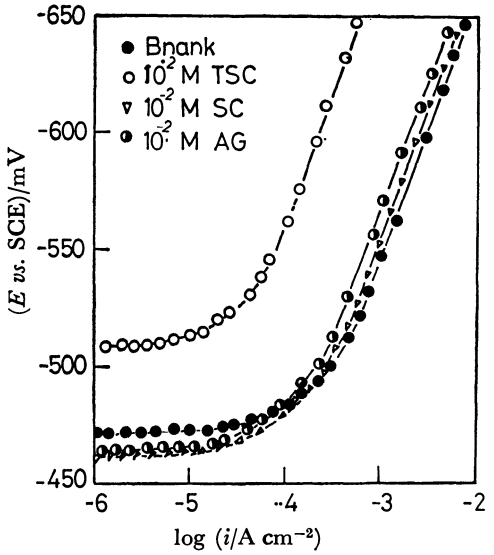

Fig. 4. Effect of TSC and AG molecules on the cathodic polarization curves of mild steel in 1.0 mol dm^{-3} H_2SO_4.

Table 2 shows the effect of TSC, TU, and TA concentrations on the exchange current density of hydrogen evolution i_0, corrosion current density i_{corr}, the protection efficiency, P, the degree of surface coverage θ and the polarization resistance R_p (see below). The protection efficiency is the parcent of relative decrease in the corrosion rate, given by

$$P(i_{corr}) = 100\left(1 - \frac{i_{corr}(\text{inhibited})}{i_{corr}(\text{blank})}\right). \quad (3)$$

The percent of relative decrease in the exchange current density is defined similarly.

The efficiency of a corrosion inhibitor may also be evaluated by measuring its effect on the polarization resistance which is defined by

$$R_p = \mathrm{d}(E - E_{corr})/\mathrm{d}i \quad \Omega\,cm^2, \quad (4)$$

where E and E_{corr} are in V and i in A cm^{-1}. Thus a plot of $(E - E_{corr})$ in the low polarization region, when $|E - E_{corr}| < 20$ mV, *vs.* current density i should give a straight line passing by the origin with a slope equal to the polarization resistance. Figure 5 shows such a

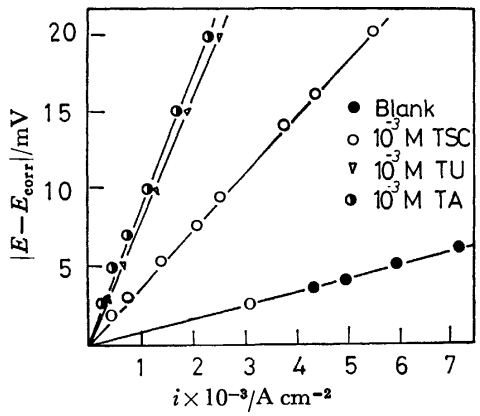

Fig. 5. The relationship between $|E-E_{corr}|$ and current density at low cathodoc polarization for mild steel in the presence of 10^3 mol dm^{-3} of each TSC, TU, and TA at 30 °C.

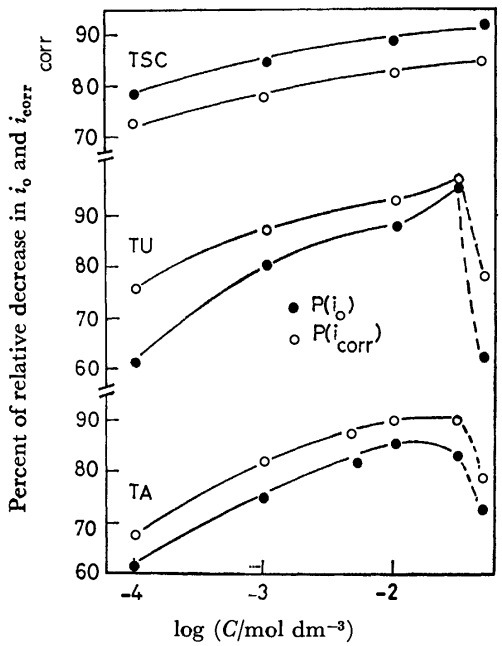

Fig. 6. Effect of inhibitor concentrations on the percent of relative decrease in i_o and i_{corr}.

plot for TSC, TU, and TA at a concentration of 10^{-3} mol dm^{-3} of each. Similar straight lines were obtained at various concentrations of each inhibitor (see Table 2).

Figure 6 shows a comparison between $P(i_{corr})$ and $P(i_0)$ for TSC, TU, and TA. It is seen that for TSC $p(i_0)>p(i_{corr})$ whereas for TU and TA $P(i_{corr})>P(i_0)$ over the entire concentration range. This indicates that for TU and TA the percentage decrease in corrosion rate is greater than the percentage decrease in the rate of the h.e.r. This can be true if the anodic reaction is also partially inhibited which supports the conclusions reached above, *viz.* that TU and TA are inhibitors of dual action.

From R_p calculations, as shown in Table 2, it is seen that for TSC the polarization resistance increases with inhibitor concentration over the indicated range. In the cases of TU and TA the polarization resistance increases with inhibitor or concentration up to a critical value above which TU and TA lose their inhibiting efficiency and eventually stimulate, rather than inhibit, corrosion. The value of this critical concentration at 30 °C is about 10^{-2} mol dm^{-3} in the case of TU and

about 3×10^{-2} mol dm^{-3} in the case of TA. Such a behaviour has not been observed with TSC up to a concentration of 5×10^{-2} mol dm^{-3}. Preliminary results suggest that this critical concentration is temperature dependent.

The reason for this behaviour of TU and TA is still in question. Thus whereas some workers[25,26] attribute it to the hydrolysis of TU to produce corrosion promoting species *e. g.* HS^- and S^{2-}, others[27,28] reported the disappearance of TU from the solution. The loss of TU in HNO_3 has been recently explained[2] by a scheme which involves its oxidation in solution followed by reduction at the metal surface. This scheme obviously cannot be applied in non-oxidizing acids *e. g.* HCl and H_2SO_4. On the other hand, the hydrolysis scheme cannot, as yet, be totally accepted since it is not clear why hydrolysis occurs to such an extent only in concentrated solutions and not in dilute ones. Determination of the equilibrium constant for such a reaction is required before a final judgement can be made with respect to this scheme.

Consideration of the Molecular Structure. The above results indicate that the order of the stability of the above thiocompounds in solution and the extent of their tendency to adsorb on, and hence protect, the iron surface are as follows: TSC>TU>TA$\gg$nonsulfur compounds. A qualitative explanation of this sequence may be found from a consideration of the electronic structure of these compounds (see Table 1). These are all similar on one side of the thiocarbonyl group and different on the other. The lone pairs of electrons on the nitrogen and sulfur atoms are delocalized and hence produce delocalization or resonance stabilization energy which stabilizes the compound.[29] There is reason to believe that the larger the number of delocalized electrons, the more stable is the structure and the more is the charge density on the "anchoring" atom (in this case S) and hence the larger is the extent of adsorption *i. e.* the larger is θ.

Therefore, where as the methyl group of TA has no delocalized electrons, the amino group of TU has one lone pair of such electrons and the hydrazine group of TSC has two such pairs. This explains the above sequence. In fact in 1.0 mol dm^{-3} H_2SO_4 medium, TA readily undergoes hydrolysis in presence of acid:

$$CH_3-\overset{\overset{S}{\|}}{C}-NH_2 + H_2O \rightleftharpoons CH_3-\overset{\overset{O}{\|}}{C}-NH_2 + H_2S. \quad (5)$$

The decomposition of TU does not go to the same extent. On the other hand, the results we obtained on TSC do not point towards measurable degree of decomposition or hydrolysis of the compound over the tested concentration range. The resulting H_2S or HS^- are known to be promotors of hydrogen discharge, hydrogen embrittlement and general acid corrosion.[30,31] Therefore, as the concentration of TA increases, the equilibrium of Eq. 5 shifts towards the right producing more H_2S which promotes the h.e.r. and hence the overall corrosion reaction. Similar considerations apply to the case of TU although obviously to a lesser extent.

Gas-Solid Chromatographic Studies of Organic Compounds on Zirconium Oxide Beads†

Nebojša M. Djordjević,†† Slobodan K. Milonjić, and Miroslav M. Kopečni*

Chemical Dynamics Laboratory, The Boris Kidric Institute of Nuclear Sciences, P.O. Box 522, 11001 Beograd, Yugoslavia

††*Chemical Industry "Petrohemija" LTCP, 26000 Pančevo, Yugoslavia*

(Received August 18, 1980)

Adsorption properties of synthetic zirconium oxide beads were investigated by the gas-solid chromatography (GSC) method. Retentions of numerous alkanes, alkenes, aromatics and chlorinated compounds were measured in a wide temperature region. It appears that the surface activity of an adsorbent can be easily changed by thermal treatment, and in connection with it, the role of crystallographic structure of the adsorbent is emphasized. Thermodynamic parameters obtained were used for explanation of the adsorbent-adsorbate interaction.

The role of GSC in chromatographic practice is twofold: its early application was mainly connected to the analytical problems, while recently there is an increasing interest in physicochemical applications of GSC, among them, special attention is devoted to the adsorption phenomena. GSC measurements offer numerous advantages, the most important are: speed, accuracy, wide temperature region, zero coverage of a surface and above all, this technique provides results in the dynamic conditions.

Apart from silica and alumina, which are extensively used both for practical and physicochemical purposes and therefore are well examined,[1-3] a very few data concerning other metal oxides are available in literature.[4-9] Analytical inapplicability of uncommon metal oxides, due to their surface inhomogeneity and polarity, makes that little attention is paid to those adsorbents. To overcome serious problems linked with surface inhomogeneity and polarity, modifications with various polymeric stationary phases are generally applied.

The first paper dealing with GSC properties of zirconium oxide,[4] thermally pretreated at 1173 K, appeared at the time when the present study was undertaken. Since zirconium oxide may appear in amorphous as well as in monoclinic and tetragonal crystal form, it is normally expected that each modification exhibits different adsorptive properties. There is no information on crystal form used by Lapteva and coworkers,[4] but thermal treatment applied strongly suggests the monoclinic structure. The authors[4] have used three alkanes, *n*-pentane to *n*-heptane, adsorption and thermodynamic data of which were evaluated for temperature region between 493 and 543 K.

Despite the lack of GSC data, zirconium oxide is widely used as an inorganic adsorbent both for anions and cations. It seems that this material deserves more detailed investigations as far as the organic molecule adsorption processes are concerned.

Experimental

The experiments were performed with zirconium oxide precipitated from aqueous zirconium dichloride oxide ($ZrOCl_2 \cdot 8H_2O$) solution with ammonia.[10]

The following procedure was adopted: 30 g of zirconium dichloride oxide was dissolved in 500 ml of 4 mol dm^{-3} of nitric acid, diluted by equal volume of deionized water, and precipitated by 1000 ml of 5% ammonia with vigorous stirring at room temperature. The resultant precipitates were filtrated, thoroughly washed with 1% ammonia solution till the negative reaction of chloride ion, then with deionized water till the neutral reaction. After that, the precipitants were dried in air at 383 K for the period of 10 d. This material was ground and sieved. The fraction of 45—60 mesh was splitted into three portions and each was thermally treated for 4,5 h in air, at 523, 873, and 1173 K, respectively. These materials were used then in GSC experiments as a column packing.

All the chemical used were of analytical grade.

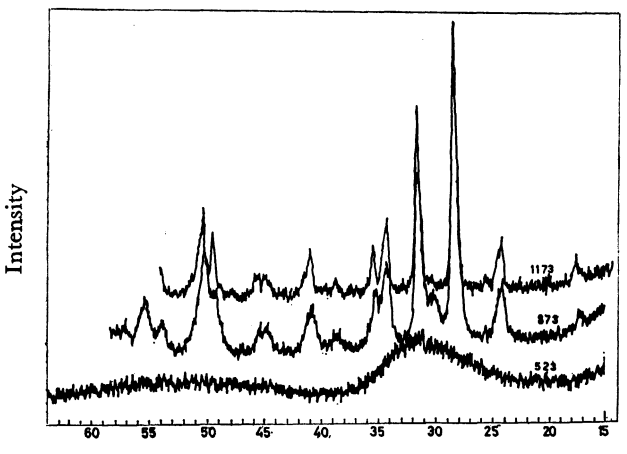

Fig. 1. X-Ray diffraction diagrams for zirconium oxide heated at various temperatures. The figures on the curves represent the heating temperatures, K.

The specific surface areas of the above materials were determined by a Ströhlein area meter using the single point nitrogen adsorption method. The values obtained were 220, 34, and 13 $m^2 g^{-1}$ for materials heated at 573, 873, and 1173 K, respectively. To determine the crystalinity of the packing used, X-ray diffraction patterns were recorded using a Siemens Kristalloflex 4 with a GM counter. The diffractograms obtained are shown in Fig. 1. Diffraction diagram for the material treated at 523 K shows a typical pattern of the amorphous species. The product heated at 873 K is mainly monoclinic with a metastable tetragonal phase indicated

† Presented at the 3rd World Chromatography Conference, July 3—4, 1980, Zürich, Switzerland.

with a small peak at 30 degrees of 2θ while that one at 1173 K shows the stable monoclinic phase only. These results are in agreement with the recent information published by Sato *et al.*[11]

All the organic compounds, obtained from various commercial sources, were of analytical reagent grade and used "as received."

A Perkin-Elmer model F 17 and 881 gas-chromatographs were used in the experiments. As a carrier, dry nitrogen was employed, and its flow, depending on the experimental conditions applied, varied in the range of 10 to 20 $cm^3\ min^{-1}$, as measured by a soap-bubble flowmeter. The adsorbates were injected as small vapour samples and the retention times were measured by a stop-watch. In all cases, stainless steel columns were used. Prior to the experiments, the packed column was conditioned overnight in a stream of nitrogen at 503 K.

The retention volumes for each adsorbate were measured at 413, 433, 453, 473, and 493 K, with the exception of adsorbates with retention times exceeding 90 min. An average retention from a multiple injection was for the following calculations, and the gas hold up time was assumed to be equal to the retention time of methane at the same temperature. No sample size and tailing effects were observed, except for aromatics at lower experimental temperatures, and such data were omitted from the calculations since they cannot be used for derivation of the thermodynamic data. Generally, sample size effect or tailing indicates inhomogeneity of the adsorbent surface, nonlinearity of the adsorption isotherm or multilayer adsorption.

The net retention volume, V_N, was calculated for each adsorbate from the usual relation,

$$V_N = j\, t'_R\, F_C, \qquad (1)$$

where t'_R is the adjusted retention time, F_C is the corrected carrier flow rate and j denotes the James-Martin pressure correction term. The net retention volumes were then converted into the adsorbate distribution coefficients, K_D, at a given temperature, deviding V_N by the total surface area of the adsorbent in the column. The values obtained correspond to the initial slope of the adsorption isotherm. The variation of K_D from one adsorbent to another for the same adsorbate was used then to quantify the changes in the properties of the adsorbents. The isosteric heat of adsorbtion, ΔH, was calculated by plotting $\ln (K_D/T)$ *vs.* $(1/T)$, where the linear least-square slopes of the plots were taken to be equal to $-\Delta H/R$ (assuming that ΔH is invariant over the temperature range examined here). The Gibbs free energies of adsorbtion, ΔG, were calculated from the relation $\Delta G = -RT \ln K_D$, where R is the gas constant. The corresponding entropies of adsorption, ΔS, were calculated from $\Delta S = (\Delta H - \Delta G/T)$.

Results and Discussion

As expected, the distribution coefficients of the adsorbates within the homologous series increase with the increasing chain length as well as with the increasing molecular weights or boiling points, the later dependence is shown in Fig. 2. The straight line connecting experimental points for benzene and its derivates is considerably above the paraffin line because of the specific interactions of adsorbent with the aromatic ring. If we assume that normal alkanes can interact with the surfacenons pecifically only, then the plots similar to Fig. 2 can be used to elucidate the nature of the specific adsorption process. Using this approach, the vertical

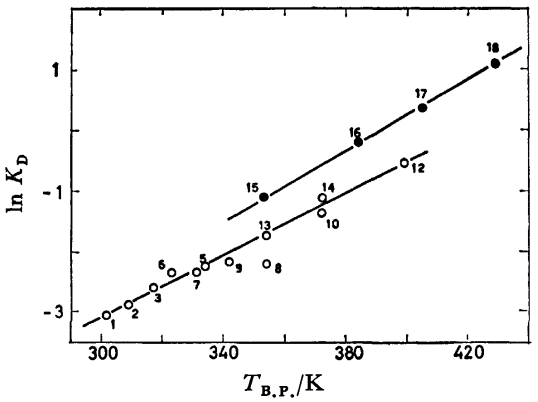

Fig. 2. Logarithm of distribution coefficient at 473 K *vs.* boiling point for zirconium oxide treated at 873 K. 1: 2-Methylbutane, 2: pentane, 3: cyclopentene, 5: 2-methylpentane, 6: 2,2-dimethylbutane, 7: 2,3-dimethylbutane, 8: cyclohexane, 9: hexane, 10: heptane, 12: Octane, 13: 2,4-dimethylpentane, 14: 2,2,4-trimethylpentane, 15: benzene, 16: toluene, 17: chlorobenzene, 18: bromobenzene.

distance between the normal alkane line (open circles) and any point on the plot for the aromatic line (filled circles) is related to the degree of specific interaction, shown by the compound representing that point.[12] The plots similar to those in Fig. 2 and conclusions that follow can be drawn for other thermal modifications of the zirconium oxide.

The role of a dominant element in GSC-geometrical factors, is evaluated by comparing the data for hexane and cyclohexane. Although cyclohexane boils 12 K higher than hexane, its retentions are shorter, regardless the thermal treatment of the column material. Due to the shorter retention, the point corresponding to cyclohexane (Fig. 2) lies considerably lower than the saturated hydrocarbon line. Explanation for such a behaviour can be easily found in geometric properties of the molecules under consideration. In the case of hexane, all the six carbon atoms can approach a plane, while for cyclohexane only three or four of them can interact with a surface at the same time, depending on the steric form that cyclohexane may take. Similarlly, the branched saturated hydrocarbons possess less carbon atoms available to contact and therefore to interact with the surface in comparison to the linear molecule with the same carbon atom number. Accordingly, all the branched hydrocarbons are eluted prior to the corresponding linear homologues.

Halogenated compounds interact with zirconium oxide to a great extent, due to their possibility to form stable zirconium dichloride oxide organic complexes.[13] We believe that this mechanism is responsible for permanent linking of chloroform, dichloromethane and carbon tetrachloride to the column material, even at higher experimental temperatures applied here. On the contrary, halogenated alkenes as well as 1,2-dichlorethane and halogenated benzene derivates are eluted from the column with quite reasonable retentions, in spite of the fact that some of these adsorbates have two possibilities to interact specifically with zirconium oxide, *e. g.* double bond and chlorine atom. Here, the

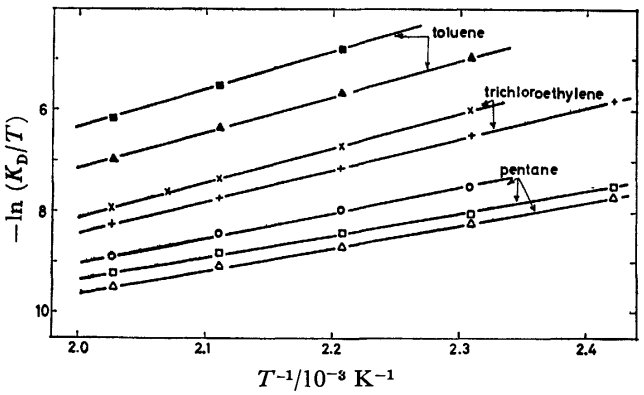

Fig. 3. Representive plots of $\ln(K_D/T)$ *vs.* $(1/T)$ for indicated adsorbates ○, ×, ● ZrO_2 heated at 523 K, △, +, ▲ heated at 873 K and □, ×, ■ heated at 1173 K.

geometric factor is obviously responsible for such a behaviour, a nature of which requires a more detailed examination.

Typical plots of the functionality, $\ln K_D = f(1/T)$ for pentane, trichlorethylene, and toluene are shown in Fig. 3. For other adsorbates studied, similar linear relationships were obtained. The ΔH values calculated from these plots and the corresponding entropies of adsorption are collected in Table 1.

The isosteric heat of adsorption for pentane, hexane and heptane reported by Lapteva and coworkers[4] are −28.9, −34.4, and −41.9 kJ mol^{-1}, respectively. These values are lower than those we found. The different temperature region used in determining the ΔH values can easily produce discrepancy between the values of the isosteric heats. In addition, the mode of preparation of the initial zirconium oxide material, may also contribute to the disagreement in ΔH values.

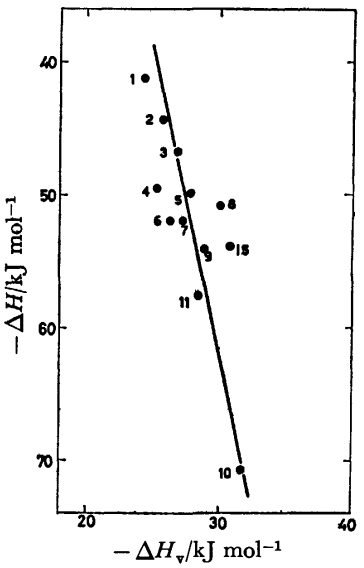

Fig. 4. Dependence of isosteric heat of adsorption on the corresponding heat of vaporization for ZrO_2 thermally treated at 523 K.
Symbols as in Fig. 2. 4: 1-Pentene, 11: 1-hexene.

Dependence of the isosteric heat of adsorption on the heat of vaporization, ΔH_v, are illustrated in Fig. 4, for zirconium oxide treated at 523 K. All the compounds lying on the common straight line represent the same interaction mechanism with the surface. The compounds falling out of the line, *e. g.* benzene, 1-pentene, and chlorinated compounds, are capable to interact, beside always acting nonspecific mode, with one or other specific mechanism.

The role of the specific part of the interaction can be evaluated considering the free energy of adsorption. The values of $\Delta(\Delta G)$ for a pair of adsorbates, benzene

and hexane at 473 K, on the zirconia treated at 523, 873, and 1173 K are −2.82, −4.29, and −6.45 kJ mol^{-1}, respectively. These values represent the contribution of three double bonds from benzene ring. It is normal that $\Delta(\Delta G)$ increases with the increasing treatment temperature; such a treatment leads to dehydroxylation of the surface and therefore to the surface activation. The increased $\Delta(\Delta G)$ values are also connected to the thermal treatment which leads to the change of the crystalinity of zirconium oxide.

Empirical dependence of ΔS on ΔH, designated in literature as a compensation effect, is shown in Fig. 5 for the material preheated at 523 K. Nonspecific interacting adsorbates lie on the same straight line, although a separate line can be constructed for the chlorinated compounds. Two separate lines indicate two different types of interactions as pointed out above.

The values of the isosteric heats of adsorption of normal alkanes on zirconium oxide are similar to those obtained on silica.[14] On the other hand, the increment of ΔH for each CH_2 group is much higher when zirconia is used as adsorbent, implying the stronger nonspecific adsorption.

Many problems in the field of GSC thermodynamics remain without definite answers. A complete explanation of the nature of the interactions acting between adsorbate and metal oxides must await further experimentations.

We are indebted to Dr. S. Malčić, from the Boris Kidrič Institute of Nuclear Sciences, for crystallographic examinations, to Miss V. Roglić for careful corrections of English, and to M.Sc. M. Trtanj for zirconium oxide grant.

Mössbauer Study of Solid State Photolysis of Alkali Tris(oxalato)ferrates(III)

Ajaib Singh BRAR* and Balwinder Singh RANDHAWA
Chemistry Department, Guru Nanak Dev University, Amritsar-143005, India
(Received August 25, 1980)

Solid state photolysis of alkali tris(oxalato)ferrates(III) (Li, Na, K, Cs, and NH_4) was studied with mercury radiation in the visible region by means of Mössbauer spectroscopy. The intermediate $K_6[Fe_2^{II}(ox)_5]$ is formed in the case of potassium tris(oxalato)ferrate(III) and $FeC_2O_4 \cdot 2H_2O$ in the case of other alkali tris(oxalato)ferrates-(III)[Li, Na, Cs, and NH_4].

Mössbauer spectroscopy is effective for detecting the change in oxidation state and structure.[1] By means of UV and visible spectroscopy and magnetic susceptibility measurements Wendlandt and Simmons[2] found that iron(II) oxalate is formed during the course of solid state photolysis of potassium tris(oxalato)ferrate(III). Bancroft *et al.*[3] reported the formation of $K_6[Fe_2^{II}(ox)_5]$ as an intermediate, the results contradicting the observation made by Wendlandt and Simmons.[2] Sato and Tominaga[4,5] investigated the photolysis of potassium bis- and tris(oxalato)ferrate(III) in solid state and frozen solutions using Mössbauer spectroscopy, their results supporting those obtained by Bancroft *et al.*[3] They also suggested the formation of metastable iron(II) species during the course of photolysis. In our earlier communication,[6] Mössbauer parameters of alkali tris-(oxalato)ferrates(III) have been reported. The effect of change of cation on the isomer shift values have been observed. In this communication, the effect of change of cation (Li, Na, K, Cs, and NH_4) on the intermediates formed during the course of solid state photolysis of these complexes is reported.

Experimental

Alkali Tris(oxalato)ferrates(III) $M_3[Fe(ox)_3]\cdot 3H_2O$ (M= Li, Na, K). These were prepared by mixing three volumes of 1.5 mol dm^{-3} alkali metal oxalate solution and one volume of 1.5 mol dm^{-3} iron (III) chloride solution with vigrous stirring. The precipitated green product, *i. e.* $M_3[Fe(ox)_3]\cdot 3H_2O$ (M=Li, Na, K), was recrystallized three times from warm water and dried in a current of warm air (45 °C) with a drier.[7] The solid product was stored in the dark in order to avoid chemical change.

Caesium Tris(oxalato)ferrate(III) Trihydrate $Cs_3[Fe(ox)_3]\cdot 3H_2O$. Caesium oxalate was prepared from caesium chloride and oxalic acid. Three volumes of 1.5 mol dm^{-3} caesium oxalate solution and one volume of 1.5 mol dm^{-3} iron (III) chloride solution were mixed with vigrous stirring. The reaction mixture was concentrated on a water bath until crystals of caesium tris (oxalato) ferrate (III) formed. The crystals were recrystallized from warm water and then stored and dried in the dark.

Ammonium Tris(oxalato)ferrate(III) Trihydrate $(NH_4)_3[Fe(ox)_3]\cdot 3H_2O$. This complex was prepared as reported.[8]

The percentage of iron in the alkali tris(oxalato)ferrates (III) was determined by electronic spectroscopy and found to agree with that of the expected value.[9] The percentage of sodium and potassium in sodium- and potassium tris(oxalato)ferrate-(III) trihydrate respectively was determined with a flame photometer.

For photo-irradiation, samples were exposed to medium pressure 125 watts mercury lamp radiations.

A Mössbauer spectrometer MBS-35 (ECIL, India) coupled with MCA-38B with constant acceleration drive was employed to record the spectrum. A 5-mi ^{57}Co (Rh) source was used. The values of isomer shift are reported with respect to naturaliron. All the spectra were recorded at temperature 25±2 °C. A sample containing approximately 10 mg/cm^2 of the natural iron was taken for each measurement. All the spectra have been fitted to Lorentzian line shape using program and fitting procedures[10] on microcomputer 2000 (DCM, India). The intensities of quadrupole doublets are almost equal, the Mössbauer spectra of the tris(oxalato)-ferrates(III) at room temperature being almost symmetrical. Slight deviations might be due to powdered random samples and due to spin lattice relaxation effect.[11]

Results and Discussion

The Mössbauer spectra of alkali tris(oxalato)ferrates-(III) at room temperature (25±2 °C) consist of a single broad absorption band due to an electronic spin relaxation effect.[11] The Mössbauer parameters of alkali tris-(oxalato)ferrates(III) are given in Table 1. The isomer shift value of 0.26 mm s^{-1} for potassium tris(oxalato)-ferrate(III) trihydrate agrees with the reported value.[1,3,4,12-14]

Table 1. Mössbauer parameters of alkali tris(oxalato)ferrates(III)

Name of complex	Isomer shift / mm s^{-1}	Width at half maximum / mm s^{-1}	Percentage absorption
$Li_3Fe(C_2O_4)_3\cdot 3H_2O$	0.03±0.02	1.39±0.02	6.09
$Na_3Fe(C_2O_4)_3\cdot 3H_2O$	0.15±0.02	1.37±0.02	2.35
$K_3Fe(C_2O_4)_3\cdot 3H_2O$	0.26±0.02	1.78±0.02	6.12
$Cs_3Fe(C_2O_4)_3\cdot 3H_2O$	0.39±0.02	0.85±0.02	3.81
$(NH_4)_3Fe(C_2O_4)_3\cdot 3H_2O$	0.21±0.02	1.16±0.02	2.07

The alkali tris(oxalato)ferrates(III) are high spin complexes having octahedral structure with oxidation state (+3) of iron. The sp^3d^2 hybridization is involued in bonding with the ligands (oxalates). The change in polarization of the alkali metal cation affects the 3s-electron density at the iron nucleus. The more electronegative cation will polarize the oxalato group causing a change in the electron density of the iron. The increase of electronegativity from caesium to lithium decreases the electron density in the 3d-orbital of iron

TABLE 2. MÖSSBAUER PARAMETERS OF THE PRODUCTS OF PHOTOLYSIS FROM ALKALI TRIS(OXALATO) FERRATES(III)

Product	Isomer shift / mm s^{-1}	Quadrupole splitting / mm s^{-1}	Tentative assignment
Product I	—	—	Parent compounds[a)]
Product II	1.16±0.04	3.89±0.04	$K_6[Fe_2^{II}(ox)_5]$
Product III	0.28±0.04	0.68±0.04	$M[Fe^{III}(ox)_2(H_2O)_2]$[b)]
Product IV	1.18±0.04	1.80±0.04	$FeC_2O_4\cdot 2H_2O$

a) The values of isomer shift and quadrupole splitting are given in Table 1. b) M=Na, K, Cs.

which affects the shielding of 3s-electron density at iron nucleus. Less electronegative cation would have less effect on the d orbital and the resulting s-electron density at the nucleus would decrease, giving higher isomer shift value. The effect of electronegativity of cation on the value of isomer shift is greater as compared with that in low spin octahedral complexes[15] [hexacyanoferrate(II) and hexacyanoferrate(III)] and high spin tetrahedral complexes[16] [alkalidithioferrate-(III)]. A linear relationship between cationic size and isomer shift has been observed in alkali tris(oxalato)-ferrates(III).[6]

The Mössbauer parameters of alkali tris(oxalato)-ferrates(III) products for the solid state photolysis are given in Table 2. The Mössbauer spectrum of potassium tris(oxalato)ferrate(III), irradiated for 30 h at room temperature (Fig. 1b) shows a broad band with isomer

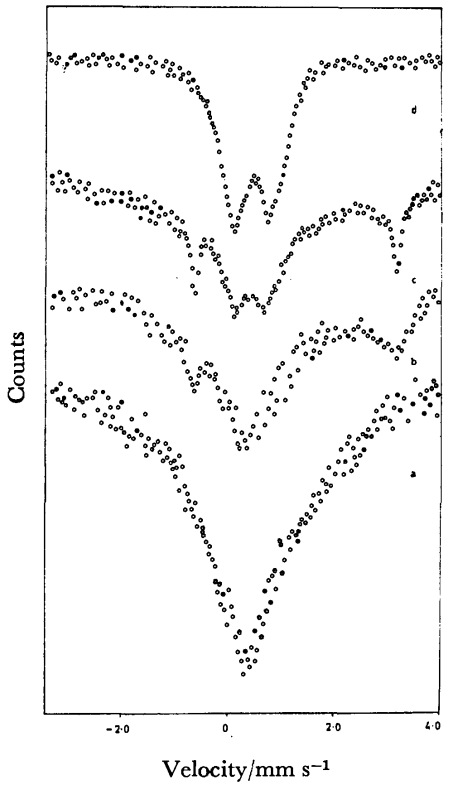

Fig. 1. Mössbauer spectra of potassium tris(oxalato)-ferrate(III) trihydrate at room temperature (25 °C). a: Unirradiated complex, b: irradiated for 30 h, c: irradiated for 60 h, d: irradiated for 200 h and on long standing in air.

shift 0.29 mm s^{-1}, indicating the presence of parent complex and a quadrupole doublet with isomer shift value 1.19 mm s^{-1} and quadrupole splitting value of 3.89 mm s^{-1} indicating the formation of $K_6[Fe_2^{II}(ox)_5]$. The Mössbauer spectrum of potassium tris(oxalato)-ferrate(III) irradiated for 60 h at room temperature (Fig. 1c) represents two sets of quadrupole doublets, one with isomer shift and quadrupole splitting value of 1.16 and 3.89 mm s^{-1}, respectively, indicating the formation of $K_6[Fe_2^{II}(ox)_5]$, and the other with isomer shift and quadrupole splitting values of 0.33 and 0.62 mm s^{-1}, respectively, indicating the formation of $K[Fe^{III}(ox)_2(H_2O)_2]$ species. Wendlandt and Simmons[2] observed the formation of FeC_2O_4 in the solid state photodecomposition of potassium tris-(oxalato)ferrate(III) by means of magnetic susceptibility measurements. However, no such results were obtained on the basis of Mössbauer studies. On further irradiation of the complex, oxidation of $K_6[Fe_2^{II}(ox)_5]$ to $K[Fe^{III}-(ox)_2(H_2O)_2]$ takes place. The isomer shift and quadrupole splitting values of this complex *i. e.* $K[Fe^{III}(ox)_2-(H_2O)_2]$ are 0.32 and 0.65 mm s^{-1}, respectively, showing that the complex has octahedral symmetry with oxidation state (+3). After irradiation with mercury radiations for a period of 200 h (Fig. 1d), the Mössbauer spectrum shows isomer shift and quadrupole splitting values of 0.32 and 0.62 mm s^{-1}, respectively, indicating complete photodecomposition to $K[Fe^{III}(ox)_2(H_2O)_2]$. No change in Mössbauer parameters has been observed on further irradiation. $K_6[Fe_2^{II}(ox)_5]$ is an unstable complex which, after being left to stand in the air for several days, gets oxidized to $K[Fe^{III}(ox)_2(H_2O)_2]$ (product III). It is possible that product III is formed by radiation and aerial oxidation. Sato and Tominaga[5] reported the formation of metastable iron(II) and $[Fe(ox)_2(H_2O)_2]^{2-}$ intermediate. The formation of these species was not observed in our experiments. This might be due to the difference in wavelength and experimental conditions. The mechanism of the solid state photodecomposition of potassium tris(oxalato)ferrate(III) is suggested as follows:

$$\underset{(I)}{K_3[Fe^{III}(ox)_3]} \xrightarrow{h\nu} \underset{(II)}{K_6[Fe_2^{II}(ox)_5]} \xrightarrow[\text{air}]{h\nu} \underset{(III)}{K[Fe^{III}(ox)_2(H_2O)_2]}.$$

The Mössbauer spectra of sodium and caesium tris(oxalato)ferrates(III) irradiated for a period of 60, 150, and 200 h are shown in Figs. 2 and 3, respectively. The Mössabauer spectra of these complexes irradiated for 60 h (Figs. 2b and 3b) show a doublet with isomer shift and quadrupole splitting values of 1.22 and 1.82

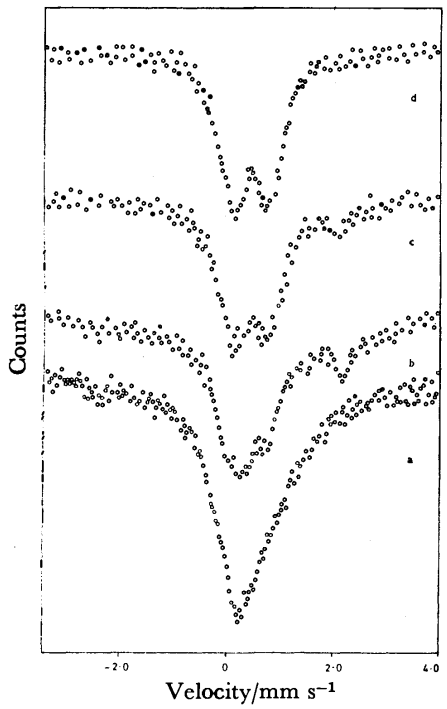

Fig. 2. Mössbauer spectra of sodium tris(oxalato)-ferrate(III) trihydrate at room temperature (25 °C).
a: Unirradiated complex, b: irradiated for 60 h, c: irradiated for 150 h, d: irradiated for 200 h.

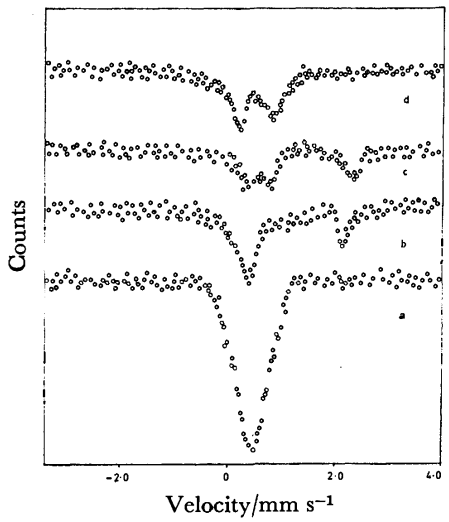

Fig. 3. Mössbauer spectra of caesium tris(oxalato)-ferrate(III) trihydrate at room temperature (25 °C).

mm s^{-1} in the case of sodium tris(oxalato)ferrate(III), and 1.18 and 1.77 mm s^{-1} in the case of caesium tris-(oxalato)ferrate(III). The values of isomer shift and quadrupole splitting are comparable to those reported for iron(II) oxalate dihydrate.[14] The same were observed in the Mössbauer spectrum of iron(II)oxalate-dihydrate (pure A.R.). On further irradiation, the Mössbauer spectrum shows a quadrupole doublet with isomer shift and quadrupole splitting values of 0.30 and 0.66 mm s^{-1} in sodium tris(oxalato)ferrate(III) (Fig. 2c) and 0.28 and 0.66 mm s^{-1} in the case of caesium tris(oxalato)ferrate(III) (Fig. 3c). These values indicate the formation of an octahedral complex with oxidation state(III). When these complexes (Na and Cs) were irradiated for 200 h and left to stand in the air for several hours, the Mössbauer spectrum represents a quadrupole doublet with isomer shift and quadrupole splitting values of 0.28 and 0.68 mm s^{-1} in sodium tris(oxalato)ferrate(III) (Fig. 2d) and 0.29 and 0.68 mm s^{-1} in the case of caesium tris(oxalato)ferrate(III) (Fig. 3d), indicating the formation of $M[Fe^{III}(ox)_2(H_2O)_2]$ complexes (M=Na, Cs). Further irradiation of these complexes shows on change in the Mössbauer spectra. The mechanism of photodecomposition of sodium- and caesium-tris(oxalato)ferrates(III) in solid state might be postulated as follows:

$$M_3[Fe^{III}(ox)_3] \xrightarrow{h\nu} \underset{(IV)}{Fe^{II}(ox)2H_2O} \xrightarrow[air]{h\nu} \underset{(M=Na,\ Cs)}{M[Fe^{III}(ox)_2(H_2O)_2]}.$$

These observations are similar to those for the products obtained by the photolysis of potassium tris(oxalato)-ferrate(III) in acidic solutions.[17] Potassium tris-(oxalato)ferrate(III) is used in actinometer. Photolysis of potassium tris(oxalato)ferrate(III) has extensively been investigated in solution as regards its use in actinometer. The formation of ferrous oxalate is observed in solutions.

In the case of lithium- and ammonium tris(oxalato)-ferrates(III) the Mössbauer spectra of these complexes irradiated for 100 h at room temperature indicate a quadrupole doublet with isomer shift and quadrupole splitting values of 1.20 and 1.77 mm s^{-1} in the case of lithium tris(oxalato)ferrate(III) (Fig. 4b) and 1.22 and 1.74 mm s^{-1} in the case of ammonium tris(oxalato)-

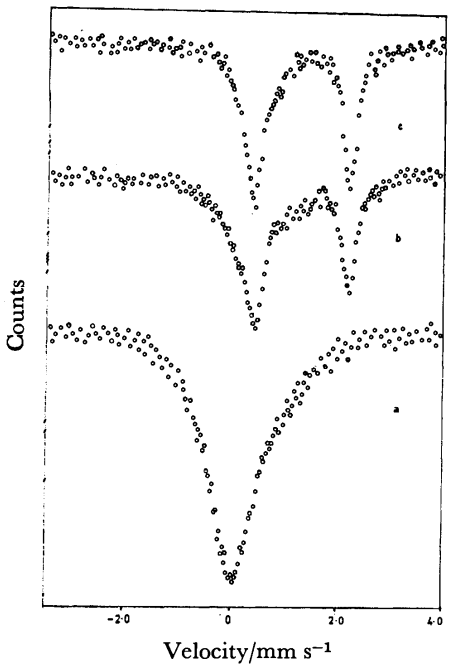

Fig. 4. Mössbauer spectra of lithium tris(oxalato)-ferrate(III) trihydrate at room temperature (25 °C).
a: Unirradiated complex, b: irradiated for 100 h, c: irradiated for 200 h.

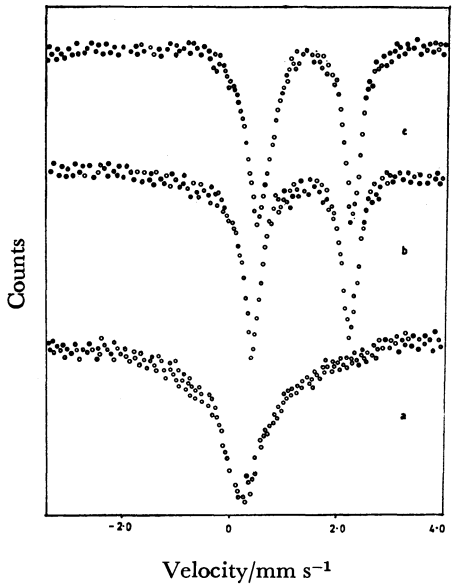

Fig. 5. Mössbauer spectra of Ammonium tris(oxalato)-ferrate(III) trihydrate at room temperature (25 °C).
a: Unirradiated complex, b: irradiated for 100 h, c: irradiated for 200 h.

ferrate(III) (Fig. 5b). On further irradiation upto 200 h (Figs. 4c and 5c) no change in the Mössbauer parameters was observed.

In the photolysis of potassium tris(oxalato)ferrate-(III), the $K_6[Fe^{II}_2(ox)_5]$ intermediate is formed and finally $K[Fe^{III}(ox)_2(H_2O)_2]$ is obtained. In sodium- and caesium tris(oxalato)ferrates(III), iron(II) oxalate has been observed as an intermediate. However, in the case of lithium- and ammonium tris(oxalato)ferrates-(III), iron(II) oxalate is formed upto 200 h of irradiation. It can be concluded that different intermediates are formed during the course of photolysis of alkali tris(oxalato)ferrates(III). The rate of photodecomposition is greater in the case of potassium- and ammonium tris(oxalato)ferrates(III). This might be the reason for the use of potassium tris(oxalato)ferrate(III) in an actinometer.

The Design of Organic Metals. Dibenzotetrathiafulvalene-2,3-Dichloro-5,6-dicyano-*p*-benzoquinone (DBTTF-DDQ)

James J. MAYERLE* and Jerry B. TORRANCE*
IBM Research Laboratory, San Jose, California 95193, U. S. A.
(Received November 4, 1980)

The electrical and optical properties of the four charge-transfer salts formed between the two donors tetrathiafulvalene (TTF) and dibenzotetrathiafulvalene (DBTTF) and the two acceptors tetracyanoquinodimethan (TCNQ) and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) are compared. The differences are rationalized on the basis of electrochemical considerations. DBTTF–TCNQ, the compound composed of the weakest donor and acceptor, is found to be a neutral complex. However, TTF–TCNQ and the new material DBTTF–DDQ are mixed valence and highly conducting. The latter material, which is the first highly conducting salt to contain the common acceptor DDQ, has a room temperature pellet electrical conductivity of 8 Ω^{-1} cm^{-1}. Finally, the combination of best donor and acceptor, TTF–DDQ, forms an insulating, completely ionic salt. The structure of this salt has been determined and found to crystallize with relatively isolated dimers of TTF and strongly distorted stacks of DDQ.

For the past few years we have been engaged in a program aimed at gaining a systematic understanding of the electronic and structural properties of organic charge-transfer complexes. As part of this work we have attempted to expand the range of materials that will form organic metals. We now report the electrical and optical properties of the new highly conducting salt DBTTF–DDQ,[1] the first[2] such material containing the common acceptor DDQ. In order to understand why DBTTF–DDQ is highly conducting, we will compare the electrical and optical properties of the four charge-transfer salts formed between the two donors DBTTF and TTF and the two acceptors DDQ and TCNQ.[1] This comparison will illustrate the dependence of the solid state electrical properties of organic charge-transfer complexes on the redox properties of the individual molecules and, consequently, will illustrate guidelines for how to make organic metals.

High conductivity requires that two conditions be fulfilled: first, the donor and acceptor must crystallize in separate (segregated) stacks and, second, the degree of charge transfer, ρ, from donor to acceptor must be fractional ($\rho<1$), *i.e.*, the resulting complex must be mixed valence. The criteria we use in selecting donors and acceptors that will meet these conditions have been discussed in detail elsewhere.[2–4] However, we will briefly mention under what conditions the criterion of incomplete charge-transfer is met[3] since it is of central importance to the results reported here.

The total binding energy of these materials per donor/acceptor pair, expressed as a function of ρ, the degree of charge-transfer, is given in Eq. 1,

$$E_B(\rho) = -\rho[\rho E_M - (I-A)], \quad (1)$$

where E_M is the Madelung (electrostatic binding) energy of the completely ionized lattice, I is the ionization potential of the donor, and A is the electron affinity of the acceptor. Since variations in E_M are smaller than variations in $(I-A)$ for the types of materials under discussion, differences in ρ between different materials should depend mainly on the quantity $(I-A)$. Since the values of I and A are generally not well known for organic molecules, however, we use the more readily obtained values of the electrochemical half-wave potentials ($E_{1/2}$) as a measure of relative donor/acceptor strength. Since ΔE_{REDOX}, the difference between the $E_{1/2}$ values of any donor/acceptor pair, can be related[5] to the quantity $(I-A)$ in Eq. 1, values of ΔE_{REDOX} can be used to predict the degree of charge-transfer in a given material. In particular, if ΔE_{REDOX} is large

TABLE 1. PROPERTIES OF DONOR/ACCEPTOR COMBINATIONS: ΔE_{REDOX}, VALENCE, AND ROOM TEMPERATURE PELLET ELECTRICAL CONDUCTIVITY

	 TCNQ ($E_{1/2}$=0.23 V)	 DDQ ($E_{1/2}$=0.56 V)
 DBTTF ($E_{1/2}$=0.55 V)	+0.32 V Neutral 10^{-7} Ω^{-1} cm^{-1}	−0.01 V Mixed valence 8 Ω^{-1} cm^{-1}
 TTF ($E_{1/2}$=0.29 V)	+0.06 V Mixed valence 70 Ω^{-1} cm^{-1}	−0.27 V Ionic 10^{-8} Ω^{-1} cm^{-1}

and positive, a neutral charge-transfer complex results, *i.e.*, for a poor donor/acceptor combination, $\rho=0$. If ΔE_{REDOX} is large and negative, a fully ionic charge-transfer salt results, *i.e.*, for a good donor/acceptor combination, $\rho=1$. For intermediate values of ΔE_{REDOX}, estimated[3] as $-1/4\,V \lesssim \Delta E_{REDOX} \lesssim 1/4\,V$, there is incomplete charge-transfer and a mixed-valence, and therefore highly conducting, compound results.

Table 1 gives $E_{1/2}$ values[6] (in parentheses) for the two donors, TTF and DBTTF, and the two acceptors, TCNQ and DDQ, as well as the ΔE_{REDOX} values for the four donor/acceptor combinations. Since donor strength increases as $E_{1/2}$ decreases, it is apparent that TTF is a considerably stronger donor than DBTTF. On the other hand, since acceptor strength increases as $E_{1/2}$ increases, it can be seen that DDQ is a much stronger acceptor than TCNQ. Thus, for TTF–TCNQ, ΔE_{REDOX} is $+0.06$ V and the material is a mixed-valence, highly conducting salt. Because of its small value (-0.01 V) of ΔE_{REDOX}, one would predict that DBTTF–DDQ would also be a mixed-valence, highly conducting solid. This is what we have found. DBTTF–TCNQ, however, has a large, positive ($+0.32$ V) value of ΔE_{REDOX}. Hence, it is a neutral insulating ($\rho=0$) solid. The ΔE_{REDOX} value of -0.27 V for TTF–DDQ lies too near the ionic boundary ($\Delta E_{REDOX} \approx -1/4$ V) to allow one to predict whether TTF–DDQ would be mixed-valence or ionic. We have found it to be, in fact, completely ionic.

The reaction of DBTTF with DDQ in toluene results in a 1 : 1 compound[7] with the relatively high room temperature powder electrical conductivity of 8 Ω^{-1} cm^{-1}, compared to values in the range of 10^{-4}—10^{-10} Ω^{-1} cm^{-1} for any of the previously known compounds of DDQ, and compared to a value of 70 Ω^{-1} cm^{-1} for TTF–TCNQ. Although we have not been able to obtain single crystals of DBTTF–DDQ suitable for X-ray diffraction, the high electrical conductivity leaves no doubt that the material is composed of mixed-valence, segregated stacks of donors and acceptors. Convincing evidence for the mixed-valence nature of DBTTF–DDQ can also be obtained from its optical spectrum, Fig. 1. Like that of TTF–TCNQ, the spectrum consists of high energy bands largely characteristic of the individual ions. In addition, and most importantly, there is a low energy band at $\approx$0.4 eV which, in the case of TTF–TCNQ, has been shown to be a mixed-valence, intrastack charge-transfer transition.[8] This mixed-valence charge-transfer band is found in and is characteristic of all known organic metals.[8] Thus, DBTTF–DDQ is mixed-valence and is the first highly conducting material that contains DDQ. This compound is one of the rare examples[4] of a highly conducting organic charge-transfer salt that does not contain TCNQ or one of its derivatives as the acceptor molecule. This compound is also significant as one of the first highly conducting materials containing DBTTF, the oldest TTF-like molecule.[9] Metallic DBTTF compounds with BF_4^- and $TCNQCl_2$ have recently been reported.[10,11]

Slow diffusion of an acetonitrile solution of TTF into a DDQ solution of the same solvent yields small, dark red crystals of almost cubic habit. A projection of the structure (space group $P\bar{1}$ with $a=10.227(4)$, $b=12.195(5)$, $c=6.609(2)$ Å, $\alpha=77.51(2)$, $\beta=81.93(2)$, and $\gamma=87.30(4)°$, with 2 formula units per unit cell) onto the (001) plane is shown in Fig. 2(a). It consists of

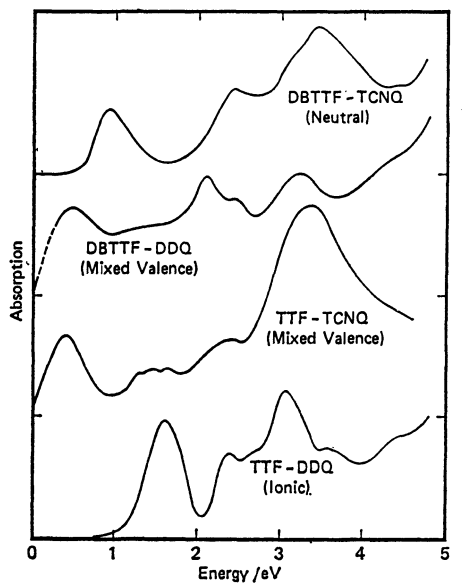

Fig. 1. Optical absorption spectra of the four complexes formed between the two donors TTF and DBTTF and the two acceptors DDQ and TCNQ.

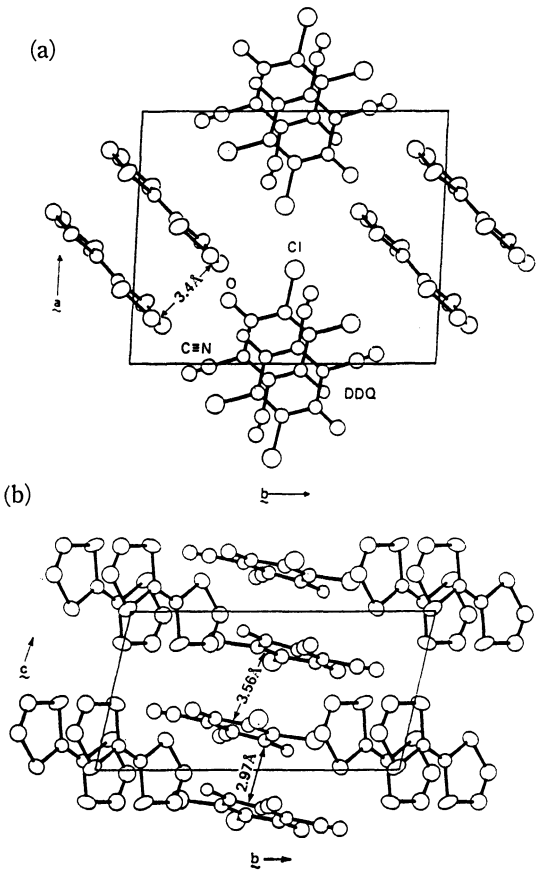

Fig. 2. Structure of TTF–DDQ projected onto the (a) (001) plane and (b) onto the (100) plane.

strongly distorted stacks of DDQ and isolated, eclipsed dimers of TTF. The interplanar spacing between the two TTF molecules comprising the dimer is ≈3.4 Å. There is virtually no overlap between adjacent dimers. The DDQ molecules also dimerize, but do so within the framework of infinite columns of DDQ stacked parallel to the c axis. The stacking of the DDQ molecules can be seen in the (100) projection of the structure, shown in Fig. 2(b). The interplanar spacing between molecules of the DDQ dimer is 3.0 Å. This is an extremely short distance. The interplanar spacing between molecules in adjacent dimers is 3.56 Å. This strong distortion of the DDQ stacks, as well as the existence of isolated dimers of TTF, accounts for the fact that there is no paramagnetic contribution to the magnetic susceptibility. The distortion of the acceptor stack is presumably caused by the same phenomenon[12] that causes the distortion in the low temperature phases of other fully ionic complexes, such as K–TCNQ.[13] The completion of the structural analysis (R=12%) has been complicated by the fact that the DDQ molecule is disordered, exhibiting partial interchange of -Cl and -C–N groups. Such disorder has previously been seen in the charge-transfer complex of DDQ with benzo[c]-phenanthrene.[14]

That ρ=1 in TTF–DDQ can be seen in its optical spectrum, shown in Fig. 1. The absence of a mixed valence charge transfer band near 0.4 eV indicates that this compound is not mixed valence. The optical spectrum is dominated by the stronger absorption of the TTF molecule and is nearly identical to that of $(TTF^+)_2$ dimers,[15] consistent with the dimers evident in the structure (Fig. 2). The optical absorption indicates that they are not neutral, but completely ionic (ρ=1) in agreement with the conclusions of Ikemoto and co-workers.[16]

The optical spectrum of DBTTF–TCNQ, also shown in Fig. 1, shows no evidence of any absorption[17] due to $TCNQ^-$ and hence must be a neutral (ρ=0) complex. (Absorption due to $DBTTF^+$, if it were present, would also appear near 2.0 eV, but would be considerably weaker than the $TCNQ^-$ absorption.) Recent ESR experiments[18] also indicate that DBTTF–TCNQ is a neutral complex. This is expected from the large positive value (+0.32 V) of ΔE_{REDOX} (Table 1). The energy of the charge transfer band at 0.91 eV is in agreement with a computed[19] value based on ΔE_{REDOX}. The second band near 2.4 eV is probably a second charge-transfer band.

In summary, it seems apparent that if the ΔE_{REDOX} value of the donor/acceptor pair in a 1 : 1 charge-transfer complex differs significantly from zero, the degree of charge-transfer in the complex will be either zero or one (ρ=0,1). If, however, ΔE_{REDOX}=0, the complex will probably be mixed-valence. As described above, we have used the ΔE_{REDOX} values in Table 1 to successfully predict that DBTTF–TCNQ would be neutral and that DBTTF–DDQ would be mixed-valence and, therefore, highly conducting. In so doing, we have convincingly demonstrated that by employing simple electrochemical considerations and readily obtainable data, one can reliably estimate the degree of charge-transfer which might be expected for a 1 : 1 compound. As a result, one can predict which combinations of donors and acceptors have a reasonable probability of giving rise to organic metals. This predictability has been used to obtain the first highly conducting salt of the common acceptor DDQ.

We wish to acknowledge the technical assistance of V. Y. Lee.

Studies in the Molten State. Viscosities of *trans*-Stilbene, *N*-Benzylideneaniline, and *N*-Benzylidene-*p*-toluidine Melts Near Their Melting Temperatures

Bimla KWATRA,† (the late)Venketachari RAMAKRISHNA, and Sushil Krishan SURI*
Chemistry Department, Indian Institute of Technology, Delhi, New Delhi-110016, India
(Received November 21, 1980)

The viscosities and densities of *trans*-stilbene, *N*-benzylideneaniline (BA) and *N*-benzylidene-*p*-toluidene (BT) melts at various temperatures near their respective melting temperatures have been determined. In all the cases, a precursor behaviour in crystal phase at temperatures below the melting temperature has been observed. The viscosity *vs.* temperature relationships have been discussed in two parts: one in the liquid state and the other in the supercooled region. The values of energy and entropy of viscous flow are indicative of molecular association in BA and BT. The enhanced viscosity in the supercooled region has been attributed to the cluster formation. The hinderance to molecular rotation, as a factor influencing viscosity can not be ruled out.

The measurement of viscosity (η) and its temperature dependence near transitions has yielded useful information regarding liquid structure both for normal and polymeric liquids and for those which are non-Newtonian.[1-5] Rotational and ordering characteristics of molecules, intermolecular complexing tendency including hydrogen bonding, precursor behaviours of melting in crystal phase at temperatures below the melting temperature (premelting phenomenon), cluster formation prior to freezing of the liquid phase (prefreezing phenomenon) and the molecular nature of the compounds have been confirmed from the log η *versus* reciprocal of temperature plots and from the thermodynamic parameters of viscous flow.[7,8] Though viscosity behaviour of many liquids like paraffins,[9] mono- and polysubstituted benzenes;[10-14] polycyclic hydrocarbons[7] *etc.* have been investigated, molecules having flexible aromatic rings as end groups attached to a rigid central group like $\diagdown\!\!\diagup C{=}C\diagdown\!\!\diagup$; $C{=}N-$, *etc.* have not received serious attention.[15,16] These type of molecules are of importance because a vast majority of compounds having such structure exhibit liquid crystallinity and constitute a potentially mesomorphic system. As a part of our investigations on such molecules,[17] we report in this paper the viscosities and densities of *trans*-stilbene, $C_6H_5CH{=}CHC_6H_5$; *N*-benzylideneaniline, $C_6H_5CH{=}NC_6H_5$ (BA); and, *N*-benzylidene-*p*-toluidine, $C_6H_5CH{=}NC_6H_4CH_3$(BT) melts at various temperatures near their respective melting region. These studies were aimed to investigate the behaviour of these compounds in molten liquid and supercooled region.

Experimental

Chemically pure sample of *trans*-stilbene (mp 124 °C) supplied by "Fluka AG" was used as such without any further purification. *N*-Benzylideneaniline (mp 51.5 °C) and *N*-benzylidene-*p*-toluidine (mp 34.2 °C) were prepared and purified following the standard established procedures.[18]

Densities of the melts were measured using a specifically designed pipette-like-pycnometer[12] of about 6 ml capacity. A fine orfice opening into the liquid prevented easy flow of the liquid after the pycnometer was filled thus reducing turbulence and crystallization in the supercooled region. The viscosities were determined with the help of an Ubbelohde suspended level viscometer. For measurements at <70 °C, a water thermostat with a temperature control of ±0.01 °C was used for maintaining constant temperature. Distilled, deionized and degassed water was used as a reference liquid in this temperature range and the literature values of the viscosities and densities[19,20] were used to calibrate the apparatus. For higher temperatures a glycerine bath was used with an accuracy in the maintenance of temperature up to ±0.03 °C. The calibration of pycnometer and viscometer was checked at different temperatures by measuring the density and viscosity of several known liquids in the desired temperature range. The maximum error in the density values was $\pm2\times10^{-5}$ g cm^{-3}. The viscosities at temperatures above the melting temperature was reproducible to within 1×10^{-6} N s cm^{-2} at temperature below 70 °C and to within 2×10^{-6} N s cm^{-2} at higher temperatures. The measurements in the supercooled region was particularly tedius and reproducibility was checked by repeating the measurements four or more times. Densities and viscosities in the supercooled region could not be reproduced to better than $\pm5\times10^{-5}$ g cm^{-3} and $\pm5\times10^{-6}$ N s m^{-2} respectively.

Results and Discussion

The densities and viscosities of the three compounds in the molten state at various temperature in the vicinity of their respective melting temperatures are recorded in Table 1.

The densities were found to vary linearly with the temperature, the deviations in most cases being within the experimental uncertainties of the data.

The results of viscosity measurements are plotted as log η *vs.* T^{-1} in Fig. 1. It is observed that the viscosities follow two different linear relationships, one above the melting point and the other in the supercooled region with a break at temperature T_t and some uncertain points around this temperature. This is an indication of premelting or prefreezing transitions taking place in these compounds. For BT the break in log η *vs.* T^{-1} plot below the melting point is not as sharp and curvature not as high as is normally expected for melts deviating from the Arrhenius equation. Nevertheless, we have satisfied ourselves that the deviations from the Arrhenius line below the melting point are significant being larger

than the order of magnitude of the experimental error involved. It is observed that at any temperature, the liquid densities of the three compounds increases in the order *trans*-stilbene<BT<BA whereas the viscosities follow the order *trans*-stilbene<BA<BT. The viscosity of BT is higher than that of BA and reveals that the substitution of methyl group by hydrogen in BT facilitates its flow.

The Arrhenius parameters for the melts have been calculated for the two regions and recorded in Table 2.

TABLEE 2. ARRHENIUS PARAMETERS FOR THE MELTS

	Temperature range / K	Slope × 10^2	Intercept.	E_{vis} / kcal mol^{-1}	ΔG^* at T_t / kcal mol^{-1}	ΔS^* / cal K^{-1} mol^{-1}
trans-Stilbene	396.1—412.3	8.85	−5.209	4.05	4.92	−2.14
	412.3—423.1	5.85	−4.484	2.68		−5.46
N-Benzylidene aniline	299.1—314.2	17.17	−7.719	7.86	4.85	9.52
	314.2—343.1	12.58	−6.256	5.75		2.82
N-Benzylidene-*p*-toluidine	293.1—302.1	16.95	−7.592	7.76		8.78
	302.1—331.1	15.18	−7.008	6.95	5.12	6.11

According to Mclaughlin,[1] E_{vis} is made up of two terms namely the energy required to overcome the barrier for transport E_1; and the energy required for forming a hole, E_2. The former is related to the energy of vaporization, $E_{vap}(\simeq 3E_1)$. The magnitude of E_2 is normally small in comparison to E_{vap} for liquids at moderate temperatures. In fact, for most of the normal liquids, the ratio $E_{vaq} : E_{vis}$ is something between 3 and 4. At sufficiently low temperatures, and, for sufficiently bulky molecules, E_2 become predominant[2] and hence the ratio tend to a value lower than 3. Grumberg and Nissan[3] pointed out that the ratio for polar associated liquids would depend upon the extent of association both in the liquid and vapours state and the geometry of packing in the liquid state. The ratio of $E_{vap} : E_{vis}$ for *trans*-stilbene, BA and BT is ≈5.2, 1.9, and 1.2 respectively. Further, the ratio $E_{vap}/\Delta G^*$ for *trans*-stilbene is ≈2.8 in agreement with the reported ratio of 2.45. For BA and BT, the value is far less. These observations are clear indicative of intramolecular association in BA and BT. The entropy of activation values recorded in Table 2 support this surmise. Tyuzyo[4] reported a value of $\Delta S^* = -2.9$ cal deg^{-1} mol^{-1} for a large number of compounds including polar ones. For *trans*-stilbene, ΔS^* is more negative in the liquid region indicating less ordering in it. Higher values of ΔS^* for BA and BT suggest that the ordering in these compounds exists to a much larger extent especially in supercooled region as compared to many organic liquids. This is also confirmed by Batschinski's plot of the viscosity data.[5,6] According to Batschinski:

$$\frac{1}{\eta} = \frac{v}{c} - \frac{v_0}{c}, \qquad (1)$$

where, v=specific volume; v_0=limiting value of specific volume at infinite viscosity and c is a constant. The plots of η^{-1} *versus* v yielded straight line plots with break at T_t and uncertain region around this temperature. The value of v_0 for the three compounds obtained from these plots are recorded in Table 3. These values, though different from those reported for many other organic liquids,[5] are close to the one reported for Cresols[14] where strong hydrogen bonding and structuring exist in the liquid state.

Several functional relationships, emperical, semi-emperical and theoretical have been proposed[6] for the viscosity in the low temperature region. For many compounds the viscosity data in this region fit into the Doolittle equation.[21]

$$\log \eta = A' + B'/(T - T_0), \qquad (2)$$

where T_0 is evisaged as a second order transition temperature. The evidence of applicability of Doolittle equation for our systems was not conclusive because the region of supercooling is rather short. A rough numerical fit yielded T_0 values of <10 K for the three compounds. These values are unexpectedly low considering that normally T_0 is about 20—100 K less than the melting temperature.[22] We consider it reasonable therefore, to assume that even below the melting temperature, the supercooled liquid follow an Arrhenius equation with different values of the constants.

It is observed that the E_{vis} and ΔS^* values are more positive in the supercooled region as compared to the high temperature region indicating an increase in association between molecules and a non-cooperative mechanism of flow. Two approaches based on the hinderance to rotation at or below T_t and on the cluster formation may be proposed to explain the enhanced viscosity in the supercooled region. The most commonly used procedure to establish the existence of hinderance to rotation is to compare the volume swept by rotation of the molecule, V_r, about a suitable axis with the actual volume available to it on the basis of experimental density data. Following Ubbelohde's procedure,[7] V_r for the molecules around the longer axis have been calculated and compared with the molar volumes in Table 3. The V_r is far in excess of the available volume, indicating that the enhanced viscosity of melts may result from hinderance to rotation.

In the alternate approach in terms of cluster formation it is assumed that the increase in viscosity and hence E_{vis} is due to the formation of clusters, the volume fraction ϕ of clusters have been calculated from the

TABLE 3. SOME CALCULATED PARAMETERS OF THE COMPOUNDS

	v_0 at temperatures		V_r / cm^3 mol^{-1}	Molar volume range[a] / cm^3 mol^{-1}	E_{vap} / kcal mol^{-1}
	$<T_t$	$<T_t$

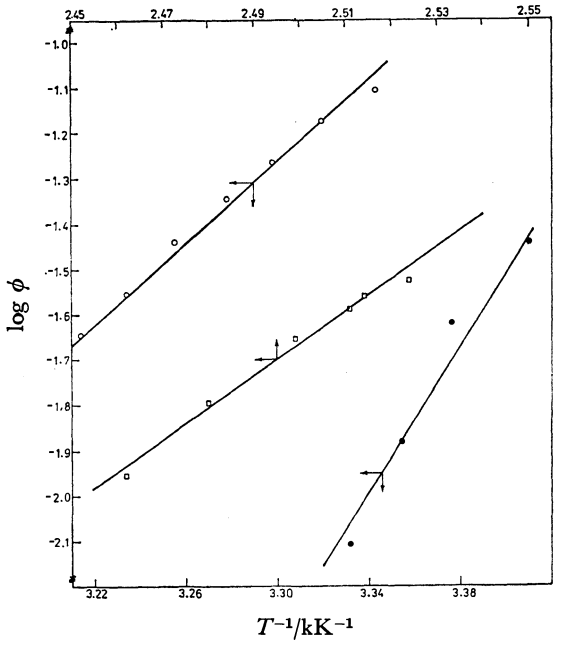

Fig. 2. The variation of Volumes fraction of Clusters (ϕ) with temperature (T) for *trans*-stilbene (□); *N*-benzylideneaniline (○); and *N*-benzylidene-*p*-toluidine (●).

Einstein equation.[23]

$$\eta/\eta_{ext.} = 1 + 2.5\phi + 7\phi^2, \quad (3)$$

where η_{ext} is the viscosity extrapolated from high temperature region and η is the actual viscosity. The plots of log ϕ *versus* T^{-1} are shown in Fig. 2. These are similar to the one obtained by Ubbelohde for dimeric, trimeric and even polymeric clusters of organic molecules. Following Ubbelohde,[23] the equilibrium constant K for the equilibrium

$$A_n \rightleftharpoons nA, \quad (4)$$

where n are the number of molecules in the cluster. We have calculated K at different temperatures for various values of n between 2 and 6, and also the heat of depolymerization of clusters, ΔH_d. It was found to be same for different values of n. The ΔH_d values have been compared with ΔH_f values for the compounds in Table 4. The ratio $\Delta H_d/\Delta H_f$, which is considered as the number of molecules in the cluster, n, is 2 for *trans*-stilbene, 3 for BA and 4 for BT. It is possible that these clusters also consitute the unit of flow thus raising the E_{vis} in the supercooled region. At the same time the volumetric effects due to the cluster formation seems to be too small to bring about any sharp change in density at T_t is passed.

Spectrophotometric Determination of Copper, Cobalt, Nickel, and Tellurium after Extraction with Morpholine-4-carbodithioate into Molten Naphthalene

Mamta GAUTAM, R. K. BANSAL, and B. K. PURI*

Department of Chemistry, Indian Institute of Technology, Hauz Khas, New Delhi-110016, India

(Received March 25, 1980)

Potassium morpholine-4-carbodithioate has been examined as a reagent for the spectrophotometric determination of copper, cobalt, nickel and tellurium after extraction into molten naphthalene. The extracted mixture of metal complex and naphthalene was dissolved in chloroform and the trace amounts of these metals determined spectrophotometrically. Beer's law holds in the concentration range Cu: 5.0—70.0, Co: 5.0—81.0, Ni: 6.0—90.0, and Te: 5.7—125.0 μg per 10 ml of the final solution. The molar absorptivity and sensitivity are calculated to be Cu: 1.067×10^4 mol^{-1} cm^{-1}, 0.0059 μg/cm^2 (440 nm), Co: 1.350×10^4 mol^{-1} cm^{-1}, 0.0043 μg/cm^2 (360 nm), Ni: 7.920×10^3 mol^{-1} cm^{-1}, 0.0088 μg/cm^2 (390 nm), and Te: 1.075×10^4 mol^{-1} cm^{-1}, 0.0110 μg/cm^2 (415 nm). Aliquots containing 25.0 μg of copper, 27.0 μg of cobalt, 24.0 μg of nickel and 25.5 μg of tellurium gave a mean absorbance of 0.420, 0.620, 0.270, and 0.215 with a relative standard deviation of 0.0016, 0.0024, 0.0015, and 0.0013 respectively. The interference of various ions has been studied in detail. Only cobalt interfered in the determination of nickel which was eliminated by extraction first at low pH. Methods were developed for the determination of copper, cobalt and nickel in various alloys. A method was also developed for simultaneous determination of tellurium and selenium in the pure solution, based upon the thermal instability of seleniumelided carbodithioate complex.

Morpholine-4-carbodithioate has been suggested as a possible analytical reagent by Beyer and Ott[1] in the spectrophotometric[2,3] and volumetric[4] determination of some metals. Recently, it has been utilized in the gravimetric determination of tellurium, copper, bismuth, palladium and nickel.[5-8] The reagent was used in the thin layer[9] and paper[10] chromatographic separation of metal complexes. A preliminary study indicated that bismuth, copper, cobalt, nickel, and tellurium formed coloured, water insoluble and thermally stable metal complexes which may be extracted with molten naphthalene. The extraction-spectrophotometric determination of bismuth has been reported.[11] Conditions have been developed for the determination of copper, cobalt, nickel and tellurium and also for the analysis of alloys containing copper, cobalt and nickel. Based upon the thermal instability of selenium complex of this reagent, a method is suggested for the simultaneous determination of tellurium and selenium using this technique and liquid-liquid extraction at room temperature.

Experimental

Reagents. Potassium morpholine-4-carbodithioate was prepared by the method given by Macrotrigiano *et al.*,[12] 0.01 M aqueous solution being used when necessary. Solutions of copper sulfate, cobalt nitrate, nickel nitrate and potassium tellurite were prepared from samples (analytical grade) in distilled water and standardized.[13] Naphthalene and chloroform (analytical grade) were checked spectrophotometrically before use. 1% alkali salt and 0.1% metal salt solutions were used to study intereference. Dilute solutions of perchloric acid and ammonia were used to adjust pH.

Equipment. An Elico pH meter and a SP-700 spectrophotometer were used.

General Procedure. To an aliquot of each metal solution taken separately was added 1.0 ml of the reagent, the pH being adjusted (Fig. 2). After being transferred to round bottomed flasks with stopper and heated in a water-bath at *ca.* 60 °C, 2 g of naphthalene was added, heating being continued till naphthalene melted and formed a separate liquid-layer. This was stirred vigorously till the naphthalene separated out as a solid mass. The contents were again heated in the water-bath to remelt the naphthalene, shaken vigorously and allowed to stand. Naphthalene was separated from the aqueous phase by filteration, dried in folds of filter paper, dissolved in chloroform and made exactly 10 ml in each case. These solutions were dried by adding 2 g of anhydrous sodium sulfate, a portion being taken in a 1 cm cell and the absorbance measured against a reagent blank. This was referred to the calibration curve constructed under similar conditions in each case.

Results and Discussion

Absorption Spectra. The absorption spectra of potassium morpholine-4-carbodithioate and its copper, cobalt, nickel, and tellurium complexes were recorded in naphthalene-chloroform solution against water and reagent blank, respectively. Copper, cobalt, nickel, and tellurium morpholine-4-carbodithioates show absorptions at 440 nm, 360 nm, 385—390 nm, and 410—420 nm, respectively, the absorption of reagent being negligible at these wavelengths (Fig. 1).

Effect of pH. Extraction was carried out at different pH, other conditions being kept constant. The characteristics of all spectral curves were the same, indicating the presence of only one complex. The absorbances of the extracts were constant in the pH range of Cu: 4.5—8.0, Co: 3.5—9.5, Ni: 6.5—9.0 and Te: 4.0—6.5 respectively. The pH effect in each case is shown in Fig. 2.

Effect of Reagent. Extraction was carried out at optimum pH and varying amounts of reagent (Fig. 3). It was found to be quantitative in the volume range of Cu: 0.8—1.5 ml, Co: 1.0—2.0 ml, Ni: 1.0—2.5 ml and Te: 0.5—1.5 ml of 0.01 M reagent.

Effect of Naphthalene. Extraction was carried out by varying the amount of naphthalene from 0.25—4.5 g at optimum pH and under constant conditions. In all cases absorbance remained constant for 1.0—

when the aqueous phase did not exceed 60 ml but not quantitative, above 60 ml of the aqueous phase (Fig. 5).

Effect of Standing Time. Absorbance of the extract in naphthalene-chloroform was constant for at least 24 h for copper and cobalt, 40 h for nickel and 3 h for tellurium.

Effect of Electrolytes. Various electrolytes such as sodium chloride, sodium nitrate, and sodium acetate (0.01—0.08 M) caused no improvement in extraction, indicating that the extraction was complete.

Composition of the Complex. The composition of the copper, cobalt, nickel, and tellurium morpholine-4-carbodithioates was established by Job's method of continuous variation and the mole-ratio method. $Cu(C_4H_8ONCS_2)_2$, $Co(C_4H_8ONCS_2)_2$, $Ni(C_4H_8ONCS_2)_2$, and $Te(C_4H_8ONCS_2)_4$ have been extracted into molten naphthalene. It has been confirmed on the basis of gravimetric[5-8,14] volumetric[4,14] and conductometric[5] studies that the ligand acts as bidentate. The following tentative structures can be assigned to these metal complexes.

Table 3. Determination of copper in various alloys

Alloy	Certified % composition	Amount of Cu taken μg	Amount of Cu found μg	Average (μg)	Error %

where $n=2$ for Cu, Co, and Ni, 4 for Te. Crystal structure study showed that in the case of the tellurium complex all four dithiocarbamate groups are bidentate and the eight sulphur atoms are bonded around the central tellurium atom in a slightly distorted dodecahedral manner;[15] in IR studies, the C···N and C···S stretching frequencies in Te(IV) complex were observed at 1000 cm^{-1} for the latter and 1480 cm^{-1} for the former. In the free ligand these modes were observed at 990 cm^{-1} and 1440 cm^{-1}, respectively.

Beer's Law and Sensitivity. Under optimum conditions described above, calibration curves were constructed at 440, 360, 385—390, and 410—420 nm against reagent blank, respectively. Beer's Law holds in the concentration range Cu: 5.0—70.0 μg, Co: 5.0—81.0 μg, Ni: 6.0—90.0 μg and Te: 5.7—125.0 μg per 10 ml of the final solution. The molar absorptivities and sensitivities in terms of Sandell's definition were calculated to be Cu: 1.067×10^4 mol^{-1} cm^{-1}, 0.0059 μg/cm^2 (440 nm); Co: 1.350×10^4 mol^{-1} cm^{-1}, 0.0043 μg/cm^2 (360 nm); Ni: 7.920×10^3 mol^{-1} cm^{-1}, 0.0088 μg/cm^2 (390 nm), and Te: 1.075×10^4 mol^{-1} cm^{-1}, 0.0110 μg/cm^2 (415 nm) respectively. Aliquots containing 25.0 μg of copper, 27.0 μg of cobalt, 24.0 μg of nickel and 25.5 μg of tellurium gave mean absorption of 0.42, 0.62, 0.27, and 0.215 with a relative standard deviation of 0.0016, 0.0024, 0.0015, and 0.0013, respectively.

Effect of Diverse Ions. 50 mg salt of the anions and 1.0 mg salt of the cations were added separately to aliquots containing 25.0 μg of copper, 27.0 μg of cobalt, 24.0 μg of nickel and 25.5 μg of tellurium, of the anions (Table 1) fluoride, citrate, tartrate, oxalate, and EDTA interfered in the determination of the metals, minor amounts of fluoride, citrate, tartrate and oxalate giving no serious effect. The extraction was almost nil in the presence of EDTA in the case of Cu, Co, and Ni probably due to higher stability of metal–EDTA complexes. A smaller amount of EDTA is allowable in the case of tellurium.

Of the cations (Table 2), Co (II) and Fe (III) interfered in the determination of copper, Cu (II) and Fe (III) in that of cobalt, and Cu (II) and Fe (III) and Co (II) in that of nickel. In all cases the relatively small amount can be tolerated except in the determination of nickel where Co(II) seriously interfered. Its interference can be eliminated by extraction first at low pH, then nickel being determined from the aqueous phase. In the determination of tellurium relatively small amounts of Cu (II), Co (II), and Fe (III) could be tolerated, nickel not interfering at all.

Determination of Copper, Cobalt, and Nickel in Various Alloys. 0.1 g of the alloy sample was taken in a beaker to which were added 10—15 ml of concentrated hydrochloric acid and a few ml of concentrated nitric acid. This was heated over a hot plate till the mixture dissolved completely and the solution was reduced to 5 ml. The solution was cooled, 10 ml of hydrochloric acid being added, then diluted and filtered. The final volume was made exactly 500 ml.

TABLE 6. SIMULTANEOUS DETERMINATION OF NICKEL AND COBALT IN AN ALLOY

Alloy	Amount of Ni/Co taken (μg)	Amount of Ni/Co found (μg)	Average (μg)	Error %
Elgiloy (M-1712)	Ni: 33.90	33.70 34.00 33.50 33.80 33.70	33.74	−0.74
	Co: 36.16	36.00 35.90 36.00 36.00 35.00	35.98	−0.55

An aliquot containing an appropriate amount of copper, cobalt or nickel was taken separately in a beaker, 1.0 ml of the reagent being added, the pH adjusted (Fig. 2), and determined by the general procedure. Results are given in Tables 3, 4, and 5 respectively.

Simultaneous Determination of Nickel and Cobalt in Alloys. Based upon the fact that the nickel complex is decomposed by ammonia to form a more stable complex whereas the cobalt morpholine-4-carbodithioate complex remains as such in chloroform, a method has been developed for the determination of nickel and cobalt present together.

An aliquot containing nickel and cobalt was taken, 2.0 ml of the reagent being added and the pH adjusted to 7.0. The solution was then extracted with molten naphthalene. Naphthalene containing nickel and cobalt morpholine-4-carbodithioate was dissolved in chloroform, the volume being made 10 ml. 5 ml of the solution was taken, dried with sodium sulfate, the absorbance being measured at 390 nm against a reagent blank. This corresponded to total absorbance due to cobalt and nickel complexes. To the other 5 ml of the solution was added 5 ml of 1:10 ammonia solution in a separating funnel. The organic phase was separated, dried by adding anhydrous sodium sulfate and the absorbance measured at 360 and 390 nm. The cobalt complex is not affected by shaking with ammonia, the absorbance at 360 nm corresponding to the amount of cobalt present. The absorbance was referred to the calibration curve for cobalt prepared under similar conditions. The amount of nickel was determined by the difference of total absorbance at 390 nm and that due to cobalt at 360 nm and referring it to the calibration curve for nickel at 390 nm. The results of the determination of nickel and cobalt in one alloy sample are given in Table 6.

Simultaneous determination may also be carried out by the control of pH. However, this is time consuming and less accurate since two steps are involved (the relative error $\approx1\%$).

Simultaneous Determination of Tellurium and Selenium. Preliminary investigations indicated that selenium is

Table 7. Simultaneous determination of tellurium and selenium

Tellurium	Selenium
Morpholine-4-carbodithioate (0.01 M): 1.0 ml.	Dithizone in CCl_4 (60 μmol/l): 5.0 ml.

a) Ref.[11]

not extracted with molten naphthalene. A method has been developed for the simultaneous determination of tellurium and selenium.

An aliquot containing appropriate amounts of these two metals was taken, 1.0 ml of the reagent being added and the pH adjusted (Fig. 2). Tellurium was then determined. From the aqueous phase selenium was extracted in 6 M HCl as a dithizone complex in carbon tetrachloride.[16] The absorbance was measured at 420 nm against a reagent blank. The amount of selenium was determined by the calibration curve prepared under similar conditions (Table 7). Selenium can be extracted with a suitable organic solvent by liquid-liquid extraction as morpholine-4-carbodithioate, but not by spectrophotometry since the complex gives no absorption.

The extraction behavior of metal morpholine-4-carbodithioates is summarized in Table 8.

One of the authors (M.G.) is grateful to the Council of Scientific and Industrial Research, New Delhi, India, for the award of Senior Research Fellowship.

The Effects of the BF_2- and $B(C_2H_5)_2$-substitution for Bridging Hydrogen Atoms in the Cobalt(II), Nickel(II), and Copper(II) Complexes with Some Oximate Ligands

Yasuomi NONAKA* and Kohsuke HAMADA

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received September 16, 1980)

Cobalt(II), nickel(II), and copper(II) complexes with dioximes substituted by BF_2- and $B(C_2H_5)_2$-groups for bridging hydrogen atoms were prepared. The BF_2-substitution caused a red-shift of d-d band and increase of $g_{//}$-value for copper(II) complexes and positive shift of polarographic half wave potential of nickel(II) complexes. In the case of the $B(C_2H_5)_2$-substituted complexes, such variations were not observed. The BF_2-substituted cobalt(II) complexes are stable under an open atmosphere at room temperature in a solid state and in a DMF solution. These were interpreted in terms of the electron-withdrawing ability of BF_2-group in the ligand.

In 1962, nickel(II) complexes with BF_2- or BR_2(R= CH_3, *n*-C_3H_7, *n*-C_4H_9, and *i*-C_4H_9)-linked dioximes were prepared and characterized by Schrauzer[1] (the structures and abbreviations of these complexes are shown in Fig. 1). In the electronic spectra of these complexes,

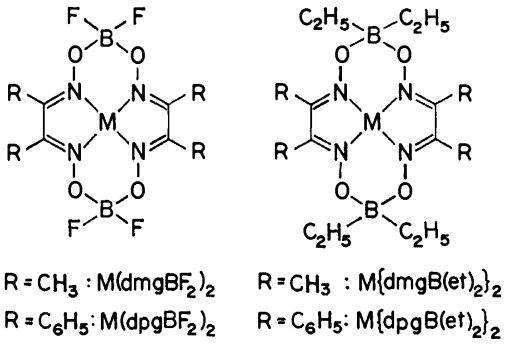

Fig. 1. Structures and abbreviations of the complexes used in this study.

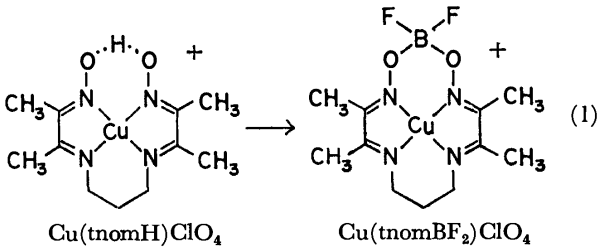
little change due to the introduction of BF_2- or BR_2-group was observed. Therefore, it was concluded that these substituents exert no effect on the ligand field around the nickel ion. Recently, Gagnè[2] obtained the dark purple complex, $Cu(tnomBF_2)ClO_4$, from brown $Cu(tnomH)ClO_4$:



(1)

Drago and Gaul[3] found that $Co(dpgBF_2)_2(N\text{-meim})_2$ formed in a solution of $Co(dpgBF_2)_2 \cdot 2CH_3OH$ containing *N*-methylimidazole (*N*-meim) is stable under aerobic conditions. The discoloration by introduction of BF_2-group (Eq. 1) and the high stability of resulting $Co(dpgBF_2)_2(N\text{-meim})_2$ complex against molecular oxygen suggest that the electronic state of the complexes is affected by the introduction of BF_2-group. Then, the substitution of BF_2-group for the bridging hydrogen may bring about change in the ring size and/or the electron density on the nitrogen atoms.

In this study, we have systematically prepared cobalt(II), nickel(II), and copper(II) complexes with BF_2- or $B(C_2H_5)_2$-substituted macrocyclic ligands as shown in Fig. 1, in order to elucidate the effects of these substituents on the electronic state of the complexes, coordination geometry, the reactivity of cobalt(II) complexes with molecular oxygen, and the equilibrium of cobalt(II) complexes with some organic bases, such as pyridine, in DMF solution.

Experimental

Synthesis. Triethylborane was prepared by the procedure of Meerwein and Mitab.[4] This material ignites spontaneously in air and hence it was used for subsequent reactions as a diethyl ether solution (*ca.* 30%).

Cu(dmgBF$_2$)$_2$·2dioxane: To a suspension of $Cu(dmgH)_2$ (4.5 g) in dioxane (90 cm^3) was added dropwise a dioxane solution (50 cm^3) containing boron trifluoride etherate (10 cm^3) at 60 °C. Reaction mixture was stirred at 80 °C for 1 h. On standing overnight, fine dark purple crystals were separated. These were recrystalized from acetone–dioxane (1 : 1).

Found: C, 33.84; H, 4.97; N, 9.93%. Calcd for $C_{16}H_{28}N_4O_8B_2F_4Cu$: C, 33.98; H, 4.99; N, 9.91%.

Cu(dpgBF$_2$)$_2$·2dioxane: This was prepared in a procedure similar to that for $Cu(dmgBF_2)_2 \cdot 2$dioxane by using $Cu(dpgH)_2$ (5.5 g) instead of $Cu(dmgH)_2$.

Found: C, 53.24; H, 4.53; N, 6.88%. Calcd for $C_{36}H_{36}N_4O_8B_2F_4Cu$: C, 53.13; H, 4.46; N, 6.88%.

Cu{dmgB(et)$_2$}$_2$: To a suspension of $Cu(dmgH)_2$ (4.5 g) in dioxane (100 cm^3) was added dropwise at room temperature 40 cm^3 of a diethyl ether solution of triethylborane. Reaction mixture was stirred at 80 °C for 1 h and concentrated to *ca.* 70 cm^3. After being left to stand overnight, the product was collected and recrystallized from dichloromethane–benzene (1 : 1) to give brown fine crystals.

Found: C, 44.73; H, 7.51; N, 13.04%. Calcd for $C_{16}H_{32}N_4O_4B_2Cu$: C, 44.31; H, 7.41; N, 13.25%.

Cu{dpgB(et)$_2$}$_2$·dioxane·H$_2$O: This was obtained in a procedure similar to that for $Cu\{dmgB(et)_2\}_2$ by using $Cu(dpgH)_2$ (5.5 g) instead of $Cu(dmgH)_2$. Recrystallization was carried out from chloroform–dioxane (1 : 1).

Found: C, 60.78; H, 6.15; N, 6.94%. Calcd for $C_{40}H_{50}N_4O_7B_2Cu$: C, 61.28; H, 6.43; N, 7.14%.

Ni(dmgBF$_2$)$_2$ and Ni(dpgBF$_2$)$_2$: These were prepared by the procedure of Schrauzer.[1]

Ni{dmgB(et)$_2$}$_2$: To a suspension of $Ni(dmgH)_2$ (4.3 g) in

dichloromethane (80 cm^3) was added dropwise 40 cm^3 of a diethyl ether solution of triethylborane at 40 °C. The solid dissolved gradually forming a red solution. The solution was evaporated to *ca.* 60 cm^3 and left stand overnight to give reddish orange fine crystals. These were recrystallized from benzene–chloroform (1 : 1).

Found: C, 45.15; H, 7.62; N, 13.18%. Calcd for $C_{16}H_{32}N_4O_4B_2Ni$: C, 45.24; H, 7.59; N, 13.19%.

Ni{dpgB(et)$_2$}$_2$·1/2CH$_2$Cl$_2$: This was prepared in a procedure similar to that for Ni{dmgB(et)$_2$}$_2$ by using Ni(dpgH)$_2$ (5.5 g) instead of Ni(dmgH)$_2$. Recrystallization was carried out from dichloromethane–diethyl ether (2 : 1).

Found: C, 61.01; H, 6.08; N, 7.57%. Calcd for $C_{36.5}H_{41}N_4O_4B_2ClNi$: C, 61.27; H, 5.78; N, 7.83%.

Co(dmgBF$_2$)$_2$·2H$_2$O: This was prepared in a procedure similar to that for Cu(dmgBF$_2$)$_2$·2dioxane by using Co(dmgH)$_2$·2H$_2$O (4.2 g) instead of Cu(dmgH)$_2$. The operations were carried out under nitrogen atmosphere and then brown fine crystals were obtained. These were dried at 80 °C for several hours under a reduced pressure over P_2O_5.

Found: C, 23.05; H, 3.87; N, 12.98%. Calcd for $C_8H_{16}N_4O_6B_2F_4Co$: C, 22.84; H, 3.83; N, 13.31%.

Co(dpgBF$_2$)$_2$·2H$_2$O·dioxane: This was prepared in the procedure similar to that by Tovrog *et al.*[5] Recrystallization was carried out from acetone–dioxane (1 : 1) under nitrogen atmosphere to give marron fine crystals.

Found: C, 50.19; H, 4.35; N, 7.40%. Calcd for $C_{32}H_{32}N_4O_8B_2F_4Co$: C, 50.76; H, 4.26; N, 7.40%.

Physical Measurements. Electronic spectra were measured at 25.0±0.2 °C with a Shimadzu Multipurpose Spectrophotometer Model MPS-5000. ESR spectra were measured with a JES-ME-3X Spectrometer using an X-band at room and liquid nitrogen temperatures. DPPH and Mn/MgO were used as standard markers. Thermogravimetric analyses were carried out with a Rigaku-denki Thermogavimetric and Differential Thermal Analyzer Model 8075E-1. All polarographic measurements were made at 25.0±0.2 °C in *N,N*-dimethylformamide (DMF), which was dried over molecular sieves (4A—1/16 type) and was distilled under nitrogen atmosphere. Tetraethylammonium perchlorate (TEAP) was used as a supporting electrolyte (0.1 mol/dm^3). The concentration of complexes was maintained constant (5×10^{-4} mol/dm^3) except for Ni(dmgH)$_2$. In the case of Ni(dmgH)$_2$, the saturated solution was used. All solutions were deoxygenated by bubbling pure nitrogen gas. A Fuso Polarographic Analyzer Model 312 was used for sampled d. c. polarography.

A three-electrode system[6] consisting of the droping mercury, the platinum wire and the saturated calomel electrodes as a working, a counter and a reference electrodes, respectively, was adopted. The saturated calomel electrode was connected to the sample solution through a salt bridge.[7]

Determination of Adduct Formation Constant. Deoxygenated DMF solution (100 cm^3) of Co(dmgBF$_2$)$_2$·2H$_2$O, Co(dpgBF$_2$)$_2$·2H$_2$O·dioxane, or Co(dpgH)$_2$·2H$_2$O was placed into a three necked flask (200 cm^3, filled with dry nitrogen) fitted with a tube connected to the cell for spectral measurement, and another neck being fitted with a buret to drop DMF solution of an organic base. After an organic base had been added to as olution of the complex, the solution was stirred for 10 min with a magnetic stirrer. The reaction mixture was led to the cell for spectral measurements. Equilibrium constants were determined at 25.0±0.2 °C by the method of Marzilli *et al.*[8]

Results and Discussion

Results of the elemental analyses and the infrared spectra suggested that the molecules of dioxane and/or water are contained in crystals of some compounds obtained. These were confirmed by thermogravimetric analyses.

All attempts to isolate a BF_2-linked metal free ligand or its alkali metal salt were unsuccessful to obtain dimethylglyoxime.

Electronic Spectra of Copper(II) Complexes. The electronic spectra of Cu(dmgH)$_2$ in various solvents[9,10] seem to consist of a number of bands overlapping each other. The d-d band[9] observed at about 22.0×10^3 cm^{-1} as a shoulder is almost concealed by an intense CT band. A methanol solution of Cu(dmgBF$_2$)$_2$ exhibits a peak at 21.5×10^3 cm^{-1} with a shoulder at 20.0×10^3 cm^{-1}. These bands regarded as d-d bands

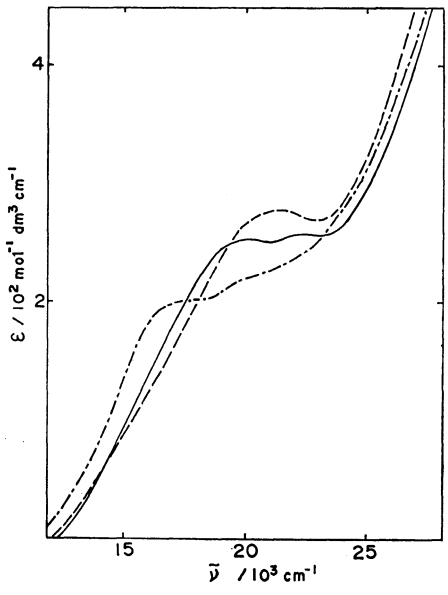


Fig. 2. Electronic spectra of Cu(dmgBF$_2$)$_2$ in methanol (----), acetone (——), and DMF (– – –).

Table 1. Electronic and ESR spectral data of copper(II) complexes

Compound	Solvent	$\tilde{\nu}$/10^3cm^{-1}	(ε/mol^{-1} dm^3 cm^{-1})	$g_{//}$	$A_{//}$/10^{-4} cm^{-1}

*: Shoulder.

were shifted to lower energy side in a DMF solution (Fig. 2). On the other hand, the spectrum of methanol solution of $Cu\{dmgB(et)_2\}_2$ is similar to that of $Cu(dmgH)_2$ (Table 1). Therefore, it can be concluded that no drastic change due to the substitution of BF_2- and $B(C_2H_5)_2$-groups for bridging hydrogen occurs in the geometric structure and that the equatorial ligand field around the copper ion is weakened on account of the electron-withdrawing effect of BF_2-group, bringing about the subsequent axial ligation of solvent molecules.

Then, the lowering of $\pi(2p)$-orbitals of nitrogen atoms should be larger than that of d_{xy}-orbital with an unpaired electron, *i.e.*, the energy separation between metal d_{xy}- and ligand $\pi(2p)$-orbitals is expected to increase. In fact, the charge transfer band at 28.5×10^3 cm^{-1} in $Cu(dmgH)_2$[9] is shifted by 2.5×10^3 cm^{-1} to higher energy side in $Cu(dmgBF_2)_2$.

ESR Spectra of Copper(II) Complexes. The ESR spectra of BF_2- or $B(C_2H_5)_2$-substituted copper(II) complexes were measured in DMF solution at room and liquid nitrogen temperatures. All these spectra are similar to those of $Cu(dmgH)_2$[11] at both temperatures and essentially axial. The characteristic feature is that the $g_{//}$-value of $Cu(dmgBF_2)_2$ is appreciably large compared with those of $Cu(dmgH)_2$ and $Cu\{dmgB(et)_2\}_2$ which are comparable to each other (Table 1). The $g_{//}$-value for copper(II) complexes with axial symmetry is approximated[12] by

$$g_{//} = 2.0 - \frac{8\lambda\alpha^2}{\Delta}, \qquad (2)$$

where λ is the spin-orbit coupling constant of the copper ion, α is the coefficient of d_{xy} in the molecular orbitals,[12,13] and Δ is the energy separation between d_{xy} and $d_{x^2-y^2}$. This shows that $g_{//}$-value increases with the decrease of energy separation Δ, because λ is negative. Therefore, the order of $g_{//}$-value is reasonable in view of that of the d-d band; $Cu(dmgH)_2 \approx Cu\{dmg(et)_2\}_2 > Cu(dmgBF_2)_2$. Such tendency is recognized in dpg-derivatives. These results support the conclusion mentioned above.

Polarography of Nickel(II) Complexes. The sampled d.c. polarograms of $Ni(dmgH)_2$, $Ni(dmgBF_2)_2$, and $Ni\{dmgB(et)_2\}_2$ were obtained in DMF solution containing TEAP (0.1 mol/dm^3). These complexes exhibited two reduction waves (Fig. 3). All these reduction waves are reversible one-electron reduction, judging from the results of coulometry. Olson and Vasilevskis[14] reported that a reduction wave corresponding to the electrode reaction, Ni(II)(14-diene)→Ni(I)(14-diene), was observed at −1.57 V *vs.* Ag–0.1 M $AgNO_3$ (1 M=1 mol/dm^3; −1.28 V *vs.* SCE) in the cyclic voltammetry of $Ni(14\text{-diene})(ClO_4)_2$ in acetonitrile. In view of this result, the first and the second waves should correspond to the following electrode processes,

$$Ni(II)L \xrightarrow{e^-} Ni(I)L$$
$$Ni(I)L \xrightarrow{e^-} Ni(O)L, \qquad (3)$$

where L denotes $(dmgH)_2$, $(dmgBF_2)_2$, and $\{dmgB(et)_2\}_2$.

The half-wave potential of $Ni(dmgBF_2)_2$ is more positive in both processes than those of $Ni(dmgH)_2$ and $Ni\{dmgB(et)_2\}_2$ which are approximatly comparable. The same tendency was found in dpg-derivatives. The BF_2-linked complexes are more facile to be reduced compared with corresponding hydrogen bridged or $B(C_2H_5)_2$-linked complexes, due to the electron-withdrawing effect of BF_2-group. Therefore, the electron-withdrawing effect of BF_2-group considerably exerts on the electronic states of the nikel(II) complexes, although Schrauzer[1] claimed that the BF_2-group little affects the ligand field around the nickel(II) ion.

The reduction potentials of $Ni(dpgX)_2$ (X denotes H, BF_2, and $B(et)_2$) are more positive than those of the corresponding $Ni(dmgX)_2$. This suggests that the electron density on nickel ion of $Ni(dpgX)_2$ decreases because of the rather weak electron-donating effect of phenyl group compared with that of methyl group.

Electronic Spectra of Nickel(II) Complexes. Schrauzer[1] reported that in the spectra of $Ni(dmgX)_2$ (X denotes H, BF_2, and BR_2) in chloroform the bands at 21.1 and 24.4×10^3 cm^{-1} of $Ni(dmgH)_2$ are little shifted by the substitution of BF_2- or BR_2-groups for bridging hydrogen atoms. We measured the spectra of these complexes in DMF and in pyridine (Fig. 4). These spectra suffer little solvent effect in these solvents except for increase of intensity, although some of these solvents are capable of coordinating to a metal ion. On the other hand, it was shown from our polarographic results that the electron density on nickel ion of $Ni(dmgBF_2)_2$ decreases considerably compared with $Ni(dmgH)_2$ and $Ni\{(dmgB(et)_2\}_2$. Consequently, the resemblance in the spectra of $Ni(dmgX)_2$ reported by Schrauzer is attributed to the fact that the axial coordination of solvents is not promoted by the substitution of BF_2-group for bridging hydrogen atom.

Formation Constants of $Co(dmgBF_2)_2(base)_n$ and $Co(dpgBF_2)_2(base)_n$ (n=1 or 2). A solution of $Co(dmgBF_2)_2$ in DMF exhibits an absorption band at 21.7×10^3 cm^{-1} (ε=2700) at 25 °C. When pyridine is added to this solution, the band diminished and a new band appeared at 23.5×10^3 cm^{-1} with an isosbestic point at 22.7×10^3 cm^{-1} (Fig. 5). The spectrum converged to one curve when pyridine concentration exceeded 0.1 mol/dm^3 (400 times of the complex

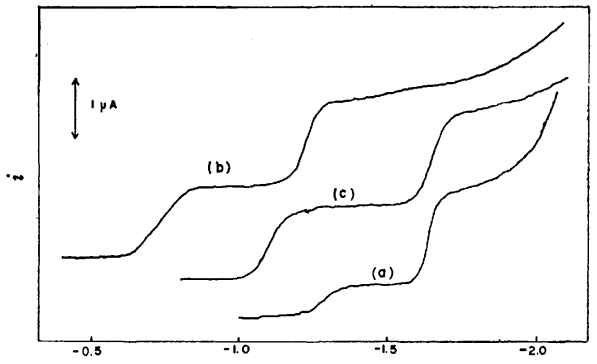

Fig. 3. Sampled d.c. polarograms of (a) $Ni(dmgH)_2$, (b) $Ni(dmgBF_2)_2$, and (c) $Ni\{dmgB(et)_2\}_2$ in DMF containing TEAP (0.1 mol/dm^3).

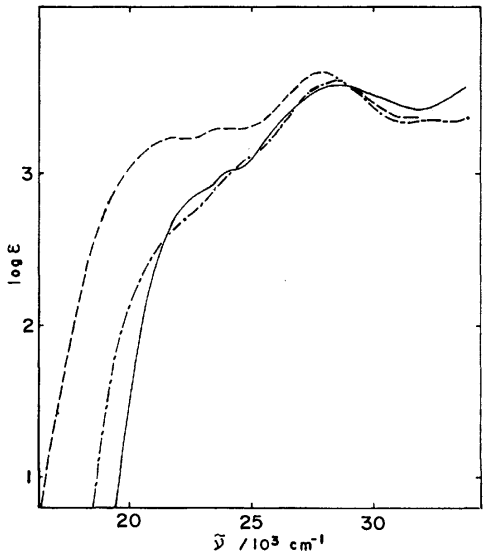

Fig. 4. Electronic spectra of $Ni(dmgBF_2)_2$ in chloroform (——), DMF (– – –), and pyridine (–·–·–).

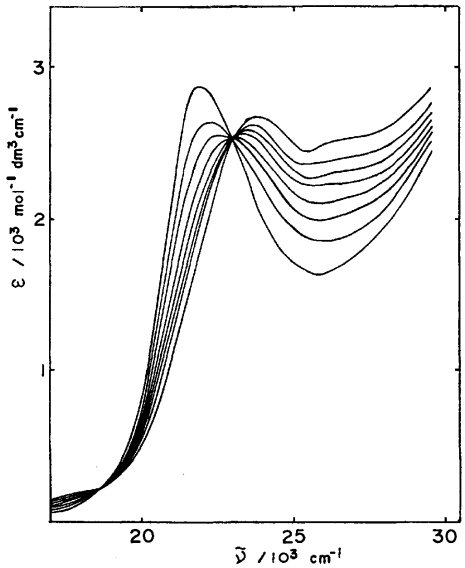

Fig. 5. Electronic spectra of $Co(dmgBF_2)_2$ in DMF with various contents of pyridine: 1), 0; 2), 1.4×10^{-3}; 3), 2.7×10^{-3}; 4), 5.9×10^{-3}; 5), 9.4×10^{-3}; 6), 1.5×10^{-2}; 7), 3.0×10^{-2}; 8), 1.0×10^{-1} mol/dm³. The concentration of $Co(dmgBF_2)_2$ is maintained constant (2.5×10^{-4} mol/dm³).

concentration). This spectral variation should correspond to the equilibrium,

$$Co(dmgBF_2)_2 + n\cdot py \rightleftharpoons Co(dmgBF_2)_2(py)_n (n=1 \text{ or } 2). \quad (4)$$

The equilibrium constant of this equation is given by the relation,

$$\beta = [Co(dmgBF_2)_2(py)_n]/[Co(dmgBF_2)_2][py]^n. \quad (5)$$

When A_0, A, and A_∞ denote the absorbances of $Co(dmgBF_2)_2$ at 21.7×10^3 cm^{-1} in the absence of pyridine, in the presence of pyridine and in the presence of large excess of pyridine, respectively, the equilibrium constant is given by

$$\log\beta = \log[(A_0-A)/(A-A_\infty)] - n\log[py]. \quad (6)$$

The free pyridine concentration [py] is corrected by

$$[py] = [py]_t - [(A_0-A)/(A_0-A_\infty)]\,[M], \quad (7)$$

where $[py]_t$ and [M] denote total concentrations of pyridine and the metal complex, respectively. Then, $\log[(A_0-A)/(A-A_\infty)]$ was plotted against log [py] which was calculated by Eq. 7 for both cases of $n=1$ and 2(Hill-plot). The plot for $n=1$ gives a straight line with a slope nearly equal to 1, and that for $n=2$ gives no straight line. Then, it became evident that one molecule of pyridine is bound to a cobalt ion. The equilibrium constant ($\log\beta$)was evaluated by extrapolating log [py] to zero. In the cases that the other organic base was used instead of pyridine, the equilibrium constants and n-values were evaluated in a similar manner as above (Table 2). For all the reactions between $Co(dmgBF_2)_2$ and organic bases, $n=1$ was

a) Jäger-type open-chain ligand. b) Protoporphyrin IX dimethyl ester. c) im: Imidazole, py: pyridine, 2-etim: 2-ethylimidazole, α-pic: α-picoline, γ-pic: γ-picoline. d) n* was evaluated from ^{14}N-superhyperfine splitting of the ESR spectrum. e) See Ref. 20. f) 1,2-Dichloroethane.

obtained. This shows that one molecule of the organic base links to the metal complex to form a five-coordinate complex $Co(dmgBF_2)_2(base)$.

The formation constants of $Co(dmgH)_2(py)$,[15] Co-(J-en)(py),[16] and Co(ppIXdme)(py)[17,18] at room temperature were reported (Table 2). In all cases, the mono-base adducts are predominant in the solution. Accordingly, it seems that square planer cobalt(II) complexes tend to form five-coordinate complexes with an organic base in solution. Thus, the present result that a five-coordinate complex, $Co(dmgBF_2)_2(base)$, is formed is consistent with this tendency.

On the other hand, two molecules of organic base coordinate to $Co(dmgBF_2)_2$ at apical sites at 77 K, judging from the five-lined ^{14}N-superhyperfine structure in ESR spectrum in DMF glass containing organic base (except for 2-ethylimidazole). Therefore, it was revealed that the coordination manner of the organic base to $Co(dmgBF_2)_2$ at room temperature is different from that at low temperature, as seen in Co(J-en)-pyridine system reported by Kubokura *et al.*[16]

The formation constants of $Co(dpgBF_2)_2(base)_n$ at 25 °C were evaluated by using the variation of absorbance at 20.0×10^3 cm^{-1} by a procedure similar to the case of $Co(dmgBF_2)_2(py)$. When pyridine, imidazole, α- and γ-picoline were used, $n=2$ was obtained from the slope of Hill-plots, and then, six-coordinate complexes $Co(dpgBF_2)_2(base)_2$ were shown to be formed, in contrast to the general tendency as mentioned above.

The electron-withdrawing effect of BF_2-group is more effectively exerted on $Co(dpgBF_2)_2$ than $Co(dmgBF_2)_2$, because the electron-donating ability of phenyl group is negligibly weak compared with that of methyl group. Consequently, the electron density on the cobalt(II) ion decreases and the axial coordination of ligands is facilitated.

When 2-ethylimidazole was used, the five-coordinate complex $Co(dpgBF_2)_2$(2-etim) was formed at 25 °C. This is explained in terms of the steric hindrance of ethyl group adjacent to the donating nitrogen atom.

Reaction of $Co(dmgBF_2)_2$ and $Co(dpgBF_2)_2$ with Molecular Oxygen. The electronic spectra of $Co(dmgBF_2)_2$ in DMF solution were measured under N_2-, O_2-, and an open atmospheres. The spectrum obtained under O_2-atmosphere is practically same as those under an open and N_2-atmospheres. This indicates that $Co(dmgBF_2)_2$ in the solution hardly reacts with molecular oxygen at room temperature.

The ESR spectrum of $Co(dpgBF_2)_2$ measured in acetonitrile frozen solution under an open atmosphere exhibited an axial pattern characteristic of low-spin, d^7-tetragonal complexes of cobalt(II) with $(d_{xy})^2(d_{z^2})^1$-ground state[19] (Fig. 6).

These results are noteworthy in contrast to the fact that the solutions of $Co(dmgH)_2$ and $Co(dpgH)_2$ are oxidized immediately on exposure to air. The d_{z^2}-orbital of $Co(dmgBF_2)_2$ and $Co(dpgBF_2)_2$ is lowlying relative to that of $Co(dmgH)_2$ and $Co(dpgH)_2$ because of the electron-withdrawing effect of BF_2-group. Accordingly, in the cases of BF_2-linked complexes the donation from metal-d_{z^2}-orbital to oxygen-π^*-orbital is

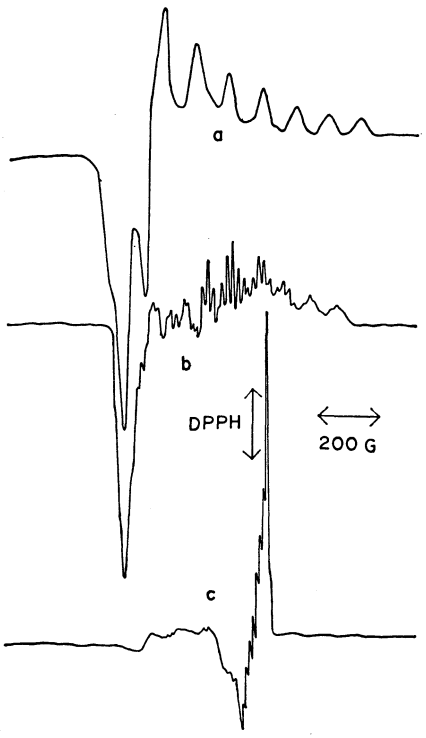

Fig. 6. ESR spectra of $Co(dpgBF_2)_2$ in (a) acetonitrile, (b) DMF–pyridine (19 : 1), and (c) DMF–2-etim (19 : 1) at liquid nitrogen temperature under aerobic conditions. ($1G=10^{-4}$ T).

diminished. Drago and Gaul[3] found that six-coordinate complex, $Co(dpgBF_2)_2(N\text{-meim})_2$, is prepared in the solution of $Co(dpgBF_2)_2$ containing *N*-methylimidazole (*N*-meim) and that no oxygenated complex is formed under aerobic conditions. The formation of the same type six-coordinate complexes is recognized in solutions of $Co(dpgBF_2)_2$ containing excess pyridine and γ-picoline under an open atmosphere (Fig. 6), although oxygenated complexes were found in a solution of $Co(dpgH)_2$ containing excess pyridine.[20] These facts suggest that decrease of the electron density on cobalt ion facilitates the formation of normal coordination bond between cobalt and organic base, and that the formation of such strong bond hinders the exchange an organic base for molecular oxygen.

ESR spectrum of the DMF frozen solution of $Co(dmgBF_2)_2$ containing excess pyridine under an open atmosphere exhibits a relatively weak, sharp signal at $g=ca.$ 2, in addition to main signal due to the di-base adduct, $Co(dmgBF_2)_2(py)_2$. This shows the slight formation of an oxygenated complex. The reason may be that the electron-withdrawing effect of BF_2-group is partially canceled by the electron-donating ability of methyl group.

The ESR spectra of $Co(dmgBF_2)_2$ and $Co(dpgBF_2)_2$ in DMF frozen solution containing excess 2-ethylimidazole under an open atmosphere (Fig. 6) are drastically different from those of the di-base adducts such as $Co(dmgBF_2)_2(py)_2$ and are characteristic of oxygenated complexes formally described as a superoxide-cobalt(III) complex.[21] As mentioned above, the five-coordinate complex is formed under an

unaerobic condition when 2-ethylimidazole was used. Thus, it becomes possible for a molecular oxygen to come close to a vacant sixth coordination site of cobalt ion.

The authors are deeply grateful to Professor Sigeo Kida, Kyushu University, for his helpful discussion. We also would like to thank Professor Makoto Aihara, Fukuoka Woman's University, for the polarographic measurements. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Preparation and Ligand Field Absorption Spectra of $[CrF_2(O\text{-}O)_2]^{3-}$ and $[CrF_2(O\text{-}O)(en)]^-$ Type Complexes

Sumio KAIZAKI,* Mieko AKAHO(nee ASADA), Yasuyo MORITA, and Kuniko UNO

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630

(Received December 15, 1980)

Two geometrical isomeric pairs of $[CrF_2(O\text{-}O)_2]^{3-}$ and either one of two possible geometrical isomers of $[CrF_2(O\text{-}O)(en)]^-$, where O–O denotes oxalate and malonate anions, were newly prepared and characterized by means of the spectral and chromatographic elution behaviors. It was found that $[CrF_2(ox)(en)]^-$ and $[CrF_2(mal)(en)]^-$ obtained take *cis* and *trans* forms, respectively. The ligand field absorption spectra of the present complexes were compared with one another, and with those of the corresponding aqua complexes of the same type. On the basis of the analyses of the absorption spectra in terms of the angular overlap model, the AOM parameters (e_σ and e_π) for the ligands concerned were estimated, and their transferability assumption and the anisotropic π interactions of Cr–O bonding with respect to the chelate plane of the dicarboxylate ligands were discussed.

There have been spectral as well as preparative studies on difluorochromium(III) complexes like *trans*-$[CrF_2(H_2O)_4]^+$ and *trans*-$[CrF_2(N)_4]^+$ type complexes.[1-4] Such complexes exhibit characteristic spectral pattern in the ligand field band region: significant splitting of the second band, which facilitates the application of the angular overlap model (AOM). These studies have been mainly concerned with linearly ligating ligands[5] such as saturated amines and halide ions, and with nonlinear ligators such as pyridine, but not with dicarboxylate chelates in which Cr–O bonding may be formed with different π-interactions vertical and parallel to the chelate planes besides with the σ-interactions.[5] The estimates of the AOM parameters for the dicarboxylate ligands provide a valuable clue to test the assumption of parameter transferability from one complex to another and to clarify the anisotropy of the Cr–O π-interactions with respect to the chelate planes. For this purpose, such high symmetry complexes as *trans*-$[CrF_2(O\text{-}O)_2]^{3-}$ and *trans*-$[CrF_2(O\text{-}O)(en)]^-$ with dicarboxylates are considered to be suitable as a simple model case, because their ligand field spectra are expected to give splitting patterns as observed for those of *trans*-difluoro chromium(III) complexes with aqua and/or ethylenediamine ligands. However, there has been known no such mixed difluorochromium(III) complex with dicarboxylates.

The present paper deals with the preparation and characterization of two geometrical isomers, *cis*- and *trans*-$[CrF_2(O\text{-}O)_2]^{3-}$, where O–O denotes oxalate and malonate ions, and those of *cis*-$[CrF_2(ox)(en)]^-$ and *trans*-$[CrF_2(mal)(en)]^-$. The spectral behavior in the ligand field band region of these complexes is explored in connection with that of the corresponding aqua complexes, $[CrF_2(H_2O)_4]^+$, $[CrF_2(en)(H_2O)_2]^+$, and $[Cr(ox)_2(H_2O)_2]^-$, and analyzed in terms of the AOM.

Experimental

Preparation of the Complexes. *(1)* cis- *and* trans-$[CrF_2(O\text{-}O)_2]^{3-}$: Five grams of *cis*-$K[Cr(ox)_2(H_2O)_2]\cdot 3H_2O$ and 0.86 g of potassium fluoride were dissolved in 300 cm^3 of water in a polyethylene beaker. After the solution was heated at 60 °C on a water bath for about 6 h, the color of the solution changed from red violet to dark green. By adding the resultant solution to a large amount of methanol, pale green precipitate was obtained. An aqueous solution of this precipitate was poured onto a column (4×60 cm) of anion exchanger (QAE-Sephadex A-25), and the column was swept with water. When the adsorbed band was eluted with a 0.1 mol dm^{-3} sodium chloride solution, the column gave five bands. Of these bands, the four faster eluted bands (B-I, B-II, B-III, and B-IV) were found to be the complexes containing fluoride, oxalate ion, and water as ligands by the qualitative analyses in terms of zirconium alizarin paper tests for fluoride and potassium permanganate tests for oxalate, and by the fact that their first d-d absorption bands are shifted to the lower frequency by increasing in pH (*ca.* 10) of the eluate with a 0.1 mol dm^{-3} sodium hydroxide solution. Taking into account of these facts and the position of the first absorption band as well as the chromatographic elution behavior, three faster eluted bands (B-I, B-II, and B-III) may be three possible geometrical isomers of $[CrF_2(ox)(H_2O)_2]^-$ and two later eluted bands (B-IV and B-V) two possible isomers of $[CrF_3(ox)(H_2O)]^{2-}$ or $[CrF(ox)_2(H_2O)]^{2-}$. But their characterization was not attempted. When the fifth band(B-V) was eluted with a sodium chloride solution (0.2 mol dm^{-3} in the early stage of elution, and then 0.25 and 0.3 mol dm^{-3} successively in the later stage), three bands (B-V′, B-VI, and B-VII) were separated. The slowest eluate (B-VII) was confirmed to be tris(oxalato)chromate(III) ion from the absorption measurement. The remaining two bands (B-V′ and B-VI) were found to be complex ions containing only fluoride and oxalate ions as ligands, because the first d-d absorption band of these eluates shows no shift with increase in pH and the qualitative analyses indicate the presence of fluoride and oxalate ions in the complexes. The yield of the B-VI band was much smaller than that of the B-V′ one. After dilution with water, each eluate was loaded again on each column of QAE-Sephadex A-25. Each adsorbed band was eluted with a 1 mol dm^{-3} sodium chloride solution. To each eluate was added a large excess of barium perchlorate. Then green fine powder was obtained. Each barium salt was converted to methylammonium salt by a batchwise method with a cation exchange resin of $CH_3NH_3^+$ form (Dowex 50w×8) in water. The resultant green solutions were separately condensed by a vacuum rotatory evaporator at about 30 °C. By adding acetone and ethanol to each condensed solution, green solid was crystallized. Each green powder was recrystallized from water and acetone. Found for the B-VI: C, 23.21; H, 5.02; N, 11.60%. Calcd for $(CH_3NH_3)_3[CrF_2(ox)_2]$: C, 22.84; H, 5.05; N, 11.24%. Found for the B-V′: C, 21.41; H, 4.33; N, 7.65%. Calcd for $(CH_3NH_3)_3[CrF_2(ox)_2]\cdot C_3H_6O\cdot 2.25NaCl$ (C_3H_6O= acetone): C, 21.71; H, 4.38; N, 7.62%.

(2) cis- *and* trans-$[CrF_2(mal)_2]^{3-}$ *Complexes*: After dissolving

3.8 g of *cis*-K[Cr(mal)$_2$(H_2O)$_2$]·3H_2O and 1.2 g of potassium fluoride in 100 cm^3 of water in a polyethlene beaker, the solution was heated at 60 °C on a water bath for about 4 h. The resulting green solution was added to a large amount of methanol. Then pale green precipitate was obtained. An aqueous solution of this precipitate was poured onto a column (4×60 cm) of QAE-Sephadex A-25. After washing the column with water, the adsorbed band was eluted with a sodium chloride solution (0.1 mol dm^{-3} in the early stage of elution, and then 0.2 and 0.3 mol dm^{-3} successively in the later stage). The column gave eleven bands. From the elution behavior and the absorption spectral change with increase in pH, the b-I—b-VIII bands were found to be univalent or bivalent complex anions containing H_2O, F^-, and mal^{2-} as ligands. The slowest eluted band (b-XI) was confirmed to be [Cr(mal)$_3$]$^{3-}$ from the absorption measurements. The two remaining eluates (b-IX and b-X) were found to be the complexes with only fluoride and malonate ions but not with water. After dilution of these eluates with water, they were reloaded on short columns of QAE-Sephadex A-25. After each column was washed well with a 0.01 mol dm^{-3} lithium chloride solution, each band was eluted with a 1.0 mol dm^{-3} lithium chloride solution. To the condensed solutions was added ethanol and acetone; then lithium salts being precipitated. Each green powder was recrystallized from water and acetone. Found for the b-IX: C, 19.41; H, 2.55%. Calcd for Li_3[CrF_2(mal)$_2$]·2.5H_2O: C, 20.02; H, 2.52%. Found for the b-X: C, 16.72; H, 2.20%. Calcd for Li_3[CrF_2(mal)$_2$]·3H_2O·1.5LiCl: C, 16.66; H, 2.33%.

The present oxalato and malonato complexes were also prepared from [CrF_2(H_2O)$_4$]NO_3, which was obtained by evaporating the reaction mixture of $Cr(NO_3)_3$·9H_2O with 40% hydrofluoric acid and formaldehyde.[2a]

(3) [CrF_2*(en)*(H_2O)$_2$]*Br*: This complex was used as a starting complex for the preparation of [CrF_2(O–O)(en)]$^-$ type complexes. The preparation of this complex was performed by the similar method to that of [CrF_2(pn)(H_2O)$_2$]Br[7] except that ethylenediamine(en) was used instead of 1,2-propanediamine(pn). Found: C, 9.14; H, 4.67; N, 10.46%. Calcd for [CrF_2(en)(H_2O)$_2$]Br: C, 9.03; H, 4.55; N, 10.53%.

(4) [CrF_2*(ox)(en)*]$^-$: A solution containing 1.0 g of [CrF_2(en)(H_2O)$_2$]Br and 0.7 g of potassium oxalate monohydrate was heated at 60 °C on a water bath for 2.5 h. After cooling the reaction mixture, the solution was added to a large amount of methanol to form violet precipitate. This solid was filtered and dissolved again in a small amount of water. The resultant solution was poured onto a column of anion exchange resin (Dowex 1×8, Cl^- form). The adsorbed band was washed with water and then eluted with a 0.05 mol dm^{-3} sodium chloride solution. The column gave three bands. The third eluate was confirmed to be [Cr(ox)$_2$(en)]$^-$ by the absorption measurement. The second band was proved to contain fluoride and oxalate ions but not water as ligands by means of the qualitative analyses for these ions and by the fact of no shift of the first band with increase in pH. This eluate was concentrated at about 25 °C by a vacuum rotatory evaporator. By adding methanol to the condensed solution, red violet crystals were obtained. Recrystallization was carried out from water and methanol several times. Found: C, 16.28; H, 3.48; N, 8.62%. Calcd for Na[CrF_2(ox)(en)]·0.75 H_2O·0.5 CH_3OH·0.6 NaCl: C, 16.60; H, 3.56; N, 8.60%.

(5) [CrF_2*(mal)(en)*]$^-$: This complex was prepared by the similar method to that of the corresponding oxalato complex as described in *(4)* except that potassium malonate was used in place of potassium oxalate. The sodium salt obtained was converted to lithium salt with a cation exchange resin (Dowex 50×8, Li^+ form) by a batchwise method. After concentrating the solution by a vacuum rotatory evapolator, red violet crystals were obtained by adding methanol and then cooling. Recrystallization was carried out from water and methanol. Found: C, 19.75; H, 4.97; N, 9.21%. Calcd for Li[CrF_2(mal)(en)]·2.5H_2O: C, 20.06; H, 5.00; N, 9.28%.

Measurements. Absorption spectra were obtained on a Shimadzu UV-200S spectrophotometer. Diffuse reflectance spectrum was measured by a Hitachi EPS-3T spectrophotometer with a reflectometer. CD curves were recorded on a JASCO MOE-1 spectropolarimeter, and infrared spectra on a JASCO DS-402G spectrophotometer.

Calculations. Computer programs for the calculations of the transition energies of the d-d bands and for the Gaussian analyses of the observed curves were based on the programs (AOM/2 and LGNCD) already obtained. The calculations were carried out by a FACOM 230-28 at the Nara Women's University.

Results and Discussion

Characterization. *1)* [CrF_2*(O–O)*$_2$]$^{3-}$ *Complexes*: In view of the chromatographic elution behavior and the absorption spectra as well as the elemental analyses for each pair of the oxalato (B-V′ and B-VI) and the malonato (b-IX and b-X) complexes, each of them corresponds to the geometrical isomeric pair with the same chemical composition. The first absorption bands of [CrF_2(O–O)$_2$]$^{3-}$ are observed near the positions predicted by the average of environment.[8] In such cases, it is empirically expected[9] that the first absorption band of *trans*-[CrF_2(O–O)$_2$]$^{3-}$ locates at the lower frequency side than that of *cis*-[CrF_2(O–O)$_2$]$^{3-}$, because the ligand fluoride lies below the ligands oxalate and malonate in the spectrochemical series.[8] Since the B-V′ isomer of the present oxalato complexes gives the first band at the lower frequency side than the B-VI one as shown in Fig. 1, the former and the latter isomers may be assigned to *trans* and *cis* forms, respectively. This assignment is confirmed by the fact that the elution order of the ion exchange chromatography agrees with that generally recognized for *cis* and *trans* geometrical

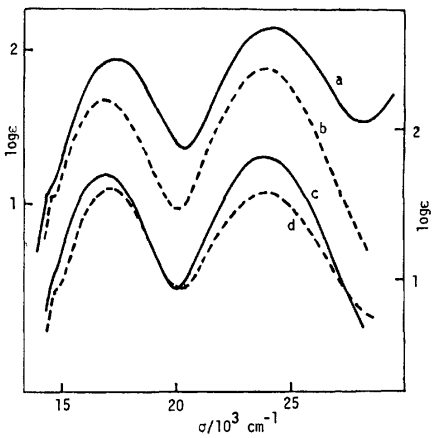

Fig. 1. Absorption curves of (a) *cis*-[CrF_2(ox)$_2$]$^{3-}$ (——), (b) *trans*-[CrF_2(ox)$_2$]$^{3-}$ (——) (left side ordinate), (c) *cis*-[CrF_2(mal)$_2$]$^{3-}$ (——), and (d) *trans*-[CrF_2(mal)$_2$]$^{3-}$ (——) (right side ordinate) in water.

isomers of $[MX_2L_4]$ type complexes,[10] and also supported by the fact that the B-VI (*cis*) isomer is found to have larger molar absorption coefficients of the d-d bands than the B-V′ (*trans*) one (Fig. 1) as noticed in the cases of $[Cr(CN)_2(en)_2]^+$[11] and $[Cr(NCS)_2(en)_2]^+$.[12] Further, the validity of this assignment is justified by the CD behavior in the first band region of these complexes in solutions containing chiral environmental substances as is applied to the structural assignments of $[SnCl_2(acac)_2]$ and the related complexes in *d*-malic acid systems.[13] That is, when the complexes at about 5×10^{-3} mol dm^{-3} in a mixture of water and acetone (1 : 1) containing *d*-cinchonine hydrochloride (15×10^{-3} mol dm^{-3}) were allowed to stand for about half an hour, the intensity of the CD extremum of the B-VI isomer in this region ($\Delta\varepsilon=+0.02$ mol^{-1} dm^{-3} cm^{-1} at 17750 cm^{-1}) is found to be much larger than that of the B-V′ isomer and to be as large as that of $[Cr(ox)_3]^{3-}$ in the analogous condition.[14] Since most bis(oxalato)-chromate(III) complexes are found to undergo rapid racemization,[15] the present complexes are expected to exhibit the CD associated with the enrichment of one enantiomer in terms of the so-called Pfeiffer effect. Thus, it appears that the B-VI isomer is a racemic mixture consisting of enantiomers with configurational chirality due to *cis* arrangement of two fluoride ions, and that the B-V′ isomer takes achiral configuration owing to *trans* coordination of two fluoride ions.

The corresponding malonato complexes show somewhat different spectral behavior from the oxalato complexes; the first absorption band of the faster eluted b-IX isomer was observed at a slightly higher frequency than that of the slower eluted b-X isomer. As shown in Fig. 1, the difference between the first band position of the b-IX isomer and that of the b-X one is too small to offer an any reliable clue for the assignment of the geometrical structures. The elution behavior on the column chromatography and the absorption intensities of the d-d bands seem to be more reliable for the structural assignments. As shown in Fig. 1, on the basis of these criterions, the b-IX and b-X isomers are to be assigned to *trans* and *cis* forms, respectively. This assignment is also supported by the CD behavior in a mixture of water and acetone containing *d*-cinchonine hydrochloride as in the case of the corresponding oxalato complexes. That is, the b-X (*cis*) isomer in such a solution gives a much stronger CD peak ($\Delta\varepsilon=+0.01$ mol^{-1} dm^3 cm^{-1} at 16880 cm^{-1}), probably due to the Pfeiffer effect, than the b-IX (*trans*) isomer. The infrared spectra of the malonato complexes may provide another clue for the assignment of the geometrical structure. Three infrared bands are observed at 1620, 1695, and 1720 cm^{-1} for the b-X isomer and only one at 1615 cm^{-1} for the b-IX isomer in the region of C=O asymmetric stretching as is observed for the corresponding diaquabis(malonato)chromate(III) complexes; *i.e.*, three components for the *cis*-isomer and one component for the *trans*-isomer. Such a difference in the number of the observed bands between the geometrical isomers of the malonato complexes may be mainly ascribed to the difference in symmetry of the complexes. Thus, these infrared spectral behavior of the malonato complexes confirms the assignment on the basis of the chromatographic elution orders, the molar absorption coefficients, and the Pfeiffer CD.

2) $[CrF_2(O-O)(en)]^-$ Complexes: For each of the oxalato and malonato complexes of this type, only one of two possible geometrical isomers could be isolated. The d-d absorption spectrum of the oxalato complex is symmetrical in shape and shows no splitting, whereas that of the malonato complex is of asymmetric shape and exhibits a shoulder at the higher frequency side for the first band and at the lower frequency side for the second band, as shown in Fig. 2. According to the

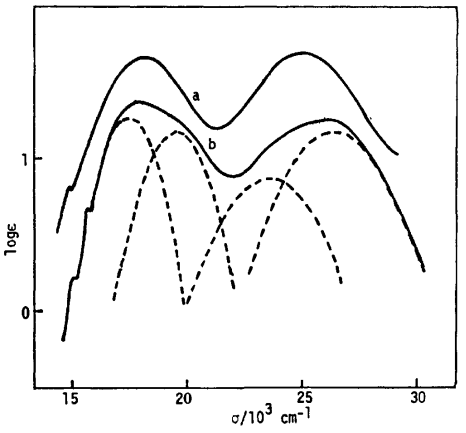

Fig. 2. Absorption curves of (a) *cis*-$[CrF_2(ox)(en)]^+$ and (b) *trans*-$[CrF_2(mal)(en)]^+$ in water, and the resolved curves of the latter complex (-----) using the Gaussian analysis.

Yamatera's rule,[16] it is suggested that the oxalato and malonato complexes take *cis* and *trans* forms, respectively. That is, it is predicted that the orbitally doubly degenerate and nondegenerate components of the $^4T_{2g}$ splitting states locate at 17390 and 19720 cm^{-1}, respectively, by using $10Dq(en)=21900$ cm^{-1}, $10Dq(F^-)=15050$ cm^{-1}, and $10Dq(mal^{2-})=17670$ cm^{-1}. These predicted transition energies lie close to the peaks and near the shoulder observed for $[CrF_2(mal)(en)]^-$. For the *cis* form, three splitting components are predicted to locate at 19100, 18100, and 17390 cm^{-1}. This splitting interval and the positions obtained may account for the observed symmetric pattern and the maximum of the first band for the oxalato complex (Fig. 2). In addition, this assignment may be confirmed by the solvent effect on the absorption spectra of these complexes. The second absorption band of *trans*-$[CrF_2(en)_2]^+$ in *N*-methylformamide (nmf) is more distinctly resolved into two components than that in water, and the corresponding *cis*-isomer gives almost unaltered behavior in these solvents. The present oxalato and malonato complexes exhibit the similar spectral behavior in water and nmf. The second band of the *trans*-difluoro malonato complex in nmf is more remarkably split than that in water, while that of the *cis*-difluoro oxalato complex remains unchanged.

Assuming that $[CrF_2(en)(H_2O)_2]^+$ takes *trans*(F) form as mentioned below, the formation of the malonato complex seems to take place with retention of configura-

tion, but the oxalato complex may be formed with conversion to *cis* configuration.

Ligand Field Absorption Bands. In spite of the fact that the ligand malonate lies at the higher position than the ligand fluoride in the spectrochemical series as in the case of the ligand oxalate,[8] the first absorption band of *trans*-$[CrF_2(mal)_2]^{3-}$ locates at the higher frequency side than that of the *cis* one; *i.e.*, contrary to the empirical prediction,[9] which is valid for the corresponding oxalato complexes as mentioned before. It is noted that the ligand field band of the malonato complexes behaves unlike that of the oxalato complexes to some significant degree. Such a difference in the ligand field band between the malonato and oxalato complexes is not observed for the absorption spectra of $[Cr(O-O)_n(en)_{3-n}]^{3-2n}$ type complexes; *e.g.*, the first band being observed at 20170 cm^{-1} for both $[Cr(ox)(en)_2]^+$ and $[Cr(mal)en)_2]^+$, at 18830 cm^{-1} for both $[Cr(ox)_2(en)]^-$ and $[Cr(mal)_2(en)]^-$, and at 17500 and 17670 cm^{-1} for $[Cr(ox)_3]^{3-}$ and $[Cr(mal)_3]^{3-}$, respectively. It is interesting to note that both the first and the second bands of the present dicarboxylato complexes are compared with those of the corresponding aqua complexes of the same types; *i.e.*, $[CrF_2(H_2O)_4]^+$, $[CrF_2(en)(H_2O)_2]^+$, and $[Cr(ox)_2(H_2O)_2]^-$. The absorption spectrum of *trans*-$[CrF_2(H_2O)_4]^+$ reported by Chia and King[1] shows a large splitting in the second absorption band region as in Fig. 3. *trans*-Diaquabis (oxalato)-

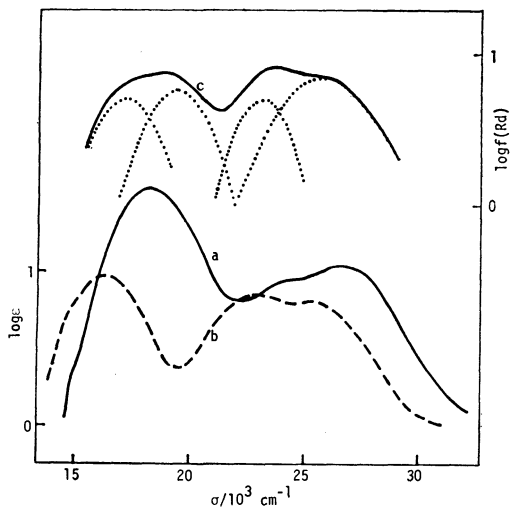

Fig. 3. Absorption curves of (a) *trans*(F)-$[CrF_2(en)(H_2O)_2]^+$ (——) and (b) *trans*-$[CrF_2(H_2O)_4]^+$ (----) (from Ref. 1) in water; diffuse reflectance spectrum of (c)*trans*-$K[Cr(ox)_2(H_2O)_2]\cdot 3H_2O$ (——) (right side ordinate) and its resolved curves using the Gaussian analysis (……).

chromate(III) complex also gives a splitting pattern for both the first and second bands, which is revealed with the aid of the Gaussian analysis of the diffuse reflectance spectrum (Fig. 3) as well as by the low-temperature single-crystal polarized spectral study.[17] Since the ligand field strength of the fluoride ligand is weaker than that of the aqua ligand,[8] it is anticipated that the splitting of the d-d absorption spectra for the present newly prepared *trans*-difluorobis(dicarboxylato) complexes is larger, at least in the first band region, than that for the diaqua complexes. Contrary to this expectation, however, both the present *trans*-difluoro complexes show the symmetrical shape and no splitting in their absorption spectra as in Fig. 1. The analogous situation is observed in the case of *trans*-$[CrF_2(O)_2(en)]$ type complexes. While the second absorption band of the malonato complex, *trans*-$[CrF_2(mal)(en)]^-$, is split similarly to that of *trans*(F)-$[CrF_2(en)(H_2O_2)]^+$, the first band exhibits a shoulder at the higher frequency side for the malonato complex, but not for the aqua complex as in Figs. 2—3.

In order to examine the different nature of Cr-ligand bonding, an attempt to estimate the angular overlap parameters is made by fitting the calculated transition energies to the observed positions of the d-d bands in terms of the angular overlap model on the assumption of orthoaxial ligation.[4] The theoretical calculations are carried out by diagonalizing full energy matrix incorporating all configurational interactions for the d^3 configuration.[18] The results are summarized in Tables 1 and 2 together with the AOM (e_σ and e_π) and Racah (B) parameter values as well as the assignments of the transition states. By using the AOM parameters for the fluoride and aqua ligands transferred from *trans*-$[CrF_2(N)_4]^+$ type and ammineaquachromium(III) complexes, $[Cr(NH_3)_n(H_2O)_{6-n}]^{3+}$,[3-4] the calculated positions of the ligand field bands for *trans*-$[CrF_2(H_2O)_4]^+$ and $[CrF_2(en)(H_2O)_2]^+$ (assumed *trans*(F) form) correspond fairly well to those of the observed ones, except that the rather large splitting of the first band is reproduced despite of the observed symmetrical envelope of this band (Fig. 1 and Table 1). Among several attempts to estimate the AOM parameters for *trans*-$[CrF_2(H_2O)_4]^+$,[19-20] the parameter values estimated by Keeton *et al.*[19] are close to the present values. Similar calculations are carried out for *trans*-$[Cr(ox)_2(H_2O)_2]^-$, *trans*-$[CrF_2(mal)(en)]^-$, and *trans*-$[CrF_2(O-O)_2]^{3-}$, assuming that the π orbitals vertical to

a) The positions are obtained by the Gaussian analyses as shown in Figs. 2—3. b) Assignments are made according to the of the theoretical calculations. c) Wavenumbers are given in 1000 cm^{-1}. d) The parameter values for the dicarboxylate ligands; the same transition energies are obtained for the oxalato and malonato complexes owing to the assumption of orthoaxial ligation.

chelate planes participate predominately in the Cr–O π-interactions: $e_{\pi//} \gg e_{\pi\perp}$.[5],† Using the AOM parameter values for the aqua ligand from *trans*-$[CrF_2(H_2O)_4]^+$ and *trans*-(F)-$[CrF_2(en)(H_2O)_2]^+$, the reproduction of both the first and the second bands of *trans*-$[Cr(ox)_2(H_2O)_2]^-$ results in the estimation of the $e_\sigma(O)$ and $e_{\pi\perp}(O)$ values for the dicarboxylates as in Table 2. In addition, use of the transferred parameter values for the dicarboxylate ligand in calculating the transition energies for *trans*-$[CrF_2(mal)(en)]^-$ leads to the reproduction of four gaussian-analyzed band positions of this complex, though the values for the fluoride and ethylenediamine ligands used in this case are estimated to be smaller than those from the aqua complex, *trans*(F)-$[CrF_2(en)(H_2O)_2]^+$, as shown in Calcd I of Table 2. The parameter values obtained for the dicarboxylates agree fairly well with those estimated by the less sophisticated analyses for the ligand field bands of oxalato Cr(III) complexes.[21] On the other hand, use of the parameters for the fluoride and ethylenediamine ligands transferred from the aqua complex requires a significant decrease in the $e_\sigma(O)$ and $e_{\pi\perp}(O)$ values for the dicarboxylate ligand (Calcd II of Table 2), in order to account for the four observed bands of *trans*-$[CrF_2(mal)(en)]^-$. The similar situation may be also encountered for $[CrF_2(O-O)_2]^{3-}$ type complexes. That is, the reproduction of the small splitting expected from the symmetrical shape of the first and the second bands of *trans*-$[CrF_2(O-O)_2]^{3-}$ results in the unlikely decrease in the AOM parameters for the fluoride and dicarboxylate ligands as is tentatively estimated (Table 2). By comparing the present parameter values which are not always the best fit ones for the ligands of the complexes concerned, it is difficult to extract some quantitative information about the bonding nature of Cr and ligator. Within the framework of the AOM, however, it is concluded that the anisotropic Cr–O π-interactions in the dicarboxylato complexes play an important role in the splitting of the ligand field band for *trans*-$[Cr(ox)_2(H_2O)_2]^-$ and *trans*-$[CrF_2(mal)(en)]^-$, and that both the σ and π antibonding interactions between Cr and ligators in the fluoro complexes with the dicarboxylate ligands become weaker than those in the aqua complexes with the fluoride or dicarboxylate ligands.

† In this case, $\Delta(10Dq)$ equals to $3e_\sigma - 2e_{\pi\perp} - 2e_{\pi//} \simeq 3e_\sigma - 2e_{\pi\perp}$.

One of the authors (S.K.) wishes to express his thanks to Professor Yoichi Shimura of Osaka University for his kind guidance and valuable discussions throughout this work and also for making the circular dichroism and infrared spectra available for the present work. Grateful acknowledgement is made to Dr. Kiyoshi Isobe of Osaka City University for his aid in obtaining the elemental analyses of the fluoro complexes. The authors also wish to thank Dr. Takashi Komorita, Osaka University, for his generous offer of the LGNCD and AOM/2 computer programs.

Unusual Transposition of the Carbonyl Group in the Reduction of 2-Amino-1-indanone

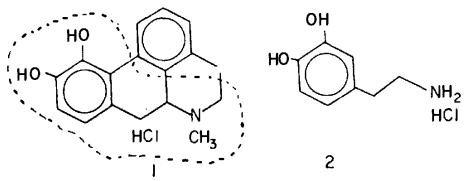
Jack C. Kim

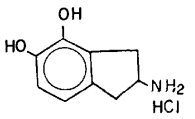
Department of Chemistry, Busan National University, Busan, Korea

(Received May 15, 1980)

The catalytic reduction procedure of 2-amino-4,5-dimethoxy-1-indanone hydrochloride gave a major reduction product of 2-amino-4,5-dimethoxyindan hydrochloride, along with a small amount of a rearranged 4,5-dimethoxy-2-indanone. The isolated intermediate, 2-amino-4,5-dimethoxy-1-indanol hydrochloride yielded exclusively 4,5-dimethoxy-2-indanone under catalytic reaction conditions (acid treatment). The unusual transformation product was verified on the basis of IR, NMR and the result of elemental analysis. A plausible mechanism for the rearrangement is discussed.

Apomorphine (**1**) which has assumed considerable importance in efforts at understanding the role of dopamine (**2**) in the etiology and therapy of Parkinsonism,[1] has structural similarities (see the dotted line) to dopamine. It is currently believed that apomorphine is a dopaminergic agonist and presumably it is through this mechanism that this agonist is effective clinically. By the Dreiding model inspection of apomorphine and dopamine, the 2-amino-4,5-indandiol hydrochloride (**3**) suggests itself as a candidate for possession of dopaminergic activity. This relationship has been noted by Rekker *et al.*[2] as the rationale for the biologically active pharmacophore of the catechole ring and the amino group of dopamine.

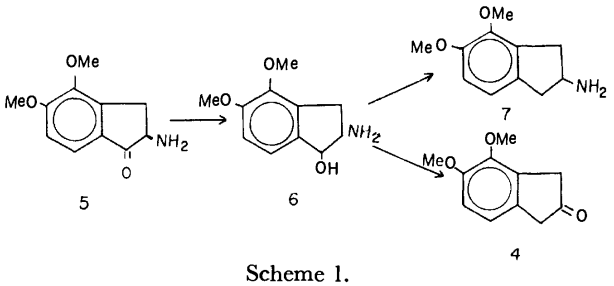




Our prior works have dealt with a synthesis[3] and dopamine-like effects[4] of 2-amino-4,5-indandiol series **3**. The objective of this investigation is to deal with the isolation and identification of an unusual rearranged product, 4,5-dimethoxy-2-indanone (**4**) from the catalytic reduction of 2-amino-4,5-dimethoxy-1-indanone (**5**).

Results and Discussion

Illustrating the previously published results[3] in brief (Scheme 1), the carbonyl group α to the benzene ring of the amino ketone **5** was removed by hydrogenolysis in the presence of palladium on charcoal; the intermediate amino alcohol, 2-amino-4,5-dimethoxy-1-indanol (**6**) was not isolated, but **6** was continuously hydrogenated in the presence of $HClO_4$ to bring about hydrogenolysis of the benzylic hydroxyl group directly to give 2-amino-4,5-dimethoxyindan (**7**). However, the catalytic reduction method of **5** gave exclusively a desired reduction product of **7**, along with a small amount of a white solid, having a higher mobility than that of **7** in thin layer chromatogram. Repeats of the catalytic hydrogenation reactions yielded consistently a small amount of a solid which has much lower melting point (89—90 °C) than those of the compounds **5** (193.5—194.5 °C) and **7** (205—206.5 °C).

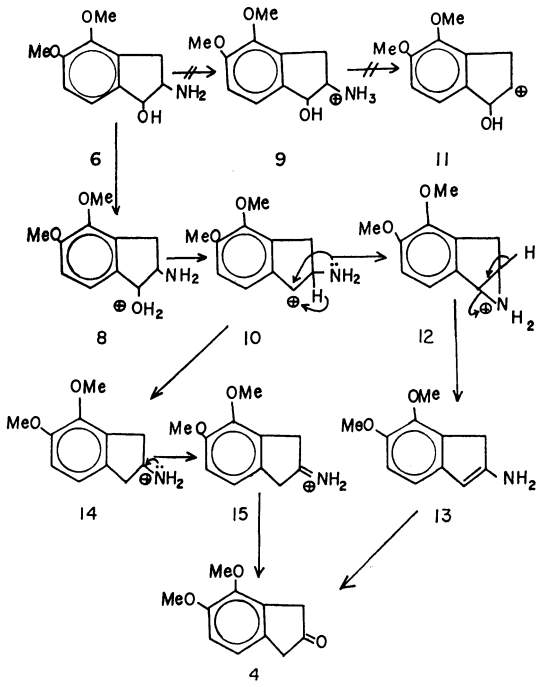


Scheme 1.

The IR spectrum (KBr) of the starting material **5** showed a benzylic carbonyl absorption peak at 1710 cm^{-1}. The unknown white solid showed a new absorption peak at 1740 cm^{-1} which is assumed to be a carbonyl stretching vibration of an isolated ketonic group. As the conjugation of the carbonyl group with the benzene ring results in delocalization of the π electrons from the carbonyl group, the C=O bond length as in **5** increases and the frequency of absorption decreases. An integration of nuclear magnetic resonance spectrum of the unknown compound demonstrated two methoxyl and two aromatic protons plus four aliphatic proton signals. The characteristic proton signal of the four aliphatic C-1 and C-3 protons gave two singlets (δ 2.51 and 2.53), quite different from those of the compounds, **5** and **7** which showed a multiplet.

The white compound is thus believed to be 4,5-dimethoxy-2-indanone **4**, in veiw of the spectral characteristics of the NMR and IR spectra, and the result of the elemental analysis.

In order to further test whether the unknown compound, 4,5-dimethoxy-2-indanone was derived from the intermediate **6**, we isolated the intermediate, 2-amino-4,5-dimethoxy-1-indanol **6**, before the $HClO_4$ treatment in the catalytic hydrogenation process (see Experimental), and treated **6** with a few drops of concentrated HCl. At this stage, a white solid **4** was exclusively obtained as a major product, and the mp and spectroscopic data of the compound was exactly identical with those of the compound obtained from the hydrogenolysis.



Scheme 2.

The following Scheme 2 shows a plausible mechanism for the rearranged product formation of **4** from **6**. A central problem in the fundamental understanding of a plausible mechanism at the amino alcohol intermediate stage, is the question of whether **6** involves either kinetically controlled protonation at the hydroxyl oxygen to form oxonium ion **8**, or thermodynamically controlled protonation at the basic nitrogen atom to form ammonium salt **9** under the acidic conditions of the catalytic hydrogenation step. Since the good leaving groups will be those that can best stabilize an extra pair of electrons, that is a week base,[6] the stronger base, NH_3 is hard to leave as a leaving group[7] as in **9**, and therefore the weaker base, OH_2 will become a better leaving group, thus making **8** the sole reactive intermediate. Secondly, the generated carbonium ion **10** has relatively good deal of influences on the speed of this ionization which partly depends on the stability of the carbonium ions formed. The much more stable, long-lived benzylic carbonium ion **10**, will predominantly favor the mechanistic routes in **8**→**10**→**12**, excluding a route **9**→**11**.

With these two controlling factors, the protonated oxonium ion **8** is preferentially formed and then converted to the enamine **13**,[8] which is hydrolyzed to give the rearranged product **4** eventually. However, the pinacol-pinacolone type rearrangement from the hydride shift of **10** to **14**, followed by the imminium salt **15**, has not been eliminated as a possibility. On the basis of the presently available data, the enamine-favored mechanistic path is more compatible, and it is reasonable to discard a route **9**→**11**.

Experimental

All melting points were determined using a Polytemp (Polyscience Corporation) or Fisher-Johns apparatus, and are uncorrected. The IR spectra were taken in KBr disks with a Shimadzu 400 spectrophotometer. The ^1H NMR spectra were obtained at 60 MHz using a Varian EM-60 spectrometer with TMS as an internal standard.

*2-Amino-4,5-dimethoxyindan Hydrochloride (**7**·**HCl**).* A mixture of 3 g (0.013 mol) of **5** and 0.6 g of 10% Pd/C in 100 ml of glacial AcOH was hydrogenated in a Parr apparatus at 38 °C under maximum pressure of 3.16 kg/cm². Uptake of 1 mol of H_2 was complete in 48 h. The reaction mixture was cooled and 3 ml of $HClO_4$ was added with rinsing with 3 ml of glacial AcOH, and hydrogenation was continued at 70 °C for 18 h employing a maximum pressure of 2.81 kg/cm². The catalyst was removed from the reaction mixture by filtration and the clear filtrate (yellow color) was treated with 6 g of KOAc; $KClO_4$ precipitated immediately and was removed by filtration. The filtrate was taken up to dryness under reduced pressure (steam bath) and 100 ml of aq 5% HCl was added to the residue and the small amounts of the insoluble solids were filtered. The aq solution was extracted with two 50 ml portions of Et_2O which were discarded. The aq phase was made strongly basic with 20% KOH, then was extracted with four 75 ml portions of Et_2O. The combined Et_2O extracts were washed with 75 ml of H_2O, 75 ml of 10% NaCl, and finally with 75 ml of H_2O and then dried ($MgSO_4$) and filtered. The filtrate was treated with ethereal HCl to form 2.13 g (71%) of a white solid. Recyrstallization from MeOH–Et_2O (charcoal) gave 1.92 g (66%) of white crystals, mp 205—206.5 °C. IR (KBr) showed a disappearance of a strong band at 1710 cm^{-1}. NMR (D_2O); δ 2.77—3.88 (m, 5H, Aliphatic H), 3.88 (s, 6H, –OMe), 7.07 (q, 2H, Aromatic H).

Found: C, 57.62; H, 7.13; N, 5.81%. Calcd for $C_{11}H_{16}ClNO_2$: C, 57.49; H, 7.02; N, 6.13%.

Evaporation of the filtrate under reduced pressure gave a yellow oil which was distilled through a "short path column" apparatus, as a clear colorless liquid, bp 115—119 °C (0.25 mmHg) to give the free base **7**.

*Isolation of the Intermediate, 2-Amino-4,5-dimethoxy-1-indanol Hydrochloride (**6**·**HCl**).* At the end of the complete uptake of 1 mol H_2, the catalyst was removed from the reaction mixture by filtration and the filtrate was evaporated under reduced pressure to obtain the oily residues. The residues were taken up into $CHCl_3$–Et_2O (1 : 6) and ethereal HCl was added to precipitate the salt. The amino-indan hydrochloride salt was very hygroscopic and was dried in a vaccum desicator. Recrystallization from EtOH–Et_2O gave a white solid, mp 163—165 °C. IR (KBr): 3327 (OH), 2892 (NH_3^+); NMR (D_2O): δ 3.18 and 3.98 (2s, 6H, OMe), 7.11 and 7.35 (dd, 2H, Aromatic H).

Found: C, 53.76; H, 6.56; N, 5.70; Cl, 14.14%. Calcd for $C_{11}H_{16}NClO_3$: C, 53.49; H, 6.51; N, 5.91%.

*Isolation of 4,5-Dimethoxy-2-indanone (**4**).* The insoluble solids and the "discarded" two 50 ml portions were combined, and evaporated under reduced pressure. The residue obtained, was crystallized from cyclohexane (charcoal) to yield a white solid, mp 89—90 °C. IR (KBr); 1740 cm^{-1}; NMR ($CDCl_3$): δ 2.51 and 2.53 (s, 4H, Aliphatic H), 3.81 and 3.87 (2s, 6H, OMe) and 7.19 (s, 2H, Aromatic H).

Found: C, 58.73; H, 6.29%. Calcd for $C_{11}H_{12}O_3$: C, 58.65; H, 6.21%.

*Reaction of **6**·**HCl** with Hydrochloric Acid (Preparation of 4,5-Dimethoxy-2-indanone).* The amino alcohol intermediate, **6**·**HCl** (1.11 g, 0.0022 mol) was dissolved in 100 ml of $CHCl_3$ and added 7 ml of concd HCl and the reaction mixture was refluxed for 18 h. At the end of the reaction, the reaction mixture was washed with three 30 ml portions of saturated $NaHCO_3$ solution, three 30 ml portions of NaCl solution,

three 30 ml portions of H_2O and the $CHCl_3$ layer was dried over $MgSO_4$. Fitration and evaporation *in vacuo* gave solid residue, which were crystallized from cyclohexane (charcoal) to give 0.39 g (55%) of white solids, mp 89—90 °C. The IR and NMR spectra were identical with that of the previously obtained compound.

Synthesis of Ethylene Glycol Acetates Catalyzed by Potassium Iodide and Metal Acetate[1)]

Kazuo SHIMIZU* and Juichi IMAMURA

National Chemical Laboratory for Industry, Yatabe-machi, Tsukuba-gun, Ibaraki 305

(Received February 9, 1981)

The catalytic activities of various kinds of binary systems consisting of KI and metal acetate were tested in liquid phase oxidation of ethylene in acetic acid at various pressures. KI–$Mn(OCOCH_3)_2$ was found to be the most reactive system and a new material, $CH_3COOCH_2CH_2OCOCH_2OCOCH_3$, was formed as a major by-product. It was also found that the main product at an early stage of the reaction was ethylene glycol monoacetate, from which other products were formed consecutively. It is considered that catalytic reaction does not proceed *via* ICH_2CH_2I, but *via* ICH_2CH_2OH which is formed by the oxidation of ethylene with HIO. On the basis of the rate equation and the results under various reaction conditions, a mechanism of the KI–$Mn(OCOCH_3)_2$-catalyzed reaction has been proposed.

At present, most of ethylene glycol is commercially manufactured by hydration of ethylene oxide. However, the total yield of ethylene glycol from ethylene is relatively low, because the selectivity of ethylene oxide production, in the vapor-phase oxidation of ethylene, is not so high.[2)] Therefore, other new methods of ethylene glycol synthesis, without ethylene oxide as an intermediate, have been proposed by several companies.[2)] Halcon International has developed a new process *via* ethylene glycol mono- and diacetates which are easily hydrolyzed to ethylene glycol and acetic acid.[3)] This process involved the acetoxylation of ethylene with KI-metal acetate catalyst. It recently attracted special interest because of the mild oxidizing conditions. Until now, however, the mechanism of this acetoxylation has not been published in detail. The authors have now studied the reaction mechanism and the results are published in this paper.

Experimental

Materials. The metal salts and acetic acid employed were all of a guaranteed grade and the ethylene and oxygen used were of a reagent grade; all were used without further purification.

Apparatus and Procedures. The reaction was performed in a closed system at higher pressure. A titanium-lined autoclave (300 ml) equipped with a magnetic stirrer and a thermocouple was used in conjunction with a pressure controller and a reservoir (469 ml) which was kept at 40 °C. The pressure inside the reservoir was measured by a strain gauge. The ethylene and oxygen gaseous mixture in a pressure ratio of 2 : 1 was preliminarily stored in this reservoir.

A mixture of the catalyst components and acetic acid was placed in the reaction vessel; the vapor phase was replaced with nitrogen, and the vessel was heated to the reaction temperature. At first, ethylene was introduced into the vessel until the desired pressure was obtained and then the mixture of ethylene and oxygen from the reservoir was introduced through the pressure controller until the pressure inside the vessel reached the reaction pressure. The gaseous mixture which decreased in pressure by dissolution and reaction was supplied continuously from the reservoir. Accordingly, the pressure inside the reaction vessel was held constant during the period of reaction.

The amount of mixed gas absorbed was measured by observing the pressure decrease inside the reservoir. The "reaction rate" means hereinafter the rate of pressure decrease during the initial stage of the reaction.

Identification and Analysis. Reaction products were identified by comparing their GC–MS(EI, CI) (JEOL, JMS-D300) and NMR (^1H, ^{13}C) (JEOL, JNM-FX100) spectra with those of authentic samples, and their amounts were determined by gas chromatography with a Shimadzu GC-4BT chromatograph (3m × 3 mm column packed with 20% Silicone DC-550 on Chromosorb WAW DMCS, from 60 to 170 °C, and 2 m × 3 mm column packed with Porapak Q, from 180 to 237 °C, He 40 ml/min). *o*-Dichlorobenzene was used as an internal standard.

