(Received January 20, 1981)

A bundle of carbon filaments, each about 20 cm in length and 7 μm in diameter, could be grown from purified graphitic material in argon plasma generated in a d.c. arc. The filaments were converted into softer filaments on heat-treatment to 3000—3400 °C. The filaments formed intercalation compounds of potassium, rubidium, and caesium. The electrical resistivities were found to be 1300, 610—660, 23—25, and 28—30 μΩ cm at 300 K for the original filament, the heat-treated filament, and the first stage golden and the second stage dark-blue intercalation compounds of the heat-treated filament, respectively.

Filamentary growth of carbons has been reported to occur when a carbon-rich gas such as carbon monoxide,[1] methane,[2] heptane,[3] and benzene[4] is pyrolyzed in the presence of some solid material, and also when carbons such as graphite[5] and carbon black[6] are heat-treated to temperatures higher than 3000 °C. Haanstra *et al.*[1] have obtained pencil-like carbon columns, 3—6 μm in diameter and about 1 mm long, by pyrolysis of carbon monoxide on a β-SiC crystal. The columns were found to have a conehelical structure; they are stacked from parallel layers of carbon atoms, bent into a cone mantle with a top-angle of about 141°.

Koyama[4] has obtained carbon fibers of a cylindrical scroll structure by pyrolyzing a mixture of benzene and hydrogen on a graphite block abraded with an emery paper. Bacon[5] grew graphite whiskers from a graphite-rod electrode in a d.c. arc under a pressure of 92 atm of argon at 3900 K. They consist of one or more concentric tubes, each in the form of a scroll or rolled-up sheet of graphite layers.

We could grow a bundle of "carbon filaments," each about 20 cm long and 7 μm in diameter, by heating purified graphitic material in argon plasma. Each filament was found to have a smooth surface and a cylindrical shape with circular cross-section of nearly constant diameter over its entire length. Each was composed of three parts: the outer sheath, the inner sheath, and the core.[7] The outher sheath, about 0.7 μm thick, consists mainly of circumferentially oriented graphitic layers; the inner sheath, about 1.4 μm thick, consists mainly of radially oriented graphitic layers. The core, about 2.8 μm in diameter, probably consists of randomly distributed minute crystallites or amorphous material, because it did not show any electron diffraction pattern. The carbon filaments were converted into softer filaments on heat-treatment to 3000—3400 °C.

In this paper we will report the electrical conductivities of these newly obtained carbonaceous filaments as well as of their alkali-metal intercalation compounds. We will discuss the conductivities in relation to their fine crystalline structures inferred not only from the X-ray and electron diffractions but also from the Raman scattering and the magnetoresistance.

Experimental

A piece of grafoil GTA (Union Carbide Co.) was immersed in hot aqua regia for a day and then purified by heating repeatedly to 800 °C for 10 min in a stream of wet chlorine. These processes reduced the concentration of impurities, for example iron, from 80 to less than 8 ppm. Carbon filaments could not be grown from unpurified grafoil. The purified grafoil, supported by a graphite rod between two graphite-rod electrodes, was heated with argon plasma generated in a d.c. arc. When the temperature of plasma exceeded 5000 °C, a bundle of carbon filaments started to grow at the rate of about 1 cm min^{-1} under the nearly atmospheric pressure of argon.

The carbon filaments thus obtained were converted into softer filaments on graphite-resistance heating at 3000 °C, or on high-frequency heating at 3400 °C. The former will be referred to as graphite 30 and the latter as graphite 34 filaments. The diameter of an individual filament was measured by means of scanning electron microscopy.

The intercalation compounds of the filaments with K, Rb, and Cs were prepared by vapor phase reaction in a dual furnace.[8] Their electrical resistivity was measured in the range from 4.2 to 300 K by a four-probe d.c. method in the same way as reported previously.[9] The four-probe contacts with the intercalation compounds were pressure-fixed before the vapor phase reaction.

Graphite 30 and 34 filaments formed lst stage compounds of brilliant golden luster and 2nd stage compounds of dark-blue luster. The X-ray diffraction from the golden compound formed between a graphite filament and Cs, for example, gave sharp spots lying perpendicular to the filament axis and diffuse spots on the axial line. The interlayer distance was determined to be 5.96 Å from the former spots, and the Cs–Cs distance to be 4.92 Å from the latter spots. These values are coincident with those reported for the compound prepared from highly-oriented pyrolytic graphite (abbreviated to HOPG) and Cs.[10] The carbon filaments as grown, on the other hand, did not change their appearance, though their resistivity was reduced by introduction of alkali-metals.

Results and Discussion

The longitudinal resistivities were found to be 1300, 660, and 610 μΩ cm for carbon, graphite 30, and graphite 34 filaments, respectively, at 300 K; these increase monotonously with decreasing temperature down to 4.2 K, as shown in Fig. 1, a—c. The re-

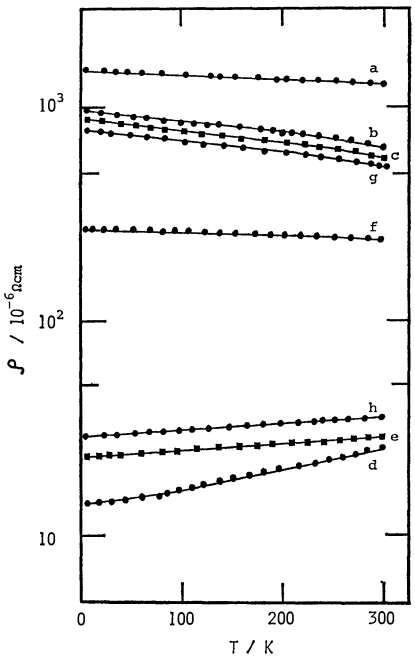

Fig. 1. Temperature dependence of resistivity for filaments.
a: Carbon, b: graphite 30, c: graphite 34, d: K-intercalated graphite (1st), e: K-intercalated graphite (2nd), f: K-intercalated carbon (1st), g: K-intercalated carbon (2nd), and h: K-intercalated graphite (1st) with hydrogen.

sistivity of the graphite filament was found to be lower than that of the carbon filament, but no great difference was found in resistivity between the graphite 30 and 34 filaments. The lower resistivity of the graphite filaments, which were obtained on heat-treatment to 3000—3400 °C, can be ascribed to the preferred alignment of the graphite-type crystallites along the filament axis.

Raman scattering induced by argon-ion laser radiation (488 nm), though it only probed an optical skin depth (<0.1 μm), gave a spectrum of a sharp and intense peak at 1582 cm^{-1} and a tiny and broad peak at 1360 cm^{-1} for the graphite filament. The Raman spectrum for the carbon filament, on the other hand, showed two broad peaks, around 1590 and 1370 cm^{-1}. The former spectrum is quite similar to that found for crudely pulverized natural graphite or for grafoil, and the latter to that of carbon black.[11]

The graphite filament exhibited sharper X-ray diffraction spots and greater intensity contrast between the dark-field (002) or (100) electron-micrograph of the outer sheath and that of the inner sheath, compared with those found for the carbon filament. These results indicate a higher degree of preferred orientation of crystallites in the graphite filament.

The resistivity of HOPG along the basal plane ρ_a has been reported to be 40 μΩ cm at 300 K,[12,13] and to show a slight rise with decreasing temperature down to around 77 K, followed by a rapid descent to 4.2 K. The resistivity along the c-axis, ρ_c has been reported to be about 0.1 Ω cm at 300 K,[12] and to increase with decreasing temperature.[14] The temperature dependence of resistivity observed for the graphite filament is different from that for HOPG, but rather similar to that found for bulk polycrystalline graphite such as grafoil[9] and that of the c-axis resistivity for pyrolytic graphite.[14]

The graphite filament was obtained on heating the carbon filament at a high temperature region where three-dimensional ordering of the layers characteristic to the graphite structure is expected to develop, but some loose aggregates of misoriented crystallites still seem to remain among graphite-type crystallites. The graphite-type crystallites which form the outer and inner sheaths of a filament are preferentially aligned with their basal planes parallel to the filament axis, so charge carriers are expected to move along the basal plane in the direction of the filament axis in each crystallite, the higher basal plane conductivity providing a lower resistivity path along that direction. Hence, the misoriented crystallites and crystalline boundaries seem to determine the value of longitudinal resistivity and to characterize the temperature dependence.

Presumably, some thermally activated process may be included in the conduction through the misoriented crystallites. Indeed, the resistivity exhibited an exponential change with reciprocal temperature in the temperature region above 150 K, and the activation energy was determined to be 0.01 eV for the graphite filament, though it still remains unknown whether this activation energy is related to the semiconducting energy gap or to some hopping process of charge carriers. Graphite whiskers[5] and graphitized carbon fibers[15] have been reported to show an HOPG-like temperature dependence of resistivity.

A preliminary measurement of transverse magnetoresistance ($\Delta\rho/\rho_0$) was carried out on single filaments in the magnetic field up to 120 kOe,††† by using an Intermagnetics MIDIBRUTE 120 superconducting magnet. Electrical contacts of a filament were made with silver paint to four thin gold wires. The magnetoresistance was found to be positive for the carbon filament and to be negative for the graphite filament at 4.2 K in the entire range of magnetic field. Rotation of a single filament around the filament axis, which was oriented perpendicular to the magnetic field, did not change the magnetoresistance.

Soft cokes heat-treated at temperatures lower than 1100 °C have been reported to show a positive magnetoresistance and those heat-treated at 1500 °C to show a negative magnetoresistance at 4.2 K.[16] A number of suggestions have been made as to the origin of the negative magnetoresistance in a wide range of carbons: crystalline size effect,[17] localized spins,[18] a mobility edge,[19] and a dependence of carrier concentration on a magnetic field.[20] It is unknown to which origin the negative magnetoresistance property observed is attributable, but it seems fairly certain that some sort of disordered state is responsible for the property.

The average carrier mobility along the filament axis, $\bar{\mu}$ was estimated to be about 300 $cm^2 V^{-1} s^{-1}$ at 4.2 K for the carbon filament; the following equa-

††† Oe=1000/4π A m^{-1}.

tion[14] was assumed to be applicable to the magnetoresistance observed:

$$\bar{\mu}=\sqrt{2}(\Delta\rho/\rho_0)^{1/2}\times 10^8/H. \quad (1)$$

Graphite filaments formed 1st stage alkali-metal intercalation compounds of such brilliant golden luster as that of HOPG-based compounds. Non-graphitizable carbons have been reported not to form intercalation compounds. This has been attributed to the cross-linking of the graphitic layers.[21] Hence, the graphite filaments in this study seem to have little cross-linking, though three-dimensional ordering of the layers did not develop on heating to 3000—3400 °C. This is the first example of brilliant golden intercalation filaments as far as we know.

The graphite filaments intercalated with K, Rb, or Cs were found to show a greatly reduced resistivity, in the range of 23—25 μΩ cm for the lst stage compounds, and in the range of 28—30 μΩ cm for the 2nd stage compounds, at 300 K. They were also found to be metallic in character, showing a decrease in resistivity with decreasing temperature (Fig. 1, d, e). No difference in resistivity value was found among the potassium, rubidium and caesium compounds.

The lst stage compounds prepared between HOPG and alkali-metals have been reported to possess the basal-plane resistivity in the range of 10—14 μΩ cm at room temperature[22,23] and to show a decreasing resistivity with decreasing temperature. The grafoil-based alkali-metal intercalation compounds showed resistivity values in the same range and a similar temperature dependence.[9]

When the lst stage golden potassium-intercalated filament was heated in a dual furnace under the conditions in which the 4th stage intercalation compound was expected to be prepared,[8] the filament turned black and showed an increase in resistivity. In general, the resistivity was found to decrease monotonously with intercalant concentration.

The carbon filament, on the other hand, provided alkali-metal intercalation compounds of the resistivity of about 240 and 550 μΩ cm at 300 K, when prepared under the same conditions of preparation as those for the lst and the 2nd stage HOPG-based compounds, respectively. The resistivity of these intercalated carbon filaments was found to increase with decreasing temperature (Fig. 1, f, g).

From these observations, it is inferred that an introduction of alkali-metal atoms not only increases the number of conducting carriers in the graphitic layers, but also eliminates some of imperfections present in the pristine graphite filaments. Certainly, the X-ray diffraction from the intercalated graphite filament gave much sharper spots than that from the pristine filament did. The electric anisotropy, ρ_c/ρ_a has been reported to be reduced from 2500 for HOPG to 34 for the intercalated compound,[22] so misorientation of crystallites seems to have less influence on resistivity value after they are intercalated with alkali-metals. The intercalated filaments were unstable in air, so they could not be taken out from a sealed glass tube. Because of the technical difficulties encountered in these reactive filaments, their magnetoresistance have not been measured yet.

A golden potassium-intercalated graphite filament turned blue and its resistivity reached 36 from 25 μΩ cm at 300 K, when hydrogen purified through a heated Pd–Ag thimble was introduced to the intercalated filament. This change is quite similar to that observed for the grafoil-based potassium intercalation compound,[9,24] and can be explained in terms of the formation of a ternary compound.[25]

The authors wish to express their hearty thanks to Professor Yoshihiro Hishiyama of Musashi Institute of Technology, and Drs. Yoichiro Sato and Takaho Tanaka of the National Institute for Research in Inorganic Materials for heat-treating the carbon filaments, and to Dr. Koshiro Toriumi of Institute for Molecular Science for his valuable discussion on the crystal structure of filaments.

Kinetics for Micelle-Monomer Association-Dissociation Reaction of Surfactants with Hydrophobic Counterions

Tohru Inoue,* Masaru Ikeuchi, Takemi Kuroda, and Ryosuke Shimozawa

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Nishi-ku, Fukuoka 814-01

(Received October 18, 1980)

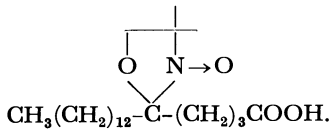
A pressure-jump technique and a spin label technique were applied to the kinetic investigation of the association-dissociation reactions between monomer and micelle in surfactant solutions of STS, TMTS, TETS, and TPTS.** The rate constants for the reactions were determined at several temperatures by the pressure-jump experiment. The ESR spectra of a spin probe, 5-SAL, solubilized in the micelles were analyzed in terms of the rotational correlation time, τ_c. A linear relationship was found between k_d, the dissociation rate constant, and τ_c^{-1}. This indicates that the dissociation rate depends on the fluidity of the micellar interior, and is in accord with the picture drawn by Aniansson *et al.* for the dissociation process. A qualitative discussion is presented on the activation parameters estimated from the present results according to the scheme presented by Aniansson *et al.*

Kinetics of relaxation processes occuring in micellar solutions have been extensively investigated using fast chemical relaxation techniques. It is established experimentally that in many surfactant solutions at least two relaxation processes exist in well-separated time domains. Kinetic information on the association-dissociation process of the monomer with the micelle is obtained from the fast relaxation time, and that on the micellization-dissolution process is obtained from the slow relaxation time.[1)]

The behavior of the relaxation times associated with these two processes is affected by the counterion;[2-4)] a relaxation study for micellar systems of *N*-alkylpyridinium salts with hydrophobic counterion has been reported by Hoffmann *et al.*[5)] In the present work, the pressure-jump measurements were carried out for the micellar systems of tetradecyl sulfate having several types of tetraalkylammonium ions as counterion; the dissociation and association rate constants of the monomer from and with the micelle were determined from the relaxation data.

Aniansson *et al.*[1)] have treated the dissociation of a surfactant monomer from the micelle as a diffusion process of a monomer in micelle perpendicular to the micellar surface; they derived an expression for the dissociation rate constant in terms of the diffusion coefficient of the leaving monomer and the free energy barrier which a monomer has to overcome to dissociate from the micelle. This model predicts that some correlation will occur between the dissociation rate and the fluidity of the micellar interior. The direct information about the fluidity can be obtained from the ESR spectra of a spin probe solubilized in the micelle. In this work, therefore, ESR measurements were also carried out with the same surfactant systems using 5-SAL (a fatty acid spin label) as a probe. The ESR spectra were analyzed in terms of the rotational correlation time, τ_c, and the relationship between τ_c and dissociation rate constant was examined.

**Abbreviations used in this paper:
STS; sodium tetradecyl sulfate, TMTS; tetramethylammonium tetradecyl sulfate, TETS; tetraethylammonium tetradecyl sulfate, TPTS; tetrapropylammonium tetradecyl sulfate, 5-SAL; 2-tridecyl-2-[3-(carboxyl)propyl]-4,4-dimethyloxazolidin-3-yloxyl



$CH_3(CH_2)_{12}$-C-$(CH_2)_3COOH$.

Experimental

Materials. The surfactants used in this study were prepared by the following procedure.[6)]

STS was prepared by the usual method from tetradecyl alcohol purified by the fractional distillation. This STS was converted to silver tetradecyl sulfate (AgTS) by repeated crystallization in aqueous solution of $AgNO_3$ at about 30 °C followed by repeated recrystallization from water. The content of Ag^+ in AgTS was assayed to be in agreement with the calculated value within 0.5% by titrating ethanolic solution of AgTS with a standard aqueous solution of NaCl, using K_2CrO_4 as an indicator.

TMTS, TETS, and TPTS were prepared by double decomposition of the above mentioned AgTS with tetramethylammonium chloride, tetraethylammonium chloride, and tetrapropylammonium iodide, respectively, in ethanol. These halides were commercial products and purified by recrystallization from ethanol. To AgTS was added a stoichiometric amount of the corresponding halide. The precipitated silver halide was removed by filtration, and a small amount of the reagents was added to the filtrate. This procedure was repeated until no precipitation was observed. The final filtrate was evaporated and the residue was dried *in vacuo*.

The spin label reagent, 5-SAL, was purchased from Syva (Palo Alto, Calif.).

Critical Micelle Concentration (CMC). The CMC's of TMTS, TETS, and TPTS were determined by the conductivity method at different temperatures. The results are summarized in Table 1, together with those of STS.

Relaxation Measurement. The pressure-jump (P-jump) apparatus with conductivity detection was described previously.[4)]

ESR Measurement. ESR spectra were recorded on a JEOL model FEIX ESR spectrometer at room temperature (24±1 °C).

Sample solutions were prepared by the following procedure. A required amount of stock solution of 5-SAL in chloroform was taken into a volumetric flask to give the desired probe/surfactant molar ratio, and the solvent was completely evaporated *in vacuo*. A stock solution of the surfactant was added, and the mixture was then shaken in

the dark overnight to assure the solubilization of the probe in micelle. This surfactant-probe stock solution was diluted to prepare the solution of desired surfactant concentration.

Results

Pressure-jump Study. It is usually difficult to observe both of the relaxation processes in micellar solution using a single relaxation technique, because of the restricted time range available for a single apparatus. Fortunately, in the case of STS, two relaxation processes can be observed by the P-jump technique.[1,7,8] However, for the present three surfactant systems, only one of the relaxations could be detected

Errors are standard deviations computed by linear regression analysis.

by P-jump measurement in spite of the identity of the long-chain ion with STS. From the relaxation time range and their concentration dependences, this appears to be the faster of the two processes. In order to confirm this assignment, P-jump measurements were carried out for the systems of TMTS and TETS mixed with STS. In these cases two relaxation processes were observed. The slow relaxation time, τ_2, obtained for TMTS–STS mixed system is plotted in Fig. 1 as a function of the mixing ratio at different surfactant concentration. It is seen from Fig. 1 that τ_2 increases with the fraction of TMTS and finally vanishes beyond the observation limit. A similar result was also obtained for TETS–STS mixed system. Thus, it can be concluded that the slow relaxation process for the present surfactants is too slow to be observed by the P-jump apparatus used in this study, whose effective time range is limited to within about 2 s because of the restricted stability of a high frequency bridge.

The plots of the reciprocal of the fast relaxation time, τ_1^{-1}, against the total surfactant concentration, C_0, are shown in Figs. 2a—c for TMTS, TETS, and TPTS, respectively. τ_1^{-1} increases linearly with C_0 in the measured concentration range.

The fast relaxation process in micellar solution has been assigned to the perturbation of the exchange equilibrium of a monomer between micellar and bulk phases. Some workers have applied the theory developed by Aniansson and Wall[9] for the analysis of the relaxation data.[1-3,5,8] In the previous paper,[10] some contradictions were pointed out in the kinetic parameters deduced from the Aniansson-Wall model, and a modification of the model was proposed to settle the contradictions. According to the modified treatment, the fast relaxation time is expressed by the following equation:

$$\tau_1^{-1} = \frac{mk_d}{\sigma^2} + k_d\frac{C_0-\bar{A}_1}{\bar{A}_1}, \quad (1)$$

where k_d is the dissociation rate constant of a monomer from the micelle, m the average aggregation number of the micelle, σ^2 the variance of the micellar size distribution curve which is assumed to be Gaussian, and $\bar{A}_1$ the equilibrium monomer concentration which may be approximated by the CMC.

According to Eq. 1, k_d and σ^2/m are obtained from the slope and intercept at the CMC of the straight line of τ_1^{-1} *vs.* C_0 plot. Furthermore, the association rate constant of a monomer with the micelle, k_a, is estimated from the following relation:

$$k_a = \frac{\alpha}{1-\alpha}\frac{k_d}{\bar{A}_1}, \quad (2)$$

where α represents the fraction of the surface area occupied by monomers at the micellar surface.

Applying Eqs. 1 and 2 to the present experimental results, the rate constants and σ^2/m value, which is a measure of the relative width of the distribution curve of the aggregation number, were determined. They are summarized in Table 2, together with those for STS. For the evaluation of these parameters, the CMC values listed in Table 1 were used as $\bar{A}_1$, and α was assumed to be 0.3.[10] Some uncertainty is associated with the absolute values of k_a because the exact values of α are not available for the respective surfactants. However, the relative values of k_a listed in Table 2 can be compared for the different surfactants under the following assumptions: (i) α is mostly determined by the type of the amphiphile ion and the aggregation number of the micelle; (ii) the aggregation numbers of the relevant surfactant micelle do not differ so significantly. At 25 °C, the relaxation was too fast to be measured by the P-jump apparatus used in this study. Thus, the values in Table 2 at this temperature, which are listed for comparison with STS, are those extraporated from the temperature dependence of the rate constants (see Fig. 3).

It is seen from Table 2 that k_d values for the present systems are smaller than that for STS and also decrease with increasing hydrophobicity of the counterion. On the other hand, k_a shows the reverse change. Furthermore, σ^2/m values decrease with increasing hydrophobicity of the counterion, although

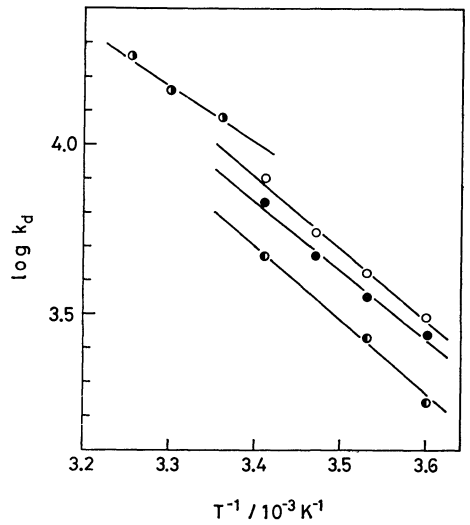

Fig. 3. Plot of log k_d *vs.* T^{-1} for different surfactant systems.

some scatter is seen for TPTS. This means that the micellar size distribution curve becomes narrower for micelles with hydrophobic counterions. The present results on the variation of k_d and σ^2/m are in agreement with those reported by Hoffmann *et al.*[5] for *N*-alkylpyridinium salts having hydrophobic counterion; however, opposite results are obtained for the variation of k_a.

In Fig. 3, the values of log k_d are plotted against $1/T$. The Arrhenius activation energies, E_d, for the dissociation process were determined from the slopes of the straight lines in this figure; these are also listed in Table 2. The E_d values for TMTS, TETS, and TPTS do not differ so significantly, but they are appreciably larger than that for STS.

ESR Study. The ESR spectra of the spin probe, 5-SAL, were analyzed in terms of an effective rotational correlation time, τ_c, which was calculated according to Eq. 3:

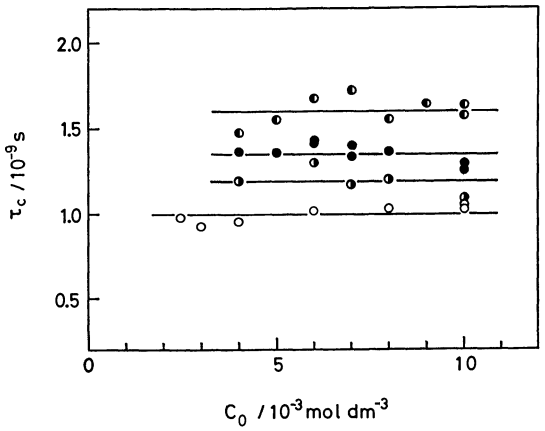

Fig. 5. Plot of τ_c against total surfactant concentration, C_0.
○: STS, ◑: TMTS, ●: TETS, ◐: TPTS. Molar ratio of 5-SAL to surfactant is 1/100.

Table 3. Values of rotational correlation time, τ_c, hyperfine coupling constant, a_N, and degree of counterion association

Surfactant	$\tau_c/10^{-9}$ s	a_N/G	Degree of counterion association
STS	1.00±0.04	15.17±0.04	0.73 (30 °C)
TMTS	1.19±0.07	14.90±0.04	0.79 (20 °C)
TETS	1.35±0.05	14.73±0.06	0.80 (20 °C)
TPTS	1.60±0.07	14.83±0.06	0.82 (20 °C)

$$\tau_c = 6.5\times10^{-10} W_0\left[\left(\frac{h_0}{h_{-1}}\right)^{1/2}+\left(\frac{h_0}{h_{+1}}\right)^{1/2}-2\right], \quad (3)$$

where W_0 is the peak-to-peak width of the center line measured in Gauss, and h_0, h_{+1}, and h_{-1} are the heights of the center, low, and high field spectral lines respectively. This expression has frequently been used to evaluate the degree of motion of probes solubilized in the micelle.[11,12] It is known that Eq. 3 is applicable to a fast isotropic motion of small molecule. The spectra of the spin probe obtained in this study showed a high degree of fast motion, yielding the τ_c values of the order of 10^{-9} s when calculated according to Eq. 3. Furthermore, the patterns of these spectra were similar to those in isotropic media. Thus, it seems reasonable to use Eq. 3 for the present purpose.

Firstly, ESR measurements were carried out for TMTS and TETS by varying the molar ratio of 5-SAL to the surfactant in the range of 1/100 to 4/100 at the fixed total surfactant concentration of 6×10^{-3} mol dm^{-3} and 1×10^{-2} mol dm^{-3}. Under these conditions, the number of the probes solubilized in one micelle is estimated to be about 1 to 5, assuming that the aggregation number of the micelle is approximately 10^2 and that the 5-SAL dissolved in bulk phase is negligibly small compared with that solubilized in the micelle. Figure 4 shows τ_c values plotted against the ratio of the probe to the surfactant. τ_c is almost independent of the ratio. This shows that the state of the micellar interior is not appreciably perturbed by the uptake of the small amounts of the probe.

Secondly, the ESR spectra were measured varying the surfactant concentration at the range above the CMC, keeping the molar ratio of the probe to surfactant constant at 1/100. The values of τ_c obtained with various surfactant systems are shown in Fig. 5 as a function of the total surfactant concentration, C_0. No systematic variations of τ_c with C_0 are seen in Fig. 5. In Table 3 are listed the τ_c values which were averaged over the whole concentration range.

It is seen from Table 3 that τ_c increases with increasing hydrophobicity of the counterion. This means that the degree of motion of the probe in the micelle decreases in the same order. Two main factors may be considered to be responsible for the difference in the degree of motion of the probe; the fluidity of the environment around the probe, and the electrostatic interaction between the negatively charged head group of the probe and the micellar surface charge which is affected by the degree of counterion association. The degree of counterion association was estimated from the counterion concentration dependence of the CMC, and is listed in Table 3. These values are not so different, although a slight regular increase with the hydrophobicity of the counterion is seen. Hence, the difference in τ_c may be mainly attributed to the difference in the fluidity around the solubilized probe.

In Table 3 are also listed the values of the hyperfine coupling constant, a_N, which were determined from the separation between the lines at low and center field in the spectra; these give information about the polarity of the environment around the spin labelled portion. The a_N values for each system were almost independent of both the probe/surfactant ratio and the surfactant concentration. Comparison of STS with other surfactants shows that a_N values for the latter are smaller than that for STS. This indicates that the polarity of the environment around the paramagnetic site becomes smaller for the surfactant with a hydrophobic counterion. For a series of surfactant micelles studied here, the region probed by 5-SAL is considered to be nearly identical, since all the micelle interiors consist of the same long-chain ion, *i.e.*, tetradecyl sulfate ion. Furthermore, the probe used here are considered to be sensing the region relatively close to the surface in the micellar interior, because the probe is the stearic acid derivative spin-labelled at the fifth carbon atom from the carboxyl carbon. Thus, the a_N values in Table 3 show that the tetradecyl sulfate micelles with hydrophobic counterions have fewer water molecules penetrated at the near surface of the micelle interior than STS has; this would be a consequence of the exclusion of water molecules due to the attachment of the hydrophobic counterion. This difference in the extent of water penetration plays a role in the difference in the fluidity at the region probed by 5-SAL.

Discussion

Aniansson *et al.*[1] have treated the dissociation of a monomer from a micelle as a diffusion process of a monomer perpendicular to the micellar surface.

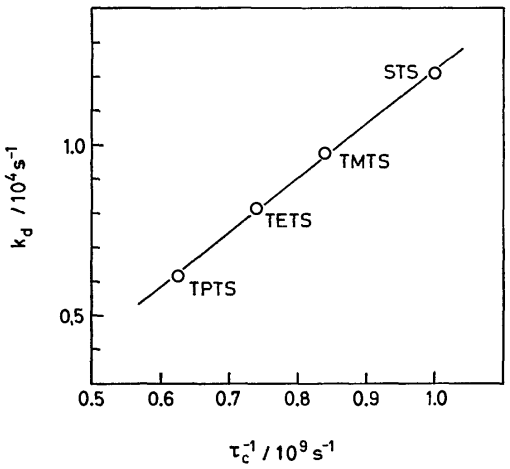

Fig. 6. Relation between dissociation rate constant, k_d, and τ_c^{-1}.
The values of k_d are at 25 °C.

According to their treatment, the dissociation rate constant, k_d, is approximately expressed by Eq. 4:

$$k_d = \frac{D_m}{l^2}\exp(-\Delta G^*/RT), \quad (4)$$

where ΔG^* is the height of the potential barrier corresponding to the activation free energy for the dissociation process, D_m is the diffusion coefficient of a monomer at the potential maximum, and l is the width of the potential maximum region. The main contribution to ΔG^* may arise from the hydrophobic energy, and also from the electrostatic interaction for a charged micelle. Equation 4 can be understood intuitively by noting that D_m/l^2 corresponds to the specific rate constant for the diffusion through the potential maximum, *i.e.*, the number of the molecules transferred through the distance l per unit time, and that $\exp(-\Delta G^*/RT)$ is the probability finding a monomer at an activated state. According to the model postulated by Aniansson *et al.*, the dissociation rate is governed by both ΔG^* and the rate at which a dissociating monomer passes through the potential maximum region.

The diffusion coefficient is proportional to the reciprocal of the viscosity. The viscosity is also reflected in the rotational correlation time of the spin probe, and is proportional to τ_c. Thus, according to the model described above, k_d may be related to τ_c^{-1} through the viscosity, assuming that τ_c well reflects the local viscosity at the region of potential maximum. When k_d was plotted against τ_c^{-1} for the series of surfactant systems studied here, a definite linear relationship was obtained, as is shown in Fig. 6. This indicates that in the series of surfactants the activation free energies, ΔG^*, are almost identical and that the difference in k_d is mainly attributed to the difference in D_m.

For a spherical particle of radius r_1 in a viscous fluid, the value of τ_c is related to the viscosity η by[13]

$$\tau_c = 4\pi\eta r_1^3/3kT. \quad (5)$$

The translational diffusion coefficient of a spherical particle of radius r_2 is related to the viscosity of the

TABLE 4. VALUES OF D_m AND ACTIVATION PARAMETERS FOR THE DISSOCIATION OF A MONOMER FROM A MICELLE ESTIMATED FROM Eqs. 4—6.

Surfactant	D_m / 10^{-7} cm^2 s^{-1}	ΔG^* / kJ mol^{-1}	ΔH^* / kJ mol^{-1}	ΔS^* / J K mol^{-1}
STS	5.6	32.5	11.3	−71
TMTS	4.7	32.6	20.7	−40
TETS	4.1	32.7	18.5	−48
TPTS	3.5	33.0	21.8	−38

medium by the Stokes-Einstein equation, *i.e.*,

$$D = kT/6\pi\eta r_2. \tag{6}$$

Assuming that 5-SAL and tetradecyl sulfate ion are spheres of radius 5 Å (*i.e.*, $r_1=r_2\approx 5$ Å), the values of D_m were estimated from Eqs. 5 and 6 for the present systems. Furthermore, using these D_m values and $l\approx 1$ Å,[1] the value of ΔG^* were estimated from Eq. 4. These values are listed in Table 4. In spite of the rather crude numerical values adopted here, D_m values are in agreement to the order of magnitude with the diffusion coefficient of a different type of spin probe in SDS micelle.[14]

ΔG^* is expressed as

$$\Delta G^* = \Delta H^* - T\Delta S^*, \tag{7}$$

where ΔH^* and ΔS^* are the activation enthalpy and entropy for the dissociation process of a monomer from a micelle. On the other hand, D_m is expressed as Eq. 8, taking into account the temperature dependence of η in Eq. 6, *i.e.*, $\eta=$constant$\cdot\exp(\Delta H_v/RT)$:[15]

$$D_m = TC\exp(-\Delta H_v/RT), \tag{8}$$

where ΔH_v is the viscous enthalpy and C a constant independent of the temperature. Then, from Eqs. 4, 7, and 8, one obtains

$$k_d = \frac{TC}{l^2}\exp(\Delta S^*/R)\exp[-(\Delta H_v+\Delta H^*)/RT]. \tag{9}$$

According to Eq. 9, $\Delta H_v+\Delta H^*$ can be evaluated from the temperature dependence of k_d. The values of $\Delta H_v+\Delta H^*$ for the present surfactant systems were determined from the slope of the $\log k_d$ *vs.* $1/T$ plot in Fig. 3. The values of ΔH^* were evaluated assuming $\Delta H_v\approx 17.6$ kJ mol^{-1} for STS.[1] Furthermore, ΔS^* values were evaluated from Eq. 7. These values of activation parameters are listed in Table 4.

The numerical values in Table 4 might not be good enough for a quantitative discussion, since they were evaluated using rather crude approximations. However, the qualitative discussion given below is reasonable.

As seen in Table 4, the values of ΔS^* are negative for all cases. This implies that the degree of freedom of the system becomes smaller through the activation process. The activated state may be described as a state where the hydrocarbon chain of the dissociating monomer partially leaves the hydrocarbon core of the micelle, while the tail end still remains in this core. Since the freedom of the dissociating monomer chain itself may increase, the observed overall decrease of the freedom may be attributed to the decrease in freedom of water molecules resulting from the formation of an ordered structure around the nonpolar portion of the dissociating monomer. Thus, the negative values of ΔS^* may be interpreted as due to an "iceberg" structure formation of water around the exposed hydrocarbon tail of the escaping monomer.

The absolute values of ΔS^* for TMTS, TETS, and TPTS do not differ significantly, although that for STS is considerably larger than the others. This means that the degree of hydration of the monomer (or degree of "iceberg" formation) at an activated state is larger for STS. This difference in hydration may be interpreted as follows. The properties of water molecules in the vicinity of the micellar surface may be altered from that of the bulk free water by the influence of the counterion present at fairly high concentration. If one assumes that only free water molecules could participate in the formation of the "iceberg" structure, one expects the existence of a water layer which is non-effective for the "iceberg" formation just outside the micellar surface. The thickness of this "non-effective" layer is expected to be larger for a bulky tetraalkylammonium ion than for the sodium ion. Thus, if one assumes, at the activated state, the hydration or "iceberg" formation around the exposed hydrocarbon chain, and also the presence of a thicker water layer which is ineffective for hydration on a micellar surface covered with bulky counterions, then the larger negative ΔS^* for STS could be qualitatively explained.

On the other hand, the values of ΔH^* are positive. This corresponds to the situation in which the energy to break the hydrocarbon contact in the micellar interior is required for activation. This energy may be partly compensated by the heat of hydration which is liberated by the attachment of water molecules to the hydrocarbon chain. Therefore, the ΔH^* value may become smaller when more hydration proceeds through the activation process. Thus, the smaller value of ΔH^* for STS system, compared with those for the others, is also understood on the basis of the difference in the degree of hydration in the activated states.

The contributions from ΔS^* and ΔH^* to the activation free energy are reverse and compensate each other; hence, nearly identical values of ΔG^* are obtained for different surfactant systems. It is considered from the values of ΔS^* and ΔH^* that the water molecules play an important role in the activated state. Furthermore, from the relation between τ_e and a_N, the water molecules present in the probed near-surface region of the micelle may also be responsible for the difference in the fluidity, which is the main factor governing the dissociation rate.

The authors wish to express their thanks to Prof. Magobe Yamamoto, Faculty of Pharmaceutical Sciences, Fukuoka University, for his kind permission and technical advice concerning the measurement of ESR spectra in his laboratory.

ESR Spectra and Structure of the Radical Anions of Organo Halosilanes

Akinori HASEGAWA,* Akihiro NAGAYAMA, and Michiro HAYASHI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Naka-ku, Hiroshima 730

(Received December 20, 1980)

The radical anions of ethyl- and vinyl- halosilanes formed in solid matrices of tetramethylsilane and their ESR spectra were investigated to be compared with results obtained from related radical anions. These radical anions have a trigonal bipyramidal structure with two axial and two equatorial positions. Ethyl and methyl groups which are less electronetative than H prefer the equatorial positons. The vinyl group with a single π electron system occupies the equatorial position due to its electron-donating capability, in spite of its larger electronegativity.

We have reported some ESR studies on the radical anions of simple halides whose central atom is a Group IV element; these anions formed in solid matrices of tetramethylsilane (TMS).[1-4] Results for some bromides will be mentioned briefly. In CF_3Br^- radical anions, the three F atoms are equivalent to one another and a large spin density is on the Br atom.[1] It was therefore concluded that the radical anions have C_{3v} symmetry and that the Br atoms are on the symmetry axes. On the other hand, a congeneric SiF_3Br^- radical anion with a central Si atom has larger contributions of spin density on the Br and one F atoms and small contributions on the other two F atoms.[2] This fact led us to the conclusion that the radical anion has trigonal bipyramidal structure with the Br atom and the first F atom in the axial positions and the other two F atoms in the equatorial positions. A similar trigonal bipyramidal structure has also been suggested for SiH_3Br^- radical anion, since hyperfine structure due to the Br and one H nuclei was observed in the ESR spectrum.[3] However, GeH_3Br^- radical anions, which are congeneric to SiH_3Br^-, have been reported to have a structure with C_{3v} symmetry, as in the case of CF_3Br^-, because the hyperfine structure of the Br nucleus in the ESR spectrum is further split by three equivalent H nuclei.[4] Thus, the structure of radical anions is significantly affected by the type of central atom present. Moreover, ESR spectra of methyl-substituted radical anions such as $CH_3SiH_2Br^-$ and $CH_3GeH_2Br^-$ have been investigated in order to confirm the structural difference between trigonal bipyramidal and C_{3v} structures.[5] No substantial change in radical structure resulted from the introduction of methyl groups, and it was therefore concluded that, even in the methyl-substituted radical anions, the silicon-centered radical anions prefer a trigonal bipyramidal structure whereas the germanium-centered radical anions have a local C_{3v} structure. For the silicon-centered radical anions, the methyl groups have been suggested to prefer the equatorial positions to the axial ones of the trigonal bipyramidal structure.

On the basis of these facts, this study was designed. Organo halosilanes $RSiH_2X$ (X=Br or I) containing different kinds of organo group R were prepared; irradiation then produces their radical anions in TMS matrices. Thus we could investigate the effect of substituent groups on radical structure and on the distribution of spin density.

Experimental

Ethylsilane and vinylsilane were prepared by reducing ethyltrichlorosilane and vinyltrichlorosilane (Tokyo Kasei), respectively, with lithium aluminium hydride in dibutyl ether. Ethylbromosilane was prepared by the reaction with mercury(II) bromide[6] and ethyliodosilane with hydrogen iodide in the presence of aluminium triiodide as a catalyst.[7] Vinylbromosilane and vinyliodosilane were similarly obtained.

All of the compounds prepared were isolated and purified by distillation *in vacuo*, and identified from IR spectra.[8]

Solid solutions of tetramethylsilane (Merck) containing 5 mol% of the appropriate silane were irradiated at 77 K with γ-rays to *ca.* 1.5 Mrad in a ^{60}Co γ-source.

ESR spectra were measured at 77 K with an X-band JES-3BSX spectrometer after irradiation.

Results and Discussion

When a solid solution of TMS containing 5 mol% of $C_2H_5SiH_2Br$ was γ-irradiated at 77 K and followed by ESR observations at 77 K, the ESR spectrum shown in Fig. 1 was observed. In addition to the central lines originating from the matrix radical $\cdot CH_2SiMe_3$, one can find an anisotropic spectrum similar to the spectra assigned to the SiH_3Br^-[3] and $CH_3SiH_2Br^-$[5] radical anions, which formed in TMS matrices and have trigonal bipyramidal structures. In accordance with the analyses reported for these radical anions, the observed spectrum is interpreted in terms of hyperfine structure due to one Br ($^{79}Br(I=3/2)50.57\%$, $^{81}Br(I=3/2)49.43\%$) and one H nuclei. The coupling constant of the H nucleus is similar in magnitude to that of H nucleus in an axial position of SiH_3Br^-[3] and to that of the H nucleus which is bonded to the Si atom and possesses an axial position of $CH_3SiH_2Br^-$.[5] Accordingly, the $C_2H_5SiH_2Br^-$ radical anions formed were concluded to have trigonal bipyramidal structure possessing the Br and H atoms with large spin densities in the axial positions and the other H atom and the C_2H_5 group in the equatorial positions.

Similar experiments were also carried out with $C_2H_5SiH_2I$ in a TMS matrix. The observed ESR spectrum was interpreted in terms of hyperfine splittings due to the axial I and H nuclei of trigonal bipyramidal $C_2H_5SiH_2I^-$ radical anions. This result is in contrast to the fact that the radical anions $CH_3SiH_2I^-$ have been assigned to have, exceptionally, a local C_{3v} struc-

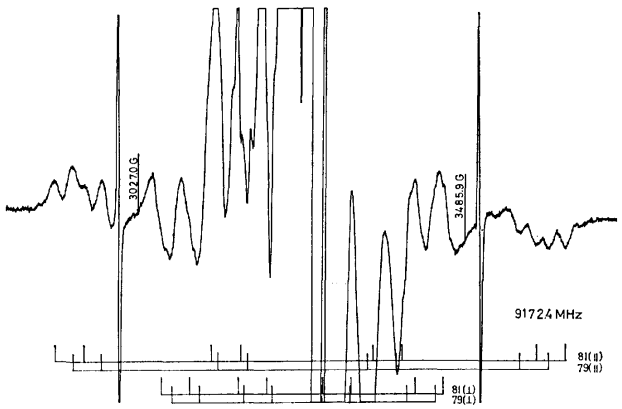

Fig. 1. First derivative ESR spectrum of a γ-irradiated solid solution of 5 mol % ethylbromosilane in tetramethylsilane, recorded at 77 K.
The stick diagrams represent the calculated line positions of the parallel (upper) and the perpendicular (lower) components for $C_2H_5SiH_2{}^{79}Br^-$ and $C_2H_5SiH_2{}^{81}Br^-$ according to the parameters listed in Table 1.

ture rather than a trigonal bipyramidal structure since the ESR spectrum consists of a sextet due to the I nucleus and a 1:2:1 triplet due to three equivalent H nuclei.[5]

Resonance line positions were calculated by a matrix diagonalization program with the ESR parameters listed in Table 1. In accordance with the above analyses, the stick diagrams calculated show good agreement with the observed spectra assigned to $C_2H_5SiH_2Br^-$ and $C_2H_5SiH_2I^-$. Spin densities were obtained by the use of the atomic values of hyperfine coupling constants[9] calculated from Froese's wave functions[10] for comparison with those of related and reported radical anions; the values are listed in Table 1 with ESR parameters. If atomic values calculated recently by Morton and Preston[11] are used, the values become smaller. In Table 1, results for $CH_3SiH_2X^-$[5] and SiH_3X^-[3] (X=Br or I) are given for comparison. Spin densities on the axial H and halogen atoms increase in the order C_2H_5, CH_3, and H for R of $RSiH_2X^-$ (X=Br or I) except for the case $CH_3SiH_2I^-$, where a local C_{3v} structure was suggested.[5] The group electronegativity of each substituent increases in the same order.

Here, it might be of interest to quote results for the SiF_3Br^-[2] and SiH_3Br^-[3] radical anions which have axial Br atoms in their trigonal bipyramidal structure. Since Br is less electronegative than F and more electronegative than H, the less electronegative Br occupies the axial position of SiF_3Br^-. Phosphoranyl radicals are isoelectronic to the silicon-centered radical anions and also have trigonal bipyramidal structures, which are similar to the structure of phosphoranes. Colussi *et al.*[12] have made INDO calculations for phosphoranyl radicals and phosphoranes. According to their results, electron densities (charge densities) in PH_4 and PH_5 are larger in the axial positions than in the equatorial positions. In the cases of PF_4 and PF_5, however, the equatorial positions have higher electron densities than the axial positions. Therefore, when a group which is more electronegative than H is replaced with an H atom of PH_4 or PH_5, the group prefers an axial position with its higher electron density. Coherently, a less electronegative group possesses an axial position with a lower electron density upon the substitution with an F atom of PF_4 or PF_5. The effect of group electronegativity on the preferential occupation of substituents has also been investigated experimentally for phosphoranyl radicals.[13] Similar

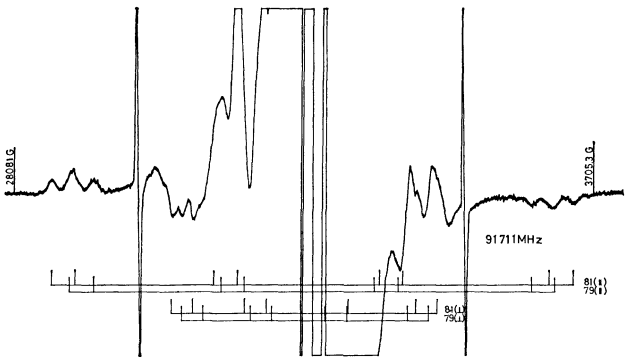

Fig. 2. ESR spectrum of a γ-irradiated solid solution of 5 mol % vinylbromosilane in tetramethylsilane, recorded at 77 K, and the stick diagrams calculated for CH_2=$CHSiH_2{}^{79}Br^-$ and CH_2=$CHSiH_2{}^{81}Br^-$.

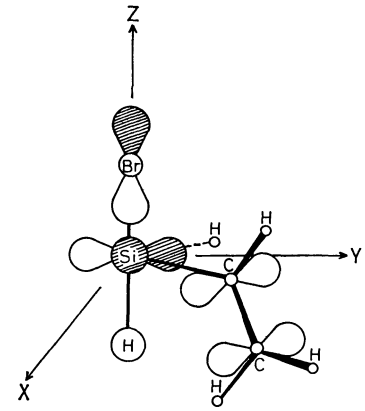

Fig. 3. A structure proposed for CH_2=$CHSiH_2Br^-$. The terminal C atom in the vinyl group is on the upper side or on the lower side of the equatorial plane.

results can be expected for the silicon-centered radical anions which are isoelectronic to phosphoranyl radicals. Accordingly, the axial positions of the Br atom in SiH_3Br^- and SiF_3Br^- are well accepted.

In the case of $RSiH_2X^-$, it is thus reasonable to expect that a group R more electronegative than H takes an axial position and that a less electronegative group R occupies an equatorial position. Indeed, as mentioned above, C_2H_5 and CH_3 groups which are less electronegative than H occupy the equatorial positions of the trigonal bipyramidal $RSiH_2X^-$ radical anions. This result is consistent with the result obtained recently for the radical anions of methylstannanes: that methyl groups prefer the equatorial positions of the trigonal bipyramidal structure.[14]

Since vinyl groups are more electronegative than H and are therefore expected to possess the axial positions of CH_2=$CHSiH_2X^-$ radical anions, a solid solution of TMS containing CH_2=$CHSiH_2Br$ was irradiated. As shown in Fig. 2, the ESR spectrum consists of the anisotropic hyperfine structure of a quartet from one Br atom and a doublet. The doublet may originate from an H atom bonded to the Si atom or from one in the vinyl group. Thus, similar experiments were carried out with CH_2=$CHSiD_2Br$. As a result, the doublet which appeared in the case of CH_2=$CHSiH_2Br$ was removed and the anisotropic quartet spectrum alone was observed. Therefore, the spectrum observed with CH_2=$CHSiH_2Br$ was interpreted to contain hyperfine splittings due to the Br atom and one of the two H atoms bonded to the Si atom. This fact leads us to the conclusion that the CH_2=$CHSiH_2Br^-$ radical anion formed has the vinyl group in the equatorial position of the trigonal bipyramidal structure, although the axial position was the first suggested.

Irrespective of the electronegativity of vinyl group, which is larger than that of H, the value of spin density on the axial Br atom of the CH_2=$CHSiH_2Br^-$ radical anions falls between those obtained for $CH_3SiH_2Br^-$ and SiH_3Br^-, while the value on the axial H atom is smaller than that for $C_2H_5SiH_2Br^-$. Similar trends were obtained between CH_2=$CHSiH_2I^-$ and the related radical anions, although $CH_3SiH_2I^-$ could not be compared because of the different structure.[5] These results may indicate that some other factor than the electronegativity of vinyl groups governs the geometrical and electronic structures of CH_2=$CHSiH_2X^-$ radical anions.

When the effect of substituent groups is considered, electronegativity is important for the inductive effect of σ electrons. However, for the groups with π electrons or nonbonding electron pairs, the more electron attractive for the inductive effect by σ electrons the groups are, the more electron donating are the groups for the π electron mesomeric effect, and the groups behave as π donors. Thus, vinyl groups are considered as electronegative groups and simultaneously as π donors.

As mentioned earlier, the electronic structure of phosphorane PH_5 as well as phosphoranyl radical PH_4 is suggestive of that of the radical anions of halosilane. Therefore, the results for PH_5 derived from extended Hückel calculations by Hoffmann *et al.*[15] may be helpful for the consideration of the effect of substituent groups in organo halosilane radical anions.

Let us first view the interactions arising between the orbitals of PH_5 and a π donor or a π acceptor.[15] For a π donor, interaction I with occupied PH_5 skeleton orbitals and interaction II with phosphorus 3d orbitals were considered, while interaction III with unfilled skeleton orbitals was neglected. I is inherently destabilizing, whereas II is inherently stabilizing, and the interaction I is more important than II. On the other hand, there is only one significant interaction (IV) between the acceptor orbital and the occupied skeletal set. Thus, for an acceptor the site with maximum interaction will be favored (IV is stabilizing), and for a donor the site with maximum interaction will be destabilized (I is a repulsive term).

Axial interactions, e_x and e_y, equatorial interactions, b_1 and b_2, and the relation between their magnitudes, $e_x \simeq e_y \simeq b_1 > b_2$, are shown in the paper by Hoffmann *et al.*[15] According to these results, π acceptors will prefer axial sites in the trigonal bipyramid so as to have the maximum interaction e_x or e_y, while π donors will occupy equatorial positions for b_2 avoiding large interactions. If a substituent has a single π system and is located in the equatorial positions, it will prefer to have its acceptor orbital perpendicular to the equa-

torial plane, having b_1 interaction, or its donor orbital in that plane, having b_2 interaction.

In the light of these results for PH_5, the vinyl group, which has a single π system in $CH_2{=}CHSiH_2X^-$ radical anion may be expected to occupy the equatorial position and to have its donor orbital in the equatorial plane, as shown in Fig. 3. The π donor orbital of the equatorial vinyl group is shown in Fig. 3 with the a_1 antibonding unpaired electron orbital composed of the p orbital of the axial Br, the s orbital of the axial H and the s and p orbitals of the central Si atom.[2-4] This is accordance with the results obtained from the ESR observations described earlier.

In conclusion, the mesomeric effect as well as the inductive effect of substituent group plays an imporant role in the geometrical preference of the substituent groups in the trigonal bipyramidal structure of organo halosilane radical anions.

(Received January 12, 1981)

The molecular and crystal structure of fortamine sulfate trihydrate, $C_8H_{18}N_2O_4 \cdot H_2SO_4 \cdot 3H_2O$, was determined by X-ray analysis. The space group is $P2_1$ with $a=7.2516(9)$, $b=11.193(1)$, $c=9.022(1)$ Å, $\beta=90.55(2)°$, and $Z=2$. The structure was solved by direct methods, and least-squares refinement using 1679 reflexions led to the final R value of 0.063. The ring conformation of fortamine sulfate is a chair form which corresponds to a chair obtained by inversion of that in the dihydrochloride. This is an extraordinary example of the cyclohexane ring inversion caused by the anion exchange in the crystal. The ring conformation of fortamines in solution and in crystal are compared and discussed.

Fortamine, 1,4-diaminocyclitol, is a component of potent aminocyclitol antibiotics fortimicins.[1] Egan *et al.* have shown that fortamine moiety takes 'B' type conformation in fortimicin B, whereas it takes 'A' type conformation in fortimicin B sulfate and fortimicin A,[2,3] as shown in Fig. 1. The conformation of fortamine moiety in fortimicins is probably related to their biological activity.[2] Therefore, it is quite interesting to deduce the factors which control the conformation of fortamine. From such points of view we have determined the molecular structures of fortamine itself[4] and its dihydrochloride salt[5] by X-ray analysis. The results showed that the conformation of the former is 'B' type, but that of the latter is 'A' type. Although it has been believed that the 'A' type conformation is rather unstable because of the inherent 1,3-diaxial interactions, the latter analysis confirmed that 'A' type conformation could exist in the crystal structure and supported the assignment made by Egan *et al.*[2]

The NMR results, however, revealed that in solution the fortamine rings of fortamine, fortamine dihydrochloride, and fortamine sulfate take essentially the same conformation, *i.e.*, the 'B' type conformation. It means that the ring conformation of fortamine dihydrochloride in the crystal is different from that in solution. This paradoxical observation has prompted us to compare the fortamine ring conformation of the sulfate in the crystal and in solution. In this connection we have undertaken the X-ray analysis of the sulfate. In this paper we will also report on the NMR results of fortamines.

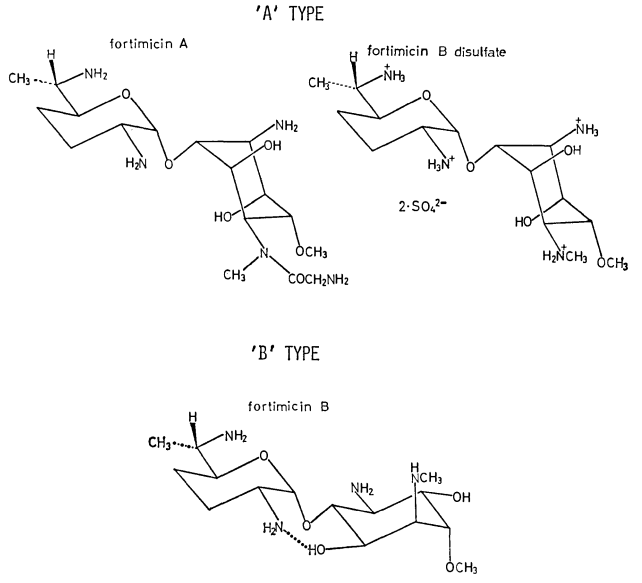

Fig. 1. Structures of fortimicins.

Experimental and Structure Determination

The prismatic crystals of the title compound were grown from a methanol solution. A crystal of $0.4\times0.4\times0.3$ mm³ sealed in a glass capillary was used for data collection on a Rigaku four-circle automated diffractometer with graphite monochromated Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). Preliminary unit-cell dimensions and space group were obtained from photographs. The space group was determined from the systematic absences ($0k0$ for odd k). Accurate cell dimensions were determined by least-squares calculation with 2θ values of 15 high-angle reflexions measured on the diffractometer. Crystal data are summarized in Table 1. All reflexions within the range of $2\theta\leqq55°$ were collected by the use of the ω-2θ scan mode with a scanning rate of $4°(2\theta)$ min^{-1}. Stationary background counts were accumulated for 10 s before and after each scan. Periodic checks of the intensity values of three standard reflexions did not reveal any significant X-ray damage. Any corrections for absorption or extinction were not applied. A total of 1773 independent reflexions were obtained, of which 1679 ($|F_o|>3.0\sigma(|F_o|)$) were considered as observed. The structure was solved by direct methods with MULTAN 78 program.[5] The best set of phases was used to calculate an E map, which gave 13 chemically significant peaks. Other non-hydrogen

atoms were located easily by the subsequent Fourier syntheses. The structural parameters were refined by block-diagonal least-squares methods with a modified HBLS program. The two of sulfate oxygen atoms were considerably disordered and when they were assumed to distribute over six positions with an occupancy of 0.3333, the refinement proceeded successfully. All hydrogen atoms except those of water molecules were located by difference syntheses. Refinement using anisotropic and isotropic thermal parameters for the non-hydrogen and hydrogen atoms, respectively, gave the final R value of 0.063 for 1679 reflexions. The weighting system used in the final stage was $w=(\sigma(|F_o|)^2+(0.015F_o)^2)^{-1}$. Atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[6] The final positional and thermal parameters are given in Table 2. OS(3) to OS(8) denote the sulfate oxygen atoms refined with occupancy of 0.3333. OW denotes the water molecule. The table of observed and calculated structure factors and the list of the anisotropic thermal parameters are kept as Document No. 8144 at the Chemical Society of Japan.

The NMR spectra were measured in D_2O solution by means of an FX100 Model apparatus, JEOL Co., using DSS as the internal standard.

Results

Conformation of the Molecule. The ring conformation of fortamine dication, as shown in Fig. 2, is the 'B' type. The signs of torsional angles listed in Table 3 also represent the 'B' type conformation. The d values[3] of each ring-carbon atoms are as follows; C(1) 0.648, C(2) 0.632, C(3) 0.611, C(4) 0.619, C(5) 0.622, and C(6) 0.644 Å. The average C–C–C–C torsional angle is 52.9° and average d is 0.629 Å. They are quite similar to those of the dihydrochloride, 52.7° and 0.627 Å, respectively and smaller than those

of the free base, 54.9° and 0.655 Å. These values show that the protonation at the nitrogen atoms causes the flattening of the fortamine ring as a whole. While C(1) and C(6) are puckered a little, C(3) and C(4) are flattened a little; the magnitude of puckering or flattening is smaller than that of the dihydrochloride and is almost the same as that of the free base. The smallest exocyclic O(5)–C(5)–C(4)–N(4) torsional angle of −45.8° is due to the intramolecular N(4)–H···O(5) hydrogen bond.

Bond Lengths and Angles. The bond lengths and angles are given in Table 4. The exocyclic C–C bond lengths are 1.512 to 1.538 Å, and the average value of 1.527 Å is essentially equal to those of the free base and the dihydrochloride. The C(2)–O(2) and C(6)–O(1) bond lengths, 1.413 and 1.416 Å, respectively, are significantly shorter than those of fortamine. This shortening is similar to that of the dihydrochloride. The C(1)–N(1), C(4)–N(4), and N(4)–C(8) bond lengths of the sulfate are as long as those of the dihydrochloride. Although the average C–C–C bond angle of 112.1° is the same as that of the dihydrochloride and larger than that of the free base, the scattering

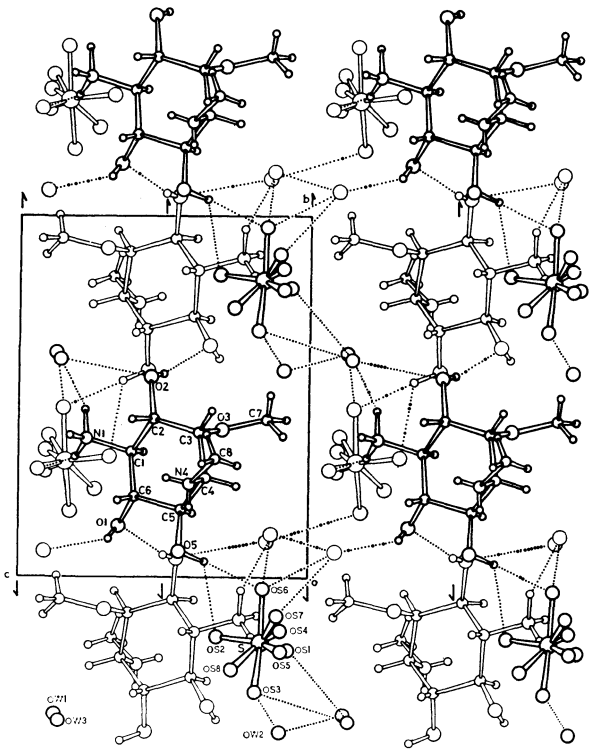

Fig. 3. Crystal structure of fortamine sulfate viewed along the a axis.

of the angles is small, *i.e.*, in the sulfate 111.4 to 113.5°, but in the dihydrochloride 109.7 to 114.3° and in the free base 109.9 to 112.6°. Most of the exocyclic bond angles are similar to those of the free base rather than those of the dihydrochloride. The bond lengths and angles show that the fortamine ring in the sulfate takes almost the same geometry as that of fortamine.

The sulfate oxygen atoms which are not involved in the hydrogen bonds are disordered; hence the relevant bond lengths and angles are distorted. The values are listed in Table 4.

Crystal Structure. The crystal structure viewed along the a axis is shown in Fig. 3. Hydrogen bond lengths and angles are listed in Table 5. Hydrogen bonds are shown by dotted lines in Fig. 3. The molecules linked by the O(2)–H···O(1) hydrogen bonds form helical chains along the b axis. There is no other intermolecular hydrogen bonds between the functional groups. The N(1) atom is hydrogen bonded to the OS(1) atom of the sulfate anion, but there is no sulfate anion sufficiently near the N(4) atom. The positive charge on N(4) may be partially transferred to O(5) through the N(4)–H···O(5) intramolecular hydrogen bond. The O(5) atom is hydrogen bonded to the OS(6) and OS(2) atoms. Therefore the positive charge may be neutralized by these hydrogen bonds. The O(1), O(2), and N(1) atoms are hydrogen bonded to water molecules. There is an extensive hydrogen bond networks between sulfate anion and water molecules.

Conformation in Solution. The NMR parameters of fortamine, its dihydrochloride, and its sulfate are shown in Table 6. The pD of the solution are 11.5, 3.5, and 1.5, respectively. The chemical shifts are

	$J_{4,5}$	4.6	4.5	4.9
	$J_{5,6}$	9.8	7.6	8.1
	$J_{6,1}$	9.8	7.6	8.1

expressed in ppm from the internal standard, DSS. The coupling constants are obtained by the first order analysis. The results apparently indicate that the ring conformations of the three are essentially same and they are in the 'B' type.

Discussion

Fortamine sulfate takes the 'B' type conformation in the crystal, whereas the chloride takes the 'A' type. It is interesting to examine the effect of different anions on the fortamine conformation in the crystal. The crystal structure of the dihydrochloride viewed along the b axis is shown in Fig. 4. In the crystal structure all functional groups are involved in intermolecular hydrogen bonds with the chloride anions, the anions locate near the two amino nitrogen atoms, and consequently the fortamine molecules are tightly packed. On the contrary, the fortamine molecules in the sulfate crystal as seen in Fig. 3 are loosely packed and anions are apparently solvated. The difference between the two crystal structures may come mainly from the different valence and the different size of the anions. In the crystal structure of the dihydrochloride, the Cl(1) atom is hydrogen bonded with the two protonated nitrogen atoms, *i.e.*, the N(1) and N(4) atoms. This makes the close packing possible. The sulfate anion, however, is divalent and bulkier than the chloride anion; hence it makes the close packing rather difficult and the structure which could accomodate the solvent molecules is built up.

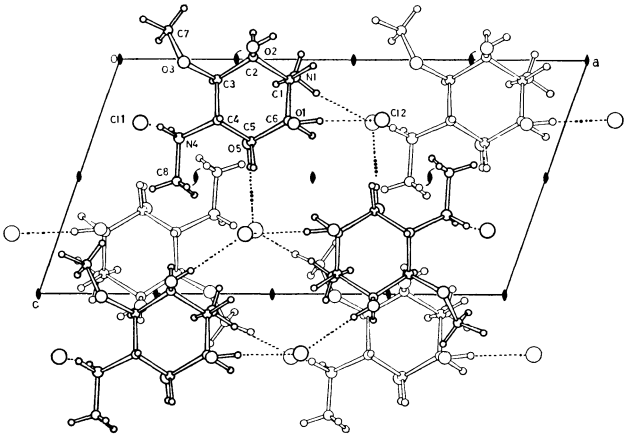

Fig. 4. Crystal structure of fortamine dihydrochloride viewed along the b axis.

The NMR results show that in aqueous solution the fortamine rings of the free base, the dihydrochloride, and the sulfate take essentially the same conformation, *i.e.*, the 'B' type conformation. In solution the anions might be solvated and they could not close to the cations easily; therefore it is conceivable that the environmental condition around the fortamine molecules in aqueous solution is close to that in the sulfate crystal. In the previous paper,[4] the electrostatic repulsion energy in the 'B' type conformation was calculated to be 0.50 kcal/mol higher than that in the 'A' type. Although further studies on the energy of molecular deformation would be required, these results suggest that intramolecular non-bonded interaction or intermolecular interaction must overcome the energy difference and the conformational change can easily occur in the stage of crystallization.

Figure 1 was drawn by TSD:XTAL, which is a computer-graphics interactive modeling programme for the NOVA 3 computer.[7]

The Capillary-tube Isotachophoretic Determination of Sodium(I), Magnesium(II), Calcium(II), Strontium(II), and Barium(II) Using Complex-forming Equilibria between CyDTA and the Metal Ions

Isoshi NUKATSUKA, Mitsuhiko TAGA, and Hitoshi YOSHIDA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received January 5, 1980)

The capillary-tube isotachophoresis technique was used to determine sodium(I), magnesium(II), calcium (II), strontium(II), and barium(II). The complex-forming equilibria between CyDTA and the metal ions were used to expand the differences among their effective mobilities. The mobilities of IIa metal ions decreased with increases in the pH of the leading electrolytes and in the CyDTA concentration in the leading electrolytes. The simultaneous determination of the above five cations could be performed when the pH of the leading electrolyte was adjusted at 5.5 or above. The relative standard deviations were 1.7—2.2% for determining 15.0—25.0 nmol of the cations when the pH of the leading electrolyte was 5.70. Magnesium(II) and calcium(II) ions underwent "enforced isotachophoretic" migration.

It is useful to apply the capillary-tube isotachophoresis technique to the analysis of small amounts of samples which contain several constituents. This method requires only a few μl of the sample solutions.

It is necessary for performing a satisfactory separation that there be enough difference among the effective mobilities of the sample ions. If the difference is not effective enough, we have to expand the difference among the mobilities.

To change the mobilities is to alter the environment of the sample constituents in the leading electrolyte. There are three main methods of doing so:[1] (1) the change in the pH of the leading electrolyte, (2) the replacement of the solvent of the leading electrolyte, and (3) the use of complex-forming equilibria.

In Method (3), various factors, *e.g.*, the kind of complexing agent and the concentration and pH of the leading electrolyte, affect the mobilities of the sample ions and may further complicate the condition. Because of the variation in the mobilities of the sample ions, the separability of the sample ions might be enhanced in some cases.

Although this method is analogous to that which is carried out in zone electrophoresis, adding complexing agents to supporting electrolyte, zone electrophoresis has little quantitative ability, whereas capillary-tube isotachophoresis has a good quantitative ability. This method has been presented in several papers,[2-4] there has, however, been little work in which this method has been applied to the determination of metal ions.

In this paper, we studied the utility of the complex-forming equilibria in determining the metal ions by capillary-tube isotachophoresis. Magnesium(II), calcium(II), strontium(II), and barium(II) were used as sample ions, and CyDTA was added to the leading electrolyte as a complexing agent. The above four cations and sodium(I) were separated and determined simultaneously, and the importance in this method of the choice of the terminating electrolyte was pointed out.

Experimental

Apparatus. Isotachopherograms were recorded with a Capillary-tube Isotachophoretic Analyzer (Shimadzu, model IP-1B, with a potential gradient detector, model PGD-1). The migration current was stabilized at 100 μA. The length of the capillary tube (PTFE, I.D. 0.5 mm) was 20 cm, and the oven temperature was 20 °C. Measurements of pH were made with an expanded-scale pH-meter (Horiba, model F-7ss). 1.0—7.0 μl portions of sample solutions were introduced into the instrument with a micro syringe.

Materials. The 1,2-cyclohexanediamine-*N,N,N',N'*-tetraacetic acid (CyDTA), 2-amino-2-hydroxymethyl-1,3-propanediol (Tris), and Triton X-100 were purchased from the Wako Pure Chemical Industry Co., Ltd. The other chemicals used were of a reagent grade and were dissolved in deionized water.

Sodium(I), Magnesium(II), Calcium(II), Strontium(II), and Barium(II) Solutions: The stock solutions were prepared by dissolving their nitrates in water. The standard solutions containing some or all of the above metal ions were obtained by mixing the stock solutions and then diluting them to the desired concentrations.

NH_4OH Solution: The NH_4OH solution was diluted to give a 1-mol dm^{-3} solution with water.

CyDTA Solution: The CyDTA was dissolved to give a 0.1-mol dm^{-3} solution in 0.4 mol dm^{-3} of an NH_4OH solution.

The leading electrolytes were obtained by mixing the NH_4OH solution and the CyDTA solution, followed by their dilution to the desired concentrations. For adjusting the pH of the leading and terminating electrolytes, acetic acid or succinic acid was used. The compositions of the leading and terminating electrolytes are shown in Table 1.

Results and Discussion

Effect of CyDTA Concentration in the Leading Electrolyte on the PR Value.† Figure 1 shows the relations between the PR values of the metal ions [magnesium-(II), calcium(II), strontium(II), and barium(II)] and the CyDTA concentration in the leading electrolyte. When CyDTA is not added to the leading electrolyte, the order of the PR values *i.e.*, the order of mobilities of the metal ions, was: barium(II)>stron-

† The PR value[4] (potential gradient ratio value) represents the ratio of the potential gradient of the leading ion to that of the sample ion (PG_L/PG_S). Therefore, this corresponds to the ratio of the mobility of the sample ion to that of the leading ion (m_S/m_L).

TABLE 1. ELECTROLYTE SYSTEMS

	Leading electrolyte[a)]		Terminating electrolyte
(I)	0.01 mol dm^{-3} NH_4OH, 0—2 mmol dm^{-3} CyDTA, acetic acid, pH 4.30	(IV)	0.01 mol dm^{-3} Tris, acetic acid, pH 4.40
(II)	0.01 mol dm^{-3} NH_4OH, 1 mmol dm^{-3} CyDTA, acetic acid, pH 4—6	(V)	0·01 mol dm^{-3} β-alanine, acetic acid, pH 4.40
(III)	0.01 mol dm^{-3} NH_4OH, 1 mmol dm^{-3} CyDTA, succinic acid, pH 5.70		

a) 0.1% Triton X-100 was added.

Electrolyte system: (I) and (IV); ■: Mg^{2+}, □: Ca^{2+}, ○: Sr^{2+}, ●: Ba^{2+}.

tium(II)≈calcium(II)>magnesium(II). It is not possible to separate calcium(II) from strontium(II). When CyDTA was added to the leading electrolyte, the PR value of the metal ions decreased with an increase in the CyDTA concentration. This indicates that the interaction between CyDTA and metal ions increases with an increase in the CyDTA concentration and that it makes possible the mutual separation between the alkaline earths.

The slopes of the curves show that the effect of an increasing CyDTA concentration on the PR value of calcium(II) and barium(II) is greater than on that of magnesium(II) and strontium(II). The variations in the mobilities of the metal ions, which result from the interaction between CyDTA and metal ions, depend on the overall stability constants of the CyDTA complexes.

Comparison of Tris and β-Alanine as Terminating Ions. As is shown in Fig. 2, the PR value of the terminating ion (Tris) became abnormally small with an increase in the pH of the leading electrolyte in the case of calcium(II), which had a rather larger complexing ability than the other IIa elements. Further, the zone length of the metal ions decreased with an increase in the pH of the leading electrolyte, and in the pH region over 5.0, first the calcium(II) ion, and next the magnesium(II) ion were unable to be detected (Fig. 3a), in spite of the fact that the PR values of the metal ions were larger than that of Tris, as is shown in Fig. 4.

On the other hand, when β-alanine was used as the terminating ion, the zone length of the metal

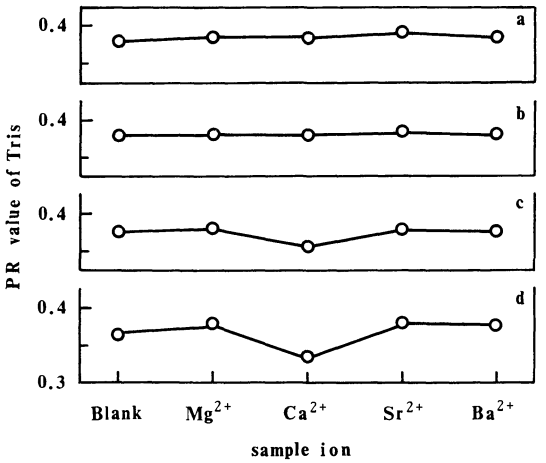

Fig. 2. Effect of pH of the leading electrolyte and sample ions on the PR value of Tris.
Electrolyte system: (II) [a) pH 3.98, b) pH 4.30, c) pH 4.50, d) pH 4.70] and (IV).

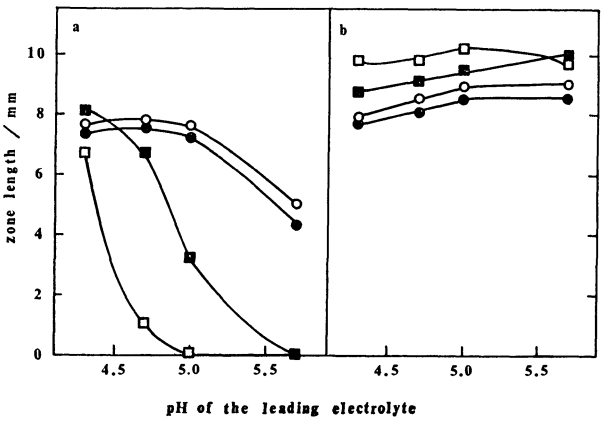

Fig. 3. Effect of terminating ions and pH of the leading electrolyte on the zone length.

ions varied little, even higher pH's of the leading electrolyte (Fig. 3b).