Results and Discussion

Reaction Products. The major reaction products were ethylene glycol monoacetate (MA), ethylene glycol diacetate (DA), ethylene glycol (EG), $AcOCH_2CH_2OCOCH_2OH$ (**1**) (Ac means CH_3CO), $HOCH_2CH_2OCOCH_2OAc$ (**2**), $AcOCH_2CH_2OCOCH_2OAc$ (**3**), and $ICH_2CH_2OCOCH_2OAc$ (**4**)—the latter four will be designated the "higher boiling products." **3** was the new material with bp 219—220 °C; MS (70 eV), *m/e* (rel intensity), 174(13), 132(12), 131(12), 101(100), 87(18), and 73(16); MS (CI, NH_3) *m/e*=222, MS (CI,

Table 1. Product distibution for the oxidation of ethylene catalyzed by potassium iodide and different metal acetates

Catalyst Metal salts/mmol	Yield/g		
	DA	MA	EG
KI–$MnOA(c)_2 \cdot 4H_2O$	1.38	0.60	0
–$Ce(OAc)_3 \cdot H_2O$	1.26	0.65	0
–$Cr(OAc)_3 \cdot H_2O$	0.70	0.29	≈0
–$Co(OAc)_24H_2O$	0.46	0.12	0

–$Ni(OAc)_2 \cdot 4H_2O$	0.38	0.14	0
–$Zn(OAc)_2 \cdot 2H_2O$	0.34	0.08	0

Reaction conditions; KI of 30 mmol, metal acetate of 5 mmol and acetic acid of 100 g (1.67 mol) were used, the ethylene pressure was 20 kg/cm², the oxygen pressure was 5 kg/cm², the reaction temperature was 140 °C and the reaction time was 60 min.

isobutane) m/e=205; ^{13}C-{^1H} NMR ($CDCl_3$) δ=171.2, 170.0, 168.2(3CO), 63.5, 62.3, 61.1($3CH_2$) and 21.2, 20.8($2CH_3$).

Minor products were ICH_2CH_2OH, ICH_2CH_2OAc, CH_2I_2, $AcOCH_2CH_2OCH_2CH_2OAc$, $AcOCH_2CH_2OCH_2CH_2I$, and $ICH_2CH_2OCH_2CH_2OH$. The seven major products were taken into account; ordinarily the yields of the others could be ignored.

Selection of Catalysts. The oxidation of ethylene at an applied pressure was carried out with different catalyst systems. The reaction conditions and results are shown in Table 1. The products which are not listed in the table are omitted because of their negligible yields under these reaction conditions. As Table 1 shows, KI–$Mn(OAc)_2$ is the most active catalyst for the oxidation; accordingly, the reaction with KI–$Mn(OAc)_2$ catalyst system was investigated in detail.

Change of Product Yield with Reaction Time. The yields of the reaction products were determined at selected time intervals. As Fig. 1 shows, MA was the main reaction product at 15 min, the yields of MA, **2** and **4** were maximum at 60 min and those of DA, EG, **3** and **1** increased with reaction time.

Effect of Oxygen Pressure. The reaction rate was of the first order in the oxygen pressure below 7.5 kg/cm and was independent of the pressure from 7.5 to 20 kg/cm^2 under the reaction conditions described in Fig. 2. The fact that the rate dependence on the oxygen pressure varied at 7.5 kg/cm^2 indicates that the reaction mechanism or the rate-determining step is different in the two regions. Figure 2 shows the effects of oxygen pressure on the product distributions after 90 min reaction. The yields of MA and **2** increased with an increase in the oxygen pressure, however, those of the other products were not affected greatly. The reaction was subsequently examined at an oxygen pressure of 7.5 kg/cm^2.

Effect of Ethylene Pressure. The reaction rate was of the first order in the ethylene pressure below 25 kg/cm^2, and independent of the pressure from 25 to 30 kg/cm^2 under the reaction conditions; KI=100 mmol, $Mn(OAc)_2\cdot4H_2O$=5 mmol, AcOH=100 g, the oxygen pressure of 7.5 kg/cm^2, the reaction temperature of 140 °C and the reaction time of 90 min. The reaction was subsequently investigated at an ethylene pressure of 20 kg/cm^2.

Effect of KI Concentration. The reaction rate was of the first order in the concentration of KI below 105 mmol/100 g AcOH under the reaction conditions destribed in Fig. 3; at concentrations above 120 mmol/100 g AcOH, a precipitate of KI was observed in the reaction mixture after the reaction. Figure 3 shows that the yields of DA and MA increased greatly with an increase in the KI concentration. On the basis of these results, the optimal concentration of KI for a fast reaction rate and selective formation of DA and MA is considered to be 120 mmol/100 g AcOH in the KI–$Mn(OAc)_2$-catalyzed reaction.

Effect of $Mn(OAc)_2$ Concentration. The reaction rate increased markedly with an increase in the $Mn(OAc)_2$ concentration between 0.1 and 1 mmol/100 g AcOH, and was independent of the concentration from

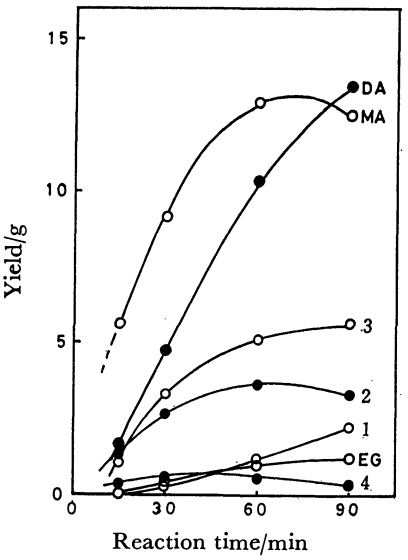

Fig. 1. Change of product yield with reaction time in the KI–$Mn(OAc)_2$-catalyzed reaction. Reaction conditions; KI=120 mmol, $Mn(OAc)_2\cdot4H_2O$=5 mmol, AcOH=100 g, the pressures of ethylene and oxygen were 20 and 5 kg/cm^2, respectively, and the reaction temperature was 140 °C.

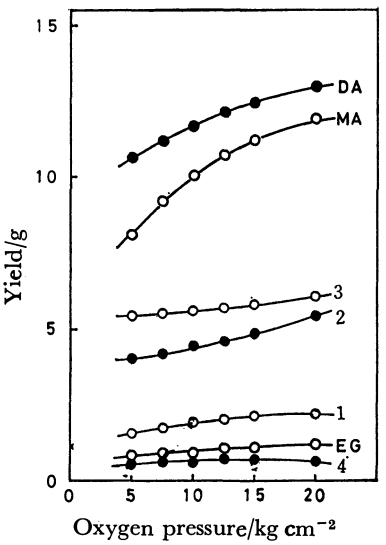

Fig. 2. Effect of the oxygen pressure on the product distributions. Reaction conditions; KI=120 mmol, $Mn(OAc)_2\cdot4H_2O$=1 mmol, AcOH=100 g, the ethylene pressure was 20 kg/cm^2, the reaction temperature was 140 °C and the reaction time was 90 min.

1 to 10 mmol/100 g AcOH under the conditions described in Fig. 4. Figure 4 shows that the $Mn(OAc)_2$ concentration hardly affected the product distributions. Therefore, the favorable region of concentration seems to be $1\leqq[Mn(OAc)_2]\leqq10$ mmol/100 g AcOH.

Mechanism of the Reaction. Y. Ogata and K. Aoki have proposed a mechanism for the reaction of propylene with a mixture of iodine and peracetic acid.[5] The mechanism of the KI–$Mn(OAc)_2$-catalyzed oxidation of ethylene is expressed as follows, by applying their mechanism to this reaction;

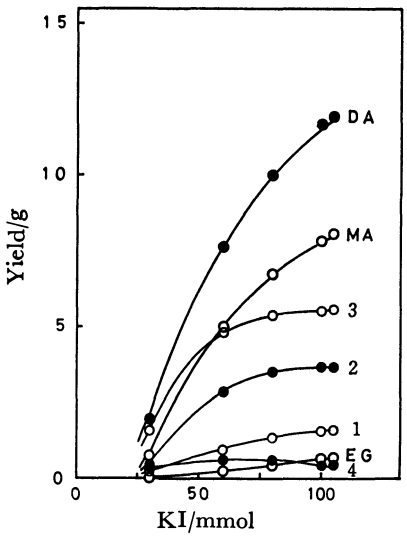

Fig. 3. Effect of the KI concentration on the product distributions. Reaction conditions; $Mn(OAc)_2 \cdot 4H_2O$ = 1 mmol, AcOH = 100 g, the pressures of ethylene and oxygen were 20 and 7.5 kg/cm², respectively, the reaction temperature was 140 °C and the reaction time was 90 min.

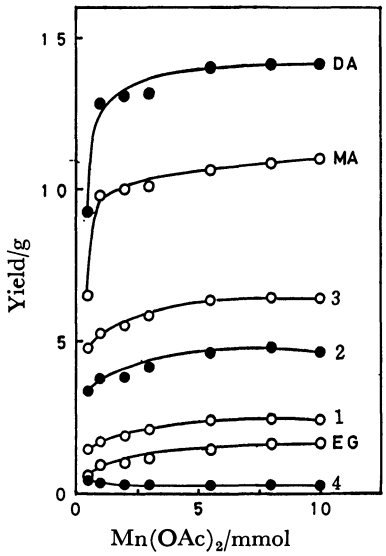

Fig. 4. Effect of the $Mn(OAc)_2$ concentration on the product distributions. Reaction conditions; KI = 120 mmol, AcOH = 100 g, the pressures of ethylene and oxygen were 20 and 7.5 kg/cm², respectively, the reaction temperature was 140 °C and the reaction time was 90 min.

Table 2. Reaction conditions and results

Acetic acid (100 g) was used unless the amount is specified. The reaction temperature was 140 °C. a) All except the amount expressed in gram. b) A Teflon-lined autoclave was used. c) 5% aq solution of KIO(40 g) was used. d) A mixture of DA(12.33 g), MA(10.46 g), EG(2.14 g), and acetic acid(5.07 g).

$$CH_2{=}CH_2 + I_2 \rightleftharpoons CH_2 \overset{I_2}{\underset{\downarrow}{\mp}} CH_2 \xrightarrow{CH_3CO_2H} ICH_2CH_2OAc + HIO.$$

If the reaction proceeds by this mechanism, the main reaction product should be ICH_2CH_2OAc or DA which is formed from ICH_2CH_2OAc by the reaction with KOAc, because of the lack of water in the reaction mixture. However, Fig. 1 indicates that the initial reaction product is MA. Accordingly, this KI–Mn(OAc)$_2$-catalyzed reaction proceeds by a mechanism different from that proposed by them.

In order to study the mechanism of the KI–Mn(OAc)$_2$-catalyzed reaction, this reaction was investigated under various conditions. Table 2 shows the reaction conditions and the results obtained.

The catalytic reaction using Mn(OAc)$_2$ alone as a catalyst yielded practically no products (Run 1), however, the reaction using only KI yielded all of the products (Run 2). The reaction using I_2 alone in the absence of oxygen yielded ICH_2CH_2I and ICH_2CH_2OAc as the major products and DA as the minor one (Run 3). However, in the presence of oxygen the yields of the major two products decreased and those of DA and MA increased with reaction time (Runs 4, 5). The results of the I_2-catalyzed reactions indicate the following reaction pathway.

$$ICH_2CH_2I \longrightarrow ICH_2CH_2OAc \longrightarrow AcOCH_2CH_2OAc \longrightarrow AcOCH_2CH_2OH$$

Indeed, ICH_2CH_2I yielded much more DA than MA (Run 6).

However, as Fig. 1 shows, MA was the main product in the beginning of the reaction and DA and EG yielded consecutively. These results imply that the catalytic reaction does not proceed *via* ICH_2CH_2I.[2] Indeed, ICH_2CH_2I, in spite of its stability under the reaction conditions (Runs 3, 4), was not detected by means of lpc in the reaction mixture.

The reaction in the absence of oxygen yielded very small amounts of products (Run 7). This result implies that oxygen does not reoxidize the reduced catalyst, but takes part in the main reaction. That is to say, oxygen and iodine (or iodine-containing compound) may form a compound (for instance, HIO) which gives a precursor of MA (Run 8), and that compound then reacts with ethylene to form ICH_2CH_2OH. The catalytic reaction seems to proceed as described above, actually, KIO and KIO_3 gave MA and DA in the reaction conditions (Runs 9, 10).

The assumption that the first reaction product is ICH_2CH_2OH is supported by the fact that a much greater amount of $BrCH_2CH_2OH$ is formed in the KBr–Mn(OAc)$_2$-catalyzed reaction than that of ICH_2CH_2OH in the KI–Mn(OAc)$_2$-catalyzed reaction. This could be explained in terms of the difference of the reactivities with KOAc between these two.

Formation-path of Higher Boiling Products. The reactions with and without Mn(OAc)$_2$ as a catalyst component showed the same product distributions (Fig. 4, Run 2). This result indicates that the Mn salt does not take part in the formation of the higher boiling products. Furthermore, neither the higher boiling products formed form DA (Run 11), nor acetoxyacetate yielded from acetic acid (Run 12).

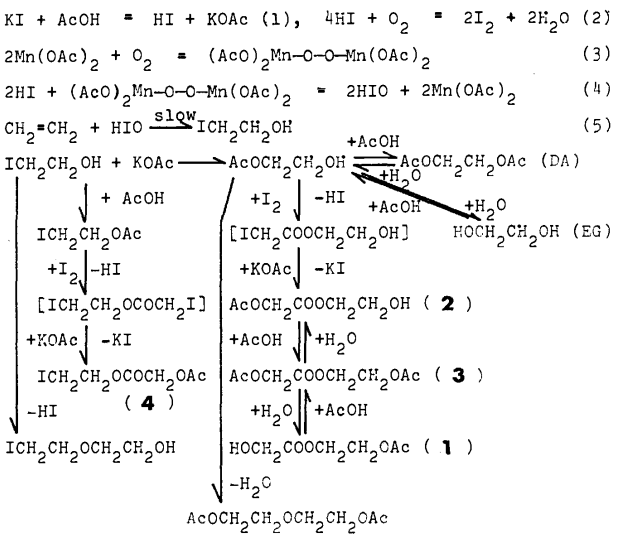
However, the higher boiling products are formed in high yields from a mixture of ethylene glycol acetates (Runs 13, 14). In addition, as Fig. 1 shows, **2** is formed first among the higher boiling products with **3** secondly and **1** only later. These results suggest that the hydrogen of the acetoxyl groups of MA is at first substituted by iodine which is replaced by acetoxyl groups to form **2**; then **3** is formed by the acetoxylation of **2**, followed by the hydrolysis of **3** to form **1**.

On addition of water to the reaction mixture, it was found that the yields of the higher boiling products decrease markedly and that of MA increases (Run 15). These facts support the idea that iodine was converted to HIO according to the equilibrium ($I_2+H_2O=HIO+HI$) in the presence of water, and that HIO promoted the formation of MA.

The reaction rate may be expressed as follows under the following conditions; oxygen pressure above 7.5 kg/cm^2, ethylene pressure below 25 kg/cm^2, KI concentration between 30 and 105 mol/100 g AcOH, Mn(OAc)$_2$ concentration between 1 and 10 mmol/100 g AcOH.

$$V = -dP/dt = k[KI][Mn(OAc)_2]^{\circ}P_{C_2H_4}P_{O_2}^{\circ}.$$

Furthermore, taking into account the above descriptions, the acidity of the reaction system and very little water in the reaction mixture in the beginning of the reaction, the catalytic reaction may be considered to proceed as follows;



The main reaction rate should be determined at the beginning of the reaction, because by-products are formed from the product of the main reaction. The above rate equation can be derived from this mechanism, by assuming that Eq. 5 is the rate-determing step, Eqs. 1, 3, and 4 are in equilibrium, P_{O_2} and [AcOH] disappear seemingly because of their sufficient amounts in the reaction mixture, and equilibrium 1 lies to the left because of the liberation of acidic HI in acetic acid.

Mn^{3+} and HIO seem to be the chemical species that are easy to form by oxidation from the viewpoint of redox potential, because the redox potentials of (HIO+

$H^+ + e = 1/2\ I_2 + H_2O$) and ($Mn^{3+} + e = Mn^{2+}$) in aqueous solution at 25 °C are 1.45 and 1.51 V, respectively,[6] and the values are not so high, although application of the values in aqueous solution to the reaction system under different conditions is questionable. Of course, the actual participating structures in the reaction system are uncertain. However, some speculation concerning a likely mechanism can be made on the basis of the known data. J. A. Elvidge and A. B. P. Lever first reported the Mn–O–O–Mn complex with Mn phthalocyanine in pyridine.[7] It is not unreasonable to consider chemical species such as $(AcO)_2Mn–O–O–Mn(OAc)_2$ and HIO even in acetic acid at higher temperature. The addition of HIO to olefines is well known to occur.[8]

Y. Ogata and K. Aoki might have observed the results of acetoxylation of the first reaction product, halohydrin, during their classical analytical operations. These required a much longer time than more rapid analytical methods such as gas chromatography.[5] Indeed, MA and ICH_2CH_2OH give corresponding acetates after a long time standing in acetic acid at room temperature.

The authors wish to express their appreciation to Dr. K. Matsuura and Dr. K. Matsushita, of JEOL, for their cooperation in the mass spectrometry and NMR spectroscopy.

The Splitting of the ESR Signal of Di-*t*-butyl Nitroxide Solubilized by Micellar Solutions

Shojun Isshiki and Yuhei Uzu*

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390

(Received January 20, 1981)

Synopsis. In a hexadecyltrimethylammonium bromide solution containing the stable micelle, a solubilized di-*t*-butyl nitroxide facilitated the partial resolution of the high-field line of the ESR spectrum, which can be associated with the radical in aqueous and micellar phases. Further analysis of the lineshape was made as a function of the surfactant concentration or the temperature.

Stable nitroxide radicals have been widely used as molecular probes or labels in order to study the dynamic effects in a variety of micellar and related membrane-like systems.[1-4] In the present study, the investigation of the ESR lineshapes of di-*t*-butyl nitroxide was made for various types of ionic micellar solutions, with the purpose of further establishing the motional contribution to the ESR linewidths in micellar systems.

Sodium dodecyl sulfate (SDS), sodium tetradecyl sulfate (STS), hexadecyltrimethylammonium bromide (CTAB), and sodium 1,2-bis(2-ethylhexyloxycarbonyl)-ethanesulfonate (AOT) were chosen as the surfactants in this study. SDS and STS were synthesized according to the conventional method. Both CTAB and AOT were specially purified reagents. Surface-tension measurements for the surfactant solutions indicated no minima at 30 °C. The nitroxide probe, di-*t*-butyl nitroxide (DTBN), was synthesized by the method of Hoffman *et al.*[5,6] Prior to the ESR measurements, all the solutions were prepared by adding DTBN to the surfactant solutions and stirring them magnetically for several hours. The concentration of DTBN added was always 4.5×10^{-4} mol dm^{-3}. All the ESR spectra were recorded on a Japan Electron Optics Laboratory JES-ME-3X spectrometer operating at the X band.

Representative ESR spectra in various types of surfactants at 30 °C are presented in Fig. 1. As was observed from the earlier finding,[1] the spectrum of DTBN in an SDS aqueous solution at concentrations below the CMC was identical with that obtained in pure water (Figs. 1(a) and 1(b)). These normal three-line spectra of nearly equal width are characteristic of a variety of rapidly tumbling nitroxides, suggesting no significant variation that might indicate the formation of premicellar aggregates or DTBN-monomer interactions. On the other hand, the high-field hyperfine line of DTBN in a 33 mmol dm^{-3} SDS micellar solution above the CMC is markedly broadened as a consequence of its interaction with the micelles. The relative magnitude of the tumbling motion of the radical is predicted from the rotational correlation time (τ_c); this value was computed from the linewidth and height of the ESR signals by the method of Martinie *et al.*[7] The values obtained in water and SDS solutions with concentrations above the CMC, where the linewidth was essentially little dependent on the SDS concentrations, were approximately 10^{-11} s and 10^{-10} s respectively. It can

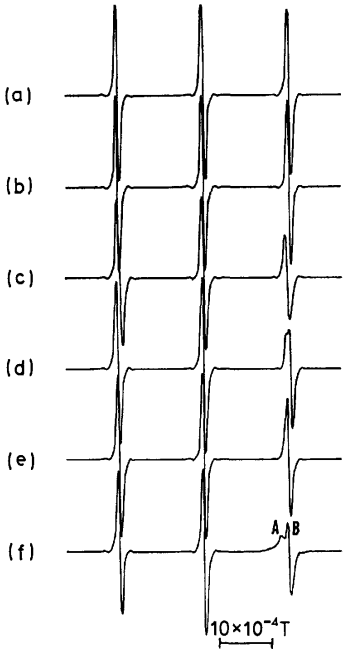

Fig. 1. Representative ESR spectra of 4.5×10^{-4} mol dm^{-3} DTBN at 30 °C.
(a): H_2O, (b): 5.5 mmol dm^{-3} SDS, (c): 33 mmol dm^{-3} SDS, (d): 14 mmol dm^{-3} STS, (e): 33 mmol dm^{-3} AOT, (f): 36 mmol dm^{-3} CTAB.

be seen that, although the experimental value for pure water agrees roughly with the one calculated (2.9×10^{-11} s) from the Stokes law (assuming the DTBN particle radius of 0.3 nm), the experimental values for the SDS solution are much smaller than that calculated for the radical rigidly adsorbed to a hypothetical rigid micelle (10^{-8} s). As has been stated in connection with other nitroxides,[1,3] the solubilized DTBN is considered to tumble too rapidly to be adsorbed on the micelles. Qualitatively, similar behavior was observed in solutions of the other surfactants studied, although there were some indications of the spectral distortion (or partial resolution) of the high-field line in both STS and CTAB micellar solutions (Figs. 1(d) and 1(f)). In the latter, most notably, the high-field line in a 36 mmol dm^{-3} CTAB micellar solution was replaced by two signals analogous to A and B. In this regard, the spectrum resembles that observed in the membrane-like system.[2] The explanation of the distortion is that signals from the radical molecule in two environments, *i.e.*, in the micelle and in the bulk aqueous solution, can be observed separately, indicating that the exchange of the radical between the two environments is very slow. On the contrary, the single signal of the high-field line observed in AOT and SDS suggests that the radical exchanges rapidly to produce a single symmetric signal, which is a weighted average of the spectra found in the two

environments. In these spectra, it seems to be unnecessary to consider the overlapping of two types of spectral lines due to the different environments of the probe. Especially, the very narrow line resulting for AOT suggests a motion which is very rapid compared with those of the other surfactants studied. In contrast with our result at 30 °C, Atherton *et al.*[5] found that the high-field line for SDS micellar solutions was barely resolved at 23 °C for DTBN in two environments. Accordingly, the rate of exchange of the radical probe for the SDS solution at 30 °C is presumed to be relatively slow compared to that of AOT; therefore, a motional behavior similar to that of STS may rather be expected. Therefore, the greater asymmetry of the lineshape, as well as the larger τ_c value, is observed with a longer length of the surfactant alkyl chain. From the ^{1}H NMR study of an SDS micellar solution containing a Tempo radical, Oakes *et al.*[4] showed that the radical-induced proton relaxation occurred preferentially at the α-methylene group of the SDS micelle. Based upon the chemical similarity of DTBN and Tempo, we find a strong indication for a solubilization mainly occurring in the outer region within the SDS micelles. With CTAB, the relative intensities of the A and B signals of the high-field line were strongly dependent upon the CTAB concentration (Fig. 2). As the concentration

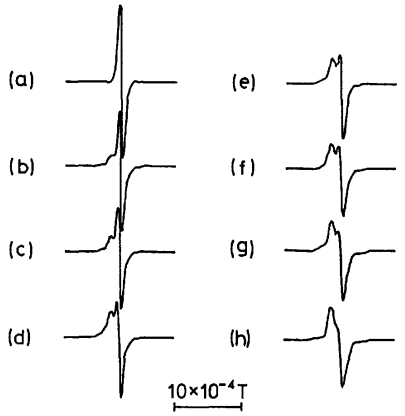

Fig. 2. Concentration dependence for the high-field line of ESR spectra in CTAB solutions at 30°C.
(a): 10, (b): 21, (c): 30, (d): 39, (e): 45, (f): 48, (g): 54, (h): 63 mmol dm^{-3} CTAB.

of CTAB is increased, an increase in Signal A and a concomitant decrease in Signal B are observed, until Signal B, due to the radical in the bulk aqueous phase, is no longer observable. This results from the relative population of the DTBN tumbling rapidly in each phase. Recently, the CTAB micelle has been described as being a more closely packed micelle or having a long-range order, giving it a somewhat solidlike character.[8] This suggestion is advantageous in explaining the above-mentioned incorporation of the DTBN in the CTAB micelle. That is, the small DTBN radical, which is nearly spherical, could rotate rapidly in a relatively rigid micelle; however, it would exhibit a slow chemical exchange of the radical between the micellar and the bulk aqueous phases. In solutions

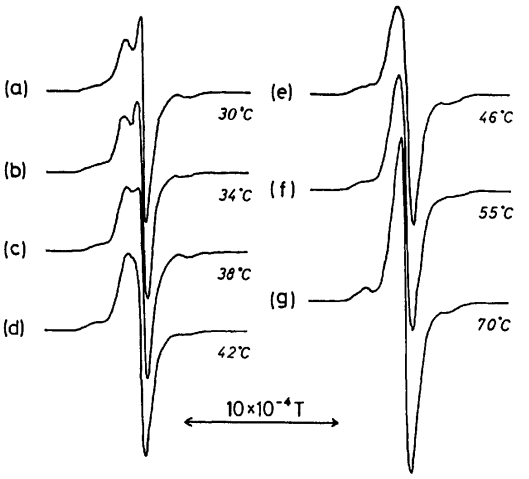

Fig. 3. Temperature dependence for the high-field line in 42 mmol dm^{-3} CTAB.

containing the more stable micelles, the DTBN radical can be expected to exhibit two distinct spectra of the high-field line.

The spectra for the 42 mmol dm^{-3} CTAB solution have also been studied over the temperature range of 30—86 °C. As the temperature is increased, the two signals of a high-field line progressively coalesce, until a single line is observed at *ca.* 46 °C (Fig. 3). The increase in the amount of solubilized radical in the micellar phase might be accounted for by the change in the micellar structure and in the solubilities of the radical in the aqueous phase. At higher temperatures above 46 °C, it is conceivable that the increase in the temperature could cause a linewidth decrease in the high-field line. This indicates that the narrowing due to the faster exchange rate between the two environments probably dominates in this temperature range. The most likely explanation is that the micelle would become less rigid as a result of the increased flexibility of the alkyl chains and that the above-mentioned packing restrictions would become less important, finally leading to a disruption of the micelles.

We are gratefully indebted to Professor Hiroshi Kato for his very generous hospitality and invaluable advice during the synthesis of di-*t*-butyl nitroxide.

Electrochemical Behavior of Alkoxo-bridged Binuclear Copper(II) Complexes with *N,N*-Dialkyl-*N'*-(hydroxyalkyl)alkanediamine

Makoto AIHARA,* Yoshiko KUBO, Yuzo NISHIDA,† and Sigeo KIDA†

Faculty of Home Life Science, Fukuoka Women's University, Higashi-ku, Fukuoka 813

†*Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812*

(Received August 11, 1980)

Synopsis. The alkoxo-bridged binuclear copper(II) complexes with *N,N*-dialkyl-*N'*-(hydroxyalkyl)alkanediamine were investigated by electrochemical methods. The binuclear complexes exhibited two non-separable sequential, one-electron steps, the half-wave potentials of which were almost identical, in *N,N*-dimethylformamide. On the other hand, the complexes gave two distinctive one-electron reduction waves in acetonitrile.

Recently electrochemical investigations of binuclear copper(II) compounds have continued to increase. One of the interests in this field is the properties of the particular proteins in which a pair of copper(II) ions is strongly anti-ferromagnetically coupled.[1] The copper atoms bound in such proteins are referred to as type III coppers. Binuclear metal nuclei in proteins usually undergo two-electron reduction in one step. A tentative series of intermediates during the reduction has been proposed.[2] Synthetic binuclear copper(II) complexes exhibit either a one-electron reduction step[3–5] or a two-electron reduction step.[6–8]

The present report deals with the electrochemical behavior of the alkoxo-bridged binuclear copper(II) complexes with *N,N*-dialkyl-*N'*-(hydroxyalkyl)alkanediamine, $[Cu(R_2N(CH_2)_3NH(CH_2)_2O)]X$ (abbreviated hereafter as [Cu(R-3-2)]X, R=H, CH_3, C_2H_5 and $X=ClO_4^-$ or $B(C_6H_5)_4^-$) in non-aqueous solvents. A schematic structure of the complexes studied is illustrated in Fig. 1.

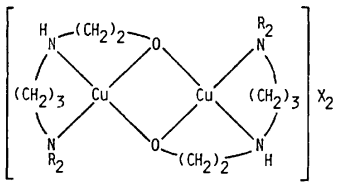

Fig. 1. Structure of the complexes of the [Cu(R-3-2)]X type.

Experimental

Synthesis of the Complexes: The complexes were prepared according to the method reported previously.[9]

Electrochemical Measurements: All measurements were carried out in an 0.1 M tetraethylammonium perchlorate (TEAP) solution of *N,N*-dimethylformamide (DMF) or acetonitrile (AN) at 25±0.1 °C. A Fuso model 312 polarograph and a DME (or HMDE) were employed for polarographic and cyclic voltammetric measurements. The reference electrode was SCE with a salt bridge.[10] Controlled-potential electrolysis was performed at a mercury pool under stirring. ESR controlled-potential electrolysis experiments were carried out under an atmosphere of nitrogen gas. The other apparatus was the same as described previously.[10]

Results and Discussion

The typical current-sampled dc polarogram for the binuclear copper(II) complex with the $[Cu(C_2H_5\text{-}3\text{-}2)]X$ formula in DMF is shown in Fig. 2. The second wave for the binuclear complex with the [Cu(H-3-2)]X type formula was observed at more negative regions (*ca.* −1.0 V *vs.* SCE) of potential, while the maxima were observed on the shoulder of the second waves for the binuclear complexes with $[Cu(C_2H_5\text{-}3\text{-}2)]X$ or $[Cu(CH_3\text{-}3\text{-}2)]X$ type formula. A detailed discussion of these waves, however, is omitted here.

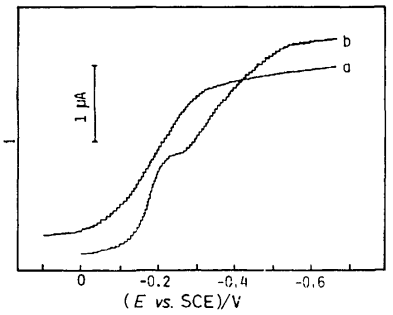

Fig. 2. Current-sampled d.c. polarograms of 0.5 mM $[Cu(C_2H_5\text{-}3\text{-}2)]X$ in DMF (curve a) and AN (curve b).

Table 1. Polarographic data for [Cu(R-3-2)]X in 0.1 M TEAP-solvent at 25 °C

	$E_{1/2}$ *vs.* SCE / V	I_d / μA	Slope / mV	$n^{a)}$
In DMF

$[Cu(CH_3\text{-}3\text{-}2)]X$	−0.327	1.70	79	2.0
$[Cu(C_2H_5\text{-}3\text{-}2)]X$	−0.212	1.50	110	1.9
In AN				
[Cu(H-3-2)]X	−0.560	2.04	116	2.1
$[Cu(CH_3\text{-}3\text{-}2\text{-})]X$	−0.237[b)]	0.73	*ca.* 50	
	−0.452[c)]	1.05	117	2.1
$[Cu(C_2H_5\text{-}3\text{-}2)]X$	−0.166[b)]	0.96	*ca.* 50	
	−0.364[c)]	1.23	116	2.0

a) These values for *n* were determined by controlledpotential electrolysis at −0.7 V *vs.* SCE. b) First wave. c) Second wave.

The limiting current of each of the first steps was found to be diffusion-controlled. Table 1 gives the results obtained.

The typical cyclic voltammogram for the binuclear complex with the $[Cu(C_2H_5\text{-}3\text{-}2)]X$ formula in DMF is shown in Fig. 3. The peak currents on the cathodic and anodic branches are nearly equal to each other, implying a reversible redox process, whereas the value of potential difference between the two redox peaks is larger than that (42 mV)[8] of the difference theoretically expected for the reversible two-electron redox step, suggesting a quasi-reversible one.

Constant potential electrolysis was performed at a fixed potential regions more negative than those of the first waves. The results of electrolysis showed the consumption of two electrons for each complex molecule, as summarized in Table 1, suggesting that this process is a two-electron reduction. On electrolytic reduction,

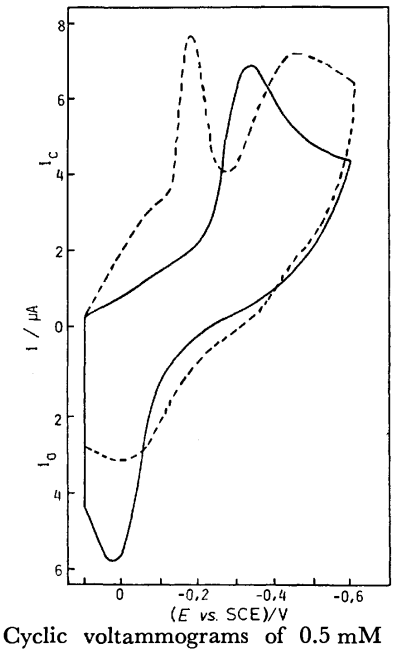

Fig. 3. Cyclic voltammograms of 0.5 mM [Cu(C_2H_5-3-2)]X in DMF (——) and AN (- - -) at HMDE, scan rate 200 mV.

the originally green solution became yellow. Exposure to air gradually restored the green color again, suggesting that chemical oxidation can take place reversibly.

The first waves observed in DMF for the binuclear complexes with the [Cu(CH_3-3-2)]X or [Cu(C_2H_5-3-2)]-X formula were found to split into two steps in AN as shown in Fig. 2. Differential pulse polarograms also showed two cathodic peak splittings.

The typical cyclic voltammogram of the binuclear complex with the [Cu(C_2H_5-3-2)]X formula in AN is shown in Fig. 3. The two peaks on the cathodic branch were clearly separated from each other, while those on the anodic one were not, suggesting an irreversible anodic process. Therefore, it was concluded that the chemical oxidation takes place reversibly, while the anodic oxidation cannot be followed due to the extremely rapid progress of the former even in a stream of nitrogen. The polarographic data are given in Table 1. Reduction of 1 mM [Cu(R-3-2)]X in AN solution at −0.7 V *vs.* SCE consumes two electrons per a complex molecule. The controlled-potential electrolysis at the potential region of the first wave in AN could not give any data available for the determination of number of electrons transferred because of a non-separable character of the first and the second waves, suggesting that no stable intermediate can exist. That is, the reduction product which had been prepared from the copper(II) complexes through the cathodic reduction did not show any anodic peak on the cyclic voltammogram. On the contrary, the reduced binuclear complexes with [Cu-(C_2H_5-3-2)]X formula in AN showed four-line ESR patterns as shown in Fig. 4. These four-line patterns obtained for the frozen solution suggest the location of odd electrons on a single copper nucleus on the ESR time scale.

Voltammetric results in DMF showed that the three complexes undergo two sequential, one-electron reduction steps in which the reduction potentials of both

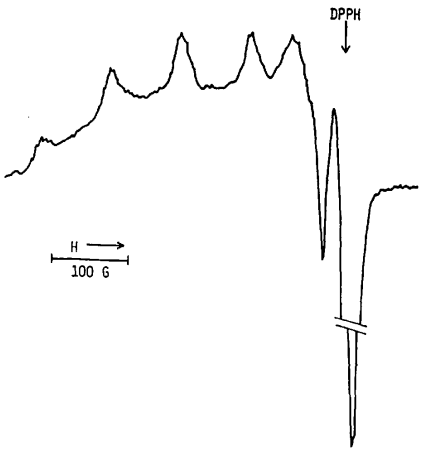

Fig. 4. ESR spectrum obtained for the frozen reduction product of the [Cu(C_2H_5-3-2)]X complex in AN, which was prepared by the controlled-potential electrolysis at −0.25 V *vs.* SCE.

steps are almost identical. The reduction process was quasi-reversible and the replacement of R by ethyl group caused a shift of the reduction potential of the first wave toward a more negative value.

On the other hand, voltammetric results in AN, coupled with those of ESR, showed two one-electron reduction steps occurring at different potentials as follows: Cu(II)-Cu(II)→Cu(II)-Cu(I)→Cu(I)-Cu(I). The solvation of AN may contribute to the formation of a "super complex" with a stable moiety of the Cu(II)-Cu(I) complex. The reduction potential of these complexes shift to a more positive direction of potential in order H-$<$ CH_3-$<$ C_2H_5-. The replacement of the *N*-substituent causes the sterical geometry of the complex to alter and simultaneously brings about the changes in properties of releasing electrons.

So far the effect of donor atoms on the standard redox potential of the coplanar Cu(II) complexes has been discussed and the order of positively-increasing redox potential of Cu(II)/Cu(I) couple was found to be $N_4$$<$$N_2O_2$$<$$N_2S_2$ donor sets.[7] The redox potential, E^0, of Cu(II)/Cu(I) couple for the binuclear complex with the [Cu(C_2H_5-3-2)]X formula in DMF was found to be −0.04 V *vs.* NHE, which was more positive than values of the Cu(II)/Cu(I) couple for the other synthetic complexes found in Ref. 7.

Selective Separation of Cr(VI) from Cr(III) in Seawater by Cobalt-1-pyrrolidinecarboditioate Coprecipitation Method

Kitao FUJIWARA,* Shozo TODA,† and Keiichiro FUWA

Department of Chemistry Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 28, 1980)

Synopsis. Specific coprecipitation of Cr(VI) in artificial seawater with Co(II)–APDC complex was investigated. The maximum recovery by coprecipitation was 60.6± 4.54% at pH 2 in which Cr(III) was completely separated from Cr(VI).

Historically, determination of Cr(VI)/Cr(III) ratio in seawater is one of the most important subjects, in chemical oceanography. From pure thermodynamic calculation, the amount of Cr(VI) is expected to be over 10^9 times more than that of Cr(III).[1,2] This means almost all chromium will exist in the Cr(VI) state. However, even under oxidative conditions, appreciable amount of Cr(III)[3,4] can be found in seawater. This discrepancy between the thermodynamic calculation and the actual finding of the Cr(VI)/Cr(III) ratio was sometimes explained in terms of the reduction of Cr(VI) by organic substances coexistent in the seawater or due to the catalytic participation of inorganic materials such as manganese nodules. On the other hand, the lack of an analytical method specific to Cr(VI) might also cause this discrepancy.

For Cr(III) ion, hydroxides of iron and zirconium have been successfully applied to seawater analysis.[4,5] Unfortunately, there is no specific method for Cr(VI) ion except solvent extraction.[5-8] However, solvent extraction might not be preferable for Cr(VI) stability because of the possibility that the use of large amount of organic solvent causes the reduction of Cr(VI), and also it is time-consuming when many samples have to be analysed.

In the present note, the coprecipitation with Co–APDC complex, which was first reported by Boyle *et al.*[9] was applied as a selective and specific method for separating Cr(VI) from seawater.

Experimental

As the chromium salts, $K_2Cr_2O_7$ and $Cr(NO_3)_3 \cdot 8H_2O$ were used. When coprecipitation was performed, the artificial seawater of 25—50 ml was taken, and 100 μl of *ammonium 1-pyrrolidinecarbodithioate* (APDC) solution (3%: ≈0.18 M) was added to the sample after adding 200 μl of cobalt solution (0.85 g $CoCl_2$-$6H_2O$/l: ≈0.3 mM). All the experiments in this paper were done with artificial seawater which was prepared according to Ref.10. Co-APDC suspension was left for about 1 h and centrifuged at 5000 $min^{-1} \times 20$ min. After drying the centrifuge tube, the precipitate was dissolved in 1 ml of 10% nitric acid solution, and chromium was determined by atomic absorption spectrometry with a carbon rod furnace (a Hitachi 170-50 atomic absorption spectrophotometer with a Jarrell-Ash FLA 100 atomizer).

Results and Discussion

The dependence of coprecipitation recovery of Cr(VI) and Cr(III) on pH of seawater is shown in Fig. 1. The values in the figure were the average of duplicate or triplicate measurements. Cr(VI) is well coprecipitated in the low pH region, being maximum at pH 1—3. When the solution was adjusted to pH 2, the recovery was 60.6±4.54% (standard deviation for nine independent coprecipitations). This value is almost constant against 0.2—10 ppb of Cr(VI) region. In the present experiment, the samples with Co–APDC suspension were left for 1 h before centrifuging. However, the recovery scarcely changed during the overnight standing of Co–APDC suspension.

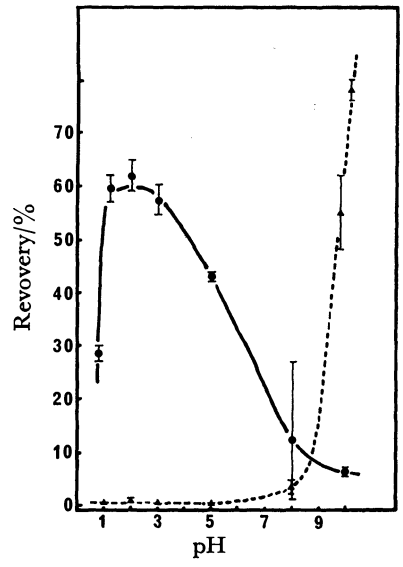

Fig. 1. Dependence of coprecipitation recovery on pH of seawater.
pH of seawater was adjusted by adding hydrochloric acid and sodium hydroxide solution. ●: Cr(VI), ▲: Cr(III).

On the other hand, the amounts of Cr(III) coprecipitated with Co–APDC are negligible at pH regions lower than 5. However, these values increase steeply above pH 9. The Cr(III) coprecipitation at low pH could be considered as contamination due to the incomplete separation of precipitate from the supernatant solution in the centrifugal process.

Figure 2 shows the effect of Cr(III) coexistence on the Cr(VI) coprecipitation. As can be seen in the figure, coexistence of Cr(III) up to 100 times more than Cr(VI) does not disturb the result of coprecipitation of Cr(VI) ion. Since oxidation of Cr(III) to Cr(VI) hardly proceeds in the present condition, the contamination of Cr(III) in the centrifugal separation might cause the increase of signal at the sample which contains 4000 ppm of Cr(III).

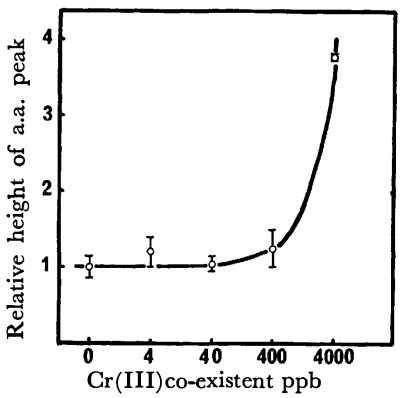

Fig. 2. The effect of Cr(III) coexistence on Cr(VI) coprecipitation.
All the solution contained 4 ppb of Cr(VI), and adjusted at pH 2.

From the present result, it has been confirmed that the cobalt 1-pyrrolidinecarbodithioate coprecipitation technique, which was first proposed for the analyses of Cu, Ni, and Cd in seawater,[9] is also effective for the selective and specific separation of Cr(VI) from seawater. Although the recovery of Co–APDC coprecipitation for Cr(VI) is only about 60%, this value is quantitative and reproducible. Therefore, the present method is a useful technique for the determination of Cr(VI) in seawater.

The authors would like to thank Prof. D. R. Kester, Univ. of Rhode Island for his suggestions concerning this work.

Preparation of Sephadex Derivatives with Optically Active Groups and Column-chromatographic Application to the Resolution of Some Cobalt(III) Complexes

Miho FUJITA,* Masanobu SAKANO,† Yuzo YOSHIKAWA,† and Hideo YAMATERA†

Department of Chemistry, Nagoya City University, Mizuho-ku, Nagoya 467

†*Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464*

(Received February 12, 1981)

Synopsis. Optically active cation-exchangers were newly prepared as Sephadex derivatives derived from L-alanine, L-valine, L-aspartic acid, and L-threonine. They were applied to the column-chromatographic resolution of some cobalt(III) complexes, partial resolution being attained.

The chromatographic method using an SP-Sephadex column has been successfully applied in the last decade to resolve optical isomers and to separate geometrical isomers of metal complexes. The method is useful for resolution, but it requires a considerable amount of optically active eluent. Direct column-chromatographic resolution without optically active eluents could be attained with use of an optically active stationary-phase. However, natural chiral substances such as quartz, starch, or lactose have been found to be unsuitable for a highly efficient resolution.

On the other hand, an ion-exchanger with optically active groups on itself could be applied to the column-chromatographic resolution of metal complexes. Two types of TA-Sephadex, TA(ET)- and TA(ES)-Sephadex, in which L-tartrate groups are linked to form ether and ester, respectively, were prepared and successfully applied to completely resolve $[Co(en)_3]^{3+}$ by column-chromatography.[1]

In the present study, a series of Sephadex derivatives with optically active cation-exchanging groups derived from L-amino acids were newly prepared and a couple of cationic and non-electrolyte complexes were chromatographed on their columns.

Experimental

Sephadex cation-exchanger with optically active groups was prepared by the following reactions:

$$\underset{\mathbf{1}}{\text{L-}H_2N\text{-}CH(R)\text{-}COOH} \xrightarrow[NaCl+NaNO_2]{1M\ HCl} Cl\text{-}CH(R)\text{-}COOH, \quad (1)$$

$$\underset{\mathbf{2}}{}$$

$$\underset{\mathbf{3}}{SD\text{-}OH} + Cl\text{-}CH(R)\text{-}COOH \xrightarrow[50\%\ NaOH]{benzene} SD\text{-}O\text{-}CH(R)\text{-}COONa, \quad (2)$$

$$\underset{\mathbf{4}}{}$$

where SD–OH (**3**) denotes Sephadex framework. The method of preparation for reaction (1) is similar to that for (*S*)(+)-2-chlorosuccinic acid from D-(−)-aspartic acid by Tosa *et al.*[2] For the reaction (2), Flodin's method of the preparation of CM-Sephadex was used with a slight modification.[3]

A typical procedure is as follows: Eighty-nine grams of L-alanine and 35 g of sodium chloride were dissolved in 900 ml of 1 M (1 M = 1 mol/dm^3) HCl by heating. To the cold solution (about 3 °C) was added 900 ml of a cold 4% $NaNO_2$ solution in small portions with stirring below 5 °C. The solution was then stirred for one day. Eight hundred milliliters of concd HCl was then added with stirring. The solution was filtered off from precipitated sodium chloride and extracted three times with ether. After concentrated extracts had been dried with anhydrous Na_2SO_4, 2-chloropropionic acid was obtained by distillation under reduced pressure: pale-yellow liquid (24 g), bp 105 °C/43 mmHg.

To the suspension of 60 g of dry Sephadex G-25 in 200 g of benzene, was added 90 g of 50% NaOH solution in small portions with stirring. Eighty-four grams of 2-chloropropionic acid was slowly poured into the mixture below 55 °C. The reaction mixture was kept standing at *ca.* 50 °C for 12 h, with constant stirring. This was filtered and washed throughly with water, methanol, and then water. This Sephadex derivative was converted into sodium form with sodium hydroxide.

The Sephadex derivative is denoted by PR-Sephadex (PR = propionate). By similar methods, three other types of Sephadex derivatives were prepared by using L-valine, L-aspartic acid, and L-threonine; they are denoted by IVA-, SU-, and HBU-Sephadex, respectively (IVA = isovalerianate, SU = succinate, and HBU = 3-hydroxybutyrate).

Five kinds of complexes were subjected to column-chromatography on each column of the Sephadex cation-exchangers prepared and CM-Sephadex (R = H, available from Pharmacia). A sodium sulfate solution was used as an eluent except for the case of *mer*-$[Co(gly)_3]$ which was eluted with water. Each 3 ml of effluent was collected and measured for the maximum absorbance of the first absorption band and for the maximum CD intensity in the corresponding region of the CD spectrum. From the results, the ratio of $\Delta\varepsilon/\varepsilon$, the apparent dissymmetric factor, was obtained for each fraction and used as a measure of resolution.

Results and Discussion

Configuration around an asymmetric carbon atom is inverted in reaction (1).[4] Thus, L-amino acids of *S*-chirality give chloro derivatives (**2**) of D-form with *R*-chirality.

Ion-exchange capacity for $[Co(en)_3]^{3+}$ of the Sephadex

Table 1. Ion-exchange capacity and column size

Sephadex derivatives	Capacity[a]	Column size
PR-Sephadex	0.91	1.8 cm × 130 cm
IVA-Sephadex	0.12	1.8 cm × 90 cm
SU-Sephadex	0.12	1.8 cm × 90 cm
HBU-Sephadex	0.53	1.8 cm × 150 cm
CM-Sephadex	1.23	1.8 cm × 130 cm

a) For $[Co(en)_3]^{3+}$ (in mmol/g).

Table 2. Apparent dissymmetric factors in the first and last fractions of elutions[a]

	PR-Sephadex	IVA-Sephadex	SU-Sephadex	HBU-Sephadex	CM-Sephadex
$[Co(en)_3]^{3+}$	—[b]	—[b]	—[b]	(+)5.8—(−)5.8 (26) (26)	(−)8.0—(+)9.2 (36) (41)
$[Co(gly)(en)_2]^{2+}$	(+)1.4—(−)2.5 (6.6) (12)	(+)0.8—(−)1.2 (3.8) (5.6)	(+)0.5—(−)0.5 (2.3) (2.3)	(+)6.0—(−)6.5 (28) (31)	(−)4.4—(+)5.5 (21) (26)
$[Co(ox)(en)_2]^{+}$	(+)2.3—(−)3.5 (9.6) (15)	(+)3.0—(−)2.9 (13) (12)	(+)2.0—(−)2.0 (8.4) (8.4)	(+)2.0—(−)3.5 (8.4) (15)	(+)11—(−)16 (46) (67)
c-$[Co(NO_2)_2(en)_2]^{+}$	—[b]	(+)2.0—(−)4.5 (11) (25)	(+)1.0—(−)1.0 (5.6) (5.6)	(+)0.8—(−)2.0 (4.5) (11)	(+)1.8—(−)2.4 (10) (14)

a) Signs and figures denote $(\Delta\varepsilon/\varepsilon)\times 10^3$ values at the main CD peak. Figures in parentheses denote optical purity (%).
b) No significant resolution.

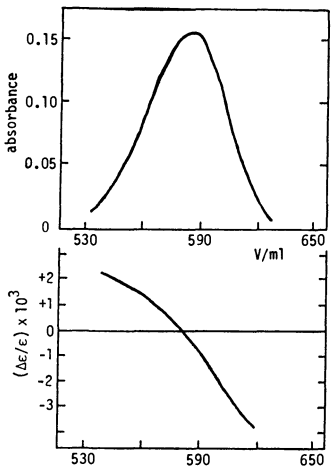

Fig. 1. The elution of $[Co(ox)(en)_2]^+$ on a PR-Sephadex column with a 0.07 M Na_2SO_4 solution.

derivatives prepared is given in Table 1 together with that of CM-Sephadex. Lower capacities of IVA- and SU-Sephadex might be attributed to lower yields of reaction (2).

The elution of $[Co(ox)(en)_2]^+$ from a PR-Sephadex column is shown as a representative example in Fig. 1. No clear-cut resolution is seen in the elution curve, but partial resolution is attained with a column of PR-Sephadex as well as other optically active Sephadex derivatives, as indicated by the change in dissymmetric factor from the top to the tail of the eluate.

The values of $\Delta\varepsilon/\varepsilon$ and optical purity in the first and the last fraction of each elution, together with the results on CM-Sephadex are summarized in Table 2. CM-Sephadex has no asymmetric centers on ion-exchange groups. Resolution with its column is, thus, due to the Sephadex skeleton which consists of dextran with a chirality similar to that of potato starch. With IVA- and SU-Sephadex, *mer*-$[Co(gly)_3]$ is resolved more efficiently than with CM-Sephadex, in spite of the fact that the ion-exchange capacities of the IVA- and SU-derivatives are only one-tenth of that of CM-Sephadex.

In the elution experiments of $[Co(gly)(en)_2]^{2+}$ with columns of Sephadex derivatives, the fast eluted enantiomer is the one with a negative CD peak. On the other hand, the enantiomer with a positive peak is eluted faster with a column of CM-Sephadex, as well as in the case of HBU-Sephadex for $[Co(en)_3]^{3+}$. Thus, optically active ion-exchanging groups on the Sephadex derivatives contribute to the resolution of the complexes. However, stereoselectivity for the complexes is opposite to that of Sephadex itself and the effect of optically active ion-exchanging groups for resolution is partially cancelled by the effect of the Sephadex skeleton.

Photochemical Nucleophilic Substitution Reactions of Methyl Substituted Derivatives of *p*- and *o*-Nitroanisole[1)]

Masaki SAWAURA and Toshio MUKAI*

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received September 29, 1980)

Synopsis. Photosubstitution reactions of several methyl substituted derivatives of *p*- and *o*-nitroanisole with hydroxide ion were investigated. The methyl substituent seemed to show an uncertain (probably electronic) effect in addition to the steric effect for the replacement of both the methoxy and the nitro groups. Mainly, the replacement reaction of the nitro group is discussed.

It is well known that aromatic nucleophilic substitution reactions take place differently in the ground state and in the excited state.[2)] Theoretical calculations[3)] support the sharp contrast between them.[4)] In the photosubstitution reaction of *m*-nitroanisole with hydroxide ion, *m*-nitrophenol was produced as a single product as was expected from the orientation rule that the nitro group activates the replacement at the meta-position.[5)] However, with *o*- and *p*-nitroanisoles the meta-orientation rule is not useful for the prediction of the product. For instance, Letsinger[6)] and Havinga[7)] independently studied the photosubstitution reactions of *p*- and *o*-nitroanisoles (**1** and **5**) with hydroxide ion and obtained *p*- and *o*-methoxyphenols (**1b** and **5b**) in addition to *p*- and *o*-nitrophenols (**1a** and **5a**). The formation of **1b** and **5b** could be explained by the orientation rule that the methoxyl group activates at the *o*- and *p*-positions.[7)] However, it has not been rationalized why methoxyl group at para or ortho positions of the nitro group is replaced and why the product ratios (**1a**/**1b** and **5a**/**5b**) are inverted in the *o*- and *p*-isomers (see Table 1). Dudell's study on the flash photolysis of **1** and **5** showed that **1a** and **5a** were formed from the triplet states,[8)] but no clear explanation has been made on the reaction machanism. In order to gain an insight into the reaction mechanism, we studied the methyl substituent-effect on the replacement of the nitro- and the methoxyl group in the derivatives, **2**—**4** and **6**—**8**, with hydroxide ion. An expectation is that the ortho-substituted methyl group should supress more effectively the π-π^* excitation than the n-π^* excitation of the nitro group, thus resulting in decrease in the replacement of the methoxyl group.

Results and Discussion

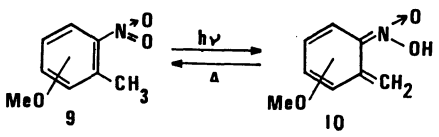
The methyl substituent-effect on the photosubstitution reactions of **1**—**8** is discussed on the basis of the quantum yields shown in Table 1. The introduction of a methyl group at a position next to the nitro group, as in **2** and **6**, resulted in a great retardation of the replacement of both the methoxyl and the nitro groups. Neither **2b** nor **6b** were detected and **2a** and **6a** were formed only in poor yields. Decrease in the reactivity of **2** and **6** is clearly to be ascribed to the steric effect of the methyl group that inhibits the coplanarity of the nitro group and the phenyl moiety (see the UV spectra).[9)] The methyl group also prevents the attack of hydroxide ion to the nitro group. In addition to these effects, the photo-valence isomerization between the nitro-form (**9**) and the aci-form (**10**) should become a main decay process in the excited state of **2** and **6**. When **2** was irradiated in dioxane containing deuterium oxide, incorporation of deuterium was found to take place in the methyl group.

With **3** and **7**, the introduction of the neighboring methyl group led to the rapid formation of **3a** and **7a**.

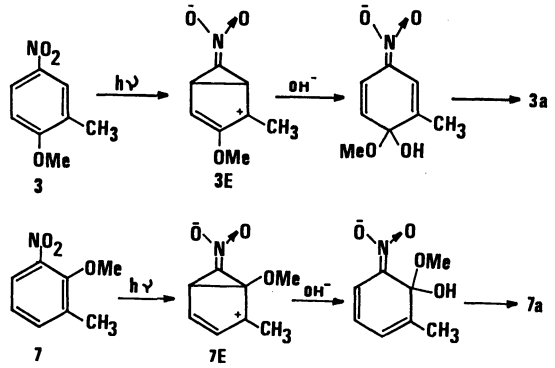
Table 1. Quantum yields[a)] for the depletion of the reactants (**1**—**8**) and for the formation of the products (**1a**, **1b**—**8a**, **8b**)

REACTANT(-Φ)		PRODUCTS(Φ)			
1	 (0.111)	1a	 (0.020)	1b	 (0.091)
2	 (0.005)	2a	 (0.005)	2b	 (0.000)
3	 (0.145)	3a	 (0.056)	3b	 (0.089)
4	 (0.005)	4a	 (0.003)	4b	 (0.002)
5	 (0.028)	5a	 (0.022)	5b	 (0.006)
6	 (0.003)	6a	 (0.003)	6b	 (0.000)
7	 (0.044)	7a	 (0.044)	7b	 (0.000)
8	 (0.008)	8a	 (0.004)	8b	 (0.004)

a) The quantum yields during the initial stage (less than 5 min) of the substitution reactionsare shown here. Side reactions appeared after prolonged irradiation.



Compared with **1** and **5** the more sterically hindered methoxyl group was replaced more easily by hydroxide ion. This can be rationalized by the stabilization of the excited states, **3E** and **7E**, by the methyl substituent meta to the nitro group as shown in the following scheme.[11]



Contrary to this, the replacement of the nitro group in **3** and **7** seemed to be retarded very little by the methyl group located ortho to the methoxyl group.

The substitution reaction of 5-methyl-2-nitroanisole (**8**) was found to occur at a slow rate, even though the methyl group is not present at the positions next to the nitro and the methoxyl groups. The formation of **8b** was not affected by the methyl substituent, but that of **8b** was retarded compared to the formation of **5a**. However, this retardation could not be accounted for by the methyl substitution present.[12] Thus, it can be concluded that the methyl group enhances the replacement of the ortho-substituted methoxyl group in *m*-nitrotoluene derivatives such as **3** and **7**, but it retards the replacement of the para- or ortho-substituted methoxyl group in *o*- and *p*-nitrotoluene derivatives **2**, **6**, and **8**.

In the photosubstitution reaction of 2,5-dimethyl-4-nitroanisole (**4**), products **4a** and **4b** were obtained in poor yields. It is difficult to predict how methyl groups affect the substitution reaction of **4**, but the effect of the methyl group ortho to the nitro group seems to be stronger than that of the methyl group meta to the nitro group.

Experimental

Materials. Methyl derivatives of nitroanisole were prepared according to the literature[13–16] and identified by their mp and spectral data.

Measurements. A spectro-photofluoromenter Hitachi MPF-4 [xenon monochromatic light (UXL-150D)] was used as the light source for the irradiation. Absorption spectra were measured with a Hitachi 340 spectrophotometer. The quantum yields were obtained by using the potassium tris-oxalatoferrate(III) chemical actoinmeter.[17] A solution (1×10^{-4} mol/dm^3) of *p*-nitroanisole (**1**) in a mixture of *t*-butyl alcohol and water (1 : 3) containing 0.2 mol/dm^3 sodium hydroxide was irradiated with monochromatic light (at 313± 20 nm) in a quartz cell under nitrogen atomsphere. The absorption maximum of *p*-nitrophenol (at 420 nm, ε=20700) was used for the reference and the quantun yield of the formation of **1a** was measured spectroscopically based on the absorption coefficient at 420 nm. The UV spectrum of this reaction mixture corresponded well with a spectrum calculated for a mixture of 82% of *p*-methoxyphenol and 18% of *p*-nitrophenol (see report by Letsinger *et al.*[6]). On the other hand, the isolation of photoproducts, **1a** and **1b**, was carried out in preparative scale experiments. The photoreactions of other derivatives (**2**—**8**) were monitored in the same way as mentioned above and the quantum yields shown in Table 1 were thus obtained.

The authors wish to thank Dr. K. Okada for his helpful discussion.

Persistent Nitrogen-centered Free Radicals, *N*-(Arylthio)-3,5-di-*t*-butylphenylaminyls. Decomposition Reactions[1)]

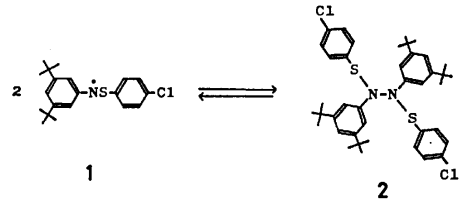
Yozo Miura,* Akifumi Yamamoto, and Masayoshi Kinoshita

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received November 27, 1980)

Synopsis. *N*-(4-Chlorophenylthio)-3,5-di-*t*-butylphenylaminyl was decomposed in oxygen-free benzene, and the products were examined. On the basis of the results, the decomposition mechanism of the radical is described.

In a previous report[1)] we described how *N*-(arylthio)-3,5-di-*t*-butylphenylaminyls are very persistent radicals and that they can be isolated as dimers which dissociate into the orginal radicals, even at room temperature ($K=[\text{radical}]^2[\text{dimer}]^{-1}=0.98\times10^{-4}$—$4.59\times10^{-4}$ mol l^{-1} in benzene at 27 °C). On standing in solution over a long period, however, the radicals gradually decompose. In order to elucidate the decomposition mechanism, *N*-(4-chlorophenylthio)-3,5-di-*t*-butylphenylaminyl (**1**), which is one of this family, was decomposed in oxygen-free benzene, and the products were examined. In this report the results will be described, and the decomposition mechanism of the radical will be presented.



1 2

The dimer, **2**, was dissolved in 30 ml of benzene, and the resultant dark blue solution (λ_{max}: 602 nm), in which 0.498 mmol of **2** and 0.043 mmol of **1** were present,[2)] was allowed to stand under oxygen-free conditions (at ≈20 °C in the dark). After *ca.* three months, the solution turned orange, indicating the complete decomposition of **1** (and **2**). The orange solution was concentrated, and the residue was chromatographed on alumina. Elution with benzene–hexane (1 : 2) gave a mixture of five products, and the subsequent elution with benzene gave *N*-(4-chlorophenylthio)-3,5-di-*t*-butylaniline (**3**). The mixture was then run on a preparative TLC (silica gel; hexane) to give 1,3,5,7-tetra-*t*-butylphenazine (**4**), bis(4-chlorophenyl) disulfide (**5**), Product **6**, *N*,*N*-bis(4-chlorophenylthio)-3,5-di-*t*-butylaniline (**7**), and 3,3′,5,5′-tetra-*t*-butylazobenzene (**8**). The results are listed in Table 1 and the yields in the table are determined by weight. Since **3** and **5** are the known compounds, they were identified by means of the melting points and by a comparison of the IR and NMR spectra with those of authentic samples. The structures of the other products were determined by means of the IR, NMR, and mass spectra and the elemental analyses. Also, Product **7** was prepared independently by the reaction of 3,5-di-*t*-butylaniline with two equivs of 4-chlorobenzenesulfenyl chloride in the presence of triethylamine. Interestingly, the substance, on photolysis with a high-pressure mercury lamp, gave **1** effectively.

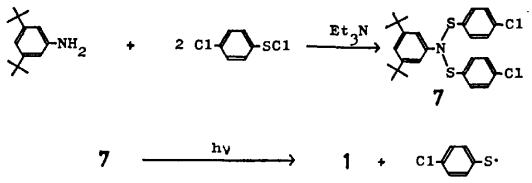


Table 1. Products of the decomposition of the dimer, **2**[a,b)]

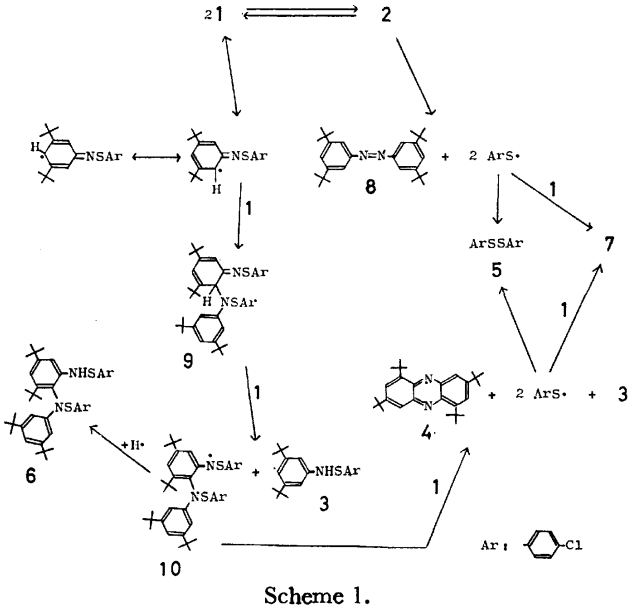
Product	Yield mg (mmol)
3	68 (0.195)
4	34 (0.084)
5	9 (0.031)
6	18 (0.026)
7	150 (0.306)
8	49 (0.121)
Total	328

a) These data are compiled from three experiments. b) Dimer, 360 mg (0.519 mmol); benzene, 30 ml; ≈20 °C.

The major products of the decomposition are **3**,[3)] **4**, **7**, and **8**. In addition, small amounts of **5** and **6**[3)] were isolated. The sum of the products isolated is 328 mg, which corresponds to 91% of the starting material (360 mg). On the basis of the results shown in Table 1, we present a decomposition mechanism of **1** (and **2**) in Scheme 1. Product **3** is formed from **1** *via* hydrogen-atom abstractions, probably from **9** or an intermediate derived from **10** which finally gives the phenazine, **4**.



Scheme 1.

Product **7** is formed *via* the radical-coupling reaction between **1** and a thiyl radical. Also, **4** is derived from **10** with the loss of a hydrogen atom and two arylthiyl radicals, and **6** is formed from **10** *via* hydrogen-atom abstractions. On the other hand, the azo compound, **8**, is considered to be derived from the dimer, **2**, with the loss of two arylthiyl radicals. If this decomposition mechanism is reasonable, the mole quantity of **3** should be equal to twice that of **4** with respect to hydrogen atoms, and with arylthiyl radicals, the sum of the mole quantity of **5** and a half that of **7** should be equal to the sum of those of **4** and **8**. As can be seen in Table 1, these stoichiometric requirements are approximately satisfied.

Experimental

All the melting points were taken on a Yanaco Model melting-point apparatus and are uncorrected. The IR spectra were run on a JASCO Model IR-G spectrometer. The ^{1}H NMR spectra were recorded with a Hitachi Perkin Elmer R-20 spectrometer, with tetramethylsilane as the internal standard. The mass spectra were obtained on either a JEOL JMS-07 or a Hitachi M-60 mass spectrometer. The dimer, **2**[1] and 3,5-di-*t*-butylaniline[4] were obtained by the reported methods.

Decomposition of The Dimer. The dimer, **2** (360 mg, 0.519 mmol), and benzene (30 ml) were placed in a glass tube, and the solution was degassed by three freeze-pump-thaw cycles and sealed under a vacuum. On standing for three months at ≈20 °C in the dark, the dark blue solution turned orange. The solvent was evaporated under reduced pressure, and the resultant residue was subjected to column chromatograph (alumina; E. Merck Art 1097; column-size: 3×30 cm). Elution with benzene–hexane (1 : 2) gave a mixture of 1,3,5,7-tetra-*t*-butylphenazine (**4**), bis(4-chlorophenyl) disulfide (**5**), Compound **6**, *N*,*N*-bis(4-chlorophenylthio)-3,5-di-*t*-butylaniline (**7**), and 3,3′,5,5′-tetra-*t*-butylazobenzene (**8**), and elution with benzene gave *N*-(4-chlorophenylthio)-3,5-di-*t*-butylaniline (**3**) (68 mg). The mixture was then run on a preparative TLC (silica gel; E. Merek Art 7730; eluent: hexane) to give **4** (34 mg), **5** (9 mg), **6** (18 mg), **7** (150 mg), and **8** (49 mg). The products were purified by recrystallization from the appropriate solvents or sublimation.

Product **3** was identified by means of its melting point.

Product 4. Light yellow crystals; mp>305 °C (sublimation); ^{1}H NMR ($CDCl_3$): δ 1.48 (s, *t*-Bu, 18H), 1.74 (s, *t*-Bu, 18H), 7.64—7.82 (m, aromatic, 4H); MS (20 eV), *m/e* (rel intensity), 404 (5, M^+), 389 (21), 362 (19), 348 (29), 347 (94), 305 (20), 158 (40), 141 (20), 127 (26), 113 (33), 99 (42), 85 (94), 71 (100), 57 (90). Found: C, 82.63; H, 10.04; N, 6.80%. Calcd for $C_{28}H_{40}N_2$: C, 83.11; H, 9.97; N, 6.92%.

Product 6. Colorless plates; mp 167—168 °C (ethanol); IR (KBr): 3400 (NH), 2950—2850 cm^{-1} (CH); ^{1}H NMR ($CDCl_3$): δ 1.24, 1.27, and 1.30 (s, *t*-Bu, 36H), 4.97 (s, NH, 1H), 6.70—7.54 (m, aromatic, 13H); MS (30 eV), *m/e* (rel intensity), 694 (6, M^++2), 692 (6, M^+), 551 (27), 550 (25), 549 (27), 408 (16), 405 (19), 350 (59), 349 (100), 347 (42), 291 (19). Found: C, 69.11; H, 7.16; N, 4.31; Cl, 10.50; S, 9.21%. Calcd for $C_{40}H_{50}Cl_2N_2S_2$: C, 69.24; H, 7.26; N, 4.04; Cl, 10.22; S, 9.24%.

Product 7. Colorless plates; mp 119—121°C(methanol); ^{1}H NMR ($CDCl_3$): δ 1.24 (s, *t*-Bu, 18H), 6.93—7.33 (m, aromatic, 11H); MS (20 eV), *m/e* (rel intensity), 489 (5, M^+), 406 (13), 349 (21), 348 (19), 347 (63), 332 (15), 311 (27), 290 (16), 288 (75), 287 (15), 286 (100), 205 (17), 204 (15), 189 (38), 144 (38), 143 (41). Found: C, 63.33; H, 5.85; N, 2.81%. Calcd for $C_{26}H_{29}Cl_2NS_2$: C, 63.66; H, 5.96; N, 2.86%.

Product 8. Orange crystals; mp 210—212 °C (methanol); ^{1}H NMR ($CDCl_3$): δ 1.39 (s, *t*-Bu, 36H), 7.48—7.72 (m, aromatic, 6H); MS (75 eV), *m/e* (rel intensity), 406 (18, M^+), 363 (8), 190 (17), 189 (100), 147 (9), 133 (24), 91 (9), 57 (92). Found: C, 82.65; H, 10.88; N, 7.12%. Calcd for $C_{28}H_{42}N_2$: C, 82.70; H, 10.41; N, 6.89%.

Product **3** was identified by the melting point [148—150 °C (hexane), lit,[1] 150—151 °C] and its IR and NMR spectra, and Product **5**, by means of its IR spectrum.

Preparation of 7. 4-Chlorobenzenesulfenyl chloride, prepared by the treatment of 4-chlorobenzenethiol (1.72 g, 11.9 mmol) with chlorine in dry chloroform at 0—5 °C, was dissolved in 50 ml of dry ether, and the solution was added, drop by drop, to a stirred solution of 3,5-di-*t*-butylaniline (1.09 g, 5.32 mmol) and triethylamine (1.3 g, 13 mmol) in dry ether (200 ml) at 0—5 °C. After being stirred for 2 h at the same temperature, the reaction mixture was filtered, concentrated, and the residue was recrystallized from methanol to give colorless plates (119—120 °C) in a 17% yield (0.22 g).

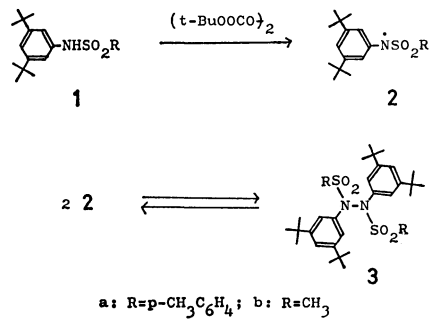
N-Sulfonylaminyls. The Isolation of Dimers and Their Properties[1)]

Yozo Miura,* Yuji Nakamura, and Masayoshi Kinoshita
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received January 9, 1981)

Synopsis. From the reaction mixtures of sulfonamides [3,5-(t-Bu)$_2$C$_6$H$_3$NHSO$_2$C$_6$H$_4$CH$_3$-p and 3,5-(t-Bu)$_2$-C$_6$H$_3$NHSO$_2$CH$_3$] with di-t-butyl diperoxyoxalate, dimers of *N*-sulfonylaminyls were isolated as pure crystals which, in solution, dissociated into the corresponding *N*-sulfonylaminyls upon heating to 60 °C.

Since *N*-sulfonylaminyls (RṄSO$_3$R′) are important intermediates in organic and photochemical reactions,[2)] the radicals have been a subject of considerable interest and have been actively investigated by means of ESR spectroscopy.[3)] We have reported the ESR spectra of *N*-sulfonyl-(3,5-di-t-butylphenyl)aminyls (**2**), which are generated by the reaction of sulfonamides **1** with di-t-butyl diperoxyoxalate.[4)] Since *N*-sulfonylaminyls are transient species, it is quite difficult to isolate them in a pure form. However, the radicals may be isolated as dimers. If the dimers are isolated, we can confirm the assignments of their ESR spectra. Also, their chemical properties are of interest in connection with the structurally related dimers, **5** and **7**.[5,6)] For this purpose, we have carefully examined the products from the reaction of **1** with di-t-butyl diperoxyoxalate and have successfully isolated *N*-sulfonylaminyl dimers, **3**, in moderate yields. This is the first isolation of *N*-sulfonylaminyl dimers.[7)] In this report we will describe the isolation of **3** and their chemical properties.



In the general procedure, an oxygen-free benzene solution of **1** and di-t-butyl diperoxyoxalate (excess) was allowed to stand for 3 d at room temperature, after which the reaction mixture was concentrated and chromatographed on silica gel, using benzene as the eluent. The second band was collected and the solvent was evaporated to give crude **3** in 17—23% yields; this was then recrystallized from hexane: colorless crystals; yield, 12—17%. In the IR spectra of the crystals, no N–H absorptions were found, and the NMR spectra and the elemental analyses were satisfactrily consistent with the structures of **3**. Also, in the mass spectra, the peaks corresponding to ions of M$^+$+1—SO$_2$C$_6$H$_4$CH$_3$ (for **3a**) and M$^+$—SO$_2$CH$_3$ (for **3b**) were found, though molecular-ion peaks could not be detected. Thus, we identified the crystals as **3** dimers.

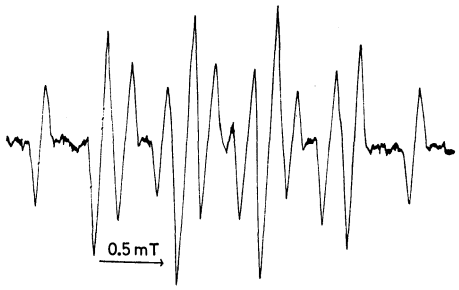


Fig. 1. ESR spectrum of **2b** detected from the solution of **3b** in benzene at 60 °C.

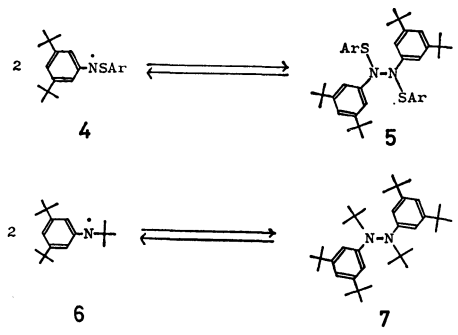
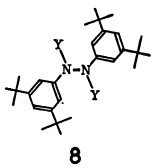
The dimers are highly soluble in most organic solvents, such as benzene, hexane, alcohols, and tetrahydrofuran, and the dimer solutions show no ESR signals. Thus, the dimers were found not to dissociate into **2** at room temperature. However, upon heating to 60 °C in benzene, the dimer solutions gave a relatively strong and clean ESR signal due to **2**, as is illustrated in Fig. 1; this finding clearly indicates that the dimer dissociate in part into **2** at this temperature. The assignments of the signals were based on their ESR parameters: a_N: 0.78; $a_{o\text{-}H}$: 0.56; $a_{p\text{-}H}$: 0.76 mT for **2a** and a_N: 0.77; $a_{o\text{-}H}$: 0.56; $a_{p\text{-}H}$: 0.77 mT for **2b**. These values are in good agreement with the previously reported values.[8)]

The equilibrium constants ([radical]^2[dimer]$^{-1}$) for the equilibria, however, are very small, even at 60 °C (probably$<10^{-9}$ mol l^{-1}). Also, upon heating at 60 °C in benzene for 2 h, trace amounts of the dimers were indicated by TLC analysis to decompose.



It is of interest to compare the equilibrium constants obtained for **3** with those reported for **5** and **7**. The reported values are 0.98×10^{-4}—4.59×10^{-4} mol l^{-1} for **5** (in benzene at 27 °C) and 6.00×10^{-6} mol l^{-1} for **7** (in methylcyclohexane at 44.7 °C). Thus, the magnitudes of the equilibrium constants of these dimers decrease in the following order: **5**>**7**>**3**. That is, when Y in **8** is an electron-donating group, –SR (dimers **5**). the equilibrium constants are remarkably increased, while when Y is an electron-withdrawing group,

$-SO_2R$ (dimers **3**), the equilibrium constants are, on the contrary, decreased. These changes in the magnitudes of the equilibrium constants may be reasonably interpreted as follows: in the case of **5**, the great electron-donating character of the –SR group enhances the dipolar repulsion between the nitrogen atoms, leading to a weakening of the nitrogen-nitrogen bond in **5**. In contrast, in the case of **3**, the electron-withdrawing character of the $-SO_2R$ group weakens the dipolar repulsion between the nitrogen atoms, leading to a strengthening of the nitrogen-nitrogen bond in **3**.



8

Experimental

All the melting points were taken on a Yanaco Model MP melting-point apparatus and are uncorrected, The IR spectra were run on a JASCO Model IR-G spectrometer, while the ^1H NMR spectra were recorded with a JEOL PS-100 spectrometer, with tetramethylsilane as the internal standard. The mass spectra were obtained on either a JEOL JMS-D-300 (for **3a**) or a Hitachi M-60 mass spectrometer (for **3b**). The ESR spectra were recorded with a JEOL JES-ME-3X spectrometer equipped with an X-band microwave unit and 100 kHz field modulation. The temperature was controlled with a JEOL JES-VT-3A temperature controller. The field sweep was calibrated by using a JEOL Mn^{2+} reference sample. *N*-(3,5-Di-*t*-butylphenyl)-*p*-toluenesulfonamide (**1a**) and *N*-(3,5-di-*t*-butylphenyl)methanesulfonamide (**1b**) were prepared by the previously reported method,[4] and di-*t*-butyl diperoxyoxalate was obtained according to Bartlett's method.[9]

N,N'-Bis(3,5-di-t-butylphenyl)-N,N'-bis(p-tolylsulfonyl)hydrazine (3a).[10] Sulfonamide **1a** (500 mg, 1.39 mmol), di-*t*-butyl diperoxyoxalate (500 mg, 2.13 mmol), and benzene (10 ml) were placed in a glass tube (1.5×40 cm), and the mixture was degassed by three freeze-pump-thaw cycles and then sealed under a vacuum. After the sealed tube had been allowed to stand for 3 d at room temperature (≈20 °C), the benzene solution was washed twice with a 10% $Na_2S_2O_3$ aqueous solution and twice with water, and then dried over anhydrous $MgSO_4$. After filtration, the solvent was evaporated under reduced pressure, and the residue was chromatographed on a silica-gel column (Mallinckrodt 100 mesh; column size: 3×50 cm), using benzene as the eluent. The second band was collected, and the solvent was evaporated to give 87 mg of crude **3a** (17%), which was afterward recrystallized from hexane to afford 61 mg of prisms (12%); mp 131—132 °C; (KBr): 2950—2850 (CH), 1160 cm^{-1} (SO_2); ^1H NMR (CCl_4) δ 1.20 (s, *t*-Bu, 36H), 2.42 (s, CH_3, 6H), 7.14—7.86 (m, aromatic, 14H); MS (70 eV), *m/e* (rel intensity), 562 ($M^+ + 1 - CH_3C_6H_4SO_2$, 6), 407 (10), 361 (20), 359 (100), 345 (24), 344 (98), 204 (42), 190 (20), 148 (20), 133 (44), 57 (37). Found: C, 70.71; H. 7.91; N, 3.74%. Calcd for $C_{42}H_{56}N_2O_4S_2$: C, 70.35; H, 7.87; N, 3.91%.

N,N'-Bis(3,5-di-t-butylphenyl)-N,N'-(methylsulfonyl)hydrazine (3b).[10] The hydrazine was prepared in a similar manner. Sulfonamide **1b** (400 mg, 1.41 mmol), di-*t*-butyl diperoxyxalate (500 mg, 2.13 mmol), and benzene (10 ml) were placed in a glass tube, degassed, and sealed as has been described above. After 3 d of standing at room temperature, the benzene solution was washed with a 10% $Na_2S_2O_3$ aqueous solution and then with water, and dried over anhydrous $MgSO_4$. After filtration, the solvent was evaporated, and the residue was chromatographed on silica gel as has been described above. The second band was collected, and the solvent was evaporated to give 90 mg of crude **3b** (23%), which was then recrystallized from hexane to afford 68 mg of needles (17%); mp 130.5—131.5 °C; IR (KBr): 2950—2850 (CH), 1160 cm^{-1} (SO_2); ^1H NMR (CCl_4) δ 1.32 (s, *t*-Bu, 36H), 3.14 (s, CH_3, 6H), 7.15—7.39 (m, aromatic, 6H); MS (30 eV), *m/e* (rel intensity), 486 ($M^+ + 1 - CH_3SO_2$, 22), 485 ($M^+ - CH_3SO_2$, 47), 408 (28), 407 (54), 341 (22), 284 (25), 269 (52), 190 (70), 133 (29), 57 (100). Found: C, 63.50; H, 8.46; N, 5.06%. Calcd for $C_{30}H_{48}N_2O_4S_2$: C, 63.79; H, 8.57; N, 4.96%.

Dissociation of 3. The dimer, **3** (20 mg), and benzene (0.2 ml) were placed in an ESR cell, and the solution was degassed as has been described above. The ESR spectra from the solution were recorded during heating at 60 °C.

10) As has been pointed out in Ref. 9, it is advisable not to scrape the crystals of di-*t*-butyl diperoxyoxalate when treating them, especially when they are completely free of a solvent. Also, a large-scale experiment must be avoided in the preparation of the dimers, **3**.

Friedel-Crafts Acylation with 2-Methyl- or 2-Benzylbutanedioic Anhydride

Iwao HASHIMOTO

Department of Industrial Chemistry, Wakayama Technical College, Noshima, Nada-cho, Gobo 649-15

(Received January 8, 1981)

Synopsis. The $AlCl_3$-catalyzed acylation of benzene with 2-methylbutanedioic anhydride afforded a mixture of 3-benzoyl-2-methylpropanoic acid and 3-benzoylbutanoic acid. The intramolecular acylation of 2-benzylbutanedioic anhydride in the presence of $AlCl_3$ gave a mixture of 4-oxo-1,2,3,4-tetrahydro-2-naphthoic acid and 3-oxo-2-indanacetic acid. The results were discussed in terms of the solvent effect on the acylations.

We have previously reported[1,2] that the $AlCl_3$-catalyzed acylations of benzene with 2-phenyl-butanedioic or -pentanedioic anhydride proceeded by means of competitive inter- and intramolecular acylations, where an electron-attracting phenyl group in the anhydrides had a strong influence on the direction of each acylation. A more detailed mechanism of the acylation with unsymmetrical dibasic acid anhydrides may be get by introducing an electron-donating methyl group into the dibasic acid anhydride and by treating individually the inter- and intramolecular acylations. The present paper deals with the acylation of benzene with 2-methybutanedioic anhydride (**1**) in the presence of $AlCl_3$ as an example of the intermolecular acylation, and with the $AlCl_3$-catalyzed condensation of 2-benzylbutanedioic anhydride (**2**) as an intramolecular example.

TABLE 1. $AlCl_3$-CATALYZED ACYLATION WITH 2-METHYL- OR 2-BENZYLBUTANEDIOIC ANHYDRIDE AT 30 °C FOR 5 h

Anhydride	Solvent (20 cm)	$[AlCl_3]$ mmol	$[C_6H_6]$ mmol	Product yields[a] %

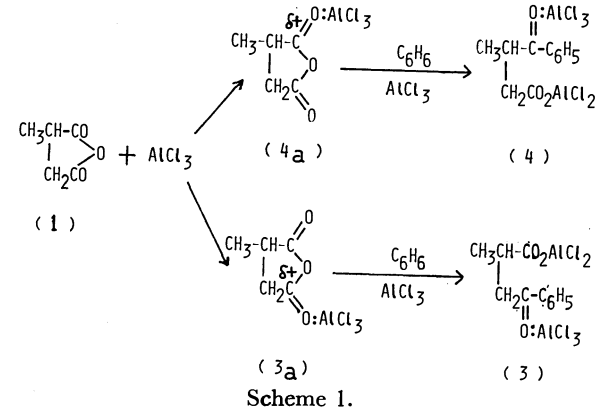
a) Calculated on the basis of the amount of anhydride used. b) At 40 °C for 2 h. c) For 24 h. d) At 40 °C. e) Two hundred mmole of concd H_2SO_4 were used as the catalyst. f) Twenty mmol of $AlBr_3$ were used as the catalyst.

Several investigators[3,4] have isolated only 2-aroyl-2-methylpropanoic acid in the condensations of some aromatic compounds with **1** in the presence of $AlCl_3$. However, when 10 mmol of **1** was condensed in the presence of 20 mmol of $AlCl_3$ with benzene, which was used in a large excess as a reactant and as a solvent, a mixture of 3-benzoyl-2-methylpropanoic acid (**3**) and the isomeric 3-benzoylbutanoic acid (**4**) was obtained; the yield of **3** was about twice that of **4**. The predominant formation of **3** was also observed in the cases using a limited amount (10 mmol) of benzene in 1,2-dichloroethane or in nitrobenzene. The lower yield of the keto acids in nitrobenzene may be a complex formation between $AlCl_3$ and nitrobenzene. The small solvent effect on the acylation of benzene with **1** suggests that the actual acylating agent in this acylation is a type of oxonium compound (**3a** and **4a**); since they are less polarized than the acylium ions, the solvent effect on them appears smaller.

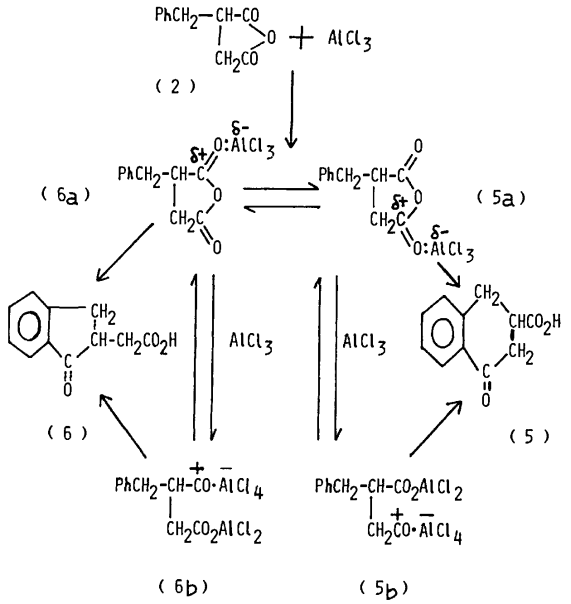


Scheme 1.

The electron-donating effect of a methyl group reduces the electrophilic reactivity of the $\overset{\delta+}{C}=O$ located closely to the methyl group; hence, the production of **3** is more favored than that of **4**.

The acylation with **2** in the presence of two equivalents of $AlCl_3$ in a large excess of benzene proceeded only intramolecularly to yield two isomeric keto acids, 4-oxo-1,2,3,4-tetrahydro-2-naphthoic acid (**5**) and 3-oxo-2-indanacetic acid (**6**), in a predominant yield, although early workers[5-8] in an analogous case succeeded in isolating only **5**. Similar results were also observed in 1,2-dichloroethane, whereas an overwhelming yield of **5** was obtained in nitrobenzene. Since the polarity of the solvent appears to affect markedly the relative yields between **5** and **6**, a reaction path including either the oxonium compounds (**5a** and **6a**) or the acylium ions (**5b** and **6b**) as the actual acylating agents may be formulated for the intramolecular acylation of **2** in the presence of $AlCl_3$.

The formation of **6a** is probably more favored than that of **5a** due to the electron-donating effect of a benzyl group,[9] although the electrophilic reactivity of $\overset{+}{C}-O$ of **5b** to a benzene nucleus may be greater than that of **6b**; a higher concentration of **6a** results in a predominant yield of **6**. On the other hand, in a polar



Scheme 2.

solvent such as nitrobenzene or in the presence of a large amount of concd H_2SO_4, the acylium ions bearing a more positive charge than the oxonium compounds may be greatly stabilized by solvation; therefore, a more reactive **5b** should give **5** in an overwhelming yield.

The product ratio obtained above dose not result from the thermodynamic equilibrium, since no isomerization between **5** and **6** was observed in the presence of two equivalents of $AlCl_3$ in 1,2-dichloroethane.

Experimental

Materials. 2-Methylbutanedioic anhydride: bp 238—240 °C. 2-Benzylbutanedioic anhydride was prepared by the method of Haworth *et al.*: mp 98.5 °C (lit,[7] mp 95—97 °C).

Acylation Procedures. The general procedure was as previously described.[1] A mixed solution of diethyl ether and methyl acetate was used to extract the keto acids.

Analyses of the Products. The acylation products of benzene with 2-methylbutanedioic anhydride, after being esterfied with an ethereal solution of diazomethane, were analyzed by GLC employing a Yanagimoto G-180 F model on a 1.5 m×3 mm column packed with Ucon Oil 50 LB 550 X (3 wt %) on Uniport KS of 60—80 mesh at 180 °C. GC analyses of the intramolecular acylation products of 2-benzylbutanedioic anhydride in the presence of $AlCl_3$ were made by using a column packed with Apiezon Grease L (3 wt %) at 170 °C or Ucon Oil 50 LB 550 X (3 wt %) at 171 °C. The compounds, **3**, **4** and **5**, were synthesized according to the method described in the literature: 3-benzoyl-2-methylpropanoic acid (**3**): mp 142 °C (lit,[10] mp 140.5 °C); 3-benzoylbutanoic acid (**4**): mp 55 °C (lit,[11] mp 59 °C); 4-oxo-1,2,3,4-tetrahydro-2-naphthoic acid (**5**): mp 149 °C (lit,[5] mp 149 °C).

3-Oxo-2-indanacetic Acid (**6**). A solution of 2-benzylbutanedioic anhydride (1.90 g) in benzene (12.1 cm^3) was treated with $AlBr_3$ (5.34 g) in benzene (10 cm^3) at 30 °C for 5 h. The reaction mixture was then work up in a usual manner. The crude keto acid was repeatedly recrystallyzed from acetic acid and then methyl acetate–petroleum ether: mp 150.5—151 °C; IR (KBr disk), 1750 (C=O), 1669, 1600 cm^{-1}; MS (methyl ester) *m/e* (%) 204 (M^+, 30), 173, 172 (M^+-OCH_3, 25), 145 ($M^+-COOCH_3$, 75), 131 ($M^+-CH_2COOCH_3$, 49), 116 (100); ^{1}H-NMR [$(CD_3)_2CO$] δ 7.4—7.7 (m, 4H, arom.), 3.5 (q, 1H, J=8), 3.0 (m, 2H), 2.7 (q, 2H, J=8); ^{13}C-NMR [$(CD_3)_2CO$] δ 209.0 (s, C=O), 175.5 (s, -COOH), 156.0 (s, C-9), 139.0 (s, C-4), 137.0, 129.5, 129.0 and 125.5 (d, C-arom.), 45.0 (d, C-2), 35.5 (t, $\underline{CH_2}$-COOH), 34.0 (t, C-3); Found: C, 69.43; H, 5.31%. Calcd for $C_{11}H_{10}O_3$: C, 69.46; H, 5.30%.

The author wishes to thank Professor Yoshiro Ogata, Nagoya University, for his valuable discussions.

Ring Monofluorinated Hydroxypyrazoles

Serry R. F. KAGARUKI, Tomoya KITAZUME, and Nobuo ISHIKAWA*

Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 16, 1981)

Synopsis. 3-Alkyl(or aryl)-4-fluoro-5-hydroxypyrazoles and their 1-methyl derivatives were prepared by the reaction of methyl α-fluoro-β-alkyl(or aryl)-β-keto esters with hydrazine hydrate or methylhydrazine in ethanol. The reaction of arylhydrazines with α-fluoro-β-keto esters gave only hydrazones which could not be cyclized to pyrazoles.

There has been the growing interest in utilization of some kind of monofluoro organic compounds because of their biological activities[1] and several practical methods for monofluorination of organic molecules have been developed in these days.[2] From this point of view, we have revealed that α-fluoro-β-keto esters (**1**), potent intermediates for monofluoroheterocycles, can be prepared easily from trifluoroethene or from hexafluoropropene.[3] As the first example of preparation of monofluoroheterocycles from α-fluoro-β-keto esters, we now wish to report the preparation of 3-alkyl(or aryl)-4-fluoro-5-hydroxypyrazoles by the reaction with hydrazine or with methylhydrazine. There has been no reports on pyrazole compounds carrying a fluorine atom directly attached to the ring.

β-Diketones are generally known to cyclize easily into pyrazoles by treating them with hydrazines.[4] The reactions between α-fluoro-β-keto esters with hydrazine or methylhydrazine proceeded smoothly in refluxing ethanol, and 3-alkyl(or aryl)-4-fluoro-5-hydroxypyrazoles (**2a**) were obtained as expected in good yields (Table 1).

TABLE 1. PREPARATION OF 3-ALKYL(OR ARYL)-4-FLUORO-5-HYDROXYPYRAZOLES **2a**[a]

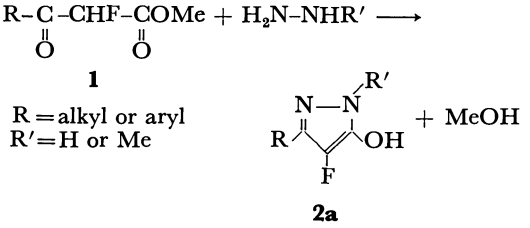
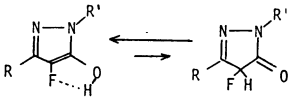
a) New compound: The structures were confirmed on the basis of their IR and NMR spectral data and the microanalysis was satisfactory agreement with the calculated value. b) Chemical shifts are given in δ ppm from ext. CF_3CO_2H in DMSO-d_6.

The structures of the fluoropyrazoles obtained was confirmed from their ^{19}F and ^{1}H NMR and mass



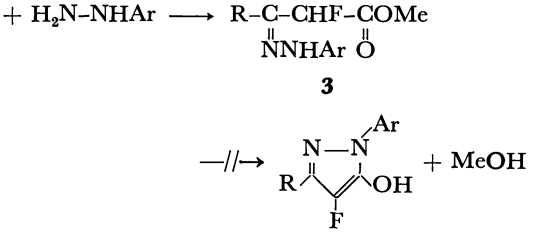
2a

spectra. The ^{19}F NMR spectra in DMSO-d_6 solution revealed only one singlet signal at about 110 ppm upfield from external CF_3CO_2H, while in the ^{1}H NMR spectra one broad signal due to the OH proton appeared at ≈δ 10 as well as the other signals due to alkyl or aryl protons. In addition, no absorption band due to a carbonyl group was observed in the spectra of these pyrazole compounds. These results suggest that these compounds prefer the hydroxypyrazole type structure to the pyrazolone type one. This may be ascribed to the hydrogen bonding formation between the oxygen atom and the fluorine atom, which stabilizes the enol form **2a** rather than the keto form **2b**.



2a 2b

Arylhydrazines and tosylhydrazine, on the other hand, reacted with **1** to give only hydrazones **3** and none of cyclized compounds were obtained. This is in contrast to the case with non-fluorinated β-keto esters, which give readily pyrazolone compounds with arylhydrazines.



Experimental

Typical procedures are described below.

4-Fluoro-5-hydroxy-1-methyl-3-phenylpyrazole (2a) (R=Ph, R′=Me). A mixture of methyl α-fluorobenzoylacetate (1.96 g, 10 mmol), methylhydrazine (0.46 g, 10 mmol), and ethanol (5 ml) was refluxed for 3 h. On cooling the reaction mixture was filtered and the solid material was recrystallized from ethanol, affording a fluoropyrazole compound in 65% yield, mp 130—132 °C. ^{1}H NMR (DMSO-d_6) δ: 3.60 (CH_3), 7.50 (ArH), 9.87 (OH); ^{19}F NMR (DMSO-d_6) δ: 110 ppm from ext. CF_3CO_2H. Found: C, 62.86; H, 4.85; N, 14.61%. Calcd for $C_{10}H_9N_2OF$: C, 62.50; H, 4.72; N, 14.57%. M^+, 192.

2,4-Dinitrophenylhydrazone of Methyl α-Fluorobenzoylacetate. A mixture of methyl α-fluorobenzoylacetate (0.4 g, 2 mmol), 2,4-dinitrophenylhydrazine (0.42 g, 2 mmol), and concd sulfuric acid (2 ml) in ethanol (10 ml) was stirred for 24 h at room temperature. The solid material was collected by filtration and recrystallized from ethanol to give the hydrazone in 80% yield, mp 196—198 °C. IR (KBr): 3300 (NH), 1760 (C=O) cm^{-1}; ^1H NMR (DMSO-d_6) δ: 3.90 (CO_2CH_3), 6.77 (CHF, J_{H-F}=45 Hz), 7.52—9.07 (ArH), 11.87 (NH); ^{19}F NMR (DMSO-d_6) δ: 112 ppm from ext. CF_3CO_2H. Found: C, 49.29; H, 3.53; N, 15.25%. Calcd for $C_{15}H_{13}N_4O_6F$: C, 49.46; H, 3.60; N, 15.38%.

A Product from the Photo-induced Reaction of Cholesterol in the Presence of Lead Tetraacetate and Iodine[1)]

Hiroshi SUGINOME*, ** and Kimitoshi KATO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 3, 1981)

Synopsis. The irradiation of a benzene solution of cholesterol in the presence of lead tetraacetate and iodine gives cholest-5-en-3β-yl *A*-homo-4-oxacholest-5-en-3α-yl ether in a 23% yield.

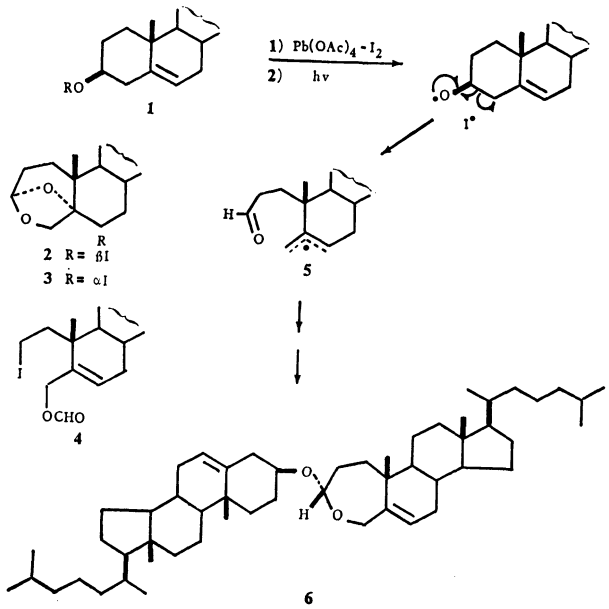
Earlier parts of this series have described the results of the investigations of the photo- and thermally-induced rearrangements of hypoiodites of cholesterol[2)] and of the related 5-cholesten-3-ols[3)] and *C*-nor-*D*-homosteroid-5-en-3β-ols[1)] in the presence of mercury(II) oxide and iodine. Cholesterol (**1**) and epicholesterol hypoiodites in benzene have been found to give two oxabicyclic compounds, 3α,5-epoxy-6β-iodo-*A*-homo-4-oxa-5β-cholestane (**2**) and its 6α-isomer (**3**), accompanied by a moderate yield of 3-formyloxy-2-iodo-*A*-nor-2,3-seco-cholest-5-ene (**4**).[2)] The introduction of methyl groups on the C-3 or C-4 of 5-cholestene framework has been found to result in appreciable variations in the products and their yields.[3)] The pathways which explain the stereochemistry of the products and the effects of alkyl substitutions have been discussed in previous papers.[2,3)]

The reaction involved a new type of ring enlargement. The active species generated from mercury(II) oxide and iodine was believed to be iodine oxide, I_2O,[4)] which reacted with intermediary radical species to lead to the products. It is of interest to see, therefore, variations in the products caused by replacing mercury(II) oxide with other oxidizing reagents, *e.g.*, lead tetraacetate. The reaction of steroidal alcohols with lead tetraacetate and iodine reagent is also believed to proceed through hypoiodite or lead(IV) alkoxide.[5,6)]

In this paper we will report on a considerable variation in the products in this reaction when the mercury-(II) oxide and iodine reagents are replaced by lead tetraacetate and iodine.[5)]

The irradiation of cholesterol in dry benzene containing a freshly prepared lead tetraacetate and iodine through Pyrex with a 100-W high pressure mercury arc under an argon atmosphere for 5 h gave a mixture of products. The examination of the products by TLC proved the absence of any oxabicyclic compounds, **2** and **3**, and formate, **4**. It showed, however, the formation of an appreciable amount of cholest-5-en-3β-yl *A*-homo-4-oxacholest-5-en-3α-yl ether (**6**), obtained from the thermally-induced reaction of cholesterol hypoiodite in the presence of mercury(II) oxide and iodine.[2)] This ether, **6**, was isolated in a 23% yield as crystals by the aid of preparative TLC. A number of other unidentified products were also formed.

The variation in the products caused by lead tetraacetate is thus significant, but the role of the reagent which makes this difference is not certain, although the oxidation of intermediary radicals (*e.g.*, **5** in Scheme 1) to a cationic species with lead tetraacetate might play a part. A probable path *via* an allyl radical (**5**) has been suggested for the dimer **6**.[2)] Since cholesterol is the steroid most abundantly available, and since **5** is readily hydrolyzed to *A*-homo-4-oxacholest-5-en-3α-ol and cholesterol with acid,[2)] the reaction may be of use for the transformation of cholesterol into biologically useful compounds.



Scheme 1.

Experimental

For the instruments used and general procedures, see Ref. 2.

Irradiation of Cholesterol in Benzene Containing Lead Tetraacetate and Iodine. Cholesterol (300 mg) in benzene (44 ml) containing a freshly prepared lead tetraacetate (1.03 g) and iodine (600 mg) in a Pyrex vessel was irradiated with a 100-W high pressure mercury arc under an argon atmosphere for 5 h. The solution was then filtered, and the filtrate was washed with a sodium hydrogensulfite solution twice, a 10% sodium carbonate solution, and water successively and thereafter dried over anhydrous sodium sulfate. The evaporation of the solvent left a redidue which was subjected to preparative TLC with a mixture of 10 : 1 chloroform and acetone to give dimeric acetal, **6** (69 mg), together with a number of ill-defined products. The compound, **6**, was shown by a direct comparison to be identical with the specimen obtained from the thermal decomposition of cholesterol hypoiodite.[2)]

The Synthesis of 2,5-Bis(*p*-methoxycinnamoyl)-1,3,4,6,7,8- and 4,5-Bis-(*p*-methoxycinnamoyl)-1,2,3,6,7,8-hexamethoxyxanthene[1)]

Heitaro OBARA,* Jun-ichi ONODERA, Takashi SAITO, Shingo SATO, Tsutomu SHIBATA, and Kimio SHIBAYAMA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received March 5, 1981)

Synopsis. In connection with studies of the structure of carthamin derivatives, 2,5-bis(*p*-methoxycinnamoyl)-1,3,4,6,7,8- and 4,5-bis(*p*-methoxycinnamoyl)-1,2,3,6,7,8-hexamethoxyxanthene were synthesized. The comparison of these two hexamethoxyxanthenes with carthamin derivatives is described.

Recently, we have obtained two hexamethoxyxanthene isomers, A-1 (mp 74—76 °C) and A-2 (mp 190—191 °C), which are presumed to be 2,5-bis(*p*-methoxycinnamoyl)-1,3,4,6,7,8-hexamethoxyxanthene (**1**) and 4,5-bis(*p*-methoxycinnamoyl)-1,2,3,6,7,8- or 2,7-bis(*p*-methoxycinnamoyl)-1,3,4,5,6,8-hexamethoxyxanthene (**2** or **3**) produced by the methylation of the hydrolysis products of carthamin, the red coloring matter of the flowers of safflower (*Carthamus tinctorius* L.).[1)]

In this paper, the synthesis of **1** and **2** and the comparison of the synthetic samples with carthamin derivatives will be described.

An equimolecular mixture of 2,3,4,6-tetrahydroxyacetophenone (**4**)[2)] and 3-formyl-2,4,5,6-tetrahydroxyacetophenone (**5**), obtained by the formylation of **4**, was refluxed in methanol containing a small amount of 50% sulfuric acid to afford the condensation product (**6**) as dark violet crystals. Compound **6** was hydrogenated in ethanol using 5% palladium charcoal as a catalyst. The reduction product was then methylated with dimethyl sulfate-potassium carbonate in acetone to give 2,5-diacetyl-1,3,4,6,7,8-hexamethoxyxanthene (**7**). The unsymmetrical structures of **6** and **7** were supported from the observation of the two separate signals of their acetyl groups in their ^{1}H-NMR spectra.

The condensation of **7** with *p*-methoxybenzaldehyde in methanol containing a 50% aqueous potassium hydroxide solution afforded **1** (mp 74—76 °C) in a 57% yield. The IR and ^{1}H-NMR spectra of **1** were completely identical with those of one of the natural derivatives, A-1.

Since the condensation of **4** with **5** did not give the other symmetrical compound, **2** was synthesized by the alternative method described below.

4,5-Diacetyl-1,2,3,6,7,8-hexamethoxyxanthene (**10**) was obtained by the methylation of 4,5-diacetyl-1,2,3,6,7,8-hexahydroxyxanthene (**9**), prepared by the C-acetylation of 1,2,3,6,7,8-hexahydroxyxanthene (**8**)[3)] with the boron trifluoride-acetic acid complex. 4,5-Bis(*p*-methoxycinnamoyl)-1,2,3,6,7,8-hexamethoxyxanthene (**2**) (mp 157—158 °C) was afforded by the condensation of **10** with *p*-methoxybenzaldehyde by a manner similar to that of **1**.

From the disagreement of this compound, **2**, with the natural derivative, A-2, it is assumed that the structure of another isomer, 2,7-bis(*p*-methoxycinnamoyl)-1,3,4,5,6,8-hexamethoxyxanthene (**3**), should be assigned for A-2.

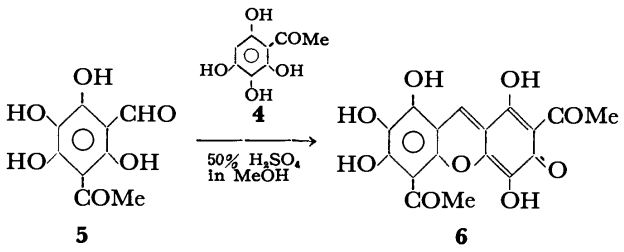
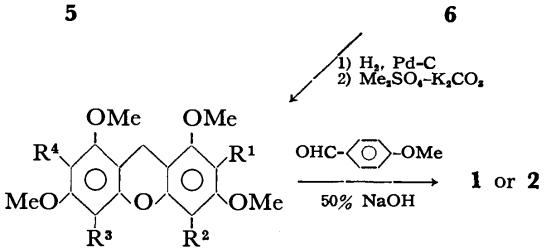
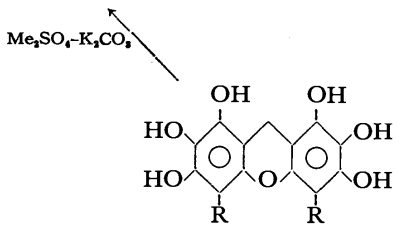
$\left(R=-CH=CH-\langle\bigcirc\rangle-OMe\right)$



5 **6**



7 $R^1=R^3=COMe$, $R^2=R^4=OMe$
10 $R^1=R^4=OMe$, $R^2=R^3=COMe$



8 R=H
9 R=COMe

Experimental

All the melting points are uncorrected. The UV and IR spectra were recorded on a Hitachi 135 spectrophotometer, and a Hitachi EPI-S2 spectrophotometer respectively. The ^{1}H-NMR spectra were measured with a Hitachi R-22 spectrometer (90 MHz), using tetramethylsilane as the internal standard. The mass spectra were obtained on a Hitachi RMU-6M mass spectrometer.

3-Formyl-2,4,5,6-tetrahydroxyacetophenone (5). Into a solution of 2,3,4,6-tetrahydroxyacetophenone (**4**)[2)] (20 g), zinc cyanide (16 g), and anhydrous aluminium chlroride (18 g) in dry ether (300 ml), dry hydrogen chloride gas was stirred for

8 h under cooling with ice water. The reaction mixture was then allowed to stand overnight at 0 °C. After the solvent had been removed by decantation, the residue was refluxed with water (100 ml) for 3 h and then filtered. After cooling, **5** (9.2 g, 40%) was obtained from the filtrate. Mp 232—236 °C, ^{1}H-NMR (DMSO-d_6) δ 2.61 (3H, s, $-COCH_3$), 9.97 (1H, s, -CHO). Found: C, 50.67; H, 3.82%; M^+, 212. Calcd for $C_9H_8O_6$: C, 50.94; H, 3.77%; M, 212.

*Condensation Product of **4** with **5**.* A mixture of **4** (500 mg), **5** (570 mg), and 50% sulfuric acid (1 ml) in methanol (30 ml) was refluxed for 10 h. After cooling, the condensation product (**6**) was obtained as dark violet crystals (mp 280 °C) in a 19% yield. UV_{max} (EtOH) 352 and 540 nm, IR (KBr) 1700 and 1620 cm^{-1} (C=O), ^{1}H-NMR (DMSO-d_6) δ 2.67 and 2.82 (each 3H, s, $-COCH_3\times2$), 8.27 (1H, s, -CH=), MS *m/e* 360 (M^+). This compound was used without purification for the next reaction.

*2,5-Diacetyl-1,3,4,6,7,8-hexamethoxyxanthene (**7**).* Compound **6** (5.0 g) was hydrogenated in ethanol (300 ml), using 5% palladium charcoal (0.8 g) as the catalyst. The reaction mixture was filtered, and the filtrate was evaporated *in vacuo* to afford an unstable reduction product (4.8 g).

A mixture of the reduction product (300 mg), dimethyl sulfate (3 ml), and potassium carbonate (5 g) in dry acetone (70 ml) was refluxed for 3 h. The reaction mixture was then worked up in the usual manner, and the crude product was chromatographed on a column of silica gel with benzene–ethyl acetate (4 : 1) to give **7** in a 27% yield. Mp 119—120 °C (from methanol), IR (KBr) 1647 cm^{-1} (C=O), ^{1}H-NMR ($CDCl_3$) δ 2.49 and 2.61 (each 3H, s, $-COCH_3\times2$), 3.77 and 3.87 (each 3H, s, $-OMe\times2$), 3.84 and 3.90 (each 6H, s, $-OMe\times4$), 3.97 (2H, s, $-CH_2-$). Found: C, 61.79; H, 5.95%; M^+, 446. Calcd for $C_{23}H_{26}O_9$: C, 61.87; H, 5.87%; M, 446.

*2,5-Bis(p-methoxycinnamoyl)-1,3,4,6,7,8-hexamethoxyxanthene (**1**).* Into a mixture of **7** (500 mg) and *p*-methoxybenzaldehyde (1 ml) in methanol (10 ml), we added a 50% aqueous potassium hydroxide solution (2.0 g) ot room temperature. The reaction mixture was warmed to 50—60 °C for 1 h and then extracted with ether. The ether was evaporated *in vacuo*, and the residue was chromatographed on a column of silica gel with benzene–ethyl acetate (9 : 1) to afford crude **1**, which was further chromatographed on silica gel with chloroform–ethyl acetate (40 : 3). Compound **1** (380 mg, 50%), mp 74—76 °C, IR (KBr) 1632 cm^{-1} (C=O), ^{1}H-NMR ($CDCl_3$) δ 3.75 (2H, s, $-CH_2-$), 3.80—4.10 (24H, m, $-OMe\times8$), 6.95—7.60 (12H, m, *p*-substituted cinnamoyl$\times2$). Found: C, 68.63; H, 5.64%; M^+, 682. Calcd for $C_{39}H_{38}O_{11}$: C, 68.61; H, 5.61%; M, 682. This compounds was completely identical with the natural derivative A-1.

*1,2,3,6,7,8-Hexahydroxyxanthene (**8**).* This compound was prepared by the reduction of the condensation product of 1,2,3,5-benzenetetrol[4] with ethyl formate as has previously been reported.[3] Although this reduction product contained a small amount of an isomer, 1,3,4,6,7,8-hexahydroxyxanthene, it was used without purification for the next reaction.

*4,5-Diacetyl-1,2,3,6,7,8-hexamethoxyxanthene (**10**).* A mixture of 1,2,3,6,7,8-hexahydroxyxanthene (**8**) (2.5 g), containing a small amount of 1,3,4,6,7,8-hexahydroxyxanthene and the boron trifluoride–acetic acid complex (10 ml) was heated on a water bath for 2 h. The reaction mixture was then stirred into an aqueous potassium acetate solution, drop by drop. The resulting precipitate was filtered, and the filtrate was concentrated to dryness to afford 4,5-diacetyl-1,2,3,6,7,8-hexahydroxyxanthene (**9**) (mp$>$280 °C), containing a small amount of 2,5-diacetyl-1,3,4,6,7,8-hexahydroxyxanthene.

A mixed solution of the above crude **9** (1.0 g), dimethyl sulfate (3.2 ml), potassium carbonate (4.6 g), and dry acetone (50 ml) was refluxed for 6 h. The reaction mixture was worked up in the usual manner, and the crude product was chromatographed on a column of silica gel with benzene–ethyl acetate (8 : 1) to afford **10** (550 mg, 45%); mp 130—131 °C, IR (KBr) 1710 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$) δ 2.44 (6H, s, $-COCH_3\times2$), 3.79 (2H, s, $-CH_2-$), 3.85, 3.87, and 3.96 (each 6H, s, $-OMe\times6$). Found: C, 61.58; H, 5.86%; M^+, 446. Calcd for $C_{23}H_{26}O_9$: C, 61.88; H, 5.87%; M, 446.

*4,5-Bis(p-methoxycinnamoyl)-1,2,3,6,7,8-hexamethoxyxanthene (**2**).* To a solution of **10** (50 mg) in methanol (0.3 ml), we added *p*-methoxybenzaldehyde (50 mg) and a 50% aqueous potassium hydroxide solution (0.2 g) at room temperature. The reaction mixture was then warmed to 50—60 °C for 1 h, and the resulting precipitate was recrystallized from methanol to give **2** as colorless needles (48 mg, 63%); mp 157—158 °C, IR (KBr) 1646 cm^{-1} (C=O), ^{1}H-NMR ($CDCl_3$) δ 3.80 (12H, s, $-OMe\times4$), 3.84 (2H, s, $-CH_2-$), 3.86 and 3.99 (each 6H, s, $-OMe\times4$), 6.68 and 7.22 (each 2H, d, J=16.0 Hz, -CH=CH-), 6.76 and 7.32 (each 4H, d, J=8.5 Hz, *p*-substituted phenyl$\times2$). Found: C, 68.42; H, 5.63%; M^+, 682. Calcd for $C_{39}H_{38}O_{11}$: C, 68.61; H, 5.61%; M, 682.

The authors wish to express their thanks to Mr. Kazuaki Sato for his microanalyses.

Low-temperature Reaction of *gem*-Dihalocyclopropanes with Activated Magnesium

Teiichi Ando,* Takeshi Muranaka, and Takashi Ishihara
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received March 23, 1981)

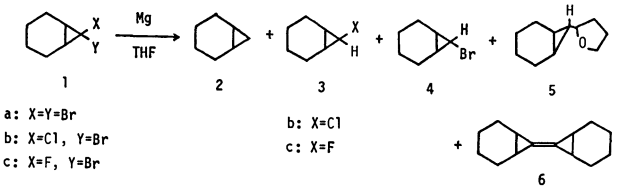
Synopsis. The reaction of 7-bromo-7-chlorobicyclo-[4.1.0]heptane and 7-bromo-7-fluorobicyclo[4.1.0]heptane with activated magnesium in THF at −50 to −40 °C gave 7-bromobicyclo[4.1.0]heptane, in addition to 7-chloro- and 7-fluorobicyclo[4.1.0]heptane, respectively.

Although much work has been done on the reaction of *gem*-dihalocyclopropanes with a variety of metals[1] or organometallic reagents,[2] there exists only scattered information on the reaction of *gem*-dihalocyclopropanes with metallic magnesium;[1c-e] the products reported are exclusively allenic compounds, derived from the intermediary cyclopropylmagnesium halides.

This paper describes the reaction of some *gem*-dihalocyclopropanes with activated magnesium, which resulted in reduction without ring opening.

Results and Discussion

The halogen compounds used in this study, 7,7-dibromo- (**1a**), 7-bromo-7-chloro- (**1b**), and 7-bromo-7-fluorobicyclo[4.1.0]heptane (**1c**), were prepared by the addition of the corresponding dihalocarbene to cyclohexene. The latter two compounds were obtained as a mixture of two geometrical isomers. The reaction was conducted by adding a solution of 7,7-dihalobicyclo-[4.1.0]heptane in THF to a suspension of finely powdered magnesium, prepared from anhydrous magnesium chloride and potassium metal in THF.[3] The products isolated in this reaction were bicyclo[4.1.0]heptane (**2**), 7-chloro- or 7-fluorobicyclo[4.1.0]heptane (**3**), 7-bromobicyclo[4.1.0]heptane (**4**), 7-(2-tetrahydrofuranyl)-bicyclo[4.1.0]heptane (**5**), and 7,7'-bi(bicyclo[4.1.0]-heptylidene) (**6**), whose structures were determined by comparison of their spectral data and other physical properties with those of authentic samples. The yields of the products were measured on GLC by use of an internal standard. Where only isomer distributions in the products (**3** and **4**) were desired, no internal standard was added. The results are summarized in Table 1.



The reaction proceeded smoothly to give the reduction products (**2**, **3**, and **4**), together with a small amount of other products (**5** and **6**) derived from decomposition of 7-halobicyclo[4.1.0]hept-7-ylmagnesium compounds. Thus, **1a** gave an isomeric mixture of 7-bromobicyclo[4.1.0]heptane (**4**) in 80% yield. The reaction of **1b** and **1c** gave bromide (**4**), in addition to 7-chloro (**3b**) and 7-fluorobicyclo[4.1.0]heptane (**3c**), respectively. To be noted is that not only the bromine atom, which is usually much more susceptible to reduction, but also the chlorine or the fluorine atom is concurrently reduced. These findings suggest that the activated magnesium metal is in a highly reactive form and thus is relatively unselective toward halogen. The higher selectivity for chlorine than for bromine (see the reduction of **1b** to **3b** and **4**) or the concurrent reduction of bromine and fluorine (see the reduction of **1c** to **3c** and **4**) may be explained by strengthening of the C–Br bond or weakening of the C–Cl or the C–F bond caused by the presence of a geminal halogen atom. A support for this rationalization was afforded by the reaction of 7-halobicyclo[4.1.0]heptanes with activated magnesium: Under the same reaction conditions, 7-bromobicyclo[4.1.0]heptane (**4**) was readily reduced to give bicyclo[4.1.0]heptane in 65% yield whereas no

Table 1. Reaction of 7,7-dihalobicyclo[4.1.0]heptanes (**1**)

Halide (*endo*-X/*exo*-X)	Yield %	Composition of products/%				
		2	**3** (*endo*-X/*exo*-X)	**4** (*endo*-Br/*exo*-Br)	**5**	**6**
1a	95	4	—	84 (14/86)	11	1
1b (47/53)	70	3	42 (39/61)	43 (10/90)	12	0

1b (0/100)	76	3	34 (16/84)	41 (5/95)	22	0
1c (34/66)	61	4	51 (34/66)	39 (9/91)	6	0
1c (100/0)	71	4	59 (100/0)	33 (6/94)	4	0

reaction occurred with 7-chloro- (**3b**) or 7-fluorobicyclo-[4.1.0]heptane (**3c**), the starting halides being recovered quantitatively.

As shown in Table 1, the isomer ratios of 7-fluorobicyclo[4.1.0]heptane (**3c**) are identical with those of the initial halide (**1c**). This indicates that the reduction takes place with complete stereospecificity, *i.e.*, with complete retention of configuration. The reduction of 7-bromo-7-chlorobicyclo[4.1.0]heptane (**1b**) to 7-chlorobicyclo[4.1.0]heptane (**3b**) proceeds in a less stereospecific manner. These trends are entirely analogous to those found in the reduction of *gem*-dihalocyclopropanes with organotin(IV) hydride[2c] and in the Hunsdiecker reaction of α-halocyclopropanecarboxylic acids,[4] both of which are believed to proceed *via* α-halocyclopropyl radicals. From the stereochemical trends cited above, it is highly probable that the reduction with activated magnesium described herein proceeds by a radical mechanism rather than a carbanionic one. The latter mechanism, however, cannot be ruled out at the present time.[5]

Experimental

All boiling and melting points are uncorrected. Infrared spectra (IR) were recorded on a Shimadzu IR-400 infrared spectrometer. A Varian EM-360 spectrometer (60 MHz) was used to measure ^{1}H NMR spectra in solutions of CCl_4 with Me_4Si as an internal standard. Mass spectra (MS) were taken on a Hitachi RMS-4 spectrometer at an ionization potential of 70 eV. Gas chromatographic analyses (GLC) were performed with a Shimadzu GC-2C or GC-6A gas chromatograph.

7,7-Dihalobicyclo[4.1.0]heptanes (1a—c). 7,7-Dibromo- (**1a**), 7-bromo-7-chloro- (**1b**), and 7-bromo-7-fluorobicyclo-[4.1.0]heptane (**1c**) were prepared by the reaction of cyclohexene with dibromo-,[6] bromochloro-,[4] and bromofluorocarbene,[7] respectively, generated by basic decomposition of the corresponding trihalomethane: **1a**, 57% yield, bp 108—111 °C/16 mmHg; **1b**, 77% yield (*exo*-Br: *endo*-Br = 47 : 53), bp 69—72 °C/4 mmHg; **1c**, 63% yield (*exo*-Br: *endo*-Br = 34 : 66), bp 70—71 °C/22 mmHg. An isomeric mixture of **1b** or **1c** was treated with hot quinoline[8] to give pure 7-*exo*-bromo-7-*endo*-chlorobicyclo[4.1.0]heptane (bp 71—72 °C/6 mmHg) and 7-*exo*-bromo-7-*endo*-fluorobicyclo[4.1.0]heptane (bp 64—66 °C/13 mmHg). Isomerically pure 7-*endo*-bromo-7-*exo*-chlorobicyclo[4.1.0]heptane was obtained according to the method of Köbrich,[9] bp 76—77 °C/5 mmHg. 7-Halobicyclo[4.1.0]-heptanes (**3** and **4**) and bicyclo[4.1.0]heptane (**2**) were synthesized by the reduction of the corresponding 7,7-dihalo compound with organotin(IV) hydride[2c] and were used for determination of the yields and the structures of products.

Reaction of 7,7-Dihalobicyclo[4.1.0]heptanes with Activated Magnesium. To a suspension of activated magnesium, prepared from anhydrous $MgCl_2$ (12.6 mmol) and potassium metal (24.0 mg-atom) in THF (14 ml), was added under nitrogen a solution of a halide (10 mmol) in THF (2 ml) at such a rate that the temperature did not rise to −40 °C. After the addition, the mixture was stirred at −50 to −40 °C for 3—8 h. The reaction was quenched with a saturated solution of ammonium chloride and the resultant mixture was repeatedly extracted with ether. The combined extracts were dried over anhydrous Na_2SO_4, filtered, and concentrated under atmospheric pressure. The residual oil was analyzed on GLC by the internal standard method to measure the yields of products.

7-exo-(2-Tetrahydrofuranyl)bicyclo[4.1.0]heptane (5): Bp 86.5—87.5 °C/6 mmHg; n_D^{23} 1.4819 (lit,[9] n_D^{20} 1.4828); IR (film) 2932, 2860, 1452, 1371, 1355, 1342, 1175, 1128, 1062, 919, 770 cm^{-1}; ^{1}H NMR δ 0.2—2.2 (m, 15H), 3.2 (m, 1H), 3.7 (m, 2H).

Use of 1,8-Diazabicyclo[5.4.0]undec-7-ene in Preparation of Trimethylsilyl Enol Ethers and Trimethylsilylacetylenes

Yoshiyuki TANIGUCHI, Junji INANAGA, and Masaru Yamaguchi*

Department of Chemistry, Kyushu University 33, Higashi-ku, Fukuoka 812

(Received March 23, 1981)

Synopsis. Trimethylsilyl enol ethers were prepared by using a combination of chlorotrimethylsilane and 1,8-diazabicyclo[5.4.0]undec-7-ene in good yields. Trimethylsilylation of acetylenes was also achieved with the same reagents in the presence of silver salt as catalyst.

Triethylamine is the most frequently used base for enol trimethylsilylation of carbonyl compounds[1] under equilibrating conditions. However, enol silylation with this base in combination with chlorotrimethylsilane requires rather vigorous conditions (refluxing in *N,N*-dimethylformamide for several hours),[2] and despite some modifications,[3] the yields have been less satisfactory than those with trimethylsilyl trifluoromethanesulfonate[4] or with trimethylsilyl nonafluorobutane-1-sulfonate formed *in situ*.[5,6]

Here, we wish to show that the use of 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) as a base in combination with chlorotrimethylsilane, provides a rapid, mild, and efficient method of enol silylation of various carbonyl compounds.

$$RCH_2COR' \xrightarrow[CH_2Cl_2]{Me_3SiCl,\ DBU} RCH{=}CR' \quad (OSiMe_3)$$

The yields are summarized in Table 1 (entry 1—15). Ketones, aldehydes, and α,β-unsaturated ketones were smoothly enol silylated at the refluxing conditions in dichloromethane. An exceptionally low yield of 3,3-dimethyl-2-trimethylsiloxy-1-butene (entry 6 in Table 1) can be ascribed to the steric crowdness of the ether which is considered to be in equilibration with the starting ketone and chlorotrimethylsilane under the presence of chloride ion.[7] It is noteworthy that the addition of silver nitrate to the reaction mixture improved the yield to 92% (entry 8). In other cases examined, the addition of silver nitrate did not show much influence on the final yields.

The poor regioselectivity of the present method is demonstrated by the silylation of 2-methylcyclohexanone (entry 3 and 4 in Table 1 and notes therein). The ratio of the two isomers did not change after prolonged reaction time (50 h).[8]

$$RC{\equiv}CH \xrightarrow[CH_3Cl_3]{Me_3SiCl,\ AgCl(cat.),\ DBU} RC{\equiv}CSiMe_3$$

In trimethylsilylation of acetylenes, strong bases such as butyl lithium[9] or Grignard reagent[10] have usually been used for the generation of acetylide anions, except for one example where monosubstituted acetylenes were heated with trialkylchlorosilanes and triethylamine in the presence of catalytic amount (0.15 mol equiv.) of copper(I) chloride at 150 °C in an autoclave for 100—120 h.[11] When the present method with DBU was applied directly to trimethylsilylation of monosubstituted acetylenes, no silylation took place despite the modifications of the reaction conditions. However, the addition of a small amount of silver salt (0.1 mol equiv.) such as silver chloride or nitrate to the reaction mixture resulted in smooth silylation in refluxing dichloromethane in good yields. They are summarized in Table 1 (entry 16—23). Because of the mildness of the reaction conditions, the present method seems to have wide applicability. The use of triethylamine in place of DBU was ineffective. In experiments with phenylacetylene, copper(I) chloride gave a less satisfactory result than[silver chloride, and zinc chloride was almost useless.

Application of the method to the formation of ketene acetals from carboxylic esters was unsuccessful.

Experimental

Commercial DBU was distilled from calcium hydride. Commercial chlorotrimethylsilane was once distilled.

Silylation of Carbonyl Compounds. For the determination of the yield given in Table 1, chlorotrimethylsilane (0.55 mmol) was added to a stirred mixture of a ketone (0.50 mmol) and DBU (0.60 mmol) in dichloromethane (500 μl) at 40 °C. The progress of the reaction was followed by GLPC (SE-30) with the addition of an appropriate internal standard. The product was identified by comparing the retention time with that of the authentic specimen prepared by one of the reported procedures.[12]

In the experiment with silver nitrate as an additive, chlorotrimethylsilane (0.55 mmol) was added to a suspension of powdered silver nitrate (0.55 mmol) in dichloromethane and stirred for 15 min. The mixture was then warmed to 40 °C and a solution of a ketone (0.50 mmol) and DBU (0.60 mmol) in dichloromethane (300 μl) was added to this.

A typical example of the isolation experiment is as follow (entry 1, Table 1): A mixture of cyclopentanone (1.23 g, 14.7 mmol), chlorotrimethylsilane (1.76 g, 16.2 mmol), and DBU (2.68 g, 17.6 mmol) in dichloromethane (15 ml) was stirred at 40 °C for 1 h. The mixture was diluted with pentane (10 ml) and washed successively with dilute hydrochloric acid (1%) and aqueous sodium hydrogencarbonate, dried over magnesium sulfate, and distilled, giving 1-trimethylsiloxycyclopentene [1.83 g (80%), bp 85 °C (bath)/6670 Pa].

Silylation of Acetylenes. A typical example is given below (entry 23, Table 1). 1-Ethynylcyclohexyl acetate (1.054 g, 6.34 mmol) and DBU (1.16 g, 7.61 mmol) were successively added to a stirred suspension of silver chloride[13] (90.0 mg, 0.634 mmol) in dichloromethane (6.5 ml). The mixture was heated at 40 °C and chlorotrimethylsilane (0.827 g, 7.61 mmol) was added to this. After stirring for 25 h at the same temperature, the mixture was cooled, diluted with pentane (15 ml), washed successively with aqueous sodium hydrogencarbonate, hydrochloric acid (1%), and water, dried, and distilled. 1-(Trimethylsilylethynyl)cyclohexyl acetate: 1.36 g (90%), bp 149 °C (bath)/8000 Pa. NMR ($CDCl_3$) δ 0.17, [s, 9H, $-Si(CH_3)_3$], 1.4—1.8 (m, 10H, $-CH_2-$), and 2.03 (s, 3H, $-COCH_3$). Found: C, 65.40; H, 9.30%. Calcd for $C_{13}H_{22}O_2Si$: C, 65.50; H, 9.30%.

Reaction of Thiobenzophenone S-Oxide (Diphenylsulfine) with Carbon Nucleophiles

Atsuyoshi OHNO,* Misao UOHAMA, and Shinzaburo OKA
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received March 26, 1981)

Synopsis. The reaction of diphenylsulfine with a Grignard reagent or alkyllithium gives a variety of products depending on the structure of the Grignard reagent or alkyllithium.

2,2,4,4-Tetramethyl-3-pentanethione *S*-oxide (di-*t*-butylsulfine) reacts with Grignard reagents affording a variety of products depending on the structure of the Grignard reagent.[1] The reactions were interpreted in terms of a delicate competition of thiophilic attack (one-electron transfer process) and proton-abstraction (acid-base reaction).

In this paper we wish to describe the reactions of thiobenzophenone *S*-oxide (diphenylsulfine) with various carbanionic reagents. The results will be compared with those from the corresponding reactions of di-*t*-butylsulfine.

Results and Discussion

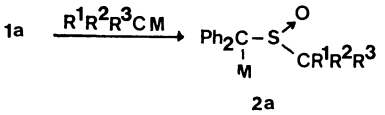
The reactions were carried out, in general, by adding a solution of diphenylsulfine, **1a**, to a solution containing

$$R_2C{=}S{\rightarrow}O$$

1a: R=Ph
1b: R=*t*-Bu

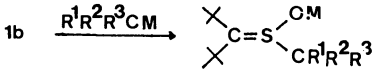
a three-fold excess of Grignard reagent at room temperature. However, it was confirmed that inverse addition did not change the products. Reaction conditions and products are summarized in Table 1 together with data from the reactions with alkyllithiums.

Products obtained by the present reactions are quite different in type from those obtained from the reactions of di-*t*-butylsulfine, **1b**. Detailed analyses of product distribution have revealed that the differences can be accounted for by the difference in the structure of initially formed anions.



2a

(1)



2b

The reaction course from **2a** seems to depend on the softness (polarizability, thiophilicity) and hardness (basicity) of the attacking reagent.

When a primary-alkyl reagent is employed in the reaction in DME, the hard base abstracts an acidic α-proton in **2a** resulting in the formation of a dianion, **3**, which is subsequently converted into an olefin through the corresponding thiocarbonyl ylide and thiirane. The electrocyclic ring-closure of a thiocarbonyl ylide has been reported.[2] Methyllithium in DME, on the other

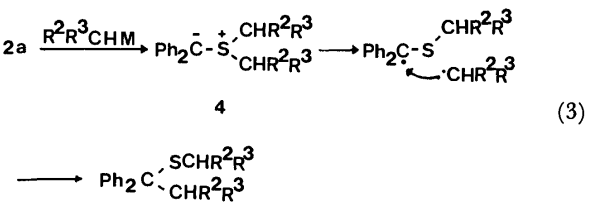
a) At room temperature for 3 h. b) Isolated yield. c) At −20°C.

hand, is a very hard reagent, and the reaction with this reagent results in an α-elimination.[3-5] An extremely hard reagent, such as lithium compounds in ether, no further reaction takes place from **2a**. It is reported that both a sulfoxide and tetraarylethylene are formed by the reaction of a diarylsulfine with methyllithium in benzene.[6] Thus, the predominancy of a course (or courses) shown in Reaction 2 depends on the reaction conditions and reagents.

A secondary-alkyl reagent forms a sulfide by the reaction in ether. Since the secondary-carbanion is soft enough to attack the sulfur and a proton in **2a** is not acidic enough to be abstracted, the reaction scheme may be represented by Reaction 3. The process from **4**



(3)

to the sulfide is well-known as the Stevens rearrangement.[7,8]

Benzylmagnesium chloride undergoes the secondary alkyl-type reaction in ether, whereas it behaves as a primary-alkyl reagent in DME. This is a marked difference between the reactions of **1a** and **1b**.[1] A further difference between the reactions of **1a** and **1b** with a secondary-alkyl reagent is that **1a** affords a sulfide which is composed of two parts of the alkyl reagent, whereas the sulfide from **1b** has only one part.[1]

t-Butylmagnesium chloride is a very soft reagent and may behave similarly to the secondary-alkyl reagent. However, the product from this reagent was the sulfoxide. Probably the steric effect of two *t*-butyl and a diphenylmethyl groups prevents this reagent from attack on sulfur.

a) At room temperature in 1,2-dimethoxyethane (DME). b) Isolated yield. c) The formation of carbanion was recognized by color and H-D exchange.

In the above discussion we proposed that **2a** is an universal intermediate in the present reactions. To test the intermediacy of **2a**, we studied the reactions from diphenylmethyl alkyl (or aryl) sulfoxide by abstracting an α-proton and the results are summarized in Table 2.[9] The formation of 1,1-diphenylethylene from diphenylmethyl methyl sulfoxide is consistent with the proposed reaction scheme. However, it is recognized, by the isolation of diphenylmethane, that S_N2-type displacement on sulfur takes place in DME competitively with the proton-abstraction.[10]

Experimental

Materials. Thiobenzophenone[11] and thiobenzophenone *S*-oxide[12] were prepared according to literature procedures. Ether and 1,2-dimethoxyethane were dried over sodium weire and distilled prior to use. Sulfoxides were obtained by oxidation of the corresponding sulfides.

General Procedure. All reactions were carried out under a nitrogen atmosphere with stirring. Into 6 mmol of a Grignard reagent (or an alkyllithium) in 10 ml of ether was added 1 mmol of the sulfine in 10 ml of ether (or 1,2-dimethoxyethane) or *vice versa*. No difference was recognized in the result by the change of the addition order. When equivalent amounts ef a Grignard reagent and the sulfine were reacted, the reaction became slower but the product was the same as that obtained from the above reaction, though the yield was poor. After usual work-up, the products were subjected to column chromatography over silica gel with hexane–benzene (4 : 1 v/v) eluent. Analytically pure products were obtained by means of preparative VPC on a Varian Aerograph 920. The same procedure was employed for the reaction of sulfoxides.

The structure of products were confirmed by the identity of spectral data with those authentic samples.

The Effect of Hydration on the Thermal Stability of Ovalbumin as Measured by Means of Differential Scanning Calorimetry

Yukihisa FUJITA* and Yukinao NODA

Department of Chemistry, Hyogo College of Medicine, Mukogawa, Nishinomiya, Hyogo 663

(Received March 27, 1981)

Synopsis. The thermal denaturation of ovalbumin (egg albumin) was investigated by means of differential scanning calorimetry in the water-content range from 0.11 to 1.15 g of water per g of protein. At water contents above 0.76 g/g, the temperature, T_d, and the enthalpy, ΔH_d, of denaturation were scarcely dependent at all on the water content. At lower water contents, however, both T_d and ΔH_d showed a marked dependence on the water content. The degree of the hydration dependence of the T_d and ΔH_d suggested that the amount of water required to hydrate ovalbumin was 0.76 g/g and that at least two types of the hydration phase contributed to the thermal stability of the protein.

It is well known that water is an essential element in many biological processes. In spite of the importance of hydration in the maintaining of protein structure some important questions on protein hydration remain unresolved. As reviewed by Kuntz and Kauzmann,[1] approximately 0.3—0.5 g of water per g of protein is bound to globular protein; its properties are evidently different from those of pure water, *e.g.*, a lowered vapor pressure, a reduced mobility, and a much-reduced freezing point.

In previous papers,[2-4] the effect of hydration on the thermal stability of lysozyme and chymotrypsinogen A was investigated by means of differential scanning calorimetry (DSC). The essential hydration values for stabilizing the spatial structure of lysozyme and chymotrypsinogen A were considerably larger than those estimated by other techniques. It was also suggested that at least two types of the hydration phase contributed to the thermal stability of the proteins.

The present work was undertaken in order to investigate the effect of hydration on the thermal stability of ovalbumin and at the same time to confirm the above suggestions.

Experimental

Materials. The chicken ovalbumin (egg albumin) used in the present study was a salt-free, five-times-crystallized sample from Miles Laboratories, Inc. The molecular weight of ovalbumin was taken as 45000.[5]

Methods. The water content of the sample was adjusted by conditioning in a constant-humidity apparatus at the appropriate relative humidity for 7 d. Higher water contents were adjusted by placing the sample in saturated vapor at 293 K for an appropriate period. The water content was determined gravimetrically by drying at 378±5 K *in vacuo* for 24 h.

The calorimetric measurements were performed with a Rigaku Denki differential scanning calorimeter and a hermetic aluminum pan at a heating rate of 2.5 K/min.

Results and Discussion

The thermal denaturation of ovalbumin was measured by means of DSC in the water-content range from 0.11 to 1.15 g of water per g of protein. The DSC curves showed an endothermic peak, having a temperature width 10—15 K. The temperature, T_d, and the enthalpy, ΔH_d, of denaturation were estimated from the peak temperature and the peak area of the DSC curve here obtained respectively. The T_d and ΔH_d are plotted as functions of the water content in Fig. 1.

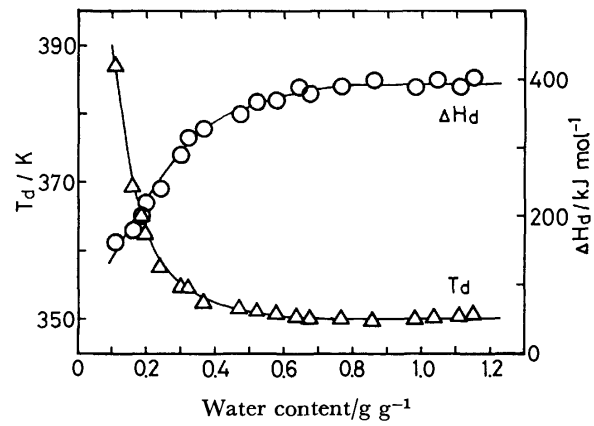

Fig. 1. The temperature, T_d, and the enthalpy, ΔH_d, of denaturation of ovalbumin as functions of the water content.

At water contents above 0.76 g/g, both T_d and ΔH_d were scarcely dependent at all on the water content. The mean values in this region were 350.5 K and 393 kJ/mol, values which were in rough agreement with those for ovalbumin in aqueous solutions.[6] Below the water content of 0.76 g/g, however, the T_d increased with a decrease in the water content. The increase became much more marked at water contents lower than about 0.35 g/g. On the other hand, the ΔH_d decreased gradually with a decrease in the water content in the same region, until the decrease became more pronounced at water contents below 0.34 g/g.

It is interesting that the T_d and ΔH_d values at water contents higher than 0.76 g/g hardly differ from those for the protein in an aqueous solution. From heat-capacity measurements on ovalbumin in the solid state with different amounts of water and in solution, Suurkuusk[7] has suggested that, between 0.1 g/g and a dilute solution, there can be no substantial change in the protein structure. It appears reasonable to assume that a conformational change similar to that which takes place in solution occurs in the solid state. In addition, it is suggested that the hydration for ovalbumin, an essential process for stabilizing its native structure, is completed at about 0.76 g/g. The hydration value is considerably higher than those determined by other techniques.[1]

According to Kauzmann,[8] the most important

contributor to the increase in heat capacity on protein denaturation is the interaction of nonpolar groups with water. At water contents below 0.76 g/g, the large decrease observed in ΔH_d may be substantially attributed to the reduction of the interactions between the exposed nonpolar groups with water, *i.e.*, the reduction of the hydrophobic hydration in the denatured state. In addition, it may be expected that, at a very low water content, the protein molecule does not completely unfold, because water is a competitor of the protein polar groups in creating "hydrogen bond." This causes a decrease in the enthalpy and entropy of protein denaturation.

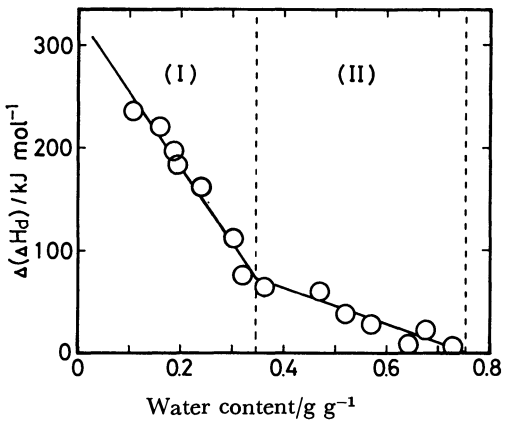

Fig. 2. The reduction in the denaturation enthalpy of ovalbumin by dehydration, $\Delta(\Delta H_d)$, as a function of the water content. The denaturation enthalpy at the full hydration is regarded as 393 kJ/mol.

Assuming that the denaturation enthalpy of ovalbumin at the full hydration is 393 kJ/mol, which is the mean at the water contents above 0.76 g/g, the reduction in the enthalpy of denaturation by dehydration, $\Delta(\Delta H_d)$, is expressed as follows:

$$\Delta(\Delta H_d) = 393 - \Delta H_d$$

where ΔH_d is the observed enthalpy of denaturation at the partial hydration. The $\Delta(\Delta H_d)$ is plotted as a function of the water content in Fig. 2. The relationship is represented by two segments of a straight line, with the break occurring at 0.34 g/g. This suggests that at least two types of phase exist in the hydration of the protein. The increase in T_d due to dehydration became much more marked at water contents below about 0.35 g/g. In an operational way, the hydration phase can be classified into two phases as follows: (I) the primary hydration phase, *i.e.*, the water contents below 0.34 g/g, and (II) the secondary hydration phase, *i.e.*, the water-content range of 0.34—0.76 g/g.

The primary hydration phase is completed at 0.34 g/g. This value is comparable to the amount of unfreezable water determined by NMR[9] and calorimetric studies,[10] which is barely sufficient to constitute a monolayer and which corresponds to 850 mol of water per mol of protein. These water molecules may be selectively arranged in the vicinity of the polar regions of a protein surface by hydrogen bonds and thus form part of a first hydration monolayer.

The secondary hydration phase is completed at 0.76 g/g. The real nature of the secondary hydration water is not yet clear, though it may be expected to play an important role in determining the structure and biological function of protein. In a recent calorimetric study of a frozen α-chymotrypsin solution, Luscher *et al.*[11] have suggested that the heat, entropy, and temperature of fusion of the secondary hydration water are lower in value than those of bulk water. This can be explained by hydrogen-bonding defects in the ice lattice. As has been pointed out by Kuntz and Kauzmann,[1] it is considered that the secondary hydration water has rotational properties only slightly different from those of bulk water and can not be readily differentiated by NMR and dielectric dispersion techniques, as there is little experimental evidence for the secondary hydration phase using either of the dispersion techniques.

(Received March 28, 1981)

Synopsis. Iodine monobromide is an extremely effective catalyst for the redistribution of alkoxyl groups on silicon atoms in dimethyldiakoxysilanes. The equilibrium constants of these reactions were determined at 40 °C by means of gas chromatography. Assuming that the reaction intermediate is the dative form of a dimethyldialkoxysilane–iodine monobromide complex, a mechanism of the reaction was proposed.

Although numerous examples of redistribution reactions in organosilicon compounds have been reported,[1–3] only a few studies concerning alkoxyl-alkoxyl exchange are found in the literature.[4–8] In these studies, the quantitative determination of the equilibria of the following reaction systems has been made by means of GLPC:

Tetramethoxysilane–Tetraethoxysilane[6,8]

Methyltrimethoxysilane–Methyltriethoxysilane[7]

Dimethyldimethoxysilane–Dimethyldiethoxysilane[7]

These reactions were carried out under rather severe conditions in the absence of a catalyst. Thus, to reach equilibrium the reaction mixtures were heated for 4 d at 150 °C,[6] 2 d at 120 °C,[8] or 7 d at 150 °C.[7] Consequently, the equilibrium data of such reactions at ordinary temperatures have not been available.

In the course of our studies of alkoxysilane–iodine complexing, we noticed that iodine or interhalogen compounds catalyzed alkoxyl-alkoxyl exchange, and that iodine monobromide was an especially favorable catalyst for the disproportionation of alkylalkoxysilanes. In the presence of iodine monobromide, the redistribution equilibrium was readily attained at the ambient temperature, and the equilibrium constants were determined by means of gas chromatography.

Results and Discussion

Redistribution Equilibria in Dimethyldialkoxysilanes. The following dimethyldialkoxysilane-systems were investigated at (40.0±0.1)°C:

$$Me_2Si(OEt)_2 + Me_2Si(OBu\text{-}n)_2 \rightleftharpoons 2Me_2Si(OEt)(OBu\text{-}n)$$

$$Me_2Si(OEt)_2 + Me_2Si(OBu\text{-}s)_2 \rightleftharpoons 2Me_2Si(OEt)(OBu\text{-}s)$$

$$Me_2Si(OEt)_2 + Me_2Si(OBu\text{-}i)_2 \rightleftharpoons 2Me_2Si(OEt)(OBu\text{-}i)$$

$$Me_2Si(OBu\text{-}n)_2 + Me_2Si(OBu\text{-}s)_2 \rightleftharpoons 2Me_2Si(OBu\text{-}n)(OBu\text{-}s)$$

$$Me_2Si(OBu\text{-}n)_2 + Me_2Si(OBu\text{-}i)_2 \rightleftharpoons 2Me_2Si(OBu\text{-}n)(OBu\text{-}i)$$

Both forward and reverse reactions proceeded in the presence of iodine monobromide. In most cases, the composition of the reaction mixture became constant within a few hours; the equilibrium constant was then evaluated from the composition. The values thus obtained for reactions from both sides agreed very well with each other; the results are summarized in Table 1.

Table 1. Equilibrium constants of the dispronportionatio of dimethyldialkoxysilanes catalyzed by iodine monobromide at (40.0±0.1) °C

$Me_2Si(OR)_2 + Me_2Si(OR')_2 \rightleftharpoons 2\ Me_2Si(OR)(OR')$

$K=[Me_2Si(OR)(OR')]^2/\{[Me_2Si(OR)_2][Me_2Si(OR')_2]\}$

Substituent OR	Substituent OR'	K (Forward reaction)	K (Reverse reaction)	K (Mean)
OEt	OBu-*n*	4.17±0.04	4.18±0.02	4.17±0.03
OEt	OBu-*s*	4.91±0.03	4.88±0.05	4.90±0.04
OEt	OBu-*i*	4.17±0.07	4.18±0.05	4.17±0.05
OBu-*n*	OBu-*s*	4.65±0.06	4.72±0.01	4.67±0.06
OBu-*n*	OBu-*i*	3.98±0.04	3.98±0.04	3.98±0.04

The K values of the reaction systems with ethoxy–butoxy, ethoxy–isobutoxy and butoxy–isobutoxy pairs are 4.17, 4.17, and 3.98, respectively, suggesting that these equilibria are close to the random distribution, where $K=4$. However, in the cases associated with the *s*-butoxyl group, $K=4.90$ and $K=4.67$, some deviation from random distribution is indicated.

Iodine monobromide was added to the reaction system as a piece of crystal, or solution in hexane, *o*- or *p*-xylene. The same equilibrium constant was obtained in each case; therefore, the influence of these solvents on the equilibrium state appeared to be negligible. The reaction was well-promoted in the presence of about 0.001 (mole fraction) of iodine monobromide.

It is noted that GLPC may be employed for the study of the disproportionation equilibria of alkylalkoxysilanes in which the rate of reaction is slow compared to the retention times of the reactants and products.[1] Hence, the following attempt was made to see if the GLPC technique could be employed for the study of the catalyzed reactions presented here.

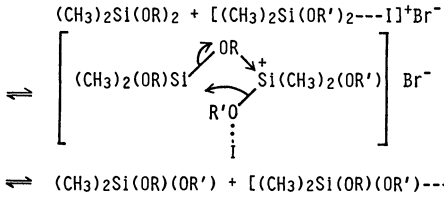
The equilibrium mixture of the ethoxy–butoxy system was divided into two parts, one of which was treated with silver powder in order to allow it to react with iodine monobromide to remove the catalyst from the reaction system,[9] while the other was left untreated. The GLPC analysis of each sample gave virtually identical results, *i.e.*, $K=4.16$ was the mean value from the former case, and $K=4.15$, from the latter. (The mean value in the table is 4.17) This means that equilibrium does not shift during GLPC analysis even in the presence of iodine monobromide, and it was concluded that the composition of the equilibrium

mixture could be directly analyzed by GLPC.

Iodine Monobromide–Dimethyldialkoxysilane Complexes. The absorption spectra of iodine monobromide solutions in dimethyldialkoxysilanes were examined with a Shimadzu model UV-200 double-beam spectrophotometer, using stoppered silica cells with a path length of 10.0 mm. The visible and ultraviolet absorption peaks were observed at 428—436 nm and 218—234 nm respectively, indicating the formation of charge-transfer complexes,[10] similarly to the iodine–tetraethoxysilane system.[11]

A CT complex is usually represented as a resonance hybrid of a no-bond form and a dative form, and the dative form of a iodine monobromide–dimethyldialkoxysilane complex is regarded as $[(CH_3)_2Si(OR)_2\cdots I]^+Br^-$.

Proposed Reaction Mechanism. In the study of the disproportionation of ethyltrimethylsilane catalyzed by aluminum bromide, Russell postulated a reaction mechanism *via* a four-centered transition state.[12] An iodine monobromide–alkoxysilane complex is apparently of an ionic character, while an alkoxyl group also has considerable polarity. Consequently, in this case, a reaction intermediate with an ionic structure can be readily deduced, leading to the following mechanism, similar to that proposed by Russell:



Experimental

General Procedure. In an about 10-cm³ reaction vessel with a sealing-cap, a certain amount of each alkoxysilane was placed; iodine monobromide was then added as a piece of crystal or a proper quantity of the solution in hexane, *o*- or *p*-xylene. Each reaction mixture thus prepared was divided into two or three parts and maintained in a thermostat setting of (40.0±0.1) °C. One of them was used to follow the time course of the reaction until the composition came to a constant, and then the others were used to determine the equillbrium composition.

Analysis. Analyses were performed by GLPC using a Shimadzu model GC-4B gas chromatograph with a thermal conductivity detector and equipped with a printing integrator.

In the case of the ethoxy–butoxy system, a 3 mm $\phi\times$5 m glass column with Neopak 1A (diatomaceous earth) supporting 25% PEG 4000 was employed at a column temp of 120 °C, the relative retention times being: $Me_2Si(OEt)_2$: 1, $Me_2(OEt)$-(OBu-*n*): 2.46, $Me_2Si(OBu\text{-}n)_2$: 5.85.

In the other cases, a 4 mm $\phi\times$6 m glass column with 5% Silicone OV-17 on Chromosorb W (diatomaceous earth) was used at a column temp of 110 °C. The relative retention times under these conditions were as follows: $Me_2Si(OEt)_2$: 1, $Me_2Si(OEt)(OBu\text{-}s)$: 2.30, $Me_2Si(OBu\text{-}s)_2$: 4.93, $Me_2Si(OEt)$-(OBu-*i*): 2.40, $Me_2Si(OBu\text{-}i)_2$: 4.95, $Me_2Si(OEt)(OBu\text{-}n)$: 3.30, $Me_2Si(OBu\text{-}n)(OBu\text{-}s)$: 6.67, $Me_2Si(OBu\text{-}n)(OBu\text{-}i)$: 6.68, $Me_2Si(OBu\text{-}n)_2$: 9.78.

Reagents. The dimethyldiethoxysilane was prepared by the reaction of octamethylcyclotetrasiloxane with tetraethoxysilane in the presence of potassium hydroxide.[13] The dimethyldibutoxysilanes and dimethylethoxybutoxysilanes were prepared by the iodine-catalyzed reaction of dimethyldiethoxysilane with butyl, *s*-butyl, or isobutyl alcohol. After the resulting ethanol and excess alcohol had been removed by distillation, each alkoxysilane was obtained by fractional distillation.

The dimethyldiethoxysilane was purified by repeated fractional distillation under ordinary pressure, while the dibutoxy-, di-*s*-butoxy-, and diisobutoxy-silanes were distilled under reduced pressure. The dialkoxysilanes with different alkoxyl groups were purified by means of GLPC fractional elution, employing a Shimadzu model GC-5A gas chromatograph, equipped with a model 4APP-5 autofraction collecteor. Stainless columns (8 mm $\phi\times$2.8—3.5 m) containing 25% Ucon oil on Chromosorb W or 35% PEG 6000 on Shimalite NAW were used at a column temp of 120—180 °C.

The iodine used in the alcoholysis of dimethyldiethoxysilane was purified by repeated sublimation with calcium oxide and potassium iodide. The iodine monobromide was prepared and purified by recrystallization as reported in the literature.[14]

The Reaction of 2-Ethoxy-1,3-oxathiolane with Carbonyl Compounds in the Presence of $ZnCl_2$ or $HgCl_2$

Shigeo TANIMOTO,* Shigeo JO,* Toyonari SUGIMOTO, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

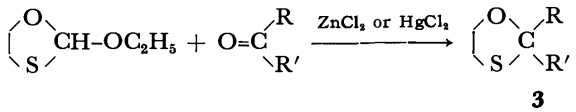
(Received February 21, 1981)

Synopsis. In the reaction of 2-ethoxy-1,3-oxathiolane with carbonyl compounds in the presence of $ZnCl_2$ or $HgCl_2$, it has been found that only the breaking of the endocyclic bond (C–O or C–S bond) occurs, while the breaking of the exocyclic C–O bond to give the 1,3-oxathiolan-2-ium ion is unfavorable. This behavior is different from that of 2-ethoxy-1,3-dithiolane, in which the breaking of the endocyclic C–S bond occurs by means of $HgCl_2$ and the exocyclic C–O bond, by means of $ZnCl_2$.

It has already been shown[1] that the reaction of 2-ethoxy-1,3-dithiolane with acetone in the presence of $HgCl_2$ gives exclusively 2,2-dimethyl-1,3-dithiolane (**1**), whereas the employment of $ZnCl_2$, under otherwise identical conditions, yields 1-(1,3-dithiolan-2-yl)-2-propanone (**2**), along with **1**. The pathway leading to **1** involves the C–S bond fission of 2-ethoxy-1,3-dithiolane, and the breaking of the exocyclic C–O bond to give the 1,3-dithiolan-2-ium ion is necessary for the formation of **2**.

This report will describe the somewhat different behavior of 2-ethoxy-1,3-oxathiolane, in which these Lewis acids cause only the breaking of the endocyclic bond, with no evidence of the formation of the 1,3-oxathiolan-2-ium ion.

When 2-ethoxy-1,3-oxathiolane was allowed to react with aldehydes or ketones in dichloromethane at room temperature, in the presence of $ZnCl_2$, the corresponding 2-substituted or 2,2-disubstituted 1,3-oxathiolane (**3**) was produced as the main product in all cases.



3

a: R=C_6H_5, R′=H **d**: R=R′=CH_3
b: R=$CH_3(CH_2)_2$, R′=H **e**: R=C_6H_5, R′=CH_3
c: R, R′=$-(CH_2)_5-$ **f**: R=C_6H_5CH=CH, R′=H

From the previously known data[1] it seems reasonable to propose that the coordination of the O atom in the ring with $ZnCl_2$ occurs preferentially, thus bringing about the formation of the resonance-stabilized thiocarbonium ion. The employment of $HgCl_2$ instead of $ZnCl_2$, under otherwise identical conditions, also yielded **3**. This may be also explained in terms of another path involving the intial coordination of the S atom with $HgCl_2$ and the subsequent formation of the resonance-stabilized oxycarbonium ion.

Ethyl acetoacetate, methyl acetoacetate, or acetylacetone was also used for the reaction with 2-ethoxy-1,3-oxathiolane in the presence of $ZnCl_2$ or $HgCl_2$. The reaction proceeded without a solvent at room temperature, and 1,3-oxathiolane derivatives of the **4** formula were isolated.

was employed, none of the product which would arise from the intermediate 1,3-oxathiolan-2-ium ion was detected. On the other hand, in our previous work[5] on the reaction of 2-ethoxy-1,3-dithiolane with active methylene compounds in the presence of $ZnCl_2$, the exclusive formation of the intermediate 1,3-dithiolan-2-ium ion was observed. When $HgCl_2$ was used instead of $ZnCl_2$, the reaction with the dithiolane proceeded *via* a resonance-stabilized thiocarbonium ion. The formation of 1,3-dithiolane derivatives with the formula of **5** in this reaction suggests that the coordination of $HgCl_2$ with the S atom in the 1,3-dithiolane ring is favorable. The products obtained in the reaction are summarized in Table 3.

c: R=C_6H_5, R'=OC_2H_5

Experimental

Reaction of 2-Ethoxy-1,3-oxathiolane with Aldehydes or Ketones. To a mixture of 2-ethoxy-1,3-oxathiolane (20 mmol) and an aldehyde (or a ketone) (20 mmol) in dichloromethane (35 ml), we added $HgCl_2$ (or $ZnCl_2$) (4 mmol) at 0—5 °C. The mixture was stirred for 16 h at room temperature and then poured into a mixture of water and dichloromethane. The organic layer was separated, and then it was combined with a dichloromethane extract of the aqueous phase. The dichloromethane solution was washed with dilute aqueous $NaHCO_3$, and then with water, dried over $MgSO_4$, and distilled.

Reaction of 2-Ethoxy-1,3-oxathiolane with Active Methylene Compoundes. To a mixture of 2-ethoxy-1,3-oxathiolane (45 mmol) and an active methylene compound (30 mmol), we added a Lewis-acid catalyst (as is shown in Table 2) at 0—5 °C. The mixture was stirred for 24 h at room temperature and then worked up as above.

Reaction of 2-Ethoxy-1,3-dithiolane with Active Methylene Compounds in the Presence of $HgCl_2$. To a mixture of 2-ethoxy-1,3-dithiolane (33 mmol) and an active methylene compound (38 mmol), we added $HgCl_2$ (or $HgBr_2$) (15 mmol) at 0—5 °C. The mixture was stirred for 24 h at room temperature and then poured into a mixture of ice water and ether. The organic layer was separated and combined with an ethereal extract of the aqueous phase. The ethereal solution was washed with dilute aqueous $NaHCO_3$, and then with water, dried over $MgSO_4$, and distilled. The product was further purified by column chromatography on silica gel, if necessary (the eluent in most cases was 50% hexane–ether).

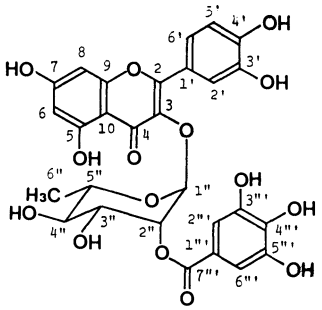
Flavonoids of *Polygonum sieboldi* and *P. filiforme*

Takahiko Isobe,* Keiji Kanazawa, Makoto Fujimura, and Yukinao Noda
Department of Chemistry, Hyogo College of Medicine, Mukogawa-cho, Nishinomiya, Hyogo 663
(Received May 25, 1981)

Synopsis. Five flavonoids containing a new flavonol glycoside were isolated from *Polygonum sieboldi* and *P. filiforme*. The structure of the new compound was determined as quercetin 3-rhamnoside 2″-gallate by chemical and spectroscopic data.

Many flavonoids have been isolated from *Polygonum* species (*Polygonaceae*), and we previously reported the identification of five flavonoids from *P. nodosum* Pers.[1,2] Further investigation of this species has led to the isolation of several flavonoids containing a new compound. Two known compounds, quercetin (**1**) and quercetin 3-rhamnoside (**2**), were isolated from *P. sieboldi* Maxim. (Akino-unagitsukami in Japanese) and four known compounds, **1**, **2**, myricetin 3-rhamnoside (**3**), and quercetin 3-glucoside 2″-gallate (**4**), and a new flavonoid glycoside (**5**) were isolated from *P. filiforme* Thunb. (Mizuhiki in Japanese). The ^{13}C NMR spectrum of **5** and the ^{1}H NMR spectrum of the TMSi ether of **5** (**6**) were almost identical with that of **4** with the exception of the sugar part, which was assignable as L-rhamnose from these spectra.[3,4] The fragment ions of **5** by MS spectrum are assignable as quercetin (*m/z* 302), gallic acid (170), and galloyl group (153). The UV spectrum of **5** shows also the presence of a substituted hydroxyl group at C-3 of flavonol by bathochromic shifts in addition of both NaOAc and $AlCl_3$–HCl.[2,4] The compound obtained by the hydrolysis of **5** with aqueous ammonia was identical with **2** by TLC. From the ^{13}C shift values ($\Delta\delta$) of C-2, C-3, and C-4 of rhamnose of **5** having *ca.* −3.0, +1.0, and −2.0, respectively,[3] and the downfield shift of H-2 (δ 5.56) of rhamnose of **6** by ^{1}H NMR spectrum, the galloyl group may be attached to C-2 of rhamnose. Accordingly, compound **5** has the structure of quercetin 3-α-L-rhamnopyranoside 2″-gallate. The similar compound, myricetin 3-α-L-rhamnopyranoside 2″-gallate[5] had been isolated some years ago.



5

Experimental

Isolation of Flavonoids. By the previous reported procedure,[2] compounds **1** and **2** from *P. Sieboldi* Maxim., and compounds **1**, **2**, **3**, **4**, and **5** from *P. filiforme* Thunb. Compounds **1**, **2**, **3**, and **4** were identified as quercetin, quercetin 3-rhamnoside, myricetin 3-rhamnoside, and quercetin 3-glucoside 2″-gallate, respectively, by comparison with the TLC and the IR spectra of authentic samples and thier acetates.

Isolation of Quercetin 3-Rhamnoside 2″-Gallate (5). Compound **5**, yellowish plates from MeOH–H_2O, mp 207—208.5 °C; $[\alpha]_D^{25}$ −1.8 (*c*=0.9, MeOH); Found: C, 50.92; H, 3.94%. Calcd for $C_{28}H_{24}O_{15}\cdot 3H_2O$: C, 51.38; H, 4.62%; MS (20 eV) *m/z* 302, 170, and 153; UV (EtOH): λ_{max} 257 (sh), 267 (ε 27900), and 351 nm (ε 16400), (+$AlCl_3$): 276, 303 (sh), and 432 nm, (+$AlCl_3$+HCl): 271, 355, and 400 nm (sh), (+NaOAc): 273 and 359 nm; IR (Nujol): ν_{max} 3250, 1710, 1655, 1605, and 1205 cm^{-1}; ^{13}C NMR (25 MHz, DMSO-d_6): δ 17.7 (C-6″), 68.6 (C-3″), 70.8 (C-5″), 71.8 (C-2″ and 4″), 93.8 (C-8), 98.5 (C-1″), 98.9 (C-6), 104.1 (C-10), 109.0 (C-2‴ and 6‴), 115.7 (C-2′ and 5′), 119.3 (C-1‴), 120.6 (C-1′), 121.2 (C-6′), 133.4 (C-3), 138.6 (C-4‴), 145.3 (C-3′), 145.5 (C-3‴ and 5‴), 148.6 (C-4′), 156.5 (C-2), 157.3 (C-9), 161.3 (C-5), 164.3 (C-7‴), 165.0 (C-7), and 177.5 (C-4).

TMSi Ether of 5 (6). ^{1}H NMR (100 MHz, $CDCl_3$): δ 0.99 (3H, d, *J*=6 Hz, H-6″), 3.4 (1H, m, H-5″), 3.57 (1H, t, *J*=8 Hz, H-4″), 4.02 (1H, dd, *J*=8 and 2 Hz, H-3″), 5.56 (1H, t, *J*=2 Hz, H-2″), 5.66 (1H, d, *J*=2 Hz, H-1″), 6.26 (1H, d, *J*=2 Hz, H-6), 6.37 (1H, d, *J*=2 Hz, H-8), 6.97 (1H, d, 8 Hz, H-5′), 7.23 (2H, s, H-2‴ and 6‴), 7.37 (1H, d, *J*=2 Hz, H-2′), and 7.51 (1H, dd, *J*=8 and 2 Hz, H-6′).

Alkaline Hydrolysis of 5. To **5** (7 mg) were added 0.1 mol dm^{-3} aqueous ammonia (0.8 ml) and MeOH (1 ml) and the mixture allowed to stand for one day at room temperature. From the TLC of the reacting solution, the product was identified as quercetin 3-rhamnoside (**2**) [on silica gel plate; solvent, EtOAc–MeCOEt–HCO_2H–H_2O, 5 : 2 : 0.1 : 1].

We are grateful to Mr. Kozo Shibata, Osaka City University, for the measurement of ^{1}H and ^{13}C NMR.

"Anomalous" Raman Polarization as Observed in Anthracene Anion

Etsuko FUJIMOTO, Toshio KAMISUKI, and Shiro MAEDA*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Midori-ku, Yokohama 227

(Received December 27, 1980)

An example of "anomalous" Raman polarization is presented by measuring the polarization dispersion of a resonant depolarized line of anthracene anion near the first absorption band. The molecular origin of the asymmetric Raman tensor is discussed on the basis of a vibronic effect associated with the resonant electronic level.

Anomalous polarization refers to an unusual aspect of polarization in vibrational Raman scattering, in which the depolarization ratio exceeds the normal maximum value $\rho=3/4$ in isotropic media. This occurs when the scattering tensor becomes appreciably asymmetric under appropriate resonance conditions. Asymmetry of the scattering tensor is by no means unusual in the Raman transition between different electronic states.[1] In vibrational Raman transitions within the non-degenerate ground state, the tensor usually has a virtually symmetric form even when an asymmetry is claimed from the group theory, leading to the well-known rule $\rho \leqq 3/4$.

Deviation from the rule was first demonstrated by Spiro and Strekas for the extreme case of $\rho \simeq \infty$ (inverse polarization) in cytochrome C and hemoglobin.[2] This remarkable state of polarization arises from an entirely antisymmetric Raman tensor, which may really exist only in molecules with three-fold or higher symmetry axes. Namely, the orbital degeneracy of electronic excited states contributing to the scattering tensor plays an essential role in bringing about the antisymmetric tensor. Less striking cases of $3/4<\rho<\infty$ were subsequently found in various porphyrins and heme proteins,[3] but the tensor asymmetry in those systems could be understood in essentially the same vibronic scheme as in the original high symmetry case. Anomalous polarization of somewhat different origin was also found out in IrX_6^{2-},[4] where the degeneracy of the electronic ground state is responsible for the tensor asymmetry.

Now, confining our attention to the usual vibrational Raman spectrum in non-degenerate ground state, it may be noted that, from the group theoretical point of view, the scattering tensor is not always symmetric but is rather often asymmetric. Particularly, in lower symmetries without any three-fold or higher axes, which occur in a majority of organic molecules, the tensor of non-totally symmetric vibrations is always asymmetric, so that the depolarization ratio is greater than 3/4. Such an argument is of little significance in ordinary non-resonant Raman observations, where the antisymmetric part of the tensor almost dies out by the nature of wave-functions,[5] but may become more realistic if an appropriate resonance condition is found. An example substantiating this remark has been given in a previous study on dehydro annulenes of D_{2h} symmetry.[6] In some point groups, on the other hand, tensor asymmetry is also possible for totally symmetric vibrations: an example of such a type of anomaly was found out very recently in Fe(II)-bis[1-(2'-pyridylmethyleneamino)-2-aminoethane] ion of C_2 symmetry.[7]

In view of the particular significance of anomalous polarization in connection with the vibronic interaction, further experimental evidence should be sought. In this context, we take anthracene anion (An^-) as a promising candidate, because our previous resonance Raman study[8] of this system recorded a remarkably resonant depolarized line at 1466 cm^{-1}, which is supposed to be 'anomalous' intrinsically. In order to study the behavior of this line more definitely, the polarization dispersion has been carefully measured near the first absorption band.

Experimental

Anthracene anion was prepared by bringing anthracene into contact with metallic sodium in tetrahydrofuran (THF). The Raman spectra were obtained by $\approx 10^{-3}$ mol dm^{-3} THF solutions at room temperature. The intensity and depolarization ratio of 1466 cm^{-1} line were determined by the band area, using 914 cm^{-1} THF line as a standard. Since there exists a weak and broad depolarized band of THF extending over 1400—1550 cm^{-1}, due correction was made by subtracting the contribution from the measured area.

The MCD spectrum was recorded for a $\approx 10^{-6}$ mol dm^{-3} THF solution under the field strength of 10^4 G.

Results and Discussion

The whole span Raman spectrum recorded by 514.5 nm excitation is shown in Fig. 1 by the parallel and perpendicular scattered components. It is observed that the depolarization ratio of 1466 cm^{-1} line is slightly but certainly greater than 3/4 even in this

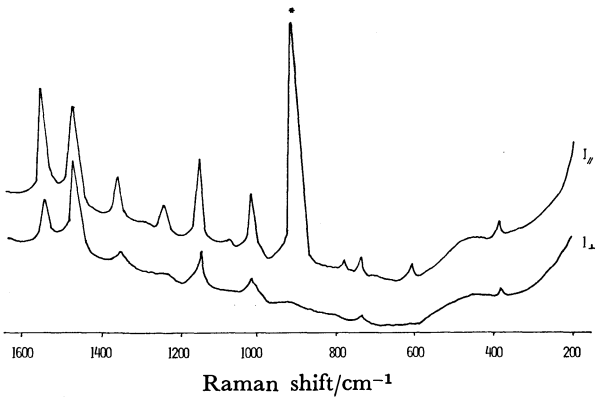

Fig. 1. Resonance Raman spectra of anthracene anion in THF solution by 514.5 nm excitation, obtained by parallel and perpendicular polarization conditions. Solvent line is marked by *.

moderately resonant condition. A partial spectral record of the interesting region is shown in Fig. 2 for some different exciting frequencies; here the dotted line indicates the baseline due to the solvent scattering as estimated in proportion to 914 cm^{-1} THF line. Uniform instrumental sensitivity for the two different analyzer settings has been confirmed by measuring well-defined depolarized lines of a known sample.

Since the deviation of ρ from the normal behavior was rather small in the observed region, the measurement was carefully made by repeated scanning with an alternating polarization sequence. The ρ values averaged for 6—7 records are plotted in Fig. 3 against the exciting laser frequency, together with the intensity plot and absorption curve. Scatter of the data was fairly small, and the composite error including the baseline uncertainty is estimated to be well within 10%. Although accurate measurement was impeded by increasing fluorescence in the more interesting region closer to the absorption maximum, the depolarization ratio has been verified to increase beyond the normal maximum of 3/4 along with the intensity, indicating the resonantly increasing tensor asymmetry.

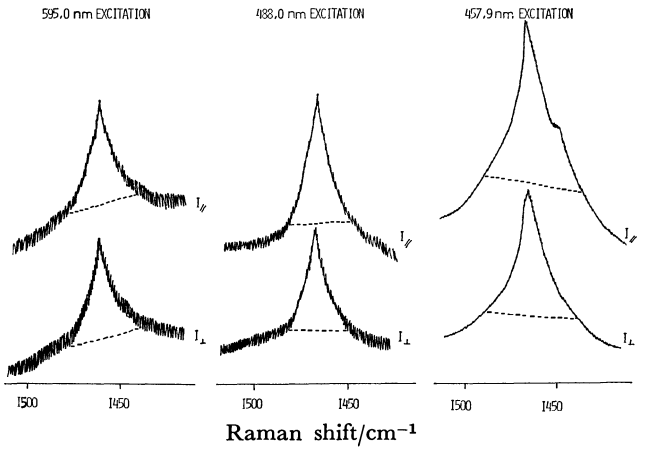

Fig. 2. Changes in polarization features of 1466 cm^{-1} line by different exciting light frequencies, where the dotted line indicates the baseline due to the solvent scattering.

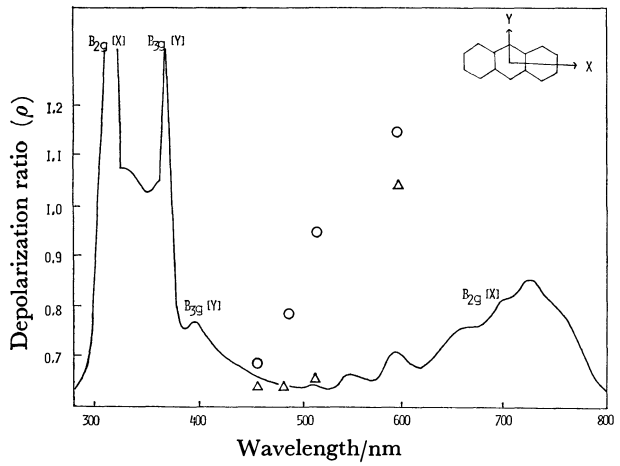

Fig. 3. Polarization dispersion (○) and excitation profile (△) of 1466 cm^{-1} line of anthracene anion in THF solution, with the electronic absorption spectrum.

The ρ value at 457.9 nm excitation is observed to be slightly lower than 3/4 in Fig. 3, in contradiction to the presumably non-totally symmetric nature of 1466 cm^{-1} mode. This is properly ascribed to the effect of a polarized line included in the measured area, because such a signal emerges at about 1450 cm^{-1} in the parallel component of 457.9 nm record as the result of much reduced resonance effect in 1466 cm^{-1} scattering. This polarized line may be reasonably assigned to an a_g mode corresponding to 1480 cm^{-1} of neutral anthracene.

The polarization dispersion as observed above is properly interpreted as due to the vibronic mixing that gives rise to a polarization change of the resonant electronic transition. In order to see the circumstances more precisely, the nature of the relevant electronic states has been investigated by a PPP-SCF-MO calculation and MCD measurement. The polarization of each transition predicted by the calculation is consistent with the sign of the observed ellipticity $[\theta]_M$, assuming B-term contributions in the MCD spectrum. The results are listed in Table 1 and the assignment of transitions is shown in Fig. 3. These results indicate that the first B_{2g} excited state with x-polarized transition moment has a good possibility to vibronically couple with the next B_{3g} states of y-polarization through b_{1g} in-plane vibrations. Then, the b_{1g} Raman tensor having the form $\begin{pmatrix} 0 & \alpha_{xy} & 0 \\ \alpha_{yx} & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$ can be appreciably asymmetric for exciting laser frequencies sufficiently close to the first absorption band, because in such a resonant condition, the non-zero element is shown to be approximately represented[6] by the predominant term as

Table 1. Assignment of electronic absorption spectrum for anthracene anion

Observed transition			Calculated transion		
Abs. spectrum	MCD spectrum		PPP-SCF-CI		
Wavelength/nm	Wavelength/nm	$[\theta]_M$	Wavelength/nm	Symmetry type	Direction of polarization
726		+	822	$B_{2g}\leftarrow B_{1u}$	x
400	410	−	485	$B_{3g}\leftarrow B_{1u}$	y
366	365	−	344	$B_{3g}\leftarrow B_{1u}$	y
326	325	+	294	$B_{2g}\leftarrow B_{1u}$	x

$$\alpha_{xy} \propto \frac{\mu_x(\partial\mu_y/\partial Q)_0}{\nu_e+\nu_R-\nu+i\Gamma}, \quad \alpha_{yx} \propto \frac{\mu_x(\partial\mu_y/\partial Q)_0}{\nu_e-\nu+i\Gamma}. \tag{1}$$

Here μ, ν_e, and Γ are the moment, frequency, and damping factor of the resonant B_{1u} (ground)$\rightarrow B_{2g}$ transition, ν_R and Q are the frequency and normal coordinate of the b_{1g} Raman mode, and ν is the laser frequency. The depolarization ratio is thus given[6] by

$$\rho = \frac{3}{4}+\frac{5}{4}\left|\frac{\alpha_{xy}-\alpha_{yx}}{\alpha_{xy}+\alpha_{yx}}\right|^2 = \frac{3}{4}+\frac{5}{16}\frac{\nu_R^2}{(\nu_e+1/2\nu_R-\nu)^2+\Gamma^2}, \tag{2}$$

which is appreciably greater than 3/4 in the resonant region.

Further insight into the origin of the asymmetric tensor may be obtained by applying Warshel's model,[9] which approximately represents the transition moment derivative by an assembly of the products of transition monopoles q_i, allocated to individual atoms, and the corresponding components of normal mode vector $L^{i\sigma}$

$$\partial\mu_\sigma/\partial Q = \sum_i q_i L^{i\sigma}(m_i\nu_R)^{-1/2}. \quad m_i\text{: atomic mass} \tag{3}$$

The transition monopoles of the first absorption band as calculated by PPP-SCF-CI method are shown by the circles in Fig. 4.

Since available vibrational data of the anion have been quite insufficient for obtaining $L^{i\sigma}$ accurately, a normal mode calculation has been made for neutral anthracene using the library programs BGLZ and LSMB at the Computer Center, the University of Tokyo. The calculated Raman frequencies are shown in Table 2 together with those observed for neutral and anion species, the force constants being given in Table 3. The vibrational mode of 1466 cm^{-1} anion line may be properly related to ν_{16} and ν_{17} modes of the neutral molecule, which are shown in Fig. 4 by calculated atomic displacements. The MO calculation suggests that the anion mode is more closely allied to the neutral ν_{16} mode, because the change in bond order from neutral to anion predicts a down-shift of ν_{16} as large as 87 cm^{-1} in contrast with only 3 cm^{-1} up-shift of ν_{17}. Then, by putting the ν_{16} neu-

tral mode in place of the 1466 cm^{-1} anion mode, we can trace the ultimate source of the off-diagonal tensor elements, Eq. 1, to the wagging motion of $B_{1u} \rightarrow B_{2g}$ transition moment μ_x, which mostly comes from the rotational motion of the four equivalent carbon atoms at 3, 6, 10, and 13 positions which carry the predominant transition monopoles.

"Anomalous" polarization as reported above is by no means a unique occurrence theoretically, but should be observed quite generally as long as it is measured under well-resonant conditions. Nevertheless, it seems still worth investigating in view of its particular significance in studying the vibronic interaction in complex molecules.

The authors wish to thank Professor Makoto Miwa and Dr. Tomoko Komiyama of Seikei University for providing the facilities of MCD measurement.

1-Chloro-1,3-butadiene Copolymers. III. Reactivity of 1-Chloro-1,3-butadiene in Radical Copolymerizations

Shinzo KOHJIYA,* Hideo TAKEUCHI, Kohshi KAWAMOTO, and Shinzo YAMASHITA

Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received November 14, 1980)

Radical copolymerizations of 1-chloro-1,3-butadiene (CB) were carried out with styrene (St), 1,3-butadiene (Bd), or chloroprene (Cp) in toluene at 70 °C by AIBN. The monomer reactivity ratios are found as follows: $r_{CB}=1.21\pm0.10$, $r_{St}=0.10\pm0.03$; $r_{CB}=0.27\pm0.02$, $r_{Bd}=0.56\pm0.03$. Copolymerization of CB and Cp showed CB was much less reactive than Cp. The Q and e values of CB were calculated to be 3.13 and +0.65, respectively. ^{1}H NMR and IR of poly(CB-co-St) showed 60% of CB units are of 1,4-configuration and the rest 3,4-configuration.

On the polymerization of 1-chloro-1,3-butadiene (CB), only a few papers[1-4] have been published up to now, while there have been so many works relevant to polychloroprene. This difference is probably due to their industrial significance. Carothers studied the polymerizations of 1,3-butadiene, chloroprene, and CB in the course of his research to synthesize a new synthetic rubber.[1] Klebanskii *et al.*[2] briefly reported the polymerizations of CB and 1-bromo-1,3-butadiene. Winston and Wichacheewa carried out the radiation-induced copolymerization of CB and styrene, and reported the monomer reactivity ratios.[3] They claimed all the CB units in the polymer are of 1,4-configuration.[3] However, in our previous studies on the polymer reactions and physical properties of CB–butadiene and CB–styrene copolymers,[4-7] it was pointed out that the CB units carried two different kinds of chlorine in their reactivity, suggesting the coexistence of two configurations of the CB unit, *i.e.*, 1,4- and 3,4-microstructures.[5-7]

In the present work, the reactivity of CB in radical polymerizations was determined relative to styrene, 1,3-butadiene or chloroprene, and the microstructure of CB units was analyzed by spectroscopic methods. This study will provide fundamental data of much importance in the syntheses and chemical modifications of CB copolymers.

Experimental

Materials. 1-Chloro-1,3-butadiene (CB) was prepared according to the method of Heasley and Lais.[8] The product was distilled twice just before use: bp 65—67 °C (lit,[8] 65—68.5 °C), yield 40%. Purity by GLPC was above 98%. Commercial 1,3-butadiene (Bd) was purified by the method previously reported.[9] Chloroprene (Cp) was distilled twice under a reduced pressure. Its purity by GLPC was 99.7%, and the trace amount of impurity (below 0.3%) was CB. Styrene (St), 2,2′-azobisisobutyronitrile (AIBN), toluene, and ethylbenzene were purified according to the usual procedures. As low mol-wt model compounds for CB units in the polymer, 1-chloro-2-butene (**1**, for the 1,4-microstructure) and 1-chloro-1-butene (**2**, for the 3,4-microstructure) were subjected to ^{1}H NMR measurements. The compound **2** was prepared by the method of Henne *et al.*,[10] and **1** was commercially available from Tokyo Kasei Kogyo Co., Ltd. Both were purified by repeated distillations.

Polymerization Procedures. Monomers, AIBN, and toluene were introduced into a glass ampoule. The ampoule was connected to a vacuum system, and was subjected to degassing, followed by the sealing *in vacuo*. When Bd was used as monomer, it was introduced into the ampoule by the vacuum distillation method. The ampoule was placed in a bath maintained at 70 °C and rotated at a speed of 24 min^{-1}. In the copolymerization of CB and Cp, the reaction was conducted under a nitrogen atmosphere and aliquots of the polymerization solution were withdrawn by a syringe at fixed time intervals. The aliquots then were mixed with acetone containing ethylbenzene as an internal standard for GLPC (carrier flow gas, hydrogen: column; LP 84, 65 °C).

Analyses of Polymers. IR and ^{1}H NMR spectra were measured on a Hitachi IR Spectrophotometer 215 and a Varian T-60A Spectrometer, respectively. Viscosity measurements were carried out in toluene using an Ubbelohde viscometer at 25.9 °C for the CB–Bd copolymer and at 30 °C for the CB–St copolymer. Copolymer compositions were determined by elemental analysis and/or ^{1}H NMR. Monomer reactivity ratios (MRRs) were calculated by the Fineman-Ross method.

Results and Discussion

Stability of CB Copolymers. The stability of poly(CB-co-Bd)s obtained by emulsion polymerization has been reported.[7] According to the results, the allylic chlorine in these CB–Bd copolymers was easily hydrolyzed to give a hydroxyl group because they were produced in an aqueous medium.[7] The CB copolymers obtained in toluene solution also contain allylic chlorines as will be described later in this paper. However, these polymers were produced under non-aqueous conditions, and could be kept unchanged for a few months. Table 1 shows the change of poly(CB-co-St) with standing time. Oxygen was detected from the CB copolymers obtained by emulsion polymeriza-

Table 1. Elemental analysis of poly(CB-co-St)[a]

tion,[7] but it is not the case for the poly(CB-co-St) by solution polymerization as indicated in Table 1. While the found values of C, H, and Cl contents were in good agreement with the theoretical ones even after the storage for 100 d, these polymers began to color slightly and became darker with time in several months. Therefore, all the copolymer samples were treated in a few months after the polymerization.

Copolymerization of CB with St or Bd. Elemental analysis is applicable to the composition determination of many copolymers. The compositions of CB–St and CB–Bd copolymers were determined by the elemental analysis of chlorine. In case of CB–St copolymers, their ^{1}H NMR spectra also allow us to evaluate the compositions since the phenyl protons of St units in the copolymer appear separately from the others at a lower field as shown later in Fig. 3. Table 2 shows the results of composition determination of poly(CB-co-St) both by elemental analysis and by ^{1}H NMR. A very good agreement was found between the compositions obtained by two methods. Thus, ^{1}H NMR was equally employed to determine the composition of CB–St copolymers.

The copolymer composition curves, A for poly(CB-co-St), and B for poly(CB-co-Bd), are shown in Fig. 1. The times of polymerizations were adjusted to get the conversions below 10% so that Mayo-Lewis' equation could be used to evaluate the MRRs. From the experimental points in Fig. 1, MRRs were given as follows:

Copolymerization of CB (M_1) and St (M_2),

$$r_1 = 1.21\pm0.10,\ r_2 = 0.10\pm0.03;$$

Copolymerization of CB (M_1) and Bd (M_2),

$$r_1 = 0.27\pm0.02,\ r_2 = 0.56\pm0.03.$$

The solid lines in Fig. 1 are calculated ones from these values and fit well with the experimental points. Q and e values for CB were evaluated from the MRRs with St as follows:

$$Q = 3.13,\ e = +0.65.$$

The same values from the copolymerization with Bd were $Q=1.01$ and $e=+0.33$. These values are understandable because CB is a conjugated diene and has an electron-withdrawing chlorine. The composition curve, B, in Fig. 1 is of an inversed sigmoid shape, which suggests an alternating tendency for CB–Bd pair. Since Bd has a negative e value (-1.05[11]), the positive e value obtained for CB is in conformity with the observed alternating tendency.

Copolymerization of CB with Cp. Both CB and Cp are diene monomers of the same molecular formula. Consequently, it was difficult to determine the composition of the copolymer accurately by elemental analysis or ^{1}H NMR. Here, in order to compare the reactivity of the two monomers, the consumptions of monomers with the time of polymerization were determined by GLPC. Figure 2 shows the amount of residual monomers plotted against time of polymerization. Curves A and B indicate the decreases of CB and Cp in their homopolymerizations, respectively, and Cp was found to be polymerized faster than CB under the present conditions. Curves C and D show the decrease of CB and Cp in their copolymerization. Again Cp was consumed faster than CB, but the difference in their consumption rates is less enhanced in the copolymerization where both polymer

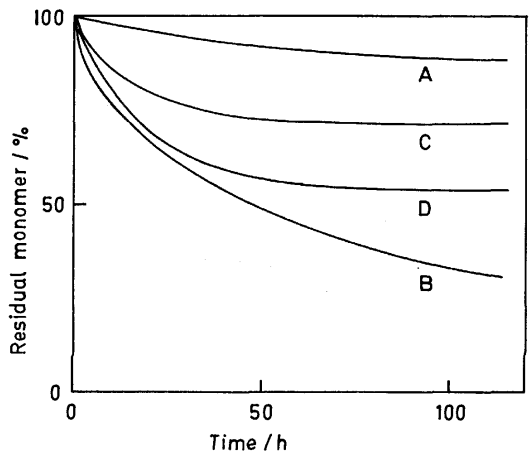

Fig. 2. Monomer consumption curves of CB(A, C) and Cp(B, D) in the homopolymerizations(A, B) and the copolymerization(C, D). Solution polymerizations in toluene at 70 °C: [AIBN]=0.04 M. Curve A; [CB]=5.4 M; curve B, [Cp]=5.4 M; curves C and D, [CB]=[Cp]=2.7 M.

radicals derived from CB and Cp are responsible for the propagation. Since the conversions from the weights of the resultant polymers agreed with those from monomer consumptions within the experimental error, it can be concluded that Cp is more reactive than CB in radical polymerization. This result is in accord with the reported difference in the reactivity between Cp and Bd ($r_{Cp}=3.41$ and $r_{Bd}=0.059$, or $r_{Cp}=2.86$ and $r_{Bd}=0.0$)[11] together with the comparable reactivity of CB with Bd described in the previous section.

Combining all the results of the polymerizations described above, we can propose the order of the monomer reactivity as follows:

$$Cp > CB \simeq Bd > St.$$

It has not been reported the successful synthesis of a new diene rubber containing chlorine by the copolymerization of Cp and Bd, probably because of the difference in their reactivities.[11] Now, CB is found to be a good candidate as a comonomer of Bd to synthesize a butadiene rubber containing chlorine. In fact, the emulsion copolymerization of CB and Bd was previously reported,[4] and the product is feasible for various chemical modifications due to allylic reactive chlorine.[6,7,12]

Intrinsic Viscosity of CB Copolymers. The three CB copolymers obtained in toluene were all soluble in toluene, and no insoluble fraction was found. In other words, the gelation did not occur in solution polymerizations, while it did occur and some insoluble parts were found in emulsion copolymerizations.[4] In Table 3 is shown the intrinsic viscosity of poly(CB-co-Bd)s prepared at various monomer feeds. The viscosities listed in Table 3 were much lower than those of the copolymers obtained by emulsion polymerization ($[\eta]=2.5$—5.5).[4] In addition, the viscosity of poly(CB-co-Bd) decreases with the increase of CB content in monomer feed. This tendency was also observed in poly(CB-co-St)s, the intrinsic viscosities of which were in the range of 0.15 to 0.30. CB monomer seems to be subject to monomer transfer reaction.

It is reasonable to get lower mol-wt copolymers by solution polymerization than by emulsion polymerization, because in the micelle the monomer can be regarded as being at the state of bulk and it is diluted in the solution. The produced polymer containing diene units is also more diluted in solution polymerization, and this fact could contribute to the absence of gelation.

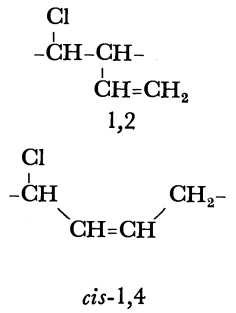
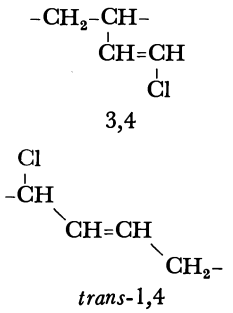
Microstructure of CB Unit. Four kinds of microstructures are possible for CB units in the polymer:





cis-1,4

trans-1,4

In the IR spectra of poly(CB-co-St), any peak ascribable to vinyl group (*ca.* 920 cm^{-1}) was not observed. In Fig. 3, ^1H NMR spectra of poly(St) (A), poly(CB) (B), and poly(CB-co-St) (C) are indicated. The peak due to olefinic methylene protons in the region of *ca.* 3.8 ppm is not observed. These two experimental findings suggest the absence of 1,2-microstructure in poly(CB-co-St), and its absence confirms the reluctance of 1,2-disubstituted olefins to polymerize,[13] because CB is involved in 1,2-propagation reaction as a 1,2-disubstituted olefin. Considering the spectra of model compounds *i.e.* **1** and **2**, an assignment of the peaks in ^1H NMR was made as listed in Table 4. It is noticeable that the protons of CB units are

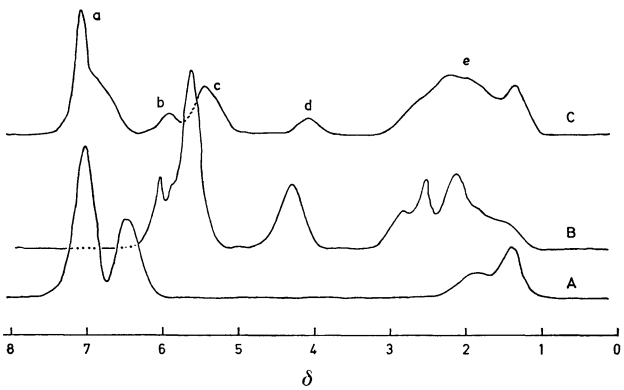


Fig. 3. ^1H NMR of polystyrene (A), poly(CB)(B), and poly(CB–co–St)(C) produced in toluene in the presence of AIBN.

Table 4. Assignment of ^1H NMR peaks in poly(CB-co-St)

Symbol	δ		Assignment
a	7.35	6.40	Phenyl proton (5H) in St
b	6.20	5.85	Olefinic proton (1H) geminal to chlorine in 3,4-CB
c	5.85	5.10	Olefinic proton in 1,4-CB (2H) and in 3,4-CB vicinal to chlorine (1H)
d	4.40	3.80	Methyne proton (1H) in 1,4-CB
e	3.20	1.10	Methyne proton in 3,4-CB (1H) and in St (1H), methylene proton in 1,4-CB (2H), in 3,4-CB (2H), and in St (2H)

subject to shielding to the higher field when CB units are incorporated in the copolymer with St. Similar shifts were observed in Bd–St and methyl methacrylate–St copolymers,[14] and this shielding effect has been interpreted in terms of the magnetic anisotropy of the phenyl group in St units. Therefore the observed shift may indicate that this poly(CB-co-St) is the true copolymer instead of the mixture of the homopolymers.

According to the assignment, the peak, a, is due to St units and the peaks, b, c, and d, are due to CB units, and the composition of poly(CB-co-St) was evaluated as shown in Table 2. Additionally, mol % of 1,4- and 3,4-microstructures could be evaluated from ^{1}H NMR, though *cis* and *trans* was not distinguishable. The results are shown in Table 5. We may conclude that in poly(CB-co-St) 60-mol% CB units are always of 1,4-configuration regardless of their contents, and the rests are of 3,4-configuration. This conclusion is in agreement with our previous estimation[5–7] from polymer reactions, while it is contrary to the result by Winston and Wichacheewa[3] who reported that all the CB units were of 1,4-configuration based on the results of the elimination reaction of hydrogen chloride from the poly(CB-co-St) obtained by the radiation-induced bulk copolymerization. Since both poly(CB-co-St)s were prepared by the radical polymerization, two copolymers have presumably almost the same microstructure. This discrepancy remains unsolved, but we suppose that their result is questionable due to the complex reactions following the hydrogen chloride elimination.

Kinetic Study of the Penetration of an Anthraquinoid Acidic Dye into Cationic Micelles

Yuuji MIYASHITA* and Shigeo HAYANO
Institute of Industrial Science, The University of Tokyo,
7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received November 15, 1980)

The penetration of an anthraquinoid acidic dye into the micelle of a cationic surfactant, hexadecyltrimethylammonium bromide (HTAB), was studied kinetically by the stopped-flow method. The rate-determining step of this process was considered to be the dye reorientation from the micelle surface to its core. The apparent rate constants, k_{app}, of the dye penetration were determined by the first-order kinetics. The k_{app} values were a function of the surfactant micellar concentration. Above a certain micellar concentration (CMC) the k_{app} values become constant. The constant k_{app} was about 0.37—0.38 s^{-1} regardless of the total dye concentration. In the lower micellar concentration, there was a linear relationship between the k_{app} value and the number of the dye molecules which penetrated into a single micelle, n. This n was one of the factors which governed the dye penetration process.

Although the static properties of surfactant micelles, of their solubilization and of their interaction with organic compounds have been investigated extensively, only a few kinetic studies have been reported, probably due to the difficulty of measuring such rapid reactions. The development of modern techniques of analyzing fast reactions, such as the stopped-flow, the temperature-jump, the pressure-jump, and the ultrasonic relaxation methods, made it possible to discuss the kinetics of the micelle formation and dissociation.[1] Kinetic studies of the dye penetration into micelles have been reported recently.[2-4]

The micelles are in a dynamic equilibrium with themselves. The relaxation times obtained by the above techniques lead to the conclusion that there are at least two relaxation processes. The slower process is the micelle formation and dissociation, and its relaxation times are calculated to be about 10^{-2} s from the results of the temperature- and/or the pressure-jump experiments.[5] The faster one is the exchange of surfactant monomers between the aqueous and the micellar phases, and its relaxation times are estimated as 10^{-6} s by the ultrasonic relaxation method.[6] Since the micellization processes were faster than the dye penetration into micelles, these effects would be negligibly small in the kinetic study of the dye penetration.[2-4]

The kinetic studies of the dye penetration have been carried out by using ionic dyes with opposite charges to that of the surfactants, by the stopped-flow method.[2-4] In all cases, the apparent rate constants, which were calculated assuming a first-order reaction, increased with the increase in surfactant micellar concentration, and subsequently became constant. The mechanism at the lower micellar concentration was not discussed in detail, probably because of some complicated and unknown factors. In the region of constant k_{app} values, the mechanism was simplified, since these factors can be neglected. Thus, the discussions have been concentrated on this region.[7]

In the present paper, the rate constants of the penetration of an anthraquinoid acidic dye into cationic micelles were determined by measuring the change of dye absorbance, using the stopped-flow method. The main purpose is to develop a reasonable mechanism. The problem in the lower micellar concentration is discussed in detail, referring to the spectroscopic data[8] on the dye-surfactant system used in this study.

Experimental

Materials. Hexadecyltrimethylammonium bromide (HTAB), was obtained from Tokyo Kasei Industries Co. Ltd., and purified by recrystallizing from ethyl acetate containing 10 vol% ethanol and vacuum-drying at 80 °C. The CMC was determined to be 9.7×10^{-4} mol dm^{-3} by conductometry.

The dye, which was synthesized from the same process as used in a previous work,[4] has the structure shown in Fig. 1. The dye was paper-chromatographically pure, and the interaction among the dye molecules themselves was negligible spectrophotometrically in the concentration range used in this study.

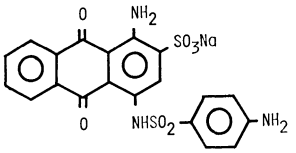

Fig. 1. Structure of an anthraquinoid acidic dye.

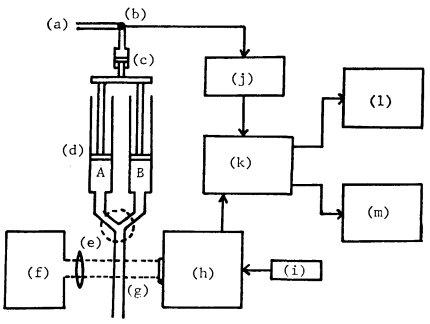

Fig. 2. Block diagram of RA-1100 and RA-108S systems.

Apparatus. The stopped-flow apparatus was a Fast Reaction Analyzer RA-1100 of Union Scientific Eng. Co. Ltd.. Its block diagram is shown in Fig. 2. The reagents were forced by a pressure of *ca.* 0.3 MPa into the optical cell, whose path was 10 mm, through a four-jet mixing cell. The mixing was established within 1 ms. The dye absorbance change at 547 nm against time was stored in the digital memory apparatus (RA-108S), and subsequently displayed on an oscilloscope or recorded on an X-Y recorder. During the experiment, the cell temperature was controlled by circulating water at 30±0.5 °C.

Methods. The sample syringes A and B were filled with a given concentration of dye solution and a certain concentration of the surfactant solution above CMC, respectively. The results were analyzed by first-order kinetics.

Results and Discussion

Some typical spectra of the dye in HTAB solution are shown in Fig. 3. The two characteristic bands at 510 and 547 nm are called α- and β-bands, respectively. The α-band appeared in absence of HTAB. In the presence of a sufficient amount of HTAB, the α-band changed to the β-band, indicating that dyes interacted with surfactants and/or micelles. The fact that the absorbance of both α- and β-bands increased in proportion to the dye concentration proved that there was no dye-dye interaction. The spectrum of the dye which had interacted with surfactants and/or micelles was similar to that the dye dissolved in methanol or acetone. These results lead to the inference that dyes are located in a methanol- or acetone-like atmosphere of the micelle core near the micellar surface. This is in agreement with the result of Sepulveda.[9]

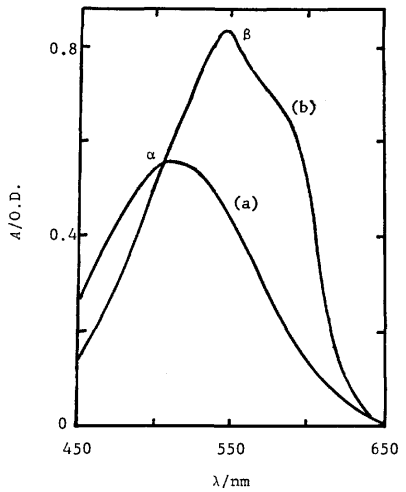

Fig. 3. Typical dye spectra.
(a) In absence of HTAB, (b) in presence of 10 mmol dm^{-3} of HTAB. The dye concentration is 0.1 mmol dm^{-3}.

Table 1. Mixing conditions and results

Run	A solution / mmol dm^{-3}	B solution / mmol dm^{-3}	Mixed solution / mmol dm^{-3}	Dynamic abs. change
1	Dye 0.2	Water	Dye 0.1	None
2	HTAB 20	Water	HTAB 10	None
3	Dye 0.2	HTAB 2	Dye 0.1 HTAB 1	Increase slightly
4	Dye 0.1 HTAB 1	HTAB 20	Dye 0.05 HTAB 10.5	Increase greatly
5	Dye 0.2	HTAB 20	Dye 0.1 HTAB 10	Increase greatly

After mixing solutions of dye and surfactant, the system was followed by the absorbance at 547 nm; the results are listed in Table 1. Then, the time scale for observation of absorbance change against time changed from 10 ms to 50 s in all the Runs. It was difficult to determine the rate constant in Run 3, since the absorbance change was very slight. On the contrary, appreciable changes were observed in Runs 4 and 5, and both the absorbance changes were nearly the same.

We have some data on the interaction between HTAB and the dye.[8] At first, the dye forms with HTAB an insoluble 1:1 salt (DS). The salt is resolved by further addition of HTAB below CMC, and the concentration of resolved salt is a linear function of that of HTAB. Thus, the authors assume that the dye forms a small complex with HTAB. The slope of the straight line shows that the complex consists of a single dye and three HTAB molecule. Moreover, the complex (DS_3) has similar spectroscopic characteristics, *i.e.* similar shape of the absorption curve and wavelength of maximum absorption (547 nm), to those of the dye which penetrated into micelles. Above CMC, the absorbance at 547 nm increases more intensively with the increase in the concentration of HTAB, and finally becomes constant. This absorbance is regarded to be caused by the dye penetration into the micelles. The magnitudes of the absorbances at 547 nm of both the complex below CMC and the dye which penetrated into micelles are proportional to the concentration of the dye, but the molar extinction coefficients are different, as shown in Table 2. The authors assume that the dye forms a complex with HTAB in the bulk of solution prior to the penetration in the mixing experiment. Consequently, the following sequence was proposed;

$$D + S \longrightarrow DS \longrightarrow DS_3 \longrightarrow D_m,$$

where D_m refers to the dye which penetrated into the micelles. Here, the process to forms DS_3 from DS would be very fast, because there exists a larger amount of DS_3 in Run 3 a short time after mixing. Accordingly, the process to form D_m from DS_3 will be the rate-determining step in the above sequence. If the dye penetration was established by the accu-

a) Ref. 8.

mulation of HTAB molecules around DS_3 (refers to the induced micellization),[2] the rate would be comparable to the micellization from the HTAB monomers. But, the relaxation in this study is much slower (about 10 s) than the micellization. A more reasonable model is though to be the adhesion of DS_3 to the micelle surface. At first, DS_3 diffuses onto the micelle surface, then the dye reorients into the inner hydrophobic portion of the micelle. The diffusion coefficient of DS_3 would be larger than that of HTAB micelle; it was estimated to be about 10^{-6} cm^2 s^{-1} by the polarographic measurements.[10] Thus, as the diffusion process of DS_3 onto the micelle surface is also expected to be fast, it is not the rate-determining step. On the micelle surface, HTAB molecules in DS_3 may be replaced by that in the micelle and in the bulk in a short time.[11] Therefore, the dye would be in the state of DS_3 or a naked state in a dynamic equilibrium. As a result, the reorientation mentioned above is the most probable rate-determining step. The previous work[4] showed that the salt addition accelerated the reaction, probably due to the reduction of the surface potential of the micelle, and it supports the above assumption. During the dye penetration, the momentary fluctuation in the physical properties of the micelle, such as the aggregation number, can be neglected, because the micelle equilibrates much faster than the dye penetration.[11]

A reformed sequence for evaluating the apparent rate constants is proposed:

$$DS_3 \rightleftharpoons D_s \underset{k'}{\overset{k}{\rightleftharpoons}} D_m,$$

where D_s, k, and k' refer to the dye which exists on the micelle surface in the state of DS_3 and/or a naked state, and to the rate constants of the forward and backward reactions, repectively. The authors postulate similar extinction coefficients for DS_3 in the bulk and D_s, since the atomosphere of the dye chromophore of D_s is not so different from that of DS_3. The rate equation is expressed as

$$-\frac{d[D_s]}{dt} = k[D_s] - k'[D_m]. \quad (1)$$

In the adsorption process prior to the dye reorientation it is assumed that the dye exists predominantly on the micelle surface and that $[DS_3]$ in the bulk is negligible; thus the equilibrium constant is expected to be about 10^4 according to the previous paper.[2] Since $[D_m]=[D]_0-[D_s]$, and $k[D_s]_e=k'\times[D_m]_e$ at equilibrium, Eq. 1 is converted to Eq. 2:

$$-\frac{d[D_s]}{dt} = \frac{[D]_0}{[D]_0-[D_s]_e} k([D_s]-[D_s]_e). \quad (2)$$

An integration of Eq. 2 with respect to time yields

$$\ln\frac{[D_s]-[D_s]_e}{[D]_0-[D_s]_e} = -\frac{[D]_0}{[D]_0-[D_s]_e} kt = -k_{app}t, \quad (3)$$

where $[D_s]$ and $[D_m]$ are the concentrations of the adsorbed dye on the micelle surface and of the dye penetrated into the micelle, respectively, and $[D]_0$ stands for the total concentration of the dye, and the subscript e refers to equilibrium.

Figure 4 shows the typical reaction curve. Absorbance increased with elapsed time, and subsequently flattened out. The total absorbance change (ΔA_0) is in proportion to the amount of the dye which penetrated into the micelle at equilibrium ($[D_m]_e$), and ΔA refers to that during the relaxation process ($[D_m]$). The subtraction of $\Delta A/\Delta A_0$ from unity yields

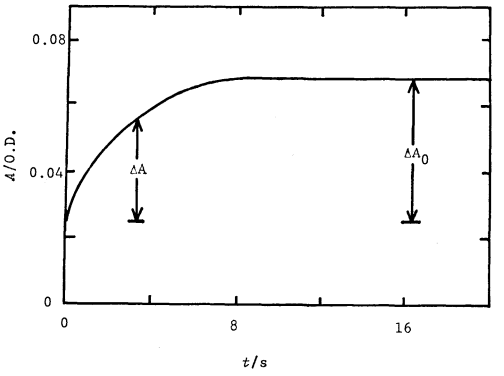

Fig. 4. Typical reaction curve.

$$1-\frac{\Delta A}{\Delta A_0} = 1-\frac{[D_m]}{[D_m]_e} = \frac{[D_s]-[D_s]_e}{[D]_0-[D_s]_e}. \quad (4)$$

Therefore, the logarithm of Eq. 4 is the same as the left-hand side of Eq. 3. The apparent rate constants, k_{app}, were calculated by Eqs. 3 and 4. The k_{app} values increased sharply with the increase in the surfactant concentration above CMC, and subsequently became constant, as shown in Fig. 5. The k_{app} had the same values regardless of the total dye concentration at high concentration of micellar surfactants.

At lower micellar concentration, some complicated factors may take part in the reaction. In papers by other workers,[2,3] there has been little explanation about the results obtained in this region. In our previous work, $[D_s]_e$ values were determined.[8] The k_{app} values were recalculated in consideration of $[D_s]_e$; these are connected by the dotted lines shown in Fig. 5. This treatment lowers k_{app} values to some extent, but no interesting result is obtained. Consequently, the $[D_s]_e$ values slightly affect k_{app} values.

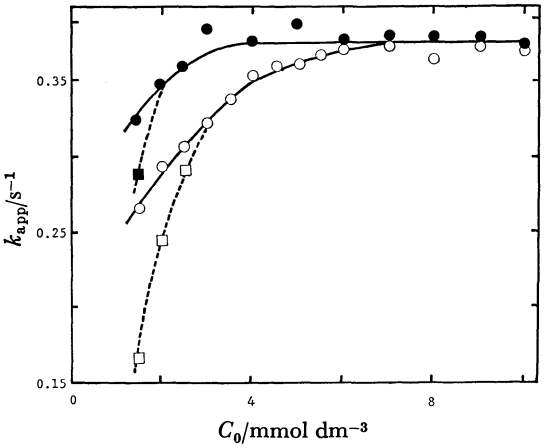

Fig. 5. Plots of k_{app} against HTAB concentration, $[C]_0$. ···●···: $[D]_0=0.05$ mmol dm^{-3}, ···○···: 0.1 mmol dm^{-3}. Recalculated k_{app} values in consideration of $[D_s]_e$ are connected by dotted line.

As one additional factor, the $[D_s]_e$ value induces the number of the dye molecules which penetrate into a single micelle, n. The n value shown in Fig. 6 was obtained use of the following equation:

$$n = \frac{N([D]_0 - [D_s]_e)}{[C]_0 - CMC}, \quad (5)$$

where N is the aggregation number of HTAB micelles,[1] and $[C]_0$ stands for the total HTAB concentration. The n decreased with the increase in the HTAB concentration until n attained unity. The n value is not actually less than unity even in the higher HTAB concentration, where there are micelles containing a single dye and those without dye. The

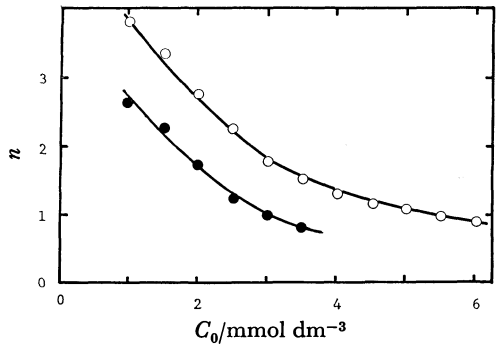

Fig. 6. Plots of the number of dye penetrated into a single micelle (n) *vs.* HTAB concentration, $[C]_0$. ···●···: $[D]_0$=0.05 mmol dm^{-3}, ···○···: 0.1 mmol dm^{-3}.

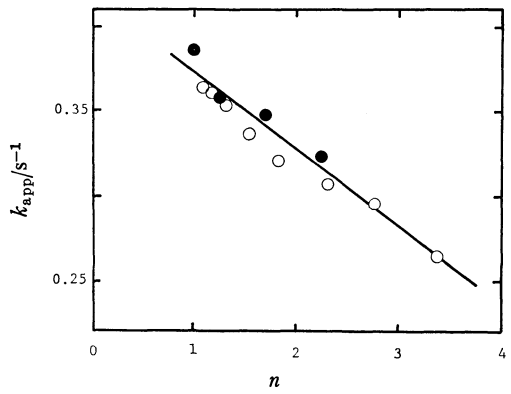

Fig. 7. Relation between k_{app} and n. ···●···: $[D]_0$=0.05 mmol dm^{-3}, ···○···: 0.1 mmol dm^{-3}.

k_{app} becomes constant at the same HTAB concentration for which n is unity. Moreover, in the lower HTAB concentration, there is a linear relationship between the k_{app} and the n value, as shown in Fig. 7. This suggests that the n value is one of the factors which govern the rate-determining step of the dye penetration. When n is unity, a single dye molecule reorients into a single micelle without any interaction with the other dyes. Then, the dye mortion seems to be dominated only by the dye structure and the properties of the micelle surface. When n values are more than unity, dyes on the surface of a single micelle reorient into its core slowly, since dyes are able to interact with each other directly and/or indirectly through the micellar surfactants. The increase in n value strengthens this interaction, and consequently the penetrating rates are further decelerated.

The dye penetration process consists of a number of elementary reactions. The inquiry into each reaction by other techniques will make it possible to gain more insight into the detailed mechanism.

We thank Dr. Noriko Shinozuka for her helpful discussions.

(Received February 7, 1981)

Molecular adsorptions of phenols and carboxylic acids on crosslinked poly(4-vinylpyridine) were studied in comparison with those on various polymeric adsorbents. Enthalpies for the adsorption of phenol on various polymeric adsorbents were evaluated based upon the temperature dependence of the phenol adsorption isotherms. The enthalpy on crosslinked poly(4-vinylpyridine) was close to that on porous poly(styrene-divinylbenzene) resin with no ion exchange functional group, and was much smaller than that on commercial weak base anion exchange resin. The relative adsorption capacities of various polymeric adsorbents for carboxylic acids and substituted phenols indicated that the acid-base interaction as well as hydrophobic interaction between these organic acids and crosslinked poly(4-vinylpyridine) was an important factor in the adsorption.

In previous papers of this series, crosslinked poly(vinylpyridine) was reported to be an excellent polymeric adsorbent for removal and recovery of phenol[1] and carboxylic acids[2] from aqueous solution. The capacities of crosslinked poly(vinylpyridine) for the adsorption of these organic acids were scarcely affected by the presence of inorganic salts. On the contrary, the capacities of commercial strong base and weak base anion exchange resins for the adsorption of these organic acids were conspicuously reduced in the presence of inorganic salts. Elution of the adsorbed organic acids from crosslinked poly(vinylpyridine) was easily accomplished by a simple treatment with organic solvents such as acetone and methanol, which was notably easier than those from anion exchange resins, and crosslinked poly(vinylpyridine) was efficiently regenerated. These observations showed that an ion exchange mechanism could not explain the adsorption of these organic acids by crosslinked poly(vinylpyridine). On the other hand, the capacities of crosslinked poly(vinylpyridine) for the adsorption of these organic acids were remarkably higher than those observed with porous poly(styrene-divinylbenzene) resin with no ion exchange functional group, in spite of the fact that the crosslinked poly(vinylpyridine) in the pulverized form was used. Therefore, a simple physical interaction between these organic acids and crosslinked poly(vinylpyridine) could not wholly explain the ability of the polymer for the adsorption of these organic acids. In this work, we have investigated the mechanism of the adsorption of phenol and carboxylic acids on crosslinked poly(vinylpyridine).

Experimental

Materials. Crosslinked poly(4-vinylpyridine) containing 72 mol% 4-vinylpyridine was prepared by a copolymerization of 4-vinylpyridine with divinylbenzene followed by griding and sifting to 60—80 mesh as was described previously.[1] The mean particle diameter was 0.20 mm in the wet state. For comparison, three commercial resins supplied by Rohm and Haas Co., Philadelphia, Pa., U. S. A., were used in this work. Amberlite IRA-400 was used as a strong base anion exchange resin, which had a styrene-divinylbenzene matrix with quarternary ammonium group. The particle size of this resin in the chloride form was 0.38—0.45 mm. This resin was used in the hydroxide form. Amberlite IRA-45 was used as a weak base anion exchange resin, which had a styrene-divinylbenzene matrix with primary, secondary, and tertiary amino groups. This resin was used in the free base form. The particle size was 0.36—0.46 mm. Amberlite XAD-4 was used as a porous poly(styrene-divinylbenzene) resin with no ion exchange functional group, which had a styrene-divinylbenzene matrix. The supplier claimed that the surface area of the resin was 784 m^2/g. These resins were preconditioned as was described previously.[1] Commercial products of phenol, *p*-cresol, *p*-nitrophenol, carboxylic acids, and other chemicals were used without further purification. Deionized water was used throughout the experiments.

Procedure. Column studies were conducted using a 1.0-cm diameter glass column with a fritted glass filter connected with a dropping funnel in a down-flow fashion at room temperature as was described in a previous paper.[1] The adsorption capacity of resins was evaluated in two ways: (i) the breakthrough capacity, which was based upon the total amount of adsorbed organic acids until the effluent concentration reached 1 mg dm^{-3} (in the adsorption of substituted phenols), or until the effluent solution became acidic using Methyl Red as the indicator (in the adsorption of carboxylic acids); (ii) the total capacity, which was based upon the total amount of adsorbed organic acids until the effluent concentration reached the influent concentration. The concentrations of phenol, *p*-cresol, and *p*-nitrophenol were determined based upon the adsorptivities at 275, 279, and 318 nm, respectively, or with aid of 4-aminoantipyrine[3] using a Shimadzu UV-200S, UV-100-01 or UV-100-02 spectrophotometer. The concentrations of carboxylic acids were determined by titration with a standard 0.1 mol dm^{-3} sodium hydroxide solution using phenolphthalein as the indicator.

Equilibrium adsorption tests were conducted by placing weighed quantities of polymeric adsorbent and samples of aqueous solution of organic acids in a 300-cm^3 Erlenmeyer flask sealed by a rubber stopper with magnetic stirring at the prescribed temperature. After the mixture reached equilibrium, the concentration of organic acids was determined.

Results and Discussion

Enthalpies for Phenol Adsorption. The experimental isotherms of phenol adsorption on crosslinked poly(4-vinylpyridine), porous poly(styrene-divinylbenzene) resin with no ion exchange functional group (Amberlite XAD-4), and weak base anion exchange resin in the free base form (Amberlite IRA-45) are shown in Figs. 1, 2, and 3, respectively. The linear relationship of Figs. 1, 2, and 3 indicates that the adsorption isotherms of phenol on these polymeric adsorbents follow the Freundlich equation. The type of adsorption of phenol on crosslinked poly(4-vinylpyridine) appears to be not unusual but commonly observed in most of liquid-phase adsorptions. The temperature dependence of isotherms was large in the adsorption of phenol on weak base anion exchange resin in the free base form (Fig. 3), when compared with that on crosslinked poly(4-vinylpyridine) (Fig. 1) and that on porous poly(styrene-divinylbenzene) resin with no ion exchange functional group (Fig. 2).

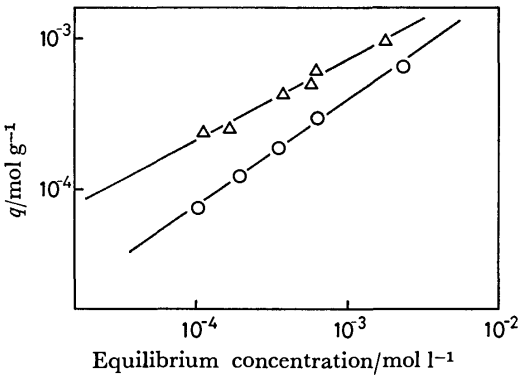

Fig. 3. Phenol adsorption isotherms on weak base anion exchange resin (Amberlite IRA-45) in the free base form.
△: 20 °C, ○: 50 °C.

In order to evaluate the temperature dependence of isotherms more quantitatively, we calculated the enthalpies for phenol adsorption on these three polymeric adsorbents. The enthalpy of adsorption on polymeric adsorbents is generally calculated from isotherms for adsorptions at two different temperatures by use of the following relationship:[4]

$$\Delta H^0 = \frac{2.303RT_1T_2}{T_2-T_1}(\log C_1 - \log C_2).$$

Here, ΔH^0 is the enthalpy of adsorption, R is the gas constant, C_1 and C_2 are the equilibrium concentrations of solute in moles per liter at the absolute temperatures T_1 and T_2, respectively. Enthalpies of phenol adsorption were calculated based upon the isotherms at 20 and 50 °C. The enthalpy of adsorption calculated by use of the above relationship depends upon the value of q, which is the number of moles of solute adsorbed per gram of dry adsorbent, and we calculated the enthalpy at four different values of q. Results are given in Table 1.

The enthalpy of phenol adsorption on weak base anion exchange resin (IRA-45) was large, and that on crosslinked poly(4-vinylpyridine) was close to that on porous poly(styrene-divinylbenzene) resin with no ion exchange functional group. These results show that the adsorption of phenol on crosslinked poly(4-

vinylpyridine) occurs through a different mechanism from that on anion exchange resin, and that the adsorption is rather close to physical adsorption.

Capacities for the Adsorption of Carboxylic Acids. Column studies were also performed in order to obtain detailed information concerning the nature and mechanism of the adsorption of phenol and carboxylic acids on crosslinked poly(4-vinylpyridine). Since the crosslinked poly(4-vinylpyridine) was developed as a polymeric adsorbent for removal and recovery of organic pollutants from waste water, the column studies were much more important and practical than the studies of adsorption equilibrium for this purpose. Relative adsorption capacities of these organic acids on the polymeric adsorbents were compared.

Effects of two factors, *i.e.*, hydrophobic interaction and acid-base or electrostatic interaction between the polymeric adsorbents and the organic acids, were evaluated on the basis of the relative adsorption capacites. The hydrophobic interaction between the polymeric adsorbents and the organic acids were evaluated in terms of the effect of the length of hydrocarbon chain. The acid-base or electrostatic interaction between the polymeric adsorbents and the organic acids were evaluated in terms of the effect of pK_a of the organic acids.

Breakthrough and total capacities of polymeric adsorbents for the adsorption of various carboxylic acids were determined by the continuous flow column method. In Table 2 are given the capacities of the porous poly(styrene-divinylbenzene) resin with no ion exchange functional group (Amberlite XAD-4). The adsorption capacity increased with the hydrocarbon chain length of the carboxylic acid, *i.e.*, in the order: formic < acetic < propionic < butyric < valeric acid. Similar tendency has been reported in the adsorption of carboxylic acids on a porous poly(styrene-divinylbenzene) resin,[5] although the results were obtained using the batch method.

The acidity of carboxylic acid did not affect significantly the adsorption capacity. For example, the adsorption capacities for valeric acid were 20—30 times larger than those for acetic acid, although pK_a values of these carboxylic acids are similar in magnitude. The adsorption capacities for formic and trifluoroacetic acid were much smaller than those for butyric and valeric acid, although the former carboxylic acids are more acidic.

In order to obtain a quantitative information about the effect of the structure of carboxylic acid on the adsorption capacity of the resin, the logarithm of the adsorption capacity was plotted against the number of carbon atoms in the carboxylic acid. The result is shown in Fig. 4. The straight line in Fig. 4 indicates that the logarithm of the adsorption capacity varies in proportion to the number of carbon atoms of the carboxylic acid.

It is widely held that the standard free energy change for transfer of hydrocarbon chains from aqueous solution to other phase varies in proportion to the num-

ber of carbon atoms.[6] For example, the standard free energy change for transfer of hydrocarbons from aqueous solution to pure liquid hydrocarbon was shown to be a linear function of the length of the hydrocarbon chain.[6,7] The free energy change for transfer of undissociated fatty acids from a dilute aqueous buffer solution to liquid heptane was also found to be proportional to the number of carbon atoms.[6,8] These relationships were explained in terms of hydrophobic interactions of the hydrocarbon chain.

The adsorption capacity obtained in column studies depends upon the diameter of the column, the flow rate, and other experimental factors. However, such factors were almost constant throughout the present study. Therefore, the relative adsorption capacity may closely relate to the thermodynamic adsorption equilibrium constant and its logarithm may correlate to the free energy change of transfer of a carboxylic acid from aqueous solution to the resin. The straight line in Fig. 4 suggests that such free energy change varies in proportion to the number of carbon atoms in the carboxylic acid.

On the basis of these arguments, it is reasonably considered that hydrophobic interactions between the hydrocarbon chain of the carboxylic acid and the resin matrix are responsible for the increase in adsorption capacity with the chain length of the carboxylic acid.

In Tables 3 and 4 are given the capacities of the weak base anion exchange resin (Amberlite IRA-45) in the free base form and those of strong base anion exchange resin (Amberlite IRA-400) in the hydroxide form for the adsorption of carboxylic acids. The adsorption capacities were not significantly affected by the chain length of the carboxylic acid. However, the adsorption capacities decreased with an increase in pK_a of the carboxylic acid. Thus, it was felt that the ion exchange or acid-base interaction between the carboxylic acid and the resin played an important role in the adsorption of carboxylic acid on these anion exchange resins.

In Table 5 are given the capacities of crosslinked poly(4-vinylpyridine) for the adsorption of carboxylic acids. The adsorption capacity for a series of saturated aliphatic carboxylic acids increased in the order: acetic<propionic<butyric<valeric acid. However, pK_a values indicate the similar acidity of these carboxylic acids. The relation between the logarithm of the adsorption capacity and the number of carbon atoms of the carboxylic acid is shown in Fig. 5. The figure shows a linear relationship for this series of saturated aliphatic carboxylic acids of similar pK_a. Therefore, hydrophobic interaction between the hydrocarbon chain of the carboxylic acid and the resin matrix seems to play an important role in the adsorption on the crosslinked poly(4-vinylpyridine).

Crosslinked poly(4-vinylpyridine) containing 72 mol% 4-vinylpyridine in the pulverized form was used as the adsorbent. b) See footnote (b) in Table 2. c) See footnote (c) in Table 2.

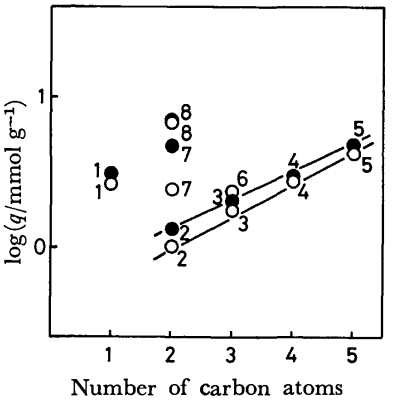

Fig. 5. Capacities of crosslinked poly(4-vinylpyridine) containing 72 mol% 4-vinylpyridine for the adsorption of carboxylic acids as a function of the number of carbon atoms of the carboxylic acids.
●: Total adsorption capacity, ○: breakthrough capacity. 1: HCOOH, 2: CH_3COOH, 3: CH_3CH_2COOH, 4: $CH_3(CH_2)_2COOH$, 5: $CH_3(CH_2)_3COOH$, 6: CH_2=CHCOOH, 7: $ClCH_2COOH$, 8: CF_3COOH.

However, marked deviations from the linear relationship of Fig. 5 were observed for formic acid (1), chloroacetic acid (7), and trifluoroacetic acid (8), in contrast to the relation shown in Fig. 4 for the adsorption on porous poly(styrene-divinylbenzene) resin with no ion exchange functional group. These carboxylic acids have much lower pK_a values than those of the saturated aliphatic carboxylic acids mentioned above. The effect of acidity on the capacity of crosslinked poly(4-vinylpyridine) for the adsorption of carboxylic acids is also demonstrated by a tendency that the adsorption capacity increased with the acidity in a series acetic<chloroacetic<trifluoroacetic acid. The larger capacity for the adsorption of acrylic acid than that for propionic acid can also be attributed to the difference in acidity of these carboxylic acids, since both of these carboxylic acids have a similar chain length. The larger adsorption capacity for formic acid than that for acetic acid cannot be explained in terms of the hydrophobic interaction, since such interaction seems to be smaller in the adsorption of formic acid as can be seen in Fig. 4. Higher acidity of formic acid may be responsible for the larger adsorption capacity. These observations clearly indicate the importance of acidity of the carboxylic acid in the adsorption on crosslinked poly(4-vinylpyridine). However, as was reported previously,[1,2] ion exchange mechanism does not appear to be suitable for the adsorption of phenol or carboxylic acids on crosslinked poly(4-vinylpyridine). Thus, the effect of acidity on the above adsorption capacity may be ascribable to the contribution of the acid-base interaction between the pyridyl group of the crosslinked poly(vinylpyridine) and the carboxyl group of the carboxylic acid. Because pyridine is an organic base, it is reasonable to consider the following interaction, where the pyridyl group of the resin uptakes a proton from the carboxylic acid to form a complex with the carboxylate anion as the associated counterion:

The formation of hydrogen bond may also contribute to the interaction between the pyridyl group and the carboxylic acid:

Such acid-base interactions may increase with acidity of carboxylic acid, and may be responsible for the remarkably higher capacity of the crosslinked poly(vinylpyridine) for the adsorption of carboxylic acid than that of the resin with no ion exchange functional group as Amberlite XAD-4.

Capacities for the Adsorption of Substituted Phenols. Breakthrough capacities of polymeric adsorbents for the adsorption of substituted phenols were also determined by the continuous flow column method. Results are given in Table 6.

Adsorption capacities of the porous poly(styrene-divinylbenzene) resin with no ion exchange functional group (XAD-4) for substituted phenols were in the order: *p*-nitrophenol ≈ phenol < *p*-cresol. The larger adsorption capacity for *p*-cresol than that for phenol may be attributed to the higher hydrophobicity

TABLE 6. BREAKTHROUGH CAPACITIES OF POLYMERIC ADSORBENTS FOR THE ADSORPTION OF SUBSTITUTED PHENOLS FROM AQUEOUS SOLUTION[a)]

Substituted phenol	pK_a	Breakthrough capacity mmol g^{-1} [b)]		
		XAD-4[c)]	IRA-45[d)]	PVP[e)]
p-Cresol	10.26 (25 °C)	2.41	2.38	3.88
Phenol	10.00 (20 °C)	1.59	2.89	2.93
p-Nitrophenol	7.15 (25 °C)	1.58	3.60	5.39

a) Determined by the continuous flow column method using 35 mmol dm^{-3} aqueous solution of substituted phenols. The flow rate was 3 bed volumes per hour. b) The total amount of adsorbed phenols before the effluent concentration reached 1 mg dm^{-3}. c) See footnote (b) in Table 1. d) See footnote (c) in Table 1. e) See footnote (a) in Table 1.

of *p*-cresol. The capacity for *p*-nitrophenol adsorption was close to that for phenol adsorption in spite of large difference in pK_a of the two phenols. This result implies that the acidity of phenolic hydroxyl group did not significantly affect the adsorption capacity. In contrast, the adsorption capacity of weak base anion exchange resin (IRA-45) in the free base form for substituted phenols was in the order: *p*-cresol < phenol < *p*-nitrophenol. Thus, the adsorption capacity increased with the acidity of adsorbate in this case. This result suggests the importance of the ion exchange or acid-base interaction between the substituted phenols and the resin.

In the adsorption on crosslinked poly(4-vinylpyridine), the capacity for *p*-cresol adsorption was higher than that for phenol adsorption. This fact may be explained in terms of higher hydrophobicity of the former adsorbate. Adsorption capacity for *p*-nitrophenol was also higher than that for phenol. Higher acidity of *p*-nitrophenol than that of phenol seems to be responsible for this result. These observations may suggest that both hydrophobic interaction and acid-base interaction played important roles in the adsorption of substituted phenols on crosslinked poly(4-vinylpyridine) as well as in the adsorption of carboxylic acids.

This work was supported in part by a Grant-in-Aid for Scientific Research No. 503042 from the Ministry of Education, Science and Culture.

Nature of Acid Sites on TiO_2, and Their Reactions with OH and NH_2 Groups of 3-Amino-1-propanol, 1-Propanol, and 1-Propylamine

Toshinori KANTOH and Susumu OKAZAKI*

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Nakanarusawa, Hitachi 316

(Received February 19, 1981)

The IR spectra for pyridine adsorbed on the surfaces of TiO_2 (SA) (anatase type), prepared from titanium tetraisopropoxide, showed the existence of only Lewis acid sites which were not converted to the Brönsted type by the addition of water. However, TiO_2 (SB) (anatase type), prepared by the hydrolysis of titanium oxide sulfate, showed both Lewis and Brönsted acidities. The Lewis acidity of SB was converted to the Brönsted type by the introduction of water vapor. The 3-amino-1-propanol compound interacted with both Lewis and Brönsted acid sites on the TiO_2 surfaces in a manner similar to propylamine rather than to 1-propanol. However, in the case of SA, interactions between OH groups of the amino alcohol and surface OH groups seemed to take place to some extent. The mode of the surface reaction of TiO_2 differes markedly from that of SiO_2 which has no surface acidity. A linear relationship between the amount of surface OH groups on SB and the amount of the reaction of 3-amino-1-propanol at 235 °C in an autoclave was observed. The formation of oriented and closely packed layers of adsorbed molecules was observed for all the combination of SB and 3-amino-1-propanol, in which some condensation (mainly dimerization) seemed to be promoted by acid sites on SB.

Recently, the acid-base properties of the TiO_2 surfaces have become the object of practical attention because of their wide use for catalysts[1] and ion exchangers.[2] Accordingly, extensive studies of the reactivity of TiO_2 surfaces have been carried out to learn their specific properties.[3] It has been shown that hydroxyl groups and metal ions on the TiO_2 surfaces are active sites for chemisorption, and the interactions of these sites with alcohol[4,5] and amines[6] have been studied. However, the reactions of amino alcohols with the TiO_2 surfaces have not been investigated. It would be of great interest to know which of the groups, OH or NH_2, interact preferentially with active sites on the TiO_2 surfaces. Furtheremore, it is worthwhile to clarify the difference in mode of interaction between an amino alcohol with two functional groups and an alkylamines or alcohol, each of which has a single functional group.

In the present investigation, the interactions of OH and NH_2 groups in 3-amino-1-propanol with the surfaces of TiO_2 were studied by comparing the infrared spectra of the adsorbed molecules with those of 1-propanol and propylamine. The infrared spectra of pyridine adsorbed on TiO_2 were first examined in order to know the nature of acid sites which would interact with NH_2 or OH groups in organic reagents. For a further study of the reactivities of OH and NH_2 groups, the reactions of 3-amino-1-propanol, 1-propanol, and propylamine with TiO_2 surfaces were carried out in an autoclave. The reactions of other amino alcohols with various types of structures were also tested for comparative purposes.

Experimental

Materials. The TiO_2 samples were used to see the effect of the solid acidity on the surface reaction. The first of the samples was prepared by the hydrolysis of titanium tetraisopropoxide (Wako Pure Chemical Co.), followed by repeated washing with deionized water. The product contained no significant traces of sulfate or chloride ions. The sample was designated as SA. The other sample (SB) was prepared using an intermediate product from the sulfuric acid process, supplied by the Sakai Chemical Co. Even after repeated washing with deionized water, SB has a considerable amount of combined sulfate ions, possibly in the form of titanium oxide sulfate. Before use, both SA and SB were heat-treated at 500 °C for 3 h. The X-ray analysis showed that both crystalline forms of SA and SB are anatase after the heat-treatment.

The organic reagents used were of a special or reagent grade from the Wako Pure Chemical Co. The propylamine was dried over solid KOH, and the other reagents, over 4A molecular sieve. Immediately before adsorption, the reagents were purified by repeating a freeze-pump-thaw cycles. The water used was distilled from an aqueous solution of $KMnO_4$.

IR Absorption Experiment. The infrared spectra of the organic reagents adsorbed on TiO_2 were measured in an *in situ* cell equipped with NaCl windows. The TiO_2 samples were ground and fabricated into discs of 20 mm in diameter. The discs were heat-treated at 500 °C before insertion in the cell. Immediately before adsorption, the discs were further treated at 250 °C for 12 more hours under evacuation at pressure of 10^{-4} mmHg.† Oxygen treatment was done by introducing O_2 into the cell, followed by heat-treatment at 250 °C for 0.5 h to burn out any organic contaminants on the TiO_2 surface. Adsorption was carried out by bringing the saturated vapor of organic reagents into contact with the TiO_2 in the cell for 0.5 h at room temperature or at 250 °C. The infrared spectra were measured after evacuation at 120 °C for 0.5 h and then cooling to room temperature. IR transmission through SA was almost zero in the wavenumber range from 2800 to 4000 cm^{-1}, probably because of the reflection of the rays due to the large particle size of the TiO_2 sample. Therefore, the infrared spectra were measured in the range below 1750 cm^{-1}, since most of the essential bands for this study are in the lower-wavenumber region.

Reaction Procedure. SA or SB (5 g) was treated with a large excess of organic reagents (about 100 m mol) diluted with hexane (30 ml) in an autoclave having a volume of 100 ml. The reactions were carried out for 1 h at 235 °C (the critical temperature of hexane) with vigorous stirring. The products were washed with hexane and then with acetone, followed by drying under evacuation at about 100 °C.

Chemical Analysis, DTA, TG, and Measurements of Surface Area and Acid-Base Amount. The carbon and nitrogen

† 1 mmHg ≈ 133.322 Pa.

contents of the products were determined by the Pregl-Dumas method.[7] The specific surface areas were determined by the BET method using N_2 at −195 °C. The solid acidities were determined by titration with butylamine, using Methyl Red ($pK_a = +4.8$) as the indicator.[8] The amount of surface OH groups was determined by a modification of Boehm's method[9]. To ascertain the thermal-decomposition or decomposition temperature, DTA and TG were carried out using a Thermoflex (Rigaku Denki Co.) by heating the sample (20 mg) at a rate of 5 °C/min in an air flow.

Results and Discussion

Crystal Forms, SO_4^{2-} Content, and Surface Properties of Samples. As is shown in Table 1, the surface areas and amounts of the surface OH groups of SB were close to those of SA when both samples were treated at 500 °C. However, the acid amount on SB was more than ten times that on SA. The large acidity of SB is probably due to sulfate ions which diffused to the surface during the heat treatment.[10] The crystal forms of SA and SB were both anatase, and SB contained a considerable amount of sulfate ions.

IR Spectra of Pyridine Adsorbed on TiO_2. The infrared spectra of pyridine adsorbed on SA evacuated at room temperature showed adsorption bands at 1145, 1220, 1442, 1485, 1575, and 1603 cm^{-1} (Fig. 1b). Except for the band at 1142 cm^{-1} the bands almost coincide with those observed on rutile by Parfitt *et al.*[11] and are assignable to Lewis-acid sites. Unlike the other bands, the band at 1145 cm^{-1} became appreciably weaker under evacuation at 250 °C. Taking into account the fact that a weak shoulder at about 1140 cm^{-1} was assigned to weakly coordinated pyridine,[11] this band at 1142 cm^{-1} may also be attributable to weak Lewis acid sites. The band is clearly detectable in this study because the sample (anatase type) was heat-treated at a temperature not so high as the rutile. On exposure to water at room temperature, the bands attributed to Lewis acid sites became weaker, but the bands characteristic of Brönsted acid sites such as that at 1540 cm^{-1} [12] did not become apparent. These facts indicate that there is no conversion of Lewis acid to Börnsted acid with the addition of water to SA, much as with the result observed when water was added to the rutile sample.[11]

On the other hand, the spectra of pyridine adsorbed on SB showed an absorption band at 1537 cm^{-1} besides the bands attributed to Lewis-acid sites at 1445 and 1575 cm^{-1} (Fig. 2). The band at 1537 cm^{-1} may be taken as the principal band due to Brönsted acid sites.[13] Upon heating up to 250 °C, this band became considerably weaker in contrast to that of the band characteristic of Lewis acid sites at 1575 cm^{-1}, which became more distinct. With the addition of water vapor, the band due to Lewis acid sites almost disappeared, while the bands due to Brönsted acid sites became more prominent. Such a conversion of Lewis to Brönsted acid sites occasioned by the addition of water vapor has also been observed for other metal oxides[12] and for SiO_2–Al_2O_3,[13] but it was not observed in the case of SA, as has just been described. The band at 1375 cm^{-1} observed in the spectrum of SB is ascribed to –O–SO_2–O– groups, which should be found at 1330—1450 cm^{-1}.[14] The

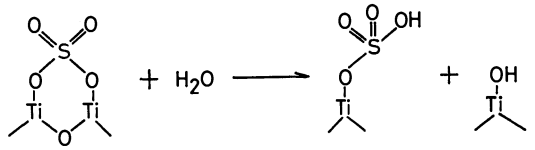
groups may withdraw electrons from adjacent OH groups and make them Brönsted acids. Upon the addition of water vapor, the band at 1375 cm^{-1} was noticeably shifted to a lower-wave number region. Since the absorption bands due to $-SO_3H$ groups should be generally found at 1150—1260 cm^{-1},[14] the –O–S–O– bond on the surface might be broken by the attack of water, as is shown below;



Also, this conversion, accompanied by the addition of water, should contribute to an increase in the Brönsted acidity.

IR Spectra of 3-Amino-1-propanol, 1-Propanol, and Propylamine Which Were Adsorbed on TiO_2. The spectra of 3-amino-1-propanol adsorbed on SA are given in Fig. 3. The spectra of 1-propanol and propylamine are given in Figs. 4 and 5 respectively for comparative purposes. The band at about 1600 cm^{-1} in the spectrum of liquid 3-amino-1-propanol (shown by Fig. 3, curve(d)) is shifted to near 1580 cm^{-1} (curves (b) and (c)) by the adsorption. Such a shift is also seen in the spectra of propylamine adsorbed on SA. Since a similar shift has been observed in the infrared spectrum of methylamine on alumina,[15] which is a typical Lewis acid, the band-shift observed here is considered to be due to the coordination of unshared electron pairs on the N atoms with Lewis acid sites or with exposed Ti ions on the surface. The shoulder at about 1650 cm^{-1} due to C=C bands in the spectra of 1-propanol adsorbed on SA (shown in Fig. 4, curves (b) and (c)) is not observed in the spectra of adsorbed 3-amino-1-propanol (Fig. 3). This fact indicates that the β-elimination of H_2O or NH_3 from the adsorbed molecules seems improbable for 3-amino-1-propanol.

Unlike the spectra of propylamine adsorbed on SA, three absorption bands, at about 1430, 1390, and 1245 cm^{-1}, are found in the spectra of the amino alcohol adsorbed on SA, and they become more marked on heating to 250 °C. The first band is also found in the spectrum of free amino alcohol (Fig. 3, curve (d)). The second band can be assigned to the C–O bond in titanium alkoxide by reference to the observation that a strong band has been found at 1385 cm^{-1} in the spectrum of aluminium ethoxide and in that of ethanol adsorbed on alumina.[16] The last band, at about 1245 cm^{-1}, was not found in the spectra of 1-propanol and propylamine, which were adsorbed on TiO_2 (SA and SB). The band is in the range of bands due to C–O stretching vibration (1000—1300 cm^{-1} [17]) and is especially assignable to the epoxy ring (strong absorption, near 1250 cm^{-1} [18]). The band in the C–N stretching vibration region (1120—1150 cm^{-1}) is broader and is shifted to a range lower than that found in the spectrum of propylamine adsorbed on SA at 250 °C. (Fig. 5(c)). Thus, it is

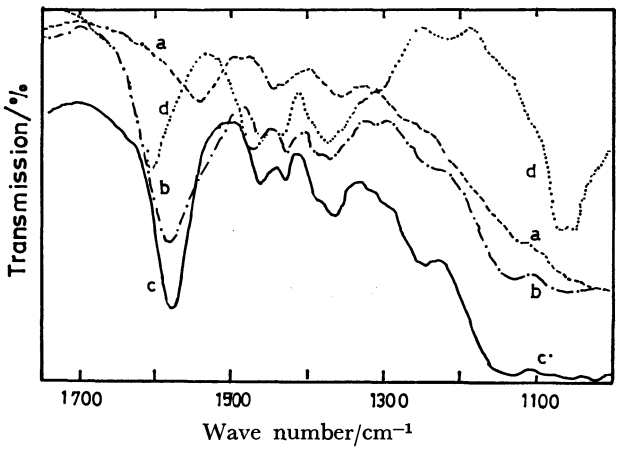

Fig. 3. IR spectra of 3-amino-1-propanol adsorbed on SA.
(a) Initial surface, (b) exposed to 3-amino-1-propanol at room temperature, (c) heated with 3-amino-1-propanol vapor at 250 °C, evacuated at 120 °C, (d) spectrum of 3-amino-1-propanol (liquid).

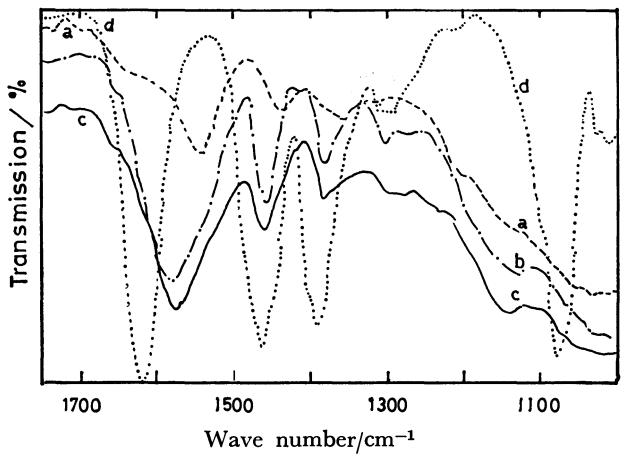

Fig. 5. IR spectra of 1-propylamine adsorbed on SA.
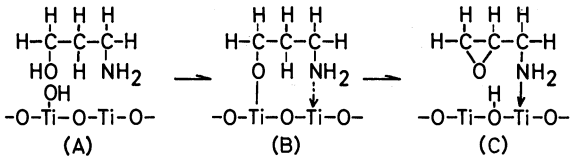
(a) Initial surface, (b) exposed to 1-propylamine at room temperature, evacuated at room temperature, (c) heated with 1-propylamine vapor at 250 °C, evacuated at 120 °C, (d) 1-propylamine (gas).

probable, although not certain, that, besides the N atom, the OH group of the amino alcohol may also participate in the surface reaction to some extent. Thus, the following reaction scheme is conceivable:



Here, the β-hydrogen atom in the (B) structure may become acidic as a result of the withdrawal of electrons by the surface Ti ion through the O atom, thus forming the OH group shown in (C) structure. The molecule formed on the TiO_2 surface may be adsorbed through the bond resulting from the coordination of the free electrons of the N atoms to the Ti ion, as is shown in the structure.

The infrared spectra of 3-amino-1-propanol, 1-propanol, and propylamine, which were all adsorbed on SB, are shown in Figs. 6, 7, and 8 respectively. As the 3-amino-1-propanol was adsorbed on SB, absorption bands at 1605 and 1510 cm^{-1} became observable. These are assigned to assymetric NH_3^+ (1560—1625 cm^{-1}) and symmetric NH_3^+ (1505—1550 cm^{-1} respectively.[19] The bands also show that Brönsted acid sites on TiO_2 probably take part in the surface reaction with the amino alcohol. The participation of Brönsted acid sites was observed in the interaction of propylamine with the SB surface at 250 °C (Fig. 8, curve(C)). However, when SB was heated up to 250 °C together with the amino alcohol, the bands due to NH_3^+ almost disappeared (Fig. 6(c)), while the band at about 1590 cm^{-1} related to the coordination bond between the Ti ion and the NH_2 groups became distinct with the heat-treatment. Such a change in the spectra indicates that the interaction of NH_2 groups with Lewis acid sites became predominant at higher temperature because of the decrease in the amount of OH groups, which may be Brönsted acid sites, as a result of dehydration. As is clear from the spectrum of the amino alcohol adsorbed on SA at 250 °C, there are no absorption bands which indicate the formation of C–O bonds. This suggests that the amino alcohol may interact with the SB surface mainly through the NH_2 groups.

Infrared spectroscopic studies of the reaction of 3-smino-1-propanol with SiO_2 surfaces have shown that free silanol reacted with alcoholic hydroxyl groups, while the NH_2 groups of the amino alcohol interacted only partially through hydrogen bonding.[20] The large difference in the mode of surface reaction between TiO_2 and SiO_2 may be due to the difference in the surface acidity. That is, the cation electronegativity

Table 2. Reactivity of TiO_2 to various reagents and decomposition temperatures of the products

Sample	Regent	Content in product wt% C	Content in product wt% N	Degree of reaction: Molecules per 100 Å² of surface calculated from content of C	Degree of reaction: Molecules per 100 Å² of surface calculated from content of N	Decomposition temperature °C: Beginning	Decomposition temperature °C: Active
SA	$CH_3(CH_2)_3OH$	2.67	0	4.9	—	140	240
	$CH_3(CH_2)_3NH_2$	2.20	0.94	4.0	4.4	160	240
	$HO(CH_2)_3NH_2$	2.67	0.99	5.0	4.7	150	230
SB	$CH_3(CH_2)_3OH$	2.54	0	4.8	—	190	260
	$CH_3(CH_2)_3NH_2$	2.45	1.12	4.6	5.4	210	255
	$HO(CH_2)_3NH_2$	3.86	1.52	7.5	7.7	180	260

of Ti^{4+} is much larger than that of Si^{4+};[21] the OH groups bound to Ti^{4+} are acidic in nature, unlike those bound to Si^{4+}, and so readily interact with NH_2 groups in the amino alcohol, resulting in the formation of NH_3^+ groups. In addition, Ti^{4+} also functions as a Lewis acid site, and the Lewis acidity should also make the reactivity of the TiO_2 surfaces higher than that of SiO_2. On the other hand, SiO_2 which has essentially no surface acidity,[22] forms only an ester due to the reaction of the silanol with the alcoholic OH groups of the amino alcohol.[20]

Comparison of the Reaction of 3-Amino-1-propanol with Those of 1-Propanol and Propylamine at Higher Temperatures in an Autoclave. Table 2 shows the results of the reactions for SA and SB. The degree of reaction was calculated on the assumption that there were no C–C bond scissions during the reaction. Except for the reaction between 3-amino-1-propanol and SB, the degree of the reaction was roughly the same for all the reactions; thus, the OH and NH_2 groups of the reagents appeared to have the same reactivity toward TiO_2 under the reaction conditions tried here. In addition, as is shown at the right end of Table 2, the temperatures at which the desorption or decomposition takes place actively were nearly the same for 3-amino-1-propanol, 1-propanol, and propylamine as long as they are adsorbed on the TiO_2 sample (SA or SB). Thus, the resistivity against heating of the adsorbed phase is considered not to differ much from reagent to reagent.

The degree of reaction per unit of surface area is calculated to be 4—5 molecules/100 Å² of the TiO_2 surface (Table 2). The areas occupied by one molecule of the reagents (20—25 Å²) nearly equal those occupied by normal alkylamine (20.5 Å²) and normal alkanols (21.6 Å²) in a unimolecular layer on water.[23] This fact suggests the formation of oriented and close-packed alkyl groups on TiO_2 surfaces. The exceptionally small value of the area occupied by 3-amino-1-propanol on SB (13 Å²) may be due to the condensation (mainly, dimerization) of the amino alcohol on the surface. The intermolecular reaction of the amino alcohol due to the OH and NH_2 groups is probably promoted by the acid sites on SB.

Effect of Surface OH Groups on the Reactivity of TiO_2 (SB). Figure 9 shows a plot of the amount of the reaction of 3-amino-1-propanol *vs.* the amount of surface OH groups on SB treated at various temperatures. Except for SB heat-treated at 300 °C, at which SB exists not as TiO_2 but as titanium hydroxide or hydrate of TiO_2,[24] a linear relationship is observed between the two amounts. From the slope of the straight line, the ratio of the amount of the reaction to that of the surface OH groups is determined to

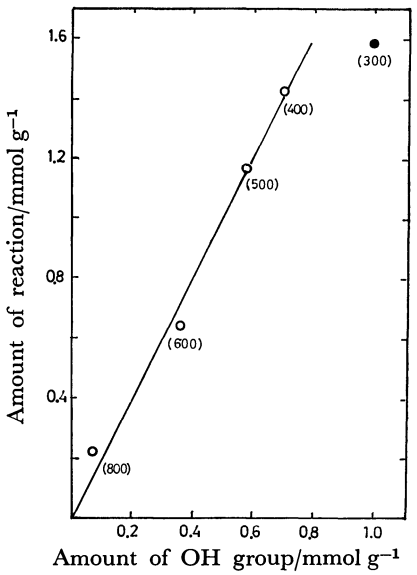

Fig. 9. Relationship between amount of reaction and that of surface OH groups on SB.
The numbers in parentheses show the heat-treatment temperature (centigrade) of the TiO_2 sample.

Table 3. Reactions of various aminoalcohols with TiO_2[a]

Sample	Aminoalcohol	Carbon content in products wt%	Density of organic groups: Number per 100Å² of surface
SA	$HO(CH_2)_2NH_2$	1.82	5.0
	$HO(CH_2)_2$ >NH $HO(CH_2)_2$	2.58	3.6
	$HO(CH_2)_2$ \ $HO(CH_2)_2$–N $HO(CH_2)_2$ /	3.29	3.1
SB	$HO(CH_2)_2NH_2$	3.98	12.0
	$HO(CH_2)_2$ >NH $HO(CH_2)_2$	6.59	10.4
	$HO(CH_2)_2$ \ $HO(CH_2)_2$–N $HO(CH_2)_2$ /	12.04	14.4

a) Preheated at 500 °C just before use.

be about 2. These facts show that NH_2 groups of the amino alcohol should react with surface OH groups on SB at a higher temperature under an autogeneous pressure, and that the amino alcohol may dimerize due to the NH_2 and/or OH groups of the molecules. The H_2O molecules generated by the dimerization or condensation may convert the Lewis acid sites on SB to Brönsted acid sites or acidic OH groups as was previously been observed in the IR study of pyridine adsorption.

Effect of Structure of Amino Alcohol on Reaction with TiO_2 Surfaces. The results of the surface reactions of various amino alcohols with SA and SB are shown in Table 3. For the reactions with SA, the amount of reaction per unit of surface area of TiO_2 decreased as the structure of amino alcohol became more complicated. For the reactions with SB, the amount of reaction per 100 Å^2 are $\geqq$10, markedly more than those for the reactions with SA. A maximum in the amount was obtained for the reaction of triethanolamine. The ratio of the amount of the reaction of the triethanolamine to that of the surface OH groups is above 4. Extensive condensations due to OH groups may be the main reason that the triethanolamine showed the highest value in the amount of the reaction in spite of its extremely bulky structure.

Mechanisms of Light-initiated Redox Reactions of Copper(II)-Cyclic Polyamine Surfactant Assemblies

Yoshikiyo Moroi

Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812

(Received March 2, 1981)

Photo-induced reduction of Cu^{2+} ion by organic electron donors was studied, main attention being paid to the decay kinetics of the cationized donor using two kinds of Cu^{2+} ions; one is free to move around the micellar surface of copper(II) dodecyl sulfate($Cu(DS)_2$), the other being fixed in a cyclic polyamine, Cu^{2+} complex of 2-tetradecyl-1,4,7,10-tetraazacyclododecane (CPA). Sodium 12-(10-phenothiazinyl)dodecanesulfonate (PTHDS) functions quite similarly to *N*-methylphenothiazine (MPTH) in an electron transfer reaction in $Cu(DS)_2$ micelles, and the reduced Cu^+ is ejected from the micelles.[1] In the MPTH–CPA system, $MPTH^+$ is completely ejected from the host micelle in the CPA micellar system. In consequence, the decay of the cationized donor obeys a second-order rate law, while the rate constant becomes much less. In PTHDS–CPA micellar system, on the other hand, the kinetics of the cationized donor is a superposition of two first-order decays of different rate constants, which suggests that the cationized donor can not escape into an intermicellar bulk phase due to the hydrophobic interaction between the long alkyl chain and its host micelle. A similar decay was also observed in the mixed micelles of the polyamine and hexadecyltrimethylammonium bromide.

Considerable effort has been expended on attempts to convert light energy to chemical energy,[2,3] and as a result mechanisms of photochemical reactions in micellar systems have become quite clear.[4–7]

Macrocyclic compounds with a long alkyl chain have been prepared for use as phase-transfer catalysts.[8] Micelle formation and surface activity of these compounds, as well as their cation transfer reaction[9] and complex formation with Cu^{2+} or Ag^+,[10] have been reported in recent publications. As described in our previous paper,[11] micellar aggregates of macrocyclic surfactant containing Cu^{2+} ion were found to exhibit a high efficiency in quenching the excited state of fluorophores such as cyanine dyes and pyrene. In the light of our previous discussion from the view point of the reaction mechanism concerning the light-induced reduction of Cu^{2+} ion by *N*-methylphenothiazine followed by the back electron transfer from the Cu^+ to the cationized *N*-methylphenothiazine in copper(II) dodecyl sulfate micelles,[12] it is worth carrying out an experimental investigation in pursuit for the effect of substitution of Cu^{2+} in the cyclic polyamine cage on the reaction sequence. Another interest is in the effect of the variation of electron donors, which would possibly cause some alteration of the decay mechanism.

The object of the present study is to make clear the mechanism of photo-redox reactions in the micellar system, *i.e.*, to derive kinetic equations capable of accounting for experimental results obtained from laser photolysis studies. Our first attention was concentrated on the difference in effects on reaction mechanism caused by two kinds of electron donors: one has a long hydrocarbon chain attached to the phenothiazine ring and the other has none. The former, even when positively charged, cannot escape into the intermicellar bulk phase due to hydrophobic interaction which is stronger than electrostatic repulsion with positively charged micelle. On the contrary, the latter, when positively charged, has the possibility of being ejected from the micelle. Our first interest was then shifted from the electron donors to electron acceptors, *i.e.*, two kinds of Cu^{2+} ions: one is free to move around the micellar surface and the other is fixed in the polyamine cage as a complex.

Experimental

Materials. The Cu^{2+} complex of 2-tetradecyl-1,4,7,10-tetraazacyclododecane (CPA) was kindly given us by Dr. P. Tundo of the Institute de Chimica Organica, University di Trino, and used as supplied. The *N*-methylphenothiazine (MPTH) and sodium 12-(10-phenothiazinyl)dodecanesulfonate (PTHDS) were synthesized by Dr. A. M. Braun in Dr. Grätzel's laboratory. The hexadecyltrimethylammonium bromide (HTAB) of certified grade was obtained from E. Merck, Darmstadt, and purified by repeated recrystallization from acetone–ethanol mixture. The copper(II) dodecyl sulfate($Cu(DS)_2$) was prepared by the method described previously.[13] The deionized water was distilled first from alkaline permanganate and then twice with a quartz still. All samples were deoxygenated by passage of nitrogen of high purity.

Apparatus. Time-resolved experiments were run by the laser photolysis technique; laser photolysis experiments employed a frequency doubled KJ-2000 ruby or neodymium laser with pulsewidth of 25 ns and energy output of *ca.* 20 mJ.

Analysis. In the cases where $PTHDS^+$ decay kinetics in PTHDS–cationic micellar systems can result from superposition of two kinds of first-order decays, the rate parameter (α_2) for slower decay was first determined from an oscilloscope trace of longer-time scale. The rate parameter(α_1) for faster decay was then evaluated from the difference between the total optical density and the extraporated optical density of the shorter-time scale which had been calculated from the optical density of longer-time scale with the aid of the rate parameter α_2.

Results and Discussion

The light-initiated redox reaction in question is represented as

$$A + D \underset{d}{\overset{h\nu}{\rightleftharpoons}} A^- + D^+, \quad (1)$$

where A and D stand for an electron acceptor and

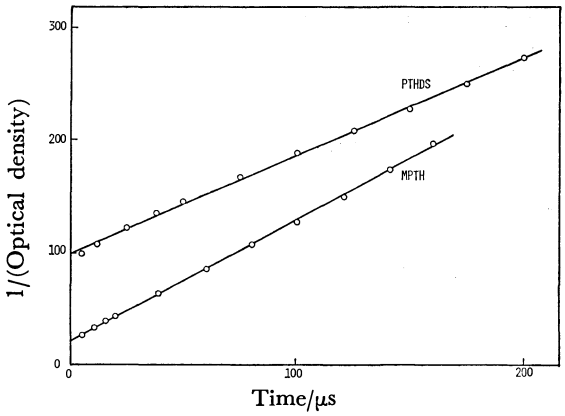

Fig. 1. Second-order plots of the 516 nm absorbance decay for MPTH (1.0×10^{-4} M†) and PTHDS (1.0×10^{-4} M) in $Cu(DS)_2$ (2.0×10^{-2} M) micellar systems.

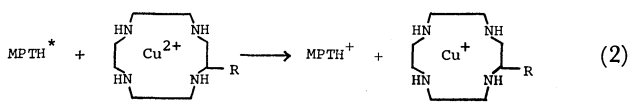
donor, respectively, corresponding to Cu^{2+} ion and MPTH or PTHDS for the present experiment. The first requirement for analyzing the reaction mechanism is to pursue the decay rate of the cationized electron donor with absorption maximum at 516 nm on an oscilloscope screen. Quantum yields of the cationized and triplet states of the donors are given in our previous paper.[11] Figure 1 shows second-order plots of the 516 nm absorption decay for the MPTH– and PTHDS–$Cu(DS)_2$ micellar solutions. It can be seen that, down to 30 percent or less of the initial optical density, a good linear relation exists between the inverse of optical density and time, *i.e.*, that the cationized donor decays according to a second-order rate law. The slopes which are almost the same with each other give the following estimates:

$$k_{obsd} = 9.3\times10^{9}\ M^{-1}s^{-1} \text{ for MPTH},$$
$$k_{obsd} = 7.9\times10^{9}\ M^{-1}s^{-1} \text{ for PTHDS}.$$

This close equality indicates similar decay mechanism in operation. PTHDS plays the same role as MPTH in reduction of Cu^{2+} and subsequent reaction mechanism. That is to say, on the analogy of the MPTH case, the reduced electron acceptor Cu^{+} is detached from its host micelle not only by electrostatic substitution with Cu^{2+} but also *via* a hopping process before recombination with the oxidized donor.[12] With this view, attempt will be made to probe further into the effect of variation of electron acceptor on the decay mechanism of the cationized donor: one is free to move around the micellar surface and the other is fixed in the polyamine cage. For the latter acceptor, the hydrophobic electron donor, MPTH, is incorporated in the polyamine aggregate. The excited state of MPTH has such a propensity for strong reduction[1] as to be expected to react with Cu^{2+} in the complex as follows:



(2)

where R refers to $C_{14}H_{29}$ and MPTH* is the excited singlet state.[11] Figure 2 shows an oscilloscope trace illustrating a transient absorption at 516 nm for

† 1 M = 1 mol dm^{-3}.

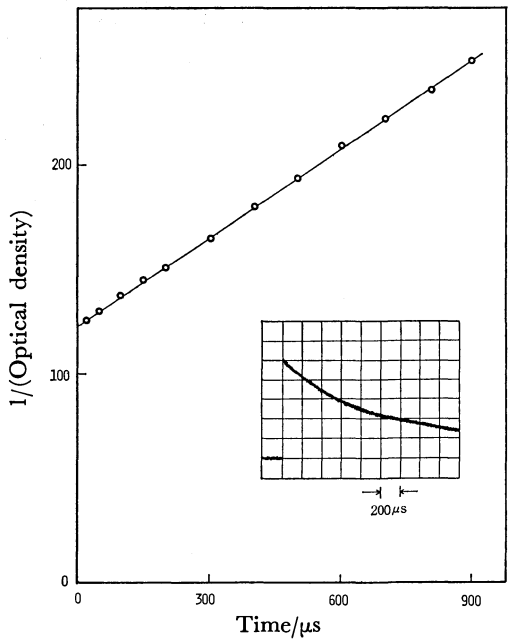


Fig. 2. Second-order plots of the 516 nm absorbance decay for MPTH (1.0×10^{-4} M) in Cu^{2+}-polyamine complex (5.0×10^{-3} M) micellar system. Insert: Oscilloscope traces showing the long-time $MPTH^{+}$ decay.

$MPTH^{+}$, together with plots of the inverse of optical density against time. The apparent decay process obeys the second-order kinetics in this case, too. The slope is, however, much less than those in the $Cu(DS)_2$ micellar assemblies.

$$k_{obsd} = 1.26\times10^{9}\ M^{-1}s^{-1}.$$

The discussion presented above leads to a possibility that either the oxidized $MPTH^{+}$ or the reduced Cu^{+} is ejected from its host micelle by electrostatic repulsion before the backward reaction occurs. If not, the decay should obey a first-order rate law because the cationized electron donor and the reduced electron acceptor ought to be paired in their host micelle. Another possibility is that both $MPTH^{+}$ and Cu^{+} leave the micelle. In this case, however, the k_{obsd} value should be larger than those for the MPTH– and PTHDS–$Cu(DS)_2$ systems because neither of the cations is trapped in the cationized micelle for a long time, resulting in a higher chance for them to come closer to each other for the backward electron transfer. In addition, not only Cu^{2+} but also Cu^{+} ions can form a stable complex with macrocyclic tetramine.[14–16] Hence, the chance that Cu^{+} leaves its mother micelle is very low.

In order to examine whether $MPTH^{+}$ is ejected, we succeeded in using PTHDS as an electron donor, since PTHDS, even when charged positively, cannot be detached from its host micelle. It will be discussed more in detail from an energy point of view. If MPTH is assumed to be twice as strong as benzene in hydrophobic interaction because of a presence of two benzene rings in the molecule, the free energy change of transfer of MPTH from aqueous bulk into micellar core is 6—7 kT.[17,18] A location of solubilized

aromatic molecules in the micellar phase is generally a palisade layer of micelle,[19] and the phenothiazine molecule is really solubilized in the palisade layer of alkyl sulfate micelles.[20] Accordingly, the free energy change for the present case is less than that value. On the other hand, the electrical surface potential is calculated[22] as 6.6 and 4.9 $e\Psi/kT$ for 1.0 and 0.2 of dissociation degree of the micelle, respectively, by using 50 A^2 for molecular surface area at the micellar surface, its CMC value for the counter-ion concentration, and 40 for the dielectric constant.[21] Suppose now that the free energy change of MPTH due to hydrophobic interaction is $6.5\,kT$. Then, a fraction of $MPTH^+$ ejected from the micelle is more than 50 and 16 percent for 1.0 and 0.2 of dissociation degree of the micelle, respectively. On the other hand, PTHDS has a longer alkyl chain of twelve carbon atoms and a free energy change of transfer per methylene group from aqueous bulk into micellar core is $1.1\,kT$.[22] Thus, the total free energy change due to hydrophobic interaction is about $22\,kT$, whereas the gross electrostatic repulsive energy due to micellar surface potential is zero even when the electron donor group is cationized, because the molecule has an SO_3^- group. Hence, just after the electron transfer reaction has taken place, some fraction of cationized donor groups is detached from its host micelle by electrostatic repulsion. However, the whole molecule cannot escape into the bulk phase, because the cationized group is anchored to the host micelle through the hydrophobic interaction between its alkyl chain and the hydrophobic micellar core.

The absorbance signal at 516 nm on the oscilloscope screen for the PTHDS–CPA system decays apparently in two steps, where the first component amounting to 55 percent of the total signal corresponds to the decay of the triplet of PTHDS. The kinetics obeys the first-order rate law with a time constant of $1.7\times10^7\ s^{-1}$.[11] The slow second component can be produced by neither the first nor the second-order kinetics but only by a superposition of two kinds of first-order decays (Fig. 3). Another difference in behavior between $MPTH^+$ and $PTHDS^+$ is that the latter decays much faster than the former as far as the apparent decay of the second component is concerned. This may be expected if the slow component is associated with the $MPTH^+$ which leaves the micellar aggregate and escapes into the intermicellar bulk phase. In contrast to $MPTH^+$ the detachment of $PTHDS^+$ will be incomplete, since the cation remains anchored to its mother micelle as mentioned above. Eventually, the charge recombination of $PTHDS^+$ and Cu^+ occurs giving rise to a faster decay process, and variation of laser intensity did not cause any change of this decay pattern, although two rate parameters, α_1 and α_2, altered in small amount (Table 1).

In the light of the above discussion, it will be inquired whether the schematic diagram for the decay processes assists us in explaining the decays of both $MPTH^+$ and $PTHDS^+$ in the Cu^{2+}–polyamine micellar systems. As was mentioned above, the forward electron transfer from the photoexcited MPTH or PTHDS (electron donor D) to Cu^{2+} in a complex form (electron acceptor A) occurs within the duration of the laser pulse. Hence, the $D^+\cdots A^-$ pairs produced at the end of the pulse are the starting state of the decay processes. The kinetic parameters in the present study are quite similar to those used in our previous paper.[12]

With the solution containing PTHDS in the micelle, $PTHDS^+$ cannot be ejected into the intermicellar phase for the above reasons. Therefore, the whole molecule of $PTHDS^+$ cannot be detached from its host micelle even during the completion of the cation decay; the relaxation time of the gross rate of micelle association reaction is more than a millisecond order.[23,24] This means that the decay of D^+ is associated with the electron transfer to D^+ either inside or outside the micelle. Thus, we have the decay processes depicted in the scheme of Fig. 4, where the rate parameter k_b^i refers to the electron back transfer of D^+ inside the micelle, k_b^o that of D^+ outside the micelle, k_e the reaction of D^+ escape from the micellar interior, and k_r the reaction of D^+ return into the micellar interior.

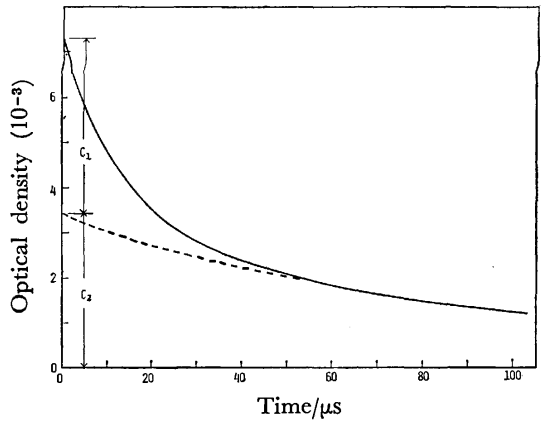

Fig. 3. The slower second-component decay of the absorbance at 516 nm for PTHDS (1.0×10^{-4} M) in Cu^{2+}–polyamine complex (5.0×10^{-3} M) micellar system.

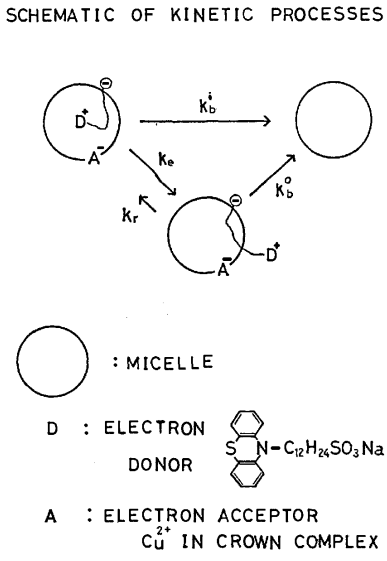

Fig. 4. Schematic illustration of the elementary processes for the decay kinetics of $PTHDS^+$ in Cu^{2+}–polyamine complex micellar system.

On the basis of the schematic diagram for the decay processes, we shall now develop kinetic equations to analyze the results. The following notations will be used for concentration terms: $C_{D^+_I}$ for micelles associated with D^+ inside the micelle; $C_{D^+_O}$ for micelles associated with D^+ outside the micelle.

$$\frac{dC_{D^+_I}}{dt} = -(k_b^I + k_e)C_{D^+_I} + k_r C_{D^+_O}, \quad (3)$$

$$\frac{dC_{D^+_O}}{dt} = -(k_b^O + k_r)C_{D^+_O} + k_e C_{D^+_I}. \quad (4)$$

From Eqs. 3 and 4, the decay rate of the total amount of the oxidized donor which is an experimentally observable quantity can be expressed as

$$\frac{d(C_{D^+_I} + C_{D^+_O})}{dt} = -k_b^I C_{D^+_I} - k_b^O C_{D^+_O}. \quad (5)$$

Introduction of Eqs. 3 and 4 into the time derivative equation of Eq. 3 gives

$$\frac{d^2C_{D^+_I}}{dt^2} + a\frac{dC_{D^+_I}}{dt} + bC_{D^+_I} = 0, \quad (6)$$

where

$$a = k_b^I + k_b^O + k_e + k_r \quad (7)$$

and

$$b = k_b^I k_b^O + k_b^I k_r + k_b^O k_e. \quad (8)$$

The solution of Eq. 6 becomes

$$C_{D^+_I} = A_1 e^{-\alpha_1 t} + A_2 e^{-\alpha_2 t}, \quad (9)$$

where $\alpha_1+\alpha_2=a$ and $\alpha_1\alpha_2=b$. Here, we assume $\alpha_1 > \alpha_2$. The boundary condition that the cation at time zero is totally $C_{D^+_I}$, reduces Eq. 9 to

$$A_1 + A_2 = C_0, \quad (10)$$

where C_0 is the total cationized donor concentration at time zero and A_1 and A_2 are integration constants. Introducing Eq. 9 into Eq. 3, $C_{D^+_O}$ can be obtained as

$$C_{D^+_O} = \frac{A_1(k_b^I + k_e - \alpha_1)}{k_r}e^{-\alpha_1 t} + \frac{A_2(k_b^I + k_e - \alpha_2)}{k_r}e^{-\alpha_2 t}. \quad (11)$$

As $C_{D^+_O}$ should be zero at time zero, we obtain for A_1 and A_2

$$A_1 = \frac{(k_b^I + k_e - \alpha_2)C_0}{\alpha_1 - \alpha_2}, \quad (12)$$

and

$$A_2 = \frac{(k_b^I + k_e - \alpha_1)C_0}{\alpha_1 - \alpha_2}. \quad (13)$$

Thus, the total decay of the cationized donor can be expressed as

$$C_{D^+_I} + C_{D^+_O} = C_1 e^{-\alpha_1 t} + C_2 e^{-\alpha_2 t}, \quad (14)$$

where

$$C_1 = \frac{A_1(k_b^I + k_e + k_r - \alpha_1)}{k_r}, \quad (15)$$

and

$$C_2 = \frac{A_2(k_b^I + k_e + k_r - \alpha_2)}{k_r}. \quad (16)$$

Hence, Eq. 14 indicates that the total decay is a superposition of the fast 1st-order decay on the slow 1st-order decay, which is the case with the present experiment. Now, we have to find a way to determine the rate parameters. Introducing Eqs. 9 and 11 into Eq. 5 and adopting the above two boundary conditions at time zero give k_b^I in the form,

$$k_b^I = \alpha_1\frac{C_1}{C_0} + \alpha_2\frac{C_2}{C_0}. \quad (17)$$

Using α_1, α_2, C_1, and C_2 which can be evaluated from the decay curves, k_b^I can be determined without any assumption and any mathematical approximation. Similarly, k_e value can also be determined by introducing Eqs. 9 and 11 into Eq. 4 and using the same boundary conditions in the following form,

$$k_e = \alpha_1\left(\frac{k_b^I + k_e - \alpha_2}{\alpha_1 - \alpha_2} - \frac{C_1}{C_0}\right) + \alpha_2\left(\frac{k_b^I + k_e - \alpha_1}{\alpha_2 - \alpha_1} - \frac{C_2}{C_0}\right). \quad (18)$$

As $k_b^I + k_e$ is nearly equal to α_1 (see Appendix), the third term cancels out and Eq. 18 can be rearranged using Eq. 17 into

$$k_e = \alpha_1 - k_b^I, \quad (19)$$

which means that Eq. 18 is consistent with the contents in the Appendix. Elimination of k_r term, using Eqs. 7 and 8, gives

$$k_b^O = \frac{k_b^{I2} + k_b^I k_e - (\alpha_1 + \alpha_2)k_b^I + \alpha_1\alpha_2}{k_e}. \quad (20)$$

Introducing k_b^I, k_b^O, and k_e thus obtained into Eq. 7, we obtain k_r value (Table 1). The k_r values for the systems are almost zero, if the experimental error is taken into account. Thus, the initial fast kinetics can be eventually represented by the equations in the Appendix. If the preceding reaction mechanisms are correct, the similar kinetic decay must be observed in the CPA–HTAB mixed micellar system. In fact, a superposition of two kinds of first-order decays took place in this system, too (Table 1), which assists the decay mechanism to be correct. A brief mention should be made of the difference in numerical values of the reaction parameters between the CPA and CPA–HTAB mixed micellar assemblies. Going back again to Table 1, we see that the k_b^I and k_e values in the mixed micellar system are much larger than those in the CPA micelle. It is highly likely, therefore, that the polyamine cage is much more mobile in the mixed micelle leading to higher k_b^I value and that the electrostatic surface potential is more positive in the mixed micelle, as reflected in the higher k_e value. The surface potential of HTAB is 9.4 $e\Psi/kT$ by a similar calculation, whereby a dissociation degree of the micelle is assumed to be 0.2, so that the value of 9.4 becomes less for the present mixed micellar system where a ratio of CPA to HTAB is 0.09. On the other hand, k_b^O is much less in the mixed system. This too is owing to higher surface potential which causes larger separation between Cu^+ and D^+ outside micelle.

Next, we proceed to the $MPTH^+$ cation decay in the Cu^{2+}–polyamine micellar system. As mentioned before, the decay kinetics obeys the 2nd-order law and $MPTH^+$, not Cu^+, escapes into an intermicellar phase due to an electrostatic repulsion between $MPTH^+$ and the positive micellar charge. This can be verified by 1) very large k_e value of the PTHDS–cationic

Table 1. Rate parameters for PTHDS (1.0×10^{-4} M) in Cu^{2+}-polyamine complex (5.0×10^{-3} M) and Cu^{2+}-polyamine complex/HTAB ($1.0\times10^{-3}/1.0\times10^{-2}$ M) mixed micellar systems

	α_1 / 10^4 s^{-1}	α_2 / 10^4 s^{-1}	k_b^i / 10^4 s^{-1}	k_b° / 10^4 s^{-1}	k_e / 10^4 s^{-1}	k_r / 10^4 s^{-1}
CPA	8.10 ± 0.36	1.04 ± 0.10	4.82	1.04	3.28	$\simeq0$
	$C_1/C_0=0.536$,	$C_2/C_0=0.464$				
CPA/HTAB	135 ± 10	0.261 ± 0.019	94.0	0.261	40.5	$\simeq0$
	$C_1/C_0=0.698$,	$C_2/C_0=0.302$				

The standard deviation for the numerical values of rate parameter is less than 10%.

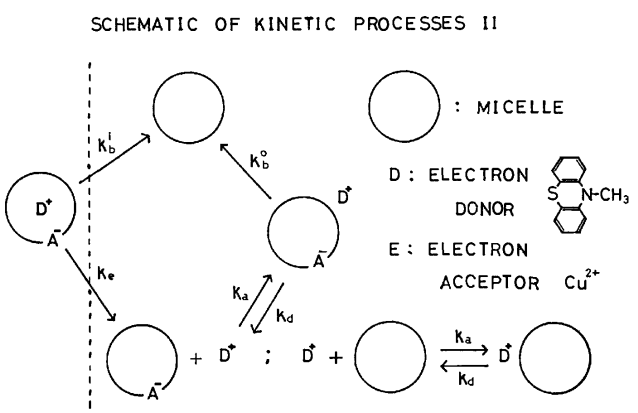

Fig. 5. Schematic illustration of the elementary processes for the decay kinetics of $MPTH^+$ in Cu^{2+}-polyamine complex micellar system.

micellar systems and 2) that the higher the surface potential of micelles, the larger the k_e value (see Table 1). In addition, as mentioned earlier, the k_r value was found to be almost zero. That is, the probability that the ejected cation donor goes back again into a micellar interior should be extremely small. Hence, the decay processes after the initial fast back electron transfer and after the cation ejection can be illustrated schematically in Fig. 5, where the reaction parameter k_a refers to the association reaction of D^+ with the micellar aggregate and k_d to the dissociation reaction of D^+ from the micellar aggregate. Now that the schematic diagram has been given, we can develop the kinetic equations for the decay processes. Following notations will be used for the concentration terms: $C_{D^+A^-}$ for micelles with simultaneous D^+ and A^- association (location of D^+ association is micellar surface); C_{D^+} for D^+ in the intermicellar bulk phase; C_{MD^+} for micelles with D^+ association; C_{MA^-} for micelles with A^- association; C_M for empty and D-containing micelles.

$$\frac{dC_{D^+A^-}}{dt} = k_a(k_b^\circ+k_d)C_{D^+A^-} + k_aC_{MA^-}C_{D^+}, \quad (21)$$

$$\frac{dC_{D^+}}{dt} = -k_aC_{D^+}(C_{MA^-}+C_M) + k_d(C_{D^+A^-}+C_{MD^+}), \quad (22)$$

$$\frac{dC_{MD^+}}{dt} = -k_dC_{MD^+} + k_aC_{D^+}C_M, \quad (23)$$

$$\frac{dC_{MA^-}}{dt} = -k_aC_{MD}C_{D^+} + k_dC_{D^+A^-}. \quad (24)$$

What we can observe experimentally is the sum of $C_{D^+A^-}+C_{D^+}+C_{MD^+}$. Hence, the decay rate of the total cationized donor is

$$\frac{d(C_{D^+A^-}+C_{D^+}+C_{MD^+})}{dt} = -k_b^\circ C_{D^+A^-}. \quad (25)$$

After the initial fast back electron transfer reaction, the concentration of D^+A^- becomes negligibly small and the system reaches a steady state for the concentration of $C_{D^+A^-}$ and for the partitioning of D^+ between the intermicellar phase and the micellar surface.[12]

$$\frac{dC_{D^+A^-}}{dt} = 0. \quad (26)$$

$$k_aC_{D^+}C_M = K_dC_{MD^+}. \quad (27)$$

An additional relationship is from the electroneutrality of the solution:

$$C_{MA^-} = C_{D^+} + C_{MD^+}. \quad (28)$$

Two equations which are derived by the introduction of Eq. 26 into Eqs. 21 and 25 give the total decay in the form,

$$\frac{d(C_{D^+}+C_{MD^+})}{dt} = -\frac{k_b^\circ k_aC_{MA^-}C_{D^+}}{k_b^\circ+k_d}. \quad (29)$$

Introducing Eqs. 27 and 28 into Eq. 29 gives

$$\frac{d(C_{D^+}+C_{MD^+})}{dt} = -k_{obsd}(C_{D^+}+C_{MD^+})^2, \quad (30)$$

where

$$k_{obsd} = \frac{k_b^\circ k_ak_d}{(k_b^\circ+k_d)(k_d+k_aC_M)}. \quad (31)$$

Thus, it has become clear that the cationized donor $MPTH^+$ is detached from the host micelle and that the decay rate of the total cation obeys the 2nd-order (Fig. 2). Namely, the mechanism depicted in Fig. 5 is consistent with the experimental results. Unfortunately, however, an evaluation of each rate parameter of this reaction system, unlike the system of MPTH in sodium dodecyl sulfate–europium decyl sulfate mixed micellar solution, can not be made only by increasing surfactant concentration,[12] because the micellar aggregation number of CPA increases with the surfactant concentration.[10] When the k_{obsd} value of $MPTH^+$ decay in the CPA micellar assembly is compared with that in the $Cu(DS)_2$ micellar assembly, we find that the former is as small as one-seventh of the latter. This is mainly attributable to the smaller k_a value for the former system which involves the repulsive force between $MPTH^+$ and the positive surface potential of CPA micelles, while, in the latter system, the

negative surface potential gives rise to an attractive force between Cu^+ and micellar surface.

The author is grateful to Professor M. Grätzel of École Polytechnique Fédérale de Lausanne in Switzerland for his helpful comments and generous permission to publish this work which was partly done during my stay there.

Appendix

In the schematic diagram of Fig. 4, the returning reaction of D^+ outside the micelle into micellar core must be very slow, because the probability that the cationized donor repelled from the micelle by an electrostatic repulsion goes back again into the micellar core must be very small. Therefore, especially when we are discussing the short-time decay just after the laser pulse, $k_r C_{D^+_o}$ term can be neglected in Eqs. 3 and 4. Hence they become

$$\frac{dC_{D^+_1}}{dt} = -(k_b^1 + k_e)C_{D^+_1}, \tag{32}$$

$$\frac{dC_{D^+_o}}{dt} = -k_b^o C_{D^+_o} + k_e C_{D^+_1}. \tag{33}$$

Integration of Eq. 32 yields

$$C_{D^+_1} = C_0 e^{-(k_b^1 + k_e)t}. \tag{34}$$

Introducing Eq. 34 into Eq. 33 and the subsequent integration give

$$C_{D^+_o} = \frac{k_e C_0}{k_b^o - (k_b^1 + k_e)}\{e^{-(k_b^1 + k_e)t} - e^{-k_b^o t}\}. \tag{35}$$

The total cation concentration then becomes

$$C_{D^+_1} + C_{D^+_o} = \frac{k_b^1 - k_b^o}{k_b^1 + k_e - k_b^o} C_0 e^{-(k_b^1 + k_e)t} \tag{36}$$

$$+ \frac{k_e}{k_b^1 + k_e - k_b^o} C_0 e^{-k_b^o t}. \tag{36}$$

Comparing Eq. 36 with Eq. 14 as respects the first part, we have the following equation concerning just the initial decay rate:

$$\alpha_1 = k_b^1 + k_e. \tag{37}$$

(Received March 2, 1981)

The intermolecular exciplex formation and electronic relaxation of 1,4-dicyanonaphthalene (DCN) with pentamethylbenzene (PMB) in the vapor phase have been studied by means of nanosecond fluorescence spectroscopy. The exciplex formation and decay-rate constants were independent of the excitation energy, while the decay-rate constants of DCN fluorescence was dependent on the excitation energy. The rate constants of the exciplex formation and decay kinetics were discussed in comparison with the collisional relaxation rate of the upper vibrational states.

The observation of the exciplex formation in the vapor phase provides valuable information concerning the electronic interaction between the electron donor and acceptor in the absence of solvent. It also provides information concerning vibrational effects on the radiative and nonradiative deactivation of the exciplex. Exciplex formation in the vapor phase has been reported on 9-cyanoanthracene and alkylamine systems.[1,2] Prochorow *et al.*[3] and Okajima and Lim[4] have reported on exciplex formation and electronic relaxation in the 1,2,4,5-tetracyanobenzene (TCNB) and *p*-xylene system in the vapor phase. Very recently, Itoh *et al.*[5,6] reported the intramolecular exciplex formation of 1-(9,10-dicyano-2-anthryl)-3-(1- or 2-naphthyl)propane (DCAN) in the vapor phase. In the collision-free vapor of DCAN, the excitation wavelength dependence in the $S_1 \leftarrow S_0$ spectral region of exciplex formation and the lifetimes was observed. A considerable blue shift of the exciplex fluorescence of the collision-free vapor on the excitation of the upper vibrational state was also observed in comparison with the excitation of the lower vibrational state. They suggested that the fluorescent relaxation from the upper vibrational state of the exciplex was significant.

This paper will describe the intermolecular exciplex formation and electronic relaxation of 1,4-dicaynonaphthalene (DCN) and also 1,4-dicyanonaphthalene-d_6 with pentamethylbenzene (PMB) in the vapor phase. The rate constants of the exciplex formation and decay kinetics were measured in the excitations at 337 and 293 nm. The lifetime of the exciplex fluorescence is independent of the excitation wavelength, while that of the DCN fluorescence is dependent. The reaction rates and the vibrational relaxation suggest that PMB may act not only as an electron donor, but also as a vibrational relaxer of the upper vibrational states of the S_1 state.

Experimental

The 1,4-dicyanonaphthalene was prepared and purified by known procedures.[7] 1,4-Dicyanonaphthalene-d_6 was prepared from naphthalene-d_8 (Merck, $C_{10}D_8$, 99%) by bromination in bromine vapor and by cyanogenation in a pyridine-d_5 (merck, C_5D_5N, 99%) solution, and was purified two times by means of silica-gel chromatography and recrystallization. Proton NMR gave an isotope purity of approximately 95%. The H-D exchange reaction was examined by the following method: after a mixture of DCN-d_6 and PMB (1:1) has been heated for 3 h at $\approx$523 K, the proton NMR signal shows that no H-D exchange reaction has occured between the two compounds. The spectral determinations in the vapor phase were made as follows: a rectangular quartz cell (1 cm) with graded seals containing solid DCN and PMB was degassed by means of a vacuum line and then sealed off. By using hexane as a buffer gas, a cell containing crystalline compounds and a trace of hexane corresponding to $\approx$500 Torr (1 Torr=133.32 Pa) at $\approx$503 K was degassed by the freeze-pump-thaw method. The absorption and fluorescence spectra and lifetimes were measured in a quartz Dewar vessel at a controlled temperature by means of a heated air flow. The absorption and fluorescence spectra were measured by means of Hitachi 220 and MPF-4 spectrophotometer, respectively. The fluorescence lifetimes were determined by excitation with a nitrogen laser and a dye laser (Molectron DL-14) with a frequency doubler (Rhamda Physik KDP unit). The fluorescence decays were measured by the use of a HTV R666 photomultiplier and by means of Tektronix 7904 (7A19 and 7B85) oscilloscope, and were analyzed by the deconvolution method.

Results and Discussion

The exciplex fluorescence at room temperature and also the excited-state complex fluorescence at low temperatures have been reported in a solution of 1,4-dicyanonaphthalene (DCN) and alkylbenzenes.[7] On the other hand, the fluorescence polarization of DCN in a rigid solution of 3-methylpentane at 77 K suggests that the absorption spectrum of DCN at 280—340 nm is attributable to the L_a ($S_1 \leftarrow S_0$) and L_b ($S_2 \leftarrow S_0$) bands. The absorption spectrum of DCN in the vapor phase shown in Fig. 1 may be ascribed to the L_a and L_b bands, though the spectral feature is quite different from that in solution. Figure 1 shows the fluorescence and excitation spectra of DCN and PMB vapor. The excitation spectra monitored at several wavelengths are identical with that of the DCN fluorescence determined in the vapor phase, which is attributable to the $S_1 \leftarrow S_0$ absorption band of DCN. The fluorescence spectrum exhibits the exciplex fluorescence ($\lambda_{max} \approx 395$ nm) in addition to the DCN fluorescence ($\lambda_{max} \approx 343$ nm). In the presence of a buffer gas (hexane, $\approx$500 Torr=6.65×10^4 Pa) which may act as a vibrational relaxer, both exciplex and DCN fluorescence increase in intensity in comparison with those in the absence of a buffer gas, as shown in Fig. 1. The fluorescence maximum of the vapor-phase exciplex exhibits a considerable blue shift from that

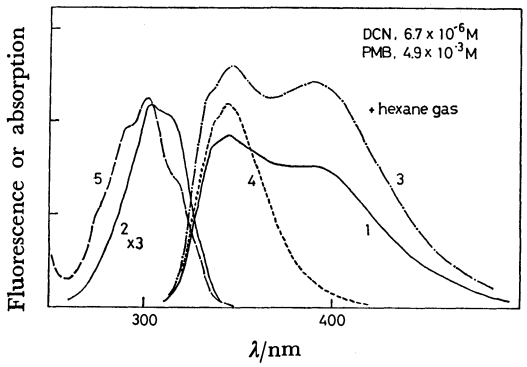

Fig. 1. (1) Fluorescence (excited at 300 nm) and (2) excitation (monitored at 450 nm) spectra of 1,4-dicyanonaphthalene and pentamenthylbenzene in the vapor phase at ≈503 K. (3) fluorescence spectrum determined in the identical condition with (1) except addition of hexane gas (≈500 Torr=6.6×10^4 Pa) as a vibrational relaxer (1 M=1 mol dm^{-3}). (4) Fluorescence (excited at 300 nm) and (5) absorption spectra of 1,4-dicyanonaphthalene vapor at ≈503 K.

in the nonpolar solution (λ_{max}≈416 nm in 3-methylpentane) at room temperature,[7] while that of the DCN fluorescence shows no significant spectral shift.

The well-known photochemical reaction scheme and decay kinetics of DCN and exciplex are as follows;[8]

$$\begin{array}{ccccc} & & A^* + D & \underset{k_4}{\overset{k_3}{\rightleftharpoons}} & (DA)^* \\ & \swarrow^{k_1} \quad \searrow^{k_2} & & & \swarrow^{k_5} \quad \searrow^{k_6} \\ A + h\nu & & A & & D + A + h\nu', \quad D + A \end{array}$$

$$[A^*] = c_1 \exp(-\lambda_1 t) + c_2 \exp(-\lambda_2 t)$$

$$[(DA)^*] = c_3 \exp(-\lambda_1 t) - c_3 \exp(-\lambda_2 t)$$

$$\lambda_1,\ \lambda_2 = \frac{1}{2}[k_1+k_2+k_3[D]+k_4+k_5+k_6 \mp (\{k_1+k_2+k_3[D]-(k_4+k_5+k_6)\}^2+4k_3k_4)^{1/2}],$$

where A and D are DCN and PMB, respectively. The time constants, λ_1 and λ_2 were determined in several concentrations of PMB in the excitation at 337 nm at ≈503 K. Figure 2 shows a plot of $\lambda_1+\lambda_2$ ($=k_1+k_2+k_3[D]+k_4+k_5+k_6$) *vs.* [D], the slope of which yields the rate constant of $k_3=1.2\times10^{11}$ dm^3 mol s^{-1}. Further, the fluorescence intensity ratio of DCN (excited at 337 nm) in the absence (I_0) and presence (I) of the electron donor (PMB) is expressed by the following equation:[8]

$$(I_0/I) - 1 = k_3[D](k_5+k_6)/(k_4+k_5+k_6)(k_1+k_2).$$

From k_3, the lifetimes of the exciplex and DCN, and the slope of the plot of I_0/I *vs.* [D], the dissociation rate constant (k_4) of the exciplex was determined to be 3.56×10^7 s^{-1}, as is summarized in Table 1.

The exciplex formation can be expressed by the following scheme:

$$\begin{array}{ccc} A^*(\nu_h) + D & \longrightarrow & (DA)^*(\nu_h) \\ \Big\downarrow + R & & \Big\downarrow + R \\ A^*(\nu_l) + D & \longrightarrow & (DA)^*(\nu_l), \end{array}$$

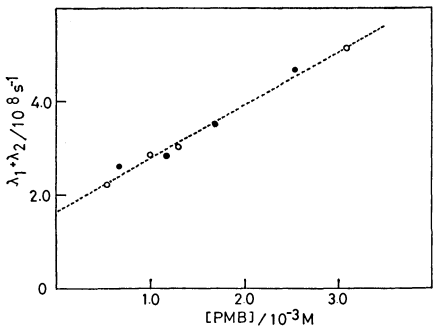

Fig. 2. Plots of $(\lambda_1+\lambda_2)$ *vs.* concentration of pentamethylbenzene in the vapor phase at 503 K; λ_1 and λ_2 were obtained from double exponential decay curves determined at 370 nm in the excitation at 337 nm.

TABLE 1. THE DECAY-RATE CONSTANTS AND THE FORMATION AND DISSOCIATION RATE CONSTANTS OF THE EXCIPLEX IN THE VAPOR PHASE AT 503 K IN THE EXCITATION AT 337 nm

Rate constant	DCN-PMB	DCN-d_6-PMB
(k_1+k_2)/s^{-1} a)	1.25×10^8	1.05×10^8
k_3/dm^3 mol^{-1} s^{-1}	1.2×10^{11}	1.2×10^{11}
$(k_4+k_5+k_6)$/s^{-1}	4.9×10^7 b)	5.2×10^7 c)
k_4/s^{-1}	3.56×10^7	4.1×10^7
k_q/dm^3 mol^{-1}	2.6×10^2	2.4×10^2

a) Determined in DCN and DCN-d_6 vapors. b) Determined in the DCN (6.7×10^{-6} mol dm^{-3}) and PMB (1.2×10^{-3} mol dm^{-3}) vapor. c) Determined in the DCN-d_6 (6.7×10^{-3} mol dm^{-3}) and PMB (1×10^{-3} mol dm^{-3}) vapor.

where ν_h and ν_l denote high and low levels of the vibrational state, respectively. R is a vibrational relaxer. In the excitation of the $S_1\leftarrow S_0$ absorption band at 337 nm, the fluorescence lifetimes of DCN vapor is 8.0 ns, while it is 3.6 ns for the $S_2\leftarrow S_0$ excitation at 292 nm. Since the energy level of the S_2 state may be very close to that of the S_1 state, and since the isoenergetic internal conversion from the S_2 state to the vibrationally hot S_1 state proceeds very rapidly, the short lifetime of DCN (3.6 ns) for the excitation of S_2 is attributable to decay from the upper vibrational state of S_1. However, the fluorescence lifetime of the exciplex in the DCN–PMB vapor does not exhibit any of the excitation-wavelength dependence mentioned above. Okajima and Lim[4] suggested that, in the vapor-phase exciplex of TCNB–*p*-xylene, the rate constant of the exciplex formation (7×10^{12} dm^3 mol^{-1} s^{-1}) between the vibrationally hot electron acceptor, A*(ν_h), *via* the S_2 excitation and the ground state of the electron donor is 10 times greater than that of the formation of (DA)*(ν_l), measured for excitation into S_1. Further, the rate constant of the intramolecular exciplex formation from the A*(ν_h) and D moieties in the collision-free vapor of DCAN was determined to be much greater than that from the A*(ν_l) and D moieties.[9] Therefore, if the rate constant of the (DA)*(ν_h) formation in the DCN–PMB vapor is assumed to be 5—10 times greater than the value of 1.2×10^{11} dm^3 mol^{-1} s^{-1} obtained in the (DA)*(ν_l) formation, the rate constant of the (DA)*(ν_h)

formation is estimated to be approximately 10^{12} dm^3 mol^{-1} s^{-1}. On the other hand, the concentration of PMB (10^{-2}—10^{-3} mol dm^{-3}) corresponds to the gas pressure of 50 Torr and to the collisional relaxation rate of 5×10^8 s^{-1} obtained by the use of a hard-sphere collision model.[4,10] Therefore, the rate of the (DA)*(ν_h) formation *via* S_2 excitation ($\approx10^{12}[D]$ s^{-1}) is greater than the decay of A*(ν_h) and the vibrational relaxation by ≈50 Torr of PMB. However, since the decay-rate constant of (DA)*(ν_h) is assumed to be approximately 3×10^7 s^{-1}, the vibrational relaxation of the upper vibrational state of (DA)*(ν_h) by PMB vapor may proceed at the rate of 5×10^8 s^{-1}, followed by the fluorescent decay from (DA)*(ν_l). These arguments are consistent with the absence of the excitation-wavelength dependence of the fluorescence lifetimes of the exciplex. The fluorescence-intensity ratio of the exciplex and DCN is not very much dependent on the absence or presence of the buffer gas, though the intensity ratio shows a slight increase in the latter, as shown in Fig. 1. This fact suggests that the exciplex formation and emission may take place according to the reaction scheme mentioned above. In the scheme, D and R are PMB as the electron donor and also as the vibrational relaxer.

The rate constants of the exciplex formation and decay kinetics were obtained in the DCN-d_6 and PMB system, as summarized in Table 1. Figure 3 compares the fluorescence spectrum of DCN-d_6 and PMB vapor with that of DCN–PMB vapor determined under identical conditions. The fluorescence-intensity ratio of the exciplex and DCN in DCN-d_6–PMB slightly increases in comparison with that of DCN–PMB. However, the rate constant of the exciplex formation (k_3) and the quenching constant (k_q) obtained from the plots shown in Figs. 2, show no significant difference between DCN-d_6 and DCN, as summarized in Table 1.[11] Okajima and Lim[4] reported that the Stern-Volmer quenching constant in the TCNB–*p*-xylene-d_{10} vapor is smaller by a factor of 1.4 than that for TCNB–*p*-xylene, and they suggested the occurence of important vibrational effects in the photoassociation. However, the lack of any significant effects of the deuterium substitution in DCN reported here suggests a slight contribution of C–D stretching to the high-frequency vibrational mode of a large molecule such as DCN in the exciplex formation and the radiationless deactivation.

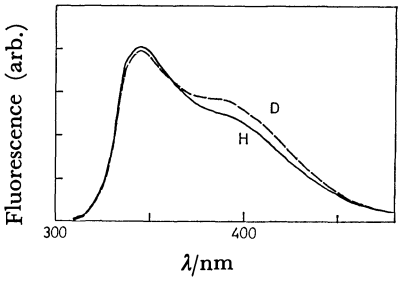

Fig. 3. (H) Fluorescence spectrum of 1,4-dicyanonaphthalene (6.7×10^{-6} mol dm^{-3}) and pentamethylbenzene (3.8×10^{-3} mol dm^{-3}) in the vapor phase at ≈503 K. (D) Fluorescence spectrum of 1,4-dicyanonaphthalene-d_6 (6.7×10^{-6} mol dm^{-3}) and pentamethylbenzene (3.8×10^{-3} mol dm^{-3}) determined in the identical condition with (H).

(Received March 4, 1981)

The magnetic susceptibility of 1,5-diphenyl-3-(4-chlorophenyl)verdazyl (Cl-TPV) has been measured on a powder sample in the temperature region between 1.8 and 80 K. It exhibited a round maximum at 21.0 K; this temperature is the highest among those observed for verdazyl monoradicals. The susceptibility can be well described by the Heisenberg linear chain model; the estimated exchange interaction parameter is $J/k=-16.4$ K. The crystal structure of Cl-TPV has been determined by means of X-ray diffraction. The crystal is orthorhombic, with the space group of Pbca and with $a=22.041(5)$, $b=7.166(4)$, $c=21.379(5)$ Å, and $Z=8$. The molecules are arranged in a column along the b axis. The exchange interaction has been discussed based on the crystal structure and the spin density distribution.

Electron spin-spin exchange interaction in a radical crystal is dependent on the crystal structure and the spin density distribution. In order to obtain the exchange interaction as a function of the interatomic distance and the spin density, 1,3,5-triphenylverdazyl (TPV) and its methyl derivatives, such as 1,3,5-triphenyl-6-methylverdazyl and 1,3-di-*p*-tolyl-5-phenylverdazyl (DTPV), have been studied to determine their magnetic susceptibilities, spin densities, and crystal structures.[2)] The C-phenyl ring in TPV lies in the nodal plane of the highest-occupied molecular orbital,[3)] so the replacement of the hydrogen atom in that ring scarcely perturbs the spin density distribution. Thus, a chlorine atom has been introduced into *para*-position and the molecular packing has been modified from that of TPV. The exchange interaction estimated from the magnetic susceptibility of this 1,5-diphenyl-3-(4-chlorophenyl)verdazyl (Cl-TPV) is the strongest among the verdazyl monoradicals examined. In order to understand the exchange interaction of Cl-TPV and to try the tractable function in Ref. 2, the crystal structure of this radical has been determined by means of X-ray diffraction.

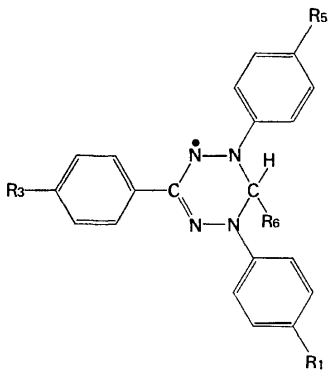

Fig. 1. Chemical structures of verdazyl radicals.

Radical	R_1	R_3	R_5	R_6
TPV	H	H	H	H
Cl-TPV	H	Cl	H	H
DTPV	CH_3	CH_3	H	H

Experimental

Cl-TPV was prepared from *p*-chlorobenzaldehyde, aniline and formaldehyde.[4)] The dark green crystals, elongated along the b axis, were purified several times through recrystallization from a mixed solution of acetone and methanol.

The magnetic susceptibility was measured on the powdered sample by means of a magnetic torsion balance.[5)] The temperature was determined using an AuCo–Cu thermocouple and a carbon resister. Manganese Tutton salt was used for the calibration of the thermometers and the field intensity.

ESR spectra of Cl-TPV and TPV in toluene were recorded on an X-band spectrometer at room temperature, in order to estimate the difference in the spin density distributions of these radicals.

The unit-cell parameters were obtained from the photographic data. The crystal data are summarized in Table 1. The Weissenberg intensity data ($h0l$—$h5l$, $0kl$—$1kl$) were collected with Cu $K\alpha$ radiation and corrected for Lorentz and polarization effects. There were 2326 independent reflections, of which 1741 were regarded as observed.

Results of Magnetic Measurements

The susceptibility data were corrected for the diamagnetic contribution using Pascal's constants.[6] The paramagnetic molar susceptibility, χ_m, is shown in Fig. 2. The susceptibility follows the Curie-Weiss law with a negative Weiss constant, $\theta = -18.4$ K, in the high temperature region. However, the susceptibility deviates from the Curie-Weiss law at low temperatures, and it shows a round maximum with a value of $\chi_{max} = 6.70 \times 10^{-3}$ cgs emu mol^{-1} at $T_{max} = 21.0$ K.*** When the temperature is lowered further, the susceptibility decreases towards a finite value at 0 K. The radical concentration, as determined from the susceptibility data at high temperatures, is 100%, with an experimental error of 3%.

The ESR spectrum of TPV exhibited nine line splittings, with the hyperfine coupling constant of 0.59 mT due to the nearly equivalent four nitrogen nuclei; the splittings from protons were unresolved. On the other hand, the spectrum from Cl-TPV showed many incompletely resolved splittings due to the protons, as is shown in Fig. 3. However, the spacing of 0.59 mT of the nine line splittings was unchanged.

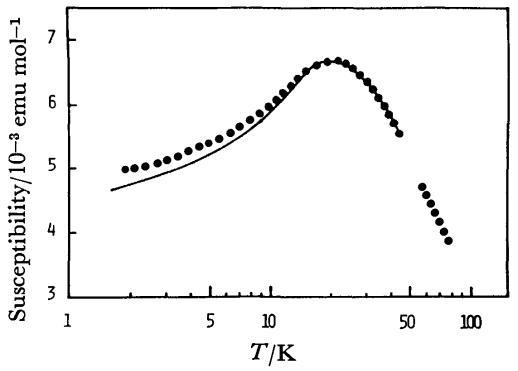

Fig. 2. Paramagnetic molar susceptibility of Cl-TPV powder. Solid circles show the experimental data and solid line is the susceptibility of the Heisenberg linear chain.

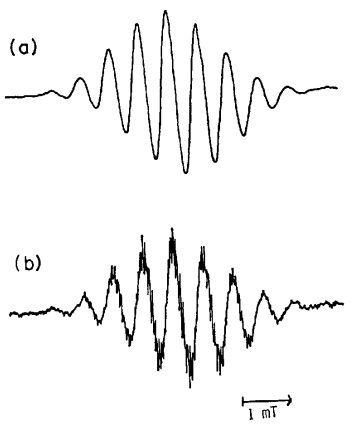

Fig. 3. ESR spectra of TPV (a) and Cl-TPV (b) in toluene.

***The value of the molar susceptibility in m^3 mol^{-1} (SI) can be obtained by multiplying the value in emu mol^{-1} (cgs) by $4\pi \times 10^{-6}$.

Structure Determination and Refinement

The crystal structure was solved by the direct method using a program written in our laboratory. The positions of all the 25 non-hydrogen atoms located on an E map were refined by the blockdiagonal least-squares procedure. The positions of all the 14 hydrogen atoms in the phenyl rings were deduced from a difference Fourier map, but both hydrogen atoms in the methylene group were located geometrically. The R value was reduced to 0.091 for 1741 observable reflections by blockdiagonal least-squares refinement with anisotropic thermal parameters for the non-hydrogen atoms and isotropic ones for the hydrogen atoms. The atomic coordinates are listed in Table 2. The atomic scattering factors for Cl, N, and C were those of the International Tables for X-Ray Crystallography.[7] For the hydrogen atom, the scattering factor was adopted from the table of Stewart *et al.*[8]

Description of the Structure

lengths and the bond angles are listed in Table 3. The four nitrogen atoms are coplanar (N-plane) within ±0.001 Å and the *sym*-tetrazinyl ring has a deformed boat form; these have been observed in other verdazyls.[9-11] The atomic deviations from N-plane are as follows: C(1)=0.62, C(2)=0.14, C(3)=−0.34, C(9)=−0.42, and C(15)=0.30 Å. These values are close to those of DTPV and TPV except that C(9) (−0.22 Å in TPV). The dihedral angles between N-plane and each plane of N(1)-, N(4)- and C(2)-phenyl rings are 37.5, (−)35.7, and 25.5°, respectively. The twist angles around the inter-ring bonds, defined by the dihedral angle between the plane of each phenyl ring and the plane through α-, β-, γ-, and γ'-atoms, are 20.9, (−)15.6, and 25.2° for N(1)–C(3), N(4)–C(9), and C(2)–C(15) bonds, respectively. The last angle is much greater than those in the other verdazyls examined, this fact is attributed to the intermolecular packing forces, as can be seen from Fig. 5.

Table 3. Bond lengths (l/Å) and bond angles (ϕ/°)
The estimated standard deviations are less than 0.01 Å and 1°, respectively.

Figure 5 shows how the Cl-TPV molecules are arranged in the unit cell. The molecules form columns along the b axis. The shortest intermolecular distance between the non-hydrogen atoms is 3.48 Å for the N(1)···C(19) contact in the column. This columnar structure seems very similar to that of DTPV, as can be seen from Fig. 6.[11] Within the column, the mean values of the intermolecular distances for the π-framework are actually 7.05 and 7.15 Å for Cl-TPV and DTPV, respectively, while they are 7.76—7.86 Å for the other verdazyls. However, there are some substantial differences between Cl-TPV and

The methyl carbon atom in C-tolyl group makes the outmost thorn of the column along the c axis.

DTPV, *e.g.* in the shortest N···N contact: 3.74 Å in the former, but 4.15 Å in the latter.

Discussion

The susceptibilities of a number of verdazyls have been described by the Heisenberg linear chain model.[2,12,13] The numerical study of the thermodynamic properties of the Heisenberg linear chain of $S=1/2$ spins has been made by Bonner and Fisher.[14] The theory predicts the following relation independent of the exchange parameter, J:

$$\chi_{max}T_{max} = 0.142. \quad (1)$$

The predicted susceptibility for antiferromagnetic coupling exhibits a round maximum at

$$T_{max} = 1.282|J|/k, \quad (2)$$

where k is the Boltzmann constant. The susceptibility of Cl-TPV gives 0.141 for Relation (1). Based on Eq. 2, the exchange parameter is estimated to be $J/k=-16.4$ K; this is the strongest antiferromagnetic exchange interaction among the verdazyl mono-radicals examined. The solid line in Fig. 2 is the susceptibility of the Heisenberg linear chain with this J value. The calculated susceptibility is very close to the observed one. The systematic disagreement in the lowest temperature region can be attributed to a small amount of impurities; it is hard to prepare and keep the radical completely pure. Therefore, an adequate model to describe the susceptibility of the Cl-TPV crystal is the Heisenberg linear chain model with $J/k=-16.4$ K.

Because the exchange interaction between the aromatic radicals is caused by the overlapping between the p_z π-orbitals, the Cl-TPV molecules in the column are coupled to one another by the exchange interaction. Therefore, a Cl-TPV crystal is a one-dimensional magnet in view of the molecular packing. This is consistent with the result derived from the susceptibility.

An approximated spin density Hamiltonian for the exchange interaction between the aromatic radicals A and B has been presented by McConnell:[15]

$$\mathscr{H}^{AB} = -\boldsymbol{S}^{A}\boldsymbol{S}^{B}\sum J_{ij}^{AB}\rho_i^A\rho_j^B, \quad (3)$$

where $\boldsymbol{S}^A$ and $\boldsymbol{S}^B$ are the total spin operators on molecules A and B, ρ_i^A and ρ_j^B are the π-spin densities on atoms i and j of A and B, respectively, and where J_{ij}^{AB} is the two-center exchange integral between i and j. The observed J corresponds to the summation in Eq. 3. Using this equation the ferromagnetic exchange interaction in a galvinoxyl radical crystal has been discussed.[16] The same procedure has been applied to TPV and its methyl derivatives.[2] According to that study, the order of the observed J's can be explained by means of the following tractable function for J_{ij}^{AB}:

$$J_{ij}^{AB} = -pC/r_{ij}^{AB}, \quad (4)$$

where C is a positive constant, r_{ij}^{AB} is the distance between atoms i and j, and where p is an angular correction. A possible angular correction is $p=\cos\theta_i^A\cos\theta_j^B$ where θ_i^A and θ_j^B are the angles between respective axes of the $p_z\pi$-orbitals of i and j atoms j and the vector distance $\boldsymbol{r}_{ij}^{AB}$.[17] However, the following rather crude correction factor was adopted:

$$p = \begin{cases} 1 & \text{when } r_{ij}^{AB} \leqq 6\text{ Å} \\ 0 & \text{when } r_{ij}^{AB} > 6\text{ Å}. \end{cases} \quad (5)$$

When the layered structure with the separation of 4 Å between the layers is assumed,

$$\left.\begin{array}{l} r_{ij}^{AB} \leqq 6\text{ Å corresponds to } \cos\theta_i^A\cos\theta_j^B \geqq 0.45 \\ \text{and} \\ r_{ij}^{AB} > 6\text{ Å corresponds to } \cos\theta_i^A\cos\theta_j^B < 0.45. \end{array}\right\} \quad (6)$$

When other functions for J_{ij}^{AB}, such as the overlap integral and exchange integral calculated by Dulčić and Herak,[18] were adopted, the order of the observed J's has been reversed.[2]

The spin densities on Cl-TPV are similar to those on TPV, in view of the same hyperfine coupling constant due to nitrogen nuclei. The same spin distribution as that of Cl-TPV can be reasonably assumed for DTPV. Therefore, the spin densities for Cl-TPV and DTPV used in the calculation are taken to be identical with those for TPV discussed elsewhere;[16] they are shown in Table 4.

Using Eqs. 4 and 5, the summation in Eq. 3 has been calculated for pairs of molecules along the three crystallographic axes. The results are summarized in Table 5, together with those for DTPV. The prominent negative value suggests the antiferromagnetic

along c axis		−21.3
Along the c axis	0.0369	
Observed J/k	−16.4 K	−11.1 K

a) The sums have been adjusted by using the factor obtained from the observed J for Cl-TPV and the calculated J along the b axis of the Cl-TPV crystal.

exchange coupling in the column along the b axis of the Cl-TPV crystal. The calculated exchange couplings between the columns are less than 1/5 of that within the column. These results are consistent with the fact derived from the susceptibility: an antiferromagnetic linear chain spin system. The ratio of the observed J of Cl-TPV to that of DTPV is 1.5. However, the calculated ratio is 0.8; this is not improved by adopting the squared cosine factor for ρ. The three other functions for J_{ij}^{AB} in Ref. 2 give the ratios of 0.7—0.004, where 0.7 is obtained with $J_{ij}^{AB}=-\rho C(r_{ij}^{AB})^{-3}$. In conclusion, Eq. 3 combined with Eqs. 4 and 5 has roughly explained the order of the observed J's of five verdazyl radicals. This tractable procedure would thus be practically more useful in correlating the exchange interaction with the crystal structure than complicated procedures, such as that adopted by Dulčić and Herak.[18]

The authors wish to thank Professors Yasuo Deguchi, Hiroaki Ohya-Nishiguchi, Noboru Hirota, and Masayoshi Kinoshita for their helpful discussions.

Magnetic Circular Dichroism Studies of 4,4′-Disubstituted Biphenyls

Hiroyuki UCHIMURA, Akio TAJIRI, and Masahiro HATANO*

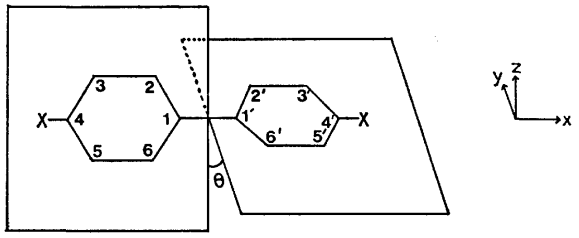
Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received March 4, 1981)

The magnetic circular dichroism (MCD) and ultraviolet (UV) absorption spectra of 4,4′-disubstituted biphenyls were measured. The MCD spectra showed diverse spectral patterns reflecting the natures of the substituent groups. These observed MCD spectra were reproduced by the theoretical calculations based on the Pariser-Parr-Pople-SCF-CI method. The dihedral angles of 4,4′-disubstituted biphenyls were estimated to be about 20° by comparing the observed MCD spectra with the calculated ones. The assignments for the MCD bands of 4,4′-disubstituted biphenyls were given on the basis of these calculations. The substituent effects of biphenyls were interpreted by the use of the coefficients of the configuration interactions.