Protons released from CyDTA by a complexing reaction with sample ions cause the pH of the sample-ion zones to decrease, and the pH of Tris zone is kept near that of the leading electrolyte. Therefore, the pH of the Tris zone seems to be higher than that of the sample-ion zones. In this case, if sample ions are transfered into the Tris zone by diffusion or any

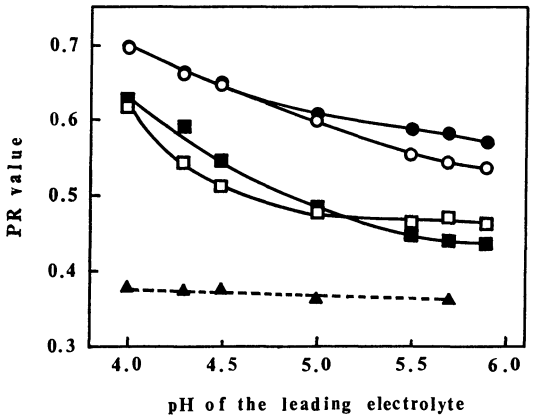

Fig. 4. Relation between the PR value and pH of the leading electrolyte.
Electrolyte system: (II) and (IV) (pH of the leading electrolyte below 4.5) and (V)(above 5.0); ▲: Tris (these values were obtained using electrolyte system (IV) even if pH of the leading electrolyte was above 5.0); other symbols are the same as in Fig. 1.

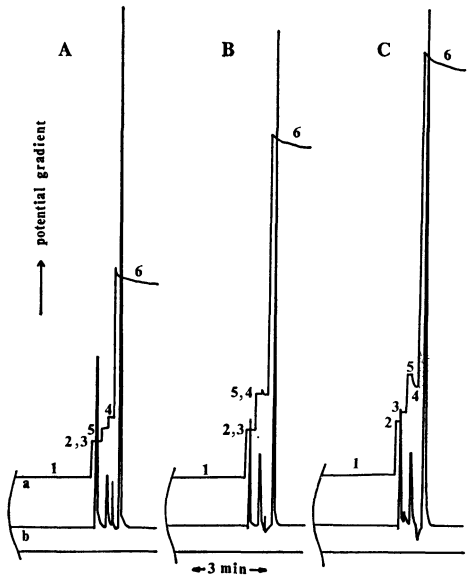

Fig. 5. Isotachopherograms.
Electrolyte system: (II) [(A) pH 4.30, (B) pH 5.00, (C) pH 5.70] and (V); a) potential gradient, b) differential potential gradient; 1) NH_4^+, 2) Ba^{2+}, 3) Sr^{2+}, 4) Ca^{2+}, 5) Mg^{2+}, 6) β-alanine.

other factors, they can not return to their own zones because their effective mobilities are smaller in higher pH zones than in lower pH zones. As a result, the zone lengths of these sample ions decrease and the PR value of Tris becomes smaller to form a mixed zone, as is shown in Figs. 2 and 3a. On the other hand, as β-alanine has a small pK_a value ($pK_{a1}=3.6$), the pH's of this zone decrease, and even if sample ions are transfered into this zone, they can return to their own zones (see Ref. 1).

Consequently, in the IIa metal-ion analysis using complex-forming equilibria, β-alanine should be used as a terminating ion, while Tris can not be applied; nevertheless, the later has a lower effective mobility

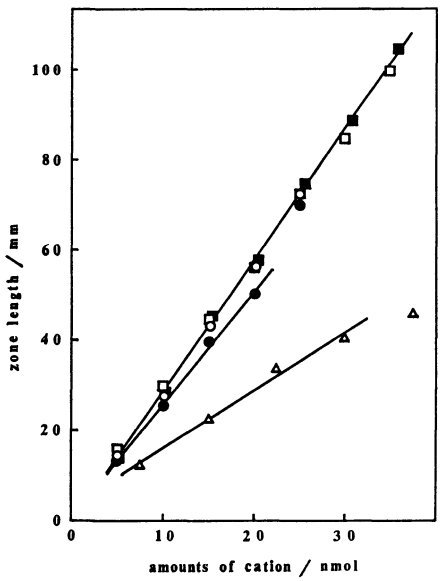

Fig. 6. Calibration curves.
Electrolyte system: (III) and (V); migration current: 100 μA; chart speed: 40 mm min^{-1}; △: Na^+; other symbols are the same as in Fig. 1; the curves of Ca^{2+} and Sr^{2+} were much the same as that of Mg^{2+}.

Table 2. Simultaneous determination of Na(I), Mg(II), Ca(II), Sr(II), and Ba(II) ions

Ion	Taken	Found	Difference	R.S.D.
	nmol	nmol	%	%
Sodium(I)	22.5	22.4	−0.44	2.2
Magnesium(II)	20.4	20.1	−1.5	1.9
Calcium(II)	25.0	25.2	0.80	1.9
Strontium(II)	20.2	19.8	−2.0	1.9
Barium(II)	15.0	15.1	0.67	1.7

The conditions are the same as in Fig. 6.

than IIa metal ions under the complex-forming equilibria.

The PR values of the sample ions are almost the same whether Tris or β-alanine is used as the terminating ion.

Relation between the PR Values and the pH of the Leading Electrolyte. The PR values of the sample ions decreased with an increase in the pH of the leading electrolyte (Fig. 4). The strontium(II) ion and the barium(II) ion were separable at a higher pH of the leading electrolyte; they were, however, not separable at a lower pH of the leading electrolyte. The magnesium(II) ion and the calcium(II) ion were also separable at a higher pH of the leading electrolyte. Four cations of IIa elements could be separated simultaneously when the pH of the leading electrolyte was adjusted to 5.5 or above. The separability of this method was larger in the higher-pH range of the leading electrolyte than in the lower range examined.

Figure 5 shows isotachopherograms of the sample ions at various pH's of the leading electrolytes, indicating that, at pH 5.00 and 5.70, the magnesium(II)

and calcium(II) ions undergo "enforced isotachophoretic"[5] migrations. This phenomenon results from the fact that the magnesium(II)-ion zone has a higher pH than the calcium(II)-ion zone, as is to be expected from the fact that the stability constant of the magnesium(II) ion is smaller than that of the calcium(II) ion.

Simultaneous Determination of Sodium(I), Magnesium(II), Calcium(II), Strontium(II), and Barium(II) Ions. Calibration curves were made by using a mixed solution of 7.5×10^{-3} mol dm^{-3} sodium(I), 5×10^{-3} mol dm^{-3} magnesium(II), calcium(II), strontium(II), and barium(II) nitrates, while varying the sampling volume from 1.0 to 7.0 μl.

For the adjusting pH of the leading electrolyte, succinic acid was used, because the buffer action of succinic acid is greater than that of acetic acid at pH 5.70.

Although the pH of the terminating electrolyte is rather lower than that of the leading electrolyte, in order to decrease the initial potential, it was adjusted to 4.40. The results are shown in Fig. 6. The linear region of the curve of the sodium(I) ion was 7.5—30.0 nmol (1.0—5.0 μl), while that of the barium(II) ion was 5—20.0 nmol (1.0—5.0 μl). When 6.0 μl of the mixture was introduced into the instrument, the sodium(I) ion exceeded the maximum load (about 30 nmol), thus making the zone length of the barium(II) ion (25 nmol) longer. If the amount of the sodium(I) ion is less than the maximum load, the linear region of the calibration curve of the barium(II) ion may be longer.

Table 2 shows the results of the simultaneous determination of the above five cations. The sample solution used was a artificial mixture of 4.5×10^{-3} mol dm^{-3} sodium(I), 4×10^{-3} mol dm^{-3} magnesium(II), 5×10^{-3} mol dm^{-3} calcium(II), 4×10^{-3} mol dm^{-3} strontium(II), and 3×10^{-3} mol dm^{-3} barium(II) nitrates; a 5.0-μl portion of the sample solution was introduced into the instrument.

The relative standard deviations were 1.7—2.2%, and the differences were −2.0—0.80% (mean values of five determinations). The time needed for an analysis was about 16—20 min.

Studies on Room Temperature Phosphorometric and Delayed Fluorometric Analysis. I. Delayed Fluorometric Analysis of Porphyrin Derivatives

Yoshiaki Onoue,* Keizō Hiraki, and Yasuharu Nishikawa
Department of Chemistry, Faculty of Science and Technology, Kinki University, 3-4-1, Kowakae, Higashi-Osaka 577
(Received September 16, 1980)

The spectral characteristics and its application to measurement of porphyrins were investigated by use of room temperature phosphorometry. Certain porphyrin compounds adsorbed on filter paper exhibit intense E-type delayed fluorescence. This could be utilized for the determination of porphyrin derivatives.

Papar and thin layer chromatography have been used for the separation and measurement of porphyrins present in biological and geological materials.[1-5] After chromatography, the porphyrin spots can be easily located on the layer by observing the orange—red fluorescence in ultraviolet radiation. However, quantitative detection of prompt fluorescence of the compounds adsorbed on the layer is tedious, because of the reflection of excitation light and the fluorescence from the support surfaces. This paper describes a new approach to the application of phosphorometric time-resolution of room temperature phosphorometry (RTP).[6,7]

Phosphorometry was usually carried out at 77 K in liquid nitrogen, a low temperature being necessary for maintaining a rigid matrix in order to minimize the effect of intermolecular collisional quenching. Walling and Schulman[8] observed the phosphorescence of various organic compounds adsorbed on filter paper, silica gel, alumina, and polycellulose at room temperature. This method (RTP) has advantages for analysis. No liquid nitrogen, cryogenic equipment, or high purity solvents are required, substances being identified in chromatographic separation without elution. In this article, application of RTP combined with paper chromatography to the analysis of porphyrins is described.

Experimental

Apparatus. Long-life emission was measured with a Hitachi-2A spectrofluorometer with a phosphorescence accessory. The sample holder was designed to fit into the standard MPF-2A phosphoroscope accessory instead of the normal cap and cylinder used for the dewar flask assembly (Fig. 1). The plate of holder was blackened to a dull, non-reflecting finish. A 150-W xenon arc lamp was used as the excitation light source, the signal being detected with a R-446 UR photomultiplier tube. The spectra were recorded on a Hitachi QPD 33 recorder.

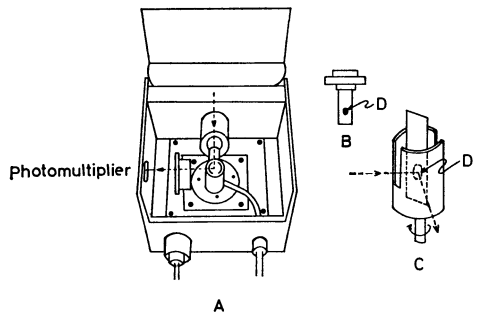

Fig. 1. Schematic diagram of filter paper cell system for room temperature phosphorescence studies.
A: Hitachi MPF-2A phosphoroscope accessory, B: sample holder, C: rotating can assembly, D: sample spot.

Reagents. Magnesium-protoporphyrin IX dimethyl ester (Mg-PPDE) was prepared by refluxing protoporphyrin IX dimethyl ester (Midori jūji Co. Ltd.) and anhydrous magnesium chloride in *N,N*-dimethylformamide.[9] Crude metal chelate was chromatographed on a cellulose column with a light-petroleum : acetone (20 : 3, v/v) eluant. Pure Mg chelate was obtained by recrystallization three times from benzene–chloroform (20 : 1, v/v) solvent. Chlorophyll a and b were extracted from spinach with a mixed solvent, methanol : acetone (1 : 1, v/v). After partial purification by the dioxane method,[10] crude pigments were chromatographed on a glucose column in order to separate chlorophyll a, b, and the other pigments. Chlorophyll c_1 and c_2 were isolated from *Undaria pinnatifida* and *Sargassum racemosum*, respectively, with methanol and acetone according to the Jeffrey method.[11] After being chromatographed, crude chlorophyll c_1 and c_2 were crystallized from pyridine–acetone. All other chemicals were of reagent grade. Toyo No. 51 filter paper was used as a support.

Procedure. The sample solution, four 0.5 μl portions, was allowed to drain slowly from the tip of a microliter syringe when it came into contact with the filter paper. After 1.0 μl of 1 mol dm^{-3} NaOH aqueous solution had been placed on a sample spot, the filter paper was dried for ca. 30 min with an infrared lamp. The samples were then directly mounted on a holder shown in Fig. 1. Since the emission is very sensitive to humidity and temperature, the sample compartment was continuously flushed with warm dried air.

Results and Discussion

As shown in Table 1, porphyrins exhibited a long-life emission (1—100 ms), but no long-life emission was observed for non-ionic porphyrin, Cu-porphyrin chelate and chlorins. The emission was studied for Mg-PPDE.

Spectral Studies of Mg-protoporphyrin IX Dimethyl Ester (Mg-PPDE). The emission spectra of Mg-PPDE adsorbed on the paper are shown in Fig. 2. The spectrum of Mg-PPDE obtained by RTP at 70 °C is almost the same as the usual prompt fluorescence spectra observed in chloroform solution and on filter paper. Phosphorescence of Mg-PPDE in solid solution at liquid nitrogen temperature (77 K) appears in the far red region as compared with the spectrum obtained by RTP. Very weak room tem-

Table 1. Properties of long-life emission from porphyrins adsorbed on filter paper[a)]

a) Measured with phosphoroscope at *ca.* 1000 min^{-1} of rotating can assembly.

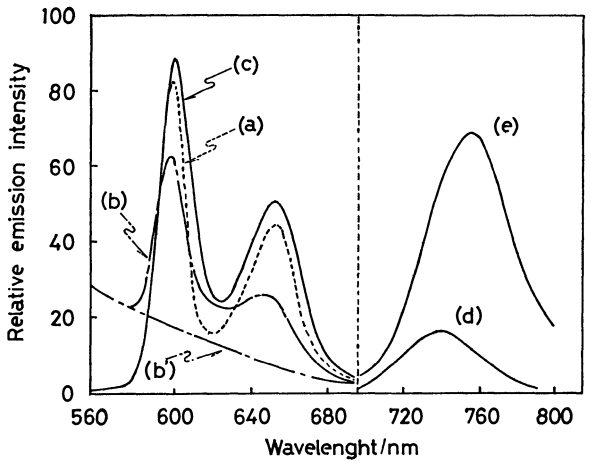

Fig. 2. Spectra of long-life emission from Mg-PPDE adsorbed on filter paper.
(a): Prompt fluorescence; 12 °C in chloroform, (b): prompt fluorescence; 12 °C adsorbed on filter paper, (b'): blank; prompt fluorescence from filter paper at 12 °C, (c): long-life emission; 70 °C adsorbed on filter paper, (d): long-life emission; 20 °C adsorbed on filter paper, (e): phosphorescence; −196 °C in methanol. Intensity scale for (d), (e) is *ca.* 100 times less than for (a)—(c).

perature phosphorescence of Mg-PPDE was also observed when a small amount of sodium iodide was present on the filter paper. The effect of temperature on the intensity of long-life emission is conspicuous. The emission intensity of Mg-PPDE increases with increase in temperature, in contrast to the case of normal prompt fluorescence and phosphorescence (Fig. 3).

Logarithm of the intensity of long-life emission, ln ϕ_e, obtained from the spectra is plotted against $1/T$

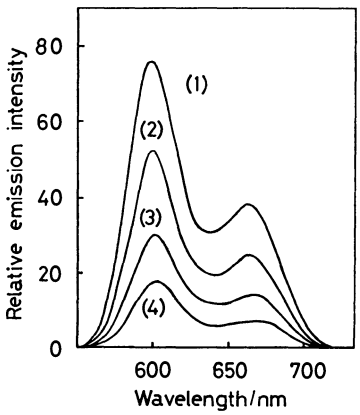

Fig. 3. Effect of temperature on long-life emission of Mg-PPDE (9.6 ng) adsorbed on filter paper.
(1): 72±1 °C, (2): 60±1 °C, (3): 55±2 °C, (4): 40±2 °C.

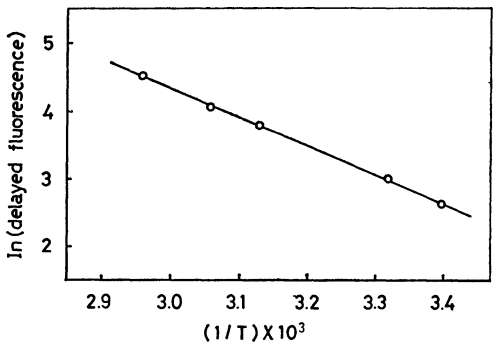

Fig. 4. E-type delayed fluorescence of Mg-PPDE (0.18 μg) adsorbed on filter paper as a function of temperature.

(Fig. 4). The plot is linear. The activation energy calculated from the slope is 0.37 eV, agreeing with the energy difference (0.38 eV) between the maxima of the two emission bands: 600 nm for specific emission, 736 nm for phosphorescence. In room temperature phosphorometry, in most cases, sodium iodide is efficient for increasing the phosphrescence quantum yield.[6)] In this study, however, the intensity of long-life emission decreased drastically in the presence of environmental sodium iodide. The long-life emission of Mg-PPDE could be attributed to E-type delayed fluorescence resulting from the thermal activation of molecules from the lowest triplet state to the first singlet state followed by radiative transition to the ground state.

The relationship between the intensity of E-type delayed fluorescence and the concentration of Mg-PPDE is linear over a wide range of ng—μg. The analytical curve indicates that E-type delayed fluorescence could be applied not only to the identification of porphyrins but also to their determination.

Application of E-type Delayed Fluorescence to Analysis of Chlorophyll c from Algae. Pigments of algae were extracted by freezing the algae fronds at −20 °C for 30 min, immersing the frozen tissue in methanol for 30 s and homogenizing in 100% acetone. Extraction was repeated several times until the cell res-

idue became colourless. The acetone and methanol extracts were separated from the tissue residues by centrifugation, and immediately mixed with diethyl ether. The mixture was shaken with 10% sodium chloride solution to wash out impurities and concentrate the pigments in the ether phase. The ether layer was made up to the designed volume. Two μl of the sample solution was spotted on Toyo No. 51 filter paper with a microsyringe. In applying the sample to the filter paper, care was taken to maintain the spot size (5 mm diameter) as constant as possible, the best reproducibility being attained when spot size was kept constant. The tip of the syringe just touched the filter paper, followed by spotting of four 0.5 μl portions. Each spotting was made at intervals to allow evaporation of the solvent. Chromatography was carried out with light petroleum ether:acetone:1-propanol (90:10:0.4, v/v). After the solvent front had ascended 10 cm, the spots were examined with a ultraviolet mineral light for orange—red fluorescence. Chlorophyll c_1 and c_2 and chlorophyllide having carboxyl side chain did not move from the origin and the spot size of chlorophyll c remained constant, the other pigments being developed. Existence of chlorophyllide, however, gave no influence on emission intensity of chlorophyll c, even when its amount was the same as that of chlorophyll c. After development, 1.0 μl of 1 mol dm^{-3} NaOH aqueous solution was added on the spot of chlorophyll c, and dried for *ca.* 10 min by infrared lamp heating, the emission intensity remaining constant for at least 20 min. The paper strip was mounted on the sample holder, and E-type delayed fluorescence of chlorophyll c was measured by use of rotating can phosphorescence assembly (Ex: 430 nm, Em:605 nm). Chlorophyll c in the concentration range 0.1 ng—μg order could be determined.

Conclusion

E-type delayed fluorescence of porphyrins observed by room temperature phosphorometry can be used for the determination of ng order of porphyrins, and it may be applied to the analysis of porphyrins in biological or geological samples, in combination with paper or thin-layer chromatographic technique.

The authors express their sincere thanks to Professor Tsunenobu Shigematsu (Faculty of General Education, Kinki University), and Professor Masayuki Tabushi (College of Medical Technology, Hirosaki University), for their advice and suggestions. Financial support from the Ministry of Education, Culture and Welfare of Japan, and Kinki University is gratefully acknowledged.

(Received November 12, 1980)

The core binding energies of N1s and S2s in *cis*-1,2-dicyano-1,2-ethanedithiolate (maleonitriledithiolate, mnt) complexes were measured by means of X-ray photoelectron spectroscopy (XPS), and the energy differences between N1s and S2s, ΔE, were found to be 171.7—172.6 eV throughout the complexes studied. The lowest ΔE value, 171.7 eV, was shown by $[Ni(mnt)_2]^-$. The electronic structures of $[Ni(mnt)_2]^-$ and $[Ni(mnt)_2]^{2-}$ were calculated by the discrete variational Xα method. The XPS measurements and the molecular orbital (MO) calculations provide consistent results that the oxidation state of the nickel atom is +2 for both nickel mnt complexes and that the highest occupied MO is $5b_{3g}$, which is mainly localized on ligands and which holds an unpaired electron in $[Ni(mnt)_2]^-$.

The metal dithiolate compounds have been of great interest to inorganic chemists because of their remarkable oxidation-reduction behavior, including the formation of abnormal valence states of the metal.[1] A typical dithiolate complex is the *cis*-1,2-dicyano-1,2-ethenedithiolate (maleonitriledithiolate, mnt) complex, in which the metal ion has a wide variety of oxidation states. Usually the oxidation state of the metal in an mnt complex is determined so as to satisfy both the stoichiometry and charge of the complex. For example, the formal oxidation state of Ni in $[Ni(mnt)_2]^-$ may be +3, on the assumption that mnt is a dinegative ion. However, the determination of the oxidation state of the metal in such a way is questionable.

There have been extensive studies of the electronic structure of these compounds by Schupack *et al.*,[2] Schmitt *et al.*,[3] Schlapfer *et al.*,[4] and Kobayashi *et al.*[5] The ESR results suggest that the ground state of $[Ni(mnt)_2]^-$ is $^2B_{3g}$, in which the half-filled out-of-plane π molecular orbital (MO) is extensively delocalized over the ligand.[3] Schlapfer *et al.*[4] measured the force constants of dithiolate complexes and estimated that 38% of the unpaired electron in the highest occupied MO of $[Ni(mnt)_2]^-$ is localized on the metal. The X-ray diffraction results of $[Ni(mnt)_2]^-$ have suggested that the ground state is either ^2A_g or $^2B_{3g}$.[5] An X-ray photoelectron spectroscopic (XPS) study of $[M(S_2C_2R_2)]^{0,1-,2-}$ (M=Ni, Pd, and Pt, and R=CN and C_6H_5) has been reported by Grim *et al.*[6] Judging from the absence of satellites and from the line-width of Ni2p XPS, they pointed out that the reduction did not appreciably change the charge on the metal, giving most of the added electronic charge to the ligands. However, there still remain problems in understanding accurately the electronic structure of mnt complexes. A detailed investigation of the electronic structures of these compounds can be expected to explain the results of ESR, IR, XPS, and so on. It has been shown in a previous work[7] that the energy difference between core orbitals gives information about the charge distribution and the electronic structure of metal complexes. The present paper will describe the results of XPS studies of $[M(mnt)_2]^{2-}$ (M=Co, Ni, Cu, and Zn) and $[M(mnt)_2]^-$ (M=Fe and Ni), and also the results of discrete variational (DV) Xα molecular orbital calculations for $[Ni(mnt)_2]^-$ and $[Ni(mnt)_2]^{2-}$. The energy difference between N1s and S2s and the electronic structures of these nickel complexes are then discussed on the basis of the XPS and DV-Xα results.

Experimental

The complexes, $[M(mnt)_2]^{2-}$ (M=Co, Ni, Cu, and Zn) and $[M(mnt)_2]^-$ (M=Fe and Ni), are all well-known and were prepared by standard methods.[8] The X-ray photoelectron spectra were recorded on a JEOL Model JESCA-3A spectrometer. Magnesium $K\alpha_{1,2}$ radiation (1253.6 eV) was used as the X-ray excitation source, and the measurements were carried out at a vacuum of 5×10^{-7} Torr (1 Torr=133.322 Pa) or below. We obtained the difference between the N1s and S2s binding energies by a synchronous measurement. The measurement was repeated several times for each sample, yielding consistent results. The average of the binding-energy difference was determined, by several runs for a given compound, with an accuracy of about ±0.1 eV.

Computational Method

The computational details of the spin-polarized DV-Xα method have been thoroughly described elsewhere.[9] In the Hartree-Fock-Slater model,[10] the exchange-correlation term is given by:

$$X_{xc\uparrow}(1) = -3\alpha[(3/4\pi)\rho_\uparrow(1)]^{1/3},$$

where $\rho_\uparrow$ (1) is the local charge density with up-spin and where α is the exchange-scaling parameter; the value of $\alpha=0.70$ is used for all atoms throughout the present calculation.[11] The spin-polarized DV-Xα self-consistent-charge (SCC) procedure[9] has been performed for both up and down spins. An approximate self-consistent molecular potential is determined from the Mulliken gross orbital populations. The numerical basis functions for up- and down-spin orbitals are obtained with an atom-like potential constructed by spherically averaging the molecular potential around the nucleus for the region inside each atomic sphere. The basis sets, including Ni1s—4p, C and N1s—2p, and S1s—3d, are utilized for the present calculations.

The molecular geometries of the complexes are de-

termined from the experimental results.[5] In the present calculations, the complexes are regarded as having the D_{2h} symmetry.

Results and Discussion

Table 1 shows the N1s and S2s core-binding energies measured for $[M(mnt)_2]^{2-}$ (M=Co, Ni, Cu, and Zn), $[M(mnt)_2]^-$ (M=Fe and Ni), and Na_2mnt. The Ni2p energies are also given for the nickel complexes. Accurate binding energies were not obtained for sulfur $2p_{3/2}$ and $2p_{1/2}$ because of their overlapping. The C1s peaks of the ligand could not be well distinguished from the peaks of various nonequivalent carbon atoms of the tetrabutylammonium ion contained as the counter ion in the sample. The measured values of the binding energies would have to be corrected for the charging and the counter-ion effect, which are hard to evaluate. Thus, the energy differences between them, which are almost free from those effects, are used to give information about the electron distribution in mnt complexes. The energy differences, ΔE, between N1s and S2s is found to be 173.0 eV for the mnt anion and to decrease to 172.6—171.7 eV by coordination to the metal. For a easy comparison of ΔE values between different metal compounds, ΔE is plotted in Fig. 1 against the atomic number of the metal. The observed ΔE value in general increases with an increase in the atomic number (Co(172.2)→Zn(172.5)). An exceptionally low value (171.7) was observed for $[Ni(mnt)_2]^-$, which is of particular interest with regard to its electronic structure. From the core-binding-energy measurements, it is found that: (1) ΔE is decreased by the coordination to the metal, (2) ΔE increases with an increase in the atomic number of the metal, and (3) different ΔE values are obtained for the two nickel complexes.

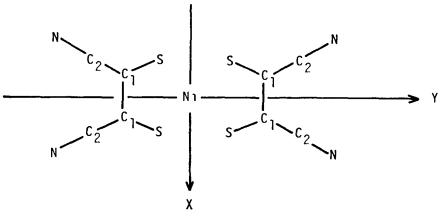

Fig. 2. The structure of mnt and the notations of atoms.

XPS Results and Charge Distributions. First, we will discuss the decrease in ΔE ($=E$(N1s)$-E$(S2s)) by the coordination to the metal in a qualitative way. When the ligand coordinates to the metal ion, electron donation takes place from sulfur to metal. The electron population on sulfur then decreases, which deepens the level of the sulfur core orbital in the first approximation, regardless of the other potentials. The ΔE value of Na_2mnt is eventually larger than those of the metal complexes.

Next, we will discuss the ΔE values of the complexes. The relation between the ΔE value and the charge distribution can be discussed in terms of Siegbahn's equation:[12]

$$E_i = E^\circ_i + k_i q_i + \sum_{i \neq j} q_j / r_{ij}. \quad (1)$$

In this equation, E_i and E°_i are the level energies of the i atom of the complexes studied and that of the reference material; q_i and q_j, the net charge on the i and j atoms respectively, and r_{ij}, the internuclear distance between the i and j atoms. The last term in Eq. 1 represents an interatomic Madelung-type potential. The value of the parameter, k_i depends on the atomic species. Using Eq. 1 and the bond distances previously reported,[5] the binding energies (in eV) for the N1s and S2s can be estimated as follows:

$$E(\text{N1s}) = E^\circ(\text{N1s}) + k_N q_N + 2.60 q_M + 10.78 q_S + 13.21 q_{C1} + 19.76 q_{C2} + 6.28 q_N, \quad (2)$$

$$E(\text{S2s}) = E^\circ(\text{S2s}) + k_S q_S + 6.70 q_M + 12.83 q_S + 19.80 q_{C1} + 13.68 q_{C2} + 10.78 q_N, \quad (3)$$

where the subscripts of q denotes the atomic species

as are shown in Fig. 2. Then, we can evaluate the energy differences between N1s and S2s from the following equation:

$$\Delta E(\mathrm{N1s-S2s}) = \Delta E^{\circ}(\mathrm{N1s-S2s}) + (k_{\mathrm{N}}-4.5)q_{\mathrm{N}} - (k_{\mathrm{S}}+2.05)q_{\mathrm{S}} - 4.10q_{\mathrm{M}} - 6.59q_{\mathrm{Cl}} + 6.08q_{\mathrm{C_2}}. \quad (4)$$

Here, k_{N} is taken as 21.5 according to Siegbahn *et al.*[12] The value of k_{S} is estimated as 21 on the basis of the 2s—3s one-center integral.[13] Thus, the difference in ΔE between the two complexes can be expressed as follows:

$$\Delta(\Delta E) = 17\delta q_{\mathrm{N}} - 23\delta q_{\mathrm{S}} - 4\delta q_{\mathrm{M}} - 7\delta_{\mathrm{Cl}} + 6\delta q_{\mathrm{C_2}}, \quad (5)$$

where δq_{i} is the difference in the effective charge on the i atom between the two complexes. Since the electronegativity of metal increases in going right across the periodic table, the metal net charge gradually decreases, though the value of q_{M} in general remains positive. This negative δq_{M} value causes a positive contribution to $\Delta(\Delta E)$. The less positive metal charge should result in a less negative ligand charge. Since the positive δq_{S} makes a negative contribution to $\Delta(\Delta E)$, opposing the observed trend in ΔE, it is probable that the contribution of δq_{S} is more or less counterbalanced by those of δq_{N}, δq_{C1}, and δq_{C2}.

Finally, the difference in the charge distribution between the two different nickel complexes will be discussed on the basis of the observed ΔE values. The photoelectron spectra show that the nickel $2p_{1/2}$—$2p_{3/2}$ energy separations are almost the same for the two mnt complexes. It has been reported that the splittings of spin-orbit components are often influenced by the oxidation state of the atom, especially for transition-metal ions.[14] If this can be applied to the present case, the almost identical $2p_{1/2}$—$2p_{3/2}$ separations may be taken as reflecting a close resemblance between the nickel electronic states of the two complexes. Thus, the δq_{M} term (with a small coefficient) is assumed to be negligible. Since all the valence electrons existing near the carbon atoms of the mnt^{2-} ligands participate in the bonding, the change in the charge of the complex would have only secondary effects on the charge densities of the carbon atoms. Thus, the δq_{C1} and δq_{C2} terms (with small coefficients) may also be neglected. With these assumptions, Eq. 5 may be approximated by:

$$\Delta(\Delta E) = 17\delta q_{\mathrm{N}} - 23\delta q_{\mathrm{S}}. \quad (6)$$

In the same way, if the difference in charge between the two nickel complexes is attributed to the difference in the nitrogen and sulphur charges, we obtain:

$$1 = 4\delta q_{\mathrm{N}} + 4\delta q_{\mathrm{S}}. \quad (7)$$

With the observed $\Delta(\Delta E)$ value of -0.7 eV ($=\Delta E([\mathrm{Ni(mnt)_2}]^{-}) - \Delta E([\mathrm{Ni(mnt)_2}]^{2-})$). Eqs. 6 and 7 give:

$$\delta q_{\mathrm{S}} = 0.12 \text{ and } \delta q_{\mathrm{N}} = 0.13.$$

In obtaining these values, it was assumed that the charges on Ni, C_1, and C_2 do not appreciably change when an electron is removed from $[\mathrm{Ni(mnt)_2}]^{2-}$. Although there are good reasons for these assumptions, as has been described above, further examination will be made below by reference to the results of the DV-Xα MO calculations.

TABLE 2. THE CORE-ORBITAL ENERGIES (eV) FOR $[\mathrm{Ni(mnt)_2}]^{2-}$ AND $[\mathrm{Ni(mnt)_2}]^{-}$ FROM DV-Xα CALCULATIONS

	$[\mathrm{Ni(mnt)_2}]^{2-}$	$[\mathrm{Ni(mnt)_2}]^{-}$
Ni2p	−827.8	−833.9
N1s	−371.8	−376.8
S_{2s}	−198.5	−204.3

Results of Molecular Orbital Calculations. Next, the results of DV-Xα MO calculations will be discussed in relation to the above XPS results, with particular reference to the electronic structure of $[\mathrm{Ni(mnt)_2}]^{-}$. Table 2 shows the calculated core orbital energies of the two nickel complexes. In order to obtain accurate ionization energies by the Xα method, calculations should be made of Slater's transition state.[10] The values in Table 2 refer to the ground state and do not allow for the relaxation effects on ionization. Thus, they can not be directly compared with the experimental binding energies. However, they may be expected to give a sufficiently good estimate for the $\Delta(\Delta E)$ value, since the relaxation effects are, for the most part, cancelled out in taking the difference between the two complexes. The values of ΔE are found to be 173.3 and 172.5 eV for $[\mathrm{Ni(mnt)_2}]^{2-}$ and $[\mathrm{Ni(mnt)_2}]^{-}$ respectively; thus, their difference, $\Delta(\Delta E)$, is -0.8 eV, in good agreement with the experimental value of -0.7 eV. The differences in the ΔE values on the DV-Xα calculation are 0.3 eV for Ni2p—S2s and 1.1 eV for Ni2p—N1s, which are comparable with the experimental values of 0.0 and 0.7 eV respectively.

The energies and components of the valence orbitals are given for $[\mathrm{Ni(mnt)_2}]^{2-}$ and $[\mathrm{Ni(mnt)_2}]^{-}$ in Table 3. The positive orbital energies for $[\mathrm{Ni(mnt)_2}]^{2-}$ result from the neglect of the Madelung potentials in the present calculation. The highest occupied molecular orbital (HOMO) for both complexes is the out-of-plane π-type $5b_{3g}$ MO, which consists mainly of S3p atomic orbitals with a minor Ni3d component. It is this orbital from which an electron is removed in going from $[\mathrm{Ni(mnt)_2}]^{2-}$ to $[\mathrm{Ni(mnt)_2}]^{-}$. The occupied MO's, whose main component is a metal d orbital, are $4b_{2g}$ (d_{xz}), $20a_g$ ($d_{x^2-y^2}$), $19a_g$ (d_{z^2}), and $4b_{3g}$ (d_{yz}). Therefore, the nickel atoms in both complexes are considered to have the d^8 configuration or the +2 oxidation state. (In spite of the Ni 3d population being slightly less than 50%, $4b_{2g}{}^{\uparrow}$ should be considered to correspond to Ni d_{xz}, since the rest of the d_{xz} population is mainly found in $3b_{2g}$, which is considered to be a ligand orbital.)

Table 4 lists the Mulliken orbital and overlap populations for $[\mathrm{Ni(mnt)_2}]^{2-}$ and $[\mathrm{Ni(mnt)_2}]^{-}$. The Ni net charges are almost the same for $[\mathrm{Ni(mnt)_2}]^{2-}$ (+0.28) and $[\mathrm{Ni(mnt)_2}]^{-}$ (+0.27). A significant mixing is seen between metal and ligand orbitals, and the net charges are greatly different from the formal charge (+2). The net charges on the sulphur and nitrogen atoms slightly increase on going from the binegative to the uninegative ion. The change in

sulphur charge is about 0.13, in accordance with the value (0.12) obtained from the XPS results by means of Siegbahn's equation. The change in the N net charge is about 0.10 (0.13), while those in the C_1 and C_2 charges are 0.03 (0.0) and −0.02 (0.0) respectively (the numerals in parentheses being the values obtained or assumed in the preceeding section). By substituting these calculated δq values into Eq. 5, we obtain the $\Delta(\Delta E)$ value of −0.9 eV, in good agreement with the XPS result of −0.7 eV and with the value of −0.8 eV obtained directly from the calculated orbital energies. The good agreements between the calculated and the XPS values demonstrated above add support to our estimate of the charge-density distribution and to our arguments made in the interpretation of the XPS results, including the idea that the electronic state of the nickel ion in $[Ni(mnt)_2]^-$ is very similar to that in $[Ni(mnt)_2]^{2-}$. The spin density on the S atom is calculated to be 0.14, which supports the conclusion from the ESR results

C_2-N	1.147	1.133		

obtained by Schmitt *et al.*[3] that the $3p_z$ spin population of the S atom is high.

The $5b_{3g}$ MO is shown schematically in Fig. 3 using the results of MO calculation for $[Ni(mnt)_2]^-$. In this MO, the interactions between Ni–S, S–C_1, and C_2–N are antibonding, while those in C_1–C_2 and C_1–C_1' are bonding. This suggests that the removal of one electron from $5b_{3g}$ MO strengthens the Ni–S, S–C_1, and C_2–N bonds, but weakens the C_1–C_2 and C_1–C_1' bond. The changes in the bond overlap populations given in Table 4 are consistent with this MO argument, demonstrating that the bond-overlap population is useful for a qualitative discussion of chemical bonding. The force constants and the bond

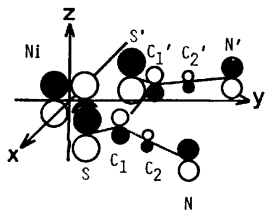

Fig. 3. The $5b_{3g}$ MO with an unpaired electron in $[Ni(S_2C_4N_2)_2]^-$. The black and white circles show positive and negative signs, respectively.

lengths of the two nickel mnt complexes measured by Schlaper *et al.*[4] and Kobayashi *et al.*[5] are given in Table 5. The force constants increase, and the bond lengths decrease, as the bond becomes stronger. Their experimental results are consistent with the calculated bond-overlap populations except for the C_1–C_2 bond. (For this bond, however, their experimental results contradict each other; that is, the force constant increases in spite of the increase in bond length in going from $[Ni(mnt)_2]^{2-}$ to $[Ni(mnt)_2]^-$.)

Conclusion

The XPS measurements have been performed in order to obtain the core binding energies for the N1s and S2s of metal mnt complexes. The DV-Xα MO calculations for two Ni complexes have also been carried out in an attempt to explain the chemical shift and the electronic structure of $[Ni(mnt)_2]^-$. The XPS measurements and the MO calculations provide consistent results that the oxidation state of the nickel atom is +2 for both $[Ni(mnt)_2]^-$ and $[Ni(mnt)_2]^{2-}$. The HOMO is $5b_{3g}$, which is mainly localized on ligands and which holds an unpaired electron in $[Ni(mnt)_2]^-$. This is consistent with other spectroscopic results, such as IR and ESR, and also with the X-ray diffraction data.

The computations reported in this paper have been carried out on the HITAC M-180 computer of the Institute for Molecular Science. This work was supported in part by a Grant-in-Aid for Scientific Research No. 510806 from the Ministry of Education, Science and Culture.

13) According to Siegbahn *et al.*,[12] k_S for S2p is taken as 13.8. By using the same k_S value for S2s, Eq. 4 becomes:

$$\Delta(\Delta E) = 17\delta q_N - 16\delta q_S - 4\delta q_M - 7\delta q_{Cl} - 6\delta q_{C_2} \quad (5')$$

and:

$$\Delta(\Delta E) = 17\delta q_N - 16\delta q_S,$$

in place of Eqs. 5 and 6. With Eq. 7, we obtain $\delta q_S = 0.15$ and $\delta q_N = 0.10$.

A Kinetic Study of the Reactions of Several Cobalt(III) Complexes with Ascorbic Acid

Keiichi TSUKAHARA* and Yasuo YAMAMOTO

Department of Chemistry, Faculty of Science, Shimane University, Nishikawatsucho, Matsue 690

(Received December 1, 1980)

The kinetics of the reactions of $[Co(phen)_3]^{3+}$, $[Co(bpy)_3]^{3+}$, and $[Co(en)(phen)_2]^{3+}$ (phen=1,10-phenanthroline, bpy=2,2′-bipyridine, and en=ethylenediamine) with ascorbic acid (H_2A) have been studied over the temperature range from 17.0 to 35.0 °C, at an ionic strength of 0.10 mol dm^{-3} ($LiClO_4$), and over the pH range from 3.60 to 5.04 (acetate buffer). The $[Co(phen)_3]^{3+}$ and $[Co(bpy)_3]^{3+}$ ions were reduced by both HA^- (k_1 path) and A^{2-} (k_2 path) ions: the second-order rate constants at 25.0 °C are (0.40 ± 0.07) dm^3 mol^{-1} s^{-1} and $(5.8\pm1.1)\times10^6$ dm^3 mol^{-1} s^{-1} for the $[Co(phen)_3]^{3+}$ ion, and (0.13 ± 0.02) dm^3 mol^{-1} s^{-1} and $(2.1\pm0.5)\times10^6$ dm^3 mol^{-1} s^{-1} for the $[Co(bpy)_3]^{3+}$ ion. The $[Co(en)(phen)_2]^{3+}$ ion was reduced only by the A^{2-} ion; $k_2=(1.0\pm0.2)\times10^6$ dm^3 mol^{-1} s^{-1} (25.0 °C). The $[Co(phen)_3]^{3+}$, $[Co(bpy)_3]^{3+}$, and $[Co(en)(phen)_2]^{3+}$ ions were not reduced by H_2A. The activation parameters (ΔH^* and ΔS^*) for the ascorbate reduction of the $[Co(phen)_3]^{3+}$ ion were larger than those of the $[Co(bpy)_3]^{3+}$ ion. This is in contrast to the results of the self-exchange reactions of the $[Co(phen)_3]^{3+/2+}$ and $[Co(bpy)_3]^{3+/2+}$ couples. The mechanisms will be discussed in terms of the activation parameters and the Marcus cross relationships.

The kinetics of the oxidation of ascorbic acid (H_2A) to dehydroascorbic acid (A) by a metal complex have been investigated extensively.[1-5] It has been shown that Cu^{2+} and $[Fe(H_2O)_6]^{3+}$ catalyze the autoxidation of ascorbic acid.[1] The kinetics of the inner-sphere oxidation of ascorbic acid by Cu^{2+} or $[Fe(H_2O)_6]^{3+}$ have been examined,[2,3] as have the outer-sphere oxidations by $[Co(H_2O)_6]^{3+}$,[4] and Fe(III), Ir(IV), and Mo(V).[5] The application of the Marcus theory allowed an estimate of the redox potential and the free energy of activation for the ascorbic acid/radical couple.[5]

Cobalt(III) complexes are very interesting in investigating the electron-transfer reactions because of the problems of the spin-multiplicity change and the ligand-reorganization energy.[6] However, the reactions of cobalt(III) complexes with ascorbic acid have rarely been investigated since Iwasaki[7] reported in 1942 that some cobalt(III) complexes catalyzed the autoxidation of ascorbic acid. As ascorbic acid is a π-donor, ascorbic acid can be expected to interact with cobalt(III) complexes with π-conjugated ligands. We have selected the cobalt(III) complexes ligating 1,10-phenanthroline or 2,2′-bipyridine in order to elucidate the mechanism of the reactions of cobalt(III) complexes with ascorbic acid.

Experimental

Reagents. The $[Co(phen)_3]Cl_3\cdot7H_2O$,[8] $[Co(bpy)_3]Cl_3\cdot3H_2O$,[8] and $[Co(en)_3]Cl_3$[9] complexes were prepared as has been described elsewhere. The perchlorate salts, $[Co(phen)_3](ClO_4)_3\cdot2H_2O$, $[Co(bpy)_3](ClO_4)_3\cdot3H_2O$, and $[Co(en)_3](ClO_4)_3$, were obtained by adding sodium perchlorate to solutions of the chloride complexes. $[Co(en)(phen)_2](ClO_4)_3\cdot2H_2O$,[10] $[Co(en)_2(phen)](ClO_4)_3$,[11] and $Na[Co(edta)]\cdot4H_2O$†,[12] were prepared according to the published procedures. The L-ascorbic acid was supplied by Wako Pure Chemical Industries. The lithium perchlorate, $LiClO_4\cdot3H_2O$, was obtained according to the procedure reported previously.[13] All the solutions used for the measurements were prepared using water obtained by the distillation of alkaline permanganate solutions. A solution of ascorbic acid, partly neutralized with lithium carbonate, was freshly prepared under a nitrogen atmosphere. The acetate buffer solutions were prepared by adding acetic acid to lithium carbonate and purged once with nitrogen gas which had been scrubbed twice with alkaline potassium pyrogallate.

Kinetic Measurements. Solutions containing a cobalt(III) complex, $LiClO_4$, and an acetate buffer were added to an optical cell, which was then sealed with a serum cap. After the solution had been purged with a nitrogen atmosphere for 15 min, the reaction was initiated by the addition of the ascorbic-acid solution by means of a syringe. The change in absorbance with time was followed with a Hitachi 200-20 spectrophotometer. The wavelengths used for the measurements were 350 nm ($[Co(bpy)_3]^{3+}$ and $[Co(en)(phen)_2]^{3+}$), 352 nm ($[Co(en)_2(phen)]^{3+}$), 353 nm ($[Co(phen)_3]^{3+}$), 466 nm ($[Co(en)_3]^{3+}$), and 535 nm ($[Co(edta)]^-$). In order to ensure a pseudo-first order condition, ascorbic acid was in at least a tenfold excess over the cobalt(III) complexes: the initial concentrations of ascorbic acid and the cobalt(III) complexes were $(0.50—1.02)\times10^{-2}$ mol dm^{-3} and $(1.64—5.16)\times10^{-4}$ mol dm^{-3} respectively.

The temperature was kept constant within 0.1 °C at each desired temperature, while the ionic strength (I) was adjusted to 0.1 mol dm^{-3} with lithium perchlorate.

The pH of the solutions was measured by the use of a Hitachi-Horiba F-7 pH meter. The $[H^+]$ was computed from the pH using a value of 0.83 (at 25 °C and I=0.10 mol dm^{-3}) for the activity coefficients of H^+.[14]

Results

In the reactions of $[Co(phen)_3]^{3+}$ and $[Co(bpy)_3]^{3+}$ with ascorbic acid, the absorbance over the range from 300 nm to 400 nm decreased with the time during the course of the reaction. As the dissociations of $[Co(phen)_3]^{2+}$ and $[Co(bpy)_3]^{2+}$ are fast (the rate constants are 0.174 s^{-1} [15] and 0.32 s^{-1} [16] at 25 °C respectively), the reaction corresponds to the absorbance change for the slow steps in the following reactions:

$$[Co(phen)_3]^{3+} \xrightarrow[\text{slow}]{H_2A} [Co(phen)_3]^{2+} \xrightarrow[\text{fast}]{} [Co(phen)_2(H_2O)_2]^{2+} \quad (1)$$

† edta: Ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetate anion.

$$[Co(bpy)_3]^{3+} \xrightarrow[\text{slow}]{H_2A} [Co(bpy)_3]^{2+} \xrightarrow[\text{fast}]{} [Co(bpy)_2(H_2O)_2]^{2+}. \quad (2)$$

Plots of $-\ln(A_t-A_\infty)$ *vs.* the time were linear for at least 85% completion (A_t and A_∞ represent the absorbance at time t and infinity respectively). The observed first-order rate constants (k_{obsd}) obtained from the slope of this straight line show also a linear dependence on the initial concentrations of ascorbic acid (Fig. 1). As the cobalt(III) complexes are one-electron oxidants, ascorbic acid radicals may be formed by the one-electron transfer from the ascorbic acid to the cobalt(III) complexes. Moreover, the dismutation of the ascorbic-acid radicals is very fast.[17] Thus, the rate law was described as follows:

$$-\frac{1}{2}d[Co(III)]/dt = k[Co(III)][H_2A]_0. \quad (3)$$

The second-order rate constants obtained from $k_{obsd}/[H_2A]_0$ increased with a decrease in the acidity (pH 3.60—5.04), as is shown in Fig. 2. The present reaction can, then, be described by this sequence:

$$H_2A \overset{K_1}{\rightleftharpoons} HA^- + H^+ \quad (4)$$

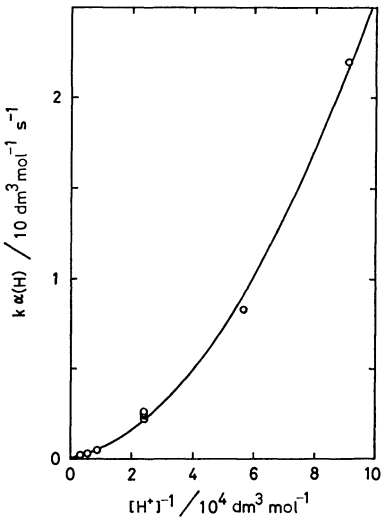

Fig. 3. Plots of $k\alpha(H)$ *vs.* $[H^+]^{-1}$ for the $[Co(phen)_3]^{3+}$–ascorbic acid system at 25.0 °C.

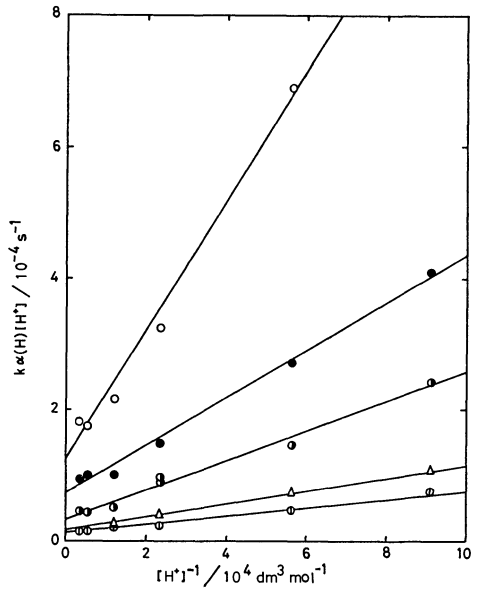

Fig. 4. Plots of $k\alpha(H)[H^+]$ *vs.* $[H^+]^{-1}$ for the $[Co(phen)_3]^{3+}$–ascorbic acid system.
◐: 17.0 °C, △: 21.0 °C, ◑: 25.0 °C, ●: 30.0 °C, ○: 35.0 °C.

$$HA^- \overset{K_2}{\rightleftharpoons} A^{2-} + H^+ \quad (5)$$

$$Co(III) + H_2A \xrightarrow{k_0} \text{radical} + Co(II) \quad (6)$$

$$Co(III) + HA^- \xrightarrow{k_1} \text{radical} + Co(II) \quad (7)$$

$$Co(III) + A^{2-} \xrightarrow{k_2} \text{radical} + Co(II) \quad (8)$$

$$2\,\text{radical} \xrightarrow{\text{fast}} H_nA^{n-2} + A + nH^+, \quad (9)$$

where n is 1 or 2. The above mechanism leads to Eq. 10 for the second-order rate constant:

$$k = \frac{k_0+k_1K_1[H^+]^{-1}+k_2K_1K_2[H^+]^{-2}}{\alpha(H)}, \quad (10)$$

where $\alpha(H)=1+K_1[H^+]^{-1}+K_1K_2[H^+]^{-2}$. As $K_1K_2[H^+]^{-2} \ll 1$ under the present experimental conditions,

Table 1. The rate constants of the reactions of $[Co(phen)_3]^{3+}$, $[Co(bpy)_3]^{3+}$, and $[Co(en)(phen)_2]^{3+}$ with ascorbic acid at $I=0.10$ mol dm^{-3} ($LiClO_4$)[a]

Oxidant	Temp °C	k_1 dm^3 mol^{-1} s^{-1}	$k_2K_1K_2$ 10^{-9} mol dm^{-3} s^{-1}	k_2 10^6 dm^3 mol^{-1} s^{-1}
$[Co(phen)_3]^{3+}$ [b]	17.0	0.22±0.05	0.77±0.35	—
	21.0	0.23±0.01	1.0±0.06	—

$[Co(bpy)_3]^{3+}$ [c]	21.0	0.047±0.021	0.59±0.15	—
	25.0	0.13±0.02	0.88±0.23	2.1±0.5
	30.0	0.12±0.04	2.0±0.7	—
	35.0	0.12±0.03	4.2±0.7	—
$[Co(en)(phen)_2]^{3+}$	25.0	≈0	0.42±0.07	1.0±0.2

a) Data were obtained from at least five determinations. b) $\Delta H_1^*(k_1)=(46\pm4)$kJ mol^{-1}, $\Delta S_1^*(k_1)=(-92\pm4)$J K^{-1} mol^{-1}; $\Delta H_2^*(k_2K_1K_2)=(109\pm8)$kJ mol^{-1}, $\Delta S_2^*(k_2K_1K_2)=(-46\pm4)$J K^{-1} mol^{-1}. c) $\Delta H_1^*(k_1)=(38\pm4)$kJ mol^{-1}, $\Delta S_1^*(k_1)=(-140\pm8)$J K^{-1} mol^{-1}; $\Delta H_2^*(k_2K_1K_2)=(80\pm4)$kJ mol^{-1}, $\Delta S_2^*(k_2K_1K_2)=(-160\pm8)$J K^{-1} mol^{-1}.

$\alpha(H)$ can be simplified as $1+K_1[H^+]^{-1}$. The plots of the values of $k\alpha(H)$ *vs.* $[H^+]^{-1}$ gave a quadratic curve (Fig. 3), and the intercept (k_0) was nearly zero. Therefore, the plots of the values of $k\alpha(H)[H^+]$ *vs.* $[H^+]^{-1}$ gave straight lines (Fig. 4). The values of k_1K_1 and $k_2K_1K_2$ are obtained from the intercept and the slope of this straight line respectively. The second-order rate constants, k_1 and k_2, calculated by the use of the values of K_1 and K_2 are listed in Table 1. The values of K_1 at each temperature were estimated from the values at 0.4, 25.0, and 40.0 °C given by Taqui Khan and Martell.[3]

An acetate buffer had little effect on the rate of the reaction of $[Co(phen)_3]^{3+}$ with ascorbic acid (at pH 4.02 and 0.05—0.25 mol dm^{-3} acetate).

For the reaction of $[Co(en)_2(phen)]^{3+}$, $[Co(en)_3]^{3+}$, or $[Co(edta)]^-$, no significant spectral change was observed at 25.0 °C and pH 5.04.

Discussion

The rate constant for the A^{2-} reduction is 10^6 times larger than that for the HA^- reduction. The difference in this reactivity is similar to that in the reactions of cytochrome c-552,[18] Horse Heart cytochrome c,[18] $[Fe(CN)_6]^{3-}$,[19] and Cu^{2+} [20] with ascorbic acid. As the cobalt(III) complexes are substitution-inert, the electron-transfer reaction is considered to occur through an outer-sphere activated complex:

$$Co(III) + HA^- \text{ (or } A^{2-}) \overset{K_{os}}{\rightleftharpoons} [Co(III)^{3+}\cdot HA^-]$$

$$\text{(or } [Co(III)^{3+}\cdot A^{2-}]) \xrightarrow{k_{et}} \text{products,} \qquad (11)$$

where K_{os} and k_{et} are the ion-pair formation constant and the rate constant of the intramolecular electron-transfer respectively. The values of K_{os} can be calculated from the Fuoss equation,[21] where the distance of the closest approach of two ions is 5×10^{-8} cm for the $[Co(phen)_3]^{3+}$ and ascorbate couple; the values of 5.3 and 90 dm^3 mol^{-1} are obtained at 25 °C and $I=0.1$ mol dm^{-3} for the reactions of HA^- and A^{2-} respectively. The large difference in reactivity cannot be elucidated by this small difference in K_{os}. It may, then, be attributed to the intramoleular electron-transfer step if Reaction 11 occurs.

The $[Co(phen)_3]^{3+}$ and $[Co(bpy)_3]^{3+}$ ions were reduced by both HA^- and A^{2-} ions under the present experimental conditions. On the other hand, the $[Co(en)(phen)_2]^{3+}$ ion was reduced only by the A^{2-} ion, and neither the $[Co(en)_2(phen)]^{3+}$ nor the $[Co(en)_3]^{3+}$ ion was reduced by ascorbate ions. These cobalt(III) complexes were not reduced by H_2A. The difference in the reactivities of these reactions may correspond to that of the redox potentials of the complexes (0.391 V for $[Co(phen)_3]^{3+/2+}$, 0.316 V for $[Co(bpy)_3]^{3+/2+}$, and −0.214 V for $[Co(en)_3]^{3+/2+}$),[22] but it cannot be explained why $[Co(edta)]^-$ is not reduced by ascorbic acid in spite of its higher redox potential (0.60 V).

Pelizzetti *et al.*[5] reported on the application of the Marcus theory, which allowed an estimate of the formal reduction potential, $E_{11}^\circ(HA\cdot/HA^-)=0.88$ V, and the intrinsic parameter, $\Delta G_{11}^*(HA\cdot/HA^-)=17$ kJ mol^{-1}. Using these values, we calculated the rate constants of the reactions of $[Co(phen)_3]^{3+}$, $[Co(bpy)_3]^{3+}$, and $[Co(en)_3]^{3+}$ with HA^- from the Marcus cross relationships,[23] neglecting the work terms, which are inferred to be small:[5,24]

$$\Delta G_{12}^* = \lambda(1+\Delta G_{12}^\circ/\lambda)^2/4 \qquad (12)$$

$$k = Z\exp(-\Delta G_{12}^*/RT) \qquad (13)$$

$$\lambda = 2(\Delta G_{11}^* + \Delta G_{22}^*), \qquad (14)$$

where Z is the collision frequency in a solution (10^{11} dm^3 mol^{-1} s^{-1}), where ΔG_{11}^* and ΔG_{22}^* refer to the self-exchange reactions of the reagents, and where ΔG_{12}° is the free-energy change of the reactions. The values calculated at 25 °C are in accord with the observed ones for the reactions of $[Co(phen)_3]^{3+}$ and $[Co(bpy)_3]^{3+}$ (Table 2).

The activation parameters of the reactions of $[Co(phen)_3]^{3+}$ with HA^- and A^{2-} are larger than those of the reactions of $[Co(bpy)_3]^{3+}$: $\Delta\Delta H_1^* = \Delta H_1^*([Co(phen)_3]^{3+}) - \Delta H_1^*([Co(bpy)_3]^{3+}) = 8$ kJ mol^{-1} and $\Delta\Delta S_1^* = \Delta S_1^*([Co(phen)_3]^{3+}) - \Delta S_1^*([Co(bpy)_3]^{3+}) = 48$

$[Co(en)_3]^{3+}$	7.7×10^{-5}[e]	86	−0.214	105	3×10^{-10}	—

a) Calculated at 25 °C and $I=0.1$ mol dm^{-3}; $E_{11}^{\circ}(HA\cdot/HA^-)=0.88$ V and $\Delta G_{11}^{*}(HA\cdot/HA^-)=17$ kJ mol^{-1}. b) The rate constant of the self-exchange of the cobalt(III) complex. c) Ref. 22. d) Ref. 25. e) F. P. Dwyer and A. M. Sargeson, *J. Phys. Chem.*, **65**, 1892 (1961).

J K^{-1} mol^{-1} for the HA^- path; $\Delta\Delta H_2^{*}=\Delta H_2^{*}([Co(phen)_3]^{3+}) - \Delta H_2^{*}([Co(bpy)_3]^{3+}) = 29$ kJ mol^{-1} and $\Delta\Delta S_2^{*}=\Delta S_2^{*}([Co(phen)_3]^{3+}) - \Delta S_2^{*}([Co(bpy)_3]^{3+}) = 110$ J K^{-1} mol^{-1} for the A^{2-} path. This is in contrast to the result of the self-exchange reactions of the $[Co(phen)_3]^{3+/2+}$ and $[Co(bpy)_3]^{3+/2+}$ couples, that is, $\Delta\Delta H^{*} = \Delta H^{*}([Co(phen)_3]^{3+}) - \Delta H^{*}([Co(bpy)_3]^{3+}) = -11$ kJ mol^{-1} and $\Delta\Delta S^{*}=\Delta S^{*}([Co(phen)_3]^{3+}) - \Delta S^{*}([Co(bpy)_3]^{3+}) = -30$ J K^{-1} mol^{-1}.[25] This suggests that the mechanism of the reactions of the cobalt(III) complexes with ascorbic acid is different from that of the self-exchange reactions of the complexes, which does not involve a π^*-π^* interaction between ligands of cobalt(II) and cobalt(III).[26] The self-exchange of $[Co(edta)]^{-/2-}$, which has a higher redox potential than these complexes, is very slow;[27] the reaction of $[Co(edta)]^-$ with ascorbic acid is also slow. Extended Hückel π-MO calculations[28] have shown that the lowest π^* orbital energy for phen is higher than that of bpy by about 8 kJ mol^{-1}.

On the basis of the above discussions, it can be thought that the reaction of the cobalt(III) complex with π-accepting ligands with π-donating ascorbic acid is much faster than that of the cobalt(III) complex without π-accepting ligands.

The Preparation and Characterization of Dichloromanganese(IV) Schiff Base Complexes

Takayuki MATSUSHITA,* Hiroshi KONO, and Toshiyuki SHONO
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received January 20, 1981)

Some chloromanganese(III) Schiff base complexes react with hydrogen chloride to give deep green complexes with the empirical formula of $MnLCl_2$ or MnL'_2Cl_2, where H_2L denotes quadridentate ligands such as *N,N'*-disalicylideneethylenediamine and its analogs, and where HL' denotes bidentate ligands such as *N*-butylsalicylideneamine and its analogs. These complexes are nonelectrolytes in acetonitrile. Their magnetic moments at room temperature fall within the range of 3.9 to 4.1 BM, and the magnetic susceptibilities obey the Curie-Weiss law with small θ values over the temperature range of 77 to 300 K, indicating that the oxidation state of the manganese ions in these complexes is +IV. The electronic spectra show an intense band around 16000 cm^{-1} which can be assigned to a charge-transfer transition. In the cyclic voltammograms, two cathodic waves are observed at half-peak potentials around +0.9 V and −0.2 V(*vs.* SCE); they can be assigned to the reductions of Mn(IV) to Mn(III) and of Mn(III) to Mn(II) respectively. The probable configurations of the complexes are discussed on the basis of the infrared spectra.

The manganese ion plays an important role in biological redox systems, which are comprised of the oxygen-evolution process of the photosystem II in green plants and the disproportionation of the superoxide ion, O_2^-, by manganese-containing superoxide dismutases. In these systems, the oxidation states of manganese(II), (III), and/or (IV) are believed to be involved.[1] In relation to its function, manganese complexes with higher oxidation states, such as +III and +IV, have been investigated.[2-6] Although manganese(III) complexes with various ligands have thus been synthesized and characterized, few manganese(IV) complexes have been isolated so far, for the manganese(IV) ion is a strong oxidant and its complexes are very unstable.[7,8]

We have found that some chloromanganese(III) Schiff base complexes react with hydrogen chloride to give the corresponding manganese(IV) complexes as deep green crystals. In this paper we will describe the preparation and characterization of a series of novel dichloromanganese(IV) Schiff base complexes.

Experimental

Preparation of Manganese(III) Complexes. The quadridentate Schiff base ligands were prepared by a condensation of the salicylaldehydes with diamines. They were recrystallized from ethanol or appropriate organic solvents. The bidentate Schiff base ligands were prepared by a condensation of the salicylaldehydes with butylamine. The 5-nitro-, 5-bromo-, and 5,6-benzo derivatives were recrystallized from ethanol. All the chloromanganese(III) Schiff base complexes (shown in Fig. 1) were prepared by a modification of the method described in the literature.[9-12] To a methanol solution of a quadridentate Schiff base ligand, an equimolar amount of manganese(III) acetate dihydrate, $Mn(CH_3COO)_3 \cdot 2H_2O$ (a half molar of it when the Schiff-bases were bidentate ligands) was added. The solution was warmed at 60 °C for 1 h, and then a 1.5-molar-fold quantity of lithium chloride over the manganese acetate was added to this solution, which was subsequently further warmed at 60 °C for 1 h. The solution was then concentrated under reduced pressure and cooled. The resulting precipitates were collected on a glass filter, washed with a small volume of water and methanol, and then with ether, and dried *in vacuo*. They were recrystallized from methanol or dichloromethane. The yields were 60—80%. The elemental analyses of the manganese(III) complexes are given in Table 1, along with their magnetic moments measured at room temperature. The magnetic moment of Mn(*N*-Bu-5-NO_2sai)$_2$Cl was found to be lower than those of the other manganese(III) complexes. This may be caused by the magnetic-exchange interaction in this complex.

Preparation of Dichloromanganese(IV) Schiff Base Complexes. Dichloro(N,N'-disalicylideneethylenediaminato)manganese(IV) Dichloromethane Adduct, Mn(salen)$Cl_2 \cdot (CH_2Cl_2)_{0.5}$: Into an acetone solution (200 cm^3) of Mn(salen)Cl·H_2O (0.5 g), a two-molar-fold portion of a methanol solution of HCl over the complex was stirred, drop by drop, at room temperature. The solution turned brown to deep green. After the solution had been filtered, the filtrate was concentrated to about 20 cm^3 under reduced pressure. Anhydrous ether (200 cm^3) was then added to this solution. The resulting green precipitates were collected on a glass filter, washed with ether,

a) Measured at room temperature.

and dried *in vacuo*. The solids were recrystallized from dichloromethane to give the above complex as deep green crystals. The yield was *ca.* 30%.

The other dichloromanganese(IV) Schiff base complexes were obtained in a similar manner. The elemental analyses of the manganese(IV) complexes obtained are given in Table 2, together with their magnetic moments measured at room temperature. These deep green complexes are soluble in dichloromethane, acetone, and acetonitrile. The solutions were stable in these solvents if kept without contact with to moisture. They were soluble in donating solvents, such as pyridine, *N*,*N*-dimethylformamide, and methanol, but these solutions gradually turned brown.

Reagents. All the reagents were of a reagent grade. The solvents were purified by refluxing over sodium (ether), calcium chloride (dichloromethane, acetone), or magnesium (methanol), and then distilled. The acetonitrile was distilled twice from diphosphorus pentaoxide prior to use.

Measurements. The UV, VIS, and NIR spectra were obtained from Hitachi EPS-3 and 340 spectrophotometers. The IR spectra were recorded on a Hitachi EPI-215 grating spectrophotometer in the 700 to 4000 cm^{-1} regions and on a Hitachi EPI-L grating spectrophotometer in the 200 to 700 cm^{-1} regions. All the spectra were measured in Nujol mulls or in a KBr disc. The magnetic susceptibilities were measured by the Gouy method at room temperature and by the Faraday method, using a Shimadzu MB 11 apparatus for the temperature range from 77 to 300 K. The conductivities were determined on a Yanagimoto MY-7 conductivity outfit. The cyclic voltammetry was performed with a Yanagimoto P8 polarograph connected with a Yanagimoto P8-PT potentiostat. The working electrode was a platinum-inlay electrode, while the auxiliary electrode was a platinum wire. The reference electrode was a saturated calomel electrode which was inserted in an aqueous solution of 1 M (1 M=1 mol dm^{-3}) KCl in a 100-cm^3 beaker connected with a conventional brown H-type cell by means of a 4% agar-saturated KCl gel bridge. Tetrabutylammonium perchlorate, Bu_4NClO_4, was used as the supporting electrolyte. The dissolved oxygen was removed by passing nitrogen gas through a sample solution for 20 min.

Results and Discussion

Figure 2 shows the spectral changes on the addition of HCl to an acetone solution of Mn(salen)Cl·H_2O in different molar ratios. The spectra change remarkably on the addition of HCl, and a new absorption band appears around 630 nm. Its intensity increases as the molar ratio of HCl to the complex increases to 4. The further addition of HCl leads to the decolorization of the solution, with the formation of white precipitates, which may consist of hydrogen chloride salts of the ligand. This was confirmed by a comparison of the IR spectra of the white

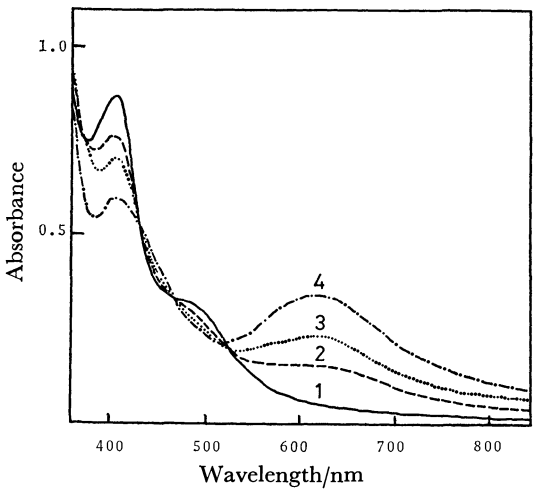

Fig. 2. Spectral changes on the addition of HCl to an acetone solution of 2×10^{-4} M Mn(salen)Cl·H_2O in different molar ratios.
(1): [HCl]/[complex]=0, (2): 1, (3): 2, (4): 4.

precipitates and of the authentic compound obtained by the reaction between salenH_2 and HCl in ether.

The deep green complexes isolated by the reactions between chloromanganese(III) Schiff base complexes and HCl are given in Table 2. Their analytical data are consistent with the empirical formula of $MnLCl_2$ or MnL'_2Cl_2, where L denotes a dianion of quadridentate Schiff base ligands, and L', a monoanion of bidentate Schiff base ligands. Some of them include dichloromethane as a crystalline solvent.

Magnetic Properties. The room-temperature magnetic moments for these complexes (given in Table 2) fall within the range of 3.9 to 4.1 BM, consistent with a calculated spin-only value expected for a complex with a d^3 high-spin configuration. Figure 3 shows the Curie-Weiss plot for Mn(salen)$Cl_2\cdot(CH_2Cl_2)_{0.5}$ over the temperature range from 77 to 300 K. The magnetic susceptibilities obey the Curie-Weiss law, $\chi_A=C/(T+\theta)$. The same behavior was observed for the complexes of Mn(5-Mesalen)$Cl_2\cdot(CH_2Cl_2)_{0.25}$ and Mn(*N*-Bu-5-NO_2sai)$_2Cl_2$. Their Weiss constants are given in Table 3. These values were obtained from an extrapolation of the plot of the reciprocal of the molar susceptibilities, χ_A, against the absolute temperature. These small θ values indicate that there are very small magnetic interactions in these complexes. These results suggest that the oxidation state of the central manganese ion in the complexes is +IV.

Conductivities. The molar conductivities for several manganese(III) and manganese(IV) complexes are summarized in Table 4. These values indicate that they are essentially nonelectrolytes in acetonitrile. The slightly large value observed for the Mn(*N*-Busai)$_2Cl_2$, complex may be caused by its lower solubility in acetonitrile. On the other hand, in methanol the molar conductivity for Mn(salen)Cl·H_2O was found to be 71 S cm^2 mol^{-1}, and that for Mn(salen)$Cl_2\cdot(CH_2Cl_2)_{0.5}$, to be 191 S cm^2 mol^{-1}. These values indicate that both complexes undergo considerable dissociation in methanol.

Electronic Spectra. Figure 4 shows the electronic spectra of Mn(salen)Cl·H_2O and Mn(salen)$Cl_2\cdot(CH_2Cl_2)_{0.5}$ in dichloromethane. In the visible region, the spectrum of the manganese(III) complex shows three absorption bands, at 15600, 20800, and 23800 cm^{-1}. They have been previously assigned to the ligand-field transitions of $d_{xy}\rightarrow d_{x^2-y^2}$ and of d_{yz}, $d_{xz}\rightarrow d_{x^2-y^2}$, and to the charge-transfer transition of $d\pi$(Mn) to π^* (azomethine), respectively.[12,13] On the other hand, the spectrum of the manganese(IV) complex shows two absorption bands, at 15400 and 23000 cm^{-1}. The lower-energy band is very intense compared with that of the manganese(III) complex. Therefore, it seems to be due to a charge-transfer transition.

Moews has reported on the absorption spectrum of $K_2Mn^{IV}Cl_6$ in fluorocarbon grease mulls; it shows two absorption bands, at 15400 (very strong) and 27400 cm^{-1} (strong) in the visible region.[8d] The lower-energy band has been assigned to a charge-transfer

transition of chlorine to manganese. Later, Jeżowska-Trzbiatowska *et al.*[14] claimed that the absorption spectrum of the same complex in 12 mol dm^{-3} HCl does not agree with that observed by Moews in the intensities of these bands. However, as was pointed out by Moews, hexachloromanganate(IV) salts are rapidly converted to the corresponding aquapentachloromanganate(III) salts on standing in moist air. Therefore, it is uncertain as to whether or not $K_2Mn^{IV}Cl_6$ exists as the $Mn^{IV}Cl_6^{2-}$ ion in 12 mol dm^{-3} HCl.

The spectral data for the manganese(IV) complexes are summarized in Table 5. All the complexes show two intense bands around 16000 and 23000 cm^{-1} in the visible region. It can be seen that the absorption maxima of the lower-energy bands are affected by the Schiff base ligands. In the complexes of the salen type, the absorption maxima are shifted to higher energies in the order of the substituents of 5-Me<5-Br<H<5-NO_2. In the complexes of the *N*-butylsalicylideneamine type, similar shifts are observed in the order of the substituents of 5,6-Benzo<5-Br<H<5-NO_2. Furthermore, the absorption maxima of the

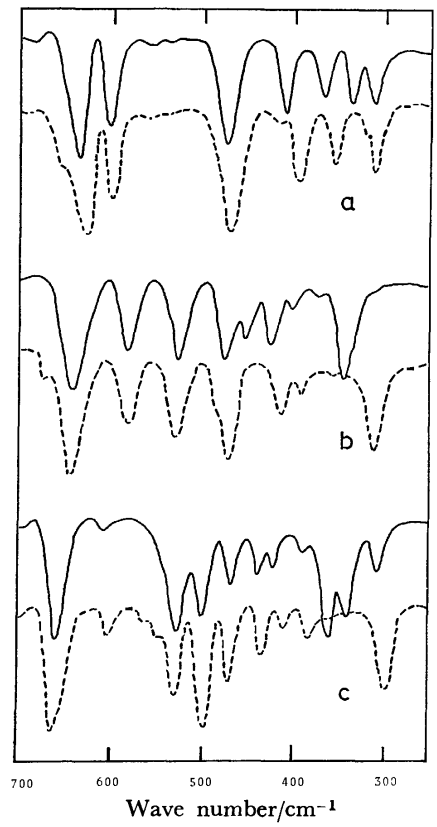

Fig. 5. Infrared spectra (in Nujol mulls). a) (——): Mn^{IV}(salen)$Cl_2\cdot(CH_2Cl_2)_{0.5}$; (– – –): Mn^{III}(salen)$Cl\cdot H_2O$, b) (——): Mn^{IV}(*N*-Busai)$_2Cl_2$; (– – –): Mn^{III}(*N*-Busai)$_2Cl$, c) (——): Mn^{IV}(*N*-Bu-5-NO_2-sai)$_2Cl_2$; (– – –): Mn^{III}(*N*-Bu-5-NO_2sai)$_2Cl$.

former complexes are observed at lower energies than those of the latter complexes. These results imply that the lower-energy bands may be assigned to a charge-transfer transition of Cl(pπ) to Mn(dπ). The absorption bands due to the ligand-field transitions expected for the manganese(IV) complexes may be obscured by these intense bands.