One of the most interesting aspects of the optical properties of biphenyl and its sterically hindered derivatives has been displayed by the appearance of an intense, structureless absorption band with its maximum at *ca.* 40000 cm^{-1}. The band is well known to be very sensitive to the variation in the torsional angle, θ, around the central carbon-carbon bond of biphenyl (see Fig. 1), giving rise to a change in both the location of the band and its intensity.[1] The conjugation between the two benzene rings becomes large with a decrease in the dihedral angle of biphenyl. Thus, if the dihedral angle decreases, this band shows a marked red-shift and an enhancement in its intensity; therefore, it is called the conjugation band. The stable conformation of biphenyl is, in principle, established on the basis of a balance between the two effects, electronic delocalization and electrostatic repulsion between non-bonded atoms.[2] Especially, however, repulsion among the hydrogen atoms at ortho positions (2, 6, 2′, and 6′ in Fig. 1) in the biphenyl skeleton is considered to be of primary importance. Accordingly, on substitution by bulky groups at the ortho positions, the dihedral angle of biphenyl increases due to the appreciable increase in steric repulsion, giving rise to a hypsochromic effect on the transition energy and a hypochromic effect on the intensity of the conjugation band. In fact, Beaven *et al.*[1] have reported that the conjugation band shifts toward a higher-energy region with a decrease in its intensity on successive substitution by methyl groups at the ortho positions of biphenyl.

On the other hand, the dihedral angle is considered to change only slightly or remain unchanged on substitution at the para positions (4 and 4′ in Fig. 1). Kurland[3] gave an equation in which the difference in chemical shift between the protons at the meta and ortho positions of biphenyl was expressed as a function of θ; using that equation, he then tried to estimate the dihedral angles, θ, of the 4,4′-disubstituted biphenyls, including 4,4′-dideuterated biphenyl. The experimental results were well reproduced by taking $\theta=45°$ in his equation. In addition, the dihedral angle is found to be independent of the substituent groups. On the other hand, Suzuki[4] tried to elucidate the UV spectra of biphenyl and estimated the dihedral angle, θ, by making use of the core-resonance integral for the central bond as a function of θ. He obtained 0°, 23°, and 43° for biphenyl in gas, solution, and a crystalline state respectively. According to his results, the dihedral angles of 4,4′-disubstituted biphenyls in solution may be expected to take a value of about 20°.



X = NH_2, OH, NO_2, CN, CH_3, Cl

Fig. 1. The nuclear skeleton and coordinate system of 4.4′-disubstituted biphenyl.

So far, MCD studies, which are very useful for the investigation of the electronic states of the compounds, have been carried out on biphenyl, para-substituted biphenyls with electron-donating groups and bridged biphenyls.[5,6] The 1st and 2nd MCD bands of the parent molecule, biphenyl, have positive and negative signs respectively, while those of the para-substituted derivatives have the opposite signs. Thus, the MCD spectra of biphenyls show an apparent substituent effect, suggesting that the MCD measurement is more sensitive with respect to the natures of the substituents than the UV measurement, and therefore useful in giving reasonable spectroscopic assignments.

The molecular orbital investigations of biphenyls were limited to those of biphenyl itself, using the Pariser-Parr-Pople method,[7,8] molecules in the molecule method,[9] and the CNDO/2 method.[10]

In this work, 4,4′-disubstituted biphenyls with various substituents are investigated by means of UV and MCD spectroscopies in order to examine the substituent effects in a systematic fashion. The calculations for the MCD spectra of these compounds were carried out on the basis of the PPP method so as to reproduce the observed MCD spectra and dihedral angles of 4,4′-disubstituted biphenyls in solutions. It seemed that it would be interesting to see to what extent the observed spectra for hindered biphenyls can be explained by theoretical calculations on the basis of a simple approximation.

Experimental

4,4′-Diaminobiphenyl, 4,4′-dihydroxybiphenyl, 4,4′-dinitrobiphenyl, 4,4′-dicyanobiphenyl, 4,4′-dichlorobiphenyl,

and 4,4'-dimethylbiphenyl obtained commercially were recrystallized several times from appropriate solvents.

All the measurements were carried out at room temperature, using ethanol, methanol, or cyclohexane as solvents for the derivatives with strong electron-donating groups, with electron-attracting groups, or with weak electron-donating groups respectively. The MCD and UV spectra were measured on a JASCO-J20A recording spectropolarimeter equipped with a 1.14 T electromagnet and on a Hitachi EPS-3T recording spectrophotometer respectively.

Theoretical

The electronic transition energies, oscillator strengths, and Faraday B values of 4,4'-disubstituted biphenyls were estimated on the basis of the PPP method,[11] including configuration interactions among singly excited configurations with transition energies below 10 eV. One-center-core and repulsion integrals were evaluated from the valence-state ionization potentials and electron affinities. Two-center-core integrals were calculated by the use of the Wolfsberg-Helmholtz equation.[12] Two-center repulsion integrals were evaluated by the use of the Nishimoto-Mataga equation.[13] The repulsion integral, γ_{pq}, within a benzene ring was evaluated according to the usual formula:

$$\gamma_{pq} = \frac{14.397}{R_{pq}+a_{pq}} \text{ (eV)}, \tag{1}$$

$$a_{pq} = \frac{28.794}{\gamma_{pp}+\gamma_{qq}}, \tag{2}$$

where R_{pq} is the distance between the p and q atoms and where γ_{pp} stands for the one-center repulsion integrals. The repulsion integral, γ_{pq}, in which the p and q atoms belong to different benzene rings was calculated using Eq. 1, while modifying a_{pq} as follows:

$$a_{pq} = \frac{28.794}{(\gamma_{pp}+\gamma_{qq})\cos^2\theta+(\gamma'_{pp}+\gamma'_{qq})\sin^2\theta}, \tag{3}$$

$$\gamma'_{pp} = \gamma_{pp} - 6F_2, \tag{4}$$

where θ is the dihedral angle and F_2 is the Slater-Condon parameter. The benzene rings in biphenyl were assumed to be regular hexagons. The coordinate system employed is represented in Fig. 1. The x axis lies along the long molecular axis, and the y axis bisects the dihedral angle, θ. Since the repulsions among orthoprotons in 4,4'-disubstituted biphenyls are considered to be equal to that in biphenyl, their dihedral angles have been assumed to be equal throughout the calculations.

The theoretical Faraday B term associated with an electronic transition, $j \leftarrow a$, is expressed as follows:

$$B(j\leftarrow a) = \mathrm{Im}\{\sum_{k\neq a}(\langle k|\vec{\mu}|a\rangle/(E_k-E_a))\cdot \langle a|\vec{M}|j\rangle \times \langle j|\vec{M}|k\rangle + \sum_{k\neq j}(\langle j|\vec{\mu}|k\rangle/(E_k-E_j))\cdot \langle a|\vec{M}|j\rangle \times \langle k|\vec{M}|a\rangle\}, \tag{5}$$

where $\vec{\mu}$ and $\vec{M}$ denote the magnetic and electronic dipole moment operators respectively. The quantities in the denominator, E_k *etc.*, are the energies of the k states. The electric-transition dipole moments were estimated on the basis of the dipole-velocity method. The atomic integrals of the electric and magnetic dipole moments were retained only for the nearest neighbor atoms, while those for the distant atoms were neglected because they were small and expected no decisive effect on the calculated results. The orthogonalized set of atomic orbitals obtained by the Löwdin procedure[14] was used for the calculations of these quantities. The calculations were carried out by using the ACOS-700 computer in the Computer Center of Tohoku University.

Results and Discussion

The UV and MCD spectra of 4,4'-dihydroxybiphenyl are represented in Fig. 2, where ε is the molar extinction coefficient in $dm^3\,mol^{-1}\,cm^{-1}$ and where $[\theta]_M$ is the molar ellipticity in degree $dm^3\,mol^{-1}\,cm^{-1}$

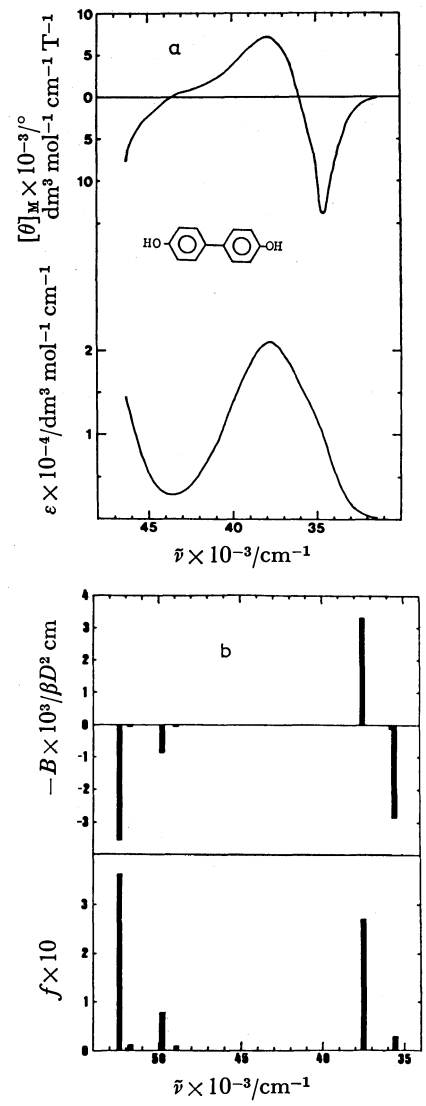


Fig. 2. The observed and calculated results of 4,4'-dihydroxybiphenyl.
(a) The MCD (top) and UV (bottom) spectra in ethanol measured at room temperature. (b) The calculated Faraday B value (top) and oscillator strength (bottom).

T^{-1}. The UV spectrum shows a single peak with its maximum at 37800 cm^{-1}, whereas the MCD spectrum exhibits a negative peak at 34600 cm^{-1} and a positive peak at 38000 cm^{-1}. 4,4′-Diaminobiphenyl shows a spectral profile (Fig. 3) similar to that of the dihydroxy derivative— a negative band at a lower frequency and a positive at a higher, but its MCD peaks shift toward a frequency region higher by about 2000 cm^{-1} in comparison with the dihydroxy derivative.

On the contrary, the MCD spectra of nitro and cyano derivatives show a positive band in the lower-frequency region and a negative in the higher, while the MCD extrema of the former are observed in a frequency region lower by about 3000 cm^{-1} than that of the latter (Figs. 4 and 5).

Furthermore, the signs of the MCD spectra of the methyl and chloro derivatives are all negative in the corresponding spectral region (Figs. 6 and 7). Thus, the UV spectrum of each compound is apparently observed as a single peak in the spectral region of 35000—40000 cm^{-1}, whereas the MCD spectra show various spectral patterns corresponding to the natures of the substituent groups.

The estimated Faraday B values (B) and oscillator strengths (f) are represented in Figs. 2—7. The longitudinal axis takes $-B$, since the Faraday parameter, B, appears as $-B$ in the expression of the molar ellipticity $[\theta]_M$. The estimated Faraday B values for the hydroxy and amino derivatives show positive signs in the lower-frequency region and negative signs in the higher, whereas those for the nitro and cyano derivatives are negative in the lower region and positive in the higher. The methyl derivatives are all predicted to have positive B values. The transition energies of hydroxy, amino, nitro, and methyl derivatives are in fairly good agreement with the experiments. However, in the cyano derivative the energy separation between the lst and 2nd MCD bands is too small in comparison with the observed

one, and the experimental MCD signs of the chloro derivative are not reproduced. The disagreement between the calculations and experiments in cyano and chloro derivatives is mainly due to the parametrizations for atomic integrals in the present calculations.

The calculated results are summarized and listed in Table 1. The 4,4′-disubstituted biphenyls belong to the point group, D_2, as well as the parent molecule. The 1st, 2nd, and 3rd $\pi^* \leftarrow \pi$ transitions of the hydroxy, amino and methyl derivatives are calculated to be $^1B_2 \leftarrow {}^1A$, $^1B_1 \leftarrow {}^1A$, and $^1B_3 \leftarrow {}^1A$ respectively, whereas those in the nitro and cyano derivatives to be $^1B_3 \leftarrow {}^1A$, $^1B_2 \leftarrow {}^1A$, and $^1B_1 \leftarrow {}^1A$. Therefore, the 1st and 2nd MCD bands of the derivatives with electron-donating groups are assigned to the $^1B_2 \leftarrow {}^1A$ and $^1B_3 \leftarrow {}^1A$ transitions respectively, and those of derivatives with electron-attracting groups, to the $^1B_3 \leftarrow {}^1A$ and $^1B_2 \leftarrow {}^1A$ transitions. The $^1B_1 \leftarrow {}^1A$ transitions in the lower-frequency region of all the compounds are considered to be too weak to be distinctly observed.

In the above MCD calculations, the dihedral angles of all the compounds were assumed to be 20°. On the contrary, according to Kurland,[3] the dihedral angles of 4,4′-disubstituted biphenyls were supposed to be 45°; in that way the observed NMR spectra were well explained. The calculation of the transition energies and Faraday B parameters was carried out for the hydroxy, amino, and nitro derivatives, in which the dihedral angles were taken to be 45°. The results are summarized and listed in Table 2, along with the results with $\theta=20°$. The results calculated with $\theta=45°$ seemed to be in poor agreement, especially with respect both to the excitation energies and Faraday B values, with the experimental values. Accordingly, it is concluded that the dihedral angles of 4,4′-disubstituted biphenyls in solution are about 20°.

In Fig. 8 the molecular orbitals of biphenyl, 4,4′-diaminobiphenyl, and 4,4′-dinitrobiphenyl are schematically illustrated in order to show the interaction between biphenyl and the substituents. In the derivatives with electron-donating groups, the molecular orbitals of substituents interact, preferably with

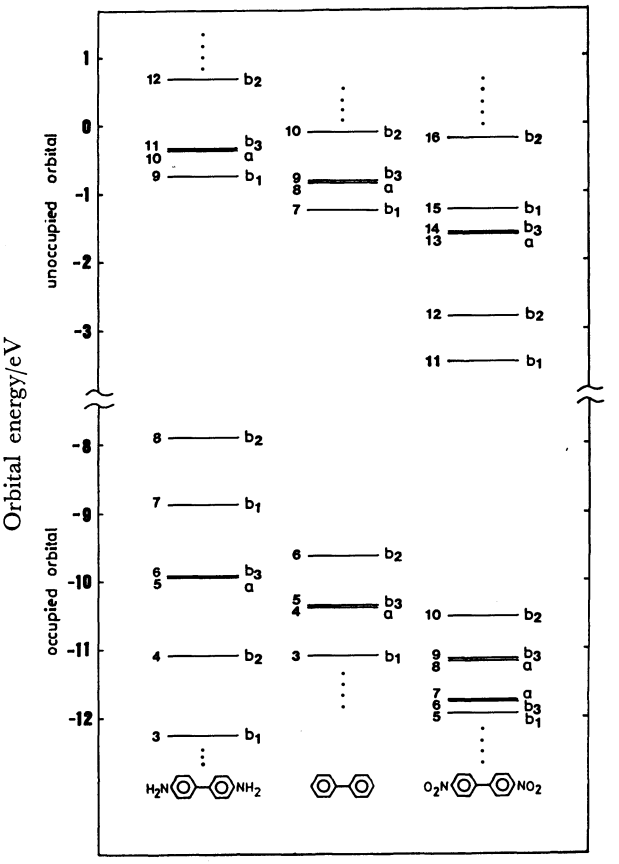

Fig. 8. The molecular orbitals of biphenyl, 4,4'-diaminobiphenyl, and 4,4'-dinitrobiphenyl.

the upper occupied orbitals of biphenyl, so that some of the occupied orbitals of biphenyl are destabilized. On the contrary, in the derivatives with electron-attracting groups, the molecular orbitals of substituents preferably interact with the lower unoccupied orbitals of biphenyl.

In Table 3 the wave functions which describe the three lowest excited states of biphenyl, 4,4'-diaminobiphenyl, and 4,4'-dinitrobiphenyl are shown, where $\psi_{k\to l}$ denotes a singly excited configuration from the k-th molecular orbital to the l-th. As is expected from Fig. 8, the lowest-energy excited state is considered to make a dominant contribution to the singly excited configuration arising from the LUMO← HOMO transition in each molecule. However, the lowest B_3 state is not able to be the lowest because of the weak configuration interaction with the higher B_3 states. On the contrary, the strong configuration interaction between $\psi_{5\to7}$ and $\psi_{6\to8}$ and that between $\psi_{4\to7}$ and $\psi_{6\to9}$ lower the B_2 and B_1 states below the B_3 state. This is also true for the amino derivative. In the nitro derivative, there exists a configuration with B_3 symmetry, $\psi_{5\to12}$, close to the $\psi_{10\to11}$ arising from the single excitation from the HOMO to the LUMO. The energy level of the B_3 state is lowered appreciably due to the configuration interaction, whereas the effect of the configuration interaction among the B_2 states, and also that among B_1 configurations, does not exceed the stabilization of the B_3 states. Consequently, the B_3 state is the lowest energy state in the nitro derivative.

The discrepancy of the MCD signs between the derivatives with the strong electron-donating groups and those with the attracting groups can then be explained. Here, only the strong MCD bands in the lower-frequency region in both derivatives are considered; they are assigned to the $^1B_2 \leftarrow {}^1A$ and $^1B_3 \leftarrow {}^1A$ transitions in the former and to $^1B_3 \leftarrow {}^1A$ and $^1B_2 \leftarrow {}^1A$ in the latter. As can clearly be seen from Eq. 5, the contribution of the 2nd term is considered to be of primary importance in the calculation of the Faraday B values because of its appreciable contribution to Eq. 5 thanks to the small energy difference in the denominator. Furthermore, the matrix element of the nearest neighboring state is of crucial importance; for example, the B_2 state mixes with B_3, and *vice versa*.

The excited electronic-wave functions of biphenyl derivatives are considered to be expressed for the lowest B_2 and B_3 states by a slight modification of the wave functions of biphenyl itself:

Table 1. Theoretical transition energies ($\tilde{\nu}$), oscillator strengths (f), and faraday B values (B) of 4,4′-disubstituted biphenyls

4,4′-Diamino-	$^1B_2$	$0.813\ \psi_{8\to10}-0.376\ (\psi_{6\to9}+\psi_{7\to11})+0.222\ \psi_{5\to12}$
	$^1B_1$	$0.824\ \psi_{8\to11}-0.392\ \psi_{7\to10}+0.340\ \psi_{5\to9}-0.211\ \psi_{6\to12}$
	$^1B_3$	$0.981\ \psi_{8\to9}-0.152\ \psi_{7\to12}$
4,4′-Dinitro-	$^1B_3$	$0.969\ \psi_{10\to11}+0.233\ \psi_{5\to12}+0.040\ (\psi_{9\to13}+\psi_{8\to14})$
	$^1B_2$	$0.814\ \psi_{9\to11}+0.422\ \psi_{8\to12}-0.395\ \psi_{10\to13}$
	$^1B_1$	$0.824\ \psi_{8\to11}+0.441\ \psi_{9\to12}-0.352\ \psi_{10\to14}$

$$\Psi_{B_2} = C_1\psi_{5\to7} - C_2\psi_{6\to8} + C_3\psi_{4\to10} - C_4\psi_{3\to9}$$
$$\Psi_{B_3} = \psi_{6\to7}, \quad (6)$$

where the coefficients, C_1—C_4, are taken to be positive. In biphenyl, C_1 is equal to C_2, and C_3 to C_4.

The Faraday B terms of the B_2 and B_3 states are expressed as follows within this nearest-neighbor approximation:

$$B(B_2\leftarrow A) = -\mathrm{Im}\langle B_2|\mu_z|B_3\rangle\langle A|M_y|B_2\rangle \times\langle B_3|M_x|A\rangle/(E_{B_3}-E_{B_2})$$
$$B(B_3\leftarrow A) = \mathrm{Im}\langle B_3|\mu_z|B_2\rangle\langle A|M_x|B_3\rangle \times\langle B_2|M_y|A\rangle/(E_{B_2}-E_{B_3}). \quad (7)$$

As can clearly be seen from Eq. 7, $B(B_2\leftarrow A) = -B(B_3\leftarrow A)$. In amino derivatives the following equations hold for the energies and the off-diagonal matrix element of the μ_z operator:

$$E_{B_2} < E_{B_3} \quad (8)$$

$$\mathrm{Im}\langle B_2|\mu_z|B_3\rangle = \beta\{C_1\langle\phi_5|\vec{r}\times\vec{\nabla}|\phi_6\rangle_z - C_2\langle\phi_8|\vec{r}\times\vec{\nabla}|\phi_7\rangle_z\} \approx \beta\{0.7C_1+1.1C_2\} > 0, \quad (9)$$

where β is the Bohr magneton and where ϕ_k denotes the k-th molecular orbital of biphenyl.

The configurations, $\psi_{5\to7}$, $\psi_{6\to8}$, $\psi_{4\to10}$, and $\psi_{3\to9}$, in biphenyl correspond to $\psi_{6\to9}$, $\psi_{8\to10}$, $\psi_{5\to12}$, and $\psi_{7\to11}$ respectively in the amino derivative. If the para-positions of biphenyl are replaced by the electron-donating groups, such as $-NH_2$ or $-OH$, the energy levels of $\psi_{6\to8}$ and $\psi_{3\to9}$ are found to be lower than those of $\psi_{5\to7}$ and $\psi_{4\to10}$ respectively, as may be seen from Fig. 8 and Table 3. This means that $C_1 < C_2$ and $C_3 < C_4$. Then, the off-diagonal matrix element of M_y, $\langle A|M_y|B_2\rangle$, is expressed as:

$$\langle A|M_y|B_2\rangle = \sqrt{2}\{C_1\langle\phi_5|m_y|\phi_7\rangle - C_2\langle\phi_6|m_y|\phi_8\rangle + C_3\langle\phi_4|m_y|\phi_{10}\rangle - C_4\langle\phi_3|m_y|\phi_9\rangle\} \approx \sqrt{2}\{(C_1-C_2)m_1+(C_3-C_4)m_2\} < 0, \quad (10)$$

where;

$$\langle\phi_5|m_y|\phi_7\rangle \approx \langle\phi_6|m_y|\phi_8\rangle \equiv m_1 > 0,$$

and

$$\langle\phi_4|m_y|\phi_{10}\rangle \approx \langle\phi_3|m_y|\phi_9\rangle \equiv m_2 > 0.$$

In addition, the matrix element, $\langle B_3|M_x|A\rangle$, is calculated to be:

$$\langle B_3|M_x|A\rangle = \sqrt{2}\langle\phi_6|m_x|\phi_7\rangle > 0. \quad (11)$$

From Eqs. 7—11, the Faraday B values for the derivatives with strong electron-donating groups are found to be:

$$B(B_2\leftarrow A) = -B(B_3\leftarrow A) > 0. \quad (12)$$

On the contrary, in the nitro derivative,

$$E_{B_3} < E_{B_4}. \quad (13)$$

Equations 9 and 11 hold for the nitro derivative as well as the amino derivative, but with $C_1 > C_2$ and $C_3 > C_4$ the matrix element, $\langle A|M_y|B_2\rangle$, of the nitro derivative has the opposite sign of that of the amino derivative. Therefore, this leads to the following relationship:

$$\langle A|M_y|B_2\rangle > 0. \quad (14)$$

From Eqs. 9, 11, 13, and 14, the signs of the Faraday B values of the nitro derivative are shown to be the same as in Eq. 12; *i.e.*,

$$B(B_2\leftarrow A) = -B(B_3\leftarrow A) > 0.$$

Equation 12 implies that the MCD band which is assigned to the $^1B_2\leftarrow{}^1A$ transition must be negative and that the MCD band which is assigned to the $^1B_3\leftarrow{}^1A$ transition must be positive. In the hydroxy and amino derivatives, the electronic transitions are $^1B_2\leftarrow{}^1A$ and $^1B_3\leftarrow{}^1A$ in the increasing order of energy; therefore the MCD profile is negative for the 1st band and positive for the 2nd band. In the nitro and cyano derivatives, the situation is completely reversed; the MCD profile is positive for the 1st MCD band and negative for the 2nd band because of the inversion of the B_2 and B_3 excited states in these molecules.

The authors wish to thank Dr. Akira Kaito for his useful advice and stimulating discussions during the course of this work.

Asymmetric Transformation of *N*-Acyl-DL-amino Acids

Chikara HONGO,* Shigeki YAMADA, and Ichiro CHIBATA
Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., 16-89, Kashima-3-chome, Yodogawa-ku, Osaka 532

(Received March 25, 1981)

The asymmetric transformation which converted *N*-acyl-DL-amino acids to the desired optically active isomers was studied. *N*-Acylamino acids such as *N*-butyrylproline, *N*-acetylleucine, and *N*-benzoylphenylglycine were easily racemized in the presence of a catalytic amount of acetic anhydride in melted states or in acetic acid or chloroform solutions. The racemic modification of these *N*-acylamino acids crystallized as a true racemic mixture suitable for optical resolution by a preferential crystallization procedure under the conditions of racemization. By combining preferential crystallization of the desired enantiomer by seeding from a supercooled melt or a supersaturated solution of a racemic modification and simultaneous racemization of the opposite isomer, *N*-acyl-DL-amino acid was partially converted to an optically active isomer and the whole reaction mixture became optically active (10—40% enantiomeric excess).

The optical resolution of DL-amino acids by a preferential crystallization procedure has been extensively investigated in our laboratory.[1-7] This procedure is considered to be one of the most useful methods for practical and industrial purposes since it enables the desired optical isomer to crystallize preferentially from a supersaturated solution of the racemic modification by simple inoculation of the same isomer.

Our previous report[6] showed that some *N*-acyl-DL-prolines were resolvable by the preferential crystallization procedure and that the undesired optically active isomer recovered from the mother liquor was completely racemized by heating at a temperature above its melting point in the presence of a catalytic amount of acetic anhydride and could be reused as the starting material. In the course of further studies, a large single crystal of almost optically pure *N*-butyryl-L-proline (*N*-Bu-L-Pro) was found to deposit in the reaction vessel when *N*-butyryl-D-proline (*N*-Bu-D-Pro) was completely racemized by heating with acetic anhydride and allowing the racemized melt to stand for 2 d at room temperature. This fact indicated that one of the optically active isomers preferentially crystallized from the super-cooled melt of *N*-butyryl-DL-proline (*N*-Bu-DL-Pro) by spontaneous crystallization of the isomer. If such optical resolution by preferential crystallization can be achieved at a high temperature, which enables the opposite isomer in the melt to racemize at a high rate, all of the racemic modification will be theoretically transformed to the optically active crystals. We were interested in the asymmetric transformation of *N*-Bu-DL-Pro by the combination of the preferential solidification from a melted racemic modification and simultaneous racemization of the opposite isomer in the melt. Besides *N*-Bu-DL-Pro, some *N*-acyl-DL-amino acids such as *N*-acetyl-DL-leucine[8] (*N*-Ac-DL-Leu) and *N*-benzoyl-DL-phenylglycine[9] (*N*-Bz-DL-PG) are known to form a true racemic mixture suitable for the optical resolution by a preferential crystallization procedure. These optically active isomers are expected to be readily racemized. Therefore, these substances were also chosen as test compounds; we sought the systems in which the asymmetric transformation took place by preferential crystallization under conditions of simultaneous racemization. The screening was carried out with combinations of the racemization process and two kinds of resolution procedures, *i.e.*, solidification from a melted racemic modification and the usual preferential crystallization from a supersaturated solution dissolving a racemic modification. In the former case, *N*-Bu-DL-Pro and *N*-Ac-DL-Leu were found to be partially converted to the respective optically active isomers and to become optically active as a whole. In the latter case, the asymmetric transformation was observed with *N*-Bu-DL-Pro, *N*-Ac-DL-Leu, and *N*-Bz-DL-PG. We wish to report here these results. A preliminary account of this work has been already published.[10]

Racemic and optically active *N*-Bu-Pro, *N*-Ac-Leu, and *N*-Bz-PG were prepared by the usual acylation of the respective amino acids. The physical properties are shown in Table 1; these indicate that these racemic modifications crystallize as a true racemic mixture suitable for the preferential crystallization procedure in the appropriate solvent. As shown in Table 2, these optically active isomers could be racemized at a very high rate by melting at a temperature near each one's melting point in the presence of a catalytic amount of acetic anhydride. Furthermore, as shown in Table 3, they could be easily racemized by heating at a relatively low temperature in acetic acid (for *N*-Ac-Leu and *N*-Bz-PG) or chloroform (for *N*-Bu-Pro) solution containing a small amount of acetic anhydride. In both cases, no racemization occurred without acetic anhydride, which was essential for the racemization process. Thus, the two important requirements for the intended asymmetric transformation were fulfilled.

The first approach for asymmetric transformation was carried out by preferential solidification from a super-cooled melt of a racemic modification. In the cases of *N*-Bu-Pro and *N*-Ac-Leu, the whole reaction mixtures became optically active (34% and 10% enantiomeric excess respectively). The second approach was carried out by preferential crystallization from a supersaturated solution of a racemic modification. In this case, two modes of operation were employed to maintain a supersaturation state during the asymmetric transformation, *i.e.*, continuous removal of solvent or addition of an inert solvent effective for reducing the solubility. In both operational modes, the asymmetric transformation of *N*-Bu-Pro, *N*-Ac-Leu, and *N*-Bz-PG was observed and the respective

optically active crystals were actually separated from the reaction mixture. From the mother liquor, the racemic modification was recovered. These results are shown in Table 4 and Table 5. In a typical experiment by addition of inert solvent, 4.70 g of *N*-Ac-L-Leu with an optical purity of 89.6% was obtained from 9.5 g of *N*-Ac-DL-Leu. From the mother liquor, 3.53 g of *N*-Ac-DL-Leu was recovered. In the usual optical resolution by the preferential crystallization procedure, the yield of the seeded isomer in one operating cycle is rather low, owing to the limitation of supersaturated state of the opposite isomer; it is usually 5 to 10% based on the original weight of racemic modification. On the other hand, the

a) Weight of seed crystals was subtracted from the net weight of the active form obtained. b) The second crop was obtained by cooling the filtrate after the separation of the first crop; the data are shown in parentheses.

asymmetric transformation proposed here can give a high yield, since the concentration of the opposite isomer is decreased by the racemization and the total extent of supersaturation of the desired isomer can be increased by using the continuous operation methods described above.

The asymmetric transformation by a combination of optical resolution by selective precipitation of the less soluble diastereoisomeric salt and epimerization of the soluble diastereoisomeric salt is well known as an asymmetric transformation of second order.[11] However, the asymmetric transformation by a combination of preferential crystallization of a desired enantiomer by seeding from a supersaturated solution of a racemic modification and simultaneous racemization of the opposite isomer is unique and has not been reported except in the case of α-amino-ε-caprolactam–nickel chloride complex[12] and a few examples of somewhat analogous asymmetric transformations.[13–15] The proposed method is very promising for industrial application because of its operational simplicity. More detailed experiments on the mechanism of this asymmetric transformation and the best conditions for practical application will be described in a subsequent paper.

Experimental

Materials and Analyses. Analytical standard grade amino acids manufactured by our company, Tanabe Seiyaku Co., Ltd., were used. Other chemicals were obtained from Tokyo Kasei Kogyo Co., Ltd. All samples were dried overnight *in vacuo* at room temperature. Melting points were measured with a Yamato MP-21 melting point apparatus in an unsealed capillary tube and are uncorrected. Infrared spectra of samples were determined in nujol using a Shimadzu infrared spectrophotometer, Model IR-27G. Optical rotations were measured with a Perkin-Elmer 141 automatic polarimeter. Elemental analyses were performed with a Perkin-Elmer 240 elemental analyzer. Solubility was determined by approaching saturation equilibrium from the side of undersaturation. Solute concentration was measured with a Karl Zeiss immersion refractometer. Identification of *N*-acylamino acids was carried out by elemental analysis, IR-spectrum, specific rotation and thin-layer chromatography (solvent system: $CHCl_3$–MeOH–AcOH, 85:15:3, v/v/v) using the ascending technique on Merck's precoated Kieselgel 60 F_{254}. The chromatograms were sprayed with 40% hydrobromic acid, heated at 105 °C for about 5 min, and stained with ninhydrin at 105 °C for 5 min. The stained spots were compared with authentic samples.

Preparation of N-*Acylamino Acids.* *N*-Bu-L- and -DL-Pro were prepared from L- and DL-proline by acylation with *n*-butyryl chloride in chilled aqueous alkali, according to the usual manner described in our previous report.[6]

The racemic modifications and L-isomers of *N*-Ac-Leu and *N*-Bz-PG were similarly prepared from DL- and L-leucine and DL- and L-phenylglycine with acetyl chloride and benzoyl chloride, respectively (yield, 80—95%). The products were used for asymmetric transformation without further purification. The elemental analyses of these *N*-acylamino acids recrystallized from chloroform (for *N*-Bu-Pro) or acetic acid (for *N*-Ac-Leu and *N*-Bz-PG) corresponded to the respective theoretical values. The properties of these *N*-acylamino acids are shown in Table 1.

Racemization of N-*Acyl*-L-*amino Acids. *Racemization by Melting in the Presence of Small Amounts of Acetic Anhydride*: A mixture of *N*-Bu-L-Pro (1.0 g) and 0.1 molar equivalents of acetic anhydride (0.05 ml) was maintained at 97 °C in a sealed tube. The mixture was liquefied with the elapse of time. After 30 min, the liquefied sample was dissolved in methanol (50 ml) and the optical rotation was measured. The initial optical rotation before the reaction was α_D^{25} −1.713°. The reaction mixture did not show any optical rotation. Therefore *N*-Bu-L-Pro seemed to be completely racemized. In the absence of acetic anhydride, the optical rotation was α_D^{25} −1.439° even after heating at 120 °C for 2 h. In this case, the racemization degree was estimated to be 16%, based on α_D^{25} −1.713° of the initial optical rotation. In similar ways, *N*-Ac-L-Leu and *N*-Bz-L-PG were maintained at 150 °C for 30 min and at 160 °C for 1 h respectively in the presence of 0.1 molar equivalents of acetic anhydride. The racemization degrees were estimated as described above. The results were compared with those in the absence of acetic anhydride and are shown in Table 2. The racemization was also confirmed by separation of the reacted *N*-acylamino acids in the following way. After the complete racemization, the mixture was cooled to room temperature and the crystallized *N*-acylamino acid was suspended with a small amount of toluene (for *N*-Bu-Pro) or water/MeOH (2/1, v/v) (for *N*-Ac-Leu and *N*-Bz-PG). The suspended *N*-acylamino acid was collected and dried. The specific rotations, melting points, and IR spectra of these separated *N*-acylamino acids showed that the products were the respective racemic modifications and the true racemic mixtures. In the case of *N*-Bz-PG, however, a slight decomposition and some by-products formation were observed.

Racemization by Heating in a Solution Containing Small Amounts of Acetic Anhydride: *N*-Bu-L-Pro (1.0 g) was dissolved in chloroform (1.2 ml) containing 0.2 molar equivalents of acetic anhydride (0.10 ml). The mixture was maintained at 50 °C for 4 h. The whole reaction mixture was dissolved in methanol (50 ml) and the optical rotation was measured, α_D^{25} −0.033°. The racemization degree was estimated to be 98%, based on the initial optical rotation, α_D^{25} −1.670°. In the absence of acetic anhydride, the racemization did not occur. In similar ways, *N*-Ac-L-Leu and *N*-Bz-L-PG were racemized in acetic acid containing 0.2 molar equivalents of acetic anhydride and the racemization degrees were estimated as described above. The results were compared with those in the absence of acetic anhydride and are shown in Table 3.

The racemization was also confirmed by separation of respective *N*-acylamino acids from the reaction mixture. After the complete racemizations, the reaction mixtures were concentrated to a half volume, and the racemized *N*-acylamino acids were crystallized at room temperature. The precipitated crystals were collected and dried. The specific rotations, melting points, and IR spectra of these separated *N*-acylamino acids showed that the products were the racemic modifications and the true racemic mixtures.

Asymmetric Transformation by Preferential Solidification from Melted Racemic Modification. N-*Bu*-DL-*Pro*: A mixture of *N*-Bu-DL-Pro (10.00 g) and acetic anhydride (0.5 ml) was melted by heating at 100 °C. The complete melt was maintained at 70 °C, seeded with finely pulverized crystals of *N*-Bu-L-Pro (0.50 g), and gently stirred in a sealed flask for 7 h. During the reaction, the crystal growth of seeded L-isomer was observed. After 7 h, toluene (10 ml) was added into the reaction mixture at the same temperature and the precipitated crystals were quickly separated by filtration and dried to give *N*-Bu-L-Pro (6.30 g), $[\alpha]_D^{25}$ −64.7° (*c* 1, water), optical purity 61.4% (3.87 g of *N*-Bu-L-Pro plus 2.43 g of *N*-Bu-DL-Pro). After the separation of the first crop, the second crop was crystallized by cooling the filtrate and was separated by filtration to give *N*-Bu-DL-Pro (3.30 g), $[\alpha]_D^{25}$ 0.0° (*c* 1, water), mp 89—90 °C. The mother liquor did not show any optical rotation. Therefore, we subtract 0.5 g of seeded *N*-Bu-L-Pro from the net weight of *N*-Bu-L-Pro obtained, and find that 3.37 g of *N*-Bu-L-Pro was newly formed from *N*-Bu-DL-Pro. That is, 3.37 g of *N*-Bu-DL-Pro was transformed to *N*-Bu-L-Pro.

N-*Ac*-DL-*Leu*: A mixture of *N*-Ac-DL-Leu (10.00 g) and acetic anhydride (0.6 ml) was melted in a sealed flask by heating at 150 °C. The complete melt was cooled to 117 °C, seeded with finely pulverized crystals of *N*-Ac-L-Leu (0.05 g), and kept at the same temperature for 18 h in a sealed flask to allow the preferential solidification of L-isomer to proceed. Then, water/MeOH (2/1, v/v, 20 ml) was added into the reaction mixture at the same temperature and the precipitated crystals were quickly separated by filtration and dried to give *N*-Ac-L-Leu (1.21 g), $[\alpha]_D^{25}$ −21.4° (*c* 1, MeOH), optical purity 85.9% (1.04 g of *N*-Ac-L-Leu plus 0.17 g of *N*-Ac-DL-Leu). The second crop was crystallized from the filtrate by stirring at a room temperature and separated by filtration to give *N*-Ac-DL-Leu (4.20 g), $[\alpha]_D^{25}$ 0.0° (*c* 1, MeOH), mp 158—159 °C. The mother liquor did not show optical rotation. Therefore, we subtract 0.05 g of seeded *N*-Ac-L-Leu from the net weight of *N*-Ac-L-Leu obtained above, and find that 0.99 g of *N*-Ac-L-Leu was transformed from *N*-Ac-DL-Leu.

Asymmetric Transformation by Preferential Crystallization from Supersaturated Solution of Racemic Modification. Crystallization by Continuous Removal of Solvent: The supersaturation state was kept by continuous removal of solvent during the preferential crystallization of L-isomer and the simultaneous racemization of D-isomer. *N*-Bu-DL-Pro (10.60 g) was dissolved in chloroform (5.2 ml) at 70 °C and maintained at 50 °C. After acetic anhydride (0.8 ml) was added to the solution, the solution was seeded with finely pulverized crystals o *N*-Bu-L-Pro (0.20 g) and stirred for 20 h at the same temperature. Since the reaction was carried out in an open vessel without condenser, the solution was spontaneously concentrated. The amount of removed solvent was calculated to be 4.4 ml from the decrease in the weight of the reaction mixture. The precipitated crystals were quickly collected by filtration, washed with a small amount of cold chloroform, and dried to give *N*-Bu-L-Pro (9.38 g), $[\alpha]_D^{25}$ −43.5° (*c* 1, water), optical purity 41.3% (3.87 g of *N*-Bu-L-Pro plus 5.51 g of *N*-Bu-DL-Pro). Although the second crop was not obtained from the mother liquor, the mother liquor did not show optical rotation. Therefore, we subtract 0.20 g of seeded *N*-Bu-L-Pro from the net weight of *N*-Bu-L-Pro obtained above and find that 3.67 g of *N*-Bu-L-Pro was transformed from *N*-Bu-DL-Pro.

The reactions of *N*-Ac-DL-Leu and *N*-Bz-DL-PG were carried out at 75 °C for 7 h by using acetic acid as a solvent.

During the reaction, the solvent was removed at the rates of 1 ml/h for *N*-Ac-Leu and 2 ml/h for *N*-Bz-PG under a slightly reduced pressure. After 7 h, the precipitated crystals were quickly filtered, washed with a small amount of acetic acid, and dried. The second crops were obtained from the mother liquors which were stirred at room temperature. The results are shown in Table 4.

Crystallization by Addition of an Inert Solvent: During the preferential crystallization of L-isomer and the simultaneous racemization of D-isomer, the supersaturation state was maintained by addition of an inert solvent which was effective for reducing the solubility of racemic modification. *N*-Ac-DL-Leu (9.50 g) was dissolved in acetic acid (10.0 ml) containing acetic anhydride (1.0 ml) at 90 °C. The solution was maintained at 75 °C and seeded with finely pulverized crystals of *N*-Ac-L-Leu (0.20 g). Then toluene (50 ml) was added to the solution over a period of 5 h under stirring at the same temperature. The precipitated crystals were quickly collected by filtration and dried to give *N*-Ac-L-Leu (4.70 g), $[\alpha]_D^{25}$ −22.3° (*c* 1, MeOH), optical purity 89.6%, (4.21 g of *N*-Ac-L-Leu plus 0.49 g of *N*-Ac-DL-Leu). The second crop (3.53 g) was recovered from the mother liquor which was stirred at room temperature, $[\alpha]_D^{25}$ 0.0° (*c* 1, MeOH), mp 158—159 °C. Therefore, we subtract 0.20 g of seeded *N*-Ac-L-Leu from the net weight of *N*-Ac-L-Leu of the first crop and find that 4.01 g of *N*-Ac-L-Leu was transformed from *N*-Ac-DL-Leu. In similar ways, the reactions of *N*-Bu-Pro and *N*-Bz-PG were carried out at 50 °C for 7 h in chloroform solution and at 75 °C for 5 h in acetic acid solution, respectively. In these cases, diisopropyl ether (for *N*-Bu-Pro) or xylene (for *N*-Bz-PG) was added into the respective solutions to reduce the solubility of racemic modification. The results are shown in Table 5.

Asymmetric Transformation of *N*-Acetyl-DL-leucine

Chikara HONGO,* Shigeki YAMADA, and Ichiro CHIBATA
Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., 16-89, Kashima-3-chome, Yodogawa-ku, Osaka 532
(Received March 25, 1981)

The asymmetric transformation of *N*-acetyl-DL-leucine by a combination of preferential crystallization of a desired isomer and simultaneous racemization of the opposite isomer was studied. The reaction was analyzed in detail and a practical method for the asymmetric transformation was established. A supersaturated solution of *N*-Ac-DL-Leu in acetic acid containing catalytic amounts of acetic anhydride was seeded with the crystals of *N*-Ac-L-Leu and cooled at a rate of 10 °C/h from 100 °C to 40 °C. As a result, almost optically pure *N*-Ac-L-Leu was obtained in a yield of 70%, based on the original weight of *N*-Ac-DL-Leu.

Our previous paper[1] reported some experimental facts demonstrating the asymmetric transformation of certain *N*-acylamino acids, including *N*-acetyl-DL-leucine (*N*-Ac-DL-Leu), *N*-butyryl-DL-proline, and *N*-benzoyl-DL-phenylglycine. The asymmetric transformation was achieved by a combination of an optical resolution process and racemization process. Among these experiments, a combination of the preferential crystallization of the seeded *N*-Ac-L-Leu from the acetic acid solution supersaturated with *N*-Ac-DL-Leu and racemization of the unseeded *N*-Ac-D-Leu remaining in the liquid phase was considered to be most promising for practical application. However, the details were not investigated and the yields were low. Subsequently to that work, the reaction was analyzed and a practical method for the asymmetric transformation of *N*-Ac-DL-Leu was established.

In the optical resolution process by preferential crystallization, the crystallization of the desired optical isomer (for example L-isomer) by seeding leads to an excess of the undesired opposite isomer (D-isomer) in the solution. This excess D-isomer also begins to crystallize spontaneously after a certain time, resulting in low enantiomeric purity of the product. Accordingly, the rate of racemization of the excess D-isomer in the optical resolution system is a very important factor in the asymmetric transformation by this type of optical resolution method. This is distinct from the common cases of a second order asymmetric transformation[2] which use the difference in solubility between the diastereoisomeric salts with a chiral resolving agent. Therefore, the factors accelerating the rate of racemization of *N*-Ac-D-Leu were investigated.

Since the presence of acetic anhydride was essential for accelerating the racemization of *N*-Ac-D-Leu, the effect of amounts of acetic anhydride was investigated at 75 °C using acetic acid as a solvent. If the racemization of *N*-Ac-D-Leu is complete in several hours, the rate of racemization is sufficient for practical asymmetric transformation. Although the rate of racemization was decreased with the decrease of the molar ratio of acetic anhydride, as can be seen in Fig. 1, a racemization rate sufficient for the asymmetric transformation was obtained even at 0.1 molar ratio of acetic anhydride. The effect of temperature on racemization was investigated under various conditions. The rate of racemization was greatly influenced by temperature and varied with the composition of the

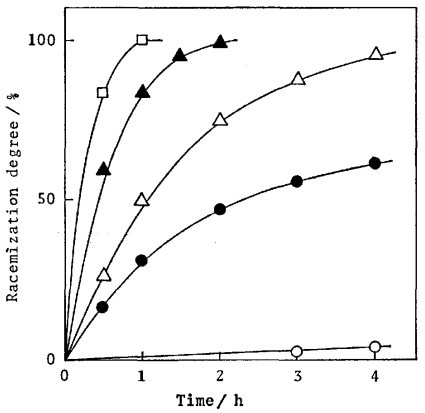

Fig. 1. Effect of acetic anhydride on racemization of *N*-Ac-D-Leu.
The solutions containing 6.0 g of *N*-Ac-D-Leu, 30 ml of AcOH and various amounts of Ac_2O were heated at 75 °C. Molar ratio of Ac_2O for *N*-Ac-D-Leu was varied from zero to 0.5: ○; zero, ●; 0.05, △; 0.1, ▲; 0.2, □; 0.5. Samples (0.5 ml) from the reaction mixture were diluted by methanol (10 ml) and optical rotations were measured. Racemization degree was calculated from the following equation:

$$\frac{\text{initial optical rotation} - \text{optical rotation after reaction}}{\text{initial optical rotation}} \times 100.$$

reaction mixture, as shown in Fig. 2. A temperature higher than 40 °C was necessary for practical racemization. The stability of crystalline optically active *N*-Ac-Leu was also investigated under the above conditions for racemization in a liquid phase. As a result, crystals of optically active *N*-Ac-Leu were found to be not racemized even at 90 °C. Thus the most essential requirement for this kind of asymmetric transformation was fulfilled.

Subsequently, optical resolution of *N*-Ac-DL-Leu by a preferential crystallization procedure was carried out at 80 °C under appropriate conditions to cause the rapid racemization of *N*-Ac-D-Leu in the liquid phase. After stirring for 1 h, all of the racemic modifications existing in excess as a supersaturation state, 12 g of *N*-Ac-DL-Leu per 100 ml of solvent, were converted to optically pure crystalline *N*-Ac-L-Leu and the filtrate was the saturated solution of *N*-Ac-DL-Leu. Figure 3 illustrates the above batch asymmetric transformation, compared with the ordinary optical resolu-

tion by a preferential crystallization procedure. In the asymmetric transformation, all of the racemic modifications existing in the supersaturation state are converted to crystalline optically active L-isomers and the supersaturation state is cancelled. On the other hand, in the ordinary optical resolution, some unseeded D-isomer remains in the liquid phase as an unstable supersaturation state. This is a marked difference between the two cases.

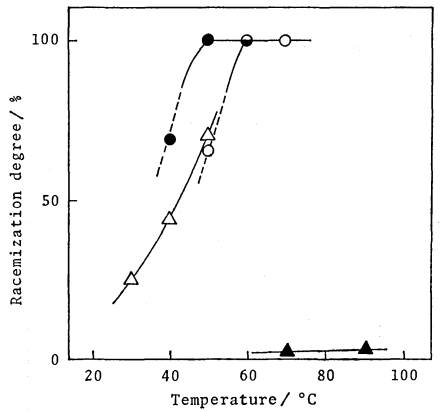

Fig. 2. Effect of temperature on racemization of *N*-Ac-D-Leu.
The mixture of the following composition was heated for 3 h. *N*-Ac-D-Leu/AcOH/Ac_2O (g/ml/ml): ○; 0.2/1.0/0.1, ●; 0.2/4.0/0.4, △; 0.2/8.0/0.8, ▲; 0.2/1.0/0.0. ----: The solid of *N*-Ac-D-Leu did not dissolve completely during the reaction. The whole reaction mixture was diluted with methanol (20 ml) and the optical rotation was measured. Racemization degree was calculated as shown in Fig. 1.

Since the driving force for the optical resolution by preferential crystallization procedure is provided only by the supersaturation degree of the racemic modification, the yield of the enantiomer produced by a simple batch experiment of this type of asymmetric transformation is dependent on the extent of the supersaturation state of the racemic modification dissolved in the reaction mixture. To obtain a higher yield of enantiomer, it is necessary to make up for the decrease of the supersaturation degree due to the preferential crystallization. This may be achieved by removal of solvent or addition of inert solvent effective for lowering the solubility of the racemic modification, as described in the previous report. In the present work, however, fresh racemic modification was added as a solid after completion of a batch asymmetric transformation and it was dissolved at an elevated temperature. In this case, fortunately, only *N*-Ac-DL-Leu in a solid mixture of newly added *N*-Ac-DL-Leu and previously crystallized *N*-Ac-L-Leu was dissolved and *N*-Ac-L-Leu was not dissolved because *N*-Ac-DL-Leu forms a true racemic mixture in the reaction system.[3] Thus a semicontinuous asymmetric transformation was able to be achieved by repeating the batch operation. The results are shown in Fig. 4, indicating that all of *N*-Ac-DL-Leu introduced successively into the reaction system was transformed to almost optically pure *N*-Ac-L-Leu. Using 2 g of seed crystals of *N*-Ac-L-Leu and 208 g of total *N*-Ac-DL-Leu on 100 ml scale, 130 g of *N*-Ac-L-Leu was obtained as 94% optically pure crystals. After the separation of *N*-Ac-L-Leu, 42 g of *N*-Ac-DL-Leu was recovered from the filtrate as the second crop.

From the practical view point, however, the above

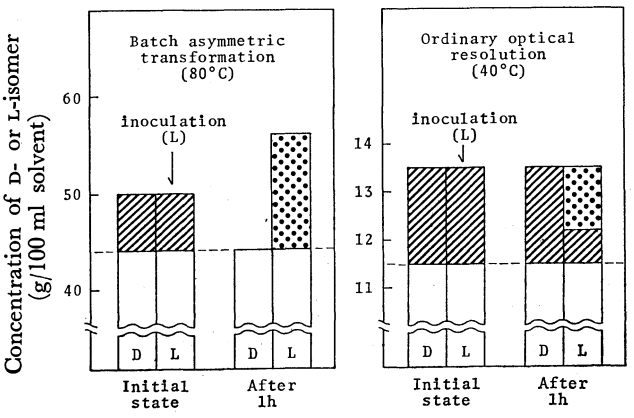

Fig. 3. Batch asymmetric transformation and ordinary optical resolution by preferential crystallization procedure of *N*-Ac-DL-Leu existing in excess as supersaturation state.
Batch asymmetric transformation was carried out under the conditions described in the text. Ordinary optical resolution was carried out at 40 °C using 0.1 g of seed crystals with the supersaturated solution of *N*-Ac-DL-Leu, 27 g/AcOH 100 ml. ----: Solubility of *N*-Ac-DL-Leu, 88 g/100 ml solvent at 80 °C and 23 g/100 ml AcOH at 40 °C, ▨: supersaturated part of *N*-Ac-Leu, ▩: crystals of *N*-Ac-L-Leu.

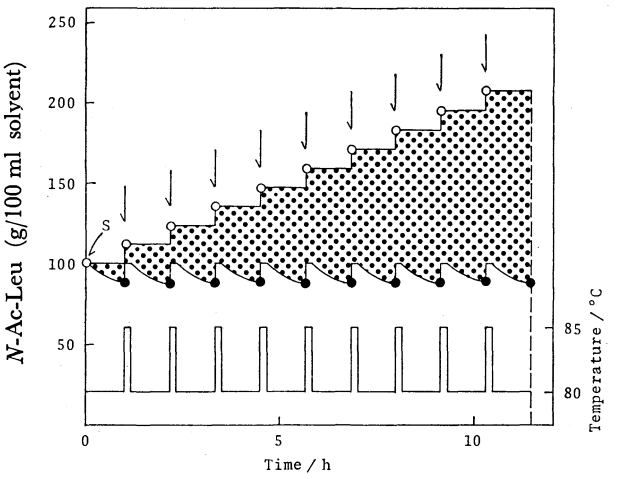

Fig. 4. Illustration of semicontinuous asymmetric transformation by repeating supply of DL-form in batch operation.
—○—: Total amount of *N*-Ac-Leu existing in the reaction mixture, —●—: concentration of *N*-Ac-Leu (almost DL-form) in the liquid phase, —: temperature, ▩: solid phase (almost L-form), ↓: addition of solid DL-form (12.0 g), S: seeding of *N*-Ac-L-Leu (2.0 g).

semicontinuous operation was considered to be complex and troublesome. The racemization experiments already demonstrated that the racemization proceeded at a rapid rate even at a relatively low temperature. Then, a continuous asymmetric transformation was carried out by a method in which the supersaturation state was continuously provided by cooling the solution from 100 °C to 40 °C. It is preferable that the rate of crystallization of the desired *N*-Ac-L-Leu is nearly equal to the rate of racemization of the undesired *N*-Ac-D-Leu in the solution. Therefore, the rate of cooling was controlled to meet those rates. When the temperature was decreased at a rate of 10 °C/h, which was selected as the optimum condition, the time course of the asymmetric transformation is shown in Fig. 5. In this experiment, acetic anhydride was supplemented after 2.5 h because its concentration had decreased at a relatively high rate, as can be seen in Fig. 5. Since the excess of the undesired *N*-Ac-D-Leu in solution was kept to a relatively low level (1±0.5 g/100 ml solvent) during the reaction,

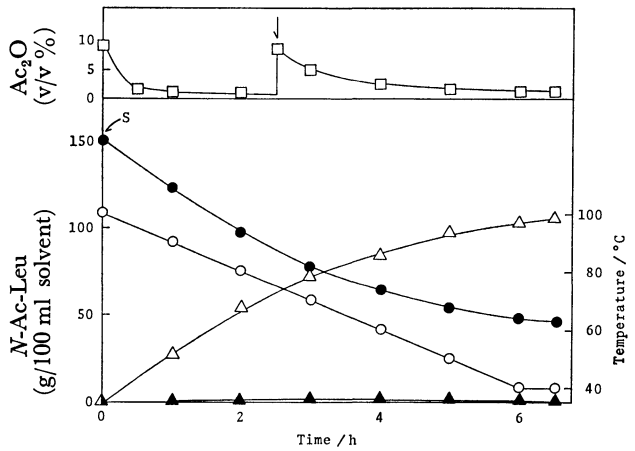

Fig. 5. Time course of continuous asymmetric transformation by gradient cooling from 100 °C to 40 °C. ○: Temperature, ●: concentration of *N*-Ac-Leu in the liquid phase, △: amount of precipitated crystals of *N*-Ac-L-Leu, which was calculated from decrease of the concentration of *N*-Ac-Leu in the liquid phase, ▲: concentration of *N*-Ac-D-Leu existing in excess in the liquid phase, □: concentration of Ac_2O, S: seeding of *N*-Ac-L-Leu (6.0 g), ↓: addition of Ac_2O (10.0 ml).

racemization seemed to proceed at a rapid rate to meet the preferential crystallization of *N*-Ac-L-Leu. The decrease in the concentration of acetic anhydride may be accounted for by the formation of a mixed anhydride or an azlactone of *N*-Ac-Leu, which are well known as racemizing intermediates.[4-6] After being cooled to 40 °C, the reaction mixture was allowed to stand for 30 min at the same temperature to complete racemization and crystallization. In this experiment, almost optically pure *N*-Ac-L-Leu was obtained in a high yield of 70%, based on the original weight of racemic modification (or 140% based on the enantiomer content of the racemic modification). The reproducibility of the reaction is demonstrated by the results of repeated runs given in Table 1.

The main disadvantage of the ordinary optical resolution by preferential crystallization is that crystallization of the desired isomer by seeding leads to an excess of the undesired isomer in the solution and the resolution system is racemic as a whole (Fig. 3). The resolution is not finished until the crystals of the desired isomer are separated from the mother liquor containing the undesired isomer. Furthermore, the yield is limited by the stability of the supersaturated state of the undesired isomer and is usually low because the supersaturation is relatively unstable. On the contrary, the asymmetric transformation now presented causes a substantial change of the composition of D- and L-isomers in the reaction system and almost optically pure crystals of the desired isomer is obtained in a high yield up to 140%, based on the enantiomer content of the racemic modification. The simplicity of the operation is also one of the advantages of the present asymmetric transformation. Therefore, application of the present method for the industrial production of L-leucine, an essential amino acid, is considered to be very promising if combined with a proper synthetic method for *N*-Ac-DL-Leu. The further applications of the asymmetric transformation combining optical resolution process and racemization process to other amino acids or their derivatives are under investigation.

Experimental

Materials and Analyses. *N*-Ac-DL-Leu, *N*-Ac-L-Leu, *N*-Ac-D-Leu, and other chemicals were the same as described

Table 1. Asymmetric transformation by cooling from 100 °C to 40 °C[a]

Exptl No.	First crop				Second crop[c]	
	Yield / g	$[\alpha]_D^{25}$/° (*c* 1, MeOH)	Optical purity / %	Transformed[b] amount / g	Yield / g	$[\alpha]_D^{25}$/° (*c* 1, MeOH)

a) Reactions were carried out on a 100 ml-scale using 150 g of *N*-Ac-DL-Leu and 6.0 g of seed crystals of *N*-Ac-L-Leu. b) Amount of seed crystals was subtracted from the amount of net optically active form separated. c) The filtrate showed no optical rotation.

previously.[1] All samples for analyses were dried overnight *in vacuo* at 40 °C. Analytical and identification methods of *N*-acylamino acids were described in the previous paper.[1] The optical purity of separated crystals was determined by measuring the optical rotation with a Perkin-Elmer 141 automatic polarimeter. The total concentration of *N*-Ac-Leu in the reaction mixture was measured as total solute concentration with a Karl Zeiss immersion refractometer. The amount of *N*-Ac-D-Leu existing in excess in liquid phase was determined by refractometric and polarimetric measurements.[7] The amount of acetic anhydride remaining in a reaction mixture was determined by a Shimadzu gas chromatograph GC-3BT using a 3 m column of 20% Silicone DC-550 on Celite 545. Temperature control for reaction was carried out by using a Chino program setter NP-121-B and a Chino electronic recording controller ET-1561.

Racemization of N-*Ac-D-Leu. Effect of Amount of Acetic Anhydride*: *N*-Ac-D-Leu (6.0 g) was dissolved in AcOH (30 ml) at an elevated temperature and maintained at 75 °C. Various amounts (0.05, 0.1, 0.2, and 0.5 molar ratio) of acetic anhydride were added to the solution under stirring. The samples (0.5 ml) were taken out from the reaction mixture at intervals of 30 or 60 min, and were added into 10 ml of methanol. The optical rotation of the solution was measured and the racemization degree was evaluated on the basis of the initial optical rotation and its decrease. It was confirmed by thin-layer chromatography that significant degradation did not occur during the reaction. The data are shown in Fig. 1.

Effect of Temperature: Since the solubility of *N*-Ac-D-Leu varied largely with temperature, the reaction was carried out in three levels of the concentration of *N*-Ac-D-Leu corresponding to the reaction temperatures. A mixture of *N*-Ac-D-Leu (0.2 g) and various amounts of AcOH–Ac_2O (10:1,v/v) solution was heated at various temperatures in a sealed tube and shaken occasionally. After 3 h, the mixture was added into 20 ml of methanol and the optical rotation was measured. The racemization degree evaluated from the decrease of optical rotation is shown in Fig. 2.

Stability of Crystalline N-*Ac-L-Leu under Conditions of Racemization.* *N*-Ac-DL-Leu (12.5 g) was dissolved in 10 ml of AcOH–Ac_2O (10:1, v/v) solution at an elevated temperature to prepare the solution saturated with *N*-Ac-DL-Leu at 90 °C. To the saturated solution maintained at 90 °C, the crystals of *N*-Ac-L-Leu (10.0 g) were added. The heterogeneous reaction mixture was stirred for 5 h at the same temperature. The insoluble crystals were quickly separated by filtration, washed with a small amount of AcOH and then toluene, and dried. The insoluble crystals were proved to be optically pure *N*-Ac-L-Leu (8.5 g), $[\alpha]_D^{25}$ −24.9° (*c* 1, MeOH).

Asymmetric Transformation. Batch Transformation: *N*-Ac-DL-Leu (100.0 g) was dissolved in 100 ml of AcOH–Ac_2O (10:1, v/v) solution at 90 °C and maintained at 80 °C. In this case, 12.0 g of *N*-Ac-DL-Leu existed as a supersaturation state, because the solubility of *N*-Ac-DL-Leu at 80 °C was 88.0 g/100 ml solvent. The supersaturated solution was seeded with finely pulverized crystals of *N*-Ac-L-Leu (2.0 g) and stirred for one hour to achieve preferential crystallization of *N*-Ac-L-Leu and simultaneous racemization of *N*-Ac-D-Leu. The precipitated crystals were quickly collected by filtration, washed with a small amount of AcOH, and dried to give *N*-Ac-L-Leu (14.5 g), $[\alpha]_D^{25}$ −24.1° (*c* 1, MeOH), optical purity 96.8% (14.0 g of *N*-Ac-L-Leu and 0.5 g of *N*-Ac-DL-Leu). Subtracting 2.0 g of seeded *N*-Ac-L-Leu, 12.0 g of pure *N*-Ac-L-Leu was obtained. After the separation of *N*-Ac-L-Leu, the filtrate was stirred at 20 °C for 2 h and the precipitated crystals were collected by filtration to give *N*-Ac-DL-Leu (57.6 g), $[\alpha]_D^{25}$ 0.0° (*c* 1, MeOH). The filtrate showed no optical rotation. Consequently, all of *N*-Ac-DL-Leu (12.0 g) existing as supersaturation was completely transformed to *N*-Ac-L-Leu. The schematic comparison of the transformation with the ordinary optical resolution is shown in Fig. 3.

Semicontinuous Transformation by Repeating a Batch Run: *N*-Ac-DL-Leu (100.0 g) was dissolved in 100 ml of AcOH–Ac_2O (10:1, v/v) solution at 90 °C and cooled to 80 °C. The solution was seeded with the crystals of *N*-Ac-L-Leu (2.0 g, 65—100 meshes) and stirred for one hour at the same temperature for preferential crystallization of *N*-Ac-L-Leu and simultaneous racemization of *N*-Ac-D-Leu. Then, finely pulverized crystals of *N*-Ac-DL-Leu (12.0 g) were added into the heterogeneous system consisting of crystals of *N*-Ac-L-Leu and the solution saturated with *N*-Ac-DL-Leu. To dissolve the added *N*-Ac-DL-Leu, the mixture was heated at 85 °C for 10 min under stirring. All of the added *N*-Ac-DL-Leu was dissolved and most of the crystallized *N*-Ac-L-Leu remained in a solid state. The mixture was cooled again to 80 °C and stirred for one hour at the same temperature for the subsequent transformation. This operation was repeated nine times under heterogeneous conditions. After the last run, the precipitated crystals were quickly collected by filtration, washed with a small amount of toluene, and dried to give *N*-Ac-L-Leu (130.0 g), $[\alpha]_D^{25}$ −23.3° (*c* 1, MeOH), optical purity 93.6% (121.7 g of *N*-Ac-L-Leu and 8.3 g of *N*-Ac-DL-Leu). If we subtract 2.0 g of seeded *N*-Ac-L-Leu, we see that 119.7 g of *N*-Ac-L-Leu was obtained. After the separation of *N*-Ac-L-Leu, the filtrate was stirred for 2 h at 20 °C and the precipitated crystals were collected by filtration to give *N*-Ac-DL-Leu (41.8 g), $[\alpha]_D^{25}$ 0.0° (*c* 1, MeOH). The filtrate showed no optical rotation. Consequently, 119.7 g of the total *N*-Ac-DL-Leu (12.0 g × 10) used to make supersaturation state was transformed to *N*-Ac-L-Leu. The process of this experiment is illustrated in Fig. 4.

Continuous Transformation by Gradient Cooling of the Solution: *N*-Ac-DL-Leu (150.0 g) was dissolved in 100 ml of AcOH–Ac_2O (10:1, v/v) solution under reflux. The solution was cooled to 100 °C, seeded with finely pulverized crystals of *N*-Ac-L-Leu (6.0 g), and then the cooling was continued at the constant speed of 10 °C/h under stirring. After 2.5 h, Ac_2O (10.0 ml) was added into the reaction mixture at 75 °C. When the temperature reached 40 °C, the cooling was stopped and the reaction mixture was stirred for 30 min at the same temperature to complete racemization and crystallization. The precipitated crystals were quickly collected by filtration, washed with a small amount of AcOH, and dried to give *N*-Ac-L-Leu (112.6 g), $[\alpha]_D^{25}$ −24.6° (*c* 1, MeOH), optical purity 98.8% (111.2 g of *N*-Ac-L-Leu and 1.4 g of *N*-Ac-DL-Leu). If we subtract 6.0 g of seeded *N*-Ac-L-Leu, we see that 105.2 g of *N*-Ac-L-Leu was obtained. After the separation of *N*-Ac-L-Leu, the filtrate was concentrated *in vacuo* to about half the initial volume, and allowed to crystallize. The precipitated crystals were collected by filtration to give *N*-Ac-DL-Leu (22.5 g), $[\alpha]_D^{25}$ 0.0° (*c* 1, MeOH). The filtrate showed no optical rotation. Consequently, about 70% of the initially used *N*-Ac-DL-Leu was transformed to *N*-Ac-L-Leu. A typical time course of the transformation is shown in Fig. 5. The results of the five experiments carried out by the same procedure as described above are shown in Table 1.

Use of Propagators in the Hückel Model. IV. Chemical Reactivity in Radiation Field

Takayuki Ohmae, Kiyoshi Nishikawa, Kisaburo Deguchi, and Shigeyuki Aono*

Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920

(Received April 7, 1981)

The propagator approach is applied to chemical reactivity in the presence of radiation field. The Woodward-Hoffmann's rule in photochemical reactions is generally derived. As an illustrative example, the ring closure or ring opening reactions are discussed.

In the previous work,[1] we have successfully applied the propagator theory to the problem of chemical reactivity and stability in the absence of radiation field. The treatment is fairly general, not restricted to the specified levels, *e.g.*, the highest occupied molecular orbital (HOMO) or the lowest unoccupied molecular orbital (LUMO) but whole electrons and levels are involved. The results have been shown analytically and, to some extent, quantitatively even though we are confined to the Hückel Hamiltonian.

In the present paper, we generalize the above theory to the chemical reactivity of photochemical reaction, and derive the Woodward-Hoffmann's rule in the presence of the radiation field.

General

As has been mentioned in early papers,[1,2] the total energy of the electronic system described by the Hamiltonian $\mathbf{H}$ is given as

$$E = \mathrm{Tr}\frac{1}{2\pi i}\int_c \mathrm{d}z\, z\mathbf{G}(z) = \mathrm{Tr}\frac{1}{2\pi i}\int_c \mathrm{d}z\, \mathbf{HG}(z), \tag{1}$$

where $\mathbf{G}(z)$ is the Green's function matrix with energy parameter z, and the integration contour, so called the Coulson contour, encloses only poles corresponding to the occupied levels. The second equality of Eq. 1. is obtained by adding and subtracting $\mathbf{H}$ to the right hand side of the first line and by noting that $(z-\mathbf{H})^{-1}=\mathbf{G}(z)$. It should be noticed that the expression of Eq. 1. is independent of the kind of representation.

Let us consider that the original system with Hamiltonian $\mathbf{h}$ is perturbed by a static interaction $\mathbf{v}$, under influence of the radiation field. The Hamiltonians to be considered are

$$\mathbf{H} = \mathbf{H}_0 + \mathbf{v}, \tag{2}$$

$$\mathbf{H}_0 = \mathbf{h} + \mathbf{F}, \tag{3}$$

where $\mathbf{F}$ denotes the radiation field and the interaction between radiation and electron. We now investigate the extra energy defined by

$$\Delta E = \mathrm{Tr}\frac{1}{2\pi i}\int_c \mathrm{d}z[\mathbf{HG}(z)-\mathbf{H}_0\mathbf{G}^0(z)]. \tag{4}$$

Substituting Eqs. 2. and 3 into Eq. 4, we obtain

$$\begin{aligned}\Delta E &= \mathrm{Tr}\frac{1}{2\pi i}\int_c \mathrm{d}z[(\mathbf{h}+\mathbf{F}+\mathbf{v})\mathbf{G}(z)-(\mathbf{h}+\mathbf{F})\mathbf{G}^0(z)] \\ &\cong \mathrm{Tr}\frac{1}{2\pi i}\int_c \mathrm{d}z[(\mathbf{h}+\mathbf{F}+\mathbf{v})(\mathbf{G}^0(z)+\mathbf{G}^0(z)\mathbf{v}\mathbf{G}^0(z)) \\ &\quad -(\mathbf{h}+\mathbf{F})\mathbf{G}^0(z)] \\ &\cong \mathrm{Tr}\frac{1}{2\pi i}\int_c \mathrm{d}z[\mathbf{v}\mathbf{G}^0(z)+(\mathbf{h}+\mathbf{F})\mathbf{G}^0(z)\mathbf{v}\mathbf{G}^0(z)].\end{aligned} \tag{5}$$

In this derivation, terms of first order with respect to $\mathbf{v}$ are retained. Further simplification shall be made: If we add and subtract z to the second term in Eq. 5, it yields that

$$\begin{aligned}&\frac{1}{2\pi i}\int_c \mathrm{d}z(\mathbf{h}+\mathbf{F})\mathbf{G}^0(z)\mathbf{v}\mathbf{G}^0(z) \\ &\quad = \frac{1}{2\pi i}\int_c \mathrm{d}z\, z\mathbf{G}^0(z)\mathbf{v}\mathbf{G}^0(z) \\ &\quad\quad -\frac{1}{2\pi i}\int_c \mathrm{d}z(z-\mathbf{h}-\mathbf{F})\mathbf{G}^0(z)\mathbf{v}\mathbf{G}^0(z).\end{aligned} \tag{6}$$

Noting that $\mathbf{G}^0(z)=(z-\mathbf{h}-\mathbf{F})^{-1}$, we can see that the second term of Eq. 6. cancel the first term by integration by part. Then we obtain

$$\Delta E \cong \mathrm{Tr}\frac{1}{2\pi i}\int_c \mathrm{d}z\, \mathbf{v}\mathbf{G}^0(z). \tag{7}$$

Certainly, Eq. 7. is exactly accordance with the first order term of our previous result (See Eq. 3. of Ref. 1.).

The Green's function, $\mathbf{G}^0(z)$ which describes the electronic structure of the system interacting with radiation, but without $\mathbf{v}$ is derived in the appendix as

$$\begin{aligned}\mathbf{G}^0(z) = [z-\mathbf{h}-&\sum_k \mathbf{f}^k n_k(z+\omega_k-\mathbf{h})^{-1}\mathbf{f}^k \\ &-\sum_k \mathbf{f}^k(1+n_k)(z-\omega_k-\mathbf{h})^{-1}\mathbf{f}^k]^{-1}.\end{aligned} \tag{8}$$

Here $\mathbf{f}^k$ is the interaction (matrix) between electron and radiation with the mode k, n_k, and ω_k are, respectively, number and angular frequency of photon with the mode k. The term with n_k is to do with absorption and the term with $(1+n_k)$ does emission.

First, if we confine ourselves, for simplicity, to the case of absorption with a single mode, it follows that

$$\mathbf{G}^0(z) = (z-\mathbf{h})^{-1} + (z-\mathbf{h})^{-1}\mathbf{f}n(z+\omega-\mathbf{h})^{-1}\mathbf{f}(z-\mathbf{h})^{-1}, \tag{9}$$

where we omitted the mode index k.

Substituting this into Eq. 7, and picking up the term relating with the radiation field, we obtain

$$\Delta E_f^a = n\,\mathrm{Tr}\frac{1}{2\pi i}\int_c \mathrm{d}z\, \mathbf{v}(z-\mathbf{h})^{-1}\mathbf{f}(z+\omega-\mathbf{h})^{-1}\mathbf{f}(z-\mathbf{h})^{-1}. \tag{10}$$

The Green's function, $(z-\mathbf{h})^{-1}$ has been precisely investigated in II[3] of this series for the case of the Hückel model.

Remembering that Eq. 10 has an expression independent of the kind of representation, we can manipulate this by the representation that the Green's functions are diagonal, namely by the MO representation. Thus

$$\Delta E_f^a = n \sum_{i,j,k} v_{ij} f_{jk} f_{ki} \frac{1}{2\pi i} \int_c dz \frac{1}{(z-\varepsilon_i)(z-\varepsilon_j)(z+\omega-\varepsilon_k)}, \tag{11}$$

where ε_i is the orbital energy or the eigenvalue of **h**. Now we impose an experimental condition usually met in the laboratory: suppose that the radiation field has a strong intensity at the frequency

$$\omega \cong \varepsilon_L - \varepsilon_H, \tag{12}$$

where ε_L and ε_H are orbital energies of LUMO and HOMO, respectively, and the electronic carries the oscillator strength only between LUMO and HOMO. Then Eq. 11 becomes

$$\Delta E_f^a = n v_{HH} |f_{HL}|^2 \frac{1}{2\pi i} \int_c dz \frac{1}{(z-\varepsilon_H)^2(z+\omega-\varepsilon_L)} + n v_{LL} |f_{LH}|^2 \frac{1}{2\pi i} \int_c dz \frac{1}{(z-\varepsilon_L)^2(z+\omega-\varepsilon_H)}. \tag{13}$$

The contour integration using the Coulson contour (Fig. 1) is easily carried out to yield

$$\Delta E_f^a = n|f_{HL}|^2 \left\{ \frac{v_{LL}}{(\varepsilon_H-\varepsilon_L-\omega)^2} - \frac{v_{HH}}{(\varepsilon_L-\varepsilon_H-\omega)^2} \right\} \cong -n|f_{HL}|^2 v_{HH}/(\varepsilon_L-\varepsilon_H-\omega)^2, \tag{14}$$

where the condition 12 is used to get the final result, neglecting the first term.

If we deal with the emission part of Eq. 8, the similar treatment gives rise to

$$\Delta E_f^e = (1+n)|f_{HL}|^2 \frac{v_{LL}}{(\varepsilon_L-\varepsilon_H-\omega)^2}. \tag{15}$$

Therefore, the net effect is

$$\Delta E_f = \Delta E_f^a + \Delta E_f^e = |f_{HL}|^2 \{-n v_{HH} + (1+n) v_{LL}\}/(\varepsilon_L-\varepsilon_H-\omega)^2, \tag{16}$$

the value of which should be negative for the photochemical reaction to take place. An analytical expression of the Woodward-Hoffmann's rule in the radiation field[4] is thus obtained.

Electrocyclic Reaction

As an illustrative example, we want to apply the general result 16 to the electrocyclic reaction. The ring closure and ring opening reactions are to be discussed, based on the same model that has been explained in III[2] of this seres. In Fig. 2 we display the model of the closure reaction of the conjugated chain molecule with N number of atoms; when the reaction path is con-rotatory the interaction between two ends, $v_{0,N-1}$ is positive, while when dis-rotatory, $v_{0,N-1}$ is negative.

In order to determine which of these two is likely to take place, it suffice to examine v_{HH} and v_{LL} in Eq. 16. As is shown in Fig. 2, the non-vanishing matrix elements of v are only $v_{0,N-1}$ and $v_{N-1,0}$, and then we can decompose these as follows

$$v_{AA} = \langle A|\mathbf{v}|A\rangle = \sum_{s,t}^{\text{sites}} \langle A|s\rangle\langle s|\mathbf{v}|t\rangle\langle t|A\rangle, \quad (A=L \text{ and } H)$$
$$= 2v_{0,N-1}\langle 0|A\rangle\langle A|N-1\rangle$$
$$= 2v_{0,N-1} \frac{1}{2\pi i} \int_A dz\, g(0, N-1; z). \tag{17}$$

The final expression is obtained by the use of the definition of the Green's function; $g(0,N-1;z)$ being the $(0,N-1)$ matrix element of the propagator. The contour A encloses only the pole at ε_A. In other words, the partial bond order between the 0-th and $(N-1)$-th atoms of the chain molecule is given by the pole strength of the corresponding propagator (except for the spin factor). The propagator $g(0, N-1; z)$ is given in II as

$$g(0, N-1; z) = \sin\theta/\sin(N+1)\theta, \quad z = 2\cos\theta. \tag{18}$$

Using these in Eq. 17, and noticing that

$$\theta_A = \pm\pi A/(n+1), \tag{19}$$

we obtain

$$v_{AA} = (-1)^{A+1} \frac{4v}{N+1} \sin^2 \pi A/(N-1), \tag{20}$$

when v is the abbreviation of $v_{0,N-1}$.

Here if we put $A=H$, and note that $L=H+1$, we obtain

$$\Delta E_f = (-1)^H v \frac{4}{N+1} \frac{|f_{HL}|^2}{(\varepsilon_L-\varepsilon_H-\omega)^2} \times \left\{ n \sin^2 \frac{\pi H}{N+1} + (1+n) \sin^2 \frac{\pi(H+1)}{N+1} \right\} \propto (-1)^H v. \tag{21}$$

This is the selection rule for the electrocyclic reaction in the presence of the radiation field. We shall examine in more detail conditions that the reaction takes place, or $\Delta E_f < 0$.

i) If H is even, the sign of v should be negative. In this case, the HOMO is designated to be the $2m$-th level (m is integer). If levels are doubly occupied up to the HOMO, namely concerned with $4m$ electrons system, the dis-rotatory reaction path is probable both for the ring closure and ring opening reaction.

ii) If H is odd, the sign of v should be positive. In this case, the HOMO is designated to be the $(2m+1)$-th level. If levels are doubly occupied up to the HOMO, namely concerned with $4m+2$ electrons system, the con-rotatory reaction path is probable both for the ring closure and the ring opening reaction. These selection rules are also tabulated in Table 1.

It should be mentioned that the above statements for the photochemical reaction give reverse prediction comparing with rules of the thermal electrocyclic reaction.[3]

Concluding Remarks

We have explained that even for the photochemical reaction the propagator approach works as well as for the ground state properties. In our theory the excited state are *virtually* taken into account, so that not only the absorption process but also the emission process are involved to photochemical reactivity. In

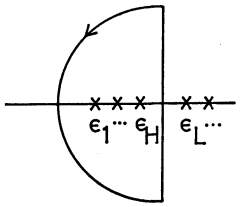

Fig. 1. Coulson contour and eigenvalues.

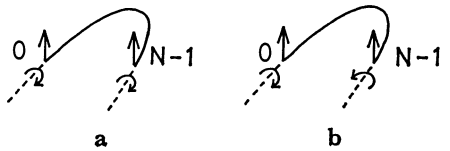

Fig. 2. Model for the ring closure reaction.
a: Con-rotatory, $v_{0,N-1}>0$, b: dis-rotatory, $v_{0,N-1}<0$.

Table 1. Selection rules of the electrocyclic reaction in the presence of radiation field

Number of electron	Condition	Path	Type of ring
$4m$	$v<0$	dis	Hückel ring
$4m+2$	$v>0$	con	Möbius ring

order to derive the Woodward-Hoffmann's rule as is written in a usual way, we have impose a special (laboratory) condition such as the relation (12) and the comments following it. However this restriction does not harm our general procedure, which ensures possibilities to analyze the more complicated phenomena and to get clear cut results.

Appendix

We derive $\mathbf{G}^0(z)$, the propagator of the electronic system in the radiation field, in a field theoretical way by means of the equation of motion method, combined by the decoupling procedure.[5,6] The Hamiltonian of the system under investigation is

$$H_0 = \sum_s \alpha_s a_s^\dagger a_s + \sum_{s,t} \beta_{st} a_s^\dagger a_t + \sum_{s,t,k} f_{st}^k a_s^\dagger a_t (c_k^\dagger + c_k) + \sum_k \omega_k c_k^\dagger c_k. \tag{A1}$$

Here matrix elements are written in the AO representation, indices s and t indicate atomic sites, and $a_s^\dagger$ (a_s) is the creation (annihilation) operator of electron at the site s, $c_k^\dagger$ (c_k) is the creation (annihilation) operator of photon with mode k, f_{st}^k, and ω_k being the electron-photon coupling constant and the photon frequency, respectively. The representation used above is only for convenience. The final result will be independent of the kind of representation.

We investigate the Green's function defined by

$$G_{rs}^0(t) = -i\langle T[a_r(t)a_s^\dagger(0)]\rangle, \tag{A2}$$

where $\langle\cdots\rangle$ denotes the ground state average, and T is the time ordering operator. The equation of motion of $G_{rs}^0(t)$ is Fourier transformed with respect to time as

$$zG_{rs}^0(z) = \delta_{rs} + \langle\langle[a_r, H_0]; a_s^\dagger\rangle\rangle_z \tag{A3}$$

where

$$G_{rs}^0(z) \equiv \langle\langle a_r; a_s^\dagger\rangle\rangle_z = \int_{-\infty}^{\infty} dt\, e^{izt}\langle\langle a_r(t); a_s^\dagger\rangle\rangle = \int_{-\infty}^{\infty} dt\, e^{izt} G_{rs}^0(z). \tag{A4}$$

The commutator in Eq. A3 is evaluated as

$$[a_r, H_0] = \alpha_r a_r + \sum_u \beta_{ru} a_u + \sum_{u,k} f_{ru}^k (c_k^\dagger + c_k) a_u. \tag{A5}$$

Using this in Eq. A3, we obtain

$$zG_{rs}^0(z) = \delta_{rs} + \alpha_r G_{rs}^0(z) + \sum_u \beta_{ru} G_{us}^0(z) + \sum_{u,k} f_{ru}^k \langle\langle c_k^\dagger a_u; a_s^\dagger\rangle\rangle_z + \sum_{u,k} f_{ru}^k \langle\langle c_k a_u; a_s^\dagger\rangle\rangle_z. \tag{A6}$$

If we want to evaluate $G_{rs}^0(z)$ utilizing this equation, we have to evaluate the higer order Green's functions:

$$M_{us}^{k+}(z) = \langle\langle c_k^\dagger a_u; a_s^\dagger\rangle\rangle_z,$$
$$M_{us}^{k}(z) = \langle\langle c_k a_u; a_s^\dagger\rangle\rangle_z. \tag{A7}$$

Again we set the equation of motions for these: this time the Kronecker delta does not appear, calculation being a little tedious, but straigtforward, and we obtain

$$zM_{us}^{k+}(z) = (a_u - \omega_k) M_{us}^{k+}(z) + \sum_v \beta_{uv} M_{vs}^{k+}(z) + \sum_{v,l} f_{uv}^l \langle\langle c_k^\dagger c_l^\dagger a_v; a_s^\dagger\rangle\rangle_z + \sum_{v,l} f_{uv}^l \langle\langle c_k^\dagger c_l a_v; a_s^\dagger\rangle\rangle_z - \sum_{v,t} f_{vt}^k \langle\langle a_v^\dagger a_t a_u; a_s^\dagger\rangle\rangle_z. \tag{A8}$$

At this stage we apply decoupling procedure as follows:

$$\langle\langle c_k^\dagger c_l a_v; a_s^\dagger\rangle\rangle_z = \langle c_k^\dagger c_l\rangle\langle\langle a_v; a_s^\dagger\rangle\rangle_z = \delta_{kl} n_k G_{vs}^0(z). \tag{A9}$$

Further we might assume that

$$\langle\langle c_k^\dagger c_l^\dagger a_v; a_s^\dagger\rangle\rangle_z = 0, \tag{A10}$$

since the two photon process described by this Green's function should be negligibly important, and we assume also

$$\langle\langle a_v^\dagger a_t a_u; a_s^\dagger\rangle\rangle_z = 0,$$

since this is a higher order correction to the electronic process. Accordingly Eq. A8 is approximately rewritten as

$$zM_{us}^{k+}(z) = (\alpha_u - \omega_k) M_{us}^{k+}(z) + \sum_v \beta_{uv} M_{vs}^{k+}(z) + n_k \sum_v f_{uv}^k G_{vs}^0(z), \tag{A11}$$

or in the matrix notation

$$z\mathbf{M}^{k+}(z) = (\mathbf{h} - \omega_k)\mathbf{M}^{k+}(z) + n_k \mathbf{f}^k \mathbf{G}^0(z),$$

or

$$\mathbf{M}^{k+}(z) = n_k (z - \mathbf{h} + \omega_k)^{-1} \mathbf{f}^k \mathbf{G}^0(z), \tag{A12}$$

where

$$\mathbf{h} = \boldsymbol{\alpha} + \boldsymbol{\beta}. \tag{A13}$$

In a similar way,

$$\mathbf{M}^{k}(z) = (1 + n_k)(z - \mathbf{h} - \omega_k)^{-1} \mathbf{f}^k \mathbf{G}^0(z). \tag{A14}$$

Substituting Eqs. A12 and A14 into Eq. A6, we obtain

$$z\mathbf{G}^0(z) = \mathbf{1} + \mathbf{h}\mathbf{G}^0(z) + \sum_k \mathbf{f}^k \mathbf{M}^{k+}(z) + \sum_k \mathbf{f}^k \mathbf{M}^{k}(z)$$
$$= \mathbf{1} + \mathbf{h}\mathbf{G}^0(z) + \sum_k \mathbf{f}^k n_k (z - \mathbf{h} + \omega_k)^{-1} \mathbf{f}^k \mathbf{G}^0(z) + \sum_k \mathbf{f}^k (1 + n_k)(z - \mathbf{h} - \omega_k)^{-1} \mathbf{f}^k \mathbf{G}^0(z),$$

or

$$\mathbf{G}^0(z) = [z - \mathbf{h} - \sum_k \mathbf{f}^k n_k (z - \mathbf{h} + \omega_k)^{-1} \mathbf{f}^k - \sum_k \mathbf{f}^k (1 + n_k)(z - \mathbf{h} - \omega_k)^{-1} \mathbf{f}^k]^{-1}. \tag{A15}$$

The Crystal Structure of *N*-Methylviologenium 2-Dicyanomethylene-1,1,3,3-tetracyanopropanediide, $[(CH_3 \cdot NC_5H_4 \cdot C_5H_4N \cdot CH_3)^{2+} \cdot (C_{10}N_6)^{2-}]$

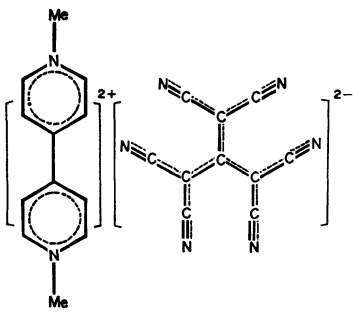
(Received April 13, 1981)

$[(CH_3 \cdot NC_5H_4 \cdot C_5H_4N \cdot CH_3)^{2+} \cdot (C_{10}N_6)^{2-}]$ crystallizes in the space group of $P2_1/c$, with four formula units. The unit-cell dimensions are; $a=14.625(2)$, $b=8.361(2)$, $c=17.332(3)$ Å, and $\beta=107.51(2)°$. The crystal structure was established by means of the symbolic addition method. For 2767 non-zero reflections, R is 0.074. In the crystal, divalent cations and divalent anions are stacked alternately to form infinite columns which are parallel to the b axis. Short atomic contacts are mostly involved between nitrogen atoms of the anion and carbon atoms of the cation. The $(C_{10}N_6)^{2-}$ anion takes a three-bladed propeller shape; however, it has no symmetry, unlike those in hexahydrated calcium and quinolinium salts. In the $[(CH_3 \cdot NC_5H_4 \cdot C_5H_4N \cdot CH_3)^{2+}]$ cation, two pyridine rings are twisted about the central C–C bond; the dihedral angle between the planes of two rings is 19.6(2)°.

In a series of structural studies of organic charge-transfer salts,[1-4] the crystal structure of *N*-methylviologenium 2-dicyanomethylene-1,1,3,3-tetracyanopropanediide, $[(CH_3 \cdot NC_5H_4 \cdot C_5H_4N \cdot CH_3)^{2+} \cdot (C_{10}N_6)^{2-}]$, has been determined by means of X-ray diffraction. This salt consists of a divalent cation and a divalent anion;



Interest in the structure of the anion in this crystal has also prompted the present study in relation to the structures of the anion in the quinolinium[3] and calcium salts.[5]

Experimental

Dark-red crystals of $[(CH_3 \cdot NC_5H_4 \cdot C_5H_4N \cdot CH_3)^{2+} \cdot (C_{10}N_6)^{2-}]$ were supplied by Professor H. Mikawa and his co-workers of this university. They were recrystallized from a saturated aqueous solution by slow evaporation at room temperature. Platelet crystals elongated along the b axis were usually obtained.

The unit-cell dimensions and the integrated intensities were measured on a Rigaku automated, four-circle diffractometer, using Ni-filtered Cu $K\alpha$ radiation. The crystal data are given in Table 1. A total of 2767 independent reflections was collected by means of the θ-2θ scan technique ($2\theta \leqq 115°$). The intensities were corrected for the usual Lorentz and polarization effects, but no absorption correction was made ($\mu/cm^{-1}=6.78$ for Cu $K\alpha$).

Solution of the Structure and Refinement

The structure was solved by the symbolic-addition procedure for the centrosymmetric space group.[6] The positional and thermal parameters were refined by the block-diagonal least-squares procedure. A difference Fourier synthesis was auxiliarily used to determine the location of hydrogen atoms. The neutral atomic-scattering factors used in the calculations were taken from those given by Hanson and his co-workers.[7]

The final positional and thermal parameters of the non-hydrogen atoms are listed in Table 2, while Table 3 gives those of hydrogen atoms.†††

Calculations of the symbolic addition procedure were done with the *SSGM* program revised by one of the present authors (N.Y.). The *HBLS* IV in the *UNICS*[8] and other programs in the *UNICS*-Osaka[9] were also used. Almost all the computations were done on a FACOM 230-60 computer at Kyoto University, with the rest being done on an ACOS Series 77 NEAC System 700 computer at Osaka University.

Results and Discussion

An *ORTEP* drawing[10] of the cation and anion is shown in Fig. 1.

††† Lists of the observed and calculated structure factors and anisotropic thermal parameters are kept at the Chemical Society of Japan; Document No. 8147.

Dihedral angles (ϕ/°) and angles between vectors and planes (ϕ/°)

Dihedral angles	between the (1) and (2) planes	19.6(2)
	between the (3) and (4) planes	18.9(2)
	between the (3) and (5) planes	23.1(2)
	between the (3) and (6) planes	27.9(2)
Angles between	N(1)-C(1) vector and the (1) plane	4.7
	N(2)-C(12) vector and the (2) plane	1.7

the deviation of C(12), attached to the N(2) atom, from the (2) plane is only 0.02 Å. This significant displacement of the methyl carbon, C(1), from the (1) ring plane probably depends upon the strong interaction between the cation and the anion. The structure of the same cation in the crystal of $[(CH_3\cdot NC_5H_4\cdot C_5H_4N\cdot CH_3)^{2+}\cdot(CuCl_4)^{2-}]$ has previously been reported;[11] in this structure two pyridine rings and two methyl carbons attached to the respective rings are all coplanar within the range of experimental error. However, in the present complex, the cations are considerably distorted, as has been mentioned above.

Structure of the $(C_{10}N_6)^{2-}$ Anion. The bond lengths and bond angles in the anion are also given in Fig. 2(b). The four central carbon atoms, C(27), C(28), C(29), and C(30), are coplanar (Table 4), while three dicyano-substituted carbon groups, $-C(CN)_2$, are tilted out of this plane; the tilt angle are 18.9(2), 23.1(2), and 27.9(2)° respectively (Table 4). The $(C_{10}N_6)^{2-}$ anion has a C_3-3 (or approximately D_3-32) symmetry in hexahydrated calcium salt[4] and a C_2-2 symmetry in quinolinium salt,[5] whereas in the present salt the anion has no symmetry. However, there is no considerable difference in the corresponding bond lengths and bond angles in these three salts.

Crystal Structure. The crystal structure as viewed along the b and a axes is shown in Figs. 3 and 4 respectively. The crystal consists of infinite columns parallel to the b axis. In the column the divalent cations and the divalent anions are stacked alternately. They lie roughly on the (022) plane. This

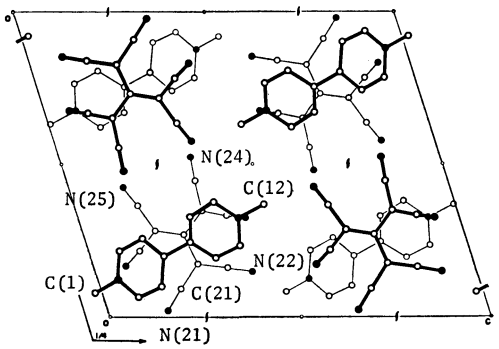

Fig. 3. Crystal structure projected along the b axis.

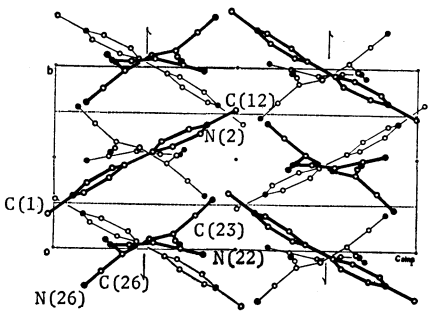

Fig. 4. Crystal structure projected along the a axis.

Table 5. Intermolecular atomic contacts (l/Å) less than 3.4 Å

(Received April 21, 1981)

In order to elucidate the details of elementary processes of photochemical charge transfer and heteroexcimer formation processes, and also in order to compare the obtained results with those of transient absorption spectral measurements, we have examined the following intramolecular heteroexcimer systems by means of ps time-resolved fluorescence measurements with a mode-locked Nd^{3+}: YAG laser and a streak camera: p-$(CH_3)_2NC_6H_4$-$(CH_2)_n$-(9-anthryl) (n=0, 1, 2, 3), p-$(CH_3)_2NC_6H_4$-$(CH_2)_n$-(1-pyrenyl) (n=1, 2, 3) and 9,9′-bianthryl. Effects of methylene chain length, solvent polarity and viscosity upon the intramolecular charge transfer processes have been clearly demonstrated. It is concluded that molecules with sandwich configuration in the ground state are not recognized in both n=3 compounds, and it takes a few ns for the heteroexcimer formation in hexane because of an extensive conformation change necessary to take sandwich configuration. Both conformation change and solvent reorientation are involved in the heteroexcimer formation processes in polar solvents, and heteroexcimer formation becomes faster with increase of solvent polarity and decrease of its viscosity. Moreover, two step conformation changes are observed in the case of the heteroexcimer formation of n=3 compounds in polar solvents, *i.e.* a heteroexcimer with loose structure is formed first, and then follows a structural change to the one of sandwich type. In acetonitrile, a strongly polar solvent, formation of heteroexcimer is very fast, occurring within the time-resolution of the picosecond apparatus.

The nature of CT (charge transfer) interactions in electronically excited states is a subject under lively investigation at present,[1] and the results appear to be important from the viewpoint of photochemical as well as photobiological reaction mechanisms.

In order to clarify the details of photo-induced CT and HE (heteroexcimer) formation processes, we have been examining intramolecular HE systems such as p-$(CH_3)_2NC_6H_4$-$(CH_2)_n$-(9-anthryl) (A_n, n=0, 1, 2, 3), p-$(CH_3)_2NC_6H_4$-$(CH_2)_n$-(1-pyrenyl) (P_n, n=1, 2, 3) and 9,9′-bianthryl (Bian), by means of ns time-resolved fluorescence and ns as well as ps time-resolved absorption spectral measurements.[2-10,12,14,16] It has been demonstrated that fluorescence spectra of A_1, A_2 and P_1 in nonpolar solvents can be ascribed to the anthracene or pyrene part (LE (locally excited state) fluorescence), and they show HE fluorescences only in polar solvents due to the solvent-induced change of electronic state during the excited state lifetime. Analogous results have been observed also for A_0. For A_3, P_3, and P_2 HE fluorescences can be observed not only in polar solvents but also in nonpolar solvents, due to a conformation change from an extended form to the sandwich or a similar structure during the excited state lifetime. Moreover, it has been demonstrated that the HE formation process is affected considerably by solvent polarity. By means of ps transient absorption measurements of P_3 in 2-propanol photoinduced CT has been found to produce at first a loose HE followed by a structural change to the more compact one.

In the present study, by means of ps time-resolved fluorescence measurements we have made direct observations of CT fluorescence rise curves as well as LE fluorescence decay curves of the above intramolecular exciplex systems in various solvents of different polarity, and have provided a systematic interpretation of photoinduced CT processes in solution.

Experimental

Apparatus and Measurements. The third harmonic (355 nm, 15 ps, 1 mJ) of a passively mode-locked Nd^{3+}:YAG laser was used as an exciting light source. The ps pulse repeated at 1 Hz. Fluorescence rise and decay curves were measured with a streak camera (HTV C979), the streak being digitized by a TV camera/microcomputer system (HTV C1000). Measurements in a few ns region were made also by a high speed tandem microchannel plate photomultiplier (HTV R1294X) connected to a transient digitizer (Tektronix R7912). All solutions for the measurements were de-aerated by freeze-pump-thaw cycles.

Materials. All solvents used were Merck spectrograde. Hexane, acetone and acetonitrile were used without further purification. 2-Propanol and butyronitrile were distilled before use. Bian was the same sample as used previously.[12] A_n (n=0, 1, 2, 3) and P_n (n=1, 2, 3) were synthesized and purified as described below.

All melting points are uncorrected. The NMR and MS spectra were recorded with a Hitachi Perkin-Elmer R-20 or a Varian XL-100 and a Hitachi RMU-7, respectively.

p-*(9-Anthryl)*-N,N-*dimethylaniline* (A_0). To a Grignard reagent prepared from p-bromo-*N,N*-dimethylaniline (20 g, 0.1 mol) and magnesium flake (2.4 g, 0.1 mol) in tetrahydrofuran, a solution of anthrone (5.82 g, 0.03 mol) in tetrahydrofuran was added with stirring over a period of 30 min at 0 °C under nitrogen atmosphere. After stirring for additional 1 h, the reaction mixture was worked up. The crude product was chromatographed on alumina and recrystallized from benzene.

A_0: yelloe granulars, 1.1 g (12.3%), mp 260—260.5 °C, NMR ($CDCl_3$) δ 3.11 (s, CH_3), 7.0—8.4 ppm (m, ArH).

Found: C, 88.94; H, 6.23; N, 4.72%; MS (*m/e*) 297 (M^+). Calcd for $C_{22}H_{19}N$: C, 88.85; H, 6.44; N, 4.71%; M, 297.38.

p-*Arylmethyl*-N,N-*dimethylaniline* (*A_1, P_1*). A mixture of *N,N*-dimethylaniline (2 ml) and 9-(bromomethyl)anthracene[19] (500 mg, 1.9 mmol) was stirred overnight at room temperature and at 40—50 °C for 30 min. After adding 10 ml of methanol to the reaction mixture, resulting precipitate was collected and washed with methanol. Recrystallization of the precipitate from acetone gave pale yellow plates of A_1 (180 mg, 30%), mp 133—134 °C. NMR ($CDCl_3$) δ 2.75 (s, CH_3), 4.82 (s, CH_2), 6.68 (m, ArH of phenyl), 7.0—8.3 ppm (m, ArH of Anthryl). Found: C, 88.45; H, 7.06; N, 4.50%, MS (*m/e*), 311 (M^+). Calcd for $C_{23}H_{21}N$: C, 88.70; H, 6.80; N, 4.50%; M, 311.41.

In a similar manner, P_1 was prepared. P_1: colorless needles from acetone, mp 103—105 °C. NMR ($CDCl_3$) δ 2.86 (s, CH_3), 4.62 (s, CH_2), 6.85 (m, ArH of phenyl), 7.7—8.4 ppm (m, ArH of pyrenyl). Found: C, 89.30; H, 6.23; N, 4.06%; MS (*m/e*), 335 (M^+). Calcd for $C_{25}H_{21}N$: C, 89.51; H, 6.31; N, 4.18%; M, 335.43.

p-*(2-Arylvinyl)*-N,N-*dimethylaniline* (*$I_{A,P}$*). To a stirred suspension of phosphonium salt (2.7 g, 5 mmol) in benzene, prepared from 9-(bromomethyl)anthracene[19] and triphenylphosphine, was added an ethereal solution of phenyllithium (1 mol dm^{-3}, 5 mmol) under nitrogen. To this mixture a solution of *p*-dimethylaminobenzaldehyde (0.75 g, 5 mmol) in benzene was added dropwise for 5 min. Stirring was continued overnight at room temperature. After working up in the usual manner the crude product was recrystallized from acetone to afford yellow needles of I_A (500 mg, 31%), mp 178—180 °C. Found: C, 88.89; H, 6.37; N, 4.26%. Calcd for $C_{24}H_{21}N$: C, 89.12; H, 6.55; N, 4.33%.

The synthesis of I_P was done in the same manner. I_P: yellow granulars from benzene–acetone, mp 193.5—195 °C. Found: C, 89.90; H, 6.08; N, 3.91%. Calcd for $C_{26}H_{21}N$: C, 89.87; H, 6.09; N, 4.03%.

p-*(2-Arylethyl)*-N,N-*dimethylaniline* (*A_2, P_2*). Catalytic hydrogenation of I_A (3.23 g, 10 mmol) in benzene was carried out by stirring with 5% Pd–C (200 mg) for 30 h. The reaction mixture was worked up and chromatographed on silica gel to afford yellow solid A_2 (1.97 g, 60.6%). A_2: yellow needles from acetone, mp 119.5—120.5 °C. NMR ($CDCl_3$) δ 2.92 (s, CH_3), 2.8—4.0 (m, CH_2), 6.9 (m, ArH of phenyl), 7.1—8.4 ppm (m, ArH of anthryl). Found: C, 88.50; H, 7.11; N, 4.26%; MS (*m/e*), 325 (M^+). Calcd for $C_{24}H_{23}N$: C, 88.57; H, 7.12; N, 4.30; M, 325.43.

The preparation of P_2 was accomplished in a similar manner. P_2: pale yellow granulars from acetone, mp 118—120 °C. NMR ($CDCl_3$) δ 2.92 (s, CH_3), 2.9—3.7 (m, CH_2), 6.94 (m, ArH of phenyl), 7.8—8.4 ppm (m, ArH of pyrenyl). Found: C, 89.41; H, 6.64; N, 3.99%, MS (*m/e*) 349 (M^+). Calcd for $C_{26}H_{23}N$: C, 89.36; H, 6.63; N, 4.01%; M, 439.45.

p-*(3-Aryl-3-oxo-1-propenyl)*-N,N-*dimethylaniline* (*$II_{A,P}$*). A mixture of 9-acetylanthracene (27.5 g, 125 mmol), *p*-dimethylaminobenzaldehyde (18.5 g, 125 mmol), and potassium cyanide (3 g, 45 mmol) in ethanol was heated under reflux for 4 h. The resulting precipitate was collected and recrystallized from toluene to yield ketone II_A (39 g, 90%), orange granulars, mp 188—189 °C. Found: C, 85.64; H, 5.76; N, 3.81%. Calcd for $C_{25}H_{21}NO$: C, 85.44; H, 6.02; N, 3.99%.

The preparation of II_P was done in the same manner. II_P: orange plates from acetone–benzene, mp 171.5—172.5 °C. Found: C, 86.12; H, 5.32; N, 3.63%. Calcd for $C_{27}H_{21}NO$: C, 86.37; H, 5.64; N, 3.73%.

p-*(3-Aryl-3-oxopropyl)*-N,N-*dimethylaniline* (*$III_{A,P}$*). The ketone II_A (20 g, 57 mmol) was reduced with lithium aluminium hydride (4 g, 110 mmol) in boiling diethyl ether for 20 h using an extractor of Soxhlet-type. After removal of the solvent, the residue was recrystallized from acetone to give pure III_A, yellow granulars, 17.4 g (87%), mp 103—103.5 °C. Found: C, 84.79; H, 6.41; N, 3.92%. Calcd for $C_{25}H_{23}NO$; C, 84.95; H, 6.56; N, 3.96%.

In the same manner III_P was prepared. III_P: yellow plates from acetone, mp 142—143 °C. Found: C, 86.09; H, 6.09;, N. 3.72%. Calcd for $C_{27}H_{23}NO$: C, 85.91; H, 6.14; N, 3.71%.

p-*(3-Arylpropyl)*-N,N-*dimethylaniline* (*A_3, P_3*). The dihydroketone III_A (2 g, 5.6 mmol) was added to a stirred suspension of lithium aluminium hydride (0.38 g, 9.8 mmol) and aluminium chloride (2.66 g, 19.6 mmol) in diethyl ether (50 ml). After stirring for 2 h under reflux, ethyl acetate, water, and 5% aq sodium hydroxide were successively added to the reaction mixture. It was extracted with diethyl ether, and the organic layer was worked up in the usual manner. The residual yellowish brown solid was chromatographed on silica gel to give A_3 (34 mg, 18%). A_3: colorless granulars from acetone, mp 105—106 °C. NMR ($CDCl_3$) δ 2.92 (s, CH_3), 1.9—3.8 (m, CH_2), 6.95 (m, ArH of phenyl), 7.3—8.3 ppm (m, ArH of anthryl). Found: C, 88.65; H, 7.29; N, 4.10% MS (*m/e*), 339 (M^+). Calcd for $C_{25}H_{25}N$: C, 88.45; H, 7.42; N, 4.13%; M, 339.46.

In the same manner P_3 was prepared. P_3: pale yellow powder, mp 97—97.5 °C. NMR ($CDCl_3$) δ 2.9 (s, CH_3), 2.0—3.5 (m, CH_2), 6.89 (m, ArH of phenyl), 7.1—8.2 ppm (m, ArH of pyrenyl). Found: C, 89.12; H, 6.95; N, 3.90%, MS (*m/e*), 363 (M^+). Calcd for $C_{27}H_{25}N$: C, 89.21; H, 6.93; N, 3.85%; M, 363.48.

Results

A_3 and P_3 in Hexane Solution. Fluorescence spectra of A_3 and P_3 in hexane are shown in Fig. 1. Decay times (τ_d) of LE fluorescence measured in the wavelength region of 390—420 nm and rise time (τ_r) of HE fluorescence observed through a filter transparent for the region longer than 550 nm are listed in Table 1. Both τ_d and τ_r values of each compound agree within experimental error.

It should be noted here that the rise curve of the HE fluorescence measured at 540 nm contains a considerable amount of the rapid component. However, the rapid component is negligible if the fluorescence is observed through a filter which is transparent above 550 nm (Fig. 2).

A_n and P_n in 2-Propanol Solution. Fluorescence spectra of A_n and P_n in 2-propanol solution are shown in Fig. 3. The HE band is shifted to considerably longer wavelength compared to that in hexane solution. Decay times of LE fluorescence observed in the region of 390—420 nm and rise times of HE fluorescence observed through a filter which is transparent above 520 nm are given in Table 2 for A_1, P_1, A_2, and P_2. The τ_d and τ_r values of each compound approximately agree, although there is a tendency that τ_r value is a little longer than that of τ_d for A_1 and P_1. As a typical example, the observed decay curve and also the rise curve of P_1 are shown in Fig. 4.

For A_3 and P_3, circumstances are somewhat complicated. By detailed observation of P_3 at 401 nm, we detected clearly a two-component decay of fluorescence as shown in Fig. 5A, from which decay times were estimated to be $\tau_d^1=340\pm20$ ps and $\tau_d^2=1.1\pm0.2$ ns.

We examined dynamic features of the HE fluorescence at several different wavelength regions. The measurement through a filter which is transparent above 680 nm indicated clearly rise and two-component decay curves (Fig. 5B). By analyzing this result, the

fluorescence rise time and the decay time of the fast component of the two-component decay curve were estimated to be $\tau_r^{HE}=345\pm50$ ps and $\tau_d^{HE}=1.1\pm0.1$ ns, respectively. We can see a good agreement be-

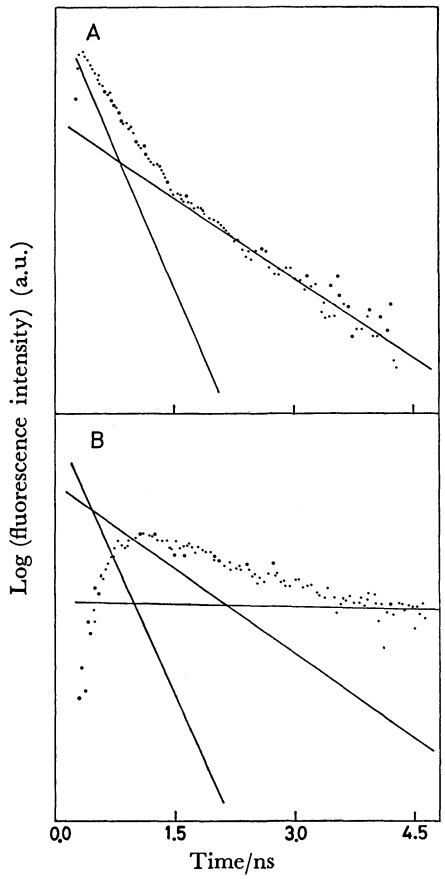

Fig. 5. Decay curve of LE fluorescence observed at 401 nm (A) and rise and decay curve of HE fluorescence observed through a filter which passes the wavelength region longer than 680 nm (B) in the case of 2-propanol solution of P_3. The observed results were calibrated for variations in the value of ps/channel in the following way. Conversion of n-th channel to the delay time $t(n)$ was made according to: $t(n)=\sum_{i=0}^{n}\Delta t(i)$, where $\Delta t(i)$ is the value of ps/channel of the i-th channel, and the observed intensity $I(i)$ at i-th channel was corrected according to: $I_{corr}(i)=I(i)/\Delta t(i)$.

tween τ_r^{HE} and τ_d^1 as well as between τ_d^{HE} and τ_d^2. Therefore, the results in Fig. 5 satisfy the ordinary kinetics of HE formation and decomposition. However, the measurement of HE fluorescence in the region including shorter wavelengths gave rather complicated results due to the contribution from the LE fluorescence.

Although we have not made such a detailed study for A_3 in 2-propanol, the circumstance seems to be analogous to P_3, since we have observed two component decay of the HE fluorescence by observing in the region longer than 650 nm and obtained the approximate τ_d^{HE} value of the fast component to be 1.5 ns.[16]

P_3 in an Acetone Solution. The results were similar to those in 2-propanol. However, the observed τ_d^1 value was much shorter (60 ps), while the τ_d^{HE} value was not so much different ($\approx$1 ns).

P_2 and P_3 in Acetonitrile Solutions. Both LE fluorescence decay and HE fluorescence rise times of P_2 in acetonitrile were shorter than 20 ps, the response time of the apparatus. The LE fluorescence decay time of P_3 was also shorter than 20 ps. Thus, the CT or HE formation becomes very fast in acetonitrile, a strongly polar and less viscous solvent. However, the ordinary kinetics for HE formation and decomposition as observed for P_3 in 2-propanol was not recognized clearly in this case.

A_0 and Bian in Polar Solvents. In the fluorescence spectra of these compounds in polar solvents, the LE and HE bands are not so distinct as those of A_n and P_n (n=1, 2, 3). One can recognize, however, that the vibrational structure of the LE band superposed upon the broad CT (HE) fluorescence band for Bian.[11,12] In accordance with this result, the decay curve of LE fluorescence in the region, 390—420 nm and the rise curve of CT fluorescence in the region above 520 nm for Bian were observed in 2-propanol (Fig. 6). In Fig. 6A, the fluorescence observed at longer delay times is due to the CT fluorescence band superposed upon the LE band. The decay time (τ_d) of the LE fluorescence and the rise time (τ_r) of the CT fluorescence of Bian in 2-propanol were estimated to be τ_d=80±17 ps and τ_r=80±20 ps. These values are in good agreement with each

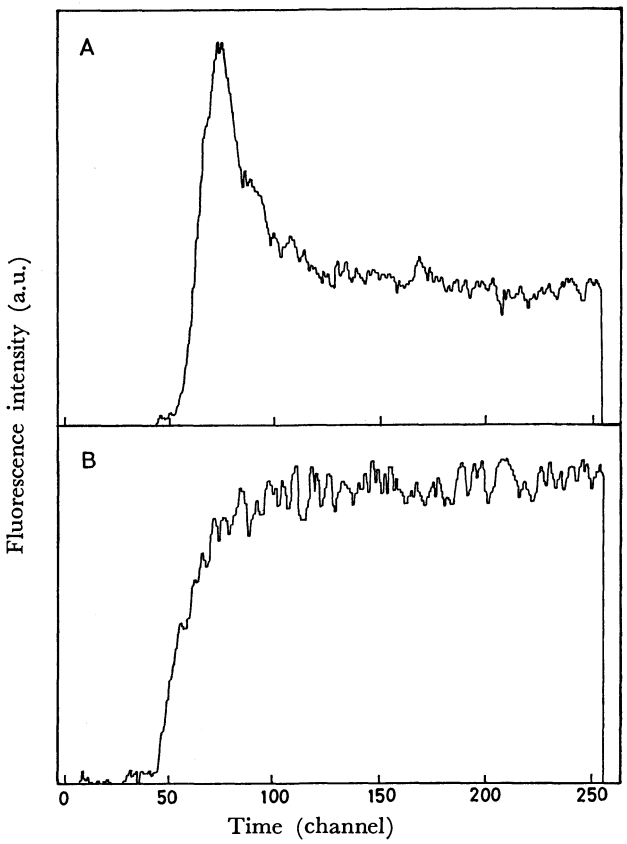

Fig. 6. Fluorescence decay and rise curves of Bian in 2-propanol.
A: Decay curve of LE fluorescence observed in the wavelength region of 320—420 nm. The long life tail is due to the CT fluorescence extending to this wavelength region, B: rise curve of CT fluorescence observed through a filter which passes the wavelength region above 520 nm.

other. Both the LE fluorescence decay and CT fluorescence rise times of Bian in acetone and acetonitrile were shorter than the response time of the apparatus (≈20 ps).

For A_0, the fluorescence spectra in polar solvents are more broad, and one cannot recognize clearly the LE fluorescence band.[2,6] In 2-propanol solution, we observed a decay curve in the region, 320—420 nm with the apparent decay time of approximately ≈70 ps, and a rise curve in the region longer than 520 nm with the apparent rise time of approximately ≈110 ps. Just as for Bian, both LE fluorescence decay and CT fluorescence rise times of A_0 in less viscous or more polar solvents like acetone, butyronitrile and acetonitrile were shorter than the response time of the apparatus (≈20 ps).

Discussion

HE Formation in Nonpolar Solvents. It is well established now that intramolecular HE formation is not possible for A_1, A_2, and P_1 in nonpolar solvents, while it is possible for A_3 and P_3 even in nonpolar solvents.[1-7] It has been confirmed already for P_3 in decalin solution that the rise time of the HE formation at room temperature is about 8 ns.[4,7] The fully slow formation process is ascribed to the internal rotations around CH_2–CH_2 bonds necessary for the conformation change and somewhat high viscosity of decalin. Both internal rotaions and solvent viscosity are affected by temperature, and the rise time becomes much longer by lowering temperature. For example, for P_3 in decalin, τ_r is 25 ns at −10 °C and 58 ns at −50 °C.[4,7]

Even if a less viscous solvent, hexane, is used, the rise of intramolecular HE fluorescence still takes a few ns for both A_3 and P_3, which indicates an important role of internal rotation for slowing down the HE formation process. Assuming the reaction mechanism of Eq. 1, where k_2 and k_3 are sum of radiative and non-radiative rate constants, the well-known Eq. 2 representing time dependence of each species is obtained.

$$\mathrm{S(A^*\ /\backslash/\backslash\ D)} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{HE_s}\left[\begin{array}{l}\text{sandwich}\\ \\ \text{heteroexcimer}\end{array}\right] \quad (1)$$

$$\downarrow k_2 \qquad\qquad \downarrow k_3$$

$$[\mathrm{S}] = C_1\exp(-\lambda_1 t) + (C_0 - C_1)\exp(-\lambda_2 t)$$
$$[\mathrm{HE_s}] = C_2[\exp(-\lambda_1 t) - \exp(-\lambda_2 t)]. \quad (2)$$

The values of λ_2^{-1} were determined as shown in Table 1, and these of λ_1^{-1} in hexane were given by the previous study as 130 ns and 87 ns for A_3 and P_3, respectively.[7]

The rapid component in the fluorescence rise curve observed at 540 nm (Fig. 2A) is indicative of the existence of ground state A_3 molecules in a sandwich configuration, which give HE fluorescence immediately after excitation as reported by Gnädig and Eisenthal.[13] However, this possibility is rejected, because no rapid component is found when the rise curve was observed only for the region longer than 550 nm (Fig. 2B).

Although the $S_n \leftarrow S_1$ spectrum of anthracene itself does not show any appreciable absorbance at 694 nm where Gnädig and Eisenthal monitored the transient absorbance of A_3 HE, we have confirmed by ps transient absorbance measurements on A_3 that the $S_n \leftarrow S_1$ spectra of anthracene are affected by alkyl substitution, and there arises some absorbance around 694 nm.[16] Thus, the rapid component observed in the ps transient absorption of A_3 can be ascribed to $S_n \leftarrow S_1$ spectra, and that shown in Fig. 2A must be ascribed to LE fluorescence.

Photo-induced CT and HE Formation of A_n and P_n (n=1, 2, 3) in Polar Solvents. In general, the wave equation and the Hamiltonian operator for the solute–solvent system may be given by

$$\mathscr{H}\Psi = E\Psi,\ \mathscr{H} = \mathscr{H}_0 + \mathscr{H}',\ \mathscr{H}' = -\vec{\mu}_{op}\cdot\vec{F}, \quad (3)$$
$$\vec{F} = \vec{\mu}\cdot f_\varepsilon/a^3,\ f_\varepsilon = 2(\varepsilon-1)/(2\varepsilon+1),\ \vec{\mu} = \langle\Psi|\vec{\mu}_{op}|\Psi\rangle,$$

where, $\mathscr{H}'$ represents the solute–solvent interaction, $\vec{\mu}_{op}$ is the dipole operator, $\vec{F}$ is the Onsager's reaction field and ε is the dielectric constant of solvent.

For an excited CT system, a simplified wavefunction may be given by

$$\Psi = C_1\Psi_{CT} + C_2\Psi_{LE}, \quad (4)$$

where Ψ_{CT} represents the CT structure A^-D^+, and Ψ_{LE} the LE structure A*D. By using Eqs. 3 and 4, the following matrix elements are defined:

$$\vec{\mu} = C_1^2\langle\Psi_{CT}|\vec{\mu}_{op}|\Psi_{CT}\rangle = C_1^2\cdot\vec{\mu}_0$$
$$\langle\Psi_{CT}|\mathscr{H}|\Psi_{CT}\rangle = \langle\Psi_{CT}|\mathscr{H}_0|\Psi_{CT}\rangle + \langle\Psi_{CT}|\mathscr{H}'|\Psi_{CT}\rangle$$
$$= E_c - \langle\Psi_{CT}|\vec{\mu}_{op}\cdot\vec{F}|\Psi_{CT}\rangle$$
$$= E_c - C_1^2(\mu_1^2/a^3)f_\varepsilon$$
$$\langle\Psi_{CT}|\mathscr{H}|\Psi_{LE}\rangle = \alpha,\ \langle\Psi_{LE}|\mathscr{H}|\Psi_{LE}\rangle = E_e. \quad (5)$$

With these matrix elements, the secular equations are written as

$$C_1(E_c - C_1^2(\mu_0^2/a^3)\cdot f_\varepsilon - E) + C_2\alpha = 0$$
$$C_1\alpha + C_2(E_e - E) = 0. \quad (6)$$

By solving these nonlinear equations and by adding the polarization energy of the solvent to the solution of Eq. 6, the energies of the states relevant to the fluorescence transition can be obtained.[1]

For A_1 and P_1, for example, α which is due to the electronic delocalization interaction between electron donor and acceptor groups may be negligibly small. Therefore, the energy of the CT state relaxed with respect to solvation may be given by,

$$E_{CT} = E_c - (1/2)(\mu_e^{eq2}/a^3)\cdot f_\varepsilon, \quad (7)$$

where $\vec{\mu}_e^{eq}$ is the dipole moment of the relaxed CT state. E_{CT} is higher than E_e in nonpolar solvents for A_1, P_1, and A_2. With increase of the solvent polarity, E_{CT} becomes lower than E_e. At the inversion point, there arises the orientational destabilization energy δE^{FC} in the Franck-Condon ground state of the fluorescence transition.

$$\delta E_g^{FC} = (1/2)\cdot(\mu_e^{eq2}/a^3)\cdot(f_\varepsilon - f_n)$$
$$f_n = 2(n^2-1)/(2n^2+1). \quad (8)$$

Therefore, in more polar solvents than that giving the inversion point, the frequency of the CT fluorescence is given by Eq. 9.

$$h\nu_e = \text{Const.} - (\mu_e^{eq2}/2a^3)(2f_\varepsilon - f_n). \quad (9)$$

We have actually observed, for A_1, P_1, and A_2, especially large red shifts of the HE fluorescence at the inversion point due to δE^{FC},[3-5] and have confirmed that Eq. 9 holds not only for the HE fluorescence of A_n and P_n (n=1, 2) but also for A_3 and P_3.[3-5]

In the present work, we are investigating the dynamic processes of appearance of the HE state. The simple picture described above seems to be especially suitable to the cases of A_1 and P_1. Thus, the time-resolved fluorescence measurements of these systems will reflect directly the solvation process in the CT state.

The results indicated in Table 2 and Fig. 4 for A_1 and P_1 in 2-propanol solution show that the relaxation processes of the decay of LE and appearance of the CT state take about 50—100 ps. These values, however, are considerably longer than the shorter reorientational relaxation time[15] (<30 ps) of 2-propanol liquid. This result seems to indicate two possibilities: (a) the relaxation process of the CT state formation involves not only the rapid reorientational relaxation of 2-propanol but also slower ones covering a wider region around the solute molecule and involving hydrogen bond breaking and formation; (b) the relaxation process involves not only the solvent reorientation and solvent-induced change in the electronic structure as outlined by Eqs. 3—7 but also the geometrical change *i.e.* internal rotations of the solute molecule around single bonds connecting the CH_2 group with two aromatic groups, and the relaxation time is inherent in this conformation change.

However, the fact the relaxation times for the CT state formation of Bian and A_0 in 2-propanol are likewise 50—100 ps indicates that this relaxation time is inherent in reorientation of 2-propanol molecules around the bichromophoric molecule in the excited CT state formation rather than its conformational change.

A little longer τ_r value than that of τ_d for A_1 and P_1 may be due to the time-dependent red shift of HE band during the rise of HE fluorescence.

The considerably longer relaxation times of A_2 and P_2 compared with those of A_1 and P_1 may be explained as due to more extensive conformational change necessary for the photo-induced CT and for taking the stable HE configuration.

The behavior of P_3 in 2-propanol is a good example of enhancement of photo-induced CT process in polar solvent, and also of the control or slowing down of the CT reaction by internal rotations which are necessary to bring A* and D to the mutual distance and orientation where the CT is possible. The latter effect of the internal rotations makes it possible to elucidate photo-induced CT processes in solution which are difficult to study in detail even by ps laser methods for free A* and D. This difficulty is caused by very rapid and mutually combined translational and rotational diffusions, and they make the result complicated.

The faster decay of LE fluorescence and the faster rise of HE fluorescence of P_3 in 2-propanol solution than in hexane solution despite the higher viscosity of 2-propanol suggest that the photo-induced CT in polar solvent is possible, even if A* and D are somewhat separated, because the energy of the CT state is lowered by the interaction with the polar solvent, and loose HE is formed. Moreover, our previous semi-quantitative studies of ps transient absorption spectra of P_3 in 2-propanol indicated a two step change of spectra which is probably due to loose HE formation followed by a conformational change into the one of sandwich-type.[8,10]

The double exponential decay of LE fluorescence observed at 401 nm and the rise as well as decay of HE fluorescence observed in the region longer than 680 nm can be well reproduced by assuming the reaction scheme of Eq. 10 and by Eq. 11 derived from it.

$$\begin{array}{ccccc} S(A^* \,/\backslash/\backslash\, D) & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & HE_1 \left[\begin{array}{c}\text{loose}\\ \\ \text{heteroexcimer}\end{array}\right] & \xrightarrow{k_2} & HE_s \left[\begin{array}{c}\text{sandwich}\\ \\ \text{heteroexcimer}\end{array}\right], \\ \downarrow k_3 & & \downarrow k_4 & & \downarrow k_5 \end{array} \quad (10)$$

where k_3, k_4, and k_5 are sums of rate constants of radiative as well as radiationless deactivations, respectively.

$$\begin{aligned}[S] &= C_1' \exp(-\lambda_1' \cdot t) + (C_0' - C_1') \exp(-\lambda_2' \cdot t)\\ [HE_1] &= C_2'[\exp(-\lambda_1' \cdot t) - \exp(-\lambda_2' \cdot t)]\\ [HE_s] &= C_3[(\lambda_1' - k_5)\exp(-\lambda_2' \cdot t) - (\lambda_2' - k_5)\exp(-\lambda_1' \cdot t)\\ &\quad - (\lambda_2' - \lambda_1')\exp(-k_5 \cdot t)]. \end{aligned} \quad (11)$$

In view of the good correspondence between the τ values, the time-dependences of fluorescence observed at 401 nm and those observed in the region longer than 680 nm are assigned to S and HE_1, respectively, from which $\tau_d = \tau_r^{HE} = \tau'^{-1}_2 \approx 350$ ps and $\tau_d = \tau_d^{HE} = \tau'^{-1}_1 \approx 1.1$ ns were obtained. The assignment of the long wavelength band to the loose HE may be supported also by the fact that the ordinary (time-integrated) fluorescence spectra of P_1 and P_2 in 2-propanol are somewhat red-shifted compared to those of P_3 in the same solvent. The latter spectra can be attributed almost completely to HE_s because of its much longer lifetime ($\approx$100 ns) compared with HE_1. Moreover, our recent results of accurate ps time-resolved absorption measurements on the same system can be explained quantitatively assuming the same scheme (10), and they give the same λ' values.[16]

The results of similar measurements in acetone solution can be interpreted by the same scheme as Eq. 10, with $\lambda'^{-1}_2 \approx 60$ ps and $\lambda'^{-1}_1 \approx 1$ ns. Since the polarity of acetone is close to that of 2-propanol, it is necessary to have a similar conformation (HE_1) for

the photo-induced CT to occur. Therefore, the much shorter value of $\lambda'_2{}^{-1}$ might be due to the considerably lower viscosity of acetone compared to 2-propanol, resulting in faster conformation change. However, the reason why the value of $\lambda'_1{}^{-1}$ is not so much different from that in 2-propanol solution is not so clear at the present stage of investigation. Presumably, the HE_1 formation may occur by solvent reorientation and a small rotation of two chromophore groups with only a slight internal rotation around CH_2–CH_2 bonds, while the HE_s formation involves extensive internal rotations which seem to determine the velocity of the process irrespective of the solvent viscosity.

The photo-induced intramolecular CT process becomes much faster in acetonitrile, a strongly polar and less viscous solvent, since CT may be possible at longer mutual distance between A* and D due to the rapid and stronger solvation. In other words, the extent of the conformation change necessary for the photo-induced CT may be much smaller in acetonitrile than in 2-propanol.

Thus, both the LE fluorescence decay time and HE fluorescence rise time of P_2 are shorter than 20 ps, the response time of the apparatus. The LE fluorescence decay time of P_3 is also shorter than 20 ps, but the corresponding rise of the HE fluorescence was not observed. The fluorescence from the loose HE formed immediately after the rapid photo-induced CT may not be detectable in the case of P_3 because of the very small fluorescence yield due to strong solvation of the ion-pair state.

Behaviors of Bian and A_0 in Polar Solvents. Interestingly Bian shows in the excited state intramolecular CT from one anthracene nucleus to another, which is caused by the interaction with polar solvent molecules.[11] This is a solvent-induced "broken symmetry" phenomenon, *i.e.* the lowering of the symmetry of the solute molecule due to the interaction with polar solvent molecules, resulting in the CT state even if the molecule is composed of two identical chromophores.[12] Direct confirmation of the intramolecular CT was made by transient absorption spectral measurements in polar solvent.[12]

In the present work, we have directly demonstrated the CT state formation process and decay of the corresponding LE state in 2-propanol. Both the CT state rise and the LE state decay times are *ca.* 80 ps, which are considerably longer than the shorter reorientational relaxation time of 2-propanol liquid at room temperature. Just as in the cases of A_1 and P_1 in 2-propanol, two interpretations might be possible. One is the relaxation process which includes some contribution from slower processes involving solvent hydrogen bond breaking and formation. The other involves not only the solvent reorientation but also the geometrical structural change of Bian, *i.e.* the rotation around the 9–9′ bond which determines the observed relaxation time.

The two π-electronic systems of Bian are oriented perpendicular to each other because of a strong steric hindrance in the relaxed ground state as well as the Franck-Condon excited state. It was suggested that the stable conformation in the excited state may not be the perpendicular one but the oblique one.[11] Since the CT fluorescent state of excited Bian may be considered as a resonance hybrid of the CT configuration mixed with the LE configuration, its solvation by polar solvents will oppose the electronic delocalization between two chromophores, because the solvation energy increases with increasing charge separation in the CT system. When the conformation is the perpendicular one, the electronic delocalization will become very small. Therefore, the excited equilibrium conformation in polar solvents will be very close to that of the excited Franck-Condon state.

The above considerations lead to the conclusion that the rate of the photo-induced CT state formation of Bian will be determined by the solvent reorientation relaxation time and will become faster in a less viscous polar solvent. Actually, we have found that the LE fluorescence decay and the CT fluorescence rise times of Bian in acetone as well as in acetonitrile are much shorter (<20 ps) than those in 2-propanol.

Although the fluorescence spectra of A_0 are quite broad, we were able to observe the LE fluorescence decay in 2-propanol solution at the shorter wavelength edge of the fluorescence band, and the CT fluorescence rise process in the longer wavelength region. This result is somewhat analogous to those of A_1, P_1, and Bian. Although the CT character of S_1 state seems to be evident from the very large red shift of fluorescence with increase of solvent polarity, another evidence comes from the measurement of the effect of solvent polarity upon the $S_n \leftarrow S_1$ spectra.[6] It has been confirmed that the $S_n \leftarrow S_1$ spectra in moderately or strongly polar solvents are comparable to the superposition of those of anthracence anion and DMA cation.[6,17]

In this case too, the LE fluorescence decay time (≈ 70 ps) as well as the CT fluorescence rise time (≈ 110 ps) in 2-propanol are considerably longer than the shorter reorientation relaxation time of 2-propanol liquid at room temperature. A little larger value of the latter compared with the former can be explained as due to the time-dependent red shift of the CT fluorescence band occuring during the CT state rise process just as for A_1 and P_1. The fact that the CT fluorescence rise time agrees approximately with the LE fluorescence decay time for Bian in 2-propanol may be explained as due to the much smaller solvent-induced red shift of the CT fluorescence band of Bian compared with A_0. Namely, the wavenumber difference between the fluorescence band maxima of Bian in hexane and 2-propanol is *ca.* 1.4×10^3 cm^{-1}, smaller compared with the corresponding value of A_0, 5.3×10^3 cm^{-1}.

Thus, there arises a similar problem with A_1, P_1, and Bian concerning the mechanism of CT state formation in 2-propanol, *i.e.* the relaxation process includes some contribution from the slower process of solvent rearrangements involving hydrogen bond breaking and formation, or it involves structural changes of A_0. The possibility of an excited equilibrium structure of A_0 in polar solvents where molecular planes of two moieties are perpendicular to each other has been discussed already.[6,18] Moreover, we have also

confirmed that the LE fluorescence decay time as well as the CT fluorescence rise time of A_0 in less viscous and polar solvents, like acetone, butyronitrile and acetonitrile are much shorter than the response time (20 ps) of the apparatus. Analogously to the cases of A_1, P_1, and Bian, the rate of the CT state formation in polar solvents for A_0 seems to be determined by the solvent reorientations.

Summary

We have observed directly by means of ps time-resolved fluorescence measurements the intramolecular HE formation process and its solvent dependence for typical hydrocarbon–amine systems and have confirmed our prediction of the enhancement of intramolecular CT process with increase of solvent polarity. Existence of loose HE's as an intermediate during sandwich type HE formation in polar solvents has been demonstrated for three methylene-chain compounds and we have found that the loose HE emits at longer wavelength than sandwich type one. Moreover, it has been found that the loose HE in strongly polar solvents is non-fluorescent. These results demonstrate clearly the effect of solvent polarity upon the photo-induced CT and HE formation processes as well as upon the electronic and geometrical structures of the formed HE's.

The cost of the present investigation was partly defrayed by the grants given by Toray Science Foundation and Mitsubishi Foundation, and also by Grant-in-Aid for Special Project Research on Photobiology from the Japanese Ministry of Education, Science and Culture.

The Hartree-Fock and Electron-Hole Potential Methods from a Hypervirial Theorem Standpoint

Makoto Isihara

Department of General Education, Shotoku-Gakuen Women's Junior College, Gifu 500

(Received April 25, 1981)

The hypervirial theorem is introduced in the second quantized expanded form, and utilized for reviewing the Hartree-Fock and electron-hole potential methods. A possibility of going beyond the latter is suggested within the scope of handy methods. Brillouin's and the extended Brillouin's theorems are shown to be contained in the hypervirial theorem.

The hypervirial theorem (HVT)[1] is nothing other than the statement that the expectation value of any physically nonpathological operator does not depend on time in stationary states, and has vast range of application because of its great fundamentality. Essential explorations of the theorem in molecular quantum mechanics have been made already in 1960's from both variation-[2] and perturbation-theoretical[3] points of view, where the form of operators is either nonspecified or given as a function of coordinates and momenta. In this paper the HVT is introduced in the second quantized form, expanded under the exponential prescription,[4] and utilized for reviewing the Hartree-Fock (HF)[5] and electron-hole potential (EHP)[6,7] methods. We can immediately arrive at the HF method in the first order one-particle HVT for the ground state; that for the excited state leads us to the EHP method and further gives a possibility of a handy modification beyond the method. Brillouin's[8] and the extended Brillouin's[6] theorems are shown to be contained in the HVT. Supplementary remarks are added on what is implied in the first order two-particle HVT for the ground state and in connection with the perturbation-theoretical approach.

The Hypervirial Theorem

Let $|\psi\rangle$ be an eigenstate of a Hamiltonian H and W be an arbitrary operator, the restriction on W being only that $W|\psi\rangle$ should not jump outside the space considered. The HVT is simply written as

$$\langle\psi|[H, W]|\psi\rangle = 0. \tag{1}$$

Take a system of identical particles and denote the creation and annihilation operators for the one-particle quantum state j by $a_j^\dagger$ and a_j respectively. Then, any one-particle operator of the system is of the following form.

$$W = \sum_{jk} w_{jk} a_j^\dagger a_k.$$

The strong requirement that Eq. 1 must hold for any W leads to the one-particle HVT:

$$\langle\psi|[H, a_p^\dagger a_q]|\psi\rangle = 0 \quad \text{(any } p, q\text{)}. \tag{2}$$

Likewise we have the two-particle HVT,

$$\langle\psi|[H, a_p^\dagger a_r^\dagger a_s a_q]|\psi\rangle = 0 \quad \text{(any } p, q, r, s\text{)}, \tag{3}$$

and so on. For arbitrary products of the creation and/or annihilation operators we have

$$\langle\psi|[H, \prod_p a_p^\dagger \prod_q a_q]|\psi\rangle = 0. \tag{4}$$

However, unless the numbers of creation and annihilation operators are equal, the relation is trivial for the particle-conservative system.

Separating a Hamiltonian into the unperturbed Hamiltonian K and the perturbation λV with a real parameter λ,

$$H = K + \lambda V, \tag{5}$$

we can obtain a perturbation expansion of Eq. 1 on the assumption that an eigenstate $|\psi\rangle$ of H is attainable from the corresponding eigenstate $|\phi\rangle$ of K through a unitary transformation:

$$|\psi\rangle = \exp(S)|\phi\rangle, \tag{6}$$

where S is an antihermitian operator independent of the energy level index.[3,4] Noting that S has no zeroth order term, we put it in the power series of λ as

$$S = \lambda S_1 + \lambda^2 S_2 + \cdots \tag{7}$$

with antihermitian operators $\{S_i\}$. Substitution of Eq. 6 into Eq. 1 rewrites the HVT as a form of the unperturbed state expectation value:

$$\langle\phi|\exp(-S)[H, W]\exp(S)|\phi\rangle = 0,$$

which is expanded by means of Eqs. 5 and 7;

$$\lambda\langle\phi|([V, W] + [[K, W], S_1])|\phi\rangle + \lambda^2\langle\phi|([[V, W], S_1] + \frac{1}{2}[[[K, W], S_1], S_1] + [[K, W], S_2])|\phi\rangle + \cdots = 0. \tag{8}$$

Thus we have the first order HVT,

$$\langle\phi|([V, W] + [[K, W], S_1])|\phi\rangle = 0, \tag{9}$$

or, using the Jacobi-Lie identity,

$$\langle\phi|[V + [K, S_1], W]|\phi\rangle = 0. \tag{10}$$

To decompose S_i into the one-particle part $S_i^{(1)}$, the two-particle one $S_i^{(2)}$, and so on,

$$S_i = S_i^{(1)} + S_i^{(2)} + \cdots, \tag{11}$$

enables us to proceed a little further. Assuming that K is one-particle and that V consists of the one- and two-particle parts,

$$V = V^{(1)} + V^{(2)}, \tag{12}$$

we can write the first order HVT as

$$\sum_{n=1,2} \langle\phi|[Y^{(n)}, W]|\phi\rangle = 0 \tag{13}$$

with

$$Y^{(n)} = V^{(n)} + [K, S_i^{(n)}]. \tag{14}$$

The terms of $n=1$ and 2 in the left-hand side of Eq. 13 concern the one- and two-particle operators for

$W=a_p^\dagger a_q$ and two- and three-particle ones for $W=a_p^\dagger a_r^\dagger a_s a_q$ respectively. We can make all $S_1^{(n)}$'s vanish for n larger than 2.

The Hartree-Fock Method

The Hamiltonian of electrons in the fixed nuclear framework is given by

$$H=\sum_{\xi\eta\mu} h_{\xi\eta} a_{\xi\mu}^\dagger a_{\eta\mu} + \frac{1}{2}\sum_{\xi\eta\theta\tau\mu\nu} v_{\eta\tau}^{\xi\theta} a_{\xi\mu}^\dagger a_{\theta\nu}^\dagger a_{\tau\nu} a_{\eta\mu}, \tag{15}$$

where the second suffices, μ and ν, refer to the electron spin. It is assumed hereafter that the matrix elements, $\{h_{\xi\eta}\}$, $\{v_{\eta\tau}^{\xi\theta}\}$, and so on, are all spin-independent. Taking a relevant hermitian one-particle operator

$$X=\sum_{\xi\eta\mu} x_{\xi\eta} a_{\xi\mu}^\dagger a_{\eta\mu},$$

which is to be determined later, we rewrite the Hamiltonian in the molecular orbital representation as

$$H=\sum_{j\mu}\varepsilon_j a_{j\mu}^\dagger a_{j\mu} + \frac{1}{2}\sum_{jklm\mu\nu} v_{km}^{jl} a_{j\mu}^\dagger a_{l\nu}^\dagger a_{m\nu} a_{k\mu} - \sum_{jk\mu} x_{jk} a_{j\mu}^\dagger a_{k\mu}. \tag{16}$$

The molecular orbital coefficients $\{u_{\xi j}\}$ and their energies $\{\varepsilon_j\}$ are determined by the eigenvalue problem diagonalizing $\{h_{\xi\eta}+x_{\xi\eta}\}$:

$$\sum_\eta (h_{\xi\eta}+x_{\xi\eta})u_{\eta j} = u_{\xi j}\varepsilon_j. \tag{17}$$

Now let us take the unperturbed Hamiltonian in Eq. 16 as

$$K=\sum_{j\mu}\varepsilon_j a_{j\mu}^\dagger a_{j\mu} \tag{18}$$

and assume that its ground state $|F\rangle$ have a closed-shell form:

$$|F\rangle = a_{f\uparrow}^\dagger a_{f\downarrow}^\dagger \cdots a_{2\uparrow}^\dagger a_{2\downarrow}^\dagger a_{1\uparrow}^\dagger a_{1\downarrow}^\dagger |0\rangle,$$

where $\uparrow$ and $\downarrow$ stand for the up- and down-spin states, respectively, and $|0\rangle$ means the vacuum state. Denoting a set of the occupied orbitals $\{1,2,\cdots,f\}$ by F and that of the unoccupied by $\overline{F}$, we define the occupation indicator as

$$\mathrm{f}(j)=\begin{cases}1 & (j\in F)\\ 0 & (j\in\overline{F}).\end{cases} \tag{19}$$

Substituting

$$V^{(1)} = -\sum_{jk\mu} x_{jk} a_{j\mu}^\dagger a_{k\mu}, \tag{20}$$

$$V^{(2)} = \frac{1}{2}\sum_{jklm\mu\nu} v_{km}^{jl} a_{j\mu}^\dagger a_{l\nu}^\dagger a_{m\nu} a_{k\mu}, \tag{21}$$

$$S_1^{(1)} = \sum_{jk\mu} s_{jk} a_{j\mu}^\dagger a_{k\mu}, \tag{22}$$

$$S_1^{(2)} = \frac{1}{2}\sum_{jklm\mu\nu} s_{km}^{jl} a_{j\mu}^\dagger a_{l\nu}^\dagger a_{m\nu} a_{k\mu}, \tag{23}$$

and Eq. 18 into Eq. 13 through Eq. 14, we obtain the first order one-particle HVT putting $W=a_{p\sigma}^\dagger a_{q\sigma}$, since the present Hamiltonian includes no spin-changing term. For the ground state, putting $|\phi\rangle=|F\rangle$, we see the following condition result from the theorem.

$$(-x_{qp}+\tilde{v}_{qp}+(\varepsilon_q-\varepsilon_p)(s_{qp}+\tilde{s}_{qp}))(\mathrm{f}(q)-\mathrm{f}(p))=0, \tag{24}$$

the quantity with a tilde being defined as

$$\tilde{t}_{jk}=\sum_m (2t_{km}^{jm}-t_{mk}^{jm})\mathrm{f}(m).$$

Although for any $p\in F$ and $q\in\overline{F}$ the same equation is obtained as for any $p\in\overline{F}$ and $q\in F$, they are not independent of each other as far as X and V are kept hermitian and S antihermitian. If we use no S, that is, take an approximation that $|\phi\rangle=|\phi\rangle$, then Eq. 24 gives

$$x_{jk}=\tilde{v}_{jk} \quad (\text{any } j\in F, k\in\overline{F} \text{ and } \textit{vice versa}), \tag{25}$$

which is just the HF condition. Note that x_{jk}'s for $j,k\in F$ and $j,k\in\overline{F}$ are, as easily seen in Eq. 24, not conditioned here, the HF ambiguity being implied. Setting $x_{jk}=\tilde{v}_{jk}$ for all j and k, we have

$$x_{\xi\eta}=\sum_m (2v_{\eta m}^{\xi m}-v_{m\eta}^{\xi m})\mathrm{f}(m), \tag{26}$$

which gives the standard HF equation, substituted into Eq. 17. For general choices of X and S Eq. 24 should be read as a mutual restriction on them. Especially, under the HF choice of X, Eq. 25, the restriction is reduced to

$$s_{jk}+\tilde{s}_{jk}=0 \quad (\text{any } j\in F, k\in\overline{F} \text{ and } \textit{vice versa}). \tag{27}$$

Denoting the singlet and triplet excited states of K by

$$|vw\pm\rangle=\sum_\mu \mathrm{L}_\mu(\pm)a_{v\mu}^\dagger a_{w\mu}|F\rangle \quad (v\in\overline{F}, w\in F) \tag{28}$$

with

$$\mathrm{L}_\mu(\pm)=(\delta_{\mu\uparrow}\pm\delta_{\mu\downarrow})/\sqrt{2}, \tag{29}$$

where $+$ and $-$ stand for the singlet and triplet states respectively, we have

$$\langle F|H|vw\pm\rangle=\sum_\mu \mathrm{L}_\mu(\pm)\langle F|[H,a_{v\mu}^\dagger a_{w\mu}]|F\rangle, \tag{30}$$

since $\langle F|a_{v\mu}^\dagger$ vanishes. Thus Brillouin's theorem is contained in the HVT

$$\langle F|[H,a_{p\sigma}^\dagger a_{q\sigma}]|F\rangle=0 \quad (p\in\overline{F}, q\in F \text{ and } \textit{vice versa}) \tag{31}$$

or equivalently

$$\langle F|[H,a_{p\sigma}^\dagger a_{q\sigma}]|F\rangle=0 \quad (\text{any } p,q), \tag{32}$$

which characterizes the HF method.

The Electron-Hole Potential Method

The evaluation of excitation energies by the closed-shell HF method[9] is to be improved in the EHP method, as far as only one specific excitation is concerned.[6] A persuasive derivation of the EHP method consists of constructing the new occupied and unoccupied orbitals, respectively, from the occupied and unoccupied HF orbitals through the variational procedure for the excited state in question. Here, confining ourselves to the single configuration excitation case, we view the method from a HVT standpoint, which seems helpful in understanding a nature of the method.

The first order one-particle HVT for the singlet and triplet excited states are obtained by putting $|\phi\rangle=|vw\pm\rangle$ after substitution of Eqs. 18, 20, 21, 22, and 23 into Eq. 13 through Eq. 14:

$$(y_{qp}+\tilde{y}_{qp}+\dot{y}(v)_{qp}-\dot{y}(w)_{qp})(\mathrm{f}(q)-\mathrm{f}(p))$$
$$+\frac{1}{2}((y_{qp}+\tilde{y}_{qp})(\delta_{qv}-\delta_{qw}-\delta_{pv}+\delta_{pw})$$
$$-(y^{qv}_{pv}-y^{qv}_{vp})(\delta_{qw}-\delta_{pw})-(y^{qw}_{pw}-y^{qw}_{wp})(\delta_{qv}-\delta_{pv}))$$
$$\pm\frac{1}{2}(y^{qv}_{vp}(\delta_{qw}-\delta_{pw})+y^{qw}_{wp}(\delta_{qv}-\delta_{pv}))=0 \qquad (33)$$

with

$$y_{jk}=-x_{jk}+(\varepsilon_j-\varepsilon_k)s_{jk}$$

and

$$y^{jl}_{km}=v^{jl}_{km}+(\varepsilon_j+\varepsilon_l-\varepsilon_m-\varepsilon_k)s^{jl}_{km},$$

the quantity with a single dot being defined as

$$\dot{t}(m)_{jk}=t^{jm}_{km}-t^{jm}_{mk}/2.$$

Consider the single-determinant approximation, the case without S. Then, Eq. 33 is reduced to the condition that

$$-x_{vj}+\tilde{v}_{vj}-v^{vw}_{jw}+v^{vw}_{wj}\pm v^{vw}_{wj}=0 \qquad (j\epsilon\bar{F}'), \quad (34a)$$
$$-x_{jw}+\tilde{v}_{jw}+v^{jv}_{wv}-v^{jv}_{vw}\pm(-v^{jv}_{vw})=0 \qquad (j\epsilon F'), \quad (34b)$$
$$-x_{wj}+\tilde{v}_{wj}+v^{wv}_{jv}-v^{ww}_{jw}\pm v^{wv}_{vj}=0 \qquad (j\epsilon\bar{F}'), \quad (34c)$$
$$-x_{jv}+\tilde{v}_{jv}+v^{jv}_{vv}-v^{jw}_{vw}\pm(-v^{jw}_{wv})=0 \qquad (j\epsilon F'), \quad (34d)$$
$$-x_{jk}+\tilde{v}_{jk}+\dot{v}(v)_{jk}-\dot{v}(w)_{jk}=0 \qquad (j\epsilon F', k\epsilon\bar{F}'), \quad (34e)$$

and

$$v^{wv}_{vv}-v^{ww}_{vw}\pm(v^{wv}_{vv}-v^{ww}_{vw})=0, \qquad (34f)$$

where the primes on F and $\bar{F}$ mean the exclusion of w and v respectively. The complex conjugate equations are omitted for brevity. If we take the canonical and virtual HF orbitals, the first and second terms in each left-hand side of Eqs. 34a, b, c, d, and e cancel out. But the rest does not vanish in general, and we see the violation of the HVT by the standard HF method. Here it is worth while to note that the orbital symmetry tends to lessen the violation.

It enables us to make Eqs. 34a and b hold that the first order one-particle HVT for the ground state imposes no condition upon x_{jk}'s for $j,k\epsilon\bar{F}$ and $j,k\epsilon F$, Eq. 25 remaining satisfied. Determine the orbitals so as to satisfy

$$x_{jk}=\tilde{v}_{jk}-v^{jw}_{kw}+v^{jw}_{wk}\pm v^{jw}_{wk} \qquad (j,k\epsilon\bar{F}) \quad (35a)$$

and

$$x_{jk}=\tilde{v}_{jk}+v^{jv}_{kv}-v^{jv}_{vk}\pm(-v^{jv}_{vk}) \qquad (j,k\epsilon F). \quad (35b)$$

Then Eqs. 34a and b clearly hold and the violation occurs in the same form in Eqs. 34c, d, e, and f as the HF case. There the orbital symmetry still inclines to diminish the violation. If the HF orbitals $\{\underline{u}_{\underline{\xi}\underline{j}}\}$ and their energies $\{\underline{\varepsilon}_{\underline{j}}\}$ are already known, we have only to work out a set of eigenvalue problems that

$$\sum_{\underline{k}\epsilon\bar{F}}(\delta_{\underline{j}\underline{k}}\underline{\varepsilon}_{\underline{j}}+z(w\pm)_{\underline{j}\underline{k}})c_{\underline{k}m}=c_{\underline{j}m}\alpha_m \qquad (\underline{j}\epsilon\bar{F}) \quad (36a)$$

and

$$\sum_{\underline{k}\epsilon F}(\delta_{\underline{j}\underline{k}}\underline{\varepsilon}_{\underline{j}}-z(v\pm)_{\underline{j}\underline{k}})d_{\underline{k}m}=d_{\underline{j}m}\beta_m \qquad (\underline{j}\epsilon F) \quad (36b)$$

with

$$z(l\pm)_{\underline{j}\underline{k}}=-v^{\underline{j}l}_{\underline{k}i}+v^{\underline{j}l}_{i\underline{k}}\pm v^{\underline{j}l}_{i\underline{k}},$$

which is equivalent to the original form of the basic equations of the EHP method.

Noting that under Eqs. 35's the one-particle HVT for the excited states without S holds for a restricted region as

$$\langle vw\pm|[H,a^\dagger_{p\sigma}a_{q\sigma}]|vw\pm\rangle=0 \quad (p,q\epsilon F \text{ and } p,q\epsilon\bar{F}), \quad (37)$$

we can prove that the extended Brillouin's theorem in the EHP method,

$$\langle vw\pm|H|v'w\pm\rangle=0 \qquad (v\neq v') \quad (38a)$$

and

$$\langle vw\pm|H|vw'\pm\rangle=0 \qquad (w\neq w'), \quad (38b)$$

is contained in the HVT as follows. Arrange the left-hand side of Eq. 38a as

$$\langle vw\pm|H|v'w\pm\rangle$$
$$=\sum_{\mu\nu}\mathrm{L}_\mu(\pm)\langle vw\pm|Ha^\dagger_{v'\mu}\delta_{\mu\nu}a_{w\nu}|F\rangle$$
$$=\sum_{\mu\nu}\mathrm{L}_\mu(\pm)\langle vw\pm|Ha^\dagger_{v'\mu}(a_{v\mu}a^\dagger_{v\nu}+a^\dagger_{v\nu}a_{v\mu})a_{w\nu}|F\rangle$$
$$=\sum_\mu\langle vw\pm|Ha^\dagger_{v'\mu}a_{v\mu}|vw\pm\rangle$$
$$=\sum_\mu\langle vw\pm|[H,a^\dagger_{v'\mu}a_{v\mu}]|vw\pm\rangle, \quad (39)$$

where the terms under the summation of the last line are independent of μ. Hence the condition

$$\langle vw\pm|[H,a^\dagger_{v'\mu}a_{v\mu}]|vw\pm\rangle=0, \quad (40)$$

which is assured by Eq. 37, is equivalent to Eq. 38a. We have similar argument for Eq. 38b.

The EHP method is characterized by the HVT Eq. 37 besides Eq. 32, so it can be said that the EHP method satisfies the HVT better than the standard HF method. The hole potential method[10] may look characterized by the HVT defined in a smaller region of p and q than Eq. 37,

$$\langle vw\pm|[H,a^\dagger_{p\sigma}a_{q\sigma}]|vw\pm\rangle=0 \quad (p,q\epsilon\bar{F}), \quad (41)$$

besides Eq. 32. However, Eq. 41 is actually independent of v, and we have Eq. 41 for all of $v\epsilon\bar{F}$. Thus it is not necessarily appropriate to regard the hole potential method as an intermediate between the standard HF and EHP methods;[6] of course, when we confine ourselves to one specific excitation, it is correct that the EHP method satisfies the HVT better than the hole potential method.

Beyond the Electron-Hole Potential Method

Let us give a perturbation expansion to the excitation energy as preliminaries. Define the excitation energy $\Delta E(I\to J)$ from the state $|\phi_I\rangle$ to $|\phi_J\rangle$ as

$$\Delta E(I\to J)=\langle\phi_J|H|\phi_J\rangle-\langle\phi_I|H|\phi_I\rangle, \quad (42)$$

which is converted with Eqs. 5, 6, and 7 into

$$\Delta E(I\to J)=K_J-K_I$$
$$+\lambda(\langle\phi_J|V|\phi_J\rangle-\langle\phi_I|V|\phi_I\rangle)$$
$$+\lambda^2(\langle\phi_J|([V,S_1]+\frac{1}{2}[[K,S_1],S_1])|\phi_J\rangle$$
$$-\langle\phi_I|([V,S_1]+\frac{1}{2}[[K,S_1],S_1])|\phi_I\rangle)+\cdots, \quad (43)$$

where $|\phi_I\rangle$ and $|\phi_J\rangle$ are, respectively, the eigen-

states with the eigenvalues K_I and K_J of K. To first order the excitation energy is independent of S. Both the HF and EHP methods calculate Eq. 43 to first order with $|\phi_I\rangle=|F\rangle$ and $|\phi_J\rangle=|vw\pm\rangle$.

Now consider to satisfy the first order one-particle HVT for the excited state as well as the ground by including S as simple as possible. Under the EHP choice of X, Eqs. 35's together with Eq. 25, the following condition results from Eq. 33.

$$(\varepsilon_v-\varepsilon_j)(s_{vj}+\bar{s}_{vj}-s^{vw}_{jw}+s^{vw}_{wj}\pm s^{vw}_{wj})=0 \qquad (j\epsilon\bar{F}'), \tag{44a}$$

$$(\varepsilon_j-\varepsilon_w)(s_{jw}+\bar{s}_{jw}+s^{jv}_{wv}-s^{jv}_{vw}\pm(-s^{jv}_{vw}))=0 \quad (j\epsilon F'), \tag{44b}$$

$$y^{wv}_{jv}-y^{ww}_{jw}\pm y^{wv}_{vj}+(\varepsilon_w-\varepsilon_j)(s_{wj}+\bar{s}_{wj})=0 \quad (j\epsilon\bar{F}'), \tag{44c}$$

$$y^{jv}_{vv}-y^{jw}_{vw}\pm(-y^{jw}_{wv})+(\varepsilon_j-\varepsilon_v)(s_{jv}+\bar{s}_{jv})=0 \qquad (j\epsilon F'), \tag{44d}$$

$$\dot{y}(v)_{jk}-\dot{y}(w)_{jk}+(\varepsilon_j-\varepsilon_k)(s_{jk}+\bar{s}_{jk})=0 \qquad (j\epsilon F', k\epsilon\bar{F}'), \tag{44e}$$

and

$$y^{wv}_{vv}-y^{ww}_{vw}\pm(y^{wv}_{vv}-y^{ww}_{vw})=0. \tag{44f}$$

Here note that any term concerning $V^{(2)}$ has one of the following forms: y^{jv}_{kv}, y^{jv}_{vk}, y^{jw}_{kw}, and y^{jw}_{wk} ($j\epsilon F$, $k\epsilon\bar{F}$). This shows a way to attain the present purpose. Set the matrix elements of S as

$$s^{jl}_{ki}=s^{ij}_{ik}=-v^{jl}_{ki}/(\varepsilon_j-\varepsilon_k) \qquad \left(\begin{array}{c} j\epsilon F, k\epsilon\bar{F} \\ \text{and } \textit{vice versa}; \\ l=w,v \end{array}\right) \tag{45a}$$

$$s^{jl}_{ik}=s^{ij}_{ki}=-v^{jl}_{ik}/(\varepsilon_j-\varepsilon_k) \tag{45b}$$

$$s_{jk}=(2v^{jw}_{kw}-v^{jw}_{wk})/(\varepsilon_j-\varepsilon_k) \tag{45c}$$

and

$$s^{jl}_{km}=s_{jk}=0 \qquad \text{(otherwise)}, \tag{45d}$$

where the one-particle terms are prepared for the condition given by Eq. 27. Clearly this choice of S suffices for the satisfaction of Eq. 33 as well as Eq. 24, and gives the second order term in Eq. 43 for $|\phi_I\rangle=|F\rangle$ and $|\phi_J\rangle=|vw\pm\rangle$ as

$$\lambda^2\mathrm{Re}\left(\sum_{\substack{j\epsilon F\\ k\epsilon\bar{F}}}\frac{2A(vw\pm)_{jk}}{\varepsilon_k-\varepsilon_j}+\sum_{j\epsilon F}\frac{B(vw\pm)_j}{\varepsilon_v-\varepsilon_j}\sum_{j\epsilon\bar{F}}\frac{C(vw\pm)_j}{\varepsilon_j-\varepsilon_w}\right) \tag{46}$$

with

$$A(vw\pm)_{jk}=D(v)_{jk}(v^{kw}_{jw}-D(v)_{kj})+D(w)_{jk}(v^{kv}_{jv}-D(w)_{kj}) -v^{jw}_{wk}v^{kw}_{jw}-v^{jv}_{vk}v^{kv}_{jv}+(1\pm1)v^{jv}_{vk}v^{kw}_{wj}, \tag{47}$$

$$B(vw\pm)_j=|v^{vw}_{jw}|^2+|v^{vw}_{wj}|^2-2(1\pm1)v^{vw}_{wj}v^{vw}_{jw}, \tag{48}$$

and

$$C(vw\pm)_j=|v^{wv}_{jv}|^2+|v^{wv}_{vj}|^2-2(1\pm1)v^{wv}_{vj}v^{jv}_{wv}, \tag{49}$$

where

$$D(l)_{jk}=v^{jl}_{ki}-v^{jl}_{ik}.$$

In the first, second, and third summations in the above correction term 46, only j and k of the same symmetry, j of the same symmetry as v, and j of the same symmetry as w have only to be taken into account respectively.

In the EHP method the orbitals are determined under the influence of the scatterings of electrons inside F and $\bar{F}$ by the potentials due to the electron in v and the hole in w respectively. Roughly speaking, the adoption of the S of Eq. 45's means to take it into account the scatterings of electrons from F to $\bar{F}$ and from $\bar{F}$ to F by the electron and hole potentials. The first order correction to the excited state has one electron in $\bar{F}$ and one hole in F besides v and w in consequence:

$$(S^{(1)}_1+S^{(2)}_1)|vw\pm\rangle=\sum_{\substack{j\epsilon\bar{F}\\ k\epsilon F}}\sum G(vw\pm)^{\mu\nu}_{jk}a^\dagger_{j\nu}a_{k\nu}a^\dagger_{v\mu}a_{w\mu}|F\rangle \tag{50}$$

with

$$G(vw\pm)^{\mu\nu}_{jk}=\mathrm{L}_\mu(\pm)(v^{jw}_{kw}-v^{jv}_{kv}-\delta_{\mu\nu}(v^{jw}_{wk}-v^{jv}_{vk}))/(\varepsilon_j-\varepsilon_k). \tag{51}$$

The ground state is not affected, because it involves neither electron in v nor hole in w. As easily seen, we have

$$(S^{(1)}_1+S^{(2)}_1)|F\rangle=0. \tag{52}$$

Before we discuss the effect of the correction 46, a considerable amount of examinational numerical calculation is to be performed, and we would like to regard the recipe as a possibility at present.

Supplementary Remarks

The First Order Two-Particle HVT. To put $W=a^\dagger_{p\sigma}a^\dagger_{r\tau}a_{s\tau}a_{q\sigma}$ in Eq. 13 gives the first order two-particle HVT, which has the following expression for the ground state after substitution of Eqs. 18, 20, 21, 22, and 23 through Eq. 14.

$$(\delta_{qp}\hat{y}_{sr}+\delta_{sr}\hat{y}_{qp}-\delta_{\sigma\tau}(\delta_{qr}\hat{y}_{sp}+\delta_{sp}\hat{y}_{qr}))(\mathrm{f}(q)\mathrm{f}(s)-\mathrm{f}(r)\mathrm{f}(p)) -(y^{qs}_{pr}-\delta_{\sigma\tau}y^{qs}_{rp})(\mathrm{g}(qs:rp)-\mathrm{g}(pr:sq))=0 \tag{53}$$

with

$$\mathrm{g}(pr:sq)=\mathrm{f}(p)\mathrm{f}(r)(\mathrm{f}(s)+\mathrm{f}(q)-1), \tag{54}$$

and

$$\hat{y}_{jk}=y_{jk}+\bar{y}_{jk}.$$

Provided that the first order one-particle HVT for the ground state is satisfied, that is,

$$\hat{y}_{jk}=0 \qquad (j\epsilon F, k\epsilon\bar{F} \text{ and } \textit{vice versa}),$$

Eq. 53 results in

$$v^{qs}_{pr}-\delta_{\sigma\tau}v^{qs}_{rp}+(\varepsilon_q+\varepsilon_s-\varepsilon_r-\varepsilon_p)(s^{qs}_{pr}-\delta_{\sigma\tau}s^{qs}_{rp})=0 \qquad (q,s\epsilon\bar{F};\ p,r\epsilon F \text{ and } \textit{vice versa}), \tag{55}$$

which leads us to

$$s^{jl}_{km}=-v^{jl}_{km}/(\varepsilon_j+\varepsilon_l-\varepsilon_m-\varepsilon_k) \qquad \left(\begin{array}{c} j,l\epsilon\bar{F};\ k,m\epsilon F \\ \text{and } \textit{vice versa} \end{array}\right). \tag{56}$$

This shows that the electron correlation in the ground state can be taken into account first by including the contribution from the double excitation configurations for any choice of orbitals satisfying Eq. 24. In using the EHP orbitals, therefore, the first aid for the ground state $|F\rangle$ is to use the S in the form of Eq. 56 likewise in using the HF orbitals. Further adopting Eq. 56 together with Eqs. 45's, we can improve the ground state, the first order one-particle HVT for the excited state remaining alive, since s^{jl}_{km}'s for $j,l\epsilon\bar{F}$, $k,m\epsilon F$ and *vice versa* do not concern $\bar{s}_{jk}$'s.

The Perturbation-Theoretical Choice. It is never futile to add some remarks in connection with the perturbation-theoretical approach. Under the exponential prescription, Eq. 6, perturbation equations in the operator form are derived from[3,4,11]

$$[\exp(-S)H\exp(S), K] = 0. \quad (57)$$

Making use of Eqs. 5 and 7, we obtain the first order perturbation equation as

$$[V+[K, S_1], K] = 0, \quad (58)$$

which becomes the two separated equations corresponding to the one- and two-particle parts after calculation with Eqs. 18, 20, 21, 22, and 23:

$$\sum_{jk\mu} y_{jk}(\varepsilon_j-\varepsilon_k)a^\dagger_{j\mu}a_{k\mu} = 0 \quad (59a)$$

and

$$\sum_{jklm\mu\nu} y^{jl}_{km}(\varepsilon_j+\varepsilon_l-\varepsilon_m-\varepsilon_k)a^\dagger_{j\mu}a^\dagger_{l\nu}a_{m\nu}a_{k\mu} = 0, \quad (59b)$$

which lead us to

$$s_{jk} = x_{jk}/(\varepsilon_j-\varepsilon_k) \qquad (j, k \text{ such that } \varepsilon_j \neq \varepsilon_k) \quad (60a)$$

and

$$s^{jl}_{km} = -v^{jl}_{km}/(\varepsilon_j+\varepsilon_l-\varepsilon_m-\varepsilon_k) \quad \begin{pmatrix} j,k,l,m \text{ such that} \\ \varepsilon_j+\varepsilon_l-\varepsilon_m-\varepsilon_k \neq 0 \end{pmatrix}. \quad (60b)$$

The matrix elements of S other than these can be set to vanish by imposing such auxiliary restriction upon S as that S should be completely off-diagonal in the representation $\{|\phi\rangle\}$.[4] Clearly Eqs. 60's satisfy the first order one-particle HVT. This perturbation-theoretical choice requires nothing of orbitals but sufficient inclusion of configurations. Hence, unless we know the well-behaved orbitals suitable for purpose beforehand, the choice is not necessarily practical.

Transmission of Low-energy Electrons (0—15 eV) through Thin Films of Ethers, Ketones, Alcohols, and Ice. Determination of the Quasifree Electron State Energy

Kenzo HIRAOKA* and Masaji NARA

Faculty of Engineering, Yamanashi University, Takeda-4, Kofu 400

(Received May 6, 1981)

The transmission of low-energy electrons (0—15 eV) through 10—100 Å films of ethers, ketones, alcohols, and ice has been studied. Structures are indicated by electron current I_t transmitted through a thin film as a function of the incident electron energy V_1, displayed as dI_t/dV_1 *vs.* V_1. With increasing the film thickness, a decrease of the height of the first peak (due to injection of electrons in the film) and an appearance of a second peak are observed for ethers and alcohols. The energies of quasifree electron state V_0 are determined by measuring the energy of the second peak from the first peak for solid diethyl ether, tetrahydrofuran, 2-methyltetrahydrofuran, methanol, ethanol, 1-propanol, 2-propanol, 1-butanol, 1-pentanol, 1-hexanol, and 1-nonanol. For acetone, diethyl ketone, dimethyl sulfoxide, and ice, neither a decrease of the first peak nor an appearance of a second peak is observed, indicating that these compounds have negative V_0 values. From the energy of the onsets of broad negative peaks appeared at ≈14 eV for ethers and alcohols, the solid phase ionization energies I_s and the polarization energies of cations P^+ by the solid media are determined.

Condensed hydrocarbons are complex and electron interactions in them are the focus of much current interest. The energies of quasifree electron state V_0 have been reported for several liquid hydrocarbons.[1-5] However, attempts to measure V_0 directly in polar or nonpolar glassy matrices have failed.[5] The V_0 values in glassy matrices have been estimated by an indirect method using Eq. 1,[5-7]

$$I_1,\ I_s = I_g + P^+ + V_0 \qquad (1)$$

where I_1 and I_s are the ionization potential of an impurity molecule A in a liquid and solid solution, respectively, I_g the gas phase ionization potential of A, and P^+ the polarization energy of the medium by the positive ion A^+.

Recently, Hiraoka and Hamill[8] and Sanche[9] reported a simple method for measuring the electronic levels of molecules supported as ultrathin films on a metal surface at ≈80 K. The film was bombarded by a beam of low-energy electrons, and the current transmitted through the film (I_t) was measured as a function of the incident electron energy (V_1). The transmission spectra, displayed as dI_t/dV_1 *vs.* V_1, were found particularly useful for detecting optically forbidden electronic transitions.[8,9] In the previous work,[10] we reported direct measurements of V_0 for solid hexane and benzene by measuring the transmission spectra dI_t/dV_1 *vs.* V_1 for 10—100 Å films of these compounds deposited on the metal block at ≈80 K. In this work, the interactions of injected excess electrons with solid films are studied by measuring the transmission spectra for ethers, ketones, alcohols and ice. The main objective of this work is to relate the energy dependence of the transmission features to specific interactions occurring in solid films.

Experimental

The experimental procedure has been described.[8,10] The temperature of the stainless steel metal block was ≈80 K and the pressure was $\leq 10^{-7}$ Pa. The cathode was modulated by 0.3 V at 78 Hz by the reference signal of a lock-in amplifier. The cathode voltage was swept upward with $I_t \leq 2\times10^{-9}$ A transmitted through the thin film. The transmission spectra were displayed as dI_t/dV_1 *vs.* V_1, where eV_1 is the energy of the incident electron. Because no established sharp transitions are available as internal standards, the zero of the electron energy scale in the present work has been chosen arbitrarily as the onset of the first peak of the spectrum dI_t/dV_1 *vs.* V_1 (*i.e.* for electron injection). The film thickness was changed by changing the deposition time with the constant vapor pressure of a sample at 1.3×10^{-5} Pa.

Results and Discussion

In the previous work,[10] the transmission spectra dI_t/dV_1 *vs.* V_1 for benzene and hexane were examined in detail. It was found that there was almost no difference in shape (height and half-width) between the first peak for the metal block and those for 2 to 10 L† thick benzene films. On the contrary, the first peak of transmission spectra for hexane decreased drastically and a second peak appeared and grew as the film thickness was increased. From these experimental results, it was concluded that solid films of benzene and hexane have negative and positive V_0, respectively. The energy of quasifree electron state V_0 for hexane, 0.9 eV, was determined by measuring the energy of the second peak from the first peak of the spectrum for the metal block as a reference. In the following sections, the results for ethers, ketones, dimethyl sulfoxide (DMSO), alcohols, and ice are summarized, and a discussion is made for the determination of the energy of quasifree electron state V_0, the solid phase ionization energy I_s and the cation polarization energy P^+ by the solid media.

Ethers. The transmission spectra, dI_t/dV_1 *vs.* V_1, for diethyl ether, tetrahydrofuran (THF), and 2-methyltetrahydrofuran (2-MTHF) have been measured. The transmission spectra for diethyl ether and 2-MTHF are shown in Figs. 1 and 2. A drastic decrease of the first peak and an appearance of the

† The amount of the gas admitted in the vacuum chamber is expressed in Langmuir units (1 L = 1.33×10^{-4} Pa·s). When the sticking probability is unity, the surface will be covered by approximately one monolayer with 1 Langmuir gas admission.

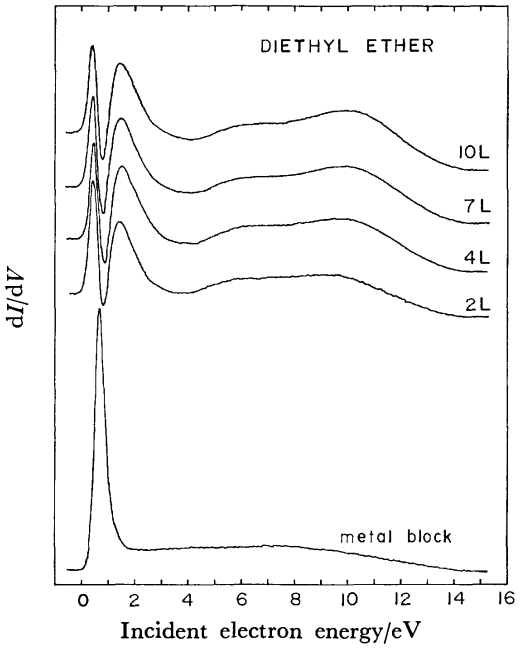

Fig. 1. The transmission spectra dI_t/dV_1 *vs.* V_1 for metal block and diethyl ether. The film thickness was changed from 2 to 10 L.

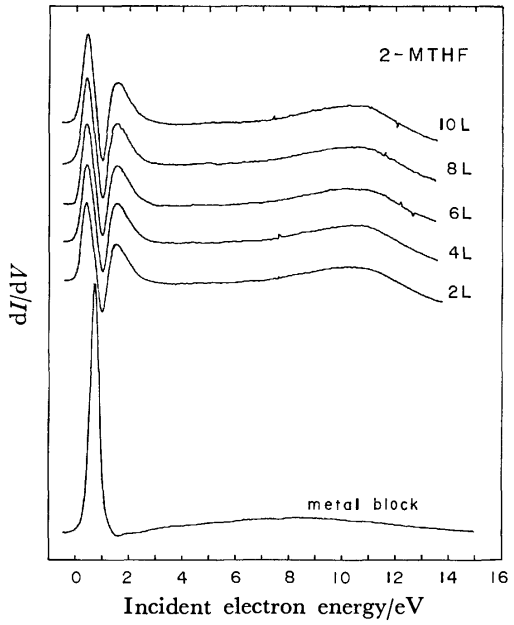

Fig. 2. The transmission spectra for metal block and 2-methyltetrahydrofuran (2-MTHF).

second peak and its strong growth are observed for all of these compounds, indicating that they have positive V_0.

Ketones and DMSO. The transmission spectra of acetone are shown in Fig. 3. The first peak of the transmission spectra for acetone and diethyl ketone shows only a slight decrease by the deposition of 2 L thick sample and the second peak does not show up for both of these compounds. These are characteristic features for solid films whose V_0 are negative. Thus the solid acetone and diethyl ketone are considered to have negative V_0s.

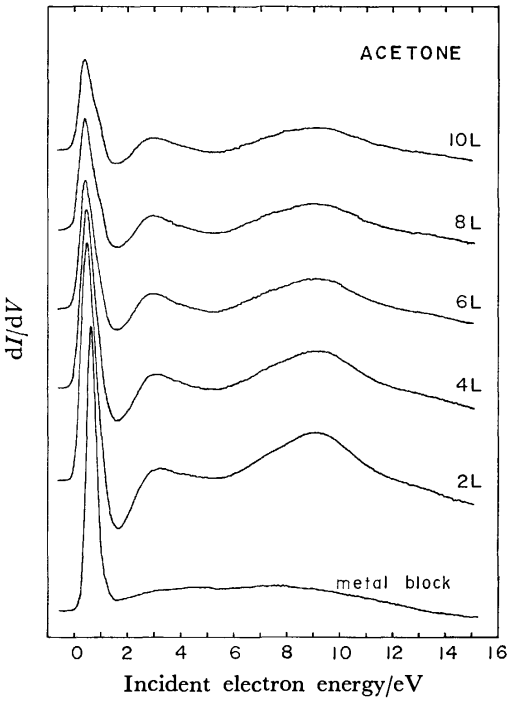

Fig. 3. The transmission spectra for metal block and acetone.

The continuous decrease of the first peak is observed for these compounds as the film thickness is increased from 2 to 10 L. This is due to the decrease of the electron emission efficiency of the cathode which is poisoned by the admission of ketone vapor in the vacuum system. The electron gun used in this experiment is a commercial TV gun (The Japan Lamp Industrial Co., Ltd) and has an indirectly heated oxide-coated cathode. This type of cathode was found to be easily poisoned by the admission of some kinds of organic vapors, especially ketones. Usually the 2 L thick film is prepared by the admission of 1.3×10^{-5} Pa vapor pressure of the sample for 20 s. In cases of acetone and diethyl ketone, 2 L thick sample was deposited by the admission of 3.3×10^{-6} Pa vapor pressure for 80 s in order to suppress the decrease of the electron emission efficiency of the cathode. This operation was successful only to some extent as shown in Fig. 3. After the samples were desorbed by increasing the temperature of the metal block, the transmission spectra were measured again. The height of the first peak for the bare metal block was found almost the same as those for 10 L thick samples at liq. N_2 temperature. If these compounds had positive V_0 values, the first peak should increase by the desorption of samples on the metal block.

In Fig. 4 are shown the transmission spectra of DMSO. The height of the first peak for 2 L thick film is even larger than that for the bare metal block and no second peak appears. There is no doubt that the solid DMSO film has a negative V_0 value.

Alcohols. The transmission spectra for methanol, ethanol, 1-propanol, 2-propanol, 1-butanol, 1-pentanol, 1-hexanol, and 1-nonanol have been measured. The transmission spectra for methanol and 1-

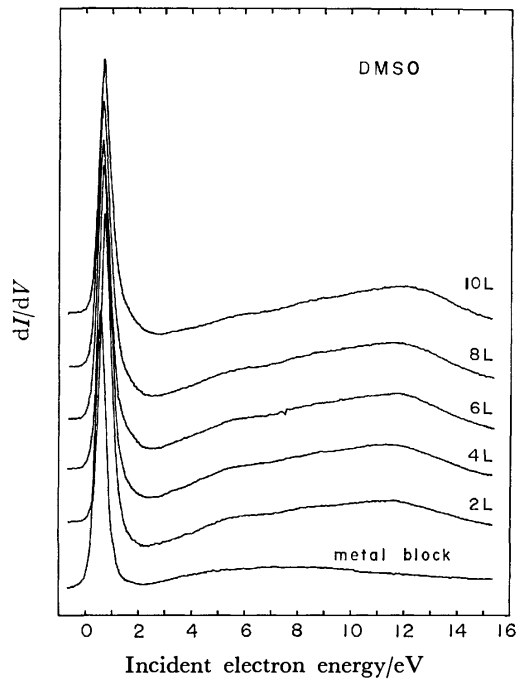

Fig. 4. The transmission spectra for metal block and dimethyl sulfoxide (DMSO).

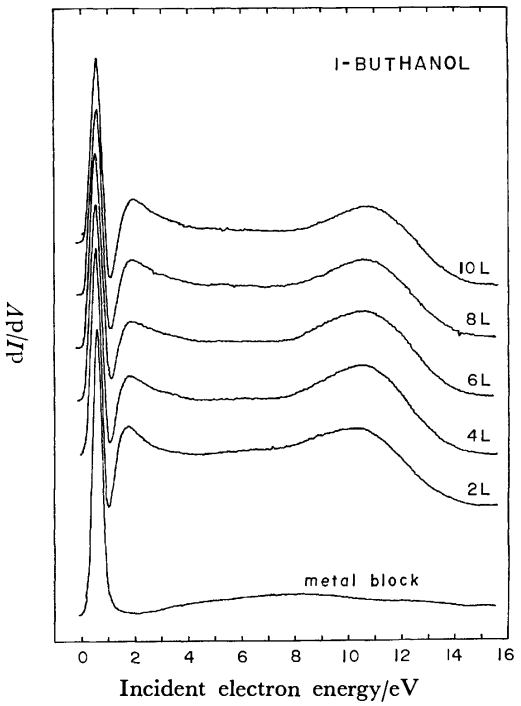

Fig. 6. The transmission spectra for metal block and 1-butanol.

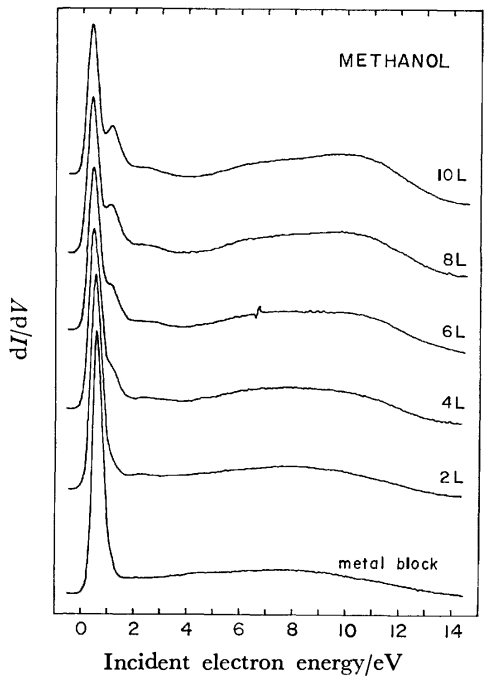

Fig. 5. The transmission spectra for metal block and methanol.

butanol are shown in Figs. 5 and 6.

A decrease of the first peak and a growth of the second peak are observed for methanol with an increase of the film thickness, indicating that the solid methanol has a positive V_0.

It was found that the film thickness dependence on the transmission spectra was very similar for ethanol and higher alcohols (see Fig. 6). For these compounds, a drastic decrease of the first peak and an appearance of a sharp second peak are observed by the deposition of 2 L thick film, indicating that these compounds have positive V_0. However, the decrease of the first peak and the increase of the second peak are only very gradual for further deposition of the sample. These results strongly suggest that electrons in solid alcohols with an energy lower than V_0 have a large contribution to the transmitted electron current to the anode.

Ice. The transmission spectra of ice are shown in Fig. 7. Contrary to the spectra of alcohols, the first peak neither decreases nor a growth of the second peak is observed with an increase of the film thickness, indicating that the energy of quasifree electron state V_0 in ice is negative.

Work Function Change of the Metal Block. It is worthy to note that in the spectra of ethers and some of alcohols, the first peak shows a negative shift when samples were deposited on the metal block. If the film was charged by the electron irradiation, the first peak should show a positive shift.[10] For all compounds measured in this experiment, the peaks of the spectra do not show any shifts under repeated electron irradiation under the present experimental conditions ($I_t \leq 2 \times 10^{-9}$ A), *i.e.*, the charging of the film is negligible. Therefore, the shift of the first peak must be due to the change of the current-voltage characteristic curve determined by the contact potential difference between the cathode and the metal block. After the samples were desorbed by increasing the temperature of the metal block, the first peak shifts back to the original energy value of the first peak for the metal block. This means that the shift of the first peak is due to the work function change of the metal block by the deposition of the sample

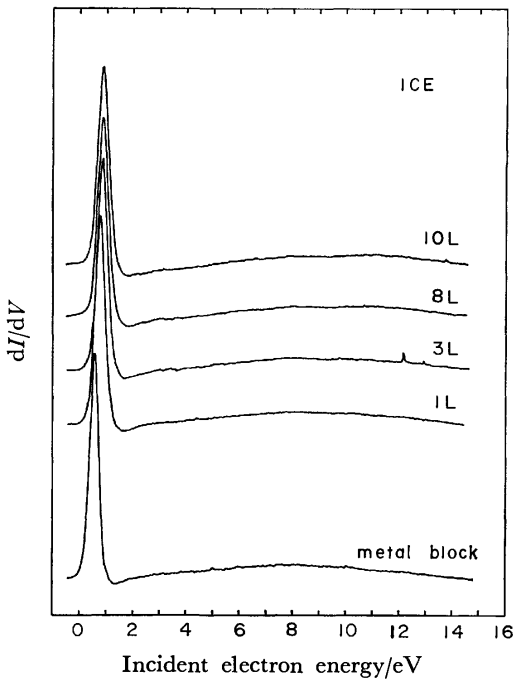

Fig. 7. The transmission spectra for metal block and ice.

on *it*.

Absorption is usually associated with a variation of the work function ϕ which provides a simple procedure for monitoring the state of a surface. Moreover, the sign of the work function change $\Delta\phi$ is connected with the direction of the electron transfer between the substrate and the adsorbate, *i.e.* with the dipole moment of the adsorbate complex. Although the surface of the stainless steel metal block used in this measurements is not characterized rigorously, it would be informative to discuss the work function changes observed by the deposition of several compounds.

The observed work function changes $\Delta\phi$ are summarized in Table 1 (column 6).†† The negative $\Delta\phi$s are observed for ethers and some of alcohols. For higher alcohols, $\Delta\phi$s are observed to become smaller. The positive $\Delta\phi$s are observed by the deposition of ice and DMSO. It has been observed that $\Delta\phi$s are nearly zero for alkanes and aromatic compounds at $\approx$80 K in the previous experiments.[10,11]

The sign and the amount of $\Delta\phi$ may give some information on the interaction of adsorbed molecules with the metal surface. The relatively large $\Delta\phi$s are observed for ethers. These compounds have large permanent dipole moments, but the positive charge is rather delocalized in molecules in comparison with the localized negative charge on oxygen atoms. Considering that the nonpolar compounds give very small $\Delta\phi$s, ethers are considered to be interacting with the metal surface directing the oxygen atoms toward the metal surface. Alcohols (protic solvents) have also negatively charged oxygen atoms but $\Delta\phi$s are generally smaller than those for ethers. This may be due to the fact that the molecules of the first monolayer on the metal surface form hydrogen bonds with molecules of the second monolayer and the dipole moments induced by the interaction between the substrate and the adsorbate are smaller than in cases for ethers. This may explain why $\Delta\phi$ becomes smaller for higher alcohols. The positive shifts for ice and DMSO are difficult to understand. It would only be suggested that the sign of the net dipole moments induced by the interactions between the substrate and these compounds are opposite to cases for ethers and alcohols.

It was found that $\Delta\phi$s are highly temperature-dependent and the sign of $\Delta\phi$s for some polar molecules changes as the temperature of the metal block is increased. A more detailed investigation on the work function changes in this respect is now in progress.

Table 1. V_0, I_s, I_g, P^+, and $\Delta\phi$

Compound	V_0/eV	I_s/eV	I_g/eV	P^+/eV	$\Delta\phi$/eV
Diethyl ether	1.0	8.4	9.5	−2.1	−0.2
THF	1.1	8.1	9.42	−2.4	−0.3
2-MTHF	1.1(1.15,[a] 0.98[b])	8.8			−0.3
Acetone	≤0				
Diethyl ketone	≤0				
DMSO	≤0				+0.1
Methanol	0.7(0.13,[a] −0.01[b])	9.2	10.84	−2.3(−1.99,[a] −1.84[b])	−0.1
Ethanol	1.1(0.34,[a] 0.24[b])	9.0	10.46	−2.5(−2.05,[a] −1.94[b])	−0.2

1-Pentanol	1.3	8.7			≈0
1-Hexanol	1.3	8.4			≈0
1-Nonanol	1.3	8.8			≈0
Ice	≤0(−0.36[b])				+0.2

a) Ref. 7. b) Ref. 5.

†† For acetone and diethyl ketone, $\Delta\phi$s are not given in Table 1 because the shifts of the first peak are partly due to the work function changes of the cathode.

The Energy of Quasifree Electron State V_0. In the previous work,[10] the V_0 values are determined by measuring the energy of the second peak from the first peak of the spectrum for the metal block as a reference. In the present study, the first peak of the spectrum for the metal block can not be chosen as a reference because the first peak shows positive or negative shifts by the deposition of the sample, as was mentioned in the previous section. In this work, V_0 is estimated by measuring the energy difference between the first and second peaks of a spectrum for each compound. Here, it is assumed implicitly that the first peak represents a crude profile of the electron energy distribution function. We think that this assumption is reasonable because the half-width of the first peak remains almost the same before and after the sample deposition. The estimated V_0s are listed in Table 1 (column 2). It is evident from our experimental results that V_0s for acetone, diethyl ketone, DMSO, and ice are negative, but the estimation of their values is difficult because of the lack of sharp structures in the transmission spectra for the calibration of the electron energy scale.

In Table 1, the values of V_0 in some solid alcohols and 2-MTHF measured by an indirect method[5,7] are also shown in parentheses of column 2. The agreement between these values and our directly measured values is good for 2-MTHF but poor for alcohols. The observed disagreement seems to be larger than the experimental errors in our measurements and it likely comes from the completely different experimental approaches for the determination of V_0. It is worthy to note that for almost all of solid alkanes,[5-7,10,11] a good agreement is observed between V_0 values determined by these two different methods. As shown in Table 1, V_0 values for alcohols obtained by an indirect method[5-7] are 0.6—0.8 eV lower than those obtained in this experiment. As is pointed out in the previous section, the contribution of electrons in solid alcohols with an energy lower than V_0 to the transmitted electron current is much larger than that in other solid samples whose V_0 are positive. This suggests the existence of dense trapping sites in solid alcohols for the efficient transport of nearly zero-energy electrons. In the indirect method, if the impurity molecules could be photoionized by ejecting electrons to the energy levels of pre-existing dense trapping sites, the onset of the recombination luminescence or of the appearance of the absorption of ionized impurity molecules would extend to lower photon energy and the rigorous determination of V_0 would be intrinsically difficult. This might explain the observed discrepancy. Although the Springett-Jortner-Cohen model[12] gives the rigorous theoretical definition for V_0, the experimentally determined V_0 represents the macroscopic "bulk" properties of the solid and the experimental V_0 could be highly dependent on each experimental method.

Cation Polarization Energy P^+ by the Medium. It has long been known that the ionization potential of a molecule in a condensed phase is lowered relative to the value measured in the gas phase. Lyons and his coworkers[13,14] emphasized the importance of the polarization of the medium P^+ around the cation and the ejected electron. Since I_g is known, the V_0 value may be derived by Eq. 1[5,7] if the cation polarization energy P^+ can be evaluated. So far, P^+ has been calculated by Eq. 2,

$$P^+ = -\frac{e^2}{2r_0}\left(1-\frac{1}{\varepsilon}\right) \quad (2)$$

where ε is the optical dielectric constant and r_0 the cation radius.

Since the V_0 values are directly measured in this experiment, P^+ may be derived by Eq. 1 if I_s can be measured experimentally. When a molecule in a solid film is ionized by an incident electron, the incident and ejected electrons in the film will have energies nearly equal to or larger than V_0 with respect to the vacuum. Because the produced hole (cation) in the film will be ultimately annihilated by a recombination or diffusion to the anode by tunneling or hopping mechanisms, the ionization of a molecule in a film by an incident electron must contribute to the "decrease" of the transmitted current. When the film has a positive V_0 value, the reflection coefficient for an electron at the film-vacuum interface is considered to be small enough that a discernable negative peak is expected to appear in the transmission spectrum. All transmission spectra for compounds whose V_0 are positive have broad negative peaks with onsets at around 9—10 eV. We think that these broad negative peaks observed at $\approx$14 eV are due to the ionization of molecules in a film.

For a film with a positive V_0, the threshold ionization energy I_s may be obtained by measuring the energy of the onset of a negative peak from the "second" peak as a reference. The measured I_s values are listed in Table 1 (column 3) with the reported I_g values (column 4). By knowing the values I_s, I_g, and V_0, the P^+ values can be derived by Eq. 1 which are shown in Table 1 (column 5), with the calculated P^+ by Eq. 2 in parentheses.[5,7] The error for values of I_s and thus P^+ which arises from the uncertainty for the determination of the onsets of the broad negative peaks may be estimated as $\pm$0.4 eV. The experimentally determined P^+ are a few tenths of an eV higher than the calculated P^+.

For a compound with $V_0<0$, the onset of a negative peak would not correspond to that for the ionization of a molecule in the film because the ejected electron with an energy $\approx V_0$ with respect to the vacuum can not escape to the vacuum due to the positive energy barrier ($-V_0$). Thus the I_s values for compounds with $V_0<0$ are difficult to estimate by the present method.

This work was partly supported by the Grant-in-Aid from the Ministry of Education, Science and Culture.

Vibrational Spectra and Normal Coordinate Calculations for Trimethylgermane

Yoshika IMAI* and Koyo AIDA

Department of Engineering Science (Chemistry), Faculty of Engineering, Tohoku University, Sendai 980

(Received May 18, 1981)

Vibrational spectra of $(CH_3)_3GeH$, $(CH_3)_3GeD$, $(CD_3)_3GeH$, and $(CD_3)_3GeD$ were obtained. Assignments for all the fundamentals except internal torsions were made by assuming the C_{3v} molecular symmetry. Normal coordinate calculations were carried out to confirm the assignments.

In our previous paper,[1] we reported on a study of vibrational spectra and normal coordinate calculations for trimethylsilane. The study has now been extended to trimethylgermane. Although numerous vibrational studies on trimethylsilane have been reported,[2] only a limited number have been reported on trimethylgermane[3-6] and most of them relate to substituent effects on the GeH stretching mode. As far as we know, study on the assignment of all the active fundamentals has been made only by Van de Vondel and Van der Kelen.[6] They made also normal coordinate calculations with no data of isotopic compounds available by assuming the methyl group as a point mass. In the paper[1] on trimethylsilane, it was pointed out that the methyl rock, the SiH bend, and the asymmetric SiC_3 stretch are fairly strongly coupled with one another. Since it may highly be expected that a similar vibrational coupling will be operative also in the case of trimethylgermane, it seems inadequate to make the calculation by assuming that the methyl group is a point mass. In this paper, we will report vibrational spectra of trimethylgermane and its deuterated analogues and results of normal coordinate calculations on these compounds carried out without assuming the methyl group as a point mass.

Experimental

$(CH_3)_3GeH$ and $(CH_3)_3GeD$ were prepared by reduction of $(CH_3)_3GeI$ with $LiAlH_4$ and $LiAlD_4$, respectively. $(CH_3)_3GeI$ was prepared through a reaction of tetramethylgermane with I_2 in a sealed tube at 50 °C. The crude trimethylgermane was purified by vacuum distillation with a conventional vacuum line. $(CD_3)_3GeH$ and $(CD_3)_3GeD$ were prepared similarly to $(CH_3)_3GeH$ and $(CH_3)_3GeD$, respectively, by using $(CD_3)_4Ge$ instead of $(CH_3)_4Ge$. The purity of the compounds was checked by their infrared spectra in the gas phase.

Infrared spectra (4000—300 cm^{-1}) and far-infrared spectra (400—80 cm^{-1}) were recorded on a Hitachi 345 spectrophotometer and on a Hitachi FIS-III spectrophotometer, respectively, in the gas phase and with solid films at liquid nitrogen temperature.

Raman spectra were recorded with liquids in capillary tubes on a JEOL JRS-S1 Raman spectrophotometer equipped with a 50 mW NEC GLG 5800 He-Ne laser.

Results and Vibrational Assignments

If each methyl group in a molecule is staggered to both the Ge–H bond and the adjacent Ge–C bonds, the molecule will have a C_{3v} symmetry. On this assumption the 36 normal vibrations are made distributed as $8A_1+4A_2+12E$. The A_1 and E modes are active in infrared and Raman spectra but the A_2 modes inactive in both.

Symmetry coordinates have been classified, according to the description of the modes of methyl group and of the skeletons in the molecules, as given in Table 1, where the numbering of the symmetry coordinates is the same as that for the corresponding coordinates for trimethylsilane.[1] Figures 1 and 2 show the infrared spectra in the gas phase and the Raman spectra in the liquid phase, respectively. Tables 2—5 list the observed fundamental frequencies.

By taking into consideration the isotopic shift and polarization of Raman bands as well as data for related compounds,[7-9] assignments for the methyl stretches and the GeH and GeD stretches may easily be made.

There should be five methyl deformations. Asymmetric deformations bonded to a metal atom are usually relatively weak and broad, and their positions in spectra do not markedly shift with change in the nature of the metal atom, whereas symmetric methyl deformations usually give relatively strong and sharp bands and exhibit slight shifts with change in the nature of the metal atom.[10] For $(CH_3)_3GeH$ and $(CH_3)_3GeD$ the asymmetric deformations are observed at *ca.* 1410 cm^{-1}. Upon deuteration of the methyl groups, these shift to *ca.* 1040 cm^{-1}. The symmetric deformations are observed at *ca.* 1250 cm^{-1} for $(CH_3)_3GeH$ and $(CH_3)_3GeD$ and at *ca.* 970 cm^{-1} for $(CD_3)_3GeH$ and $(CD_3)_3GeD$.

Three methyl rocks, two GeC_3 stretches, and a GeH or GeD bend are expected to appear in the

Table 1. Description of the symmetry coordinates for trimethylgermane[a]

Vibrational mode	Coordinate		
	A_1	A_2	E
Stretching $(CH_3)_a$ or $(CD_3)_a$	S_1	S_9	S_{13}, S_{14}
Stretching $(CH_3)_s$ or $(CD_3)_s$	S_2		S_{15}
Stretching (GeH) or (GeD)	S_3		
Deformation $(CH_3)_a$ or $(CD_3)_a$	S_4	S_{10}	S_{16}, S_{17}
Deformation $(CH_3)_s$ or $(CD_3)_s$	S_5		S_{18}
Rocking (CH_3) or (CD_3)	S_6	S_{11}	S_{19}, S_{20}
Bending (GeH) or (GeD)			S_{21}
Stretching (GeC_3)	S_7		S_{22}
Deformation (GeC_3)	S_8		S_{23}
Torsion		S_{12}	S_{24}

a) Abbreviations used: a, asymmetric; s, symmetric.

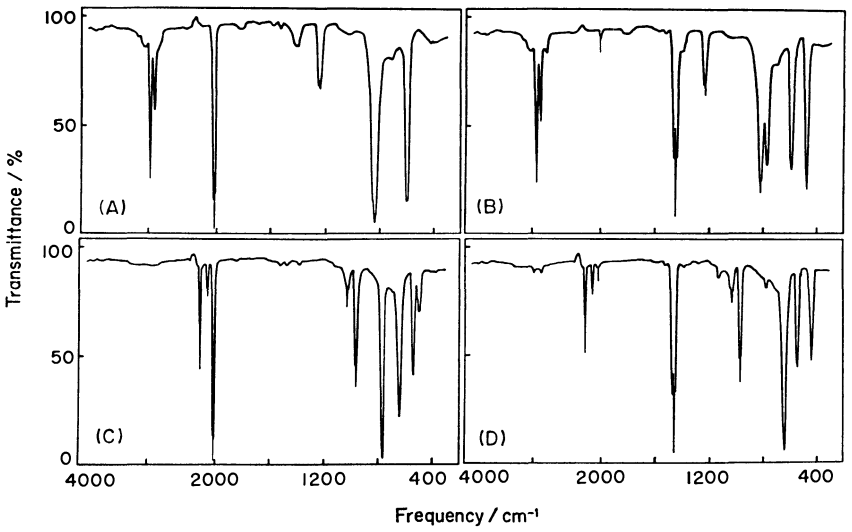

Fig. 1. Infrared spectra of $(CH_3)_3GeH$ (A), $(CH_3)_3GeD$ (B), $(CD_3)_3GeH$ (C), and $(CD_3)_3GeD$ (D) in the gas phase.

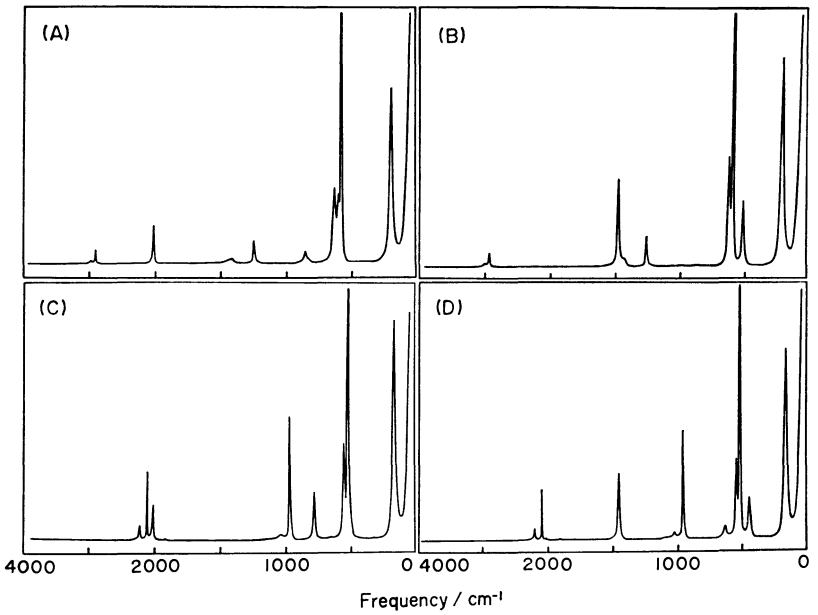

Fig. 2. Raman spectra of $(CH_3)_3GeH$ (A), $(CH_3)_3GeD$ (B), $(CD_3)_3GeH$ (C), and $(CD_3)_3GeD$ (D) in the liquid.

range 900—400 cm^{-1}. Of these vibrations the A_1 GeC_3 stretching mode should give an intense polarized Raman band. Therefore, the Raman bands at *ca.* 550 cm^{-1} for $(CH_3)_3GeH$ and $(CH_3)_3GeD$ may undoubtedly be assigned to this mode. Upon deuteration of methyl groups these shift to 520 cm^{-1}. A_1 methyl rocking frequencies are expected to be approximately identical with each other for $(CH_3)_3GeH$ and $(CH_3)_3GeD$ and for $(CD_3)_3GeH$ and $(CD_3)_3GeD$, since it is also the case with trimethylsilane (850 cm^{-1} for $(CH_3)_3SiH$ and 847 cm^{-1} for $(CH_3)_3SiD$; 704 cm^{-1} for $(CD_3)_3SiH$ and 705 cm^{-1} for $(CD_3)_3SiD$).[1] On this basis, to this mode we have assigned the Raman bands at 830 cm^{-1} for $(CH_3)_3GeH$ and $(CH_3)_3GeD$ and at *ca.* 650 cm^{-1} for $(CD_3)_3GeH$ and $(CD_3)_3GeD$. However, these Raman bands are only partly polarized. This suggests that there are some other vibrations in the E class coinciding on these bands. The most probable candidate is the E methyl rock, since the same accidental degeneracy is found in the A_1 and E methyl rocks in $(CH_3)_3GeCl$,[7] $(CH_3)_3GeCF_3$,[9] and $(CH_3)_3GeGeH_3$.[11]

The remaining bands observed in the range 900—400 cm^{-1} may be considered to be the vibrations due to the E modes but it is not easy to assign these bands. However, the 480 cm^{-1} band in $(CH_3)_3GeD$ and the 780 cm^{-1} one in $(CD_3)_3GeH$ are probably due to the GeD and GeH bends, respectively, since no corresponding Raman bands are observed for $(CH_3)_3GeH$ or $(CD_3)_3GeD$ in the same region. Assignment of the other bands is impossible without the aid of normal coordinate calculations.

The two GeC_3 deformation modes (A_1 and E) should be expected in the region below 300 cm^{-1},

However, only one band is observed in the infrared and Raman spectra for each isotopic compound below 300 cm^{-1}. It may be considered that these two vibrations coincide with each other in the present compounds, since in $(CH_3)_3GeCl$ the A_1 and E GeC_3 deformation modes are observed in the Raman spectra as two closely positioned bands at 193 and 185 cm^{-1}.[7]

Normal Coordinate Calculations and Discussion

Normal coordinate calculations were carried out by Wilson's GF-matrix method on an ACOS 77/900 computer at the Computer Center, Tohoku University, the iterative least-squares procedure being used in the usual way. The G matrix was calculated by

use of the molecular parameters determined from microwave study[12] (r(Ge–H)=0.1532 nm, r(Ge–C)=0.1947 nm, r(C–H)=0.1905 nm, ∠C–Ge–C=109.6°) and by assuming a tetrahedral angle around carbon atoms. In the calculations the observed frequencies were weighted by $(1/\lambda)$. The torsional mode was neglected in the E class.

A least-squares refinement was carried out in terms of symmetry force constants which had been fitted simultaneously to the observed frequencies for the four isotopic species. This refinement was carried out in the same manner as with the acetonitrile-borane adduct[13] and trimethylsilane.[1] The calculated frequencies have an average error of 0.39% for A_1 vibrations and 0.59% for E vibrations. The sum of the weighted squares of errors $\Sigma(\lambda_{obsd}-\lambda_{calcd})^2/\lambda_{obsd}$ was 1.7×10^{-3} for A_1 vibrations and 3.2×10^{-3} for E vibrations. The symmetry force constants, together with the uncertainty ranges from the last cycle in the least-squares refinement, are given in Table 6.

Table 6. Symmetry force constants for trimethylgermane[a]

			$F_{21,22}$	0.016	0.026

a) The stretching force constants are given in 10^2 N m^{-1}, the deformation force constants in 10^{-18} N m rad^{-2}, and the stretching-deformation interaction constants in 10^{-8} N rad^{-1}. The subscript number i in F_i corresponds with that in S_i in Table 1.

Table 7. Comparison of force constants (10^2 N m^{-1}), bond distances (nm), and bond angles (°)

	f(Ge–CH_3)	r(Ge–CH_3)	(CH_3–Ge–CH_3)
$(CH_3)_3GeCN$	2.83[8]	0.1930±0.0006[15]	114.8±0.1[15]
$(CH_3)_3GeCl$	2.69[7]	0.1940±0.0003[16]	112.8±0.5[16]
$(CH_3)_3GeH$	2.67[a]	0.1947±0.0006[12]	109.6±0.2[12]
$(CH_3)_4Ge$	2.65[14]	0.1945±0.0003[17]	109.5[17]

a) Present work.

Potential energy distributions also are given in Tables 2—5. It is clear from these tables that the methyl rocks (S_{19} and S_{20}) and the GeH or GeD bend (S_{21}) are strongly coupled with each other.

The valence force constant of the Ge–CH_3 bond, derived from the symmetry force constants, is given in Table 7, together with those of the related compounds. The Ge–CH_3 bond distances and CH_3–Ge–CH_3 angles, determined by the microwave and electron diffraction study, are included for each compound in Table 7. The Ge–CH_3 force constant for the present compound is nearly equal to those for $(CH_3)_4Ge$ and $(CH_3)_3GeCl$ and slightly smaller than that for $(CH_3)_3GeCN$. This is in agreement with what might be expected from the Ge–CH_3 bond distances and CH_3–Ge–CH_3 bond angles.

This work was partly supported by a grant from the Asahi Glass Foundation for Industrial Technology to which our thanks are due. One of the authors (Y. I.) wishes to express his thanks to Prof. Fumio Watari, Iwate University, for the computer programs used in calculations.

Mass-spectrometric Study of the Vaporization of Magnesium Oxide from Magnesium Aluminate Spinel

Tadashi SASAMOTO,*,† Hiroshi HARA,†† and Toshiyuki SATA

Research Laboratory of Engineering Materials, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received Nobember 7, 1980)

The partial vapor pressures of Mg(g) over the spinel solid solution system, $MgO \cdot nAl_2O_3$(n=1.0, 2.0, and 2.8), have been measured by the mass-spectrometric Knudsen-cell method. In the temperature range from 1850 to 2300 K, the pressures are described by these equations:

$\log[P(\mathrm{Mg,g})\text{ over }1.0\text{-spinel/atm}] = 7.72 \pm 0.24 - (26900 \pm 490)/T$,

$\log[P(\mathrm{Mg,g})\text{ over }2.0\text{-spinel/atm}] = 7.72 \pm 0.32 - (27400 \pm 670)/T$,

$\log[P(\mathrm{Mg,g})\text{ over }2.8\text{-spinel/atm}] = 7.78 \pm 0.42 - (27900 \pm 1220)/T$.

These observed values were discussed in comparison with the calculated ones obtained by an approximate thermodynamic treatment of an ionic solid solution with composition-dependent vacancies.

In a previous paper[1] one of the present authors (T. Sata) reported that the vaporization of a magnesia component from spinels, $MgO \cdot 0.9Al_2O_3$ and $MgO \cdot 2.8Al_2O_3$, proceeds in two stages: the initial stage with a constant rate before the free surface is covered with the corundum precipitating during the preferential vaporization of the magnesia component, and the second stage controlled by the diffusion of O^{2-} ions through the corundum layer. It was concluded that the vaporization rate at the initial stage was controlled by the decomposition reaction, the activation energies of which were 587 and 327 kJ/mol for $MgO \cdot 0.9Al_2O_3$ and $MgO \cdot 2.8Al_2O_3$ respectively.

The aim of the present study is to measure the equilibrium vapor pressures and vaporization coefficients of Mg(g) and the activities of the magnesia component in the initial stage of the vaporization reaction in the spinel solid solution system, $MgAl_2O_4$–Al_2O_3, and to provide data for discussing the detailed mechanism of the vaporization of a defective spinel the vapor pressure of which is affected by vacancies induced by the dissolution of Al_2O_3, and to compare the observed vapor pressures with those calculated by the approximate treatment of thermodynamics, considering the electrical neutrality condition and the vacancy concentrations.

Experimental

Instrument. The instrument used for the measurement of the vapor pressure was a JMS-01BK-type double-focussing mass spectrometer equipped with a Knudsen-cell ion source, which had been described by Watanabe *et al.*[2,3] The main advantages of this mass spectrometer in the Knudsen measurement are: (1) high resolution, (2) the two ion-detecting systems of the electrical and photographic methods, and (3) the facility of sample exchange.

The Knudsen cell assembly, the ion source, and the slit system are shown in Fig. 1. The Knudsen cells, made of tungsten, sometimes has a ThO_2 liner; they were about 10 mm in both inner diameter and height. The knife-edge effusion orifice of the W or ThO_2 lid was 0.5 mm or 0.3 mm in diameter, so that the ratio of the effusion hole area to the sample surface area was less than about 1/400. The cell was set within the outer cell by means of the three legs and indirectly heated by the radiation from the outer cell, which was heated by electron bombardment. Although the temperature gradient in the cell was not checked, it must has been sufficiently small because the cell was set in an outer cell as a thermal block and the positions of the W-filaments for the electron bombardment were carefuly regulated. The cell temperature was measured both with the optical pyrometer, which was sighted into the orifice of the cell through a quartz window, and with a W-5%Re/W-26%Re thermocouple positioned under the bottom of the cell. The calibration for the thermocouple was carried out by comparison with the temperature of the cell with a graphite liner measured by the pyrometer calibrated against the standard lamp and by taking advantage of the plateau of the ion intensity on the basis of the constancy of the vapor pressure at the melting points of several high-purity metals. The estimated uncertainty of the determined temperature was less than ±1%.

The resolving power, $M/\Delta M$, measured using the peaks of two silver ions, $^{107}Ag^+$ and $^{109}Ag^+$, was about 2600 for

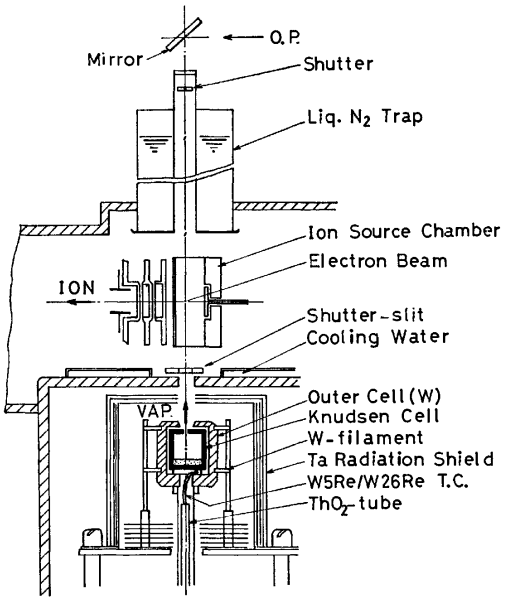

Fig. 1. Mass spectrometer with Knudsen-cell ion source.

† Present address: Tokyo National Technical College, 1220-2 Kunugida, Hachioji, Tokyo 193.

†† Present address: The Institute of Public Health, 4-6-1 Shirokanedai, Minato-ku, Tokyo 108.

the main slit width of 30 μm. It was enough for separating peaks of metal ions from the background peaks of hydrocarbon caused mainly by the decomposition of the diffusion oil. Since the shutter effect for permanent gases like oxygen was difficult to be obtained because of the imperfection of the slit mechanism and the insufficient evacuating ability, it was not possible for such a permanent gas to be distinguished from non-condensable residual gases in the source region of the mass spectrometer. The partial pressures of O_2 and O, therefore, could not be measured in this experiment.

The operational conditions of the ion source were as follows: ionization potential, 30 eV; ionization current, 500 μA; ion-accelerating voltage, 7.8 kV, and temperature of ionization chamber, 250 °C.

Procedure. About 350 mg of a sample (35—100 mesh grains) was placed in the cell with a weighed quantity of about 3 mg of the silver powder used as the reference material for vapor pressure. The Knudsen cell was then evacuated and heated by radiation from W-filaments up to 1400 K, followed by the electron bombardment. The vacuum was kept approximately in the 10^{-9} atm region at elevated temperatures.

When the temperature reached about 1300 K, the silver vapor beam effusing from the cell was ionized by electron impact with an energy of 30 eV, and the intensity of the $^{107}Ag^+$ ion beam was measured in order to determine the relation between the vapor pressure inside the cell and the intensity of the corresponding ion. After the silver had been completely vaporized, the temperature of the cell was rapidly raised up to a given temperature of from 1800 to 2300 K, and then we began to measure the Mg^+ ion intensity.

In the experiments using a photoplate as a detector, a few mg of copper were placed in the W-cell, together with a sample, as the reference material for both the vapor pressure and the calibration of the sensitivity of the photoplate(Ilford Q2). The conversion of the blackness of the spectrum on the plate into the relative ion intensity was carried out by means of Seidel's blackness *versus* relative ion-intensity curve, obtained by the two-line method using two isotope ions, $^{63}Cu^+$ and $^{65}Cu^+$. Sometimes, instead of copper, such stable background peaks as CO^+, N_2^+, O_2^+, and CO_2^+ were also successfully used.

The conversion of the ion intensities to the absolute pressures of Mg(g) was calculated by using the following equations:[4]

$$P(\mathrm{Mg}) = K_1 K_2 I(^{24}\mathrm{Mg}^+) T(\mathrm{Mg}), \quad (1)$$

$$K_1 = \frac{P(\mathrm{Ag}) r(^{107}\mathrm{Ag})}{I(^{107}\mathrm{Ag}^+) T(\mathrm{Ag})}, \quad (2)$$

$$K_2 = \frac{\sigma(\mathrm{Ag}) \Delta E(\mathrm{Ag}^+) \gamma(\mathrm{Ag}^+)}{\sigma(\mathrm{Mg}) \Delta E(\mathrm{Mg}^+) \gamma(^{24}\mathrm{Mg}^+)}, \quad (3)$$

where K_1 and K_2 were the proportionality constants and P was the vapor pressure; I, the ion current; T, the absolute cell temperature; σ, the first ionization cross section given by Mann;[5] r, the isotopic abundance ratio; γ, the electron multiplier efficiency for ions in the first stage of the dynode, and $\Delta E = E - E_{AP}$, where E_{AP} was the appearance potential, and E, the energy of the ionization electron in eV. K_1 is called the calibration factor or the sensitivity factor.

Samples. Three kinds of single-crystal spinels with molar ratios of MgO to Al_2O_3 of 1.0 to 1.0 (called 1.0-spinel for simplicity), 1.0 to 2.0 (2.0-spinel), and 1.0 to 2.8 (2.8-spinel), prepared by the flame-fusion method, were used. The molar ratios of MgO to Al_2O_3 were determined by measuring the X-ray lattice parameters on the basis of the data of Shirasuga *et al.*[6] The lattice parameters calculated from the (8.4.4), and (9.3.1) peaks were $a=8.079$ Å for the stoichiometric spinel, 1.0-spinel, $a=7.992$ Å for the 2.0-spinel, and $a=7.978$ Å for the 2.8-spinel.

Results

Vaporization of Spinel from Tungsten Cell. The intensities of ions formed from the gaseous species over the spinel/W-cell system were measured by the photographic detecting method. Figure 2 shows the time dependence of the ion intensities for the 2.8-spinel/W-cell system at 2180 K. Of these ions, the parent ones were determined from the appearance-potential data to be Mg^+, WO_2^+, WO_2^+, WO_3^+, Al^+, and AlO^+. This shows that the tungsten cell reacts with MgO to produce volatile W-oxides. The vapor pressure ratios, WO_2/WO_3 and AlO/Al, were about 2 and 27 respectively, these ratios agreed with those in the mass-spectrometric studies of the kinetics of the W–O_2 reaction by Berkowitz-Mattuck *et al.*[7] and Shissel *et al.*[8] and with those of the equilibrium vapor pressures in the W–Al_2O_3 system reported by Drowart *et al.*[9] Although the peak at $m/e=40$ corresponding to MgO(g) was observed, the existence of molecular species MgO(g) was ambiguous because of the superposition of the $^{40}(MgO)^+$ and $^{40}Ca^+$ peaks, as was pointed out by Drowart *et al.*[10] No other complex vapor, such as Al_2O, Al_2O_2, and $(WO_3)_n (n>4)$, was detected, since such vapors were present in quantities less than the detection limit of the instrument. The time dependences of the vapor-pressure ratios of Mg(g) to Al(g) at each temperature are shown in Fig. 3. These values lay approximately in the range from 10^2 to 10^3.

Figure 4 plots the partial vapor pressures of Mg(g),

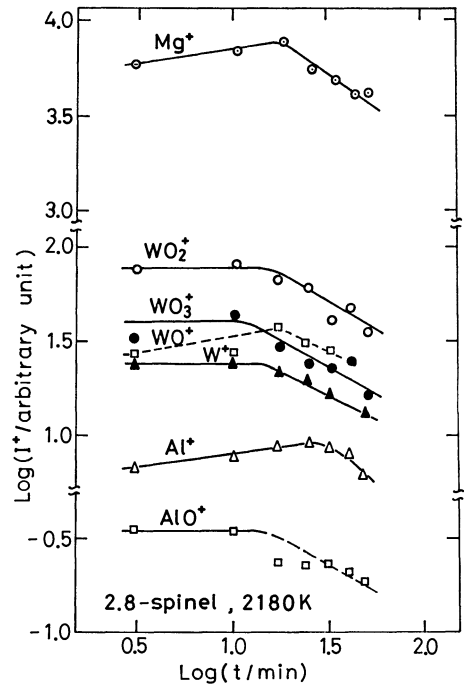

Fig. 2. Intensity of ions formed from gas species over the 2.8-spinel/W-cell system at 2180 K detected by a photographic plate.

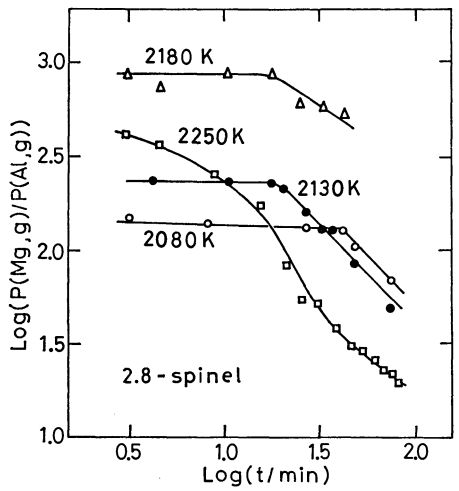

Fig. 3. Time-dependence of ratio of P(Mg,g) to P(Al, g) in the system 2.8-spinel/W-cell.

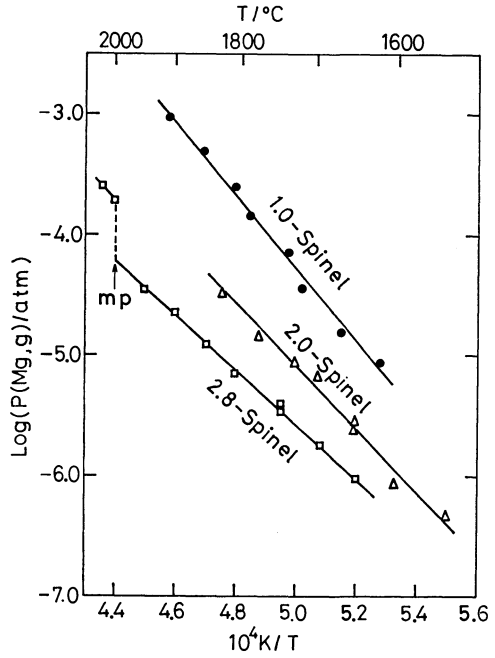

Fig. 4. Partial pressures of Mg(g) over the n-spinel/W-cell system as a function of reciprocal absolute temperature.

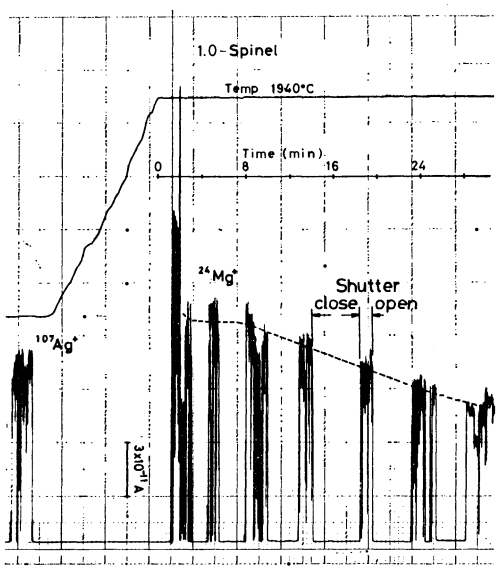
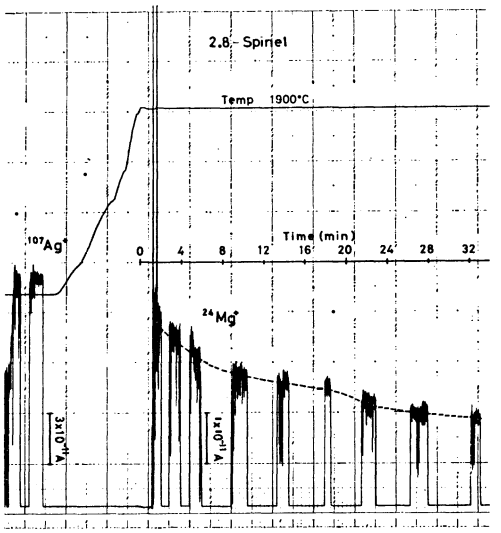
P(Mg), as a function of $1/T$. From the slopes of these lines, the heats of vaporization for Mg(g) over spinel were calculated to be 574, 494, and 436 kJ/mol for 1.0-, 2.0-, and 2.8-spinel respectively. The heat of vaporization for Mg(g) over pure MgO(s) was also determined to be 418 kJ/mol.

Vaporization of Spinels from W-Cell with a ThO_2 Liner. Figure 5 shows a typical time-dependence of the ion intensities of $^{24}Mg^+$ detected by means of a secondary electron multiplier (SEM) for 1.0- and 2.8-spinels. The appearance potential for Mg^+ obtained from the ionization efficiency measurement was 7.3 eV. This value means that the Mg^+ ion results from the simple ionization process. As can be seen in Fig. 5(A), a plateau of ion intensity was initially observed for the 1.0-spinel; a similar result was also obtained for the



(A)



(B)

Fig. 5. Typical examples of the time-dependence of the ion intensities of $^{24}Mg^+$ on (A) 1.0-spinel and (B) 2.8-spinel.

2.0-spinel. In the case of the 2.8-spinel, however, no plateau appeared and the ion intensity decreased with time, as is shown in Fig. 5(B). This was because the vaporizing surface was gradually covered with the precipitated alumina. Therefore, the ion intensities extrapolated to the intercept of time=0 were employed in the calculation of the equilibrium vapor pressure.

Figure 6 shows the van't Hoff plots of magnesium vapor pressure over the 1.0-spinel, P(Mg, g), calculated from Eq. 1 using the values of the ion intensity obtained by the step-by-step measurement in which the temperature was raised, step by step, at intervals of from 5 to 10 min. The vapor pressures obtained by both the step-by-step and isothermal measurements were in good agreement with each other. The values of P(Mg) over the 1.0-spinel were about half of that over pure MgO and were formulated by the least-squares method in the temperature range from 1850

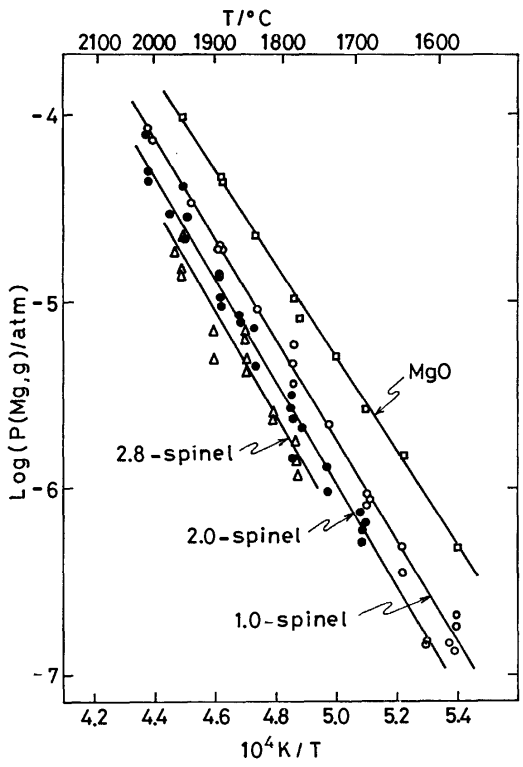


Fig. 6. Equilibrium vapor pressures of Mg(g) over the systems of *n*-spinel or magnesia/ThO_2-lined W-cell.

to 2300 K as follows:

$$\log[P(\mathrm{Mg,\ g})/\mathrm{atm}] = 7.72\pm0.24 - (26900\pm490)/T. \quad (4)$$

A similar temperature-dependence was obtained in the isothermal:

$$\log[P(\mathrm{Mg,\ g})/\mathrm{atm}] = 7.72\pm0.32 - (27400\pm670)/T. \quad (5)$$

For the 2.8-spinel, the initial values obtained in the isothermal experiment were plotted against $1/T$ for the reason described above, and the following equation was obtained:

$$\log[P(\mathrm{Mg,\ g})/\mathrm{atm}] = 7.78\pm0.42 - (27900\pm1220)/T. \quad (6)$$

The vapor pressures of P(Mg) over pure MgO(s) were given by this equation:

$$\log[P(\mathrm{Mg,\ g})/\mathrm{atm}] = 7.29\pm0.18 - (25200\pm310)/T. \quad (7)$$

Table 1 shows the activities of the magnesia component, a(MgO), as calculated by this equation:

$$a(\mathrm{MgO}) = \frac{P(\mathrm{Mg,\ g})\text{ over }n\text{-spinel(s)}}{P(\mathrm{Mg,\ g})\text{ over MgO(s)}}, \quad (8)$$

using P(Mg, g) over MgO and the *n*-spinel given by Eqs. 4 to 7.

Using the Langmuir vapor pressures given by Sata *et al.*,[1] the apparent vaporization coefficient of Mg(g) over the 1.0-spinel was given by this equation:

$$\log \alpha_v = \log[P_L(\mathrm{Mg,\ g})/P_K(\mathrm{Mg,\ g})], \quad (9)$$

$$= -0.833 - (1330/T) \quad (10)$$

where P_L is the vapor pressure in the Langmuir free vaporization, and P_K the Knudsen vapor pressure, the equilibrium vapor pressure. From this equation, α_v at the melting point, $\simeq$2100 °C, was found not to be equal to unity; this was also observed in the experiment on the 2.8-spinel/W-cell system, as is shown in Fig. 4. These results differed from those for α's for MgO[11] and $MgCr_2O_4$.[12]

Discussion

If we use the phase diagrams of the MgO–Al_2O_3 system[13,14] and the *JANAF Tables*[15] for the following reaction:

$$MgAl_2O_4(s) = Mg(g) + \frac{1}{2}O_2(g) + Al_2O_3(s), \quad (11)$$

and calculate the activities of the magnesium component, a(Mg), at 1800 °C in a spinel solution on the basis of Raoult's law, we could expect the relation between a(MgO) and Al_2O_3 composition shown in Fig. 7. The measured values plotted in the figure, however, greatly deviated from the expected ones. This might come from the application of Eq. 11 as the vaporization reaction for this case; the Al_2O_3 on the right-hand side in Eq. 11 should be replaced by the spinel solid solution ($n>1$), because $MgAl_2O_4$ and Al_2O_3 do not exist together, as can be seen from the phase diagram of Fig. 7. In fact, as is shown in Fig. 8, the P(Mg) values over $MgAl_2O_4$(s) calculated from the *JANAF Tables*[15] on the basis of $MgAl_2O_4(s) = Mg(g) + 1/2O_2(g) + Al_2O_3(s)$ were smaller than our values and those of the literature.[16,17] Altman[16] suggested that the alumina produced by the vaporization reaction immediately formed a spinel solid solution with $MgAl_2O_4$ and decreased the activity of MgO.

Considering the above discussion, the desired P-(Mg) over the single-phase of *n*-spinel, $P_{Mg/n\text{-spinel}}$, was determined by the following steps: first, P(Mg) over the two-phase region of the spinel-corundum, $P_{Mg/two\text{-}phase}$, was calculated using mainly the *JANAF*

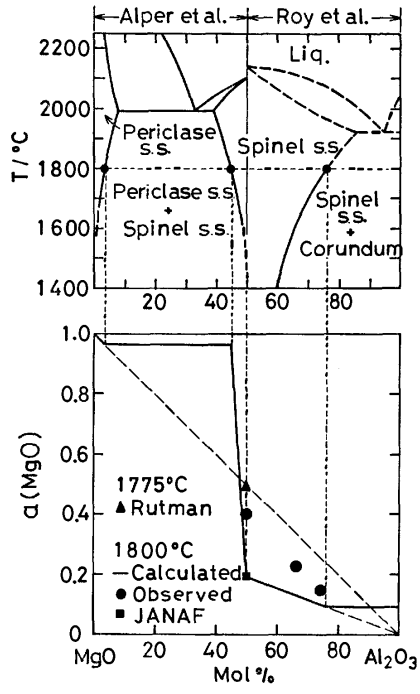

Fig. 7. Calculated relative vapor pressure of Mg(g) over the MgO–Al_2O_3 system assuming the Raoult's law.

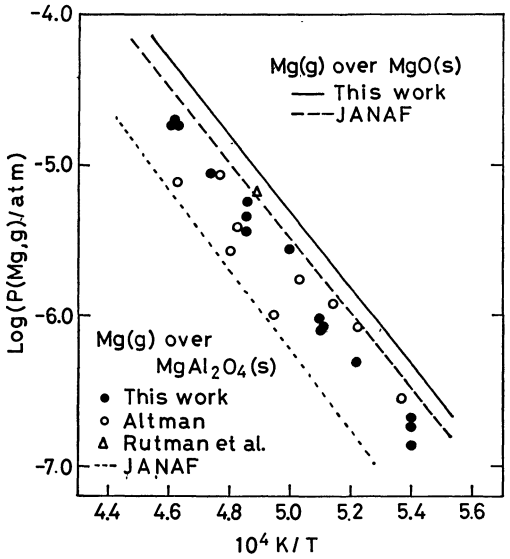

Fig. 8. Comparison of observed Knudsen vapor pressures of Mg(g) over 1.0-spinel with JANAF data.

Tables; next, the relative $P(\mathrm{Mg})$ over the single n-spinel on an arbitrary basis, $P'_{\mathrm{Mg}/n\text{-spinel}}$, was estimated as a function of the composition, n, by applying the method by Nakano[18] and Koumoto *et al.*;[19] and finally, $P'_{\mathrm{Mg}/n\text{-spinel}}$ was converted to $P_{\mathrm{Mg}/n\text{-spinel}}$ using an appropriate correction factor, which was obtained by comparing $P'_{\mathrm{Mg}/n\text{-spinel}}$ with $P_{\mathrm{Mg}/\mathrm{two\text{-}phase}}$ at the solubility limit of Al_2O_3 in the spinel.

The vaporization reaction in the two-phase region is as follows:

$$\mathrm{Mg}_{4/3n+1}\mathrm{Al}_{8n/3n+1}\mathrm{O}_4(\mathrm{s}) = \frac{4}{3n+1}\mathrm{Mg}(\mathrm{g}) + \frac{1}{3n+1}\mathrm{O}_2(\mathrm{g}) + \frac{4n}{3n+1}\mathrm{Al}_2\mathrm{O}_3(\mathrm{s},\alpha) + \Delta G_{\mathrm{v}}, \tag{12}$$

where α donates alpha-type alumina, *i.e.*, corundum. This reaction is decomposed into the following three reactions:

$$\frac{4}{3n+1}\mathrm{MgAl}_2\mathrm{O}_4(\mathrm{s}) + \frac{4(n-1)}{3n+1}\mathrm{Al}_2\mathrm{O}_3(\mathrm{s},\alpha) = \mathrm{Mg}_{4/3n+1}\mathrm{Al}_{8n/3n+1}\mathrm{O}_4(\mathrm{s}) + \Delta G_1, \tag{13}$$

$$\mathrm{MgO}(\mathrm{s}) + \mathrm{Al}_2\mathrm{O}_3(\mathrm{s},\alpha) = \mathrm{MgAl}_2\mathrm{O}_4(\mathrm{s}) + \Delta G_2, \tag{14}$$

$$\mathrm{MgO}(\mathrm{s}) = \mathrm{Mg}(\mathrm{g}) + \frac{1}{2}\mathrm{O}_2(\mathrm{g}) + \Delta G_3, \tag{15}$$

where ΔG denotes the Gibbs energy. By combining Eqs. 13, 14, and 15, the following equation was derived:

$$\frac{P_{\mathrm{Mg}/n\text{-spinel}}}{P_{\mathrm{Mg/MgO}}} = \exp\left[\frac{3n+1}{6}\left(\frac{\Delta G_1}{RT}\right)+\frac{2}{3}\left(\frac{\Delta G_2}{RT}\right)\right], \tag{16}$$

where $P_{\mathrm{Mg}/n\text{-spinel}}$ and $P_{\mathrm{Mg/MgO}}$ stand for the partial pressure of Mg(g) over the n-spinel(s) and MgO(s) respectively.

Here, ΔG_2 can be obtained from the *JANAF Tables*.[15] On the other hand, the ΔG_1 for the formation reaction of a solid solution in Eq. 13 is given as the sum of the following two Gibbs energies:

Table 1. Activities of magnesia component, $a(\mathrm{MgO})$, in the spinel solid-solution system $\mathrm{MgO}\cdot n\mathrm{Al}_2\mathrm{O}_3$

Specimen	a(MgO)			
	1700 °C	1800 °C	1900 °C	2000 °C
1.0-Spinel	0.376	0.408	0.444	0.481
2.0-Spinel	0.206	0.234	0.262	0.290
2.8-Spinel	—	0.154	0.177	0.200

$$\frac{4}{3n+1}\mathrm{MgAl}_2\mathrm{O}_4(\mathrm{s}) + \frac{3(n-1)}{3n+1}\mathrm{Al}_{8/3}\mathrm{O}_4(\mathrm{s},\gamma) = \mathrm{Mg}_{4/3n+1}\mathrm{Al}_{8n/3n+1}\mathrm{O}_4(\mathrm{s}) + \Delta G_1', \tag{17}$$

$$\frac{4(n-1)}{3n+1}\mathrm{Al}_2\mathrm{O}_3(\mathrm{s},\alpha = \frac{4(n-1)}{3n+1}\mathrm{Al}_2\mathrm{O}_3(\mathrm{s},\gamma) + \Delta G_1'', \tag{18}$$

$$\Delta G_1 = \Delta G_1' + \Delta G_1'', \tag{19}$$

where γ stands for γ-type alumina.

Shirasuka *et al.*[20,21] have recently reported, on the basis of the DTA experiment, that the exsolution of alumina from the spinel body with $n=1.5$—5.6 was exothermic. It is thought that this exothermic reaction resulted from the γ to α-transformation reaction, as is shown in Eq. 18.

The $\Delta G_1''$ in Eq. 18 can be obtained from the *JANAF Tables*. The $\Delta G_1'$ for Eq. 17 was obtained in the following manner. As the change in the volume of this reaction was very small (for examples, −0.16% for 3.0-spinel), the enthalpy change for the reaction was considered to be negligibly small. Therefore, $\Delta G_1'$ is reduced to:

$$\Delta G_1' \simeq -T\Delta S_{\mathrm{m}}, \tag{20}$$

where ΔS_{m} is the mixing entropy for Eq. 17. Here, ΔS_{m} is obtained by simple statistical thermodynamics on the assumption that the cations and cation vacancies are distributed randomly at tetrahedral and octahedral sites at a high temperature in the case of a spinel solid solution with the composition of $\mathrm{MgO}\cdot n\mathrm{Al}_2\mathrm{O}_3=(3n+1)/4\mathrm{Mg}_{4/(3n+1)}\mathrm{Al}_{8n/(3n+1)}\square_{(n-1)/(3n+1)}\mathrm{O}_4$. Let N_{t} be the total number of cation sites, and let N_{Mg}, N_{Al}, and N_{v} be the numbers of the Mg^{2+}, Al^{3+}, and cation vacancies respectively. Then, the following relationships hold:

$$\left.\begin{aligned} N_{\mathrm{t}} &= 3N_{\mathrm{A}},\\ N_{\mathrm{Mg}} &= \left(\frac{4}{3n+1}\right)\frac{N_{\mathrm{t}}}{3},\\ N_{\mathrm{Al}} &= \left(\frac{8n}{3n+1}\right)\frac{N_{\mathrm{t}}}{3},\\ N_{\mathrm{v}} &= N_{\mathrm{t}} - N_{\mathrm{Mg}} - N_{\mathrm{Al}} = \left(\frac{n-1}{3n+1}\right)\frac{N_{\mathrm{t}}}{3}, \end{aligned}\right\} \tag{21}$$

where N_{A} is Avogadro's constant. The number of distinguishable arrangements of cations and cation vacancies, W, is expressed as follows:

$$W = \frac{N_{\mathrm{t}}!}{N_{\mathrm{Mg}}!\,N_{\mathrm{Al}}!\,N_{\mathrm{v}}!}. \tag{22}$$

The contribution of mixing term to the entropy is expressed as:

$$S_{\mathrm{c}} = k\ln W, \tag{23}$$

Table 2. Gibbs energies relating to the vaporization reaction of spinels and the partial pressures of Mg(g) over various n-spinels

T/°C	n at T °C[a]	$\Delta G_1'$ for Eq. 17[b] kJ/mol	$\Delta G_1''$ for Eq. 18[c] kJ/mol	ΔG_2 for Eq. 14[c] kJ/mol	a(MgO) from Eq. 16	P(Mg) over n-spinel atm
1500	1.67	−6.116	8.588	−35.12	0.242	1.86×10^{-8}

1700	2.95	−8.077	6.950	−36.30	0.205	4.49×10^{-7}
1800	4.26	−7.951	6.129	−36.98	0.188	1.73×10^{-6}
1900	6.81	−6.941	5.291	−37.73	0.180	6.08×10^{-6}

a) n in $MgO\cdot nAl_2O_3$ on the solubility limit line at temperatures in the first column. b) Calculated from Eq. 25. c) From *JANAF Tables*.

where S_c denotes the configurational entropy. The substitution of Eqs. 21 and 22 into Eq. 23 yields the desired equation:

$$S_c(n) = -3R\left(\frac{N_{Mg}}{N_t}\ln\frac{N_{Mg}}{N_t}+\frac{N_{Al}}{N_t}\ln\frac{N_{Al}}{N_t}+\frac{N_v}{N_t}\ln\frac{N_v}{N_t}\right)$$
$$= \frac{-R}{3n+1}[4\ln4+8n\ln8n+(n-1)\ln(n-1)$$
$$-3(3n+1)\ln3(3n+1)], \quad (24)$$

and thus:

$$\Delta G_1' \simeq -T\Delta S_m$$
$$-\left[-T\left[S_c(n=n)-\frac{4}{3n+1}S_c(n=1)-\frac{3(n-1)}{3n+1}S_c(n=\infty)\right]\right]$$
$$= \frac{-RT}{3n+1}[8n\ln8n+(n-1)\ln(n-1)$$
$$-3(3n+1)\ln3(3n+1)+3.139n+10.045]. \quad (25)$$

The Gibbs energies of $\Delta G_1'$, $\Delta G_1''$, and ΔG_2 for the n-spinel on the solubility limit line at several temperatures between 1500 and 1900 °C are summarized in Table 2. From these Gibbs energies, and by applying Eq. 16, the ratios of P_{Mg} over the n-spinel(s) to P_{Mg} over MgO(s), *i.e.*, a(MgO), were calculated. The partial pressures of Mg(g) over the n-spinel, calculated using this a(MgO) and *JANAF* data for P(Mg) over pure MgO(s), are also shown in the last column in Table 2 and graphically in Fig. 9.

The partial pressures of Mg(g) over the spinel solid solution in the single-phase region are given by the following equation:[18,19]

$$\ln P(Mg,g)^{3/2} = \ln\frac{4}{3(3n+1)}\left[\frac{n-1}{3(3n+1)}\right]^{-1/4}+C$$
$$C = \frac{h_{MgO}-K_{Mg}-1/2K_{O_2}}{RT}, \quad (26)$$

where h_{MgO} is the enthalpy term and where K_{Mg} and K_{O_2} are constants independent of the composition. As it was assumed that a spinel solid solution is ideal; that $\Delta H_m\simeq0$, and that every vapor species behaves as a perfect gas, C should be constant. P(Mg) over n-spinel(s) in the single-solid solution region, therefore, can be obtained by shifting the P(Mg) calculated from Eq. 26 in the direction of the "pressure-axis" of the diagram for log$P$-*vs.*-n and joining it to the P(Mg) in the two-phase region. The results are shown in Fig. 9, along with the experimental values. The calculated values agreed with those obtained by mass spectrometry.

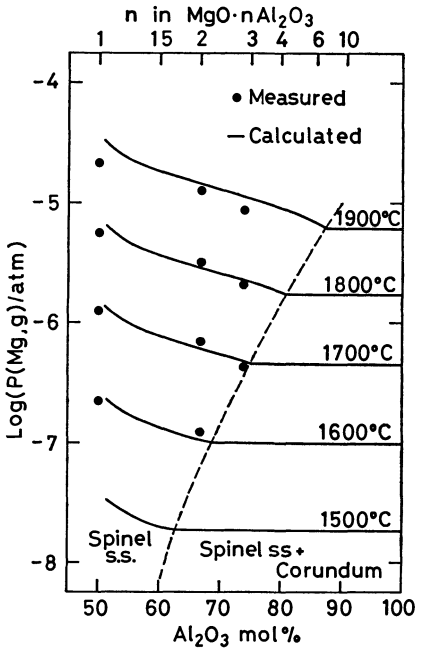

Fig. 9. Calculated and measured vapor pressures of Mg(g) over the system $MgAl_2O_4$–Al_2O_3.

We would like to thank Mr. Ryoichi Kondoh of the Tokyo Denki Kagaku Co., Ltd., for his assistance in obtaining the mass-spectrometric data.

The Formation Constants and Configurations of the Complexes of Cr(II), Mn(II), Fe(II), Co(II), Cu(II), and Zn(II) with 2,2′-Bipyridine and of Co(II) with 2,2′:6′,2″-Terpyridine in Hexamethylphosphoric Triamide

Yuriko Abe* and Goro Wada

Department of Chemistry, Nara Women's University, Nara 630

(Received December 13, 1980)

The absorption spectra and the first formation constants, K_1, of complexes $[M(bpy)]^{2+}$ (M(II)=Cr(II), Mn(II), Fe(II), Co(II), Cu(II), and Zn(II), bpy=2,2′-bipyridine) were determined spectrophotometrically in hexamethylphosphoric triamide(HMPA). The values of $\log K_1$ obtained were 4.61±0.02, 3.10±0.12, 4.82±0.04, 5.84±0.07, 7.33±0.02, and 1.77±0.07 for respective metal ions. The configurations of complexes $[M(bpy)]^{2+}$ were discussed on the basis of these data. The K_1 values of $[Cr(bpy)]^{2+}$, $[Mn(bpy)]^{2+}$, $[Fe(bpy)]^{2+}$, and $[Co(bpy)]^{2+}$ in HMPA are slightly larger than those in H_2O, indicating that their configurations are tetrahedral, whereas the value of $[Cu(bpy)]^{2+}$ in HMPA is slightly smaller than that in H_2O, indicating that its configuration in HMPA is either square planar or tetragonal. It seems that $[Zn(bpy)]^{2+}$ is octahedral in HMPA, because its K_1 value is smaller about three orders of magnitude than that in H_2O. In addition, the second formation constant, K_2, of complex $[Co(bpy)_2]^{2+}$, and the first and second formation constants of complexes $[Co(terpy)]^{2+}$ and $[Co(terpy)_2]^{2+}$ (terpy=2,2′:6′,2″-terpyridine) were also determined to be $\log K_2=3.59\pm0.03$ for the bpy complex, and $\log K_1=4.87\pm0.01$ and $\log K_2=3.35\pm0.01$ for the terpy complexes, respectively. These three complexes are concluded to be octahedral.

In a previous paper,[1] the configurations of solvated complex ions of the first transition metals (Mn(II), Fe(II), Co(II), Ni(II), Cu(II), and Zn(II)) in hexamethylphosphoric triamide (HMPA) were reported. It was found that the metal ions are tetrahedrally solvated in the cases of Mn(II), Fe(II), Co(II), and Cu(II), while equilibria are established among octahedral, square planar and tetrahedral solvated species in the case of Ni(II), and that Zn(II) forms probably an octahedrally solvated complex ion.

Now the problems on the complex-forming equilibria between the first transition metal ions and a ligand in HMPA are very interesting, since the configurations of the solvated ions in HMPA are widely different from those in water or in a number of other organic solvents, such as dimethyl sulfoxide, *N,N*-dimethylformamide, and methanol, in any of which the solvated ions are generally octahedral.

Up to date, however, no thermodynamic studies have been done yet except for the case of Co(II) complexes in HMPA.[2,3] In the present study, the absorption spectra and the values of the formation constants of the following complexes will be reported: the first formation constants, K_1, of complexes $[M(bpy)]^{2+}$ (M(II)=Cr(II), Mn(II), Fe(II), Co(II), Cu(II), or Zn(II), bpy=2,2′-bipyridine),† the second formation constant, K_2, of the complex $[Co(bpy)_2]^{2+}$, and the first and second formation constants of the complexes $[Co(terpy)]^{2+}$ and $[Co(terpy)_2]^{2+}$ (terpy=2,2′:6′,2″-terpyridine). The configurations of $[M(bpy)]^{2+}$ in HMPA will be discussed on the basis of these data.

Experimental

Materials and Procedure. HMPA of guaranteed reagent grade was purified as described elsewhere.[1] Bpy was recrystallized from hexane, and terpy was used without further purification. Anhydrous sodium perchlorate was prepared by heating monohydrous salt which had been recrystallized twice from water. Complexes of various metal ions $[M(hmpa)_4](ClO_4)_2$ (M(II)=Mn(II), Fe(II), Co(II), Cu(II), or Zn(II)) were synthesized according to the methods by Donoghue and Drago.[4,5] Stock solutions of these metal perchlorates were prepared, and portions of them were taken to analyze the metal ion concentrations by the spectrophotometric methods already published.[1] Complex solutions were prepared by mixing the aliquots of stock solutions of metal perchlorates with those of bpy or terpy solutions. The ionic strength was kept at $I=0.06$ mol dm^{-3} with sodium perchlorate.

Solution of chromium(II) perchlorate in HMPA was prepared under nitrogen atmosphere as follows. Metallic chromium was dissolved in aqueous solution of perchloric acid, and the hydrated perchlorate was crystallized from it. After the removal of water in vacuum at room temperature until the blue crystals turned white, the white crystals were treated with a slight excess of HMPA and an appropriate amount of ether and crystals of chromium perchlorate solvated by HMPA were obtained and dissolved in HMPA. The total chromium(II) ion concentration in solution was determined spectrophotometrically by diphenylcarbazide method[6] (molar absorptivity $\varepsilon=6.590\times10^4$ dm^3 mol^{-1} cm^{-1} at 540 nm).

Apparatus. The absorptivities of complex solutions were measured using a Hitachi Spectrophotometer Model 100-40 and a Hitachi Recording Spectrophotometer Model EPS-3T, with a thermostated cell compartment, respectively. The temperature was kept at 25.0±0.1 °C.

Results

The values of K_1 were obtained by a method by use of Job's curves (Method I),[7] the linear relationship method (Method II),[7] and the relative stability constant method (Method III).[8]

Determination of K_1 by Method I. The curves of Job's continuous variation method were obtained at two different total concentrations ($c=c_a$ and c_b) of M(II) (M(II)=Mn(II), Fe(II), Co(II), or Zn(II)) and bpy; an example is given in Fig. 1, essentially

† In this expression, HMPA molecules solvating the metal ions are omitted.

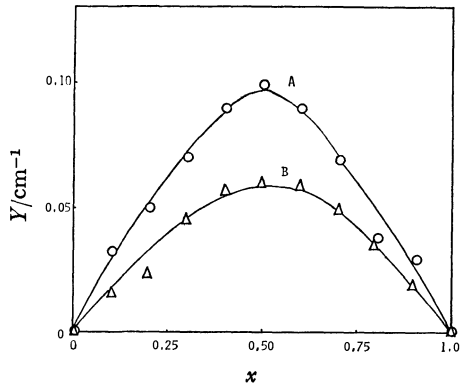

Fig. 1. Job's curves for Mn(II)+bpy system in HMPA at 317 nm.
Curve A: $c_a=1.00\times10^{-3}$ mol dm^{-3}, curve B: $c_b=7.00\times10^{-4}$ mol dm^{-3}.

similar data being obtained in other cases. Curves A and B indicate that the 1:1 complex $[M(bpy)]^{2+}$ is predominantly formed between M(II) and bpy, so that the following relations are established:

$$M^{2+} + bpy \overset{K_1}{\rightleftharpoons} [M(bpy)]^{2+}, \quad (1)$$

$$K_1 = \frac{[[M(bpy)]^{2+}]}{[M^{2+}][bpy]}. \quad (2)$$

In the Figure, the abscissa shows $x=[bpy]_0/c$, and the ordinate Y is defined as follows:

$$Y = (\varepsilon_1-\varepsilon_0-\varepsilon_b)[[M(bpy)]^{2+}] \quad (3)$$

in which ε_0, ε_1, and ε_b are the molar absorptivities of M^{2+}, $[M(bpy)]^{2+}$, and bpy, respectively. The values of K_1 and ε_1 are calculated by Eq. 3 and the following equations from curves A and B.[7]

$$[[M(bpy)]^{2+}] = \frac{x_a(1-x_a)c_a^2-x_b(1-x_b)c_b^2}{c_a-c_b}, \quad (4)$$

$$[M^{2+}] = x_a c_a - [[M(bpy)]^{2+}], \quad (5)$$

$$[bpy] = (1-x_a)c_a - [[M(bpy)]^{2+}], \quad (6)$$

where x_a and x_b are the x values having a common Y value on curves A and B. The results are summarized in Table 1.

Determination of K_1 and K_2 by Method II.[7] At concentrations of both M(II) and bpy low enough so that the amount of $[M(bpy)_2]^{2+}$ formed is negligibly small, the apparent molar absorptivity of M(II), ε, is expressed by a linear relationship, Eq. 7, with $(\varepsilon_0-\varepsilon)/[bpy]$.[7] When the molar absorptivity of M^{2+}, ε_0, is zero, Eq. 8 holds.

$$\varepsilon = \varepsilon_1 + \frac{1}{K_1}\frac{(\varepsilon_0-\varepsilon)}{[bpy]} \quad (7)$$

$$\frac{1}{\varepsilon} = \frac{1}{\varepsilon_1} + \frac{1}{K_1\varepsilon_1}\frac{1}{[bpy]} \quad (8)$$

Accordingly, plotting ε *vs.* $(\varepsilon_0-\varepsilon)/[bpy]$ or $1/\varepsilon$ *vs.* $1/[bpy]$ will give the values of K_1 and ε_1 from the slope and the intercept. Figure 2 shows the linear relationship of Co(II)+bpy system; similar relationships were obtained for Mn(II)+bpy and Fe(II)+bpy systems, respectively. The values of K_1 and ε_1 thus obtained are also summarized in Table 1. These values of K_1 are in good agreement with those obtained by Method I.

The second complex formation constant of $[Co(bpy)_2]^{2+}$, $K_2=[[Co(bpy)_2]^{2+}]/[[Co(bpy)]^{2+}][bpy]$, is obtained from Eq. 9 in the more concentrated regions for both Co(II) and bpy than in Fig. 2,

$$\varepsilon = \varepsilon_2 + \frac{1}{K_2}\frac{(\varepsilon_0-\varepsilon)+(\varepsilon_1-\varepsilon)K_1[bpy]}{K_1[bpy]^2}, \quad (9)$$

where ε_2 is the molar absorptivity of $[Co(bpy)_2]^{2+}$. The linearity is obvious between ε and $\{(\varepsilon_0-\varepsilon)+(\varepsilon_1-\varepsilon)K_1[bpy]\}/K_1[bpy]^2$ as shown in Fig. 3, giving the value of K_2 from the slope. The first and second formation constants of Co(II)-terpy complexes are also determined by the same method, the results being listed in Table 2.

Determination of K_1 by Method III.[8] When both M^{2+} and M_a^{2+} ions coexist in HMPA, equilibria (1)

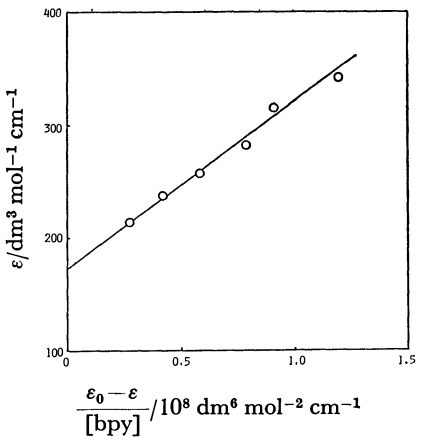

Fig. 2. Linear relation of ε against $(\varepsilon_0-\varepsilon)/[bpy]$ in HMPA at 630 nm.
$[Co(II)]=8.00\times10^{-4}$ mol dm^{-3}, $[bpy]_0=1.00\times10^{-4}$—$6.00\times10^{-4}$ mol dm^{-3}.

Table 1. First formation constants of the complexes of Mn(II), Fe(II), Co(II), or Zn(II) with bpy in HMPA by method I and method II

Method		Mn(II)	Fe(II)	Co(II)	Zn(II)
Method I	$\log K_1$	3.21±0.24	4.86±0.11	5.77±0.22	1.77±0.07
	$\log \varepsilon_1$	2.81±0.07[a]	3.88±0.02[b]	3.95±0.03[c]	3.10±0.06[d]
Method II	$\log K_1$	2.98±0.02	4.78±0.02	5.90±0.02	—
	$\log \varepsilon_1$	1.26±0.09[e]	2.42±0.04[f]	2.25±0.05[g]	—

The following values were adopted in Method I: a) $\log\varepsilon_0=0.60$, $\log\varepsilon_b=2.02$ at 317 nm, b) $\log\varepsilon_0=3.20$, $\log\varepsilon_b=2.90$ at 310 nm, c) $\varepsilon_0=0$, $\log\varepsilon_b=3.36$ at 305 nm, d) $\log\varepsilon_0=0.48$, $\log\varepsilon_b=2.02$ at 317 nm. The following wavelengths were used in Method II: e) 380 nm, f) 522 nm, g) 630 nm.

and (10) hold simultaneously among those ions and bpy,

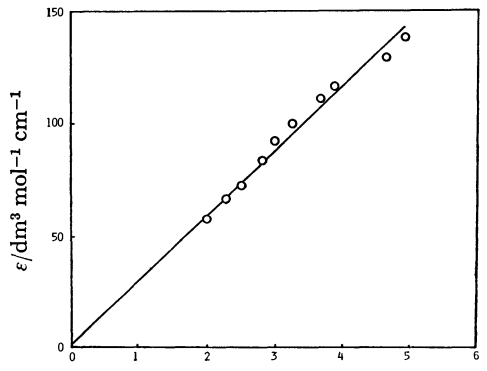

Fig. 3. Linear relation of ε against $((\varepsilon_0-\varepsilon)+(\varepsilon_1-\varepsilon)\times K_1[\mathrm{bpy}])/K_1[\mathrm{bpy}]^2$ in HMPA at 580 nm. $[\mathrm{Co(II)}]=3.20\times10^{-3}$ mol dm^{-3}, $[\mathrm{bpy}]_0=3.80\times10^{-3}$—$5.60\times10^{-3}$ mol dm^{-3}.

Table 2. Comparison of first and second formation constants of the complexes of Co(II) with bpy or terpy in HMPA and H_2O

Ligand	Solvent	$\log K_1$	$\log K_2$	$\log K_3$
bpy	HMPA	5.84±0.07	3.59±0.03	<1[a]
	H_2O[9]	5.65	5.60	4.80
terpy	HMPA	4.87±0.01	3.35±0.01	
	H_2O[9]	8.4	9.9	

a) This value was calculated on an assumption that ε of $[\mathrm{Co(bpy)_3}]^{2+}$ in HMPA is the same value as that in H_2O. $[\mathrm{Co(II)}]=1.00\times10^{-2}$ mol dm^{-3}, $[\mathrm{bpy}]_0=1.50\times10^{-1}$ mol dm^{-3}.

$$M_a^{2+} + \mathrm{bpy} \overset{K_a}{\rightleftharpoons} [M_a(\mathrm{bpy})]^{2+}, \quad (10)$$

where K_a is the formation constant of $[M_a(\mathrm{bpy})]^{2+}$. Therefore, an equilibrium (11) is also established with a formation constant K_r as expressed by Eq. 12.

$$M^{2+} + [M_a(\mathrm{bpy})]^{2+} \overset{K_r}{\rightleftharpoons} M_a^{2+} + [M(\mathrm{bpy})]^{2+}, \quad (11)$$

$$K_r = \frac{[M_a^{2+}][[M(\mathrm{bpy})]^{2+}]}{[M^{2+}][[M_a(\mathrm{bpy})]^{2+}]} = \frac{K_1}{K_a}. \quad (12)$$

The absorptivity of the solution, A, is defined by the following equation:

$$A = \varepsilon_0[M^{2+}] + \varepsilon_1[[M(\mathrm{bpy})]^{2+}] + \varepsilon_a[M_a^{2+}] + \varepsilon'_a[[M_a(\mathrm{bpy})]^{2+}], \quad (13)$$

where ε_a and ε_a' are the molar absorptivities of M_a^{2+} and $[M_a(\mathrm{bpy})]^{2+}$, respectively. When both the values of K_1 and K_a are considerably large, the concentration of free bpy will be negligibly small, and therefore, the total concentration of bpy, $[\mathrm{bpy}]_0$, will be equal to the sum of $[[M(\mathrm{bpy})]^{2+}]$ and $[[M_a(\mathrm{bpy})]^{2+}]$. Consequently, when the molar absorptivities of M^{2+}, $[M(\mathrm{bpy})]^{2+}$, M_a^{2+}, and $[M_a(\mathrm{bpy})]^{2+}$ are known, the value of K_r can be obtained because the total concentrations of M(II), M_a(II), and bpy and observed A are known. Therefore, the value of K_1 is given by virtue of the relationship $K_1=K_aK_r$ and the known K_a value. For the determination of the formation constants, K_1, of $[\mathrm{Cu(bpy)}]^{2+}$ and $[\mathrm{Cr(bpy)}]^{2+}$, Co(II) was used as M_a^{2+} ion in equilibrium (10). Since the molar absorptivity of $[M(\mathrm{bpy})]^{2+}$ can not be obtained directly, the absorptivity of the solution, A, was determined at the wavelength of the isosbestic point between M^{2+} and $[M(\mathrm{bpy})]^{2+}$ ($\varepsilon_0=\varepsilon_1$). The results are summarized in Tables 3 and 4.

Absorption Spectra of bpy- and terpy-Complexes. The absorption spectra of pure bpy- or terpy-complexes can be calculated from the apparent spectra of the

Discussion

Configurations of $[Cr(bpy)]^{2+}$, $[Mn(bpy)]^{2+}$, $[Fe(bpy)]^{2+}$, and $[Co(bpy)]^{2+}$ in HMPA. The K_1 values observed for bpy-complexes are in a sequence Cr(II)> Mn(II)<Fe(II)<Co(II)<Cu(II)>Zn(II) in HMPA. Figure 7 shows the comparison of the K_1 values in HMPA and in H_2O.[9] The factors which would make the values of the formation constants (K) in HMPA differ from those in H_2O or in other organic solvents might be the dielectric constants, basicities, and steric effects of the solvents. Since bpy and terpy ligands are electrically neutral, the K values might be little affected by the dielectric constant of the solvents. Since the competitive coordination to a metal ion occurs between bpy (or terpy) and the solvent molecules, the increase in basicity and in the degree of steric hindrance of the solvent would result in a decrease in K value.

It was reported[1] that the solvated Mn^{2+}, Fe^{2+}, Co^{2+}, and Cu^{2+} ions are tetrahedral in contrast with the octahedrally solvated Zn^{2+} ion in HMPA. Because an HMPA molecule is very bulky, solvated metal ions in HMPA will prefer the tetrahedral configurations to the octahedral ones.[1] If their bpy-complexes tend to form octahedral configurations in HMPA, K_1 values in HMPA would become smaller than those in H_2O or in DMSO because of a larger basicity and steric hindrance of HMPA molecules which would be more closely packed in the octahedral coordination sphere. However, since the observed K_1 values of Cr(II), Mn(II), Fe(II), and Co(II) in HMPA are slightly larger than those in H_2O as shown in Fig. 7, it is supposed that their bpy-complexes would not be octahedral. According to Gutmann *et al.*,[10] the donor strength of HMPA towards Co(II) is smaller

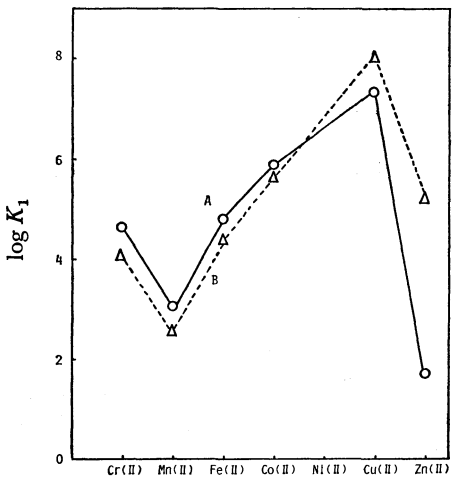

Fig. 7. Comparison of log K_1 in HMPA (A:—) and in H_2O (B:- - -).

than that expected from its donor number and the coordination center in $[Co(hmpa)_4]^{2+}$ is rattling within the tetrahedron formed by the bulky HMPA molecules. When their bpy-complexes in HMPA are also assumed to be tetrahedral, the K_1 values in HMPA would not be much smaller than those in H_2O because of the smaller steric hindrance and the decreased donor strength of HMPA molecules. Actually, the absorption spectrum of $[Co(bpy)]^{2+}$ in HMPA exhibits the spectral pattern characteristic of tetrahedral complexes as is seen in Fig. 5, having the absorption band due to $\nu_3(^4T_1(P)\leftarrow{}^4A_2)$, ($\varepsilon=100$—$2000$ dm^3 mol^{-1} cm^{-1}) in the visible region.[11] Although the configurations of bpy-complexes of Cr(II), Mn(II), and Fe(II) can not be judged from the observed absorption spectra, they would be also tetrahedral because their K_1 values in HMPA, as well as the K_1 value of tetrahedral $[Co(bpy)(hmpa)_2]^{2+}$, are similarly larger than those in H_2O. Then, the following equilibrium seems to be established in all these cases.

$$\underset{\text{tetrahedral}}{[M(hmpa)_4]^{2+}} + bpy \overset{K_1}{\rightleftharpoons} \underset{\text{tetrahedral}}{[M(bpy)(hmpa)_2]^{2+}} + 2hmpa \tag{14}$$

M(II) = Cr(II), Mn(II), Fe(II), or Co(II)

On the other hand, the absorption spectrum of bis(bpy)cobalt(II) complex in HMPA as is shown in Fig. 5 has a spectral pattern characteristic of the octahedral complexes, having the absorption band near 500 nm ($\varepsilon=5$—40 dm^3 mol^{-1} cm^{-1}).[11] Therefore, the following tetrahedral↔octahedral configurational equilibrium must be established;

$$\underset{\text{tetrahedral}}{[Co(bpy)(hmpa)_2]^{2+}} + bpy \overset{K_2}{\rightleftharpoons} \underset{\text{octahedral}}{[Co(bpy)_2(hmpa)_2]^{2+}}, \tag{15}$$

$$\underset{\text{octahedral}}{[Co(bpy)_2(hmpa)_2]^{2+}} + bpy \overset{K_3}{\rightleftharpoons} \underset{\text{octahedral}}{[Co(bpy)_3]^{2+}} + 2hmpa. \tag{16}$$

When terpy as a terdentate ligand coordinates to Co^{2+} ion, the 1:1 complex is octahedral as is shown from its absorption spectrum[11] in Fig. 5. Accordingly, this equilibrium is also a tetrahedral↔octahedral configurational change;

$$\underset{\text{tetrahedral}}{[Co(hmpa)_4]^{2+}} + terpy \overset{K_1}{\rightleftharpoons} \underset{\text{octahedral}}{[Co(terpy)(hmpa)_3]^{2+}} + hmpa, \tag{17}$$

$$\underset{\text{octahedral}}{[Co(terpy)(hmpa)_3]^{2+}} + terpy \overset{K_2}{\rightleftharpoons} \underset{\text{octahedral}}{[Co(terpy)_2]^{2+}} + 3hmpa. \tag{18}$$

As is evident from Table 2, the K_2 value of $[Co(bpy)_2]^{2+}$ and the K_1 value of $[Co(terpy)]^{2+}$ are remarkably smaller than those in H_2O, because the steric hindrance of HMPA molecules in octahedral $[Co(bpy)_2]^{2+}$ and octahedral $[Co(terpy)]^{2+}$ may be large. The reason why the K_3 value of $[Co(bpy)_3]^{2+}$ and the K_2 value of $[Co(terpy)_2]^{2+}$ in HMPA are extremely smaller than those in H_2O is probably the larger effect of the basicity of HMPA molecules than that due to their steric hindrance.

Configurations of $[Cu(bpy)]^{2+}$, and $[Zn(bpy)]^{2+}$ in HMPA. Since the steric hindrance caused by HMPA in the square planar complex or tetragonal complex is larger than that in the tetrahedral complex, but smaller than that in the octahedral one, it seems that K_1 value of the square planar or tetragonal complex in HMPA would be smaller than that in H_2O. According to both the K_1 value and the absorption spectrum observed for Cu(II)–bpy complex, it is safely said that its configuration is square planar or tetragonal.[11] Therefore, one of the following two equilibria may hold:

$$\left.\begin{aligned} &\underset{\text{tetrahedral}}{[Cu(hmpa)_4]^{2+}} + bpy \overset{K_1}{\rightleftharpoons} \underset{\text{square planar}}{[Cu(bpy)(hmpa)_2]^{2+}} + 2hmpa \\ &\text{or} \\ &\underset{\text{tetrahedral}}{[Cu(hmpa)_4]^{2+}} + bpy \overset{K_1}{\rightleftharpoons} \underset{\text{tetragonal}}{[Cu(bpy)(hmpa)_4]^{2+}}. \end{aligned}\right\} \tag{19}$$

We have reported that the solvated Zn^{2+} ion in HMPA may be octahedral, since its Stokes radius is larger than that expected if it were tetrahedral.[1] The fact that the K_1 value in HMPA is smaller about three orders of magnitude than that in H_2O is accounted for by a larger steric hindrance of HMPA molecules in octahedral $[Zn(bpy)(hmpa)_4]^{2+}$ and their larger basicity than those in the case of H_2O molecules. Accordingly, the following equilibrium seems to be established;

$$\underset{\text{octahedral}}{[Zn(hmpa)_6]^{2+}} + bpy \overset{K_1}{\rightleftharpoons} \underset{\text{octahedral}}{[Zn(bpy)(hmpa)_4]^{2+}} + 2hmpa. \tag{20}$$

General Conclusion. In HMPA, solvated Mn^{2+}, Fe^{2+}, Co^{2+}, and Cu^{2+} are tetrahedral, while solvated Zn^{2+} ion is octahedral.[1] Since an HMPA molecule is very bulky, it seems that solvated metal ions prefer the tetrahedral configurations to the octahedral ones. Gutmann and Weisz reported that mono-, di-, tri-, and tetrahalo complexes of cobalt(II) are tetrahedral in HMPA (halide ion=Cl^-, Br^-, or I^-).[2] When multidentate ligands such as bpy and terpy coordinate to metal ions in HMPA, the configurations of $[Cr(bpy)]^{2+}$, $[Mn(bpy)]^{2+}$, $[Fe(bpy)]^{2+}$, and $[Co(bpy)]^{2+}$ are also tetrahedral, while that of $[Cu(bpy)]^{2+}$ is either square planar or tetragonal. In the case of Zn(II), its configuration seems to be octahedral. The K_1 value and the absorption spectrum of Ni(II)-complex was not obtained, because the equilibria among the tetrahedral, square planar and octahedral solvated-species were too complicated to analyze them.[1] The configurations of both $[Co(bpy)_2]^{2+}$ and $[Co(terpy)]^{2+}$ are octahedral. In conclusion, it is likely that the complexes coordinated by more than three nitrogen atoms are mostly octahedral in HMPA.

The Kinetics and Mechanisms of the Racemization of Tris(*N,N'*-dimethylethanediimine)iron(II)

Satoshi TACHIYASHIKI*,† and Hideo YAMATERA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received December 15, 1980)

Tris(*N,N'*-dimethylethanediimine)iron(II) (trivial name: tris(glyoxal-bis-*N*-methylimine)iron(II)[1]), $[Fe(gmi)_3]^{2+}$, has been resolved for the first time, and its racemization mechanism has been investigated in acid solutions. A mechanism similar to that for tris(2,2'-bipyridine)iron(II) was verified from the acid dependence of the racemization rate. At 69.4 °C, 30% of the racemization proceeded by means of an intramolecular bond-rupture mechanism and the remainder by means of an intramolecular twist mechanism. The activation enthalpy and the activation entropy for the twist path were 148($\Delta H^{\ddagger}$/kJ mol^{-1}) and 110($\Delta S^{\ddagger}$/J K^{-1} mol^{-1}) respectively. These values were compared with 127 and 114 for $[Fe(bpy)_3]^{2+}$ (bpy=2,2'-bipyridine) and with 119 and 91 for $[Fe(phen)_3]^{2+}$ (phen=1,10-phenanthroline). The racemization rate was larger in organic solvents, increasing in the order water<nitromethane<formamide<dimethyl sulfoxide, which is the same as the order for the bpy and phen complexes. The rate was less dependent on the solvent in the order $[Fe(phen)_3]^{2+}>[Fe(bpy)_3]^{2+}>[Fe(gmi)_3]^{2+}$. A salt effect on the racemization rates was also observed.

The intramolecular twist mechanism[2] is one of the basic mechanisms of the stereochemical rearrangement of metal chelates. The nature of the mechanism, however, does not seem to be fully understood.[3] Many investigations have been made concerning the intramolecular stereochemical rearrangement of stereochemically nonrigid complexes by means of dynamic nuclear magnetic resonance spectroscopy.[4] The mechanisms proposed in these studies have, however, been mainly based on indirect evidence. On the other hand, the studies of inert complexes based on rather classical kinetic methods have given more definitive evidence to show the reaction mechanisms.[5]

Tris(1,10-phenanthroline)iron(II)[6] is one of the few examples of such inert complexes which racemize by means of an intramolecular twist mechanism. Iron(II) forms very stable, strongly colored complexes not only with bpy and phen, but also with *N,N'*-dialkyl-1,2-diimines.[7] The racemization of the simple *N,N'*-dialkyl-1,2-diimine complex, $[Fe(gmi)_3]^{2+}$ (gmi=$CH_3N{=}CH{-}CH{=}NCH_3$), has been studied to disclose whether or not a twist mechanism also occurs in this case, and to gain a better understanding of the characteristics of the twist mechanism.

Experimental

Materials. Preparation and Resolution of the Complexes: Tris(*N,N'*-dimethylethanediimine)iron(II) iodide, $[Fe(gmi)_3]I_2\cdot 3H_2O$, was prepared by Krumholtz's method.[1] The complex was resolved for the first time by the fractional crystallization of its $(+)_{589}$-tartratoantimonate. Racemic iodide (2.0 g, 3.6×10^{-3} mol) was dissolved in water (10.5 cm^3), and, to the resulting solution, silver $(+)_{589}$-tartratoantimonate (2.8 g, 7.2×10^{-3} mol) was added with vigorous stirring. The stirring was continued for several minutes, during which double decomposition was completed to yield the solution of the $(+)_{589}$-tartratoantimonate of the racemic complex and the insoluble silver iodide. After the latter was filtered off, the solution was heated to 40 °C and ethanol was slowly added to it until the solution became slightly cloudy. The solution was then kept overnight at 0 °C to give a crystalline precipitate. Crystals of the $(+)_{589}$-tartratoantimonate of this complex, $(-)_{589}$-$[Fe(gmi)_3](Sbtart)_2$, were filtered off from the solution, and the crystals of $(+)_{589}$-$[Fe(gmi)_3](Sbtart)_2$ were precipitated by adding ethanol to the filtrate. By repeating the fractional crystallization five times, 0.15 g of $(+)_{589}$-diastereomer ($\Delta\varepsilon_{570}=+32$) and 0.32 g of $(-)_{589}$-diastereomer ($\Delta\varepsilon_{570}=-30$) were obtained. These diastereomers were converted into active bromide by the use of the anion-exchange resin, Dowex 2-X8, by the column method. The $[\alpha]_{589}$ values for $(+)_{589}$- and $(-)_{589}$-enantiomers were +950° and −900° respectively. Anal. $(+)_{589}$-$[Fe(gmi)_3]Br_2\cdot 3H_2O$: Found: C, 27.40; H, 5.49; N, 15.96; Calcd for $C_{12}H_{30}N_6O_3Br_2Fe$: C, 27.61; H, 5.75; N, 16.10.

Tris(1,10-phenanthroline)iron(II) perchlorate was resolved through precipitation as $(+)_{589}$-tartratoantimonate according to the method of Dwyer and Gyarfas;[8] $[\alpha]_{589}=+1460°$. The resolution of tris(2,2'-bipyridine)iron(II) perchlorate through precipitation as iodide $(+)_{589}$-tartratoantimonate was carried out in a manner similar to that previously described;[9] $[\alpha]_{589}=+4970°$.

Solvent: Nitromethane was refluxed with urea, dried with anhydrous sodium sulfate, and distilled. Dimethyl sulfoxide was distilled under reduced pressure, treated with alumina, and distilled again under reduced pressure. Formamide was dried with anhydrous sodium sulfate and distilled twice under reduced pressure.

Other Reagents: Guaranteed-grade potassium chloride and potassium iodide were recrystallized from water. Guaranteed-grade hydrochloric acid was purified by azeotropic distillation. Guaranteed-grade potassium thiocyanate was recrystallized from an aqueous ethanolic (1:1) solution. All the other chemicals were of a guaranteed grade and were used without purification.

Experimental Procedure. Racemization and Dissociation of $[Fe(gmi)_3]^{2+}$: The optically active bromide was dissolved in a given solvent ($(0.42-2.5)\times10^{-4}$ M††), containing other chemicals whenever necessary. Aliquots of the solution were sealed in eleven small test tubes. They were placed in a thermostat(±0.1 °C) and taken out, one by one, at proper intervals. They were then cooled in ice water, and their circular dichroism(CD) strength was measured at 570 nm and their absorbance, at 560 nm. The apparent racemization (rate constant: k_r^{app}) was studied by following the loss of optical activity for one to five half-lives. From the changes in the absorbance of the solution during the apparent racemization, the dissociation rate (rate constant: k_d) was calculated. Both the apparent racemization and the

† Present address: Kagawa Nutrition College, Sakado, Saitama 350-02.

†† 1 M=1 mol dm^{-3}.

dissociation were first-order with respect to the metal-complex concentration in the time range of the experiments. The net rate of racemization (rate constant: k_r^{net}) was obtained as $k_r^{net}=k_r^{app}-k_d$.

Racemization of $[Fe(bpy)_3]^{2+}$ *and* $[Fe(phen)_3]^{2+}$: The $(0.5-1.0)\times10^{-4}$ M solutions of optically active perchlorates were placed in a thermostatted (±0.1 °C) quartz cell, and the change in the optical rotation (at 510 nm for the phenanthroline complex, 525 nm for the bipyridine complex) was followed on a recorder. The temperature was measured during the reaction by putting a thermister directly in the solution. The reactions were followed for one to two half-lives.

Dissociation of $[Fe(bpy)_3]^{2+}$ *and* $[Fe(phen)_3]^{2+}$: The 0.5×10^{-4} M solutions of the complex were placed in a thermostatted (±0.1 °C) quartz cell, and the change in the absorbance (at 510 nm for the phen complex, 520 nm for the bpy complex) of the solution was followed on a recorder.

The racemization and dissociation rate constants were calculated by the usual method for first-order reactions. The racemization rate constant was defined as $k_r=[\ln(\alpha_0/\alpha_t)]/t$, where α_0 and α_t are the optical rotations or the CD strengths at time zero and t respectively.

Apparatus. A JASCO ORD/UV-5 with a CD attachment was used for measuring the CD strength and the optical rotation, and for recording the CD spectra. A Hitachi 323 Spectrometer was used for recording the absorption spectra, and Hitachi 101 and 124 Spectrophotometers, for measuring the absorbances.

Results and Discussion

CD Spectrum. Figure 1 shows the absorption and CD spectra of the resolved complex. The CD spectrum of the complex is very similar to those of the bpy and phen complexes;[10] the positive and negative CD peaks near 20×10^3 cm^{-1} are attributed to charge-transfer transitions by analogy with the corresponding bands in the bpy and phen complexes. The CD peak at 28.5×10^3 cm^{-1} is that of the d-d transition ($^1T_{2g}\leftarrow{}^1A_{1g}$ in octahedral approximation), in agreement with the assignment of the absorption band near 28.5×10^3 cm^{-1} by Ito *et al.*[11] On the other hand, the CD peaks at $(25-26)\times10^3$ cm^{-1} of $[Fe(phen)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ were suggested to be

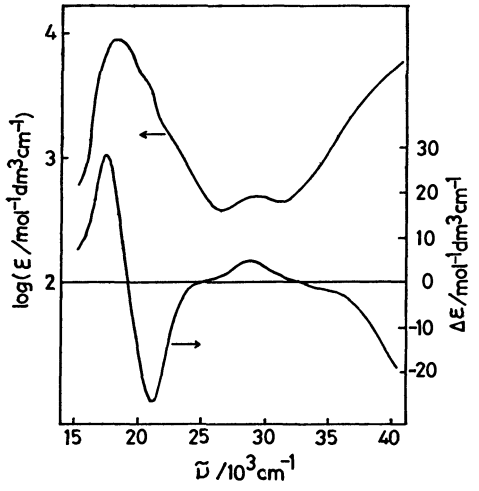

Fig. 1. Absorption (AB) and circular dichroism (CD) spectra of $(+)_{589}[Fe(gmi)_3]Br_2$ in aqueous solution.

of metal-to-ligand charge-transfer transitions.[10] In view of the d-d spectral parameters of $[Fe(phen)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$,[12] a d-d absorption band ($^1T_{2g}\leftarrow{}^1A_{1g}$ in O_h approximation) is suspected to exist around $(25-26)\times10^3$ cm^{-1}, though it is hidden by the strong CT-bands. Thus, the CD peaks of tris(1,2-diimine)-iron(II) at $(25-30)\times10^3$ cm^{-1} are probably of $^1T_{2g}\leftarrow{}^1A_{1g}$ d-d transition. The observed intensities of these CD peaks of magnetically forbidden d-d transitions may be attributed to a trigonal distortion of the complex and to mixing with charge-transfer transition.

Kinetics and Mechanism of Racemization. Racemization in a Neutral Solution: The apparent racemization, as measured by the change in optical activity, was first-order throughout approximately 90% of the reaction. The CD strength throughout the spectrum diminished monotonously to zero as the reaction proceeded. The decrease in absorbance (A) observed during this apparent racemization gave a straight line in the graph of log A *vs.* time. The decrease in absorbance was attributed to the dissociation of the complex, since the monotonous absorbance change occurred over the whole range of the absorption spectrum. The dissociation of the complex was an irreversible reaction, probably due to the immediate hydrolysis of the dissociated ligand. The formation of the bis complex from the tris complex was regarded as rate-determining;[13] *i.e.*, once one gmi ligand has been released from the tris complex, the complex will decompose irreversibly to yield an aqua-complex. Thus, the net racemization of this complex will take place exclusively by means of intramolecular mechanisms and not by intermolecular ligand-exchange processes. The net racemization rates were not affected by the presence of possible decomposition products of the complex (methylamine and/or glyoxal).

Racemization in an Acidic Solution: The decomposition of the complex is known to be acid-catalyzed,[14] and the rate expression is known to be similar to that for $[Fe(bpy)_3]^{2+}$,[6] which dissociates through an intermediate with one bond ruptured. In order to clarify the role of this process in the racemization, the racemization rate was measured at various acid concentrations. The results are depicted in Fig. 2. The observed acid dependence of the rates can be explained by the reaction scheme shown in Fig. 3. In the reaction scheme, k_r^t and $k_r^{b.r.}$ represent the rate constants of an intramolecular twist racemization process and that of an intramolecular bond-rupture racemization process respectively.

The rate constant for the apparent racemization, k_r^{app}, can be expressed as:

$$k_r^{app}=k_r^t+k_1\left(\frac{k_2+k_r^{b.r.}+k_3[H^+]}{k_{-1}+k_2+k_r^{b.r.}+k_3[H^+]}\right), \quad (1)$$

if the steady-state approximation is applied to the bond-rupture intermediate. The rate constant of acid dissociation, k_d, can be expressed as:

$$k_d=k_1\left(\frac{k_2+k_3[H^+]}{k_{-1}+k_2+k_3[H^+]}\right). \quad (2)$$

The net rate of racemization is given by: $k_r^{net}=k_r^{app}-k_d$.

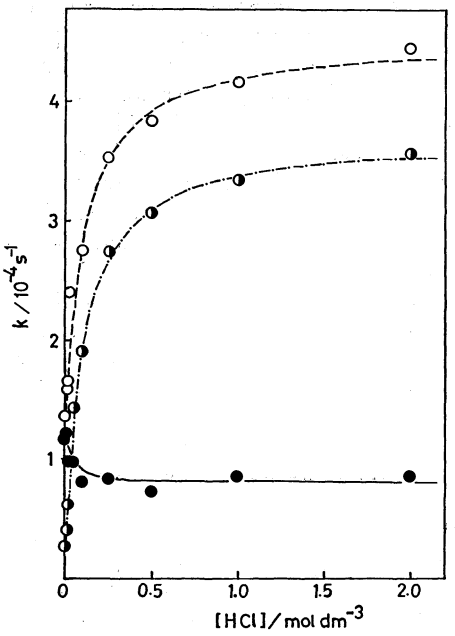

Fig. 2. Influence of acid concentration on the racemization and dissociation rate constants of $[Fe(gmi)_3]^{2+}$ at 69.4 °C and I=2.00 (HCl–KCl).
○: k_r^{app}, ◑: k_d, ●: k_r^{net}.

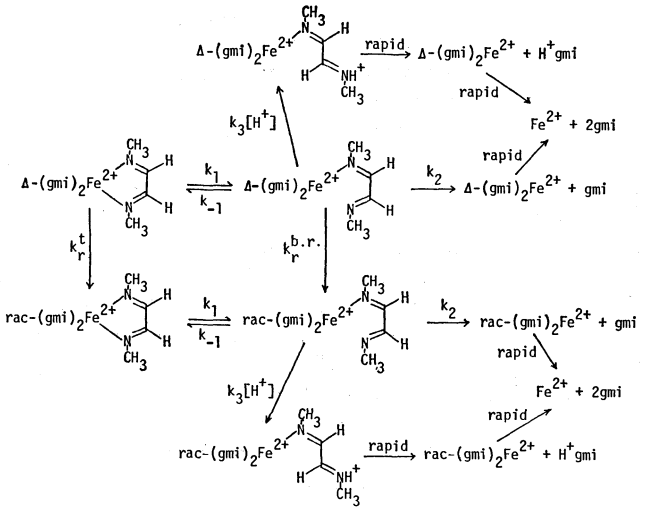

Fig. 3. The reaction scheme.

When [H⁺] is sufficiently low, the values of k_r^{app} and k_d will be approximately equal to the respective limiting values given by:

$$k_r^\circ = k_r^t + k_1\left(\frac{k_2+k_r^{b.r.}}{k_{-1}+k_2+k_r^{b.r.}}\right), \quad (3)$$

$$k_d^\circ = k_1\left(\frac{k_2}{k_{-1}+k_2}\right). \quad (4)$$

Then, Eqs. 1 and 2 can be transformed into:

$$k_r^{app} = (k_1+k_r^t) - \frac{k_{-1}+k_2+k_r^{b.r.}}{k_3}\frac{k_r^{app}-k_r^\circ}{[H^+]}, \quad (5)$$

$$k_d = k_1 + \frac{k_{-1}+k_2}{k_3}\frac{k_d-k_d^\circ}{[H^+]}. \quad (6)$$

In Fig. 4, the k_r^{app} and k_d values, observed in aqueous HCl–KCl solutions (I=2.00) at 69.4 °C, are plotted against $(k_r^{app}-k_r^\circ)/[H^+]$ and $(k_d-k_d^\circ)/[H^+]$ respectively. The values, $k_r^{app}=(1.39\pm0.02)\times10^{-4}$ s^{-1} and $k_d=(2.7\pm0.1)\times10^{-5}$ s^{-1}, observed in 2 M KCl were taken as the k_r° and k_d° values respectively. The intercepts and the slopes of the lines shown in Fig. 4 give $k_1=(3.70\pm0.10)\times10^{-4}$ s^{-1}, $(k_{-1}+k_2)/k_3=(0.102\pm0.005)$ mol dm^{-3}, $(k_1+k_r^t)=(4.52\pm0.12)\times10^{-4}$ s^{-1}, and $(k_{-1}+k_2+k_r^{b.r.})/k_3=(0.125\pm0.010)$ mol dm^{-3}. These values, together with $k_r^\circ=(1.39\pm0.02)\times10^{-4}$ s^{-1} and $k_d^\circ=(2.7\pm0.1)\times10^{-5}$ s^{-1}, lead to $k_{-1}/k_2=12.7\pm0.9$, $k_3/k_2=(129\pm13)$ mol^{-1} dm^3, and $k_r^{b.r.}/k_2=1.41\pm0.41$. The curves in Fig. 2 are the theoretical ones for k_r^{app}, k_d, and k_r^{net}, obtained on the basis of the above values.

Racemization Mechanism: The results discussed above indicate that, in a solution containing no hydrochloric acid at 69.4 °C, 70% of the racemization of $[Fe(gmi)_3]^{2+}$ occurred by way of an intramolecular twist mechanism, and the remainder, by means of an intramolecular bond-rupture mechanism. Thus, complexes with flexible ligands, such as bpy and gmi, racemize intramolecularly by means of a bond-rupture mechanism as well as by means of a twist mechanism. This is in contrast to $[Fe(phen)_3]^{2+}$, which is known to

undergo intramolecular racemization only by means of a twist mechanism because of the rigidity of the ligand. It is not clear whether a twist process proceeds *via* a trigonal or a rhombic intermediate and whether the bond-rupture intermediate is a square pyramid or a trigonal bipyramid.

Activation Parameters: Table 1 shows the racemization and dissociation rate constants of $[Fe(gmi)_3]^{2+}$ at various temperatures. Those of $[Fe(bpy)_3]^{2+}$ and $[Fe(phen)_3]^{2+}$ are listed in Table 2 for the sake of comparison. The racemization rate constants in media of different salt and acid concentrations are given in Table 3. As has been described above for the case of $[Fe(gmi)_3]^{2+}$, the nearly identical values for the racemization rate constants at acid concentrations of 1 M and 2 M suggests that the net racemization rates of the complexes in 2 M HCl correspond to the rates of twist racemization. Table 4 shows the activation parameters of the three complexes for dissociation and twist racemization; the values obtained for $[Fe(phen)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ are in good agreement with the literature values[6] (see Table 4) except that the low ΔH^* and ΔS^* values previously reported for the twist racemization of $[Fe(bpy)_3]^{2+}$ may be accompanied by greater errors than those accompanied by the present values, because the number of experimental data is smaller in the former case.

Although the complexes differ in hydrophobic properties, and thus in solvation, the entropies of activation for the twist racemization of the complexes are very similar. The large, positive activation entropies may be related to the formation of bond-expanded high-spin reaction intermediates[3] and/or to the rearrangement of the solvent sheath during the twist motion. These large, positive entropies of activation will lower the barrier for the operation of the twist mechanism by canceling a considerable part of the large activation enthalpies. The differences in activation enthalpies for the twist process between the complexes may come from differences in the ligand-field strength, which are shown by the CD spectra of the complexes. The ligand-field activation energies will become greater with the increase in the ligand-field strength if the reaction intermediates of racemization are similar for the three complexes. The observed activation parameters suggest that the ligand-field strength influences the ligand-field activation energy, but not so greatly as to change the mechanism.

The activation enthalpies of $[Fe(gmi)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ for the dissociation *via* bond-rupture intermediates are lower than those for the twist racemization, while the enthalpy of activation for the dissociation of $[Fe(phen)_3]^{2+}$ is higher than that for the twist racemization. Unlike the flexible bpy and gmi, the rigid phenanthroline ligand hardly serves at all as a monodentate ligand to form a bond-rupture intermediate leading to dissociation. Thus, two bonds have to be broken simultaneously in order for the ligand to be liberated from the complex, and a greater activation enthalpy is required for the dissociation of $[Fe(phen)_3]^{2+}$.

Salt Effects: The racemization of $[Fe(phen)_3]^{2+}$ was found to be retarded by KCl and accelerated by KI and KSCN. These salt effects have been attributed to ion-pair formation.[15] The salt effects on the racemization of $[Fe(gmi)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ have also been studied. The racemization rates of the complexes decreased with an increase in the KCl concentration, as is shown in Table 3. The racemization rates of $[Fe(gmi)_3]^{2+}$ increased in the presence of KSCN, but the addition of KI had no effect. The dissociation rates of $[Fe(gmi)_3]^{2+}$ increased in the presence of KSCN, but decreased slightly in the presence of KI. The results are shown in Fig. 5. Analyses of the data with due consideration of ion-pair formation[15] gave the racemization and dissociation rate constants of free and ion-paired complexes, and also the ion-association constants (Table 5). The curves in Fig. 5 were obtained by calculation on the basis of the values listed in Table 5.

The intramolecular racemization rates of the ion-pair increase in the order $I \approx Cl < SCN$, and the dissociation rates, $I < Cl < SCN$. The sequence is similar to that for $[Fe(phen)_3]^{2+}$; this gives support for the previously proposed mechanism of the nucleophilic

interaction of the anions with complex cations.[15]

Solvent Effects: In spite of several investigations carried out thus far,[16] the nature of the solvent effects on the racemization rates of tris(1,2-diimine)iron(II) is not yet well understood. In order to compare the effects of solvents on the racemization rates of $[Fe(gmi)_3]^{2+}$, $[Fe(bpy)_3]^{2+}$, and $[Fe(phen)_3]^{2+}$, their racemization rates were observed in water, dimethyl sulfoxide (DMSO), nitromethane, and formamide. The results are summarized in Table 6. The net racemization rates were larger in organic solvents than in an aqueous solution. The dissociation rates of $[Fe(bpy)_3]^{2+}$ and $[Fe(phen)_3]^{2+}$ were reported to be not so large as the racemization rates in organic solvents.[16b,17] Thus, the increase in racemization rates in organic solvents can reasonably be considered to be due to the acceleration of the intramolecular process.

The abilities of the solvents accelerating the racemization were in the order DMSO>formamide>nitromethane>water for the three complexes. This order may be correlated with the polarizability of a solvent, by analogy with the fact that the effect of nucleophiles accelerating the intramolecular racemization of $[Fe(phen)_3]^{2+}$ in an aqueous solution is correlated with their polarizability.[15] The electronic polarization of a solvent is related to its refractive index on the Na D line, the values being 1.476, 1.446, 1.380, and 1.333 for DMSO, formamide, nitromethane, and water respectively; this order of decreasing refractive index is consistent with the decreasing order of the accelerating ability of a solvent shown above. However, this cannot be extended to other solvents. The order of the ability to accelerate the racemization of $[Fe(phen)_3]^{2+}$ was observed to be DMSO>acetone≈methanol > acetonitrile > formamide > nitrobenzene ≈ nitromethane>water,[18] whereas the order of the refractive index was nitrobenzene>DMSO>formamide >nitromethane>acetone > acetonitrile > water > methanol.

For the racemization of $[Ge(acac)_3]^{+}$ [19] and $[Ni(phen)_3]^{2+}$ [20] in organic solvents, the accelerating ability of the solvent was nicely correlated with Gutmann's donor number,[21] a parameter to express the electron-donating ability of a solvent molecule, although the mechanism for racemization differs from complex to complex. For the racemization of $[Fe(1,2\text{-diimine})_3]^{2+}$, the accelerating ability of a solvent may also be correlated with the donor number, the order of which is DMSO>methanol≳H_2O≳acetone>acetonitrile>nitrobenzene>nitromethane, in rough agreement with the trend in the acceleration of the racemization, if water is regarded as an exception. The correlation of the racemization rate of $[Fe(1,2\text{-diimine})_3]^{2+}$ in organic solvents with the polarizability and/or donor number of the solvents may indicate the assistance of solvent molecules in the twist racemization.

As is shown in Table 6, the extent to which the rate is affected by the solvent is decreased in the order $[Fe(phen)_3]^{2+}$>$[Fe(bpy)_3]^{2+}$>$[Fe(gmi)_3]^{2+}$. This order is consistent with the expectation that the most hydrophobic substance $[Fe(phen)_3]^{2+}$ would interact with an organic solvent most strongly, and the least hydrophobic substance $[Fe(gmi)_3]^{2+}$, least strongly. Thus, solvation plays some role in the racemization of tris(1,2-diimine)iron(II) complexes, as was suggested by Van Meter and Neumann.[16c]

13) Gmi, one of the Shiff bases, is synthesized from glyoxal and methylamine by only a template reaction. It is not stable in a free form. Once the ligand has been released from the complex cation, it is immediately hydrolyzed to give the starting materials. This was supported by the fact that the addition of $CoCl_2$ or $NiCl_2$ (5×10^{-4}—0.5 M) as a masking agent of the released free ligand did not change the dissociation rates. The dissociation rate constant thus obtained was independent of the wavelength (in the visible range) where the measurements were made. The reaction was first-order in the complex from the very beginning. Thus, the formation of a bis complex from a tris one must be rate-determining, as was the case with $[Fe(bpy)_3]^{2+}$ and $[Fe(phen)_3]^{2+}$.

Study on the Regeneration of Mn_2O_3 Catalyst for Simultaneous Abatement of NO_x and SO_x

Toshio Sato, Akifumi Ueno,*,† Naoyuki Todo, Minoru Kurita, Hiroyuki Hagiwara, Akiko Nishijima, and Yoshimichi Kiyozumi

National Chemical Laboratory for Industry, Yatabe-cho, Tsukubagun, Ibaraki 305

(Received December 22, 1980)

A technique to regenerate catalysts used for the simultaneous abatement of NO_x and SO_x in flue gases was investigated. Formation of sulfate ions on the metal which is an active component of the catalyst was proved to be a poison for the catalysis. The most effective means to remove the sulfate ions on the catalyst is to heat the used catalyst at 300 °C in NH_3–water vapor.

It has been proposed to make use of coal for saving liquid fuels, although emission of NO_x and SO_x may be enhanced by the coal combustion. Hence, the development of catalysts to remove NO_x and SO_x simultaneously has been desired. The present authors have investigated catalysts for the removal of NO_x in flue gases using NH_3 as reducing reagent,[1] and have started to develop catalysts for the simultaneous removal of NO_x and SO_x on the basis of the results obtained so far. The principle of our techniques for the simultaneous abatement was reported in the previous paper.[2] It was also reported that Mn_2O_3 and Mn_2O_3/Co_3O_4 had the highest activities for the removal of NO_x and SO_x of all the transition metal oxides and their mixtures.[2] The activities, however, decreased with the reaction time, and became about 50% of the initial values. The purpose of the present work is to study the mechanism of the catalyst deactivation and to develop the techniques to regenerate the used catalysts.

Experimental

The catalyst employed in the present work is Mn_2O_3 which was prepared by the precipitation method using $Mn(NO_3)_2 \cdot 6H_2O$ and Na_2CO_3. The precipitates obtained were calcined in air at 550 °C for 3 h. The catalyst thus prepared was crushed to particles with ≈1 mm in diameter. The experiments were carried out using a conventional flow reactor with 5 ml of the catalyst at a space velocity of 10000 h^{-1}. The composition of the gas passed through the catalyst bed was as follows; ≈500 ppm of SO_2, ≈250 ppm of NO, ≈500 ppm of NH_3, ≈3% of oxygen, ≈10% of water vapor, and nitrogen as a balance gas. The activities were measured by the analyses of NO and SO_2 concentrations at the inlet and outlet of the reactor, which were made using an NO analyser of chemiluminescence type and an SO_2 analyser of NDIR type, respectively. The surface area of the catalyst was measured by the BET method using nitrogen at −196 °C. An infrared spectroscopy was used to identify the species formed on the catalyst during the reaction. Experiments for the catalyst regeneration were made in the same reactor employed for the activity measurements. The catalysts used were regenerated in the following gases: 1) ≈20% of water vapor in N_2, 2) ≈20% of water vapor in CO_2, and 3) ≈20% of water vapor and ≈5% of NH_3 in N_2 stream. The temperature employed in the regeneration experiment was in the range of 250—350 °C. To estimate the performance of the catalyst for practical use, a life test was performed for 200 h with the regeneration of the catalyst after every 20 h of the reaction. In this experiment a swing reactor[3] was employed, which consisted of two reactors with the same amount of catalyst peacked in each reactor. While one reactor was used for the reaction, the other was used for the regeneration.

Results

The activity of Mn_2O_3 catalyst for SO_2 acceptance was measured at the temperatures between 150—400 °C (Fig. 1). The amount of SO_2 absorbed in the catalyst was estimated in a similar way shown in the previous paper.[2] Infrared spectra were measured for the catalysts used at various temperatures so as to identify the species formed by SO_2 absorption (Fig. 2). The regeneration of the catalyst which was used for the reaction at 200 °C for 40 h was done by heating it in various gases. The results obtained were summarized in Table 1. In Fig. 3 the surface area of the catalysts regenerated is shown. The result seems to indicate that the activities of the catalysts recovered were proportional to the surface areas of the catalysts regenerated. Accordingly, the life test of the catalyst was carried out with subsequent regeneration using ≈20% of water vapor and ≈5% of NH_3 in N_2 stream at 300 °C, under whose conditions the surface areas of the used catalysts were recovered almost completely. Infrared spectra of the catalysts regenerated were shown in Fig. 4. Figure 4-c shows an infrared spectrum of the catalyst regenerated by water vapor and NH_3 in N_2 stream at 300 °C for 2 h. Figure 4-d shows an infrared spectrum of the catalyst after 4 cycles of the reaction (20 h) and

Discussion

The adsorption of SO_2 on metal oxides was studied by Galderbank *et al.*,[4] who reported that the adsorption isotherms at low temperatures were expressed in a different form from those at high temperatures. In the present work it was observed that the amount of SO_2 accepted in the catalyst decreased up to 250 °C, and then increased with the elevation of the temperature (Fig. 1). To understand this result, it is important to know the species formed on the catalyst when SO_2 was accepted at various temperatures. The catalyst used for the reaction was submitted to an infrared analysis. As is seen in Fig. 2, the species formed in the catalyst were different depending on the temperatures of the reaction. Manogue[5] and Lunsford[6] studied the adsorption of SO_2 on CuO and MgO, respectively, by means of infrared spectroscopy. They observed formation of sulfate and sulfite ions on both oxides. Furthermore, they revealed that sulfate ions in the bulk oxides showed infrared bands at the lower wave numbers (704 cm^{-1} for CuO and probably 860 cm^{-1} for MgO), while those on the surface of the oxides were not detected because of their structual symmetry. In the present study, an infrared band appeared at 820 cm^{-1} for the catalyst used at the temperatures higher than 300 °C (Fig. 2-b), while a trace or no absorption band was observed in the temperatures lower than 300 °C (Fig. 2-c). This means that the migration of the sulfate ions into the bulk of the catalyst will be enhanced at the temperatures higher than 300 °C, as was reported by Keppler[7] who observed the formation of bulk sulfate ions around 350 °C in metal oxides. When the catalyst was used at 200 °C, infrared bands were observed at 1410 cm^{-1} and 1175 cm^{-1}, and weakly around 3300 cm^{-1}. These bands mean that ammonium sulfates or sulfites were formed on the catalyst at this reaction temperature, since the band at 1410 cm^{-1} is characteristic of ammonium ions and that at 1175 cm^{-1} of both sulfates and sulfites. The weak band around 3300 cm^{-1} showed an existence of the species containing NH_x group. These bands were not observed at the higher temperatures due to the decomposition of the ammonium salts, their decomposition temperatures being about 250 °C. A band appeared at 1610 cm^{-1} when the reaction was carried out at 150 °C (Fig. 2-b). This band may be assigned to the water vapor condensed on the surface of the catalyst. As SO_2 and SO_3 on the catalyst may react with this water vapor to form H_2SO_3 and H_2SO_4, the band at 1175 cm^{-1} characteristic of sulfates and sulfites became strong (Fig. 2-d). The band at 1410 cm^{-1} shows that a small amount of ammonium salts were produced. From these observations it was concluded that the species formed on the catalyst were classified as follows depending on temperatures;

1) Temperatures around 150 °C: SO_2 was accepted in the forms of H_2SO_4 and H_2SO_3 as well as in the forms of ammonium salts.
2) Temperatures around 200 °C: Main species produced were ammonium salts.
3) Temperatures around 250 °C: The ammonium salts were decomposed to ammonia and SO_x adsorbed on the catalyst. A part of SO_x was released to gas phase and the others migrated into the bulk of the catalyst.
4) Temperatures higher than 300 °C: The migration of the sulfate ions was enhanced, and a large amount of the bulk sulfates was produced.

Thus, SO_2 was trapped and accumulated in the catalyst in the present experimental conditions. Hence, a regeneration technique was necessary to be developed for practical use of this catalyst. There have been several papers which proposed catalyst regenerations by heating at high temperatures. Kasaoka *et al.*[8] studied the sulfation of metal oxides and the thermal regeneration of the metal sulfates to the oxides at 700—750 °C in N_2 and air streams. After 30 min of sulfation, the catalysts were well regenerated. They did not mention, however, how well the catalysts were regenerated when the catalysts had been used for a prolonged time. In our experiments, it was observed that about 30% of Mn_2O_3 became $MnSO_4$ or $MnSO_3$ after 30 h reaction at 400 °C. It was also observed that the regeneration to Mn_2O_3 needed the temperature as high as 850 °C in N_2 and air streams. The surface area of the catalyst thus regenerated was less than 0.1 m^2/g, and no activity for the SO_2 acceptance was recovered (Table 1 and Fig. 3). Accordingly, we studied the regeneration at lower temperatures using a few kinds of gas mixtures to prevent reduction of the surface area of the catalyst.

Another point to be mentioned in our regeneration experiments was that the abatement reaction of both NO_x and SO_x was carried out at the temperatures as low as 200 °C, since the bulk sulfates formed at high temperatures were hard to be removed from the catalyst by our regeneration methods. The space velocity employed for the regeneration was 5000 h^{-1}. As the gas for regeneration CO_2 was employed, since $MnSO_4$ was expected to be regenerated to Mn_2O_3 through the formation of $MnCO_3$.[9] Ammonia was employed to let it react with SO_x adsorbed on the catalyst surface and form ammonium salts which are

then decomposed to NH_3 and SO_2 in the gas phase. This method seems to prevent the surface sulfate ions from migrating into the bulk of the catalyst. As is seen in Fig. 3 and Table 1, the most effective means to regenerate the surface area and the activity of the catalyst was to heat in the gas stream containing ≈20% water vapor and ≈5% of ammonia at 300 °C for 2 h. The infrared spectrum of the catalyst thus regenerated showed that a small amount of the sulfates remained unremoved (Fig. 4-c). Unfortunately, this bulk sulfates unremoved proved to accumulate in the catalyst in the every regeneration procedure, reducing the life of the catalyst. The most important point for the regeneration techniques seems to sweep out the sulfates completely from the catalyst. During the life test of the catalyst with the subsequent regeneration after 20 h of the reaction, a small part of the catalyst was submitted to the measurement of the surface area. The surface area of the catalyst regenerated decreased after every regeneration probably due to the accumulation of the sulfates. The rate of deactivation of the catalyst regenerated also became higher after every regeneration (Figs. 5 and 6). The infrared spectrum shown in Fig. 4-d corresponds to the catalyst observed after 4th regeneration procedure. This represents the accumulation of the sulfate ions in the catalyst.

Metal Complexes Coordinating Pyridine Derivatives. II.[1] Circular Dichroism and Magnetic Circular Dichroism Spectra of Chromium(III) Complexes in the Region of Pyridine Ring Absorption Band

Yukihiro YAMAMOTO* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560

(Received December 22, 1980)

Dianionochromium(III) complexes coordinating (*S*)-*N*,*N*′-bis(2-pyridylmethyl)propylenediamine (abbrev. *S*-picpn) or (*S*)-1-(2-pyridyl)ethylamine (abbrev. *S*-pea) show CD spectra of a dispersion type in the region of pyridine ring absorption band. Utilizing the data of X-ray crystal structure analysis of *Δ-cis-α*-[$CrCl_2$(*S*-picpn)]Cl, the difluoro complex shows the correct exciton CD sign pattern expected from a simple theory but the dichloro and dibromo complexes the inverse sign pattern. The latter fact is explained in terms of overlapping of the pyridine ring absorption band with the halogeno-to-chromium charge transfer band, referring to MCD spectra. The absorption and MCD bands appeared in the region 30—35 × 10^3 cm^{-1} for all the chromium(III) complexes are assigned to the spin-forbidden $\pi\rightarrow\pi^*$ transition of the coordinated pyridine group.

When two or three ligands having a π electron system coordinate to take a chiral configuration around a metal ion, an exciton splitting of the CD (circular dichroism) band emerges in the region of the $\pi\rightarrow\pi^*$ transition,[2-4] 1,10-phenanthroline, 2,2′-bipyridine, acetylacetonato,[5,6] and tropolonato[7] ligands being typical examples. Several reports are available also for the exciton CD splitting of pyridine ring absorption band, but the treatment remained so far quite unsatisfactory. Bosnich pointed out firstly the occurence of exciton coupling in *cis-α*-[CoX_2(*S*-picpn)]$^{n+}$ and *cis*-[$CrCl_2$(*S*-picpn)]$^+$ complexes[8] (*S*-picpn=(*S*)-*N*,*N*′-bis-(2-pyridylmethyl))propylenediamine). Later Cragel and Brubaker discussed the case of the *cis-β*-cobalt(III) complexes,[9] but assigned incorrectly the *cis-β* structure for a violet $(+)^{C.D.}_{600}$-*cis-α*-[$CoCl_2$(*S*-picpn)]$^+$.[1] On the other hand, it has been claimed by Branca *et al.* that no exciton interaction occurs between the two pyridine rings in *trans* positions for iron(III) complexes coordinating *N*,*N*′-bis(2-pyridylmethyl)ethylenediamine (abbrev. picen) because of far distance of the two pyridine rings.[10]

In the present paper, we deal with the exciton splitting of chromium(III) and cobalt(III) complexes of *S*-picpn, picen, pma (=2-pyridylmethylamine), and *S*-pea (=(*S*)-1-(2-pyridyl)ethylamine), referring to the MCD (magnetic circular dichroism) spectra. Moreover, the assignment of a weak absorption band which emerges in the region of 30—35 × 10^3 cm^{-1} for the complexes having the coordinated pyridine group, is attempted.

Experimental

Ligands. *2-Pyridylmethylamine (pma)*: This ligand was purchased from Aldrich Co.

(S)-1-(2-Pyridyl)ethylamine (S-pea): The (*R*,*R*)-hydrogen tartrate diastereomer was prepared by the method in literature;[11] $[\alpha]_{589}$ +3.9° (c=1.00 × 10^{-2} g cm^{-1}, water) (lit,[11] $[\alpha]_{589}$ +4.3°). To an aqueous solution of the diastereomer was added an equimolar amount of barium chloride. After filtering off the precipitated barium (*R*,*R*)-tartrate, an excess amount of potassium hydroxide was added to the filtrate. An oily product separated was extracted with ether. The ether solution was dried on anhydrous sodium sulfate and ether was evaporated off to obtain the free amine. The free amine was distilled at atmospheric pressure; bp 189 °C, $[\alpha]^{14}_{589}$ −27.7° (c=0.01 g cm^{-3}, water).

(S)-N,N′-Bis(2-pyridylmethyl)propylenediamine (S-picpn) and N,N′-Bis(2-pyridylmethyl)ethylenediamine (picen): These were prepared from (*S*)-propylenediamine or ethylenediamine and 2-pyridinecarbaldehyde by the method of Goodwin and Lions.[12]

Cobalt(III) Complexes. *Δ-(−)*$_{589}$-[$CoCl_2$(*en*)$_2$]$Cl\cdot H_2O$: The racemic complex was resolved with ammonium $(+)_{589}$-(1*R*, 3*S*, 4*S*, 7*R*)-3-bromocamphor-9-sulfonate.[13]

trans(*py*)cis(*H_2O*)-[*Co*(H_2O)$_2$(*pma*)$_2$]$HSO_4\cdot SO_4$: The complex was prepared by the method of literature.[14]

cis-[*Co*(H_2O)$_2$(*en*)$_2$]Cl_3: This was prepared by the method of the literature.[15]

Δ-cis-α-[*$CoCl_2$*(S-*picpn*)]*Cl*: The complex was prepared previously.[1]

Chromium(III) Complexes. *Λ-(−)*$_{589}$-[*$CrCl_2$*(*en*)$_2$]$Cl\cdot H_2O$: The racemic complex was prepared as reported by Pedersen[16] and resolved by the method of Selbin and Bailar[17] with ammonium $(+)_{589}$-(1*R*,3*S*,4*S*,7*R*)-3-bromocamphor-9-sulfonate.

cis-[*CrF_2*(*en*)$_2$]*I*: This was prepared by the method of literature.[18]

trans-[*CrF_2*(*py*)$_4$]*Br*: This complex was prepared by the method of literature.[19]

Δ-trans(*py*)cis(*Cl*)-[*$CrCl_2$*(*pma*)$_2$]ClO_4, trans(*py*)cis(*F*)-[*CrF_2*(*pma*)$_2$]*Br*, trans(*py*)cis(*Cl*)-[*$CrCl_2$*(*pma*)$_2$]*Cl*, trans(*py*)-cis(*H_2O*)-[*Cr*(H_2O)$_2$(*pma*)$_2$](NO_3)$_3$, cis-α-[*$CrCl_2$*(*picen*)]*Cl*, *and* cis-*β*-[*$CrCl_2$*(*picen*)]NO_3: These were prepared by the methods of Michelsen.[20]

fac-[*$CrCl_3$*(*py*)$_3$]: This was prepared by the method in the literature.[21]

Λ-trans(*py*)cis(*Cl*)-[*$CrCl_2$*(S-*pea*)$_2$]*X*: The samples prepared by the following three methods showed the same CD spectra; that is, only one isomer was obtained.

(a) Chromium shot (0.5 g, 10 mmol) was crushed and dissolved in 6 mol dm^{-3} hydrochloric acid (15 cm^3) under a current of nitrogen. The blue solution was evaporated in a vacuum rotary evaporator and heated to dryness. To the residue was added *S*-pea (2.5 g, 20 mmol in 10 cm^3 pyridine). The mixture was heated and then a solution of iodine (1.2 g, 4.7 mmol in 4 cm^3 pyridine) was added. After refluxing for twenty minutes, the violet precipitate was filtered and washed with ethanol. The crude product was treated with silver chloride, the resulting iodide being filtered. The filtered solution was poured onto an SP-

Sephadex C-25 column ($\phi 35 \times 400$ mm) and eluted with 0.1 mol dm^{-3} sodium chloride aqueous solution acidified with hydrochloric acid (0.12 mol dm^{-3}). Only one band was eluted and collected in several fractions. The former 90% parts of the fractions showed the same CD spectrum; they were combined and concentrated in a vacuum rotary evaporator. The deposited sodium chloride was removed from the concentrated solution, to which was added sodium iodide. The desired violet complex precipitated. Found: C, 31.53; H, 4.43; N, 10.33%. Calcd for $[CrCl_2(S\text{-pea})_2]I \cdot 2H_2O = C_{14}H_{20}N_4Cl_2CrI \cdot 2H_2O$: C, 31.72; H, 4.56; N, 10.57%.

(*b*) The preparation was performed as in (*a*) using hydrobromic acid instead of hydrochloric acid. The obtained complex was adsorbed on an SP-Sephadex C-25 column and eluted with 0.5 mol dm^{-3} sodium chloride aqueous solution. The only one band was eluted and collected in several fractions, all of which showed the same CD spectrum. The product was a dinuclear complex. Found: C, 28.62; H, 4.12; N, 9.55%. Calcd for $[\{Cr(OH)(S\text{-pea})_2\}_2]I_4 \cdot 2.5H_2O = C_{28}H_{42}N_8O_2Cr_2I_4 \cdot 2.5H_2O$: C, 28.52; H, 4.02; N. 9.50%. The dinuclear complex was dissolved in water and sodium perchlorate was added. The obtained perchlorate salt of dinuclear complex was dissolved in concd hydrochloric acid. After 10 d, several drops of 70% perchloric acid was added. After ten more days, violet crystals of the desired mononuclear complex appeared. Found: C, 33.64; H, 4.74; N, 11.11%. Calcd for $[CrCl_2(S\text{-pea})_2]ClO_4 \cdot 2H_2O = C_{14}H_{20}N_4O_4Cl_3Cr \cdot 2H_2O$: C, 33.45; H, 4.81; N, 11.41%.

(*c*) Anhydrous chromium(III) chloride (3.9 g, 24.6 mmol) was suspended in dimethyl sulfoxide (12 cm^3). Six grams of *S*-pea (49.1 mmol) was added with stirring. After half an hour, ethanol (20 cm^3) was added to the reaction mixture, and the red-violet product was filtered. The product was extracted with an appropriate amount of hot water (70 °C). The extracted solution was poured onto an SP-Sephadex C-25 column ($\phi 40 \times 400$ mm) and eluted with 0.1 mol dm^{-3} sodium chloride aqueous solution acidified with hydrochloric acid (0.12 mol dm^{-3}). Five bands, a violet one (i), a red-violet one (ii), blue violet one (iii), and two violet ones (iv) and (v), were eluted in this order. Eluate (i) was condensed to a small volume in a vacuum rotary evaporator; violet crystals began to appear and whole was left in a refrigerator overnight. Violet crystals were filtered and washed with ethanol–water (1:1), ethanol and ether. Found: C, 37.75; H, 5.42; N, 12.51%. Calcd for $[CrCl_2(S\text{-pea})_2]Cl \cdot 2.5H_2O = C_{14}H_{20}N_4Cl_3Cr \cdot 2.5H_2O$: C, 37.56; H, 5.63; N, 12.51%. From eluates (ii), (iii), (iv), and (v), no pure crystals were obtained.

Λ-trans*(py)*cis*(F)*-[*CrF*$_2$(S-*pea*)$_2$]*Br*: To a solution of $[CrF_2(py)_4]Br$ (0.50 g) in 2-methoxyethanol was added *S*-pea (0.25 g) and the mixture was refluxed for twenty minutes, A saturated ethanol solution of LiBr was added to it and the precipitates obtained were recrystallized twice from water by adding a saturated ethanol solution of LiBr. Found: C, 30.37; H, 4.56; N, 10.09%. Calcd for $[CrF_2(S\text{-pea})_2]Br \cdot 2.5H_2O \cdot LiBr = C_{14}H_{20}N_4BrCrF_2 \cdot 2.5H_2O \cdot LiBr$: C, 31.05; H, 4.56; N, 10.34%. The complex was dissolved in concd HCl and saturated with HCl gas. After three days, the solution was concentrated and the precipitate was recrystallized from water. Found: C, 34.95; H, 5.02; N, 11.70%. Calcd for $[CrCl_2(S\text{-pea})_2]Br \cdot 2H_2O = C_{14}H_{20}N_4BrCl_2Cr \cdot 2H_2O$: C, 34.80; H, 5.01; N, 11.60%. The CD spectrum of this dichloro complex was the same as that of $[CrCl_2(S\text{-pea})_2]X$ prepared in the above section.

Δ-cis-α-[*CrCl*$_2$(S-*picpn*)]*Cl*, Λ-cis-α-[*CrCl*$_2$(S-*picpn*)]*Cl*, Δ-cis-α-[*CrBr*$_2$(S-*picpn*)]*I*, Λ-cis-α-[*CrBr*$_2$(S-*picpn*)]*Br*, *and* Λ-cis-α-[*CrF*$_2$(S-*picpn*)]*Br*: The preparations of these complexes was described in a previous paper.[1]

cis-α-[*CrF*$_2$*(picen)*]*Br*: To a solution of $[CrF_2(py)_4]Br$ in 2-methoxyethanol was added the stoichiometric amount of picen and the mixture was refluxed for thirty minutes. After cooling, a saturated ethanol solution of LiBr was added. The obtained precipitates were recrystallized from water. The product was eluted with 0.1 mol dm^{-3} NaCl aqueous solution on an SP-Sephadex C-25 column, only one band being observed. Found: C, 34.06; H, 4.85; N, 11.88%. Calcd for $[CrF_2(picen)]Br \cdot 2.5H_2O \cdot 0.3LiBr = C_{14}H_{18}N_4BrCrF_2 \cdot 2.5H_2O \cdot 0.3LiBr$: C, 34.58; H, 4.77; N, 11.52%. The complex was dissolved in concd HCl and saturated with HCl gas below −13 °C. The solution was left for three days and then concentrated with a rotary evaporator. The precipitated product was recrystallized from water and dried in a vacuum desiccator over $CaCl_2$. Found: C, 41.12; H, 4.43; N, 13.76%. Calcd for $[CrCl_2(picen)]Cl \cdot 0.5H_2O = C_{14}H_{18}N_4Cl_3Cr \cdot 0.5H_2O$: C, 41.05; H, 4.68; N, 13.68%. The absorption spectrum of this dichloro complex was the same as that of *cis*-α-$[CrCl_2(picen)]Cl$. Thus, the structure of the difluoro picen complex is determined to be *cis*-α.