Infrared Spectra. In the region from 4000 to 500 cm^{-1} the infrared spectra of the manganese(IV) complexes are almost the same as those of the cor-

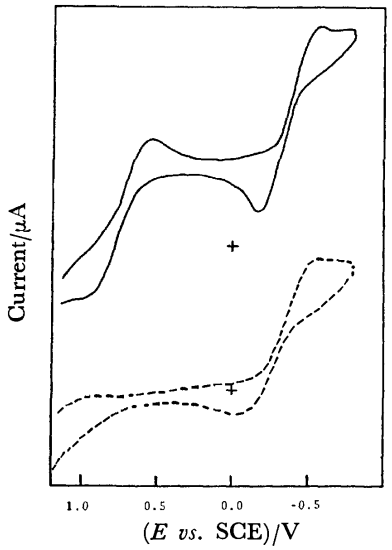

Fig. 6. Current potential curves in acetonitrile. (——): $Mn^{IV}(salen)Cl_2\cdot(CH_2Cl_2)_{0.5}$; (– – –): Mn^{III}-(salen)$Cl\cdot H_2O$.

responding manganese(III) complexes, except around 1290 cm^{-1}, where the absorption band due to ν(C–O) should be observed. This indicates that there is no change in the coordination features of the Schiff base ligands in either manganese(III) or manganese(IV) complexes. In the ν(C–O) region, lower-energy shifts of about 10 cm^{-1} were observed on going from the manganese(III) complexes to the manganese(IV) complexes; they may be caused by the change of the oxidation state of the central manganese ion from +III to +IV. In the region from 200 to 500 cm^{-1}, the spectra of the manganese(IV) complexes show the strong absorption bands at about 340 cm^{-1}, unlike those of the corresponding manganese(III) complexes. Figure 5-a shows the spectra of $Mn^{IV}(salen)Cl_2\cdot(CH_2Cl_2)_{0.5}$ and $Mn^{III}(salen)Cl\cdot H_2O$. The band observed at 341 cm^{-1} for the manganese(IV) complex may be assigned to ν(Mn–Cl). Figure 5-b shows the spectra of Mn^{IV}(*N*-Busai)$_2Cl_2$ and Mn^{III}(*N*-Busai)$_2$Cl. The band observed at 348 cm^{-1} for the manganese(IV) complex may be assigned to ν(Mn–Cl). On the other hand, as is shown in Fig. 5-c, the spectrum of Mn^{IV}(*N*-Bu-5-NO_2sai)$_2Cl_2$ exhibits two strong bands, at 364 and 333 cm^{-1}, which may be assigned to ν(Mn–Cl). The frequencies of the characteristic bands assigned to ν(Mn–Cl) for the manganese(IV) complexes are summarized in Table 5. In the complexes of the salen type, one band assignable to ν(Mn–Cl) was observed, whereas in the Mn^{IV}(*N*-Bu-5-NO_2sai)$_2Cl_2$ complex, two bands were observed. For the octahedral complexes of the MA_4Cl_2 type (A denotes unidentate ligands such as ammonia), one band due to ν(M–Cl) should be observed in the case of a *trans*-configuration, whereas two strong bands should be observed in the case of a *cis*-configuration.[15] These results suggest that the manganese(IV) complexes of the salen type may have a *trans*-octahedral configuration, while in the manganese(IV) complexes of the bidentate Schiff bases, *trans*- and *cis*-octahedral configurations may be probable.

Table 6. Reduction potentials for manganese(IV) complexes

Complex	$E_{p/2}$ *vs.* SCE[a] / V	
	$Mn^{IV}\rightarrow Mn^{III}$	$Mn^{III}\rightarrow Mn^{II}$
$Mn(salen)Cl_2\cdot(CH_2Cl_2)_{0.5}$	0.76	−0.37 (−0.38)[b]
$Mn(5\text{-}Brsalen)Cl_2$	0.85	−0.16 (+0.01)

a) Measured in acetonitrile at 25 °C. b) Half-peak potentials observed for the corresponding manganese(III) complexes.

Electrochemical Properties. Figure 6 shows some typical current-potential curves of $Mn^{III}(salen)Cl\cdot H_2O$ and $Mn^{IV}(salen)Cl_2\cdot(CH_2Cl_2)_{0.5}$ measured in acetonitrile. In the manganese(III) complex, one cathodic wave is observed at −0.38 V(*vs.* SCE); it can be assigned to the reduction of Mn(III) to Mn(II). On the other hand, in the manganese(IV) complex, two cathodic waves are observed, at +0.76 and −0.37 V(*vs.* SCE), with similar wave heights; they can be assigned to the reductions of Mn(IV) to Mn(III) and of Mn(III) to Mn(II) respectively. The separations of the peak potentials between the cathodic wave and the corresponding anodic wave for both redox waves are larger than the 57 mV expected for a reversible one-electron redox wave, so these electrode reactions may be irreversible.

All the manganese(IV) complexes show two cathodic waves around +0.85 V and −0.20 V(*vs.* SCE). The half-peak potentials for the reductions of the manganese(IV) complexes are summarized in Table 6, together with those of the corresponding manganese(III) complexes. As has been discussed in connection with the electronic spectra, the potentials for both reductions are also affected by the Schiff base ligands. The reduction potentials are shifted to more positive values upon the introduction of an electron-withdrawing substituent such as the 5-NO_2 group in both types of the complexes. Furthermore, the reduction potentials for the complexes of the *N*-butylsalicylideneamine type are observed at more positive values than those for the complexes of the salen type. These shifts can be explained in terms of the electron density on the central manganese ion in the complexes.

Reactions. These manganese(IV) complexes have reduction potentials high enough to oxidize water. Thus, we have attempted their reactions with water. Figure 7 shows the spectral changes on the addition of water to an acetonitrile solution of $Mn(salen)Cl_2\cdot(CH_2Cl_2)_{0.5}$ in different molar ratios. The

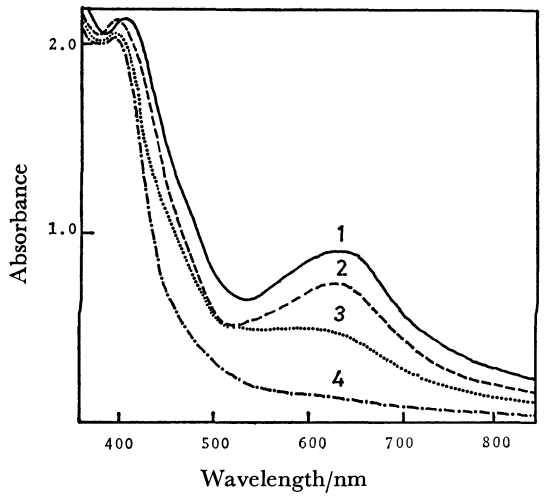

Fig. 7. Spectral changes on the addition of H_2O to an acetonitrile solution of 4×10^{-4} M $Mn(salen)Cl_2\cdot(CH_2Cl_2)_{0.5}$ in different molar ratios.
(1): $[H_2O]/[complex]=0$, (2): 10, (3): 20, (4): 40.

intensity of the characteristic absorption band at 624 nm decreased with an increase in the molar ratio of water to the complex. The final absorption spectrum is almost identical with that of the corresponding manganese(III) complex in the acetonitrile and water mixture, indicating that water reduced the manganese(IV) complex to the manganese(III) complex. We have also succeeded in detecting free "molecular oxygen" liberated during the reactions of the manganese(IV) complexes with water by means of the spectrophotometry of an alkaline pyrogallol solution and a dissolved oxygen probe.[16] The details will be described in the near future.

Some novel dichloromanganese(IV) Schiff base complexes have been prepared and characterized. The higher oxidation state of the manganese ion may be stabilized by charge neutralization with chloride ions. The mechanism for the reaction of the manganese(III) complexes with HCl has not been clarified in this work. However, some experimental evidence suggests that the manganese(IV) complexes may result from a disproportionation of the manganese(III) complexes: manganese(II) compounds are often formed as contaminants in the preparation of the manganese(IV) complexes, and their yields are always 50% or below.

Reaction between Aluminium Trichloride and Steam in the Vapor Phase and Properties of the Aluminium Oxide Formed

Yuichi Shoji, Ryoko Matsuzaki, and Yuzo Saeki*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received February 2, 1981)

The reaction between gaseous $AlCl_3$ and steam, and the products formed were examined by X-ray analysis, TG, DTA, and electron microscopy. The thermal transitions of the Al_2O_3 formed under various conditions were also examined. The reaction between gaseous $AlCl_3$ and steam occurs even at 150 °C and proceeds rapidly above about 400 °C. The product is amorphous Al_2O_3 below 600 °C, amorphous Al_2O_3 containing poorly crystallized γ-Al_2O_3 at 800 °C, γ-Al_2O_3 containing amorphous Al_2O_3 at 900 °C, and γ-Al_2O_3 at 1000 °C. Also, it was observed that the Al_2O_3 formed below 900 °C included a chloride oxide of aluminium, which decomposed in the vicinity of 830 °C to form γ-Al_2O_3 with the evolution of gaseous $AlCl_3$. On heating the amorphous Al_2O_3 formed by the reaction between gaseous $AlCl_3$ and steam, the transition: amorphous $\xrightarrow{ca.\ 700\,^\circ C}$ χ $\xrightarrow{ca.\ 800\,^\circ C}$ κ $\xrightarrow{ca.\ 1000\,^\circ C}$ α occurs; and on heating the γ-Al_2O_3 formed by the same reaction, the transition: γ $\xrightarrow{ca.\ 900\,^\circ C}$ δ $\xrightarrow{ca.\ 1000\,^\circ C}$ θ $\xrightarrow{ca.\ 1000\,^\circ C}$ α occurs.

The reaction of volatile metal chlorides with oxygen or steam has recently become important for the preparation of fine powders of pure metal oxides, because it is possible to carry out the reaction in the vapor phase. To develop a chemical process for preparing fine powders of aluminium oxide (Al_2O_3) by the vapor-phase oxidation of aluminium trichloride ($AlCl_3$), the authors[1] have examined the reaction between $AlCl_3$ and oxygen in the vapor phase and the properties of the Al_2O_3 formed.

There are limited data on the reaction between $AlCl_3$ and steam in the vapor phase. Kato *et al.*[2] have studied the reaction product between gaseous $AlCl_3$ and excess steam at 700—1100 °C and reported that the reaction product is amorphous Al_2O_3 which includes a Cl-containing compound, presumably AlClO, at 700 and 900 °C and δ-Al_2O_3 with or without a small amount of κ-Al_2O_3 at 1100 °C. They have also reported that the amorphous Al_2O_3 crystallizes to κ-Al_2O_3 on heating up to 830 °C in the air and that the δ-Al_2O_3 transforms to α-Al_2O_3 by the heat treatment a 1100 °C in the air.

In this paper, the reaction between gaseous $AlCl_3$ and steam and the product formed have been examined in detail by X-ray analysis, thermogravimetry (TG), differential thermal analysis (DTA), and electron microscopy. The thermal transition of the Al_2O_3 formed under various conditions has also been examined.

Experimental

The $AlCl_3$ used was prepared by the reaction between pure aluminium(Al:99.99%) and chlorine at 400 °C.[1]

A transparent quartz reaction tube (1000 mm length) with an inner concentric tube was used. Gaseous $AlCl_3$ was formed by heating $AlCl_3$ placed in the inner tube at 150 °C, and was carried by a stream of argon (40 cm^3/min) to the reaction zone (27 mm i.d. and 250 mm length) held at a specified temperature. In the meantime, a stream of argon (100 cm^3/min) containing a specified amount of steam was introduced through a separate tube into the reaction zone. The mean flow-rate of the $AlCl_3$ was approximately 3.8 cm^3 Al_2Cl_6(g)/min. The reaction was allowed to proceed for 2 h.

Hydrogen chloride(HCl) formed during the reaction was absorbed in a known amount of 0.1 M† sodium hydroxide (NaOH) solution, and was determined by neutralization titration of the excess NaOH.

The unreacted $AlCl_3$, which was deposited outside the reaction zone together with the reaction product, was separated by heating the mixture in an argon stream at 250 °C. The $AlCl_3$ adsorbed on Al_2O_3 formed was separated by washing the Al_2O_3 with ethanol at boiling point with stirring.[1]

X-Ray analysis of soild product was performed with an X-ray powder diffractometer equipped with a proportional counter, using Ni filtered Cu radiation. TG and DTA were performed in an argon stream and a heating rate of 5 °C/min was employed. The sensitivity of the quartz helix used for TG was approximately 71 mm/g. α-Al_2O_3 was used as a reference for DTA.

Throughout this work, $AlCl_3$ and reaction products were handled in an argon atmosphere or *in vacuo* to prevent any contamination from moisture in the air.

Results and Discussion

Reaction between Gaseous Aluminium Trichloride and Steam. The amounts of HCl formed by the reaction between gaseous $AlCl_3$ and steam(H_2O) at various temperatures were examined. When gaseous $AlCl_3$ and a stream of argon containing excess H_2O (15 vol% H_2O), more than the value calculated as needed to form Al_2O_3 and HCl, was introduced into the reaction zone, a part of the HCl formed by the reaction was dissolved in the unreacted H_2O which condensed outside the heating zone. Aluminium trichloride hexahydrate was also formed from the Al_2O_3 and the HCl. So, the experiments were thus carried out by introducing into the reaction zone a stream of argon containing an amount of H_2O (9, 5, or 2 vol% H_2O) smaller than the calculated value. The reaction temperature above 150 °C was employed, because gaseous $AlCl_3$ was generated by heating $AlCl_3$ at 150 °C. The results are shown in Fig. 1. The broken lines in Fig. 1 show the calculated values of the amount

† 1 M = 1 mol dm^{-3}.

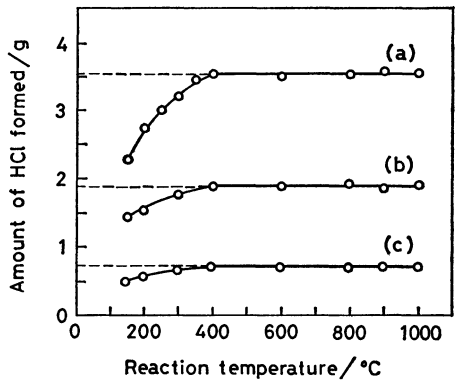

Fig. 1. Amounts of HCl formed by the reaction between gaseous $AlCl_3$ and steam at various temperatures.
Steam content in Ar: (a) 9 vol%, (b) 5 vol%, (c) 2 vol%.

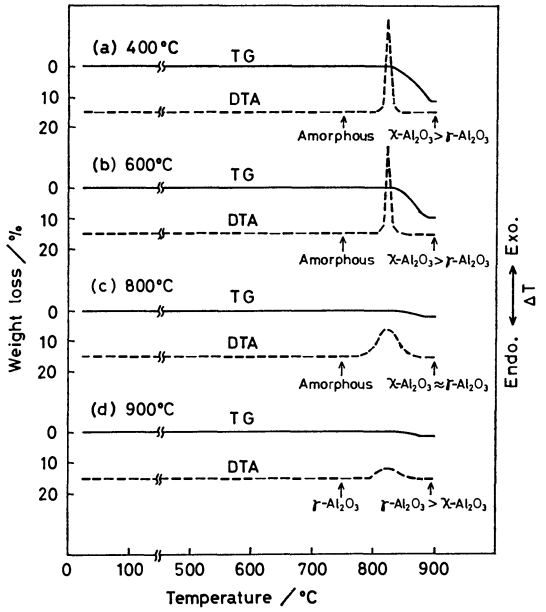

Fig. 2. TG and DTA curves of the products formed by the reaction between gaseous $AlCl_3$ and steam at 400—900 °C.

of HCl, based on the assumption that all the H_2O introduced reacts with gaseous $AlCl_3$ to form HCl.

From the results, the reaction between gaseous $AlCl_3$ and H_2O begins even at 150 °C, and all the H_2O introduced reacts with gaseous $AlCl_3$ above about 400 °C.

To determine the reaction product of gaseous $AlCl_3$ with H_2O, the products formed by introducing a stream of argon containing 9 vol% H_2O at reaction temperatures above 400 °C were examined by X-ray analysis, TG, and DTA.

The X-ray analysis of the reaction products formed at 400 and 600 °C showed no diffraction line. The TG and DTA curves of the products are shown in Figs. 2(a) and (b).

The samples obtained after heating both the products up to 750 °C gave no change in X-ray diffraction pattern (amorphous). The samples obtained after heating up to 900 °C gave diffraction lines corresponding to both χ-Al_2O_3[3,4] and γ-Al_2O_3.[3,5] From these results and the fact that the amorphous Al_2O_3 formed by the reaction between gaseous $AlCl_3$ and oxygen crystallizes to χ-Al_2O_3 in the vicinity of 820 °C with an exothermic effect as previously reported,[1] the exothermic effect observed in the vicinity of 820 °C was considered to be due to the crystallization of amorphous Al_2O_3. During the weight losses in the vicinity of 830 °C which appeared in the TG curves (12% for the product at 400 °C; 10% for the product at 600 °C), it was observed that a white powder was deposited on a cooler part outside the heating zone. The white powder was identified as $AlCl_3$ by chemical analysis. This result and the fact that diffraction lines corresponding to γ-Al_2O_3 in addition to χ-Al_2O_3 based on the crystallization of amorphous Al_2O_3 were observed in both samples obtained after heating up to 900 °C led us to conclude that the products formed by the reaction at 400 and 600 °C were amorphous Al_2O_3 containing a compound which decomposed in the vicinity of 830 °C to form γ-Al_2O_3 with the evolution of gaseous $AlCl_3$. Also, the results of IR spectroscopy confirmed that the reaction products contained neither H_2O nor OH^-. These results indicated that the compound mentioned above was a chloride oxide of aluminium.

The reaction product formed at 800 °C was found to be amorphous by X-ray analysis and its TG and DTA curves are shown in Fig. 2(c). The exothermic effect due to the crystallization of amorphous Al_2O_3 in the vicinity of 820 °C became weak and diffuse. Although the weight loss in the vicinity of 830 °C (3%) was rather small compared with those of the reaction products formed at 400 and 600 °C, the sample obtained after heating up to 900 °C gave diffraction lines corresponding to both χ-Al_2O_3 and γ-Al_2O_3. These results indicated that the reaction product formed at 800 °C was amorphous Al_2O_3 containing poorly crystallized γ-Al_2O_3 and a small amount of the chloride oxide. This estimation was confirmed by the experimental results on the thermal transitions of the Al_2O_3 formed under various conditions, as described later.

The reaction product formed at 900 °C gave diffraction lines corresponding to γ-Al_2O_3. But the DTA curve (Fig. 2(d)) showed a weak exothermic effect due to the crystallization of amorphous Al_2O_3, and the sample obtained after heating up to 900 °C showed diffraction lines corresponding to χ-Al_2O_3 in addition to γ-Al_2O_3. Also, a slight weight loss (1%) due to the thermal decomposition of the chloride oxide was observed. These results indicated that the reaction product formed at 900 °C was γ-Al_2O_3 containing amorphous Al_2O_3 and a small amount of the chloride oxide.

The reaction product formed at 1000 °C gave diffraction lines corresponding to γ-Al_2O_3, and gave no thermal effect in the DTA, and no weight change in the TG. The sample obtained after heating up to 900 °C gave diffraction lines corresponding to γ-Al_2O_3 alone. From these results, the reaction product formed at 1000 °C was found to be γ-Al_2O_3.

The reaction products formed by introducing gaseous

Table 1. Thermal transitions of Al_2O_3 formed at various temperatures

1300	—	—	—	—	—	—	—	α

Amorphous: amorphous Al_2O_3, χ: χ-Al_2O_3, κ: κ-Al_2O_3,[3,6] γ: γ-Al_2O_3, δ: δ-Al_2O_3,[3,7] α: α-Al_2O_3,[8] θ: θ-Al_2O_3.[9]

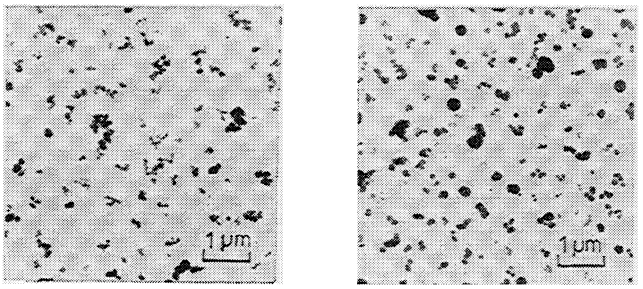
$AlCl_3$ and a stream of argon containing 5 vol% H_2O were examined in the manner described above. The results indicated that the reaction product at each temperature was similar to that formed by introducing a stream of argon containing 9 vol% H_2O, described above.

These experimental results show that the reaction between gaseous $AlCl_3$ and H_2O occurs even at 150 °C and proceeds rapidly above about 400 °C. The reaction product formed is amorphous Al_2O_3 at 400—600 °C, amorphous Al_2O_3 containing poorly crystallized γ-Al_2O_3 at 800 °C, γ-Al_2O_3 containing amorphous Al_2O_3 at 900 °C, and γ-Al_2O_3 at 1000 °C. In addition, the Al_2O_3 formed below 900 °C includes the chloride oxide of aluminium, which decomposes in the vicinity of 830 °C to form γ-Al_2O_3 with the evolution of gaseous $AlCl_3$. The amount of the chloride oxide decreased with increasing the reaction temperature, and the formation of the chloride oxide was not observed at 1000 °C.

Kato *et al.*[2] have reported that the products formed by the reaction between gaseous $AlCl_3$ and H_2O at 700 and 900 °C are amorphous and have estimated that the products include a Cl-containing compound, presumably AlClO, from the result that, on heating the products in the air, they lose weight in the vicinity of 800 °C with the evolution of chlorine. In the present work, it was also observed that the Al_2O_3 formed below 900 °C included a chloride oxide of aluminium. The only known chloride oxide of aluminium is AlClO. But, the composition of the chloride oxide formed in these experiments was not evaluated by chemical analysis, because the chloride oxide was included in the Al_2O_3 formed.

As described in the previous report,[1] the reaction between gaseous $AlCl_3$ and oxygen occurs above about 400 °C and proceeds appreciably above about 800 °C. While, the reaction with H_2O was found to proceed rapidly at rather low temperatures. The modification of the Al_2O_3 formed by the reaction with H_2O at each temperature was the same as that of the Al_2O_3 formed by the reaction with oxygen,[1] except that the Al_2O_3 formed by the reaction with oxygen at 800 °C is amorphous Al_2O_3.

The reaction products formed by introducing gaseous $AlCl_3$ and a stream of argon containing 9 or 5 vol% H_2O at various temperatures were examined by electron microscopy. Typical electron micrographs of the Al_2O_3 formed are shown in Fig. 3.



(a) 800°C (b) 1000°C

Fig. 3. Electron micrographs of the Al_2O_3 formed by the reaction between gaseous $AlCl_3$ and steam at 800 and 1000 °C (Steam content in Ar: 9 vol%).

As reported before,[1] the Al_2O_3 formed by the reaction with oxygen is relatively uniform, ultrafine powders with diameters of the order of 1/100 μm. While, the range of particle sizes of the Al_2O_3 formed by the reaction with H_2O was found to be wide, as seen from Fig. 3.

Thermal Transition of the Aluminium Oxide Formed by the Reaction between Gaseous Aluminium Trichloride and Steam. The thermal transitions of the Al_2O_3 formed under various conditions were examined. The samples obtained by heating the Al_2O_3 at a specified temperature for 2 h both in an argon atmosphere and in the air were examined by X-ray analysis.

The results for the Al_2O_3 formed by introducing a stream of argon containing 9 vol% H_2O are shown in Table 1. As examples, the X-ray diffraction patterns of the samples obtained after heating the amorphous Al_2O_3, formed at 400 °C, at various temperatures in an argon atmosphere and after heating the γ-Al_2O_3, formed at 1000 °C, at various temperatures in the air are illustrated in Figs. 4 and 5, respectively.

These experimental results show that, on heating the amorphous Al_2O_3, formed at 400 and 600 °C, both in an argon atmosphere and in the air, the amorphous $\xrightarrow{ca.\ 700\ °C}$ χ $\xrightarrow{ca.\ 800\ °C}$ κ $\xrightarrow{ca.\ 1000\ °C}$ α transition occurs regardless of the heating atmosphere. The γ-Al_2O_3 observed in the samples obtained after heating

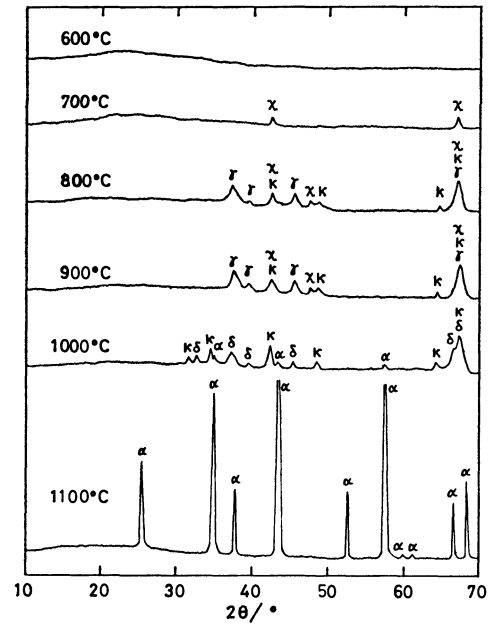


Fig. 4. X-Ray diffraction patterns of the samples obtained after heating the amorphous Al_2O_3, formed at 400 °C, at various temperatures in an argon atmosphere.

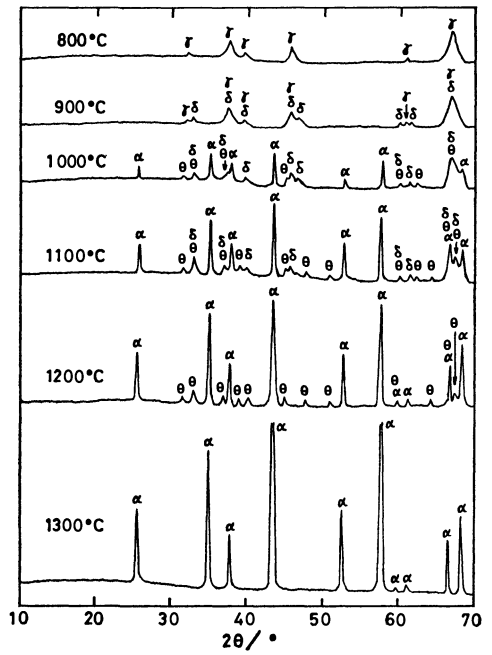

Fig. 5. X-Ray diffraction patterns of the samples obtained after heating the γ-Al_2O_3, formed at 1000 °C, at various temperatures in the air.

at 800 and 900 °C in an argon atmosphere was considered to be due to the decomposition of the chloride oxide, as mentioned before, and the δ-Al_2O_3 observed at 1000 °C was considered to be due to the thermal transition of the γ-Al_2O_3 formed. The samples obtained after heating the amorphous Al_2O_3 in the air gave neither diffraction lines corresponding to γ-Al_2O_3 nor diffraction lines corresponding to δ-Al_2O_3. This fact was considered to indicate that, on heating the chloride oxide in the air, it was oxidized to amorphous Al_2O_3, which transformed in the same manner as the amorphous Al_2O_3 formed by the reaction between gaseous $AlCl_3$ and H_2O.

The result for the γ-Al_2O_3 formed at 1000 °C indicates that, on heating the γ-Al_2O_3, the $\gamma \xrightarrow[\text{ca. 900 °C}]{} \delta \xrightarrow[\text{ca. 1000 °C}]{} \theta \xrightarrow[\text{ca. 1000 °C}]{} \alpha$ transition occurs regardless of the heating atmosphere.

On heating the γ-Al_2O_3 containing amorphous Al_2O_3, formed at 900 °C, and the amorphous Al_2O_3 containing poorly crystallized γ-Al_2O_3, formed at 800 °C, both the amorphous$\rightarrow\chi\rightarrow\kappa\rightarrow\alpha$ and $\gamma\rightarrow\delta\rightarrow\theta\rightarrow\alpha$ transitions occur, as is expected from the above results.

As mentioned above, it was observed that, on heating the Al_2O_3 formed at 800 °C in the air, the $\gamma\rightarrow\delta\rightarrow\theta\rightarrow\alpha$ transition occurred. Also, let us assume that the γ-Al_2O_3 observed in the samples obtained after heating the Al_2O_3 formed at 800 °C both in an argon atmosphere and in the air is due to the thermal decomposition of the chloride oxide included in the Al_2O_3. Then θ-Al_2O_3 should not be observed in the samples obtained after heating at 1000 °C, as seen from the results obtained on heating the amorphous Al_2O_3, formed at 400 and 600 °C, in an argon atmosphere. These results support the estimation, described in the previous paragraph, that the Al_2O_3 formed at 800 °C is amorphous Al_2O_3 containing poorly crystallized γ-Al_2O_3.

The experimental results for the Al_2O_3 formed by introducing a stream of argon containing 5 vol% H_2O were similar to those for the Al_2O_3 formed at 9 vol% H_2O, described above.

These experimental results show that, on heating the amorphous Al_2O_3 formed by the reaction between gaseous $AlCl_3$ and H_2O, the amorphous $\xrightarrow[\text{ca. 700 °C}]{} \chi \xrightarrow[\text{ca. 800 °C}]{} \kappa \xrightarrow[\text{ca. 1000 °C}]{} \alpha$ transition occurs, and on heating the γ-Al_2O_3 formed, the $\gamma \xrightarrow[\text{ca. 900 °C}]{} \delta \xrightarrow[\text{ca. 1000 °C}]{} \theta \xrightarrow[\text{ca. 1000 °C}]{} \alpha$ transition occurs.

As previously reported,[1] on heating the amorphous Al_2O_3 formed by the reaction with oxygen, the amorphous $\xrightarrow[\text{ca. 700 °C}]{} \chi \xrightarrow[\text{ca. 800 °C}]{} \kappa \xrightarrow[\text{ca. 1000 °C}]{} \alpha$ transition occurs. On heating the γ-Al_2O_3 formed, the $\gamma \xrightarrow[\text{ca. 1000 °C}]{} \delta \xrightarrow[\text{ca. 1100 °C}]{} \theta \xrightarrow[\text{ca. 1100 °C}]{} \alpha$ transition occurs. The transition temperatures of $\gamma\rightarrow\delta$, $\delta\rightarrow\theta$, and $\theta\rightarrow\alpha$ on heating the γ-Al_2O_3 formed by the reaction with H_2O are approximately 100 °C lower than those of the γ-Al_2O_3 formed by the reaction with oxygen.

Extraction of Bivalent Manganese, Cobalt, Copper, Zinc, and Cadmium from Hydrochloric Acid Solutions by Long-chain Alkyl Quaternary Ammonium Chloride in Various Organic Solvents

Taichi SATO,* Takato NAKAMURA, and Teruo FUJIMATSU

Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432

(Received January 20, 1981)

The extraction of bivalent manganese, cobalt, copper, zinc and cadmium from hydrochloric acid solutions by tricaprylmethylammonium chloride (Aliquat-336) has been examined using various diluents such as benzene, chlorobenzene, *o*-dichlorobenzene, toluene, *o*-xylene, *m*-xylene, nitrobenzene, carbon tetrachloride, chloroform, and 1,2-dichloroethane. It was found that by assuming a regular solution, the distribution coefficient and the enthalpy change associated with metal extraction can be expressed in terms of the solubility parameters of Aliquat-336, diluent and the complex formed in the organic phase and their molar volumes. An empirical relation holds between distribution coefficient and the viscosity of diluent.

The influence of diluent on solvent extraction of metal has been studied by a number of researchers who attempted to correlate the distribution of metal between organic and aqueous phases with the physicochemical properties of organic solvent such as dielectric constant,[1,2] dipole moment,[1] and solubility parameter.[3-8] Nevertheless the role of diluent in the extraction process of metal has not been elucidated satisfactorily.

In the extraction of cadmium(II), zinc(II), lead(II), and copper(II) from 2 mol dm^{-3} hydrochloric acid solutions by octadecylbenzyldimethylammonium chloride in various diluents, Leszko and Zaborska[8] suggested that the relationship between the distribution coefficient and the solubility parameter of diluent derived by Vdovenko *et al.*[5] is applicable not to the extraction of lead(II) and copper(II) but to the extraction of cadmium(II) and zinc(II). Studies have been carried out on the extraction of zirconium(IV),[9] vanadium(IV),[10] and uranium(VI)[11] from hydrochloric acid solutions by tricaprylmethylammonium chloride (Aliquat-336, $R_3R'NCl$; R=C_8—C_{10}). In the present work, the extraction of bivalent manganese, cobalt, copper, zinc, and cadmium by Aliquat-336 in various organic solvent has been studied in order to examine the correlation between the distribution coefficient and physicochemical properties of diluent.

Experimental

Reagent. Aliquat-336 (General Mills) purified by washing several times with aqueous sodium chloride solution and hexane[9] was diluted in benzene, chlorobenzene, *o*-dichlorobenzene, toluene, *o*-xylene, *m*-xylene, nitrobenzene, carbon tetrachloride, chloroform, and 1,2-dichloroethane. The concentration of Aliquat-336 in organic solvents was determined by Volhard's method with nitrobenzene. Aqueous solutions of bivalent manganese, cobalt, copper, zinc, and cadmium were prepared by dissolving their chlorides ($MnCl_2\cdot4H_2O$, $CoCl_2\cdot6H_2O$, $CuCl_2\cdot2H_2O$, $ZnCl_2$, and $CdCl_2\cdot2.5H_2O$) in hydrochloric acid. The chemicals used were of analytical reagent grade.

Extraction and Analytical Procedures. Equal volumes (15 ml) of organic and aqueous phases, placed in 50 ml stoppered conical flasks, were shaken for 10 min (preliminary experiments showed that equilibration was complete in 10 min) in a water-bath maintained at the required temperature. The initial concentration of metal chloride in aqueous phase was 0.01 mol dm^{-3}. After equilibrium, the mixture was centrifuged and separated and then the aliquots of both phases were pipetted to determine the distribution coefficient (the ratio of the equilibrium concentration of metal in the organic phase to that in the aqueous phase, D). Manganese, cobalt, copper, and zinc in the organic phase were stripped with 0.1 mol dm^{-3} HCl, and cadmium in the organic phase with 1 mol dm^{-3} HNO_3. The concentration of metal in the aqueous solutions was determined by edta titration using the following indicator: XO (Xylenol Orange) for cobalt,[12] copper,[12] and zinc;[13] BT (Eriochrome Black T) for manganese;[14] Cu–PAN (PAN=1-(2-Pyridylazo)-2-naphthol) for cadmium.[15]

Results and Discussion

Extraction Isotherm. When bivalent manganese, cobalt, copper, zinc, and cadmium are extracted into benzene solution of Aliquat-336 from aqueous solutions of their chlorides at 0.01 mol dm^{-3} containing hydrochloric acid of varying acidity at 20 °C, the extraction efficiency is in the order Cd>Zn>Cu>Co>Mn for [HCl]<5 mol dm^{-3} and Cd>Zn>Co>Cu>Mn for [HCl]>5 mol dm^{-3} (Fig. 1). The distribution coefficient rises with increasing aqueous acidity to a maximum occurring at initial hydrochloric acid concentration of 8, 8, 5, 2, and 1 mol dm^{-3} for manganese, cobalt, copper, zinc, and cadmium, respectively, and then falling again. The shape of the extraction curves is not much influenced by the kind of diluent (Table 1). Thus the extractions are expressed by a reaction similar to that for zirconium(IV),[9] vanadium(IV),[10] and uranium(VI),[11]

$$MCl_4^{2-}(a) + 2R_3R'NCl(o) \rightleftharpoons (R_3R'N)_2MCl_4(o) + 2Cl^-(a), \quad (1)$$

where M=Mn, Co, Cu, Zn, and Cd, (a) and (o) denote aqueous and organic phases, respectively. This is supported by the results for the dependency of distribution coefficient on the extractant concentration and variation of metal concentration in the organic phase as a function of initial aqueous metal concentration at a constant acidity.

The extraction efficiency of Aliquat-336 for bivalent metal depends on the nature of the diluent and is in the following order: for manganese(II) 1,2-$C_2H_4Cl_2$>

a) The concentration of Aliquat-336 is 0.05 mol dm^{-3} for manganese, cobalt, and zinc, 0.025 mol dm^{-3} for copper and 0.03 mol dm^{-3} for cadmium. b) No datum.

o-$C_6H_4Cl_2$ > $C_6H_5NO_2$ > C_6H_5Cl > C_6H_6 > CCl_4 > m-$C_6H_4(CH_3)_2$ > $C_6H_5CH_3$ > o-$C_6H_4(CH_3)_2$ > $CHCl_3$ from 3 mol dm^{-3} HCl; for cobalt(II) 1,2-$C_2H_4Cl_2$ > $C_6H_5NO_2$ > o-$C_6H_4Cl_2$ > C_6H_5Cl > CCl_4 > o-$C_6H_4(CH_3)_2$ > C_6H_6 > m-$C_6H_4(CH_3)_2$ > $CHCl_3$ > $C_6H_5CH_3$ from 3 mol dm^{-3} HCl; for copper(II) o-$C_6H_4Cl_2$ > 1,2-$C_2H_4Cl_2$ > $C_6H_5NO_2$ > C_6H_5Cl > C_6H_6 > $C_6H_5CH_3$ > o-$C_6H_4(CH_3)_2$ > m-$C_6H_4(CH_3)_2$ > CCl_4 > $CHCl_3$ from 2 mol dm^{-3} HCl; for zinc(II) 1,2-$C_2H_4Cl_2$ > $C_6H_5NO_2$ > o-$C_6H_4Cl_2$ > C_6H_5Cl > C_6H_6 > $C_6H_5CH_3$ > m-$C_6H_4(CH_3)_2$ > CCl_4 > $CHCl_3$ from 0.05 mol dm^{-3} HCl and for cadmium(II) o-$C_6H_4Cl_2$ > C_6H_5Cl > $C_6H_5NO_2$ > C_6H_6 > 1,2-$C_2H_4Cl_2$ > $C_6H_5CH_3$ > m-$C_6H_4(CH_3)_2$ > CCl_4 > $CHCl_3$ from 0.02 mol dm^{-3} HCl. We see that the extraction efficiency of Aliquat-336 in aromatic solvent with electron-accepting radical such as Cl or NO_2 is higher than that with electron-donating one like CH_3, and that chloroform reveals a very poor extraction because of a hydrogen bond-

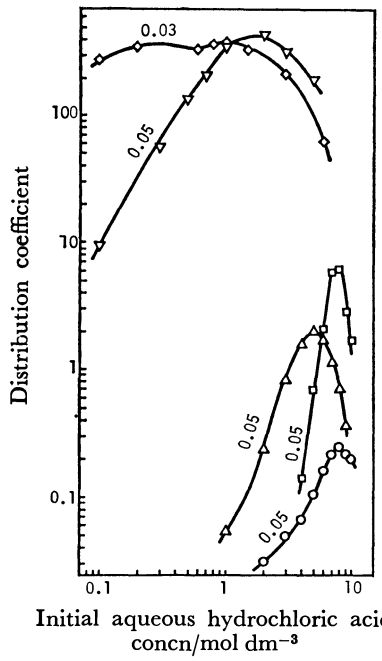

Fig. 1. Extraction of bivalent manganese, cobalt, copper, zinc, and cadmium from hydrochloric acid solutions by Aliquat-336 in benzene (numerals on curves are Aliquat-336 concentrations, mol dm^{-3}; ○ Mn, □ Co, △ Cu, ▽ Zn, ◇ Cd).

ing to extractant. However, no simple relation exists between the distribution coefficient and the dipole moment and dielectric constant of diluent which represent the polarities of molecule and solution, respectively.

Dependence of Distribution Coefficient on Viscosity. The variation of the distribution coefficient for bivalent manganese, cobalt, copper, zinc, and cadmium plotted as a function of the absolute viscosity of diluent, η_d, is given in Fig. 2. The value of η_d are as follows: 0.65, 0,59, 0.81, 0.61, 0.82, 1.23, 2.01, 0.56, 0.97, and 0.80 cp for benzene, toluene, *o*-xylene, *m*-xylene, chlorobenzene, *o*-dichlorobenzene, nitrobenzene, chloroform, carbon tetrachloride, and 1,2-dichloroethane. The distribution coefficients for manganese, cobalt, copper, zinc, and cadmium are indicated by means of the data for the extraction at 3, 3, 2, 0.05, and 0.02 mol dm^{-3}, respectively, in the lowest hydrochloric acid concentrations shown in Table 1. Since the reaction[15]

$$R_3R'NCl(o) + H^+(a) + Cl^-(a) \rightleftharpoons R_3R'NCl\cdot HCl(o) \quad (2)$$

takes place at higher aqueous acidity, the data at low acidity are used to avoid the reduction on the distribution of metal resulting from the competition between reactions (1) and (2).

The distribution coefficient increases with increase in the viscosity of diluent at $\eta_d \leq 1$ cp, but little change occurs at $\eta_d \leq 1$ cp (Fig. 2). In all the extraction systems studied, the distribution coefficient becomes constant as the viscosity of diluent approaches that of water. An empirical correlation is found between the distribution coefficient and the viscosity of diluent in the range $\eta_d \leq 1$ cp:

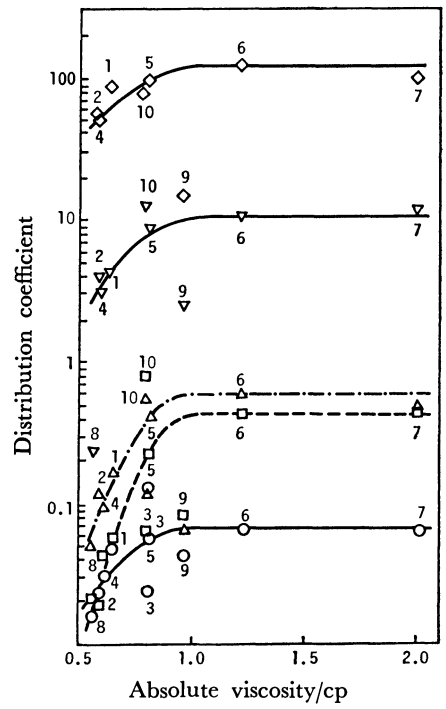

Fig. 2. Dependence of the distribution coefficient on absolute viscosity of diluent (○, □, △, ▽, and, represent the extractions of Mn(II) from 3 mol dm^{-3} HCl soln, Co(II) from 3 mol dm^{-3} HCl soln., Cu(II) from 2 mol dm^{-3} HCl soln, Zn(II) from 0.05 mol dm^{-3} HCl soln, and Cd(II) from 0.02 mol dm^{-3} HCl soln., respectively): 1) benzene, 2) toluene, 3) *o*-xylene, 4) *m*-xylene, 5) chlorobenzene, 6) *o*-dichlorobenzene, 7) nitrobenzene, 8) chloroform, 9) carbon tetrachloride, 10) 1,2-dichloroethane.

$$\log D/D_o = A(\eta_d - 1)^2, \quad (3)$$

where D_o denotes the distribution coefficient for *o*-dichlorobenzene, and A the slope obtained when log D/D_o is plotted against $(\eta_d \leq 1)^2$. Values of the slope calculated by the method of least squares are −2.59, −7.04, −4.93, −2.94, and −2.03 for manganese, cobalt, copper, zinc, and cadmium, respectively.

Effect of Solubility Parameter. From the Hildebrand-Scatchard equation[16] for the excess free energy of a regular solution, formula was worked out by Vdovenko *et al.*[15] for the distribution coefficient in terms of the solubility parameter:

$$\log D = (2/2.3RT)(V_c\delta_c - nV_e\delta_e)\delta_d + \{(nV_e - V_c)/2.3\}(\delta_d^2/RT - 1/V_d) + \text{const}, \quad (4)$$

where V and δ denote molar volume and solubility parameter, respectively, subscripts c, e, and d being the complex formed in the organic phase, extractant and diluent, respectively. Assuming that the composition in aqueous phase and the concentration of extractant in various diluents are constant, and the molar volumes of diluents do not differ from each other, the following relation is derived:

$$\{1/(\delta_d - \delta_s)\}\log(D/D_o) = \{(nV_e - V_c)/2.3RT\}(\delta_d + \delta_s) + 2(V_c\delta_c - nV_e\delta_e)/2.3RT, \quad (5)$$

where the subscript s refers to the diluent chosen as standard

a) The concentration of hydrochloric acid is 3 mol dm^{-3} for manganese and cobalt, 2 mol dm^{-3} for copper, 0.05 mol dm^{-3} for zinc, and 0.02 mol dm^{-3} for cadmium. b) The concentration of Aliquat-336 is 0.05 mol dm^{-3} for manganese, cobalt, and zinc, 0.025 mol dm^{-3} for copper, and 0.03 mol dm^{-3} for cadmium. c) Temperature of extraction.

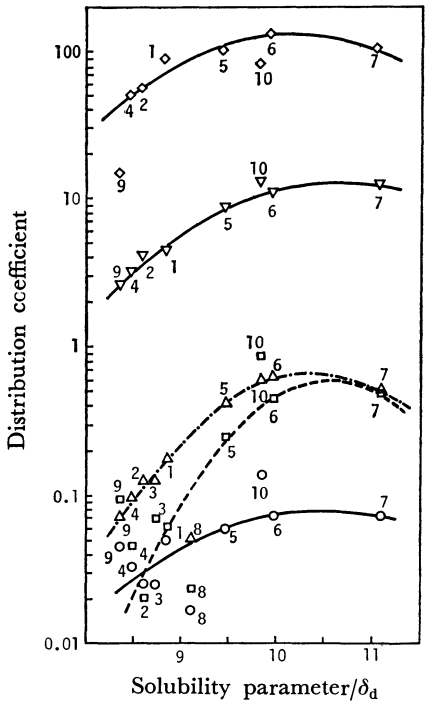

Fig. 3. Dependence of the distribution coefficient on the solubility parameter of diluent (○, □, △, ▽, and ◇ represent the extractions of Mn(II) from 3 mol dm^{-3} HCl soln, Co(II) from 3 mol dm^{-3} HCl soln, Cu(II) from 2 mol dm^{-3} HCl soln, Zn(II) from 0.05 mol dm^{-3} HCl soln, and Cd(II) from 0.02 mol dm^{-3} HCl soln, respectively): 1) benzene, 2) toluene, 3) *o*-xylene, 4) *m*-xylene, 5) chlorobenzene, 6) *o*-dichlorobenzene, 7) nitrobenzene, 8) chloroform, 9) carbon tetrachloride, 10) 1,2-dichloroethane.

In Fig. 3 showing the plots of log D *vs.* δ_d, the curves for manganese, cobalt, copper, zinc, and cadmium are obtained from the values of $(nV_e-V_e)/2.3RT$ as −0.165, −0.510, −0.370, −2.00, and −0.210, respectively, and $2(V_c\delta_c-nV_e\delta_e)/2.3RT$ as 3.45, 10.7, 7.64, 4.22, and 4.27, respectively, which are estimated by Eq. 5 using nitrobenzene as standard. In this case, the values of δ_d are as follows: 9.1, 8.9, 9.0, 8.8, 9.6, 10.0, 10.9, 9.3, 8.7, and 9.9 for benzene, toluene, *o*-xylene, *m*-xylene, chlorobenzene, *o*-dichlorobenzene, nitrobenzene, chloroform, carbon tetrachloride, and 1,2-dichloroethane, respectively. The parabolic dependence of distribution coefficients on the solubility parameter is obtained, suggesting that Eq. 4 gives a good estimate for the value of distribution coefficients in the extraction of these bivalent metals from hydrochloric acid solutions by Aliquat-336. However, since the large deviation from the parabola is observed in the extraction with chloroform, it seems that the negative deviation arises from the non-random interaction due to hydrogen bonding between chloroform and Aliquat-336.

Temperature Effect. The equilibrium constant in reaction (1) and the distribution coefficient are given by

$$K = [(R_3R'N)_2MCl_4][Cl^-]^2/[MCl_4^{2-}][R_3R'NCl]^2 \quad (6)$$

and

$$D = [(R_3R'N)_2MCl_4]/[M^{2+}](1+\Sigma\beta_i[Cl^-]^i), \quad (7)$$

where β_i refers to the overall stability constant in the reaction

$$M^{2+}(a) + iCl^-(a) \rightleftharpoons MCl_i^{(2-i)+}(a). \quad (8)$$

From Eqs. 6 and 7 the following relationship is obtained:

$$K = D(1+\Sigma\beta_i[Cl^-]^i)/\beta_4[Cl^-]^2[R_3R'NCl]^2. \quad (9)$$

By assuming that the values of overall stability constant β_4 and the term $(1+\Sigma\beta_i[Cl^-]^i)$ do not change significantly in the temperature range studied, the change in enthalpy, ΔH, associated with the reaction(1) can be estimated by means of the Van't Hoff equation. The distribution coefficients for bivalent manganese, cobalt, copper, zinc, and cadmium from aqueous hydrochloric acid solutions with solutions of Aliquat-336 in various diluents, measured in the temperature range 10—40 °C, are summarised in Table 2 in comparison with the values of ΔH.

The extraction process of bivalent metals is considered by a Born-Harber type of cycle. The change in enthalpy observed is the sum of five terms which represent enthalpies for dehydration of the species MCl_4^{2-} $(-\Delta H_1)$, for desolvation of $R_3R'NCl$ $(-\Delta H_2)$, for the reaction of MCl_4^{2-} with $R_3R'NCl$ (ΔH_3), for hydration of Cl^- (ΔH_4) and for dissolution of the complex $(R_3R'N)_2MCl_4$ into organic phase (ΔH_5). The magnitude and sign of the change in enthalpy observed depend on the contribution from enthalpies in these processes. The ΔH_1 and ΔH_4 values are correlated with the composition of aqueous acidity, since the water activity decreases with increase in hydrochloric acid concentration, while the ΔH_3 value is independent of the kind of diluent. If the concentration of hydrochloric acid in the aqueous phase remains constant, the change in enthalpy observed is expressed by

$$\Delta H = -2\Delta H_2 + \Delta H_5 + \text{const.} \quad (10)$$

Partial molar enthalpies for dissolution of Aliquat-336 and the complex $(R_3R'N)_2MCl_4$ into organic solvent given by $V_e\phi_d^2(\delta_d-\delta_e)^2$ and $V_c\phi'^2_d(\delta_d-\delta_c)^2$, from regular solution theory,[17] give the equation

$$\Delta H = -2V_e\phi_d^2(\delta_d-\delta_e)^2 + V_c\phi'^2_d(\delta_d-\delta_c)^2 + \text{const}, \quad (11)$$

where ϕ_d and ϕ'_d refer to the volume fraction of diluent. This provides the equation

$$\Delta H = (V_c\phi'^2_d-2V_e\phi_d^2)\delta_d^2 + 2(2V_e\phi_d^2\delta_e-V_c\phi'^2_d\delta_c)\delta_d + \text{const.} \quad (12)$$

We see that when ΔH is plotted against δ_d, its shape depends on the magnitude of the term $(V_c\phi'^2_d-2V_e\phi_d^2)$. For $V_c\phi'^2_d<2V_e\phi_d^2$ or $V_c\phi'^2_d>2V_e\phi_d^2$, the plot should give a parabola with a maximum or minimum at $\delta_d=(V_c\phi'^2_d\delta_c-2V_e\phi_d^2\delta_e)/(V_c\phi'^2_d-2V_e\phi_d^2)$. In contrast, a linear relationship is expected for $V_c\phi'^2_d=2V_e\phi_d^2$. The value of $(V_c\phi'^2_d-2V_e\phi_d^2)$ is determined by means of

$$(\Delta H-\Delta H_s)/(\delta_d-\delta_s) = (V_c\phi'^2_d-2V_e\phi_d^2)(\delta_d+\delta_s) + 2(2V_e\phi_d^2\delta_e-V_c\phi'^2_d\delta_c). \quad (13)$$

The $(V_c\phi'^2_d-2V_e\phi_d^2)$ and $2(2V_e\phi_d^2\delta_e-V_c\phi'^2_d\delta_c)$ are the slope and intercept of the line, respectively, when

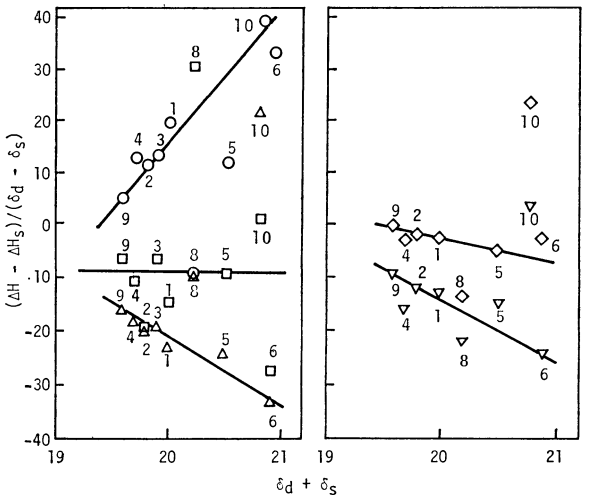

Fig. 4. Correlation between $(\Delta H-\Delta H_s)/(\delta_d-\delta_s)$ and $\delta_d+\delta_s$ for the correlation of bivalent manganese, cobalt, copper, zinc, and cadmium from hydrochloric acid solutions by Aliquat-336 in various diluents (○ Mn, □ Co, △ Cu, ▽ Zn, ◇ Cd): 1) benzene, 2) toluene, 3) *o*-xylene, 4) *m*-xylene, 5) chlorobenzene, 6) *o*-dichlorobenzene, 7) nitrobenzene, 8) chloroform, 9) carbon tetrachloride, 10) 1,2-dichloroethane.

$(\Delta H-\Delta H_s)/(\delta_d-\delta_s)$ is plotted as a function of $(\delta_d+\delta_s)$. The plots for manganese, cobalt, copper, zinc and cadmium show the linear relationship in Fig. 4, although the points for chloroform and 1,2-dichloroethane deviate from the lines in all the cases studied. The values of $(V_e\phi'^2_d-2V_e\phi_d^2)$ obtained indicate that $V_e\phi'^2_d>2V_e\phi_d^2$ is satisfied for manganese (as 6.2), $V_e\phi'^2_d=2V_e\phi_d^2$ for cobalt (as zero), and $V_e\phi'^2_d<2V_e\phi_d^2$ for copper, zinc and cadmium (as −3.1, −2.7, and −3.2, respectively). The plots of ΔH against δ_d confirm that Eq. 12 holds in the enthalpy change for various diluents. This suggests that the change in enthalpy for the extraction of bivalent manganese, cobalt, copper, zinc, and cadmium by Aliquat-336 in various diluents depends on the solubility parameter of diluent, the molar volume of the complex formed in the organic phase and Aliquat-336, and the volume fraction of diluent.

Conclusion

A parabolic dependency of the distribution coefficient on the solubility parameter of diluent is observed in the extraction by Aliquat-336 in organic solvents except chloroform and 1,2-dichloroethane, indicating that Eq. 4 derived from the regular solution theory is satisfied. The enthalpy change associated with metal extraction is also explained by assuming a regular solution. It is concluded that in the extraction of bivalent manganese, cobalt, copper, zinc, and cadmium from hydrochloric acid solutions by Aliquat-336 in various organic solvents, the distribution coefficient depends on the solubility of the complex formed in the organic diluent and the solubility parameter being an important factor for evaluation the distribution coefficient.

Distribution coefficients increase with increase in the viscosity of diluent in the range $\eta_d\leq 1$ cp, and an empirical relation is obtained between the distribution coefficient and the viscosity of diluent. It is found that in the extraction by Aliquat-336 in aromatic solvents, the distribution coefficient in the diluents with electron-accepting radical is higher than that with an electron-donating one.

The authors wish to thank Messrs. Wataru Sangawa, Tadashi Fujishita, and Akihiro Takahashi for their assistance in experiments.

The Correlation between the Bonding Properties of Ligands and the Irradiation Effects of Gamma-rays on Iron Compounds

Yonezo MAEDA,* Yoshihiro KATSUKI, Tooru MORINAGA, and Yoshimasa TAKASHIMA

Department of Chemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812

(Received August 5, 1980)

Various iron compounds have been irradiated with gamma-rays of cobalt-60. The foreign-charge states of the irradiated compounds were confirmed by means of Mössbauer spectroscopy. The results showed that high-spin iron(III) compounds with large conjugated molecules and low-spin iron(II) compounds are insensitive to γ-radiations. However, iron(III) compounds with carboxyl groups or reducing ligands and low-spin iron (III) compounds are sensitive to γ-radiations. Further, $FeCl_2 \cdot 4H_2O$ was found to be insensitive to radiation up to a total exposure dose of 10^9 R, in contrast to other ionic iron(II) compounds.

The gamma-ray sensitivity of solid coordination compounds has long been studied[1-6] and studies of the after-effect associated with the EC decay of ^{57}Co have increased in the past several years.[7-11] These after-effects have been attributed to radiolytic self-decomposition in the molecular environment of a decaying atom by low-energy electrons emitted during the Auger cascade, and to the subsequent stabilization of foreign-charge states by virtue of the redox properties of the radicals so produced. We have studied the effect of the electronic state and nature of the ligands on the sensitivity of iron compounds to gamma-ray irradiation by means of Mössbauer spectroscopy.

Experimental

The composition of the samples listed in Tables 1 and 2 was checked by elemental analyses for C, H, and N at the Elemental Analysis Center, Kyushu University. The phosphorus contents were colorimetrically determined with the formation of orthophosphate heteropoly blue using a molybdenum(V)–molybdenum(VI) reagent.[12] The results were in agreement with the calculated values. The metal complexes sealed in a glass tube *in vacuo* were irradiated with gamma-rays of 4000 Ci cobalt-60 in the Gamma-ray Irradiation Laboratory, Kyushu University. The irradiation was carried out at room temperature at a dose rate of 0.35—0.39×10^6 R h^{-1} or 1.17—1.19×10^6 R h^{-1}.

The Mössbauer spectra were measured immediately after the appropriate total exposure dose has been accumulated. Mössbauer measurements were carried out at 80 K with a spectrometer described elsewhere.[13] A cobalt-57 source diffused into a palladium foil was used. The isomer shift, δ_{Fe} was measured relative to the center of the spectrum of an iron foil enriched with ^{57}Fe at 296 K, which was also used as a standard material for the velocity calibration. The infrared spectra of the samples in the potassium bromide region(650—4000 cm^{-1}) were obtained using a Hitachi Grating Infrared Spectrophotometer, type 215.

Results and Discussion

Only the species stabilized during the irradiation of the investigated compounds were determined in the present study, since the Mössbauer measurements were carried out after an elongated irradiation. The Mössbauer parameters measured for the compounds before and after gamma-ray irradiation are listed in Tables 1 and 2. The Mössbauer data in Tables 1 and 2 were calculated using a least-squares method at the Computer Center, Kyushu University.

The compounds studied are classified into three groups in terms of the relation of the irradiation effects, such as the change in the oxidation state of iron with the chemical properties of the ligands, and the results of the Mössbauer spectra of the irradiated complexes are discussed in each case.

Group A. Group A consists of iron(III) compounds for which chemical changes were observed through the use of Mössbauer spectroscopy after irradiation.

A-1: This sub-group includes iron(III) compounds with only monodentate ligands. Compounds $FeCl_3 \cdot 2CH_3OH$, $[Fe(en)_3]Cl_3$ (en: ethylenediamine), $FeCl_3 \cdot$(1,4-dioxane), and $FeCl_3 \cdot dma \cdot 2H_2O$ (dma: *N,N*-dimethylacetamide) were sensitive to radiation. Some Mössbauer spectra of these compounds are shown in Figs. 1—3. New absorption lines due to bivalent iron were observed in the Mössbauer spectra of these compounds after irradiation. The ratio of the absorption area of the new lines to the total absorption area increased with the increase in the exposure dose, as is shown in Figs. 1 and 2. From this behavior

a) Full width at half-maximum of the lower energy peak. b) Full width at half-maximum of the higher energy peak. c) New peak due to irradiation. d) The errors are estimated to be ± 0.1 mm s^{-1}. The errors of the other data are ± 0.02 mm s^{-1} or less.

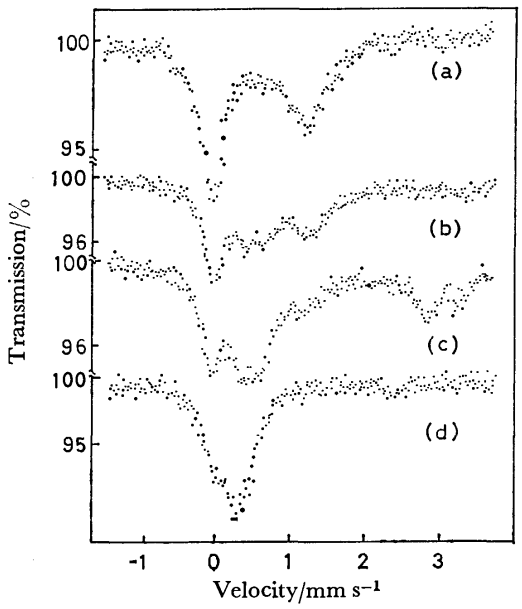

Fig. 2. Mössbauer spectra of $FeCl_3 \cdot$ (1,4-dioxane), (a) non-irradiated, (b) 1.1×10^8 R, (c) 2.5×10^8 R, and (d) 4.5×10^8 R irradiated.

of the ratio, the iron(III) ion in these compounds is confirmed to be reduced to an iron(II) ion under irradiation.

Figure 1 shows the Mössbauer spectra for $[Fe(en)_3]Cl_3$ at successive stages of irradiation. Compound $[Fe(en)_3]Cl_3$ is in a low-spin state. The Mössbauer parameters of the new lines produced by irradiation are as follows: The quadrupole splitting, $\Delta E = 1.85$ mm s^{-1}; the isomer shift, $\delta_{Fe} = 1.07$ mm s^{-1}. These values range among those for high-spin iron(II) compounds. The Mössbauer parameters for $[Fe(en)_3]Cl_2$ have not yet been reported because the compound is very unstable in air. It is very probable, however, that the orbital ground state of $[Fe(en)_3]Cl_2$ is in a high-spin state as a result of the strength of the ligand field of ethylenediamine.[14] The isomer shift of 1.07 mm s^{-1} at 80 K is smaller than that for high-spin hexacoordinated iron(II) compounds. However, the radiolysis of ethylenediamine ligands might have resulted in a smaller coordination number about the central iron atom, thus causing a small value of the isomer shift because of the change in bonding from d^2sp^3 hybridized orbitals to sp^3.

In the IR spectrum of the irradiated $FeCl_3 \cdot 2CH_3OH$, new lines appeared at 2850 and 2900 cm^{-1}; they are assigned to the vibration of the C–H of a formyl group. A characteristic vibration band for the formyl group appears at about 1700 cm^{-1},[15] but this band

a) koj: kojate ion.

is obscured because of overlapping with the very strong band at 1600 cm^{-1}. The reduction of iron(III) chloride in a methanol solution has been studied extensively.[16] The production of H_2, CH_2O, CH_4, and glycol has been reported. The following steps are inferred to be involved in the reaction induced by the gamma-ray irradiation of $FeCl_3 \cdot 2CH_3OH$ on the assumption that the radiolysis of $FeCl_3 \cdot 2CH_3OH$ undergoes a series of reactions similar to those of iron-(III) chloride in a methanol solution:[17]

$$CH_3OH \longrightarrow \cdot CH_2OH + \cdot H$$

$$Fe^{3+} + \cdot CH_2OH \longrightarrow Fe^{2+} + HCHO + H^+$$

$$Fe^{3+} + \cdot H \longrightarrow Fe^{2+} + H^+$$

$$Fe^{3+} + Cl^- \longrightarrow Fe^{2+} + Cl.$$

The $Fe_3(OCH_3)_9$ compound was insensitive to radiation, as will be described later. The $\cdot CH_2OH$ radical may be reactive in redox reactions, while CH_3O^- may not.

Figure 2 shows the Mössbauer spectra for irradiated $FeCl_3 \cdot$(1,4-dioxane) at successive stages of irradiation. Iron(II) ions initially reduced by gamma-ray irradiation are oxidized to iron(III) ions upon further irradiation. The total exposure dose of 4.5×10^8 R causes serious damage to this compound, as may be seen in Fig. 2(d). The main decomposition products of dioxane have been reported to be HCHO(G=9.7), HCOO–CH_2–CH_2OH(G=8.5), and H_2(G=1.4).[18]

The compound $FeCl_3 \cdot$dma$\cdot 2H_2O$ was also sensitive to radiation. That is, iron(II) absorption lines were observed in the Mössbauer spectrum of this compound after irradiation. The new bands found in the IR spectrum can be assigned to the formyl, which is known to have absorption in the region from 2800 to 2900 cm^{-1}.

A-2: This sub-group is composed of iron(III) compounds with a carboxyl group. Glycine(Hgly) is comprised of carboxyl and amino groups. The carboxyl group is known to be very sensitive to radiation and to produce reductive radicals, as has been reported by many workers.[19,20] The G values ($Fe^{3+} \rightarrow Fe^{2+}$) for $FeCl_2 \cdot$gly(Hgly)$\cdot 7/2H_2O$ and $[Fe_3(HCO_2)_6]$ $[Fe(HCO_2)_6] \cdot 8H_2O$ were estimated to be about 2.5±

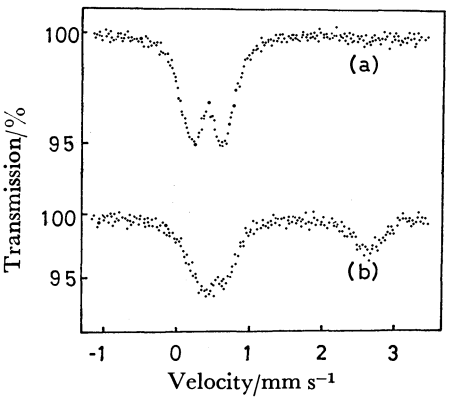

Fig. 3. Mössbauer spectra of (a) non-irradiated and (b) 8.3×10^8 R irradiated $Fe_2(HPO_3)_3\cdot9H_2O$.

0.5 (at a total exposure dose of 6.7×10^8 R) and 3.2± 0.5 (at a total exposure dose of 9.0×10^8 R) respectively from analyses of the Mössbauer spectra using equation:

$$G=\frac{\text{A}_\text{I}\text{(the absorption area of a new peak)}}{\text{A(the total absorption area)}}\times\frac{100}{\text{the absorption energy(eV)}}$$

and assuming that the recoilless fractions of the original peaks and the new peaks are equal, and that an exposure dose of 1 R gives an absorbed dose of 1 rad for these compounds. The initial G values, however, will be larger than these values.

A-3: This sub-group is composed of iron(III) compounds with reducing ligands. The $H_2PO_2^-$ and HPO_3^{2-} ions are considered to be reducing ions. The iron(III) ions in $Fe(H_2PO_2)_3$ and $Fe_2(HPO_3)_3\cdot9H_2O$ were reduced to iron(II) ions under irradiation. The G value of the decomposition for $Fe(H_2PO_2)_3$ is reported to be 3.4±0.4[21] and the main decomposition products after it had been dissolved in water were confirmed chemically to be phosphate and phosphonate ions.[22,23] That is, the P(I) ligand is oxidized to P(III) and P(V) under irradiation. Figure 3 shows the Mössbauer spectra for $Fe_2(HPO_3)_3\cdot9H_2O$ before and after irradiation. The oxidation state of phosphorus of this compound is trivalent, and may be oxidized to P(V) upon irradiation.

A-4: This sub-group is composed of iron(III) compounds with a low-spin state. The Mössbauer parameters of the new lines for irradiated $[Fe(bpy)_2(CN)_2]NO_3$(bpy: 2,2′-bipyridyl) were $\Delta E=0.62$ mm s^{-1}, $\delta_{Fe}=0.23$ mm s^{-1}. These values are similar to those of nonirradiated $Fe(bpy)_2(CN)_2$ ($\Delta E=0.62$ mm s^{-1}, $\delta_{Fe}=0.19$ mm s^{-1}). This similarity of the Mössbauer parameters suggests that the iron(II) ion produced under irradiation has the same coordination structure as the nonirradiated $Fe(bpy)_2(CN)_2$. The iron(III) ion of $[Fe(phen)_3](ClO_4)_3\cdot2H_2O$ has been reported to be reduced to the Fe(II) ion upon irradiation.[4] The iron(III) compounds in a low-spin state may be supposed to be reduced to iron(II) easily upon irradiation, although they contain large conjugated ligands.

Group B. Group B consists of iron(III) compounds in which no change of valence was observed in the Mössbauer spectra. The Mössbauer parameters of these compounds are shown in Table 2. A total exposure dose of 1×10^9 R or more was delivered to the compounds of this group.

B-1: This sub-group is made up of iron(III) compounds with large conjugated ligands. In this group, no reduced iron(II) species were observed in the Mössbauer spectra after irradiation. Iron(III) kojate and $FeCl_3\cdot(pyrazole)_3$ show broad Mössbauer spectra attributable to a relaxation effect. There was no change in the width at the half-maximum in the spectra between before and after irradiation. Although a part of the ligands are initially excited upon irradiation, the excitation energy is considered to be distributed in a short time through the conjugated bonds and delocalized over all of the molecules. Therefore, the fragmentation and the excitation of the molecules due to irradiation may be minimized. Compounds $[Fe(bpy)_2Cl_2][FeCl_4]$ and $[Fe(pyridine)_5ClO_4](ClO_4)_2$ were also insensitive to radiation.

B-2: This sub-group is made up of iron(III) compounds without large conjugated ligands. No influence of radiation was observed in $[Co(pn)_3][FeCl_4]$ (pn: 1,2-propanediamine) and $[Co(NH_3)_6][FeCl_6]$, although the radiolysis of 1,2-propanediamine and ammonia would be expected because iron(II) species are observed in the spectra of irradiated $[Fe(en)_3]Cl_3$. This fact shows that the iron ion is well shielded in $[Co(pn)_3][FeCl_4]$ and $[Co(NH_3)_6][FeCl_6]$ by the large volume of chloride ions from the electrons and the radicals produced upon irradiation.

Each iron atom in $FePO_4\cdot2H_2O$ is surrounded by four oxygen atoms of the PO_4^{3-} ions and two oxygen atoms of the water molecules.[24] The oxygen atoms of the PO_4^{3-} ions, however, coordinate tetrahedrally to the iron atom as the nearest atoms, and the two oxygen atoms of water molecules coordinate to the iron atom as the next nearest atoms. It is concluded that the radicals resulting from the radiolysis of water molecules were not able to react with the central iron(III) atom during the life-time of the radicals because the distance between the iron atom and water molecules is large, or because the iron atom is shielded by the four oxygen atoms of PO_4^{3-} ions from the electrons and the radicals as has been described above. The influence of the radiolysis of water molecules on the redox of the iron atom was not observed for the compounds studied in this paper. One of the reasons for this is that the $G(-H_2O)$ value for the decomposition of the water is as small as 0.1. The $G(-H_2O)$ value is less than 0.01 for the hydrates, whereas for ice it is known to be greater than 0.1.[25]

Compound $Fe_3(OCH_3)_9$ was also insensitive to radiation, although the bond-dissociation energy of methanol is 389 kJ mol^{-1} for $HOCH_2$–H, 383 kJ mol^{-1} for H_3C–OH, and 418 kJ mol^{-1} for CH_3O–H,[26] and the bond-dissociation energies of $HOCH_2$–H and H_3C–OH are lower than that of CH_3O–H. The following reaction of the hydrated electron is known in the pulse radiolysis of a water–methanol solution:[17]

$$e_{aq}^- + CH_3OH \longrightarrow CH_3O^- + H$$

$$e_{aq}^- + CH_3OH \longrightarrow CH_3 + OH^-.$$

In a solid phase, the bare electron produced by ir-

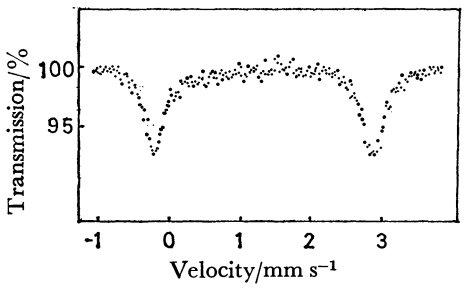

Fig. 4. Mössbauer spectrum of 10×10^8 R irradiated $FeCl_2\cdot4H_2O$.

radiation may take the place of the hydrated electron. Thus, CH_3O^- would not react with electrons and the $G(H_2)$ from $Fe_3(OCH_3)_9$ would be smaller than that from $FeCl_3\cdot2CH_3OH$.

Group C. Generally, high-spin iron(II) compounds, such as $(NH_4)_2Fe(SO_4)_2\cdot6H_2O$ and $FeSO_4\cdot7H_2O$, are easily oxidized to basic iron(III) species upon irradiation.[27] Although the iron(II) ions of both compounds are surrounded by six water molecules, the reducing radicals produced from the decomposition of the water may react with other species, such as NH_4^+ and SO_4^{2-}, by preference, for the Fe(III) ion, the sulfite ion, and hydrogen have been reported to exist as products of decomposition.[28]

Group C consists of iron(II) compounds in which no chemical change was observed through the Mössbauer spectra. The compounds of this group were subjected to a total exposure dose of 1.0×10^9 R or more.

C-1: This sub-group contains high-spin iron(II) compounds in which no change of valence was observed. That is, $Fe(H_2PO_2)_2$ and $FeCl_2\cdot4H_2O$ were insensitive to radiation up to an exposure dose of 1.0×10^9 R.

The $H_2PO_2^-$ anion is a strong reducing ion. The decomposed fractions of $H_2PO_2^-$ in 400 Mrad delivered $Fe(H_2PO_2)_2$ and $Fe(H_2PO_2)_3$ were 5 and 10% respectively.[21] The compounds with a lower valent iron(II) ion and a strong reducing anion, iron (II) oxalate, are also radioresistant.[1] The remarkably high stability upon the irradiation of these compounds must involve the process of the recombination of radicals and electrons due to the absence of a redox reaction between radicals and central metal ions.