Measurements. The visible and ultraviolet absorption spectra were measured with a Shimadzu UV-200 and a Hitachi 330 spectrophotometers. The CD and MCD spectra were measured on a JASCO MOE-1 spectropolarimeter. The specific rotation was measured with a JASCO DIP-4 polarimeter. All the measurements were performed at room temperature.

Results and Discussion

Structural Assignments of the Complexes. The structures of *S*-picpn complexes were assigned previously.[1] Only one isomer was prepared for the dinuclear *S*-pea complex, $[\{Cr(OH)(S\text{-pea})_2\}_2]^{4+}$, the structure of which has been determined as *Λ-trans*(py)*trans*(py),[22] the most probable one from the viewpoint of avoiding the steric hindrance between four pyridine rings. The $[CrCl_2(S\text{-pea})_2]^+$ complex derived from the dinuclear complex is assigned to the *trans*(py)*cis*(Cl) structure. The absolute configuration of this *S*-pea complex is assigned to *Λ* from the comparison of CD spectrum in the d-d transition region with that of *Λ*-$[CrCl_2(en)_2]^+$. No other isomer was obtained for the dichloro complex in any of the three different preparations. The stereospecificity may exist in the formation of $[CrCl_2(S\text{-pea})_2]^+$ complex to produce only the *Λ-trans*(py) isomer. The structures of $[CrF_2(S\text{-pea})_2]^+$ and $[CrF_2(picen)]^+$ are *Λ-trans*(py)*cis*(F), and *cis*-α, respectively (see Experimental).

Exciton Interaction between Pyridine Rings. When two identical chromophores (π system) exist in a chiral molecule, they couple to produce an exciton splitting in absorption and related CD bands, the splitting interval being expressed by exciton interaction energy $2V_{12}$ (Fig. 1).[23] The following explanation is restricted to the coupled chromophore having C_2 symmetry, being harmonized with all the present complexes, which have at least one C_2 or pseudo C_2 axis. In Fig. 1 is shown the exciton splitting for positive V_{12}; the splitting component due to the transition moment pair A symmetry is higher in energy than that of B. The rotatory strength R of A and B com-

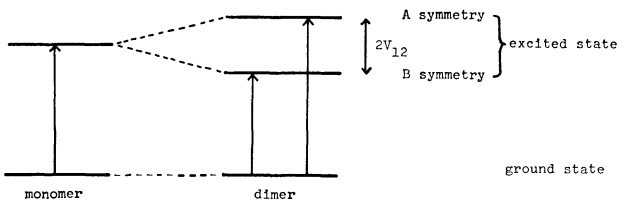

Fig. 1. The exciton splitting with positive V_{12}.

ponents are given by $(\pi\bar{\nu}/2)R'$ and $-(\pi\bar{\nu}/2)R'$, respectively, $\bar{\nu}$ being the wave number of the transition. The rotatory element, R', is written as follows:

$$\vec{R}' = \vec{\mu}_1 \times \vec{R}_{12} \times \vec{\mu}_2 \quad (1)$$

$$= \mu^2 d \sin\alpha \sin\beta \sin\theta, \quad (1)'$$

$$(0<\alpha<180°,\ 0<\beta<180°)$$

where $\vec{\mu}_k$ (k=1 or 2) are transition moments, $\vec{R}_{12}$ is vector from the center of gravity of $\vec{\mu}_2$ to that of $\vec{\mu}_1$, and μ is the magnitude of transition moment. The definition of parameters, d, α, β, and θ are shown in Fig. 2, where d is the distance between the two transition moments AB (chromophore 1) and A'B' (chromophore 2), and θ the dihedral angle between the two planes BCC' and B'C'C, its displayed orientation being taken as positive. Thus, R' is positive at $0<\theta<180°$; and negative at $0>\theta>-180°$.

The absorption spectrum of pma is shown in Fig. 3. In this study the lower energy band, ^1L_b, of pyridine ring at about 39800 cm^{-1} is treated. The transition moment direction of this absorption band is depicted with an arrow in Fig. 3, and supposed to be independent of the alkyl substitution (R) at 2 position of pyridine ring.

In Fig. 4 is shown the transition moments in the

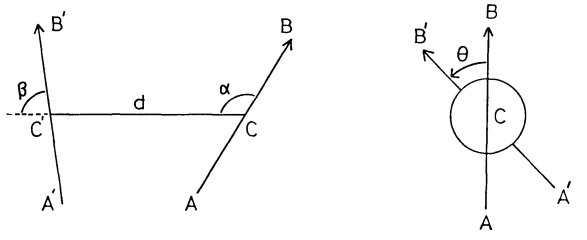

Fig. 2. The parameters, d, α, β, and θ defining the rotatory element R'.

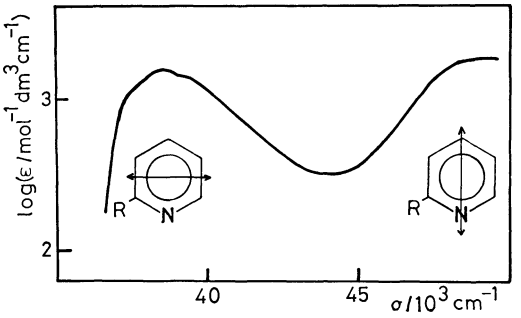

Fig. 3. Absorption Spectrum of pma ($R=CH_2NH_2$) in water, and the directions of transition moments for ^1L_b (lower energy) and ^1L_a (higher energy) bands.

case of Λ-*cis*-α-$[CrCl_2(picen)]^+$. The exciton interaction energy, V_{12}, is generally written,[23b]

$$V_{12} = \frac{1}{d^3}\{(\vec{\mu}_1\cdot\vec{\mu}_2) - 3(\vec{\mu}_1\cdot\vec{R}_{12})(\vec{\mu}_2\cdot\vec{R}_{12})/d^2\}. \quad (2)$$

The centers of gravity of transition moments being set on the x axis and the exciton interaction energy being approximated as coulomb interaction energy between point dipoles, V_{12} can be written as follows,[23b]

$$V_{12} = \frac{\mu^2}{d^3}(m_1m_2 + n_1n_2 - 2l_1l_2),$$

where l_k, m_k, and n_k (k=1 or 2) are the direction cosines for the transition moment k against the coordination axes x, y, and z, respectively (x, y, and z are taken as shown in Fig. 4).

It has been reported for Λ-*fac*-$[Co(S\text{-pea})_3]^{3+}$ [24] that the angles $<NCrN_{py}$ (N_{py} stands for pyridine nitrogen) in the chelate rings are not exactly 90°. Thus the angles ω_{x1} and ω_{x2}, which are the angles between the transition moments and the +x axis, are introduced as shown in Fig. 5, where $\omega_{x1}+\omega_{x2}=180°$. Consequently, the interaction energy V_{12} is approximately expressed as follows:

$$V_{12} = \frac{\mu^2}{d^3}(\cos\theta + 2\cos^2\omega_{x1}). \quad (2)'$$

The rotatory element R' and the exciton interaction energy V_{12} can be calculated approximately from the relative orientation of the transition moments on the two pyridine rings by Eqs. 1 and 2 (or Eqs. 1' and

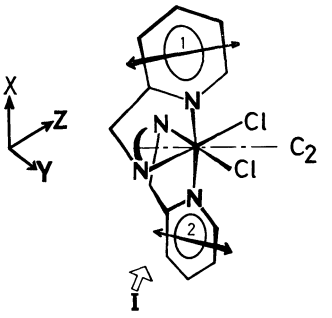

Fig. 4. The structure of Λ-*cis*-α-$[CrCl_2(picen)]^+$ and the directions of the transition moments for the ^1L_b band. The C_2 axis coincides with the bisector between y and z axis.

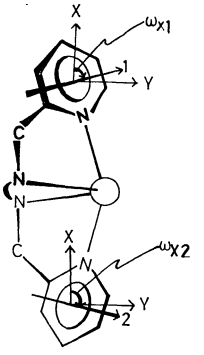

Fig. 5. The transition moment pair of A symmetry viewed from $-z$ direction (from the arrow I in Fig. 4).

2′) respectively. The expected CD patterns are given in Table 1 for the four combinations of R' and V_{12}; for example, when R' and V_{12} are positive, a negative and then a positive component from the lower energy side, (−,+), are expected.

CD and MCD Spectra of the Pyridine Ring Absorption Band (^1L_b Transition). The absorption and CD data of *cis*-α-$[CrX_2(S\text{-picpn})]^+$ (X=F, Cl, and Br) are exhibited in Table 2 (the band assignments are shown in the Table) and Figs. 6, 7, and 9. All the *S*-picpn complexes show (+,−) or (−,+) dispersion type CD pattern in the pyridine ring absorption band region (^1L_b transition). For the *Λ* difluoro complex, a typical (+,−) pattern is observed clearly (Fig. 6). The CD sign pattern is (−,+) from the lower energy side for the *Λ* complexes except for the difluoro complex, and that of the *Δ* complexes is (+,−) for the dichloro and the dibromo complexes (Table 2).

By using the atomic positions (Table 3) of pyridine ring carbon atoms determined in the X-ray structure analysis of *Λ*-*cis*-α-$[CrCl_2(S\text{-picpn})]Cl$,[25] the exciton CD pattern is estimated from Eqs. 1′ and 2. The numbering scheme of the carbon atoms is shown in Fig. 8. In the explanation of the component A symmetry, the directions of transition moments are taken from the midpoint of C(4) and C(5) to that of C(1) and C(2), and from the midpoint of C(10) and C(11) to that of C(13) and C(14). The evaluated values of R' and V_{12} from Eqs. 1′ and 2 are both negative. Thus the expected CD pattern is (−,+) from the lower energy side (Table 1), which is inverse to those observed for the dichloro and dibromo *Λ* complexes.

For the *Λ* complex, the expected exciton CD pattern is (+,−), since it is probable that the relative orientation of the two pyridine rings in the *Λ* complex is not so much different from the mirror image of that in the *Δ* complex. Only the difluoro *Λ* complex matches this calculated CD pattern.

The absorption and CD spectra of *cis*-$[CrX_2(en)_2]^+$ (X=F or Cl) are shown in Figs. 6 and 7. The ligand-to-metal charge-transfer (CT) band of the dichloro complex is located near the pyridine ^1L_b band, but

that of the difluoro complex is far from the pyridine ^1L_b band (the absorption band at ca. 40000 cm^{-1} in *cis*-$[CrF_2(en)_2]^+$ is the third spin-allowed d-d transition band). Also in Figs. 6 and 7 are shown the MCD spectra of *cis*-α-$[CrX_2(picen)]^+$, *cis*-$[CrX_2(en)_2]^+$ (X=F or Cl), and pma. No MCD band was observed for the *cis*-$[CrF_2(en)_2]^+$ complex in the 35000—40000 cm^{-1} region, but a very strong tail of higher energy MCD band for the dichloro complex, *cis*-$[CrCl_2(en)_2]^+$, in that region. In *cis*-α-$[CrF_2(picen)]^+$ complex a broad MCD band of pyridine rings is observed, while in the *cis*-α-$[CrCl_2(picen)]^+$ complex, the rather complicated MCD spectra indicate an overlap of the bands due to pyridine ring and CT transitions.

It has been established that exciton coupling is not observed in MCD spectra of tris(phenanthroline) metal complexes.[26] Likewise, the present complexes having two pyridine rings show no exciton coupling in the MCD spectra. The exciton coupling CD pattern in the dichloro complexes is considered to suffer from the overlap of CT bands. The CD spectrum of the difluoro complex shows the unperturbed pattern and correct signs in this region. In the dibromo complexes, it is clear that the bromo-to-chromium CT bands overlap with the pyridine ring absorption band. The exciton treatment can not be made in the case of overlapping of charge transfer band to the pyridine ring absorption band and the overlapping of CT band can be distinguished more clearly by using MCD spectrum.

The absorption and CD spectra of *trans*(py)*cis*(F)-$[CrF_2(S\text{-pea})_2]^+$ are shown in Fig. 9 with the MCD spectrum of *trans*(py)*cis*(F)-$[CrF_2(pma)_2]^+$. The MCD spectra in the pyridine ring absorption band region shows a similarity to that of pma; that is, only the B term of pyridine ring is observed.[27] The exciton CD spectra of the difluoro complexes are expected to show the CD pattern estimated by the simple theory. Though the observed CD spectrum is somewhat shifted to the positive area, the CD pattern is (+,−) from the lower energy side. This case is explained by using the Eqs. 1′ and 2′ and Fig. 5. An X-ray analysis of *Δ-fac*-$[Co(S\text{-pea})_3](ClO_4)_3\cdot 2H_2O$ showed that the pyridine ring of each *S*-pea ligand is tilted against the plane determined by cobalt and two nitrogen atoms of the ligand.[24] The tilt angle is 13—17°. Since the central chelate ring in Fig. 5 is absent, the

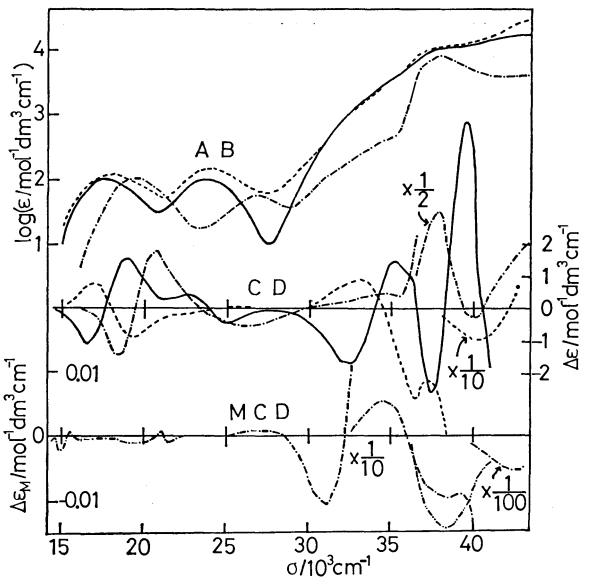

Fig. 9. Absorption (AB) and CD spectra of *Δ-cis*-α-$[CrBr_2(S\text{-picpn})]Br$ (- - -), *Λ-cis*-α-$[CrBr_2(S\text{-picpn})]I$ (——) in 0.1 mol dm^{-3} HCl, and *Λ-trans*(py)*cis*(F)-$[CrF_2(S\text{-pea})_2]Br$ in water (-·-·-). MCD spectra of *trans*(py)*cis*(F)-$[CrF_2(pma)_2]Br$ in water (-·-·-) and pma in water (-··-··-).

angle $|\theta|$ becomes larger than 90°, being estimated to be *ca.* 120°. From Eqs. 1′ and 2′ (ω_{x1}=*ca.* 84° was estimated from the X-ray analysis of *Δ-cis*-α-$[CrCl_2(S\text{-picpn})]Cl$[25]) the value of V_{12} becomes negative and R' is positive. Thus, a (+,−)CD pattern is expected from Table 1, which coincides with the observed pattern. It is established that the exciton CD between the two pyridine rings depends on the chelate ring conformations containing the pyridine rings.

In the case of *Λ-trans*(py)*cis*(Cl)-$[CrCl_2(S\text{-pea})_2]^+$ complex, (Fig. 10), the observed (+,−,+) CD pattern does not coincides with the expected exciton pattern. For the complex *Λ-trans*(py)*cis*(Cl)-$[CrCl_2(pma)_2]^+$, a vibrational pattern is observed in the CD spectrum. Moreover, the *S*-pea and pma complexes change the CD spectra by solvent change.

The observed CD pattern in the pyridine ring absorption band of *Δ-cis*-α-$[CoCl_2(S\text{-picpn})]^+$ (Fig. 10) coincides with the expected pattern. In the cobalt(III) complex, the chloro-to-cobalt CT band overlaps with the pyridine ring absorption band. Thus the coincidence between the observed and expected patterns might be accidental.

Solvent Effect. The absorption and CD spectra of all the chromium(III) complexes treated here were also measured in methanol and the spectral data are shown in Table 2. The absorption spectra in methanol are generally shifted to the lower energy side as compared with those measured in hydrochloric acid or water in the d-d transition region. But they show rather small change in the pyridine ring absorption band region. A solvent effect studies have been reported previously for the typical cobalt(III) and chromium(III) complexes,[28] which showed red shift by the solvent change from water to alcohols,

2-Pyridylmethylamine	38460	−14			py (^1L_b)

a) $\Delta\varepsilon_M$ is given in $mol^{-1}\,dm^3\,cm^{-1}\,T^{-1}$. b) Measured in methanol, because of decomposition in water or in 0.1 mol dm^{-3} HCl. c) Data were not obtained because of low solubility. CT: Charge transfer band.

The same trend is observed in this study. The CD spectra of all the complexes show the red shift in the d-d transition region and large shift or change in the pyridine ring absorption band region. Especially, the dichloro complexes show remarkable changes in this region; that is, the (+,−) or (−,+) dispersion type CD pattern can more clearly be observed in methanol solution than in hydrochloric acid solution, large shift to the lower energy side being also observed.

The spectral change in the dibromo complexes is also distinctive in the pyridine ring absorption band region. The red shift in $30—35\times10^3\,cm^{-1}$ region is larger than that in the other regions.

Spin-forbidden Transition of the Coordinated Pyridine Groups. The MCD spectral data are shown in Table 4. In the pyridine ring absorption band region, the MCD change by the solvent change show a similar tendency to that observed in the CD spectra.

Some peculiar MCD spectra are observed in $30—35\times10^3\,cm^{-1}$ region. Only weak CD spectra are observed in this region for the difluoro and dichloro complexes, but a (−,+) MCD pattern from the lower energy side is observed in all the complexes with coordinated pyridine groups. In methanol solution the strength of the band is strengthened for all the complexes including *cis*-β-$[CrCl_2(picen)]^+$ (Fig. 11) and *trans*-$[CrF_2(py)_4]^+$ (Fig. 11). There are three possibilities for the assignment of this band.

(1) CT transition from pyridine to chromium ($\pi\rightarrow$ d),
(2) CT transition from chromium to pyridine (d$\rightarrow$ π^*),
(3) spin-forbidden transition of pyridine.

If it is the CT band (1), the position will change by changing the central metal, because the energy of the CT band is inversely proportional to the optical electronegativity of the metal (1.9 and 2.3 for Cr(III) and Co(III), respectively).[29] The absorption spectra of *cis*(H_2O)*trans*(py)-$[Cr(H_2O)_2(pma)_2]^{3+}$ and the cobalt(III) analog are shown in Fig. 11. The band for the chromium complex locates at lower energy than that for the cobalt complex. Moreover, from

Absorption (AB) and CD spectra of Δ-*cis*-α-[$CoCl_2$(*S*-picpn)]Cl (- - -), and Δ-*cis*-[$CoCl_2$-$(en)_2$]Cl (···) in 0.1 mol dm^{-3} HCl.

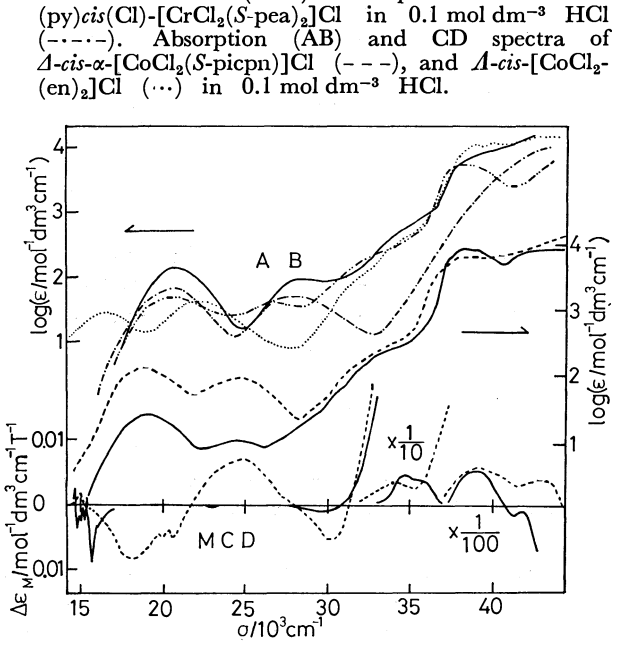

Fig. 11. Absorption (AB) (lower curves) and MCD spectra of *cis*-β-[$CrCl_2$(picen)]NO_3 in 0.1 mol dm^{-3} HCl (- - -) and *trans*-[$CrF_2(py)_4$]Br in water (——). Absorption (AB) (upper curves) spectra of *trans*(py)-*cis*(H_2O)-[$Co(H_2O)_2(pma)_2$]$HSO_4 \cdot SO_4$ (——), *cis*-[$Co(H_2O)_2(en)_2$]Cl_3 (-·-·-), *trans*(py)*cis*(H_2O)-[$Cr(H_2O)_2(pma)_2$]$(NO_3)_3$ (-···-···-) in 0.1 mol dm^{-3} HCl, and [$CrCl_3(py)_3$] in methanol (···).

the data of [$CrCl_3(py)_3$] and [$MoCl_3(py)_3$][30] this kind of bands are observed in almost the same position (the optical electronegativity value of Mo(III) is 1.7[29]). Accordingly, the possibility of (1) is diminished. Jørgensen observed such band for several iridium(III) complexes coordinating pyridine and named it "Ir-(III)-pyridine band,"[31] which changes the position by changing the number of the coordinated pyridine ligands or their relative positions in coordination octahedron. In our complexes treated here, the position does not change by the number of the coordinated pyridine groups. Furthermore, *cis*-α- and *cis*-β-[$CrCl_2$-(picen)]$^+$ complexes, which has *trans*(py) and *cis*(py) structure, respectively, show the MCD bands of the transition at about the same position (Table 4). Thus the assignment (2) is ruled out. The third assignment is most plausible because the position of this band in absorption or MCD spectra is not so much deviated from complex to complex. Evans found a fine structure of the spin-forbidden band of pyridine in this region under a high pressure of oxygen and assigned it $\pi \rightarrow \pi^*$ singlet-triplet transition.[32] A similar vibrational structure is observed for the *trans*-[$CrF_2(py)_4$]$^+$ complex in the absorption band (Fig. 11 and Table 2), and for some present complexes in the CD band (Table 2).

Kinetics of Monomerization or Polymerization Reaction for Bis(*N*-phenylsalicylideneaminato)nickel(II) and Bis(*N*-methylsalicylideneaminato)nickel(II) in Solid Phase

Kikuo Miyokawa,* Hidenori Hirashima, and Isao Masuda

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Nishi-ku, Fukuoka 814-01

(Received January 12, 1981)

A kinetic investigation was carried out by means of a thermomagnetic analysis on two structural transformation reactions in solid phase: monomeric square planar-to-polymeric octahedral for Ni(*N*-Me-salam)$_2$ and polymeric octahedral-to-monomeric square planar for Ni(*N*-Ph-salam)$_2$. The polymerization process followed the Avrami-Erofeev equation ($n=2$) with $E_a=303$ kJ/mol and the monomerization followed the first order equation with $E_a=78$ kJ/mol. The thermal pyridine liberating reaction of Ni(*N*-Ph-salam)$_2$py$_2$, involving an octahedral-to-square planar transformation, has been investigated isothermally and found to follow the first order equation with $E_a=167$ kJ/mol.

Extensive investigations of the nickel(II) complexes having the formula Ni(*N*-R-X-salam)$_2$ (where *N*-R-X-salam represents an anion of the Schiff bases derived from the ring-substituted salicylaldehydes X-sal and amine R–NH$_2$) have revealed that the complexes exist in several structural forms with different coordination geometries: *i.e.*, square planar,[1] tetrahedral,[1-3] dimeric square bi-pyramidal,[4] and polymeric octahedral[5,6] structures. Isomerization reactions in solid phase have also been found to occur for some complexes of these structural forms.[3,6-9] However, the kinetics of the isomerization reaction has remained ambiguous.

In this work, the kinetics of the transformation reactions in solid phase, monomer-to-polymer of Ni(*N*-Me-salam)$_2$ and polymer-to-monomer of Ni(*N*-Ph-salam)$_2$, have been investigated by means of a thermomagnetic analysis measuring magnetic susceptibility changes of the sample under isothermal or dynamic conditions.

Experimental

Materials. Diamagnetic dark green complexes, Ni(*N*-Me-salam)$_2$ and Ni(*N*-Ph-salam)$_2$ (Form I), were prepared by the published procedure.[7,8,10,11] The paramagnetic light green modification (Form II) of Ni(*N*-Ph-salam)$_2$ was prepared in the following manner: the Form I complex was saturated into dichloromethane (50 ml) at *ca.* 35 °C, then to the solution was added ethanol (50 ml). The mixture was kept at room temperature under stirring until light green crystals separated.

The bis(pyridine) adduct Ni(*N*-Ph-salam)$_2$py$_2$ was precipitated from pyridine solution saturated with the Form I complex by addition of ethanol.

Found for Form II: C, 69.07; H, 4.51; N, 6.39; Ni, 13.19 %. Calcd for $C_{26}H_{20}N_2O_2Ni$: C, 69.22; H, 4.44; N, 6.21; Ni, 13.02%. Found for the pyridine adduct: Ni, 9.75%. Calcd for $C_{36}H_{30}N_4O_2Ni$: Ni, 9.64%.

Neodymium oxide was purified by repeating the following procedure: commercial reagent grade Nd_2O_3 was dissolved in aqueous HCl, and the solution was evaporated to dryness. The residue was dissolved in water, and to the resulting solution was added aqueous oxalic acid to precipitate neodymium oxalate. The oxalate thus obtained was collected on a filter, and then pyrolyzed at *ca.* 800 °C to give Nd_2O_3. The purity was ascertained by Nd-content analysis using the EDTA titration method.

Measurements. Thermogravimetric (TG) and differential scanning calorimetric (DSC) curves, and X-ray powder diffraction patterns were recorded as described in a previous paper.[12] Reflectance spectra were measured by means of an opal glass method[13] using a Shimadzu MPS 5000 spectrophotometer. The isothermal weight-loss measurements were made with a Sinku Riko micro DTA apparatus TGD-3000-RH, under a constant flow of nitrogen.

A thermomagnetic analysis[14] was carried out by using a thermomagnetic analysis instrument which was constructed by assembling a Faraday type magnetobalance and an infrared lamp furnace.[15] The sample was heated at a constant heating rate or kept at a desired temperature with a Sinku Riko temperature controller HPC-3000. On this instrument the following thermomagnetic curves were recorded: the isothermal thermomagnetic curve (hereafter abbreviated as ITM curve), obtained by plotting the magnetic susceptibility change of the sample against time while it was kept under isothermal conditions; the sample was usually heated to the desired temperature at a heating rate of 200 °C min^{-1}; and the dynamic thermomagnetic curve (DTM curve), obtained by plotting the magnetic susceptibility change of the sample under dynamic conditions against temperature; the sample was usually heated at a heating rate 1 °C min^{-1}. These measurements were carried out in a nitrogen atmosphere. The magnetobalance was calibrated by using $[Ni(en)_3]S_2O_3$ and Nd_2O_3, and the strenght of the applied magnetic field was regulated to an appropriate constant value around 0.85 T.

Results

The magnetic and electronic spectral data of the complexes in the solid state are given in Table 1. Whereas the dark green Form I isomer of Ni(*N*-Ph-salam)$_2$ is diamagnetic and is considered to have a square planar structure,[10] the light green Form II

Table 1. Magnetic and electronic spectral data

Complex	μ_{eff}[a] / μ_B	ν_{max}[b] / 10^3 cm^{-1}
Ni(*N*-Ph-salam)$_2$, Form I	dia[c]	16.3
Ni(*N*-Ph-salam)$_2$, Form II	3.28	10.1, 16.6
Ni(*N*-Ph-salam)$_2$py$_2$	3.09	9.9, 16.8
Ni(*N*-Me-salam)$_2$	dia	16.6
Ni(*N*-Me-salam)$_2$	3.30[d]	12.7, 18.0

a) Determined at room temperature, 22—25 °C. b) Powder reflectance. c) dia: Diamagnetic. d) See Refs. 7 and 8.

isomer prepared in the present work is paramagnetic with $\mu_{eff}=3.28\,\mu_B$. The electronic reflectance spectrum of the Form I isomer exhibits a peak with the maximum at $16.3\times10^3\,cm^{-1}$ ascribed to the square-planar crystal field band of Ni(II), $^1A_{1g}\rightarrow{}^1A_{2g}$ transition,[16] while the spectrum of the Form II isomer is composed of two peaks with the maxima at 10.1 and $16.6\times10^3\,cm^{-1}$; these may be ascribed respectively to the $^3A_{2g}\rightarrow{}^3T_{2g}$ and $^3A_{2g}\rightarrow{}^3T_{1g}(F)$ transitions of the octahedral crystal field bands.[16] The paramagnetism and the spectral data are indicative of an octahedral coordination and hence a polymeric structure for the Form II isomer.

The TG and DSC curves of the Form I and II isomers of Ni(*N*-Ph-salam)$_2$ are shown in Figs. 1-a and -b. No weight-loss is observed up to 320 °C in these TG curves. In the DSC curves of both isomers, however, an endothermic peak is observed at 280 °C due to the melting. An exothermic peak at 210 °C observed for the Form II isomer may be attributed to the transformation reaction into the Form I isomer. The X-ray diffraction pattern of the product obtained by heating the Form II isomer at 230 °C coincided with that of the Form I isomer.

As for diamagnetic Ni(*N*-Me-salam)$_2$, the TG curve shown in Fig. 1-c exhibits no weight-loss up to 290 °C; the DSC curve shows two endothermic peaks due to the melting at 215 and 302 °C. The former melting is found to be followed by the solidification of the melt; this does not disagree with the observation under microscope by Sacconi *et al.*[7] On heating diamagnetic Ni(*N*-Me-salam)$_2$ at 230 °C, a paramagnetic complex was obtained which showed quite different X-ray powder pattern from that of starting diamagnetic complex. Thus, the melting at 215 °C is thought to occur together with the transformation reaction of diamagnetic Ni(*N*-Me-salam)$_2$ into the paramagnetic complex; the latter melts at 302 °C with a partial decomposition.

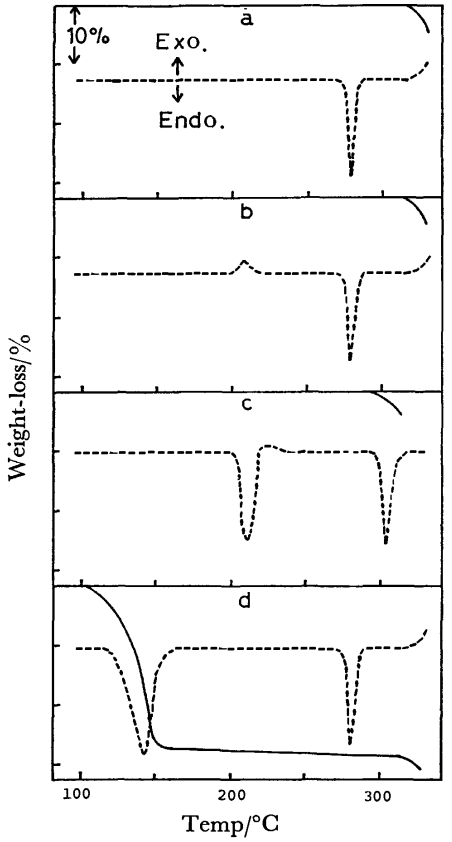

Fig. 1. TG(——) and DSC(- - -) curves; heating rate, 10 °C min^{-1}, in a static air atmosphere.
(a): Ni(*N*-Ph-salam)$_2$ (Form I), (b): Ni(*N*-Ph-salam)$_2$ (Form II), (c): diamagnetic Ni(*N*-Me-salam)$_2$, (d): Ni(*N*-Ph-salam)$_2$py$_2$.

The DTM curve of the paramagnetic Form II isomer of Ni(*N*-Ph-salam)$_2$ is presented in Fig. 2. When W mg of the sample is placed in the magnetic field, the response of the electrobalance, W' mg, is expressed by Eq. 1:

$$W' = W + W\cdot\chi_g^s\cdot H_c, \qquad (1)$$

where χ_g^s is the apparent gram magnetic susceptibility of the sample, and H_c a constant value which is determined by the apparatus and the strength of the applied magnetic field. The DTM curve shown by Fig. 2-a is obtained by plotting $(W'-W)/W$ value *vs.* temperature under dynamic conditions of a heating rate of 1 °C min^{-1}. In this curve a large decrease in the magnetic susceptibility of the Form II isomer is seen in the 170—230 °C region. This may correspond to the transformation reaction of the paramagnetic Form II to the diamagnetic Form I isomer, which is consistent with the results of the thermal analyses. On the basis of the DTM data, $\chi_{Ni(II)}$, the apparent susceptibility per mole of Ni(II), not corrected for the diamagnetism of all atoms, was calculated by Eq. 2:

$$\chi_{Ni(II)} = (W'-W)M/(H_cW), \qquad (2)$$

where M is relative molecular mass of the complex, 450.7. The H_c value has been determined by using

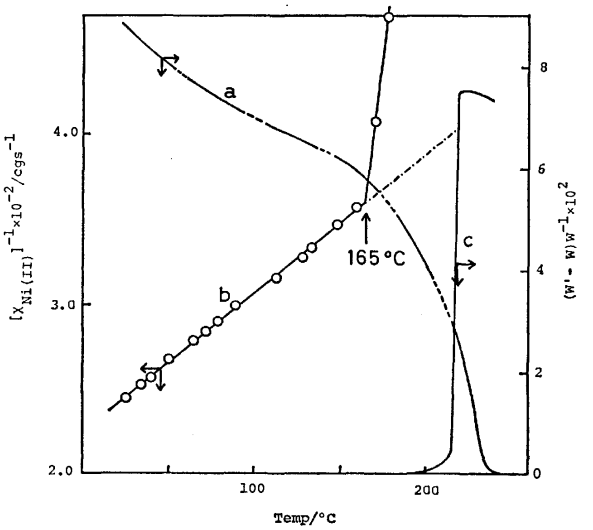

Fig. 2. DTM curve for Ni(*N*-Ph-salam)$_2$ (Form II), (a); plots of reciprocal $\chi_{Ni(II)}$ *vs.* temperature, for Form II, (b); sample, 18.40 mg. DTM curve for diamagnetic Ni(*N*-Me-salam)$_2$, (c); sample, 18.40 mg. Heating rate, 1 °C min^{-1}. On the dashed line in the curve (a) magnetic-field strength was attenuated to zero to check the base line.

Nd_2O_3 as a standard[17] to be 8.40×10^3 under the present experimental conditions; it is practically constant in the range 25—300 °C. And the plots of reciprocal $\chi_{Ni(II)}$ against temperature give a curve shown by Fig. 2-b. The curve indicates that a Curie-Weiss dependence of the magnetic susceptibility of the Form II isomer is broken at 165 °C; at this temperature the transformation reaction from the Form II to Form I isomer is thought to occur.

The ITM curves for the Form II isomer recorded under isothermal conditions at 175.6, 180.9, 186.1, and 191.3 °C are shown in Fig. 3. The apparent gram susceptibility of the sample, χ_g^s, can be expressed by Eq. 3, where χ_g^I, χ_g^{II}, and α are the gram susceptibilities of the Form I and II isomers, and the molar fraction of Form II transformed into Form I, respectively:

$$M\cdot\chi_g^s=[\chi_g^{II}(1-\alpha)+\chi_g^I\cdot\alpha]M. \quad (3)$$

Then, the α value is given as

$$\alpha=(\chi_g^s-\chi_g^{II})/(\chi_g^I-\chi_g^{II}). \quad (4)$$

The χ_g^I value was found to be practically zero and χ_g^{II} was evaluated from a Curie-Weiss dependence, *i.e.*, by extrapolating the linear part below 165 °C of the line in Fig. 2-b to each desired temperature. As shown in Fig. 4, the transformation reaction pursued at four different temperatures is found to be well described by the first order equation: $-\ln(1-\alpha)=kt$, where k and t are the rate constant and time. On the basis of these data, the activation energy E_a and pre-exponential factor A in the Arrhenius equation were determined to be 78 kJ/mol and 1×10^7.

In the case of diamagnetic Ni(N-Me-salam)$_2$, the DTM curve shown in Fig. 2-c indicates that the magnetic susceptibility begins to increase gradually at 190 °C, and rapidly increases at ⩾215 °C, which corresponds to the DSC peak temperature due to the melting. The ITM curves recorded at 186.7, 191.3, and 197.7 °C for the transformation to the paramagnetic form are shown in Fig. 5. In this case the χ_g^I and χ_g^{II} in Eq. 3 are the gram magnetic susceptibilities of the paramagnetic and diamagnetic Ni(N-Me-salam)$_2$, respectively. The χ_g^I values at these temperatures were determined after the reaction was completed, and χ_g^{II} was found to be practically zero. As shown

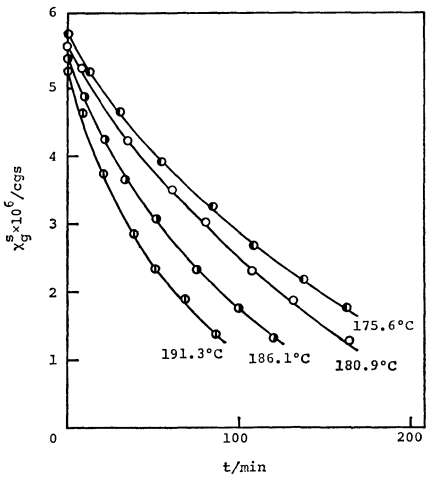

Fig. 3. ITM curves for Ni(N-Ph-salam)$_2$ (Form II); polymer-to-monomer transformation under isothermal conditions.

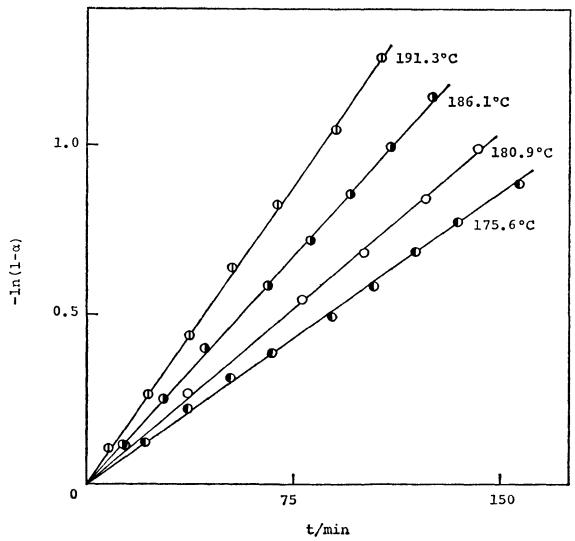

Fig. 4. First order rate plots for polymer-to-monomer transformation of Ni(N-Ph-salam)$_2$ (Form II).

Table 2. Kinetic data of transformation reactions in solid phase

Complex	Reaction Mode	Reaction Scheme	E_a / kJ mol^{-1}	log (A/min^{-1})	k / 10^{-2} min^{-1}	Temp / °C
Ni(N-Ph-salam)$_2$	a)	$-\ln(1-\alpha)=kt$	78± 5	7.0±0.6	0.723	175.6
					0.867	180.9
					1.13	186.1
					1.46	191.3
Ni(N-Me-salam)$_2$	b)	$-\ln(1-\alpha)=(kt)^2$	303±11	33±2	3.76	186.7
					7.81	191.3
					24.9	197.7
Ni(N-Ph-salam)$_2$py$_2$	c)	$-\ln(1-\alpha)=kt$	167±12	22±1	0.668	86.8
					0.937	88.8
					1.23	90.6
					1.73	93.0

a) Polymer-to-monomer. b) Monomer-to-polymer. c) Monomer(octahedral)-to-monomer(square-planar).

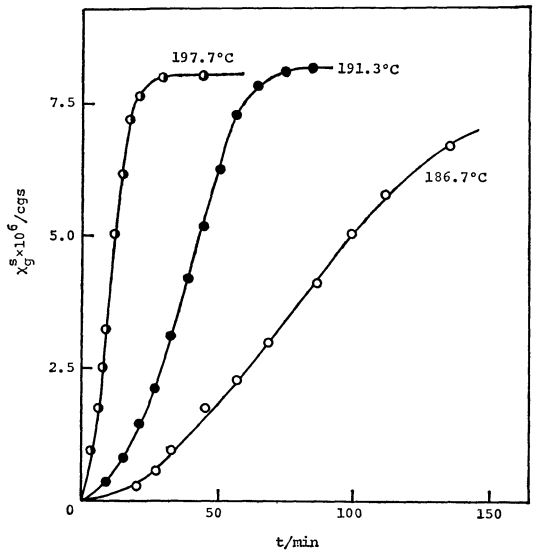

Fig. 5. ITM curves for diamagnetic Ni(*N*-Me-salam)$_2$; monomer-to-polymer transformation under isothermal conditions.

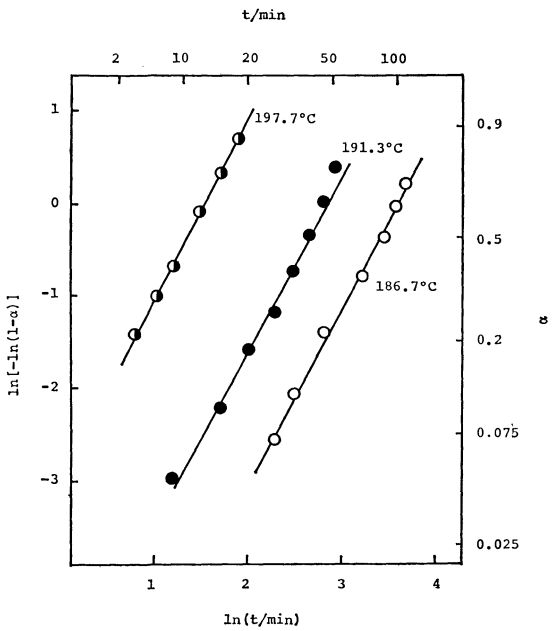

Fig. 6. Plots of ln[$-$ln(1$-\alpha$)] *vs.* ln(t) for monomer-to-polymer transformation of Ni(*N*-Me-salam)$_2$.

in Fig. 6, the transformation isotherms thus obtained are well fitted to the Avrami-Erofeev equation:[18]

$$-\ln[-\ln(1-\alpha)] = (kt)^n. \quad [n=1.94\text{—}2.02] \qquad (5)$$

The kinetic parameters, E_a and A, were calculated to be 303 kJ/mol and 1×10^{33}, respectively.

For the purpose of comparison, the thermal dissociation reaction of the axial pyridine molecules of Ni(*N*-Ph-salam)$_2$py$_2$ has been subjected to kinetic analysis. The DSC curve of the adduct shown in Fig. 1-d exhibits two endothermic peaks at 140 and 280 °C; the former peak is accompanied by 26.0% weight-loss in the range 100—150 °C, which corresponds to the elimination of 2 mol of pyridine per mol of the adduct, while the latter one is accompanied by no

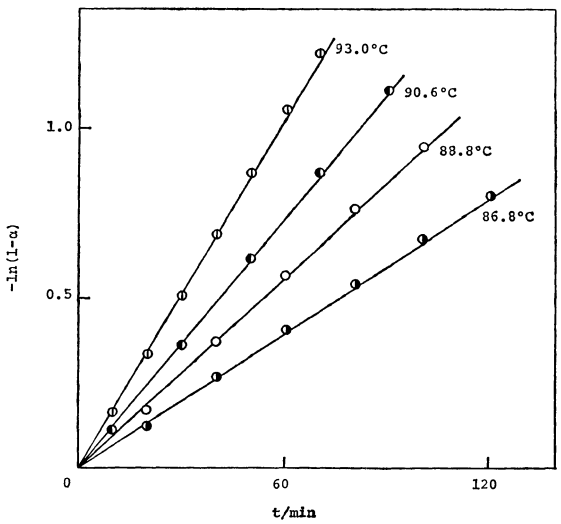

Fig. 7. First order rate plots for pyridine-liberating reaction of Ni(*N*-Ph-salam)$_2$py$_2$.

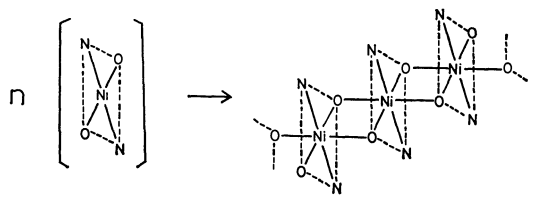

Fig. 8. Skeletal representation of monomer-to-polymer transformation.

weight-loss, and corresponds to the melting of the Form I isomer of Ni(*N*-Ph-salam)$_2$. The X-ray diffraction pattern of the sample obtained after heating at *ca.* 150 °C was identical to that of an authentic Form I isomer. The pyridine-liberating reaction of the adduct could easily be followed by the isothermal weight-loss measurements. The liberation isotherms obtained at 86.8, 88.8, 90.6, and 93.0 °C fit well to the first order equation, as shown in Fig. 7. The kinetic parameters, E_a and A, were calculated to be 167 kJ/mol and 1×10^{22}, respectively.

Discussion

The polymerization reaction of Ni(*N*-Me-salam)$_2$ including the alteration of the spin-state of central Ni(II), singlet(monomer)-to-triplet(polymer), has been considered to progress through the further coordination of the phenolato oxygen atoms in the complex molecule to a Ni(II) ion of adjacent molecules at the apical position, forming octahedral coordination geometry around the Ni(II) ion, as drawn above.[8] The polymerization kinetics is found to be depicted by the Avrami-Erofeev equation with n=2, suggesting that the reaction rate is determined either by two dimensional growth of nuclei[19] or by random nucleation and one dimensional growth of nuclei.[20] By taking into account the fact that the proposed polymeric structure includes a one-dimensionally extended monomer, the latter model seems to be preferable for the present polymerization. On the other hand, the monomerization reaction of Ni(*N*-Ph-salam)$_2$ includes the

spin-state alteration of Ni(II), triplet(polymer)-to-singlet(monomer); the monomerization kinetics fits the first order equation. The thermal pyridine liberating reaction of Ni(*N*-Ph-salam)$_2$py$_2$, which occurred with the accompanying triplet-to-singlet alteration of Ni(II) and the formation of monomeric Ni(*N*-Ph-salam)$_2$, is also depicted by the first order equation.

As shown in Table 2, the larger E_a and A values for the polymerization of Ni(*N*-Me-salam)$_2$ than those for the monomerization of Ni(*N*-Ph-salam)$_2$ could be understood by speculating that the progress of the polymerization requires more extensive movement of the molecules than that of the monomerization does.

We can compare the polymer complex and the pyridine adduct of Ni(*N*-Ph-salam)$_2$, both having octahedral and triplet Ni(II); the larger E_a value for the pyridine-liberating reaction than for the monomerization reaction seems to reflect a weaker association interaction than the adduct-formation interaction.

The Solvent Extraction of Np(III) by Means of Bis(2-ethyhexyl)-hydrogenphosphate in an Octane Solution and the Absorption Spectrum of the Organic Phase

Isamu KAWASUJI,* Akiko SATÔ, and Shin SUZUKI
The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira, Sendai 980

(Received February 20, 1981)

Tervalent neptunium in an $HClO_4$ solution was extracted by means of bis(2-ethylhexyl)hydrogenphosphate, HDEHP, in an octane solution. The oxidation state of neptunium in the organic phase was determined by spectrophotometry. The intense peak in the absorption spectrum of tervalent neptunium was found at 348 nm, this peak was attributed to the $f \rightarrow d$ transition. The oxidation rate of the Np(III)–HDEHP complex in an oxygen-free octane solution was about 10%/h.

It has been well known that the tervalent neptunium ion in an acidic solution is fairly stable in an oxygen-free atmosphere. However, during a chemical operation like solvent extraction or ion exchange, it is difficult to maintain the neptunium ion in a tervalent state. Consequently, the study of the aqueous chemistry of Np(III) has been made mainly by means of the spectrophotometric technique. Shiloh and Marcus[1] found the characteristic absorption peaks of 384 nm and 387 nm in the chloride and bromide solution of Np(III) respectively. They determined the stability constants of the chloride and bromide complexes by measuring the increases in their characteristic peaks as the concentrations of the chloride and bromide ions increased.

Inoue *et al.*[2] recently investigated the effect of the neptunium concentration on the fraction of tervalent neptunium produced by hydrogen reduction. They concluded that neptunium was quantitatively reduced to the tervalent state at concentrations higher than 10^{-3} M (1 M=1 mol dm^{-3}), while the tracer concentrations of neptunium were quantitatively reduced to the tervalent state in the presence of more than 10^{-3} M Sn(II).

It has not been reported up to the present, however, that tervalent neptunium could be evidently extracted to the organic phase in the solvent extraction, which has been one of the most effective methods of investigating aqueous chemistry. In order to extract the tervalent neptunium, and in order to determine the oxidation state of the extracted neptunium by spectrophotometry, we made a specially designed reduction and extraction apparatus with reference to other authors'.[2,3] The apparatus was constituted of two parts: the spectrophotometric cell in which the extracted tervalent neptunium was introduced, and the reduction and extraction part.

HDEHP was used as the extractant, and octane, as the solvent, in this work.

Experimental

The ^{237}Np was obtained from the Radiochemical Centre, Amersham, and was purified by the method of Moore,[4] while the final stock solution was 10 M HNO_3. The concentration of ^{237}Np in the stock solution was determined by the α-counting method using a surface barrier Si-detector and the EDTA titration method. The results of the two methods agreed well within the limits of experimental error.

HDEHP was purified by the way of McDowell *et al.*[5] and was stocked as the copper salt. The desired quantities of the copper salt were weighed and then dissolved in octane. After the copper had been removed by shaking with an acid solution, the concentration of HDEHP in the octane solution was determined by the titration of the NaOH solution. The results of the titration method agreed well with the results of the gravimetry, within the limits of experimental error.

For the measurement of the absorption spectrum, a Hitachi 330 recording spectrophotometer was used.

The experimental apparatus used in this work is shown in Fig. 1. It was made of quartz, and at the top of it, a polyethylene plug was placed, through which Teflon tubes passed. At the end of the Teflon tubes, freshly prepared platinum-black-coils were fixed.

Three milliliters of the 2 M HDEHP/octane solution was placed in the spectrophotometric cell, while the same volume of a 0.3 M $HClO_4$ solution containing 20 mg of ^{237}Np (2.7×10^{-2} M) was placed in the other part.

The hydrogen gas, which had been deoxidized by passing through a pyrogallol–KOH solution, was bubbled into the Np/$HClO_4$ solution, and the neptunium was reduced to the tervalent state by the hydrogen gas catalyzed by the platinum-black-coil. A part of the deoxidized hydrogen gas was passed through the octane solution and then bubbled into the HDEHP/octane solution.

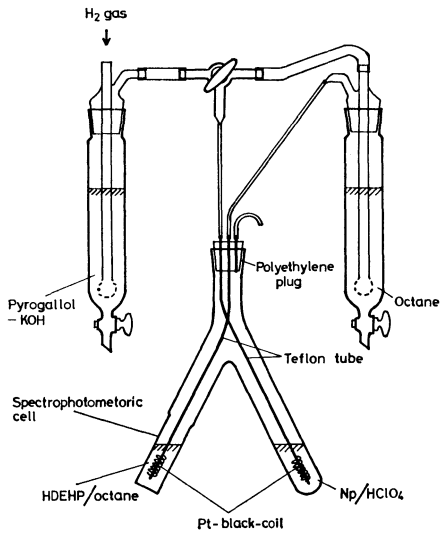

Fig. 1. Experimental apparatus.

The neptunium in the $HClO_4$ solution was completely reduced to the tervalent state about after three hours bubbling, as was recognized by the change in color. Then the apparatus was tilted and the HDEHP/octane solution in the spectrophotometric cell was introduced into the other part. The apparatus was shaken about ten minutes while the hydrogen gas was bubbling. After the two phases had separated, the organic phase was introduced to the spectrophotometric cell and the absorption spectrum was immediately measured. The Teflon tube and the platinum-black-coil were placed in the upper side so as not to disturb the measurement of the absorption spectra. The spectrophotometry of the organic phase was carried out every hour after the extraction in order to investigate the stability of the Np(III)–HDEHP complex in an octane solution. The absorption spectrum of the Np(IV)–HDEHP complex in an octane solution was measured after the oxidation had been completely concluded.

The absorption spectra of Np(III) and Np(IV) in 0.3 M $HClO_4$ solution were also measured.

An aliquot part of the organic phase was placed in the polyethylene test tube, and the concentration of the ^{237}Np was determined by γ-ray spectrometry. For the γ-ray spectrometry, a Tracor Northern TN-4000 pulse-height analyzer and a pure-Ge detector were used. The peak at 86.49 keV, the characteristic peak of ^{237}Np, was used to determine the concentration of neptunium. ^{233}Pa, the daughter of ^{237}Np, also has a weak peak at 86.59 keV. These two peaks could not be separated, so the contribution of the peak at 86.59 keV to the peak at 86.49 keV was eliminated by the γ-ray spectrometry of pure ^{233}Pa.

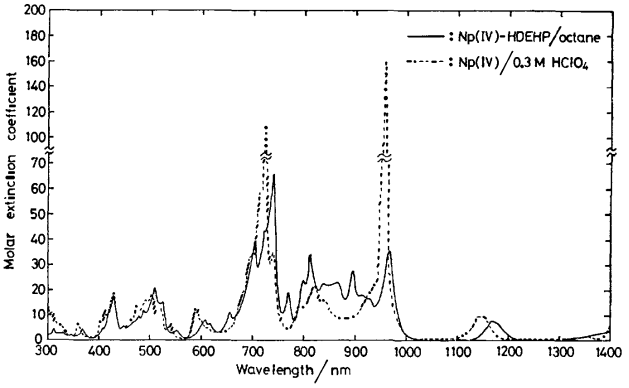

Fig. 2. Absorption spectra of Np(IV) in $HClO_4$ solution and Np(IV)–HDEHP complex in octane solution.

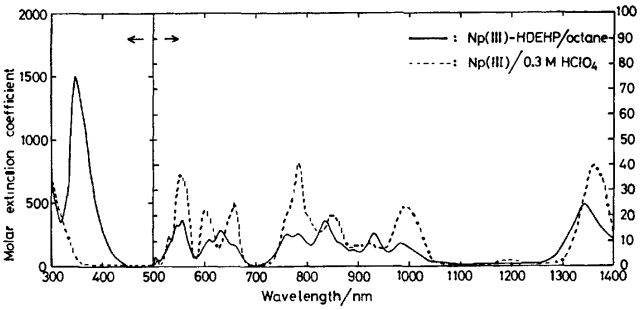

Fig. 3. Absorption spectra of Np(III) in $HClO_4$ solution and Np(III)–HDEHP complex in octane solution.

Results and Discussion

The absorption spectrum of the Np(IV)–HDEHP complex in an octane solution shown in Fig. 2 is very similar to the spectrum of Np(IV) in a 0.3 M $HClO_4$ solution except in the region of 900 nm. The characteristic peaks of the former are 427, 508, 735, 812, 896, 968, and 1167 nm, and the former shifts toward a lower energy compared with the latter. This shift may be caused by the nephelauxetic effect.[6]

On the other hand, the absorption spectrum of the Np(III)–HDEHP complex (shown in Fig. 3) is not so similar to the spectrum of Np(III) in the 0.3 M $HClO_4$ solution. This shows that the $f \rightarrow f$ transition was affected by the environment, *e.g.*, the ligand or the crystal field. The characteristic peaks of the former are 348, 557, 630, 760, 782, 835, 931, 987, and 1345 nm. Among these, the peak of 348 nm is clearly distinguished from the other peaks, which are attributed to the $f \rightarrow f$ transition in the visible and near-infrared regions. The molar extinction coefficient, ε_m, of this peak is about 1500, while the half-width toward the lower energy, $\sigma(-)$, is 1500 cm^{-1}. This peak is attributed to the $f \rightarrow d$ transition or the electron-transfer-from-ligand transition. Usually, the former band is relatively more intense and narrow than the latter.[7] However, it is difficult to discriminate between them. Poturaj-Gutniak and Taube[8] identified the absorption peak as the $f \rightarrow d$ transition by $\varepsilon_m > 3000$, and $\sigma(-) < 2000$ cm^{-1}, and as electron-transfer by $\varepsilon_m < 3000$, and $\sigma(-) > 2000$ cm^{-1}.

The characteristic peaks of Np(III) in concentrated LiCl and LiBr solution found by Shiloh and Marcus[1] are $\varepsilon_m = 1170$ and $\sigma(-) = 2400$ cm^{-1} at 384 nm (26000 cm^{-1}) in LiCl and $\varepsilon_m = 830$ and $\sigma(-) = 2400$ cm^{-1} at 387 nm (25800 cm^{-1}) in LiBr. These bands are attributed to the $f \rightarrow d$ transition.

The peak at 348 nm (28700 cm^{-1}) found in this work seemed to have the same cause as the peaks found by Shiloh and Marcus described above. The shifts of these peaks effected by the ligands are small. Generally, the shift of the $f \rightarrow d$ transition with a ligand is much less than that observed in the case of the electron-transfer band.[7] For example, the shift of the electron-transfer is 7000—9000 cm^{-1}; on the other hand, that of the $f \rightarrow d$ transfition is about 1000 cm^{-1} in tervalent actinoide hexahalides.[9] Therefore, the peak at 348 nm is ascribed to the $f \rightarrow d$ transition.

The Np(III)–HDEHP complex in an octane solution is unstable and is oxidized to the quadrivalent state, even in an oxygen-free atmosphere. The oxidation rate was found to be about 10%/h by the spectrophotometry that was carried out every hour after the extraction.

The color of the Np(III)–HDEHP complex in an octane solution is golden yellow, while that of the Np(IV)–HDEHP complex is slightly greenish yellow. It is difficult to distinguish between them by color, especially at a low concentration of neptunium.

High-performance Liquid Chromatographic Determination of Organic Substances by Metal Chelate Derivatization. I. Dithiocarbamate Chelates of Aliphatic Amines

Masataka Moriyasu,* Yohei Hashimoto, and Masaru Endo**

Kobe Women's College of Pharmacy, Motoyamakita-machi, Higashinada-ku, Kobe 658

***Kinki District Narcotic Control Office, Uchikyuhoji-machi, Higashi-ku, Osaka 540*

(Received March 2, 1981)

The use of the conversion of aliphatic primary and secondary amines into metal dithiocarbamate chelates was examined for high-performance liquid chromatographic determination of these amines. Characteristic chromatogram patterns based on the difference in the rate of ligand exchange were obtained for different central metal ions. When Hg(II) chelates were tested, trace determination of individual secondary amines was possible because only the peaks of binary complexes corresponding to each amine appeared on chromatograms. When Ni(II) and Pd(II) chelates were tested, peaks to ternary complexes as well as those of binary complexes appeared on chromatograms. This phenomenon was applied to the determination of optical purity of optically active amines. A description is given of applications to microdetermination of antiasthmatic ephedrine isomers, to determination of their optical purity in Chinese crude drugs, and to their preparation.

The metal chelate formation is widely applied to the colorimetric determination of metal ions. Since most chelating reagents are synthesized from organic substances, there have been made several attempts to determine organic substances after their conversion into metal chelates. Along with the recent progress of high-performance liquid chromatography(HPLC), a large number of UV-visible derivatization methods have been presented, but with little attention paid to utilization of the metal chelate formation for derivatization reactions of organic substances; this situation seems ascribable to the presumption that, as is often the case in gas chromatography, metal chelates usually undergo decomposition in course of chromatography. The purpose of the present series research is to clarify to what extent the metal chelate formation is useful for the UV-visible derivatization method in HPLC. The present report is concerned with conversion of aliphatic primary and secondary amines into dithiocarbamate chelates. We have described[1] an HPLC determination of various metal ions with the aid of their conversion into diethyldithiocarbamate chelates, and successively characterized[2,3] their chromatograms by means of ligand exchange. In experimental investigation on the application of the metal chelate formation to an analysis of organic substances, we should take into account the following two factors: (1) the organic substance needs to be converted into so stable a chelate as to undergo no decomposition in course of chromatography; (2) the ratio of central metal ion to ligand is of importance. If only 1:1 complexes are allowed to form, the determination of each organic substance may be performed easily. If 1:2 complexes are allowed to form, the ternary complex formation needs to be taken into consideration. When the ternary complex is very labile, it will undergo disproportionation into two binary complexes ($2MAB \rightarrow MA_2 + MB_2$) as soon as it gets separated; in this case, only the peaks for the binary complexes appear on the chromatogram, making the determination of individual organic substances possible. When the ternary complex is fairly inert, the peaks for ternary complex MAB will also appear on the chromatogram, complicating the chromatogram.

Experimental

Reagents. Sodium salts of various *N,N*-disubstituted and *N*-monosubstituted dithiocarbamic acids were prepared by mixing an aliphatic amine, carbon disulfide, and sodium hydroxide. The following aliphatic primary and secondary amines were used: dimethylamine, diethylamine, dipropylamine, dibutylamine, diisopropylamine, diisobutylamine, pyrrolidine, piperidine, perhydroazepine, morpholine, dibenzylamine, methylamine, ethylamine, propylamine, phenethylamine, and *l*-ephedrine. Each sodium salt was recrystallized from chloroform–methanol or chloroform–hexane. Standard solutions of each metal ion (0.1 M, 1 M=1 mol dm^{-3}) were prepared by dissolving each metal salt in water. The metal ions used are Mn(II), Fe(III), Co(II), Ni(II), Cu(II), Zn(II), Ag(I), Cd(II), Hg(II), Pb(II), Bi(III), and Pd(II).

Apparatus. The HPLC apparatus used was the same as the one used previously.[1-3] Absorption spectra of metal chelates were recorded on a Model-124 Hitachi double-beam spectrometer.

Results and Discussion

Relationship between Stability Constant and Chromatographic Behavior of Metal Chelates. Solutions of various dithiocarbamate chelates were prepared by mixing each of sodium dithiocarbamates and each metal ion at a suitable pH. The chelate formed was extracted with chloroform. Except Fe(III) and Mn(III), all the dithiocarbamate chelates derived from the secondary amines gave solutions stable at least for 2 d. Since dithiocarbamates derived from primary amines in general have a strong reducing property, the metal chelates for Ag(I), Hg(II), and Cu(II) decomposed readily, whereas those for Pd(II), Ni(II), and Co(III) were stable.

The HPLC of various metal diethyldithiocarbamate chelates has been described in several reports[4-8] and ours.[1] Chromatographic behaviors of various dithiocarbamate chelates were examined. Of the chelates tested, Hg(II), Pd(II), Cu(II), Ni(II), and Co(III) chelates gave good chromatograms without any occurrence of decomposition. All of these chelates, except chemically unstable Hg(II) and Cu-

(II) chelates derived from primary amines, gave linear calibration curves over the range from a few μg to a few ng. Chelates of other metals, Mn(III), Fe(III), Zn(II), Cd(II), Pb(II), and Bi(III), sometimes accompanied decomposition when sample amounts were small, giving nonlinear calibration curves. Ag(I) chelates were adsorbed on the silica-gel surface too strongly to be eluted out. The stability of metal dithiocarbamate chelates has been investigated by several workers.[9-13] For example, Bode and Tusche reported the following order of increasing stability: Mn(III) < Fe(III) < Zn(II) < Cd(II) < Co(III) < Pb(II) < Bi(III) < Ni(II) < Cu(II) < Ag(I) < Pd(II) < Hg(II). The present results suggest that no decomposition occurs when the metal chelate is very stable (Hg(II), Pd(II), Cu(II), and Ni(II)) or robust (Co(III)).

Formation of Dithiocarbamate Chelates and Exchange of Central Metal Ion. An examination was made in pursuit for the optimum conditions for the formation of metal dithiocarbamate chelates from aliphatic amines. Since, of various metal ions, Hg(II), Pd(II), Cu(II), Ni(II), and Co(III) had formed chelates stable enough for amine analysis, the examination was limited to these metal ions. The formation of dithiocarbamates and metal chelates is expressed by

$$R_1R_2NH + CS_2 + OH^- \rightleftharpoons R_1R_2NCSS^- + H_2O \quad (1)$$

and

$$nR_1R_2NCSS^- + M^{n+} \longrightarrow M(R_1R_2NCSS)_n. \quad (2)$$

Reaction 1 cannot go to completion in the forward direction because in acidic media the backward reaction is allowed to proceed. As the metal chelate formation proceeds and the chelate formed is caused to go into the the organic layer, free dithiocarbamate ion in aqueous solution gets removed from the aqueous layer, thereby leading the entire reaction to completion. Of various procedures tested, the following was capable of giving quantitative results: To 1 cm^3 of dilute amine solution were added 1 cm^3 of 0.1 M standard solution of each metal ion, 1 cm^3 of conc aqueous ammonia, and 5 cm^3 of chloroform containing 2% carbon disulfide. The mixed solution in a test tube equipped with a ground glass stopper was shaken vigorously for about 30 s to complete the reaction. The chloroform layer was washed with water three times. Pd(II), Ni(II) and Co(III) chelates allowed the reaction to proceed quantitatively (>98%) for both primary and secondary amines. Cu(II) gave quantitative results only for secondary amines since the Cu(II) chelates obtained from primary amines were chemically unstable. This procedure was inapplicable to Hg(II) chelates because Hg(II) salts are insoluble in conc aqueous ammonia. Hg(II) chelates of secondary amines were formed quantitatively by means of exchange of central metal ion as follows. To chloroform solution of corresponding Ni(II) dithiocarbamate chelates, which are brownish yellow, $HgCl_2$ aqueous solution was added and the mixture was shaken vigorously for a few seconds. Since stability constants of Hg(II) chelates are much larger than those of Ni(II) chelates, exchange of central metal ion occurred according to

$$[Ni(R_1R_2NCSS)_2]_{org} + [Hg(II)]_w \longrightarrow [Hg(R_1R_2NCSS)_2]_{org} + [Ni(II)]_w, \quad (3)$$

where org and w denote the organic and the aqueous phase, respectively. Hg(II) chelates allowing no absorption in the visible range, the brownish yellow color of chloroform layer was caused to disappear, indicating the completion of the exchange of central metal ion. Hg(II) chelates thus prepared gave good chromatograms without any occurrence of decomposition.

Chromatograms of Ni(II) and Pd(II) Complexes. Various dithiocarbamate chelates were prepared by the methods given above and their elution behaviors put into examination. When diethylamine was used, the following elution sequence for central metal ions was obtained in parallel with increase in retention time: Hg(II) < Cu(II) < Ni(II) < Pd(II) < Co(III). Similar results were obtained for diisopropylamine and piperidine. For Ni(II) chelates derived from various amines was obtained the increasing order of retention time as follows: dibutylamine < diisobutylamine < dipropylamine < dibenzylamine < diisopropylamine < perhydrazepine < diethylamine < piperidine < pyrrolidine < dimethylamine < propylamine < phenethylamine < morpholine < ethylamine < methylamine < *l*-ephedrine; the retention time was found to increase with increase in the carbon number of alkyl chains. This may be interpreted in terms of the solubility of metal chelates in eluents because the solubility increases with increase in the chain length of hydrophobic alkyl groups. The prolonged retention times of morpholine and *l*-ephedrine may be interpreted from the fact that oxygen atoms included in these amines will be adsorbed strongly on the silica-gel surface.

Chromatograms of mixtures of two different amines were examined, the results being exemplified in Fig. 1. Both Ni(II) (Fig. 1(a)) and Pd(II) (Fig. 1(b)) gave three peaks. This implies that a ternary complex is formed according to the following equation and that the ternary complex formed is inert enough to be eluted out without being subjected to disproportionation during the course of chromatographic run:[2,3]

$$MA_2 + MB_2 \rightleftharpoons 2MAB \quad (4)$$

with

$$K = [MAB]^2/[MA_2][MB_2]. \quad (5)$$

This phenomenon which results in complicate chromatogram patterns has led Liska *et al.*[14] to claim that it is difficult to determine amines by application of the conversion into dithiocarbamate chelates. However, as described previously,[15] the present authors think that this phenomenon has some analytical value for the determination of optical purity of optically active amines. When an racemic mixture of amines exists in solution, the following optically active chelates will be formed:

$$MD_2 + ML_2 \rightleftharpoons 2MDL, \quad (6)$$

where D and L represent derivatives derived from *d*- and *l*-isomers, respectively. Since MD_2 and ML_2 are enantiomers and their chemical properties except optical activity are identical, they cannot be separated

Eluent: hexane:isopropyl acetate=100:11.5 (water saturated). Flow rate: 2.5 cm³/min. Detector: 325 nm. Sample: (a) 0.2 mM *l*-ephedrine(*d*-ephedrine gave similar chromatograms), (b) 0.2 mM *dl*-ephedrine Sample size: 50 μl.

from each other. On the other hand, MD_2 (or ML_2) and MDL are diastereomers, and can possibly be separated. Figures 2(a) and (b) show chromatograms of Ni(II) chelates derived from *l*- and *dl*-ephedrine, respectively. The *l*-isomer exists in nature and has widely been used as an antiasthmatic agent. On the contrary, *d*-isomer, not known to exist in nature, is ineffective as antiasthmatic agent. As shown in Fig. 2(b), the racemate gave two peaks, one being assigned to MD_2+ML_2 and the other to MDL. In Fig. 2(b), the peak area of the former (S_1) is equal to that of the latter (S_2), which suggests that the ternary complex formation according to Eq. 6 is controlled statistically ($K=[MDL]^2/([MD_2][ML_2])=4.0$). The optical purity of *dl*-mixture is determined as follows: When the initial concentrations of *d*- and *l*-isomers and d_0 and l_0, respectively, the equilibrium concentrations of MD_2 and ML_2 are $d_0-r/2$ and $l_0-r/2$, respectively, where r is the concentration of MDL. Since the ternary complex formation is controlled statistically, it is derived that $r=2d_0l_0/(d_0+l_0)$. The following relation will then hold between two peak areas S_1 and S_2:

$$\begin{aligned} S_2/(S_1+S_2) &= [MDL]/([MD_2]+[ML_2]+[MDL]) \\ &= r/(l_0+d_0) = 2d_0l_0/(d_0+l_0)^2 = 2p(1-p) \\ &= -2(p-1/2)^2+1/2, \end{aligned} \quad (7)$$

where $p=d_0/(d_0+l_0)$. Figure 3 shows parabolic plots for Eq. 7 with different ratios of *d*- to *l*-isomer. Both the calculated and observed results agreed well. The total ephedrine content was determined from the sum of the two peak areas S_1+S_2.

Pd(II) chelates gave similar results, with retention times slightly longer than those of corresponding Ni(II) complexes.

Chromatograms of Co(III) Complexes. It is well known that, when Co(II) ion reacts with dithiocarbamates to form metal chelates, Co(III) chelates are formed as a result of oxidation of Co(II) ion.[16] As shown in Fig. 1(d) four peaks, each assigned to MA_3, MA_2B, MAB_2, and MB_3, appeared on chromatograms when Co(II) solution was added. This result indicates that oxidation of the central metal ion occurs with formation of 1:3 complexes. No further investigation was made toward analytical application.

Chromatograms of Cu(II) Complexes. Figure 1(c) shows an example chromatogram for a mixture of two Cu(II) chelates. Since Cu(II) chelates are labile, their ternary complexes partially undergo disproportionation into two binary complexes during the course

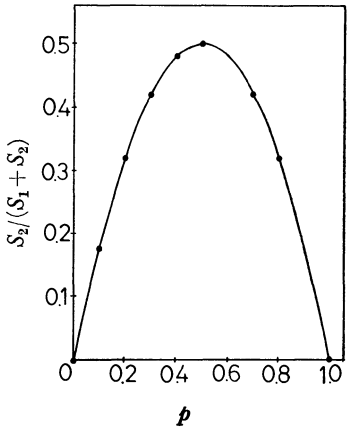

Fig. 3. Plot of Eq. 7 at various *d*- and *l*-isomer ratio chromatographic conditions were similar to those shown in Fig. 2.
——: Calculated value, ●: observed value.

of chromatographic run. The degree of the progress of disproportionation was sensitive to experimental conditions[3] such as the flow rate of pump and column temperature. The disproportionation within the column proceeded with increased proportions at higher column temperatures or at lower flow rates. Since the chromatogram pattern is very sensitive to experimental conditions, the analytical application seems unpromising.

Chromatograms of Hg(II) Complexes. Figure 4 shows chromatograms of Hg(II) chelates derived from mixtures of various aliphatic secondary amines. Unlike the other metal ions, only the peaks of the binary complexes corresponding to each amine appeared on chromatograms. The following aleternative explanations are plausible, the second being more likely: (1) no ternary complex formation occurs for Hg(II) chelates; (2) since Hg(II) complexes are very labile, the ternary complexes formed in the equilibrium state undergo disproportionation almost instantaneously after they are separated from the binary complexes. This seems a reasonable explanation because the rate of ligand exchange for Hg(II) complexes is known to be very high.

Figure 4 suggests that determination of individual amines will be possible when Hg(II) chelates are used. The mixture of samples shown in Fig. 4 was diluted to various concentrations and supplied for HPLC. The chromatograms were unsusceptible to experimental conditions and calibration curves were linear within a wide range of sample amounts. Thus, about 5 ng of each amine could be detected.

Application to Antiasthmatic Agents. Aliphatic amines usually show no or weak absorption in the UV or visible range. Since metal dithiocarbamate chelates show very strong absorption in th UV or visible range (log $\varepsilon > 4$), the present method will be useful for color-producing reactions. The present method was applied to the determination of ephedrines in crude drugs and Chinese crude drug preparations.

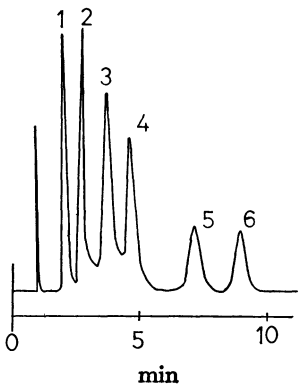

Fig. 4. Chromatograms of Hg(II) chelates derived from the mixture of various secondary amines.
Column: LiChrosorb SI 100 (4 mm × 15 cm).
Eluent: hexane:ethyl acetate=100:3 (water saturated). Flow rate: 2.5 cm³/min. Detector: 273 nm. Sample size: 50 μl (Concentrations of each amine were about 0.03 mM).
1: Dipropylamine, 2: dibenzylamine, 3: diethylamine, 4: piperidine, 5: pyrrolidine, 6: dimethylamine.

Four ephedrine isomers, *l*-, *d*-, *l*-pseudo, and *d*-pseudoephedrine exist. Ephedra herba, which is one of the most important Chinese crude drugs and has widely been used as an antiasthmatic agent or for cough remedy, contains two isomers, *l*- and *d*-pseudoephedrine, the former being more effective. The synthesized racemates *dl*- and *dl*-pseudoephedrine are less pharmacologically active because *d*- or *l*-pseudoephedrine is not effective. Thus, the determination of total content and optical purity of ephedrines is important. Sample treatment was made as follows: to 200 mg of powdered ephedra herba or Chinese crude drug preparations, 40 cm³ of 0.5 M H_2SO_4 was added. The extraction was carried out for 1 hr three times. Then, to the combined extract 100 cm³ of 0.05 M $NiCl_2$ in conc aqueous ammonia and 40 cm³ of chloroform containing 2% carbon disulfide were added, and the mixture was shaken vigorously for about 30 s. A brownish yellow color appeared in the chloroform layer. The chloroform layer was washed with water three times and the

Eluent: hexane:isopropyl acetate=(A) 100:12 (B) 100:25 (water saturated). Flow rate: 2.5 cm³/min. Detector: (a)(c), and (e) 325 nm, (b), (d), and (f) 273 nm. Sample size: 50 μl.
Sample: (a) and (b) ephedra herba, (c) and (d) chinese crude drug preparations (Kakkonto), (e) and (f) ephedra herba+*d*-ephedrine: (a),(c), and (e) Ni(II) chelates (b), (d), and (f) Hg(II) chelates. 1: M(*l*-EP)$_2$, 1′: M(*d*-EP)$_2$+M(*l*-EP)$_2$, 2: M(*d*-ϕ-EP)$_2$, 3: M(*l*-EP)(*d*-EP), 4: M(*l*-EP)(*d*-ϕ-EP), 5: M(*d*-EP)(*d*-ϕ-EP). *l*-EP, *d*-EP, and *d*-ϕ-EP denote dithiocarbamates derived from *l*-ephedrine, *d*-ephedrine, and *d*-ϕ-ephedrine, respectively.

extract was divided into two parts, one of which was supplied directly for HPLC (Ni(II) chelates). To the other part 1 mM $HgCl_2$ aqueous solution was added and the mixture was shaken for a few seconds. The brownish yellow color disappeared immediately as a result of the progress of the exchange of central metal ion according to Eq. 3. The solution was then supplied for HPLC (Hg(II) chelates). Figure 5 shows example chromatograms. Since *l*- and *d*-pseudoephedrine are diastereomers, two peaks corresponding to individual amines appeared on chromatograms when Hg(II) chelates were tested (Figs. 5(b) and (d)). Contrary to this, three peaks including the peak of ternary complex appeared on chromatograms when Ni(II) chelates were tested (Figs. 5(a) and (c)). Figures 5(a) and (c) show that no *d*-ephedrine is contained in these samples. Figure 5(e) shows chromatograms of Ni(II) chelates when a small amount of *d*-ephedrine was added. Two new peaks, assignable to ternary complexes M(*d*-EP)(*d*-ϕ-EP) and M(*d*-EP)(*l*-EP), appeared on chromatograms (Fig. 5(e)). The optical purity of *dl*-mixture of ephedrine in this sample can be determined by the following two methods: (1) equation 7 gives optical purity by comparing two peak areas of peaks 1′ ($M(l\text{-EP})_2+M(d\text{-EP})_2$) and 3 (M(*d*-EP)(*l*-EP)); (2) the ratio of two peak areas of peaks 4 (M(*l*-EP)(*d*-ϕ-EP)) and 5 (M(*d*-EP)(*d*-ϕ-EP)) directly indicates the ratio of *d*- and *l*-isomer. Contrary to the case with Ni(II) chelates, no chromatogram patterns of Hg(II) chelates were affected by addition of *d*-ephedrine (Fig. 5(f)). The peak height of the former was increased by addition of *d*-ephedrine while that of the latter unaffected. The area of the former peak 1 indicates the total content of *dl*-mixture of ephedrine. These results permit the calculation of individual contents of *l*-, *d*-, and *d*-pseudoephedrine.

Kinetic Studies of Fast Equilibrium by Means of High-performance Liquid Chromatography. III. Ternary Complex Formation between Ni(II) Diethyldithiocarbamate and Other Unlike Ni(II) Chelates

Masataka Moriyasu* and Yohei Hashimoto

Kobe Women's College of Pharmacy, Motoyamakita-machi, Higashinada-ku, Kobe 658

(Received March 23, 1981)

The labile ternary complex formation ($MA_2+MB_2 \rightleftarrows 2MAB$ with $K=[MAB]^2/([MA_2][MB_2])$) between Ni(II) diethyldithiocarbamate(MA_2) and other several Ni(II) chelates(MB_2) was investigated by high-performance liquid chromatography; two solutions of MA_2 and MB_2 were mixed and equilibrated. The tendency to form a ternary complex is summarized as follows: (1) no ternary complex formation takes place (B=dimethylglyoxime and 1-(2-pyridylazo)-2-naphthol), for which high structural stability of binary complex MB_2 is responsible; (2) the ternary complex formation is controlled statistically ($K=4.0$), suggesting the absence of any factor to stabilize or unstabilize the ternary complex (B=*N*,*N*-disubstituted dithiocarbamates and *N*-monosubstituted dithiocarbamates); (3) the ternary complex formation is favored ($K>4.0$) (B=xanthates); and (4) all initial binary complexes are converted into a very stable species which is possibly a ternary complex (B=dithizone). Kinetic characteristics of these ternary complex formations are examined.

Ternary complex formation usually occurs as follows when two solutions of labile binary complexes are mixed:

$$MA_2 + MB_2 \underset{k_-}{\overset{k}{\rightleftharpoons}} 2MAB \qquad (1)$$

with

$$K = [MAB]^2/[MA_2][MB_2] = k/k_-. \qquad (2)$$

Study of the ternary complex formation has been carried out mainly by the spectroscopic method since many ternary complexes have characteristic absorption bands. However, this method cannot be applied if the ternary complex gives rise to no characteristic absorption. Our previous studies[1,2] made use of the high-performance liquid chromatography (HPLC) to investigate the ternary complex formation between two different *N*,*N*-disubstituted dithiocarbamate chelates of Ni(II) or Cu(II). In this method two solutions of MA_2 and MB_2 are mixed, kept standing to reach the equilibrium state for the ternary complex formation, and a portion of the mixture is subjected to the HPLC. The separation speed of HPLC is so high that labile ternary complexes are allowed to be eluted out without undergoing any disproportionation. Thus, considerably fast equilibria can be traced by the HPLC based on the conventional principle. Rate constants k and k_- can be determined as follows: when two very dilute solutions of MA_2 and MB_2 are mixed, the ternary complex will gradually be produced until the equilibrium shown in Eq. 1 is attained. During the progress of ternary complex formation, portions of the mixed solution are taken out to be subjected to HPLC. The progress of the reaction is caused to stop immediately after the solution is injected into the column. Thus, concentrations of each species can be determined as a function of time, allowing the determination of k and k_-.

It was confirmed in our previous report[2] that labile ternary complex formations between two different *N*,*N*-disubstituted dithiocarbamate chelates are controlled statistically with a factor of $K=4.0$ in the case of Ni(II) and Cu(II); different factors are expected in cases where two binary complexes whose coordinated ligands are different in property from each other are mixed, depending on the nature of the ligands. The purpose of the present study is to clarify to what extent the HPLC is applicable to the investigation of labile ternary complex formation. We selected Ni(II) chelates since they provide ternary complex formations of such a moderately high rate as to allow kinetic studies to be carried out easily.

Experimental

Reagents. The chelating reagents used are sodium diethyldithiocarbamate (NaDEDTC), sidum ethyldithiocarbamate (NaEDTC), sodium propyldithiocarbamate (NaPDTC), pottasium ethylxanthate (KEXAN), pottasium propylxanthate (KPXAN), 1-(2-pyridylazo)-2-naphthol (HPAN), dimethylglyoxime (HDMG), dithizone (H_2Dz), oxine, salicylaldehyde oxime, 1-nitroso-2-naphthol, and (*E*)-benzoin oxime. NaEDTC and NaPDTC were prepared by the usual procedure[3] from alkylamine, carbon disulfide, and sodium hydroxide. KPXAN was prepared from 1-propanol, carbon disulfide, and pottasium hydroxide.[4] These salts were recrystallized from chloroform–methanol. The other chelating reagents were obtained commercially and purified when necessary. NaDEDTC, NaEDTC, NaPDTC, KEXAN, and KPXAN were dissolved in water. H_2Dz was dissolved in chloroform and the content was determined by measuring the absorption at 606 nm ($\varepsilon=4.06\times10^4$).[5,6] The other chelating reagents which are sparingly soluble in water were dissolved in suitable organic solvents such as chloroform and methanol. The standard solution of Ni(II) was prepared by dissolving $NiCl_2\cdot6H_2O$ in water. The content of Ni(II) was determined by colorimetry on its diethyldithiocarbamate. Before use all solvents used for HPLC were saturated with water.

Apparatus. The HPLC apparatus used in this study is similar to the one described previously.[1,7] Absorption spectra of each metal chelate were measured by a Model-124 Hitachi double-beam spectrometer.

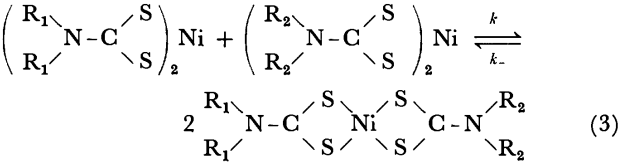
Procedure. The Ni(II) chelates of DEDTC, EDTC, PDTC, EXAN, and PXAN were prepared by mixing the Ni(II) standard solution and the corresponding chelating reagent in water. The metal chelates prepared were extracted with chloroform under the condition for complete extraction. In order to remove residual free ligands in chloroform, the extract was washed with water four times. The Ni(II) chelate of dithizone was prepared in the following

way: To the Ni(II) aqueous standard solution, a slight excess of dithizone in chloroform was added. Since in acidic media the rates of formation and extraction of Ni(II) dithizonate are slow,[8] a small amount of dilute aqueous ammonia (0.5 vol%) was added and the mixture was shaken vigorously for 30 min. Then, the chloroform layer was washed three times with 0.2 vol% aqueous ammonia to remove the residual free dithizone in chloroform. The solutions of the other Ni(II) chelates were prepared by mixing the Ni(II) standard solution and the corresponding chelating reagent in an organic solvent, and diluting the resulting solution with chloroform to a proper concentration.

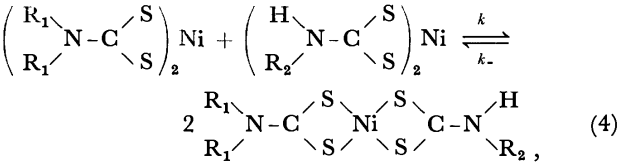
Results and Discussion

HPLC of Various Ni(II) Chelates. Chromatographic behavior of various Ni(II) chelates was examined on silica gel packings. Among them, Ni(DEDTC)$_2$, Ni(EDTC)$_2$, Ni(PDTC)$_2$, Ni(EXAN)$_2$, Ni(PXAN)$_2$, Ni(DMG)$_2$, Ni(PAN)$_2$, and Ni(HDz)$_2$ gave good chromatograms. Calibration curves of these metal chelates are linear over a wide range of sample amounts. Contrary to this, the Ni(II) chelates of oxine, salicylaldehyde oxime, 1-nitroso-2-naphthol, and (*E*)-benzoin oxime gave no quantitative results because partial or complete decomposition takes place in the course of chromgatography. Silica gel seems too active for these chelates of relatively low stability and other less active packings are expected to give satisfactory results. In the present research these Ni(II) chelates which failed to give quantitative results on silica gel packings were left omitted from further examination.

Ni(DEDTC)$_2$–Ni(EDTC)$_2$. These two binary chelates were mixed at 25 °C and after kept standing long enough to attain the equilibrium, the mixture was supplied for HPLC. Three peaks corresponding to Ni(DEDTC)$_2$, Ni(EDTC)$_2$, and Ni(DEDTC)(EDTC) appeared on chromatograms (Fig. 1). The heights of each peak were independent of flow rate, suggesting that no disproportionation of the ternary complex occurs in course of chromatography. Similar to the system composed of two different Ni(II) *N,N*-disubstituted dithiocarbamate chelates,[1,2] the equilibrium constant K was 4.0. The system Ni(DEDTC)$_2$–Ni(PDTC)$_2$ gave similar results. From these results it can be concluded that the ternary complex formation according to the following equations is controlled statistically, *i.e.*, there exists no factor in operation which makes the ternary complex stable or unstable:



(3)



(4)

where R_1 and R_2 denote alkyl groups.

Rate constants k and k_- were determined by the following equation with a procedure similar to the one described in our previous report:[2]

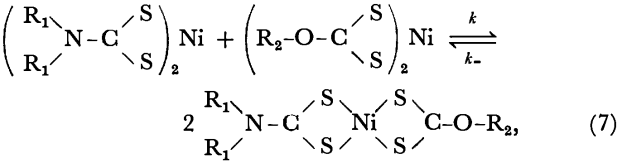
$$k = -(1/a_0 t)\ln(1-y/a_0) \tag{5}$$

with

$$k_- = k/4, \tag{6}$$

where the initial concentrations of two binary complexes MA_2 and MB_2 are designed to be the same ($=a_0$) with each other and y is the concentration of ternary complex MAB at a reaction time t after mixing. Thus, rate constants k and k_- were determined to be $(1.6\pm0.25)\times10^2$ mol^{-1} dm^3 s^{-1} and $(4.0\pm0.6)\times10^1$ mol^{-1} dm^3 s^{-1}, respectively, for the system Ni(DEDTC)$_2$–Ni(EDTC)$_2$ (in chloroform: ethyl acetate: hexane=1:1:3) at 25 °C. These values are similar to those reported in our previous report[2] for corresponding complex formations between Ni(DEDTC)$_2$ and other various Ni(II) *N,N*-disubstituted dithiocarbamate chelates.

Ni(DEDTC)$_2$–Ni(EXAN)$_2$. Both dithiocarbamates and xanthates are *S,S*-coordinates chelating reagents and their chemical structures are similar to one another. When solutions of two binary complexes of Ni(II) dithiocarbamate and xanthate are mixed, the following ternary complex formation occurs:



(7)

as evidenced by Fig. 2. Unlike the system composed

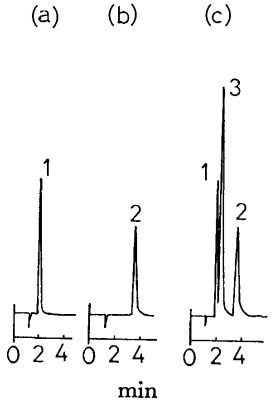


Fig. 1. Ternary complex formation between Ni(DEDTC)$_2$ and Ni(EDTC)$_2$.

1: Ni(DEDTC)$_2$, 2: Ni(EXAN)$_2$, 3: Ni(DEDTC)-(EXAN).

of two Ni(II) dithiocarbamate chelates, this system gave an equilibrium constant K larger than 4.0 (8.3±1.2, in chloroform:ethyl acetate:hexane=1:1:3) at 25 °C, and about 60% of the initial binary complexes was converted into the ternary complex. This result suggests the presence of some factor to stabilize the ternary complex, even though there seem to exist none of apparent driving factors in favor of the ternary complex formation, such as steric factors, π-bond formation, hydrogen bond formation, and neutralization of the charge.[9]

When K is not equal to 4.0, rate constants k and k_- should be determined from the following rather complicated equation[10] derived on the assumption that a bimolecular collisional process is operating in the ternary complex formation:

$$k = (2/m_0t)\left[\ln\frac{\left(\frac{2a_0+m_0}{1-4/K}-y\right)}{\left(\frac{2a_0-m_0}{1-4/K}-y\right)}+\ln\left(\frac{2a_0-m_0}{2a_0+m_0}\right)\right], \quad (8)$$

where

$$m_0 = 4a_0\sqrt{1/K}. \quad (9)$$

Two solutions of MA_2 and MB_2 were mixed at 25 °C and after a measured time a portion of the mixed solution was supplied for HPLC. With the lapse of time the peak of the ternary complex rose while those of the binary complexes fell, the results being plotted in Fig. 3. The validity of the bimolecular collisional process was confirmed by changing the initial concentration a_0. Rate constants k and k_- were determined to be $(1.3\pm0.1)\times10^2$ mol^{-1} dm^3 s^{-1} and $(1.6\pm0.2)\times10^1$ mol^{-1} dm^3 s^{-1}, respectively, (in chloroform:

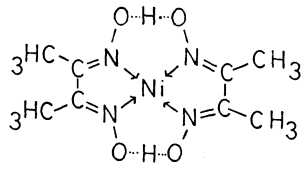
1: Ni(DEDTC)$_2$, 2: Ni(PAN)$_2$, 3: Ni(DMG)$_2$.

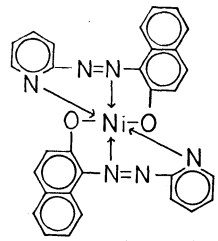
ethyl acetate:hexane=1:1:3) at 25 °C.

Similar results were obtained for the system Ni(DEDTC)$_2$–Ni(PXAN)$_2$. Equilibrium constant K and rate constants k and k_- for the ternary complex formation were also determined ($K=7.6\pm1.4$, $k=(1.0\pm0.1)\times10^2$ mol^{-1} dm^3 s^{-1}, and $k_-=(1.3\pm0.25)\times10^1$ mol^{-1} dm^3 s^{-1}, in chloroform:ethyl acetate:hexane=1:1:3) at 25 °C.

Ni(DEDTC)$_2$–Ni(PAN)$_2$–Ni(DMG)$_2$. When these two or three binary metal chelates were mixed, the peaks of the initial binary chelates alone appeared on chromatograms (Fig. 4). Then, an attempt was made to cause ternary complexes to be formed in the following way: Two or three free chelating reagents in methanol were mixed and then the Ni(II) aqueous solution was added to form metal chelates. The metal chelates were extracted with chloroform and then supplied for HPLC. The chromatogram

patterns were similar to those shown in Fig. 4, excluding the possibility of the formation of any stable ternary complexes. Thus, the following alternative explanations are plausible: (1) no ternary complex formation occurs because initial binary complexes have very stable structures; and (2) a very labile ternary complex is formed. In this case, the ternary complex formed should undergo disproportionation into two binary complexes almost instantaneously in the column, resulting in the appearance of only the peaks of binary complexes on chromatograms. The present authors regard the former explanation as the more plausible for the following reasons: as shown below, $Ni(DMG)_2$ has a very stable structure by dint of hydrogen bond formation[11] and $Ni(PAN)_2$ has a stable six-coordinated structure.[12] When a ternary complex





is to be formed, either the hydrogen bond should be broken or the five-coordinated ternary chelate formed. These ternary chelates will be rather unstable energetically. The chromatogram patterns shown in Fig. 4 were independent of experimental conditions such as flow rate, column temperature, and initial concentrations of binary complexes, which is in favor of the former explanation.[2] If the latter explanation is correct, the Ni(II) ternary complex formed should be extraordinarily labile in comparison with other various Ni(II) chelates.

$Ni(DEDTC)_2$–$Ni(HDz)_2$. When these two binary complexes were mixed, characteristic chromatograms different from those for the other systems were obtained. As ashown in Fig. 5, with the lapse of time, the peaks of binary complexes fell while a new peak appeared and grew gradually. The progress of the reaction was slow at room temperature. After 1-d standing, the peaks of the binary complexes disappeared completely when the initial concentrations of two binary complexes had been chosen the same ($=a_0$). There seems to remain some debatable points on what reaction occurred in the mixed solution. To the solution given in Fig. 5(g), in which the reaction had been completed, dilute aqueous ammonia (0.5 vol%) was added and the mixture was shaken vigorously for about 30 s. No free dithizone was extracted out into the aqueous layer, excluding the possibility of free dithizone being liberated in the reaction. It is reported[8] that Ni(II) dithizonate may exist in two forms, *i.e.*, as the keto-form complex $Ni(HDz)_2$ and enol-form complex NiDz. The Ni(II) chelates used in the present research was spectroscopically confirmed to be the keto-form complex. The absorption spectrum of the species produced, shown in Fig. 6(c), is different from those of such species as the initial binary complexes and free dithizone. It is different also from the one of the enol-form complex NiDz.[13] These results suggest that a new species was produced in the reaction. The absorption spectrum of the new species resembles the one of $Ni(HDz)_2$ in the visible range, with weaker absorption; in the UV range the absorption maximum ($=312$ nm) appeared between those of $Ni(DEDTC)_2$ ($=325$ nm) and $Ni(HDz)_2$ ($=280$ nm). These phenomena may be interpreted well in terms of the ternary complex formation. The possibility of the formation of higher-order complexes such as polynuclear com-

Column: LiChrosorb SI 100 (4 mm×25 cm). Eluent: hexane:ethyl acetate=100:10 (water saturated). Flow rate: 3.2 cm³/min. Detector: 312 nm. Sample size: 50 μl. Sample: 2.5×10^{-5} mol dm^{-3} $Ni(DEDTC)_2$+2.5×10^{-5} mol dm^{-3} $Ni(HDz)_2$ (a); after mixing 1 min, (b); 3.5 min (c); 6 min, (d); 8.5 min, (e); 11 min, (f); 13.5 min, (g); 1 d. These samples are solutions in chloroform:ethyl acetate: hexane=1:1:3 at 50 °C.
1: $Ni(DEDTC)_2$, 2: $Ni(HDz)_2$, 3: a new species (see text).

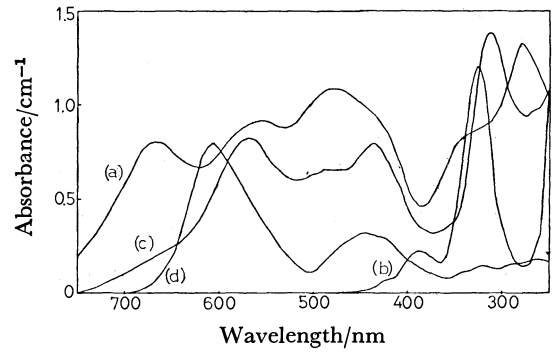

Fig. 6. Absorption spectra of various species in the system $Ni(DEDTC)_2$–$Ni(HDz)_2$.
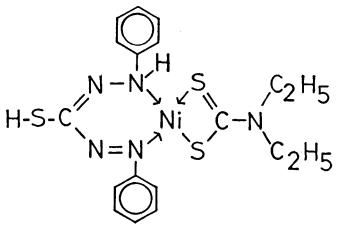
(a): 4.0×10^{-5} mol dm^{-3} $Ni(HDz)_2$, (b): 4.0×10^{-5} mol $Ni(DEDTC)_2$, (c): the reaction product between 4.0×10^{-5} mol dm^{-3} $Ni(HDz)_2$ and 4.0×10^{-5} mol dm^{-3} $Ni(DEDTC)_2$, (d): 2.0×10^{-5} mol dm^{-3} H_2Dz. These samples are solutions in chloroform.

plex, however, cannot completely be ruled out for the following reason: It should be noted that Ni(HDz)$_2$ has the *N,N*-coordinated structure,[14] though most of other metal dithizonates have the *N,S*-coordinated structure. Some intramolecular structural rearrangement which stabilizes the ternary complex might occur during the course of ternary complex formation. The structure of the possible ternary complex will be as follows, provided that no structural rearrangement occurs.



The following chemical equation will hold for the possible ternary complex formation since the reverse reaction can be neglected:

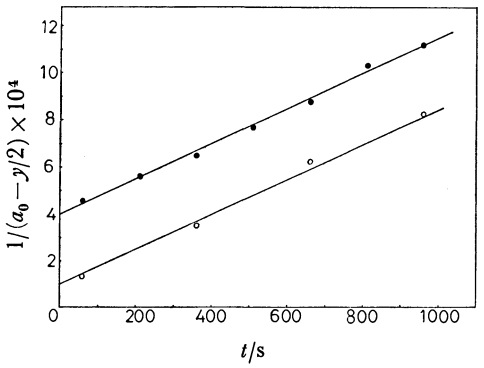


Fig. 7. Plot of Eq. 12.
Chromatographic conditions were similar to those shown in Fig. 5.
○: $a_0=1.0\times10^{-4}$ mol dm^{-3}, ●: $a_0=2.5\times10^{-5}$ mol dm^{-3}.
These samples are solutions in chloroform:ethyl acetate: hexane=1:1:3 at 50 °C.

$$\mathrm{Ni(DEDTC)_2} + \mathrm{Ni(HDz)_2} \xrightarrow{k} 2\mathrm{Ni(DEDTC)(HDz)}. \quad (10)$$

Rate constant k of this reaction will be obtained from the following equations based on the bimoelcular collisional process:

$$1/x = 1/a_0 + kt \quad (11)$$

$$1/(a_0-y/2) = 1/a_0 + kt, \quad (12)$$

where x and y are concentrations of Ni(DEDTC)$_2$ (=Ni(HDz)$_2$) and Ni(DEDTC)(HDz), respectively, at a reaction time t after mixing. Figure 7 shows plots for Eq. 12. The validity of the bimolecular process was confirmed by changing the initial concentration a_0. Rate constant k was thus determined to be $(1.8\pm0.2)\times10^1$ mol^{-1} dm^3 s^{-1} and $(7.4\pm0.4)\times10^1$ mol^{-1} dm^3 s^{-1} at 25 °C and 50 °C, recepectively (in chloroform: ethyl acetate:hexane=1:1:3).

(Received March 5, 1981)

Kinctics of outer-sphere oxidations of $[Mo^{V}_{2}O_4(hedta)(H_2O)]^-$ (**1**) (H_3hedta=*N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid) with $[Ir^{IV}Cl_6]^{2-}$ ($[H^+]=10^{-5.8}$—0.10 M (1 M=1 mol dm^{-3}); ionic strength, I=0.1 M (adjusted with $LiClO_4$); 25—45 °C) and with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ ($[H^+]$=0.01—0.30 M; I=0.1 and 2.0 M; 10—30 °C), were studied under pseudo-first-order conditions (the reductant in large excess). The following reaction scheme is consistent with the observed rate laws:

$$\mathbf{1} \overset{K_a}{\rightleftharpoons} [Mo^{V}_{2}O_4(hedta)(OH)]^{2-} (\mathbf{2}) + H^+$$

$$\mathbf{1} + [Ir^{IV}Cl_6]^{2-} \xrightarrow{k_{(a)}} (Mo^{V}Mo^{VI}) + [Ir^{III}Cl_6]^{3-}$$

$$\mathbf{2} + [Ir^{IV}Cl_6]^{2-} \xrightarrow{k_{(b)}} (Mo^{V}Mo^{VI}) + [Ir^{III}Cl_6]^{3-}$$

$$\mathbf{1} + [\mu\text{-}O_2^{(-)}]^{5+} \overset{K_{IP(a)}}{\rightleftharpoons} IP(a) \text{ (ion-pair)}$$

$$\mathbf{2} + [\mu\text{-}O_2^{(-)}]^{5+} \overset{K_{IP(b)}}{\rightleftharpoons} IP(b) \text{ (ion-pair)}$$

$$IP(b) \xrightarrow{k_{e(b)}} (Mo^{V}Mo^{VI}) + [\mu\text{-}O_2^{(2-)}]^{4+}$$

$$(Mo^{V}Mo^{VI}) + \text{oxidant} \xrightarrow{\text{fast}} 2(Mo(VI)).$$

At 25 °C and I=0.1 M, K_a, $k_{(a)}$, $k_{(b)}$, $K_{IP(a)}$, $K_{IP(b)}$, and $k_{e(b)}$ are 7.9×10^{-4} M, 23 M^{-1} s^{-1}, 1.11×10^{4} M^{-1} s^{-1}, 40.5 M^{-1}, 1046 M^{-1}, and 2.56 s^{-1}, respectively. Activation parameters for the $k_{(b)}$ path are $\Delta H^{*}=38\pm8$ kJ mol^{-1} and $\Delta S^{*}=-25\pm29$ J K^{-1} mol^{-1}. The product $k_{e(b)}K_{IP(b)}K_a$ is 7.35×10^{-2} s^{-1} at 25 °C and I=2.0 M, and the corresponding activation parameters are $\Delta H^{*}=67\pm8$ kJ mol^{-1} and $\Delta S^{*}=-34\pm29$ J K^{-1} mol^{-1}. The oxidation of **2** is *ca.* 10^4 times as fast as that of **1**. The results are compared with the oxidation reactions of other $Mo^{V}_{2}O_4^{2+}$-complexes.

Redox reactions of molybdenum(V) complexes are attracting interest not only of coordination chemists but also of biochemists because of their importance in biochemical studies and biomimetic approach to complex catalysis.[1] We reported the kinetics of oxidations of two molybdenum(V) complexes containing di-μ-oxo-bis[oxomolybdenum(V)] ($Mo^{V}_{2}O_4^{2+}$) core, $[Mo^{V}_{2}O_4(edta)]^{2-}$ (H_4edta=ethylenediaminetetraacetic acid) and $[Mo^{V}_{2}O_4(H_2O)_n]^{2+}$, with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ in aqueous perchloric acid solution,[2] and of $[Mo^{V}_{2}O_4(pdta)]^{2-}$ (H_4pdta=propylenediaminetetraacetic acid) with $[(en)_2Co^{III}(\mu\text{-}NH_2,O_2^{(-)})Co^{III}(en)_2]^{4+}$ (en=ethylenediamine) in aqueous solution at pH 4.6.[3] Sykes and his co-workers studied the oxidation of edta and aqua complexes of the molybdenum(V) dimer with $[Fe^{III}(phen)_3]^{3+}$ (phen=1,10-phenanthroline) and with $[Ir^{IV}Cl_6]^{2-}$ in aqueous perchloric acid solution.[4,5] All these reactions proceeded via the outer-sphere mechanism. The rate of oxidation of $[Mo^{V}_{2}O_4(edta)]^{2-}$ with these one-electron oxidants is of first-order with respect to the concentration of $[Mo^{V}_{2}O_4(edta)]^{2-}$ and of the oxidant at 1.0 and 2.0 M (1 M=1 mol dm^{-3}) of ionic strength I, and is independent of $[H^+]$ (0.01—0.5 M).[2,4]

The rate of the predominant pathway for the oxidation of $[Mo^{V}_{2}O_4(H_2O)_n]^{2+}$ is, on the contrary, independent of the concentration of the oxidant and reciprocally dependent on $[H^+]$.[2,5] The proposed mechanism involves a rate-determining cleavage of one of the oxo bridges in $[Mo^{V}_{2}O_4(OH)(H_2O)_{n-1}]^{+}$ to give a single-bridged molybdenum(V) dimer prior to electron-transfer.[2,5]

The ligand environment including the presence of aqua ligands should play an important role in determining the pattern of oxidation mechanism. In order to clarify the factors controlling the oxidation mechanism, we have extended our study to the oxidation of $[Mo^{V}_{2}O_4(hedta)(H_2O)]^-$ (H_3hedta=*N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid),[6] which is structurally similar to $[Mo^{V}_{2}O_4(edta)]^{2-}$ but has no coordinated water molecule. Kinetics of the oxidation of the hedta complex with $[Ir^{IV}Cl_6]^{2-}$, $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$, and $[(en)_2Co^{III}(\mu\text{-}NH_2,O_2^{(-)})Co^{III}(en)_2]^{4+}$ are discussed in this paper.

Experimental

Materials. Sodium aqua-μ(*N*,*N*′)-*N*-(2-hydroxyethyl)-ethylenediamine-*N*,*N*′,*N*′-triacetato-di-μ-oxo-bis[oxomolybdate(V)] dihydrate, $Na[Mo^{V}_{2}O_4(hedta)(H_2O)]\cdot2H_2O$,[6] μ-hyperoxo-bis[pentaamminecobalt(III)] perchlorate dihydrate, $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5](ClO_4)_5\cdot2H_2O$,[2] and μ-amido-μ-hyperoxo-bis[bis(ethylenediamine)cobalt(III)] chloride trihydrate, $[(en)_2Co^{III}(\mu\text{-}NH_2,O_2^{(-)})Co^{III}(en)_2]Cl_4\cdot3H_2O$,[7] were prepared by the known methods. Sodium hexachloroiridate(IV) hexahydrate, $Na_2[Ir^{IV}Cl_6]\cdot6H_2O$ (Johnson Matthey Chemical Limited), was used without further purification. Aqueous solution of lithium perchlorate was prepared as described previously.[2]

Kinetic Runs. All the kinetic runs were carried out under pseudo-first-order condition with the molybdenum(V)

complex in at least ten fold excess to the oxidant. The oxidation with $[Ir^{IV}Cl_6]^{2-}$ was studied by the stopped-flow method. The decrease in the concentration of $[Ir^{IV}Cl_6]^{2-}$ was followed by using its absorption peak at 487 nm (ε= 4070 M^{-1} cm^{-1}).[4] The rate of oxidation with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ was markedly affected by the ionic strength of aqueous solution. The conventional spectrophotometry and the stopped-flow method were used for reactions at I=2.0 and 0.1 M, respectively. The decrease in the concentration of $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ was followed by using its absorption peak at 670 nm (ε= 832 M^{-1} cm^{-1}).[8] The rate of oxidation with $[(en)_2Co^{III}(\mu\text{-}NH_2,O_2^{(-)})Co^{III}(en)_2]^{4+}$ was followed by the stopped-flow method by using its absorption peak at 690 nm (ε= 485 M^{-1} cm^{-1}).[7] Errors for the activation parameters were determined by the least squares treatment with a confidence level 0.95.

Measurements. A Hitachi 124 spectrophotometer with a Hitachi recorder QPD-34 and a Union-Giken RA-401 stopped-flow spectrophotometer were used for kinetic measurement. The acid dissociation constant of $[Mo^{V}_2O_4(hedta)(H_2O)]^-$ was determined by the pH titration with a Model E300B pH meter of Metrohm Herisau, which was standardized against perchloric acid solutions in 2.0 and 0.1 M $LiClO_4$ to find the concentration rather than the activity of hydrogen ions.

Results

Preliminary Studies. The binuclear complex anion $[Mo^{V}_2O_4(hedta)(H_2O)]^-$ undergoes acid hydrolysis in aqueous perchloric acid solution ($[H^+]>0.5$ M).[6] The complex is oxidized with $[Ir^{IV}Cl_6]^{2-}$, $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$, and $[(en)_2Co^{III}(\mu\text{-}NH_2,O_2^{(-)})Co^{III}(en)_2]^{4+}$ in aqueous solution. The μ-hyperoxo complex $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ decomposes slowly in aqueous solutions containing less than 0.01 M H^+.[2] The other two oxidants are stable over the pH range 1—5.8. Stoichiometries of the oxidation with $[Ir^{IV}Cl_6]^{2-}$ and with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ were determined in 0.01 M perchloric acid solution at 25 °C. Solutions were prepared to contain 2 to 10 fold excess (in molar ratio of the complex ions) of the oxidant to the molybdenum complex (*ca.* 5×10^{-4} M). The amount of unreacted oxidant was estimated as soon as the redox reaction was completed, so that the error caused by the slow decomposition of the oxidant was minimized. Two moles of both oxidants are consumed per one mole of the molybdenum complex. The overall reaction can be written similarly to that of the oxidation of $[Mo^{V}_2O_4(edta)]^{2-}$ with these oxidants.[2,4]

$$[Mo^{V}_2O_4(hedta)(H_2O)]^- + 2[Ir^{IV}Cl_6]^{2-} \longrightarrow 2\text{"Mo(VI)"} + \text{"HEDTA"} + 2[Ir^{III}Cl_6]^{3-} \quad (1)$$

$$[Mo^{V}_2O_4(hedta)(H_2O)]^- + 2[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+} \longrightarrow 2\text{"Mo(VI)"} + \text{"HEDTA"} + 4\text{"Co(II)"} + 2O_2 + 20NH_4^+. \quad (2)$$

Here, "Mo(VI)" and "Co(II)" represent Mo(VI) and Co(II) species, respectively, present in the solution, whose structures are not specified. "HEDTA" represents variously protonated forms of the ligand which would possibly coordinate to Mo(VI) and/or Co(II) under the given conditions.

Kinetics of the Oxidation with $[Ir^{IV}Cl_6]^{2-}$. This was studied at I=0.1 M for most runs and at 25—45 °C. First-order plots $\log(OD_t-OD_\infty)$ *vs.* t gave excellent straight lines up to almost completion of the reaction, where OD_t stands for the absorbance at 487 nm at time t. The first-order rate constant, k_{obsd}, was not affected by the concentration of $[Ir^{IV}Cl_6]^{2-}$ (hereafter $[Ir^{IV}]$) (1.89×10^{-5}—9.90×10^{-5} M) at $[H^+]$=0.1 and $10^{-5.1}$ M. Values of k_{obsd} at a given $[H^+]$ are proportional to the concentration of $[Mo^{V}_2O_4(hedta)(H_2O)]^-$ (hereafter $[Mo_2]$) (5.22×10^{-4}—4.28×10^{-3} M), and expressed by Eq. 3. The

$$-d[Ir^{IV}]/dt = k_{obsd}[Ir^{IV}] = k_1[Mo_2][Ir^{IV}] \quad (3)$$

dependence of k_1 on $[H^+]^{-1}$ ($[H^+]$=0.01—0.10 M) is given in Fig. 1. The plot gives a straight line with a small intercept (Fig. 1(a)), as formulated by Eq. 4.

$$k_1 = k_2 + k_3[H^+]^{-1}. \quad (4)$$

Values of k_2 and k_3 are 45±17 M^{-1} s^{-1} and 16.5±0.4 s^{-1} at 25 °C, and 58±32 M^{-1} s^{-1} and 27.7±0.7 s^{-1} at 35 °C, respectively.

The k_1 value increases further in lower $[H^+]$ regions to reach a limiting value (k_4) at about $[H^+]=10^{-4.5}$ M (Fig. 1(b)). Values of k_4 at $[H^+]=10^{-5.1}$ M are 2.22×10^4, 2.95×10^4, 4.08×10^4, 4.83×10^4, and 6.86×10^4 M^{-1} s^{-1} at 25, 30, 35, 40, and 45 °C, respectively. Activation parameters are ΔH^*=38±8 kJ mol^{-1} and ΔS^*=−29±29 J K^{-1} mol^{-1}. The effect of ionic strength was briefly investigated; k_4 values at I=0.5 and 1.0 M at $[H^+]=10^{-5.1}$ M are 3.42×10^4 and 4.23×10^4 M^{-1} s^{-1}, respectively, at 25 °C.

Kinetics of the Oxidation with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ *at Ionic Strength 2.0 M.* This was studied at 10—30 °C and $[H^+]$=0.01—0.30 M. First-order plots, $\log(OD_t')$ *vs.* t, were linear to more than 90% of the course of reaction for most runs, where

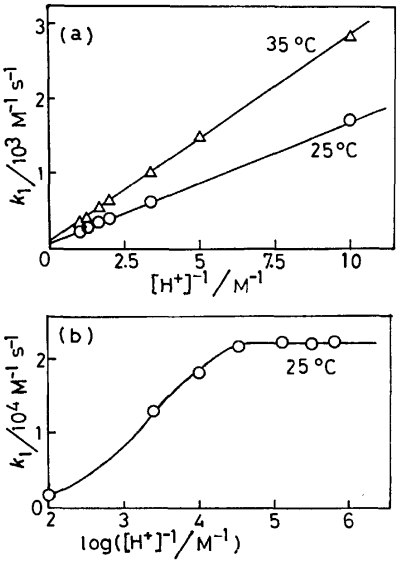

Fig. 1. The dependence of second-order rate constants, k_1, on $[H^+]^{-1}$ for the oxidation of $[Mo^{V}_2O_4(hedta)(H_2O)]^-$ with $[Ir^{IV}Cl_6]^{2-}$ at I=0.1 M ($LiClO_4$), (a) in aqueous perchloric acid solutions and (b) in acetate buffer solutions.

OD_t' stands for the absorbance at 670 nm at time t. The first-order rate constant, k_{obsd}, was not affected by the concentration of $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ (hereafter $[\mu\text{-}O_2^{(-)}]$) ($(2.96-8.05)\times 10^{-4}$ M). First-order plot at $[H^+]=0.3$ M was not linear, probably due to acid hydrolysis of the oxidant,[6] and k_{obsd} was obtained from the initial part of the plot.

The k_{obsd} value depends linearly on $[Mo_2]$ at a given $[H^+]$ (Fig. 2), and is reciprocally dependent on $[H^+]$ at given concentrations of the reactants (Fig. 3). The rate law is expressed by Eq. 5. Values of

$$-d[\mu\text{-}O_2^{(-)}]/dt = k_{obsd}[\mu\text{-}O_2^{(-)}] = k_5[H^+]^{-1}[Mo_2][\mu\text{-}O_2^{(-)}] \quad (5)$$

k_5 are 3.17×10^{-2}, 6.39×10^{-2}, 0.100, 0.147, and 0.222 s^{-1} at 10.5, 16.0, 22.0, 25.5, and 30.0 °C, respectively. Activation parameters are $\Delta H^*=67\pm8$ kJ mol^{-1} and $\Delta S^*=-38\pm29$ J K^{-1} mol^{-1}.

Kinetics of the Oxidation with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ at Ionic Strength 0.1 M. This was studied at 25 and 30.6 °C and $[H^+]=0.02$—0.10 M. First-order plots deviated from straight lines for the initial part of the reaction for *ca.* 1 s regardless of reactant concentrations and of $[H^+]$. The first-order rate constant (k_{obsd}) was obtained from the linear part of the plot. The dependence of k_{obsd} on $[Mo_2]$ at a given $[H^+]$ was not linear (Fig. 4), but plot of k_{obsd}^{-1} *vs.* $[Mo_2]^{-1}$ gave a straight line with a positive intercept at each $[H^+]$. Therefore, k_{obsd} can be expressed by Eq. 6 at a given $[H^+]$. Values of x and

$$k_{obsd}^{-1} = x + y[Mo_2]^{-1} \quad (6)$$

y were obtained from 52 kinetic runs and their dependences on $[H^+]$ are shown in Figs. 5 and 6.

Kinetics of the Oxidation with $[(en)_2Co^{III}(\mu\text{-}NH_2,O_2^{(-)})Co^{III}(en)_2]^{4+}$. This was studied briefly at $[H^+]=10^{-5.1}$ and $10^{-5.8}$ M, $I=0.1$ M and at 25 °C. First-order plots gave good straight lines up to almost completion of the reaction. The k_{obsd} values for $[Mo_2]=1.04\times10^{-3}$ M at $[H^+]=10^{-5.1}$ and $10^{-5.8}$ M are 11.1 and 11.6 s^{-1}, respectively, suggesting that the dependence on $[H^+]$ is negligible in this $[H^+]$ range. The dependence of k_{obsd} on $[Mo_2]$ ($[Mo_2]=5.19\times10^{-4}$—3.11×10^{-3} M; [oxidant]$=9.24\times10^{-5}$ M) con-

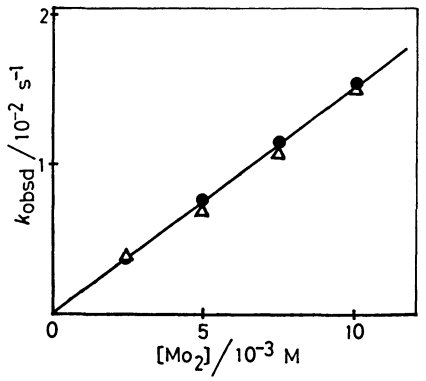

Fig. 2. The dependence of k_{obsd} on $[Mo_2^{V}O_4(hedta)(H_2O)^-]$ for the oxidation of $[Mo_2^{V}O_4(hedta)(H_2O)]^-$ with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ in 0.1 M $HClO_4$ solution at 25 °C and $I=2.0$ M. $[\mu\text{-}O_2^{(-)}]=5.21\times10^{-4}$ (●) and 2.96×10^{-4} M (△).

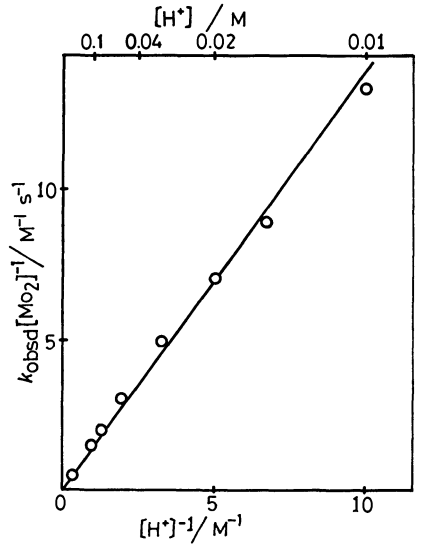

Fig. 3. The dependence of $k_{obsd}/[Mo_2]$ on $[H^+]^{-1}$ for the oxidation of $[Mo_2^{V}O_4(hedta)(H_2O)]^-$ with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ at 25 °C and $I=2.0$ M with $[Mo_2^{V}]$ in large excess.

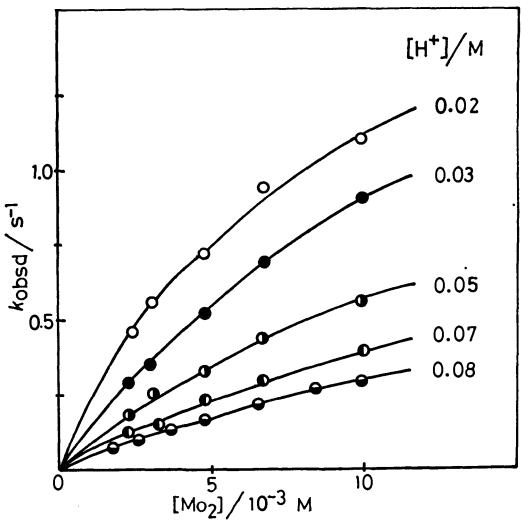

Fig. 4. The dependence of k_{obsd} on $[Mo_2^{V}O_4(hedta)(H_2O)^-]$ for the oxidation of $[Mo_2^{V}O_4(hedta)(H_2O)]^-$ with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ at $I=0.1$ M in aqueous perchlorate media ($HClO_4$–$LiClO_4$) at 25 °C and $[\mu\text{-}O_2^{(-)}]=3.0\times10^{-4}$ M.

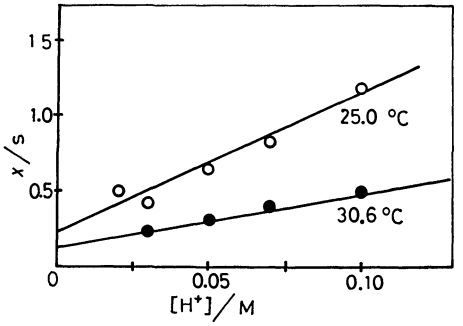

Fig. 5. The dependence of x on $[H^+]$ for the oxidation of $[Mo_2^{V}O_4(hedta)(H_2O)]^-$ with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ at $I=0.1$ M.

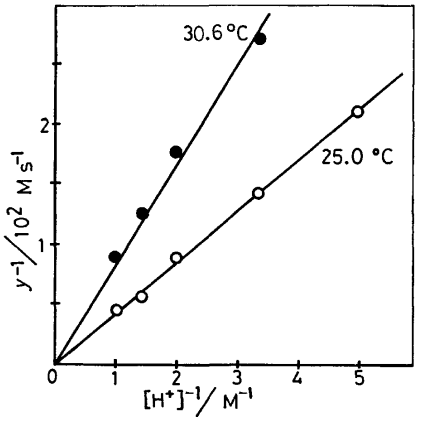

Fig. 6. The dependence of y^{-1} on $[H^+]^{-1}$ for the oxidation of $[Mo^{V}_2O_4(hedta)(H_2O)]^-$ with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ at I=0.1 M.

formed to the rate law (6). Values of x and y at $[H^+]=10^{-5.1}$ M are $(1.7\pm0.6)\times10^{-2}$ s and $(7.9\pm0.6)\times10^{-5}$ M^{-1} s, respectively.

Effect of Added Halide Ions. The effect of added chloride and bromide ions was studied with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ as oxidant at given concentrations of the reactants (Table 1). The pseudo-first-order rate constant becomes smaller on addition of halide ions. Various conditions shown in the footnote of Table 1 do not seem to change the degree of influence by the halide ions.

The pK_a Value of $[Mo^{V}_2O_4(hedta)(H_2O)]^-$. Values of p$K_a$ of this complex are 3.10 and 3.25 at 25 °C and I=0.1 and 2.0 M, respectively. The latter value was carefully determined, since it is clearly different from our previously determined value (3.02);[6] the value should therefore be revised to 3.25. At 35 °C pK_a is 3.18 (I=0.1 M).

Table 1. The effect of halide ions on the rate of oxidation of $[Mo^{V}_2O_4(hedta)(H_2O)]^-$ with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ at 25 °C[a]

a) I=2.0 M ($LiClO_4$), $[H^+]$=0.10 M ($HClO_4$), $[Mo_2]=5\times10^{-3}$ M, $[\mu\text{-}O_2^{(-)}]=5\times10^{-4}$ M. b) The μ-hyperoxo complex solution containing lithium halide was mixed with the molybdenum solution to cause the electron transfer to start. c—e) The μ-hyperoxo complex solution was mixed with the molybdenum complex solution containing lithium chloride to cause the electron transfer reaction to start. Lithium chloride was added to the molybdenum complex solution c) 40 m, d) 220 m, and e) 345 m before the redox reagents were mixed.

Discussion

Interpretation of Kinetic Data. None of the three oxidants is likely to be protonated or deprotonated in the pH range employed. Therefore, the pH dependence of the oxidation rate should be interpreted by considering the protonation-deprotonation equilibrium of the reductant. A consideration similar to those for the oxidation[2,4] of $[Mo^{V}_2O_4(edta)]^{2-}$ suggests that the oxidation of the first molybdenum(V) ion in the dimer is the rate-determining step, which is followed by a rapid oxidation of the second molybdenum(V) ion.

The Oxidation with $[Ir^{IV}Cl_6]^{2-}$: Kinetic data were most reasonably interpreted in terms of the following mechanism.

$$[Mo^{V}_2O_4(hedta)(H_2O)]^- + [Ir^{IV}Cl_6]^{2-} \xrightarrow{k_{(a)}} \text{“}Mo^{V}Mo^{VI}\text{”} + [Ir^{III}Cl_6]^{3-}$$

$$K_a \downarrow\uparrow$$

$$[Mo^{V}_2O_4(hedta)(OH)]^{2-} + [Ir^{IV}Cl_6]^{2-} \xrightarrow{k_{(b)}} \text{“}Mo^{V}Mo^{VI}\text{”} + [Ir^{III}Cl_6]^{3-}$$

Rate law (7) is obtained for this mechanism. A

$$d[Ir^{IV}]/dt = \{2(k_{(a)}[H^+]+K_ak_{(b)})[Mo_2][Ir^{IV}]\}/(K_a+[H^+]) \quad (7)$$

comparison with the experimental rate law (4) indicates that $k_{(a)}$ and $K_ak_{(b)}$ correspond to $k_2/2$ and $k_3/2$, respectively, under the condition $K_{(a)}\ll[H^+]$. The term $k_{(b)}$ should correspond to $k_4/2$, since $k_{(a)}[H^+]$ is negligible as compared with $K_ak_{(b)}$ at $[H^+]\ll K_a$. The K_a values determined by the pH titration and the observed k_3 values give $k_{(b)}$ as 1.04×10^4 and 2.09×10^4 M^{-1} s^{-1} at 25 and 35 °C, respectively. These values are in excellent agreement with the experimentally obtained $k_4/2$ values at given temperatures. Also the pK_a values (3.13 and 3.17 at 25 and 35 °C, respectively) calculated from the observed values of k_3 and k_4 are in good agreement with those determined by the pH titration. These facts support the proposed mechanism. Activation parameters for $k_4/2$ must correspond to those for $k_{(b)}$ ($\Delta H^*=38\pm8$ kJ mol^{-1}, $\Delta S^*=-42\pm29$ J K^{-1} mol^{-1}). Those for $k_{(a)}$ were not obtained because of big uncertainty in k_2 values.

The Oxidation with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$: The marked influence of ionic strength upon the rate suggests the importance of electrostatic interaction of the charged redox couple. The kinetics can be more precisely discussed at lower ionic strengths where such an interaction is expected to be stronger.

The observed rate law at I=0.1 M (Eq. 6) is consistent with a mechanism involving an ion-pair formation prior to electron transfer. Thus, the following mechanism is considered.[10] The terms $K_{IP(a)}$ and $K_{IP(b)}$ stand for the ion-pair formation constants for the original complex and its conjugate base, respec-

$$[Mo^{V}_{2}O_4L(H_2O)]^- + [\mu\text{-}O_2^{(-)}]^{5+} \overset{K_{IP(a)}}{\rightleftharpoons} [Mo_2O_4L(H_2O)\cdots\mu\text{-}O_2^{(-)}]^{4+} \xrightarrow{k_{e(a)}}$$
$$K_a \Big\downarrow\Big\uparrow \qquad\qquad K_a' \Big\downarrow\Big\uparrow \quad \text{(IP(a))}$$
$$[Mo^{V}_{2}O_4L(OH)]^{2-} + [\mu\text{-}O_2^{(-)}]^{5+} \overset{K_{IP(b)}}{\rightleftharpoons} [Mo_2O_4L(OH)\cdots\mu\text{-}O_2^{(-)}]^{3+} \xrightarrow{k_{e(b)}}$$
$$\text{(IP(b))}$$

tively, L^{3-} is $hedta^{3-}$, and $k_{e(a)}$ and $k_{e(b)}$ are the rate constants for the electron transfer within the ion-pairs, IP(a) and IP(b), respectively. The following rate law is derived for this mechanism. Thus, k_{obsd} is expressed by Eq. 9. The terms x and y in Eq. 6

$$-\frac{d[\mu\text{-}O_2^{(-)}]}{dt} = \frac{2\{k_{e(a)}K_{IP(a)}[H^+]+k_{e(b)}K_{IP(b)}K_a\}[Mo_2][\mu\text{-}O_2^{(-)}]}{K_a+[H^+]+\{K_{IP(a)}[H^+]+K_{IP(b)}K_a\}[Mo_2]} \quad (8)$$

$$k_{obsd} = \frac{2\{k_{e(a)}K_{IP(a)}[H^+]+k_{e(b)}K_{IP(b)}K_a\}[Mo_2]}{K_a+[H^+]+\{K_{IP(a)}[H^+]+K_{IP(b)}K_a\}[Mo_2]} \quad (9)$$

are expressed by Eqs. 10 and 11, respectively. Since $K_a \ll [H^+]$, Eq. 11 is rearranged to Eq. 12. A plot

$$x = \{K_{IP(a)}[H^+]+K_{IP(b)}K_a\}/2\{k_{e(a)}K_{IP(a)}[H^+] + k_{e(b)}K_{IP(b)}K_a\} \quad (10)$$

$$y = (K_a+[H^+])/2\{k_{e(a)}K_{IP(a)}[H^+]+k_{e(b)}K_{IP(b)}K_a\} \quad (11)$$

$$y^{-1} = 2\{k_{e(a)}K_{IP(a)}+k_{e(b)}K_{IP(b)}K_a[H^+]^{-1}\} \quad (12)$$

of experimental y^{-1} against $[H^+]^{-1}$ gives a straight line without intercept (Fig. 6). This fact suggests that $k_{e(a)}K_{IP(a)}$ is negligible as compared with $k_{e(b)} \times K_{IP(b)}K_a[H^+]^{-1}$ and x is rewritten to Eq. 13. A plot

$$x = \{K_{IP(a)}[H^+]/2k_{e(b)}K_{IP(b)}K_a\} + 1/(2k_{e(b)}) \quad (13)$$

of x against $[H^+]$ gives a straight line (Fig. 5). All the parameters are obtained as follows by use of the K_a value (7.9×10^{-4} M) at I=0.1 M and 25 °C: $K_{IP(a)}$= 40.5 M^{-1}, $K_{IP(b)}$=1046 M^{-1}, $k_{e(a)}$ not observed, and $k_{e(b)}$=2.56 s^{-1} at 25 °C; $K_{IP(a)}$=30 M^{-1}, $K_{IP(b)}$=1100 M^{-1}, $k_{e(a)}$ not observed, and $k_{e(b)}$=4.3 s^{-1} at 35 °C. These values are subject to nearly 50% uncertainty because of such a complicated analysis. No further trials for obtaining their temperature dependence were made. Nevertheless, the results provide additional example of first-order rate constant for the electron transfer within an ion-pair.[2,3,11,12]

For the reaction at I=2.0 M, the following assumptions are required to obtain a rate law which is of a form similar to the experimentally obtained rate law, Eq. 5: (i) the third term in the denominator of Eq. 9 is negligible (reasonable since the ion-pair formation at higher ionic strengths is expected to be less significant); (ii) $k_{e(a)}K_{IP(a)}$ is negligible as compared with $k_{e(b)}K_{IP(b)}K_a[H^+]^{-1}$ (this relation is experimentally derived at I=0.1 M (*vide supra*)); (iii) K_a is negligible as compared with $[H^+]$ (experimental condition). Under these assumptions Eq. 9 is simplified to Eq. 14.

$$k_{obsd} = 2k_{e(b)}K_{IP(b)}K_a[H^+]^{-1}[Mo_2] \quad (14)$$

The product $k_{e(b)}K_{IP(b)}K_a$ is 7.35×10^{-2} s^{-1} at 25.5 °C, thus $k_{e(b)}K_{IP(b)}$ is estimated to be 2.97×10^4 M^{-1} s^{-1} by use of the pK_a value (3.25).

The Oxidation with $[(en)_2Co^{III}(\mu\text{-}NH_2,O_2^{(-)})Co^{III}(en)_2]^{4+}$: The molybdenum(V) dimer is present almost entirely in the conjugate base form, $[Mo^{V}_{2}O_4(hedta)(OH)]^{2-}$, at $[H^+]=10^{-5.1}$ and $10^{-5.8}$ M. The following scheme is consistent with the kinetic behavior of the system (Eq. 6). The following rate law 15

$$[Mo^{V}_{2}O_4(hedta)(OH)]^{2-} + [\mu\text{-}NH_2,O_2^{(-)}]^{4+} \overset{K_{IP(c)}}{\rightleftharpoons} \text{IP(c)} \xrightarrow{k_{e(c)}} \text{products}$$

is derived for this mechanism. A comparison of Eq. 15 with Eq. 6 leads to the values $K_{IP(c)}=210\pm90$

$$k_{obsd} = 2k_{e(c)}K_{IP(c)}[Mo_2]/\{1+K_{IP(c)}[Mo_2]\} \quad (15)$$

M^{-1} and $k_{e(c)}=30\pm10$ s^{-1} at I=0.1 M and at 25 °C.

Ion-pair Formation Constants. The ion-pair formation constant between $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ and $[Mo^{V}_{2}O_4(hedta)(OH)]^{2-}$ at I=0.1 M (1046 M^{-1} at 25 °C) is *ca.* 4 times bigger than that between the $\mu\text{-}O_2^{(-)}$ complex and $[Mo^{V}_{2}O_4(edta)]^{2-}$ (270 M^{-1} at 40 °C).[2] The electronic charge may be more localized in $[Mo^{V}_{2}O_4(hedta)(OH)]^{2-}$ than in the more symmetrical edta complex. Such a locarization would produce a more negatively charged site within the complex anion, at which the ion-pair formation would be more extensive.

Reaction Mechanism. Present reactions must proceed *via* the outer-sphere mechanism for the following reasons. The oxidation of $[Mo^{V}_{2}O_4(edta)]^{2-}$ with $[Ir^{IV}Cl_6]^{2-}$ and with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ are believed to occur by the outer-sphere mechanism, since these oxidants are unable to coordinate to the molybdenum(V) unless the edta ligand is partially displaced.[2,4,13] The present hedta complex has a coordinated water, for which the oxidant can substitute. The remarkable increase in the rate of oxidation on changing from $[Mo^{V}_{2}O_4(hedta)(H_2O)]^-$ to its conjugate base, $[Mo^{V}_{2}O_4(hedta)(OH)]^{2-}$, does not support the inner-sphere mechanism, however, since the OH^- ligand is more strongly coordinated than H_2O and should be less easily dissociated from the metal ion.[14] There seems to be no example that μ-hyperoxo-dicobalt(III) complexes behave as inner-sphere oxidants.[3,16]

The Marcus theory predicts that when a series of oxidants are reduced by two different reductants *via* the outer-sphere process, ratio of the two rate constants should be similar for all members of the series.[17,18] Such ratios are often used as a diagnostic criterion for assigning redox reactions involving chromium(II), vanadium(II), *etc.* as proceeding by an outer-sphere mechanism.[19] Ratios of the oxidation rate of $[Mo^{V}_{2}O_4(hedta)(OH)]^{2-}$ to that of $[Mo^{V}_{2}O_4(edta)]^{2-}$ ($k_{hedta(OH)}/k_{edta}$) are listed in Table 2. Ratios for the two oppositely charged oxidants are within one order of magnitude, and can be taken as an evidence for the outer-sphere mechanism for the present reactions.

Table 2. Ratios of the rate constant for the oxidation of $[Mo^{V}_{2}O_4(hedta)(OH)]^{2-}$ ($k_{hedta(OH)}$) to that of $[Mo^{V}_{2}O_4(edta)]^{2-}$ (k_{edta}) with the given oxidant at 25 °C

Oxidant	I/M	Order of the rate constant	$k_{hedta(OH)}/k_{edta}$
$[Ir^{IV}Cl_6]^{2-}$	1.0	second-order[b]	3.9×10^3
$[\mu\text{-}O_2^{(-)}]^{5+}$ [a]	0.1	first-order (k_e)[c]	9.8×10^3
	2.0	second-order (k_eK_{IP})[c]	29.7×10^3

a) $[\mu\text{-}O_2^{(-)}]^{5+}=[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$. b) The $k_{hedta(OH)}$ value at $I=0.1$ M was estimated from those at $I=0.1$ and 2.0 M, to be 3.9×10^4 M^{-1} s^{-1}. c) The k_{edta} values at 25 °C were calculated from the activation parameters in Ref. 2, to be 2.60×10^{-4} s^{-1} and 8.81×10^{-3} M^{-1} s^{-1} at $I=0.1$ and 2.0 M, respectively.

Ratio of the first-order rate constants k_e for the oxidation with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ at $I=0.1$ M is *ca.* 3 times smaller than that of k_eK_{IP} at $I=2.0$ M, where k_e and K_{IP} values cannot be obtained separately. The difference in K_{IP} values should be responsible for such a difference in the ratios. This fact indicates that electrostatic interactions should significantly affect the ratio of the redox rates which are usually obtained as a product of k_e and K_{IP}.

Comparison with Other Reactions. Rate of the Reaction: The second-order rate constants of the oxidations of $Mo^{V}_{2}O_4^{2+}$-complexes with $[Ir^{IV}Cl_6]^{2-}$, $[Fe^{III}(phen)_3]^{3+}$, $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$, and $[(en)_2Co^{III}(\mu\text{-}NH_2,O_2^{(-)})Co^{III}(en)_2]^{4+}$ are summarized in Table 3. The following sequence is given for the decrease in oxidation rate. This sequence suggests

$[Mo^{V}_{2}O_4(hedta)(OH)]^{2-} > [Mo^{V}_{2}O_4(hedta)(H_2O)]^{-}$
$> [Mo^{V}_{2}O_4(edta)]^{2-} > [Mo^{V}_{2}O_4(H_2O)_n]^{2+}$

($[Mo^{V}_{2}O_4(OH)(H_2O)_{n-1}]^{+}$ must be more reactive than $[Mo^{V}_{2}O_4(hedta)(H_2O)]^{-}$)

that the total charge of the complex is not important in determining the rate. The two hydroxo complexes are significantly more reactive than thier conjugate acids. A possible interpretation may be that the stronger Lewis base, the hydroxide, makes the metal ion more negative and more electron donating. Outer-sphere oxidations of $[V^{III}(H_2O)_6]^{3+}$,[20] $[V^{IV}O(H_2O)_n]^{2+}$,[21] $[V^{IV}O(pmida)(H_2O)]$ ($H_2pmida=N$-(2-pyridylmethyl)-iminodiacetic acid),[22] $[V^{IV}O(nta)(H_2O)]^{-}$ (H_3nta =nitrilotriacetic acid),[22] and $[Ti^{III}(H_2O)_6]^{3+}$ [23,24] with various oxidants exhibit predominant rate-terms proportional to $[H^+]^{-1}$. The products in all of these reactions are mono- or dioxo metal ions; the number of oxo ligands increases and protons are reliesed on the oxidation. Such a structural requirement was claimed to be responsible for the higher reactivity of conjugate bases of these complexes.[24] A similar interpretation may be applied to the oxidation of $Mo^{V}_{2}O_4^{2+}$-complexes, although the rate-determining electron-transfer gives a mixed valence (V, VI) dimer as an immediate product, the structure of which is not known.

Activation Parameters: Table 4 shows that $\Delta H^{\neq}$ for $[Mo^{V}_{2}O_4(hedta)(OH)]^{2-}$ is significantly smaller than that for $[Mo^{V}_{2}O_4(edta)]^{2-}$ whenever a common oxidant is used. The big difference in oxidation rate between these two complexes seems to be due to the difference in $\Delta H^{\neq}$ rather than $\Delta S^{\neq}$.

The activation entropy for a given molybdenum(V) complex is more positive and the activation enthalpy is bigger for the oxidation with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$ than those for the oxidation with $[Ir^{IV}Cl_6]^{2-}$. Such differences can be explained in terms of the change in solvation accompanied by the encounter complex formation from the separated reactants. Negative $\Delta S^{\neq}$ for redox reactions between reactants with charges of the same sign were claimed to be largely the result of the charge concentration on encounter complex formation, which causes substantial mutual ordering of the solvated water molecules.[25] On the other hand, the positive entropy brought about on the encounter complex (ion-pair) formation between oppositely charged reactants,[2,11] may be attributed to the weakening of solute-solvent interaction by the partial compensation of charges in the ion-pair. The change in $\Delta H^{\neq}$ with the charge of oxidant is more difficult to explain. The contributions of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ to the rate constant seem

Table 3. A comparison of second-order rate constants/M^{-1} s^{-1} at 25 °C for the oxidations of some $Mo^{V}_{2}O_4^{2+}$-complexes with four oxidants

$Mo^{V}_{2}O_4^{2+}$-complexes	Oxidants				Ref.
	$[Ir^{IV}Cl_6]^{2-}$	$[Fe^{III}(phen)_3]^{3+}$	$[\mu\text{-}O_2^{(-)}]^{5+}$ [a]	$[\mu\text{-}NH_2,O_2^{(-)}]^{4+}$ [b]	
$[Mo^{V}_{2}O_4(edta)]^{2-}$	6.6[c]	1.9×10^3 [c]	8.8×10^{-3} [d,e]		2, 4
$[Mo^{V}_{2}O_4(pdta)]^{2-}$				1.87×10^{-1} [f]	3
$[Mo^{V}_{2}O_4(hedta)(OH)]^{2-}$	1.1×10^4 [g]		2.62×10^2 [e]	6.30×10^3 [g]	This work
$[Mo^{V}_{2}O_4(hedta)(H_2O)]^{-}$	2.3×10^1 [f]		5×10^{-2} [e]		This work
$[Mo^{V}_{2}O_4(OH)(H_2O)_{n-1}]^{+}$	$26<$[c,h,i]	$3000<$[c,h,i]	(Not observed)[j]		2, 5
$[Mo^{V}_{2}O_4(H_2O)_n]^{2+}$	5.7×10^{-2} [c]	1.6×10^1 [c]	(Not observed)[j]		2, 5

a) $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$. b) $[(en)_2Co^{III}(\mu\text{-}NH_2,O_2^{(-)})Co^{III}(en)_2]^{4+}$. c) $I=1.0$ M. d) Calculated from the activation parameters in Ref. 2. e) $I=2.0$ M. f) $I=0.2$ M. g) $I=0.1$ M. h) Estimated on the reasonable assumption that the acid-dissociation constant of $[Mo^{V}_{2}O_4(H_2O)_n]^{2+}$ is less than 10^{-3} M. i) For these reactions, significant part of the redox reaction proceeds *via* a pathway independent of the oxidant concentration.[5] j) The oxidation rate is independent of the concentration of the μ-hyperoxo complex.[2]

Table 4. Activation parameters for the oxidation of the complexes with $Mo^{V}_{2}O_4^{2+}$-core

Oxidant		I/M	$\Delta H^{\ddagger}$/kJ mol^{-1}	$\Delta S^{\ddagger}$/J K^{-1} mol^{-1}	Ref.
$[Ir^{IV}Cl_6]^{2-}$	$[Mo^{V}_{2}O_4(edta)]^{2-}$	1.0	56± 1	−42± 4	4
	$[Mo^{V}_{2}O_4(hedta)(OH)]^{2-}$	0.1	38± 8	−29±29	This work
$[\mu\text{-}O_2^{(-)}]^{5+}$ a)	$[Mo^{V}_{2}O_4(edta)]^{2-}$	0.1 b)	118±17	76±46	2
	$[Mo^{V}_{2}O_4(edta)]^{2-}$	2.0	111± 3	88±13	2
	$[Mo^{V}_{2}O_4(hedta)(OH)]^{2-}$	2.0	80±13	55±42	This work

a) $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$. b) For the first-order rate constant of the electron-transfer within the ion-pair. c) In evaluating $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, it is assumed that ΔH° and ΔS° for K_a are −8——15 kJ mol^{-1} and −80——100 J K^{-1} mol^{-1}, respectively, which were estimated from the K_a data at 25 and 35 °C as given in the text.

to compensate each other. Such a relationship is more clearly observed for the oxidations of $[V^{IV}O(pmida)(OH)]^{-}$ and $[V^{IV}O(nta)(OH)]^{2-}$ with $[Ir^{IV}Cl_6]^{2-}$ and $[(en)_2Co^{III}(\mu\text{-}NH_2,O_2^{(-)})Co^{III}(en)_2]^{4+}$ (isokinetic relationship is observed).[22] This fact suggests that the factors controlling $\Delta H^{\ddagger}$ must be closely related to those controlling $\Delta S^{\ddagger}$. Therefore, the solvation state of the encounter complex would be important in determining $\Delta H^{\ddagger}$. Activation enthalpy is smaller for redox reactions involving more solvated encounter complexes, and is larger for reactions between oppositely charged reactants which form less solvated encounter complexes.[22]

Reaction Pattern: Existence of a rate-term independent of the oxidant concentration is the characteristic feature of the oxidation of $[Mo^{V}_{2}O_4(OH)(H_2O)_{n-1}]^{+}$ with the three oxidants in Table 3.[2,5] The cleavage of one of the two oxo-bridges to give a single-bridged species was claimed to be the rate-determining step, the OH^{-} ligand being responsible for the bridge cleavage.[2] Chloride ions were found to catalyze markedly the oxidation of $[Mo^{V}_{2}O_4(H_2O)_n]^{2+}$ with $[(NH_3)_5Co^{III}(\mu\text{-}O_2^{(-)})Co^{III}(NH_3)_5]^{5+}$. The chloride ion was reckoned to substitute for the coordinated water and facilitate the bridge cleavage.[2] Such a mechanism is not plausible for the present reaction, since the rate formulae misses the term independent of the oxidant concentration and the positive catalytic effect by the halide ion was not observed. $[Mo^{V}_{2}O_4(H_2O)_n]^{2+}$ and $[Mo^{V}_{2}O_4(hedta)(H_2O)]^{-}$ are oxidized mainly *via* their conjugate bases, but mechanism is different. The present work stresses that the rate and mechanism of oxidations of the complexes with $Mo^{V}_{2}O_4^{2+}$-core depend significantly on the ligand environment.

This work is a part of the project supported by a Grant-in-Aid (511301) which is given to Professor Kazuo Saito from the Ministry of Education, Science and Culture. We are grateful to Professor K. Saito for his constant encouragement and valuable discussions throughout this work. We thank Mr. Susumu Kondo for the preparation of $[(en)_2Co^{III}(\mu\text{-}NH_2,O_2^{(-)})Co^{III}(en)_2]Cl_4\cdot 3H_2O$.

9) Transient absorption spectra during the course of the redox reaction measured by a rapid-scanning technique, did not show any evidence for intermediate formation. Since the deviation from the straight line for the first-order plot was small, we did not attempt to find the reason for the behavior further.

10) An alternative mechanism consistent with the rate law 6 is that the μ-hyperoxo complex formed an active intermediate which oxidized the molybdenum(V) dimer (a steady-state treatment for the active intermediate leads to the expected rate law). Although the kinetics of the oxidation with the μ-hyperoxo complexes were studied for various reductants, none of these reactions proceeded through such an active intermediate. Since the mechanism proposed in the text is reasonable, we exclude this alternative mechanism for the present reaction.

13) The dissociation of edta ligand from $[Mo^{V}_{2}O_4(edta)]^{2-}$ takes place in acid solution ($[H^{+}]>0.5$ M), the rate of which is accelerated as $[H^{+}]$ increases (Y. Sasaki and A. G. Sykes, *J. Chem. Soc., Dalton Trans.*, **1974**, 1468). The oxidation of $[Mo^{V}_{2}O_4(edta)]^{2-}$ is $[H^{+}]$ independent at $[H^{+}]=0.01$—0.10 M, which would not support the inner-sphere precursor complex formation accompanied by partial replacement of the edta ligand.

14) Partial dissociation of the hedta ligand, if occured, can be faster in the conjugate base complex, $[Mo^{V}_{2}O_4(hedta)(OH)]^{2-}$, than in $[Mo^{V}_{2}O_4(hedta)(H_2O)]^{-}$. We do not consider that the electron transfer mechanism involving an inner-sphere precursor formed by the rate-determining partial dissociation of the hedta ligand in $[Mo^{V}_{2}O_4(hedta)(OH)]^{2-}$, is likely, since the activation enthalpies for ligand substitution reactions *via* the conjugate base are usually bigger than 80 kJ mol^{-1},[15] while those for the present reactions are much smaller.

Studies on Electronic Spectrum and Electron Spin Resonance of Vanadium(IV) Complexes with Organophosphorus Compounds and High Molecular Weight Amines

Taichi SATO* and Takato NAKAMURA

Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432

(Received March 5, 1981)

In the extraction of vanadium(IV) from aqueous solutions containing hydrochloric acid and/or a mixture of hydrochloric acid and lithium chloride by bis(2-ethylhexyl) hydrogenphosphate (DEHPA; HX), trioctylmethylammonium chloride (Aliquat-336), trioctylamine (TOA), trioctylphosphine oxide (TOPO) and tributyl phosphate (TBP), the complexes formed in the organic phases have been examined by spectrophotometry and electron spin resonance spectroscopy. It is found that in the extraction by DEHPA, the vanadium in the organic phase exists as the monomeric species, $VO(X_2H)_2$, or the polymeric one, $(VOX_2)_n$, and that in the extractions by Aliquat-336, TOA, TOPO, and TBP, tetravalent vanadium complexes are stable in the organic phases extracted from a mixed solution of hydrochloric acid and lithium chloride, while complexes containing pentavalent vanadium and VOV^{4+} ions are formed in the organic phases extracted from hydrochloric acid solutions.

For the extraction of vanadium(IV) from hydrochloric acid solutions by trioctylmethylammonium chloride (Aliquat-336; $R_3R'NCl$), trioctylamine (TOA, R_3N), trioctylphosphine oxide (TOPO; R_3PO), and tributyl phosphate (TBP; $(RO)_3PO$), the spectral properties of the organic phases have been discussed in a previous paper.[1] The present paper extends the work to the extraction by bis(2-ethylhexyl) hydrogenphosphate (DEHPA; HX; $(RO)_2POOH$), and observations on the difference in the structure among the complexes formed in the organic phase with those acid, basic, and neutral extractants are reported on the basis of the results obtained by spectrophotometry and electron spin resonance (ESR) measurement.

Experimental

Chemicals. DEHPA (Daihachi Chemical Industry Co., Ltd.), Aliquat-336 (General Mills) and TBP (Daihachi Chemical Industry Co., Ltd.) were purified by the usual methods,[2-4] and diluted with hexane or benzene. TOA (Kao Soap Co., Ltd.) and TOPO (Hokko Chemical Industry Co., Ltd.) were used without purification. The vanadium(IV) chloride oxide solutions were prepared by dissolving vanadium(IV) chloride oxide, VCl_2O, in hydrochloric acid solutions of the required concentration. The chemicals used were of analytical reagent grade.

Extraction Procedures. Equal volumes (15 cm^3 each) of the aqueous and organic phases were shaken for 10 min in 50 cm^3 stoppered conical flasks in a thermostated water bath at 20 °C. The mixture was centrifuged and separated, and then the concentrations of vanadium in both phases were determined by edta titration as described already.[5] (In this case vanadium in the organic phase was stripped with 0.1 mol dm^{-3} hydrochloric acid). The complexes were isolated by drying the organic phases *in vacuo* at 50—60 °C.

Spectrophotometrical and ESR Measurements. The electronic spectra were obtained on a Shimadzu Model QV-50 spectrometer, using matched 1.00 cm fused silica cells. ESR spectra were recorded at 20 °C with a high sensitivity X-band spectrometer, designed in the Research Institute of Electronics, Shizuoka University, and at −30 °C with a JEOL JES-PE-3X X-band spectrometer, which operated at about 9.3 GHz using 100 kHz field modulation. Field calibration was checked by using DPPH and MnO doped in MgO. The calculation of ESR derivative line shape was made by using the computers of FACOM 230-45S and MELCOM COSMO 500.[6]

Results and Discussion

Electronic Spectra. The representative electronic spectra of organic phases for the extraction from aqueous hydrochloric acid solutions containing 0.036 mol dm^{-3} vanadium(IV) chloride oxide with 0.05 mol dm^{-3} DEHPA, 0.05 mol dm^{-3} Aliquat-336, 0.05 mol dm^{-3} TOA, 0.05 mol dm^{-3} TOPO, and 0.5 mol dm^{-3} TBP at 20 °C are shown in Fig. 1. The blue organic phase is obtained in the extraction by DEHPA. In the extractions by Aliquat-336, TOA, TOPO, and TBP,

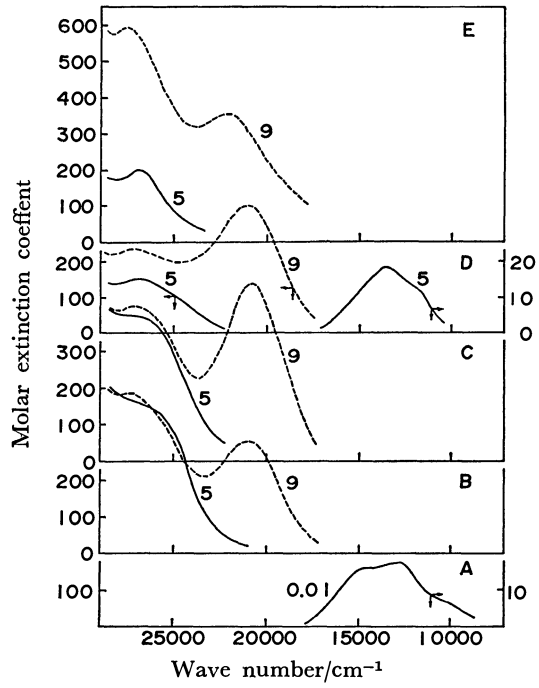

Fig. 1. Electronic spectra of organic phases from the extraction of aqueous solutions containing vanadium (IV) chloride oxide of 0.0036 mol dm^{-3} in hydrochloric acid with 0.05 mol dm^{-3} DEHPA (A), 0.05 mol dm^{-3} Aliquat-336 (B), 0.05 mol dm^{-3} TOA (C), 0.05 mol dm^{-3} TOPO (D), and 0.5 mol dm^{-3} TBP (E) (numerals on curves are hydrochloric acid concentrations in aqueous phase, mol dm^{-3}).

the organic phases depend on the kind of extractants in colour (yellow for Aliquat-336 and TOA, greenish yellow for TOPO, and pale yellow for TBP) at the aqueous hydrochloric acid concentration below 7 mol dm^{-3}, but at higher acidity above 8 mol dm^{-3} redish orange colour is developed in these organic extracts.

The spectra of the organic phases from the extraction by DEHPA, classified as acid extractant, show the d-d bands at 14700 and 12700 cm^{-1} accompanied by a shoulder around 9530 cm^{-1}. From the results obtained previously,[7] it is deduced that their bands rise from those of monomeric species VOX_4H_2 and/or polymeric one $(VOX_2)_n$. In both the complexes, the X^- group is bound to vanadium ion through the oxygen atoms which occupy the corner of a square, implying that the ligand field effect to vanadium ion resemble each other. Assuming that the extracted species is in a point group C_{4v} symmetry, the absorption bands at 14700 and 12700 cm^{-1} are assigned to the transitions $^2B_2 \rightarrow {}^2B_1$ and $^2B_2 \rightarrow {}^2E(I)$, respectively.

In the extractions by Aliquat-336 and TOA, classified as basic extractant, the spectra of yellow organic solutions exhibit no band due to the d-d transition of tetravalent vanadium ion but a band at 26000—27000 cm^{-1}. These organic solutions do not reveal a signal in the ESR experiment. In the extraction from 9 mol dm^{-3} hydrochloric acid solution, the absorption at about 21000 cm^{-1} appears in the spectra of redish orange organic solutions. This band probably arises from binuclear ion VOV^{4+}, which is an intermediate in the reaction between di- and tetravalent vanadium ions.[8] Accordingly it is considered that in the extractions by Aliquat-336 and TOA at the aqueous hydrochloric acid concentration below 7 mol dm^{-3}, the vanadium is oxidized during the extraction process, while the species formed in the extraction at higher acidity exists as a polymer containing ion such as VOV^{4+}.

In the extractions by neutral extractants, the spectra of organic phases for the extraction from 9 mol dm^{-3} hydrochloric acid solution are analogous to those with the basic extractants. In contrast, the spectrum of organic phase from 5 mol dm^{-3} hydrochloric acid solution with TOPO exhibits the absorption bands at 11600, 13500, and 26700 cm^{-1} due to $^2B_2 \rightarrow {}^2B_1$, $^2B_2 \rightarrow {}^2E(I)$, and $^2B_2 \rightarrow {}^2A_1$, respectively, indicating that the complex formed in the organic phase contains tetravalent vanadium ion. In addition the spectrum of the organic phase with TBP reveals a trace of band at about 14000 cm^{-1} similar to that with TOPO, although those absorption bands are hard to assign because of its low extractability.

On the other hand, the spectra of organic phase for the extraction from aqueous solution containing 0.036 mol dm^{-3} vanadium (IV) chloride oxide in a mixture of 0.06 mol dm^{-3} hydrochloric acid and 10 mol dm^{-3} lithium chloride by Aliquat-336, TOA, TOPO, and TBP exhibit the d-d bands in the range of 10000—14000 cm^{-1} (Fig. 2), which are characteristic bands of VO^{2+} ion. In the extraction by TOPO, the spectrum of the organic phase from mixed solution of hydrochloric acid and lithium chloride is similar to that from 5 mol dm^{-3} hydrochloric acid solution

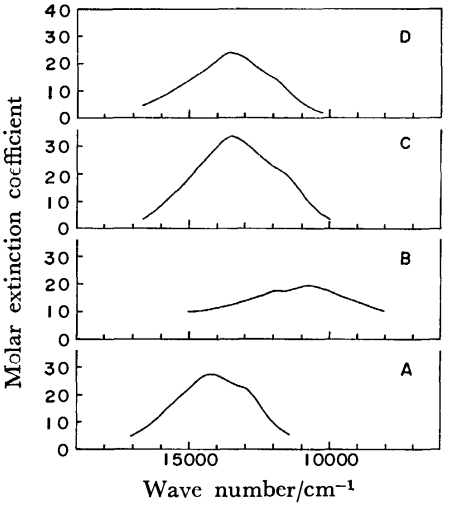

Fig. 2. Electronic spectra of organic phases from the extraction of aqueous solutions containing vanadium (IV) chloride oxide of 0.036 mol dm^{-3} in a mixture of 0.06 mol dm^{-3} hydrochloric acid and 10 mol dm^{-3} lithium chloride with 0.05 mol dm^{-3} Aliquat-336 (A), 0.05 mol dm^{-3} TOA (B), 0.05 mol dm^{-3} TOPO (C), and 0.5 mol dm^{-3} TBP (D) in benzene.