Figure 4 shows the Mössbauer spectrum of irradiated $FeCl_2\cdot4H_2O$. This compound contains four water molecules which are arranged around an iron(II) ion.[29] It is easy for the radicals produced from the radiolysis of water molecules to react with an iron(II) ion because water molecules are coordinated directly with the iron(II) ion. Nevertheless, the iron ion of $FeCl_2\cdot4H_2O$ was not oxidized to an iron(III) ion. This suggests that the radicals formed on the radiolysis of H_2O will be inclined to participate in the recombination reaction, as the chloride ion is not easily oxidized or reduced. Kopcewicz *et al.*[30] reported that they observed the Fe_3O_4, $Fe_{1-x}O$, and $FeCl_2\cdot2H_2O$ species, in proton-irradiated $FeCl_2\cdot4H_2O$. The effects observed were interpreted in terms of the "thermal spike" model. Friedt *et al.*[31] reported the emission spectra of $^{57}CoCl_2\cdot X(X=2H_2O$ and $6H_2O)$ to show the existence of two kinds of Fe(III) species and two kinds of Fe(II) species, due to the self-radiolysis of the ligand environment by the low-energy electrons and X-rays emitted during the Auger cascade. As our experimental method has the limitation that only stabilized changes after irradiation can be observed the metastable species with a short lifetime can not be observed in the Mössbauer spectra. Emission experiments, on the other hand, might sometimes show the metastable state. Compound $Fe(bpy)_2Cl_2$, which has a high degree of conjugation, showed no chemical change due to irradiation.

C-2: This sub-group is composed of the low-spin iron(II) compounds. Compounds $[Fe(bpy)_3]Cl_2\cdot4H_2O$, $[Fe(bpy)_2(CN)_2]\cdot4H_2O$, $[Fe(phen)_3](NO_2)_2\cdot5H_2O$-(phen: 1,10-phenanthroline), and $[Fe(phen)_2(NO_2)_2]\cdot1/2H_2O$ were insensitive to radiation, and the oxidation state of iron(III) was not observed in the Mössbauer spectra up to an exposure dose of 1.0×10^9 R.

The electron configurations of high-spin iron(II) and iron(III) ions in octahedral complexes are $t^4_{2g}e^2_g$ and $t^3_{2g}e^2_g$ respectively. The reduction of the iron-(III) ion to the iron(II) ion results in the transfer of an electron from ligands to a t_{2g} orbital of the Fe (III) ion, the rate of which is faster than that to an e_g orbital in an octahedral complex.[32] The situation is the same for iron ions in a low-spin state in an octahedral complex, for the electronic configurations of the low-spin iron(II) and iron(III) ions are t^6_{2g} and t^5_{2g} respectively. However, some of the compounds were highly radioresistant. The high-spin iron(III) compounds with large conjugated ligands and low-spin iron(II) compounds exhibited especially strong radioresistant properties. The fact that the orbital ground states of high-spin iron(III) and low-spin iron (II) ions have more stability than high-spin iron(II) and low-spin iron(III) ions respectively would affect the reaction of electrons and radicals formed under the action of radiation, thus leading to the observed stability of the compounds of both categories upon irradiation.

The width of the Mössbauer spectra of the compounds which were insensitive to radiation became broad, and the spectra showed a little distortion. This means that considerable damage in the coordination structure has taken place under irradiation, although no changes in the valence of the iron ion were detected in the Mössbauer spectra.

The Spectrophotometric Determination of Ethylene Diamine with Phthalaldehyde and 2-Mercaptoethanol

Goro HIHARA,* Hiroshi MIYAMAE, and Miharu NAGATA

Department of Chemistry, Faculty of Science, Josai University, Sakado, Saitama 350

(Received January 16, 1981)

A simple spectrophotometric method has been developed for the determination of ethylenediamine in an aqueous or ethanolic solution. This method is based on the reaction of ethylenediamine with phthalaldehyde and 2-mercaptoethanol, and on the measurement of the absorbance of the yellow-developed solution at 430 nm. Beer's law holds for 0.5—10 μg of ethylenediamine per 1 ml. Secondary and tertiary amines do not interfere with theestimation. Two of the primary amines, diethylenetriamine and triethylenetetramine, interfere with the estimation when present in quantities of more than 10 μg per ml of the sample solutions. 1,3-Propanediamine interferes seriously. The colored compound was found to be composed of ethylenediamine, phthalaldehyde, and 2-mercaptoethanol in a molar ratio of 1:2:1.

Several spectrophotometric methods for the determination of ethylenediamine have already been reported.[1-4] These methods, however, have low sensitivities. Roth[5] developed a highly sensitive fluorophotometric method for amino acids, in which the amino acids were combined with phthalaldehyde and 2-mercaptoethanol in an alkaline medium to grow fluorescent materials. Roth[6] and Svedas *et al.*[7] improved this method so that these products could be detected by a method of spectrophotometric estimation. Simons and Johnson[8] made it clear that this fluorogenic compound was 1-alkylthio-2-alkyl-substituted isoindole by a reaction of propylamine with phthalaldehyde and 2-mercaptoethanol. Moreover, they found that phthalaldehyde reacts only primary amines and not with secondary amines.

The objective of this paper is to examine the effects of various factors on the coloration and to present a spectrophotometric method for ethylenediamine in an aqueous or ethanolic solution.

Experimental

Apparatus. A Hitachi 101 spectrophotometer was used for the measurement of the absorbance, while a Hitachi EPS-3 spectrophotometer was used to estimate the absorption spectra with 10-mm glass cells. For the adjustment of the pH of the buffer solutions, a Toa Denpa HM-5A pH meter was used.

Reagents. Phthalaldehyde of a biochemical grade and ethylenediamine with a 99.5% purity were obtained from Wako Pure Chemical Industries, Ltd. 2-Mercaptoethanol was also obtained with a purity of 98%. The other reagents, except for the secondary and tertiary amines, were of a guaranteed grade.

Buffered Reagent for Coloration. A 0.1 M† solution of sodium tetraborate was adjusted to pH 9.5 with a concentrated NaOH solution. Into 100 ml of this borate buffer solution, 1 ml of an ethanol solution containing 20 mg of phthalaldehyde and 1 ml of an ethanolic solution of 70 mg of 2-mercaptoethanol were then mixed. This reagent was stable for at least two days at room temperature.

Procedure A for the Measurement of Ethylenediamine in an Aqueous Solution. 1.0 ml of an aqueous sample solution containing 0.5—10 μg of ethylenediamine was mixed with 1 ml of ethanol and 3 ml of the buffered reagent, after which the mixture was allowed to stand for 30 min at 26±0.5 °C in a thermostat. Then the absorbance of the solution was measured at 430 nm against the reagent blank.

Procedure B for the Measurement of Ethylenediamine in an Ethanolic Solution. The procedure was the same as in Procedure A, except that 1 ml of pure water was used in place of 1 ml of ethanol.

† 1 M = 1 mol dm^{-3}.

Results and Discussion

Influence of the pH of the Buffered Reagent. One-ml portions of an aqueous solution containing 4.68 μg of ethylenediamine were mixed with 1 ml of distilled water and 3 ml of a buffered reagent, the pH of which was varied in the range of 5—11, the absorption spectrum was then examined. As is shown in Fig. 1, the absorption maximum in every spectrum shifted toward lower wavelength, as the pH of the solution became higher, converging on 430 nm in the pH range of 9—11. The intensity of the absorbance also varied with the change in the pH. It seemed to become highest in the 9—10 pH range. Figure 2

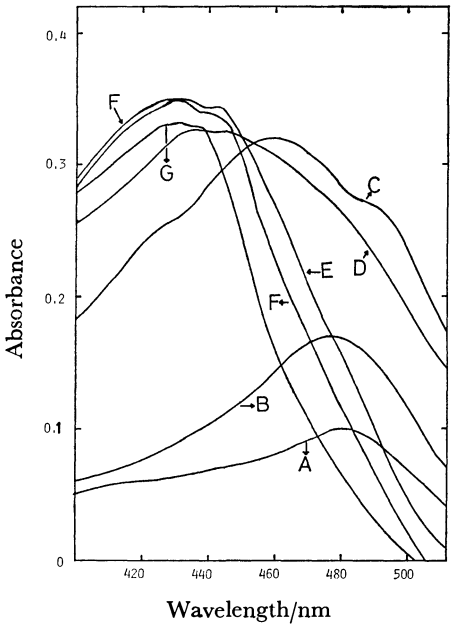

Fig. 1. The absorption curves at the various values of pH.
A: pH 5, B: pH 6, C: pH 7, D: pH 8, E: pH 9, F: pH 10, G: pH 11. KH_2PO_4–Na_2HPO_4 buffer solutions were used in pH 5—8, HCl–$Na_2B_4O_7$ in pH9, and NaOH–$Na_2B_4O_7$ in pH 10 and 11.

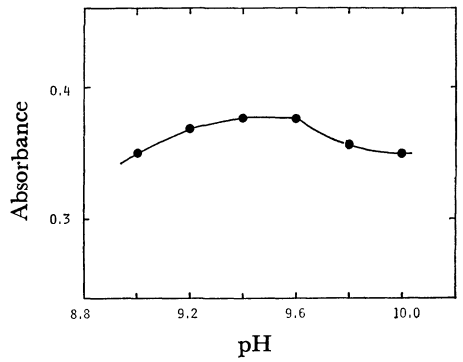

Fig. 2. Effect of pH on the absorbance at 430 nm between pH 9.0 and 10.0. 1 ml of an aqueous solution of ethylenediamine (4.68 μg/ml) was used.

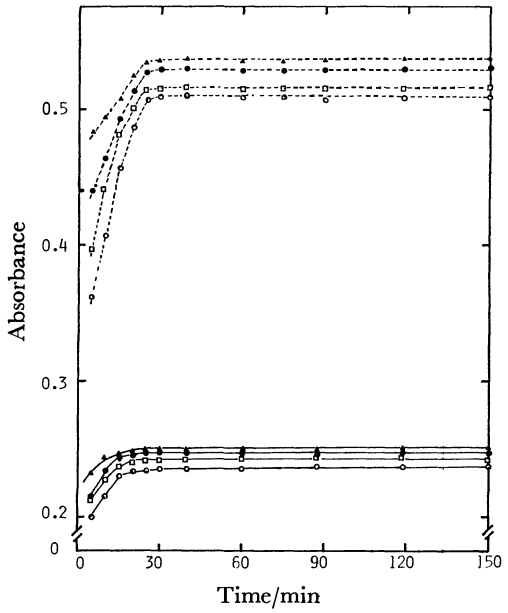

Fig. 3. Influence of temperature and time-dependance of the coloration.
——: Concentration of ethylenediamine 1.56 μg/ml, ···: 3.12 μg/ml, ○: 20 °C, □: 23 °C, ▲: 26 °C, ●: 30 °C.

shows that the absorbance measured at 430 nm attained its maximum value at the pH values of 9.4 and 9.6. Thus, the borate solution of pH 9.5 was used as a buffer in the color reaction throughout this work, and the absorbance was measured at 430 nm.

Influence of Time Delay and Reaction Temperature. After 2-ml portions of the ethylenediamine solution (1.56 and 3.12 μg/ml) had been mixed with 3 ml of the buffered reagent, they were held in a thermostat at various temperatures between 20—30 °C, while the absorbances of the solution were measured at regular time intervals. The results are shown in Fig. 3. The absorbances of every solution attained constancy within 30 min, and thereafter remained unchanged for 150 min regardless of the reaction temperatures. However, the intensities of the absorption were slightly affected by the reaction temperature and showed their maximum at 26 °C.

Influence of Addition of Ethanol and Other Organic Solvents. When 1 ml of distilled water was added instead of 1 ml of ethanol in Procedure A, Beer's law was adopted for the relation of the absorbance *vs.*

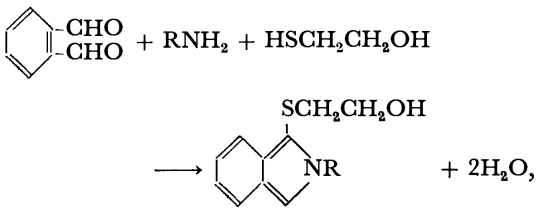
Urea	500	1.01
Thiourea	500	1.00
Pb^{2+} (from $Pb(NO_3)_2$)	100	1.02
I^- (from KI)	1000	1.02
NH^+_4 (from NH_4Cl)	10	1.03

a) This value is the ratio of the absorbance with and without the compound listed in the left colum. A 1-ml portion of the ethylenediamine solution(4.68 μg/ml) was chosen. b) ppt means that the precipitate formed when the buffered reagent was added. c) dien, trien, and HMTA represent diethylenetriamine, triethylenetetramine, and hexamethylenetetramine respectively.

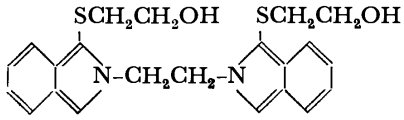
the ethylenediamine concentration only in the range of 0.5—5.0 μg of ethylenediamine contents, the absorbance showed a negative deviation from Beer's law at larger concentrations of ethylenediamine as is shown in Fig. 4. In order to improve the linearity in the relation of the absorbance *vs.* the ethylenediamine content, the addition of organic solvents miscible with water was tested. The addition of acetone remarkably reduced the coloration. Methanol and ethanol increased the absorbance, with no fluctuation in the absorption maximum in wavelength. With the addition of 1 ml of ethanol, the linearity was extended up to an ethylenediamine content of 10 μg, as is shown in Fig. 4.

Influence of Active Compounds and Ions. The influence of the addition of several compounds and ions which may interfere with the coloration in the present method was also examined. A 1-ml portion of an aqueous solution of each compound listed in Table 1 was mixed with 1 ml of an aqueous solution of ethylenediamine and 3 ml of the buffered reagent, and the absorbance was estimated at 430 nm. The results of the examination are shown in Table 1. Dimethylamine and trimethylamine did not interfere, and propylamine reduced the absorbance only slightly. This corresponds to the conclusion suggested by Simons *et al.* that phthalaldehyde reacts only with primary amines and not with secondary and tertiary amines. Among the tested compounds, only 1,3-propanediamine interferes significantly.

The Composition of the Product. Simons *et al.* offered the following equation for the reaction of primary amines with phthalaldehyde and 2-mercaptoethanol:



where R is an alkyl group. When ethylenediamine reacts on phthalaldehyde with 2-mercaptoethanol, the product may be supposed to have the structure shown as (I).



(I)

In order to elucidate the structure of the product, 0.06 g of ethylenediamine (1 mmol) was added to 50 ml of a borate buffer solution (pH 9.5) containing 0.27 g of phthalaldehyde (2 mmol) and 0.16 g of 2-mercaptoethanol (2 mmol). A yellow precipitate formed very soon, it had turned brown within one or two hours after it was separated from the solution. Therefore, the composition of the product only was determined as follows: to 1-ml portions of ethylenediamine solutions (3.12, 6.24, and 9.36 μg/ml), various amounts of a 2-mercaptoethanol aqueous solution (10.9 μg/ml) were added, and then the containers were filled up to 3 ml with pure water. Then 2 ml of a borate-buffer solution (pH 9.5) containing phthalaldehyde (0.2 mg/ml) was added, and the absorbance at 430 nm was estimated after 30 min. The relationships are shown in Fig. 5 between the absorbances and the amounts of 2-mercaptoethanol added. A similar relation is given in Fig. 6, where ethylenedi-

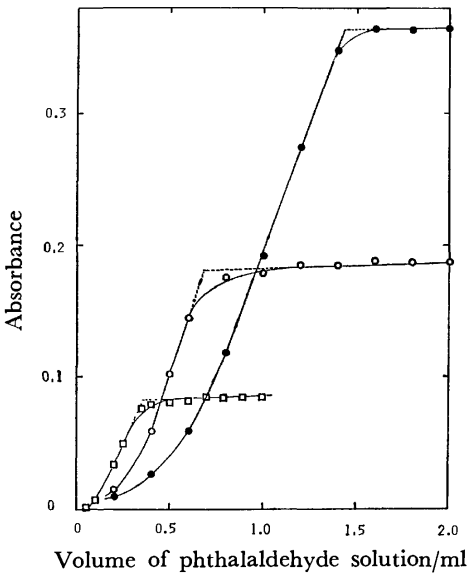

Fig. 6. Relationships between the absorbance and the added volume of an aqueous solution of phthalaldehyde (20.0 μg/ml) in the presence of excess of 2-mercaptoethanol.
Borate buffer solution (pH 9.5) was used containing 2-mercaptoethanol (0.7 mg/ml). □: Ethylenediamine 1.56 μg/ml, ○: ethylenediamine 3.12 μg/ml, ●: ethylenediamine 6.24 μg/ml.

amine reacts with phthalaldehyde in the presence of an excess amount of 2-mercaptoethanol. The absorbances were nearly equal, regardless of the amount of ethylenediamine present, and increased proportionally to a certain point as the amount of 2-mercaptoethanol increased when there was a large excess of phthalaldehyde. On the other hand, in the presence of a large excess of 2-mercaptoethanol, the absorbances increased only a little as the content of phthalaldehyde increased. They began to increase proportionally to the amount of phthalaldehyde after the molar ratio of phthalaldehyde/ethylenediamine became nearly 1:1. This can be explained by assuming that phthalaldehyde reacts with ethylenediamine to give an intermediate product consisting of 1:1 (=phthalaldehyde: ethylenediamine), which does not have the absorption near 430 nm. The intermediate then reacts with one more mole of ethylenediamine to give a final product having its absorption peak at 430 nm. Two tangential lines are drawn per curve in Figs. 5 and 6, one in the range where the absorbances increase linearly with the amount of 2-mercaptoethanol or phthalaldehyde added, and the other in the plateau range where the absorbances become almost constant. These lines were then extended, and the point of intersection was found. These points were 0.35, 0.68, and 1.43 ml of the phthalaldehyde solution when the concentrations of ethylenediamine were 1.56, 3.12, and 6.24 μg/ml respectively. The molar ratios of phthalaldehyde/ethylenediamine were calculated to be 2.01, 1.96, and 2.06 respectively. In Fig. 5 the points of intersection are 0.43, 0.74, and 1.04 ml of a 2-mercaptoethanol solution when the concentrations of ethylenediamine are 3.12, 6.24, and 9.36 μg/ml, and 1.16, 0.99, and 0.93 respectively, in terms of the molar ratio of 2-mercaptoethanol/ethylenediamine. The composition of the product was found to be 1:2:1(ethylenediamine: phthalaldehyde: 2-mercaptoethanol).

Precision. The precision of Procedure A was checked with a sample containing a known amount of ethylenediamine. Based on six determinations, the relative standard deviations were 1.2% at the level of 1.56 μg and 1.0% at 9.36 μg.

This method is less sensitive than the fluorophotometric one reported by Benson and Hare[10] who determined primary amines in the range of picomole. This method is very simple and convenient for use assaying ethylenediamine in an aqueous or ethanolic solution, even in the presence of secondary and tertiary amines.

Bis(cyclohexyl isocyanide)palladium(II) Halides and Their Benzene Complexes

Tsunesuke KAJIMOTO,* Yukishige KITANO,** Hidetaka TAKAHASHI, and Jiro TSUJI***

Basic Research Laboratories, Toray Industries, Inc., Tebiro, Kamakura, Kanagawa 248

(Received February 17, 1981)

Bis(cyclohexyl isocyanide)palladium(II) chloride, $PdCl_2(C_6H_{11}NC)_2$ (**1**) was prepared from $PdCl_2$. The configuration of the complex **1** is cis with respect to the isocyanides. The isocyano group in one cyclohexyl isocyanide takes axial conformation to chair form cyclohexyl group, while another takes equatorial conformation. By recrystallization of **1** from benzene bis(cyclohexyl isocyanide)palladium(II) chloride–benzene, $PdCl_2(C_6H_{11}NC)_2(C_6H_6)_2$ (**2**) was prepared. IR spectrum of **2** shows a characteristic absorption at 700 cm^{-1} which is due to the benzene incorporated in the complex. Similar benzene complex was also prepared from $PdBr_2$.

Many benzenoid complexes are known with various transition metals, but a few with palladium.[1] Synthesis of a unique benzene–palladium(II) complex with the formula of $[PdAl_2Cl_7(C_6H_6)]_2$ was reported and its X-ray structural analysis showed that the Pd–Pd system is sandwitched between two benzene rings with each palladium essentially associated with three carbon atoms of each benzene.[2] Formation of an unstable benzene–palladium(I) complex was also reported.[3] In the preceeding paper we reported an insertion reaction of cyclohexyl isocyanide to π-allylpalladium chloride.[4] Palladium halides have been reported to react readily with aryl isocyanides yielding stable complexes, $PdX_2(RNC)_2$.[5] These complexes had been treated with benzene, but benzene complex was not reported to be formed. We obtained bis(cyclohexyl isocyanide)palladium(II) chloride, $PdCl_2(C_6H_{11}NC)_2$(**1**) by the use of cyclohexyl isocyanide in place of aryl isocyanide and found that the complex **1** has a unique structure and gives a new benzene complex, bis(cyclohexyl isocyanide)palladium(II) chloride–benzene, $PdCl_2(C_6H_{11}NC)_2(C_6H_6)$(**2**) by recrystallization from benzene. Similar benzene complex was also prepared from palladium bromide. Details of the reaction and IR spectroscopic analyses of the complexes are presented in this paper.

Results and Discussion

The complex **1** was obtained as white precipitates by the reaction of two molar equivalents of cyclohexyl isocyanide with palladium(II) chloride in benzene, successive concentration and dilution with ethyl ether. Recrystallization of **1** from hot benzene gave a yellow complex **2**, the analysis of which suggested the molecular formula, $PdCl_2(C_6H_{11}NC)_2(C_6H_6)$. On the other hand, recrystallization of **1** from *p*-xylene or toluene gave no complex containing xylene or toluene and the complex **1** was recovered. IR spectra of **1** and **2** are shown in Fig. 1.

$$PdCl_2 + 2C_6H_{11}NC \longrightarrow \underset{\textbf{1}}{cis\text{-}PdCl_2(C_6H_{11}NC)_2} \underset{Et_2O}{\overset{C_6H_6}{\rightleftharpoons}} \underset{\textbf{2}}{PdCl_2(C_6H_{11}NC)_2(C_6H_6)}$$

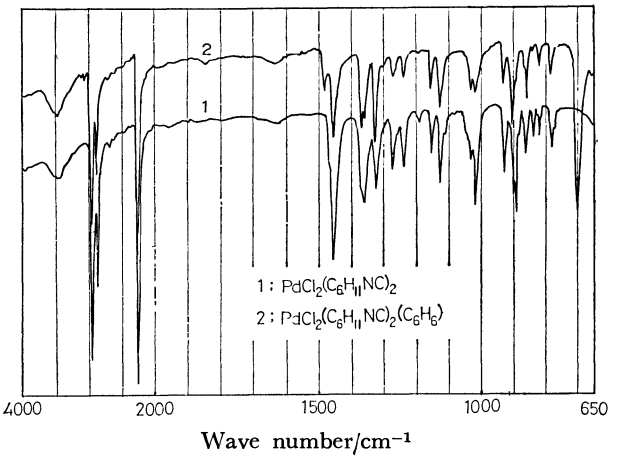

Fig. 1. IR spectra of $PdCl_2(C_6H_{11}NC)_2$ and $PdCl_2(C_6H_{11}NC)_2(C_6H_6)$.

By heating at 95 °C for 15 min, **2** was transformed into **1**, but **2** is fairly stable in air at room temperature and decomposes slowly with liberation of benzene. The complex **2** was also transformed into **1** by treating with ethyl ether. This result was ascertained by IR spectrum and elemental analysis of the complex obtained. The presence of benzene in the ether after contacting with **2** was confirmed by UV spectrum.

The IR spectrum of **2** shows several characteristic absorptions at 700, 1480, 1840, 1985, 3030, and 3075 cm^{-1} which are thought to be originated from the benzene incorporated in the complex. Especially the strong absorption at 700 cm^{-1} is worth noticing. It is well-known that the absorption of out of plane deformation band of benzene proton(ν_{11}) is observed at 672 cm^{-1} in vapor or liquid state, and at 687 cm^{-1} in solid state with free benzene as a stronger and broader absorption.[6] Shifting of the absorption to higher wave length suggests some probable interaction of benzene with palladium in the complex.

Crystallographic analyses of these complexes have been carried out and the crystal data are shown in Table 1. It is noteworthy that the extent of symmetry of **2** is higher than that of **1**. This result also suggests an interaction of benzene with palladium in complex **2**. We could not succeed in obtaining precise X-ray structural analysis of **2** because of its de-

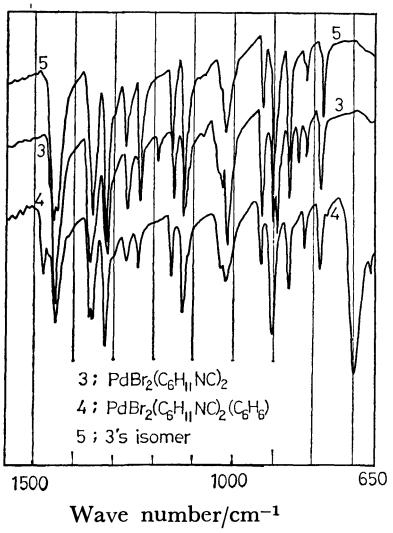

Fig. 3. IR spectra of $PdBr_2(C_6H_{11}NC)_2$, its isomer and $PdBr_2(C_6H_{11}NC)_2(C_6H_6)$.

composition during the diffraction analysis. It is suspected that **2** is five-co-ordinate with a π-bond of benzene, two chlorines and two isocyanides. X-ray structural analysis showed that the complex **1** has the structure shown in Fig. 2. Details of the analysis will be given in a forthcoming paper, but it should be noticed that the configuration of **1** is cis with respect to the isocyanides. Furthermore it is quite interesting that one isocyano group takes equatorial conformation and another isocyano group takes axial conformation to chair form cyclohexyl group.

The reaction of palladium(II) bromide with cyclohexyl isocyanide gave bis(cyclohexyl isocyanide)palladium(II) bromide, $PdBr_2(C_6H_{11}NC)_2$(**3**). By recrystallization of **3** from hot benzene, another benzene complex, bis(cyclohexyl isocyanide)palladium(II) bromide–benzene, $PdBr_2(C_6H_{11}NC)_2(C_6H_6)$(**4**) was obtained. Two kinds of complexes having the same molecular formula; $PdBr_2(C_6H_{11}NC)_2$ and different IR absorptions were obtained from the complex **4**. By washing with ethyl ether, **4** was transformed into **3**, but by heating at 100 °C for 1 h, **4** was transformed into another complex **5**. Recrystallization of **3** from hot *p*-xylene gave the complex **5** too. The complexes **3** and **5** are thought to be stereoisomers, but it is not clear why the two distinct IR absorptions at 860 and 1180 cm^{-1} observed with **3** are not in the spectrum of **5** as shown in Fig. 3.

$$PdBr_2 + 2C_6H_{11}NC \longrightarrow PdBr_2(C_6H_{11}NC)_2 \ (\mathbf{3}) \xrightarrow{p\text{-Xylene}} PdBr_2(C_6H_{11}NC)_2 \ (\mathbf{5})$$

$$\mathbf{3} \underset{Et_2O}{\overset{C_6H_6}{\rightleftarrows}} PdBr_2(C_6H_{11}NC)_2(C_6H_6) \ (\mathbf{4}) \xrightarrow{100\,^\circ C} \mathbf{5}$$

As a related reaction, it was reported that $RuCl_2(C_6H_{11}NC)_2(C_6H_6)$ was formed by the reaction of $[RuCl_2(C_6H_6)]_2$ with cyclohexyl isocyanide, while only $RuCl_2(C_6H_5NC)_4$ was formed with phenyl isocyanide.[7] Formation of benzene complex from $PdCl_2(C_6H_5NC)_2$ is not known as described in the introduction. On the other hand, the benzene complexes were obtained from the cyclohexyl isocyanide complexes. According to these facts cyclohexyl isocyanide rather than phenyl isocyanide is essential as the ligand in order to obtain benzene complexes from palladium halides and ruthenium halides.

Experimental

*Preparation of $PdCl_2(C_6H_{11}NC)_2$ (**1**).* To a benzene solution (100 cm^3) containing palladium chloride (4.5 mmol, 0.80 g) was added cyclohexyl isocyanide (9 mmol, 1.1 cm^3)

with continuous stirring by a magnetic stirrer and the mixture was heated at temperatures between 70 °C and 80 °C to give a yellow solution. After filtration the hot solution to remove the remaining palladium chloride (0.08 g), the filtrate was concentrated under reduced pressure and ethyl ether (100 cm^3) was added to give white precipitates (1.43 g); mp 123 °C.

Found: C, 42.52; H, 5.58; N, 7.14; Cl, 18.17; ash, 27.2%. Calcd for $C_{14}H_{22}N_2Cl_2Pd$: C, 42.51; H, 5.58; N, 7.09; Cl, 17.93; ash, 26.90%.

Preparation of $PdCl_2(C_6H_{11}NC)_2(C_6H_6)$ ***(2)***. $PdCl_2(C_6H_{11}NC)_2$ (0.5 g) was recrystallized from hot benzene (20 cm^3) to give yellow crystals (0.52 g); mp 127—128 °C.

Found: C, 50.67; H, 5.98; N, 6.04; Cl, 15.28; ash, 22.6%. Calcd for $C_{20}H_{28}N_2Cl_2Pd$: C, 50.70; H, 5.97; N, 5.91; Cl, 14.97; ash, 22.47%.

Preparation of $PdBr_2(C_6H_{11}NC)_2$ ***(3)***. To a benzene solution (125 cm^3) containing palladium bromide (5 mmol, 1.33 g) was added cyclohexyl isocyanide (10 mmol, 1.2 cm^3) with stirring and the mixture was heated at temperatures between 70 °C and 80 °C to give a yellow solution. After filtration of the hot solution to remove the remaining palladium bromide, the filtrate was concentrated under reduced pressure and ethyl ether (150 cm^3) was added to give pale yellow crystals (1.81 g); mp 152 °C.

Found: C, 34.71; H, 4.58; N, 5.86; ash, 22.1%. Calcd for $C_{14}H_{22}N_2Br_2Pd$: C, 34.70; H, 4.58; N, 5.78; ash, 21.96%.

Preparation of $PdBr_2(C_6H_{11}NC)_2(C_6H_6)$ ***(4)***. The complex **3** was recrystallized from hot benzene to give yellow crystals; mp 155—160 °C.

Found: C, 42.44; H, 5.02; N, 5.10; Br, 28.52; ash, 19.2%. Calcd for $C_{20}H_{28}N_2Br_2Pd$: C, 42.70; H, 5.01; N, 4.98; Br, 28.42; ash, 18.90%.

Preparation of $PdBr_2(C_6H_{11}NC)_2$ ***(5)***. The complex **4** was treated with ethyl ether and dried under reduced pressure to give pale yellow powder; mp 152 °C.

Found: C, 34.80; H, 4.59; N, 5.86; ash, 22.1%. Calcd for $C_{14}H_{22}N_2Br_2Pd$: C, 34.70; H, 4.58; N, 5.78; ash, 21.96%.

Apparatus. IR spectra were obtained on a Perkin-Elmer 125 spectrometer and Hitachi EPI-S spectrometer in KBr disks, UV spectra on a Varian Cary 14 spectrometer. X-ray spectra were obtained on a Rigakudenki AFC-6A diffractometer.

An Improved Ion-exchanger Colorimetry for the Determination of a Trace Amount of Phosphate

Kiichi MATSUHISA,** Kunio OHZEKI, and Tomihito KAMBARA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

** *Division of Environmental Conservation, Graduate School of Environmental Science, Hokkaido University, Sapporo 060*

(Received March 3, 1981)

A highly sensitive and selective method has been developed for the determination of a trace amount of phosphate. It is based on the concentration of phosphate as the familiar molybdenum blue complex on the coagulated material prepared from finely divided anion and cation exchangers, collection of the mixed resin on a filter paper, and the subsequent measurement of the absorbance of the complex on the resulting thin layer of resin phase. The calibration curve shows a good proportionality in the concentration range of 1 to 6 μg P l^{-1}. The absorbance corresponding to 1 μg P l^{-1} is 0.095. The method is successfully applied to the determination of phosphate in a tap water and a river water.

Ion-exchanger colorimetry[1,2] was developed by Yoshimura *et al.* A colored metal complex is collected by batch method on the ion-exchanger, the size of which is ranging from 200 to 400 mesh. A part of the resin is then transferred into a cell of 0.1 cm in thickness, and the complex on the resin phase is determined colorimetrically. Trace amounts of chromiun(VI)[3] and zinc[4] were determined. The method was also applied to the determination of phosphate.[5] Phosphate was concentrated on the molybdate-loaded ion-exchanger and determined as the molybdenum blue complex.

An improved ion-exchanger colorimetry[6] was reported for the determination of chromium(VI). The method utilizes a mixture of finely divided anion and cation exchangers. Finely divided cation exchanger collects chromium(VI)–diphenylcarbazide complex rapidly by batch method in combination with anion exchanger to form bulky material. The coagulated resin is then separated by filtration and the resulting thin layer of the colored resin on a filter paper is directly subjected to spectrophotometric measurement.

In the present paper, an improved ion-exchanger colorimetry is reported for the determination of phosphate. The molybdenum blue complex is insistently fixed to the coagulated ion-exchangers. A highly sensitive and selective method is developed.

Experimental

Reagents. All reagents used were of analytical reagent grade. Freshly dried potassium dihydrogenphosphate was dissolved into deionized water to give a solution of 50 mg P l^{-1} (1 l=1 dm^3). A solution containing 0.05 μg P ml^{-1} (1 ml=1 cm^3) was prepared fresh daily by dilution of the stock solution. Twenty grams of hexaammonium heptamolybdate tetrahydrate were dissolved and diluted to 500 ml with water. Ascorbic acid solution of 0.1 mol dm^{-3} was made fresh dialy. Potassium antimony tartrate was dissolved into water to give a solution of 1 mg Sb ml^{-1}.

Mixed Reagent A: A 100-ml portion of 2.5 mol dm^{-3} sulfuric acid was mixed with 30 ml of the ammonium molybdata solution.

Mixed Reagent B: A 60-ml portion of 0.1 mol dm^{-3} ascorbic acid was mixed with 10 ml of the potassium antimony tartrate solution.

Dipping Solution: A 5-ml portion of 2.5 mol dm^{-3} sulfuric acid, 6 ml of 0.1 mol dm^{-3} ascorbic acid and 1 ml of potassium antimony tartrate solutions were mixed and diluted to 50 ml with water.

Mixed reagents and the dipping solution were prepared fresh daily and stored in a thermostat kept at 25±1 °C.

Ion-exchange Resins. Macroreticular type Amberlyst 15 and A-27 (both Rohm and Haas Co.) in RSO_3H and $RN(CH_3)_3Cl$ forms, respectively, were used. Suspension of the respective resins was prepared according to the method reported.[7] The stock suspension was stored as required in the thermostat kept at 25±1 °C. The solution was well shaken before being pipetted out. The mutual coagulation of the finely divided anion and cation exchangers was examined as follows. The varying amounts of the anionic resin suspension (ARS) up to 20 ml were separately taken into a 50-ml beaker and diluted to 30 ml with water. A 10-ml portion of 0.25 mol dm^{-3} potassium chloride solution was added to keep the constant ionic strength. A 2.0-ml aliquot of the cationic resin suspension (CRS) was then added and the final volume of the solution was adjusted to 50 ml with water. The mixture was stirred magnetically for 10 min and filtered. The absorbance of filtrate was determined at 500 nm against water.

Apparatus. A Shimadzu UV-140-01 spectrophotometer was used. Filter papers (Toyo Roshi No. 5 A) were cut in 3 cm×6 cm wide strips. A Toyo KG 25 filter holder (Toyo Roshi Co.) was used.

General Procedure. A 50-ml aliquot of the solution containing less than 0.3 μg phosphorus as phosphate was placed in a 100-ml beaker set in a water bath kept at 25± 1 °C. A 6.0-ml portion of the mixed reagent A, 3.0-ml of the mixed reagent B, 6.0 ml of ARS and finally 2.0 ml of CRS were added to the sample solution. The mixture was stirred by means of a magnetic stirrer for 10 min. The resulting coagulated material was collected on one end of the filter strip placed on a holder. A disk of colored resin of the 17-mm diameter and about 0.3 mm in thickness was formed. The filter strip was dipped in the dipping solution for 20 min. It was then fixed on a glass plate fitted to the cell holder. The absorbance of the resin phase was measured at 700 nm against the other end of filter paper.

Another disk of resin was prepared without addition of phosphate. The absorbance corresponding to the reagent blank including the resins was also measured. The net absorbance of the complex on the resin was obtained by the difference.

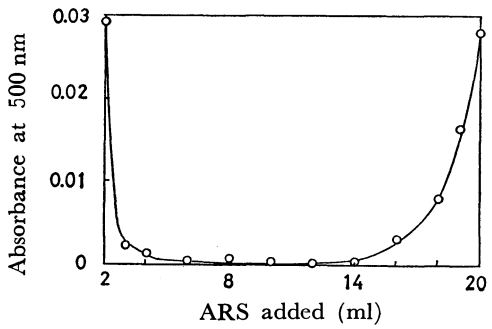

Fig. 1. Coagulation of the suspensions of finely divided cation and anion exchangers (CRS and ARS). A 2-ml portion of CRS was mixed with ARS in 50 ml of 0.05 mol dm^{-3} potassium chloride solution.

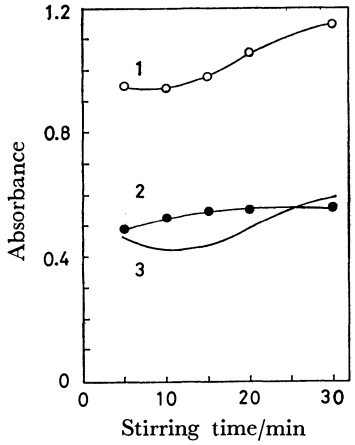

Fig. 2. Effects of shaking time on the fixation of the molybdenum blue compound on the mixed resin from the 50-ml solution containing 0.25 μg P (1), and without addition of P (2). Curve 3 indicates the net absorbance at 700 nm.

Results and Discussion

Ion-exchanger. In the previous works[6-8] Amberlyst 15 and A-26 were used. In this work A-27 was used in place of A-26. The ion-exchange capacities of A-26 and A-27[9] have been reported as 4.4 and 2.6 meq g^{-1}, respectively. The pore radius range of A-26 is 14—22 nm and that of A-27 is 21—120 nm. Amberlyst A-27 is well suited for fixing the bulky anions.

Suspension. The suspension of Amberlyst 15 is slightly brown while that of A-27 is white. The ion-exchange capacities of ARS and CRS were determined by conductometric titration with the standard silver nitrate and sodium hydroxide solutions, respectively. The exchange capacities were 2.54×10^{-3} meq ml^{-1} for ARS and 5.21×10^{-3} meq ml^{-1} for CRS. The anion exchanger is 4—16 ml of ARS was almost completely coagulated with the cation exchanger in 2 ml of CRS (Fig. 1). The resulting mixed resin was easily separated by filtration from the solution. The combination of 2.0 ml of CRS and 6.0 ml of ARS was used throughout the following experiments.

Effect of Temperature. The preliminary experiments revealed that the development of coloration

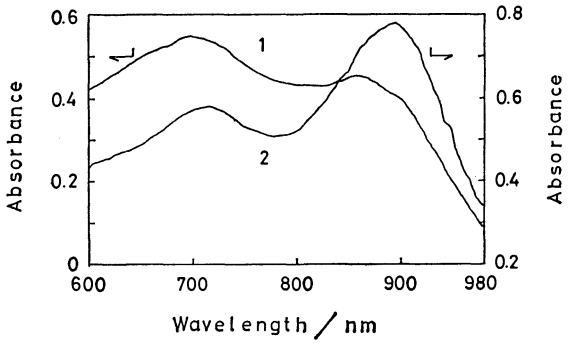

Fig. 3. Absorption curves of the molybdenum blue compound; (1) on the thin layer of mixed resin prepared from 50 ml of solution containing 0.3 μg P as phosphate, and (2) in aqueous solution containing 1 μg P ml^{-1} (1-cm cell).

was seriously affected by the temperature of reaction solution. Hence, all experiments were carried out at a constant temperature of 25 °C.

Shaking Time. During the course of shaking, the anionic molybdenum blue complex is fixed on the anion exchanger, which combines with cation exchanger to form the coagulated material. The effect of shaking time was examined (Fig. 2). The absorbance of sample disk was almost constant in the shaking period of 5—10 min. With a prolonged shaking, the absorbance increased gradually. On the other hand, the blank value increased slowly with increasing shaking time. The net absorbance showed a constant value between 10 to 15 min.

Standing Time. The coagulated resin was filtered with a gentle suction. The resulting thin layer was stored wet in the dipping solution, the composition being determined after many trials. Almost a constant coloration was kept for 10—60 min.

Absorption Curve. The absorption curve of the molybdenum blue in the resin phase was different from that of in the solution (Fig. 3). The maximum at 890 nm in the solution[10] disappered when the complex was fixed on the ion-exchange resin. The complex on the resin has an absorption maximum at 700 nm.[5]

Calibration Curve. A calibration curve showed a proportionality in the concentration range of 1 to 6 ppb (μg l^{-1}) P as phosphate. The mean absorbance of blank value with the standard deviation was 0.535± 0.024 (n=7). The net absorbance for 6 ppb P were 0.550±0.038 (n=8). The variation would be reduced if a temperature could be much more exactly controlled.

Effects of Forein Ions. The effects of arsenate and silicate were examined. The duplicate determinations of 0.2 μg P were carried out in the presence of one of them. The equal amount of As as arsenate gave a relative error of +8.1% and a 5000-fold amount of SiO_2 as silicate showed the deviation of +3.9%.

Analysis. The method was applied to the determination of phosphate in a tap water and a river water (Table 1). The standard addition method together with the original calibration method was applied to the analysis of a tap water. Both plots show-

Table 1. Results of analysis of a tap water for phosphate

Date 1980	Sample volume (ml)	P found (μg)	P in tap water ($\mu g\ l^{-1}$)

	10.0	0.203	20.3
14/11	10.0	0.156	15.6
	10.0	0.165	16.5

a) 0.100-μg P was added. b) 0.200-μg P was added.

ed good linearity with the same slope (Fig. 4). This result indicated that the recovery of phosphate as the molybdenum blue complex was quantitative from the sample solution to the mixed resin, although there were many competing ions for the ion-exchange sites. The variation of the phosphate content in the tap water supplied to our laboratory was examined. The water sample was taken freshly each day. As shown in Table 1, no significant variation was found in the period studied.

A river water was filtered through a filter paper (Toyo Roshi No. 5C) as soon as possible. The concentration was found to be 12 ppb P as phosphate. The value increased to 50 ppb P when the filtrate was treated with sulfuric and nitric acids to decompose the organic substances according to JIS method.[11] The considerable amounts of phosphate were found to originate from the organic substances in the river water.

The method was ascertained to be highly selective and sensitive for the determination of phosphate in water samples. Only small amount of sample water was required.

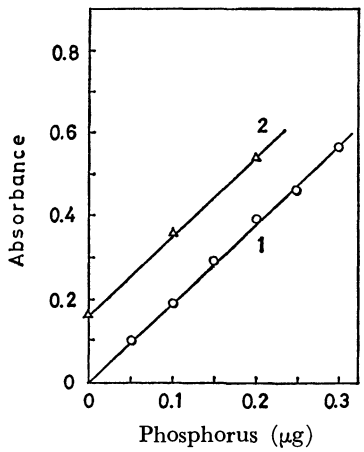

Fig. 4. Calibration curve (1) and the result of the standard addition method (2). Sample amount: 50 ml.

Preparation and Electronic Spectra of Dichlorobis(1,10-phenanthroline)-molybdenum(III) and Dichlorobis(2,2′-bipyridine)molybdenum(III) Ions

Tomoji S. Morita, Yoichi Sasaki,* and Kazuo Saito

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received March 14, 1981)

A preparation method of pure crystalline salts, *cis*-$[MoCl_2(phen)_2]X$ (phen, 1,10-phenanthroline; X^-= Cl^-, Br^-, $CH_3C_6H_4SO_3^-$) and *cis*-$[MoCl_2(bpy)_2]Cl$ (bpy, 2,2′-bipyridine), has been established. They are stable in solid state under oxygen- and moisture-free conditions. They deteriorate within one hour in water at room temperature, but are much more stable in various organic solvents free from oxygen. In the visible region, two absorption peaks were observed in methanol at 21510 cm^{-1} (ε=2570 $dm^3\ mol^{-1}\ cm^{-1}$) and 26740 cm^{-1} (ε=4420 $dm^3\ mol^{-1}\ cm^{-1}$) for the phen complex, and one broad peak at 22820 cm^{-1} (ε=3630 $dm^3\ mol^{-1}\ cm^{-1}$) for the bpy complex, which are assigned to the metal-to-ligand d-π^* charge transfer transition.

The coordination chemistry of molybdenum(III) has been less known as compared with that of chromium(III). Particularly, there are very few well characterized monomeric molybdenum(III) complexes containing amino carboxylates or aliphatic amines.[1,2] While chromium(III) complexes are inert to the oxidation with common oxidants, molybdenum(III) complexes are easily oxidized by air and by a variety of mild oxidants.[1] Nevertheless molybdenum(III) complexes have drawn interest as a counterpart of the well studied chromium(III) chemistry.

2,2′-Bipyridine(bpy) and 1,10-phenanthroline(phen) provide a variety of stable complexes of transition elements in low oxidation states.[3,4] Several monomeric molybdenum(III) complexes have been reported,[5-10] containing one to three 2,2′-bipyridine or 1,10-phenanthroline. However, some of them were not well characterized, and chemical properties of the characterized species are uncertain. Particularly only a few electronic absorption data are available.

We have isolated pure dichlorobis(2,2′-bipyridine)- and dichlorobis(1,10-phenanthroline)molybdenum(III) complexes in crystalline state and observed their electronic absorption spectra in various solvents.

Experimental

Materials. 2,2′-Bipyridine, 1,10-phenanthroline, and *p*-toluenesulfonic acid (Wako pure chemical industries, Ltd.) were used without further purification. Ammonium pentachloroaquamolybdate(III), $(NH_4)_2[MoCl_5(H_2O)]$, was prepared by the known method.[11] Organic solvents except acetone for the spectrometry were dehydrated with Molecular Shieves 4A and used without distillation. Acetone (Dotite spectrosol) was used as received. The concentration of water in these solvents was $(2—20)\times10^{-3}$ mol dm^{-3}.

Preparation of the Complexes. The bis(bpy) and bis(phen) complexes were synthesized by substituting the aromatic ligands for the aqua and the chloro ligands in $[Mo^{III}Cl_5(H_2O)]^{2-}$.

Dichlorobis(1,10-phenanthroline)molybdenum(III) Chloride Tetrahydrate, $[MoCl_2(phen)_2]Cl\cdot4H_2O$: A three-necked round-bottomed flask (1 dm^3) was connected to a dropping funnel and a reflux condenser,[12] the top of which was connected to a manifold for vacuum and nitrogen gas. Aqueous ethanol (40% v/v, 200 cm^3) containing 16 g of 1,10-phenanthroline and 5 g of *p*-toluenesulfonic acid was placed in the flask and the content was stirred with a teflon-coated bar. The whole system was evacuated and nitrogen gas was introduced. The purge cycle was repeated more than ten times. A solution of $(NH_4)_2[MoCl_5(H_2O)]$ (4.3 g) in 1.0 mol dm^{-3} hydrochloric acid (100 cm^3) was prepared in a 300 cm^3 round-bottomed Schlenk tube filled with nitrogen, transfered to the dropping funnel through a transfer tube, and added dropwise (6 h) to the phen solution at 50 °C with stirring. The red mixture was refluxed in an oil bath (*ca.* 100 °C) for 24 h. The color turned deep violet and then dark orange. The solution was allowed to cool slowly and kept in a refrigerator for 24 h. Yellowish orange needles appeared during storage, which were filtered off with a fritted funnel under nitrogen atmosphere, dried under a stream of nitrogen, dried *in vacuo*, and recrystallized from methanol. The deep orange prismatic crystals were washed with diethyl ether and dried *in vacuo*. Yield 2.2 g (35% from $(NH_4)_2[MoCl_5(H_2O)]$). Found: C, 45.94; H, 3.55; N, 8.85; Cl, 16.79%. Calcd for $C_{24}H_{24}N_4O_4Cl_3Mo$: C, 45.41; H, 3.81; N, 8.83; Cl. 16.76%. $[MoCl_2(phen)_2]Cl\cdot4H_2O$ is soluble in water, propylene carbonate, acetonitrile, *N,N*-dimethylformamide, methanol, ethanol, acetone and dichloromethane, slightly soluble in acetic acid, and insoluble in diethyl ether and 1,4-dioxane. The magnetic moment of the solid was 3.20 BM (292 K).

Dichlorobis(1,10-phenanthroline)molybdenum(III) p-Toluenesulfonate Sesquihydrate, $[MoCl_2(phen)_2](CH_3C_6H_4SO_3)\cdot1.5H_2O$: This was prepared similarly to the chloride salt by use of 20 g (instead of 5 g) of *p*-toluenesulfonic acid in aqueous ethanol to obtain large dark orange prismatic crystals. Yield 4.6 g (50% from $(NH_4)_2[MoCl_5(H_2O)]$). Found: C, 51.31; H, 3.65; N, 7.77; Cl, 9.72; S, 4.48%. Calcd for $C_{31}H_{26}N_4O_{4.5}Cl_2SMo$: C, 51.32; H, 3.61; N, 7.72; Cl, 9.77; S, 4.42%.

Dichlorobis(1,10-phenanthroline)molybdenum(III) Bromide Tetrahydrate, $[MoCl_2(phen)_2]Br\cdot4H_2O$: The preparation method was similar to that of the chloride salt except using 1.0 mol dm^{-3} hydrobromic acid in place of 1.0 mol dm^{-3} hydrochloric acid. The solution of $(NH_4)_2[MoCl_5(H_2O)]$ in 1.0 mol dm^{-3} hydrobromic acid (100 cm^3) was stirred for 24 h, and then added to the phen solution. Yield of orange powder, 15%. Found: C, 41.54; H, 2.90; N, 8.94; Cl, 10.32; Br, 11.62%. Calcd for $C_{24}H_{24}N_4O_4BrCl_2Mo$: C, 42.44; H, 3.56; N, 8.25; Cl, 10.44; Br, 11.76%.

Dichlorobis(2,2′-bipyridine)molybdenum(III) Chloride Dihydrate, $[MoCl_2(bpy)_2]Cl\cdot2H_2O$: This was made by a method similar to that for the phen complex chloride. Yield 2.3 g (31% from $(NH_4)_2[MoCl_5(H_2O)]$). Found: C, 43.65; H, 3.56; N, 10.16; Cl, 18.67%. Calcd for $C_{20}H_{20}N_4O_2Cl_3Mo$: C, 43.62; H, 3.66; N, 10.17; Cl, 19.31%. The orange crystals of $[MoCl_2(bpy)_2]Cl\cdot2H_2O$ are soluble in the same solvents as mentioned for $[MoCl_2(phen)_2]Cl\cdot4H_2O$.

Stability of the Complexes. The complex solids are stable under nitrogen atmosphere or *in vacuo* for at least one month, and relatively stable in dry air for at least two

days at room temperature. Their solutions in organic solvents free from oxygen are stable for at least 1 h at room temperature. Aqueous solutions (pH $\approx$7) are very unstable at room temperature even in the absence of oxygen.

Measurements. Ultraviolet and visible absorption spectra were recorded on a Hitachi 330 spectrophotometer under nitrogen atmosphere by the syringe technique.[12] Air was eliminated and nitrogen or argon was introduced into the solvents before measurement. Infrared spectra were recorded on a JASCO IRA-1 and a Hitachi 215 infrared spectrophotometer in KBr disks. The magnetic susceptibility was measured by the Faraday method in the Physics Department of this University at room temperature.

The concentration of water in organic solvents was determined by the Karl Fischer method with a Metrohm Karl Fischer-Automat E547, equipped with a Multi-Dosimat E415 and a Multi-Bürette E485.

Results and Discussion

Preparation. Bis(2,2'-bipyridine) and Bis(1,10-phenanthroline) Complexes: $[MoCl_2(phen)_2]Cl$ was prepared by Du Bois *et al.* from $[Mo^{III}Cl_3(py)_3]$ (py= pyridine) and phen in xylene.[9] The complexes, $[Mo^{III}I_2L_2]X$ (L=bpy, phen; $X^-=I^-$, $B(C_6H_5)_4^-$) were prepared by Westland and Muriithi,[10] by treating MoI_3 and the ligands in tetralin at 160—170 °C for 24 h. When MoI_3 and phen were mixed in benzonitrile at 180 °C for 3 d, $[Mo^{II}I_2(phen)_2]$ was claimed to be formed.[10] The products were reported to be powder, and the formulations were based on analytical data of Mo, and Cl or I alone. No electronic absorption spectrum was reported.

The elemental analysis of the present complexes are consistent with the given formulae. The magnetic moment of $[MoCl_2(phen)_2]Cl\cdot 4H_2O$ (3.20 BM) is similar to those of other monomeric molybdenum(III) complexes.[1] Three salts of the bis(phen) complexes gave almost identical absorption spectra in the visible region in methanol, indicating that all the samples contain the same complex cation. $[MoCl_2(phen)_2]Cl\cdot 4H_2O$ and $[MoCl_2(bpy)_2]Cl\cdot 2H_2O$ gave infrared absorption bands at 325 cm^{-1} and 323 cm^{-1}, respectively, which are assigned to $M^{III}o$–Cl stretching frequency (*cf.* Mo^{III}–Cl stretching frequency at 305 cm^{-1} in $K_3[MoCl_6]$[13,14]).

The bis-chelate complexes were successfully synthesized by the dilution method; *i.e.* $[Mo^{III}Cl_5(H_2O)]^{2-}$ in 1.0 mol dm^{-3} hydrochloric acid slowly added to the ligand solution. The ligand solution contains *p*-toluenesulfonic acid as 'inert' acid (perchloric acid is known to oxidize Mo(III)[11]) to keep reaction mixture acidic and low chloride concentration. The initial red reaction mixture turned violet within twenty minutes and then dark orange within 1 h. The violet color may indicate the formation of an intermediate $[MoCl_4L]^-$ (L=bpy, phen).[8] When the solutions of the ligand and of $[Mo^{III}Cl_5(H_2O)]^{2-}$ were rapidly mixed, a red-violet precipitate was formed, which was first assigned to $[MoL_3]Cl_3$ (L=bpy, phen) by Steele,[5] but later claimed to be $[MoCl_2L_2][MoCl_4L]$, $(LH)[MoCl_4L]$ or their mixture by Marzilli and Buckingham.[8] Our results of elemental analysis (C, H, N, Cl) of the red-violet precipitate fell between the calculated values for the last two formulations. Carmichael *et al.* reported that a similar insoluble salt was obtained by the reaction of molybdenum(III) trichloride or potassium hexachloromolybdate(III) with molten bipyridine.[7] It seems that under the reaction conditions where substantial amounts of $[MoCl_4L]^-$ and $[MoCl_2L_2]^+$ (or LH^+) are present, an insoluble salt between these two ions precipitated.

A large excess of the ligand (more than 8 times of the molybdenum) was also required to obtain the bis complex in high yield. When only 2.5 molar excess of the ligand was used, a red-violet precipitate was formed, which can be $[MoCl_2L_2][MoCl_4L]$. Substantial amount of $[MoCl_2L_2]Cl$ was also obtained from the filtrate.

Attempts to Prepare the Tris-chelate Complexes, $[Mo(bpy)_3]^{3+}$ and $[Mo(phen)_3]^{3+}$: Various attempts by the ligand substitution method were unsuccessful. Prolonged refluxing (1—10 d) of the reaction mixture used for the preparation of the bis-chelate complexes (*vide supra*) always resulted in exclusive formation of the bis-chelate complexes. We thought that the third bpy or phen would not coordinate to molybdenum(III) in a strongly acid medium. Addition of a small amount of 0.5 mol dm^{-3} sodium hydroxide solution free from oxygen to the reaction mixture gave a blue solution even at a pH less than unity. This solution was evaporated to dryness to leave a purple-gray residue which gave an infrared absorption band at 950 cm^{-1}, suggesting the presence of Mo=O bond.[1] When $[MoCl_2(phen)_2]Cl\cdot 4H_2O$ and phen were mixed in ethanol free from oxygen in the Schlenk tube, the color also turned blue within 1 h. When this complex was dissolved in ethanol without phen, the color remained orange for 1 h even in the presence of oxygen. This solution turned black, and then almost colorless after 1 d. No attempt was made for clarifying the oxidation process of the molybdenum(III).

Preparation of $[MoL_3]X_3$ (L=bpy, phen; $X^-=Cl^-$, Br^-, I^-) was reported previously by Steele[5] and Carmichael *et al.*[7] We repeated Carmichael's method,[7] *i.e.* MoI_3 was treated with molten bipyridine, and obtained a black-brown powder, of which the elemental analysis (C, H, N, I) was closer to $[MoI_2(bpy)_2]I$ rather than to $[Mo(bpy)_3]I_3$. Further attempts to obtain crystals of $[MoI_2(bpy)_2]I$ or $[Mo(bpy)_3]I_3$ from the powder were unsuccessful. Thus the hitherto reported "tris-chelate complexes" deserve further experimental evidence for the formulation.

Tris(bpy) and tris(phen) complexes of chromium(III) have not been prepared by the ligand substitution,[15,16] but obtained by the oxidation of the tris-chelate complexes of chromium(II).[16,17] Such an oxidation method cannot be applied to the molybdenum(III) complexes since the corresponding uninuclear molybdenum(II) complexes are not known.

Geometrical Structure. The present complexes, $[MoCl_2L_2]^+$ can occur in *cis* and *trans* forms. The shape of crystals (orange prismatic crystals in the case of $[MoCl_2(phen)_2]Cl\cdot 4H_2O$) of the complex salts and their absorption patterns in solution did not change on further recrystallization from methanol, ethanol or acetonitrile, suggesting no change in the

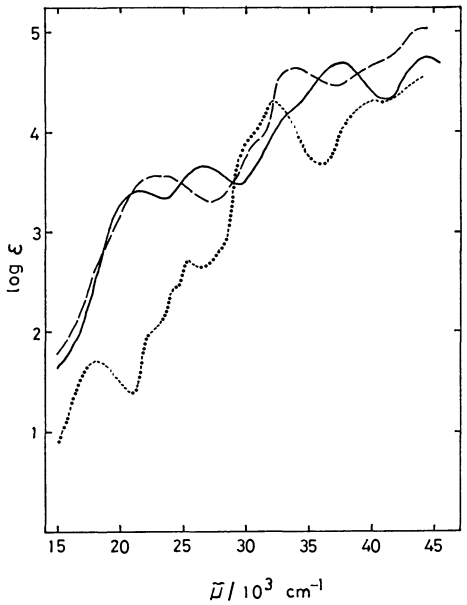

Fig. 1. Absorption spectra of $[MoCl_2(bpy)_2]Cl \cdot 2H_2O$ in methanol (— —), *cis*-$[MoCl_2(phen)_2]Cl \cdot 4H_2O$ in methanol (——) (under nitrogen atmosphere) and *cis*-$[CrCl_2(bpy)_2]Cl$[19] in 1:1 aqueous methanol (----).

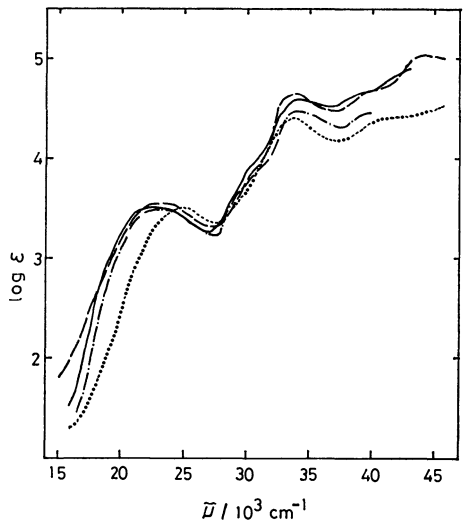

Fig. 2. Absorption spectra of $[MoCl_2(bpy)_2]Cl \cdot 2H_2O$ in dichloromethane (——), in acetonitrile (— —), in methanol (—·—) and 0.1 mol dm^{-3} hydrochloric acid (----) (under nitrogen atmosphere).

geometrical structure of molybdenum complex cation. The X-Ray diffraction method disclosed *cis* structure for $[MoCl_2(phen)_2]Cl \cdot 4H_2O$.[18] No such information is available for the salts of $[MoCl_2(bpy)_2]^+$.

Electronic and infrared absorption spectra did not give straightforward evidence for their geometrical isomerism. Absorption spectral patterns of the two complex cations in the visible region are apparently different from each other (Fig. 1); two peaks for the phen complex and one broad band for the bpy complex in the region from 20000 to 30000 cm^{-1}. However, such a difference cannot be taken as an evidence for different geometrical isomerism of these two complex cations, since the nature of the absorption bands are of charge-transfer type (*vide infra*) and their relation to the geometrical isomers would not be simple. Since all the known geometrical structures of dihalobis(2,2'-bipyridine) type complexes with various metal ions are *cis*,[19-25] we tend to consider that the bpy complex is also of the *cis* form.

Absorption Spectra. The absorption spectra in all the solvents except water changed only very slightly over 100 min at room temperature. Whenever the spectrum (patterns and/or intensity) changed, it was measured for 100 min at ten minutes intervals and the original pattern was estimated by the extrapolation to zero time. The spectrum changed so rapidly in water (pH $\approx$7) that the zero-time spectrum was not obtained. The complex solution in 0.1 mol dm^{-3} hydrochloric acid was relatively stable, and the original absorption spectrum was estimated.

General Features: The absorption curves of the 2,2'-bipyridine and 1,10-phenanthroline complexes are shown in Fig. 1, together with that of *cis*-$[CrCl_2(bpy)_2]^+$.[19] In the visible region (<30000 cm^{-1}), the bpy and the phen complexes of molybdenum(III) have one broad and two distinct peaks, respectively, with extinction coefficients between 2000 and 4000 dm^3 mol^{-1} cm^{-1}. Two or three much stronger absorption peaks ($\log \varepsilon > 4$) are observed in the ultraviolet region (>30000 cm^{-1}). Some of the peaks shift in different solvents, but the overall pattern remains almost unchanged, and the nature of absorption bands is discussed on the basis of the spectra in methanol (Fig. 1, *vide infra*).

Bands in the Ultraviolet Region: The phen complex shows two distinct bands at 44250 cm^{-1} and 37840 cm^{-1}, which are assigned to the intraligand transitions corresponding to the two bands of free 1,10-phenanthroline at 44440 cm^{-1} and 37880 cm^{-1} in methanol. Similarly, bands of the bpy complex at 40000 cm^{-1} and 33900 cm^{-1}, are of intraligand transition nature corresponding to the two bands of free 2,2'-bipyridine at 42550 cm^{-1} and 35570 cm^{-1}. The peaks of free ligand shift to lower energy on coordination to the metal ion, as reported for other metal complexes.[26,27]

Bands in the Visible Region: The bpy complex in methanol gives apparently one very broad maximum at 22800 cm^{-1}, which seems to involve two or more transitions as indicated by the spectra in different solvents (Fig. 2); *i.e.* the bpy complex gives a maximum at 24770 cm^{-1} and no shoulder is appreciable in 0.1 mol dm^{-3} hydrochloric acid, but a prominent shoulder is observed at a lower wave number in a less polar solvent. The phen complex gives two bands at 26740 cm^{-1} and 21510 cm^{-1} in methanol. The shape of the two bands of $[MoCl_2(phen)_2]^+$ did not change in different solvents (Fig. 3).

All these bands have extinction coefficients between 2000 and 4000 dm^3 mol^{-1} cm^{-1}, too strong to be assigned to the d-d transition. The spectral data of the other metal complexes having the same ligand environment are shown in Table 1. The extinction coefficients of the complexes of chromium(III),[19] cobalt(III),[20,21] and rhodium(III)[22,28] are different from those of the complexes of iridium(III),[23,28] iron-

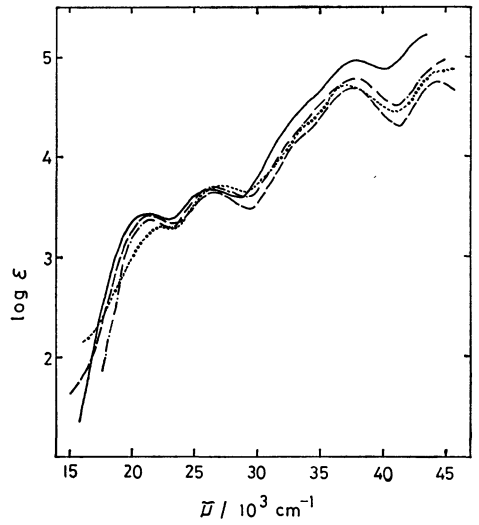

Fig. 3. Absorption spectra of *cis*-$[MoCl_2(phen)_2]Cl \cdot 4H_2O$ in dichloromethane (——), in acetonitrile (— —), in methanol (—·—), and in 0.1 mol dm^{-3} hydrochloric acid (----) (under nitrogen atmosphere).

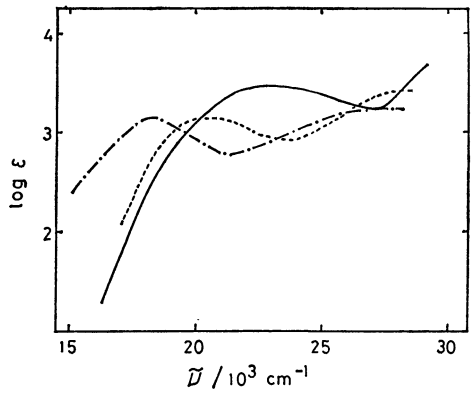

Fig. 4. Absorption spectra in *N*,*N*-dimethylformamide of $[MoCl_2(bpy)_2]^+$ (——), $[MoCl_3(bpy)(py)]$[8] (----), and $[MoCl_4(bpy)]^-$ [8] (—·—) (under nitrogen atmosphere).

(II),[24] ruthenium(II),[24,25] and osmium(II).[24,25] The absorption bands of the former and the latter group of complexes have been assigned to the d-d transitions, and the metal-to-ligand charge transfer (d-π*) transitions, respectively. The extinction coefficient, as well as the ease of oxidation of molybdenum(III) state, suggest that the bands of *cis*-$[MoCl_2(phen)_2]^+$ and $[MoCl_2(bpy)_2]^+$ in the visible region are of the d-π* charge transfer type.

The difference in spectral pattern of d-π* transitions between the bpy and the phen complexes is found in the complexes of other metal ions. The d-π* transitions (near 23000 cm^{-1}) appear as a sharp maximum and a prominent shoulder for $[Ru^{II}(bpy)_3]^{2+}$ and two distinct peaks for $[Ru^{II}(phen)_3]^{2+}$.[29] *cis*-$[Ir^{III}Cl_2(bpy)_2]^+$ shows one maximum near 28000 cm^{-1},[28,30] while *cis*-$[Ir^{III}Cl_2(phen)_2]^+$ shows one maximum and a prominent shoulder.[23,31] Also an appreciable difference is observed between the tris(bpy) and the tris(phen) complexes of iron(II)[32] as well as osmium(II).[33] On the other hand, the difference is very small between *cis*-$[Fe^{II}Cl_2(bpy)_2]$ and *cis*-$[Fe^{II}Cl_2(phen)_2]$.[24,25,34]

Thus the d-π* spectral pattern is not necessarily similar between the bpy and the phen complexes. The difference of the spectral patterns of the present complexes does not contradict our assignment of the d-π* charge transfer transitions.

Comparison with Analogous Molybdenum(III) Complexes in the Visible Region: The absorption bands of (bpyH)-[$MoCl_4$(bpy)] and [$MoCl_3$(bpy)py] in the visible region[8] (Fig. 4) must be of charge-transfer type as judged from their intensity. The absorption peaks give blue shift with decrease in number of chloride ligand. This fact implies that these bands involve the transition from d-orbitals of molybdenum(III) to the ligand π^*-orbital. The increase in number of nitrogen (the decrease in number of chloride) causes the increase in the degree of d-orbital splitting which would increase the gap between the occupied d-orbitals and the ligand π^*-orbitals. The change in overall charge of the complexes can be also responsible for the band shift.[35]

T.S.M. has learned the technique of handling air-sensitive materials from Professor Junnosuke Fujita and his collaborators at Nagoya University (Department of Chemistry), to whom the authors' thanks are due. The authors also would like to thank Professor Toyonobu Asao of Tohoku University (College of General Education) for the measurement of the infrared spectra (Hitachi 215) and Dr. M. Kogi of Tohoku University (Department of Physics) for the measurement of the magnetic moment.

(Received March 26, 1981)

A series of complexes, $[Co(en)_n\{NH_2CH_2CH_2P(CH_3)_2\}_{3-n}]^{3+}$ (en=ethylenediamine, n=0,1,2) and three bis(ethylenediamine)cobalt(III) complexes of the related ligands, $NH_2CH_2CH_2P(C_6H_5)_2$, (*S*)-$NH_2CH(CH_3)CH_2P(C_6H_5)_2$, and *rac*-$NH_2CH_2CH_2P(C_4H_9)(C_6H_5)$ were prepared and resolved (or separated) into optical isomers, and their absorption and circular dichroism spectra were recorded. The molecular structure and the absolute configuration of $(+)_{589}$-*fac*-$[Co\{NH_2CH_2CH_2P(CH_3)_2\}_3]Br_3\cdot 3H_2O$ were determined by X-ray analysis. The crystals are lemon-yellow, orthorhombic, a=26.501(8), b=9.573(4), c=10.081(5) Å, space group $P2_12_12_1$, z=4. The Co atom is surrounded by 3P and 3N in the facial manner with the average distances of 2.237 and 2.041 Å, respectively. The absolute configuration of the complex ion is Δ. The chelate rings are puckered and chiral to form a pseudo λ gauche conformation.

Most of cobalt(III) complexes of tertiary phosphines so far known are those formed with unsaturated ligands such as dimethylglyoximate or acetylacetonate ions, and no complex with saturated ligands such as ammonia or ethylenediamine seems to be reported.[1] In a previous paper,[2] we have reported that (2-aminoethyl)diphenylphosphine and its related ligands, $NH_2CH(R^1)CH_2PR^2R^3$, give stable bis(acetylacetonato)cobalt(III)-type complexes, forming a five- membered chelate ring. This paper is concerned with preparation, resolution, and absorption and circular dichroism (CD) spectra of a series of complexes, $[Co(en)_n\{NH_2CH_2CH_2P(CH_3)_2\}_{3-n}]^{3+}$ (en=ethylenediamine, n=0, 1, 2), and the related complexes. These diamine–alkylphosphine complexes would be useful for studying ligand field absorption spectra of a cobalt(III)–phosphine complex of which little work has been done, since they have no unsaturated group which often shows strong absorption bands in the region where ligand field absorption bands would arise. The paper also reports the molecular structure and absolute configuration of $(+)_{589}$-*fac*-Δ-$[Co\{NH_2CH_2CH_2P(CH_3)_2\}_3]^{3+}$ determined by the X-ray method.

Experimental

Free aminoalkylphosphines were handled under nitrogen atmosphere until they formed air-stable cobalt(III) complexes. Absorption, CD, and ^1H and ^{13}C NMR spectra were recorded on a Hitachi 323 spectrophotometer, a JASCO J-40 spectropolarimeter, and JEOL JNM-PMX 60 and JNM-FX 100 spectrometers, respectively.

Preparation of Ligands. *(2-Aminoethyl)dimethylphosphine (edmp)*: To liquid ammonia (100 cm³) containing metallic sodium (1.08 g, 0.047 mol) in a 300 cm³ three-necked, round-bottomed flask equipped with a mechanical stirrer and an ammonia gas inlet was added tetramethyldiphosphine[3] (2.88 g, 0.024 mol) with stirring at −78 °C. After 30 min, 2-chloroethylamine hydrochloride (2.74 g, 0.024 mol) was added with small portions, giving a colorless solution. On evaporation of liquid ammonia, a mixture of a white solid and oily edmp was obtained. The edmp was extracted with chloroform (50 cm³). The chloroform was removed *in vacuo* to give transparent, colorless liquid of edmp (1.1 g). It was used for the preparation of complexes without further purification.

(2-Aminoethyl)diphenylphosphine (edpp),[4] *(S)-(2-aminopropyl)-diphenylphosphine (pdpp)*,[2] and racemic[5] and optically active[6] *(2-aminoethyl)butylphenylphosphine (ebpp)* were prepared according to the procedures reported.

Preparation of Complexes. *$[Co(edmp)_3]^{3+}$, $[Co(en)(edmp)_2]^{3+}$, and $[Co(en)_2(edmp)]^{3+}$*: These complexes and the known $[Co(en)_3]^{3+}$ complex were yielded by the reaction of *cis*-$[CoCl_2(en)_2]Cl$ with edmp in *N*,*N*-dimethylformamide (DMF). To a DMF solution (50 cm³) of *cis*-$[CoCl_2(en)_2]Cl$ (285 mg, 1 mmol) was added edmp (105 mg, 3 mmol) with stirring. The resulting blue-green solution was allowed to stirr overnight at room temperature to give a yellow precipitate, which was filtered and dissolved in water. The solution was poured onto a column (ϕ 2.7×80 cm) of SP-Sephadex C-25, and the product adsorbed was eluted with an aqueous 0.4 mol/dm³ NaBr solution. A good separation into four yellow bands was observed. The last orange yellow eluate contained $[Co(en)_3]^{3+}$. Each of the other three eluates was diluted ten times with water and poured again onto a small column of SP-Sephadex C-25. The complex adsorbed was eluted with an aqueous 1 mol/dm³ NaBr solution, and the eluate was concentrated in a vacuum desiccator over P_4O_{10} to give yellow crystals, which were filtered, washed with a small amount of water, and air-dried. The first, second, and third eluates gave racemates of $[Co(edmp)_3]Br_3\cdot 3H_2O$, $[Co(en)(edmp)_2]Br_3\cdot H_2O$, and $[Co(en)_2(edmp)]Br_3\cdot H_2O$, respectively. Although the first two complexes can have geometrical isomers, only one isomer was yielded for each of them, no indication for the presence of other isomers being observed on column chromatography. The total yield of the four complexes including $[Co(en)_3]^{3+}$ was *ca.* 70%, and the formation ratio was *ca.* 8:2:1:7 for $[Co(edmp)_3]^{3+}$: $[Co(en)(edmp)_2]^{3+}$: $[Co(en)_2(edmp)]^{3+}$: $[C(en)_3]^{3+}$.

The racemates were resolved by SP-Sephadex column chromatography. Each racemate charged on the top of a column (ϕ 2.7×80 cm) of SP-Sephadex C-25 was eluted with an aqueous 0.2 mol/dm³ sodium $(+)_{589}$-tartratoantimonate(III) solution. A good separation between enantiomers was observed. In the case of $[Co(edmp)_3]^{3+}$ lemon-yellow crystals of optically active $[Co(edmp)_3]Br_3\cdot 3H_2O$ were obtained by the same method as that for the racemate,

en: $NH_2CH_2CH_2NH_2$.

The enantiomer obtained from the faster moving band showed negative rotation at 589 nm (Λ-isomer). In the cases of $[Co(en)(edmp)_2]^{3+}$ and $[Co(en)_2(edmp)]^{3+}$, however, the enantiomers were not isolated because of small amounts, and the CD spectra were obtained by the following method. Each eluate of the enantiomers was diluted with water and poured onto a small column of SP-Sephadex C-25. After washing the column with 0.05 mol/dm^3 hydrochloric acid, the enantiomer was eluted with 1 mol/dm^3 hydrochloric acid. The eluate was evaporated to dryness under reduced pressure, and the residue was dissolved in water. On addition of $K_3[Co(CN)_6]$, a yellow precipitate was obtained. It was filtered, washed with water, and then mixed with Dowex 1×8 anion exchange resin in the bromide form and a small amount of water. The mixture was stirred for a few hours and filtered. The filtrate which contains the complex bromide was used for CD measurement, and its concentration was determined from ε values of the racemate. In all the resolutions, the Λ isomers were always eluted faster than their antipodes.

$[Co(en)_2(edpp)]^{3+}$. A DMF solution (50 cm^3) containing *cis*-$[CoCl_2(en)_2]Cl$ (363 mg) and edpp (292 mg) was stirred overnight at room temperature. The resulting brown solution was poured into 1 dm^3 of water to give a precipitate, which was filtered off. The filtrate was poured onto a column (ϕ 2.7×80 cm) of SP-Sephadex C-25, and the product adsorbed was eluted with an aqueous 0.2 mol/dm^3 Na_2SO_4 solution. Many bands were observed. The first and second orange yellow eluates contained $[Co(en)_3]^{3+}$ and $[Co(en)_2(edpp)]^{3+}$, respectively. The second eluate was evaporated to dryness under reduced pressure, and the complex was extracted with methanol. The extract was diluted with water and poured onto a column (ϕ 2.7×80 cm) of SP-Sephadex C-25. By elution with an aqueous 0.2 mol/dm^3 sodium $(+)_{589}$-tartratoantimonate(III) solution, two bands corresponding to a pair of enantiomers were obtained. Each eluate was diluted with water, poured again onto a small column of SP-Sephadex C-25, and the enantiomer adsorbed was eluted with an aqueous 1 mol/dm^3 NaBr solution. On concentration *in vacuo*, the eluate gave orange yellow crystals of optically active $[Co(en)_2(edpp)]Br_3\cdot 2H_2O$, which were collected and washed with a small amount of water. Yield: 30 mg for each enantiomer.

*$[Co(en)_2$(S-*pdpp*$)]^{+}$.* This complex was prepared by a method similar to that for the edpp complex using *S*-pdpp (242 mg) and *cis*-$[CoCl_2(en)_2]Cl$ (285 mg). A pair of diastereomers were separated by similar column chromatography using an aqueous 0.2 mol/dm^3 sodium $(+)_{589}$-tartratoantimonate(III) solution as an eluent. Yellow crystals of Λ-$[Co(en)_2(S$-pdpp$)]Br_3\cdot 2H_2O$ (55 mg) were isolated by a method similar to that for the edpp complex, but another diastereomer was not isolated because of a very small amount.

*$[Co(en)_2$(rac-*ebpp*$)]^{3+}$.* Four isomers of this complex were obtained by a method similar to that for the edpp complex, using *rac*-ebpp (252 mg) and *cis*-$[CoCl_2(en)_2]Cl$ (343 mg). By elution with an aqueous 0.2 mol/dm^3 Na_2SO_4 solution, the orange yellow band of $[Co(en)_3]^{3+}$ and two yellow bands, I and II were eluted in succession. Bands I and II correspond to a pair of racemates, $\Lambda(R)$ and $\Lambda(S)$, and $\Lambda(S)$ and $\Lambda(R)$ isomers, respectively. The former racemate was resolved by the same column chromatographic method as that for the edpp complex. Yellow crystals of Λ-$[Co(en)_2(R$-ebpp$)]Br_3\cdot 4NaBr$ (8 mg) were obtained from the faster moving eluate. However, the yield of the latter racemate was poor, and thus the complex was isolated as the racemate, $[Co(en)_2(rac$-ebpp$)]Br_3\cdot 2H_2O$ (3.9 mg). The CD spectrum was determined by a method similar to that for the en-edmp complexes without isolating the active complex, the $\Lambda(S)$ isomer being eluted faster.

Analytical data of the new complexes are given in Table 1.

Structure Determination of $(+)_{589}$-$[Co(edmp)_3]Br_3\cdot 3H_2O$. Crystal data: orthorhombic, a=26.501(8), b=9.573(4), c=10.081(5) Å, U=2557.5(15), D_m=1.73, D_c=1.73 g cm^{-3}, Z=4, μ(Mo $K\alpha$)=58.3 cm^{-1}, λ(Mo $K\alpha$)=0.7107 Å, space group $P2_12_12_1$. The Laue symmetry, space group extinctions, and approximate unit-cell dimensions were obtained from Weissenberg photographs. The unit-cell dimensions were refined by the least squares analysis of 38θ values automatically centered on a Phillips PW 1100 diffractometer by the use of Mo $K\alpha$ radiation. The intensity data (2θ=52°) were collected on the diffractometer using Graphite-monochromated Mo $K\alpha$ radiation. The specimen size was 0.17×0.18×0.28 mm^3. The ω-2θ scan mode was employed. The scan range was $(0.7+0.2\tan\theta)°$, and the scan speed, 0.025 °/s. The background was counted for half of the scan time as each end of the scan range. During the data collection, the intensities of 3 standard reflections were monitored every 4 h in order to check the orientation and stability of the crystal. No appreciable decay was observed. A total of 1924 reflections with $I>3\sigma(I)$ were observed and used in the subsequent structure determination and refinement. The observed intensities were corrected for Lorents-polarization and absorption effect, and the relative structure factors were derived.

The crystal structure was solved by the heavy-atom method. The parameters of all the non-hydrogen atoms were refined by the block-diagonal least-squares method, using anisotropic temperature factors for the Br, Co, and P atoms. The final agreement indices, R and $Rw=|W\Delta F^2/WF_o^2|^{1/2}$, were 6.57 and 6.55%, respectively. The function minimized was $\sum W(F_o-|F_c|)^2$, with $W=1/\sigma^2(F_o)$ being used. No attempt was made to locate H atoms. All the parameter shifts in the final cycle refinement were less than 0.5σ. The

final difference Fourier map was rather flat and showed no peak of structural significance. The atomic scattering factors were taken from Ref. 7. The real and imaginary parts of the anomalous dispersion correction were applied for the Br, Co, and P atoms. The atomic coordinates and the temperature factors are listed in Table 2. A complete list of observed and calculated structure factors is preserved by the Chemical Society of Japan (Document No. 8146).

The absolute configuration of the complex cation was determined by the anomalous dispersion technique. Table 3 gives the calculated structure amplitudes of several Bijvoet pairs and the observed inequality relationships which were obtained from Weissenberg photographs taken with Cu $K\alpha$ radiation. The observed relationships indicate that the absolute configuration of the complex ion is $\Lambda(\lambda\lambda\lambda)$.

Results and Discussion

Preparation and Properties of the Complexes. The reaction of edmp with *cis*-$[CoCl_2(en)_2]^+$ in the mole ratio of 3:1 in DMF under nitrogen atmosphere gives a series of complexes, $[Co(edmp)_3]^{3+}$, $[Co(en)(edmp)_2]^{3+}$, $[Co(en)_2(edmp)]^{3+}$, and $[Co(en)_3]^{3+}$ in the ratio of 8:2:1:7. The formation ratio of these tris-type complexes varies on changing the mole ratio of the starting materials. The reaction with a large excess of edmp affords almost only $[Co(edmp)_3]^{3+}$. However, the product obtained with an equivalent mole of the ligand involves the blue *trans*-$[CoCl_2(edmp)_2]^+$ complex, which can be isolated.[8] This suggests that the en ligands in *cis*-$[CoCl_2(en)_2]^+$ are easily replaced by edmp without dissociating the chloride ions. The fact that on addition of edmp the DMF solution of *cis*-$[CoCl_2(en)_2]^+$ changes almost instantly from violet to blue-green also implies the rapid formation of *trans*-$[CoCl_2(edmp)_2]^+$ (Experimental). The dichloro complex thus formed will be transformed to the tris en-edmp complexes by substitution reactions with free en or edmp ligands. On the other hand, the other phenyl- and diphenyl-(aminoalkyl)-phosphines form only $[Co(en)_2$(aminoalkylphos-

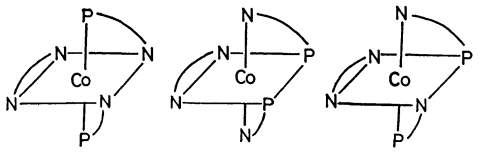

Fig. 1. Three geometrical isomers of $[Co(en)(N\text{-}P)_2]^{3+}$.

phine)]$^{3+}$ by similar reactions with *cis*-$[CoCl_2(en)_2]^+$. Aminoalkylphosphines with a bulky and electron withdrawing phenyl group on the phosphorus atom seem to have weaker affinity than edmp toward the cobalt(III) ion. All the aminoalkylphosphine complexes thus obtained are stable in both the solid state and aqueous solutions.

The $[Co(edmp)_3]^{3+}$ and $[Co(en)(edmp)_2]^{3+}$ complexes have two (*mer* and *fac*) and three (*trans*(P,P), *trans*(N,N), and *trans*(P,N)) possible geometrical isomers, respectively, for the arrangement of P and N atoms of edmp (Fig. 1). However, each complex gives only one isomer by the reactions under the conditions given. The *S*-pdpp complex which has a chiral carbon atom on the chelate ring yields almost one diastereomer stereoselectively, a very small amount of another diastereomer being observed in column chromatography. The *rac*-ebpp ligand has a chiral phosphorus donor atom and its bis-en complex gives a pair of racemates, $\Lambda(R)$ and $\Delta(S)$, and $\Lambda(S)$ and $\Delta(R)$, but there is also a fairly difference between the yields of the racemates. All racemates of the aminoalkylphosphine complexes were resolved completely by the SP-Sephadex column chromatographic method using 0.2 mol/dm^3 sodium $(+)_{589}$-tartratoantimonate(III) as an eluent. The Λ isomers are always eluted faster than the Δ isomers. The isomers are stable to racemization in aqueous solutions.

The Structure of $(+)_{589}$-$[Co(edmp)_3]Br_3\cdot 3H_2O$. A perspective view of the $(+)_{589}$-$[Co(edmp)_3]^{3+}$ ion is shown in Fig. 2. Table 4 gives the interatomic distances and bond angles within the complex ion. The complex ion has approximate C_3 symmetry, and the P atoms are arranged in the facial manner. The absolute configuration is determined to be Δ on the basis of the data given in Table 3. The chelate rings are puckered with a pseudo λ gauche form. The C–C bonds are nearly parallel to the C_3 axis of the complex ion. Thus, the complex ion can be designated as the $lel_3(\Delta(\lambda\lambda\lambda))$ isomer. The average Co–P distance of 2.237 Å is fairly short as compared with those (2.3—2.4 Å) reported for $[CoX(PR_3)(dmg)_2]$-type complexes (R=–C_6H_5, –C_4H_9; dmg=dimethylglyoximate ion).[9] The Co–N distance averages 2.041 Å, which is significantly longer than that of 1.978 Å in $[Co(en)_3]^{3+}$.[10] The elongation of Co–N distances can be attributed to the strong *trans* effect of the donating P atoms. Each ligand forms a five-membered chelate ring with an average P–Co–N angle of 84.8°, which is nearly the same as the average N–Co–N angle of 85.4° in $[Co(en)_3]^{3+}$.[10] The average distances of P–CH_3 and P–CH_2 are 1.827 and 1.859 Å, respectively. The average angle of P–Co–P (94.3°) is fairly larger than that of N–Co–N (85.8°), and the

TABLE 3. OBSERVED AND CALCULATED INTENSITIES BETWEEN SOME *hkl* AND $\bar{h}kl$ REFLECTIONS

hkl	$\lvert F_c(hkl)\rvert$	$\lvert F_c(\bar{h}kl)\rvert$	Observed
221	85	73	>
321	71	50	>
421	121	127	<
521	222	193	>
131	59	35	>
511	159	171	<
322	124	96	>
323	129	141	<
423	99	110	<

average Co–P–CH_3(//) angle of 122.7° is also larger than the other Co–P–CH_3($\perp$) and Co–P–CH_2 angles as shown in Table 4, where the CH_3(//) and CH_3($\perp$) denote those parallel and perpendicular to the C_3 axis of the complex ion, respectively. Thus the overcrowding due to the facial three CH_3(//) groups is relieved, although the non-bonded C···C distances (3.51—3.62 Å) among these CH_3(//) groups are still shorter than the sum of the van der Waals radius of a methyl group (4 Å). The non-bonded C···C distances between the CH_3($\perp$) and the P–CH_2 are also shorter than 4 Å. Such a crowded structure seems to afford the conformation of the chelate ring differing from the typical gauche form. The dihedral angles of the N–C–C–P moieties are 53.3°, 48.7°, and 44.3°.

The packing mode of the complex ions, bromide ions, and water molecules is illustrated in Fig. 3. Some short interatomic distances outside the complex ions are listed in Table 5. One out of three bromide ions lies approximately on the C_3 axis of the complex ion to form weak N–H···Br hydrogen bonds (3.38—3.56 Å) with three N–H atoms parallel to the C_3 axis in the three facial NH_2 groups. The other N–H groups are also linked by N–H···O or N–H···Br hydrogen bonds.

Absorption and CD Spectra. Absorption spectra of a series of the $[Co(en)_n(edmp)_{3-n}]^{3+}$ complexes are shown in Fig. 4, and the data given in Table 6. With an increase in the number of ligating phosphorus

atoms, the first absorption bands are shifted to higher wavenumbers and increase the intensity. The wavenumber difference in the first absorption bands between $[Co(edmp)_3]^{3+}$ and $[Co(en)_3]^{3+}$ amounts to 2300 cm^{-1}, and edmp stands at a fairly higher position than en in the spectrochemical series. The band of $[Co(edmp)_3]^{3+}$ is symmetrical and shows no splitting, which agrees with a pattern expected from Yamatera's rule[11] for a complex with C_3 symmetry (*fac* isomer). The *fac* structure was confirmed by X-ray analysis (*vide ante*). The $[Co(en)_2(edmp)]^{3+}$ complex gives the first absorption band at 22400 cm^{-1}. This value is just an average of those of *fac*-$[Co(edmp)_3]^{3+}$ and $[Co(en)_3]^{3+}$, and also agrees with that expected for one of two components split in the first absorption band.[11] Another component which should be at the same wavenumber as that of the first absorption band of $[Co(en)_3]^{3+}$ would be hidden by this strong component. The first absorption band of $[Co(en)(edmp)_2]^{3+}$ shows the maximum at 23700 cm^{-1} and a shoulder at 21000 cm^{-1}. These values quite agree with those calculated for the *trans*(P,P) isomer according to Yamatera's rule. Thus the complex can be assigned to the *trans*(P,P) isomer. However, the absorption spectrum of this complex is very similar over the whole region to that of $[Co(en)_2(P\text{–}P)]^{3+}$ (P–P=1,2-bis(dimethylphosphino)ethane), which forms necessarily *cis*(P,P) configuration.[12] In general, ligands which exhibit the strong *trans* effect such as a phosphine tend to occupy the *cis* positions to each other in metal complexes.[13] In fact, the $[Co(edmp)_3]^{3+}$ complex yielded only the *fac* isomer, despite its structure seems to be more crowded than

the *mer* isomer. In column chromatographic resolution using SP-Sephadex C-25 and a sodium $(+)_{589}$-tartratoantimonate(III) solution, the *Λ*-isomers are eluted faster for both $[Co(edmp)_3]^{3+}$ and $[Co(en)(edmp)_2]^{3+}$. For five-membered chelate complexes, it is reported that in complexes with three facial NH_2 groups which can form hydrogen bonds with the $(+)_{589}$-tartratoantimonate(III) ion, a *Λ* isomer is eluted almost always faster than the antipode.[14] For complexes with no such facial NH_2 groups; for example $[Co(en)_2(C_2O_4)]^+$ [14] and $[Co(en)_2(P\text{-}P)]^{3+}$ [12], the elution order is reversed to give a *Λ* isomer as the faster moving enantiomer. The $[Co(en)(edmp)_2]^{3+}$ complex can have the three facial NH_2 groups in only the *trans*(P,N) isomer. These considerations lead to the conclusion that $[Co(en)(edmp)_2]^{3+}$ is the *trans*-(P,N) isomer. This isomer has C_1 symmetry and the two edmp ligands are not in equivalent environment. Thus NMR spectroscopy would give useful information for assigning the structure. However, the ^1H NMR spectrum was too complicated to assign, and no good ^{13}C NMR spectrum was obtained because of the small amount of the complex. Thus the structure of $[Co(en)(edmp)_2]^{3+}$ remains unknown.

In contrast with the first absorption bands, the second absorption bands of the edmp complexes do not show any remarkable shift when en is replaced by edmp. Thus the energy difference between the first and the second absorption bands in the edmp complexes becomes small as compared with that in $[Co(en)_3]^{3+}$. The energy difference between the first and the second absorption bands is expressed by 16B, where *B* is the Racah's parameter of interelectronic repulsion.[15] The *B* value is known to be a measure for representing covalent character of the bond between a ligand and a metal ion, the smaller the value the more the covalent character.[16] The *B* values for *fac*-$[Co(edmp)_3]^{3+}$ and $[Co(en)_3]^{3+}$ are 406 and 506 cm^{-1}, respectively. The value of 406 cm^{-1} is as small as that of $[Co(CN)_6]^{3-}$ (416 cm^{-1}).[17] The coordinate bond between the edmp ligand and the cobalt(III) ion might involve fairly strong covalent character.

The edmp complexes show a strong absorption band around 40000 cm^{-1}, which can be assigned to the charge transfer band from the phosphine group to the cobalt(III) ion. With an increase in the number of ligating phosphorus atoms, these bands increase the intensity, while the absorptions around 46000 cm^{-1} which can be assigned to the charge transfer band from the amine group to the cobalt(III) ion decrease the intensity.

Absorption spectra of $[Co(en)_2(edpp)]^{3+}$ and $[Co(en)_2(ebpp)]^{3+}$ (lst fraction) are compared with that of $[Co(en)_2(edmp)]^{3+}$ in Fig. 5. By replacing the methyl group in edmp by a phenyl group, both the first and the charge transfer absorption bands are shifted progressively to smaller wavenumbers. The shift of the latter bands are particularly noticeable and the second absorption bands are hidden by these bands. The maximum wavenumber of the first absorption band of the edpp complex is nearly the same as that of $[Co(en)_3]^{3+}$.

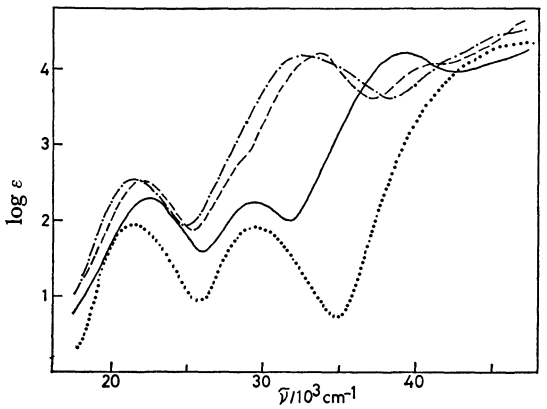

Fig. 5. Absorption spectra of $[Co(en)_2(edmp)]^{3+}$ (——), $[Co(en)_2(ebpp)]^{3+}$ (----), $[Co(en)_2(edpp)]^{3+}$ (—·—), and $[Co(en)_3]^{3+}$ (·····).

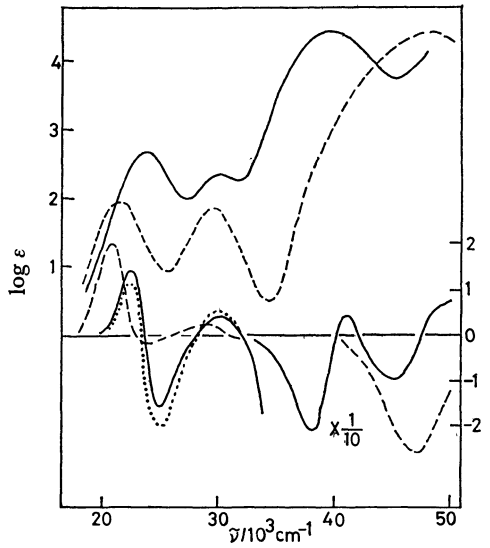

Fig. 6. Absorption and CD spectra of *Λ*-*fac*-$[Co(edmp)_3]^{3+}$ in water (——) and in 0.1 mol/dm³ PO_4^{3-} (·····), and *Λ*-$[Co(en)_3]^{3+}$ in water (----).

The CD spectrum of $(-)_{589}$-*Λ*-*fac*-$[Co(edmp)_3]^{3+}$ is compared with that of *Λ*-$[Co(en)_3]^{3+}$ in Fig. 6. Both complexes show a similar CD pattern in the first absorption band region, although the negative component of *Λ*-*fac*-$[Co(edmp)_3]^{3+}$ is very strong. On addition of phosphate ions, the positive and the negative components are diminished and enhanced, respectively. The same effect is well known to occur in the CD spectrum of *Λ*-$[Co(en)_3]^{3+}$.[17] In the ultraviolet region, a negative and a positive CD band are observed corresponding to each charge transfer band from the phosphine and the amine groups to the cobalt(III) ion. The appearance of the negative CD band in the small wavenumber side in each charge transfer region is the same as cases of tris-diamine complexes in the *Λ* configuration.[18] Thus the CD spectrum of *fac*-$[Co(edmp)_3]^{3+}$ can be understood on the basis of that of $[Co(en)_3]^{3+}$. Figure 7 shows the CD spectra of $[Co(en)_n(edmp)_{3-n}]^{3+}$, all of which are eluted faster on column chromatography. All the complexes can be assigned to *Λ* configuration

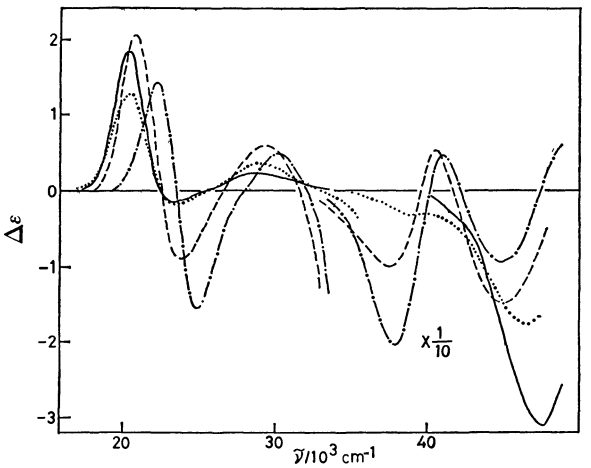

Fig. 7. CD spectra of *Λ*-$[Co(edmp)_3]^{3+}$ (—·—·—), *Λ*-$[Co(en)(edmp)_2]^{3+}$ (----), *Λ*-$[Co(en)_2(edmp)]^{3+}$ (·····), and *Λ*-$[Co(en)_3]^{3+}$ (——).

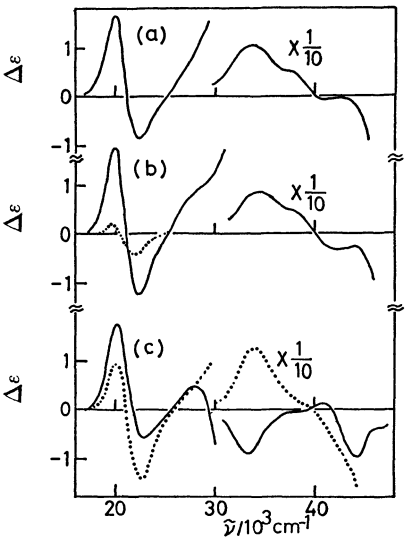

Fig. 8. CD spectra of *Λ*-$[Co(en)_2(N-P)]^{3+}$. N-P: (a) edpp, (b) *S*-pdpp (——) and the vicinal effect curve of *S*-pdpp (·····) (see text), and (c) *R*-ebpp (——) and *S*-ebpp (·····).

from the CD patterns in the first absorption band region. The CD bands corresponding to the charge transfer transitions from the phosphine and the amine groups to the cobalt(III) ion decrease or increase the strength depending on the number of phosphorus or nitrogen donor atoms. In Fig. 8 are shown the CD spectra of $[Co(en)_2(N-P)]^{3+}$ (N–P=edpp, *S*-pdpp, and *S*- and *R*-ebpp). The CD patterns in the first absorption band region are all similar, and these enantiomers can be assigned to *Λ* configuration. However, the CD spectra in the ultraviolet region differ from those of the edmp complexes probably because of the presence of the phenyl group or the chiral phosphorus or carbon atom. The absolute configurations of the phosphorus atoms in the diastereomeric ebpp complexes were assigned by comparing the CD spectra with those of the authentic complexes prepared by use of optically active *S*-ebpp.[6,19]

The *S*-pdpp complex involves a chiral chelate ligand.

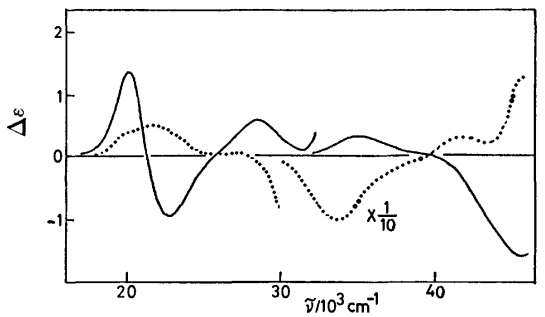

Fig. 9. Configurational(Λ) (——) and vicinal(R) (……) effect CD curves of $[Co(en)_2(ebpp)]^{3+}$.

When the additivity[20] in CD between the configurational and vicinal effects holds in the CD of this complex, the vicinal effect of S-pdpp can be estimated by subtracting the CD spectrum of Λ-$[Co(en)_2(edpp)]^{3+}$ from that of Λ-$[Co(en)_2(S\text{-pdpp})]^{3+}$. The vicinal CD curve thus obtained quite resemble those of (S)-propylenediamine (S-pn) chelate ligands in some S-pn complexes[20-22] (Fig. 8), indicating the same conformational chirality for both S-pdpp and S-pn chelate rings. Thus the S-pdpp chelate ring is assumed to be stabilized in a δ gauche conformation with the equatorial methyl group as seen in the S-pn chelate ring.[23] The ebpp complex has a chiral donating phosphorus atom, and gives a pair of diastereomers, $\Lambda(R)$ and $\Lambda(S)$. These diastereomers show a similar CD pattern in the first absorption band region, but give a CD band with the different sign from each other around 34000 cm^{-1}, where the charge transfer transition between the phosphine group and the cobalt(III) ion arises. From these CD spectra, the configurational (Λ) and vicinal (R) curves are obtained by the usual method[20] (Fig. 9). The configurational CD curve resembles the CD spectra of the other aminoalkylphosphine complexes. The curve in the ultraviolet region seems to be an average of the CD spectra of the edpp and the emdp complexes. The vicinal CD curve shows a positive and a negative peak in the regions of the first and the charge transfer, from the phosphine group to the cobalt(III) ion, bands, respectively. The vicinal effect of chiral phosphorus atoms donating to the cobalt(III) ion is only known for the $[Co(acac)_2(ebpp)]^+$ (acac=acetylacetonate ion).[2] In order to discuss such optical activity, more data will be needed.

Isomers of Tris[(*R*)-1-phenyl-1,2-ethanediamine]- and Tris[(*S*)-3,3-dimethyl-1,2-butanediamine]cobalt(III), and the Related Complexes

Masaaki Kojima and Junnosuke Fujita*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 21, 1981)

The $[Co\{(R)\text{-1-phenyl-1,2-ethanediamine}\}_3]^{3+}$ complex yielded all of the four possible isomers, *mer*-$\Lambda(lel_3)$, *mer*-$\Lambda(ob_3)$, *fac*-$\Lambda(lel_3)$, and *fac*-$\Lambda(ob_3)$, while the $[Co\{(S)\text{-3,3-dimethyl-1,2-butanediamine}\}_3]^{3+}$ complex gave only two isomers of *mer*-$\Lambda(lel_3)$ and *fac*-$\Lambda(lel_3)$. Two isomers, $\Lambda(lel_3)$ and $\Delta(ob_3)$ of the $[Co\{(S,S)\text{-2,3-butanediamine}\}_3]^{3+}$ complex were obtained. The formation ratios of these tris(1,2-diamine)cobalt(III) complexes were compared with those of the analogous complexes and discussed. The tetraammine complexes of all those diamines were also prepared. Absorption and circular dichroism spectra of all the complexes were recorded.

Recently Bernth and Larsen[1] isolated three out of four possible isomers of $[Co(R\text{-pen})_3]^{3+}$ (*R*-pen=(*R*)-1-phenyl-1,2-ethanediamine), and reported their circular dichroism (CD) spectra. This paper deals with the isolation and CD spectra of all the isomers. The CD spectrum of one isomer (*mer*-$\Lambda(ob_3)$) reported by Bernth and Larsen differs markedly from that obtained in this study. The present paper also reports the preparation and CD spectra of two isomers of $[Co(S\text{-dmbn})_3]^{3+}$ (*S*-dmbn=(*S*)-3,3-dimethyl-1,2-butanediamine), two isomers of $[Co(SS\text{-2,3-bn})_3]^{3+}$ (*SS*-2,3-bn=(*S,S*)-2,3-butanediamine), and the tetraammine complexes of those diamines. The *R*-pen and *S*-dmbn ligands have a bulky substituent on the carbon atom, and the *SS*-2,3-bn the methyl group on each carbon atom.

Experimental

Ligands. 1-Phenyl-1,2-ethanediamine (pen) was obtained by reducing 2-amino-2-phenylethaneamide which was derived from 2-amino-2-phenylacetic acid (Tokyo Kasei Co.), with $LiAlH_4$ according to the known method,[2] and resolved with (+)-tartaric acid to give *R*-pen by the method of Reihlen *et al.*[3] Optically active *R*-pen was also derived from (−)-(*R*)-2-amino-2-phenylacetic acid (Aldrich Chem. Co.) by the same method. However, the product was not optically pure so that the procedure of resolution given above was necessary.

(+)-(*S*)-3,3-Dimethyl-1,2-butanediamine (*S*-dmbn) was obtained by the method of Hawkins and Peachey.[4] The dihydrochloride salt (*S*-dmbn·2HCl) was used to prepare cobalt(III) complexes.

2,3-Butanediamine (2,3-bn) was prepared by the method of Bailar *et al.*[5] and separated into the *meso* and *racemic* isomers by the method of Billo and Vitiello.[6] The (+)-*SS*-2,3-bn isomer was obtained from the racemate by the method of Dickey *et al.*[7]

mer-Δ- *and* fac-Δ-$[Co(\text{R-}pen)_3]Cl_3\cdot 2.5H_2O$, mer-Λ-$[Co(\text{R-}pen)_3]Cl_3\cdot 3H_2O$, *and* fac-Λ-$[Co(\text{R-}pen)_3]Cl_3\cdot 4H_2O$.
A mixture of $[Co(NH_3)_5(H_2O)](ClO_4)_3$ (0.5 g, 1.1 mmol), *R*-pen (0.68 g, 5 mmol), and active charcoal (0.2 g) in 30 cm³ of water was heated at 60 °C for 5 h, and filtered. The filtrate was diluted with 1 dm³ of water and passed through an SP-Sephadex column ($\phi 2.7\times 3$ cm). The Sephadex charged with the product was placed on the top of an SP-Sephadex column ($\phi 2.7\times 120$ cm). By elution with 0.2 mol/dm³ Na_2SO_4, the orange band separated into four bands, I, II, III, and IV named in the order of elution, which were *mer*-Δ, *fac*-Δ, *mer*-Λ, and *fac*-Λ isomers of $[Co(R\text{-pen})_3]^{3+}$, respectively. Each eluate was diluted with water and poured again on a small column of SP-Sephadex. After the column had been washed with 10^{-2} mol/dm³ HCl (*ca.* 5 dm³), the adsorbed complex was eluted with 1 mol/dm³ HCl. The eluate was concentrated in a vacuum desiccator over P_2O_5 and NaOH to give orange crystals, which were filtered and washed with a small amount of water. The total yield was almost quantitative, and the formation ratio, I:II:III:IV was *ca.* 17:8:4:1. I. Found: C, 46.5; H, 6.6; N, 13.8%. II. Found: C, 46.6; H, 6.7; N, 13.8%. Calcd for $[Co(\text{R-pen})_3]Cl_3\cdot 2.5H_2O$: C, 46.6; H, 6.7; N, 13.6%. III. Found: C, 45.6; H, 6.7; N, 13.6%. Calcd for $[Co(\text{R-pen})_3]Cl_3\cdot 3H_2O$: C, 45.9; H, 6.7; N, 13.4%. IV. Found: C, 44.6; H, 6.3; N, 12.8%. Calcd for $[Co(R\text{-pen})_3]Cl_3\cdot 4H_2O$: C, 44.6; H, 6.9; N, 13.0%.

mer-Λ- *and* fac-Λ-$[Co(\text{S-}dmbn)_3](ClO_4)_3\cdot 3H_2O$. The $[Co(S\text{-dmbn})_3]^{3+}$ complex was prepared and separated into the isomers by a method similar to that for $[Co(R\text{-pen})_3]^{3+}$, using *S*-dmbn which was obtained by neutralizing the dihydrochloride with an aqueous NaOH solution, instead of *R*-pen. Only two isomers, A(*mer*-Λ) and B(*fac*-Λ) were yielded in nearly the same amount, A being eluted faster than B in column chromatography. The isomers were isolated as perchlorates by use of 1.5 mol/dm³ $HClO_4$ instead of 1 mol/dm³ HCl. Yield: *ca.* 40% for each isomer. A. Found: C, 28.8; H, 7.1; N, 11.0%. B. Found: C, 28.5; H, 6.8; N, 11.0%. Calcd for $[Co(\text{S-dmbn})_3](ClO_4)_3\cdot 3H_2O$: C, 28.5; H, 7.2; N, 11.1%.

The $[Co(S\text{-dmbn})_3]^{3+}$ complex was also obtained by mixing a methanol solution (15 cm³) of *trans*-$[CoCl_2(\text{pyridine})_4]Cl\cdot 6H_2O$ (0.59 g, 1 mmol)[8] and a methanol solution (15 cm³) containing *S*-dmbn·2HCl (0.57 g, 3 mmol) and $NaOCH_3$ (0.32 g, 6 mmol). The reaction took place almost instantly to give a yellow solution. It was diluted with water and chromatographed by the same method as the above to give the *mer*-Λ and *fac*-Λ isomers. The formation ratio, *mer*-Λ: *fac*-Λ was 3:1, no Δ isomer being yielded.

Λ-$[Co(\text{SS-}2,3\text{-}bn)_3]Cl_3\cdot 1.5H_2O$ *and* Δ-$[Co(\text{SS-}2,3\text{-}bn)_3]Cl_3\cdot 5H_2O$. Two isomers of $[Co(SS\text{-2,3-bn})_3]^{3+}$ were obtained by a method similar to that for $[Co(R\text{-pen})_3]^{3+}$ using *SS*-2,3-bn instead of *R*-pen. The formation ratio of the $\Lambda(lel_3)$ to the $\Delta(ob_3)$ isomers was *ca.* 10:1. The Λ isomer. Found: C, 31.7; H, 8.6; N, 18.1%. Calcd for $[Co(SS\text{-2,3-bn})_3]Cl_3\cdot 1.5H_2O$: C, 31.7; H, 8.6; N, 18.4%. The Δ isomer. Found: C, 28.0; H, 8.7; N, 16.5%. Calcd for $[Co(SS\text{-2,3-bn})_3]Cl_3\cdot 5H_2O$: C, 27.7; H, 8.9; N, 16.2%.

$[Co(NH_3)_4(\text{R-}pen)](ClO_4)_3\cdot 2H_2O$ *and* $[Co(NH_3)_4(\text{S-}dmbn)](ClO_4)_3$. These complexes were prepared from $[Co(NH_3)_5(H_2O)](ClO_4)_3$ and *R*-pen or *S*-dmbn·2HCl in dimethyl sulfoxide (DMSO) by a method similar to that reported.[9,10] Yield: *ca.* 20% (*R*-pen complex). *ca.* 10% (*S*-dmbn complex). The *R*-pen complex. Found: C, 16.2; H, 4.7; N, 14.1%. Calcd for $[Co(NH_3)_4(R\text{-pen})](ClO_4)_3\cdot 2H_2O$: C, 16.1; H, 4.7; N, 14.1%. The *S*-dmbn complex. Found: C, 13.4; H, 5.1; N, 15.8%. Calcd for $[Co(NH_3)_4$-

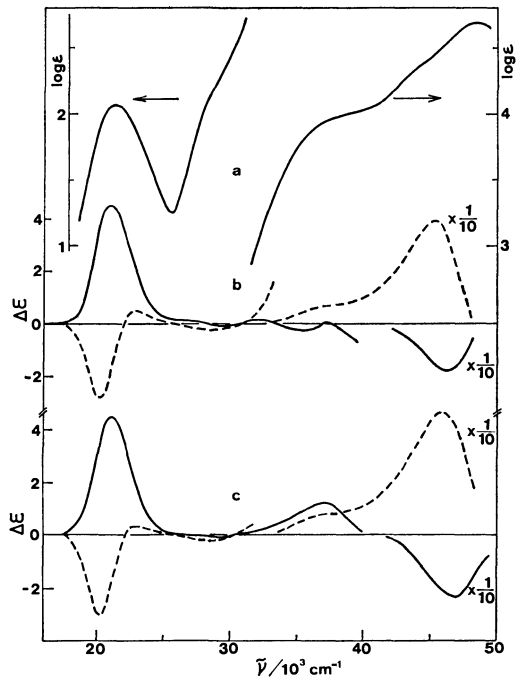

Fig. 1. a: Absorption spectrum of *fac*-*Λ*-[Co(*R*-pen)$_3$]$^{3+}$ (IV). b: CD spectra of *fac*-*Λ*-[Co(*R*-pen)$_3$]$^{3+}$ (IV) (——) and *fac*-*Δ*-[Co(*R*-pen)$_3$]$^{3+}$ (II) (----). c: CD spectra of *mer*-*Λ*-[Co(*R*-pen)$_3$]$^{3+}$ (III) (——) and *mer*-*Δ*-[Co(*R*-pen)$_3$]$^{3+}$ (I) (----).

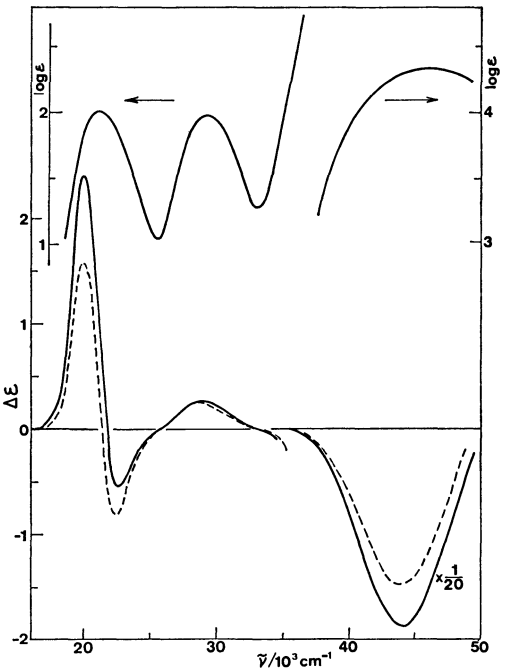

Fig. 2. Absorption spectrum of *mer*-*Λ*-[Co(*S*-dmbn)$_3$]$^{3+}$ (A), and CD spectra of *mer*-*Λ*-[Co(*S*-dmbn)$_3$]$^{3+}$ (A) (——) and *fac*-*Λ*-[Co(*S*-dmbn)$_3$]$^{3+}$ (B) (----).

(*S*-dmbn)](ClO$_4$)$_3$: C, 13.3; H, 5.2; N, 15.8%.

[Co(NH$_3$)$_4$(SS-2,3-bn)](ClO$_4$)$_3$. This complex was prepared by a method similar to that of Mizukami *et al.*[11] for the corresponding (*R*,*R*)-2,4-pentanediamine complex. The method for the above *R*-pen and *S*-dmbn complexes gives a large amount of [Co(*SS*-2,3-bn)$_3$]$^{3+}$ owing to disproportionation. The NH$_4$[Co(SO$_3$)$_2$(NH$_3$)$_2$(*SS*-2,3-bn)] complex (not analyzed) prepared from NH$_4$[Co(SO$_3$)$_2$-(NH$_3$)$_4$][12] and *SS*-2,3-bn was allowed to react with 47% hydrobromic acid to yield *trans*(Br,Br)-[CoBr$_2$(NH$_3$)$_2$(*SS*-2,3-bn)]Br (not analyzed). It was dissolved in liquid ammonia to give an orange solution. A crude complex which remained on evaporation of the liquid ammonia was purified by column chromatography with SP-Sephadex. The complex was isolated as perchlorate by a method similar to that for [Co(*S*-dmbn)$_3$]$^{3+}$. Yield: *ca.* 10%. Found: C, 9.2; H, 4.6; N, 16.7%. Calcd for [Co(NH$_3$)$_4$(*SS*-2,3-bn)] (ClO$_4$)$_3$: C, 9.4; H, 4.7; N, 16.4%.

Equilibrium Studies. Each isomer of *mer*-*Λ*- and *fac*-*Λ*-[Co(*S*-dmbn)$_3$](ClO$_4$)$_3$ was refluxed in water (50 cm^3) in the presence of active charcoal (0.1 g) for 3—8 h. The charcoal was filtered off and the filtrate was subjected to SP-Sephadex column chromatography in order to see the distributions of isomers. The ratio, *mer*-*Λ*:*fac*-*Λ*=1:1 was obtained, no formation of the *Δ* isomer being observed. The *Λ*-[Co(*SS*-2,3-bn)$_3$]Cl$_3$·1.5H$_2$O complex was equilibrated by the same method, giving the ratio, *Λ*:*Δ*=10:1. The ratios for both complexes thus obtained are the same as the respective formation ratios obtained when the complexes were prepared in the presence of active charcoal. Equilibration of [Co(*R*-pen)$_3$]$^{3+}$ by the same method as the above was accompanied with reduction of Co(III) to Co(II).

Measurements. Absorption and CD spectra were recorded on a Hitachi 323 spectrophotometer and a JASCO J-40CS spectropolarimeter, respectively. ^{1}H NMR spectra in DMSO-d_6 solutions and ^{13}C NMR spectra in DMSO solutions were obtained with a JEOL PMX-60 and a JEOL FX-60 spectrometer, respectively.

Results and Discussion

Four isomers (I, II, III, IV) of the [Co(*R*-pen)$_3$]$^{3+}$ complex are easily assigned on the basis of the ^{13}C NMR and CD spectra. II and IV give only one kind of signal for each resonance of the methylene (II, 49.3 ppm; IV, 49.8 ppm) and methine (II, 61.2 ppm; IV 60.4 ppm) carbons, while I and III show more than two signals (unresolved peaks) for each of the corresponding carbons. Thus the former two and the latter two can be assigned to the *fac*(C_3) and *mer*(C_1) configurations, respectively. In the first absorption band region, I and II show a negative main CD band, and III and IV a strong positive CD band (Fig. 1). Thus I, II, III, and IV are assigned to the *mer*-*Δ*, *fac*-*Δ*, *mer*-*Λ*, and *fac*-*Λ* isomers, respectively. The [Co(*S*-dmbn)$_3$]$^{3+}$ complex yielded only two isomers, A and B out of four possible isomers. ^{1}H NMR spectra of A and B exhibit two and one signals, respectively, in the resonance region of the t-butyl group. Both isomers show a similar CD pattern which is characteristic of the *Λ* configuration (Fig. 2). Thus A and B can be assigned to the *mer*-*Λ* and *fac*-*Λ* isomers, respectively.

The *Δ*- and *Λ*-[Co(*R*-pen)$_3$]$^{3+}$, and *Λ*-[Co(*S*-dmbn)$_3$]$^{3+}$ complexes have the *lel*$_3$, *ob*$_3$, and *lel*$_3$ structures, respectively, since the *R*-pen and *S*-dmbn chelate rings should be stabilized in the *λ* and *δ* conformations, respectively, with the phenyl or *t*-butyl group disposed equatorially. For a [Co(1,2-diamine)$_3$]$^{3+}$ complex, the *lel*$_3$ isomer is known to be more stable than the *ob*$_3$ one.[13] The relative amounts of the *lel*$_3$ to the *ob*$_3$

isomers in equilibrium at 373 K for $[Co(R\text{-pn})_3]^{3+}$ (*R*-pn=(*R*)-1,2-propanediamine),[14] $[Co(SS\text{-2,3-bn})_3]^{3+}$, and $[Co(RR\text{-chxn})_3]^{3+}$ (*RR*-chxn=(*R*,*R*)-*trans*-1,2-cyclohexanediamine)[15] are 8.8:1, 10:1, and 14:1, respectively. In the present study, $[Co(S\text{-dmbn})_3]^{3+}$ yielded only the *lel*$_3$ form by either preparative method and by heating the complex in water with active charcoal (Experimental). The relative stability of the *ob*$_3$ to the *lel*$_3$ isomers seems to decrease as the substituent becomes larger and the number of the substituent increases.

On the other hand, the formation ratio of the *lel*$_3$ to the *ob*$_3$ isomers of $[Co(R\text{-pen})_3]^{3+}$ was 5:1. Although the equilibration study was unsuccessful because of decomposition of the complex, this value can be regarded as that at equilibrium, since the reaction was carried out by prolonged heating in the presence of active charcoal (Experimental). The value of 5:1 indicates that the *ob*$_3$ isomer of $[Co(R\text{-pen})_3]^{3+}$ is fairly stable as compared with those of the other complexes given above, despite the ligand has a bulky phenyl substituent. Bosnich and Harrowfield[16] reported that for the $[Co\{(-)\text{-dpen}\}_3]^{3+}$ complex ((−)-dpen=(−)-1,2-diphenyl-1,2-ethanediamine), in which each chelate ring has two phenyl substituents, the (−)-isomer predominates to the extent of at least 90% over the (+)-isomer at equilibrium. Later Kuroda and Mason[17] determined the absolute configuration of (+)-$[Co\{(-)\text{-dpen}\}_3]^{3+}$ by X-ray analysis to be Λ(*lel*$_3$)-$[Co(SS\text{-dpen})_3]^{3+}$. These reports show that in $[Co(SS\text{-dpen})_3]^{3+}$ the *ob*$_3$ isomer is much more stable than the *lel*$_3$ one. Thus it is concluded that tris-type complexes of 1,2-diamines with phenyl substituents tend to stabilize the *ob*$_3$ isomer, contrary to those of 1,2-diamines with alkyl substituents.

It is known that the *mer* and *fac* isomers of $[Co(R\text{-pn})_3]^{3+}$ with the same absolute configuration give essentially the same CD spectra.[18] The corresponding isomers of $[Co(R\text{-pen})_3]^{3+}$ show a small difference in the CD spectra, but there is a fairly large difference between *mer*- and *fac*-Λ-$[Co(S\text{-dmbn})_3]^{3+}$. In the first absorption band region, the CD patterns of Δ(*lel*$_3$) and Λ(*ob*$_3$) isomers of $[Co(R\text{-pen})_3]^{3+}$ (*mer* and *fac*)

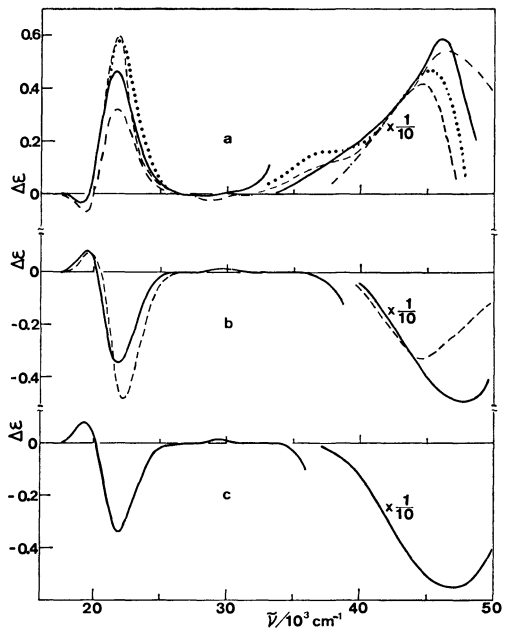

Fig. 3. a: Observed CD spectra of $[Co(NH_3)_4(R\text{-pen})]^{3+}$ (——) and $[Co(NH_3)_4(R\text{-pn})]^{3+}$ (—·—·—), and calculated CD curves, $1/6\{\Delta\varepsilon(fac\text{-}\Lambda\text{-}[Co(R\text{-pen})_3]^{3+}) + \Delta\varepsilon(fac\text{-}\Delta\text{-}[Co(R\text{-pen})_3]^{3+})\}$ (----) and $1/6\{\Delta\varepsilon(mer\text{-}\Lambda\text{-}[Co(R\text{-pen})_3]^{3+}) + \Delta\varepsilon(mer\text{-}\Delta\text{-}[Co(R\text{-pen})_3]^{3+})\}$ (....). b: Observed CD spectrum of $[Co(NH_3)_4(SS\text{-2,3-bn})]^{3+}$ (——) and calculated CD curve, $1/6\{\Delta\varepsilon(\Lambda\text{-}[Co(SS\text{-2,3-bn})_3]^{3+}) + \Delta\varepsilon(\Delta\text{-}[Co\text{-}(SS\text{-2,3-bn})_3]^{3+})\}$ (----). c: CD spectrum of $[Co(NH_3)_4(S\text{-dmbn})]^{3+}$.

quite resemble those of Δ- and Λ-$[Co(R\text{-pn})_3]^{3+}$ (*mer* and *fac*), respectively, although the CD strengths of $\Lambda(ob_3)$ isomers of the *R*-pen complex are much larger than those of the corresponding isomers of the *R*-pn complex (Table 1). The CD strength of *mer*-$\Lambda(ob_3)$-$[Co(R\text{-pen})_3]^{3+}$ reported by Bernth and Larsen[1] is about 2.5 times as small as ours. For tris(1,2-diamine)–cobalt(III) complexes reported so far, the ob_3 isomer gives always stronger CD than does the lel_3 one in the first absorption band region.

The vicinal CD curve of *R*-pen derived from the CD spectra of *fac*-Λ and *fac*-Λ (or *mer*-Λ and *mer*-Λ) isomers of $[Co(R\text{-pen})_3]^{3+}$ is similar to the observed CD spectrum of $[Co(NH_3)_4(R\text{-pen})]^{3+}$ over the whole region (Fig. 3). The CD patterns of $[Co(NH_3)_4(R\text{-pen})]^{3+}$ and $[Co(NH_3)_4(R\text{-pn})]^{3+}$ are very similar in the first absorption band region, although the CD strength of the former is fairly larger than that of the latter. The vicinal CD curve of *SS*-2,3-bn derived from Δ- and Λ-$[Co(SS\text{-2,3-bn})_3]^{3+}$ resembles the observed CD spectrum of $[Co(NH_3)_4(SS\text{-2,3-bn})]^{3+}$. The CD patterns of $[Co(NH_3)_4(SS\text{-2,3-bn})]^{3+}$ and $[Co(NH_3)_4(S\text{-dmbn})]^{3+}$ are almost mirror images of those of the corresponding *R*-pen and *R*-pn complexes. These results indicate that the *R*-pen and *S*-dmbn chelate rings are stabilized in the λ and δ gauche conformations, respectively, and that the vicinal effects of chiral 1,2-diamines in the $[CoN_6]$-type complexes are little dependent on the kind and the number of substituents on skeletal carbon atoms.

Kinetics and Mechanism of Cobalt(II) Incorporation into *meso*-Tetra(4-pyridyl)porphine in Acetic Acid[1)]

Shigenobu Funahashi, Keiji Saito, and Motoharu Tanaka*

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 30, 1981)

The kinetics of reactions of *meso*-tetra(4-pyridyl)porphine (H_2TPyP) with cobalt(II) acetate and cobalt(II) nitrate was studied in acetic acid spectrophotometrically. The rate of cobalt incorporation into H_2TPyP is first-order in H_2TPyP. The conditional first-order rate constants are expressed as follows: for the cobalt(II) acetate system $k_{0(Co)}=K[Co(OAc)_2]_0(1+K[Co(OAc)_2]_0)^{-1}(k_1+k_2[Co(OAc)_2]_0)$, where at 25 °C $K=(5.5\pm2.0)\times10^4$ kg mol^{-1} ($\Delta H=-36\pm15$ kJ mol^{-1}, $\Delta S=-30\pm30$ J mol^{-1} K^{-1}), $k_1=(6.3\pm0.5)\times10^{-5}$ s^{-1} ($\Delta H^*=89\pm8$ kJ mol^{-1}, $\Delta S^*=-27\pm15$ J mol^{-1} K^{-1}), and $k_2=(1.17\pm0.05)\times10^{-1}$ kg mol^{-1} s^{-1} ($\Delta H^*=75\pm3$ kJ mol^{-1}, $\Delta S^*=-11\pm8$ J mol^{-1} K^{-1}); for the cobalt nitrate system $k_{0(Co)}=K_1[Co(NO_3)_2]_0(1+K_1[Co(NO_3)_2]_0)^{-1}(k_1+k_2[Co(NO_3)_2]_0+k_3K_2[Co(NO_3)_2]_0^2)$, where at 25 °C $k_1=(5.1\pm0.5)\times10^{-5}$ s^{-1}, $k_2=(2.0\pm0.1)\times10^{-1}$ kg mol^{-1} s^{-1}, $K_1=(7.2\pm2.0)\times10^4$ kg mol^{-1}, and $k_3K_2=(1.6\pm0.15)\times10^2$ kg^2 mol^{-2} s^{-1}. Formation constants of sitting-atop complexes were determined dynamically. Mechanisms are proposed for metal ion incorporation and some discussions are made on the difference in the reactivities of acetate and nitrate of cobalt(II) in acetic acid.

Metalloporphyrins are ubiquitous in living systems. For understanding the possible role of enzymatic catalysis of a variety of porphyrins related to biologically relevant material and the metalation mechanism from the viewpoint of coordination chemistry, thorough kinetic studies are required. Several reviews of metalloporphyrin formation are available.[2-4)]

Metalloporphyrins in which the metal is bonded to fewer than four nitrogen atoms, sitting-atop complexes, have been considered as models for the initial steps of the metalation of the macrocycle. Such complexes are known for rhenium and technetium,[5)] platinum,[6)] and rhodium.[7,8)] Several examples of mercury complexes have also been formulated.[9-11)]

Recently Hambright,[12)] Krishnamurthy,[13)] and Lavallee[14)] have proposed mechanisms for the formation of metalloporphyrins. Despite the numerous investigations on the formation of metalloporphyrins, many of basic features of the reaction are still conjectural.

We have investigated the rates of reaction of *meso*-tetra(4-pyridyl)porphine with cobalt(II) acetate and cobalt(II) nitrate in acetic acid. Similar measurements have been made in acetic acid/water solutions,[15)] where the nature of the metal ion reactants is often in doubt. We describe the kinetic proof for the existence of a cobalt(II) porphyrin sitting-atop complex. In acetic acid metal salts are all in the undissociated form, since it is a non-dissociating solvent having low dielectric constant ($D=6.18$ at 20 °C).[16)] Thus in this solvent we have no complication arising from the presence of dissociated anions and from ionic strentgh.

Experimental

Reagents. It is very important that all reagents be as dry as possible. Therefore, extreme care was taken in the purification and preparation of all reagents and compounds. Solutions of reagents were prepared in a glove box filled with dried air.

Anhydrous Acetic Acid: The preparation of acetic acid was described previously.[17)] The amount of water in the acetic acid was less than 9×10^{-3} %.

Porphyrin: *meso*-Tetra(4-pyridyl)porphine (Strem Chemicals) was chromatographed on an alumina column by elution with chloroform.

Cobalt(II) Acetate: Thirty grams of cobalt(II) acetate hydrate was refluxed in 300 cm^3 of acetic anhydride for 3 h. After centrifugation the precipitates were washed four times with anhydrous acetic acid. The crystals $(Co(OAc)_2\cdot4HOAc)$ were dried at 120 °C for 3 h to obtain $Co(OAc)_2$. The quantitative change of $Co(OAc)_2\cdot4HOAc$ to $Co(OAc)_2$ was confirmed thermogravimetrically.

Cobalt(II) Nitrate: Reagent grade cobalt(II) nitrate hydrate was recrystallized from distilled water. The hydrate was dissolved in acetic acid. Acetic anhydride equivalent to the water involved was added to the cobalt(II) nitrate solution. Several days were required for complete reaction of water with acetic anhydride. The concentration of cobalt was standardized against EDTA using Methylthymol Blue as indicator.

Ammonium Nitrate: Reagent grade ammonium nitrate was recrystallized from water. The crystals were dried at 120 °C for 3 h under reduced pressure.

Cobalt(II) acetate, ammonium nitrate, and porphyrin solutions were prepared by weighing corresponding crystals. We use molal units (mol kg^{-1}).

Measurements. Spectral measurements were performed on a highly sensitive spectrophotometer (SM401, Union Giken Co., Ltd.). The concentration of water was determined by the Karl-Fisher aquametry. A thermogravimeter (Thermal Analyzer DT-30 Shimadzu) was used to check the thermal stability.

The reactions were followed spectrophotometrically with a Union Giken spectrophotometer with a thermostated cell compartment maintained within ±0.1 °C. All the reactions were carried out in 1.00-cm cells by mixing reactants pre-equilibrated at the reaction temperature. The metalloporphyrin Co-TPyP was made in solution by addition of a large excess of cobalt(II) to H_2TPyP. The absorption spectra as a function of time showed excellent isosbestic points within several hours. The metalloporphyrin tended to precipitate after about 20 h at room temperature. The reaction was followed at 418 nm for the $Co(OAc)_2$ system and at 422 nm for the $Co(NO_3)_2$ system.

Under pseudo-first-order conditions with an excess of total cobalt over porphyrin, reactions were followed and pseudo-first-order rate constants were obtained from the data. Under conditions where the cobalt concentration

is about 10^{-3} mol kg^{-1}, the half-life time of formation of the metalloporphyrin is several tens of minutes. At such higher concentrations of cobalt, the linearity of first-order plot is good and gives the conditional first-order rate constant. The rate constants are obtained by an initial rate method or by the Guggenheim method,[18] which does not require a final absorbance value. Most of conditional first-order rate constants at lower concentration of cobalt were obtained by an initial rate method in order to avoid complications due to the precipitation of metalloporphyrin.

Equilibria. Recently equilibria of aquation for cobalt (II) acetate[19] and cobalt(II) perchlorate[20] in acetic acid have been studied.

$$Co(OAc)_2(HOAc)_4 + nH_2O \overset{\beta_n}{\rightleftharpoons} Co(OAc)_2(H_2O)_n(HOAc)_{4-n}, \quad (1)$$

($\beta_1 = 6.7$ kg mol^{-1}, $\beta_2 = 11$ kg^2 mol^{-2}, $\beta_3 = 28$ kg^3 mol^{-3})

$$Co(HOAc)_6(ClO_4)_2 + nH_2O \overset{\beta_n}{\rightleftharpoons} Co(H_2O)_n(HOAc)_{6-n}(ClO_4)_2, \quad (2)$$

($\beta_1 = 34$ kg mol^{-1}, $\beta_2 = 850$ kg^2 mol^{-2})

where equilibrium constants are given in parentheses. No data have been published for the equilibrium constant for aquation of cobalt(II) nitrate, although, presumably, it would not be much different from that of cobalt(II) perchlorate. Thus in the present systems no appreciable amount of aqua complexes was thought to be present: cobalt(II) acetate is in the form of diacetatotetrasolvatocobalt(II) and cobalt(II) nitrate exists as an ion-pair involving hexasolvatocobalt(II) [$Co(HOAc)_6^{2+}$][$2NO_3^-$] (*vide infra*).

TPyP showed no spectral evidence for protonation in acetic acid: the spectrum of TPyP in acetic acid was the same as that in chloroform. Thus TPyP is entirely in the free base form (H_2TPyP) in acetic acid.

Results

Reaction of H_2TPyP with $Co(OAc)_2$. Values of $k_{0(Co)}$ obtained at constant cobalt(II) acetate concentration (4.80×10^{-4} mol kg^{-1}) and at various concentrations of H_2TPyP (1.88, 2.32, 3.05, 5.37×10^{-6} mol kg^{-1}) were the same ($(1.06 \pm 0.03) \times 10^{-4}$ s^{-1}) within experimental errors. The rate for formation of metalloporphyrin (Co-TPyP) is first order in porphyrin:

$$\frac{d[\text{Co-TPyP}]}{dt} = -\frac{d[H_2\text{TPyP}']}{dt} = k_{0(Co)}[H_2\text{TPyP}'], \quad (3)$$

where $k_{0(Co)}$ is the conditional first-order rate constant involving cobalt concentration and [H_2TPyP'] is the total concentration of porphyrin minus the concentration of metalloporphyrin. The values of $k_{0(Co)}$ at 20.0, 25.0, and 30.0 °C are plotted against initial concentration of cobalt(II) acetate $[Co(OAc)_2]_0$ in Fig. 1. The logarithmic relationship between rate constants and cobalt concentrations is shown in Fig. 2. As apparent from curve A in Fig. 2, at lower and higher cobalt concentration $k_{0(Co)}$ tends to be first order in $[Co(OAc)_2]_0$, while at the intermediate cobalt concentration $k_{0(Co)}$ changes with $[Co(OAc)_2]_0$ to a lesser extent. This kinetic behavior of formation of metalloporphyrin can be formulated by the following equation:

$$H_2\text{TPyP} + Co(OAc)_2 \rightleftharpoons H_2\text{TPyP}\cdots Co(OAc)_2, \ K, \quad (4)$$

The solid curves are calculated with the rate constants and formation constants obtained.

$$SAT \longrightarrow \text{Co-TPyP} + 2HOAc, \qquad k_1 \quad (5)$$

$$SAT + Co(OAc)_2 \longrightarrow \text{Co-TPyP} + Co(OAc)_2 + 2HOAc, \qquad k_2 \quad (6)$$

where H_2TPyP$\cdots Co(OAc)_2$ is an intermediate which may be so-called sitting-atop complex and is denoted as SAT. For simplicity, acetic acid molecules in the reactions are omitted. If one assumes a rapid pre-equilibrium step of Eq. 4 and two parallel rate-determining steps of Eqs. 5 and 6, then an expression for $k_{0(Co)}$ can be derived for this mechanism and it is

given below

$$k_{0(Co)}=\frac{K[Co(OAc)_2]_0}{1+K[Co(OAc)_2]_0}(k_1+k_2[Co(OAc)_2]_0). \quad (7)$$

The experimental rate data fit this expression very well as illustrated in Fig. 1. In Reaction 5, the metal ion in the sitting-atop complex just drops into the porphyrin ring, and Reaction 6 indicates that a second metal is inserted from the opposite side. Values of k_1, k_2, and K were determined by a non-linear least squares method.[21] The rate constants, formation constants, and their corresponding parameters are tabulated in Table 1.

An introduction of 0.5% water into the solvent acetic acid did not affect the rate constants within experimental errors. Errors for estimation of rate constants were within 10%. Since the water concentration of our systems is much less than 0.5%, we believe with confidence that the presence of water, if any, did not affect our results.

Reaction of H_2TPyP with $Co(NO_3)_2$. The relationship between $k_{0(Co)}$ and initial concentration of cobalt(II) nitrate is shown in Fig. 2. The cobalt dependence of $k_{0(Co)}$ at lower concentration of cobalt nitrate is similar to that in the cobalt acetate system. At higher concentration of cobalt nitrate, however, the conditional rate tends to be second-order in cobalt nitrate concentration (see curve B in Fig. 2). The mechanism of the reaction is postulated as follows:

$$H_2TPyP + Co(NO_3)_2 \rightleftharpoons H_2TPyP\cdots Co(NO_3)_2, \quad K_1 \quad (8)$$

$$SAT + Co(NO_3)_2 \rightleftharpoons SAT\cdots Co(NO_3)_2, \quad K_2 \quad (9)$$

$$SAT \longrightarrow Co\text{-}TPyP + 2HNO_3, \quad k_1 \quad (10)$$

$$SAT + Co(NO_3)_2 \longrightarrow Co\text{-}TPyP + Co(NO_3)_2 + 2HNO_3, \quad k_2 \quad (11)$$

$$SAT\cdots Co(NO_3)_2 + Co(NO_3)_2 \longrightarrow Co\text{-}TPyP + 2Co(NO_3)_2 + 2HNO_3, \quad k_3 \quad (12)$$

where $H_2TPyP\cdots Co(NO_3)_2$ is a sitting-atop complex denoted as SAT, and $SAT\cdots Co(NO_3)_2$ is a complex formed by interaction of cobalt with a nitrogen atom of pyridyl groups in porphyrin (*vide infra*). With steps 10, 11, and 12 as rate determining and steps 8 and 9 as rapid preequilibria, Eq. 13 can be readily derived.

$$k_{0(Co)}=\frac{K_1[Co(NO_3)_2]_0}{1+K_1[Co(NO_3)_2]_0+K_1K_2[Co(NO_3)_2]_0^2}\times(k_1+k_2[Co(NO_3)_2]_0+k_3K_2[Co(NO_3)_2]_0^2) \quad (13)$$

Table 2. Effect of ammonium nitrate on the rate for Co-TPyP formation

$10^5[Co(NO_3)_2]_0$ / mol kg^{-1}	$10^4[NH_4NO_3]$ / mol kg^{-1}	$10^5k_{0(Co)}$ / s^{-1}
8.81	0	6.19
8.6	0.84	6.7
8.6	1.2	5.2
8.6	1.37	4.8
14.4	0	7.1
14.4	1.4	6.9
14.4	2.23	6.1
14.4	3.73	5.7
14.4	6.78	5.5

The data obtained indicate that the third term of the denominator in Eq. 13, $K_1K_2[Co(NO_3)_2]_0^2$, is negligible all over the range of cobalt concentrations. As illustrated in Fig. 2, the empirical kinetic data are best described by Eq. 13 without the term $K_1K_2[Co(NO_3)_2]_0^2$. Constants in the TPyP–$Co(NO_3)_2$ system are tabulated in Table 1.

The kinetics of cobalt incorporation into H_2TPyP have been studied in the presence of ammonium nitrate. Conditional first-order rate constants obtained in the presence of ammonium nitrate are summarized in Table 2. Values of $k_{0(Co)}$ tend to decrease only slightly as the concentration of ammonium nitrate increases. Therefore the second order cobalt nitrate dependence is in fact due to the participation of the second cobalt and not of nitrate in the reaction.

Discussion

There have been several studies of the kinetics of metal acetate incorporation into porphyrin molecules in acetic acid.[15,22-25] The kinetic results are discouragingly inconsistent with each other. Choi and Fleisher[15] found the reaction between TPyP and manganese, cobalt, nickel, and copper in glacial acetic acid to be first order in metal in every case. Brisbin and Balahura[25] and Kingham and Brisbin[24] found the reaction between hematoporphyrin and manganese, iron, cobalt, copper, and zinc to be first order in metal and that between hematoporphyrin and nickel to be half order in metal. Brisbin and Richards[23] studied the reaction between protoporphyrin IX di-

methyl ester (Proto-IX-DME) and some first-row transition metals in glacial acetic acid. The reaction appears to be half order in cobalt and nickel and close to half order in copper and shows orders between one-half and one in manganese and zinc.

The results by Choi and Fleischer[15] are inconsistent with ours. Their experiments were conducted over a very narrow range of metal concentrations: $(3—6)\times10^{-3}$ M, and they found the reaction of cobalt(II) acetate with TPyP to be first order with respect to metal.[15] It seems quite likely that if the kinetics were investigated over a wider range of concentration, the simple rate laws would not be found to hold. In fact, it is possible to estimate the first order metal dependence from the range of $(3—6)\times10^{-3}$ M metal concentration from Fig. 1. Moreover, assuming the similar reactivity of cobalt for TPyP and Proto-IX-DME, the decision of about half order in cobalt for the reaction of Proto-IX-DME with $(2—8)\times10^{-4}$ M cobalt is possible, as apparent from Fig. 2. Therefore it is indispensable in these studies to conduct experiments over as wide a concentration range as possible.

The first metal ion forms a SAT complex to deform the porphyrin (Eqs. 4 and 8). This step is not rate-limiting. The metal in the SAT complex just drops into the porphyrin ring (the k_1-path given by Eqs. 5 and 10). It is the k_2-path that a second metal attacks from the opposite side (Eqs. 6 and 11). The two metals in transition state are considered to be on opposite sides of the porphyrin plane according to the crystal structure of several bi-metalloporphyrins.[26] This is also supported by results on the mechanisms of electrophilic exchange between one metal ion and another complexed in a porphyrin molecule.[27,28]

Kinetic studies[28] on the Zn/Cd–TPP (TPP: tetraphenylporphine) and Zn/Hg–TPP systems revealed rate laws of first order in each reactant. Because of their large ionic radii, cadmium and mercury can not fit as well into the plane of the four central porphyrin nitrogen atoms. It is thus considered that Hg–TPP and Cd–TPP complexes have a configuration favorable for the attack by zinc from the back. So these reactions corresponds to the k_2-path in the present systems.

Recently large metallic ions such as mercury(II), cadmium(II), and lead(II) have been found to accelerate the complex formation of manganese(II), cobalt(II), copper(II), and nickel(II) with *meso*-tetra(4-sulfonatophenyl)porphine.[29] A heterobinuclear transition state has been proposed for these systems, and it may be appropriate to postulate a homobinuclear transition state for the present system. Coordination of the first metal ion makes the configuration of porphine favorable for the attack by the second metal ion from the back. At the same time it may facilitate the dissociation of the pyrrole proton in porphine, which seems important in the formation of metalloporphyrins.

If the dissociation of solvent from metal ions were important in the formation of metalloporphyrins, $Co(OAc)_2$ should react faster than $Co(NO_3)_2$, since electron donor ability of acetate is higher than nitrate.[30,31] In this respect it is interesting to observe no appreciable difference in k_1 and k_2 between $Co(OAc)_2$ and $Co(NO_3)_2$ reactions (see Table 1).

In solvent of low dielectric constant such as acetic acid, it is valuable to consider both ionization and dissociation of reactants. Overall dissociation of AB is written as

$$AB \overset{K_I}{\rightleftharpoons} A^+B^- \overset{K_d}{\rightleftharpoons} A^+ + B^-$$

with an overall dissociation constant K_D:

$$K_D = \frac{[A^+]+[B^-]}{[AB]+[A^+B^-]} = \frac{K_I K_d}{1+K_I},$$

where K_I is an ionization constant and K_d is a dissociation constant. Available values of K_D in acetic acid are $10^{-10.1}$ for H_2O,[32] $10^{-10.1}$ for HNO_3,[33] and $10^{-7.56}$ for $Co(OAc)_2$ ($Co(OAc)_2 \rightleftharpoons CoOAc^+ + OAc^-$).[34] K_d can be calculated by an equation of the type derived by Fuoss for ion-pair formation.[35] Unknown K_d values may be predicted, at least to a correct order of magnitude. On this basis, K_d may be estimated to be about 10^{-6} M for all of these 1:1 electrolytes in acetic acid. Therefore in the concentration higher than 10^{-4} M, 1:1 electrolytes exist as undissociated ion-pair. Water, nitric acid, and cobalt acetate[36] are largely unionized, while cobalt nitrate and ammonium nitrate should be to a considerable extent in the form of undissociated ion-pair. The breaking of pyrrole type protons is involved in metalloporphyrin formation reactions. Protons released as reaction proceeds react rapidly with OAc^- and NO_3^- to form HOAc and HNO_3 molecules.

The k_3-path found for the $Co(NO_3)_2$ system is missing in the $Co(OAc)_2$ system. It may arise from the interaction of $Co(NO_3)_2$ with pyridyl nitrogen in TPyP. The interaction should lower the basicity of pyrrole in TPyP through the change of peripheral charge. This may make easy the deprotonation of H_2TPyP and thus the k_3-path requires lower activation energy than the k_2-path. Since $Co(NO_3)_2$ is more electropositive than $Co(OAc)_2$, $Co(NO_3)_2$ is more reactive than $Co(OAc)_2$. Consequently the k_3-path should not be appreciable, if any, for $Co(OAc)_2$ system.

We are grateful to the Japanese Ministry of Education, Science and Culture for support of this work through Grant No. 584023.

Determination of Ultratrace Zinc by Enzymatic Activity of Carbonic Anhydrase. II. Use of Carbonate Hydro-lyase Activity

Kensei KOBAYASHI, Kitao FUJIWARA, Hiroki HARAGUCHI, and Keiichiro FUWA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 9, 1981)

A method for the determination of trace zinc has been investigated using hydro-lyase activity of carbonic anhydrase. It was proved theoretically and experimentally that the activation rate of the apo-carbonic anhydrase with zinc is proportional to the amount of zinc present in the solution. Hydro-lyase activity was measured electrochemically using sodium hydrogencarbonate as a substrate. The limit of detection was 0.89 ng/ml or 40 pg of zinc, lower than that obtained by the esterase activity method. Application of the present method to the determination of zinc in real samples has been examined in order to evaluate its analytical feasibility.

At the present time, enzymes show high potentiality for utilization in analytical chemistry in terms of their selectivity for substrates and high sensitivity originating from biochemical amplification.[1,2] Actually, the availability of enzyme electrode or enzyme colorimeter is well recognized, especially in clinical and agricultual fields.[3,4] Of the enzymes, metalloenzymes have specific metal ions located at their active centers, which play essential roles in enzymatic activities. The specificity of enzymatic activity to certain metal ions of metalloenzymes indicates the possibility of determination of trace metal ions. Only a few workers have studied the determination of zinc and copper by enzymatic activity of metalloenzymes, such as aminopeptidase,[5] alkaline phosphatase,[6] and polyphenoloxidase (tyrosinase).[7,8]

In a previous paper, we reported on the determination of trace zinc using the esterase activity of carbonic anhydrase, the recovery of the esterase activity of apo-enzyme (a zinc-free enzyme) being monitored by colorimetric technique.[9] The carbonic anhydrase method has a high selectivity to zinc, and is useful for determining trace zinc ion in natural samples such as fruit juices. On the other hand, carbonic anhydrase has another function, *i.e.*, hydration-dehydration catalysis of carbon dioxide (hereafter referred to as "hydro-lyase activity"), which is more essential in biological systems and has a higher turn-over rate than its esterase activity.