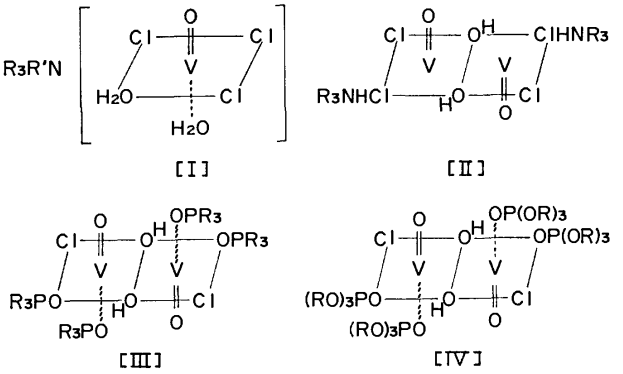
except that the former molar extinction coefficient of the band at 13500 cm^{-1} is larger than the latter one. This implies that the tetra- and pentavalent vanadium complexes coexist in the latter organic phase. In other spectra, the bands are assigned as follows: for Aliquat-336 26500, 14300, and 12800 cm^{-1} to $^2B_2 \rightarrow {}^2A_1$, $^2B_2 \rightarrow {}^2E(I)$, and $^2B_2 \rightarrow {}^2B_1$, respectively; for TOA 26700, 12300, and 10600 cm^{-1} to $^2B_2 \rightarrow {}^2A_1$, $^2B_2 \rightarrow {}^2B_1$, and $^2B_2 \rightarrow {}^2E(I)$, respectively; for TBP 27000, 13500, and 11800 cm^{-1} to $^2B_2 \rightarrow {}^2A_1$, $^2B_2 \rightarrow {}^2E(I)$, and $^2B_2 \rightarrow {}^2B_1$, respectively. As the complexes contained in these organic solutions could be formulated as $VOCl_2 \cdot R_3R'NCl \cdot xH_2O$, $VO(OH)Cl \cdot R_3NHCl$, $VO(OH)Cl \cdot 2R_3PO$, and $VO(OH)Cl \cdot 2(RO)_3PO$, respectively,[1] the following structures are presumed to satisfy an octahedral or square pyramidal coordination:



ESR Spectra. ESR spectra of organic phases from the extraction of aqueous solutions containing vanadium(IV) chloride oxide in 0.01 mol dm^{-3} hydrochloric acid with 0.05 mol dm^{-3} DEHPA in hexane at 20 °C are shown in Fig. 3. The well resolved hyperfine line with eight components is observed in the spectrum at the molar ratio of $[DEHPA]/[V]_{org} = 10.2$, which is assigned to that of the monomeric species

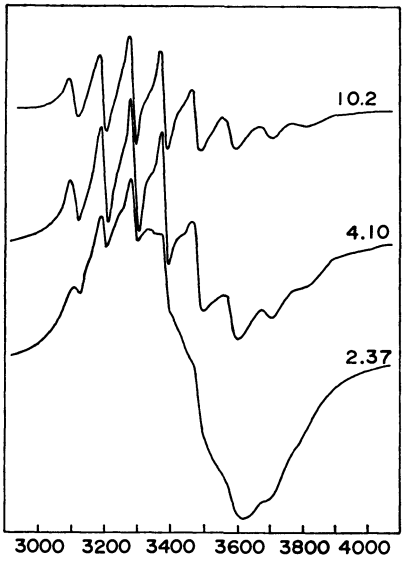


Fig. 3. ESR spectra of the organic phases from the extraction of vanadium(IV) by 0.05 mol dm^{-3} DEHPA in hexane (numerals on curves are the molar ratio of $[HX]/[V]_{org}$).

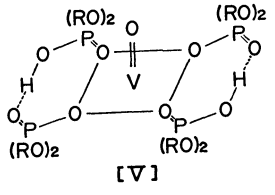
VOX_4H_2. On the one hand, the spectrum at the molar ratio of $[DEHPA]/[V]_{org}=4.10$ contains the broad line showing no hyperfine structure, and that at the molar ratio of $[DEHPA]/[V]_{org}=2.37$ is so broadened that the hyperfine structure is unresolved, although the spectra of aqueous solutions exhibit hyperfine structure, indicating that the vanadium ion concentration in the aqueous phases before extraction is magnetically diluted. This broadening is probably due to the exchange interaction among the unpaired electrons of vanadium ions, suggesting that the polymeric species is formed in the organic phase by substituting the hydrogen ions of the monomeric species VOX_4H_2 for VO^{2+} ion in the aqueous phase. It is thus considered that the anisotropy in ESR spectrum of the organic extract prepared by drying the organic phase for the extraction of 0.0072 mol dm^{-3} vanadium(IV) chloride oxide solution containing 0.01 mol dm^{-3} hydrochloric acid with 0.05 mol dm^{-3} DEHPA in hexane is due to that of the monomeric species



[V]

because of the molar ratio of $[DEHPA]/[V]_{org}=7.14>4$.

In the extraction of aqueous solution containing 0.036 mol dm^{-3} vanadium(IV) chloride oxide in a mixture of 0.06 mol dm^{-3} hydrochloric acid and 10 mol dm^{-3} lithium chloride with 0.05 mol dm^{-3} Aliquat-336, 0.05 mol dm^{-3} TOA, 0.05 mol dm^{-3} TOPO, and 0.5 mol dm^{-3} TBP in benzene, the ESR spectra of the frozen organic phases were measured at −30 °C in order to estimate ESR parameters (Fig. 4), because apparent change in the colour of organic phases was observed during the evaporation of benzene to isolate the complexes by drying. As the transition due to $S_1 \cdot S_2$ is not observed in the spectra of the organic solutions extracted with TOA, TOPO, and TBP, the exchange interaction between vanadium ion in the complexes [II], [III], and [IV] is presumed to be weak and/or less anisotropic. In addition the difference to be expected in the x, y components is not resolved in the spectra. Therefore those spectra can be described by the axially symmetric spin Hamiltonian including the terms of Zeeman and nuclear-electron hyperfine interactions:

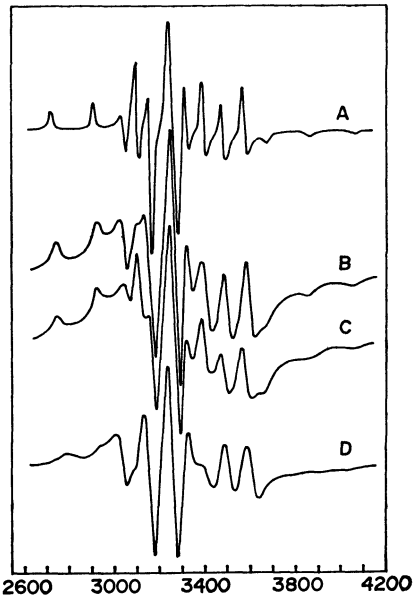


Fig. 4. ESR spectra of frozen organic phases from the extraction of aqueous solutions containing vanadium (IV) chloride oxide of 0.036 mol dm^{-3} in a mixture of 0.06 mol dm^{-3} hydrochloric acid and 10 mol dm^{-3} lithium chloride with 0.05 mol dm^{-3} Aliquat-336 (A), 0.05 mol dm^{-3} TOA (B), 0.05 mol dm^{-3} TOPO (C), and 0.5 mol dm^{-3} TBP (D) in benzene.

$$\boldsymbol{H} = \beta H(g_{//}S_z\cos\theta + 2g_{\perp}S_x\sin\theta) + A_zS_z + B(S_xI_x + S_yI_y) \quad (1)$$

where β is the Bohr magneton, H the applied magnetic field, $g_{//}$ and $g_{\perp}$ the g-tensor values parallel and perpendicular, respectively, to z-axis corresponding to the V=O bond direction, θ the angle between H and z-axis, $S_{x,y,z}$ and $I_{x,y,z}$ the components of the electron and nuclear spin vectors, respectively, and A and B the hyperfine splitting constants for vanadium nucleus. Computer simulation method described in an earlier paper[6] is used for determining the ESR parameters of VO^{2+} complexes with DEHPA, Aliquat-336, TOA, TOPO, and TBP. The resulting parameters are shown in Table 1.

The g-values and hyperfine splitting constants are related to the energy levels and bonding parameters. For the purpose of estimating approximate bonding parameters, it is assumed that the complexes are ap-

proximately in a point group C_{4v} symmetry, because the parameters indicating the difference in bonding between two perpendicular directions can not be obtained, and that the b_2 orbital is a non-bonding orbital. This leads to the following relationship:

$$\Delta g_{//} = 8\lambda_v\beta_1^{*2}/\Delta_{//}, \quad (2)$$

$$\Delta g_{\perp} = 2\lambda_v\varepsilon_\pi^{*2}/\Delta_{\perp}, \quad (3)$$

$$A = P[-(4/7+\kappa_v) - 8(\lambda_v\beta_1^{*2}/\Delta_{//}) - 6/7(\lambda_v\varepsilon_\pi^{*2}/\Delta_{\perp})], \quad (4)$$

and

$$B = P[2(2/7-\kappa_v) - 11/7(\lambda_v\varepsilon_\pi^{*2}/\Delta_{\perp})], \quad (5)$$

where $\Delta g_{//}=2.002-g_{//}$, $\Delta g_{\perp}=2.002-g_{\perp}$, β_1^{*2} and ε_π^{*2} are the fractional contributions of the orbitals $d_{x^2-y^2}$ and d_{xz} (and/or d_{yz}) in antibonding molecular orbitals $^2B_1$ and $^2E(I)$, respectively, λ the spin-orbital coupling constant for the free ion of vanadium, κ_v the Fermi contact term for the vanadium atom, $P=2.002g_N-\beta\beta_N\langle r^{-3}\rangle$ in which r is the distance from the central nucleus to the electron and β_N the nuclear magneton, $\Delta_{\perp}$ the energy in the transition $^2B_2\rightarrow{}^2E(I)$ and $\Delta_{//}$ the energy in the transition $^2B_2\rightarrow{}^2B_1$. The molecular parameters of the VO^{2+} complexes with DEHPA, Aliquat-336, TOA, TOPO, and TBP obtained from simultaneous solution of Eqs. 3—6 are given in Table 1. The values of β_1^{*2} for those complexes range from 0.50 to 0.59 except that of the complex with DEHPA being 0.78. This means that for the complexes with Aliquat-336, TOA, TOPO, and TBP the in-plane σ bonding is covalent so that the unpaired electron is delocalized, while somewhat covalent for that with DEHPA. This values of ε_π^{*2} range from 0.66 to 0.98, implying that the out-of-plane π bonding is almost completely ionic for the complexes with DEHPA, Aliquat-336, and TBP, somewhat covalent for that with TOPO and covalent for that with TOA.

Table 1. Estimated ESR parameters of the vanadium(IV) complexes with DEHPA, Aliquat-336, TOA, TOPO, and TBP

Parameter	Vanadium(IV) complex				
	DEHPA	Aliquat-336	TOA	TOPO	TBP
$g_{//}$	1.930	1.940	1.947	1.935	1.945
$g_{\perp}$	1.976	1.979	1.980	1.980	1.978
$\lvert A\rvert$/cm^{-1}	0.0147	0.0177	0.0170	0.0170	0.0155
$\lvert B\rvert$/cm^{-1}	0.0063	0.0067	0.0069	0.0069	0.0074

Conclusion

In the extraction by DEHPA, the monomeric species, $VO(X_2H)_2$, in which central vanadium ion possesses little π bonding of coordinated oxygen atoms of DEHPA, is formed when DEHPA is present in excess, and an increase in the organic vanadium concentration involves the formation of polymeric species arising from the substitution of the hydrogen ion of coordinated anion X_2H^- by vanadium ion in aqueous phase. In the extraction by Aliquat-336, the tetravalent vanadium species, $R_3R'NVOCl_3$, which is also deduced from the extractions of other metals, exists stably in the organic phase extracted from a mixed solution of hydrochloric acid and lithium chloride, and while the hydrolytic tetravalent vanadium species, $VO(OH)Cl\cdot nL$, are found in the extractions by TOA, TOPO, and TBP.

We wish to thank Dr. Kenzo Watanabe of the Research Institute of Electronics, Shizuoka University, and Prof. Takafumi Kanazawa, Dr. Hiroshi Kawazoe, and Mr. Hideo Hosono of the Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University for the ESR spectral measurements, and also the Kao Soap Co., Ltd. for the sample of TOA, the Hokko Chemical Industry Co., Ltd. for the sample of TOPO, and the Daihachi Chemical Industry Co., Ltd. for the samples of DEHPA and TBP.

Mass-spectrometric Measurement of Activities in Both Solid and Liquid Solutions of the KCl–NaCl System

Mitsuru ITOH,* Tadashi SASAMOTO,† and Toshiyuki SATA

Research Laboratory of Engineering Materials, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received April 3, 1981)

The activities of the KCl–NaCl system were mass-spectrometrically determined by the ion-current-ratio method in the temperature range from 793 to 1083 K. As a result, the activities of KCl or NaCl in the solid solution showed greatly positive deviations from Raoult's law while the liquid solution at 1083 K gave slightly negative values. The heats of mixing in the solid solution were calculated from the temperature dependence of the modified ion-current ratios, $[(I_{Na_2Cl^+}/X^2_{NaCl})/(I_{K_2Cl^+}/X^2_{KCl})]$. The excess entropy of mixing in the solid solution was attributed to the change in the vibrational spectrum, and the vibrational contribution to the heat of mixing was evaluated.

The Knudsen-cell mass-spectrometric method developed by Belton and Fruehan[1] has been applied to the determination of the thermodynamic properties of metallic solutions at elevated temperatures and has proved to be very useful. However, there have been few reports concerning the application of this method in activity measurements in inorganic-solid-solution systems between compounds. In the case of the activity measurement of a solid-solution system, a difficult problem is a surface depletion caused by the preferential vaporization of certain components.

In this study, the applicability of the mass-spectrometric method has been checked for the measurement of activities in the KCl–NaCl system. This system is proper for a discussion of the adaptability of the mass spectrometry to the activity measurements in an inorganic-solid-solution system because of the relatively small difference in the vapor pressures of the components (the ratio of the vapor pressure of KCl to that of NaCl is about two) and the ease of thermodynamical analysis from the observed data.

Experimental

The instrument used was a doubly focused mass spectrometer (JEOL JMS-01/BK) with a Knudsen-cell source (*cf.* Fig. 1). The Knudsen cell(G), made of alumina, had dimensions of 8 mm I.D. by 8 mm in height and had a cylindrical orifice 0.2—0.7 mm in diameter bored in the center of a lid about 1 mm thick. The cell was heated by radiation from tungsten ribbon heaters(H). The temperature of the cell was measured with a W5%Re–W26%Re thermocouple attached at the inner bottom of the outer cell(F), which had been calibrated in advance from the difference in the temperatures between the inside and outside of the cell (containing a sample), the difference having been determined using a PR13 thermocouple (0.2 mm in diameter) inserted through the orifice. Samples in the KCl–NaCl solid solutions were prepared by the melting a mixture of exactly weighted KCl and NaCl powders dried in a vacuum for a day and by then quenching them to room temperature in a quartz tube. They were crushed to powder just before the measurement, and about 300 mg was used in the Knudsen cell for each run of an experiment.

The ion intensity for the derived species was measured by the usual mass-spectrometrical technique in the temperature range from 793 to 1083 K, changing the temperature in steps of 40 K intervals. The temperature was held for about 15 min at each temperature level in order to obtain the constant ion intensity indicating the chemical equilibrium. The total weight loss of the sample after each run was about 0.1 mg in the solid state and about 3 mg in the liquid state. If a perfect shutter effect could not be obtained because of the contamination by alkali halide vapors, the ion source was completely cleaned. The ionization potential of 25 eV was used.

Results and Discussion

The detected ion species were Na^+, K^+, $NaCl^+$, KCl^+, Na_2Cl^+, K_2Cl^+, $NaKCl^+$, and Cl^+. Their apperance potentials, referred to H_2O^+, were 10.3, 11.0, 10.0, 10.5, 10.0, 10.8, 10.5, and 15.5 eV respectively. The ion intensities of the $Na_3Cl_2^+$ and $K_3Cl_2^+$ trimers were under 1/100 for those of the Na_2Cl^+ and K_2Cl^+.

† Present address: Tokyo National Technical College, 1220-2, Kunugida, Hachioji, Tokyo 193.

Both by considering the temperature dependences of the ion currents and by using an analogy with other chlorides,[2,3] the formation processes of ions from the alkali-halide vapors were estimated to be as follows:

$$MCl + e^- = M^+ + Cl + 2e^-, \quad (1)$$

$$MCl + e^- = MCl^+ + 2e^-, \quad (2)$$

$$M_2Cl_2 + e^- = M_2Cl^+ + Cl + 2e^-, \quad (3)$$

$$MM'Cl + e^- = MM'Cl^+ + Cl + 2e^-, \quad (4)$$

$$Cl + e^- = Cl^+ + 2e^-, \quad (5)$$

where M and M′ stand for Na or K. That is to say, MCl^+, M_2Cl^+, and $MM'Cl^+$ were the molecular(or parent) ions formed by the simple ionization, while M^+ and Cl^+ were the fragment ions. Therefore, we considered that the sum of the ion currents of M^+ and MCl^+ was proportional to the vapor pressure of MCl(g).

In order to confirm the equilibrium in the cell, the dimer ion-current ratio, $I_{Na_2Cl^+}/I_{K_2Cl^+}$ was measured at 913 K as a function of the orifice diameter, as shown in Fig. 2. From the results, the equilibrium in the cell was confirmed.

Belton and Fruehan[1] have derived expressions relating to the activity of a solution which is favorable to mass spectrometry. The activity in the system was determined using the expression for the ion-current ratios of any two peaks for Na_2Cl^+, K_2Cl^+, or $NaKCl^+$. For example, the activity coefficient for the KCl component, γ_{KCl}, is given by:

$$\ln\gamma_{KCl} = -\int_{X_{KCl}=1}^{X_{KCl}} \frac{X_{NaCl}}{2} \times d\{\ln(I_{Na_2Cl^+}/I_{K_2Cl^+}) - \ln(X_{NaCl}/X_{KCl})^2\}, \quad (6)$$

where X_i is the mole fraction. This equation means that the activity can be determined from the ion-current ratio, $I_{Na_2Cl^+}/I_{K_2Cl^+}$, as a function of the composition. The experimental results are shown in Fig. 3 as plots of $\ln(I_{Na_2Cl^+}/I_{K_2Cl^+})$ *vs.* $1/T$. These plots for each composition fall on straight lines, the slopes of which are given in Table 1. The broken lines in Fig. 3, located on the gaps between the two straight lines in the lower and higher temperature sides, correspond to the regions where the solid and liquid coexist. The solidus and liquidus temperatures obtained from this figure agreed approximately with those in the phase diagram.[4] In order to graphically integrate Eq. 6, the term of $\{\ln(I_{Na_2Cl^+}/I_{K_2Cl^+}) - \ln(X_{NaCl}/X_{KCl})^2\}$ was plotted against the composition, X, as is illustrated in Fig. 4. Using this figure, the

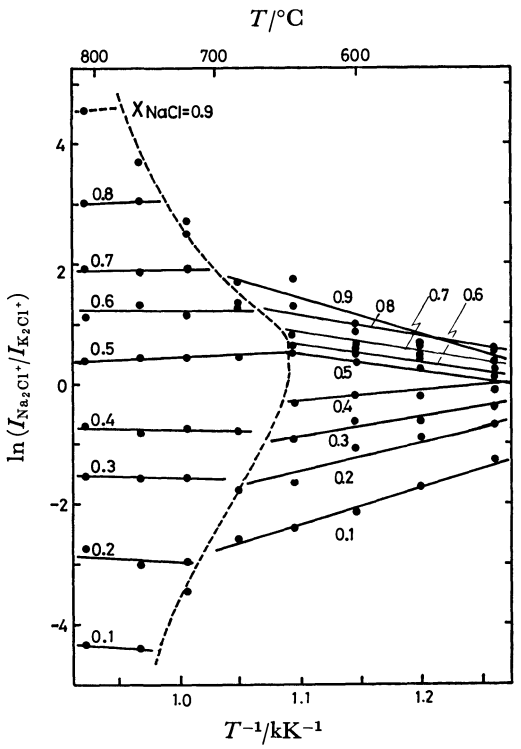

Fig. 3. The observed ion current ratio of dimer ions in the KCl–NaCl system.

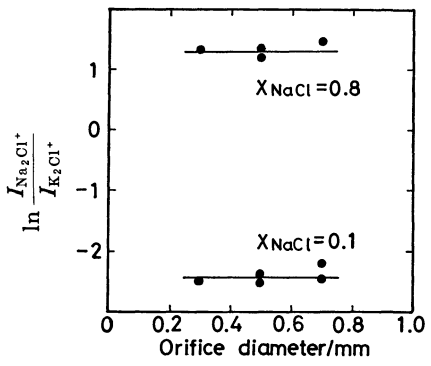

Fig. 2. Orifice diameter dependence of $\ln(I_{K_2Cl^+}/I_{Na_2Cl^+})$.

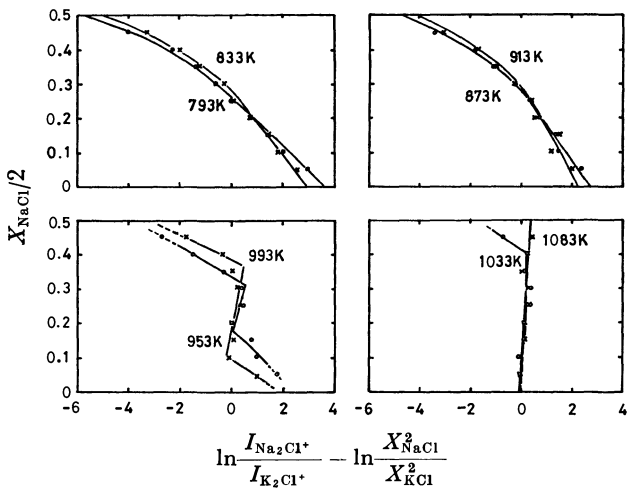

Fig. 4. Preliminary curves for the graphical integration in Eq. 6.

Table 1. Values of slopes for the lines drawn in Fig. 3

X_{NaCl}	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9
$d\ln\left(\frac{I_{Na_2Cl^+}}{I_{K_2Cl^+}}\right)/d(1/T)$	6250	5030	3050	1240	−470	−990	−2970	−4310	−6830

activity coefficients for NaCl and KCl are calculated by the graphical integration on the basis of Eq. 6. The results are shown in Fig. 5.

The activity can be obtained also using a complex dimer, $NaKCl_2(g)$, in the following manner. The equilibrium reaction between the gas and the condenced phases containing the complex vapor:

$$Na_2Cl_2(g) + KCl(c) = NaKCl_2(g) + NaCl(c) \quad (7)$$

gives another expression for the activity coefficient corresponding to Eq. 6:

$$\ln\gamma_{KCl} = -\int_{X_{KCl}=1}^{X_{KCl}} X_{NaCl} \times d\{\ln(I_{NaKCl^+}/I_{K_2Cl^+}) - \ln(X_{NaCl}/X_{KCl})\}. \quad (8)$$

The obtained ion-current ratios *vs.* $1/T$ and the $\{\ln(I_{NaKCl^+}/I_{K_2Cl^+}) - \ln(X_{NaCl}/X_{KCl})\}$ *vs.* composition are shown in Figs. 6 and 7. The activities derived from Fig. 7 are shown in Fig. 8; they are in close agreement with those shown previously in Fig. 5. The closed circles in Fig. 8 indicate that the activities of NaCl at 1083 K were determined by the monomer-dimer method,[5] in which the following equation was used:

$$a_{NaCl} = (I_{Na_2Cl^+}/I_{NaCl^+})_{solution}/(I_{Na_2Cl^+}/I_{NaCl^+})_{pure}. \quad (9)$$

The plots were in good agreement with the values determined by the ion-current-ratio method. This fact supports the idea that the following fragmentation can be neglected:

$$Na_2Cl_2 + e^- \rightarrow Na^+ + NaCl + Cl + 2e^-, \quad (10)$$

$$Na_2Cl_2 + e^- \rightarrow NaCl^+ + NaCl + 2e^-. \quad (11)$$

Topor and Topor[6] have determined the activity of the KCl-NaCl system at 1153 K by means of the galvanic-cell method. The activity reported by them (Fig. 5) shows a great positive deviation from that for the ideal solution, while their values disagree with those extrapolated from our data up to 1153 K. When the excess partial entropy of mixing was evaluated using Topor and Topor's activity data and Hersh and Kleppa's calorimetric data,[7] the value of −0.72

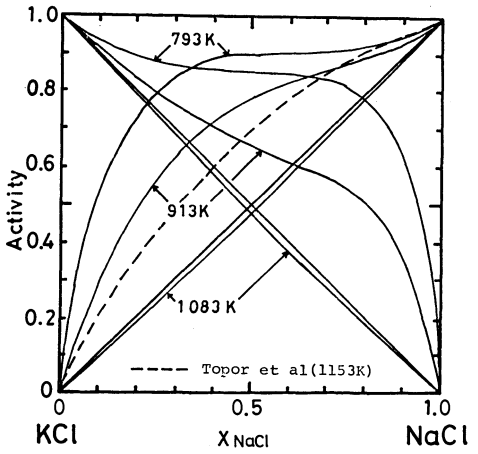

Fig. 5. Activities in the KCl-NaCl system.

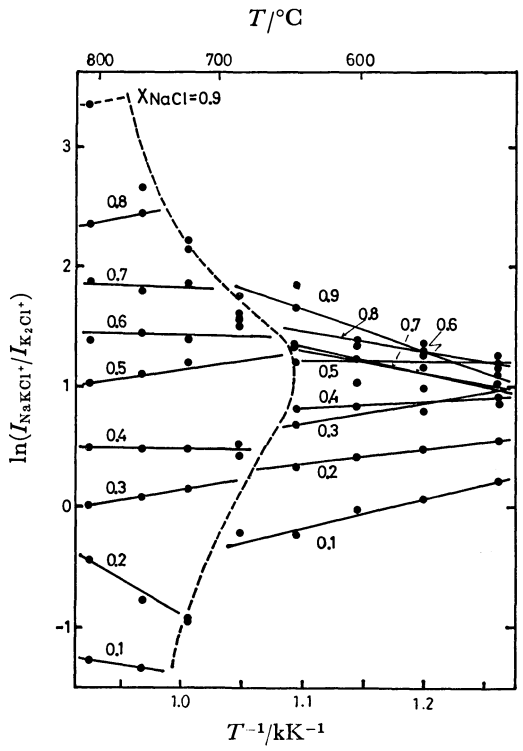

Fig. 6. The observed ion current ratio of dimer ions in the KCl-NaCl system.

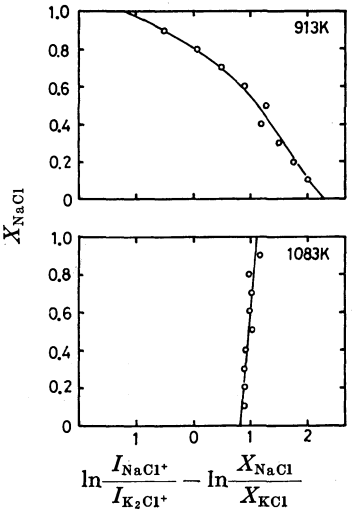

Fig. 7. Preliminary curves for the graphical integration in Eq. 8.

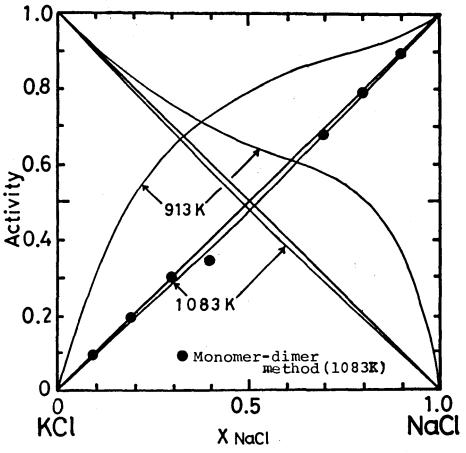

Fig. 8. Activities in the KCl-NaCl system.

e.u. was obtained for the composition of $X_{NaCl}=0.5$. This value, however, is considered to be too large for this simple system.

The heats of mixing, ΔH^M, for the solid solution were determined by a graphical integration of Eq. 12:[1]

$$\Delta\bar{H}_{KCl} = -R\int_{X_{KCl}=1}^{X_{KCl}} \frac{X_{NaCl}}{2} \times d\left[\frac{d\ln\{I_{Na_2Cl^+}\cdot X_{KCl}^3/I_{K_2Cl^+}\cdot X_{NaCl}^2\}}{d(1/T)}\right], \quad (12)$$

using the values of the slope given in Table 1. The integration along the curve in Fig. 9 yields Fig. 10. The large positive heat of mixing in the solid solution system probably arises from the difference in radius between the radii of Na^+ (0.96 Å) and K^+ (1.33 Å). As is shown in Fig. 10, $\Delta\bar{H}_{KCl}$ is larger than $\Delta\bar{H}_{NaCl}$. This is due to a requirement of a larger energy than that for the case of a small ion for the introduction of a large ion into a lattice. If the ionic radii in the state of solid solution and bulk moduli of the ions are known, the contribution of the strain energy to the heat of mixing can be estimated. In the KCl–NaCl system, the cations may take an arrangement with a short-range order in order to reduce the strain energy.

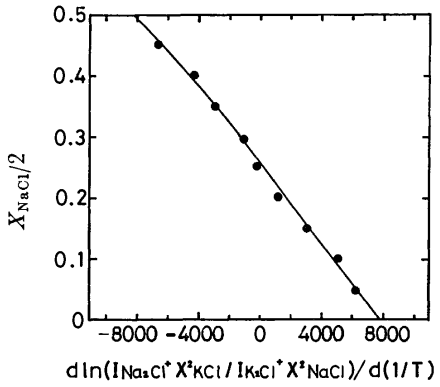

Fig. 9. Integration plot for the KCl–NaCl system.

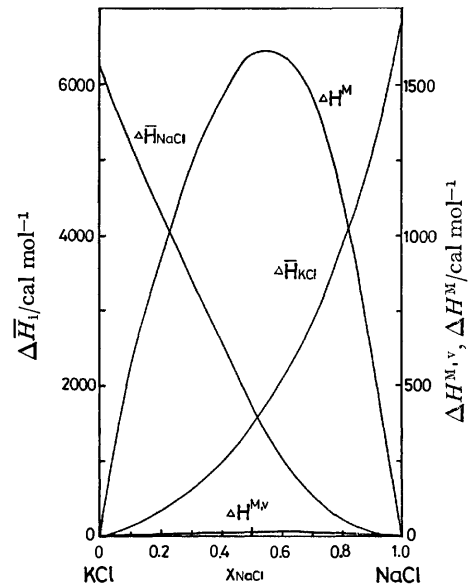

Fig. 10. Heats of mixing in the KCl–NaCl solid solution system.

The entropy of mixing, ΔS^M, in the solid solution was calculated from the well-known thermodynamic relation:

$$\Delta S^M = -(\Delta H^M - \Delta G^M)/T. \quad (13)$$

It is shown in Fig. 11. If the arrangement of the cations is close to the random state in the solid solution, the entropy is given by only the ideal configurational term, ΔS^M_{ideal}:

$$\Delta S^M_{ideal} = -R(X_{KCl}\ln X_{KCl} + X_{NaCl}\ln X_{NaCl}). \quad (14)$$

ΔS^M_{ideal} is also plotted in Fig. 11. Then the excess entropy, ΔS^M_{excess}, is given by:

$$\Delta S^M_{excess} = \Delta S^M - \Delta S^M_{ideal}. \quad (15)$$

The entropy of mixing in the liquid solution shown in Fig. 11 was calculated from the activities from Hersh and Kleppa's calorimetric data. The small excess entropy of mixing and the small heat of mixing suggest that the liquid solution is nearly an ideal solution. The large positive excess entropy of mixing in the solid solution is considered to arise from a change in the vibrational entropy associated with a change in the vibrational spectrum. The vibrational entropies(ΔS^M) of KCl and NaCl can be calculated from Debye's theory[8] using the Debye temperatures[9-11] of KCl (235 K) and NaCl (321 K). The vibrational entropy of solid solution(S^v) is the mean vibrational entropy, $S^v_{mean}(=X_{KCl}S^v_{KCl}+X_{NaCl}S^v_{NaCl})$, plus the excess entropy, ΔS^M_{excess}. The calculated S^v's are shown in Fig. 12. The Debye temperature of the solid solution was calculated from the S^v; it is shown in Fig. 13, along with the Debye temperature, θ_D, corresponding to the S^v_{mean}. It is also possible to calculate the heat capacity, C_v, for the KCl–NaCl solid solution. The change in the heat capacity to form the solid solution is:

$$\Delta C_v = C_{v,\text{solid solution}} - X_{KCl}C_{v,KCl} - X_{NaCl}C_{v,NaCl}. \quad (16)$$

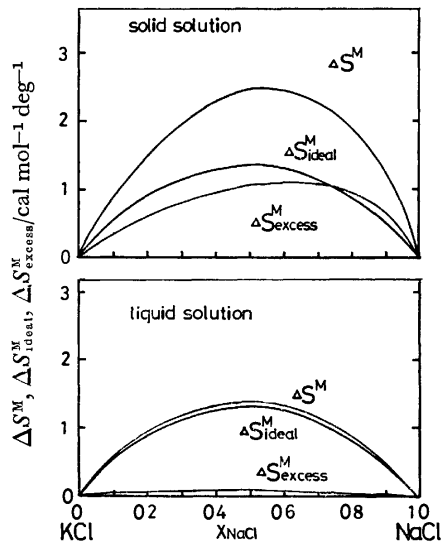

Fig. 11. Entropies of mixing in the KCl–NaCl solid solution and liquid solution systems.

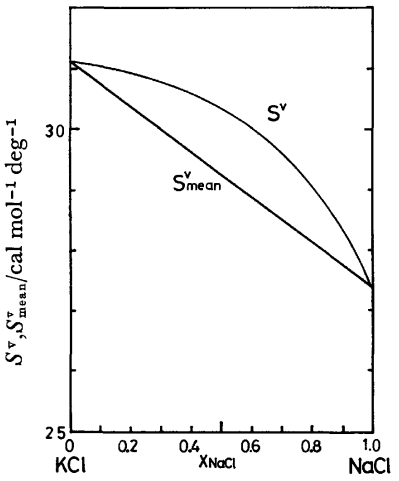

Fig. 12. Vibrational entropy and mean entropy of the KCl–NaCl solid solution system.

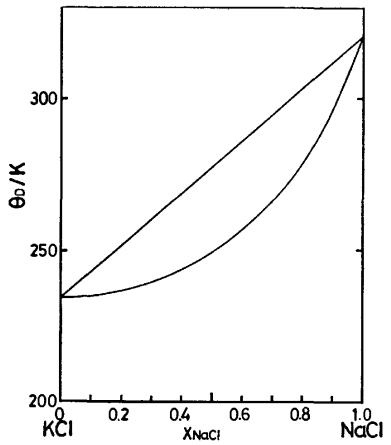

Fig. 13. Debye temperature for the KCl–NaCl solid solution system.

The change in the heat of mixing caused by the change in the vibrational spectrum is calculated using the following equation:

$$\Delta H^{M,v} = \int_0^T \Delta C_p dT. \quad (17)$$

The results are shown in Fig. 10. For the purposes of this study, it is possible to estimate that ΔC_p is close to ΔC_v. As is shown in Fig. 10, $\Delta H^{M,v}$ makes only a small contribution to ΔH^M.

Conclusion

(1) The activities of KCl and NaCl in the solid solution showed greatly positive deviations from Raoult's law, while the liquid solution gave slightly negative values.

(2) The large positive heat of mixing in the solid solution was attributed to the strain energy which arises from the difference in radius between the radii of Na^+ and K^+.

(3) The large positive excess entropy of mixing in the solid solution is considered to arise from a change in the vibrational spectrum.

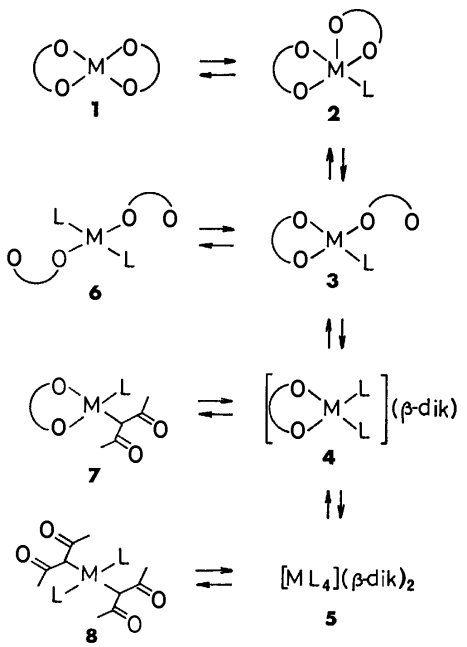
(Received April 22, 1981)

Bis(β-diketonato)palladium(II) and -platinum(II) readily react with tertiary phosphines (L) to afford [M(β-dik)(β-dik-*O*)L], [M(β-dik)L_2](β-dik), [ML_4](β-dik)$_2$, [M(β-dik-*O*)$_2L_2$], and [M(β-dik)(β-dik-*C*)L] complexes, which were characterized mainly by infrared and ^{1}H and ^{13}C NMR spectroscopy. Factors influencing the relative stability of each bonding mode of β-diketonate anions were investigated.

Since bis(2,4-pentanedionato)palladium(II) was found to react readily with Lewis bases such as triphenylphosphine, pyridine, and diethylamine to convert one of the chelating ligands into the central-carbon-bonded state,[1] we have carried out comprehensive studies on the reactions of various bis(β-diketonato)palladium(II) and -platinum(II) complexes, [M(β-dik)$_2$], with a wide variety of nitrogen and phosphorus bases. In a previous paper[2a] the reactions of [Pd(β-dik)$_2$] with nitrogen bases were summarized in Scheme 1. Besides compounds **7** and **8** containing the carbon-bonded β-dik ligand, secondary and primary amines gave the cationic complexes **4** and **5**, respectively, which contain the β-dik anion as the counter ion in the outer sphere. In the platinum(II) case, compounds of the type **6** were also isolated as the linkage isomer of **4**.[2,3]

Since the kinetic study[4] revealed that compound **7** is produced *via* **4** and not directly from **1**, compound **4** seems to be formed *via* **3** which contains the oxygen-bonded β-dik as a unidentate ligand. However, no compounds of types **2** and **3** have been isolated in the reactions between [M(β-dik)$_2$] and nitrogen bases. Then the reactions with phosphorus bases have been examined, which proceed in a similar manner to those with nitrogen bases following Scheme 1, giving **2** and **3** as well as **4**, **5**, **6**, and **7**.

Several five-coordinate complexes [M(hfac)$_2$L] were prepared by the reactions of [M(hfac)$_2$] (M=Pd and Pt) with P(*o*-tolyl)$_3$, PCy_3, and PPh(*o*-tolyl)$_2$ as L. The square-pyramidal structure of these complexes was inferred by the ^{1}H, ^{13}C, and ^{19}F NMR studies, and confirmed by X-ray analysis in the case of [Pd(hfac)$_2$P(*o*-tolyl)$_3$] and [Pt(hfac)$_2$$PCy_3$].[5] Ito *et al.* also examined the reactions between [Pt(acac)$_2$] and phosphorus bases to obtain [Pt(acac-*O*)$_2$(PEt_3)$_2$][6] as well as [Pt(acac)(acac-*C*^{3})L] (L=PPh_3 and PCy_3),[7] which were characterized by the NMR spectroscopy. The present paper reports the other new compounds obtained by the reactions of [M(β-dik)$_2$] (M=Pd and Pt; β-dik=mainly acac, tfac, and hfac) as well as mixed-ligand chelates [M(acac)(tfac)] and [M(acac)(hfac)] with several kinds of tertiary phosphines.



Scheme 1.

Experimental

Preparation of Complexes. The starting bis(β-diketonato)palladium(II) and -platinum(II) complexes were prepared by the methods reported recently.[8] Most of tertiary phosphines were purchased and used without further purification, but less stable triethylphosphine was distilled under reduced pressure before use and tri-*o*-tolylphosphine was purified by recrystallization from ethanol.

*1,1,1-Trifluoro-2,4-pentanedionato(1,1,1-trifluoro-2,4-pentanedionato-O)(tri-o-tolylphosphine)palladium(II), [Pd(tfac)(tfac-O){P(o-tolyl)$_3$}] (**3a**)*: Hexane (10 cm^3) was added to a red solution of [Pd(tfac)$_2$] (886 mg, 2.15 mmol) and P(*o*-tolyl)$_3$ (663 mg, 2.18 mmol) in hot benzene (15 cm^3) and the mixture was left to stand overnight at room temperature. Orange plates deposited were filtered, washed with diethyl ether (10 cm^3) and air-dried. The yield was 1.12 g (73%).

*[Pd(tfac)(tfac-O)(PCy_3)] (**3c**)*: [Pd(tfac)$_2$] (151 mg, 0.366 mmol) and tricyclohexylphosphine (PCy_3) (110 mg, 0.392 mmol) were dissolved in dichloromethane (2 cm^3) to result in a red solution. The solvent was allowed to evaporate spontaneously at room temperature to leave orange needles, which were recrystallized from hexane. The yield was 60 mg (24%).

†† In this paper the chelated, single oxygen bonded, and central carbon bonded anions of β-diketones such as 2,4-pentanedione (acacH), 1,1,1-trifluoro-2,4-pentanedione (tfacH), 1,1,1,5,5,5-hexafluoro-2,4-pentanedione (hfacH), 1-phenyl-1,3-butanedione (bzacH), and 1-(2-thienyl)-4,4,4-trifluoro-1,3-butanedione (ttaH) are represented by β-dik, β-dik-*O*, and β-dik-*C*, respectively, and β-dik in the outer sphere shows a counter ion. Other abbreviations: PCy_3, tricyclohexylphosphine; dpe, *cis*-1,2-bis(diphenylphosphino)-ethylene; dppe, 1,2-bis(diphenylphosphino)ethane.

*[Pd(acac)(tfac-O){P(o-tolyl)$_3$}] (**3d**)*: Hexane (2 cm^3) was added to a red solution of [Pd(acac)(tfac)] (108 mg, 0.301 mmol) and P(*o*-tolyl)$_3$ (94 mg, 0.31 mmol) in benzene (1.5 cm^3), and the mixture was left to stand at ambient temperature to deposit orange yellow columns. The product was filtered, washed with petroleum ether (bp$<$50 °C), and air-dried. The yield was 83 mg (42%).

*[Pt(acac)(acac-O){P(o-tolyl)$_3$}] (**3e**)*: A toluene solution (15 cm^3) containing [Pt(acac)$_2$] (327 mg, 0.831 mmol) and P(*o*-tolyl)$_3$ (1.024 mg, 3.36 mmol) was refluxed for 5.5 h. Hexane (20 cm^3) was added to the solution and the mixture was left to attain room temperature. Yellow needles formed were filtered, washed with hexane and dried *in vacuo*. The yield was 393 mg (68%).

*[Pt(tfac)(tfac-O){P(o-tolyl)$_3$}] (**3f**)*: A solution of *cis*-[Pt(tfac)$_2$] (300 mg, 0.599 mmol) and P(*o*-tolyl)$_3$ (203 mg, 0.667 mmol) in toluene (30 cm^3) was heated under reflux for 3 h. The solvent was then distilled away under reduced pressure to leave a yellow powder, which was washed with diethyl ether. The product was dissolved in dichloromethane and recrystallized by addition of hexane to afford yellow needles (271 mg) in a 56% yield. A similar reaction of *trans*-[Pt(tfac)$_2$] also gave **3f** in a 48% yield.

*[Pt(acac)(tfac-O){P(o-tolyl)$_3$}] (**3h**)*: The reaction of [Pt(acac)(tfac)] with three times molar amount of P(*o*-tolyl)$_3$ and work up in a similar manner as above gave tiny white needles of **3h** in a 46% yield.

*[Pt(acac)(tfac-O)(PPh$_3$)] (**3i**)*: [Pt(acac)(tfac)] (133 mg, 0.297 mmol) and triphenylphosphine (79 mg, 0.30 mmol) were dissolved in dichloromethane (1 cm^3) and the solvent was allowed to evaporate spontaneously at room temperature to leave yellow needles, which were gathered, washed with hexane, and dried *in vacuo*. The yield was 125 mg (59%).

*[Pt(acac)(tfac-O)(PEt$_3$)] (**3j**)*: A dichloromethane solution (2 cm^3) of triethylphosphine (25 mg, 0.21 mmol) was added dropwise to a solution of [Pt(acac)(tfac)] (73 mg, 0.163 mmol) in the same solvent with stirring. The solvent was then allowed to evaporate spontaneously at room temperature to deposit colorless cubes. Recrystallization from dichloromethane–hexane gave white plates (11 mg) in a 12% yield.

*Bis(tricyclohexylphosphine)(1,1,1-trifluoro-2,4-pentanedionato)-palladium(II) 1,1,1-Trifluoro-2,4-pentanedionate, [Pd(tfac)-(PCy$_3$)$_2$](tfac) (**4a**)*: [Pd(tfac)$_2$] (210 mg, 0.509 mmol) and PCy$_3$ (290 mg, 1.03 mmol) were dissolved in dichloromethane to afford an orange yellow solution. The solvent was allowed to evaporate spontaneously at room temperature to leave viscous red-orange oil, to which was added hexane (1 cm^3) to deposit a yellow precipitate. Recrystallization from dichloromethane–hexane gave a yellow crystalline solid (116 mg) in a 33% yield.

*[Pt(acac)(PPh$_3$)$_2$](tfac) (**4d**)*: A solution of [Pt(acac)-(tfac)] (145 mg, 0.324 mmol) and PPh$_3$ (176 mg, 0.671 mmol) in diethyl ether was kept in a refrigerator for two days to precipitate white plates, which were filtered and dried *in vacuo*. The yield was 232 mg (74%).

*Bis[cis-1,2-bis(diphenylphosphino)ethylene]palladium(II) 1,1,1-Trifluoro-2,4-pentanedionate, [Pd(dpe)$_2$](tfac)$_2$ (**5a**)*: To a suspension of [Pd(tfac)$_2$] (206 mg, 0.500 mmol) in dichloromethane (4 cm^3) was added dpe (396 mg, 1.00 mmol) to result in a clear yellow solution, which on standing for several minutes began to deposit pale yellow plates. After being left overnight, the precipitate was filtered, washed with dichloromethane, and dried *in vacuo*. The yield was 536 mg (89%).

*[Pd(PMe$_2$Ph)$_4$](hfac)$_2$ (**5b**)*: To a solution of [Pd(hfac)$_2$] (520 mg, 0.996 mmol) in diethyl ether (4 cm^3) was added a solution of about four times molar amount of dimethylphenylphosphine (PMe$_2$Ph) (0.7 cm^3) in the same solvent. Color of the solution changed immediately from red to orange yellow and yellow needles precipitated, which were filtered and washed five times with diethyl ether. Addition of hexane to a mixture of the filtrate and washings gave another crop of the product. The total yield of yellow crystals was 880 mg (82%).

*[Pd(dpe)$_2$](hfac)$_2$ (**5c**)*: When dpe (159 mg, 0.401 mmol) was added to a solution of [Pd(hfac)$_2$] (104 mg, 0.199 mmol) in dichloromethane (1 cm^3), the red color of the solution became light, precipitating white plates, which were filtered, washed with small portions of dichloromethane and diethyl ether, and dried *in vacuo*. The yield was 243 mg (92%).

*[Pt(PMe$_2$Ph)$_4$](tfac)$_2$ (**5d**)*: On addition of a solution of PMe$_2$Ph (100 mg, 0.725 mmol) in diethyl ether (1 cm^3) to a solution of *cis*-[Pt(tfac)$_2$] (106 mg, 0.212 mmol) in the same solvent, a creamy precipitate appeared immediately. After being washed three times with diethyl ether, the crude product (174 mg) was dissolved in hot dichloromethane (4 cm^3). A small amount of petroleum ether was added to the solution to deposit a white crystalline solid, which was filtered and washed with acetone. The yield was 82 mg (37%).

*[Pt(dppe)$_2$](tfac)$_2$ (**5e**)*: A white precipitate appeared immediately after addition of a solution of 1,2-bis(diphenylphosphino)ethane (dppe) (130 mg, 0.327 mmol) in dichloromethane (3 cm^3) to a solution of [Pt(tfac)$_2$] (80 mg, 0.16 mmol) in the same solvent (3 cm^3). Recrystallization from dichloromethane–hexane gave colorless columns (96 mg) in a 46% yield.

*[Pt(dppe)$_2$](hfac)$_2$ (**5h**) and [Pt(dppe)$_2$](acac)(tfac) (**5j**)*: Similar reactions of [Pt(hfac)$_2$] and [Pt(acac)(tfac)] with dppe in dichloromethane gave colorless plates of **5h** and pale yellow crystals of **5j** in 65 and 64% yields, respectively.

*[Pd(dpe)$_2$](tfac)$_2$·1/4CH$_2$Cl$_2$ (**5f**)*: To a solution of *cis*-[Pt(tfac)$_2$] (170 mg, 0.339 mmol) in dichloromethane (5 cm^3) was added dpe (278 mg, 0.702 mmol). After being left overnight, white plates produced were filtered, washed with dichloromethane, and dried *in vacuo*. The yield was 415 mg (93%).

*[Pt(dpe)$_2$](hfac)$_2$ (**5i**)*: White plates of **5i** were similarly prepared by the reaction between [Pt(hfac)$_2$] and dpe in dichloromethane. The yield was 96%.

*[Pt(PMe$_2$Ph)$_4$](hfac)$_2$ (**5g**)*: White columns of **5g** (109 mg) were obtained in a 38% yield by the reaction of [Pt(hfac)$_2$] (150 mg, 0.246 mmol) with PMe$_2$Ph (115 mg, 0.833 mmol) in diethyl ether (3 cm^3).

*Bis(1,1,1-trifluoro-2,4-pentanedionato-O)bis(triethylphosphine)-platinum(II), [Pt(tfac-O)$_2$(PEt$_3$)$_2$] (**6a**)*: To a solution of *cis*-[Pt(tfac)$_2$] (72 mg, 0.14 mmol) in dichloromethane (0.5 cm^3) was added PEt$_3$ (35 mg, 0.30 mmol) followed by a small amount of petroleum ether and the mixture was left overnight to allow spontaneous evaporation of the solvents. Colorless plates left were gathered, washed with a mixture of diethyl ether and ethanol (1:1 by volume) followed by neat ether, and air-dried. The yield was 67 mg (63%). *trans*-[Pt(tfac)$_2$] also gave the same product in *ca.* 50% yield.

*[Pt(tfac-O)$_2$(PCy$_3$)$_2$] (**6b**)*: The reaction of [Pt(tfac)$_2$] with PCy$_3$ in a similar manner as above afforded yellow plates of **6b** in an 87% yield. Recrystallization from dichloromethane–hexane gave rise to colorless transparent plates, which became opaque on drying *in vacuo*. The final yield was 112 mg (50%).

*[Pt(acac-O)(tfac-O)(PEt$_3$)$_2$] (**6c**)*: Addition of a dichloromethane solution (0.5 cm^3) of PEt$_3$ (57 mg, 0.48 mmol)

to a solution of [Pt(acac)(tfac)] (81 mg, 0.18 mmol) in the same solvent (1 cm^3) changed the solution colorless. Hexane (2 cm^3) was added to the solution and the mixture was left standing overnight at room temperature. The mixed solvent was then evaporated spontaneously to deposit colorless plates, which were washed repeatedly with ethanol until odor of the phosphine was lost and dried *in vacuo*. The yield was 89 mg (79%).

2,4-Pentanedionato(2,4-pentanedionato-C^3)(triethylphosphine)palladium(II), *[Pd(acac)(acac-C^3)(PEt_3)]* ***(7a)***: Triethylphosphine (43 mg, 0.36 mmol) was added dropwise to a solution of [$Pd(acac)_2$] (101 mg, 0.331 mmol) in chloroform (0.4 cm^3) with stirring. After addition of petroleum ether (0.5 cm^3) to the solution, the solvent mixture was vaporized spontaneously at ambient temperature to deposit yellow plates on the wall of vessel, which were filtered and washed with a mixture of ethanol and hexane (1:5 by volume). The yield was 31 mg (22%).

[Pd(acac)(acac-C^3)($PMePh_2$)] ***(7c)***: To a suspension of [$Pd(acac)_2$] (76 mg, 0.25 mmol) in benzene (2 cm^3) was added $PMePh_2$ (52 mg, 0.26 mmol) to result in a red solution. After addition of petroleum ether (2 cm^3) to the solution, the solvent mixture was allowed to evaporate spontaneously at room temperature to leave yellow plates on the wall, which were gathered and washed with diethyl ether. The crude product (74 mg, 59% yield) was dissolved in dichloromethane and recrystallized as yellow cubes on addition of petroleum ether. The final yield was 40 mg (32%).

1-Phenyl-1,3-butanedionato(1-phenyl-1,3-butanedionato-C^2)(triphenylphosphine)palladium(II), *[Pd(bzac)(bzac-C^2)(PPh_3)]* ***(7d)***: A mixture of [$Pd(bzac)_2$] (100 mg, 0.233 mmol) and PPh_3 (61 mg, 0.23 mmol) in diethyl ether (2 cm^3) was stirred for *ca.* 4 h at room temperature. A yellow precipitate formed was filtered and washed with diethyl ether. The yield was 57 mg (35%). Recrystallization was performed from dichloromethane–hexane.

1-(2-Thienyl)-4,4,4-trifluoro-1,3-butanedionato[1-(2-thienyl)-4,4,4-trifluoro-1,3-butanedionato-C^2](triphenylphosphine)palladium(II), *[Pd(tta)(tta-C^2)(PPh_3)]* ***(7e)***: The reaction of [$Pd(tta)_2$] with equimolar PPh_3 in diethyl ether in a similar manner as above gave a yellow powder of **7e** in a 60% yield.

Measurements. Infrared spectra were obtained in Nujol mull with Hitachi EPI-S and 295 infrared spectrophotometers. NMR spectra were recorded on JEOL-C60HL and JNM-MH100 (in the case of ^1H), FX60Q (for ^1H and ^{13}C), and FX90Q (for ^{19}F and ^{31}P) instruments. Molecular weight was determined in dichloromethane at 27 °C with a vapor pressure osmometer manufactured by Knauer, West Berlin, West Germany.

Results and Discussion

Tertiary phosphines react quite readily with [$M(\beta\text{-dik})_2$] (**1**) at room temperature. Table 1 lists the new compounds prepared by these reactions in appropriate organic solvents. In contrast to the case of nitrogen-base complexes, compounds **3** containing a tertiary phosphine as L and an O-unidentate β-dik ligand are sufficiently stable to be isolated and characterized. The π bonding between the d^8 metals and the phosphine ligands may strengthen not only the M–L bond but also the M–O(β-dik) bond by decreasing the electron density at the metal atom. Furthermore bulky phosphines are prone to prevent formation of the type **4** complexes.

In Table 2 are shown the infrared bands observed in the 1500—1800-cm^{-1} region for the representative complexes of each type. The frequencies of these bands assignable to the $\nu(C{=}O)+\nu(C{=}C)$ vibrations are helpful for diagnosing the bonding mode of β-dik anions. Ito *et al* pointed out that the $\nu(C{=}O)$ and $\nu(C{-}O)$ bands at 1650 and 1160 cm^{-1}, respectively, are characteristic of the unidentate acac ligand in [$Pt(acac\text{-}O)_2(PEt_3)_2$].[6] Each of compounds **3** and **6** also shows a band in the 1640—1660-cm^{-1} region ascribable to the $\nu(C{=}O)$ vibration of the O-bonded β-dik ligand. In addition, **3e** exhibits a strong $\nu(C{-}O)$ band at 1165 cm^{-1}. In the case of the tfac and hfac complexes, however, very strong $\nu(C{-}F)$ bands appear in the 1100—1200-cm^{-1} region, making the absorption due to the $\nu(C{-}O)$ vibration indiscernible.

Compared with **6**, compounds **3** show a few additional IR bands in the 1500—1625-cm^{-1} region caused by the chelated β-dik ligand. The tfac and hfac anions involved in the outer sphere of compounds **4** and **5** exhibit a single band in the 1604—1612-cm^{-1} and 1676—1680-cm^{-1} regions, respectively. The latter frequency coincides with that (1670—1680 cm^{-1}) recorded for the corresponding hfac compounds **4** and **5** containing nitrogen bases as L.[2] On the other hand, the former frequency for the tfac anions in **4** and **5** is *ca.* 30 cm^{-1} lower than that (1630—1640 cm^{-1}) observed for the corresponding nitrogen-base complexes.[2] The cause of this discrepancy is not rationalized at present. Compounds **7** show one or two bands in the 1650—1683-cm^{-1} region assignable to the $\nu(C{=}O)$ vibration of the C-bonded β-dik ligands.

^1H NMR Spectra. The ^1H NMR data for complexes **5** are listed in Table 3. A single set of the methyl and methine signals was observed for each complex, indicating that the two β-dik anions are environmentally equivalent. Much higher solubilities of **5** in methanol than in less polar solvents and absence of the Pt–H coupling in the proton signals from the β-dik anions in compounds **5d**—**5j** accord with the proposed salt-like structure. On the other hand, the methyl-proton signals from PMe_2Ph in **5d** and **5g** show coupling to platinum certifying that the phosphine is coordinated to the metal. The methine proton of the hfac anion in [$Pd(PMe_2Ph)_4$](hfac)$_2$ (**5b**) resonates at higher field (5.67 and 5.57 ppm in $CDCl_3$ and CD_3OD, respectively) than that in [$Pd(hfac)_2$] (6.42 and 6.50 ppm in respective solvents) because of the higher charge density on the noncoordinating anion. The methine signal from **5b** in C_6D_6 is shifted downfield by *ca.* 0.7 ppm, while the methyl signal from PMe_2Ph is shifted upfield by *ca.* 0.4 ppm as compared with the corresponding signals in $CDCl_3$. Similar phenomena were noted previously for analogous complexes containing nitrogen bases and attributed to the stereospecific interaction between the square planer complex and benzene molecules.[2]

In CD_3OD solution, the methine-proton signal from the tfac anion in **5** diminishes and instead a broad OH-proton signal becomes larger with time, attaining equilibrium in 2—3 h. Such a kind of H-D exchange is also observed in solutions of potassium β-diketonates

Table 1. Analytical data of the newly prepared complexes,[a] [M(β-dik)(β-dik-*O*)L] (**3**), [M(β-dik)L$_2$](β-dik) (**4**), [ML$_4$](β-dik)$_2$ (**5**), [Pt(β-dik-*O*)$_2$L$_2$] (**6**), and [Pd(β-dik)(β-dik-*C*)L] (**7**)

7d	Pd	bzac	PPh$_3$	154—156	65.72(66.05)	4.85(4.81)
7e	Pd	tta	PPh$_3$	115—125	49.81(50.35)	2.94(2.86)

a) The following compounds were not isolated, but characterized by IR and/or NMR spectroscopy in solution: [Pd(tfac)(tfac-*O*)(PPh$_3$)] (**3b**), [Pt(tfac)(tfac-*O*)(PPh$_3$)] (**3g**), [Pt(acac)(hfac-*O*)(PPh$_3$)] (**3k**), [Pd(tfac)(PPh$_3$)$_2$](tfac) (**4b**), [Pt(tfac)(PPh$_3$)$_2$](tfac) (**4c**), [Pt(acac)(PPh$_3$)$_2$](hfac) (**4e**), [Pd(acac)(acac-*C*^{3})(PMe$_2$Ph)] (**7b**), and [Pd(tfac)-(tfac-*C*^{3})(PPh$_3$)] (**7f**). b) The acac ligand is chelated. c) Including ¼CH_2Cl_2.

in D_2O and the rate decreases in the sequence of basicity: acac>tfac>hfac. The same trend is noted in the present complexes **5**–CD_3OD systems, the hfac anion reacting very slowly except that in **5g** which attains the exchange equilibrium in 24 h. Of the two methine proton signals from [Pt(dppe)$_2$](acac)(tfac) (**5j**), the one at δ 5.56 attains the exchange equilibrium in 3 min but the signal at δ 5.30 diminishes very slowly. Thus the former signal is assigned to the acac anion and the latter to tfac. Previously the analogous compounds **4** and **5** containing amines as L were found to exchange the amine protons and the methine proton of β-dik in the outer sphere with $CDCl_3$, the rate paralleling the basicity of β-dik.[2,9]

Compounds **4**, on the other hand, exhibit two sets of methyl and methine signals from tfac anions (Table 4). The signals assignable to acac in [Pt(acac)-(PPh$_3$)$_2$](tfac) (**4d**) are flanked by the ^{195}Pt satellites, while those from tfac are not, indicating that acac was retained in and tfac was repelled from the coordination sphere in the reaction of [Pt(acac)(tfac)] with PPh$_3$. When increasing amounts of PPh$_3$ was added to [Pt(acac)(hfac)] in $CDCl_3$, signals assignable to [Pt(acac)(hfac-*O*)(PPh$_3$)] (**3k**) grew at first (*vide infra*). After the amount of PPh$_3$ exceeded the equimolar level, signals attributable to [Pt(acac)-(PPh$_3$)$_2$](hfac) (**4e**) appeared and increased gradually at the expense of the **3k** signals, which disappeared almost completely when three times molar PPh$_3$ was added. Thus the difference in the coordinating ability of β-dik ligands in the mixed chelates is manifested by the reaction with PPh$_3$, the fluorinated β-dik ligands being displaced in preference to acac.

When twice molar PPh$_3$ reacted with *cis*-[Pt(tfac)$_2$] in $CDCl_3$, two sets of methyl and methine signals attributable to the tfac anions in [Pt(tfac)(PPh$_3$)$_2$]-

(tfac) (**4c**) were observed. Unfortunately, however, a spectrum distinct enough to allow the determination of exact coupling constants to ^{195}Pt could not be recorded, since the succeeding reactions gave rise to [Pt(tfac(2—)-*C,O*)(PPh_3)$_2$] containing a C,O-chelated 1,1,1-trifluoro-2,4-pentanedionate dianion.[10] On the contrary, the reaction mixture of [Pd(tfac)$_2$] and twice molar PPh_3 in CD_2Cl_2 at room temperature exhibited one set of broad methyl and methine signals, which became sharper with increasing temperature. At −45 °C, on the other hand, two sets of sharp signals were observed and assigned to the tfac anions in the inner and outer spheres of [Pt(tfac)(PPh_3)$_2$]-(tfac) (**4b**), and the temperature change of spectrum was reversible. The proposed structure is also supported by the ^{13}C NMR spectroscopy (*vide infra*). It is not certain at the present stage whether the rapid interchange of the tfac anions at room temperature occurs directly,

$$[Pd(tfac)(PPh_3)_2](tfac^*) \rightleftharpoons [Pd(tfac^*)(PPh_3)_2](tfac), \quad (1)$$

or is effected by the forward and reverse processes of

$$[Pd(tfac)(PPh_3)_2](tfac) \rightleftharpoons [Pd(tfac)_2] + 2PPh_3. \quad (2)$$

The fact that [Pd(tfac)(PCy_3)$_2$](tfac) (**4a**) shows no sign of the tfac exchange seems to suggest the associative nature of the ligand exchange, since the bulky PCy_3 ligands may prevent attack of tfac on palladium. Complex **4c** does not undergo the tfac exchange either, probably because of its substitution inertness as compared with the corresponding Pd(II) complex **4b**.

The methyl protons of the chelated β-dik ligands in complexes **4b**—**4e** resonate at δ 1.5—1.7. They are upfield shifted by 0.3—0.8 ppm compared with **4a** and complexes **4** containing nitrogen bases as L.[2] The phenyl rings of PPh_3 situated at the adjacent coordination sites seem to exert the anisotropic magnetic effect.[1a] Similar upfield shift of the methyl proton signals caused by the adjacent PPh_3 ligand is also noticed for complexes **3** and **7**.

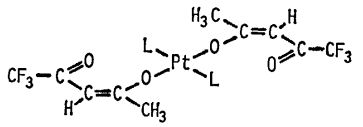
a), b) Same as footnotes for Table 3. IS and OS abbreviate the inner and outer spheres, respectively. c) L is PPh_3 except for **4a** which has PCy_3 as L. d) [M(tfac)(PPh$_3$)$_2$](tfac), where M=Pd (**4b**) and Pt (**4c**), were prepared in solution by the reactions of [M(tfac)$_2$] with twice molar PPh_3, and [Pt(acac)(PPh$_3$)$_2$](hfac) (**4e**) was formed by the reaction of [Pt(acac)(hfac)] with excess PPh_3. See text. e) The β-dik anions in IS and OS are interchanging with each other rapidly at 25 °C. f) At −45 °C.

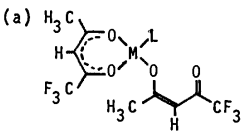
The ^{1}H NMR data for complexes **6** are included in Table 3. They are quite similar to those for *trans*-[Pt(acac-*O*)$_2$(PEt$_3$)$_2$][6] and *trans*-[Pt(acac-*O*)$_2$(pip)$_2$],[3] where pip represents piperidine. Each of **6a** and **6b** exhibits single tfac-methyl signal flanked by the ^{195}Pt satellites, indicating that the acetyl oxygen is preferentially bonded to the metal. The characteristic quintet resonance (J=8 Hz) of the methyl protons of PEt_3 in **6a** and **6c** suggests the trans arrangement of the PEt_3 ligands.[11] Even when *cis*-[Pt(tfac)$_2$] reacted with the phosphine, the product was *trans*-[Pt-



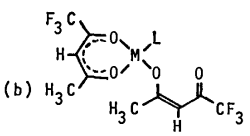
L=PEt_3 (**6a**) and PCy_3 (**6b**)

(tfac-*O*)$_2$L$_2$] exclusively. The trans configuration seems to be thermodynamically more stable and may have been realized by the geometrical isomerization catalyzed by the tertiary phosphine[12] contained in excess in the reaction mixture. The cis-trans isomerization may proceed by means of the intramolecular rearrangement of a five-coordinate intermediate. The dynamic behavior in solution of the five-coordinate complexes [M(hfac)$_2${P(*o*-tolyl)$_3$}] (M=Pd and Pt) was elucidated by the ^{13}C and ^{19}F NMR spectroscopy and interpreted based on a proposed mechanism.[5]

Complexes **3** are stable in solution. Molecular weights of **3a** and **3e** were determined in dichloromethane to be 716 and 659, which are near the calculated values, 717 and 698, respectively. The ^{1}H NMR data for **3** are listed in Table 5. Since the tfac anion is unsymmetric, the following two geometrical isomers are conceivable even though the unidentate tfac is bound to the metal preferentially *via* the more basic acetyl oxygen as was the case for com-



cis(Me,L)



trans(Me,L)

plexes **6**. Thus four tfac-methyl signals are observed for **3f** at 1.63, 1.92, 1.97, and 2.11 ppm with the area ratio of 1:1:4:4, disclosing coexistence of the two isomers in the 1:4 ratio. The signal at the highest field is readily assigned to CH_3(a) of the chelating tfac in the *cis*(Me,L) isomer and in turn the signal at δ 1.92 to CH_3 of the O-unidentate tfac in the same isomer. The remaining signals at δ 1.97 and 2.11 are attributed to the *trans*(Me,L) isomer, but discrimination of them is not straightforward. The higher-field signal (δ 1.97) near the above one at δ 1.92 is tentatively assigned to CH_3 of the O-unidentate tfac and the one at δ 2.11 to CH_3(b) of the chelating tfac. The assignment is supported by the fact that the methyl protons of the chelating tfac in the *trans*(Me,L) isomer of [Pd(tfac)(tfac-*C*^{3})(PPh$_3$)] (**7f**) also resonate at 2.22 ppm. It is noteworthy that the CH_3(a) protons couple to ^{195}Pt (^4J=4 Hz) but CH_3(b) does not in accordance with the higher trans influence of the tertiary phosphine than that of the O-unidentate β-dik which is shown by the following ^{31}P NMR data.

Figure 1 displays the ^{19}F{^{1}H} NMR spectrum of **3f** in $CDCl_3$. Two overlapping triplets are observed at 72.81 and 72.96 ppm upfield from external $CFCl_3$,

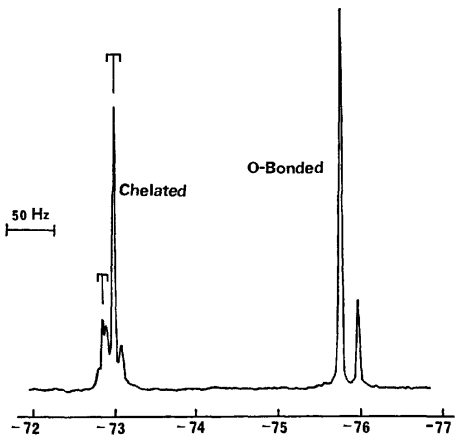


Fig. 1. ^{19}F{^{1}H} NMR spectrum at 84.31 MHz of [Pt(tfac)(tfac-*O*){P(*o*-tolyl)$_3$}] (**3f**) in $CDCl_3$.

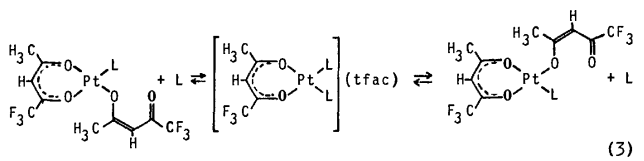
a) Same as footnote(a) for Table 3. Cis and trans abbreviate *cis*(Me,L) and *trans*(Me,L), respectively. See text. b) dd: doublet of doublets. The coupling constants ^3J(P–H) and ^3J(C–H) are given in brackets and parentheses, respectively. c) Indiscernible because of overlapping with other signals. d) Determined in a mixture of $CDCl_3$ and C_6D_6 (2:1 by volume). e) Phenyl protons of the bzac and PPh_3 ligands resonate at 6.9—7.9 ppm. f) Two isomers coexist in approximately equal proportions but are indistinguishable.

^4J(Pt–F) being *ca.* 10 and 16 Hz, respectively. On the basis of their relative intensities, the more intense higher-field signal is assigned to CF_3 of the chelating tfac in the *trans*(Me,L) isomer and the lower-field one to that in the *cis*(Me,L) isomer. Two sharp singlets observed at 75.74 and 75.97 ppm upfield from external $CFCl_3$ with the area ratio of 4:1 are assigned to the CF_3 groups of unidentate tfac in the *trans*(Me,L) and *cis*(Me,L) isomers, respectively. It should be noted that the dangling CF_3CO group has no bonding interaction with the platinum atom, exhibiting a sharp ^{19}F singlet. The five coordinate complex [Pt(hfac)$_2$-{P(*o*-tolyl)$_3$}] containing the phosphine ligand in the basal plane of a square pyramid structure[5] exhibits an analogous ^{19}F NMR spectrum, but the higher-field singlet is broad, indicating coupling to platinum.

The ^{31}P{^{1}H} NMR spectrum of **3f** in $CDCl_3$ shows two signals at 4.5_1 and 5.2_5 ppm upfield from external H_3PO_4 flanked by the ^{195}Pt satellites with ^1J(Pt–P)= 4410 and 4380 Hz, respectively. Based on the relative intensities, they are assigned to the *cis*(Me,L) and *trans*(Me,L) isomers, respectively. The minor signal at 4.5_1 appears as a quartet with ^5J(F–P)=1.1 Hz, certifying that the CF_3 group occupies the trans position to the phosphine ligand in the *cis*(Me,L) isomer. The larger ^1J(Pt–P) value for the *cis*(Me,L) isomer than that for *trans*(Me,L) suggests that the poorer donor-ability of the CF_3CO moiety than that of CH_3CO decreases the charge density at platinum, suppressing the π-character and increasing the σ-character of the trans Pt–P bond.

Complex **3f** was produced by the reaction of P(*o*-tolyl)$_3$ with either of *cis*- and *trans*-[Pt(tfac)$_2$] and the ratio of *cis*(Me,L) and *trans*(Me,L) is almost constant. Geometrical isomerization catalyzed by the tertiary phosphine *via* a five-coordinate intermediate as mentioned above may have occurred to result in the equilibrium mixture of **3f**, since the bulkiness (cone angle 194°)[13] of P(*o*-tolyl)$_3$ seems to make the consecutive substitution mechanism (Eq. 3) *via* a bis(phosphine) complex less probable.

[Pt(acac)(acac-*O*){P(*o*-tolyl)$_3$}] (**3e**) exhibits four acetyl-methyl signals, which were assigned by reference to **3f** and [Pt(acac)(acac-*C*^{3})(PPh_3)].[7] Proton res-



cis(Me,L) trans(Me,L) (3)

onances from other complexes **3** were assigned in a similar way and listed in Table 5. It should be noted that the CH_3(a) protons in [Pd(tfac)(tfac-*O*)(PCy$_3$)] (**3c**) resonate at much lower field as 2.13 ppm than those in other complexes containing the triarylphosphine as L.

[Pt(acac)(tfac-*O*){P(*o*-tolyl)$_3$}] (**3h**) exhibits two acetyl-methyl signals at 1.48 and 1.95 ppm in the area ratio of 1:2. The peak at δ 1.48 is assigned to CH_3(a) of the chelated acac and the other to CH_3(b) of acac and CH_3 of the O-unidentate tfac which resonate at the same field accidentally. If tfac were chelated alternatively to Pt and acac served as the unidentate ligand, more peaks (at most six) should appear, since two geometrical isomers are possible and the unidentate acac should exhibit two separate methyl signals. The corresponding palladium(II) complex **3d** shows three signals at 1.56, 2.05, and 1.93 ppm, of which the former two are assigned to the chelated acac and the last one to the unidentate tfac in a similar manner as above.

Thus the chelated tfac has stronger tendency than acac to transform into the O-unidentate state. In fact [Pd(acac)$_2$] did not react with three times molar P(*o*-tolyl)$_3$ even when kept in boiling toluene for 5 h, whereas [Pd(tfac)(tfac-*O*){P(*o*-tolyl)$_3$}] (**3a**) was formed in a good yield when equimolar amounts of [Pd(tfac)$_2$] and P(*o*-tolyl)$_3$ were mixed in hot benzene and the mixture was kept overnight at room temperature. However, compound **3d** is not so stable in $CDCl_3$, but about 30% of P(*o*-tolyl)$_3$ is liberated according to

$$[Pd(acac)(tfac\text{-}O)\{P(o\text{-tolyl})_3\}] \rightleftharpoons [Pd(acac)(tfac)] + P(o\text{-tolyl})_3. \quad (4)$$

On addition of excess phosphine, the equilibrium is shifted to left and proton signals from [Pd(acac)(tfac)] disappears. On the contrary, complex **3h** is quite stable in solution and shows no sign of dissociation. Thus the platinum(II) complexes of type **3** seem more stable than the corresponding palladium(II) complexes.

The proton signal pattern of [Pt(acac)(tfac-*O*)(PPh$_3$)] (**3i**) in $CDCl_3$ resembles quite well to that of **3h**. On addition of C_6D_6 to this solution, the overlapped methyl signal at 2.00 ppm was separated, giving rise to three equi-intensity methyl signals. It has been reported that as compared with the spectra in other solvents, C_6D_6 shifts the methyl and methine signlas from the chelated β-dik to the higher field and those from β-dik in the outer sphere to the lower field.[2,8b] The δ 1.45, 1.81, and 5.23 signals observed in the mixed solvent lie in the higher field than the corresponding ones in $CDCl_3$ and are assigned to CH_3(a), CH_3(b), and CH of the chelated acac, respectively. The remaining peaks at δ 2.05 and 6.44 are then ascribed to CH_3 and CH of the unidentate tfac, indicating that C_6D_6 shifts these resonances to the lower field in a similar way as it shifts the signals from β-dik in the outer sphere. Thus the two CH signals for **3i** were distinguished, the higher-field one being assigned to the chelated β-dik and the lower-field one to the O-unidentate β-dik. Similarly methine signals from each of compounds **3** were distinguished and listed in Table 5.

When PEt_3 was added in small portions to $CDCl_3$ solutions of [Pt(acac)$_2$] and [Pt(tfac)$_2$], proton signals attributable to [Pt(β-dik-*O*)$_2$(PEt$_3$)$_2$] (**6**) appeared, but those assignable to the intermediate complexes **3** could not be observed. On the other hand, addition of PEt_3 to a solution of [Pt(acac)(tfac)] in $CDCl_3$ gave rise to new signals at 5.48 and 6.47 ppm, which are assigned to methine protons of [Pt(acac)(tfac-*O*)(PEt$_3$)] (**3j**). Methyl resonances of **3j** were indiscernible because of overlapping with signals from **6c**, successor of **3j**. In a similar manner, addition of PPh_3 in limited amounts to a $CDCl_3$ solution of [Pt(acac)(hfac)] produced proton signals due to [Pt(acac)(hfac-*O*)(PPh$_3$)] (**3k**) as recorded in Table 5. Compound **3j** was isolated, while **3k** was not. However, characterization of these compounds in solution suggests that compounds [Pt(acac)(β-dik-*O*)L] containing chelated acac and unidentate β-dik other than acac are more stable than the corresponding compounds **3** containing one kind of β-dik.

As is noticed in Table 5, the *trans*(Me,L) isomers of compounds **3** containing tfac are invariably more stable than the *cis*(Me,L) isomers. The σ-donating ability of the CH_3CO moiety is higher than that of the CF_3CO moiety, strengthening the Pt–phosphine π-bonding. Although the σ-character of the Pt–P bond is decreased in this case as was evidenced by the lower ^1J(Pt–P) value for *trans*(Me,L)-**3f** than that for the cis isomer, the overall stability of the *trans*-(Me,L) isomer is higher, suggesting that the π-bonding of Pt–phosphine is more important than the σ-bonding in these complexes.

The ^{1}H NMR spectrum of the O-unidentate acac was first recorded for R_3Si(acac-*O*) by Pinnavaia and his collaborators.[14] It is composed of two sets of signals assignable to two geometrical isomers. The trans isomer, in which the acetyl and R_3SiO groups occupy the trans positions around the C=C bond, exhibits a methine multiplet and two acac methyl doublets as the result of the spin-spin coupling between the methine proton and both methyl groups. On the other hand, the cis isomer shows a methine singlet and a methyl singlet due to a rapid fluxional motion at room temperature interchanging intramolecularly the coordinating oxygen atom of the unidentate acac ligand. The unidentate acac in **3e** and **6c** exhibits one methine and two methyl resonances showing no coupling to each other. Similarly the unidentate tfac in each of other compounds **3** and **6** gives only one set of mutually uncoupled methine and methyl signals for the *cis*(Me,L) or *trans*(Me,L) isomer. These results indicate that the unidentate acac and tfac ligands always have the stereochemically rigid cis structure as depicted above. The O-unidentate β-dik originates from the O,O′-chelate and

cis configuration around the C=C bond was reserved during the reactions with phosphines under the mild conditions.

Table 5 includes the ^{1}H NMR data for complexes **7** inclusive of **7b** and **7f** which were not isolated. Proton signals from [Pd(acac)(acac-C^3)L] (L=PEt_3 (**7a**), PMe_2Ph (**7b**), and $PMePh_2$ (**7c**)) were assigned by reference to [Pd(acac)(acac-C^3)(PPh_3)].[18] There exist *cis*(Me,L) and *trans*(Me,L) isomers in the case of **7d**, **7e**, and **7f** containing unsymmetrical β-dik, and the signals were assigned by reference to the data for [Pt(etac)(etac-C^2)(PPh_3)],[15] of which etac represents the 1-ethoxy-1,3-butanedionate anion. Since [Pd(tta)(tta-C^2)(PPh_3)] (**7e**) lacks the methyl group, the geometrical isomers are indistinguishable though two sets of methine signals indicate their coexistence. When an equimolar amount of PPh_3 was added to a solution of [Pd(tfac)$_2$] in $CDCl_3$, proton signals ascribable to [Pd(tfac)(tfac-*O*)(PPh_3)] (**3b**) appeared first followed by those due to [Pd(tfac)(tfac-C^3)(PPh_3)] (**7f**), which is more stable and was the sole product after 1 h. [Pd(bzac)(bzac-C^2)(PPh_3)] (**7d**) is also stable in dichloromethane, giving a molecular-weight value of 640 near the calculated value (691).

^{13}C NMR Spectra. The ^{13}C NMR data for compounds **5** are listed in Table 6. None of the carbon signals from β-dik in **5** is flanked by ^{195}Pt satellites, indicating that the β-dik anions are not coordinated with the metal atom. The CH_3 and CF_3 carbon signals from β-dik in the outer sphere show downfield shift of 2—4 ppm, while the CH carbon upfield shift of 3—10 ppm as compared with the corresponding carbons in [M(β-dik)$_2$]. The ^1J(C-F) value for compounds **5** is more than 5 Hz larger and ^2J(C-F) is about 4 Hz smaller than those for the corresponding carbons in the bis-chelates. Similar trend was also noted for complexes of the type **5** containing nitrogen bases as L[2] and for [K(18-Crown-6)](β-dik).

Compound **4a** exhibits two sets of carbon signals from β-dik, which were easily assigned as is listed in Table 7 based on the above information. The CH_3 carbon of the chelated tfac appears as a doublet of doublets due to coupling to both ^{31}P atoms, ^4J(P-C) being 5 Hz to trans P and 2 Hz to cis P. The CF_3 carbon, on the other hand, couples only to trans P(^4J=9 Hz). The acetyl carbon, $CH_3\underline{C}O$, also couples only to trans P and the ^3J(P-C) is smaller (2.5 Hz) than that for CH_3 which is remote from P. Similar situation is observed for [Pt(β-dik)$_2$];[8] the ^3J(Pt-C) values for CH_3, CF_3, and CH are about twice

a, b) Same as footnotes for Table 6. c)  d) IS and OS refer to tfac in the inner and outer spheres.

e) Only one set of broad signals for tfac was observed due to the rapid exchange reaction between tfac anions in the inner and outer spheres.

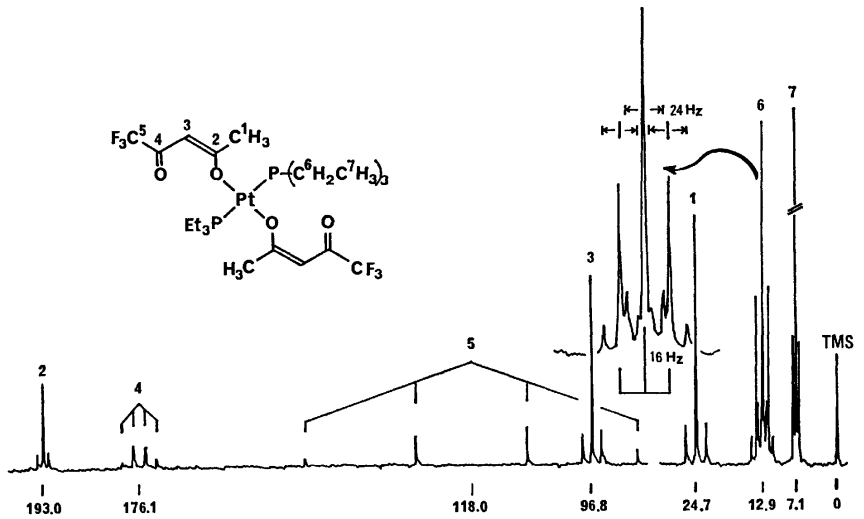

Fig. 2. $^{13}C\{^1H\}$ NMR spectrum at 15.04 MHz of [Pt(tfac-*O*)$_2$(PEt$_3$)$_2$] (**6a**) in $CDCl_3$. The J(Pt–C) values are 55, 28, and 55 Hz for CH_3, CO, and CH of tfac, respectively, and 24 and 15 Hz for CH_2 and CH_3 of PEt_3, respectively. ^1J(C–F)=292 Hz, ^2J(C–F)=31 Hz.

as large as the ^2J(Pt–C) values for $CH_3\underline{C}O$ and $CF_3\underline{C}O$.

Compound **4b** shows one set of carbon signals from β-dik, which are broad, sharpening at higher temperature, and their chemical shifts are rough average of those for tfac anions in the inner and outer spheres of **4a** except the CH_3 carbon. The exchange reaction between tfac anions in **4b** is occurring in $CDCl_3$ solution rapidly on the NMR time scale as was also evidenced by the ^1H NMR spectra (*vide supra*).

Figure 2 displays the $^{13}C\{^1H\}$ spectrum of [Pt(tfac-*O*)$_2$(PEt$_3$)$_2$] (**6a**) in $CDCl_3$. Each carbon of the CH_3COCH moiety couples to ^{195}Pt (J=55, 28, and 55 Hz, respectively), whereas CF_3 does not, implying that the tfac ligands coordinate to the metal *via* the acetyl oxygen without bonding interaction through CF_3CO. The CH_2 carbon of PEt_3 resonates at 12.9 ppm as a 1:2:1 triplet (J(P–C)=16 Hz) flanked by ^{195}Pt satellites. Although the $^{13}C\{^1H\}$ NMR spectra were first thought to provide a powerful tool for determining the stereochemistry of bis(phosphine) metal complexes,[16] later studies have questioned this proposal.[17] Nelson and his collaborators[18] showed that normally the ^{13}C resonances for the cis isomers of the square-planar $MX_2(PR_3)_2$ type complexes should appear as a quintet, a non 1:2:1 triplet, a doublet of doublets, or a doublet depending on the relative values of ^2J(P–P′) and $|^1J(P–C)^3-J(P'–C)|^2$, while those for the trans isomers with large ^2J(P–P′) always appear as 1:2:1 triplets. The 1:2:1 appearance of the CH_2 carbon of PEt_3 in **6a** seems to support the trans structure of **6a** in accordance with the ^1H NMR evidence (*vide supra*). The fact that the ^{13}C signals from the O-unidentate tfac ligands in **6a** show no coupling to ^{31}P is also in conformity with the trans structure.

The complex $^{13}C\{^1H\}$ NMR spectra of compounds **3** were analyzed based on the above-mentioned characteristics of the O-unidentate β-dik and also on the equilibrium ratio of the *cis*(Me,L) and *trans*(Me,L) isomers determined by the ^1H NMR spectroscopy. As is noticed in Table 8, the difference in the ^{13}C shielding between the two geometrical isomers is more remarkable for the chelated tfac than for the O-unidentate tfac. It seems to be caused by the larger difference in the trans influence between the tertiary phosphine and the O-unidentate tfac than that between the CH_3CO and CF_3CO moieties of the chelated tfac ligand.

The ^{13}C NMR data for [Pd(bzac)(bzac-*C*^{2})(PPh$_3$)] (**7d**) and [Pd(tfac)(tfac-*C*^{3})(PPh$_3$)] (**7f**), both having unsymmetric β-dik, are included in Table 8. Their spectra resemble those of [M(acac)(acac-*C*^{3})(PPh$_3$)] (M=Pd and Pt)[7] but are more complex due to coexistence of the geometrical isomers. The isomer ratio determined by the ^1H NMR spectroscopy was again helpful in assigning the ^{13}C signals. In a similar manner as the case of compounds **3**, the difference in the ^{13}C shielding between the *cis*(Me,L) and *trans*(Me,L) isomers is more remarkable for the chelated bzac and tfac ligands than for the central-carbon bonded ones. It is worth noting that the carbon-bonded tfac discriminates the geometry of the chelated tfac, whereas the carbon-bonded bzac is insensitive to the configuration of the chelated bzac. Thus the two signals assigned to C^8 of *cis*-**7f** and *trans*-**7f** are 0.5 ppm apart from each other, while C^8 of **7d** resonates as a single peak. The difference in trans influence between the CH_3CO and CF_3CO moieties in the chelated tfac seems to be larger than that between the CH_3CO and C_6H_5CO moieties in the chelated bzac.

The Sequence of Reactions between [M(β-dik)$_2$] and Tertiary Phosphines and Relative Stabilities of Various Products. Compounds **2**—**7** in Scheme 1 were obtained by the reactions of [M(β-dik)$_2$] with tertiary phosphines. When an equimolar amount of PPh_3 was added to a solution of [Pd(tfac)$_2$] in $CDCl_3$, the ^1H NMR signals attributable to **3b** appeared first prior to those assignable to **7f** which was the final product in this case. Employment of twice molar PPh_3 gave rise to **4b**, which was characterized in solution. Thus,

a, b) Same as footnotes for Table 6. c) The phenyl-ring carbons of bzac and PPh_3 resonate in the 126.5—141.5 ppm region and are indiscernible because of overlapping except the quaternary carbon (C^{10}) of the C-bonded bzac resonating at 141.5 ppm and the ortho carbon of PPh_3 at 134.8 ppm with $^2J(P\text{-}C) = 11$ Hz.

compound **7** seems to be formed by a sequence of reactions **1**→(**2**)→**3**→**4**→**7** as was the case for [Pd(acac)(acac-C^3)Et$_2$NH].[4] The reaction **4**⇄**7** is reversible and controlled by relative concentrations of the reactants. The five-coordinate complex of the type **2** was not identified for this reaction system, but is presumed to be involved as an intermediate, since stable compound **2** was isolated in the reaction of [Pd(hfac)$_2$] with P(*o*-tolyl)$_3$.[5]

When *cis*-[Pt(tfac)$_2$] was allowed to react with an equimolar amount of PPh$_3$, the product was exclusively **3g**, which was converted to **4c** by the reaction with another equivalent of PPh$_3$. Similar NMR spectroscopic observation of the reaction sequence was also performed for [Pt(acac)(hfac)].

Relative stabilities of these ternary complexes are determined by the natures of the metal ion, β-dik, and L, and also by the combination of these components. The O-unidentate linkage of β-dik in complexes **3** and **6** seems to be more favorable for Pt(II) than for Pd(II) as suggested by Table 1. For instance, [Pt(acac)$_2$] reacts with P(*o*-tolyl)$_3$ to yield **3e**, while [Pd(acac)$_2$] does not. Both of [M(tfac)$_2$] (M= Pt and Pd) react with equimolar PCy$_3$ to produce compounds **3**, but the succeeding reactions with another mole of PCy$_3$ give rise to **6b** in the Pt(II) case, while to **4a** in the Pd(II) case. It is noteworthy that Pd(II) prefers [Pd(tfac)(PCy$_3$)$_2$](tfac) (**4a**) over the *trans*-[Pd(tfac-*O*)$_2$(PCy$_3$)$_2$] structure in spite of the mutual steric hindrance of the two PCy$_3$ ligands at the cis positions in **4a**.

The central carbon bonding in **7** is much more favorable for Pd(II) than for Pt(II). Thus the reaction of PEt$_3$ with [Pd(acac)$_2$] gives **7a** exclusively, whereas that with [Pt(acac)$_2$] results only in [Pt(acac-*O*)$_2$(PEt$_3$)$_2$].[6] In the reactions of [M(acac)$_2$] with secondary amines, Pd(II)[2a] gave complexes of types **4** and **7**, while Pt(II)[2b] **4** and **6**. On the other hand, [Pt(acac)$_2$] was reported to produce [Pt(acac-C^3)$_2$(py)$_2$] besides [Pt(acac)(acac-C^3)(py)],[19] but [Pd(acac)$_2$] gave only the latter type-**7** complex.[1a] Platinum looks to prefer carbon bonding with acac more strongly than palladium does in this [Pd(acac)$_2$]–py system, although reasonable rationalization is difficult.

As to the role of β-dik, the basicity is the most important factor. Thus the reactivity of [Pd(β-dik)$_2$] with nitrogen bases was in the sequence acac<tfac< hfac, half prefering most strongly to go out of the coordination sphere.[2] Similar trend is also observed for reactions with less bulky tertiary phosphines (Table 1). The type-**2** complexes were obtained only from [M(hfac)$_2$] whose acidity may be the highest among the [M(β-dik)$_2$] complexes due to the lowest basicity of hfac.

The unsymmetric tfac anion seems to stabilize the O-unidentate linkage as compared with acac, giving many kinds of compounds of the **3** and **6** types. On the other hand, [M(acac)$_2$] gave **7** by the reactions with phosphines[1a,7] except P(*o*-tolyl)$_3$ and PEt$_3$ which reacted with [Pt(acac)$_2$] to afford **3e** and the type-**6** complex,[6] respectively. The central carbon bonding is more favorable for acac than for tfac and hfac. Ito and Yamamoto[20] examined the reactions of [Pt(acac)(acac-C^3)(PPh$_3$)] with several β-dicarbonyl compounds (β-dikH) in refluxing toluene and found that the keto-favoring β-dikH could replace the carbon-bonded acac more easily.

The reactions of [M(acac)(β-dik)] with phosphines clearly distinguish the labilities of the β-dik ligands. The tfac or hfac chelate is preferentially cleaved firstly, the acac chelate being preserved intact. Complexes **3** and **4** derived from the mixed ligand chelates seem to be more stable than those from the binary chelates. The acac ligand preferring the chelated state and tfac which is suitable as the unidentate ligand or counter anion may cooperate to stabilize **3** and **4**.

The σ-basicity of tertiary phosphines was deduced from the frequency of the A_1 carbonyl mode of Ni(CO)$_3$L in CH$_2$Cl$_2$ to be in the sequence,[13] PCy$_3$> PEt$_3$ > PMe$_2$Ph > P(*o*-tolyl)$_3$ > PMePh$_2$ > PPh$_3$. The fact that the reaction of [Pt(acac)$_2$] with PPh$_3$ gives **7**,[7] whereas that with PEt$_3$ results solely in **6**[6] seems to reflect the electronic effect of phosphines on the choice of the bonding mode of β-dik ligands. In complexes **7**, less σ-basic and more π-acidic triarylphosphines will diminish the charge density on the metal atom, strengthening the bond with strong σ-donors such as the carbon-bonded β-dik. On the other hand, strongly σ-basic trialkylphosphines will prefer the O-unidentate β-dik which is a weak σ-donor to the carbon-bonded one, stabilizing complexes **6**.

The steric effect of tertiary phosphines is more remarkable. For example, P(*o*-tolyl)$_3$ can convert only one of the chelating ligands in [M(β-dik)$_2$] into the O-unidentate state to result in complexes **3**, but can not give succeeding products. Bulky P(*o*-tolyl)$_3$ (cone angle 194°)[13] in the coordination sphere might prevent attack of the second phosphine molecule on the central metal in both the kinetic and thermodynamic senses. On the other hand, PPh$_3$ (cone angle 145°)[13] can conduct reactions to give **3**→**4**→**7**. Less bulky PMe$_2$Ph (122°) and dppe (125°)[13] afford complexes **5** although the electronic factor might also be favorable.

We wish to thank Mr. Junichi Gohda for the elemental analysis and Mr. Tetsu Hinomoto of JEOL, Ltd. for the measurements of ^{19}F and ^{31}P NMR spectra. S. O. and S. K. are also grateful to the Ministry of Education, Science, and Culture for Grant-in-Aid for Scientific Research, Nos. 454196 and 243014, respectively.

Synergistic Extraction of Vanadium(V, IV) with Dithizone

Hideo AKAIWA,* Hiroshi KAWAMOTO, and Etsuo HIYAMUTA
Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376
(Received April 23, 1981)

By employing the synergistic extraction technique, vanadium(V,IV) has been found to form the primary dithizonate in the presence of a synergist. The extraction of the element proceeds according to the following equations.

$$VO_2^+ + H_2dz_{,org} + TBPO_{org} \rightleftharpoons VO_2(Hdz)(TBPO)_{org} + H^+,$$

and

$$VOOH^+ + H_2dz_{,org} + TOPO_{org} \rightleftharpoons VOOH(Hdz)(TOPO)_{org} + H^+,$$

where H_2dz, TBPO, and TOPO denote dithizone, tributylphosphine oxide and trioctylphosphine oxide, respectively, and the subscript org indicates the benzene phase. The resulting adduct $VO_2(Hdz)(TBPO)$ has an absorption maximum at 503 nm and is stable for at least 1 h. However, the red color of VOOH(Hdz)(TOPO) in benzene fades away during the standing time, probably due to the dimerization of the initially extracted monomeric species.

Since the introduction of dithizone(3-mercapto-1,5-diphenylformazan=H_2dz) into the field of analytical chemistry by H. Fischer,[1] extensive studies have been made with the reagent because of its excellent nature as a chelating agent.[2] However, the complexation of vanadium(V,IV) with dithizone has not been reported so far. In the work described below, sufficient evidence for the formation of dithizonatovanadium(V, IV) is given by employing the synergistic extraction technique.

Experimental

Reagent. A stock solution of vanadium(V) (100 μg cm^{-3}) was prepared by dissolving a weighed amount of ammonium metavanadate (NH_4VO_3, Wako Pure Chemicals) in water. Similarly, a stock solution of vanadium(IV) (100 μg cm^{-3}) was prepared by using vanadyl sulfate($VOSO_4$ $3H_2O$, Nakarai Chemicals). Trioctylphosphine oxide (TOPO), tributylphosphine oxide(TBPO), and dithizone were obtained from Wako Pure Chemicals and used without further purification. Benzene and all other reagents used in this work were of guaranteed grade.

Apparatus. The absorbance measurements were conducted with a Hitachi Model 200-10 type spectrophotometer and 1.00 cm glass cells. The pH of the aqueous phase was measured with a Hitachi-Horiba F-7_{ss} type pH meter, and the extraction was carried out by using a Iwaki KM type shaker.

Procedure. The aqueous phase containing 1.96×10^{-5} mol dm^{-3} vanadium(V) or vanadium(IV) was shaken vigorously for 10 min in a separatory funnel with an equal volume of the organic phase(benzene) containing dithizone and a synergist. After the phases were allowed to separate, the vanadium(V) or vanadium(IV) remaining in the aqueous phase was determined spectrophotometrically by using 4-(2-pyridylazo)resorcinol.[3] The pH of the aqueous phase, which was preliminarily adjusted with nitric acid or acetate buffer solution, was measured after the extraction. All experiments were conducted at room temperature.

Results and Discussion

No extraction of vanadium(V and IV) with dithizone(H_2dz) in benzene has been confirmed at any pH range, although vanadyl ion was reported to interfere with the spectrophotometric determination of lead(II).[4,5] In contrast, when the aqueous solution containing vanadium(V) or vanadium(IV) was shaken with a mixture of dithizone and trioctylphosphine oxide (TOPO), the organic phase was observed to change in its color from green to red though the color was not very stable. This phenomenon indicates the possible formation of dithizonatovanadium(V) and vanadium(IV) in the presence of a synergist.

Extraction of Vanadium(V). Although the mechanism was not clear, a stable reddish dithizonatovanadium(V) could be extracted into benzene by using tributylphosphine oxide(TBPO) as a synergist. In this extraction system, HVO_3 was reported to react with dithizone to form $VO_2(Hdz)(TBPO)$ by the present authors.[6] However, this conclusion has become dubious because the formation of $VO_2(Hdz)$-(TBPO) can also be explained by the reactive nature of VO_2^+ toward dithizone.

The effect of the TBPO concentration on the spectrum of the extract is given in Fig. 1. Below 2.0×10^{-3} mol dm^{-3} TBPO, each spectrum agrees with that of dithizone, indicating no formation of the colored

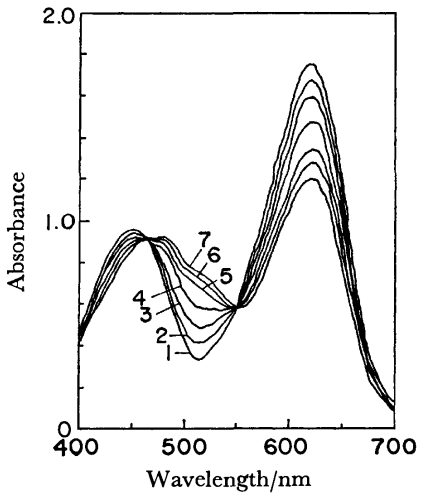

Fig. 1. Effect of TBPO concentration on the absorption spectrum of the organic phase.
H_2dz: 3.9×10^{-5} mol dm^{-3}, pH: 4.10, TBPO(mol dm^{-3}): 1; 2.0×10^{-3}, 2; 6.0×10^{-3}, 3; 1.0×10^{-2}, 4; 2.0×10^{-2}, 5; 4.0×10^{-2}, 6; 6.0×10^{-2}, 7; 1.0×10^{-1}.

vanadium(V) complex. On the other hand, in the higher concentration range of TBPO, the reddish dithizonatovanadium(V) is formed; this has an absorption maximum at 503 nm and is stable for at least 1 h (Fig. 2). The two isosbestic points seen in Fig. 1 suggest that only two kinds of colored species, dithizone and VO_2(Hdz)(TBPO), exist in the organic phase. The shape of the spectrum depends upon the pH of the aqueous phase, as can be seen in Fig. 3, and the existence of two isosbestic points here also supports the above assertion. Therefore, only VO_2(Hdz)(TBPO) is considered to be extracted at any pH region.

Since the concentration of the polynuclear complex of vanadium(V), $H_1V_{10}O_{28}^{1-6}$ can be neglected compared with those of VO_2^+, HVO_3, and VO_3^-, according to the previous observation,[7] the reactions in the aqueous phase can be written by Eqs. 1 and 2 in all cases.

$$VO_2^+ + H_2O \rightleftharpoons HVO_3 + H^+ \quad (1)$$

and

$$HVO_3 \rightleftharpoons VO_3^- + H^+. \quad (2)$$

The equilibrium constants for the above reactions are defined by Eqs. 3 and 4.

$$K_1 = \frac{[HVO_3][H^+]}{[VO_2^+]} \quad (3)$$

and

$$K_2 = \frac{[VO_3^-][H^+]}{[HVO_3]}. \quad (4)$$

The extractions of vanadium(V) with 1-butanol (*n*-BuOH) and trialkylphosphine oxide(TAPO) were ascribed to the formations of $HVO_3(BuOH)_2$ and HVO_3-$(TAPO)_2$, respectively.[8,9] In both cases BuOH and TAPO can be considered to act as solvating agents, although the detailed scheme of solvation is still unknown. In our previous report, the extraction of vanadium(V) with a mixture of dithizone and TBPO was estimated to proceed according to the reaction: $HVO_3 + H_2dz_{,org} + TBPO_{org} \rightleftharpoons VO_2(Hdz)(TBPO)_{org} + H_2O$, where the subscript org denotes the organic phase.[6] And the pH of the maximal extraction of vanadium(V) in the dithizone-TBPO system agreed well with those obtained by alcohol extractions.[7,10] At that time, therefore, we concluded that HVO_3 might react with dithizone in this case. However, if we assume HVO_3 to be a reacting species, the extraction of vanadium(V) should be expressed as the OH^- releasing reaction: $VO_2(OH) + H_2dz \rightleftharpoons VO_2(Hdz) + H_2O$; here, HVO_3 seems to act as a base, in contradiction to Eq. 2. And the synergistic extraction of vanadium(V) with a chelating agent has generally been explained by the reactive nature of VO_2^+ instead of HVO_3.

Moreover, the extraction of 8-quinolinolatovanadium(V) in the presence of alcohol(ROH) was found to proceed according to the reaction: $VO_2^+ + 2HQ_{org} + ROH_{org} \rightleftharpoons VOQ_2(OR)_{org} + H^+ + H_2O$.[11] Similarly, vanadium(V)/2-thenoyltrifluoroacetone (TTA=Htta)/1-butanol or TOPO systems were explained by the reactions: $VO_2^+ + 2Htta_{,org} + BuOH_{org} \rightleftharpoons VO(tta)_2(BuO)_{org} + H^+ + H_2O$ and $VO_2^+ + Htta_{,org} + TOPO_{org} \rightleftharpoons VO_2(tta)(TOPO)_{org} + H^+$.[7] Consideration of these examples suggests that complexation of vanadium(V) with a chelating agent may start from VO_2^+ as a Lewis acid.

The extracted species was shown spectrophotometrically to be only one, *e.g.* VO_2(Hdz)(TBPO), which is formed by the reaction:

$$VO_2^+ + H_2dz_{,org} + TBPO_{org} \rightleftharpoons VO_2(Hdz)(TBPO)_{org} + H^+ \quad (5)$$

for which the extraction constant is defined as follows:

$$K_{ex} = \frac{[VO_2(Hdz)(TBPO)]_{org}[H^+]}{[VO_2^+][H_2dz]_{org}[TBPO]_{org}}. \quad (6)$$

The distribution ratio of vanadium(V) is written by Eq. 7:

$$D = \frac{[VO_2(Hdz)(TBPO)]_{org}}{[VO_2^+]+[HVO_3]+[VO_3^-]}. \quad (7)$$

Combining Eqs. 3, 4, 6, and 7, the following equation can be obtained:

$$\log D = \log \frac{K_{ex}}{K_1} + \log [H_2dz]_{org} + \log [TBPO]_{org} - \log\left(\frac{[H^+]}{K_1}+1+\frac{K_2}{[H^+]}\right), \quad (8)$$

where $[H_2dz]_{org}$=(total concentration of dithizone)−$[VO_2(Hdz)(TBPO)]_{org}$.

A logarithmic plot of D against $[H_2dz]_{org}$ is shown in Fig. 4; a straight line having a slope of unity is obtained. Similarly, the plot given in Fig. 5 shows a straight line with a slope of unity. The above results are in good agreement with those expected from Eq. 8. In addition, the pH dependence of log D also supports Eq. 8 (Fig. 6). By employing the curve-fitting method, K_1 and K_2 were estimated to be 1.9×10^{-4} and 1.3×10^{-4} respectively, K_{ex} being 3.0×10^2.

Extraction of Vanadium(IV). Vanadium(IV) was also found to react with dithizone in the presence of TOPO; the spectra of the resulting reddish complex, along with standing time in the organic phase, are given in Fig. 7. The vanadium(IV)–dithizone–TOPO complex is not very stable, but it is assumed that the complex may be stable during the extraction process and the changes in the spectrum may start after the phase separation. Assuming that the extraction of vanadium(IV) proceeds according to the following reaction:

$$VOOH^+ + H_2dz_{,org} + TOPO_{org} \rightleftharpoons VOOH(Hdz)(TOPO)_{org} + H^+, \quad (9)$$

the extraction constant may be defined by Eq. 10.

$$K^*_{ex} = \frac{[VOOH(Hdz)(TOPO)]_{org}[H^+]}{[VOOH^+][H_2dz]_{org}[TOPO]_{org}} \quad (10)$$

Neglecting $(VOOH)_2^{2+}$ compared with VO^{2+} and $VOOH^+$, the distribution ratio can be written as follows:

$$D = \frac{[VOOH(Hdz)(TOPO)]_{org}}{[VO^{2+}]+[VOOH^+]}. \quad (11)$$

Hydrolysis of VO^{2+} in the aqueous phase can be expressed by Eq. 12 and the equilibrium constant can be written by Eq. 13:

$$VO^{2+} + H_2O \rightleftharpoons VOOH^+ + H^+ \quad (12)$$

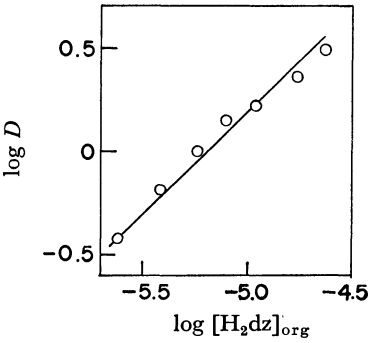

Fig. 4. Effect of dithizone concentration on the extraction of vanadium(V).
TBPO: 1.0×10^{-1} mol dm^{-3}, pH: 4.1.

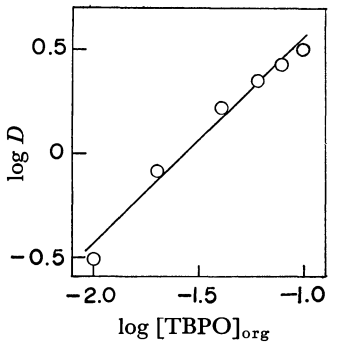

Fig. 5. Effect of TBPO concentration on the extraction of vanadium(V).

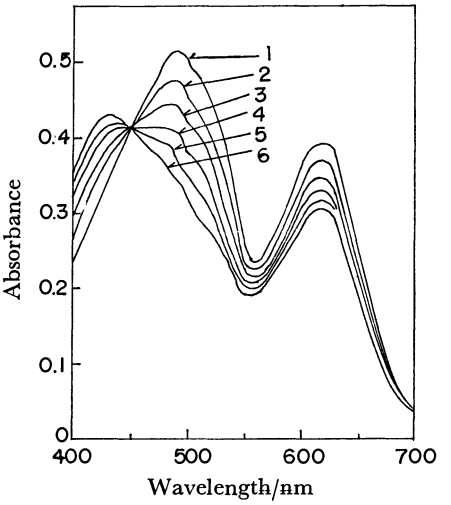

Fig. 7. Absorption spectra of the organic phase.
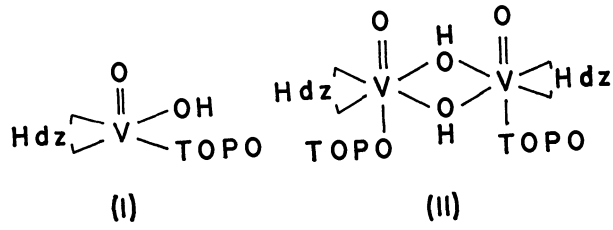
H_2dz: 3.9×10^{-5} mol dm^{-3}, TOPO: 1.0×10^{-1} mol dm^{-3}, vanadium(IV): 1.96×10^{-4} mol dm^{-3}, pH: 3.96, standing time after the extraction(min): 1; 10, 2; 20, 3; 30, 4; 40, 5; 50, 6; 60.

$$K_h = \frac{[VOOH^+][H^+]}{[VO^{2+}]}. \quad (13)$$

Combining Eqs. 10, 11, and 13, Eq. 14 can be obtained:

$$\log D = \log K^*_{ex} + \log [H_2dz]_{org} + \log [TOPO]_{org} + pH - \log\left(\frac{[H^+]}{K_h}+1\right). \quad (14)$$

As is seen in Fig. 8, a logarithmic plot of D against dithizone concentration shows a straight line having a slope of unity in the high concentration region of dithizone. Deviations from the straight line at low dithizone concentration may be due to extraction of vanadium(IV) with TOPO alone. A logarithmic plot of D against TOPO concentration given in Fig. 9 also shows a straight line having a slope of unity regardless of the presence of dithizone. But it should be mentioned that the D value obtained by TOPO alone is negligibly small compared with that given by a mixture of dithizone and TOPO. The above results coincide with those expected from Eq. 14. The pH dependency of log D given in Fig. 10 fits a curve obtained by calculation using $Y=pH-\log([H^+]/K_h+1)$, indicating that the extracted species may contain $VOOH^+$. This is also valid at low dithizone concentration region, in which the free concentration of dithizone can be calculated by using the equation: $[H_2dz]_{org}=$(total concentration of dithizone)$-[$vanadium(IV)$]_{org}$. A plot of $(\log D-\log [H_2dz]_{org})$ against pH also fits the above curve (Fig. 11). The deviations of some experimental values from the calculated ones above pH 4.6 may be due to the formation of unreactive $(VOOH)_2^{2+}$ in the aqueous phase. From the results given in Figs. 9 and 10, K_h was estimated to be $10^{3.6}$, K^*_{ex} being $10^{2.5\pm0.3}$. As a result, the synergistic extraction of vanadium(IV) with a mixture of dithizone and TOPO proceeds according to Eq. 9. For the composition of the extracted species, VOOH(Hdz)(TOPO), two types of structure can be assumed:



(I) (II)

where type I is a monomer and presumably extracted initially. The existence of an isosbestic point observed in Fig. 7 shows that VOOH(Hdz)(TOPO) in the organic phase may be converted to another stable complex, *e.g.* type II. That is to say, the instability

of VOOH(Hdz)(TOPO) can not simply be attributed to decomposition, as is observed in the cases of dithizonato complexes of manganese(II) and iron(II). It should be mentioned that stable dithizonatovanadium(IV) could be obtained by the extraction with a mixture of dithizone and TBPO. At present, we cannot explain the difference in the stability between TOPO and TBPO complexes.

(Received December 26, 1980)

Octaethylporphyrinatoiron(III) perchlorate, its mono(pyridine) and mono(4-substituted pyridine) adducts and bis(tetrahydrofuran)octaethylporphyrinatoiron(III) perchlorate were prepared to mimic the ferricytochrome c′. Magnetic susceptibilities, Mössbauer spectra, and ESR spectra have been measured. Magnetic properties in the crystalline state revealed; (i) Octaethylporphyrinatoiron(III) perchlorate, $OEPFe^{III}ClO_4$ and bis(tetrahydrofuran)octaethylporphyrinatoiron(III) perchlorate, $OEPFe^{III}(THF)_2ClO_4$ are of intermediate-spin state(S=3/2). (ii) Magnetic susceptibilities and Mössbauer parameters of mono(pyridine) and mono(4-substituted pyridine)octaethylporphyrinatoiron(III) perchlorate, $OEPFe^{III}$(4-X-py)ClO_4 [X=CHO, X=CN, and X=H] are rather similar to those of the low-spin(S=1/2) states. Absorption spectra showed that octaethylporphyrinatoiron(III) perchlorate is of intermediate-spin state in dichloromethane solution, but of high spin state in acetone solution. Close spectral resemblance of these complexes to the ferricytochrome c′ at physiological pH suggests that the latter is in intermediate-spin state.

Ferrihemoproteins and ferriheme enzymes in general have been classified into two spin-states, that is, the five-coordinated high-spin (S=5/2) state and the six-coordinated low-spin (S=1/2) state. It is noted that the ferricytochrome c′ isolated from photosynthetic and denitrifying bacteria[1–4] have anomalous magnetic properties defined as intermediate-spin state (S=3/2). An unusual electronic spectrum is found in cytochrome c′. The oxidized form[5] in alkaline solution shows a hemichrome spectrum of the low-spin. Below pH 11 the spectrum reverts to a chracteristic of high-spin ferric hemes with split Soret bands. Further change of electronic spectrum is observed as pH decreases. The magnetic moment at physiological condition anomalously shows intermediate values between high-spin and low-spin.[6,7] Mössbauer spectra[8] show large quadrupole splittings which are comparable to those of methemoglobin with the opposite sign.

In order to aid understanding anomalous spin-state, there have been reported few simulations to intermediate-spin complexes by synthetic hemes. In previous communication,[9] we reported briefly syntheses and some magnetic properties of octaethylporphyrinatoiron(III) perchlorate and its mono(amine) adducts. We have described the unusual magnetic moments of these complexes at 288 K as an admixture of the high-spin and low-spin states as follows:

$$^6A_1 \rightleftharpoons {}^2T_2.$$

Since then, two groups have reinvestigated the physicochemical properties of the perchlorate salts of ferric porphyrins. Dolphin and his coworkers[10] reexamined magnetic moments and measured Mössbauer spectra of octaethylporphyrinatoiron(III) perchlorate and bis(ethanol)octaethylporphyrinatoiron(III) perchlorate. They have, however, suggested that these complexes possesses an intermediate-spin iron(III) atom, with the S=3/2 at the ground state possibly involving some high-spin character. Scheidt and his coworkers[11] have reported physicochemical properties of diaqua-$\alpha,\beta,\gamma,\delta$-tetraphenylporphyrinatoiron(III) perchlorate and perchlorate-$\alpha,\beta,\gamma,\delta$-tetraphenylporphyrinatoiron(III). We have studied crystal structure of the perchlorate complex[12] and its paramagnetic ^{1}H-NMR spectra in organic solvents.[13] In a previous communication,[9] we also reported the first syntheses of mono(amine) adducts and their magnetic moments at room temperature. We wish to report here elaborate measurements on magnetic susceptibilities, Mössbauer spectra, and ESR spectra of octaethylporphyrinatoiron(III) perchlorate, and three mono(amine) adducts in solid state.

Experimental

Preparation of Compounds. Ocatethylporphyrinatoiron(III) Perchlorate [$OEPFe^{III}ClO_4$] (1): To 500 mg of $OEPFe^{III}Cl$[14] in benzene (200 ml) was added 500 mg of anhydrous silver perchlorate and the solution was refluxed gently for 1 h. The hot solution was filtered and then allowed to stand overnight at room temperature. The resultant needle crystals (450 mg) were collected, washed with petroleum ether and dried under vacuum. Bis(tetrahydrofuran)octaethylporphyrinatoiron(III) perchlorate [$OEPFe^{III}(THF)_2ClO_4$] (**2**). To 100 mg of **1** in dichloromethane (20 ml) was added tetrahydrofuran (10 ml). The solution was warmed for 15 min and allowed to come to room temperature. The crystals were collected, washed with tetrahydrofuran, and dried under vacuum (95 mg).

(4-Formylpyridine)octaethylporphyrinatoiron(III) Perchlorate [$OEPFe^{III}$(4-CHO-py)ClO_4] (3): To 100 mg of **1** in dry benzene (100 ml) was added 0.5 ml of 4-formylpyridine. The solution was refluxed for 2 h, condensed to a small volume and allowed to stand overnight at room temperature. The resulting dark brown crystals were filtered, washed with petroleum ether and dried under vacuum (90 mg).

(4-Cyanopyridne)octaethylporphyrinatoiron(III) Perchlorate [$OEPFe^{III}$(4-CN-py)ClO_4] (4): The preparative method is identical with that described above. The dark brown crystals (95 mg) were obtained from 100 mg of **1**.

(Pyridine)octaethylporphyrinatoiron(III) Perchlorate [$OEPFe^{III}$(py)ClO_4] (5): To 100 mg of **1** in dry benzene (100 ml)

		C (%)		H (%)		N (%)	
		Calcd	Found	Calcd	Found	Calcd	Found
(1)	$C_{36}H_{44}N_4O_4ClFe$	62.84	62.94	6.45	6.48	8.14	8.04
(2)	$C_{44}H_{60}N_4O_6ClFe$	63.50	63.45	7.27	7.26	6.73	6.79
(3)	$C_{42}H_{49}N_5O_5ClFe$	63.44	63.36	6.21	6.28	8.81	8.89

was added 0.5 ml of pyridine and the solution was refluxed for 20 min. The deep red precipitates were collected, washed with benzene, and dried under vacuum (95 mg). The results of elemental analyses are tabulated above.

Magnetic and Spectral Measurements. *Magnetic Susceptibilities*: A Faraday magnetic balance was employed for measurements of magnetic susceptibilities from 77 K to 300 K. The magnetic susceptibilities of anhydrous hexaammine-chromium chloride powder was used as a "thermometer" which was calibrated at each run to an atmospheric liquid nitrogen temperature with corrections for the Hg-barometer and gravitational constant following the procedure of Linder.[15] The accuracy for the measurements was not less than 10%. The diamagnetic susceptibilities of porphyrin ligand and axial ligands were corrected by measurement of free base octaethylporphyrin and by Pascal's rule.

Mössbauer Spectra: Mössbauer spectra were obtained with a scanned velocity spectrometer operating in the time mode. The velocity scale was calibrated absolutely from an independent Mössbauer run using a thin metallic iron absorber and the center of symmetry of the spectrum was taken as zero velocity. The velocity was determined to an accuracy of ± 0.01 mm/s.

ESR Spectra: The ESR spectra of polycrystalline sample and in dichloromethane glass were measured at 77 K and at 293 K by using a JEOL X-band spectrometer.

Results

Figure 1 shows effective magnetic moments of **1**, **2**, **3**, **4**, and **5** at various temperatures from 77 K to 270 K. The effective magnetic moments of **1** and **2** are lower than those of typical high-spin state (5.9 BM) and higher than typical low-spin state (2.15—2.72 BM).[16] On the other hand, for mono(amine) adducts, **3**, **4**, and **5**, the effective magnetic moments vary greatly with the kinds of substituent at 4-position of pyridine. The effective magnetic moments of mono(pyridine) adduct **5** and mono(4-cyanopyridine) adduct **4** are closely similar to the six-coordinated low-spin complexes[16] at low temperature, but at high temperature these values become larger than those of low-spin complexes. It is noted that the magnetic moments of the 4-formyl pyridine adduct **3** are larger than those of mono(amine) adducts **4** and **5**, but smaller than those of the perchlorates **1** and **2**.

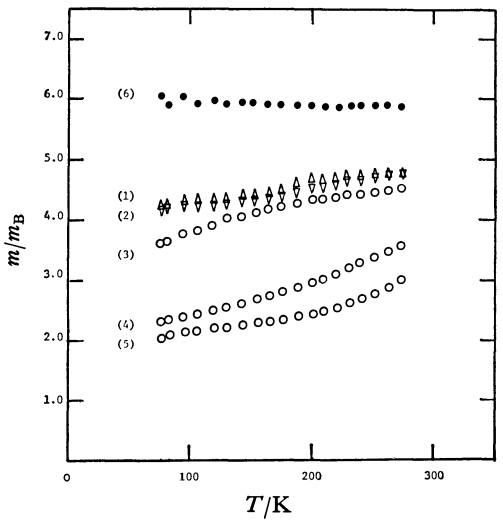

Fig. 1. Effective magnetic moments *versus* temperatures. (1): OEPFe(III)ClO_4, (2): OEPFe(III)$(THF)_2ClO_4$, (3): OEPFe(III)(4-CHO-py)ClO_4, (4): OEPFe(III)-(4-CN-py)ClO_4, (5): OEPFe(III)(py)ClO_4, (6): OEPFe(III)SCN.

Table 1 summarizes the Mössbauer parameters, isomer shifts δ (mm/s) and quadrupole splitting ΔE_Q (mm/s) of complexes at various temperatures. The isomer shifts of all these complexes are in the range of 0.2—0.4 mm/s, indicating typical iron(III) state. On the other hand, the quadrupole splittings of **1** and **2** show 3.14 and 3.08 mm/s at room temperature, respectively. These values are very large compared with those of usual iron(III) complexes and identical with those reported by Dolphin and his coworkers.[10] Mono(amine) adducts **3**, **4**, and **5** have smaller quadrupole splittings than the complexes **1** and **2**. In particular Mössbauer parameters of the mono(pyridine) adducts **3**—**5** are close to those of the six-coordinated low-spin complexes.[16] As shown in Figs. 2—6, high velocity lines of the complexes **4** and **5** are broadened at lower temperatures. Therefore, the sign of the quadrupole coupling can be determined to be positive. In the case of mono(4-formylpyridine) adduct **3**, the line broadening at high velocity due to the

relaxating is much smaller than the other two mono-(amine) adducts even at 4.2 K.

ESR spectra of these complexes in solid state at 293 and 77 K are shown in Figs. 7 and 8, respectively, and observed g-values are summarized in Table 2. Complexes **1** and **2** show very broad signals at around $g=4$ at room temperature. On the other hand the mono(amine) adducts **3**, **4**, and **5** show also broad signals at $g=4.41$, 3.75, and 2.40 with very weak peaks around $g=2$, respectively. The line shapes and g-values of these complexes at room temperature are very much different from those of ordinary high-spin or low-spin iron(III) complexes hitherto reported. For mono(pyridine) adduct **5**, the signal at $g=2.06$ seems to be contaminated by organic radical species. The ESR spectra at 77 K were remarkably different from those at room temperature as shown in Fig. 8. The complex **2** shows still one broad signal at $g=4.61$ in solid state, but anisotropic g-values at $g=4.68$ and 2.00 in dichloromethane glass. The complex **1** shows a pair of anisotropic g-values at 5.83 and 1.48. On the other hand, three mono-(amine) adducts exhibit similar spectra with a pair of anisotropic g-values at low temperature, although the g-values are slightly different from each other. The g-values are markedly changed from 4.69 to 5.40 upon introduction of the formyl group at the 4-position of pyridine. The ESR spectra of **1** and **2** at 77 K show entirely different signals from those of

usual high-spin or low-spin complexes of ferric porphyrin. The ESR spectra of mono(amine) adducts **3**, **4**, and **5** exhibit the strong broad signals at high g-values(lower magnetic field) and the maximum absorption (zero derivative) is shifted towards lower g-values(higher magnetic field).

Absorption spectrum of the complex **1** changes remarkably with polarity of solvent as shown in Fig. 9. In acetone the complex **1** exhibits a spectral characteristic of the high-spin complexes, whereas in dichloromethane the Soret band is largely broadened and slightly splitted. The band at 630 nm assigned to a charge transfer band is shifted to longer wave length (636 nm) in dichloromethane than in acetone (628 nm).

Discussion

The complex **1** showed effective magnetic moments μ_{eff}=4.2 BM at 77 K and 4.7 BM at 275 K. Then these values are compared with calculated spin only values μ_{eff}=5.92, 3.87, and 1.73 BM for S=5/2, 3/2, and 1/2, respectively. The complexes **1** and **2** can be

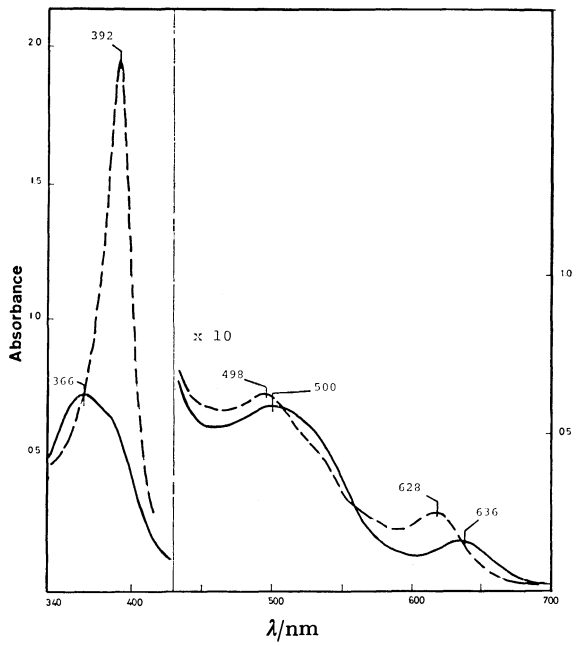

Fig. 9. Absorption spectra of OEPFe(III)ClO_4, (——) in CH_2Cl_2 and (----) in acetone.

regarded as intermediate-spin complexes. Harris has predicted a possible existence of pure quartet ground state ($S=3/2$) on theoretical consideration by using a strong crystal field model.[17] The ESR signals in the tetragonal symmetry might have only one transition between the exited state doublets with $g=2$ and 4. The intensity of this transition should be temperature dependent and also should vary with extent of spin-orbital coupling.[18] In fact the complexes **1** and **2** give a very broad signal at about $g=$ 3.9 as shown in Fig. 7, whose patterns are very similar to that of iron(III) bis(thiocarbamates) characterized as an intermediate-spin complex.[16] At low temperature, the complex **1** has some anisotropic character so that g-value at around 4 seems to split into the two values $g=5.83$ and 1.48, as shown in Fig. 8. On the other hand, the complex **2** in solid state has no anisotropic character even at 77 K, but in dichloromethane glass it gives anisotropic g-values at 4.68 and 2.00. The Mössbauer spectra of the complexes **1** and **2** did not show any relaxation broadning, as mentioned by Dolphin and his coworkers, suggesting fast spin relaxation between both $|\pm 1/2>$ and $|\pm 3/2>$ doublets. Comparison of the magnetic susceptibilities, the ESR spectra and the Mössbauer spectra leads us to conclude that the complexes **1** and **2** are of intermediate-spin state.

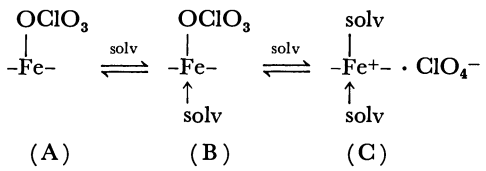
Mono(amine) adducts **3**, **4**, and **5** have effective magnetic moments between the low-spin and the intermediate-spin states. The ESR spectra of these compounds give anisotropic g-values at $g=5.47$—4.67 and $g=1.70$—2.05 at 77 K. In particular, the magnetic moments and Mössbauer parameters of the mono(pyridine) adduct **5** indicate that the spin state of **5** at low temperature is essentially low-spin state. However, the ESR spectrum of **5** is different from that of the hexa-coordinated low-spin complex. This fact suggests that mono(amine) adducts do not exist in pure low-spin state, but in a mixed spin state with low-spin($S=1/2$) and intermediate-spin($S=3/2$) states. Small differences in the magnetic properties among them may be attributed to the extent of admixture of two spin states. Weight of the quartet state in the mixed spin state increases in the following order, **3**>**4**>**5**. Magnetic properties of the 4-formylpyridine adduct **3** are very close to those of the complex **1**. Also magnetic properties of the mono(amine) adducts are consistent with the theoretical prediction for a quartet-doublet mixed spin iron(III) ion by Harris.[17] The effective magnetic moments of ferricytochrome c′ at pH 7[20] have been reported to be 5.15 BM at 293 K and 3.4 BM at 2.8 K. Ferricytochrome c′ shows anomalous feature in the ESR parameters and the shape of the Soret band in absorption spectrum. The ferricytochrome c′ at physiological pH exhibits a strong ESR absorption at high g-value $g=4.77$ and a weaker one at $g=1.99$.[20] The former absorption is much broadened and its maximum absorption (zero derivative) is shifted toward lower g-values than ferrimyoglobin and ferrileghemoglobin.[7] Maltempo has described unusual properties of ferricytochrome c′ by assuming that the electronic comfiguration of hemin at the ground state consists of substantial quantum mechanical admixture of intermediate-spin($S=3/2$) and high-spin($S=5/2$) states, coupled *via* the spin-orbit interaction. Therefore, intermediate spin complexes **1** and **2** seem to be good models for ferricytochrome c′ at physiological pH.

Present results lead us to postulate that a histidyl imidazole coordinates weakly to the iron(III) atom of ferricytochrome c′ even at physiological pH. Therefore, the mono(amine) adducts rather than complexes **1** and **2** are better model complexes for the ferricytochrome c′.

As is seen in Figs. 7 and 8, the mono(amine) adducts can duplicate unusual ESR specturm of ferricytochrome c′. The g-values of ferricytochrome c′ at the various conditions are referred in Table 2. Comparison of its g-values with model compounds suggests that the ground state of the ferricytochrome c′ at low temperature is similar to those of the mono(amine) adducts. Histidyl imidazole is considered to be most probable axial ligand to the heme in the enzyme. Analysis of amino acid sequence of apocytochrome c′ rationalizes possible ligation of the histidyl imidazole as fifth axial ligand.[21] There are, however, so many candidates of the sixth ligand such as water, aspartic acid, glutamic acid, and lysine.[22] On the basis of physicochemical properties of model complexes, it is proposed that relatively weak ligand coordinates to the hemin in cytochrome c′, and the bonding between iron atom and sixth ligand has more ionic character than that of the ferric hemoproteins. Positive charge seems to be localized on the iron(III) atom relative to the penta-coordinate ferric high-spin state. As is stated by Strekas and Spiro,[23] the differences of energy levels between d_π orbital and d_{z^2} or d_{z^2} and $d_{x^2-y^2}$ orbitals are very sensitive to the nature of axial ligands. Spin state of ferric porphyrin complex is markedly dependent on strength of axial ligation of the fifth and sixth ligands. Coordination of the histidyl

imidazole seems to be strongly influenced by changes in environment near proximity of the heme, which are induced by pH and temperature. Extensive investigations on the ferric porphyrin complex conclude that spin state is generally determined by coordination numbers of axial ligands. Namely it has been believed that the high-spin state and low-spin state constitute the five-coordinated complex of square pyramidal structure and the six-coordinated complexes of octahedral structure, respectively. We have found new iron(III) complexes having anomalous spin-state and coordination numbers, when a weak field ligand such ClO_4^- was employed.[13] Recently LaMar[24] and Scheidt's[11] groups have pointed out the existence of the six-coordinated high-spin species in the solution or in crystalline state.

Visible spectrum of ferricytochrome c′ shows absorptions at 400, 490, and 632 nm.[25] The absorption at 632 nm is explained as a charge transfer band. There is no essential difference between the electronic structure of d_π-orbital for intermediate spin($S=3/2$) and high spin($S=5/2$). Absorption spectra of **1** in CH_2Cl_2 and solid state can duplicate that of the oxidized form of cytochrome c′. Penta-coordinated iron(III) complex **1** shows remarkable solvent effect on electronic spectrum.[13] Axial ligation of polar solvent molecule results in formation of asymmetric hexa-coordinated (B) and symmetric hexa-coordinated iron(III) complex(C). The complex **2** is defined as the



solv: solvent molecule

type (C). New hexa-coordinated complexes **3**—**5** constitute asymmetric coordinated complex at axial fifth and sixth sites. Addition of strong basic ligand such as imidazole to the hemin affords bis(imidazole) adduct. Consequently, spin state of the hemin is sensitive to coordination of axial ligand and delocalization of positive charge. These two factors are very important in biological systems. The spin state of the prosthetic heme in hemoproteins is determined by axial ligation of the residue of amino acid and polarity near proximity of the heme.

From present results, we are enforced to support that the ground state electronic configuration of the ferricytochrome c′ at physiological pH is of substantial quantum mechanical admixture of quartet and sextet states. Furthermore, a possibility of an admixture of quartet and doublet states is also proposed for the ferricytochrome c′ at low temperature.

A Reexamination of the Robinson Annelation of 2-Methylcyclohexanone with 3-Penten-2-one and 4-Phenyl-3-buten-2-one[1]

Mitsuko KIKUCHI* and Akira YOSHIKOSHI†

College of Engineering, Nihon University, Koriyama, Fukushima 963

† *Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai 980*

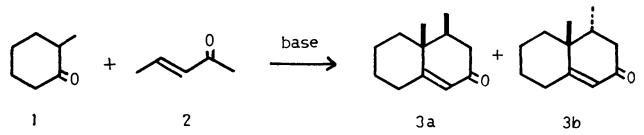
(Received February 10, 1981)

The reported Robinson annelation of 2-methylcyclohexanone with 3-penten-2-one has been reexamined. In contrast to the previous result, it was found that the reaction product was not only obtained in a low yield, but also the solvent-depending stereoselectivity in the formation of *cis*-4,4a-dimethyl-4,4a,5,6,7,8-hexahydronaphthalen-2(3*H*)-one (**3a**) and its *trans* isomer (**3b**) was considerably lower than that reported. As expected, regioisomers, 4β,8α-dimethyl-4,4aβ,5,6,7,8-hexahydronaphthalen-2(3*H*)-one and 4β,8β-dimethyl-4,4aα,5,6,7,8-hexahydronaphthalen-2(3*H*)-one, were also formed in the annelation. A similar tendency was observed in the reaction with 4-phenyl-3-penten-2-one. The annelation products, **3a**, **3b**, *cis*-4-phenyl-4a-methyl-4,4a,5,6,7,8-hexahydronaphthalen-2(3*H*)-one, and *trans*-4-phenyl-4a-methyl-4,4a,5,6,7,8-hexahydronaphthalen-2(3*H*)-one, were also synthesized by an alternative route.

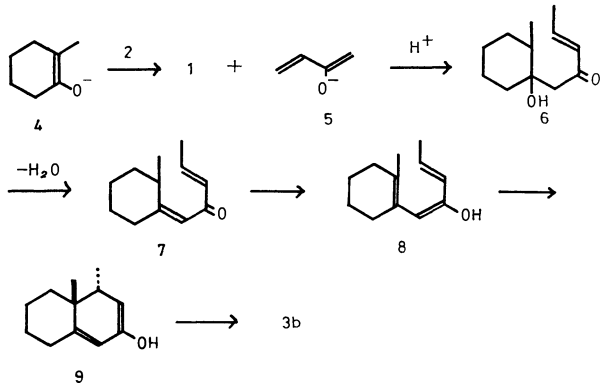
The Robinson annelation has most widely been employed as a useful method of synthesizing *cis*-1,8a-dimethyldecalins, the fundamental structures of eremophilanoids.

Scanio and Starrett[2] recently reported that *cis*-dimethyloctalone (**3a**) in an isomeric purity exceeding 95% was produced by the Robinson annelation of 2-methylcyclohexanone (**1**) with 3-penten-2-one (**2**) in dioxane, while change of the solvent to dimethyl sulfoxide dramatically altered the ratio of the diastereomers to give *trans*-dimethyloctalone (**3b**) in a high isomeric purity (over 95%) (Scheme 1). They also proposed a reaction mechanism (Scheme 2) for the predominant formation of the *trans*-isomer **3b** in dimethyl sulfoxide; the enolate, **4**, of 2-methylcyclohexanone (**1**) gives the 1,3-butadien-2-olate anion (**5**) by proton exchange, and the latter attacks the regenerated ketone, **1**, to yield olefinic alcohol, **6**. Under these reaction conditions, **6** is dehydrated to crossed dienone **7**, and its enol form, **8**, thermally cyclizes in a disrotatory manner to yield **9** predominantly.

To test their hypothesis concerning this unusual Robinson annelation in dimethyl sulfoxide, we reexamined their reaction of **1** and **2**, and also that of **1** and 4-phenyl-3-buten-2-one (**11**) for comparison.

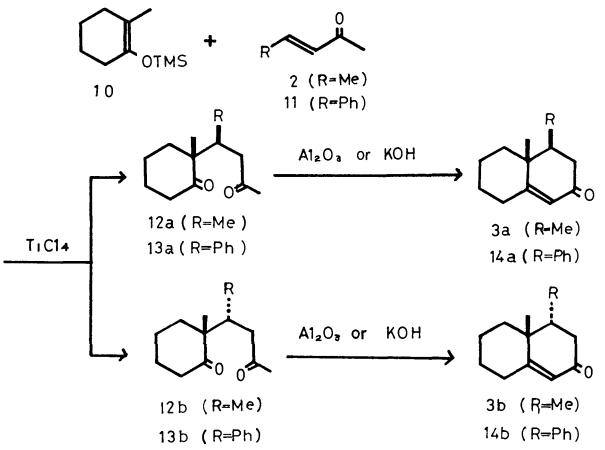


Scheme 1.



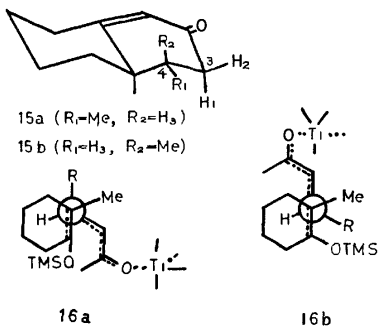
Scheme 2.

In order to obtain authentic samples for the GLC analysis of the annelation products, four octalones, **3a**, **3b**, **14a**, and **14b**, were synthesized by the alternative route shown in Scheme 3, because, contrary to the claim of Scanio and Starrett, these compounds were obtained only in poor yields under similar reaction conditions, as will be discussed later.



Scheme 3.

Silyl enol ether (**10**), prepared from 2-methylcyclohexanone (**1**), was treated with 3-penten-2-one (**2**) (or 4-phenyl-3-buten-2-one (**11**)) in dichloromethane in the presence of titanium tetrachloride,[3] thus giving a mixture of 1,5-diones **12a** and **12b** in a ratio of 25:75 (or **13a** and **13b** in a ratio of 71:29) and in a good yield. These diones were separated by chromatography and then submitted to aldol cyclization to give **3a** and **3b** (or **14a** and **14b**) respectively. The stereochemistry of the octalones thus obtained was assigned by means of ^{1}H NMR.[4] In the lanthanoid-shifted spectra of **3a** using Eu(dpm)$_3$, the signals of the protons on C(3) and C(4) were assigned by a concentration dependence of their chemical shifts on the shift reagent; coupling were confirmed by decoupling experiments, as is shown in Table 1 (cf. the conformational structure **15a**). The large coupling constant (J, 13 Hz) between H(1)- and H(3)-protons



clearly demonstrated a *trans* diaxial disposition of these protons, leading to the *cis*-dimethyloctalone structure **3a**. On the other hand, the **3b** isomer showed a small coupling between these protons (J, 5 Hz), which indicated this compound to be a *trans*-dimethyloctalone, **3b** (*cf.* **15b**). Similar reasoning may also be applicable to **14a** and **14b**.

It is worth a short comment that, in the Lewis acid-promoted Michael addition of **10**, the erythro-threo ratio of the product was reversed, depending on the acceptor used. Considering two preferable conformations, **16a** and **16b**, in the transition states, the R substituent (methyl or phenyl) would control the population of these conformers. When R is methyl, **16b** is more favored than **16a** because the bulkier acetonyl would be disposed between the methyl and cyclohexane methylene groups, yielding the threo isomer, **12a**. Meanwhile, phenyl is bulkier than acetonyl, and the favored conformation in the transition state of the reaction with **11** must be **16a**, which leads to the erythro isomer, **13b**.

With the four authentic octalones, **3a**, **3b**, **14a**, and **14b**, in our hands, we set about the GLC analysis[5] of the Robinson annelation product of **1** with **2** or **11**. The results of the analysis are shown in Table 2.

Entry 1 indicates the analytical result of the enone fraction of the product obtained from **1** and **2** under the reaction conditions described by the original authors. The combined yield of enones was quite low, and the major products were, rather, the regioisomer, **17a** or **17b**, and the dienone, **18**. These by-products were separated by preparative GLC, and their structures were assigned spectroscopically; the enone showed a carbonyl absorption at 1668 cm^{-1} in the IR spectrum. Two pairs of methyl doublets in the ^1H NMR spectrum demonstrated this compound to be a regioisomer of **3a**; meanwhile, in the lanthanoid-shifted ^1H NMR, its C(3)-methylene protons exhibited a coupling pattern (J, 18 and 12 Hz for H(1) and 18 and 6 Hz for H(2)) which was very similar to that of **3a**. This result supported the idea that the C(4)-methyl in the regioisomeric enone must be equatorial. From these results, we concluded that the **17a** or **17b** stereostructure should be assigned to this compound because this compound was produced under equilibrating con-

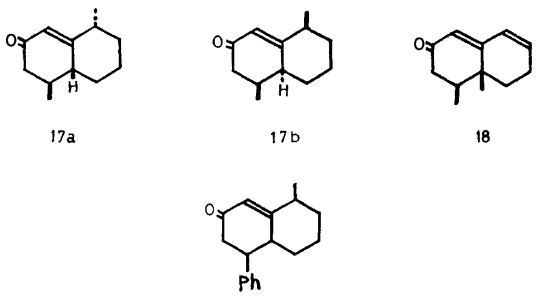


Table 1. Lanthanoid-shifted ^1H NMR of some protons of the octalones[a]

a) A, dioxane; B, dimethyl sulfoxide. b) *Cf.* Ref. 5 for the analytical method,

ditions.

Another crystalline by-product showed a carbonyl absorption at 1659 cm^{-1} in the IR spectrum and a strong UV absorption at 239 nm, which indicated an $\alpha,\beta,\gamma,\delta$-unsaturated dienone chromophore. The dehydrogenation of **3a** with chloranil in *t*-butyl alcohol afforded the same dienone. Thus, this dienone is unambiguously shown by the formula **18**. This dienone was probably produced by the air oxidation of **3a** for a long period.

When the reaction time was shortened (Entry 2), the combined yield of the product was slightly raised and the only detectable by-product was the regioisomeric enone **17**.

In the reaction employing dimethyl sulfoxide as the solvent, the ratio of **3a** and **3b** was reversed (Entries 3 and 4), although the stereoselectivity of the reaction was not so high as Scanio and Starrett stated.[2] Unlike the reaction with 3-penten-2-one, no regioisomer was detectable in the reaction in dimethyl sulfoxide.

In the reaction of **1** and **11** employing dioxane as the solvent, the product was a mixture of *cis*- and *trans*-enone (**14a** and **14b**) and the regioisomer **19a**, in which the *cis*-enone **14a** was predominant (Entries 5 and 6). The structure of the regioisomer was supported by a carbonyl absorption at 1661 cm^{-1} in the IR spectrum and a three-proton doublet in the ^1H NMR spectrum. On the other hand, a comparable formation ratio of the *cis*- and *trans*-enones (**14a** and **14b**) was observed in the reaction using dimethyl sulfoxide as the solvent (Entries 7 and 8). Two regioisomers, **19a** and **19b**, were also isolated. The structures of the by-products were confirmed by the IR (1661 cm^{-1}) and ^1H NMR (a three-proton doublet) spectra, which demonstrated that these by-products must both be stereoisomers. However, we have obtained no evidence that allowed us to assign stereostructures to these regioisomers.

In conclusion, we could not observe such high stereoselectivity as was reported by Scanio and Starrett[2] in the Robinson annelation of 2-methylcyclohexanone and 3-penten-2-one, although a change in the formation ratio of the **3a** and **3b** stereoisomers was observed to some extent by replacing the reaction solvent. Accordingly, we are suspicious of the reaction mechanism (Scheme 2) they have proposed for the annelation in dimethyl sulfoxide, for if it will operate, the reaction would proceed much more stereoselectively.

Experimental

All the melting and boiling points are uncorrected. The IR spectra were taken on a Hitachi G-2 or 215 spectrophotometer. The ^1H NMR spectra were recorded on a Hitachi R-22 (90 MHz) or JEOL PS-100 (100 MHz) instrument, using TMS as the internal standard and $CDCl_3$ as the solvent. The recorded chemical shifts are on the δ (ppm) scale. The high resolution mass spectra were recorded on a JEOL JMS-OISC spectrometer. The GLC analysis was performed on a Shimadzu Model 5A instrument using the following columns: A (5% OV-17, 2 m×3 mm) and B (5% SE-30, 2 m×3 mm). The formation ratios of the reaction products were all determined by GLC.[5] The elemental analyses were performed in the microanalytical laboratory of the Chemical Research Institute of Non-Aqueous Solutions, Tohoku University.

2-Methylcyclohexanone (1). The ketone of a reagent grade (Tokyo Kasei Corp.) was distilled, and a fraction boiling at 163.2 °C was utilized.

3-Penten-2-one (2). This enone was prepared according to the method of Lawesson *et al.*[6] A fraction boiling at 52—54 °C/260 mmHg was immediately used.

1,5-Diketones 12a and 12b. These diketones were prepared according to the method of Mukaiyama *et al.*[3] A solution of $TiCl_4$ (570 mg, 3 mmol) in CH_2Cl_2 (12 ml) was cooled to −78 °C under N_2. Solutions of **2** (303 mg, 3.6 mmol) and **10**[8] (552 mg, 3 mmol) in the same solvent (5.4 and 4.5 ml respectively) were added successively to the above solution with stirring. After stirring for 30 min at −78 °C, the mixture was quenched with aqueous K_2CO_3 (1.05 g in 22 ml of water), and the resultant precipitates were filtered off. The filtrate was extracted with pentane, and the extract was washed with water and brine. After the removal of the solvent, the crude product (553 mg) was distilled in a vacuum to give the main fraction (374 mg; bp 102—126 °C (bath temperature)/1 mmHg††), which consisted of two isomers, **12a** and **12b** (25:75). Because the separation of these isomers by preparative TLC ($AgNO_3$-impregnated silica gel, hexane–AcOEt (5:1)) was incomplete, only one isomer, **12b** was separated in the pure state (21 mg, 13%). In order to separate the isomers completely, preparative GLC (Column B at 140 °C) was utilized. **12a**: R_t 6.7 min (Column B at 140 °C); IR ($CHCl_3$) 1700 cm^{-1}; ^1H NMR 0.86 (3H, d, J=7 Hz), 0.91 (3H, s), and 2.09 (3H, s). **12b**: R_t 7.8 min, IR ($CHCl_3$) 1700 and 1209 cm^{-1}; ^1H NMR 0.73 (3H, d, J=7 Hz), 0.94 (3H, s), and 2.17 (3H, s).

cis-4,4a-Dimethyl-4,4a,5,6,7,8-hexahydronaphthalen-2(3H)-one (3a). A mixture of **12a** (40 mg, 0.2 mmol), active alumina (activity II, 1.6 g), water (1.33 ml), and dioxane (4 ml) was heated at 105—109 °C under reflux for 3 h with stirring under N_2. Then the mixture was filtered, and the crude product (88 mg) was obtained from the filtrate on the removal of the solvent. Pure **3a** (21 mg, 58%) was obtained by preparative TLC repeated four times, using cyclohexane–AcOEt (10:1) as the solvent. IR ($CHCl_3$) 1660 and 1616 cm^{-1}; ^1H NMR 0.95 (3H, d, J=6 Hz), 1.09 (3H, s), and 5.98 (1H, d). The lanthanoid-shifted ^1H NMR spectra were taken as follows: an exact amount of $Eu(dpm)_3$ was added, portion by portion to a solution of **3a** (20 mg) in $CDCl_3$; the spectrum was recorded after each addition until the molar ratio of the substrate and the reagent reached 3:1. The experimental results obtained are shown in Table 1.

trans-4,4a-Dimethyl-4,4a,5,6,7,8-hexahydronaphthalen-2(3H)-one (3b). Pure **3b** (23 mg, 80%) was obtained from **12b** (32 mg, 0.16 mmol) in the same manner as has been described for **3a**. IR ($CHCl_3$) 1660 and 1618 cm^{-1}; ^1H NMR 0.98 (3H, d, J=6 Hz), 1.28 (3H, s), and 5.78 (1H, d). Found: C, 81.04; H, 10.34%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

1,5-Diketones 13a and 13b. A solution of freshly distilled $TiCl_4$ (380 mg, 2 mmol) in CH_2Cl_2 (8 ml) was cooled to −78 °C under N_2. A solution of **11**[7] (308 mg, 2.1 mmol) and **10** (450 mg, 2.4 mmol) in the same solvent (3 ml both) were added successively to the above solution with stirring. The mixture was then further stirred at −78 °C for 2.5 h. After quenching with aqueous K_2CO_3 (0.7 g in 15 ml of water), the resultant precipitates were

†† 1 mmHg≈133.322 Pa.

filtered off. The filtrate was extracted with CH_2Cl_2 and the extract was washed with water and brine. The subsequent removal of the solvent gave the crude product (598 mg). GLC (Column A at 180 °C) indicated two isomers (**13a** and **13b**, 71:29). Without distillation, the crude product was separated by preparative TLC, using hexane–AcOEt (5:1), to afford the respective isomers, **13a** (114 mg, 22%) and **13b** (211 mg, 41%). **13a**: R_t 9.4 min (Column A at 180 °C), IR ($CHCl_3$) 1702 and 1690 cm^{-1}; ^1H NMR 0.99 (3H, s) 1.98 (3H, s), 3.01 (H_1, dd, $J_{1,2}=16$, $J_{1,3}=10$ Hz), 2.48 (H_2, dd, $J_{1,2}=16$, $J_{2,3}=4$ Hz), 3.93 (H_3, dd, $J_{1,3}=10$, $J_{2,3}=4$ Hz) and 7.36 (5H, s). Found: C, 79.36; H, 8.91%. Calcd for $C_{17}H_{22}O_2$: C, 79.03; H, 8.58%. **13b**: R_t 10.1 min, IR ($CHCl_3$) 1701 and 1689 cm^{-1}; ^1H NMR 1.00 (3H, s). 2.03 (3H, s), 2.68 (H_1, dd, $J_{1,2}=16$, $J_{1,3}=4$ Hz), 3.03 (H_2, dd, $J_{1,2}=16$, $J_{2,3}=11$ Hz), 3.83 (H_3, dd, $J_{1,3}=4$, $J_{2,3}=11$ Hz), and 7.35 (5H, s). Found: C, 79.30; H, 8.83%. Calcd for $C_{17}H_{22}O_2$: C, 79.03; H, 8.58%.

cis-*4-Phenyl-4a-methyl-4,4a,5,6,7,8-hexahydronaphthalen-2(3H)-one (14a)*. Aqueous KOH (213 mg in 0.39 ml of water) was added to a mixture of **13a** (128 mg, 0.50 mmol) and ethanol (3 ml) with stirring under N_2. The whole mixture was heated at 90 °C under reflux for 4 h. The mixture was then cooled with ice, and 2% HCl was dropped into the mixture until the solution became pH 4. The resulting solution was extracted with CH_2Cl_2, and the extract washed with water and brine. The subsequent removal of the solvent gave the crude product (187 mg). Preparative TLC, using cyclohexane–AcOEt (4:1) as the solvent, gave the pure enone (90 mg, 76%), which solidified on distillation (bp 123—186 °C (bath temperature)/1 mmHg, mp 70.2—72 °C (recrystallized from pentane–benzene (5:1)); IR ($CHCl_3$) 1662 and 1616 cm^{-1}; ^1H NMR 1.10 (3H, s), 5.98 (1H, d), and 7.44 (5H, m). Found: C, 84.67; H, 8.29%. Calcd for $C_{17}H_{20}O$: C, 84.95; H, 8.39%.

trans-*4-Phenyl-4a-methyl-4,4a,5,6,7,8-hexahydronaphthalen-2-(3H)-one (14b)*. Pure **14b** (109 mg, 73%) was obtained from **13b** (161 mg, 0.63 mmol) in a similar manner. Distillation (bp 101—121 °C (bath temperature)/1 mmHg) of the enone gave a soft mass; mp 48.5—52 °C. No appropriate solvent was found for recrystallization. IR ($CHCl_3$) 1662 and 1614 cm^{-1}; ^1H NMR 1.35 (3H, s), 6.14 (1H, d), and 7.48 (5H, m). Found: C, 84.64; H, 8.29%. Calcd for $C_{17}H_{20}O$: C, 84.95; H, 8.39%.

The Annelation Reaction of 2-Methylcyclohexanone with 3-Penten-2-one. In Dioxane: NaH (178 mg, 3.6 mmol) was suspended in a solution of **1** (345 mg, 3.0 mmol) and dioxane (10 ml), and the mixture was stirred at 112—117 °C for 3 h under N_2. After cooling to room temperature, a solution of **2** (313 mg, 3.7 mmol) in dioxane (4 ml) was added, and the whole mixture was stirred for 9 h at room temperature. After the subsequent addition of a small amount of cold water, the mixture was extracted with pentane. The extract was washed with water and brine, and dried. After the removal of the solvent, the residue (512 mg) was distilled in a vacuum (bp 110—159 °C (bath temperature)/1 mmHg). The distillate (245 mg) was separated by preparative TLC, repeated four times, using cyclohexane–AcOEt (7:1) as the solvent; this gave two main fractions (R_f 4.8, 50 mg, 9% and R_f 5.3, 28 mg, 5%). The polar fraction was shown to be a mixture consisting of **3a** and **3b** (84:16), which was identified with authentic samples by GLC; however, the attempted separation of these isomers by GLC was fruitless. The by-product, **17a** (9 mg; mp 38.5—39 °C), in the less polar fraction was isolated by preparative GLC (Column A at 140 °C) and crystallized on standing, although no appropriate recrystallization solvent was found. IR ($CHCl_3$) 1668 and 1619 cm^{-1}; ^1H NMR 1.07 (3H, d, $J=6$ Hz), 1.16 (3H, d, $J=6$ Hz), and 5.86 (1H, s). Found: M^+ 178.1357. Calcd for $C_{12}H_{18}O$: M^+ 178.1357.

In a similar manner, **1** (337 mg, 3.0 mmol) and **2** (270 mg, 3.2 mmol) were allowed to react in dioxane for 100 h, after which the reaction mixture was worked up as above. A fraction (164 mg) obtained by short-path distillation was chromatographed on a silica-gel column, using hexane–AcOEt (7:1) as the solvent, thus giving an oil (46 mg, 9.0%). The GLC analysis (Column B at 140 °C) of the oil showed two peaks, **17a** (R_t 7.9 min) and **18** (R_t 11.2 min), along with those of **3a** and **3b**. Two by-products were separated by preparative GLC (Column B at 140 °C); **17a** (25 mg) and **18** (13 mg). The former by-product, **17a**, was identified by spectral comparison with the authentic compound. The latter one, **18**, solidified on standing; mp 39.8—42.5 °C; IR ($CHCl_3$) 1659 and 1622 cm^{-1}; ^1H NMR 0.98 (3H, d, $J=7$ Hz), 1.01 (3H, s), 5.72 (1H, s), and 6.21 (2H, br s); UV_{max} (95% EtOH) 239 nm (ε 12122); MS, *m/e* (rel intensity) 176 (M^+, 98), 134 (100), 119 (45), 105 (48), 91 (65).

This dienone was identified by spectral comparison with the authentic compound prepared by the dehydrogenation of **3a** (*vide post*).

In Dimethyl Sulfoxide (DMSO): A suspension of NaH (178 mg, 3.6 mmol) in DMSO (6 ml) was stirred at 75 °C for 30 min. After the addition of a solution of **1** (340 mg, 3 mmol) in DMSO (2 ml) and stirring for 3 h at room temperature, a solution of **2** (307 mg, 3 mmol) in the same solvent (3 ml) was added. The whole mixture was then stirred for 3 h at room temperature. After the subsequent addition of a small amount of ice water, the mixture was extracted with pentane. The extract was washed with water and brine, and dried. The evaporation of the solvent left an oil (373 mg), which was distilled in a vacuum (bp 114—158 °C (bath temperature)/1 mmHg) to give an oil (306 mg). The oil was purified by preparative TLC, repeated three times, using cyclohexane–AcOEt (7:1) as the solvent, to afford the main fraction (R_f 3.3, 193 mg, 36%). The GLC analysis of the fraction with a capillary column showed two peaks, **3a** and **3b** (29:71). Two other unidentified by-products were detected by the GLC (Column A at 140 °C, R_t 3.3 and 3.4 min) of the crude product.

Dehydrogenation of 3a with Chloranil. Authentic **18** was obtained by dehydrogenation according to the method of Agnello and Laubach.[10] A mixture of pure **3a** (36 mg, 0.2 mmol), chloranil (149 mg, 0.6 mmol), and *t*-butyl alcohol (5.5 ml) was heated at 80—90 °C for 3.5 h under N_2 with stirring. The reaction mixture was extracted with $CHCl_3$, and the extract was successively washed with water, 5% aqueous NaOH, water, and brine, and dried. After the removal of the solvent, the residue (30 mg) was purified directly by preparative TLC, using hexane–AcOEt (5:1) as the solvent, to give pure **18** (18 mg, 50%) as a soft mass (mp 39—42 °C).

The Annelation of 2-Methylcyclohexanone with 4-Phenyl-3-buten-2-one. In Dioxane: By a similar treatment, a crude product (952 mg) was obtained from **1** (336 mg, 3 mmol) and **11** (438 mg, 3 mmol) by allowing them to react at 112—117 °C for 3 h; subsequent distillation in a vacuum gave a fraction (bp 158—190 °C (bath temperature)/1 mmHg, 439 mg)) which was separated by preparative TLC, repeated twice, using hexane–AcOEt (15:1) as the solvent, to give two fractions (R_f 4.3 and 4.8). The two main compounds in the polar fraction (145 mg, 20%) were **14a** and **14b** (78:22), as identified with an authentic sample by GLC. The less polar fraction (113 mg, 16%) gave **19a** as the main

component upon preparative GLC (Column B at 180 °C, R_t 10.7 min, 9 mg); IR ($CHCl_3$) 1668 and 1619 cm^{-1}; ^1H NMR 1.19 (3H, d, J=7 Hz), 5.90 (1H, br s), and 7.24 (5H, m).

In DMSO: By a similar treatment, a crude product (990 mg) was obtained from **1** (449 mg, 4 mmol) and **11** (584 mg, 4 mmol) by a reaction at room temperature for 6 h. Vacuum distillation afforded a fraction (364 mg; bp 135—200 °C (bath temperature)/1 mmHg) which was subsequently separated by preparative TLC, using hexane–AcOEt (5:1) as the solvent, to give two fractions (R_f 3.5, 165 mg and R_f 4.0, 84 mg). Two enones, **14a** (10 mg) and **14b** (12 mg), were separated from the polar fraction by preparative GLC (Column A at 180 °C). **14a**, R_t 13.4 min; IR ($CHCl_3$) 1658 and 1616 cm^{-1}; ^1H NMR 1.09 (3H, s), 5.86 (1H, br s), and 7.31 (5H, m). **14b**, R_t 11.5 min; IR ($CHCl_3$) 1650 and 1618 cm^{-1}; ^1H NMR 1.33 (3H, s), 2.73 (1H, q, J=5 and 16 Hz), 3.0 and 3.12 (2H, in total), 5.96 (1H, br s), and 7.30 (5H, m). The two main components, **19a** (13 mg) and **19b** (24 mg), were separated from the less polar fraction by preparative GLC (Column A at 180 °C). **19a**, R_t 10.7 min; IR ($CHCl_3$) 1661 and 1601 cm^{-1}; ^1H NMR 1.19 (3H, d, J=7 Hz), 5.96 (1H, s), and 7.33 (5H, m). Found: M^+ 240.1520. Calcd for $C_{17}H_{20}O$: M^+ 240.1513. **19b**, R_t 12.3 min; IR ($CHCl_3$) 1661 and 1619 cm^{-1}; ^1H NMR 1.16 (3H, d, J=6 Hz), 5.79 (1H, s), and 7.36 (5H, m). Found: M^+ 240.1525. Calcd for $C_{17}H_{20}O$: M^+ 240.1513.

We wish to thank Professor Toshitaka Tamura, College of Science and Technology, Nihon University, for his measurements of the high-resolution mass spectra.

Preparation and Physicochemical Properties of Tervalent Cobalt Complexes of Porphyrins

Hiroshi SUGIMOTO,* Nobuhiro UEDA, and Masayasu MORI
Faculty of Science, Osaka City University, Sugimoto, Sumiyoshi-ku, Osaka 558

(Received March 9, 1981)

Tervalent cobalt complexes of octaethylporphyrin (OEP) and tetraphenylporphyrin (TPP), $[Co^{III}(OEP)(H_2O)_2]X$ (X=ClO_4, BF_4), $[Co^{III}(OEP)(THF)_2]ClO_4$, $[Co^{III}(TPP)(H_2O)_2]X$ (X=ClO_4, BF_4), and $[Co^{III}(TPP)(H_2O)Y]$ (Y=Cl, Br, SCN, N_3) were synthesized. Molecular weight measurements indicate that only $[Co^{III}(TPP)(H_2O)_2]BF_4$ and $[Co^{III}(TPP)(H_2O)_2]ClO_4$ aggregate at higher concentrations in chloroform. In polar solvents such as methanol, all are monomeric. In nonpolar solvents, all the complexes show Soret bands at shorter wavelengths and somewhat paramagnetic ^1H NMR spectra; these anomalies are absent in polar solvents. Tetrafluoroborates and perchlorates react with ethyl vinyl ether smoothly to form 2,2-diethoxyethylcobalt(III) complexes which are easily converted to formylmethylcobalt(III) complexes. ^1H NMR and absorption spectra of the amine adducts prepared in this study, $[Co^{III}(OEP)(L)_2]ClO_4$ (L=pyridine, 2-methylimidazole) and $[Co^{III}(TPP)(L')_2]ClO_4$ (L'=pyridine, 4-cyanopyridine, 4-methylpyridine), indicate that the two amine molecules coordinate to the central cobalt atom. As regards redox potentials for the Co(III)/Co(II) couple as measured by cyclic voltammetry, the cobalt(III) porphyrins are categorized into three groups: (i) BF_4 and ClO_4 salts with redox potentials at about 0.7 V; (ii) halides and pseudohalides with those at 0.2—0.3 V; and (iii) bis(amine) adducts with those at −0.3—+0.1 V. In polar solvents, however, the redox potentials of (i) and (ii) are very similar to one another.

It is well known that the active site of vitamin B_{12} is the cobalt complex of the corrin ligand and that its coenzyme form and related alkylcobalamin are the only organometallic compounds hitherto found in nature. Since the discovery of the cobalt σ-bond between cobalt(III) and 5'-carbon of an adenine moiety through crystallographic studies by Hodgkin,[1] a large number of model compounds have been synthesized to elucidate the basic chemistry of the cobalt-carbon bond in square planar macrocyclic systems.[2-8] Metal complexes of porphyrin are particularly suitable for model studies on the structure and reaction of coenzyme B_{12}, because both porphyrin and corrin[9] are of tetrapyrrole macrocycle. Since the rapture and recombination of the cobalt-carbon bond are key steps to achieve the enzymatic catalysis, main interes thas existed in the formation and cleavage of the cobalt-carbon bond by uni-, bi-, and tervalent metal complexes. The formation of the cobalt-carbon bond through nucleophilic reactions of Co(I) toward organic halides has been investigated in relation to the reaction of coenzyme B_{12}. Similar nucleophilic reactions of Co(I) species were found in porphyrin complexes of Rh(I)[10] and Ir.[11] On the other hand, another mode for the cobalt-carbon bond formation was recently found in an electrophilic reaction of coenzyme B_{12} having a tervalent cobalt atom[12] with alkyl vinyl ether. Ogoshi *et al.*[13] reported that a tervalent rhodium complex of porphyrin reacted with ethyl vinyl ether to give a rhodium-carbon bond. Silverman and Dolphin[12] also showed a cobalt-carbon bond formation by the electrophilic reaction of cobalt(III) oxime with vinyl ether. Dolphin suggested the intermediacy of an olefin π-complex of cobalt(III) in the reaction. However, there has hitherto been no report about the electrophilic reaction of cobalt(III) porphyrins toward electron rich olefins. This is probably because tervalent cobalt atoms of usual cobalt(III) porphyrin complexes have no sufficient cationic character to cause the reaction. Thus, usual cobalt(III) porphyrins are six-coordinated by inclusion of halogens and/or amines in the coordination sphere, such as $[Co^{III}(porphyrin)(amine)_2]X$ and $[Co^{III}(porphyrin)(amine)X]$, and the electrophilicity or cationic character of the central cobalt(III) ion is thereby reduced. In order that cobalt(III) porphyrins should have sufficient electrophilicity to react with various organic nucleophiles, therefore, the electron-donating ability of the counter anion should be sufficiently weak. In this sense it was thought of utmost importance to compare cobalt(III) complexes of porphyrins having various types of axial ligands: weak ligands such as BF_4 and ClO_4 ions; intermediate ligand such as halides and pseudohalides; and strong ligands such as amines. Although active investigations[14] have been made for bromides and chlorides and their amine adducts, for perchlorates only our research group[15,16] has recently reported of syntheses and X-ray crystallographic data. This paper is concerned with synthetic methods, electrophilic reactions toward electron rich olefins, and redox potentials for various tervalent cobalt complexes of octaethylporphyrin and tetraphenylporphyrin, and discusses the relation between mode of coordination of counter anions to the central cobalt atom and physicochemical properties such as absorption and ^1H NMR spectra, particularly redox potentials of the cobalt atom.**

Experimental

Synthesis. $[Co^{III}(OEP)(THF)_2]ClO_4$ (*1*): Octaethylporphyrinatocobalt(II) $Co^{II}(OEP)$, (100 mg) was dissolved in tetrahydrofuran (100 cm^3) containing 1 cm^3 of 70% perchloric acid. The reaction mixture was stirred for 24 h under an aerobic condition until black crystals

** Abbreviations used are: OEP, octaethylporphyrin; TPP, $\alpha,\beta,\gamma,\delta$-tetraphenylporphyrin; THF, tetrahydrofuran; py, pyridine; 2-MeIm, 2-methylimidazole; 4-CNpy, 4-cyanopyridine; 4-Mepy, 4-methylpyridine; TBAP, tetrabutylammonium perchlorate; TBAF, tetrabutylammonium fluoroborate; TBAB, tetrabutylammonium bromide; TBAC, tetra butylammonium chloride.

were precipitated. The crystals thus obtained were collected and washed with petroleum ether. Recrystallization from benzene–THF afforded reddish purple crystals (75 mg) in 53% yield. Found: C, 63.28; H, 7.43; N, 6.76%. Calcd for $C_{44}H_{60}N_4ClO_6Co$: C, 63.26; H, 7.24; N, 6.71%.

[Co^{III}(OEP)(H$_2$O)$_2$]ClO$_4$ (2): Recrystallization of **1** from benzene–dichloromethane saturated with water gave dark red, slightly hygroscopic crystals in a quantitative yield. Found: C, 59.00; H, 6.29; N, 6.99%. Calcd for $C_{36}H_{48}N_4ClO_6Co$: C, 59.46; H, 6.65; N, 7.70%.

[Co^{III}(OEP)(H$_2$O)$_2$]BF$_4$ (3): To a solution of Co^{II}(OEP) (100 mg) in methanol (100 cm^3) was added 10% tetrafluoroboric acid (2—3 cm^3) and the solution was stirred for several hours. Then the solvent was removed carefully under reduced pressure until fine purple crystals were precipitated. The crystals were collected, washed with water, and dried over P_2O_5 *in vacuo* to give **3** in 70% yield. Found: C, 61.62; H, 6.72; N, 7.87%. Calcd for $C_{36}H_{48}N_4BF_4O_2Co$: C, 60.51; H, 6.77; N, 7.84%.

[Co^{III}(OEP)(py)$_2$]ClO$_4$ (4): Recrystallization of **1** from benzene containing an excess amount of pyridine gave reddish purple crystals in almost a quantitative yield. Found: C, 64.56; H, 6.63; N, 9.69%. Calcd for $C_{46}H_{54}N_4ClO_4Co$: C, 65.05; H, 6.40; N, 9.89%.

[Co^{III}(OEP)(2-MeIm)$_2$]ClO$_4$ (5): Recrystallization of **1** from benzene–dichloromethane containing an excess amount of 2-methylimidazole afforded reddish purple crystals in a quantitative yield. Found: C, 61.94; H, 6.83; N, 12.90%. Calcd for $C_{44}H_{56}N_8ClO_4Co$: C, 61.78; H, 6.60; N, 13.10%.

[Co^{III}(OEP)CH$_2$CH(OCH$_2$CH$_3$)$_2$] (6): To an ethanol solution (100 cm^3) of **1** (100 mg) were added vinyl ethyl ether (100 mg) and triethylamine (0.5 cm^3). The reaction mixture was stirred at room temperature until a fine powder was precipitated. The powder thus obtained was collected and recrystallized from benzene–dichloromethane to afford reddish purple crystals (64 mg) in 75% yield. Found: C, 71.47; H, 7.55; N, 8.07%. Calcd for $C_{42}H_{57}N_4O_2Co$: C, 71.16; H, 8.10; N, 7.90%.

[Co^{III}(OEP)CH$_2$CHO] (7): A dichloromethane solution of **6** was treated with silica gel or allowed to stand for 1 d. The solvent was evaporated under reduced pressure. The residual solid was recrystallized from benzene to afford orange red crystals in almost a quantitative yield. Found: C, 71.14; H, 7.51; N, 8.46%. Calcd for $C_{38}H_{47}N_4OCo$: C, 71.90; H, 7.48; N, 8.84%.

[Co^{III}(TPP)(H$_2$O)$_2$]ClO$_4$ (8): To a suspension of Co^{II}(TPP) (100 mg) in methanol (100 cm^3) was added 10% perchloric acid (1—2 cm^3) and the solution was stirred for about 10 h to almost complete dissolution. The solvent was removed under reduced pressure. The residual solid was recrystallized from methanol–benzene to give reddish purple crystals in 75% yield. Found: C, 66.23; H, 3.77; N, 7.09%. Calcd for $C_{44}H_{40}N_4ClO_4Co$: C, 66.62; H, 4.32; N, 7.06%.

[Co^{III}(TPP)(H$_2$O)$_2$]BF$_4$ (9): To a solution of Co^{II}(TPP) (100 mg) in dioxane (100 cm^3) was added 10% tetrafluoroboric acid (2—5 cm^3) and the solution was stirred for about 1 h. Then the solvent was removed carefully under reduced pressure until fine crystals were precipitated. The crystals were collected, washed with water and dried over P_2O_5 *in vacuo* to give **9** in 65% yield. Found: C, 63.62; H, 4.42; N, 6.63%. Calcd for $C_{44}H_{36}N_4BF_4Co$: C, 63.63; H, 4.37; N, 6.75%.

[Co^{III}(TPP)(H$_2$O)I] (10): A dichloromethane solution of **8** was washed with an aqueous sodium iodide solution several times and then with water and dried over Na_2SO_4. The solvent was removed under reduced pressure. The residual solid was recrystallized from methanol to give reddish purple crystals in almost a quantitative yield. Found: C, 64.97; H, 4.08; N, 6.36%. Calcd for $C_{44}H_{30}N_4OICo$: C, 64.72; H, 3.70; N, 6.86%.

[Co^{III}(TPP)(H$_2$O)Br] (11): To a suspension of Co^{II}(TPP) in methanol was added 10% hydrobromic acid and the mixture was stirred for 20 h. Methanol was removed under reduced pressure. The residual solid was recrystallized from methanol to give reddish purple crystals in a quantitative yield. Found: C, 68.38; H, 3.96; N, 7.29%. Calcd for $C_{44}H_{30}N_4OBrCo$: C, 68.31; H, 4.17; N, 7.41%.

[Co^{III}(TPP)(H$_2$O)Cl] (12): This was synthesized by the method reported by Yamamoto *et al.*[14h,l]

[Co^{III}(TPP)(H$_2$O)SCN] (13): This was prepared by the same procedure as for **10** except that KI was replaced by KSCN. Found: C, 72.73; H, 3.86; N, 9.50%. Calcd for $C_{45}H_{30}N_5OSCo$: C, 72.28; H, 4.04; N, 9.37%.

[Co^{III}(TPP)(H$_2$O)N$_3$] (14): This complex also was prepared by the same procedure as for **10** but by using NaN_3 in place of KI. Found: C, 72.85; H, 4.12; N, 13.36%. Calcd for $C_{44}H_{30}N_7OCo$: C, 72.22; H, 4.13; N, 13.40%.

[Co^{III}(TPP)(py)$_2$]ClO$_4$ (15): Recrystallization of **8** from benzene–pyridine (10:1 vol/vol) gave reddish purple crystals in 80% yield. Found: C, 70.14; H, 4.33; N, 8.72%. Calcd for $C_{54}H_{38}N_6ClO_4Co$: C, 69.79; H, 4.12; N, 9.04%.

[Co^{III}(TPP)(4-CNpy)$_2$]ClO$_4$ (16): Recrystallization of **8** from benzene containing an excess amount of 4-cyanopyridine gave reddish purple crystals. Found: C, 68.37; H, 3.69; N, 11.39%. Calcd for $C_{56}H_{36}N_8ClO_4Co$: C, 68.68; H, 3.71; N, 11.44%.

[Co^{III}(TPP)(4-Mepy)$_2$]ClO$_4$ (17): Recrystallization of **8** from benzene containing an excess amount of 4-methylpyridine gave reddish purple crystals in a quantitative yield. Found: C, 70.78; H, 4.70; N, 9.19%. Calcd for $C_{56}H_{42}N_6ClO_4$: C, 70.25; H, 4.42; N, 8.78%.

[Co^{III}(TPP)(py)$_2$]Cl (18): Recrystallization of **12** from benzene–pyridine (1:1 vol/vol) gave reddish purple crystals. Found: C, 74.73; H, 4.87; N, 9.67%. Calcd for $C_{54}H_{46}N_6ClCo$: C, 74.60; H, 4.87; N, 9.67%.

[Co^{III}(TPP)(py)Cl] (19): This was prepared by the method previously reported,[14l] and also obtained from recrystallization of **18** from benzene–dichloromethane.

[Co^{III}(TPP)CH$_2$CH(OCH$_2$CH$_3$)$_2$] (20): The procedure for preparation was the same as that described for octaethylporphyrin complex **6**. Found: C, 75.73; H, 4.92; N, 7.32%. Calcd for $C_{51}H_{45}N_4O_2Co$: C, 76.10; H, 5.64; N, 6.96%.

[Co^{III}(TPP)CH$_2$CHO] (21): A dichloromethane solution of **20** was treated with silica gel as described for **7**. Found: C, 76.93; H, 4.42; N, 7.99%. Calcd for $C_{46}H_{35}N_4OCo$: C, 76.87; H, 4.91; N, 7.80%.

Molecular Weight. Molecular weights were measured by the vapour pressure osmometry at 31.5 °C in chloroform and methanol on a Knour vapour pressure osmometer.

Spectral Measurements. ^{1}H NMR spectra were obtained on Varian HA-100D and JEOL HM-100 spectrometers. Infrared spectra were measured on a Hitachi G-3 spectrometer and absorption spectra on a Hitachi model 200-10 spectrophotometer.

Cyclic Voltammetry. All solvents were dried and distilled before use. As a supporting electrolyte, tetrabutylammonium perchlorate (TBAP) was used after being subjected twice to crystallization from benzene. Cyclic voltammograms were obtained on a HA-104 potentiostat (Hokuto Denko) in combination with an HB-107A function generator. A three-electrode system was used which consisted of platinum working and counter electrodes and

a commercial saturated calomel electrode (SCE) separated from the bulk of solution by a bridge filled with solvent and supporting electrolyte. The bridge had its solution changed periodically to avoid aqueous contaminants from entering the cell *via* the SCE. All solutions were purged of oxygen by passing purified nitrogen through them for 10 min just before taking cyclic voltammograms. After the degassing a blanket of nitrogen was kept over the solution. The half-wave potential $E_{1/2}$ was taken as that potential lying midway between the oxidation and reduction peaks for a given couple. All experiments were carried out at room temperature (20 °C) and the potentials reported refer to the SCE.

Results and Discussion

Synthesis. All the tervalent cobalt complexes were prepared generally by air oxidation of their corresponding bivalent cobalt complexes in the presence of aqueous acid.[14] Perchlorate, tetrafluoroborate, bromide, and chloride salts of tetraphenylporphyrin complexes **8**, **9**, **11**, and **12** were obtained in methanol. Iodide and pseudohalide salts **10**, **13**, and **14** were obtained through anion exchange from the perchlorate salt. The bis(tetrahydrofuran) adduct of the perchlorate salt of cobalt(III) octaethylporphyrin **1** was obtained by using tetrahydrofuran as the solvent. This could easily be converted to bis(aqua) adduct **2** by recrystallization from benzene–dichloromethane saturated with water. The tetrafluoroborate salt of octaethylporphyrinatocobalt(III) was obtained by the same method as that for tetraphenylporphyrin derivative **9**. Bis(amine) adducts **4**, **5**, **15**, **16**, **17**, **18**, and **19** were prepared by recrystallization from benzene containing each amine in excess. The bis(pyridine) adduct of chloride salt **18** was easily converted into mono(pyridine) adduct **19** by recrystallization from benzene–chloroform. However, the bis(pyridine) adduct of perchlorate salt **15** could not be converted into mono(pyridine) adduct. These two types of pyridine adducts were confirmed by elemental analysis and ^{1}H NMR spectra.

Molecular Weights. For cobalt(III) complexes of porphyrin, no aggregation phenomena have been reported.[17] However, the molecular weight measurements in chloroform indicate that two of the complexes, **8** and **9**, tend to aggregate as the concentration is increased. For example, Fig. 1 shows the concentration dependence of molecular weight for **9** and **3**. At low concentrations around 0.01 mol dm^{-3}, both the complexes assume monomeric molecular weights. However, as the concentration is increased, the molecular weight of **9** is gradually increased. As high concentrations around 0.05 mol dm^{-3}, complex **9** is almost dimeric; in polar solvents such as methanol all of the tervalent complexes are monomeric at these high concentrations. As will be described below, ^{1}H NMR spectra of complexes **8** and **9** show no significant changes when the concentration is increased from 0.01 to 0.05 mol dm^{-3}. The observed molecular weights indicate that the complexes are not ionized in these solvents. When the anions are coordinated, the solute species are considered to be of nonelectrolyte; otherwise, they should be of ion pair or ion-pair aggregate.

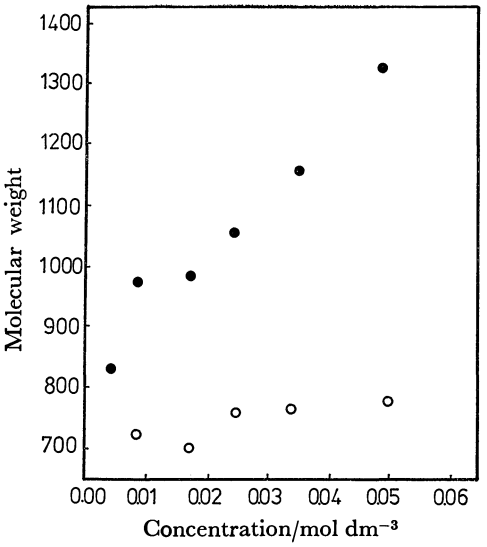

Fig. 1. Concentration dependency of the molecular weight in chloroform.
●: $[Co^{III}(TPP)(H_2O)_2]BF_4$, ○: $[Co^{III}(OEP)(H_2O)_2]BF_4$.

In the case of tetraphenylporphyrin derivatives **8** and **9** where higher molecular weights were observed, the aggregation mode of ion pair is not considered to be the stacking of porphyrin planes *via* a sort of the π-π interaction,[17] because such stacking is more difficult to be realized in the case of tetraphenylporphyrin derivatives because of the large steric hindrance of phenyl groups; this is contrary to the present situation. The most probable picture for the aggregation seems to be that in which the ion-pairs are bound through hydrogen bonding between the aqua ligands and the perchlorate (or tetrafluoroborate) anions as is realized in crystals.[16] Such hydrogen bonding seems to be more favorable in the case of tetraphenylporphyrin derivatives than in the case of octaethylporphyrin derivatives owing to the electron-withdrawing character of the former.

Absorption Spectra. Absorption spectral data are summarized in Table 1. Absorption spectra of the tervalent cobalt complexes except the amine complexes are highly dependent on properties of solvents.[15] Halides and pseudohalides **10**—**14** showed Soret bands at about 400—407 nm in nonpolar solvents such as dichloromethane. Addition of polar solvents such as methanol gave shifts toward longer wavelengths. In methanol the spectra of these complexes are very similar to one another. This can be explained in terms of the coordination of polar solvent molecules to form $[Co^{III}(TPP)(solvent)_2]^+$ species. On the other hand, BF_4 and ClO_4 salts **8** and **9** showed Soret bands at 426 nm in dichloromethane which are close to those in methanol (425 nm). This result indicates that, in dichloromethane, the cobalt atoms of BF_4 and ClO_4 salts are coordinated by water molecules as the fifth and sixth axial ligands.[16] In methanol these water molecules seem to be replaced with solvent molecules as suggested by the ^{1}H NMR and the cyclic voltammetry studies described below. The six-coordinated species $[Co^{III}(TPP)(H_2O)_2]^+$ or $[Co^{III}(TPP)(solvent)_2]^+$

Table 1. Absorption spectra of tervalent cobalt porphyrins

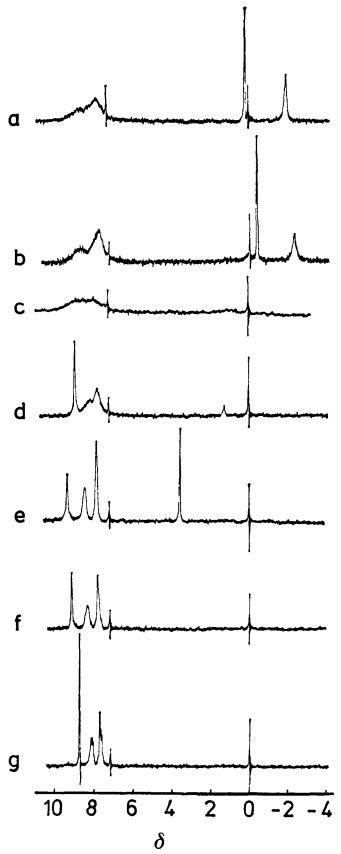

Fig. 2. ^{1}H NMR spectra in chloroform at 31.5 °C. (a): $[Co^{III}(TPP)(H_2O)_2]BF_4$, (b): $[Co^{III}(TPP)(H_2O)_2]ClO_4$, (c): $[Co^{III}(TPP)(H_2O)Cl]$, (d): $[Co^{III}(TPP)(H_2O)Br]$, (e): $[Co^{III}(TPP)(H_2O)I]$, (f): $[Co^{III}(TPP)(H_2O)N_3]$, (g): $[Co^{III}(TPP)(H_2O)SCN]$.

can be expected to have a cationic character, if the solvent molecule is allowed to dissociate easily due to weak solvation. Neither the bis(amine) adducts nor the mono(amine) adduct was much influenced by solvent polarity. This result indicates that there exists tight coordination of the amine molecules to the cobalt atom, which is consistent with results from ^{1}H NMR spectra.

^{1}H NMR Spectra. ^{1}H NMR data are summarized in Table 2. In nonpolar solvents such as dichloromethane and chloroform these tervalent cobalt complexes except the amine adducts and organocobalt complexes show very broad and shifted signals. Figure 2 illustrates the ^{1}H NMR spectra of **8**—**14** in chloroform at room temperature. The signals of the phenyl and β-pyrrole protons are significantly broad and shifted compared with those for usual diamagnetic spectrum. This phenomenon is qualitatively the same as that reported by Yamamoto *et al.* in the case of chloride salt **12**.[14k] It is noteworthy that the signals of the pyrrole β-protons for complexes **8** and **9** are very much shifted toward higher magnetic fields.[18] The magnetic moments of complexes **8** and **9** in chloroform at room temperature (31 °C) showed smaller paramagnetism (about 0.7 BM) than the one for a chloride salt (1.66 BM) previously reported.[14k] Such large upfield shifts of pyrrole β-protons and small paramagnetism, as compared with those of the chloride salt, suggest that the mechanisms of the spin delocalization on the porphyrin plane are somewhat different from each other. The difference in the mechanism of spin delocalization between the group of ClO_4 and BF_4 salts and the group of Cl, Br, I, and N_3 salts may result from the different coordination modes. Sakurai *et al.*[14h,i] reported that the cobalt atom in the chloride salt is coordinated by the chlorine atom as the fifth ligand. In perchlorate salt **8**, on the other hand, the cobalt atom is coordinated by two water molecules as described above.[16]

In polar solvents these complexes showed usual diamagnetic ^{1}H NMR spectra. The addition of amines such as pyridine gave also diamagnetic spectra which were very similar to those of bis(amine) adducts. For example, bis(tetrahydrofuran) adduct **1** showed only one broad signal at about 2 ppm in chloroform, but an addition of pyridine in twice the equivalent gave a spectrum indicating the existence of the bis(pyridine) adduct and free tetrahydrofuran.[15] The ^{1}H NMR spectra of amine adducts **4**, **5**, and **15**—**20** indicate a coordination of these amine molecules to the cobalt atom. In particular, it is noteworthy that both bis(pyridine) adduct **19** and mono(pyridine) adduct **20** can be isolated in the case of chloride salt,

TABLE 2. ^{1}H NMR DATA OF TERVALENT COBALT PORPHYRINS (δ VALUES)[a)]

	Solvent	*meso*	α-CH_2	β-CH_3	Others
1	CD_2Cl_2	Very broad signal at about 2

although mono(pyridine) adduct can not be isolated in the case of perchlorate salt. Moreover, the ^1H NMR spectrum of 2-methylimidazole adduct **5** showed tight coordination of such a sterically-hindered axial base.

Cyclic Voltammetry. The electrochemical behavior of cobalt porphyrin complexes has actively been investigated.[19,20] These studies usually dealt with cobalt(II) porphyrins and disclosed two distinct redox couples for the metal redox processes, Co(III)/Co(II) and Co(II)/Co(I). Addition of various types of amines to such systems was found to bring about shifts of the redox potentials for Co(III)/Co(II) to more negative values, the shift getting greater as the basicity of the amine is increased. The redox couple Co(II)/Co(I), on the other hand, was almost insensitive. However, there have been no reports on redox process of Co(III) porphyrins in which anions are present either as axial ligands or as counter ions. Study of such process seems to be of importance for estimation of the influence by such anions on the electrophilicity of cobalt atoms. There have been some reports on the effect of anions in the supporting electrolyte on the redox couple Co(III)/Co(II) associated with cobalt(II) porphyrins,[20a] but no study on such factors can give any direct information and we have no assurance that the anion is coordinated during the oxidation process.

Table 3 summarizes the half wave potentials ($E_{1/2}$) of tervalent cobalt porphyrins. One of the most outstanding features is that in dichloromethane these tervalent cobalt porphyrins have Co(III)/Co(II) redox couples varing in their combination significantly with counter anions or axial ligands and that accordingly, they can be categorized into three groups: Group (i) complexes have BF_4^- or ClO_4^- as the counter anion and have the most positive redox values similar to that of the bivalent complex $Co^{II}(TPP)$. Group (ii) includes salts of Cl^-, Br^-, SCN^-, and N_3^- and have less positive redox potentials by about 0.4 V which varies slightly with the kind of counter anions. These values reveal that there is no exchange of the axially coordinated anion with the perchlorate ion of the supporting electrolyte TBAP; otherwise, the redox values for these complexes would be close to that of the perchlorate salt. Group (iii) complexes have various amines as axial ligands and have the lowest redox potentials.

The difference between the redox potentials of Groups (i) and (ii) may be explained in terms of different modes of coordination. As previously discussed, two water molecules are coordinated axially in $[Co^{III}(TPP)(H_2O)_2]ClO_4$ and the same is expected to be true with the tetrafluoroborate salt and its corresponding OEP derivatives. The fact that the values for both Group (i) complexes and the bivalent complex are quite similar to one another, indicates that coordination of the axial water molecules is very weak and that it has little influence on the redox potentials in dichloromethane. On the other hand, the chloride anion, and probably other halide and pseudohalide anions, too, coordinate to the cobalt atom directly as the fifth ligand, and the increasing covalency of such axial ligands seems to lower the redox potential of the Co(III)/Co(II) couple.

It is interesting to compare the Co(III)/Co(II) potentials of Co(III) porphyrins with those of $Co^{II}(TPP)$ with various supporting electrolytes, reported by Truxillo and Davis.[20a] Thus, the redox values for $[Co^{III}(TPP)(H_2O)_2]X$ ($X=ClO_4$, BF_4) and $[Co^{III}(TPP)(H_2O)Y]$ ($Y=Br$, Cl) are +0.72, +0.72, +0.38, and +0.27, respectively. The redox values for the Co(III)/Co(II) couple of $Co^{II}(TPP)$ are reported to be +0.75, +0.94, +0.29, and +0.74 volt for electrolytes TBAP, TBAF, TBAB, and TBAC, respectively. Slightly lower values of the cobalt(III) porphyrin

Table 3. Half-wave potentials for bi- and tervalent cobalt porphyrins

$[Co^{III}(TPP)(H_2O)_2]ClO_4$		+0.32	−0.95
$[Co^{III}(TPP)(H_2O)Br]$		+0.27	−0.96
$[Co^{III}(TPP)(H_2O)Cl]$		+0.28	−0.99
$[Co^{III}(TPP)(H_2O)N_3]$		+0.29	−0.99

perchlorate and tetrafluoroborate than those of Co(II) porphyrin in TBAP and TBAF can reasonably be explained in terms of the presence of axially coordinated water molecules which have a weak electron-donating character. On the other hand, the much higher potential of the Co(II) porphyrin in the presence of TBAC than that of $[Co^{III}(TPP)(H_2O)Cl]$ indicates that the chloride ion in the supporting electrolyte coordinate neither to Co(II) porphyrin nor to Co(III) formed by the oxidation of Co(II) porphyrin during the time of voltage cyclings.

In dichloromethane–ethanol solution the tervalent cobalt complexes studies showed almost the same redox potentials with one another, referring presumably to $[Co^{III}(TPP)(EtOH)_2]^+$ (0.27—0.33 V), in conformity with the replacement of the axial anion by the solvent molecules as has just been concluded from the absorption spectra.

In the case of Group (iii) porphyrins, the redox potentials are still lower and dependent predominantly on the nature of axial ligands, which is consistent with the results in the case of bivalent cobalt porphyrins with various amines, reported by Walker *et al.*[20e] The ^1H NMR spectra of these complexes in chloroform indicate a tight coordination of two amine molecules. Large irreversibility for the bis(amine) adduct, compared with that for other tervalent complexes, suggests a considerable dissociation of the axial amines in the reduced state. In fact, it is well known that bivalent cobalt complexes prefer five-coordination to six-coordination.[22]

Reaction with Ethyl Vinyl Ether. We previously reported[15] that perchlorate salts **1** and **2**, and **8** react with ethyl vinyl ether to afford organocobalt(III) complexes **6** and **20**, respectively. Other halides and pseudohalides also gave similar reaction products in ethanol solution although their yields are low. This result indicates that the solvent-coordinated species (B) has sufficient electrophilicity toward ethyl vinyl ether to form organocobalt complex (D) probably *via* π-complex (C). The obtained 2,2-diethoxyethylcobalt(III) complexes **6** and **20** could easily be converted to formylmethylcobalt(III) complexes **7** and **21**, respectively. These organocobalt complexes have been well characterized by elemental analysis and spectroscopic measurements, in particular ^1H NMR spectra. Figure 3 shows the ^1H NMR spectra of **20** and **21**. The presence of 2,2-diethoxyethyl and

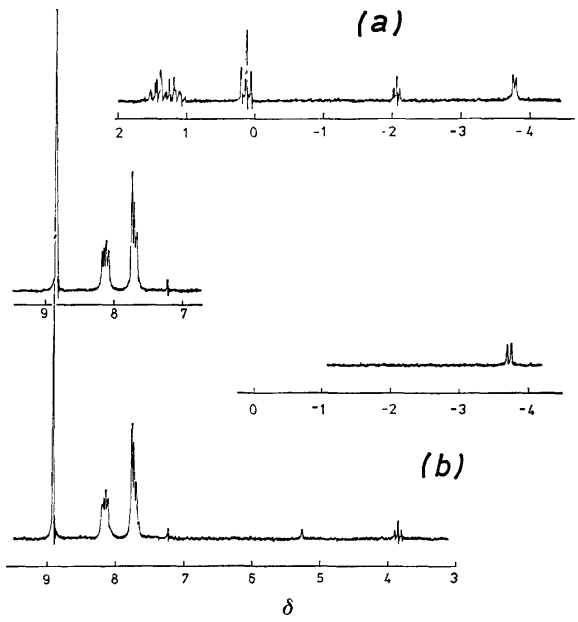

Fig. 3. ^1H NMR spectra of (a) $[Co^{III}(TPP)CH_2CH(OC_2H_5)_2]$ and (b) $[Co^{III}(TPP)CH_2CHO]$ in chloroform.

formylmethyl groups bonded to the central metal ion can reasonably be confirmed by the high field shift of the protons in the groups due to the large diamagnetic ring-current effect of porphyrin ring. Assignments of the protons are listed in Table 2.

This synthetic method for organocobalt(III) complexes of porphyrins is very convenient for the model study of vitamin B_{12}, because it is very simple and gives high yields, compared with the reaction of Co(I) species with organo halides.

On the other hand, bis(amine) adducts or mono(amine) adduct reacted with ethyl vinyl ether to give only reduced bivalent cobalt porphyrins. These results indicate that the strong electrophilic property of central cobalt(III) ion in the amine adducts is cancelled by the strong ligation of amine molecules and that only the electron transfer from ethyl vinyl ether to cobalt ion occurs.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Neighboring Effect of Mercapto Group in the Silver Ion-promoted Aminolysis of *S*-Monoacyldihydrolipoamide

Yoko NAMBU,* Takeshi ENDO, and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received December 10, 1980)

The aminolysis of *N*-benzyl-8-*S*-(*p*-nitrobenzoyl)dihydrolipoamide has been enhanced remarkably with excess silver perchlorate compared with that of *N*-benzyl-*S*,*S*′-bis(*p*-nitrobenzoyl)dihydrolipoamide. From the results of kinetics and complex formation followed by UV and IR spectra, the large enhancement in the reaction has been concluded to be derived from the activation of acyl group through the binding of two equivalents of silver ion to the neighboring mercapto group.

Whereas arenethiol ester is one of the activated esters which is able to be utilized for the activation of amino acids and peptide syntheses, less reactive alkanethiol esters are scarcely used for the activation of acyl group.

On the other hand, it is well known that 5-(1,2-dithiolan-3-yl)pentanoic acid (lipoic acid) plays an important role in transfer of acetyl group enzymatically from pyruvic acid-thiamine adduct to coenzyme A (CoASH), and the thiol ester (CoASAc) thus produced, in turn, is transferred into TCA cycle.

Further, the aminolysis of thiol esters has been shown to be catalyzed with various metal ions such as silver and mercuric ions.[1]

As part of the investigation on the synthesis and reaction of lipoic acid derivatives, we have already reported the silver ion-promoted acyl transfer on *S*,*S*′-diacyl-6,8-dimercaptooctanoic acid (*S*,*S*′-diacyldihydrolipoic acid) derivatives to nucleophiles such as amines and alcohols[2] and applied to the polymeric system to provide polymeric acylating agents.[3] In the previous report,[2] we mentioned briefly that aminolysis of 8-*S*-acetyldihydrolipoamide which had a neighboring mercapto group was enhanced remarkably with silver ion compared to that of *S*,*S*′-diacetyl derivatives. It is interesting to study the mechanism of the neighboring effect of mercapto group in this reaction, related to the similarity of the relative position between mercapto and acylthio groups in 8-*S*-acetyl derivative to the 6-*S*-acetyl isomer isolated from a natural enzymatic system, to the applicability of this system for polymeric acylating agents,[11] and to the activation of acyl group through complex formation in the metal-ion-promoted hydrolysis of 8-quinolyloxycarbonyl derivatives of amines.[4] We report here the mechanistic study on the aminolysis of *N*-benzyl-8-*S*-(*p*-nitrobenzoyl)dihydrolipoamide (**1**) with cyclohexylamine in the presence of silver perchlorate ($AgClO_4$) followed spectrophotometrically and the comparison of the result with that of the *S*,*S*′-diacyl derivative (**2**).

2: X=Y=-CO-R (R= )

Experimental

Materials. Silver perchlorate was purchased from Kojima Chemical Co., Ltd. *N*-Benzyl-*S*,*S*′-bis(*p*-nitrobenzoyl)dihydrolipoamide (**2**) was prepared by the method reported previously.[3] Solvents were purified by the usual procedure.

Preparation of N-*Benzyl-8-(*S-p-*nitrobenzoyl)dihydrolipoamide (**1**).* To a solution of *N*-benzyllipoamide[3] (295 mg, 1 mmol) in methanol (15 ml), sodium borohydride (95 mg, 2.5 mmol) was added portionwise at 0 °C and stirred for 2 h at room temperature under nitrogen. Reaction mixture was then acidified to pH 2 with 0.1 M† hydrochloric acid. The solution was extracted with dichloromethane (50 ml) and the organic layer was dried over $MgSO_4$. To the dichloromethane solution were added *p*-nitrobenzoyl chloride (196 mg, 1 mmol) and triethylamine (0.1 ml) under nitrogen, and the solution was stirred for 15 h at room temperature. The solvent was removed by evaporation and the obtained residue was dissolved in ether. The precipitated triethylamine hydrochloride was filtered off and the filtrate was evaporated to afford an oily residue, which was recrystallized from ether to give **1** (160 mg, 36%): mp 71—73 °C; NMR ($CDCl_3$) δ=1.41 (d, 1, J=7.5 Hz, SH), 1.5—2.0 (m, 8, CH_2), 2.2 (d, 2, J=6.0 Hz, $COCH_2$), 2.9 (m, 1, >CHS–), 3.3 (t, 2, J=6.0 Hz, CH_2SCO), 4.4 (d, 2, J=5.7 Hz, $C_6H_5CH_2$), 5.9 (s, 1, NHCO), 7.3 (s, 5, C_6H_5), and 8.2 ppm (q, 4, $C_6H_4NO_2$); IR (THF) 3550, 1670, 1525, and 1345 cm^{-1}; UV_{max}(THF)(log ε) 260 (4.15) and 290 nm (shoulder, 4.02); Found: C, 59.11; H, 6.00; N, 6.01%. Calcd for $C_{22}H_{26}N_2O_4S_2$: C, 59.18; H, 5.87; N, 6.28%.

Kinetic Measurements. To a tetrahydrofuran (THF) solution of acyl derivative **1** or **2** and cyclohexylamine, silver perchlorate was added at 35.5 °C under nitrogen. Final concentrations were [**1** or **2**]=2.5×10^{-4} M, [cyclohexylamine]=3—12×10^{-3} M, [$AgClO_4$]=1.5—10×10^{-3} M. A portion of the reaction mixture taken out with a pipet was centrifuged to remove the white thiolate. The supernatant was diluted with THF to obtain an appropriate absorbance in UV spectra. The absorbance at 290 nm was measured as a function of time. The measured data were treated as first-order kinetics by plotting $\ln|A_\infty - A_t|$ *versus* time. The slope of this line was taken as the pseudo-first-order rate constant k, k_0, or k'.

Reaction Products. A preparative scale experiment was carried out with mono(*S*-ester) **1**. The white precipitate formed was collected by centrifuging the reaction mixture. The precipitate was washed well with THF and dried to give the silver thiolate (**4**) which showed amide bands at 1540 and 1630 cm^{-1}, but showed no NO_2 band in IR spec-

† 1 M=1 mol dm^{-3}.

trum (Found: C, 24.73; H, 2.75; N, 2.14%. Calcd for $C_{15}H_{21}NO_5Ag_3Cl$: C, 25.17; H, 2.95; N, 1.95%). After evaporation of the supernatant, the resulting oily residue was dissolved in ethyl acetate and washed with aqueous hydrochloric acid. *N*-Cyclohexyl-*p*-nitrobenzamide (**3**) obtained from the organic layer was recognized by comparing the IR and UV spectra with those of the authentic sample, which was prepared from *p*-nitrobenzoyl chloride and cyclohexylamine (Found; C, 62.55; H, 6.48; N, 11.32%. Calcd for $C_{13}H_{16}N_2O_3$: C, 62.89; H, 6.50; N, 11.28%); IR (KBr) 3410, 1640, 1545, and 1345 cm^{-1}; UV_{max} (THF) (log ε) 266 nm (4.10).

Spectral Measurements. ^1H NMR spectra were measured with a varian EM 360 NMR spectrometer in chloroform-*d* with tetramethylsilane as the internal standard. IR spectra were recorded on a Hitachi EPI-S2 spectrophotometer. UV absorption spectra were recorded on a Hitachi 200-10 spectrophotometer.

Results and Discussion

Reaction of Mono(S-ester) 1 with Cyclohexylamine. Aminolysis of **1** with cyclohexylamine was carried out by mixing **1** and excess cyclohexylamine in THF at 35.5 °C. No appreciable reaction was observed in the absence of $AgClO_4$. A white precipitate (**4**), however, was produced gradually by adding $AgClO_4$. The change of absorption spectra at various time intervals for the supernatant liquid obtained by centrifuging the reaction mixture is shown in Fig. 1. The absorption spectrum (A) in Fig. 1 is ascribed to thiol ester **1** which was scarcely affected by adding excess cyclohexylamine, but changed to spectrum (B) immediately by adding $AgClO_4$. Spectrum (B) changed further to spectrum (C) in the rate depending on the concentration of $AgClO_4$. Spectrum (C) finally changed to spectrum (D) which corresponded to *N*-cyclohexyl-*p*-nitrobenzamide (**3**) in the slower rate than that of (B) to (C). The change in absorbance at 266 nm from (B) to (C) and from (C) to (D) followed first-order-kinetics, and the pseudo first-order rate constants k_0 for (B) to (C) and k for (C) to (D) were obtained.

As shown in the dependences of k_0 or k on the concentration of $AgClO_4$ (Fig. 2), only the change from (B) to (C) was observed at the lower concentration of $AgClO_4$. At the higher concentration of $AgClO_4$, however, faster change from (B) to (C) and slower change from (C) to (D) were observed. The both process were remarkably accelerated as the concentration of $AgClO_4$ increased, and k increased linearly at the concentration of $AgClO_4$ higher than that of cyclohexylamine.

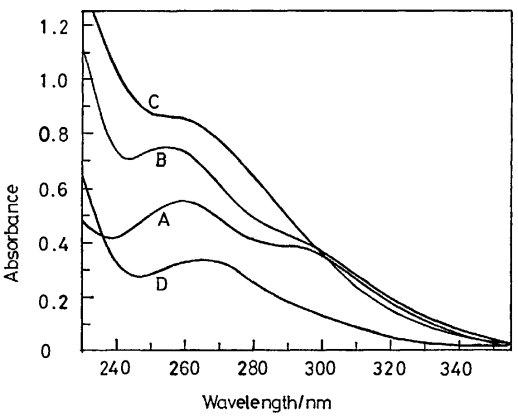

Fig. 1. Change of UV absorption in aminolysis of mono(*S*-ester) **1** with cyclohexylamine in the presence of $AgClO_4$, [**1**]$=2.5\times10^{-4}$ M, [$C_6H_{11}NH_2$]$=5.0\times10^{-3}$ M, [$AgClO_4$]$=4.8\times10^{-3}$ M, THF, 35.5 °C.
A: **1** and cyclohexylamine, B: 0 min, C: 60 min, D: 1 550 min.

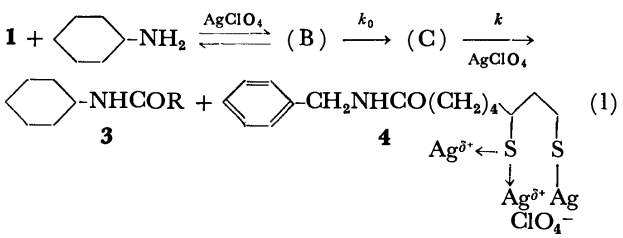

Figure 3 shows the dependence of k on the concentration of cyclohexylamine. Aminolysis was retarded considerably at the concentration of cyclohexylamine higher than that of $AgClO_4$.

Reaction of Di(S-ester) 2 with Cyclohexylamine. Aminolysis of **2** with cyclohexylamine was followed spectrophotometrically and the change of UV spectra

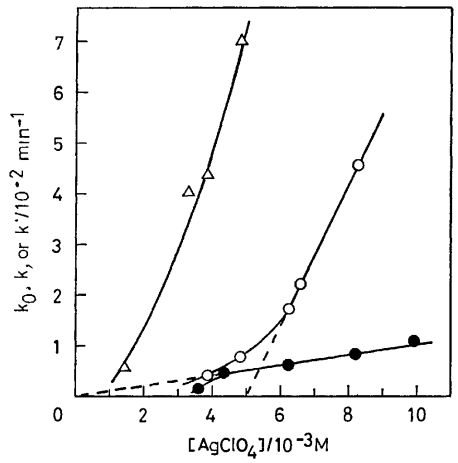

Fig. 2. Dependence of k_0, k, or k' on the concentration of $AgClO_4$ [**1** or **2**]$=2.5\times10^{-4}$ M (SCO unit), [$C_6H_{11}NH_2$]$=5.0\times10^{-3}$ M, THF, 35.5 °C.

is shown in Fig. 4. Contrary to the case of mono(*S*-ester) **1**, di(*S*-ester) **2** showed no spectral change by adding $AgClO_4$. In the presence of excess $AgClO_4$ and cyclohexylamine, the spectrum of **2** changed gradually to that of amide **3**. Pseudo-first-order rate constant k' was obtained by following the decrease of absorbance at 300 nm. As shown additionally in Fig. 2, k' increased linearly by increasing the concentration of $AgClO_4$, but was not so much accelerated as in the case of **1**.

$$\mathbf{2} + \bigcirc\!\!-NH_2 \xrightarrow[AgClO_4]{k'} \mathbf{3} + \mathbf{4} \qquad (2)$$

Complex formation from Mono(S-ester) 1 and $AgClO_4$. The large enhancement of aminolysis of mono(*S*-ester) **1** at the higher concentration of $AgClO_4$ compared to that of di(*S*-ester) **2** is considered to be due to the formation of active complex from **1** and $AgClO_4$ as observed in the change of UV spectra of **1** (Figs. 1 (B) and (C)). This was further examined with molar ratio method,[5] by plotting the observed absorbances at 260 nm against the molar ratio of $AgClO_4$ to **1** with a fixed concentration of mono(*S*-ester) **1** in THF as shown in Fig. 5. The absorbance at 260 nm increased linearly by increasing the ratio of $AgClO_4$ to **1** up to 1, where the curve broke sharply. Further addition of $AgClO_4$ resulted in the minimum absorbance at a molar ratio of 2. These results suggested the formation of a tight 1:1 complex and a 1:2 complex respectively from **1** and $AgClO_4$. Further binding of $AgClO_4$ to the complex was presumed to be occurred from the increase of absorbance again by increasing the molar ratio. On the other hand, in the presence of excess cyclohexylamine, a different curve was obtained at a ratio of more than 1, as shown with the dotted line in Fig. 5. This result suggested that a different complex might be formed in the presence of amine.

Silver thiolates are well known to be formed from Ag^+ ion and thiols, therefore, the tight 1:1 complex deduced by the molar ratio method is presumed to be a thiolate (**5**) of mono(*S*-ester) **1**. Owing to the

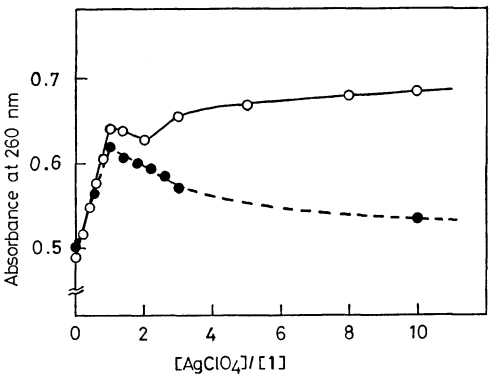

Fig. 5. Change of $A_{260\text{ nm}}$ in molar ratio method by complex formation from $AgClO_4$ and **1**, $[\mathbf{1}]=3.9\times10^{-5}$ M.
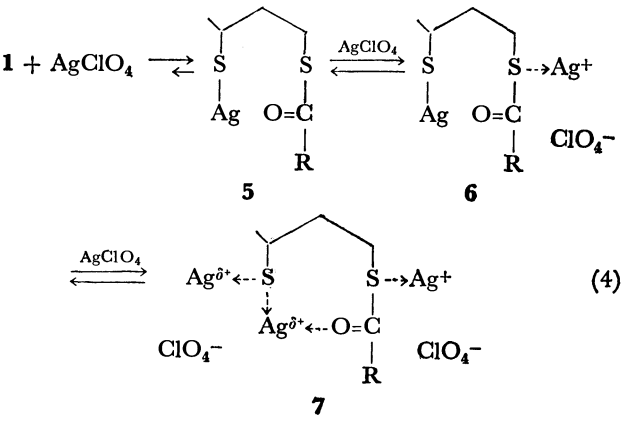
○: In the absence of amine, ●: in the presence of amine, $[C_6H_{11}NH_2]=9.9\times10^{-4}$ M.

strong affinity of silver ion to sulfur atom, further 1:2 complex (**6**) is considered to be formed through binding another Ag^+ ion to the sulfur atom of acylthio group.

In addition, silver thiolates are known to form further complexes with excess Ag^+ ion[6] (Eq. 3), which is suppressed in the presence of amine.[7]

$$RSAg + Ag^+ \longrightarrow (RSAg)Ag^+ \qquad (3)$$

In the present case, further binding of Ag^+ ion to the thiolate might be facilitated to form complex (**7**) in the presence of free Ag^+ ion. Thus complexes formed from **1** and $AgClO_4$ are formulated as follows.



(4)

The IR spectrum of a THF solution of mono(*S*-ester) is shown in Fig. 6. In the presence of more than 3 equivalents of $AgClO_4$ to **1**, >C=O stretching band shifted from 1670 cm^{-1} to 1640 cm^{-1}, which might be attributed to the formation of the complex **7**.

Complex Formation from $AgClO_4$ and Cyclohexylamine. Ag^+ ion is known to form 1:1 and 1:2 complexes with amines in aqueous media.[8] Here the complex formation of $AgClO_4$ with cyclohexylamine in THF was examined by the molar ratio method in the presence of mono(*S*-ester) **1**. Figure 7 shows the change of absorbance at 260 nm against the molar ratio of cyclohexylamine to $AgClO_4$ with a fixed concentration of $AgClO_4$ (7.96×10^{-4} M) and **1** (3.92×10^{-4} M). The line bent gradually at a ratio of 1 and broke

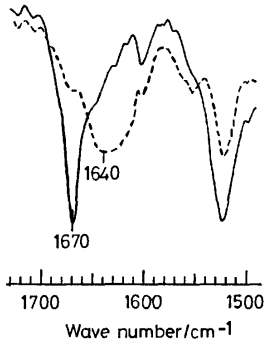


Fig. 6. IR spectra of **1** in THF.
—: **1**, ----: **1** and 3 eq. of $AgClO_4$.

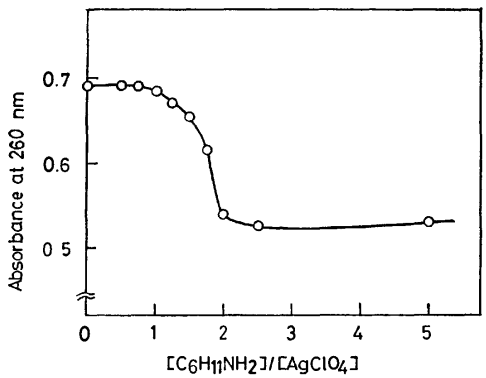

Fig. 7. Change of $A_{260\ nm}$ in molar ratio method by complex formation from $AgClO_4$ and cyclohexylamine in the presence of **1**, $[1]=3.9\times10^{-5}$ M, $[AgClO_4]=8.0\times10^{-4}$ M.

sharply at a ratio of 2. These results suggested that $AgClO_4$ might form a 1:1 complex (**8**) and a tight 1:2 complex (**9**) with cyclohexylamine (Eq. 5), and each complex formed further complex with mono(*S*-ester) **1** to cause the spectral change.

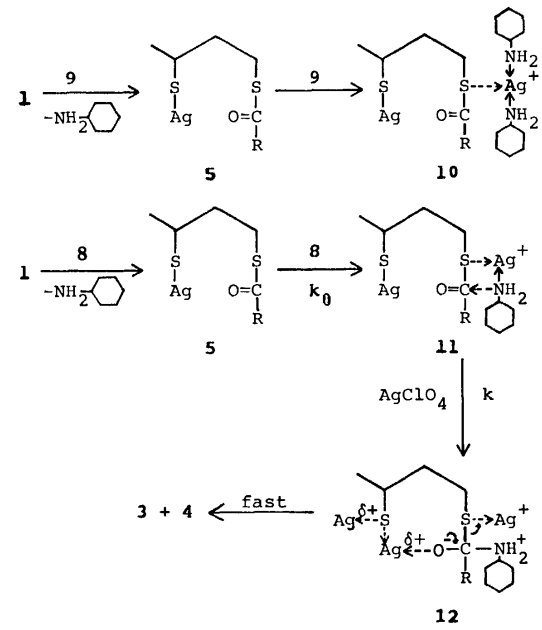
9

Mechanism of Acyl Activation by Silver Ion. From the results of kinetics and complex formation, Scheme 1 may be proposed for the silver ion-promoted aminolysis of mono(*S*-ester) **1** with cyclohexylamine.

At the lower concentration of $AgClO_4$, silver ion exists mainly in the form of complex **9** (Eq. 5), where silver ion has less affinity to sulfur atom, caused by the coordination of two basic ligands, therefore, the complex (**10**) losely formed from **1** and **9** showed no further change. Increasing the concentration of $AgClO_4$, complex **8** coexists with **9** following to Eq. 5 and complex **5** is formed immediately from **1** and **8**, corresponding to the spectral change from (A) to (B). Complex (**11**) is further formed from **5** and **8** which might be derived from the stronger affinity of one-coordinated silver ion to sulfur atom compared



Scheme 1. Proposed mechanism.

to the two-coordinated one, corresponding to the spectral change from (B) to (C). The increase of the rate constant k_0 obtained from the spectral change of (B) to (C) by increasing the concentration of $AgClO_4$ might therefore correspond to the resulting increase of the concentration of **8**.

At the higher concentration of $AgClO_4$, active intermediate (**12**) would be formed from **11** in the presence of free silver ion to result in the activation of acyl group by interaction between Ag^+ ion binding to –SAg and >C=O group, which is well correlated to the lowering shift of >C=O band[9] in the IR spectrum of **1** in the presence of three equivalents of $AgClO_4$ (Fig. 6). Amide **3** and complex **4** are formed from **11** *via* activated intermediate **12**, corresponding to the spectral change from (C) to (D). Linear dependence of k on the concentration of $AgClO_4$ at this region is well correlated to Scheme 1.

In the presence of excess cyclohexylamine, the formation of **12** is suppressed by consumption of both free Ag^+ ion and complex **8** following to Eq. 5, which is also correlated to the rate-retardation at the higher concentration of amine as shown in Fig. 3.

Thus the acceleration effect of silver ion on the aminolysis of thiol ester having neighboring mercapto group is explained by the binding of 2 equivalents of silver ion to the mercapto group to lead to the activation of acyl group.

On the other hand, in the case of aminolysis of di(*S*-ester) **2**, the rate was accelerated linearly by increasing the concentration of $AgClO_4$ in the region that complex **8** was formed mainly. These results suggest that the rate-limiting step in this case is the binding of complex **8** to **2**, as reported in the case of aminolysis of *S*-ethyl thiobenzoate,[1b] where the acyl group was not so much activated as in the case of aminolysis of **1**. Therefore, the rate enhancement remained less than that in the aminolysis of **1** as shown in Fig. 1.

Takagi *et al.*[10] have reported the accelerated reaction of *S*-acyldihydrolipoic acid and alcohol with iodine. However, the probability of similar oxidative activation resulted in the formation of lipoic acid structure (S–S formation) with silver ion as formulated in Eq. 6 was ruled out in our case from the analysis of the reaction product **4**, as described in the experimental section.

Platinum Chloride–Diphosphine–Tin(II) Halide Systems as Active and Selective Hydroformylation Catalysts

Teruyuki HAYASHI,* Yasuziro KAWABATA, Toyoshiro ISOYAMA, and Ikuei OGATA
National Chemical Laboratory for Industry, Yatabe, Ibaraki 305
(Received January 8, 1981)

The hydroformylation of 1-alkenes was efficiently catalyzed by $PtCl_2$–diphosphine–SnX_2 systems whose diphosphines were 1,4-bis(diphenylphosphino)butane derivatives with rigid ring skeletons. The effects of the structure of diphosphines, the P/Pt atomic ratio, the sort of tin(II) halide or solvent, the reaction variables, and the structure of olefins on the relative rate and the product distribution were investigated. A higher reaction rate than when using $HRh(CO)(PPh_3)_3$, and a linearity of aldehydes up to 99%, were attained. The coordination structure of the effective diphosphines as well as the reasons for the rate enhancement and for the excellent selectivity were discussed.

Industrial hydroformylation processes have been carried out by the use of cobalt or rhodium-complexes as catalysts.[1] Of the two, the latter has been known to be 10^3 times more active than the former.[2] On the other hand, platinum-tin-complex catalysts were investigated by Orchin *et al.*[3] or by Knifton *et al.*[4] with triphenylphosphine as a ligand. They reported that the complex is more active than cobalt-complexes, but far less active than rhodium-complexes, and that, moreover, it gives aldehydes with a high molar ratio of a linear aldehyde to the total aldehydes from a 1-alkene without the addition of any excess of the phosphine. It has also been reported[4] that the activity of the complex was markedly reduced by the addition of 1,2-bis(diphenylphosphino)ethane which can make up a strong chelate ring.

The present authors have found, however, in the course of the study of asymmetric induction in the hydroformylation of butenes using the $PtCl_2$((−)-DIOP)–$SnCl_2$ system,[5] that (−)-DIOP, (4*R*,5*R*)-2,2-dimethyl-4,5-bis(diphenylphosphinomethyl)-1,3-dioxolane, strikingly raises the activity of the platinum-tin system, though it is one of the chelating phosphines. Through a study using $Ph_2P(CH_2)_nPPh_2$,[6] it was revealed that the diphosphine of $n=4$ is particularly effective, while (−)-DIOP is even more so. In this paper, the full details of the study will be described, along with those of further studies undertaken to elucidate the structure of the active catalyst species and the cause of the marked enhancement of the catalytic activity and the selectivity for linear aldehyde.

Experimental

1-Pentene was degassed before use. Thiophene-free benzene was dried over Na and distilled under N_2. The hydrogen was of a pure grade (99.99%), while the CO was of a research grade (99.95%).

The $PtCl_2(PhCN)_2$,[7] (1*R*,2*R*)-1,2-bis(diphenylphosphinomethyl)cyclohexane (II),[8] *trans*-1,2-bis(diphenylphosphinomethyl)cyclopentane (III),[9] (−)-DIOP,[10] (1*S*,2*S*)-1,2-bis(diphenylphosphinomethyl)cyclobutane (IV),[8] *trans*-1,2-bis(diphenylphosphinooxy)cyclopentane (VI),[11] and 1,4-bis(dicyclohexylphosphino)butane (VIII)[12] were prepared according to the literature. The $HRh(CO)(PPh_3)_3$ was purchased (Strem). The (+)-DIOP was presented by Dr. Iwao Ojima, Sagami Chemical Research Center. All the manipurations to prepare phosphines were carried out under N_2.

trans-2,3-Bis(diphenylphosphinomethyl)norbornane (V). To an ether (100 cm³) suspension of $LiAlH_4$ (7.8 g) was added an ether (800 cm³) solution of *trans*-5-norbornene-2,3-dicarboxylic acid[13] at a rate to maintain a gentle reflux. After a refluxing for further 40 min, water (7.8 cm³), 15% NaOH aq. solution (7.8 cm³) and three portions of water (7.8 cm³ × 3) were added to the cooled solution succesively. After the decomposition was complete, the solution was filtered to separate the precipitate and was dried over Na_2SO_4; this afforded 10.2 g (98%) of *trans*-5,6-bis(hydroxymethyl)-2-norbornene.

A methanol (100 cm³) solution of the diol was added to a methanol (10 cm³) suspension of PtO_2 (0.25 g), and the mixture was stirred under a H_2 atmosphere for 6 h at room temperature until the gas absorption ceased. The filtrate gave *trans*-2,3-bis(hydroxymethyl)norbornane (9.6 g, 93%). The diol was then dissolved in dry pyridine (50 cm³) and added to a pyridine (110 cm³) solution of tosyl chloride (35 g) at −20 °C. The solution was stirred for 4 h, while the temperature was allowed to rise to room temperature. The mixture was then poured into 250 cm³ of ice water, and the colorless precipitate thus formed was separated by filtration and dried *in vacuo*. Recrystallization from MeOH gave 25.8 g (90%) of the ditosylate; mp 101.8—102.8 °C.

The diphosphine was obtained from the ditosylate as a viscous oil according to the procedure in Ref. 8, bp 226—228 °C (bath temperature)/4×10^{-2} Pa, 16.6 g (78%). Found: C, 80.32; H, 7.06%. Calcd for $C_{33}H_{34}P_2$: C, 80.47; H, 6.96%.

2-endo-3-endo-2,3-Bis(diphenylphosphinomethyl)norbornane (XI). 2-*endo*-3-*endo*-2,3-Bis(hydroxymethyl)norbornane[14] (3.1 g) was ditosylated as above and recrystallized from MeOH; 4.6 g (51%). The diphosphine was again prepared according to Ref. 8 as a viscous oil; bp 245—248 °C (bath temperature)/5×10^{-2} Pa, 1.3 g (27%). Found: C, 79.84; H, 6.96%. Calcd for $C_{33}H_{34}P_2$: C, 80.47; H, 6.96%.

cis-1,2-Bis(diphenylphosphinomethyl)cyclohexane (X). X was prepared from the corresponding ditosylate as a viscous oil according to the procedure used for the *trans*-isomer II; bp 215—220 °C (bath temperature)/5×10^{-2} Pa. 65% Yield. Found: C, 79.88; H, 7.15%. Calcd for $C_{32}H_{34}P_2$: C, 79.98; H, 7.13%.

α,α′-Bis(diphenylphosphino)-o-xylene (VII). α,α′-Dibromo-*o*-xylene (Tokyo Kasei) (11 g) was added to a solution of $LiPPh_2$ (prepared from 21.8 g of PPh_3 and 2.6 g of Li in THF (140 cm³), followed by *t*-BuCl treatment) at 0 °C. After the addition, the mixture was stirred as the temperature rised and refluxed for 30 min. After the solution had cooled, the THF was removed and 40 cm³ of water was added. The diphosphine was extracted with benzene (100 cm³, 50 cm³ × 2) and recrystallized from EtOH–benzene twice; 13.4 g

(68%); mp 117.0—118.0 °C. Found: C, 81.58; H, 6.08%. Calcd for $C_{32}H_{28}P_2$: C, 81.00; H, 5.95%.

α,α'-Bis(diphenylphosphino)-p-xylene (IX). IX was prepared as above from α,α'-dibromo-*p*-xylene (6.1 g) and recrystallized from toluene; 5.5 g (50%); mp 177—179 °C. Found: C, 80.92; H, 6.03%. Calcd for $C_{32}H_{28}P_2$: C, 81.00; H, 5.95%.

Hydroformylation Procedure. A typical procedure was as follows: $PtCl_2(PhCN)_2$ 3.2×10^{-5} mol, (−)-DIOP 3.2×10^{-5} mol, and $SnCl_2\cdot2H_2O$ 1.6×10^{-4} mol were placed in a 50 cm³ Schlenk-tube type high-pressure reactor made of SUS-316, whose inside atmosphere was then replaced by N_2 (99.995%). Benzene (18 cm³) and 1-pentene (3 cm³) were added by the use of syringes. Carbon monoxide was pressurised up to 50 kg/cm² (at room temperature); then H_2 (up to 100 kg/cm²) was added into the reactor, and then heated in a 100 °C oil bath with magnetic stirring. The maximum slope of the pressure-*vs.*-time plot, recorded automatically, was adopted as the measure of the relative rate. The rate in the above reaction when $2PPh_3$ was used in place of (−)-DIOP was taken as the base (100). After the pressure drop had ceased, the reactor was cooled and the residual gas (which was usually about 65 kg/cm² at room temperature) was discharged. The reaction solution was then subjected to GLC analysis. Hydrocarbons were analyzed by gas chromatography on a Shimadzu GC-4B apparatus equipped with a column (2 mm i.d.×3 m) of VZ-7 at room temperature. The aldehydes were analyzed on a Shimadzu GC-4A apparatus with a Golay column of DDP-90 at 60 °C.

Results

Catalytic reactions were conducted with the amounts of platinum complexes of 3.2×10^{-5} mol in Figs. 1, 3, and 5, and Tables 2—4, or of 3.2×10^{-6} mol in Figs. 4, 7—13, and Table 1.

Effect of the Structure of Diphosphines. Several α,ω-bis(diphenylphosphino)alkanes, $Ph_2P(CH_2)_nPPh_2$ (n=1—6, 10), were used for activating the $PtCl_2$-$(PhCN)_2$–$SnCl_2\cdot2H_2O$ system as hydroformylation catalysts and compared with PPh_3. The results are presented in Fig. 1. Bis(diphenylphosphino)methane as well as 1,2-bis(diphenylphosphino)ethane were almost completely ineffective. The diphosphine of n=3 was equally as effective as PPh_3, and the rate enhancement effect attained maximum at n=4, where the reaction rate observed was several times higher than when PPh_3 was used. When n exceeded four, the effectiveness was reduced abruptly, and it gradually vanished. The linearity of the aldehydes formed, *i.e.*, the molar ratio of hexanal to the total aldehydes formed (hexanal, 2-methylpentanal, and 2-ethylbutanal) was 91—94%, and it did not greatly depend on the n of $Ph_2P(CH_2)_nPPh_2$ except in the case of n=3 in which the linearity was reduced to *ca.* 69%. This exceptional linearity at n=3 may be caused by the instability of the chelating coordination because of the steric repulsion of 1,3-diaxial phenyl groups of the six-membered chelate ring, which is made up by the coordination of the two phosphorus atoms to the platinum center. A similar exception to the regioselectivity of hydroformylation has been observed in the rhodium-diphosphine-catalyzed reaction of methyl methacrylate or methyl crotonate using $Ph_2P(CH_2)_3PPh_2$.[15]

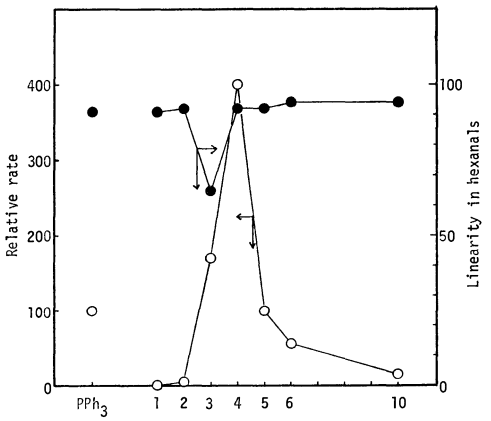

Fig. 1. Effect of methylene chain length of diphosphine ligands in $PtCl_2(PhCN)_2$–$SnCl_2\cdot2H_2O$-catalyzed hydroformylation of 1-pentene.
1-Pentene 3 cm³, benzene 18 cm³, $PtCl_2(PhCN)_2$ 3.2×10^{-5} mol, Pt/P/Sn=1/2/5 (atomic ratio), p(CO)=p(H_2)=50 kg/cm² initial at room temperature, reaction temperature 100 °C.

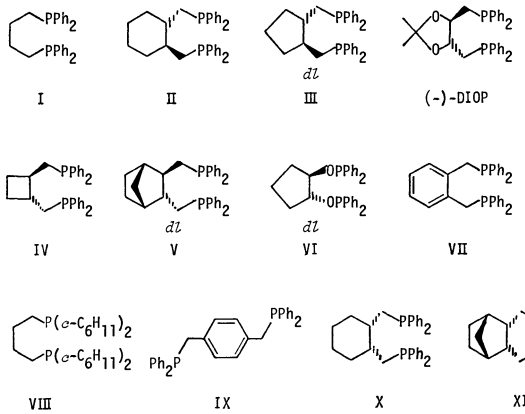

Fig. 2. Bidentate phosphorus ligands used with $PtCl_2$-$(PhCN)_2$–SnX_2 system.

In order to clarify the effect of the structure of the derivatives of 1,4-bis(diphenylphosphino)butane (I) and related compounds on the reaction rate and the product distribution, several diphosphines and phosphorus ligands capable of forming a seven-membered chelate ring like I were prepared and applied to the reactions (Fig. 2). The results are compared with that using the $HRh(CO)(PPh_3)_3$ catalyst. In these reactions, the catalyst concentration was reduced to one-tenth of that in Fig. 1 so that reaction rate could be compared exactly (Table 1).

Under these reaction conditions, the rate-enhancement effect of I (Run 2) was 7.5 times higher than that of PPh_3. It is noteworthy, however, that the reaction time required for complete conversion using I was incomparably shorter than that using PPh_3, because the dependence on the olefin concentration of a reaction rate using a diphosphine was smaller than that of one using PPh_3 as will be discussed later.

The effectiveness of I was further enhanced by bridging the 2- and 3-carbon to construct a rigid and

1-Pentene, 3 cm³; benzene, 18 cm³; $PtCl_2(PhCN)_2$, 3.2×10^{-6} mol; $SnCl_2\cdot2H_2O$, 1.6×10^{-5} mol; Pt/P = 1/2 (atomic ratio), $p(CO)=p(H_2)=50$ kg/cm² at room temperature; reaction temperature, 100 °C.
a) The maximum rate of the pressure drop in Run 1 was taken as the base (10). b) $p(CO)=150$ kg/cm². c) Rh: $HRh(CO)(PPh_3)_3$. d) Pt or Rh 3.2×10^{-5} mol, reaction temperature 70 °C. e) The molar ratio of each product. The deficiency was ascribed to some high-boiling product which might be formed through the condensation of aldehydes.

saturated ring skeleton. Both the reaction rate and the product linearity increased distinctly upon the use of *trans*-1,2-bis(diphenylphosphinomethyl)cyclopentane (III) (Run 4), and they increased further upon the use of (1*S*,2*S*)-1,2-bis(diphenylphosphinomethyl)cyclobutane (IV) with a saturated four-membered ring (Run 9). The effectiveness of (1*R*,2*R*)-1,2-bis(diphenylphosphinomethyl)cyclohexane (II) as a ligand (Run 3) was almost identical with that of I; that is, the attempt at the construction of a flexible six-membered ring skeleton was ineffective. The higher effectiveness of (−)-DIOP (Run 5) than that of III (Run 4) may be due to the somewhat smaller size of the dioxolane ring than that of the cyclopentane ring.

These diphosphines, however, accelerated not only the hydroformylation reaction, but also such side reactions as the hydrogenation[16] and isomerization of the olefin. Of course, the side reactions could be diminished by raising the carbon monoxide partial pressure, as is shown by the comparison of Runs 5 and 8. Even in this case, however, the reaction rate was not sacrificed because of the nearly zero-order rate dependence on the pressure, which will be discussed later. By the use of IV, which has a more rigid ring skeleton, the relative rate was increased 31 times in comparison with that when PPh_3 was used, and the product linearity was raised up to 99%. The reaction rate observed using IV was apparently higher than that in the reaction catalyzed by $HRh(CO)(PPh_3)_3$ in the absence of excess PPh_3 (Run 11). The superiority of the $PtCl_2$–IV–$SnCl_2\cdot2H_2O$ system to $HRh(CO)(PPh_3)_3$ was distinctly shown in the reactions with higher catalyst concentrations at the lower reaction temperature of 70 °C (Runs 14 and 15).

A bicyclic diphosphine, *trans*-2,3-bis(diphenylphosphinomethyl)norbornane (V) (Run 10), showed the highest effectiveness as a catalyst ligand; the observed relative rate was 44 times higher than that observed using PPh_3.

As has been shown by Knifton *et al.*[4] with various monodentate ligands, such as PPh_3 or $P(n\text{-}Bu)_3$, the electronic effect of phosphines did not influence the result in Pt-Sn catalyzed hydroformylation very much. This was fairly true for bidentate ligands; *trans*-1,2-bis(diphenylphosphinooxy)cyclopentane VI (Run 12) and III (Run 4), which are sterically similar but electronically different, gave similar results. Further, α,α′-bis(diphenylphosphino)-*o*-xylene VII (Run 13), which must be electronically different from II, caused an activity similar to that caused by II. Thus, the effectiveness of diphosphines as catalyst ligands is considered to be determined mainly by a steric factor. However, the difference in electron-donating ability between a diarylphosphino group and a dialkylphosphino one may be multiplied when they are in bidentate ligand. In fact, 1,4-bis(dicyclohexylphosphino)-butane (VIII) (Table 2) was far less effective than I, and also less effective than the monodentate ligand PPh_3, probably because its donating ability is too high.

In order to elucidate the further steric requirements, closely related isomers of diphosphines were prepared and their degrees of effectiveness were compared. The catalyst-system concentration was the same as in Fig. 1 (Table 2). α,α′-Bis(diphenylphosphino)-*p*-xylene (IX), which is unable to effect chelation, was distinctly less effective than the position isomer, VII, and also

less effective than monophosphines. On the other hand, among the stereo isomers of 1,2-bis(diphenylphosphinomethyl)cyclohexanes (II and the *cis*-isomer X) and 2,3-bis(diphenylphosphinomethel)norbornane (V and the *endo*, *endo*-isomer XI), *cis*-isomers were half as effective as the corresponding *trans*-isomers. That is, a *trans*-configuration of the ring skeleton of the diphosphines was more favorable to rate enhancement than a *cis*-configuration, although the former seems to be fairly disadvantageous to chelating coordination.

Effect of P/Pt Atomic Ratio. It is well known that the amount of excess phosphine plays a significant role in the activity and selectivity of rhodium catalysts in hydroformylation.[17] However, in the $PtCl_2$–$SnCl_2$ catalyzed hydroformylation,[4] it was reported only that excess PPh_3 retarded the reaction, even at P/Pt=4. In contrast with this, the effect of the P/Pt ratio of diphosphines on the reaction rate was more serious than has been expected, as is shown in Fig. 3. That is, the optimum P/Pt ratio to attain the maximum reaction rate was between 1.0 and 2.0, but not so distinct when a monophosphine such as PPh_3 or PPh_2Et was used. In contrast, when diphosphine I was used, the optimum P/Pt value increased to 2.0 and became distinct. By the use of a more effective diphosphine, (−)-DIOP, this value became about 2.5—3.0. That is, the more effective the ligand, the higher the optimum P/Pt atomic ratio.

By the use of the most effective ligand, V, the effect of the P/Pt ratio was investigated with a catalyst amount one-tenth of that in Fig. 3. At this concentration, the optimum ratio of (−)-DIOP increased somewhat to about 3 as is shown in Fig. 4, while the reaction rate obtained by the use of V showed a plateau between 2.0—3.5 values of the P/Pt ratio.

Effect of Tin (II) Halide. It has been reported that the effectiveness of tin(II) halide as a cocatalyst for $PtCl_2(PPh_3)_2$ was in the order of $SnCl_2 \cdot 2H_2O$>

The reaction conditions are the same as in Table 2.

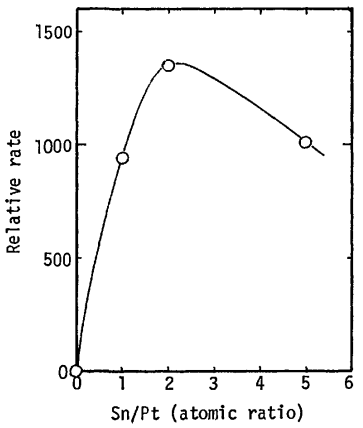

Fig. 5. Effect of tin to platinum ratio in $PtCl_2(PhCN)_2$–(−)-DIOP–$SnCl_2 \cdot 2H_2O$-catalyzed hydroformylation of 1-pentene.
Reaction conditions are the same as in Fig. 1 except $SnCl_2 \cdot 2H_2O$ amount.

$SnBr_2 > SnI_2$.[4] Tin(II) fluoride, which had not yet been used, was less effective than bromide (Table 3). However, the fluoride was more effective than $SnBr_2$, and as effective as $SnCl_2 \cdot 2H_2O$, when a diphosphine, (−)-DIOP, was used. Although it is uncertain how much SnX_2 operates as an anionic ligand, SnX_2Cl, as in the case of $SnCl_2$,[18] these results indicated that the effect of a cocatalyst was different depending on whether a phosphorus ligand was monodentate or bidentate.

The effect of the Sn/Pt atomic ratio was examined by the use of the most effective $SnCl_2 \cdot 2H_2O$ as a cocatalyst for $PtCl_2$–(−)-DIOP-system; the results are shown in Fig. 5. The system had no activity without tin(II) halide, and the significant activity appeared even at Sn/Pt=1, which suggests that one $SnCl_3$ group is necessary for, and also enough for the catalytically active species.

Choice of Solvent. The effect of the solvent on the reaction rate using the $PtCl_2$–diphosphine–$SnCl_2$ system was examined, the results are listed in Table 4. The relative rate was the highest when benzene or CH_2Cl_2 was used. In the latter, however, the linearity was low (89%), and, after the reaction, some metal deposit was observed. Acetone, which was one of the best solvents for the $PtCl_2(PPh_3)_2$–$SnCl_2$ system,[4] was not so suitable for the diphosphine system. Thus, it was best to carry out the reaction in benzene when diphosphines were used.

TABLE 4. RELATIVE RATE IN THE HYDROFORMYLATION OF 1-PENTENE CATALYZED BY $PtCl_2(PhCN)_2$–(−)-DIOP–$SnCl_2 \cdot 2H_2O$ IN VARIOUS SOLVENTS

Solvent	Relative rate
Benzene	1010

Acetone	350
THF	170
CH_3CN	130
Hexane	45
MeOH	5

The reaction conditions are the same as in Table 2 except for the solvent.

Effect of Reaction Variables. A diphosphine must coordinate to a platinum-metal center competing with olefin, hydrogen, and carbon monoxide. Therefore, the behavior of a diphosphine can be clarified if the effect of the catalyst or olefin concentration and the H_2 and CO partial pressure are examined. Thus, these variables were altered by the use of (−)-DIOP and benzene as diphosphine and solvent respectively, and the relative rate was measured.

The relative rate was plotted full-logarithmically against the charged amount of the catalyst system. The slope means that the order to the catalyst concentration was about 0.7 (Fig. 6)

On the other hand, the relation between the initial olefin concentration and relative rate (Fig. 7) showed the order of *ca.* 0.3, which was remarkably low for the dependence on the olefin concentration in hydroformylation. Hence, the reaction rate was nearly constant until almost all the olefin had been consumed, and the total reaction time required for a complete conversion was remarkably shorter than would be expected from the relative rate comparison between

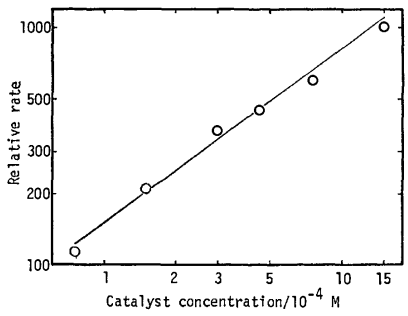

Fig. 6. Full-log plot of relative rate *vs.* catalyst system concentration in $PtCl_2(PhCN)_2$–(−)-DIOP–$SnCl_2 \cdot 2H_2O$-catalyzed hydroformylation of 1-pentene.

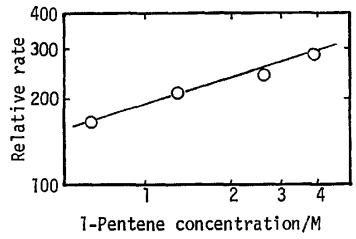

Fig. 7. Full-log plot of relative rate *vs.* 1-pentene concentration in $PtCl_2(PhCN)_2$–(−)-DIOP–$SnCl_2 \cdot 2H_2O$ catalyzed hydroformylation of 1-pentene.
Reaction conditions are the same as in Table 1 except 1-pentene concentration.

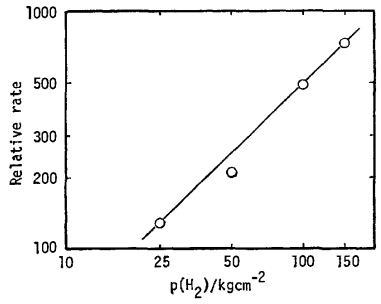

Fig. 8. Full-log plot of relative rate *vs.* $p(H_2)$ (initial at room temperature) in $PtCl_2(PhCN)_2$–(−)-DIOP–$SnCl_2 \cdot 2H_2O$-catalyzed hydroformylation of 1-pentene.
Reaction conditions are the same as in Table 1 except $p(H_2)$.

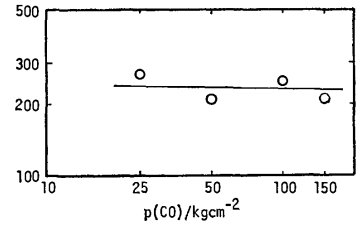

Fig. 9. Full-log plot of relative rate *vs.* p(CO) (initial at room temperature) in $PtCl_2(PhCN)_2$–(−)-DIOP–$SnCl_2 \cdot 2H_2O$-catalyzed hydroformylation of 1-pentene.
Reaction conditions are the same as in Table 1 except p(CO).

the case of (−)-DIOP and that of PPh_3.

The rate was proportional to the H_2 partial pressure, $p(H_2)$ (Fig. 8). The reaction order was almost 1.0 with respect to $p(H_2)$, as in other hydroformylation catalyst systems. On the other hand, the rate hardly depended on p(CO) at all, and Fig. 9 indicates an order of nearly zero.

The product distribution virtually did not depend at all on the reaction variables except on the partial pressures of CO and H_2. Isomerization was suppressed by increasing $p(H_2)$ or p(CO), while hydrogenation was suppressed by increasing p(CO) or decreasing $p(H_2)$.

Although the kinetic order described above was rather qualitative, the results can be represented by the following rate expression in the range of the above-mentioned reaction conditions:

$$\text{Rate} \propto [\text{Pt}]^{0.7}[\text{1-Pentene}]^{0.3}p(H_2)^{1.0}p(\text{CO})^{0.0}. \quad (1)$$

Effect of the Structure of Olefins. In the previous sections, 1-pentene has been used as the substrate because it is easy to handle and also easy to analyze the isomerization or hydrogenation products. The present catalyst system was further applied to propene or 1-butene hydroformylation, and the results were compared with that of 1-pentene. As is shown in Fig. 10, the shorter a 1-alkene was, the lower the product linearity. However, the effect of the rigid ring skeleton of a diphosphine on the linearity became distinct with shorter olefins.

Internal olefins reacted only sluggishly. For example, the rate of *cis*-2-pentene hydroformylation was one twentieth that of 1-pentene, and the product was composed of aldehydes (linearity 65%) 43%, *trans*-2-pentene 38%, *cis*-2-pentene 11%, and pentane 4%.

Effect of Temperature. The hydroformylation of propene was carried out at various temperatures between 80—140 °C by the use of the $PtCl_2$–IV–$5SnCl_2 \cdot 2H_2O$ catalyst system (Fig. 11). Lowering the reaction temperature improved the yield of aldehydes, which means the competitive hydrogenation or aldehyde loss was almost entirely suppressed. The linearity in aldehydes was also improved by lowering the temperature.

Effect of Total Pressure. It is important, from the industrial point of view to know to what degree

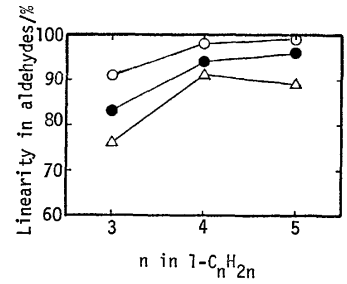

Fig. 10. Effect of the structure of diphosphines and the chain length of 1-alkene on the selectivity to the straight-chain aldehyde.
Other conditions are the same as in Table 1. ○: IV, ●: (−)-DIOP, △: II.

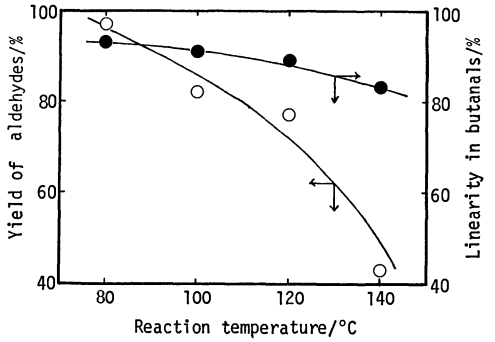

Fig. 11. Effect of reaction temperature in the hydroformylation of propene catalyzed by $PtCl_2(PhCN)_2$–IV–$SnCl_2 \cdot 2H_2O$-system.
Propene(l) 3 cm³, other conditions are the same as in Table 1 except reaction temperature.

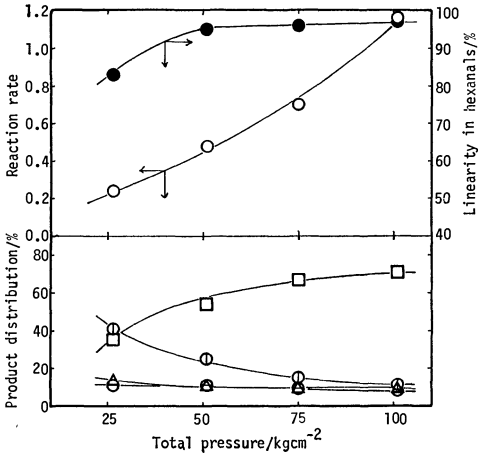

Fig. 12. Effect of total pressure ($CO/H_2=1$) on the product distribution, linearity in the aldehydes, and reaction rate in $PtCl_2(PhCN)_2$–(−)-DIOP–$SnCl_2 \cdot 2H_2O$-catalyzed hydroformylation of 1-pentene at constant pressure.
Reaction conditions are the same as in Table 1 except gas pressures. □: Hexanals, △: pentane, ⓘ: *trans*-2-pentene, ⊖: *cis*-2-pentene.

the total gas pressure can be lowered. Thus, 1-pentene was hydroformylated by the use of $PtCl_2(PhCN)_2$–[(−)-DIOP]–$SnCl_2 \cdot 2H_2O$ (Pt/P/Sn=1/2/5, atomic ratio) at a constant pressure (Fig. 12). Lowering the pressure decreased the relative rate, as was expected from the effect of partial pressures shown in Figs. 8 and 9. Aldehyde linearity was almost constant down to a pressure of 50 kg/cm², but it was lowered gradually below that pressure. The product distribution showed an interesting pattern; with a lowering of the total pressure, the yield of aldehydes was decreased until *ca.* 35% at 25 kg/cm², while those of *cis*-2-pentene and pentane remained almost constant, and only that of *trans*-2-pentene increased.

Also, in the reaction of propene carried out by the use of the most active catalyst system, $PtCl_2(PhCN)_2$–V–$SnCl_2 \cdot 2H_2O$, at the optimum atomic ratio of Pt/P/Sn (1/3/2.5) (Fig. 13), the relative rate decreased with a lowering of the pressure, as above. On the other hand, the yield of aldehydes and its

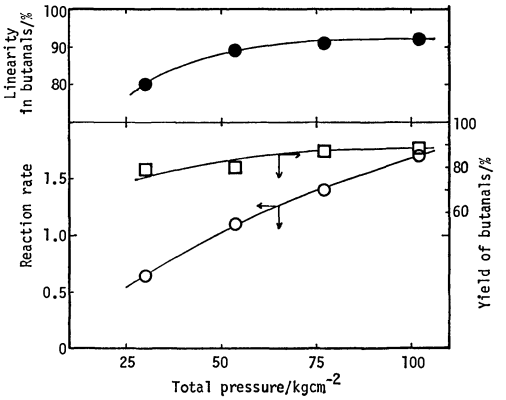

Fig. 13. Effect of total pressure ($CO/H_2=1$) on $PtCl_2(PhCN)_2$–V–$SnCl_2 \cdot 2H_2O$ catalyzed hydroformylation of propene at constant pressure.
Propene(l) 3 cm³, Pt/P/Sn=1/3/2.5, other conditions are the same as in Table 1 except gas pressures.

linearity was not so much lowered, because the isomerization of the olefin is excluded; *i.e.*, even at a total gas pressure of 25 kg/cm², both values were more than 80%.

Discussion

The rate-enhancement effect of diphosphines in hydroformylation has been observed in the rhodium-catalyzed reaction of 1-alkenes by the use of $Ph_2P(CH_2)_nPPh_2$ (n=2—4)[19] or IV.[20] However, the degree of the enhancement was low, *i.e.*, two times at the most. These effects can be interpreted as showing that a little excess of diphosphine plays the role of a large excess of monophosphine in keeping the rhodium complex catalytically active by coordination. The effect became more distinct in the rhodium-catalyzed hydroformylation of ethyl acrylate.[15] However, the operating mechanism of diphosphines in the rate enhancement seems to be qualitatively different from that of the platinum–diphosphine-catalyzed hydroformylation presented in this paper, because, in the rhodium-catalyzed reaction, $Ph_2P(CH_2)_nPPh_2$ are effective only for ethyl acrylate, and the diphosphines of n=2 and 3, which were ineffective in the platinum-catalyzed reaction, also accelerated this reaction.

Figure 14 shows the conceivable coordination types of diphosphines in square-planar platinum complexes. Among these, **A** was postulated for the $PtCl(SnCl_3)$-[(−)-DIOP] complex.[21] A complex of the **B** type was prepared with $(t\text{-Bu})_2P(CH_2)_nP(t\text{-Bu})_2$, $n \geqq 9$.[22] A di- or trinuclear complex of the **C** or **D** type was isolated by the use of $Ph_2P(CH_2)_nPPh_2$ of n=3 or 4 respectively.[23]

As has been reported in Ref. 4, 1,2-bis(diphenylphosphino)ethane, which is known to form a complex of the **A** type, inhibited the reaction almost completely. Moreover, $Ph_2PCH_2PPh_2$ was also completely ineffective (Fig. 1), and the recovered precipitate in the reaction solution showed a ^{31}P NMR spectrum which was ascribable to a chelating form rather than a bridged one.[24] However, many results in this paper support the idea that the active species has a form

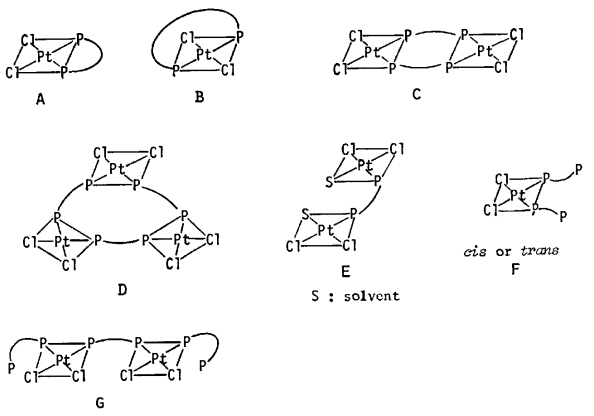

Fig. 14. Conceivable coordination types of diphosphines in square planar platinum complexes.

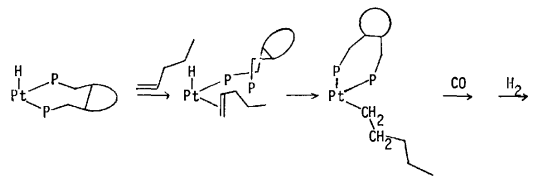
of the **A** type, where the chelating coordination is rather loose. In $Ph_2P(CH_2)_nPPh_2$ (n=1—10), only that of n=4 was prominent as a catalyst ligand (Fig. 1), and so the possibility of **B**-type coordination can be excluded. On the other hand, the possibility that a diphosphine bridges two platinum centers in the active species is negligible judging from the following considerations: 1) If the active species is a di- or trinuclear complex of the **C** or **D** type, with two or three bridging diphosphine molecules, the result of the reaction by the use of the *dl*-form of a diphosphine would be different from the result when only one antipode of the diphosphine is used, because the former might give a complex which has both antipodes. However, the result using *dl*-DIOP was almost the same as that when (−)-DIOP or (+)-one was used. 2) An α,α′-bis(diphenylphosphino)-*p*-xylene, IX, which is able to make only a bridging coordination, was much less effective than the *o*-isomer, VII, which is electronically similar to IX but which is able to form a *cis*-chelation complex of the **A** type. 3) The reaction rate depended on the charged-catalyst amount in the order of *ca.* 0.7 (Fig. 6), which may be due to the aggregation of the active species of the **A** type by the formation of inactive bridging complexes, such as **C** or **D**, with an increase in the catalyst concentration. Thus, the bridging-type coordination of **C** and **D** can be excluded.

As is shown in Fig. 3, the effectiveness of diphosphines I and (−)-DIOP was extremely low at the P/Pt atomic ratio of 1, in contrast with the inefficiency at P/Pt=2, and there was no significant difference either in rate enhancement or in product linearity between diphosphines and monophosphines so long as the P/Pt ratio in the reaction system was 1. This result suggests that, even if another bridging complex of the **E** type is formed at P/Pt=1, it operates as if it were a monophosphine complex of P/Pt=1. On the other hand, the presence of excess diphosphine retarded the reaction distinctly; the relative rate at P/Pt=4 was similar to that using PPh_2Et at P/Pt=2, probably because the diphosphines at a high P/Pt ratio behave as monodentate ligands, as in Type **F** or **G**.

Rather high optimum ratios of P/Pt of *ca.* 3 was observed for diphosphines with a rigid ring skeleton, as is shown in Figs. 3 and 4. This may be explained as follows. Because of the steric rigidity, it is difficult for these diphosphines to make a *cis*-chelating coordination. Therefore, not enough of the catalytically active species of Type **A** is formed at P/Pt up to 2, while some bridged complexes, such as **C** and **D**, may be formed. When excess diphosphine is added, it may displace one phosphorus end of bridging diphosphine in, for example, **C** to make up a bridging complex such as **G**, whose P/Pt ratio is 3. This dinuclear complex then dissociates to give the active species, **A**, and the inactive complex, **F**. Thus, some excess of diphosphine is necessary to maximize the concentration of the active species, **A**.

On the other hand, the ineffectiveness of 1,2-bis(diphenylphosphino)ethane and 1,4-bis(dicyclohexylphosphino)butane indicates the necessity of the dissociation of a chelating diphosphine during the catalytic cycle. The necessity of the loose *cis*-chelation of a diphosphine can be explained as follows. In contrast with a rhodium or cobalt system, $SnCl_3$ is necessary as a supplementary ligand, and it is considered to occupy one coordination site throughout the catalytic cycle; moreover, one phosphorus atom, probably trans to $SnCl_3$, has to dissociate to provide a vacant site for the activation of olefin, CO, and H_2. As Pt–P bonds are comparatively stable,[25] the dissociation can not easily occur without the aid of the instability of a seven-membered chelate ring, which is increased by the construction of a rigid ring skeleton.

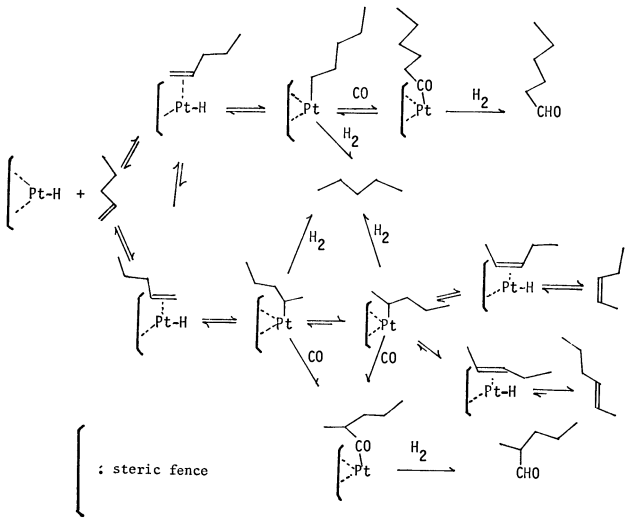


Scheme 1.

As is shown in Scheme 1, the reaction site for olefin is provided by the dissociation of one phosphorus end of the diphosphine, and the following *cis*-addition of H–Pt to the C=C bond of the olefin to give the σ-alkyl complex may be accelerated[26] by the recoordination of the dissociated phosphorus end, which is forced to be located near the reaction site by the steric bulkiness of the rigid ring skeleton of the diphosphine itself. This process may operate in successive steps of CO insertion and/or hydrogenolysis. In this manner, 1,4-bis(diphenylphosphino)butane derivatives can enhance the hydroformylation as well as competitive hydrogenation. On the other hand, the hydroformylation catalyzed by the $PtCl_2$–diphosphine–$SnCl_2\cdot 2H_2O$ system showed a low-order dependence of the rate on the CO partial pressure and on the olefin concentration in comparison with the reactions catalyzed by the $PtCl_2(PPh_3)_2$–$SnCl_2\cdot 2H_2O$ system,[4] $Co_2(CO)_8$,[27] and $Rh_4(CO)_{12}$[28] where the rate expressions were proportional to $[Pt]^{1.5}[Olefin]^{1.0}p(H_2)^{1.0}\cdot p(CO)^{-0.5}$, $p(H_2)/[p(H_2)+p(CO)]\times[Co][Olefin]$, and $[Rh][Olefin]p(H_2)/p(CO)$ respectively. The low dependence of the rate on [Olefin] suggests a spontaneous dissociation of one phosphorus end of the chelated

diphosphine, affording a vacant site. The low dependence on the CO partial pressure also suggests that the diphosphine keeps off the excess coordination of CO, which retards the reaction. However, the first-order dependence of the reaction rate on $p(H_2)$ is like that in a rhodium- or cobalt-catalyzed reaction, in which the rate-determining step is considered to be the hydrogenolysis of an acyl complex.

Not only the remarkable rate enhancement, but also the improvement of linearity in aldehydes produced was brought about by diphosphines bearing rigid ring skeletons. The linearity is originally as high as 92% (Table 1), even when the $PtCl_2(PPh_3)_2$–$SnCl_2 \cdot 2H_2O$ catalyst was used, much higher than when the $HRh(CO)(PPh_3)_3$ or cobalt catalyst was used, this difference may be ascribed to both the steric bulkiness of the $SnCl_3$ ligand and that of the two PPh_3 ones, which do not easily dissociate. The rigidity and bulkiness of the ring skeletons of diphosphines must cause a larger steric hindrance, not only when the diphosphine makes a *cis*-chelating coordination, but also when its one phosphorus end dissociates in order to receive substrate or reactant molecules.



Scheme 2.

The process of how a terminal olefin gives linear aldehyde is shown schematically in Scheme 2. The increase in isomerized *trans*-2-pentene in comparison with *cis*-pentene with a prolonged reaction time can also be explained by the scheme. The steric hindrance is considered to prevent *trans*-2-pentene from taking part in the catalytic cycle again.

The authors wish to thank Mr. Kazuteru Ebata and Mr. Yukio Izawa for their experimental assistance.

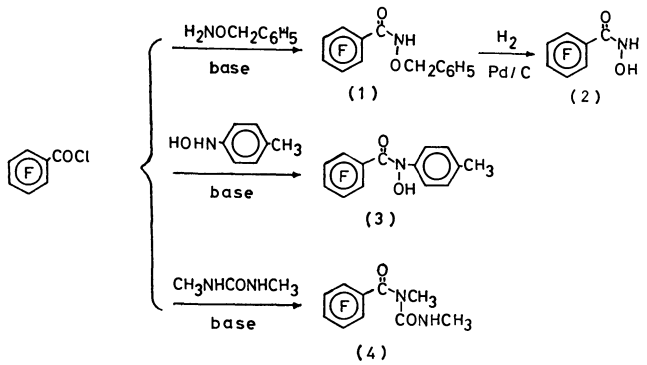
With the intention of achieving the selective *ortho*-substitution of *F*-benzoic acid and *F*-phenol *via* intramolecular nucleophilic cyclization, preparation of some requisite precursory *F*-benzoyl- and *F*-phenoxy compounds and their nucleophilic cyclization reactions were examined. 1,2-(*F*-Benz)isoxazol-3(2*H*)-one, 2-(*p*-tolyl)-1,2-(*F*-benz)isoxazol-3(2*H*)-one, 1,3-dimethyl(*F*-benzo)pyrimidine-2,4(1*H*,3*H*)-dione, and 1,4-(*F*-Benz)oxazin-3(2*H*)-one were obtained from the respective precursory *F*-benzohydroxamic acid, *N*-(*p*-tolyl)-*N*-hydroxy-*F*-benzamide, *N*,*N*'-dimethyl-*N*-(*F*-benzoyl)urea, and 2-(*F*-phenoxy)acetohydrazide. Attempted cyclizations of 2-(*F*-phenoxy)acetohydroxamic acid and (*F*-phenoxy)acetic acid were accompanied by simultaneous ring-opening and resulted in the formation of the identical product: (2-hydroxy-*F*-phenoxy)acetic acid. Transamidation of ethyl *F*-benzoate with hydroxylamine failed to give *F*-benzohydroxamic acid, which was then obtained by the catalytic debenzylation of *N*-benzyloxy-*F*-benzamide.

In the continuation of studies on the preparation of (*F*-benzo)heterocyclic compounds[1] from simple and readily accessible monofunctional *F*-benzenes by intramolecular cyclization,[2,3] syntheses and cyclization of some precursory compounds were investigated by use of *F*-benzoic acid and *F*-phenol as the starting substances.

Results and Discussion

Preparation of the Requisite Precursors. From F-Benzoic Acid: The precursory *F*-benzoyl compounds were fabricated by *F*-benzoylation of the amino compound carrying a cyclizing agent by use of *F*-benzoyl chloride, as shown in Scheme 1.

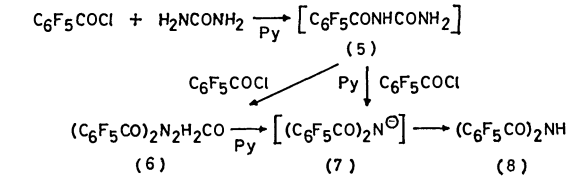


Scheme 1.

The oxygen in a *N*-hydroxycarbamoyl group is known to be one of the most effective nucleophiles, and is regarded as an effective cyclizing agent readily associable with an *F*-benzoyl group. Attempts to prepare *F*-benzohydroxamic acid (**2**)[4] from ethyl *F*-benzoate and hydroxylamine resulted in failure.[5] In the present case, *F*-benzohydroxamic acid (**2**) could be attained by the reductive debenzylation of *N*-benzyloxy-*F*-benzamide (**1**), which was derived from *F*-benzoyl chloride by the reaction with *O*-benzylhydroxylamine in the presence of base.

On the other hand, *N*-(*p*-tolyl)hydroxylamine reacted with *F*-benzoyl chloride to give *N*-(*p*-tolyl)-*N*-hydroxy-*F*-benzamide (**3**) in a usual manner.[6] Here, the *p*-tolyl group was introduced onto the amide nitrogen in such a way as to be favorable to the subsequent intramolecular cyclization due to its steric bulkiness.

The nitrogen of urea was also regarded as a nucleophile capable of replacing the fluorine atom on an *F*-phenyl nucleus. Then, we examined whether an *F*-benzoyl group could be combined with a urea molecule at the nitrogen only on one side. The reaction of *F*-benzoyl chloride with urea in the presence of pyridine, however, afforded none of the expected *N*-(*F*-benzoyl)urea (**5**). From the reaction mixture, di-(*F*-benzoyl)amine (**8**) was isolated and the mass spectrum of the crude product indicated the formation of a compound whose molecular weight corresponded to di(*F*-benzoyl)urea (**6**) as a minor by-product. Occurrence of the dibenzoylamine (**8**) indicates that, as shown in Scheme 2, the intermediary *F*-benzoyl derivatives, (**5**) and/or (**6**), cleaved in some way at the α–β bond relative to the *F*-benzoyl group prior to the intramolecular cyclization, to liberate di(*F*-benzoyl)amide anion (**7**) in the presence of pyridine.



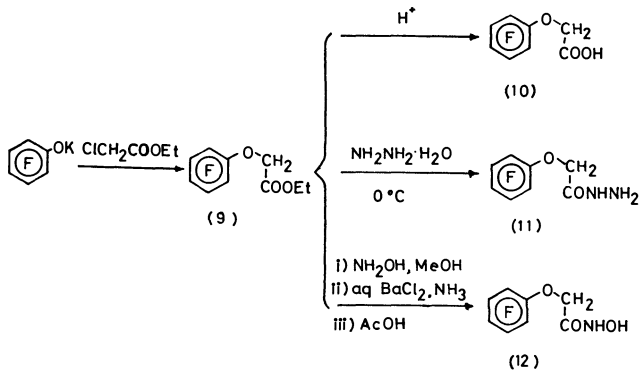
Scheme 2.

On the other hand, the reaction with *N*,*N*'-dimethylurea gave *N*,*N*'-dimethyl-*N*-(*F*-benzoyl)urea (**4**), in which no protic hydrogen was present at the α-amide nitrogen and the second *F*-benzoylation at the same site could not occur. Thus, the α–β bond cleavage seems to be suppressed. The electron-donation due to the methyl group on the nitrogen atom might also contribute to this stabilization.

† Present address: Government Industrial Research Institute in Kyushu, Shukumachi, Tosu, Saga 841.

From F-*Phenol*: For this purpose, we used ethyl (*F*-phenoxy)acetate (**9**), which was prepared by the reaction of potassium *F*-phenolate with ethyl chloroacetate.[7]

The carboxylic acid (**10**) from the ester (**9**), and its acyl derivatives, (**11**) and (**12**), were examined as the potential precursors for the subsequent intramolecular cyclization; they were prepared as shown in Scheme 3.



Scheme 3.

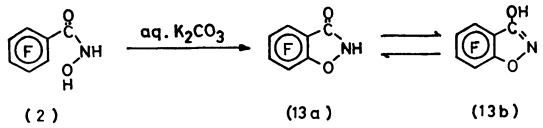
The ester function of the (*F*-phenoxy)acetate (**9**) was converted to a hydrazide to yield 2-(*F*-phenoxy)-acetohydrazide (**11**) by the reaction with hydrazine hydrate at 0 °C. Although the reactions were usually performed by heating under reflux,[8] the present ester (**9**) was treated under much milder conditions lest it should result in the formation of hydrazinium *F*-phenoxide.[9]

An oxygen nucleophile was fabricated at the terminal position of the side chain in the form of 2-(*F*-phenoxy)-acetohydroxamic acid (**12**), which was prepared in a usual manner.[5] Under a prolonged reaction time, the yield of the acetohydroxamic acid (**12**) decreased, while the more amount of *F*-phenol was generated as a by-product. The C–O bond fission to liberate *F*-phenol seems due to the higher stability of *F*-phenoxide, as often encountered in the reaction of *F*-phenoxy compounds in the presence of base.[10]

(*F*-Phenoxy)acetic acid (**10**) was regarded as another precursor carrying an oxygen nucleophile at the terminal position. The acetic acid (**10**) was obtained by the hydrolysis of the ester (**9**) in a good yield.[11]

Intramolecular Nucleophilic Cyclization. From F-*Benzoyl Compounds*: (*F*-Benzo)heterocyclic compounds were prepared by the base-catalyzed cyclization of the precursory *F*-benzoyl compounds (**2**, **3**, and **4**).

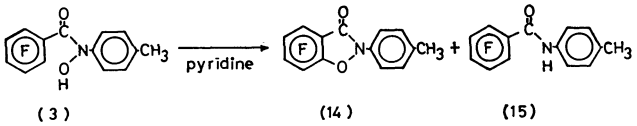
F-Benzohydroxamic acid (**2**) was refluxed with alkali in an aqueous solvent. The reaction proceeded to give 1,2-(*F*-benz)isoxazol-3(2*H*)-one (**13a**), *F*-aniline, and *F*-benzoic acid. The ^{1}H-NMR spectrum of the (*F*-benz)isoxazoline (**13**) indicated that it was a mixture of tautomers, (**13a**) and (**13b**). The ^{1}H-NMR signal in acetone-d_6 showed a broad peak centered at δ=6.2 at 35 °C, while at −58 °C the peak is separated into two peaks centered at δ=5.5 and 8.5, which correspond to the hydrogens of hydroxyl group in **13b** and amino group in **13a**. *F*-Aniline was the product which resulted from Lossen rearrangement[12]



Scheme 4.

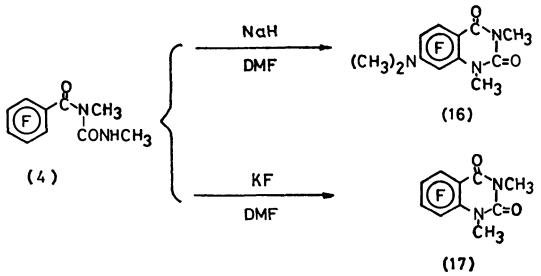
of *F*-benzohydroxamic acid (**2**), and *F*-benzoic acid could be generated by hydrolysis of the same compound (**2**). In order to prevent the hydrolysis, *F*-benzohydroxamic acid (**2**) was treated with base in anhydrous solvents such as DMF, DMSO, and pyridine. The reactions, however, were unsuccessful, resulting in a trace amount of the heterocyclic compound (**13**).

The reaction of *N*-(*p*-tolyl)-*N*-hydroxy-*F*-benzamide (**3**) showed somewhat peculiar behavior in basic media. In anhydrous pyridine, 2-(*p*-tolyl)-1,2-(*F*-benz)isoxazol-3(2*H*)-one (**14**) was isolated together with *N*-(*p*-tolyl)-*F*-benzamide (**15**) as a major product. When treated with base in an aqueous solvent of DMF, the sole product was the benzamide (**15**). The formation of the benzamide (**15**) suggested that the *N*-hydroxy-*F*-benzamide (**3**) favored the cleavage of N–O bond rather than the intramolecular cyclization in basic media. This N–O bond cleavage was presumably related with the electron-withdrawing effect of *F*-phenyl group. No further details of the mechanism were examined.



Scheme 5.

The *F*-benzoylurea (**4**) was intramolecularly cyclized to give 1,3-dimethyl-7-dimethylamino(*F*-benzo)pyrimidine-2,4(1*H*,3*H*)dione (**16**) in the presence of sodium hydride in anhydrous DMF. ^{19}F-NMR spectrum of the product shows three signals of equal intensity; their splitting patterns indicate that the product is of a 1,2,4-trisubstituted *F*-benzene structure. The assignment of the fluorine atom at 8-position of the product (**16**) is due to its multiplet peak, owing to the coupling between the adjacent *N*-methyl hydrogens and other fluorines.[13] The long-range coupling (J=9 Hz) of *N*-methyl hydrogens with the fluorine at the 8-position was also observed in the ^{1}H-NMR spectrum of the product (**16**). Such long-range coupling over five bonds between fluorine and hydrogen



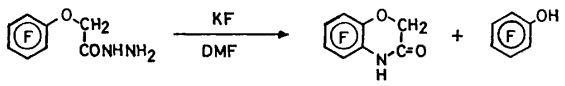
Scheme 6.

has been encountered sometimes in methylaminosubstituted *F*-benzenes.[14] On the other hand, the assignment of the fluorine atom at 5-position in the (*F*-benzo)pyrimidinedione (**16**) is based on its simple double-doublet peak due to the coupling with two unequivalent fluorines. The position of dimethylamino group is, therefore, assigned to 7-position of the product.

On the other hand, the *F*-benzoylurea (**4**) was cyclized into the expected 1,3-dimethyl(*F*-benzo)pyrimidine-2,4(1*H*,3*H*)-dione (**17**), in the presence of potassium fluoride in anhydrous DMF.[15] The ^{19}F-NMR spectrum of the product shows four signals of equal intensity, and their splitting patterns show that the product is of an *ortho*-disubstituted *F*-benzene structure. The long-range coupling (J_{8-H}=9 Hz) between the fluorine at the 8-position and *N*-methyl hydrogens was again observed in both ^{19}F- and ^{1}H-NMR spectra of the heterocyclic compound (**17**).[13]

The dimethylamino group present in the former product (**16**) is considered to come from DMF, where DMF plays the parts of both dimethylaminating agent and solvent in the nucleophilic cyclization reaction at the presence of sodium hydride.

From F-*Phenoxy Compounds*: The reaction of 2-(*F*-phenoxy)acetohydrazide (**11**) with potassium fluoride in DMF gave 1,4-(*F*-benz)oxazin-3(2*H*)-one (**18**), though in a poor yield. A great majority of the product was *F*-phenol, which resulted from the C–O bond cleavage during the reaction. The heterocyclic compound (**18**) was identical with that previously derived from *F*-aniline,[3] and would be formed by cyclization accompanied with the simultaneous cleavage of N–N bond of the terminal hydrazide functions. Under some other basic conditions, such as pyridine and potassium carbonate in DMF, no definite products were obtained except *F*-phenol.

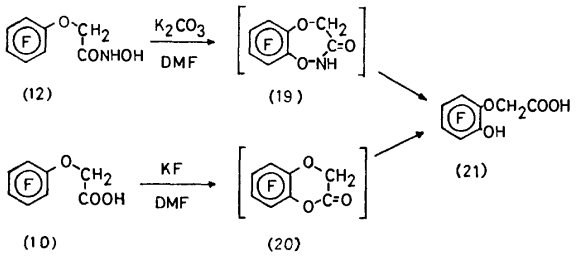


(11) (18)

Scheme 7.

We tried to cyclize the acetohydroxamic acid (**12**) by heating under reflux with potassium carbonate in DMF. The reaction proceeded to give (2-hydroxy-*F*-phenoxy)acetic acid (**21**), while the expected intermediary heterocyclic compound (**19**) could not be isolated. The ^{19}F-NMR spectrum of the product shows four signals of equal intensity; their splitting patterns indicate that the product is of an *ortho*-disubstituted *F*-benzene structure. The assignment of the fluorine atom at the 6-position in the product (**21**) is based upon its multiplet peak, due to the coupling with the adjacent *O*-methylene hydrogens and three other ring-fluorines. The assignment of the fluorine at the 3-position is based upon its doubled double-doublet peak, due to the coupling with three ring-fluorines.

We tried to cyclize the acetic acid (**10**) by refluxing it in the presence of potassium fluoride in DMF.[16,17] The reaction also proceeded to give (2-hydroxy-*F*-phenoxy)acetic acid (**21**); again the expected intermediary heterocyclic compound (**20**) could not be isolated.



(12) (19) (21) (10) (20)

Scheme 8.

The reactions of the two different precursors, (**10**) and (**12**), resulted in the direct formation of the identical *ortho*-disubstituted *F*-benzene (**21**) under basic conditions.

Experimental

Melting points are uncorrected. The spectral data are those obtained on the following instruments and apparatus unless otherwise noted: IR spectra: JASCO DS-403G, A-1, and A-102. UV spectra: Hitachi 124 and 220. ^{1}H-NMR spectra: Varian A-60 and Hitachi R-24B against the internal TMS reference. ^{19}F-NMR spectra: JEOL PS-100 as the positive value downfield from the internal F-benzene reference. Mass spectra: JEOL JMS-07 and 01SG.

N-*Benzyloxy*-F-*benzamide (1)*. *F*-Benzoyl chloride (2.70 g, 12 mmol) was added dropwise to a stirred mixture of *O*-benzylhydroxylamine (31 mmol),[18] anhydrous pyridine (1.96 g, 25 mmol), and absolute ether (50 ml) over a 30-min period. The mixture was refluxed for an additional 1.5 h, cooled, and filtered. The filtrate was washed successively, with water, diluted hydrochloric acid, and water, and dried over magnesium sulfate. The residue obtained after evaporation *in vacuo* was recrystallized from benzene, to give *N*-benzyloxy-*F*-benzamide (**1**) (3.18 g, 85%) in colorless plates, mp 140.0—141.0 °C. IR(KBr): 3120 (NH) and 1670 cm^{-1} (C=O). ^{1}H-NMR (acetone-d_6) δ=5.50 (s, 2H, CH_2), 7.4 (s, 5H, arom.), and 10.7—11.1 (br. s, 1H, NH). Found: C, 52.95; H, 2.52; N, 4.32%. Calcd for $C_{14}H_8NF_5O_2$: C, 53.01; H, 2.54; N, 4.42%.

F-*Benzohydroxamic Acid (2)*. The *N*-(benzyloxy)amide (**1**) (1.73 g, 5.4 mmol) dissolved in methanol (50 ml) was hydrogenated in the presence of 5% palladium on charcoal (0.30 g) under atmospheric pressure at room temperature. The catalyst was filtered out, and the filtrate was evaporated to dryness *in vacuo*. Recrystallization from benzene gave *F*-benzohydroxamic acid (**2**) (1.00 g, 80%) in colorless needles, mp 140.0—141.0 °C. IR(KBr): 3230 (NH, OH) and 1650 cm^{-1} (C=O). ^{1}H-NMR (acetone-d_6) δ=7.35 (s, 1H, OH) and 9.4—10.1 (br. s, 1H, NH). Found: C, 37.04; H, 1.00; N, 6.60%. Calcd for $C_2H_2NF_5O_2$: C, 37.02; H, 0.89; N, 6.17%. The hydroxamic test using iron(III) chloride solution was positive.

N-(p-*Tolyl*)-N-*hydroxy*-F-*benzamide (3)*. *F*-Benzoyl chloride (3.30 g, 14 mmol) was added dropwise to a stirred mixture of ethereal *N*-(*p*-tolyl)hydroxylamine (2.10 g, 17 mmol in 80 ml of ether) and aqueous sodium hydrogencarbonate (2.60 g, 31 mmol in 15 ml of water) over a 1-h period at 0 °C. The mixture was stirred at 0 °C for an additional 2 h, and poured into ether. The ethereal solution was washed with water, dried over sodium sulfate, and evaporated to dryness *in vacuo*. The residue was recrystallized from aqueous methanol to give *N*-(*p*-tolyl)-*N*-hydroxy-*F*-

benzamide (**3**) (3.80 g, 84%) in colorless needles, mp 178—179 °C. IR(KBr): 3200 (OH) and 1650 cm^{-1} (C=O). Found: C, 53.05; H, 2.67; N, 4.40%. Calcd for $C_{14}H_8NF_5O_2$; C, 53.01; H, 2.54; N, 4.42%. The hydroxamic test using iron(III) chloride solution was positive.

Reaction of F-*Benzoyl Chloride with Urea.* *F*-Benzoyl chloride (1.00 g, 4.3 mmol) was added dropwise to a stirred mixture of urea (0.25 g, 4.2 mmol), anhydrous DMF (7 ml), and anhydrous pyridine (2 ml) over a 30-min period at room temperature and under a dry nitrogen atmosphere. The mixture was refluxed for an additional 30 min, cooled, and poured into ether. The ethereal solution was washed with water, dried over sodium sulfate, and evaporated to dryness *in vacuo*. The residue was recrystallized from aqueous methanol to give a white solid (315 mg). MS of the white solid; Found: *m/e*, 448. Calcd for $C_{15}H_2N_2F_{10}O_3$; 448. The solid was chromatographed on a silica-gel column. The fraction eluted with hexane–chloroform was sublimed to give di(*F*-benzoyl)amine (**8**) (27 mg, 3%) in colorless needles, mp 157—158 °C. IR(KBr): 3280, 3200 (NH), and 1750 cm^{-1} (C=O). Found: C, 41.54; H, 0.35; N, 3.56%; M^+, 405. Calcd for $C_{14}HNF_{10}O_2$: C, 41.50; H, 0.25; N, 3.46%; M, 405.

N,N′-*Dimethyl*-N-*(F-benzoyl)urea (4).* *F*-Benzoyl chloride (4.25 g, 18 mmol) was added dropwise to a stirred mixture of *N,N′*-dimethylurea (2.20 g, 25 mmol) and anhydrous pyridine (15 ml) over a 20-min period at room temperature. The mixture was refluxed for an additional 6 h, cooled, and poured into ether. The ethereal solution was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on a silica-gel column. The fraction eluted with hexane–chloroform and that with chloroform–dichloromethane gave *N,N′*-dimethyl-*N*-(*F*-benzoyl)urea (**4**) (2.30 g, 44%). Recrystallization from cyclohexane afforded colorless needles, mp 62—63 °C. IR(KBr): 1720 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$) δ=2.85 (d, J=4 Hz, 3H, NCH_3), 3.15 (s, 3H, CH_3), and 8.15—8.75 (br. s, 1H, NH). Found: C, 42.56; H, 2.50; N, 9.84%; M^+, 282. Calcd for $C_{10}H_7N_2F_5O_2$: C, 42.57; H, 2.50; N, 9.93%; M, 282.

2-(F-Phenoxy)acetohydrazide (11). A solution of ethyl (*F*-phenoxy)acetate (**9**) (8.10 g, 30 mmol) in ethanol (5 ml) was added dropwise to a stirred solution of 100% hydrazine hydrate (4.50 g, 90 mmol) in ethanol (5 ml) over a 10-min period at 0 °C. The mixture was stirred at 0 °C for an additional 20 min, and poured into saturated aqueous sodium chloride. The resulting solid was filtered, washed with water, and air-dried. Sublimation gave 2-(*F*-phenoxy)-acetohydrazide (**11**) (7.20 g, 94%) in colorless needles, mp 67—69 °C. IR(KBr): 3330 cm^{-1} (NH). Found: C, 37.52; H, 1.98; N, 10.94%. Calcd for $C_8H_5N_2F_5O_2$: C, 37.71; H, 2.14; N, 10.85%.

2-(F-Phenoxy)acetohydroxamic Acid (12). A solution of potassium hydroxide (2.40 g, 43 mmol) in methanol (7.5 ml) was added to a stirred solution of hydroxylamine hydrochloride (2.40 g, 35 mmol) in methanol (13.5 ml) at room temperature. Ethyl (*F*-phenoxy)acetate (**9**) (3.50 g, 13 mmol) was added to the stirred mixture, and then the mixture was filtered immediately. The filtrate was left standing overnight at room temperature, poured into water, and acidified with diluted hydrochloric acid. Barium chloride (3.50 g, 15 mmol) was dissolved in the acidified solution, and then the solution was basified with aqueous ammonia. The resulting precipitates were collected by filtration, washed with water, and air-dried. The solid (3.5 g) was warmed to dissolve in 10% aqueous acetic acid (20 ml) for a few minutes, and cooled to room temperature. The resulting precipitates were collected by filtration, washed with water, and air-dried. Recrystallization from petroleum ether–ethyl acetate gave 2-(*F*-phenoxy)acetohydroxamic acid (**12**) (2.10 g, 59%) in colorless plates, mp 106—108 °C. IR (KBr): 3220 (OH, NH) and 1650 cm^{-1} (C=O). Found: C, 37.37; H, 1.57; N, 5.45%. Calcd for $C_8H_4NF_5O_3$: C, 37.31; H, 1.62; N, 5.48%. The hydroxamic test using iron(III) chloride solution was positive.

1,2-(F-Benz)isoxazol-3(2H)-one (13a). A mixture of *F*-benzohydroxamic acid (**2**) (1.00 g, 4.4 mmol), potassium carbonate (1.00 g, 1.2 mmol), and water (20 ml) was refluxed for 10 h with stirring and cooled. *F*-Aniline (90 mg, 11%) deposited on the inside of a condencer, and was identified by comparison with an authentic specimen.[3] The reaction mixture was neutralized, and extracted with ether. The ethereal extract was dried over magnesium sulfate, and evaporated *in vacuo*. The residual solid was chromatographed on a silica-gel column by elution with benzene. An earlier fraction gave the starting material (**2**) (75 mg, 7.5%). A later fraction gave 1,2-(*F*-benz)isoxazol-3-(2*H*)-one (**13a**) (55 mg, 6%). Recrystallization from benzene afforded colorless prisms, mp 171.0—172.0 °C. IR (KBr): 3400 (OH), 3000 (NH), and 1665 cm^{-1} (C=N). ^{1}H-NMR (acetone-d_6) δ at 35 °C=6.2 (br. s); δ at −58 °C=5.5 (br. s) and 8.5 (br. s). Found; C, 40.44; H, 0.70; N, 6.25%; M^+, 207. Calcd for $C_7NHF_4O_2$; C, 40.60; H, 0.49; N, 6.77%; M, 207.

The neutral aqueous layer was acidified and then extracted with ether repeatedly. The combined extracts were treated in a similar manner to that described above. Upon elution chromatography with ethyl acetate–chloroform on a silica-gel column, an earlier fraction gave the heterocyclic compound (**13**) (85 mg, 9%). A later fraction gave *F*-benzoic acid (50 mg, 5%), which was identified by comparison with an authentic specimen.[20]

2-(p-Tolyl)-1,2-(F-benz)isoxazol-3(2H)-one (14). A solution of *N*-(*p*-tolyl)-*N*-hydroxy-*F*-benzamide (**3**) (427 mg, 1.3 mmol) in anhydrous pyridine (15 ml) was refluxed for 10 h with stirring, cooled, and poured into ether. The ethereal solution was washed with water and dried over sodium sulfate. Evaporation *in vacuo* gave a residual oil, which was chromatographed on a silica-gel column.

The fraction eluted with hexane gave 2-(*p*-tolyl)-1,2-(*F*-benz)isoxazol-3(2*H*)-one (**14**) (35 mg, 9%). Sublimation afforded colorless needles, mp 116.0—117.0 °C. IR (KBr): 1780 cm^{-1} (C=O). Found: C, 56.42; H, 2.35; N, 4.62; F, 25.50%; M^+, 297. Calcd for $C_{14}H_7NF_4O_2$: C, 56.58; H, 2.37; N, 4.71; F, 25.59%; M, 297.

The fraction eluted with hexane–chloroform and that with chloroform gave *N*-(*p*-tolyl)-*F*-benzamide (**15**) (80 mg, 20%). Recrystallization from cyclohexane–ethanol afforded colorless needles, mp 198.5—199.5 °C. IR (KBr); 3240 (NH) and 1670 cm^{-1} (C=O). Found: C, 55.89; H, 2.83; N, 4.59%. Calcd for $C_{14}H_8NOF_5$: C, 55.82; H, 2.68; N, 4.65%.

1,3-Dimethyl-7-dimethylamino(F-benzo)pyrimidine-2,4(1H,3H)-dione (16). A solution of *N,N′*-dimethyl-*N*-(*F*-benzoyl)urea (**4**) (595 mg, 2.1 mmol) in anhydrous DMF (10 ml) was added dropwise to a stirred suspension of sodium hydride (3.3 mmol) and anhydrous DMF (10 ml) over a 15-min period at room temperature. The mixture was refluxed for an additional 5 h, cooled, and poured into ether. The ethereal solution was washed with water, dried over sodium sulfate, and evaporated to dryness *in vacuo*. The residue was chromatographed on a silica-gel column. The fraction eluted with chloroform gave 1,3-dimethyl-7-dimethylamino(*F*-benzo)pyrimidine-2,4(1*H*,3*H*)-dione (**16**) (0.40 g,

66%). Recrystallization from benzene afforded colorless needles, mp 186—187.5 °C. IR (KBr): 1700 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$) δ=3.05 (m, 6H, CH_3), 3.35 (s, 3H, CH_3) and 3.67 (d, J=9 Hz, 3H, CH_3). ^{19}F-NMR ($CHCl_3$) δ=9.5 (d.sep, 1F, F^6), 19.9 (dd, 1F, F^5), and 24.3 (m, 1F, F^8), (J_{5-8}=11.5, J_{5-6}=20.0, J_{H-6}=3.0 Hz). Found: C, 50.19; H, 4.23; N, 14.65; F, 19.6%; M^+, 287. Calcd for $C_{12}H_{12}N_3O_2F_3$: C, 50.18; H, 4.21; N, 14.63; F, 19.8%; M, 287.

1,3-Dimethyl(F-benzo)pyrimidine-2,4(1H,3H)-dione (17). A solution of *N,N'*-dimethyl-*N*-(*F*-benzoyl)urea (**4**) (2.44 g, 8.7 mmol) in anhydrous DMF (20 ml) was added dropwise to a stirred mixture of potassium fluoride (1.00 g, 18 mmol) and anhydrous DMF (30 ml) over a 30-min period at room temperature. The mixture was refluxed for an additional 7 h, cooled, and poured into ether. The ethereal solution was worked up in a similar manner to that described above. The chromatographic fraction eluted with hexane–chloroform gave 1,3-dimethyl(*F*-benzo)pyrimidine-2,4(1*H*,3*H*)-dione (**17**) (1.12 g, 49%). Recrystallization from cyclohexane afforded colorless needles, mp 102—104 °C. IR (KBr): 1720 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$) δ=3.35 (s, 3H, CH_3) and 3.73 (d, J=9 Hz, 3H, CH_3). ^{19}F-NMR ($CHCl_3$) δ=0.05 (dd, 1F, F^6), 12.8 (ddq, 1F, F^8), 17.3 (ddd, 1F, F^7), and 24.2 (ddd, 1F, F^5), (J_{5-6}=J_{6-7}=23.0, J_{7-8}=21.0, J_{5-8}=13.0, J_{5-7}=11.5, J_{6-8}=1.0, and J_{8-H}=9 Hz). UV (EtOH); λ_{max} (log ε); 218 (4.49) and 313 nm (3.45). Found: C, 45.93; H, 2.34; N, 10.53; F, 29.1%; M^+, 262. Calcd for $C_{10}H_6N_2F_4O_2$: C, 45.82; H, 2.31; N, 10.69; F, 29.0%; M, 262.

Reaction of 2-(F-Phenoxy)acetohydrazide (11) with Potassium Fluoride in DMF. A mixture of 2-(*F*-phenoxy)acetohydrazide (**11**) (1.04 g, 4.0 mmol), potassium fluoride (0.57 g, 9.8 mmol), and anhydrous DMF (15 ml) was refluxed for 13.5 h with stirring and then, after being cooled, was poured into ether. The ethereal solution was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on a silica-gel column. The fraction eluted with chloroform contained *F*-phenol, which was identified by spectral comparisons with an authentic specimen.[7] The residual solid from the fraction eluted with chloroform, was sublimed to give 1,4-(*F*-benz)-oxazin-3(2*H*)-one (**18**) (13 mg, 1.5%) in colorless needles, mp 190—191.5 °C measured in a sealed tube. The product was identified by comparison with an authentic specimen.[3] Found: M^+, 221.012. Calcd for $C_8H_3NF_4O_2$: M, 221.016.

Reaction of 2-(F-Phenoxy)acetohydroxamic Acid (12) with Base. A mixture of 2-(*F*-phenoxy)acetohydroxamic acid (**12**) (1.00 g, 3.9 mmol), potassium carbonate (0.60 g, 4.3 mmol), and anhydrous DMF (20 ml) was refluxed for 10 h, cooled, and poured into ether. The ethereal solution was washed with 3% hydrochloric acid and water, successively, and dried over magnesium sulfate. The residue from evaporation was sublimed to give (2-hydroxy-*F*-phenoxy)acetic acid (**21**) (95 mg, 11%). Recrystallization from cyclohexane–chloroform afforded colorless needles, mp 114—116 °C. IR (KBr): 3520 and 3460 (phenolic OH), and 1720 cm^{-1} (C=O). ^{19}F-NMR[21] (MeOH) δ=−2.2 (dm, 1F, F^6), 3.1 (ddd, 1F, F^3), 4.8 (ddd, 1F, F^4), and 11.8 (ddd, 1F, F^5), (J_{3-4}=J_{4-5}=J_{5-6}=22.5, J_{4-6}=3.0, J_{3-6}=5.5, and J_{3-5}=6.5 Hz). The phenol test using iron(III) chloride solution was positive.

Reaction of (F-Phenoxy)acetic Acid (10) with Potassium Fluoride. A mixture of (*F*-phenoxy)acetic acid (**10**)[22] (1.02 g, 4.2 mmol), potassium fluoride (0.57 g, 9.7 mmol), and anhydrous DMF (15 ml) was refluxed for 13.5 h with stirring, cooled, and poured into ether. The ethereal solution was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on a silica-gel column. The fraction eluted with dichloromethane gave a solid product. Recrystallization from benzene followed by sublimation afforded (2-hydroxy-*F*-phenoxy)acetic acid (**21**) (56 mg, 6%) in colorless needles, mp 113—114 °C. The product was identified by comparison with an authentic specimen obatained by the above reaction.

We wish to express our sincere thanks to Professor Keihei Ueno of Kyushu University for his continuous encouragement throughout this study.

We also wish to thank Messrs. Akira Kito and Atsushi Iyoda of the Government Industrial Research Institute at Osaka for their measurements of the ^{19}F-NMR spectra. Financial support from the Ministry of Education, Science and Culture under a Grant-in-Aid for Developmental Scientific Research (2) (Project No. 585221) is gratefully acknowledged.

Photoreaction of *N,N'*-Dibromo-2,5-piperazinedione

Akira SERA,* Kuniaki ITOH, Hiroshi YAMADA, and Ryuichi AOKI

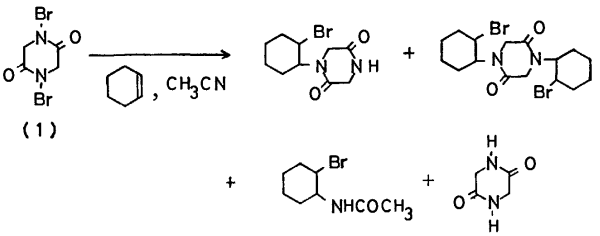
Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657

(Received January 21, 1981)

The photolysis of *N,N'*-dibromo-2,5-piperazinedione in dichloromethane gave an unstable photoproduct. The alcoholysis of the photoproduct in the presence of a small amount of hydrogen bromide yielded 3,6-diethoxy-2,5-piperazinedione and its alcoholyzed products, ethyl diethoxyacetate, ethyl 2-(diethoxyacetylamino)-2-ethoxyacetate, *N*-(1-ethoxy-1-ethoxycarbonylmethyl)oxamide, and ethyl *N*-(diethoxyacetyl)glycinate. The reactions of the photoproduct with other nucleophiles also gave the corresponding substituted 2,5-piperazinediones. The structure of the primary photoproduct was deduced to be 3,6-dibromo-2,5-piperazinedione on the basis of these observations.

In recent years, attention has been focused on the chemical reactivity and selectivity of the succinimido radical produced from *N*-bromosuccinimide(NBS).[1-3] The preferential attack of the succinimido radical to a carbon-carbon double bond has been reported to proceed in competition with hydrogen abstraction reactions.[2,3] The presence of two states of the imido radical, a ground state π-radical and an exited state σ-radical was suggested to explain the reaction patterns observed under homogeneous conditions.

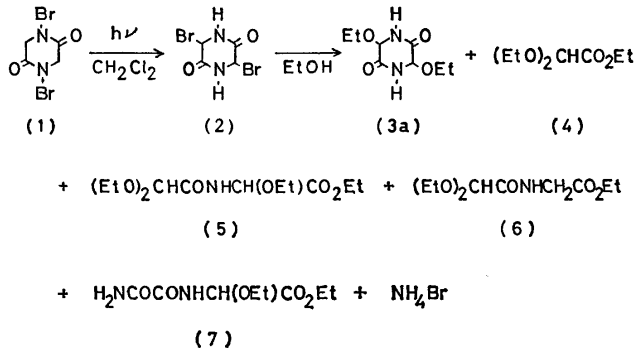
In the course of our investigation on the reactivity of *N,N'*-dibromo-2,5-piperazinedione (**1**, NBP), we reported a photo-induced alkoxybromination of some olefins with NBP in the presence of alcohols.[4] Because the structure of NBP is similar to that of NBS, photoreactions of NBP with olefins proceeded easily to give the corresponding addition products in aprotic media. A solvent incorporated product was also produced. However, no rearranged product was detected, such as was often found in the photoreactions of NBS. Thus, detailed examination of the photochemical behavior of NBP is desirable. This paper concerns the photoreaction of NBP in dichloromethane.



Results and Discussion

Photolysis of NBP in dichloromethane was carried out in a Pyrex apparatus. The concentration of NBP was usually around 0.4 mol dm^{-3}. Because of the low solubility of NBP in dichloromethane (and in most of organic solvents), the irradiation was carried out under heterogeneous conditions with agitation. In a few hours the reaction mixture turned red. After 8 h, the photolysate was filtered to give a pale yellow solid (**2**) which was found not to be NBP. The solid **2** was so unstable that we could not recrystallize it satisfactorily. However, the bromine analysis of a specimen of **2** (not completely pure)[5] revealed the presence of two bromine atoms in the molecule. The methine proton signal was observed at δ=5.0. A photo-enolization of the amide group of NBP and a subsequent 1,3-bromine shift might result in the unstable **2**.

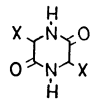
Accordingly, immediately after filtration and quick rinsing with dichloromethane, **2** was allowed to react with ethanol to give 3,6-diethoxy-2,5-piperazinedione (**3a**, 3%), ethyl diethoxyacetate (**4**, 4%), ethyl 2-(diethoxyacetylamino)-2-ethoxyacetate (**5**, 25%), ethyl *N*-(diethoxyacetyl)glycinate (**6**, 16%), *N*-(1-ethoxy-1-ethoxycarbonylmethyl)oxamide (**7**, 2%), and ammonium bromide, respectively.



The structures of the above products were all determined taking into account their elemental analyses, and IR, NMR, and mass spectra. Compound **3a** had an infrared absorption pattern in its finger print region similar to that of 2,5-piperazinedione, except for the presence of C–O stretching bands in the former. The NMR spectrum of **3a** showed a distinct ring proton signal at δ=4.5 (dd, J=4 and 1 Hz), an NH proton signal (δ=8.9, d, J=4 Hz), and ethoxy proton signals. Elemental analysis and the MS fragment pattern[6] also confirmed the structure of **3a**. Compound **3a** was considered to be a primary alcoholysis product of **2** as described latter. The spectra of **4** were found to be identical with those of authentic ethyl diethoxyacetate prepared by the recorded method.[7] Compound **5** showed IR absorptions at 3400(ν_{NH}), 1760, 1710($\nu_{C=O}$)cm^{-1}, and its NMR spectra revealed the presence of two methine protons (δ=4.7, s and 5.3, d, J=9 Hz), one NH proton (δ=7.3, d, J=9 Hz), and four ethoxyl groups. Compound **6** also showed C=O (1760, 1690 cm^{-1}) and NH (3350 cm^{-1}) absorptions, and CH_2 (δ=3.9, d, J=6 Hz), CH (δ=4.7, s), NH (δ=7.0, t, J=6 Hz), and three ethoxyl proton signals. Both NMR spectra [δ=1.1 (CH_3), 3.5 (CH_2 of ethoxyl group), 4.1 (CH_2 of ethoxycarbonyl group),

5.2 (CH), 7.8 and 8.0 (NH_2), and 9.1 (NH)] and IR absorptions [3380 and 3270 (NH) and 1760 and 1680 (C=O) cm^{-1}] supported the structure of **7** to be that depicted above. The amide protons of **7** resonated at $\delta=7.8$ and 8.0 (DMSO-d_6) at ambient temperature. These two signals began to coalesce at around 100 °C, indicating the presence of restricted rotation around a formal single bond.[8]

Because the structure of **5** is composed of two glyoxalic acid units, **4** was thought to be produced from **5** in the course of the treatment of ethanol. Actually the ethanolysis of **5** in the presence of hydrochloric acid gave **4**. The same treatment of **6** also yielded **4** and ethyl glycinate hydrochloride. In addition, the treatment of **3a** with ethanol containing hydrogen bromide gave **4** and **5**. Thus **3a** was a key intermediate of the successive reactions of **2** giving **4** and **5**, where hydrogen bromide liberated from **2** played a catalytic role in the ethanolysis. The alcoholysis reactivity of **3a** seemed rather high, but one can anticipate that an addition of a hydrogen bromide scavenger can increase the yield of **3**. The yield of 3,6-dialkoxy derivative was found as follows. Reactions were carried out using methanol instead of ethanol: a 5% yield of 3,6-dimethoxy-2,5-piperazinedione (**3b**) was obtained by an irradiation of NBP in dichloromethane and a subsequent treatment of the remaining solid with methanol; 48% was obtained by the same irradiation followed by a treatment with methanol–pyridine. As expected, **2** reacted with other nucleophiles; water, acetic acid, and an azide ion.



3b; X=OMe
3c; X=OH
3d; X=OAc
3e; $X=N_3$

The whole reaction scheme will be represented as follows: the photoisomerization of NBP gave the intermediate **2**, which on ethanolysis yielded **3a**. A nucleophilic attack of ethanol to the carbonyl group of **3a** and a subsequent ring opening followed by transacetalization gave **5**, which in turn yielded **4** by ethanolysis. A part of NBP was converted to *N*-bromo-2,5-piperazinedione by the protodebromination with hydrogen bromide.[9] A similar photoisomerization-ethanolysis of this *N*-bromo compound could give 3-ethoxy-2,5-piperazinedione and the corresponding ring opening product (**6**). The formation mechanism of **7** is not determined at present.

One of characteristic features of the photoreaction of NBP is the absence of the photo ring opening reaction, which has been often encountered in reactions of NBS giving 3-bromopropionyl isocyanate in a variety of conditions.[1,10] Massive evidence exists that the succinimido radical isomerizes to $\cdot CH_2CH_2CONCO$ by a photochemical α-cleavage-like reaction, and the latter radical abstracts a bromine atom of NBS to give 3-bromopropionyl isocyanate. However, in the case of NBP, this was not the case. This characteristic may arise from the structural feature of NBP, which is characterized as a bromide of cyclic diamide. Investigations are in progress to elucidate the dissimilarity of NBP to NBS in reactivity.

Experimental

Melting points were determined on a Yanagimoto hot stage and were uncorrected. NMR spectra were determined on a JEOL PMX-60 spectrometer using TMS as the internal standard. IR spectra were recorded on a JASCO IRA-1 spectrometer. Mass spectra were recorded on Hitachi RMU-6MG and JEOL JMS-01SG-2 spectrometers. All irradiations were carried out using Ushio UM 453B(450 w) and Halos EHB-WU(100 w) high pressure mercury arc lamps. Dichloromethane was washed with sulfuric acid to remove the contained ethanol, washed thoroughly with water, dried and distilled. *N,N'*-Dibromo-2,5-piperazinedione was prepared as described in the literature.[4]

Photoreaction of NBP. A suspension of NBP (**1**, 10 g) in 100 cm^3 of dichloromethane in a Pyrex vessel was irradiated by a high pressure Hg arc lamp for 8 h with stirring at ambient temperature. The mixture was filtered to give a pale yellow solid (**2**). In the filtrate, nothing was found but bromine. The solid **2** was quite unstable.[5] The color of **2** turned red, and meanwhile **2** decomposed spontaneously to a clear viscous liquid. Accordingly **2** was rinsed quickly with dichloromethane and was added into ethanol. The mixture was stirred overnight at room temperature, and was filtered to give white crystals. Recrystallization from ethanol gave 240 mg (3.3% based on NBP) of 3,6-diethoxy-2,5-piperazinedione (**3a**), mp 217 °C (dec). IR: 3230, 1680 cm^{-1}; NMR (DMSO-d_6): $\delta=1.1$ (6H, t, $J=7$ Hz), 3.5 (4H, q, $J=7$ Hz), 4.5 (2H, dd, $J=4$ and 1.2 Hz), 8.9 (2H, broad d, $J=4$ Hz); MS (*m/e*)[6]: 174 (M^+), 131, 115, 72, 60. Found: C, 47.83; H, 6.98; N, 13.97%. Calcd for $C_8H_{14}N_2O_4$: C, 47.52; H, 6.93; N, 13.86%.

The ethanolic filtrate was evaporated up to a syrup (11.5 g) which was separated on siliga-gel column to afford products in the following order. Yields are given on the basis of NBP employed.

Elution with benzene–ether (9:1) gave 530 mg (4.2%) of ethyl diethoxyacetate (**4**), a colorless liquid. IR: 1760 cm^{-1}; NMR (CCl_4): $\delta=1.1$ (9H, m), 3.5 (4H, q, $J=7$ Hz), 4.0 (2H, q, $J=7$ Hz), 4.6 (1H, s). Found: C, 53.88; H, 9.10%. Calcd for $C_8H_{16}O_4$: C, 54.55; H, 9.11%. The IR and NMR spectra of this compound were found to be identical to those of an authentic sample prepared by a recorded method.[7]

Further elution gave 2.48 g (24.8%) of ethyl 2-(diethoxyacetylamino)-2-ethoxyacetate (**5**) as a colorless liquid. IR: 3400, 1760, 1710 cm^{-1}; NMR (CCl_4): $\delta=1.2$ (12H, m), 3.5 (6H, q, $J=7$ Hz), 4.1 (2H, q, $J=7$ Hz), 4.7 (1H, s), 5.3 (1H, d, $J=9$ Hz), 7.3 (1H, broad d, $J=7$ Hz); MS (*m/e*): no M^+, 131, 130. Found: C, 51.25; H, 8.41; N, 4.79%. Calcd for $C_{12}H_{23}NO_6$: C, 51.95; H, 8.31; N, 5.05%.

Next the column was eluted with benzene–acetone (4:1) to give 128 mg (1.6%) of *N*-(1-ethoxy-1-ethoxycarbonylmethyl)oxamide (**7**) as white crystals, mp 163—165 °C. IR: 3380, 3270, 1760, 1690 cm^{-1}; NMR (DMSO-d_6): $\delta=1.1$ (6H, m), 3.5 (2H, q, $J=7$ Hz), 4.1 (2H, q, $J=7$ Hz), 5.2 (1H, d, $J=8$ Hz), 7.8 and 8.0 (2H, rotation restricted NH_2), 9.1 (1H, broad d, $J=8$ Hz); MS (*m/e*): 218 (M^+), 173, 145, 116. Found: C, 44.06; H, 6.60; N, 12.80%. Calcd for $C_8H_{14}N_2O_5$: C, 44.04; H, 6.42; N, 12.84%.

Elution with benzene–ethanol (9:1) afforded 1.11 g (13%) of ethyl *N*-(diethoxyacetyl)glycinate (**6**) as a yellow liquid.

IR: 3350, 1760, 1690 cm^{-1}; NMR (CCl_4): δ=1.2 (9H, m), 3.6 (4H, q, J=7 Hz), 3.9 (2H, d, J=6 Hz), 4.1 (2H, q, J=7 Hz), 4.7 (1H, s), 7.0 (1H, broad t, J=6 Hz); MS (*m/e*): no M^+, 174, 131, 130. Found: C, 51.38; H, 8.11; N, 5.77%. Calcd for $C_{10}H_{19}NO_5$: C, 51.50; H, 8.15; N, 6.01%.

Elution was continued using benzene–ethanol (4:1) and a compound was isolated. The structure of this compound has not been determined yet. Final elution with ethanol afforded ammonium bromide (2.3 g, 28%).

*Ethanolysis of 3,6-Diethoxy-2,5-piperazinedione (**3a**).* Compound **3a** (1 g) was refluxed in a 0.5 mol dm^{-3} ethanolic hydrogen bromide solution for 1.5 h. After the usual work-up and column chromatography, 270 mg (31%) of **4** and 230 mg (42%) of **5** were obtained.

*Ethanolysis of Ethyl 2-(Diethoxyacetylamino)-2-ethoxyacetate (**5**).* Compound **5** (1 g) was refluxed in an ethanol solution containing 0.5 mol dm^{-3} hydrochloric acid for 3 h. After the usual work-up and column chromatography, 570 mg (39%) of **4** and unchanged **5** (280 mg, 28%) were obtained.

*Ethanolysis of Ethyl N-(Diethoxyacetyl)glycinate (**6**).* A similar treatment of **6** (450 mg) gave **4** (138 mg, 38%), unchanged **6** (240 mg, 53%), and ethyl glycinate hydrochloride (100 mg, 35%): mp 133—135 °C; IR: 3400, 1750 cm^{-1}; NMR (DMSO-d_6): δ=1.1 (3H, t, J=7 Hz), 3.7 (2H, s), 4.1 (2H, q, J=7 Hz), 8.4 (2H, s).

*Reaction of the Primary Photoproduct (**2**) with Other Nucleophiles.* The reaction of **2** with methanol (or methanol–pyridine) for 6 h at room temperature gave 3,6-dimethoxy-2,5-piperazinedione (**3b**) in 5% (or 48%) yield; mp 226 °C (dec); IR: 3250, 3180, 1680 cm^{-1}; NMR (DMSO-d_6): δ=3.3 (6H, s), 4.5 (2H, dd, J=4 and 1.2 Hz), 8.9 (2H, broad d, J=4 Hz); Found: C, 41.38; H, 6.02; N, 16.30%. Calcd for $C_6H_{10}N_2O_4$: C, 41.38; H, 5.75; N, 16.09%.

Similar treatment of **2** with aqueous acetone, acetic acid–triethylamine, and sodium azide yielded 3,6-dihydroxy-, 3,6-diacetoxy-, and 3,6-diazido-2,5-piperazinediones, respectively. 3,6-Dihydroxy-2,5-piperazinedione (**3c**); 22% yield; mp 260 °C (dec); IR: 3380, 3200, 1690 cm^{-1}; NMR (DMSO-d_6): δ=4.6—4.8 (2H, dd, J=4 and 1.2 Hz and d, J=2 Hz), 5.9 (2H, broad s), 8.3 (1H, broad s), 8.4 (1H, broad d, J=4 Hz); Found: C, 32.73; H, 4.29; N, 19.19%. Calcd for $C_4H_6N_2O_4$: C, 32.88, H, 4.11; N, 19.18%. 3,6-Diacetoxy-2,5-piperazinedione (**3d**); 44% yield; mp 185 °C (dec); IR: 3200, 3120, 1760, 1720 cm^{-1}; NMR (DMSO-d_6): δ=2.1 (6H, s), 5.8 (2H, dd, J=5 and 1.2 Hz), 9.3 (2H, broad d, J=5 Hz), Found: C, 41.77; H, 4.63; N, 11.99%. Calcd for $C_8H_{10}N_2O_4$: C, 41.74; H, 4.35; N, 12.17%. 3,6-Diazido-2,5-piperazinedione (**3e**); 32% yield; mp 168 °C; IR: 3250, 2150, 1700 cm^{-1}; NMR (DMSO-d_6): δ=5.2—5.4 (2H, dd, J=4 and 1.2 Hz, and d, J=2 Hz), 9.1 (2H, broad s); Found: C, 24.57; H, 2.25; N, 57.08%. Calcd for $C_4H_4N_8O_2$: C, 24.49; H, 2.04; N, 57.14%.

Electrochemical Conjugate Additions of the Allyl Groups in Substituted Allyl Halides to α,β-Unsaturated Esters

Shohei SATOH, Hiroshi SUGINOME, and Masao TOKUDA*

Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received January 30, 1981)

Electrolysis of allyl halides and diethyl fumarate (**2**) in *N,N*-dimethylformamide containing 0.2 M† tetraethylammonium tosylate gave a conjugate addition product, ethyl 3-(ethoxycarbonyl)-5-hexenoate, in a moderate yield. The electrochemical reaction of 1-chloro-3-methyl-2-butene (**4**) with **2**, that of allyl chloride **4** with methyl crotonate (**6**), and that of methyl 4-halo-2-butenoate with **2** likewise gave the corresponding conjugate addition products, ethyl 3-(ethoxycarbonyl)-6-methyl-5-heptenoate, methyl 3,4,4-trimethyl-5-hexenoate, and ethyl 3-(ethoxycarbonyl)-4-(methoxycarbonyl)-5-hexenoate, respectively. The addition reaction of **4** to **2** takes place at the α-carbon terminus of **4** exclusively, whereas the addition of **4** to **6** at the γ-carbon terminus of **4**. These regioselectivities of the additions and pathways of the reactions are discussed.

The electrochemical reduction of organic halides has been extensively studied, but most of these studies have been concerned with the elucidation of the mechanism of the cleavage of the carbon-halogen bond.[1] These studies have shown that the electrochemical reduction of carbon-halogen bonds generally gives radical or carbanion intermediates[2] which result in the formation of dimers or hydrocarbons.[1]

Although these species generated by ordinary chemical reaction are widely used in a variety of organic syntheses, only a limited number of investigations have been reported on the application of these species generated by the electrochemical reduction of organic halides to the formation of the carbon-carbon bond. These electrochemical investigations include ones on the cyclization of α,ω-dihalides,[3] cyclization of acetylenic halides,[4] alkylation of substrates containing an acidic hydrogen by alkyl halides,[5] acylation of benzyl halides,[6] and addition of alkyl halides to carbon-carbon[7] or to carbon-nitrogen double bonds.[8] The electrochemical addition of allyl bromide to acrylonitrile, ethyl acrylate, or diethyl maleate has also been reported to give a conjugate addition products.[7a]

In this paper we report a conjugate addition of the allyl group in allyl halides to α,β-unsaturated esters by the electrochemical reduction. The electrochemical conjugate additions of the allyl groups in substituted allyl halides to α,β-unsaturated esters were found to take place in a regioselective manner at either their α- or γ-carbon terminus.

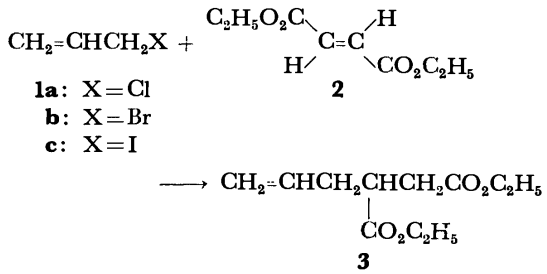
Results and Discussion

The electrolysis of allyl chloride (**1a**), allyl bromide (**1b**), or allyl iodide (**1c**) together with diethyl fumarate (**2**) in *N,N*-dimethylformamide (DMF) containing 0.2 M tetraethylammonium tosylate as a supporting electrolyte gave a conjugate addition product, ethyl 3-(ethoxycarbonyl)-5-hexenoate (**3**), in the yields shown in Table 1. Electrolyses were carried out at a constant current in a normal undivided cell with two platinum plate electrodes. Electrolysis of **1b** in the presence of tenfold excess of **2** gave **3** in a 70% yield, although electrolysis of **1a** or **1c** under the same conditions gave a lower yield of **3**.

Table 1. Results of electrochemical additions of allyl groups in allyl halides (**1a**, **1b**, and **1c**) to diethyl fumarate (**2**)[a]

	1 (mmol)	2 (mmol)	F/mol	Conv./% of 1	Yield/%[b] of 3
1a	1.7	15	2	—	15
1b	1.5	1.5	4	100	36
	1.5	3	2	68	58
	1.5	3	4	75	61
	1.5	15	2	85	70
1c	1.5	15	2	90	39

a) Conducted at 5 mA/cm² in DMF containing 0.2 M Et_4NOTs. b) Yields are based on **1** consumed.



Scheme 1.

When substituted allyl halides are used in this electrolysis, the formation of a mixture of two isomers arising from the combination of the allyl halides at their α- and γ-carbon termini to α,β-unsaturated ester might be expected. The electrochemical reaction of a substituted allyl chloride, 1-chloro-3-methyl-2-butene (**4**), with a two-fold excess of diethyl fumarate (**2**) at 0 °C, however, gave exclusively ethyl 3-(ethoxycarbonyl)-6-methyl-5-heptenoate (**5**) in a 15% yield, in which a less heavily substituted carbon terminus of the allyl group was attached to the α,β-unsaturated ester. The electrolysis was conducted in DMF containing 0.2 M tetraethylammonium tosylate at a constant current of 25 mA/cm². Electricity passed was 2 Faraday per mole of **4**. On the other hand, the electrochemical reaction of **4** with methyl crotonate (**6**) gave methyl 3,4,4-trimethyl-5-hexenoate (**7**) as a single product, in which a more heavily substituted

	8 (mmol)	**2** (mmol)	Curr. dens. mA cm^{-2}	F/mol	Yield/%[b] of **9**
8a	1.5	15	5[c]	2	16
	1.5	15	5	2	39
	1.5	15	5	4	18
	1.5	15	25	2	14
	1.5	5	5	2	20
	1.5	15	5[d]	2	27
	1.5	15	5[d]	4	31
8b	1.5	15	5	2	11
	1.5	15	5[d]	2	11

a) Conducted at −40 °C in DMF containing 0.2 M Et_4NOTs using a platinum cathode. b) Yields are based on **8** used. c) Conducted at 0 °C. d) Mercury pool was used as a cathode.

carbon of the allyl group was attached to the α,β-unsaturated ester, in a 22% yield. The structures of **5** and **7** were determined by elemental analyses and spectroscopies. The ^1H NMR spectrum of **7** gave well-resolved signals consistent with the assigned structure by an addition of 40 mol% of tris(dipivaloylmethanato)europium.

Electrolysis of methyl 4-bromo- (**8a**) or methyl 4-iodo-2-butenoate (**8b**) with ten-fold excess of **2** gave ethyl 3-(ethoxycarbonyl)-4-(methoxycarbonyl)-5-hexenoate (**9**) as the major product, in which the allyl group was again combined to the α,β-unsaturated ester with an allylic rearrangement. The structure of **9** was confirmed by the elemental analysis and spectroscopy. Traces of two isomeric products (**10** and **11**) were also obtained in this electrolysis. Table 2 shows the yields of **9** under various conditions. When electrolysis was conducted at −40 °C, **9** was obtained in a higher yield than at 0 °C. This is probably due to the decomposition or the condensation of the anion generated from **8** at room temperature. It is also seen that platinum is better than mercury as a cathode material.

The allyl groups were thus regioselectively com-