In the present investigation, the hydro-lyase activity of carbonic anhydrase was used for the determination of zinc in combination with the electrochemical detection method. We have found an almost linear relationship between the recovery of enzymatic activity and the amount of zinc. Since this method is more sensitive and convenient than the previous one, it was applied to the determination of zinc in natural water.

Theoretical Consideration

Carbonic anhydrase (CA) has one zinc atom at its active center, the atom being essential for its enzymatic activity (All symbols which follow are described in the Appendix.). Under the conditions $[E_a]_0 \gg [Zn]_0$, the equation between metal ion and apo-CA concentration is written as follws:[9]

$$[E] = K[E_a]_0[Zn]_0/(1+K[Zn]_0). \quad (1)$$

Since the relation $K[E_a]_0 \gg 1$ can be assumed, we obtain

$$[E] \simeq [Zn]_0. \quad (2)$$

CA catalyzes the following hydration-dehydration equilibrium,

$$H_2O + CO_2 \underset{A}{\rightleftharpoons} H_2CO_3 \underset{B}{\rightleftharpoons} H^+ + HCO_3^-, \quad (3)$$

where A is the rate-determining step. Thus, Eq. 3 can be written as

$$H_2O + CO_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} H^+ + HCO_3^-. \quad (4)$$

When sodium hydrogencarbonate is used as a substrate, the non-enzymatic reaction rate can be expressed as the decrease of hydrogen ion concentration:

$$(d[H^+]/dt)_{non} = k_1[H_2O][CO_2] - k_{-1}[HCO_3^-][H^+]. \quad (5)$$

The reaction rate for the enzymatic process can also be expressed as

$$(d[H^+]/dt)_{enz} = [E](V'_m[HCO_3^-]/K'_m - V_m[CO_2]/K_m)/(1+[HCO_3^-]/K'_m+[CO_2]/K_m). \quad (6)$$

The total reaction rate, $d[H^+]/dt$, is given by the summation of Eqs. 5 and 6. Under the conditions in which the concentration of total carbonate (*i.e.*, $[HCO_3^-]+[CO_2]$) and the initial pH are constant, V'_m, V_m, $[HCO_3^-]$, and $[CO_2]$ are represented as the functions of $[H^+]$. We then have

$$d[H^+]/dt = [E]f([H^+]) + g([H^+]), \quad (7)$$

where $f([H^+])=(d[H^+]/dt)_{enz}/[E]$, and $g([H^+])=(d[H^+]/dt)_{non}$. Here we define τ and τ_0 as the time required for the pH change from pH_A to pH_B, when CA is added and not added, respectively. Then τ and τ_0 can be expressed as follows:

$$\tau = \int_{[H^+]_A}^{[H^+]_B} (dt/d[H^+])d[H^+] = \int_{[H^+]_A}^{[H^+]_B} [1/\{[E]f([H^+])+g([H^+])\}]d[H^+], \quad (8)$$

$$\tau_0 = \int_{[H^+]_A}^{[H^+]_B} \{1/g([H^+])\}d[H^+]. \quad (9)$$

Since the condition $[E]\,f([H^+]) \gg g([H^+])$ is easily satisfied because of the high turn-over rate of carbonic anhydrase, we obtain

$$1/\tau = [E]/\int_{[H^+]_A}^{[H^+]_B} d[H^+]/f([H^+]) + \int_{[H^+]_A}^{[H^+]_B} \{g([H^+])/f^2([H^+])\}d[H^+]/\left\{\int_{[H^+]_A}^{[H^+]_B} d[H^+]/f([H^+])\right\}^2. \quad (10)$$

When we take $1\Big/\int_{[H^+]_B}^{[H^+]_A} d[H^+]/f([H^+])$ as c, and the second term as c', we get

$$1/\tau = c[E] + c', \quad (11)$$

which shows that a plot of $1/\tau$ against [E] is linear. When $[H^+]_B$ is nearly equal to $[H^+]_A$, c' could be approximated to $1/\tau_0$. After all, the following expression is derived from Eqs. 2 and 11:

$$1/\tau = c[Zn]_0 + 1/\tau_0. \quad (12)$$

Namely, the amount of zinc in the solutions can be determined from the plot of $1/\tau$ *vs.* $[Zn]_0$.

Experimental

Chemicals. Bovine carbonic anhydrase C-7500 (EC 4. 2. 1. 1, abbreviation BCA, Sigma Chem. Co.) was used. Buffer (barbital sodium–HCl, abbreviation Veronal) was purified by means of solvent extraction using a 0.001% dithizone–chloroform solution.[11] The substrate, sodium hydrogencarbonate (Wako Pure Chemicals) was of pH measurement grade. Sodium salts of analytical grade were used as anion standards, and metal chlorides (except $Pb(NO_3)_2$ and $FeSO_4(NH_4)_2SO_4$) of analytical grade were used as metal ion standards, both purchased from Wako Pure Chemicals. The distilled water was prepared by a Daiken Sekiei subboiling distiller, zinc content not exceeding 20 pg/ml.[12]

Instruments. A Toa pH meter HM-5B with a glass electrode GS-125C, a pH stat HSM-10A, and a recorder EPR-200A, were used for the measurement of hydro-lyase activity of carbonic anhydrase. A Hitachi 170-50 atomic absorption spectrophotometer with a Jarrel-Ash FLA-100 carbon rod atomizer was used to determine the zinc content in the sample solutions. UV absorption was measured with Shimadzu UV-210A spectrophotometer. All the pH measurements and ultrafiltration were performed in a Thomas Scientific bath circulator TRL-111SP.

Preparation of the Apo-enzyme. A zinc-free enzyme (apo-enzyme) was prepared by a modified method of Hunt *et al.*,[13] which also differs from the previous method.[9] The procedure is as follows: 30 mg BCA was dissolved in 5 ml of 25 mM Veronal buffer (pH 7.0) containing 50 mM 2,6-pyridinedicarboxylic acid (referred to as PDA solution) (1 M=1 mol dm^{-3}). The enzyme was placed in an Amicon Diaflo cell (type 12), and the PDA solution placed in the reservoir was allowed to run through the Amicon UM-10 ultrafiltration membrane for several hours. Zinc concentration of the effluent was monitored by atomic absorption spectrometry. After zinc concentration of the effluent was as low as the original PDA solution and constant, sub-boiling-distilled water was allowed to flow through the ultrafiltration membrane until the UV absorbance of the effluent at 271 nm (due to PDA) was negligible. All the ultrafiltration was done at 0.5 °C. The residue in the cell (apo-BCA solution) was then taken out and filled up to 3 ml as a "stock reagent," and zinc and protein concentrations were measured by atomic absorption and micro-biuret methods,[14] respectively.

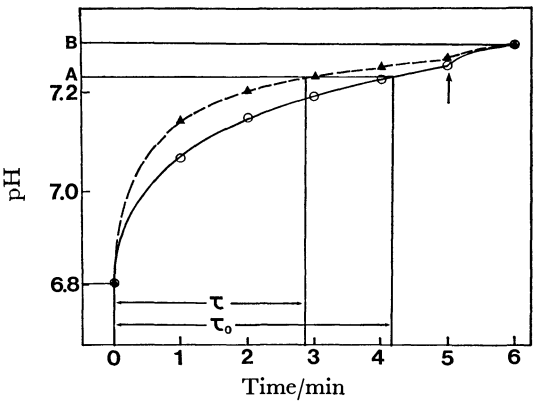

Fig. 2. Time dependence of pH change. ○——○: Without BCA, ▲----▲: with 5 nmol apo-BCA and 230 pg zinc ion, ——→: excess holo-BCA is added, A: $pH_{90\%}$, B: pH_{eq}.

Measurement of Enzymatic Activity. There are some conventional methods for measuring the hydro-lyase activity of BCA,[15,16] where carbon dioxide or sodium hydrogencarbonate is usually used as a substrate, but these are not suitable for zinc-determination. We have used sodium hydrogencarbonate as a substrate, working out a new method to determine zinc. The reaction vessel for this method is shown in Fig. 1. Reaction temperature was maintained at 0.5±0.2 °C.

In order to accelerate the reaction between the apo-enzyme and zinc in the sample, 20 μl of 200 μM apo-BCA solution was pre-incubated with a mixture of 100 μl of the Veronal buffer (pH 6.8) and 100 μl of the sample for 5 min. The mixture was added to the measurement media of 20 ml of the Veronal buffer (pH 6.8). After stirring for 1 min (t=6 min) the substrate solution, 100 μl of 0.65 M sodium hydrogencarbonate, was added to the reaction vessel. The pH change of the mixture resulting from the enzymatic reaction was recorded (Fig. 2). After equilibrium was reached (*ca.* 5 min after mixing the substrate), $[H^+]_{90\%}$ was calculated by the equation

$$[H^+]_{90\%} = \{[H^+]_0 + 9[H^+]_{eq}\}/10. \quad (13)$$

τ is defined as the time required to reach $[H^+]_{90\%}$ (Fig. 2).

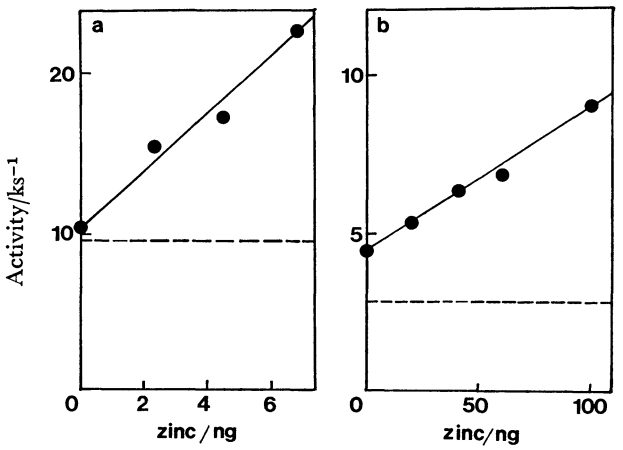

Fig. 3. Calibration curve for zinc measured by hydro-lyase activity of Bovine carbonic anhydrase.
a) Pre-incubation was done. 4.1 ng of apo-BCA and zinc sample were mixed in a separate vessel for 5 min, and added into the reaction vessel. b) No pre-incubation was done. 18 ng of apo-BCA and zinc sample were added directly into the reaction vessel, and kept 5 min before measurement.

Results

Calibration Curve for Zinc. The calibration curve for zinc under the conditions described (see Experimental), is shown in Fig. 3a. The detection limit is 0.89 ng/ml or 40 pg of zinc. The detection limit and dynamic range of the method are dependent on the amount of apo-BCA, the volume of the sample-apo-BCA mixture, and the incubation time in the vessel.

By this method, the dimension of enzymatic activity value is time^{-1} (*i.e.*, reciprocal of τ). When activity becomes high, τ-value becomes smaller, and $1/\tau$ value varies widely. The upper limit of detection is restricted by the deviation of $1/\tau$ value.

Interference of Coexistent Metal Ions. The interferences of the concomitant metal ions under the conditions $\sum_i [M_i^{2+}]_0 \gtrsim [E_a]_0$ are summarized in Table 1. Only Co^{2+} at a concentration equal to that of zinc ion increases the hydro-lyase activity by *ca.* 50%. Other metal ions might interfere with the enzymatic activity, particularly Hg^{2+}. When $\sum_i [M_i^{2+}]_0 \ll [E_a]_0$, the influence of concomitant metal ions is small.

Interference of Coexistent Anions. The interference of the concomitant anions in the present method is given in Table 2. Excess amounts of cyanide and perchlorate ions (100 times more than $[Zn^{2+}]$,) significantly interfere with the analytical results as in the esterase method. On the other hand, thiocyanate and nitrite ions at high level (1000 times in excess of $[Zn^{2+}]$) appear to activate enzymatic activity. If interference of the concomitants occurs. the standard addition method should be employed.

For the determination of zinc in sea water, we studied the influence of 0.5 M NaCl in order to estimate the ppb-level of zinc. No apparent inhibition was observed, the calibration curve for zinc being the same as that without NaCl.

Table 1. Effect of metal ions on hydro-lyase activity of carbonic anhydrase[a)]

Coexistent metal ions	Concentration of coexistent metal ions/ppb				
	10000	1000	100	10	1
Hg^{2+}		10	50	74	96
Co^{2+}			150		
Cu^{2+}	3	16	101		
Fe^{2+}	74	104	101		
Ni^{2+}	45	99	97		
Mn^{2+}	91	96	98		
Cd^{2+}	6	30	100		
Pb^{2+}	22	112	105		

a) The ratio (%) of the enzymatic activities measured with and without coexistent metal ions. Zn^{2+}: 35 pmol (100 ppb) apo-BCA: 140 pmol, incubation time: 5 min.

Table 2. Effect of anions on hydro-lyase activity of BCA[a)]

Anions	Concentration/mM	Activity/%[b)]
CN^-	100	45
	10	57
SCN^-	100	990
	10	228
	1	107
NO_2^-	100	290
	10	126
ClO_4^-	100	43
I^-	100	68
Br^-	100	82
Cl^-	100	106
F^-	100	89
CH_3COO^-	100	90
NO_3^-	100	84

a) Zn^{2+}: 1.5 μM (100 ppb), apo-BCA: 6.0 μM, incubation time: 5 min. b) Ratio (%) of the enzymatic activities measured with and without the anions.

Table 3. Determination of zinc in real samples

Sample	Zinc concentration/(ng/ml)	
	Present method[a)]	Atomic absorption
City water	155	157
Orange juice	131	124

a) apo-BCA: 200 pmol, sample: 20 μl, incubation time: 5 min.

Determination of Zinc in Real Samples. Analytical results for orange juice and city water (Both filtrated with a membrane filter; pore size 0.2 μm) are given in Table 3, together with the amount of zinc in the samples determined by flame atomic absorption spectrometry. The analytical values are in line with those obtained by atomic absorption spectrometry.

Discussion

Consideration for Incubation. The formation reac-

tion between zinc and apo-BCA is

$$E_a + Zn \underset{k_f}{\longrightarrow} E. \quad (14)$$

The k_f value estimated by Henken *et al.*[17] is *ca.* 10^4 $M^{-1}\,s^{-1}$. When $[E_a]_0 \gg [Zn]_0$, the concentration of holo-BCA ([E]) obtained after the incubation for t s is

$$[E] = [Zn]_0\{1-\exp(k_f[E_a]_0 t)\}. \quad (15)$$

By this equation, 1 min is enough to complete the reaction of forming holo-BCA, since $[E_a]_0$ is *ca.* 5 μM by the esterase method.

In the present system, the amount of apo-enzyme needed for analysis is less than that for the esterase method. This is due to the higher activity of BCA in the hydro-lyase reaction than that in the esterase reaction. The use of a less amount of apo-BCA reduces background activity which is due to the contaminant zinc in apo-enzyme. The incubation time in the analytical procedure should be prolonged as can be estimated from Eq. 15. The sample and apo-enzyme were pre-incubated before detection, using a separate vessel so as to increase the net value of $[E_a]_0$ in Eq. 15. The analytical time could be reduced to *ca.* 1% of that in the direct analysis (without pre-incubation (*ca.* 5 min).

No pre-incubation was required for the determination of zinc in high concentration, because τ in Eq. 8 became too small. The calibration curve for zinc in the case of without pre-incubation is shown in Fig. 3b. Here Eq. 2 does not hold, while holo-BCA is approximately proportional to zinc content if incubation time is kept constant (Eq. 15). Employing these two methods (with and without pre-incubation) properly according to the zinc concentration, we could get a wide dynamic range from 40 pg to 100 ng for zinc.

Interference of Coexistent Metal Ions. Several transition metal ions such as copper(II), iron(II), cadmium(II), mercury(II), cobalt(II), and zinc(II) can coordinate to the active center of apo-BCA. Only cobalt-BCA and zinc-BCA have hydro-lyase and esterase activities.[18] Let us assume the following equilibrium between metal ions (M_i^{2+}) and the apo-BCA in solution,

$$E_a + M_i^{2+} \underset{K_i}{\rightleftharpoons} M_i^{2+}\text{-}E_a, \quad (16)$$

$$K_i = [M_i^{2+}\text{-}E_a]/[E_a][M_i^{2+}]. \quad (17)$$

Metal ions interfere with the reaction by sharing the coordination sites of the active center in apo-BCA, inhibiting the association of zinc(II) and apo-BCA. When $\sum_i [M_i^{2+}]_0 \ll [E_a]_0$, the influence of concomitant metal ions is small. Conversely, when $\sum_i [M_i^{2+}]_0 \simeq [E_a]_0$, the influence of metal ions becomes appreciable according to the K_i values which are specific to each concomitant metal ion, M_i^{2+}, as shown by

$$[E] \simeq K_{Zn}[Zn]/\sum_i K_i[M_i^{2+}]. \quad (18)$$

The degree of interference due to the concomitant metal ions is given in Table 1. Generally, interference of metal ions, except mercury(II) ion (for K_{Hg} is not small) and cobalt(II) ion can be neglected when $[M_i^{2+}]_0 < [E_a]_0$. The level of mercury(II) ion or cobalt(II) ion contained in most of the real samples, such as biological samples and sea water, is much lower than that of zinc(II) ion,[19,20] so that the interferences of metal(II) ions can be ignored.

Interference of Coexistent Anions. The effects of the coexisting anions (X^-) on the activity of carbonic anhydrase[21] are based on the fact that the holo-BCA forms 1:1 complexes with monovalent anions which have no enzymatic activity.

$$Zn\text{-}BCA + X_j^- \underset{K_j}{\rightleftharpoons} BCA\text{-}Zn\text{-}X_j^-, \quad (19)$$

where

$$K_j = [BCA\text{-}Zn\text{-}X_j^-]/[Zn\text{-}BCA][X_j^-]. \quad (20)$$

From Eq. 16, we get

$$\alpha = [BCA\text{-}Zn\text{-}X_j^-]/[BCA\text{-}Zn] = [X_j^-]K_j. \quad (21)$$

As compared to the esterase method, samples are more diluted with buffer in the present method, indicating the lowering in α-value (*i.e.*, the interference rate of anions,) and reduction of anion effects.

Application to Zinc Determination in Real Samples. The results shown in Table 2 indicate that the present method can be applied to the determination of zinc in water. The fact that the concentrations of zinc analyzed by the present method are close to those obtained by atomic absorption spectrometry in most of the samples shows that zinc in such samples is dissolved as the reactive form with apo-BCA (exchangeable zinc.) Since the present method is applicable to samples with high salinity, the zinc at the proper concentration in sea water could be directly analyzed by this method.

In the esterase activity method, non-specific esterases in real samples might interfere with the results.[9] By contrast, hydro-lyase activity is specific to carbonic anhydrase, so only its contamination in samples such as serums, should be taken into account. Precision in the present method would thus be better than that in the previous method.

Conclusion

The hydro-lyase method shows promise for determining trace zinc. Carbonic anhydrase has the following characteristics.

1) Reversible dissociation of zinc from protein; zinc-free apo-enzyme has no activities.

2) High specificity to zinc ion as a central metal ion; other than zinc ion, only cobalt(II) ion reactivates apo-enzyme.

3) High biochemical amplification; hydro-lyase activity of carbonic anhydrase has maximum turn-over rate.

4) Linearity between metal concentration and enzyme activity; *i.e.*, only one zinc ion per enzyme.

5) Easy enzymatic assay.

6) An enzyme easily available.

These characteristics, especially 2) and 4), indicate the superiority of carbonic anhydrase over other zinc metalloenzymes for zinc determination.

The present method is superior in selectivity and

sensitivity to the conventional colorimetric method such as the dithizone method.[22] It is possible to determine zinc in a concentrated salt solution, such as sea water, which is one of the most difficult subjects in furnace atomic absorption spectrometry.

The Steric Hindrance of the Stepwise Reaction of *N*-Carboxy α-Amino Acid Anhydride with the α-Amino Acid Ester

Masanao Ōya* and Tomoko Takahashi

Department of Chemistry, College of Technology, Gunma University, Tenjin-cho, Kiryu, Gunma 376

(Received July 21, 1980)

The mechanisms of the reactions of 4-alkyloxazolidinediones (**1**) (*N*-carboxy α-amino acid anhydrides(NCAs)) with α-amino acid benzyl ester *p*-toluenesulfonates (**2**) were investigated in acetonitrile containing triethylamine at low and room temperatures. Two types of reactions were observed: (1) the polymerization of NCAs was initiated with a small amount of **2** to produce polypeptides (**6**), and (2) the dipeptide benzyl esters (**4**) were produced by the stepwise reaction of NCAs with the esters. Both the polymerization and the dipeptide formation (**1**+**2**) seemed to be initiated by the nucleophilic attack of the amino group of the ester on the C-5 carbon of NCAs. The polymerization proceeded when the side chains of the amino acid esters (R^2) were more bulky than those of the NCAs (R^1). On the contrary, dipeptide esters were produced when the side chains of the NCAs (R^1) were more bulky than those of the esters (R^2).

The mechanisms of the polymerization of *N*-carboxy α-amino acid anhydrides (NCAs) are extensively studied. The mechanisms involve the initiation of the polymerizations of the NCAs with amines, sodium alcoholates, inorganic salts such as lithium chloride, and organometallic compounds, followed by propagation reactions.[1-4] In comparison, there is little information on the stepwise reaction of NCAs with compounds having an α-amino group to produce α-amino acid amides or their derivatives. The mechanism of the reaction of the glycine ethyl ester with the NCAs derived from other α-amino acids to produce dipeptide-ethyl esters is regarded as the stepwise reaction of an α-amino group with NCAs.[5] This stepwise reaction does not occur for any α-amino acid esters except for the glycine ester (with NCAs) in anhydrous media, because the polymerization reaction of NCAs occur.[6]

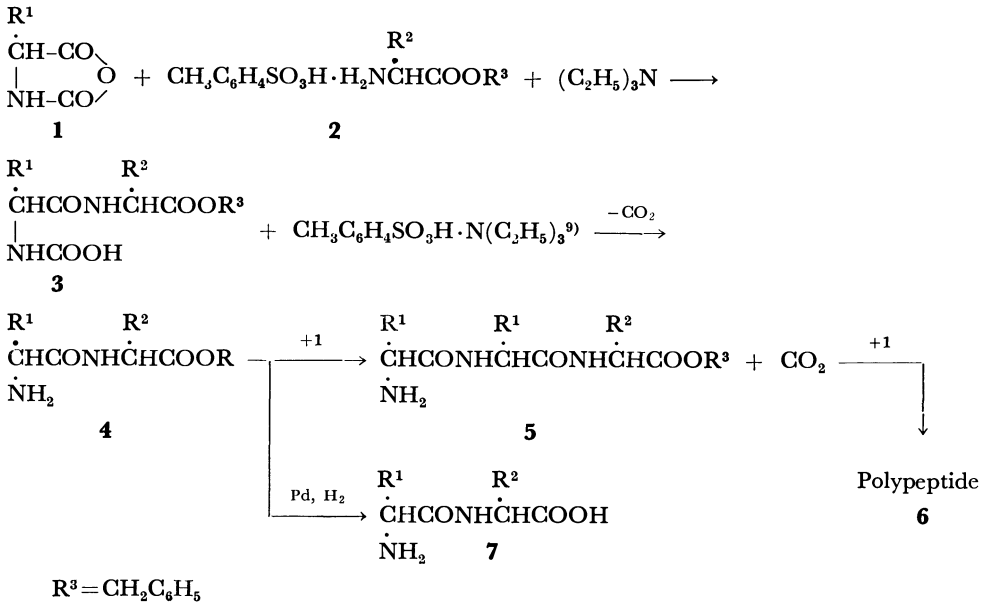
We previously synthesized oligopeptides with regular sequences by the stepwise reaction of α-amino acid sodium salts with NCAs in a water–acetonitrile system.[7] In another previous study, we synthesized dipeptides and cyclodipeptides by the stepwise reaction of α-amino acid benzyl ester *p*-toluenesulfonates with NCAs in anhydrous acetonitrile in the precence of triethylamine.[8] No mechanism of the reaction was discussed in detail, however.

In this paper, the mechanisms of the reactions are discussed with regard to the steric hindrance of the side chains of both α-amino acid esters and NCAs.

Results and Discussion

The reactions of NCAs (**1**) with α-amino acid benzyl-ester *p*-toluenesulfonates (**2**) were carried out in acetonitrile containing triethylamine at low and room temperatures (Eq. 1). The reactions which occured may be classified as the following types: (1) polypeptides were obtained by the polymerization of NCAs initiated with a small amount of the amino acid esters, (2) dipeptide esters were produced by the stepwise reaction of NCAs with the amino acid esters, and (3) both the polypeptides and dipeptide esters were produced by the polymerizations and the stepwise reactions. The results are shown in Table 1.

In the polymerization of γ-benzyl L-glutamate NCA with a primary amine in dioxane, it has been reported that 70% of the initiator (the amine) was involved



(1)

Table 1. Reaction of NCA with amino acid benzyl ester in acetonitrile

Reactant[a]		Product yield/%			
		Dipeptide (**7**)[b]		Polypeptide (**6**)[c]

in the attack on the C-5 carbonyl carbon of the NCA, while the remaining 30% of the amine was involved in the abstraction of the proton attached to the nitrogen of NCA.[3-4] When the polymerization of NCAs was initiated by the proton abstraction, the propagation could not be controlled because of the fast polymerization.

It has been concluded that the reactions of NCAs with amino groups are initiated only by the C-5 attack in acetonitrile.[10] As is shown in Eq. 1, the polymerization of NCAs should not proceed when the reaction of **1** with **2** is faster than that of **4** with **1**. The following mechanism are assumed. (1) Since the carbamic acid (**3**) is stable, the reaction from **3** to **4** should be very slow. (2) The basicity of the amino group of the amino acid ester (**2**) may be stronger than that of the dipeptide and tripeptide esters, so that the reaction of **1** with **2** is predominant compared to that of **1** with **4** or **5**. (3) An unknown mechanism other than (1) and (2) proceeds. As is shown in Table 1, glycine NCA is polymerized by all amino acid esters. Alanine NCA ($R^2=CH_3$) was usually polymerized with amino acid esters, but it produced the alanylglycine benzyl ester in 80% yield when reacted with the glycine ester ($R^2=H$). Valine and leucine NCAs were polymerized when the reactions were carried out with the amino acid esters having side chains more bulky than those of NCAs. Phenylalanine NCA produced the dipeptide esters without the polymerization of NCAs, even when the NCAs were allowed to react with the phenylalanine benzyl ester having the same side chain as that of the NCA.

It is known that a carbamic acid is stable in a basic medium at a low temperature.[5] The decarboxylation reaction from the carbamic acid occurs through the zwitter ion as the temperature increases.[11] If the decarboxylation reactions (**3**→**4**) were influenced by the temperature in Eq. 1, the yields of the polypeptides would also be influenced by the temperature. Table 1 shows, however, that the yields of the polypeptides and dipeptides were not influenced by the rise in temperature from −20 °C to 20 °C. Therefore, the decarboxylation reactions (**3**→**4**) can not be considered to have been influenced by the temperature and has to be the rate-determining step in the reactions.

It has generally been considered that the basicity of the amino group on dipeptides is slightly stronger than that of the corresponding amino acid.[12] This

may be also the case with the basicity of the dipeptide benzyl ester and the corresponding amino acid benzyl esters. If such a consideration could be applied to Eq. 1, the polymerization would proceed in all cases. The polymerization, however, proceeds only when the side chains of the esters are more bulky than that of NCAs. From these results, it is concluded that the steric hindrance of the side chains of both NCAs and esters affected whether the polymerization of NCAs proceeds or whether the stepwise reaction proceeds to produce the dipeptide esters.

Experimental

The α-amino acid benzyl esters[13] and NCAs[10,14] were prepared by the methods reported previously.

Reaction of NCAs (1) with α-Amino Acid Benzyl Esters (2). General Procedure: To the α-amino acid benzyl ester *p*-toluenesulfonate (**2**) (10 mmol) was added NCA (**1**) (10 mmol) in acetonitrile (25 cm^3) containing triethylamine (10 mmol). The mixture was thus stirred for 4 h. When the polypeptide formed by the polymerization of NCA was precipitated, it was separated by filtration and dried *in vacuo* to determine the extent of polymerization. The clear solution of the resulting mixture or the filtrate was distilled *in vacuo* to remove the solvent. The residual oily product was washed with ethyl ether and hydrogenated with palladium black in a mixture of acetic acid, *t*-butyl alcohol, and water. Dipeptide was thus obtained (**7**). When the NCA was partly polymerized, the final product was mixture of amino acid and dipeptide. The isolated polypeptides, dipeptides, and these mixtures, when analyzed on C, H, N, and by means of the NMR and IR spectra, proved identical with independently synthesized authentic specimens.[7,8]

Valylalanine ($R^1=(CH_3)_2CH$, $R^2=CH_3$): ^{1}H-NMR (CF_3COOH): δ 1.2—1.3(d, 6H), 1.6—1.7(d, 3H), 2.1—2.6(m, H), 4.1—4.4(q, H), 4.8—4.9(t, H), 7.3(s, H), 7.7—7.8(d, H). Found: C, 50.77; H, 8.59; N, 14.68%. Calcd for $C_8H_{16}O_3N_2$: C, 51.06; H, 8.51; N, 14.87%.

Further, the polypeptides were analyzed by means of X-ray diffraction measurement.[15]

The residual NCA after finishing the reaction was analyzed by the method of Berger.[16]

The Photochemistry of the Host-Guest Complex. V. The Effect of the Sodium Ion on the Photoreaction of Benzil Derivatives with a Crown Ether Moiety

Hideki HIRANO, Katsuyuki KURUMAYA, and Masaru TADA*

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received September 8, 1980)

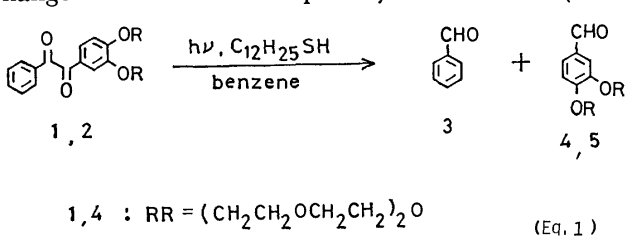
The photolysis of 4′-(2-phenyl-1,2-dioxoethyl)benzo-15-crown-5 in benzene containing 1-dodecanethiol gives benzaldehyde and 4′-formylbenzo-15-crown-5. The formation of the aldehydes was inhibited by the sodium ion, whereas the photolysis of 1-(3,4-dimethoxyphenyl)-2-phenylethanedione was not inhibited by the sodium ion. This inhibition must be due to the decrease in the formation of benzoyl radicals from the triplet excited state of the crown ether derivative. The salt effect was discussed on the basis of the spectral data.

We have been studying the effect of a guest ion on the photoreactivity of crown ether derivatives,[1] and have shown that the formation of a host-guest complex affects the photoreaction in several aspects. In the course of our study of the photoreaction of a host-guest complex, the photoreactivity of benzil derivatives was tested in the presence of a guest cation.[2] In this paper we wish to report the photolyses of 4′-(2-phenyl-1,2-dioxoethyl)benzo-15-crown-5 (**1**) and 1-(3,4-dimethoxyphenyl)-2-phenylethanedione (**2**) in benzene containing 1-dodecanethiol.

The excitation of benzil in hydrogen-donating solvents gives a complex mixture of products,[3] which derives from the ketyl radical[4] formed by hydrogen abstraction by a triplet-excited benzil.[5] However, the excitation of benzil in benzene does not cause a remarkable reaction. This behavior of benzil must be due to the lack of ketyl-radical formation in benzene, a poor hydrogen-donating solvent. Another photochemical process of benzil is the formation of benzoyl radicals by an α-cleavage, but the benzoyl radicals preferentially recombine to regenerate the starting material. In the present study, 1-dodecanethiol was added to the reaction mixture as a scavenger of the benzoyl radicals[6] formed by the α-cleavage of the benzil derivative.

Results and Discussion

Photoreactions of Benzil Derivatives in the Absence or Presence of the Sodium Ion. The irradiation of **1** in deoxygenated benzene–acetonitrile (6:4) containing 1-dodecanethiol gave benzaldehyde (**3**) and 4′-formylbenzo-15-crown-5 (**4**). The irradiation of **2** in the same manner gave benzaldehyde (**3**) and 3,4-dimethoxybenzaldehyde (**5**). All the products were identified by comparison with authentic aldehydes. The starting material in the reaction mixture did not change in the dark. The photolyses of **1** and **2** (2.5×10^{-2} mol dm^{-3}) are sluggish, and only *ca.* 30% of the starting materials disappeared after irradiation for 40 h (see the experimental section for details of the reaction conditions). The sluggishness of the photolyses of **1** and **2** is accounted for by the rapid recombination of benzoyl radicals in a solvent cage. It has been reported that 0.03 mol dm^{-3} of 1-dodecanethiol scavenges the cage-free benzoyl radical formed by the photolysis of 1,2-diphenylethanone.[6] In the present study, we used enough 1-dodecanethiol (0.25 mol dm^{-3}) as the scavenger of benzoyl radicals.



1, 4 : RR = $(CH_2CH_2OCH_2CH_2)_2O$
2, 5 : R = CH_3 (Eq. 1)

The effect of the guest cation on the photoreactivity of the crown ether derivative (**1**) was tested by adding varying amounts of sodium perchlorate. Figure 1 shows the effects of the added sodium perchlorate on the relative quantum yield (ϕ_{rel}) of aldehyde **3** and **4**. The depressing in ϕ_{rel} can not be due to the perchlorate anion, since the addition of tetrabutylammonium perchlorate stimulated ϕ_{rel}. The photolysis of **2** in the presence of sodium perchlorate gave an entirely different result from that of the photolysis of **1**, and the addition of sodium perchlorate increased the formation of aldehyde **3** and **5** (Fig. 2). These results clearly show that the effect

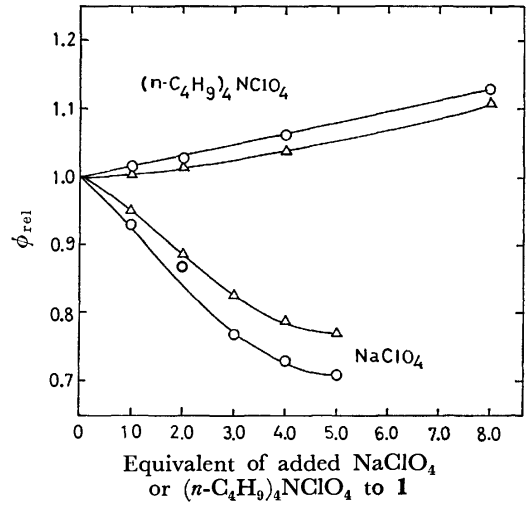


Fig. 1. Relative quantum yield of the formation of benzaldehyde (**3**) (△——△) and 4′-formylbenzo-15-crown-5 (**4**) (○——○) on the photolysis of crown ether derivative (**1**) (2.5×10^{-2} mol dm^{-3}) in the presence of $NaClO_4$ or $(C_4H_9)_4N\cdot ClO_4$.

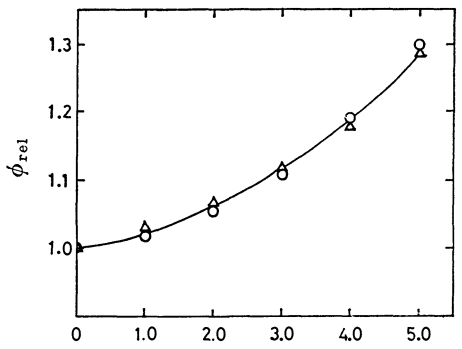

Fig. 2. Relative quantum yield of benzaldehyde (**3**) (△——△) and 3,4-dimethoxybenzaldehyde (**5**) (○——○) on the photolysis of dimethoxy compound (**2**) (2.5×10^{-2} mol dm^{-3}) in the presence of $NaClO_4$.

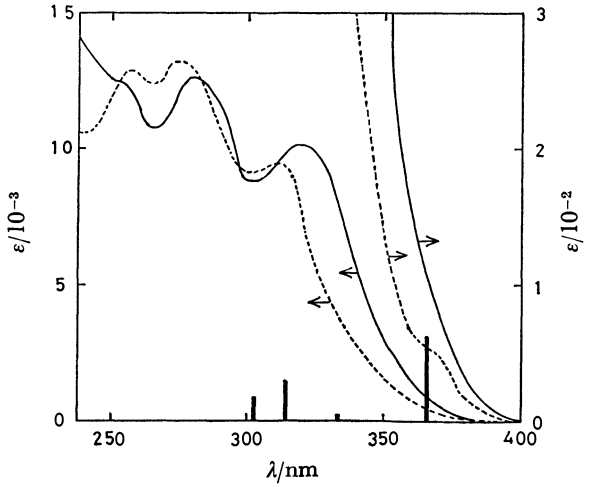

Fig. 3. UV absorption spectra of 4′-(2-phenyl-1,2-dioxoethyl)benzo-15-crown-5 (**1**) (1.00×10^{-4} mol dm^{-3} in acetonitrile) in the absence (——) and presence (·····) of $NaClO_4$ (20 equivalents), and emission lines from a high pressure mercury lamp in 300—400 nm region

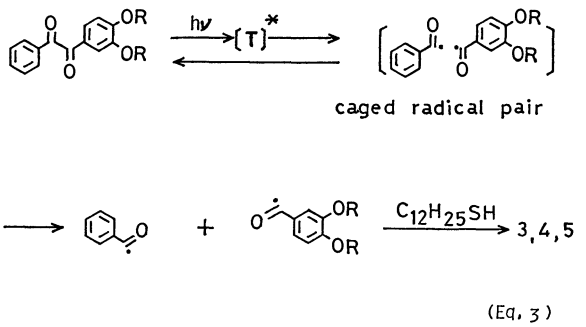
of the sodium salt on the photoreactivity of **1** is related to the complex formation between the sodium ion and the crown ether derivative (**1**).

Discussion of the Salt-effect Based on the Spectroscopic Data. The ultraviolet absorption of **1** changes upon the addition of sodium perchlorate due to the formation of a host-guest complex (Fig. 3). The absorption of **2** is essentially the same as that of **1**, but it does not change upon the addition of sodium perchlorate. The formation constant ($K=2.8\times10^3$ mol^{-1} dm^3 in acetonitrile) of the complex between **1** and the sodium ion can be obtained by the analysis of the spectral change by means of the Benesi-Hildebrand equation (Eq. 2),[7] in which **Abs** denotes the absorbance (solution thickness: 1.0 cm) of the mixture of **1** and the sodium ion, while $\Delta\varepsilon$ denotes the difference in the molar absorptivity of **1** and the complex. From Eq. 2 we calculated $\Delta\varepsilon(=674)$ at 366 nm, at which a high-pressure Hg lamp has a strong emission line. The $\Delta\varepsilon$ thus obtained and the molar absorptivity of **1** at 366 nm ($\varepsilon=962$) gave the molar absorptivity of the host-guest complex at 366 nm ($\varepsilon=268$). We photolyzed a 2.5×10^{-2} mol dm^{-3} solution of the crown ether derivative (**1**) in the presence of varying amounts of sodium perchlorate (0.0—1.25×10^{-1} mol dm^{-3}). The absorbance of the reaction solution at 366 nm is calculated to be **Abs**(366)=6.7 (path length: 1.0 cm) when the crown ether derivative (**1**) exists entirely as the complex. This analysis shows that the **Abs** (366 nm) of the reaction mixture must be larger than 5.7, even at a solution thickness of 1.0 mm, and that a 366-nm light is almost completely absorbed by the reaction mixture contained in a Pyrex tube 1 cm in diameter. The reaction mixtures containing varying amounts of the sodium salt, therefore, must absorb the same number of photons under the present conditions. Other emission lines (304, 313, and 334 nm) from the Pyrex-filtered lamp should be completely absorbed by the reaction mixture, since it has large absorption coefficients at these wave lengths (see Fig. 3) and since the number of the excited molecule is

$$\frac{[\mathbf{1}]\cdot[Na^+]}{\mathbf{Abs}} = \frac{[Na^+]}{\Delta\varepsilon} + \frac{1}{\Delta\varepsilon\cdot K} \qquad (2)$$



(Eq. 3)

essentially not affected by the existence of the sodium ion.

1-Dodecanethiol is an efficient scavenger of a cage-free benzoyl radical,[6] and the decrease in ϕ_{rel} upon the complex formation with the sodium ion must be due to the retardation of benzoyl-radical formation from the crown ether derivative (**1**).

The phosphorescence from **1** in glassy EPA (1.02×10^{-4} mol dm^{-3}) shows a spectrum with a diffused vibrational structure, presumably from the $^3(n\pi^*)$ or $^3(\pi\pi^*)$ of a considerable mixing with $^3(n\pi^*)$, and the emission neither shifts nor changes its shape on the addition of sodium perchlorate. The intensity of the phosphorescence from **1**, however, diminishes by *ca.* 15% upon the addition of sodium perchlorate (7.05×10^{-4} mol dm^{-3}). The dimethoxy analog (**2**) shows essentially the same phosphorescence spectrum as that of the crown ether derivative (**1**), but the spectrum is not affected by the addition of sodium perchlorate or tetrabutylammonium perchlorate. The lifetime of the emissive state of **1** was determined to be $\tau=54$ ms, and it was not affected by the sodium salt. Since the lifetime of the triplet state of **1** is insensitive to the sodium ion, the decreases in the ϕ_{rel} of the reaction and the phosphorescence intensity can not be attributed to the additional decay process of the triplet state, but must be attributable to the decrease in the quantum yield of the triplet state upon

the complex formation. Decreases in the rate of intersystem crossing are attributable to several factors: (i) an electronic-field perturbation by the added electrolyte, (ii) an external heavy-atom effect, and (iii) the energy gap between the S_1 and T_1 states (ΔE_{ST}). The first two factors can not be important in the present case, however, since another intersystem crossing, $T_1 \rightarrow S_0$, is not affected, as is evidenced by the insensitivity of the lifetime of the phosphorescence to the sodium salt. The energy level of the triplet state (T_1) of **1** does not change upon the complex formation, as is evidenced by the wavelength of the phosphorescence, whereas the complexation of **1** with the sodium ion raises the energy level of the singlet excited state (S_1) of **1**, as is evidenced by the absorption spectrum in acetonitrile; λ_{max}: 319 nm (without Na^+) and λ_{max}: 310 nm (with Na^+). This increase in ΔE_{ST} is one of the most probable factors in retarding the intersystem crossing ($S_1 \rightarrow T_1$) and, hence, the formation of a benzoyl-radical pair from the T_1 state.

It is still uncertain why the relative reactivities of **1** and **2** increase upon the addition of the ammonium perchlorate. Since the addition of sodium perchlorate to the reaction system of **2** (see Fig. 2) increases its photoreactivity, these effects must, however, be related to the perchlorate anion. We must await further studies about other aspects for the solution to this problem.

Experimental

Synthesis of 4′-(2-Phenyl-1,2-dioxoethyl)benzo-15-crown-5 (1). A mixture of benzo-15-crown-5 (2.68 g, 1.0×10^{-2} mol) and phenylacetic acid (2.04 g, 1.5×10^{-2} mol) in 10 cm³ of polyphosphoric acid was stirred for 5 h at 70 °C. After cooling, the mixture was poured into ice water (*ca.* 15 cm³); the new solution was stirred for 1 h to hydrolyze polyphosphoric acid, and the resulting aqueous mixture was extracted by chloroform (20 cm³×3). The evaporation of the extract after successive washing by water and a saturated solution of sodium hydrogencarbonate and drying over magnesium sulfate gave a pale yellow solid. The chromatography of the crude product on an alumina column (1.0(ϕ)×20 cm) (chloroform, 70 cm³), followed by recrystallization from methanol, gave 4′-(2-phenyl-1-oxoethyl)benzo-15-crown-5; 1.62 g (42%). Mp 73.5—74.5 °C; IR(CCl_4): 1660, 1590, 1510, 1425, 1262, and 1130 cm⁻¹; NMR($CDCl_3$): δ 7.50—7.35 (2H, m), 7.14 (5H, m), 6.63 (1H, d, J=8 Hz), 4.02 (2H, s), 3.99 (4H, m), 3.75 (4H, m), and 3.57 (18H, diff. s).

A mixture of 4′-(2-phenyl-1-oxoethyl)benzo-15-crown-5 (1.0 g, 2.6×10^{-3} mol), selenium dioxide (0.35 g, 3.2×10^{-3} mol), dioxane (20 cm³), and water (10 cm³) was refluxed for 15 h, after which the solvent were removed *in vacuo*. Benzene (20 cm³) was then added to the residue, and the mixture was evaporated twice to remove the residual dioxane and water. The solid residue was dissolved in chloroform (20 cm³) and filtered to remove the solid selenium. The filtrate was condensed *in vacuo* after drying over magnesium sulfate to give a pale yellow product. The purification of the product by passing it through a column of alumina (1.0(ϕ)×10 cm, and chloroform 70 cm³) and subsequent recrystallization from methanol gave 4′-(2-phenyl-1,2-dioxoethyl)benzo-15-crown-5 (**1**); 0.78 g, (75%). Mp 110—112 °C; Found: C, 65.85; H, 5.97%. Calcd for $C_{22}H_{24}O_7$: C, 65.99; H, 6.04%. $\lambda_{max}^{CH_3CN}$: (ε) 252 (1.26×10^4), 282 (1.26×10^4), and 318 nm (1.01×10^4); IR($CHCl_3$): 1665, 1595, 1510, 1438, 1280, and 1135 cm⁻¹; NMR($CDCl_3$): δ 7.95(2H, m), 7.52(5H, m), 6.72(1H, d, J=8 Hz), 4.15 (4H, m), 3.75(4H, m), and 3.66(8H, diff. s).

Synthesis of 1-(3,4-Dimethoxyphenyl)-2-phenylethanedione (2). 1-(3,4-Dimethoxyphenyl)-2-phenylethanone was prepared from 1,2-dimethoxybenzene (13.8 g, 1.0×10^{-1} mol) and phenylacetic acid (17.0 g, 1.25×10^{-1} mol) in polyphosphoric acid (100 cm³) by the procedure used for the preparation of 4′-(2-phenyl-1-oxoethyl)benzo-15-crown-5. The crude product was purified by distillation under reduced pressure (230 °C/0.15 mmHg(20.0 Pa)); subsequent recrystallization from methanol gave 20.0 g (78%) of the product. Mp 79—80 °C; IR(CCl_4): 1675, 1590, 1520, 1420, 1152, and 1012 cm⁻¹; NMR($CDCl_3$): δ 7.46(1H, dd, J=8 and 2 Hz), 7.42 (1H, s), 7.18(5H, m), 6.68(1H, d, J=8 Hz), 4.05(2H, s), and 3.77(6H, s).

1-(3,4-Dimethoxyphenyl)-2-phenyl-1-ethanone (12.88 g, 5.0×10^{-2} mol) was oxidized by selenium dioxide (7.0 g, 6.3×10^{-2} mol) in dioxane (70 cm³) and water (30 cm³) by means of the procedure used for the preparation of 4′-(2-phenyl-1,2-dioxoethyl)benzo-15-crown-5 (**1**). The product was purified by recrystallization from methanol to give 12.0 g (89%) of 1-(3,4-dimethoxyphenyl)-2-phenylethanedione (**2**). Mp 111—113 °C; Found: C, 71.42; H, 5.09%. Calcd for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22%. $\lambda_{max}^{CH_3CN}$: (ε) 253(1.28×10^4), 281(1.26×10^4), and 319 nm(1.04×10^4); IR (CCl_4): 1663, 1585, 1512, 1252, and 862 cm⁻¹; NMR (CCl_4): δ 7.90(2H, m), 7.60—7.20(5H, m), 6.75(1H, d, J=8 Hz), and 3.83(6H, s).

Photoreaction of 4′-(2-Phenyl-1,2-dioxoethyl)benzo-15-crown-5 (1) in the Presence of 1-Dodecanethiol. To a solution of **1** (100 mg, 2.5×10^{-4} mol) and 1-dodecanethiol (505 mg, 2.5×10^{-3} mol) in 10 cm³ of a mixed solvent of benzene–acetonitrile (6:4) were added varying amounts of sodium perchlorate (0.0—1.25×10^{-3} mol). The solutions, placed in Pyrex tubes, were dipped in an ultrasonic bath and bubbled with nitrogen from a syringe needle for 10 min. The solutions were then irradiated externally for 40 h with a 450-w high-pressure Hg lamp mounted in a rotary irradiation apparatus (Rikosha RH-400), the distance between the lamp and the reaction tube being *ca.* 5 cm. The reaction mixtures were condensed to *ca.* 3 cm³, a 4-cm³ portion of chloroform was added, and the solutions were dried over magnesium sulfate. After the removal of the drying agent and the precipitated sodium perchlorate, the solutions were condensed to *ca.* 0.5 cm³, and a weighed amount of tetrachloroethane was added as an internal reference for the determination of the relative yields of aldehydes, benzaldehyde, and 4′-formylbenzo-15-crown-5. The results are shown in Fig. 1. Under these conditions about 35% of the starting diketone was photolyzed to give 4′-formylbenzo-15-crown-5 (**4**). The chromatography of the reaction mixture from the photolysis without sodium perchlorate on a column of silica-gel (1.0(ϕ)×10 cm) removed 1-dodecanethiol as a hexane eluate and gave the product mixture as a methanol. 4′-Formylbenzo-15-crown-5 (**4**) was separated from the product mixture by preparative TLC on a silica-gel plate using a mixed solvent of chloroform–methanol (50:7); it was identical with an authentic sample prepared by a previously reported procedure.[8]

Photolysis of 1-(3,4-Dimethoxyphenyl)-2-phenylethanedione (2) in the Presence of 1-Dodecanethiol. 1-(3,4-Dimethoxyphenyl)-2-phenylethanedione (**2**) was photolyzed in the manner used for the photolysis of the crown ether derivative (**1**). The product aldehydes, benzaldehyde, and 3,4-dimethoxybenzaldehyde (**5**), were found to be identical with authentic

samples in terms of GLC results (PEG-20M on Chromosorb W, N_2, 200 °C) and their NMR spectra. Fig. 2 shows the effect of the added sodium perchlorate on the photoreactivity of **2**.

Photolysis of 4'-(2-Phenyl-1,2-dioxoethyl)benzo-15-crown-5 (1) in the Presence of Tetrabutylammonium Perchlorate. A mixture of the crown ether derivative (**1**) (2.5×10^{-2} mol dm^{-3}) and 1-dodecanethiol (2.5×10^{-1} mol dm^{-3}) was photolyzed in the presence of tetrabutylammonium perchlorate (0—8 equivalents) in the same manner as was used for the photolysis in the presence of sodium perchlorate. The results are shown in Fig. 1.

Phosphorescence from 4'-(2-Phenyl-1,2-dioxoethyl)benzo-15-crown-5 (1) and 1-(3,4-Dimethoxyphenyl)-2-phenylethanedione (2). The phosphorescence spectra were measured by means of a Hitachi EPA-4 spectrometer at 77 K in EPA (ether–isopentane–ethanol, 5:5:1). **1** and **2** show phosphorescence spectra similar in wave length (440—600 nm (λ_{max}^{emiss}: 498 nm)) and in intensity. The addition of sodium perchlorate or tetrabutylammonium perchlorate (7 equivalents) to the dimethoxy analog (**2**) did not affect the spectrum. In contrast, the addition of sodium perchlorate to **1** (7 equivalents) gave a spectrum similar in wave length, but decreased the intensity by *ca.* 15%.

Reaction of Organic Sulfur Compounds with Hyperoxide Anion ($O_2^{\cdot-}$). IV.[1] Evidence for Formation of Peroxysulfur Intermediates: Oxidation of Sulfoxides, Phosphines, and Olefins[2] with Intermediary Peroxysulfur Species

Shigeru OAE,* Toshikazu TAKATA, and Yong Hae KIM†
Department of Chemistry, The University of Tsukuba, Sakura, Ibaraki 305
(Received October 15, 1980)

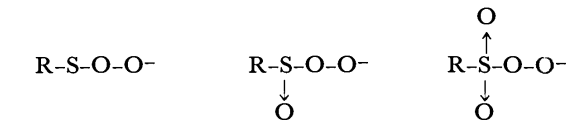
Formations of peroxy-sulfenate(I), -sulfinate(II), and -sulfonate(III) as intermediates have been confirmed by stripping the peroxy oxygen with three kinds of trapping agents such as sulfoxides, phosphines, and olefins, added in the reaction systems of various organic sulfur compounds with hyperoxide anion ($O_2^{\cdot-}$). These sulfoxides, phosphines, and olefins were inert to $O_2^{\cdot-}$ alone while electrophilic olefins, such as α,β-unsaturated ketones reacted readily with $O_2^{\cdot-}$ to afford the carboxylic acid. Sulfoxides, added into the reaction system of disulfide, thiosulfinic *S*-ester, thiosulfonic *S*-ester, or sulfonyl chloride with $O_2^{\cdot-}$, were found to be oxidized to the sulfones with peroxysulfur intermediates formed *in situ* in the system. Phosphines, added into the reaction system of disuflide or sodium thiolate with $O_2^{\cdot-}$ were also oxidized to the phosphine oxides. Not only stilbene and acenaphthylene but also chalcone and its derivatives, placed in the reactions of sulfonyl chloride, sulfinyl chloride and thiosulfonic *S*-ester with $O_2^{\cdot-}$ were found to be oxidized to the corresponding epoxides. These observations suggest clearly that the intermediary peroxysulfur compounds can act as oxidizing agents which oxidize these trapping agents by the nucleophilic oxygenative oxidation. Similar intermediates were postulated and confirmed in the alkaline autoxidations of thiol and disulfide in which added phosphines and sulfoxides were also found to be oxidized to their oxides. The mechanisms of the reactions of these trapping agents with peroxysulfur intermediates are discussed.

The discovery of superoxide dismutase(SOD) by Fridovich and McCord in 1969[3] has given the considerably vital energies on the investigation of hyperoxide anion radical($O_2^{\cdot-}$), not only in biochemistry but also in organic chemistry.

Since the observation of Valentine and Curtis in which KO_2 can be appreciably dissolved in aprotic solvents, by complexation with crown ethers,[4] has quickly promoted the use of this reagent for many reactions with simple organic substrates, numerous reports dealing with reactions of various organic substrates with "naked" hyperoxide anion have appeared within only five years. However, nobody has looked into the reaction of organic sulfur compounds with $O_2^{\cdot-}$ till we initiated as a part of our works on the oxygenative oxidation of organic sulfur compounds,[5] except some sporadic experiments.[6]

The oxidation with $O_2^{\cdot-}$ may be limited partly due to its relatively weak reactivity. In fact, $O_2^{\cdot-}$ has been called as a moderate reducing agent but a pitifully weak oxidizing agent.[7] However, its reactivity has been seen in oxidation, reduction, nucleophilic substitutions, and also radical reactions.

We reported recently that several organic sulfur compounds are oxidized with $O_2^{\cdot-}$ generated *in situ* from KO_2 and 18-crown-6 to the corresponding sulfinic and sulfonic acids under mild conditions.[5a,b] These organic sulfur compounds are either those which have sulfur–sulfur linkage such as disulfide, thiosulfinic *S*-ester, thiosulfonic *S*-ester, or thiolate and sulfinate, all of which are expected to give peroxy-sulfur compounds such as peroxy-sulfenate(I), -sulfinate(II), and -sulfonate (III) as initial intermediates in the reactions with $O_2^{\cdot-}$. In fact, Berger already postulated the intermediary peroxy-sulfenate(I) and -sulfinate(II) in the autoxidation of thiol to the sulfinic and sulfonic acids in strong alkali media.[8] Since the two reactions give both sulfinic and sulfonic acids and are presumed to involve common intermediates of peroxysulfur species, we have carried out the experiments which would suggest the formation of these peroxysulfur intermediates in the reactions with $O_2^{\cdot-}$, and obtained evidence to support the intermediary formations of these new class of peroxy compounds (I—III) in the reactions of several sulfur compounds with $O_2^{\cdot-}$. Namely, sulfoxides, phosphines, and olefins(which are inert to $O_2^{\cdot-}$ without any one of sulfur substrates) were found to be oxidized to their oxides in the reaction systems of various sulfur compounds with $O_2^{\cdot-}$. Similar results were obtained in the alkaline autoxidations of thiol and disulfide.



Peroxysulfenate I Peroxysulfinate II Peroxysulfonate III

Results and Discussion

All of the sulfur compounds shown below, *i.e.* **1**, **2**, **3**, **4**, and **5** have been found in our earlier study to be oxidized with $O_2^{\cdot-}$ to afford the corresponding sulfinic and sulfonic acids,[5a,b] while sulfenyl(**6**), sulfinyl(**7**) and sulfonyl(**8**) chlorides have also been found to be oxidized to the corresponding sulfinic and sulfonic acids. When unsymmetrical thiosulfinic and thiosulfonic *S*-esters were treated with KO_2 and 18-crown-6, formation of symmetrical disulfides from only the sulfenyl sulfur side was observed.

Since the peroxysulfur species, formed *in situ* during the reaction of these sulfur compounds with $O_2^{\cdot-}$, are

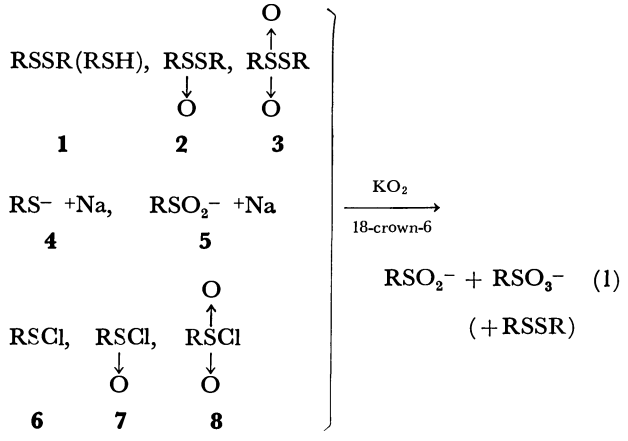
believed to have fairly strong nucleophilic oxidizing abilities, sulfoxides, phosphines, and olefins, which are relatively inert to $O_2^{\cdot-}$ alone but reactive with rather strong nucleophilic oxidizing agents, were added into the reaction system of one of these sulfur substrates with $O_2^{\cdot-}$, expecting that these additives would be oxidized to the corresponding oxides. Indeed, while the organic sulfur compounds were all oxidized to the sulfinic and sulfonic acids, added sulfoxides, phosphines, or olefins were also found to be oxidized to the corresponding sulfones, phosphine oxides, or epoxides. The added substrates, *i.e.* **9**, **10**, and **11**, are thus believed to be oxidized by the intermediary peroxysulfur compounds(I—III) formed *in situ* during the reactions of these sulfur compounds with $O_2^{\cdot-}$.



Oxidation of Sulfoxide. As a typical run, a solution of a selected sulfoxide (**9**, 0.5—6 eq.) and an organic sulfur compound (one of **1**—**8**, 1 eq.) in dry pyridine or acetonitrile was added into a heterogeneous solution of KO_2 (1—6 eq., finely powdered) and dry 18-crown-6 (0.5—1.0 eq.) in the same solvent at a set temperature and the resulting mixture was stirred under argon atmosphere. After extraction or filtration, the corresponding sulfone was obtained in the yield shown in Table 1. In the aqueous layer both sulfinic and sulfonic acids were obtained as reported previously.[5a,b] Yield of the sulfone obtained thus was determined by isolation by means of column chromatography on silica gel, or by comparison of the integral ratio of the NMR spectrum of the reaction mixture after evaporation of organic solvent. The sulfones were produced in most cases, except methyl phenyl sulfoxide which was not oxidized in the reaction system of benzenesulfenyl chloride with $O_2^{\cdot-}$ but reduced exothermically to the corresponding sulfide by the sulfenyl chloride in a very short time (≈5 min), like the reduction by sulfinyl chloride.[9] However, the sulfenyl chloride itself was readily oxidized with $O_2^{\cdot-}$ to the corresponding sulfinic and sulfonic acids.

Table notes are same as those in Table 1.

Sulfoxides were shown to be rather inert to O_2^- by Valentine and Curtis who revealed that KO_2 is nicely soluble in DMSO by complexation with perhydrodibenzo-18-crown-6.[4] Effects of solvent, temperature, and added sulfoxide were then investigated. The oxidation of sulfoxides during the reaction of organic sulfur compounds with KO_2 and the crown ether has been found to be affected by both solvent and temperature (entries 1—5, Table 2). Sulfoxides were oxidized in better yields in acetonitrile than in pyridine. Decomposition of $RS(O)_xOO^-$ (x=0—2: I—III) is presumably facilitated in pyridine, while acetonitrile may interact with the peroxysulfur species which might live longer in acetonitrile than in pyridine and hence would be a better nucleophilic oxidizing agent for sulfoxide. However, acetonitrile was found to react with disulfide in the presence of O_2^-, forming bis(arylthio)acetonitrile in the yield of 25—50%.[5b] A radical process shown below (Eqs. 2—4) seems to be responsible for the formation of bis(arylthio)-

acetonitrile, and details of the reaction are under investigation.

$$O_2^{\cdot-} + CH_3CN \longrightarrow HO_2^- + \cdot CH_2CN \quad (2)$$

$$ArSSAr + \cdot CH_2CN \longrightarrow ArSCH_2CN \quad (3)$$

$$ArSCH_2CN \xrightarrow{O_2^{\cdot-}} \xrightarrow{ArSSAr} (ArS)_2CHCN \quad (4)$$

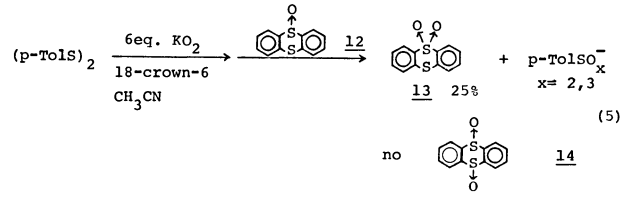
The yield of diphenyl sulfone from the added sulfoxide into the reaction system of **2** with $O_2^{\cdot-}$ increased as the temperature of the reaction was raised (entries 6—9). Change of sulfoxide did not affect much the yield of the corresponding sulfone in the reaction of di-*p*-toly disulfide with $O_2^{\cdot-}$ (entries 10—14). However, in the reaction of *p*-toluenesulfinyl chloride with $O_2^{\cdot-}$, dimethyl sulfone was obtained in a much better yield than methyl *p*-chlorophenyl sulfone (entries 15 and 16). An analogous result was observed in the oxidation of sodium *p*-toluenethiolate(entries 4 and 5), though the conditions of the above two reactions are somewhat different.

Meanwhile, since the yield of the sulfone was calculated based on the amount of the starting organic sulfur compound used, the yield of sulfone more than 100% (111%, entry 17) is not surprizing, as the amount of the added sulfoxide was six equivalent to the organic sulfur compound used. This may mean that more than an equimolar amount of peroxysulfur intermediate(s) is produced from the organic sulfur compound during the reaction. Thus, the yield of the sulfone clearly increased as the amount of the added sulfoxide to the reaction system increased.

Sulfoxide, having *p*-nitrophenyl group, such as *p*-nitrophenyl phenyl and methyl *p*-nitrophenyl sulfoxides, were not oxidized to the sulfones but presumably reacted with $O_2^{\cdot-}$. The reaction mixture turned to reddish brown and no product, even the starting material, was obtained from the organic layer.

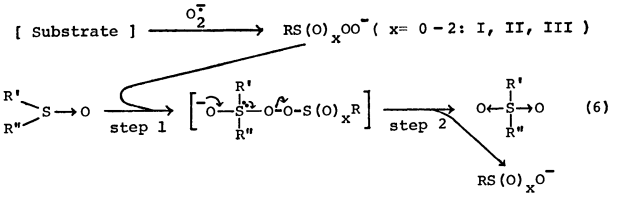
Common sulfides such as diethyl, methyl phenyl, and diphenyl sulfides were found not to be oxidized at all under the conditions, as in the reaction with $O_2^{\cdot-}$ which was reported to be unreactive toward sulfides.[10]

In order to reconfirm the facile reaction of sulfoxides and no reactivity of sulfides in these oxidation systems, thianthrene 9-oxide (**12**) was used as the trapping agent, and found to be oxidized to thianthrene 9,9-dioxide(**13**), but not to the 9,10-dioxide(**14**) in the reaction of di-*p*-tolyl disulfide with $O_2^{\cdot-}$ in CH_3CN at 25 °C for 4 h (Eq. 5). This result clearly indicates that the peroxysulfur intermediates formed during the reaction oxidize trivalent sulfinyl function but not divalent sulfenyl function.



Although oxygenation of sulfide is well-known to be initiated by the electrophilic attack of oxidant on the sulfide, oxygenation of the sulfoxide involves either the initial electrophilic attack of the electrophilic oxidant,[11a] or the nucleophilic attack of nucleophilic oxidant.[11b,c] In general, the anions of peroxy acid and hydroperoxide which are well-known to be powerful α-nucleophiles,[12] have been shown to oxidize sulfoxide through the nucleophilic attack on the trivalent sulfur.[11b,13] Therefore, peroxysulfur intermediates, being α-nucleophiles, would oxidize similarly the sulfoxide by nucleophilic oxidation.[11c]

The yield of the sulfone alone cannot give any difinite information on the effect of substituent in these oxidations of various sulfoxides with the peroxysulfur intermediates (Table 2). Modena *et al.* showed that the electron-withdrawing substituent on sulfoxide accelerates the rate of the oxidation of sulfoxide but could not obtain any clear-cut relationship on the effect of the substituent,[11b] since decomposition of the sulfurane intermediate is also a slow reaction and could become the rate-determining step of the overall reaction. The two successive reaction steps, *i.e.* the nucleophilic attack of acyloxy anion on sulfur atom and the collapse of the sulfurane intermediate, demand the entirely opposite electronic environments. The oxidation of sulfoxide with the peroxysulfur intermediates is considered to proceed similarly. As shown in Eq. 6, sulfoxide would be attacked by one



of the peroxysulfur intermediates generated *in situ*, forming incipiently the sulfurane intermediate which collapses to sulfone and $RS(O)_xO^-$ in the subsequent step.

An alternative mechanism which involves radical species of peroxysulfur intermediates in the oxidation of sulfoxide to the sulfone may be postulated. However, this seems to be quite unlikely because of the lack of nucleophilicity of the radical species, as was suggested earlier in the oxidation of dimethyl sulfoxide with *t*-butyl hydroperoxide.[14]

Oxidation of Phosphines. Both triphenyl- and tributylphosphines were also selected as trapping agents. Although these phosphines are known to be oxidized readily to the phosphine oxides with molecular oxygen,[15] both phosphines were quite inert under the present oxidation conditions in pyridine in dry argon atmosphere. The reaction procedure is identical to that in "*Oxidation of Sulfoxide.*" However, when the phosphines are used as trapping agents no oxygenated sulfur compounds could be used as the substrate for the oxidation with $O_2^{\cdot-}$, since the oxygenated sulfur compounds (**2**, **3** *etc.*) are known to be reduced readily with phosphines.[16] In fact, thiosulfinic *S*-ester was very readily reduced to the disulfide with triphenylphosphine in pyridine even at −25 °C. This reduction of thiosulfinic *S*-ester with triphenylphosphine is considered to compete with the reaction of thiosulfinic *S*-ester with $O_2^{\cdot-}$. Therefore,

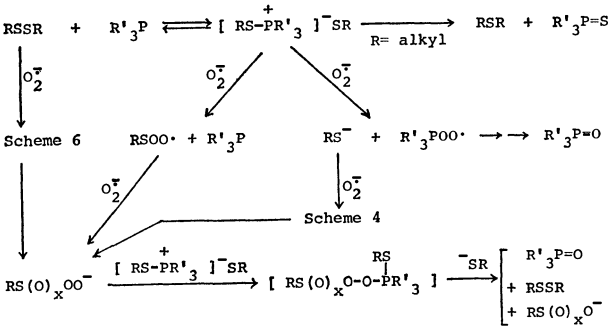
a) Yields were determined by GC.

the disulfide and sodium thiolate were chosen as the substrates in the reaction with $O_2^{\cdot-}$ in the presence of the phosphine to yield the phosphine oxide (Table 3). Yields of the phosphine oxides were determined directly by GC in order to avoid the autoxidation of phosphines. When tributylphosphine was added as a trapping agent of the peroxysulfur intermediate in the oxidation of disulfide with $O_2^{\cdot-}$, a vigorous exothermic reaction took place and the phosphine oxide was formed quantitatively within an hour, during which the conversion of the disulfide to the acids was still incomplete as shown in Table 3 (entry 3). In the oxidation of alkyl disulfide such as dibenzyl disulfide, triphenylphosphine was not only oxidized to the phosphine oxide but also converted to the phosphine sulfide. The phosphine sulfide thus formed along with the phosphine oxide was found to be quite inert to $O_2^{\cdot-}$ and recovered completely when it was added into the reaction system of disulfide with $O_2^{\cdot-}$ (entry 4). Therefore, formation of the phosphine oxide is not derived from the phosphine sulfide which is a simple by-product formed by the nucleophilic attack of the phosphine to the disulfide. Here again, triphenylphosphine was oxidized in a better yield in acetonitrile than in pyridine (entries 8 and 9), suggesting the reaction to proceed *via* an ionic pathway.

Phosphines are known to react with alkyl disulfide in an equilibrium reaction and generally yield the phosphine sulfide and monosulfide.[17] In the reaction of alkyl disulfide with $O_2^{\cdot-}$ in the presence of the phosphine the initial step is also considered to be the formation of alkylthiophosphonium ion which undergoes the Albuzov type reaction to yield the phosphine sulfide, by the nucleophilic attack of thiolate anion (counter anion of the phosphonium salt) on the carbon atom attached to the sulfur atom (Scheme 2). Due to the lack of nucleophilic attack of arenethiolate anion on aromatic carbon, diaryl disulfide did not give any phosphine sulfide (Table 3). Meanwhile, the formation of the phosphine oxide would be rationalized by Scheme 2. While $O_2^{\cdot-}$ can attack directly the disuflide as shown by Scheme 6, $O_2^{\cdot-}$ can attack competitively both sulfur and phosphorous atoms of the



Scheme 2.

phosphonium ion. Although direct attack of $O_2^{\cdot-}$ on phosphorus atom may finally afford phosphine oxide, peroxysulfur species formed during the reaction, being good nucleophiles, may also attack the phosphorus atom of the phosphonium ion to afford an incipient phosphorane intermediate which upon nucleophilic attack of thiolate anion on the sulfur atom can give the phosphine oxide, as shown in Scheme 2. The rapid oxidation of tributylphosphine, therefore, may be due to the shift of the equilibrium between disulfide and the phosphine to right side to form the phosphonium ion which then would preferentially be attacked by $O_2^{\cdot-}$ on the phosphorus atom, to afford tributylphosphine oxide quantitatively before all the disulfide was oxidized to the acids.

Triphenylphosphine was not oxidized quantitatively in the reaction of sodium thiolate with $O_2^{\cdot-}$. The oxidation of triphenylphosphine in the reaction of sodium thiolate with $O_2^{\cdot-}$ seems to be different from that in the reaction of disulfide with $O_2^{\cdot-}$. The initial step is very likely the one electron transfer from thiolate anion to $O_2^{\cdot-}$ in view of the reducing nature of $O_2^{\cdot-}$.[18] Then, the peroxysulfur free radical formed *in situ* may oxidize directly the phosphine as reported in the autoxidation of trialkylphosphines.[15] Another possibility for the oxidation of the phosphine involves the initial reaction of thiyl radical with the phosphine to form arylthiophosphoryl radical, which can react with either $O_2^{\cdot-}$ or $RS(O)_xOO\cdot$ to give a phosphorane

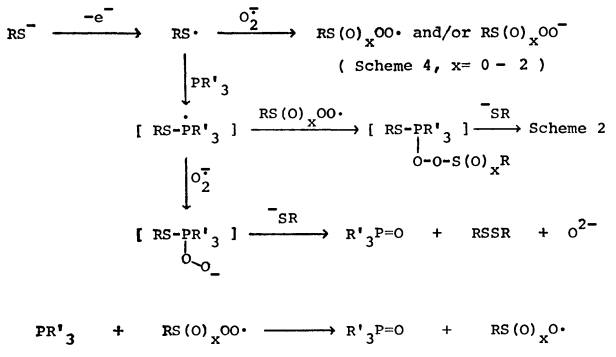
intermediate which then reacts according to Scheme 2(Scheme 2′).

Oxidation of Olefin. Several olefins were found to be readily oxidized to the corresponding epoxides in appreciable yields when these olefins were added into the reaction system of any one of the organic sulfur compounds (**3**, **7**, and **8**) with O_2^-. Since the epoxide formed was sensitive to alkaline media, the reaction mixture was immediately filtrated to remove alkali and the yields of the epoxides were obtained by measuring the NMR spectra of the mixtures, and the epoxides were isolated through column chromatography on silica gel using benzene–hexane mixture as an eluent. In NMR spectra of the epoxides, signals of methine protons of the usual three membered oxyrane ring appear at high fields (Table 4). Olefins used are the following three compounds, *i.e.* chalcone derivatives(**15**), stilbene(**16**), and acenaphthylene(**17**). Both **16** and **17** were quite inert to O_2^- while **15** and its derivatives were found to react with O_2^- as described later. Most epoxides obtained in the reactions were *trans* since the olefins used were also *trans*. However,



Scheme 2′.

the epoxide obtained from acenaphthylene was apparently *cis* but not *trans*, indicating that all the epoxidations in these systems were found to take place in *cis* fashion. Results obtained are listed in Tables 5 and 6, though the yields are not optimized.

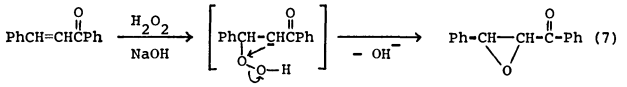
The epoxidation proceeds very little when disulfide (**1**) and thiosulfinic *S*-ester (**2**) were used. Sodium thiolate(**4**) and sulfenyl chloride(**6**), both of which can be oxidized with $O_2^{\cdot-}$, were effective for the epoxidation of none of these olefins, giving complicated reaction mixtures with no epoxide.

Other olefins such as cyclohexene and cinnamonitrile were not oxidized and recovered nearly quantitatively under the conditions, while dibenzoylethylene was very readily oxidized (<1 h) by $O_2^{\cdot-}$ with and without the sulfur compounds to give benzoylformic acid in a good yield as reported previously.[19]

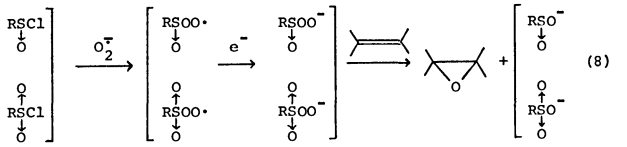
Recently the epoxidation of stilbene, in the reaction system of benzoyl chloride with $O_2^{\cdot-}$, was observed by Hirobe *et al.*[24] We also confirmed the epoxidation of stilbene in the same system (entry 8, Table 5; entries 8 and 9, Table 6). By-products in these reactions are carboxylic acids formed by direct oxidation of olefin and the epoxide with $O_2^{\cdot-}$.

Solvent, crown ether, and substrate also affected the epoxidation (Table 6). Inspection of data in Table 6 reveals that such a polar solvent as acetonitrile is better than dichloromethane or benzene in the epoxidation of chalcones, and the yield of the epoxide increased as the polarity of the solvent increased. However, acetonitrile was not a good solvent in the epoxidation of stilbene since other polar products including benzaldehyde were formed by the cleavage of C–C bond. This was confirmed in both cases using tosyl and benzoyl chlorides. Without crown ether, the yield of the epoxide was rather little in benzene but remained nearly the same in acetonitrile as shown in Table 6 (entries 10 and 11). Even the sterically hindered mesitylene and (+)-*d*-camphor-10-sulfonyl chlorides were also found to be effective in the epoxidation of olefins, however, the yields of the epoxides were relatively low and the rate of the reaction seemed to be slower than that with tosyl chloride. Chalcone epoxide, obtained by the oxidation of chalcone added in the reaction system of (+)-*d*-camphor-10-sulfonyl chloride ($[\alpha]_D^{25}$+20.9°) with $O_2^{\cdot-}$, did not show any optical activity, presumably because the optically active center is so far away from the reaction center.

The yield of stilbene oxide was lower than that of the epoxide from chalcone and its derivatives. Epoxidation of chalcone is known to be initiated by nucleophilic attack of an oxidant such as hydrogen peroxide anion as shown below (Eq. 7).[25] Even stilbene is known to undergo the Michael type addition by the attack of a strong nucleophile in some cases.[26]

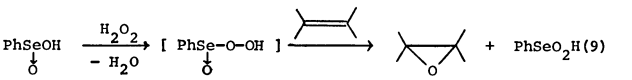


Chalcone, added in the reaction system of disulfide (**1**) with $O_2^{\cdot-}$ in acetonitrile, was not oxidized much, however, upon heating the reaction mixture in the absence of air at 50 °C chalcone decomposed to the corresponding carboxylic acids by the cleavage of C–C bond, as was reported by Rosenthal and Frimer.[27] Chalcone was oxidized in argon atmosphere much more readily without organosulfur compounds than in the presence, revealing that the rate of the reaction of chalcone with $O_2^{\cdot-}$ is appreciably slower than that of the reaction of organic sulfur compound with $O_2^{\cdot-}$. Since the reactions of both sulfinyl and sulfonyl chlorides with $O_2^{\cdot-}$ are considerably faster than that of chalcone with $O_2^{\cdot-}$, the epoxidation is considered to proceed *via* the initial nucleophilic substitution of the chlorides with $O_2^{\cdot-}$ and subsequent one electron transfer to afford the peroxysulfinate(II) and peroxysulfonate (III) which then oxidize olefin to the epoxide as shown in Eq. 8.



Nucleophilicity of $O_2^{\cdot-}$ has been nicely demonstrated in the reactions of various organic compounds with $O_2^{\cdot-}$,[28] and also in the complete inversion of configuration in the S_N2 reaction of an optically active aliphatic halide with $O_2^{\cdot-}$.[29] While none of the electrophilic olefins used was epoxidized with $O_2^{\cdot-}$ alone in our experiment, some cyclic α,β-unsaturated ketones were shown to be epoxidized with $O_2^{\cdot-}$ though in considerably low yields.[30]

Recently, Grieco and his-coworkers found that common nucleophilic olefins are nicely oxidized to the epoxides with benzeneperoxyseleninic acid which is generated *in situ* from benzeneseleninic acid and hydrogen peroxide,[31] apparently suggesting the formation of analogous intermediary peroxyselenium compound (Eq. 9).



Oxidation Mechanisms of Several Sulfur Compounds with $O_2^{\cdot-}$. We have shown previously that several sulfur compounds (**1**—**8**) are oxidized to the corresponding sulfinic and sulfonic acids,[5a,b] and have suggested that the oxidation proceeds *via* formation of peroxysulfur intermediates (I, II, and III). Now let us consider the mechanisms of oxidations of several these

sulfur compounds with $O_2^{\cdot-}$ to the sulfinic and sulfonic acids.

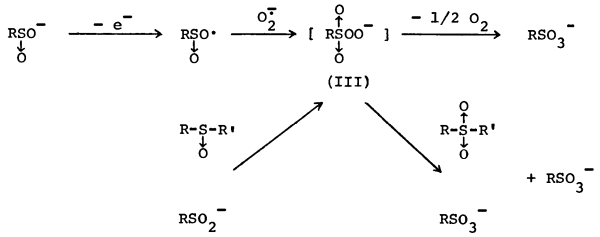
Oxidation of Sodium Sulfinate with $O_2^{\cdot-}$. Anhydrous sodium arenesulfinate can be oxidized with an equimolar amount of $O_2^{\cdot-}$ to afford mainly the sulfonic acid in pyridine at 25 °C for 2.5 h (Eq. 10).[5b] The

$$\mathrm{RSO_2Na} \xrightarrow[\text{18-crown-6}]{\text{eq. } KO_2} \mathrm{RSO_3^-} \quad (+\mathrm{RSO_2^-}: \text{recovery}) \qquad (10)$$

R = Ph, *p*-Tol; pyridine, 25 °C, 2.5 h; ≈80%; ≈17%

initial step of the reaction would be the electron transfer. The resulting sulfonyl radical is known to be an excellent initiator in the polymerization of vinyl monomers or in the autoxidation of sulfinic acid.[32] Peroxysulfonyl radical, $RS(O)_2OO\cdot$, was also postulated in the photolysis of sulfur dioxide[33] in air and also in the autoxidation of sulfinic acid.[32,34] Thus, the oxidation of arenesulfinate with $O_2^{\cdot-}$ is considered to be initiated by one electron transfer and proceed *via* subsequent coupling of the resulted arenesulfonyl radical with $O_2^{\cdot-}$. The peroxyarenesulfonate(III) formed thus would slowly decompose to the sulfonic acid and molecular oxygen, or oxidize the present sulfinate or added sulfoxide to the sulfonate or the sulfone (Scheme 3).

The one electron transfer process from $O_2^{\cdot-}$ or to $O_2^{\cdot-}$ has been shown to be in operation in several reactions of $O_2^{\cdot-}$.[18] In view of the redox potentials of O_2—$O_2^{\cdot-}$ and $O_2^{\cdot-}$—H_2O_2 at neutral pH being −0.33 and +0.94 V, respectively, this radical anion is considered to act as a reductant in the presence of an electron acceptor and as an oxidant in the presence of an electron donor.[19] In fact, during a series of these experiments, evolution of molecular oxygen was observed by gas-mass spectrometry at the peak height of oxygen (*m/e* 32) along with that of argon (*m/e* 40) used, when the reaction was carried out in argon gas. This observation also seems to support the one electron transfer from $O_2^{\cdot-}$.



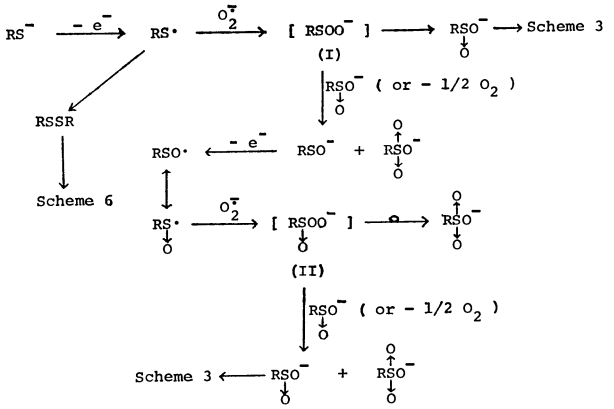
Scheme 3.

Oxidation of Sodium Thiolate with $O_2^{\cdot-}$. Sodium arenethiolate was also found to be oxidized to afford the corresponding sulfinic and sulfonic acids with a small amount of disuflide (Eq. 11).[5b] A similar one

$$\mathrm{RS^-{+}Na} \xrightarrow[\text{18-crown-6, r.t., pyridine, 4 h}]{\text{3eq. } KO_2} \mathrm{RSO_2^-} + \mathrm{RSO_3^-} + \mathrm{RSSR} \qquad (11)$$

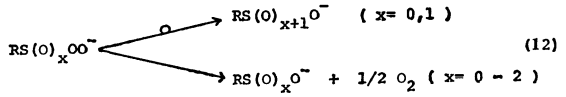
≈10%; ≈86%; trace

electron transfer process is important in this oxidation. Recently, Degrand and Lund suggested that radical recombination of thiyl radical and $O_2^{\cdot-}$ gives sulfinate *via* the rearrangement of the peroxysulfenate(I) in



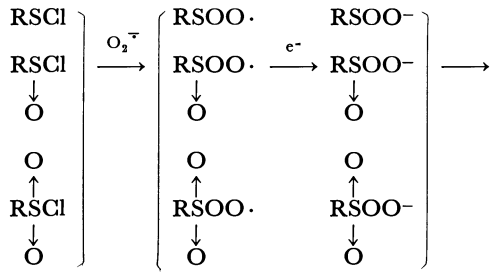
Scheme 4.

the electrochemical synthesis of sulfinic acid from alkyl disulfide and molecular oxygen.[35] As shown in Scheme 4, the thiyl radical thus formed would either dimerize to the disulfide or react with $O_2^{\cdot-}$ to form the incipient peroxysulfenate(I). Recombination of two thiyl radicals has been reported to be very fast ($k = 10^9$—10^{10} M^{-1} s^{-1}).[36] In the reaction of arenethiolate with $O_2^{\cdot-}$ all the intermediates (I—III) can thus be produced and would oxidize the added sulfoxides or the phosphines to the sulfones or the phosphine oxides. Rearrangement of the intermediates(I and II) to the sulfinate and the sulfonate are also conceivable while the degradation of all the intermediates may give both molecular oxygen and the acids (Eq. 12). Peroxysulfur intermediates may also



oxidize arenesulfinate directly to the sulfonate since the added trivalent sulfoxide is readily oxidized and the sulfinate is also another trivalent sulfur compound. Formation of a small amount of disulfide should be due to the recombination of the thiyl radicals. A small amount of diaryl disulfide was also obtained in the alkaline autooxidation of arenethiol, in which thiyl radical and $O_2^{\cdot-}$ were considered to be formed *via* one electron transfer.[36b] This oxidation of thiolate with $O_2^{\cdot-}$ required a little longer reaction time than that of sulfinate, in keeping with the suggested mechanism.

Oxidation of Sulfenyl, Sulfinyl, and Sulfonyl Chlorides with $O_2^{\cdot-}$. The reactions of arene-sulfenyl, -sulfinyl, and -sulfonyl chlorides with $O_2^{\cdot-}$ are considered to be initiated by nucleophilic substitution of the chlorides



with $O_2^{\cdot-}$. Therefore, these three systems should be the best systems to give three peroxysulfur intermediates cleanly (Eq. 13). These three radicals, RSOO·, RS(O)OO·, and $RS(O)_2OO\cdot$, thus formed readily undergo one electron transfer from $O_2^{\cdot-}$ to form the corresponding peroxysulfur anions, which oxidize sulfoxides and olefins, added into the reaction system. The reaction of a sulfonyl chloride with NaO_2 without crown ether have already been reported to afford the corresponding sulfonate in refluxing benzene.[6a]

Oxidation of Thiol and Disulfide with $O_2^{\cdot-}$. Thiols react very readily with $O_2^{\cdot-}$ at first to afford the disulfides, which are then oxidized with $O_2^{\cdot-}$ to the corresponding sulfinic and sulfonic acids (Eq. 14). The

$$RSH \xrightarrow{O_2^{\cdot-}} RSSR \xrightarrow[\text{18-crown-6, r.t.}\atop\text{pyridine or}\atop\text{acetonitrile}]{\text{6 eq. } KO_2} RSO_2^- + RSO_3^- \qquad (14)$$

$$RSH + O_2^{\cdot-} \longrightarrow RS\cdot + HOO^-(RS^- + HOO\cdot)$$
$$2RS\cdot \longrightarrow RSSR$$
$$HOO^- \longrightarrow 1/2O_2 + HO^-$$

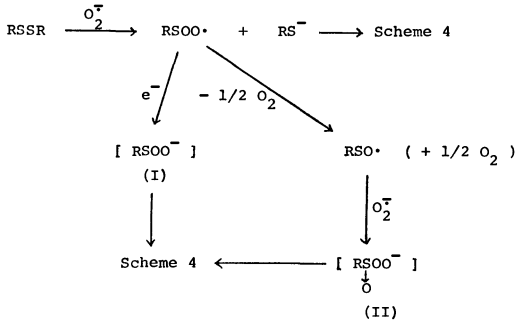
Scheme 5.

initial step of the reaction is the formation of the hydroperoxide anion and the thiyl radical which rapidly coupled to give the disulfide, while hydroperoxide anion may decompose slowly to molecular oxygen and hydroxide anion (Scheme 5).

The reaction of disulfide with $O_2^{\cdot-}$ undoubtedly involves nucleophilic attack of $O_2^{\cdot-}$ on S–S bond. Aromatic disulfide reacts faster than aliphatic disulfide, in keeping with the mechanism involvling the initial nucleophilic attack of $O_2^{\cdot-}$ on disulfide bond. Solvent effect may also support this process.[5b]

The peroxysulfenyl radical formed at the initial stage would undergo one electron transfer or collapse to form I or sulfinyl radical and molecular oxygen, as shown in Scheme 6. The peroxysulfur intermediates can oxidize the added sulfoxides or phosphines to the oxides.

Recently, Hirobe *et al.* reported[24] that two symmetrical disulfides, upon reacting with electrochemically generated $O_2^{\cdot-}$, gave three disulfides involving a new unsymmetrical disulfide in a theoretical ratio of the equilibrium mixture (1:2:1), without any oxidized product. This is quite reasonable if a very small amount of $O_2^{\cdot-}$ (only 1/60 amount of our case) was used. The reaction is considered to generate



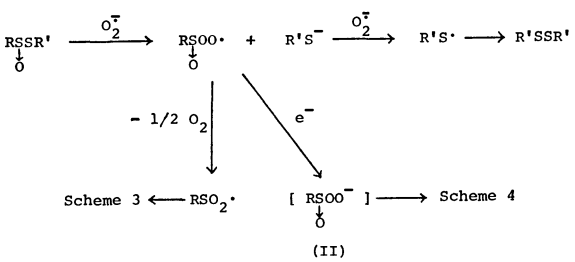
Scheme 6.

the thiyl radical either through the initial one electron transfer from $O_2^{\cdot-}$ to the disulfide or direct S_N2 type displacement of the disulfide with $O_2^{\cdot-}$. The thiyl radical thus formed would scramble the disuflides through S_N2 process rapidly, eventually resulting in the formation of the equilibrium mixture of disulfides.[37] However, when the amount of $O_2^{\cdot-}$ is abundant the initial step should be the nucleophilic reaction of $O_2^{\cdot-}$ on S–S linkage in view of the solvent effect[5b] and the following order of the reactivities, *i.e.* thiosulfinic *S*-ester > thiosulfonic *S*-ester > disulfide.[5b]

Oxidation of Thiosulfinic S-*Ester with* $O_2^{\cdot-}$. Thiosulfinic *S*-ester was found to react with $O_2^{\cdot-}$ more easily than any other sulfur compounds used.[5b] The reaction proceeded readily even at −40 °C within an hour, and not only sulfinic and sulfonic acids but also symmetrical disulfide were obtained (Eq. 15).[5]

$$\underset{\text{O}}{\overset{\downarrow}{\text{RSSR}'}} \xrightarrow[\text{18-crown-6}\atop\text{pyridine, } -40\,^\circ\text{C}\atop\text{within 1 h}]{\text{5 eq. } KO_2} \underset{\text{trace}}{RSO_2^-} + \underset{\approx 48\%}{RSO_3^-} + \underset{\approx 50\%}{R'SSR'} \qquad (15)$$

The symmetrical disulfide was formed in ≈50% yield only from the sulfenyl side and the two acids only from the sulfinyl side, revealing that the nucleophilic attack of $O_2^{\cdot-}$ occurs only on the sulfinyl sulfur of the unsymmetrical thiosulfinic *S*-ester. The predominant formation of the sulfonic acid may indicate that the main reaction path after the attack of $O_2^{\cdot-}$ is the rearrangement of peroxysulfinate(II) to the sulfonate. Therefore, peroxysulfinate(II) would be unstable enough to rearrange to the sulfonate under these conditions, and hence it would not be a good oxidizing agent of sulfoxide, thus yield of the sulfone being rather small (Table 2). Only when the temperature was elevated, the yield of the sulfone gradually increased (Table 2).



Scheme 7.

Oxidation of Thiosulfonic S-*Ester with* $O_2^{\cdot-}$. In the reaction of unsymmetrical thiosulfonic *S*-ester with $O_2^{\cdot-}$, however, two sulfinic and two sulfonic acids were obtained from both sulfur sides along with a small amount of symmetrical disulfide (*ca.* 25%) from the sulfenyl sulfur side (Eq. 16),[5b] revealing clearly that

$$\begin{array}{c}\text{O}\\\uparrow\\\text{RSSR}'\\\downarrow\\\text{O}\end{array} \xrightarrow[\text{18-crown-6}\atop\text{pyridine, } 0\,^\circ\text{C}\atop\approx 30\text{ min}]{\text{4 eq. } KO_2} \begin{bmatrix}RSO_2^-\\R'SO_2^-\end{bmatrix} + \begin{bmatrix}RSO_3^-\\R'SO_3^-\end{bmatrix} + R'SSR' \qquad (16)$$

the nucleophilic attack of $O_2^{\cdot-}$ occurs at both sulfenyl (a) and sulfonyl (b) sulfur atoms of the thiosulfonic *S*-ester (Scheme 8). The thiolate anion formed in the initial step must be converted to the disulfide by

Table 7. Change of product distribution[a)]

Entry No.	Substrate	Temp/°C	Time/min	Solvent	Additive	Yield/%	Yield/%

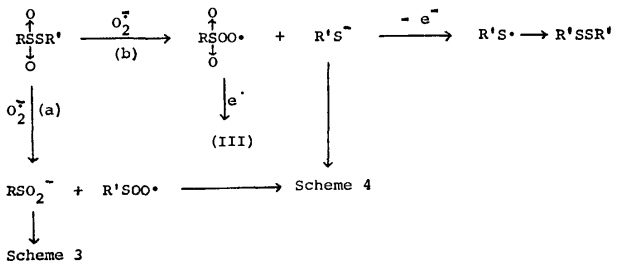


Scheme 8.

rapid recombination of the thiyl radicals after one electron transfer. At *ca.* 0 °C, the sulfinate would not be oxidized any further. The low yield of the sulfone formation from added sulfoxide should be also due to the low reaction temperature.

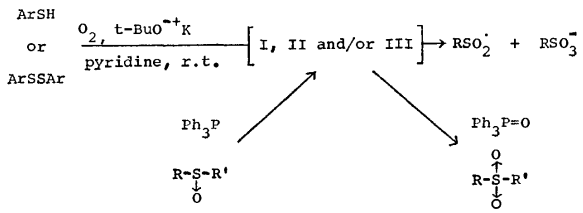
Both this reaction and that of thiosulfinic *S*-ester clearly involve the initial nucleophilic attack of $O_2^{\cdot-}$ at sulfur atoms of S–S linkage and gave partially the disulfide. A similar nucleophilic substitution(S_N2) on sulfur atom of S–S linkage has been observed in the alkaline hydrolyses of both compounds.[37)]††

Addition of the sulfoxide or the phosphine as a trapping agent into the reaction systems of disulfide and thiosulfinic *S*-ester with $O_2^{\cdot-}$ changed distribution of the products (Table 7). Amount of the sulfinate increased appreciably while that of sulfonate decreased only a little by the additives, very likely due to the two competitive reactions, *i.e.* the reactions of peroxysulfinate(II) with sulfoxides or phosphines to the sulfones or the phosphine oxides and the rearrangement of II to the sulfonate.

Thus, the reactions of these organosulfur compounds each having S–S linkage with $O_2^{\cdot-}$ are another S_N2 processes, like the nucleophilic substitution of alkyl halide or tosylate with $O_2^{\cdot-}$.[39)] This S_N2 mechanism with $O_2^{\cdot-}$ is in good accordance with the order of the reactivities of the three disulfidic species (**2**>**3**>**1**).[5)] This order is identical to that of the reactivities of the three in the alkaline hydrolyses.[38)]

Among a few trapping agents used, dimethyl sulfoxide was found to be the best reagent. Phosphines were not the good trapping agents since they reacted easily with several substrates. Olefins are relatively less reactive while the epoxides formed are usually so reactive that the epoxide itself reacted with various species present in the reaction system.

Since the alkaline autoxidation of thiols and disulfides gives sulfinate and sulfonate, and is expected to involve the peroxysulfur intermediates,[8,40)] a mixture of the sulfoxide or the phosphine (2 mmol), thiol or disulfide (1 mmol) and potassium *t*-butoxide (2 mmol) was treated in pyridine (5 ml) under pure oxygen atmosphere at room temperature for 0.5—11 h. Indeed, the sulfone (≈10.6%) or the phosphine oxide (≈20.2%) was obtained besides the autoxidation products of sulfinic and sulfonic acids[41)] (Scheme 9). Both sulfoxides and phosphines were inert under the conditions without any one of these sulfur compounds. Thus, the mechanism for the autoxidation suggested by Berger[8)] is considered to be identical to that of the reactions of disulfides and other related sulfur compounds with $O_2^{\cdot-}$, involving the common peroxysulfur intermediates (I, II, and/or III).



Scheme 9.

Among these peroxysulfur intermediates the peroxysulfenate(I) seems to collapse most readily. The oxidation of sulfoxide with I—III seems to be faster than that of olefin (Tables 1, 2, 5, and 6). The peroxysulfinate(II) is more stable and fairly reactive while only the peroxysulfonate(III) is stable enough to be characterized and hence be utilized for the oxidation of sulfoxide and olefin.

Experimental

General. All the reactions with $O_2^{\cdot-}$ were carried

†† These two reactions can be also conceivable but the second reaction (B) should be minor since amount of $O_2^{\cdot-}$ is considerably large at the initial stage in the reactions of both **2** and **3**.

$$R\text{-}S(O)_x\text{-}S\text{-}R' \xrightarrow{O_2^{\cdot-}} R\text{-}S(O)_xOO\cdot + R'\text{-}S^- \quad (A)$$

$$R\text{-}S(O)_x\text{-}S\text{-}R' + R'\text{-}S^- \longrightarrow RS(O)_x^- + R'SSR' \quad (B)$$

out under dry argon atmosphere.

Melting points were taken on a Yanaco instrument. NMR spectra were recorded on a Hitachi Perkin-Elmer R-20 spectrometer. Gas and liquid chromatographic analyses were carried out with Shimadzu GC-6A and Yanaco L-1030 instruments, respectively. Specific rotations were calculated from the values of optical rotations which were measured by a JASCO DIP-140 polarimeter using a 5 cm quartz cell.

Materials. KO_2 was obtained from Ventron Products. 18-Crown-6 was from Wako Pure Chemical Ind. and used after drying *in vacuo* by heating at 60—70 °C. All the solvents used except for CH_2Cl_2 were purified by distillation and dried with drying agent, as shown in the preceding paper.[5b] Purification of CH_2Cl_2 was performed at first by drying with $CaCl_2$ and then distillation after filtration. Distilled CH_2Cl_2 was stored in dark under N_2 in the presence of $CaCl_2$.

Preparation and purification of all the disulfides, thiosulfinic *S*-esters, thiosulfonic *S*-esters, sodium thiolates, and sodium sulfinates as substrates are reported in our previous paper.[5b]

Extra pure reagent grade triphenyl- and tributylphosphines, *trans*-stilbene and trichloromethanesulfonyl chloride from Wako Pure Chemical Ind. were directly used without any treatment. Tosyl and mesitylene-sulfonyl chlorides from Wako were used after recrystallization from hexane. Benzoyl chloride was purified by distillation and dehydration with $CaCl_2$, and DMSO was purified by distillation and stored under dry nitrogen gas. Diphenyl sulfoxide and acenaphthylene from Tokyo Kasei Kogyo were also used after recrystallyzation. Three chalcone derivatives were all from Aldrich Chemical Company and directly used for the reaction.

Sulfoxides, *i.e.* *p*-chlorophenyl methyl, methyl *p*-tolyl, and methyl phenyl sulfoxides, were prepared by oxidations of the corresponding sulfides with H_2O_2 in AcOH.[42] All the sulfoxides were determined by measuring the absorption peaks at the region of 1040—1060 cm^{-1} in their IR spectra. Thianthrene 9-oxide was prepared by a known method.[43] Benzenesulfenyl chloride was prepared by the reaction of benzenethiol with gaseous chlorine according to a known method.[44] The crude product was purified by distillation (bp 75—79 °C/3.0 Torr (1 Torr=133.322 Pa)). *p*-Toluenesulfinyl chloride was also prepared by the reaction of *p*-toluenethiol with gaseous chlorine in the presence of acetic anhydride.[44] The crude product was purified by distillation (bp 110 °C/2.5 Torr).

(+)-d-Camphor-10-sulfonyl chloride was prepared by treating (+)-*d*-camphor-10-sulfonic acid (from Wako) with PCl_5. To the sulfonic acid (0.5 mol) dissolved in $CHCl_3$ (150 ml) was added slowly solid PCl_5 (0.7—0.9 mol). After slow evolution of HCl gas, the mixture was heated at refluxing temperature for *ca.* 1 h. The resulting clean colorless mixture was washed more than three times with water. Organic layer was dried with $MgSO_4$ and the solvent was evaporated to afford the sulfonyl chloride which was purified by recrystallization from hexane. Yield 72%. IR (KBr, cm^{-1}, S=O) 1365 and 1168. $[\alpha]_D^{25}+20.9°$ (c=4.3, $CHCl_3$) (lit,[45] $[\alpha]_D^{25}+28.8°$ (C=4.2, $CHCl_3$).

Oxygen Trapping Reaction. The amount of KO_2 in the reaction of each substrate was not kept constant and hence is shown in each Table, which also shows reaction time, molar ratio of additives, and solvent used.

Oxidation of Additives Added in The Reaction System with $O_2^{\cdot-}$. The following is a typical run for the "*Oxidation of Sulfoxide.*" A solution of diphenyl sulfoxide (2 mmol) and di-*p*-tolyl disulfide (1 mmol) in dry acetonitrile (5 ml) was added with a syringe into a heterogeneous solution of KO_2 (6 mmol, finely powdered in advance and stored under nitrogen) and dry 18-crown-6 (1 mmol, dried *in vacuo* at 60—70 °C) in the same solvent in a two-necked flask under dry argon atmosphere at 21 °C. The resulting heterogeneous mixture was stirred at the same temperature for 6 h, during which the substrate generally disappears nearly completely. After the consumption of the substrate the reaction mixture was quenched by pouring into excess cold water containing crushed ice. Extraction with $CHCl_3$, drying with $MgSO_4$ and evaporation of $CHCl_3$ gave an oily residue. The residue, containing oxidized sulfone, unreacted sulfoxide, and crown ether, was subjected to column chromatography through silica gel using an eluent of a mixed solvent of hexane:EtOAc:$CHCl_3$=4:1:1. Yield of sulfone was 54% based on the starting disulfide.

When a sulfoxide bearing methyl group was used the yield of the sulfone was directly determined by integration ratio of the NMR spectrum of the crude mixture. The sulfones formed were identified by comparing the melting points or chemical shifts in NMR spectra with those of authentic samples.

Oxidation of phosphines in the reaction system was carried out according to the same procedure as mentioned for sulfoxide. The yield of the phosphine oxide was measured by injecting the reaction mixture directly into GC since the phosphine was actually oxidized in the usual work-up. The phosphine oxide was not produced at all, even if the reaction mixture was injected directly into GC instrument. The phosphine oxides obtained were found to be identical to the authentic samples by comparing the retention times in GC.

Epoxidation of olefin in the reaction system was also carried out similarly. However, the work-up was different, *i.e.* the reaction mixture, after stirring till the disappearance of most of substrate, was stirred further for a few hours. The resulting heterogeneous reaction mixture was filtered and the residue was washed with a large amount of CH_2Cl_2 ($\approx$40 ml). The combined organic layer was subjected to the assay after evaporation of organic solvent. Yield of the epoxide in the residue was sometimes determined by isolation by column chromatography through silica gel using benzene (or benzene–hexane) as an eluent. However, the amount of the epoxide was determined usually by HPLC. In some cases, the yield of the epoxide was directly estimated by measuring the NMR spectrum of the residual mixture. Epoxides thus obtained were identified by comparing the chemical shifts of the methine protons with those of the authentic samples as shown in Table 4.

The Liquid-phase Oxidation of Methylbenzenes by the Cobalt–Copper–Bromide System

Toshihiko OKADA* and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 30, 1980)

The liquid-phase oxidation of methylbenzenes catalyzed by a catalyst system composed of cobalt(II) and copper(II) acetates and sodium bromide was carried out in acetic acid at 150 °C. The corresponding benzyl acetates and benzaldehydes were obtained in high selectivities in most cases. A nuclear-brominated product, *i.e.*, 3-bromo-4-methoxytoluene was also obtained in the oxidation of *p*-methoxytoluene, which has two different reaction sites, *i.e.*, *o*-positions to the electron-donating methoxyl substituent and the benzyl position. However, the substitution of the bromide ion for the acetate ion in the catalyst system gave satisfactory selectivities for the side-chain oxidation products. In *p*-xylene oxidation, α,α′-diacetoxy-*p*-xylene and *p*-(acetoxymethyl)benzonic acid were also obtained, as well as *p*-methylbenzyl acetate, though their amounts were small. The oxidation of polymethylbenzenes was also carried out.

There have been many reports concerning liquid-phase oxidations catalyzed by transition metal ions.[1] In general, however, primary products (*e.g.*, aldehyde or alchhol) are more sensitive toward oxidation than the starting substrate, and the selective synthesis of alcohols with the liquid-phase oxidation has some limitations.[2] An improved method for the alcohol and glycol synthesis is to use the acetoxylation of them, by which the resulting primary products are restrained toward the secondary oxidation. In acetoxylation, many transition metals are employed as catalysts: palladium(II) acetate for a nuclear[3] and a side-chain acetoxylation of aromatic hydrocarbons,[4] silver(I) acetate for a side-chain acetoxylation,[5] and copper(II) acetate–lithium bromide,[6] and tellurium dioxide–hydrogen bromide[7] for olefens. In a previous report,[8] we have studied the liquid-phase oxidation of toluene catalyzed by a cobalt(II) acetate–sodium bromide catalyst in the presence of copper(II) acetate in acetic acid, we found that benzyl acetate, which is a useful organic intermediate for benzaldehyde and benzyl alcohol synthesis, can be synthesized in one pot.

In the oxidation of toluene catalyzed by the Co–Cu–Br system, the reaction can be considered to proceed through the abstraction of α-hydrogen by bromide atoms (from cobalt(III) bromide or copper(II) bromide), the ligand-transfer of the resulting benzil radical by copper(II) bromide to benzyl bromide, and the replacement of benzyl bromide with the acetate ion to give benzyl acetate.

Here, we wish to report on the liquid-phase oxidation of substituted toluenes and polymethylbenzenes catalyzed by the Co–Cu–Br system as an extension of the study of the oxidative side-chain acetoxylation of aromatic hydrocarbons.

Experimental

General. *p*-Methoxytoluene, *p*-xylene, *p*-chlorotoluene, *p*-*t*-butyltoluene, *p*-nitrotoluene, *etc.*, mesitylene, durene, and hexamethylbenzene were purified by usual methods. When a substrate easily oxidized to the hydroperoxides was used, the substrate was further treated with an active alumina.

Acetic acid, cobalt(II) acetate tetrahydrate, copper(II) acetate monohydrate, and sodium bromide of a reagent grade were used without further purification. The products were identified by means of IR (Shimadzu IR 420) ^{1}H-NMR (Varian EM 360A), and GC-MS (ANELVA TE 600S).

Oxidation Procedure. A 200-ml Ti-made autoclave equipped with a gas inlet, a magnetic-induced stirrer, and a pressure gauge was charged with *ca.* 50 mmol of a substrate, 4 mmol of cobalt(II) acetate, 4 mmol of copper(II) acetate, 28 mmol of sodium bromide, and 60 ml of acetic acid. Then, the autoclave, pressured with air to 40 kg/cm^2 was placed in an electric furnace and heated to 150 °C.

After 1.0 h, the autoclave was cooled with water and vented. Internal standards (chlorobenzene, *p*-bromoanisole, and 1-chloronaphthalene) were then added to the autoclave. The contents were poured into ice water and then extracted with ether.

The extract was washed with water and a saturated sodium carbonate solution, and subsequently dried (sodium sulfate), and the ether was removed on a rotary evaporator. The residue was submitted to GC analysis.

The substituted benzoic acids isolated by the acidification of the combined aqueous solution were determined by the weighing of their quantities or by ^{1}H-NMR analysis. The GC analysis was mainly conducted on a Shimadzu GC-3T gas chromatograph, using a 10% PEG 20 M on Uniport B column operated isothermally at 180 °C.

Results and Discussion

The liquid-phase oxidations of the substituted toluenes were carried out in acetic acid, using cobalt(II) and copper(II) acetates and a sodium bromide system with air. The results are summarized in Table 1. As may be seen from the Table, a corresponding substituted benzyl acetate was obtained as the main product, along with a significant amount of the substituted benzaldehyde. The increase in the electron-donating ability of the substituent on the ring caused the higher conversion, which is roughly accordant with the tendencies on the oxidation of substituted toluenes catalyzed by a cobalt–bromide system[9] and on the bromination with NBS.[10] As compared with the palladium-catalyzed side-chain acetoxylation of methylbenzenes, the Co–Cu–Br catalyzed reaction seems to be more useful because of the lower cost of the catalyst and because of the possibility of a wider application to the acetoxylation of many methylbenzenes (the palladium-catalyzed reactions of

Table 1. Oxidation of substituted toluenes catalyzed by the Co–Cu–Br system

p-Tolualdehyde[d]	98	0	1
p-Methylbenzyl acetate[e]	82	44	17

Reaction conditions: $[Co(OAc)_2]=[Cu(OAc)_2]=5.7\times10^{-2}$ M,† [NaBr]=0.4 M, [Substrate]=0.7 M, air pressure; 40 kg/cm², 1.0 h, 150 °C. a) Based on the substrate consumed. b) 3-Bromo-4-methoxytoluene (20%) was also obtained. c) The evolution of carbon dioxide was observed. d) The other product was *p*-toluic acid. e) *p*-Tolualdehyde (16%) and *p*-acetoxymethylbenzoic acid (8%) were also obtained, accompanied by *p*-toluic acid (10%).

toulenes bearing substituents such as chloro, nitro, and methyl groups more than two on the ring are very slow[4]). It is noteworthy that the benzaldehyde, as a by-product, can also be obtained in many cases. However, in the *p*-methoxytoluene oxidation, as will be described later in detail, a ring bromination occurred, because 3-bromo-4-methoxytoluene was detected. On the other hand, it is interesting that *p*-acetoxymethylbenzoic acid can be produced, though its yield is low in the oxidation of *p*-toluic acid. The oxidation of *p*-tolualdehyde gave *p*-toluic acid as the sole product, suggesting that the aldehyde group in the catalyst system is more sensitive toward the oxidation. On the other hand, the mechanism in the oxidation by the Co–Cu–Br system has been estimated on the basis of the results of an earlier variable study.[8] It could be considered to proceed through the pathway of the bromination with copper(II) bromides of the benzyl radical, which can be produced from the hydrogen abstraction of benzylic hydrogen by cobalt(III) bromide and/or bromine atoms arising from the rapid reaction of cobalt(II) bromide and the peroxyl radical[9] and from the decomposition of copper(II) bromide,[11] *i.e.*,

$$ArCH_3 \xrightarrow[\text{and/or Br}\cdot]{\text{Co(III)Br}} ArCH_2\cdot \xrightarrow{\text{Cu(II) Br}} ArCH_2Br \xrightarrow{OAc^-} ArCH_2OAc.$$

Although aryl alkyl bromides can usually be detected under the given conditions because of the low substitution rate of aryl alkyl bromide with the acetate ion, aryl alkyl bromide could hardly be detected under the conditions employed here suggesting that the substitution is rapid. Furthermore, the rate of the ligand transfer by copper(II) halides is known to be diffusion-controlled according to the study by

† 1M=1 mol dm^{-3}.

Table 2. Oxidation of *p*-methoxytoluene catalyzed by the Co–Cu system

Sodium salt	*p*-Methoxytoluene conversion/%	Products (mol%)[a] $ArCH_2OAc$	Products (mol%)[a] ArCHO	Products (mol%)[a] [A][b]

Reaction conditions: $[Co(OAc)_2]=[Cu(OAc)_2]=5.7\times10^{-2}$ M, [Sodium salt]=0.4 M, [*p*-Methoxytoluene]=1.4 M, air pressure; 40 kg/cm², 1.0 h, 150 °C. a) Based on the *p*-methoxytoluene consumed. b) [A] represents 3-bromo-4-methoxy toluene. c) This run was carried out under the conditions: 100 °C, 20 h, air flow. e) Acetic anhydride (5 ml) was added. d) [*p*-Methoxytoluene]=0.7 M.

Kochi.[12] Therefore, the substituents on the ring can be considered to influence the hydrogen abstraction of benzylic hydrogen.

As has been mentioned above, 3-bromo-4-methoxytoluene and *p*-anisic acid were both obtained as by-products in the oxidation of *p*-methoxytoluene. In order to avoid the ring bromination, some experiments were carried out (Table 2). Many works have reported on the ring halogenation of aromatic hydrocarbons with copper(II) halides at high temperatures,[13] and it is a useful method for the halogenation even now. On the other hand, a cobalt(III) acetate and halogen-ion system such as cobalt(III) chloride,[14] has also the ability to effect ring halogenation as well as side-chain halogenation. Accordingly, it appears to be difficult to prevent the ring bromination in the Co–Cu–Br catalyzed oxidation of *p*-methoxytoluene, because the above two systems exist. Indeed, the ratio of the amount of the benzyl acetate to the ring-bromination product at a low conversion shows nearly the same value as at a high conversion (Table 2). The ^{1}H-NMR analysis of the reaction mixture (an ether residue) showed the formation of 3-bromo-4-methoxybenzyl acetate when the conversion of *p*-methoxytoluene was completely achieved. A ring bromination similar to the oxidation of *p*-methoxytoluene was observed in the oxidation of 1-methylnaphthalene, *m*-phenoxytoluene, and mesitylene (*e.g.*, in the oxidation of 1-methylnaphtalene, 4-bromo-1-methylnaphthalene(12%) was obtained, accompanied by 1-naphthaldehyde(18%) and 1-acetoxymethylnaphthalene-(39%) at a 70% conversion of 1-methylnaphthalene). Since *p*-methoxytoluene, having a relatively lower ionization potential, could be supposed to react with cobalt(III) acetate even in the presence of copper(II) acetate, a run with no bromide ion was examined. However, the induction period was found to be very long in the cobalt(II) and copper(II) acetates system. The addition of the acetate ion to the system, however, caused a rapid oxidation, in which satisfactory selectivities for the benzyl acetate and the benzaldehyde were achieved. It is interesting that an unusual selectivity for *p*-anisaldehyde was obtained. Fur-

Table 3. Oxidation of *p*-xylene catalyzed by the Co–Cu–Br system

Run	1	2

Terephthalic acid	0	—
p-Acetoxymethylbenzoic acid	4	—

Reaction conditions: $[Co(OAc)_2]=[Cu(OAc)_2]=5.7\times10^{-2}$ M, [NaBr]=0.4 M, air pressure: 40 kg/cm², 150 °C, 1.0 h. a) Based on the *p*-xylene consumed. b) No determination.

thermore, the addition of acetic anhydride accelerated the oxidation and caused a higher selectivity for the benzyl acetate. Recently, Imamura has reported in detail on the oxidation of *p*-methoxytoluene catalyzed by the addition of cobalt(II) acetate and a small amount of a bromide-ion system to *p*-anisaldehyde, he found that *p*-methoxybenzyl acetate was also obtained under the given conditions.[15] However, our results are somewhat better than their results in the selectivity for *p*-methoxybenzyl acetate. As it is now well established that cobalt(III) acetate can oxidize alkyl aromatics such as toluene by direct electron-transfer, even in the presence of oxygen,[16] the mechanism in the Co–Cu–OAc system can be estimated to be as follows:

$$Co(III) + p\text{-}MeOC_6H_4CH_3 \rightleftharpoons Co(II) + (p\text{-}MeOC_6H_4CH_3)^{+}$$

$$(p\text{-}MeOC_6H_4CH_3)^{+} \longrightarrow p\text{-}MeOC_6H_4CH_2\cdot + H^{+}$$

$$p\text{-}MeOC_6H_4CH_2\cdot + Co(III) \text{ and/or } Cu(II) \longrightarrow p\text{-}MeOC_6H_4CH_2OAc$$

$$p\text{-}MeOC_6H_4CH_2\cdot + O_2 \longrightarrow p\text{-}MeOC_6H_4CH_2OO\cdot \xrightarrow[Co(III)]{} p\text{-}MeOC_6H_4CHO.$$

However, as has previously been reported, it should be mentioned that the oxidizing activity of cobalt(III) acetate was lowered by the binuclear complex formation with copper(II) acetate.[17]

As has been described above, many important oxidation products of *p*-xylene are used as monomers in the polymer industry.[18] α,α′-*p*-Xylene-diol and *p*-hydroxymethylbenzoic acid as well as terephthalic acid are of particular interest.

Thus, we attemped the synthesis of these compounds in the oxidation of *p*-xylene by the Co–Cu–Br system. The results are presented in Table 3. At a low conversion of *p*-xylene, the products are *p*-methylbenzyl acetate and *p*-tolualdehyde, by analogy with the substituted toluene oxidations. On the other hand, at a high conversion, since *p*-xylene has two methyl groups, many products were obtained. It was found that *p*-xylene-α,α′-diol and *p*-acetoxymethylbenzoic acid are obtainable, though small amounts. Thus, the secondary oxidations of *p*-methylbenzyl acetate, *p*-toluic acid, and *p*-tolualdehyde were investigated. As has already been shown in Table 1, although no effort to seek out the optimum conditions for the selective oxidation was made, the expected compounds were obtained in considerable amounts. In the oxidation of *p*-methylbenzyl acetate, *p*-tolualdehyde was also obtained, even at a low conversion (for example, at a 44% conversion, 17% of *p*-tolualdehyde as well as 54% of α,α′-diacetoxy-*p*-xylene and 20% of *p*-acetoxymethylbenzaldehyde were obtained), indicating that the further oxidation of the benzyl acetate can not be ignored in these cases. Under these conditions, the oxidation of benzyl acetate gave benzaldehyde(14%) and benzoic acid(76%) at a 55% conversion of benzyl acetate. Therefore, there appears to be a limitation in the one-step synthesis of α,α′-diacetoxy-*p*-xylene with the oxidation of *p*-xylene. However, the results of the oxidation of *p*-tolualdehyde and *p*-toluic acid indicate that the formation of *p*-acetoxymethylbenzoic acid in the oxidation of *p*-xylene is through the pathway of the secondary oxidation of *p*-methylbenzyl acetate, because of the low rate of *p*-toluic acid oxidation and the high rate of *p*-tolualdehyde oxidation.

Table 4. Oxidation of polymethylbenzenes catalyzed by the Co–Cu–Br system

Substrate	Conversion %	Products (mol%)[a]	
		$ArCH_2OAc$	ArCHO
o-Xylene[b]	89	34	1
p-Xylene[b]	34	34	13
Mesitylene	89	49	11
Durene	98	63	10
Hexamethylbenzene	99	45	8

Reaction conditions: $[Co(OAc)_2]=[Cu(OAc)_2]=5.7\times10^{-2}$ M, [NaBr]=0.4 M, [Substrate]=0.7 M, air pressure; 20 kg/cm², 150 °C, 1.0 h. a) Based on the substrate consumed. b) Air pressure; 40 kg/cm².

Accordingly, it was concluded that two synthetically useful compounds, α,α′-diacetoxy-*p*-xylene and *p*-acetoxymethylbenzoic acid, were obtainable in the oxidation of *p*-methylbenzyl acetate, for the by-products are the precursors of *p*-acetoxymethylbenzoic acid.

$$p\text{-}CH_3C_6H_4CH_2OAc \xrightarrow{Co\text{-}Cu\text{-}Br} p\text{-}AcOCH_2C_6H_4CH_2OAc,\ p\text{-}AcOCH_2C_6H_4COOH$$

$$p\text{-}CH_3C_6H_4CHO \qquad p\text{-}AcOCH_2C_6H_4CHO$$

By-products

$$p\text{-}CH_3C_6H_4COOH \qquad p\text{-}AcOCH_2C_6H_4COOH$$

Finally, the Co–Cu–Br catalyzed oxidations of *o*- and *p*-xylenes, mesitylene, durene, and hexamethylbenzene were conducted. The results are summarized in Table 4. Since these compounds have more

than two methyl groups and low ionization potentials, they were very reactive as compared with the palladium-catalyzed side-chain acetoxylation. In the oxidation of hexamethylbenzene, for example, the products which have more than two oxidized methyl groups were detected, though they could not be completely determined before the whole conversion.

Then, the reaction was controlled by the amount of oxygen charged. As may be seen from Table 4, the monoacetoxylated compounds can be synthesized in high selectivities, even if at a high conversion.

In the oxidation of mesitylene, as has been reported by many workers,[19] the ring bromination occurred, though its amount was not determined.

In conclusion, the Co–Cu–Br system previously reported in the oxidative side-chain acetoxylation of toluene was found to be applicable to the side-chain acetoxylation of substituted toluenes and polymethylbenzenes. In the oxidation of *p*-methoxytoluene, ring bromination also occurred, although the side reaction could be removed by replacing the bromide ion in the catalyst system with the acetate ion.

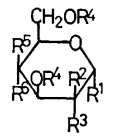
The Synthesis of α-D-Galactopyranosyl and α-D-Mannopyranosyl 2-Amino-2-deoxy-α-D-glucopyranosides and the Conformation of Their Glycoside Linkage[1]

Shinkiti Koto,* Shigeru Inada, and Shonosuke Zen
School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108
(Received November 14, 1980)

A new analog of trehalosamine, α-D-galactopyranosyl 2-amino-2-deoxy-α-D-glucopyranoside, was synthesized by the glycosylation of 2,3,4,6-tetra-*O*-(*p*-chlorobenzyl)-α-D-galactopyranose with 3,4,6-tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranosyl bromide, using silver perchlorate and tribenzylamine in benzene, followed by chromatographic separation and the subsequent removal of the protecting groups. Similarly, α-D-mannopyranosyl 2-amino-2-deoxy-α-D-glucopyranoside was synthesized. The conformation of the glycoside linkage of these α,α-disaccharides is discussed in relation to the ^{13}C chemical shifts of their anomeric carbons.

Trehalosamine (**25**)[2] and its analogs[3] are unique antimicrobial aminoglycosides which are 1,1′-linked disaccharides. However, since the synthesis of **25**,[4] only a few non-symmetrical α-glycosyl α-glycosides with an amino group have thus far been synthesized,[5] although the chemical modification of α,α-trehalose has often been performed recently.[6,7] Interestingly, some antibiotics possess the structure of 1,1′-linked glycosyl glycoside.[8] Such circumstances prompted us to synthesize the *galacto* analog (**17**) as well as the *manno* one (**21**) of trehalosamine. After our work had been completed, a synthesis of **21** *via* a different route was described.[9]



Compound	R^1	R^2	R^3	R^4	R^5	R^6
1	Br	H	NHDp	Ac	H	OAc
2	OH	H	OCb	Cb	OCb	H

4	OH	H	OCb	Cb	H	OCb
5	OH	H	NHDp	Ac	H	OAc

Ac=acetyl, Cb=*p*-chlorobenyl, Dp=2,4-dinitrophenyl.

3,4,6-Tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranosyl bromide (**1**),[10] occasionally used for synthesizing various 2-amino-2-deoxy-α-D-glucopyranosides,[11] was chosen to perform the glycosylation of 2,3,4,6-tetra-*O*-(*p*-chlorobenzyl)-α-D-galactopyranose (**2**).[12] The condensation using silver perchlorate[13] and tribenzylamine[14] in benzene at room temperature gave the α,α-form of the 1,1′-linked disaccharide derivative (**6**) as the main product. The chromatography of the reaction mixture gave **6** and three other configurational isomers (**7**, **8**, and **8a**) in yields of 35, 15, 9, and 3% respectively.

The protecting groups of **6** were removed in the order of deacetylation with a dil solution of sodium methoxide in methanol, dedinitrophenylation with a basic resin in aq acetone, and dechlorobenzylation by catalytic hydrogenolysis over palladium black in aq acetic acid, followed by deionization with a basic resin to afford **17** in a 16% yield from **2**. When the other three isomers **7**, **8**, and **8a**, were subjected to the above set of deprotection processes, they were converted into **18**, **19**, and **20** respectively.

The glycosylation of the mannose derivative (**3**) with **1** was next performed similarly to furnish the α,α-linked disaccharide derivative (**9**) in a 31% yield. Again, three isomers (**10**, **11**, and **12**) were separated from the glycosylation mixture. The deprotection of **9** gave the *manno* analog of trehalosamine, **21**, in a 16% yield from **3**.

Trehalosamine, **25**, was itself similarly synthesized from **1** and the α-glucopyranose derivative (**4**) *via* the afore-mentioned glycosylation.

Synthetically speaking, two facts are worthy of notice: first, even in the case of a configurationally pure α-D-hexopyranose derivative (**2**, **3**, or **4**),[12] all four configurational isomers of the 1,1′-linked heterodisaccharides were always formed in such glycosylation; secondly, small amounts of the self-condensation products of such hexopyranose derivatives were always formed during the reaction.

Based on the magnitude of the specific rotation of hexosyl glucosaminides (**17**—**28**), the structure of the most *dextro*-rotatory α,α-isomers and the most *levo*-rotatory β,β-isomers were readily assigned. The molecular rotations of **17** and **21** and their acetates (**29** and **30**) reasonably coincide with those of the structurally related 1,1′-linked disaccharides and their acetates (Table 1). The anomeric configurations of twelve 1,1′-linked hexosyl glucosaminides were then checked by measuring the ^1H chemical shifts of the anomeric hydrogens (Table 2). The pH-dependent

^{13}C NMR signals[8b,15] (Tables 3, 4, and 5) were quite useful in assigning the signal of C-1[16] of the two anomeric carbons in 1,1′-linked disaccharides, since, at a lower pH, the signal of the C-1 neighboring the carbon bearing amino group moved upfield, while that of C-1′ did not. The differences (Δ) in the value of the pH-dependent ^{13}C chemical shift of C-1 (Tables 3, 4, and 5) are almost constant, regardless of the configurations of C-1 and C-1′ (-3.7 ± 0.2 ppm). The data in Tables 3—5 show that the signal of C-2 was of use in diagnosing the anomeric configuration of glucosaminides (56.1 ± 0.1 ppm for the α-anomers and 57.4 ± 0.1 ppm for the β-anomers), whereas that of C-4′, which is insensitive to the anomeric

configuration, was good as a probe of the galactopyranosyl (69.5±0.2 ppm) and mannopyranosyl (67.9 ±0.1 ppm) moieties.

One of our aims in the present study was to observe the ^{13}C chemical shifts of the anomeric carbons of 1,1′-linked disaccharides, in which the conformation of the glycoside linkage would be influenced by the *exo*-anomeric effect[17] exterted by both glycoside bonds, C-1–O and C-1′–O. The data in Tables 3—5 show that the ^{13}C chemical shifts of the anomeric carbons of the α,α- and β,β-isomers of 1,1′-linked disaccharides always appear at field above those of the α,β- and β,α-isomers; those up-field shifts are the same in nature with those observed in the cases of α,α- and β,β-trehaloses.[18] Because fully benzylated α,α- and β,β-trehaloses also exhibit such properties[19,20] (Table 6), inter-unit hydrogen-bondings[18] seem hardly responsible for them. Instead, the α,α- and β,β-isomers of trehalose are considered to adopt the conformation in which the dihedral angles of O-5–C-1–O–C-1′ and O-5′–C-1′–O–C-1 are $\approx +60°$ (α,α-isomer) or $\approx -60°$ (β,β-isomer), as is shown in Fig. 1. The fact that such an upfield shielding of the ^{13}C chemical shifts of the anomeric carbons of α,α- and β,β-isomers is observed regardless of the configuration at C-2′ (Tables 3—5) is consistent with the conformation in Fig. 1, where the substituents at C-2 and C-2′ are completely separated from each other. It is, then, conceivable that the *gauche* effect[21] would work on such a conformation so that the ^{13}C chemical shifts of both anomeric carbons, C-1 and C-1′, can be expected to appear at an upper field, as has been observed.

The *galacto* analog of trehalosamine was as active (cylinder plate assay) against the *Escherichia coli* NIHJ strain as, but a little less active against the *Mycobacterium smegmatis* ATCC 607 strain than, trehalosamine, **25**, and its *manno* analog, **21**.

Experimental

General. The melting points were determined by means of a MP-1 melting point apparatus (Yanagimoto). The specific rotations were measured in a jacketed 1-dm cell by means of a DIP-180 automatic polarimeter (Japan Spectroscopic) at 20 °C. The IR spectra were determined by means of a JASCO IRA-1 infrared spectrometer. The ^1H NMR spectra were recorded by a Varian S-60T spectrometer and a JEOL-PS-100 spectrometer. The ^{13}C NMR spectra were recorded by means of JEOL-PS-100 spectrometer equipped with a JEOL-EC-100 computer using a 8-mmϕ tube at 37 °C (noise decoupled; pulse width, 13 μs (45°); repetition, 2 s; frequency range, 5000 Hz; 8 K data points). A PT-3D digital pH/mV meter with a PCE-101S electrode (Toyo Kagaku) was used for the determination of the pD value, deutrium chloride (*ca.* 20% in deuterium oxide) was used as a titrant. Chromatography on silica gel (Kanto Kagaku) was done using a mixture of benzene and butanone (Solvent-BB) or of benzene and ethanol (Solvent-BE). TLC was carried out using silica gel (Merck 7731). Ascending paper chromatography was practiced by the use of Toyo filter paper (No. 50), developed by a solvent system of 1-butanol–pyridine–water–acetic acid (6:4:3:1) and then heated after having been sprayed with ninhydrin in ethanol (0.3%) containing pyridine. Compounds **1**, **2**, **3**, and **4**, as well as silver perchlorate (Alpha) and tribenzylamine (Tokyo Kasei), were kept *in vacuo* over phosphorus pentaoxide before use. All the reactions were conducted at room temperature (20—25 °C), while evaporation was done at 35—40 °C under reduced pressure, unless otherwise stated.

*α-D-Galactopyranosyl 2-Amino-2-deoxy-α-D-glucopyranoside (**17**) and Its Isomers (**18**, **19**, and **20**).* A mixture of **1** (854 mg, 1.6 mmol), **2** (1085 mg, 1.6 mmol), silver perchlorate (331 mg, 1.6 mmol), and tribenzylamine (459 mg, 1.6 mmol) in benzene (8 ml) was vigorously stirred in the dark for 24 h. The resulting mixture was poured onto a column of silica gel (30 g), which was then developed with Solvent-BB (100:1→5:1, gradient, 10-ml fraction). Fraction A (Nos. 12 and 13) gave **32** (43.4 mg, 4.1%), identified with the sample prepared alternatively as below. Fraction B (Nos. 19—30) was a mixture (852.2 mg) of **6** and unchanged **2**. Fraction C (Nos. 31—38) consisted of impure **8** (408.9 mg). Fraction D (Nos. 40—42) was a mixture (414.0 mg) of **7** and **8a**. Fraction E (Nos. 43—46) was 3,4,6-tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranose (**5**) (192.6 mg, 25.6%); mp 150—154 °C [lit,[9] mp 154—156 °C].

A portion of Fraction B was purified by means of TLC to give a glass of **6**; $[\alpha]_D +128°$ (*c* 0.7, $CHCl_3$). Found:

C, 55.16; H. 4.56; N, 3.49%. Calcd for $C_{52}H_{51}Cl_4N_3O_{17}$: C, 55.18; H, 4.54; N, 3.71%. The rest of Fraction B was treated with a solution of sodium methoxide in methanol (0.05 M, 25 ml) overnight, followed by neutralization with acetic acid and chromatography (Solvent-BB, 10:1→1:1, gradient), to give unchanged **2** (240.4 mg, 22.2%) and the pure de-*O*-acetate of **6** (563.9 mg, 35% from **2**). This was agitated for 5 h in aq acetone (80%, 50 ml) in which Dowex 1×2 (OH-form, 15 ml) has been suspended. After filtration and evaporation, chromatography using Solvent-BE (10:1→5:1, gradient) gave a colorless mass (388.2 mg). This was hydrogenated over palladium black (390 mg) in acetic acid (10 ml) at 340 kPa overnight. After the removal of the catalyst, followed by concentration, the residue obtained was chromatographed on Dowex 1×2 (OH-form, 20×1ϕ cm, 5-ml fraction) developed with water; each fraction was examined by paper chromatography. Fraction Nos. 10—20 gave a ninhydrin-positive, homogeneous glass of **17** (106.3 mg, 19% from **2**); $[\alpha]_D$+198° (*c* 1.0, H_2O). Found: C, 40.79; H, 6.85; N, 3.79%. Calcd for $C_{12}H_{23}NO_{10}\cdot 0.75H_2O$: C, 40.69; H, 6.96; N, 3.95%.

The treatment of this (14 mg) with a mixture of acetic anhydride (2 ml) and pyridine (2 ml) for 4 d gave the acetate (**29**) (25 mg, 94%); mp 222—223 °C, $[\alpha]_D$+181° (*c* 0.3, $CHCl_3$), IR(KBr)ν: 1745 (OAc), 1645, 1545 (NHAc), NMR ($CDCl_3$, TMS) δ: 2.01 (3H, s, $NHCOCH_3$), 2.03, 2.04, 2.05, 2.09, 2.17 (3H, 6H, 3H, 6H, 3H, $OCOCH_3$), 6.20 (1H, d, J=8.0 Hz, NHAc). Found: C, 49.93; H, 5.95; N, 1.97%. Calcd for $C_{28}H_{39}NO_8$: C, 49.63; H, 5.80; N, 2.07%.

The purification of Fraction C gave **8** (163.0 mg, 9%); mp 79—80 °C, $[\alpha]_D$+70° (*c* 0.9, $CHCl_3$). Found: C, 54.90; H, 4.79; N, 3.98%. Calcd for $C_{52}H_{51}Cl_4N_3O_{17}$: C, 55.18; H, 4.54; N, 3.71%. This was treated with a dil solution of sodium methoxide in methanol and then with Dowex resin in aq acetone and successively hydrogenated to afford glass of **19** (26 mg); $[\alpha]_D$+117° (*c* 0.4, H_2O). Found: C, 41.91; H, 7.03; N, 4.09%. Calcd for $C_{12}H_{23}NO_{10}$: C, 42.23; H, 6.79; N, 4.10%.

A sample of (≈30 mg) of Fraction D was purified by TLC to furnish **7**; mp 74—77 °C, $[\alpha]_D$−11° (*c* 0.9, $CHCl_3$). Found: C, 54.43; H, 4.73; N, 4.18%. Calcd for $C_{52}H_{51}Cl_4N_3O_{17}$: C, 55.18; H, 4.54; N, 3.71%. The rest of Fraction D was treated with a dil solution of sodium methoxide in methanol and chromatographed as described above to furnish the de-*O*-acetate of **7** (238.9 mg, 15% from **2**) and then that of **8a** (52.4 mg, 3% from **2**). The former compound was treated with Dowex resin in aq acetone and then hydrogenated to afford **18** (55.3 mg); $[\alpha]_D$+93° (*c* 0.4, H_2O). Found: C, 40.84; H, 6.92; N, 3.81%. Calcd for $C_{12}H_{23}NO\cdot 0.75H_2O$: C, 40.62; H, 6.96; N, 3.95%. The latter compound was subjected to the same deprotection process to afford **20** (7 mg); $[\alpha]_D$−19° (*c* 0.3, H_2O). Found: C, 41.43; H, 7.02; N, 3.91%. Calcd for $C_{12}H_{23}NO_{10}\cdot 0.5H_2O$: C, 41.14; H, 6.91; N, 4.00%.

*α-D-Mannopyranosyl 2-Amino-2-deoxy-α-D-glucopyranoside (**21**) and Its Isomers (**22**, **23**, and **24**).* A mixture of **1** (854 mg, 1.6 mmol), **3** (1085 mg, 1.6 mmol), silver perchlorate (331 mg, 1.6 mmol), and tribenzylamine (459 mg, 1.6 mmol) in benzene (8 ml) was stirred in the dark for 24 h. The subsequent chromatography of the reaction mixture (silica gel (30 g) and Solvent-BB (100:1→5:1, gradient, 10-ml fraction)) gave five fractions: A (Nos. 17 and 18), B (Nos. 22—29), C (No. 30), D (Nos. 31—35), and E (Nos. 38—41).

Fraction A gave **33** (59.3 mg, 5.5%), which was identified with the sample prepared alternatively as below.

A small portion of Fraction B was purified by TLC to furnish **9**; $[\alpha]_D$+104° (*c* 0.8, $CHCl_3$). Found: C, 55.92; H, 4.91; N, 3.49%. Calcd for $C_{52}H_{51}Cl_4N_3O_{17}$: C, 55.18; H, 4.54; N, 3.71%. The rest of Fraction B was treated with a dil solution of sodium methoxide in methanol, followed by chromatography, to afford unchanged **3** (382.6 mg, 30%) and the yellow de-*O*-acetate of **9** (496.5 mg, 31% from **3**). This was treated with Dowex resin in aq acetone to give a colorless mass of **15** (303.2 mg); mp 149—153 °C, $[\alpha]_D$+53° (*c* 0.2, MeOH). Found: C, 56.38; H, 5.11; N, 1.57%. Calcd for $C_{40}H_{41}Cl_4NO_{10}\cdot H_2O$: C, 56.15; H, 5.06; N, 1.64%. Compound **15** was then hydrogenated and deionized to afford **21** (94.0 mg 16% from **3**); $[\alpha]_D$ +141° (*c* 0.4, H_2O). Found: C, 40.46; H, 6.74; N, 3.91%. Calcd for $C_{12}H_{23}NO_{10}\cdot 0.75H_2O$: C, 40.62; H, 6.96; N, 3.95%.

An aqueous solution of this (32 mg) was acidified with hydrochloric acid (35%) to pH 3 and then freeze-dried to give crystals. Recrystallization from methanol containing acetone afforded needles of **31** (*ca.* 20 mg); mp 194—195 °C (dec), $[\alpha]_D$ +110° (*c* 0.5, H_2O) [lit,[3a] mp 230 °C (dec), $[\alpha]_D^{23}$ +91.3° (*c* 2, H_2O)], NMR (D_2O, ext. TMS) δ: 5.64 (1H, d, J=1.9 Hz, H-1′), 5.90 (1H, d, J=3.8 Hz, H-1′). Found: C, 37.07; H, 6.32; N, 3.37%. Calcd for $C_{12}H_{23}NO_{10}\cdot HCl\cdot 0.5H_2O$: C, 37.26; H, 6.52; N, 3.62%.

The treatment of **9** (22 mg) with pyridine and acetic anhydride afforded octaacetate, **30** (38.2 mg, 87%); mp 90—93 °C, $[\alpha]_D$ +106° (*c* 1.0, $CHCl_3$) [lit,[3a] mp 91.5—93 °C]; IR(KBr)ν: 1745 (OAc), 1660, 1540 (NHAc); NMR ($CDCl_3$, TMS) δ: 1.97 (3H, s, $NHCOCH_3$), 2.03, 2.05, 2.07, 2.08, 2.16 (3H,6H,6H,3H,3H, $OCOCH_3$), 6.25 (1H, d, J=8 Hz, NH). Found: C, 49.49; H, 5.89; N, 1.97%. Calcd for $C_{28}H_{39}NO_{18}$: C, 49.63; H, 5.80; N, 2.07%.

Fraction C was **11** (200.3 mg, 11% from **3**); mp 77—79 °C, $[\alpha]_D$ −1° (*c* 1.0, $CHCl_3$). Found: C, 55.13; H, 4.50; N, 3.61%. Calcd for $C_{52}H_{51}Cl_4N_3O_{17}$: C, 55.18; H, 4.54; N, 3.71%. Removal of the protecting groups from **11** furnished **23** (38.4 mg); $[\alpha]_D$ +71° (*c* 1.0, $CHCl_3$). Found: C, 40.81; H, 6.68; N, 3.89%. Calcd for $C_{12}H_{23}NO_{10}\cdot 0.75H_2O$: C, 40.62; H, 6.96; N, 3.95%.

A portion of Fraction D was purified by means of TLC to give **10**; mp 70—73 °C, $[\alpha]_D$ −49° (*c* 1.0, $CHCl_3$) (Found: C, 55.29; H, 4.03; N, 3.76%. Calcd for $C_{52}H_{51}Cl_4N_3O_{17}$: C, 55.18; H, 4.54; N, 3.71%) and **12**; mp 74—75 °C, $[\alpha]_D$ −55° (*c* 1.0, $CHCl_3$) (Found: C, 54.99; H, 4.40; N, 3.72%. Calcd for $C_{52}H_{51}Cl_4N_3O_{17}$: C, 55.18; H, 4.54; N, 3.71%). The rest of Fraction D was treated with a dil solution of sodium methoxide in methanol, followed by chromatography, to afford the de-*O*-acetate of **10** (394.4 mg, 25% from **3**) first and then that of **12** (54 mg, 3.3% from **3**). These compounds were subsequently subjected to the de-protection processes to give **22** (82.1 mg); $[\alpha]_D$ +34° (*c* 1.0, H_2O) (Found: C, 41.18; H, 6.82; N, 3.90%. Calcd for $C_{12}H_{23}NO_{10}\cdot 0.5H_2O$: C, 41.14; H, 6.91; N, 4.00%) and **24** (9.2 mg), $[\alpha]_D$ −71° (*c* 0.1, H_2O) (Found: C, 39.85, H, 6.61; N, 3.64%. Calcd for $C_{12}H_{23}NO_{10}\cdot H_2O$: C, 40.11; H, 7.01; N, 3.90), respectively.

*α-D-Glucopyranosyl 2-Amino-2-deoxy-α-D-glucopyranoside (**25**) and Its Isomers (**26**, **27**, and **28**).* A mixture of **1** (1068 mg, 2.0 mmol), **4** (1356 mg, 2.0 mmol), silver perchlorate (414 mg, 2.0 mmol), and tribenzylamine (574 mg, 2.0 mmol) in benzene (10.6 ml) was vigorously stirred in the dark for 24 h. Chromatography on silica gel (50 g) with Solvent-BB (100:1→10:1, gradient, 15-ml fraction) gave five fractions: A (Nos. 17—20), B (Nos. 21—31), C (Nos. 32—36), D (Nos. 37—41) and E.

Fraction B (1335 mg) was composed of the fast-moving, major yellow band and unchanged **4**. A sample of Fraction B (≈50 mg) was subjected to TLC (25 mg/20×20×0.05 cm, developed with Solvent-BB (20:1), 15 times) to

give two yellow products, **13a** (minor faster-moving) and **13** (major slower-moving); mp 125—130 °C, $[\alpha]_D$ +112° (*c* 0.9, $CHCl_3$). Found: C, 55.41; H, 4.66; N, 3.76%. Calcd for $C_{52}H_{51}Cl_4N_3O_{17}$: C, 55.18; H, 4.54; N, 3.71%. The rest of Fraction B was treated with a mixture of a methanolic solution of sodium methoxide (0.05 M, 34 ml) and 1,4-dioxane (10 ml), followed by neutralization with acetic acid and chromatography, to give a mixture (717 mg, 36% from **4**) of the de-*O*-acetates of **13** and **13a**. A portion of this was treated with Dowex resin in aq acetone, followed by chromatography (Solvent-BE) and recrystallization from diisopropyl ether containing ethanol, to give **16**; mp 153—156 °C; $[\alpha]_D$ +108° (*c* 0.3, MeOH). Found: C, 56.58; H, 5.09; N, 1.53%. Calcd for $C_{40}H_{41}Cl_4NO_{10}\cdot 0.5H_2O$: C, 56.75; H, 5.00; N, 1.65%. The mixture (*ca.* 650 mg) of the de-*O*-acetates of **13** and **13a** was subjected to the deprotecting processes as described above to afford a free base whose ^{13}C NMR (D_2O) showed the presence of **25** and **27** (*ca.* 3:1). The free base (110 mg) was then dissolved in water (6 ml), and to the mixture 2,4-dinitrofluorobenzene (Wako, 70 mg), sodium hydrogencarbonate (45 mg) and ethanol (3 ml) were added. After this mixture had been stirred for 2 d, a yellow mixture was acidified and evaporated to give a residue which was further treated with pyridine and acetic anhydride. The yellow product (230 mg) composed of two compounds (R_f=0.55 (major) and 0.45, ethyl acetate–1,2-dichloroethane (1:3)) gave a homogeneous faster-moving compound (>126 mg) after preparative TLC. The treatment of this with a dil solution of sodium methoxide in methanol and then Dowex resin in aq acetone, followed by passing it through a little column of the resin, afforded $[\alpha]_D$ +183° (*c* 0.9, H_2O). Found: C, 40.66; H, 6.81; N, 3.87%. Calcd for $C_{12}H_{23}NO_{10}\cdot 0.75H_2O$: C, 40.62; H, 6.96; N, 3.93%.

The treatment of this with acetic anhydride and pyridine gave octaacetate of **25**; mp 98—100 °C, $[\alpha]_D$ +151° (*c* 0.5, $CHCl_3$) [lit, mp 100—102 °C,[1] 99 °C,[3] $[\alpha]_D$ +163.5° ($CHCl_3$),[1] +152° (*c* 1.08, $CHCl_3$, at 25 °C)[3]].

The slower-moving, yellow band obtained by preparative TLC mentioned just above furnished a homogeneous glass (≈45 mg) which was later converted into **27** (15 mg); $[\alpha]_D$ +111° (*c* 0.4, H_2O). Found: C, 41.30; H, 7.19; N, 3.87%. Calcd for $C_{12}H_{23}NO_{10}\cdot 0.5H_2O$: C, 41.14; H, 6.91; N, 4.00%.

Fraction C (352.5 mg) was treated with a dil solution of sodium methoxide in methanol and chromatographed to give the de-*O*-acetate of **14a** (131.7 mg, 6.6% from **4**). This was then converted into **28** (29 mg), $[\alpha]_D$ −43° (*c* 0.3, H_2O). Found: C, 40.92; H, 7.09; N, 4.02%. Calcd for $C_{12}H_{23}NO_{10}\cdot 0.5H_2O$: C, 41.14; H, 6.91; N, 4.00%.

Fraction D was purified by rechromatography to give **14** (581.7 mg, 26% from **4**); mp 73—75 °C, $[\alpha]_D$ −51° (*c* 0.3, $CHCl_3$). Found: C, 55.32; H, 4.81; N, 3.71%. Calcd for $C_{52}H_{51}Cl_4N_3O_{17}$: C, 55.18; H, 4.51; N, 3.71%. Fraction D was subjected to deprotection processes to furnish **26** (87 mg), $[\alpha]_D$ +81° (*c* 0.3, H_2O). Found: C, 40.64; H, 6.79; N, 3.85%. Calcd for $C_{12}H_{23}NO_{10}\cdot 0.75H_2O$: C, 40.62; H, 6.96; N, 3.95%.

*2,3,4,6-Tetra-O-(p-chlorobenzyl)-α-D-galactopyranosyl 2,3,4,6-Tetra-O-(p-chlorobenzyl)-α-D-galactopyranoside (**32**).* A mixture of **2** (136 mg, 0.2 mmol), silver *p*-nitrobenzenesulfonate[20] (62 mg, 0.2 mmol), and diphenyldichlorosilane (21 μl, 0.1 mmol) in dichloromethane (0.7 ml) was stirred at 0 °C in the dark for 6 h. The subsequent chromatography of the reaction mixture using Solvent-BB on silica gel gave **32** (106.6 mg, 79%); $[\alpha]_D$ +81° (*c* 0.8, $CHCl_3$). Found: C, 61.30; H, 4.57%. Calcd for $C_{68}H_{62}Cl_8O_{11}$: C, 61.00; H, 4.64%.

The hydrogenation of **32** in acetic acid in the presence of palladium black gave α-D-galactopyranosyl α-D-galactopyranoside; mp 268—269 °C, $[\alpha]_D$ +211° (*c* 0.5, H_2O) [lit,[18] 264—267 °C, $[\alpha]_D^{20}$ +235° (*c* 0.35, H_2O)].

*2,3,4,6-Tetra-O-(p-chlorobenzyl)-α-D-mannopyranosyl 2,3,4,6-Tetra-O-(p-chlorobenzyl)-α-D-mannopyranoside (**33**).* Compound **3** (136 mg, 0.2 mmol) was similarly condensed to afford **33** (81.2 mg, 60%); $[\alpha]_D$ +21° (*c* 1, $CHCl_3$). Found: C, 60.62; H, 4.57%. Calcd for $C_{68}H_{62}Cl_8O_{11}$: C, 61.00; H, 4.67%.

The hydrogenolysis of **33** in acetic acid in the presence of palladium black furnished α-D-mannopyranosyl α-D-mannopyranoside; mp 245—246 °C, $[\alpha]_D$ +122° (*c* 0.3, H_2O) [lit,[21] mp 240—243 °C, $[\alpha]_D^{20}$ +124° (*c* 1, H_2O)], ^{13}C-NMR (D_2O, ext, TMS) δ: 96.4, 74.6, 71.4, 71.1, 67.8, 62.0.

We are grateful to Professor Satoshi Ōmura and Mr. Rokuro Masuma for their microbial assays.

A Novel Ring-closure Reaction between 1,4-Dihydroxyanthraquinone and Diamines Promoted by Copper Ions

Toshio Takei, Masaru Matsuoka,* and Teijiro Kitao

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received November 17, 1980)

The reaction of 1,4-dihydroxyanthraquinone(DHAQ, **1**) with various diamines were carried out in the presence of $CuCl_2$. Primary 1,2-ethylenediamines or 1,2-cyclohexanediamine afforded the ring-closure products, 6-hydroxy-1,2,3,4-tetrahydronaphtho[2,3-*f*]quinoxaline-7,12-dione derivatives, in good yields of 70—98%. On the other hand, in the cases of *N*-alkylethylenediamines or 2-(alkylamino)ethanols, the major products were the 2-aminated 1,4-dihydroxyanthraquinones. The direct 2-amination of **1** was greatly inhibited when an alkyl group was introduced to the amino group because of its steric requirement. The role of copper ions, the effect of a steric requirement of the *N*-alkyl substituent of amines, and the effect of the chain length of alkanediamines in the reaction of **1** with amines were studied. It was proposed that the reaction was initiated by the direct 2-amination of **1** *via* the copper complex, followed by the intramolecular nucleophilic substitution of the 2-amino group on the 2-alkylamino substituent to give the ring-closure product.

Aminoanthraquinone derivatives are very important compound as dyes or dye intermediates. A large number of papers and patents have been reported on substitution reactions introducing amino groups into the anthraquinone nucleus,[1] but little is known about the direct amination of the anthraquinone nucleus.

The direct amination of anthraquinone or aminoanthraquinones with hydroxylamine catalyzed by iron sulfate or vanadium pentaoxide has been described, but it produces random substitution products.[2] Hida *et al.*[3] recently reported the direct amination of anthraquinone catalyzed by a rhodium complex to give α-aminoanthraquinones. Recently, the present authors reported[4,5] the metal-promoted direct alkylamination of α-substituted anthraquinones, in which the amination products were obtained in good yields under mild conditions. On the other hand, in the reaction of DHAQ (**1**) with ethylenediamine (ETDA) in the presence of copper ions, a ring-closure product, 6-hydroxy-1,2,3,4-tetrahydronaphtho[2,3-*f*]quinoxaline-7,12-dione (**3a**), was obtained in a quantitative yield at the ambient temperature.[6] Such a metal-promoted direct amination of α-substituted anthraquinones is a useful method for preparing some aminoanthraquinone derivatives.

In this paper, we whish to report on the reaction of **1** with diamines in detail and propose a possible mechanism of this novel ring-closure reaction.

Results and Discussion

In our previous paper,[6] it was reported that the reaction of DHAQ (**1**) with ethylenediamine (ETDA) in the presence of $CuCl_2$ afforded the ring-closure products, 6-hydroxy-1,2,3,4-tetrahydronaphtho[2,3-*f*]-quinoxaline-7,12-dione (**3a**), in a 98% yield at the ambient temperature (Run 1). Without copper ions under atmospheric oxygen, **3a** was obtained in a 47% yield, together with a 15% yield of leucoquinizarin (1,4-dihydro-9,10-dihydroxyanthracene-1,4-dione) and a 9% recovery of **1** (Run 2). The reaction of **1** with ETDA in the presence of CuCl under the conditions without oxygen gave **3a** in a 96.6% yield, together with the deposition of metal copper in a 44.1% yield (Run 3). On the other hand, the reaction of ETDA with quinizarinquinone (1,4,9,10-tetrahydroanthracene-1,4,9,10-tetrone, **4**), which has previously been prepared by the oxidation of **1** with lead tetraacetate,[7] gave **3a** in a 90.7% yield, along with a 1.2% yield of **1** (Run 4). These results suggested that the role of copper ions is the same as in our previous cases of the quantitative 2-butylamination of **1**,[4] that is; the copper ions oxidize **1** to quinizarinquinone (**4**) *via* the copper complex,[8] and the copper ions are reduced to metal copper. Thus, the formation of **3a** was proposed to proceed as follows: the reaction was initiated by the 2-amination of **1** to give **2a**, followed by the ring-closure reaction. The reaction of **1** with 1,3-propanediamine in the presence of $CuCl_2$ did not give the rin -closure product **3b**), but 2-(3-aminopropylamino)-1,4-dihydroxyanthraquinone (**2b**) in a 95% yield (Run 5). The facile ring-closure of **1** with ETDA, but not with 1,3-propanediamine, was proposed to result from the fact that the spontaneous formation of the six-membered ring in **3a** was much more favorable in entropy than that of the seven-membered ring in **3b**. The six-membered ring could be formed by the intramolecular nucleophilic substitution of the 2-aminoethylamino group to the 1-hydroxyl group of **2a**, as is shown in Scheme 1. The reaction of **1** with 1,2-propanediamine (Run 6) or 1,2-cyclohexanediamine (Run 7) gave **3c** or **3d** in a yield of 89.5% or 68.9% respectively, but none of the corresponding **2c** or **2d** was obtained. These results suggested that the ring-closure reaction was not inhibited by the alkyl substituents at the 1 and/or 2-position of ETDA. On the

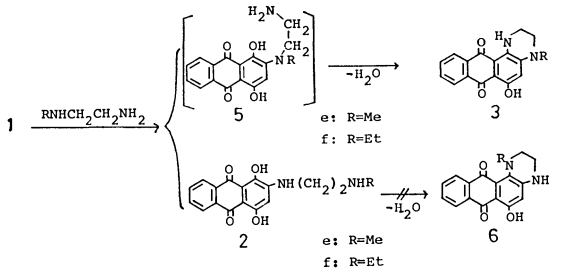
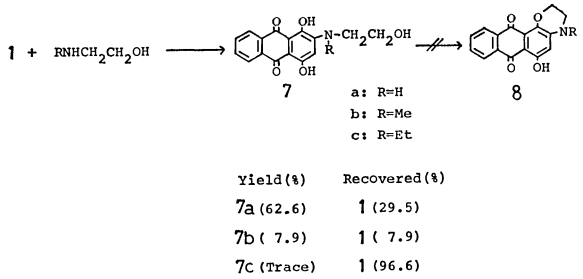
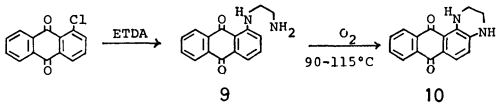
a) Reactant **1**(2.5 mmol) and diamine(12 ml) were stirred with or without copper salts(5.0 mmol) in pyridine (6 ml) at 30 °C for 6 h. Unless otherwise noted, the reaction was carried out under atmospheric oxygen. b) Leucoquinizarin was obtained in a 15% yield. c) Reaction was carried out under reduced pressure without oxygen. Metal copper was obtained in a 44.1% yield. d) Quinizarinquinone (**4**) was used as the reactant instead of **1**. e) The instability of **4** as a reactant caused a decrease in the yield of **3a**, and a 1.2% yield of **1**, which is the reduced product of **4**, was obtained. f) A complex mixture of compounds(246 mg) was obtained, but these compounds were not identified.



Scheme 2.



Scheme 3.



Scheme 4.[9)]

other hand, the *N*-alkyl substituent of ETDA markedly inhibited both the 2-amination and the ring-closure reaction. The reaction of **1** with *N*-methylethylenediamine gave **3e** in a 31% yield, together with **2e** in a 31% yield (Run 8). The yield of **3e** was greatly decreased in comparison with that of **3a** (Run 1). The reactions of **1** with various diamines are summarized in Table 1. As is shown in Scheme 2, the formation of **5e** and **2e** should compete on the 2-amination of **1** with *N*-methylethylenediamine. On the other hand, the formation of **5e** was much more unfavorable than that of **2e** because of the steric hindrance of the *N*-methyl group; the **5e** intermediate could be easily cyclized to give **3e**, and no **5e** was obtained. On the other hand, **2e** could not give the ring-closure product (**6e**) because of the steric hindrance of the *N*-methyl group. Another example of the steric hindrance was observed in the reaction of **1** with *N*-ethylethylenediamine (Run 9). The ring-closure product (**3f**) *via* **5f** was obtained only in a 3.6% yield, while **2f** was obtained in a 93.3% yield. The competitive 2-amination of **1** with *N*-ethylethylenediamine was obviously much more likely to give **2f** than **5f**, and only a small amount of **3f** was obtained. Compound **2f** could not be converted to **6f** because of the steric hindrance under these conditions, just as in the case of **2e**. Under the more severe conditions of 95—100 °C for 96 h, **2f** afforded **3a**, the deethylation product of **6f**, in a 19.7% yield, along with a 61% recovery of **2f**, but no **6f** was obtained. A similar steric hindrance of the *N*-alkyl group of amines in the 2-amination of **1** was also observed in the case of the reaction of **1** with 2-(alkylamino)ethanols (Scheme 3). The yield of **7** was markedly decreased with the increase in the size of *N*-alkyl substituents, and none of the ring-closure product (**8**) was obtained.

From these results, together with our previous results obtained from the reactions of **1** with various amines,[4)] another possibility of ring-closure reaction (shown in Scheme 4) was excluded; it had been reported in the case of the reaction of 1-chloroanthraquinone with ETDA under atmospheric oxygen at 90—115 °C.[9)] In this reaction, α-amination took place first, followed by direct β-amination at a higher temperature.

On the basis of the experimental results described above, together with previous results,[4)] the mechanism of this ring-closure reaction of **1** with ETDA was

$$\mathbf{1} + \text{ETDA(excess)} \longrightarrow \text{Dianion} \quad (1)$$

$$\left.\begin{array}{l}\text{Dianion} + \text{CuCl}_2(\text{CuCl}_2:\mathbf{1}=2:1) \longrightarrow \\ \qquad 2:1\ \text{Copper(II) complex[I]} \\ \text{Dianion} + \text{CuCl}_2(\text{CuCl}_2:\mathbf{1}=1:1) \longrightarrow \\ \qquad 1:1\ \text{Copper(II) complex[II]} \\ \text{Dianion} + \text{CuCl(CuCl}:\mathbf{1}=2:1) \longrightarrow \\ \qquad 2:1\ \text{Copper(I) complex[III]}\end{array}\right\} \quad (2)$$

Scheme 5.

proposed to be as is shown in Scheme 5. The formation of dianion was proved by the color change of the reaction mixture from orange to violet (λ_{max} 566, 606 nm) after the addition of excess amines (Eq. 1). The formation of the copper complex (Eq. 2) and the redox system of the copper complex (Eq. 3) have previously been reported in the cases of the reactions of **1** with amines in our previous paper;[4] the deposition of metal copper, the effect of the atmosphere (with or without O_2), the effect of the molar ratio of copper salts, and the effect of the kind of copper salt were there discussed in detail. Without copper salts, atmospheric oxygen oxidized **1** to **4** (Eq. 4), and/or **1** spontaneously disproportionated to **4** and leucoquinizarin (Eq. 5), and 47% of **3a** was obtained, together with 15% of leucoquinizarin (Run 2). Similar results (48% yield) were obtained in the 2-amination of **1** with butylamine under the same conditions.[4] When the reaction was carried out without either O_2 or copper salts, none of the oxidizing agent was present, **1** spontaneously disproportionated to **4** and leucoquinizarin (Eq. 5), and the yield of the 2-aminated product was reduced from 48.1% to 13.1%.[4] Without copper salt, leucoquinizarin was also obtained in a 15% yield (Run 2). The Michael-type addition of ETDA to **1** give rise to **2a** (Eq. 6). The intramolecular substitution of the 2-aminoethylamino group with the 1-hydroxyl group of **2a** gives rise to the ring-closure product **3a** (Eq. 7).

Experimental

The melting points are uncorrected. The visible spectra were measured using a Hitachi EPS-3T spectrophotometer. The ^{1}H-NMR spectra were recorded on a Hitachi Perkin Elmer Model R-20 spectrometer, with TMS as the internal standard. The elemental analyses were recorded on a Yanaco CHN recorder, MT-2. Column chromatography was carried out on silica gel (Wakogel C-300), using benzene as the eluent. The structural assignment of the products were done by means of their NMR, Mass spectra, and elemental analyses.

Materials. 1,4-Dihydroxyanthraquinone(**1**) was supplied by the Mitsubishi Chemical Industry, Inc., and was purified by column chromatography, using benzene as an eluent, followed by recrystallization from benzene. The metal salts, amines, and solvents were of a reagent grade and were used without further purification.

*Reaction of **1** with Various Diamines.* A typical example of the reaction is shown below: *N*-ethylethylenediamine (12 ml, 135 mmol) was added into a mixture of **1** (0.6 g, 2.5 mmol), pyridine (6 ml), and $CuCl_2$ (0.63 g, 5.0 mmol), after which the mixture was stirred under atmospheric oxygen for 5 h at room temperature and then poured into a solution of concd HCl (40 ml) and water (100 ml). The separated products were filtered, washed with water, dried, and extracted with benzene. The extract was concentrated and separated by column chromatography, using benzene as the eluent, to give **3f** (28 mg, 3.6%), which was then recrystallized from 1-butanol. The residue was washed with benzene several times to give the HCl salt of **2f** (845 mg, 93.3%).

The reactions of **1** with other diamines were carried out in the same way.

In the reaction of **1** with 1,2-cyclohexanediamine(Run 7), two isomeric compounds of **3d** were obtained; they were identified on the basis of their ^{1}H-NMR spectra. Similar compounds had previously been reported by Koeliker *et al.*[9] in the reaction of 1-chloroanthraquinone with 1,2-cyclohexanediamine.

*Reaction of **1** with 2-(Alkylamino)ethanols.* A typical example of the reaction is shown below: 2-aminoethanol (12 ml, 200 mmol) was added to a mixture of **1** (0.6 g, 2.5 mmol), pyridine (6 ml), and $CuCl_2$ (0.673 g, 5.0 mmol), after which the mixture was stirred under atmospheric oxygen at room temperature for 5 h. The mixture was then poured into water and the separated products were filtered, washed with water, and dried. The residue was boiled in an aqueous solution of oxalic acid and filtered, washed with water, dried, and chromatographed using a mixture of benzene–methanol (95:5) as the eluent to give **1** (177 mg 29.5%) and **7d** (468 mg 62.2%).

The reactions of **1** with other 2-(alkylamino)ethanol were carried out in the same way.

Characterization and Identification of Products. Compounds **2b** and **3a** were already reported in our previous paper.[6]

Pseudo-sugars. VII. Synthesis of Pseudo-hexopyranose Derivatives with α- and β-Gluco Configurations[1]

Seiichiro OGAWA,* Tatsushi TOYOKUNI, Takashi KONDOH, Yoshihisa HATTORI, Shinichi IWASAKI, Masaru SUETSUGU, and Tetsuo SUAMI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received December 3, 1980)

Several derivatives of pseudo-hexopyranose (5-hydroxymethyl-1,2,3,4-cyclohexanetetrol) with α-gluco, (1,2,4/3,5), and β-gluco, (1,3,5/2,4), configurations were synthesized starting from the compounds obtained by *cis*-hydroxylation and oxyamination of DL-di-*O*-acetyl-(1,3/2)-3-bromomethyl-5-cyclohexene-1,2-diol. The ^{1}H NMR chemical shifts of the acetyl methyl protons of the several acetyl derivatives of *N*-(*p*-tolylsulfonyl)-pseudo-glucosamines are discussed.

In connection with the preceding paper of this series,[2] the synthesis of pseudo-hexopyranose (5-hydroxymethyl-1,2,3,4-cyclohexanetetrol) derivatives having α- and β-gluco configurations are described. It has been hoped that pseudo-sugars, biologically interesting analogs, *e.g.* of glucose, galactose, and mannose, will be accepted by some enzymes or biological systems in place of corresponding true sugars, and may have useful biological properties.[3] On the other hand, pseudo-amino sugars related to 2-amino-2-deoxy-, 6-amino-6-deoxy-, and 2,6-diamino-2,6-dideoxy-D-glucose, components of some clinically important amino sugar antibiotics,[4] are also expected to be useful for study on a structure-activity relationship of the antibiotics.

In the present study, *cis*-hydroxylation and oxyamination reactions of the unsaturated derivatives (**3** and **4**) of pseudo-hexopyranoses were carried out.

Debromination of DL-di-*O*-acetyl-(1,3/2,4,6)-3,4-dibromo-6-bromomethyl-1,2-cyclohexanediol (**1**)[5] with an excess of zinc dust in acetic acid at 70 °C for 10 min gave DL-di-*O*-acetyl-(1,3/2)-3-bromomethyl-5-cyclohexene-1,2-diol (**3**) in 92% yield. The ^{1}H NMR spectrum of **3** showed the signals for two acetoxyl groups as singlets at δ 2.01 and 2.03, and those for the H-2 and H-6 protons as a triplet of doublets (J= 3, 7.5, and 7.5 Hz) and a broad doublet (J=*ca.* 11 Hz) at δ 5.02 and 5.77, respectively. Treatment of **1** with 4 molar equivalent of sodium benzoate in 80% aqueous ethanol under reflux for 2 d gave the 7-*O*-benzoate (**2**) in 66% yield. The structure was confirmed by the ^{1}H NMR spectrum that showed the down-field shift of the signal for the C-7 methylene group resulting from the replacement of the bromine atom by a benzoyloxyl group. Compound **2** was debrominated similarly with zinc dust to give DL-di-*O*-acetyl-(1,3/2)-3-benzoyloxymethyl-5-cyclohexene-1,2-diol (**4**) in 70% yield, which was also obtained from **3** by treatment with sodium benzoate in refluxing aqueous 2-methoxyethanol for 5 h. The above results confirmed the proposed structures of **3** and **4**. These olefins may be considered as the pseudo-glycal derivatives, versatile intermediates, for the preparation of pseudo-sugar derivatives.

Oxidation of **3** with osmium tetraoxide and hydrogen peroxide in *t*-butyl alcohol, followed by acetylation with acetic anhydride in pyridine, gave mainly a crystalline DL-tetra-*O*-acetyl-(1,2,4/3,5)-5-bromomethyl-1,2,3,4-cyclohexanetetrol (**6**) in 37% yield, together with a small proportion of a sirupy DL-*trans*-2,4-diacetoxy-5-bromomethyl-2-cyclohexanone (**5**), which was isolated in 7.5% yield by chromatography on silica gel. The structure of **5** was tentatively assigned by the elemental analysis and ^{1}H NMR spectral data, the latter of which showed the presence of two acetoxyl groups (δ 2.15 and 2.22) and an olefinic proton (doublet, J=2.5 Hz, δ 6.47), and the remarkable down-field shift of the signal (broad doublet, δ 2.72) for the C-7 methylene protons. In the ^{1}H NMR spectrum of **6**, the signals for H-1, H-2, H-3,

and H-4 protons appeared as a quartet (J=3.5 Hz), a doublet of doublets (J=3.5 and 10.5 Hz), a triplet (J=10.5 Hz), and a triplet (J=10.5 Hz) at δ 5.39, 4.87, 5.23, and 4.94, respectively, which indicated the equatorial-axial-axial-axial conformations for H-1, H-2, H-3, and H-4, being consistent with the assigned structure. Treatment of **6** with an excess of sodium acetate in refluxing aqueous 2-methoxyethanol, followed by conventional acetylation, gave DL-penta-*O*-acetyl-(1,2,4/3,5)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (pseudo-α-DL-glucopyranose) (**7**)[6] in 70% yield. Similar treatment of **6** with sodium azide gave the corresponding C-7 azido derivative (**8**) in 80% yield, which was subsequently converted to the acetamide (**9**) in 31% yield[7] by hydrogenation in ethanol containing acetic anhydride in the presence of Raney nickel T-4.[8] Hydrogenolysis of **6** in ethyl acetate with Raney nickel and Amberlite IR-45 (OH^-) gave the 7-deoxy compound (**10**) in 70% yield. The ^{1}H NMR spectra of **6**—**9** substantially resemble one another in the region for ring protons, except for signals for the exocyclic methylene groups carrying the different functions.

In order to synthesize the same series of compounds with the β-gluco configurations, DL-tetra-*O*-acetyl-(1,3,5/2,4)-5-bromomethyl-1,2,3,4-cyclohexanetetrol (**12**) was prepared, in 91% yield, by treatment of the corresponding C-7 acetate (**11**)[9] with 10% hydrogen bromide in acetic acid in a sealed tube at 80 °C overnight. The corresponding C-7 azido (**13**), acetamido (**14**), and deoxy derivatives (**15**) were obtained analogously starting from **12** in appropriate yields. The structures were confirmed similarly by the ^{1}H NMR spectral data.

Next, several carbocyclic analogs of glucosamine derivatives were synthesized from **3** and **4**. Treatment of **3** with osmium tetroxide and chloramine T in chloroform–water (1:1) in the presence of triethylbenzylammonium chloride at 60 °C for 40 h, (essentially the procedure of Sharpless and his coworkers)[10] gave a mixture of at least four products. The major product was easily separated by crystallization from ethanol–ether to give DL-3,4-di-*O*-acetyl-(1,2,4/3,5)-5-bromomethyl-2-(*p*-toluenesulfonamido)-1,3,4-cyclohexanetriol (**16**) in 31% isolated yield, which was further characterized as the triacetate (**17**).[11] In the ^{1}H NMR spectrum of **17**, the signals for H-2, H-3, and H-4 protons appeared as a triplet of doublets (J=3, 11, and 11 Hz), a triplet (J=11 Hz), and a triplet (J=11 Hz) at δ 3.49, 5.09, and 4.88, respectively. Upon deuteration, a doublet (J=11 Hz, δ 5.42) due to the amido proton disappeared and the H-2 signal changed to a doublet of doublets (J=3 and 11Hz). Therefore, the conformations of H-1, H-2, and H-3 were shown to be equatorial-axial-axial, supporting the structure assigned above. Similar *cis*-oxyamination of **4** gave mainly the pseudo-glucosamine derivative (**18**) in 30% yield, which was converted to triacetate (**19**). The structure of **18** could be correlated to that of **16** by comparison of the ^{1}H NMR spectral data.[12]

Treatment of **16** with sodium acetate in refluxing aqueous 2-methoxyethanol gave its triacetate (**20**) in 57% yield, which was further acetylated to give the tetraacetate (**21**). The ^{1}H NMR spectrum of **20** resembled that of **16** in the region for ring protons, apart from that the signal for the C-7 methylene protons was shifted down field.

Azidolysis of **16** with sodium azide in *N*,*N*-dimethylformamide (DMF) at 80 °C for 2 h gave the azido derivative (**22**) in 90% yield, which was converted to the corresponding acetamide (**23**) in 57% yield. Tetra-*N*,*O*-acetyl derivative (**24**) was prepared. Hydrogenolysis of **16** gave the C-7 debromo compound (**25**) in 82% yield. The ^{1}H NMR spectra of **22**—**25** were all consistent with the assigned structures.

On the other hand, to obtain the derivatives having the β-gluco configuration, an inversion of the C-1 configuration was attempted by a direct substitution reaction of the 1-*O*-methanesulfonate (**26**) of **16**. Thus, **26** was prepared in 69% yield by treatment of **16** with an excess of methanesulfonyl chloride in pyridine. Azidolysis of **26** with 1.5 molar equivalent of sodium azide in DMF at 80 °C for 2 h gave preferentially the C-7 azido derivative (**27**) in 68% yield. While, on treatment with 5 molar equivalent of sodium azide at 85 °C for a prolonged period (20 h), the diazido derivative (**28**) was obtained mainly in 71% yield. Hydrogenation of **27** and **28** followed by acetylation gave the corresponding acetamide (**29**) and diacetamide (**30**) in 65 and 66% yields, respectively. As the side product of the hydrogenation of **28**, DL-1,2-di-*O*-acetyl-(1,3/2,6)-3-acetamidomethyl-6-(*p*-toluenesulfonamido)-1,2-cyclohexanediol (**31**) was isolated in 18% yield, which might arise from the elimination of the C-4 azido group under slightly basic conditions.

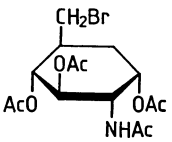
35



36

Reaction of **26** with an excess of sodium acetate in DMF at 80 °C for 20 h gave a mixture of products from which DL-tetra-*O*-acetyl-(1,3,5/2,4)-5-hydroxymethyl-2-(*p*-toluenesulfonamido)-1,3,4-cyclohexanetriol (**32**), DL-1,2-di-*O*-acetyl-(1,3/2,6)-3-hydroxymethyl-6-(*p*-toluenesulfonamido)-4-cyclohexene-1,2-diol (**33**), and DL-1,2-di-*O*-acetyl-(1/2,6)-3-methylene-6-(*p*-toluenesulfonamido)-4-cyclohexene-1,2-diol (**35**) were isolated in 10, 28, and 7% yields, respectively, by chromatography on silica gel. The structures were determined by the elemental analysis and ^{1}H NMR spectral data. The ^{1}H NMR spectrum of **32** in chloroform-*d* showed the signal for the H-2 proton as a quartet (J=10 Hz) at δ 3.65, which changed to a triplet upon deuteration, indicating the *trans*-diaxial arrangement of H-1 and H-2. The structure of **33** was assigned by the appearance of two-proton singlet at δ 5.50 attributable to two olefinic protons. In the spectrum of **35**, the signals for the exocyclic methylene protons appeared as a broad singlet at δ 4.96

Table 1. Chemical shifts of acetyl methyl protons[a)]

Compound	1-OAc	3-OAc	4-OAc	7-OAc
16		1.62	2.00

32	1.71[b)]	1.79[b)]	1.97	2.03

a) Taken at 90 MHz in $CDCl_3$ with reference to TMS. Chemical shifts are given in terms of δ-values. b) Assignments may be reversed.

and 5.06.[13)]

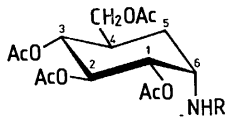
The elimination occurred predominantly in the reaction of **29** with sodium acetate in DMF giving rise to DL-1,2-di-*O*-acetyl-(1,3/2,6)-3-acetamidomethyl-6-(*p*-toluenesulfonamido)-4-cyclohexene-1,2-diol (**34**) in 59% yield. The ^1H NMR spectrum showed the signals for two olefinic protons as two triplets of doublets (J=2, 2, and 12 Hz) at δ 5.34 (H-4) and 5.57 (H-5).

The olefins **33**, **34**, and **35** thus obtained may be good precursors for preparation of branched-chain amino- and diaminocyclitols. Removal of the *N*-(*p*-tolylsulfonyl) group can usually be performed by the influence of sodium in liquid ammonia. Alternatively, on treatment with 20% hydrogen bromide in acetic acid in a sealed tube at 70 °C overnight, **16** gave the corresponding tri-*O*-acetyl amine hydrobromide, which was successively acetylated to the peracetyl derivative (**36**) in 69% yield. This procedure may be used for a small scale deprotection of *N*-(*p*-tolylsulfonyl) derivatives.

We are studying to prepare glycosides of **20** and **22**, which would provide the pseudo analogs of antibiotic trehalosamine and its related compounds.[14)]

Assignment of Acetyl Methyl Protons of N-(p-*Tolylsulfonyl) Derivatives of Pseudo-glucosamine.* Comparison of the ^1H NMR spectra of **16**, **17**, **20**, and **21** allowed to assign all the signals due to the acetyl methyl protons (Table 1). The appreciable up-field shift of the signal for the C-3 equatorial acetoxyl group is observed (at least 0.20 ppm), which may be attributed to a shielding effect by the aromatic ring of the C-2 equatorial *p*-toluenesulfonamido group being in the position perpendicular to the acetyl methyl protons.[15,16a)] Whereas, the C-1 axial acetoxyl group resonates slightly up-shifted by *ca.* 0.10 ppm in the region of δ 2.05—2.10.[16)] These results are consistent with the structure of **32**, in which the presence of two equatorial acetoxyl groups at C-1 and C-3 may be supported by appearance of two up-shifted acetyl signals.

The *N*-(*p*-tolylsulfonyl) derivative (**37**) of validamine was prepared[17)] in order to see the shielding effect of the axially oriented *p*-toluenesulfonamido function. The ^1H NMR spectrum of **37** revealed the acetyl signals as two singlets at δ 1.79 and 2.00 in a ratio of 1:3, while, those of the peracetyl derivative (**38**)[9)]



37 R = Ts
38 R = Ac

showed three singlets at δ 1.99, 2.01, and 2.03 in a ratio of 1:2:2. Therefore, the C-1 acetoxymethyl-signal seems to be shifted to higher field by at least 0.20 ppm due to the C-6 axail *p*-toluenesulfonamido group.

Experimental

Melting points were determined on a Büchi 510 capillary melting point apparatus and are uncorrected. Solutions were concentrated below 50 °C under reduced pressure. Catalytic hydrogenations were carried out in a Parr shaker type apparatus in the initial hydrogen pressure of 3.4 kg/cm² at ambient temperature. Unless otherwise noted, ^1H NMR spectra were taken on a Varian EM-390 (90 MHz) spectrometer in chloroform-*d* ($CDCl_3$) or dimethyl-d_6 sulfoxide (DMSO-d_6) with reference to tetramethylsilane as an internal standard. The peak positions are given in terms of δ-values and values given for coupling constants are of first-order. TLC was performed on precoated silica gel 60 F-254 plaques (Merck, Darmstadt; 0.25 mm thickness). The silica gel used for a column chromatography was Wakogel C-300 (Wako Pure Chemical Industries, Ltd.).

DL-*Di-O-acetyl-(1,3/2,4,6)-3,4-dibromo-6-benzoyloxymethyl-1,2-cyclohexanediol (2).* A mixture of DL-di-*O*-acetyl-(1,3/2,4,6)-3,4-dibromo-6-bromomethyl-1,2-cyclohexanediol (**1**, 2 g),[4)] sodium benzoate (2.56 g, 4 molar equivalent), and 80% aqueous ethanol (50 ml) was refluxed for 2 d. The reaction mixture was allowed to stand in a refrigerator overnight, and the resulting crystals were collected by filtration. Recrystallization from ethanol gave **2** (1.44 g, 66%) as colorless plates: mp 154—155 °C. ^1H NMR ($CDCl_3$, 60 MHz)[18)] δ 1.96 (3H, s) and 2.03 (3H, s) (OAc), 3.80—4.30 (4H, m, H-3, H-4, and $C\underline{H}_2OBz$), 4.70—5.35 (2H, m, H-1 and H-2), 7.05—7.90 (5H, m, phenyl).

Found: C, 44.00; H, 4.15; Br, 32.52%. Calcd for $C_{18}H_{20}Br_6$: C, 43.93; H, 4.10; Br, 32.47%.

DL-*Di-O-acetyl-(1,3/2)-3-bromomethyl-5-cyclohexene-1,2-diol (3).* To a solution of **1** (10 g) in acetic acid (70 ml) was added zinc dust (5.76 g) in three portions at 70 °C. The reaction mixture was stirred vigorously at 70 °C for 10 min and then cooled immediately, and the white precipitates and an excess of zinc dust were removed by filtration. The filtrate was concentrated to give a sirup which crystallized from ethanol–water to give **3** (5.96 g, 92%) as plates: mp 83—84 °C. ^1H NMR ($CDCl_3$) δ 2.01 (3H, s) and 2.03 (3H, s) (OAc), 3.19—3.52 (2H, m, $C\underline{H}_2Br$), 5.02 (1H, td, J=3, 7.5, and 7.5 Hz, H-2), 5.29—5.53 (2H, m, H-1 and H-5), 5.63—5.91 (1H, broad d, J=*ca.* 11 Hz, H-6).

Found: C, 45.16; H, 5.04; Br, 27.70%. Calcd for $C_{11}H_{15}BrO_4$: C, 45.37; H, 5.20; Br, 27.44%.

DL-*Di-O-acetyl-(1,3/2)-3-benzoyloxymethyl-5-cyclohexene-1,2-diol (4).* *a)* A stirred suspension of **2** (1 g) and zinc dust (0.53 g) in acetic acid (10 ml) was heated at 70 °C for 0.5 h. After cooling, the reaction mixture was processed as described for the preparation of **3**. The crystalline product was recrystallized from ethanol to give **4** (0.47 g, 70%)

as prisms: mp 75—76.5 °C. ^{1}H NMR ($CDCl_3$) δ 2.02 (6H, s, two OAc), 4.22 (1H, dd, J=5.3 and 12 Hz, H-7), 4.40 (1H, dd, J=4.2 and 12 Hz, H-7'), 5.25 (1H, dd, J=7.7 and 10.5 Hz, H-2), 5.40—5.66 (2H, m, H-1 and H-5), 5.69—5.99 (1H, broad d, J=*ca.* 11 Hz, H-6), 7.34—7.60 (2H, m) and 7.93—8.12 (2H, m) (phenyl).

Found: C, 64.82; H, 6.09%. Calcd for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07%.

b) A mixture of **3** (1.5 g) and sodium benzoate (1.5 g, 2 molar equivalent) in 80% aqueous 2-methoxyethanol (30 ml) was refluxed for 5 h. Then the mixture was concentrated to dryness and the residue was treated with acetic anhydride (10 ml) and pyridine (10 ml) at amibient temperature overnight. An insoluble material was removed by filtration and the filtrate was concentrated. The residue was dissolved in chloroform (20 ml) and passed through a short column of alumina. The filtrate and washings were combined and concentrated. Recrystallization of the residue from ethanol–hexane gave **4** (1.15 g, 67%) as prisms: mp 75—76 °C. This compound was identical with the compound obtained from **2**.

*Oxidation of **3** with Osmium Tetroxide.* *a)* To a solution of **3** (4.37 g) in *t*-butyl alcohol (75 ml) and 35% hydrogen peroxide (15 ml) was added a solution of osmium tetroxide (0.16 g) in *t*-butyl alcohol (15 ml), and the mixture was kept at 30 °C for 24 h under dark. At that time, TLC indicated the disappearance of **3** and the formation of three components (R_f 0.45, 0.38, and 0.34) in 1:1 2-butanone–toluene. The reaction mixture was concentrated and the residue was treated with acetic anhydride and pyridine in usual way. Evaporation of the excess reagent gave a sirup, which was crystallized from ethanol to give DL-tetra-*O*-acetyl-(1,2,4/3,5)-5-bromomethyl-1,2,3,4-cyclohexanetetrol (**6**, 2.24 g, 36.5%). Recrystallization from ethanol gave an analytical sample: mp 137—138 °C. ^{1}H NMR ($CDCl_3$) δ 1.98 (3H, s), 2.00 (3H, s), 2.06 (3H, s), and 2.12 (3H, s) (OAc), 3.34 (2H, d, J=4.5 Hz, C$\underline{H}_2$Br), 4.87 (1H, dd, J=3.5 and 10.5 Hz, H-2), 4.94 (1H, t, J=10.5 Hz, H-4), 5.23 (1H, t, J=10.5 Hz, H-3), 5.39 (1H, q, J=3.5 Hz, H-1).

Found: C, 43.79; H, 5.18; Br, 19.74%. Calcd for $C_{15}H_{21}BrO_8$: C, 44.02; H, 5.17; Br, 19.53%.

The mother liquor from **6** was concentrated and the sirupy residue (2.3 g) was chromatographed on a silica-gel column (40 g) with 1:6 2-butanone–toluene as an eluent. The fractions containing the faster moving component were collected and concentrated to give DL-*trans*-2,4-diacetoxy-5-bromomethyl-2-cyclohexenone (**5**, 0.34 g, 7.5%) as a chromatographically homogeneous sirup. ^{1}H NMR ($CDCl_3$, 60 MHz)[18] δ 2.15 (3H, s) and 2.22 (3H, s) (OAc), 2.72 (2H, broad d, J=2.5 Hz, ring methylene), 3.50 (2H, broad d, J=2.5 Hz, C$\underline{H}_2$Br), 5.70 (1H, symmetric m, H-4), 6.47 (1H, d, J=2.5 Hz, H-3).

Found: C, 43.14; H, 4.50; Br, 26.34%. Calcd for $C_{11}H_{13}BrO_5$: C, 43.30; H, 4.29; Br, 26.19%.

b) To a mixture of **3** (4 g), 35% hydrogen peroxide (15 ml), and *t*-butyl alcohol (75 ml) was added a solution of osmium tetroxide (0.2 g) in *t*-butyl alcohol (40 ml) and the reaction mixture was stirred at 25 °C overnight. The mixture was processed similarly as described in *a)* and the product directly crystallized from ethanol to give **6** (2.6 g, 46%) as prisms: mp 137—138 °C.

DL-*Penta*-O-*acetyl*-*(1,2,4/3,5)*-*5*-*hydroxymethyl*-*1,2,3,4*-*cyclohexanetetrol* (**7**). A mixture of **6** (0.82 g), anhydrous sodium acetate (0.49 g), and 90% aqueous 2-methoxyethanol (20 ml) was refluxed for 20 h. The reaction mixture was concentrated and the residue was treated with acetic anhydride and pyridine in the usual way. The reaction mixture was filtered and the filtrate was concentrated. The residue was triturated with chloroform and the suspension was passed through a short column of alumina. The filtrate was concentrated and the residue was crystallized from ethanol–ether to give **7** (0.32 h, 42%) as needles mp 110—111 °C. ^{1}H NMR ($CDCl_3$) δ 1.99 (3H, s) 2.00 (3H, s), 2.03 (3H, s), 2.05 (3H, s), and 2.13 (3H, s) (OAc), 3.86 (1H, dd, J=3.5 and 11 Hz, H-7), 4.11 (1H, dd, J=4.5 and 11 Hz, H-7'), 4.89 (1H, dd, J=3 and 10.5 Hz, H-2), 4.99 (1H, dd, J=9 and 10.5 Hz, H-4), 5.39 (1H, t, J=10.5 Hz, H-3), 5.41 (1H, q, J=3 Hz, H-1).

Found C, 52.65; H, 6.18%. Calcd for $C_{17}H_{24}O_{10}$: C, 52.57; H, 6.23%.

DL-*Tetra*-O-*acetyl*-*(1,2,4/3,5)*-*5*-*azidomethyl*-*1,2,3,4*-*cyclohexanetetrol* (**8**). A mixture of **6** (0.82 g), sodium azide (0.78 g), and 90% aqueous 2-methoxyethanol (20 ml) was refluxed for 20 h. The reaction mixture was concentrated and the residue was treated with acetic anhydride and pyridine in usual way. The reaction mixture was processed as described for the preparation of **7** to give crystals which were recrystallized from ethanol–ether to give **8** (0.55 g, 74%) as prisms: mp 85—86 °C. ^{1}H NMR ($CDCl_3$, 60 MHz)[18] δ 2.00 (6H, s), 2.07 (3H, s), and 2.13 (3H, s) (OAc), 3.27—3.35 (2H, m, CH_2N_3), 4.85 (1H, dd, J=3 and 9.5 Hz, H-2), 4.92 (1H, broad t, J=9.5 Hz, H-4), 5.38 (1H, broad t, J=9.5 Hz, H-3), 5.45 (1H, q, J=3 Hz, H-1).

Found: C, 48.77; H, 5.81; N, 11.53%. Calcd for $C_{15}H_{21}N_3O_8$: C, 48.52; H, 5.70; N, 11.32%.

DL-*Tetra*-O-*acetyl*-*(1,2,4/3,5)*-*5*-*acetamidomethyl*-*1,2,3,4*-*cyclohexanetetrol* (**9**). A solution of **8** (0.3 g) in ethanol (10 ml) containing acetic anhydride (0.4 ml) was hydrogenated in the presence of Raney nickel T-4[8] overnight. The catalyst was removed by filtration and the filtrate was concentrated. The product was purified by passage through a short column of alumina with chloroform. The filtrate was concentrated and the residue was crystallized from ethanol–ether to give **9** (0.10 g, 31%) as needles: mp 150—151 °C. ^{1}H NMR ($CDCl_3$, 60 MHz)[18] δ 1.99 (9H, s) and 2.08 (6H, s) (NAc and OAc), 3.33—3.95 (2H, m, C$\underline{H}_2$NHAc), 4.78 (1H, broad t, J=9.5 Hz, H-4), 4.84 (1H, dd, J=3 and 9.5 Hz, H-2), 5.33 (1H, q, J=3 Hz, H-1), 5.40 (1H, broad t, J=9.5 Hz, H-3), 6.07 (1H, t, J=5.5 Hz, N$\underline{H}$).

Found: C, 52.87; H, 6.49; N, 3.65%. Calcd for $C_{17}H_{25}NO_9$: C, 52.71; H, 6.51; N, 3.62%.

DL-*Tetra*-O-*acetyl*-*(1,2,4/3,5)*-*5*-*methyl*-*1,2,3,4*-*cyclohexanetetrol* (**10**). A solution of **6** (0.8 g) in ethyl acetate (10 ml) was hydrogenated in the presence of Raney nickel T-4 (one spoonful) and Amberlite IR-45 (OH^-) (5 ml) overnight. The catalyst and the resin were removed by filtration and the filtrate was concentrated. The residue was crystallized from ethanol to give **10** (0.45 g, 70%) as plates: mp 137—138 °C. ^{1}H NMR ($CDCl_3$) δ 0.93 (3H, d, J=6 Hz, methyl), 1.98 (6H, s), 2.03 (3H, s), and 2.10 (3H, s) (OAc), 4.71 (1H, t, J=10.5 Hz, H-4), 4.87 (1H, dd, J=3 and 10.5 Hz, H-2), 5.30 (1H, t, J=10.5 Hz, H-3), 5.31 (1H, q, J=3 Hz H-1).

Found: C 54.82; H, 6.69%. Calcd for $C_{15}H_{22}O_8$: C, 54.54: H, 6.71%.

DL-*Tetra*-O-*acetyl*-*(1,3,5/2,4)*-*5*-*bromomethyl*-*1,2,3,4*-*cyclohexanetetrol* (**12**). A mixture of DL-penta-*O*-acetyl-(1,3,5/2,4)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**11**, 1.0 g)[9] and 10% hydrogen bromide in acetic acid (4.5 ml) was heated in a sealed tube at 80 °C for 16 h. The reaction mixture was poured into ice–water (40 ml) and the precipitates were collected by filtration. Recrystallization from ethanol gave **12** (0.88 g, 83%) as plates: mp 128—129.5 °C. ^{1}H NMR ($CDCl_3$, 60 MHz)[18] δ 1.98 (3H, s), 2.00 (3H,

s), 2.03 (3H, s), and 2.06 (3H, s) (OAc), 3.38 (1H, broad d, J=4 Hz, C$\underline{H}_2$Br), 4.8—5.2 (4H, m, H-1, H-2, H-3, and H-4).

Found: C, 44.20; H, 5.19; Br, 19.67%. Calcd for $C_{15}H_{21}BrO_8$: C, 44.03; H, 5.17; Br, 19.52%.

DL-*Tetra*-O-*acetyl*-*(1,3,5/2,4)*-*5*-*azidomethyl*-*1,2,3,4*-*cyclohexanatetrol* (**13**). A mixture of **12** (0.2 g), sodium azide (0.06 g), and 90% aqueous *N,N*-dimethylformamide (DMF) (5 ml) was stirred at 80 °C for 7 h. The reaction mixture was concentrated and the residue was processed as described for the preparation of **8**. The crude product was recrystallized from ethanol to give **13** (0.16 g, 85%) as prisms: mp 101—102 °C. ^{1}H NMR ($CDCl_3$) δ 1.97 (3H, s), 1.99 (3H, s), 2.02 (3H, s), and 2.03 (3H, s) (OAc), 3.22 (1H, dd, J=6 and 13 Hz, H-7), 3.39 (1H, dd, J=5 and 13 Hz, H-7′), 4.67—5.20 (4H m, H-1, H-2, H-3, and H-4).

Found: C, 48.61; H, 5.71; N, 11.28%. Calcd for $C_{15}H_{21}N_3O_8$: C, 48.52; H, 5.70; N, 11.32%.

DL-*Tetra*-O-*acetyl*-*(1,3,5/2,4)*-*5*-*acetamidomethyl*-*1,2,3,4*-*cyclohexanetetrol* (**14**). A solution of **13** (0.10 g) in ethanol (20 ml) was hydrogenated in the presence of Raney nickel T-4 (one spoonful) overnight. The catalyst was removed by filtration and the filtrate was concentrated. The residue was acetylated in the usual way. The product was crystallized from ethanol to give **14** (60 mg, 58%) as needles: mp 210—211 °C. ^{1}H NMR ($CDCl_3$) δ 1.97 (12H, s) and 2.06 (3H, s) (NAc and OAc), 2.75 (1H, td, J=5, 5, and 14 Hz, H-7, changes to a doublet of doublets with 5 and 14 Hz splittings on deuteration), 3.69 (1H, ddd, J=3, 8, and 14 Hz, H-7′, changes to a doublet of doublets with 3 and 14 Hz splittings on deuteration), 4.63—5.16 (4H, m, H-1, H-2, H-3, and H-4), 5.99 (1H, broad dd, J=5 and 8 Hz, N$\underline{H}$, disappears on deuteration).

Found: C, 52.80; H, 6.46; N, 3.50%. Calcd for $C_{17}H_{25}NO_9$: C, 52.71; H, 6.51; N, 3.62%.

DL-*Tetra*-O-*acetyl*-*(1,3,5/2,4)*-*5*-*methyl*-*1,2,3,4*-*cyclohexanetetrol* (**15**). A solution of **12** (0.2 g) in ethyl acetate (15 ml) was hydrogenated as described for the preparation of **10**. The product was recrystallized from ethanol to give **15** (0.13 g, 82%) as prisms: mp 110—111 °C. ^{1}H NMR ($CDCl_3$) δ 0.94 (3H, d, J=6 Hz, methyl), 1.12—2.02 (3H, m, H-5, H-6, and H-6′), 1.97 (3H, s), 1.98 (3H, s), 2.00 (3H, s), and 2.02 (3H, s) (OAc), 4.59—5.17 (4H, m, H-1, H-2, H-3, and H-4).

Found: C, 54.41; H, 6.69%. Calcd for $C_{15}H_{22}O_8$: C, 54.54; H, 6.71%.

DL-*3,4-Di*-O-*acetyl*-*(1,2,4/3,5)*-*2*-*(*p-*toluenesulfonamido)*-*5*-*bromomethyl*-*1,3,4*-*cyclohexanetriol* (**16**). To a solution of **3** (1.5 g, 5.2 mmol) in chloroform (25 ml) was added a solution of osmium tetroxide in *t*-butyl alcohol (2.6 ml, 0.052 mmol), chloramine T (trihydrate) (1.82 g), triethylbenzylammonium chloride (0.06 g), and water (25 ml). The mixture was stirred at 60 °C for 40 h. At that time, TLC indicated the formation of the major (R_f 0.64) and three minor components (R_f 0.60, 0.49, and 0.45), together with a trace of **3** (R_f 0.85) in 1:8 ethanol–toluene. Sodium hydrogensulfite (1.5 g) was added to the mixture and it was refluxed for 5 h. Chloroform (50 ml) was added to the cooled mixture, and the organic layer was separated, washed successively with 1% aqueous sodium hydroxide and brine, and dried over anhydrous sodium sulfate. Evaporation of the solvent gave a sirup from which the major product was crystallized out on addition of ethanol. Recrystallization from ethanol gave **16** (0.76 g, 31%) as prisms: mp 196—197 °C. ^{1}H NMR ($CDCl_3$) δ 1.62 (3H, s) and 2.00 (3H, s) (OAc), 2.42 (3H, s, tosyl methyl), 3.01 (1H, d, J=4 Hz, O$\underline{H}$, disappears on deuteration), 3.18—3.51 (1H, m, H-2), 3.32 (2H, d, J=4 Hz, C$\underline{H}_2$Br), 4.07—4.26 (1H, m, H-1), 4.86 (1H, J=10 Hz, H-4), 5.09 (1H, t, J=10 Hz, H-3), 5.62 (1H, d, J=8 Hz, N$\underline{H}$, disappears on deuteration), 7.28 (2H, d) and 7.75 (2H, d) (J=9 Hz, phenyl).

Found: C, 44.94; H, 5.04; N, 2.78%. Calcd for $C_{18}H_{24}BrNO_7S$: C, 45.20; H, 5.06; N, 2.93%.

Acetylation of **16** (0.1 g) in the usual way gave the triacetate (**17**), which was recrystallized from ethanol to give an analytical sample (0.07 g, 66%) as prisms: mp 192—193 °C. ^{1}H NMR ($CDCl_3$) δ 1.76 (3H, s), 1.99 (3H, s), and 2.06 (3H, s) (OAc), 2.40 (3H, s, tosyl methyl), 3.29 (2H, d, J=3 Hz, C$\underline{H}_2$Br), 3.49 (1H, ddd, J=3, 9, and 11 Hz, H-2, changes to a doublet of doublets with 3 and 11 Hz splittings on deuteration), 4.88 (1H, t, J=11 Hz, H-4), 5.09 (1H, t, J=11 Hz, H-3), 7.42 (2H, d) and 7.69 (2H, d) (J=9 Hz, phenyl).

Found: C, 45.96; H, 5.07; N, 2.46%. Calcd for $C_{20}H_{26}BrNO_8S$: C, 46.16; H, 5.04; N, 2.69%.

DL-*3,4-Di*-O-*acetyl*-*(1,2,4/3,5)*-*5*-*benzoyloxymethyl*-*2*-*(*p-*toluenesulfonamido)*-*1,3,4*-*cyclohexanetriol* (**18**). To a solution of **4** (2 g, 6 mmol) in chloroform (30 ml) was added a solution of osmium tetroxide in *t*-butyl alcohol (4.5 ml, 0.09 mmol), chloramine T (trihydrate) (2.1 g), benzyltriethylammonium chloride (0.07 g), and water (30 ml), and the mixture was heated at 60 °C under stirring for 2 d. At that time, TLC indicated the formation of one major (R_f 0.45) and one minor products (R_f 0.28), together with **4** (R_f 0.75) in 1:10 ethanol–toluene. The reaction mixture was processed as described for the preparation of **16**. The crude product was purified by passage through a short column of caoline and silica gel with chloroform. Recrystallization from toluene gave **18** (0.93 g, 30%) as prisms: mp 150—152 °C. ^{1}H NMR ($CDCl_3$) δ 1.64 (3H, s), 1.97 (3H, s) (OAc), 2.38 (3H, s, tosyl methyl), 3.41 (1H, dd, J=2.5 and 10 Hz, H-2), 4.99 (1H, t, J=9 Hz, H-4), 5.17 (1H, t, J=9 Hz, H-3), 5.85 (1H d J=9 Hz N$\underline{H}$), 7.18—8.13 (9H, m, phenyl).

Found: C, 57.74; H, 5.70; N, 2.55; S, 6.15%. Calcd for $C_{25}H_{29}NO_9S$: C, 57.79; H, 5.63; N, 2.70; S, 6.17%.

Compound **18** was converted into the triacetate (**19**) by the conventional manner. An analytical sample was obtained by recrystallization from ethanol: mp 200—201 °C. ^{1}H NMR ($CDCl_3$) δ 1.78 (3H, s), 1.98 (3H, s), and 2.10 (3H, s) (OAc), 2.40 (3H, s, tosyl methyl), 3.55 (1H, td, J=5, 9, and 9 Hz, H-2), 4.23 (2H, d, J=4 Hz, C$\underline{H}_2$OBz), 4.91—5.20 (3H, m, H-1, H-3, and H-4), 5.28 (1H, d, J=9 Hz, N$\underline{H}$), 7.13—8.13 (9H, m, phenyl).

Found: C, 57.46; H, 5.57; N, 2.36; S, 5.50%. Calcd for $C_{27}H_{31}NO_{10}S$: C, 57.74; H, 5.56; N, 2.49; S, 5.71%.

DL-*3,4,7-Tri*-O-*acetyl*-*(1,2,4/3,5)*-*5*-*hydroxymethyl*-*2*-*(*p-*toluenesulfonamido)*-*1,3,4*-*cyclohexanetriol* (**20**). A mixture of **16** (0.2 g), anhydrous sodium acetate (0.086 g), and DMF (5 ml) was heated at 80 °C for 3 d. The reaction mixture was concentrated and the residue was extracted with hot ethyl acetate (20 ml) and the extracts were washed with water. The solution was dried and concentrated to give crystals which were recrystallized from ethanol to give **20** (0.11 g, 57%) as prisms: mp 174—175 °C. ^{1}H NMR ($CDCl_3$) δ 1.60 (3H, s), 1.97 (3H, s), and 2.02 (3H, s) (OAc), 2.39 (3H, s, tosyl methyl), 3.32 (1H, td, J=3, 9, and 9 Hz, H-2), 3.81 (1H, dd, J=3 and 11 Hz, H-7), 4.05 (1H, dd, J=5 and 11 Hz, H-7′), 4.81 (1H, t, J=10 Hz, H-4), 5.03 (1H, t, J=10 Hz, H-3), 5.64 (1H, d, J=8 Hz, N$\underline{H}$), 7.23 (2H, d) and 7.68 (2H, d) (J=9 Hz, phenyl).

Found: C, 52.23; H, 5.92; N, 3.01; S, 6.76%. Calcd for $C_{20}H_{27}NO_9S$: C, 52.51; H, 5.95; N, 3.06; S, 7.01%.

Compound **20** (75 mg) was converted into the tetraacetate (**21**) by the conventional manner. The product was crystallized from ethanol to give an analytical sample (73 mg, 90%) as prisms: mp 173.5—174.5 °C. ^{1}H NMR ($CDCl_3$) δ 1.72 (3H, s), 1.97 (3H, s), 2.01 (3H, s), and 2.05 (3H, s) (OAc), 2.37 (3H, s, tosyl methyl), 3.47 (1H, dd, J= 3.2 and 10.5 Hz, H-2, on deuteration), 3.73 (1H, dd, J= 3.3 and 11.7 Hz, H-7), 4.02 (1H, dd, J=4.5 and 11.7 Hz, H-7′), 4.65—5.25 (3H, m, H-1, H-3, and H-4), 5.29 (1H, d, J=9 Hz, NH, disappears on deuteration), 7.22 (2H, d) and 7.67 (2H, d) (J=9 Hz, phenyl).

Found: C, 52.61; H, 5.76; N, 2.78; S, 6.53%. Calcd for $C_{22}H_{29}NO_{10}S$: C, 52.90; H, 5.85; N, 2.80; S, 6.42%.

DL-*3,4-Di*-O-*acetyl*-*(1,2,4/3,5)*-5-*azidomethyl*-2-(p-*toluenesulfonamido*)-1,3,4-*cyclohexanetriol* (**22**). A mixture of **16** (0.5 g), sodium azide (0.56 g, 4 molar equiv.), and DMF (10 ml) was heated at 80 °C for 3 h under stirring. The reaction mixture was diluted with water (4 ml) and extracted with ethyl acetate (3×5 ml), and the extracts were washed with water and dried. Evaporation of the solvent gave a crystalline residue which was recrystallized from ethanol to give **22** (0.42 g, 90%) as prisms: mp 185—186 °C. ^{1}H NMR ($CDCl_3$) δ 1.61 (3H, s) and 2.01 (3H, s) (OAc), 2.41 (3H, s, tosyl methyl), 3.16—3.47 (3H, m, H-2 and CH_2N_3), 4.02—4.23 (1H, m, H-1), 4.80 (1H, dd, J=11 and 12 Hz, H-4), 5.04 (1H, t, J=11 Hz, H-3), 5.62 (1H, d, J=8 Hz, NH), 7.24 (2H, d) and 7.69 (2H, d) (J=9 Hz, phenyl).

Found: C, 49.10; H, 5.47; N, 12.46; S, 7.04%. Calcd for $C_{18}H_{24}N_4O_7S$: C, 49.08; H, 5.49; N, 12.72; S, 7.28%.

DL-*3,4-Di*-O-*acetyl*-*(1,2,4/3,5)*-5-*acetamidomethyl*-2-(p-*toluenesulfonamido*)-1,3,4-*cyclohexanetriol* (**23**). A solution of **22** (0.25 g) in methanol (15 ml) containing acetic anhydride (0.1 ml) was hydrogenated in the presence of Raney nickel T-4 for 3 d. The catalyst was removed by filtration and the filtrate was concentrated to give crystals which were recrystallized from methanol to give **23** (0.14 g, 57%) as prisms: mp 233.5—234 °C. ^{1}H NMR (DMSO-d_6) δ 1.65 (3H, s), 1.76 (3H, s), and 1.90 (3H, s) (NAc and OAc), 2.32 (3H, s, tosyl methyl), 2.8—3.1 (2H, broad s, CH_2NHAc, changes to a broad doublet with 5 Hz splitting on deuteration), 4.67 (1H, t, J=11 Hz, H-4), 4.91 (1H, t, J= 11 Hz, H-3), 7.32 (2H, d) and 7.67 (2H, d) (J=9 Hz, phenyl).

Found: C, 52.61; H, 6.14; N, 5.87; S, 7.15%. Calcd for $C_{20}H_{28}N_2O_8S$: C, 52.62; H, 6.18; N, 6.14; S, 7.02%.

Compound **23** was converted to triacetate (**24**) in the conventional method. An analytical sample was prepared by recrystallization from ethanol: mp 194—195 °C. ^{1}H NMR ($CDCl_3$) δ 1.83 (3H, s), 1.96 (3H, s), and 2.07 (6H, s) (NAc and OAc), 2.41 (3H, s, tosyl methyl), 2.77 (1H, td, J=5, 5, and 14 Hz, CH_2NHAc, changes to a doublet of doublets with 5 and 14 Hz splittings on deuteration), 3.45 (1H, dd, J=4 and 11 Hz, H-2, on deuteration), 3.62 (1H, dd, J=4 and 14 Hz, H-7′, on deuteration), 4.72 (1H, t, J=11 Hz, H-4), 5.10 (1H, t, J=11 Hz, H-3), 5.51 (1H, d, J=9 Hz, NHTs), 6.02 (1H, dd, J=5 and 8 Hz, NHAc), 7.23 (2H, d) and 7.65 (2H, d) (J=9 Hz, phenyl).

Found: C, 53.16; H, 6.05; N, 5.43; S, 6.13%. Calcd for $C_{22}H_{30}N_2O_9S$: C, 53.00; H, 6.07; N, 5.62; S, 6.43%.

DL-*3,4-Di*-O-*acetyl*-*(1,2,4/3,5)*-2-(p-*toluenesulfonamido*)-5-*methyl*-1,3,4-*cyclohexanetriol* (**25**). A solution of **16** (0.2 g) in ethyl acetate (15 ml) was hydrogenated in the presence of Raney nickel T-4 (one spoonful) and Amberlite IR-45 (OH^-) (3 ml) overnight. The reaction mixture was processed in the usual way. The product was crystallized from ethanol to give **25** (0.14 g, 82%) as plates: mp 179.5—180 °C. ^{1}H NMR ($CDCl_3$) δ 0.88 (3H, d, J=6 Hz, methyl), 1.60 (3H, s) and 1.97 (3H, s) (OAc), 2.39 (3H, s, tosyl methyl), 3.27 (1H, broad d, H-2, changes to a doublet of doublets with 3 and 10 Hz splittings on deuteration), 3.49—4.10 (1H, m, H-1), 4.56 (1H, dd, J=9 and 10 Hz, H-4), 4.99 (1H, t, J=10 Hz, H-3), 5.34—5.80 (1H, m, NH), 7.24 (2H, d) and 7.69 (2H, d) (J=9 Hz, phenyl).

Found: C, 53.89; H, 6.24; N, 3.38; S, 7.78%. Calcd for $C_{18}H_{25}NO_7S$: C, 54.12; H, 6.31; N, 3.51; S, 8.03%.

DL-*3,4-Di*-O-*acetyl*-1-O-*methylsulfonyl*-*(1,2,4/3,5)*-5-*bromomethyl*-2-(p-*toluenesulfonamido*)-1,3,4-*cyclohexanetriol* (**26**). To a solution of **16** (1.0 g) in pyridine (10 ml) was added methanesulfonyl chloride (0.36 g) under ice cooling, and then the reaction mixture was stirred at ambient temperature overnight. The mixture was poured into ice-water (50 ml) and the crystals were collected and dried. Recrystallization from ethanol gave **26** (0.81 g, 69%) as needles: mp 187—188 °C. ^{1}H NMR ($CDCl_3$) δ 1.66 (3H, s) and 2.01 (3H, s) (OAc), 2.40 (3H, s, tosyl methyl), 3.17 (3H s mesyl methyl), 3.25—3.59 (3H, m, H-3 and CH_2Br), 4.71—5.03 (3H, m, H-1, H-2, and H-3), 5.68 (1H, d, J= 8 Hz, NH), 7.26 (2H, d) and 7.68 (2H, d) (J=9 Hz, phenyl).

Found: C, 41.27; H, 4.79; N, 2.61%. Calcd for $C_{19}H_{26}BrNO_9S_2$: C, 41.01; H, 4.71; N, 2.52%.

DL-*3,4-Di*-O-*acetyl*-1-O-*methylsulfonyl*-*(1,2,4/3,5)*-5-*azidomethyl*-2-(p-*toluenesulfonamido*)-1,3,4-*cyclohexanetriol* (**27**). A mixture of **26** (0.39 g), sodium azide (0.05 g, 1.5 molar equiv.), and DMF (10 ml) was stirred at 80 °C for 2 h. The reaction mixture was processed as described for the preparation of **8**. The product was crystallized from ethanol to give **27** (0.22 g, 68%) as plates: mp 173.5—174.5 °C. ^{1}H NMR ($CDCl_3$) δ 1.60 (3H, s) and 2.00 (3H, s) (OAc), 2.40 (3H, s, tosyl methyl), 3.15 (3H, s, mesyl methyl), 3.21—3.60 (3H, m, H-3 and CH_2N_3), 4.66—5.12 (3H, m, H-1, H-2, and H-4), 5.59 (1H, d, J=8 Hz, NH), 7.29 (2H, d) and 7.66 (2H, d) (J=8 Hz, phenyl).

Found: C, 43.85; H, 4.99; N, 10.52; S, 12.48%. Calcd for $C_{19}H_{26}N_4O_9S_2$: C, 44.01; H, 5.05; N, 10.80; S, 12.36%.

DL-*1,2-Di*-O-*acetyl*-*(1,3/2,4,6)*-4-*azido*-6-*azidomethyl*-3-(p-*toluenesulfonamido*)-1,2-*cyclohexanediol* (**28**). A mixture of **26** (0.4 g), sodium azide (0.24 g, 5 molar equivalent), and DMF (10 ml) was stirred at 85 °C for 20 h. The reaction mixture was processed as described for the preparation of **8**. The product was crystallized from ethanol to give **28** (0.24 g, 71%) as prisms: mp 130—131 °C. ^{1}H NMR ($CDCl_3$) δ 1.90 (3H, s) and 2.03 (3H, s) (OAc), 2.39 (3H, s, tosyl methyl), 3.00—3.65 (4H, m, H-3, H-4, and CH_2N_3), 4.85—4.95 (2H, m, H-1 and H-2), 5.41 (1H, d, J=9 Hz, NH), 7.24 (2H, d) and 7.73 (2H, d) (J=8 Hz, phenyl).

Found: C, 46.39; H, 4.95; N, 20.76; S, 6.69%. Calcd for $C_{18}H_{23}N_7O_6S$: C, 46.45; H, 4.98; N, 21.06; S, 6.89%.

DL-*3,4-Di*-O-*acetyl*-1-O-*methylsulfonyl*-*(1,2,4/3,5)*-5-*acetamidomethyl*-2-(p-*toluenesulfonamido*)-1,3,4-*cyclohexanetriol* (**29**). A solution of **27** (0.18 g) in methanol (15 ml) containing acetic anhydride (0.11 ml) was hydrogenated in the presence of Raney nickel T-4 overnight. The product was recrystallized from ethanol to give **29** (0.12 g, 65%) as powder: mp 215—215.5 °C. ^{1}H NMR (DMSO-d_6) δ 1.55 (3H, s), 1.76 (3H, s), and 1.89 (3H, s) (NAc and OAc), 2.38 (3H, s, tosyl methyl), 2.85—3.10 (2H, m, CH_2NHAc), 3.16 (3H, s, mesyl ethyl), 3.59—3.88 (1H, m, H-3), 4.55—5.00 (3H, m, H-1, H-2, and H-4), 7.33 (2H, d) and 7.68 (2H, d) (J= 8 Hz, phenyl), 8.20 (1H, broad s, NH).

Found: C, 46.98; H, 5.63; N, 4.97; S, 11.68%. Calcd for $C_{21}H_{30}N_2O_{10}S_2$: C, 47.18; H, 5.66; N, 5.42; S, 11.99%.

DL-*1,2-Di*-O-*acetyl*-*(1,3/2,4,6)*-4-*acetamido*-6-*acetamidomethyl*-3-(p-*toluenesulfonamido*)-1,2-*cyclohexanediol* (**30**). A solution of **28** (42 mg) in methanol (5 ml) containing acetic

anhydride (0.05 ml) was hydrogenated in the presence of Raney nickel T-4 overnight. At that time, TLC indicated the disappearance of **28** and the formation of a major product along with a minor product. The mixture was fractionated on a silica-gel column with 1:3 ethanol–toluene. The fractions containing the minor product were concentrated to give DL-1,2-di-*O*-acetyl-(1,3/2,6)-3-acetamidomethyl-6-(*p*-toluensulfonamido)-1,2-cyclohexanediol (**31**, 7 mg, 18%) as powder: mp 227.5—228.5 °C. ^{1}H NMR ($CDCl_3$ and D_2O) δ 1.76 (3H, s), 1.97 (3H, s), and 2.03 (3H, s) (NAc and OAc), 2.40 (3H, s, tosyl methyl), 2.72 (1H, dd, J=4 and 14 Hz, H-7), 3.23 (1H, broad dt, J=3, 3, and ca. 9 Hz, H-6), 3.62 (1H, dd, J=3 and 14 Hz, H-7′), 4.52—4.78 (2H, m, H-1 and H-2), 7.25 (2H, d) and 7.67 (2H, d) (J=8 Hz, phenyl).

Found: C, 54.23; H, 6.16; N, 6.05%. Calcd for $C_{20}H_{28}N_2O_7S$: C, 54.53; H, 6.41; N, 6.36%.

The fractions containing the major product gave **30** (29 mg, 66%) as a homogeneous sirup, which solidified on standing. Attempts to crystallize it from several solvents failed. ^{1}H NMR ($CDCl_3$ and D_2O) δ 1.49 (3H, s), 1.87 (3H, s), 1.96 (3H, s) (NAc and OAc), 2.38 (3H, s, tosyl methyl), 2.83 (1H, dd, J=6 and 14 Hz, H-7), 3.32 (1H, dd, J=9 and 11 Hz, H-3), 3.50 (1H, dd, J=3 and 14 Hz, H-7′), 3.90 (1H, ddd, J=4, 11, and 12 Hz, H-4), 4.67 (1H, t, J=9 Hz, H-1), 4.92 (1H, t, J=9 Hz, H-2), 7.22 (2H, d) and 7.67 (2H, d) (J=8 Hz, phenyl).

Found: C, 52.77; H, 6.13; N, 8.13%. Calcd for $C_{22}H_{31}N_3O_8S$: C, 53.12; H, 6.28; N, 8.45%.

*Reaction of **26** with Sodium Acetate.* A mixture of **26** (0.2 g) and anhydrous sodium acetate (0.12 g, 4 molar equiv.) in DMF (5 ml) was stirred at 80 °C for 20 h. At that time, **26** still remained in the mixture. Then the mixture was further heated at 80 °C overnight with addition of sodium acetate (0.06 g, 2 molar equivalent). The reaction mixture was processed as described for the preparation of **27**. The products were fractionated by a silica-gel column with 1:4 2-butanone–toluene. The fractions containing the faster-moving component (R_f 0.48) were concentrated to give DL-1,2-di-*O*-acetyl-(1/2,6)-3-methylene-6-(*p*-toluenesulfonamido)-4-cyclohexene-1,2-diol (**35**, 10 mg, 7%) as crystals: mp 129—130 °C. ^{1}H NMR ($CDCl_3$ and D_2O) δ 1.77 (3H, s) and 2.05 (3H, s) (OAc), 2.40 (3H, s, tosyl methyl), 4.06 (1H broad d, J=8 Hz, H-1), 4.86 (1H, broad d, J=8 Hz, H-1), 4.96 (1H, broad s, H-7), 5.06 (1H, broad s, H-7′), 5.46 (1H, broad d, J=*ca.* 10 Hz, H-5), 5.56 (1H, broad d, J=8 Hz, H-2), 7.23 (2H, d) and 7.68 (2H, d) (J=9 Hz, phenyl).

Found: C, 56.65; H, 5.48; N, 3.48%. Calcd for $C_{18}H_{21}NO_6S$: C, 56.98; H, 5.58; N, 3.69%.

The second fractions (R_f 0.24) gave crystals of DL-1,2,7-tri-*O*-acetyl-(1,3/2,6)-3-hydroxymethyl-6-(*p*-toluenesulfonamido)-4-cyclohexene-1,2-diol (**33**, 44 mg, 28%): mp 156—157 °C. ^{1}H NMR ($CDCl_3$ and D_2O) δ 1.74 (3H, s), 1.99 (3H, s), and 2.02 (3H, s) (OAc), 2.41 (3H, s, tosyl methyl), 3.88 (1H, dd, J=7 and 12 Hz, H-7), 4.06 (1H, dd, J=5 and 12 Hz, H-7′), 4.78—5.28 (3H, m, H-1 and H-2), 5.50 (2H, s, H-4 and H-5), 7.23 (2H, d) and 7.68 (2H, d) (J=8 Hz, phenyl).

Found: C, 54.60; H, 5.72; N, 3.21%. Calcd for $C_{20}H_{25}NO_8S$: C, 54.66; H, 5.73; N, 3.19%.

The third fractions gave DL-tetra-*O*-acetyl-(1,3,5/2,4)-5-hydroxymethyl-2-(*p*-toluenesulfonamido)-1,3,4-cyclohexanetriol (**32**, 15 mg, 10%) as crystals: mp 137—138 °C. Recrystallization from ethanol gave an analytical sample. ^{1}H NMR ($CDCl_3$ and D_2O) δ 1.71 (3H, s), 1.79 (3H, s), 1.97 (3H, s), and 2.03 (3H, s) (OAc), 2.37 (3H, s, tosyl methyl), 3.65 (1H, t, J=10 Hz, H-2), 3.85 (1H, dd, J=2 and 11 Hz, H-7), 4.02 (1H, dd, J=4 and 11 Hz, H-7′), 4.6—5.0 (3H, m, H-1, H-2, and H-4), 7.22 (2H, d) and 7.67 (2H, d) (J=9 Hz, phenyl).

Found: C, 52.70; H, 5.76; N, 2.75%. Calcd for $C_{22}H_{29}NO_{10}S$: C, 52.90; H, 5.85; N, 2.80%.

*Reaction of **29** with Sodium Acetate.* A mixture of **29** (0.12 g), anhydrous sodium acetate (0.055 g, 3 molar equivalent), and DMF (5 ml) was stirred at 80 °C for 2 d. The reaction mixture was concentrated and the residue was taken up in chloroform and filtered. The filtrate was concentrated and the residual product was fractionated on a silica-gel column with 1:4 ethanol–toluene as an eluent. The fractions containing the major product gave crystals of DL-1,2-di-*O*-acetyl-(1,3/2,6)-3-acetamidomethyl-6-(*p*-toluenesulfonamido)-4-cyclohexene-1,2-diol (**34**). Recrystallization from ethanol–ether gave an analytical sample (58 mg, 59%): mp 193.5—194.5 °C. ^{1}H NMR ($CDCl_3$ and D_2O) δ 1.78 (3H, s), 1.92 (3H, s), and 2.02 (3H, s) (NAc and OAc), 2.38 (3H, s, tosyl methyl), 2.90 (1H, dd, J=5 and 14 Hz, H-7), 3.64 (1H, dd, J=4 and 14 Hz, H-7′), 3.99 (1H, broad d, J=8 Hz, H-6), 4.65—5.10 (2H, m, H-1 and H-2), 5.34 (1H, td, J=2, 2, and 12 Hz, H-4), 5.57 (1H, td, J=2, 2, and 12 Hz, H-5), 7.26 (2H, d) and 7.67 (2H, d) (J=8 Hz, phenyl).

Found: C, 54.51; H, 5.96; N, 6.19; S, 7.06%. Calcd for $C_{20}H_{26}N_2O_7S$: C, 54.78; H, 5.98; N, 6.39; S, 7.31%.

*DL-1,3,4-Tri-O-acetyl-(1,2,4/3,5)-2-acetamido-5-bromomethyl-1,3,4-cyclohexanetriol (**36**).* Compound **16** (0.2 g) was heated with 20% hydrogen bromide in acetic acid (3.5 ml) in a sealed tube at 80 °C for 20 h. The mixture was poured into ice–water (50 ml) and, after overnight, the solution was extracted with chloroform (3×10 ml). The extracts were dried and concentrated to give *p*-toluenesulfonic acid (77 mg). The aqueous layer was concentrated to dryness and the residue was treated with acetic anhydride and pyridine in usual way. The product was purified by passage through a short column of alumina with chloroform. Recrystallization from ethanol–ether gave **36** (124 mg, 69%) as needles: mp 177—178 °C. ^{1}H NMR ($CDCl_3$) δ 1.96 (3H, s), 1.98 (3H, s), 2.05 (3H, s), and 2.18 (3H, s) (NAc and OAc), 3.37 (2H, d, J=4.5 Hz, C$\underline{H}_2$Br), 4.21 (1H, td, J=3, 9, and 9 Hz, H-2), 4.82—5.30 (3H, m, H-1, H-3, and H-4), 6.23 (1H, d, J=9 Hz, N$\underline{H}$).

Found: C, 43.94; H, 5.30; N, 3.37; Br, 19.69%. Calcd for $C_{15}H_{22}BrNO_7$: C, 44.13; H, 5.43; N, 3.43; Br, 19.57%.

The authors wish to express their thanks to Mr. Saburo Nakada for elemental analyses.

Regio- and Stereoselective Cyclopentannulation with Ketones and Propargyl Alcohol Derivatives. Synthesis of *dl*-Nootkatone and *dl*-Muscopyridine

Tamejiro HIYAMA,* Masaki SHINODA, Hiroyuki SAIMOTO, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received January 27, 1981)

A highly regio- and stereoselective five-membered ring annulation involving the acid-treatment of propargyl alcohol dianion adducts of ketones is described. The propargyl alcohol adduct of 2-octanone was converted into 2-methyl-3-pentyl-2-cyclopentenone by treatment with sulfuric acid–methanol (1:1) at 0 °C. As the major product, 1-methylbicyclo[5.3.0]dec-6-en-8-one was produced from 2-methylcycloheptanone. Remarkable regioselective cyclopentannulation was observed in 2-methylcyclohexanone and 2,3-dimethylcyclohexanone wherein 1-methyl- and *trans*-1,2-dimethyl-substituted bicyclo[4.3.0]non-5-en-7-one (BNO) are produced, respectively. With 3-butyn-2-ol, 2-methylcyclohexanone was converted into the *cis*-1,9-dimethyl-substituted BNO. 4-Isopropyl-2-methylcyclohexanone was transformed into an 83—85:17—15 mixture of *c*-3-isopropyl-*r*-1,*c*-9-dimethyl-BNO and its 3-epimer. These results are explained in terms of the conrotatory ring-closure of thermodynamically most favorable hydroxypentadienyl cation intermediates. 3-Methoxycarbonyl-*cis*-1,9-dimethyl-BNO produced from 4-methoxycarbonyl-2-methylcyclohexanone and 3-butyn-2-ol was successfully transformed into *dl*-nootkatone by converting the methoxycarbonyl group into isopropenyl of correct stereochemistry followed by ring enlargement. Cyclopentannulation using propargyl alcohol dianion adducts of 2-cycloalkenones is discussed. Annulation takes place regioselectively to give conjugated dienones, *e.g.*, (*E*)-bicyclo[10.3.0]pentadeca-1(12),2-dien-13-one from 2-cyclododecenone. This product is led to *dl*-muscopyridine by conjugate 1,6-addition of methyl group followed by ring expansion and finally by aromatization with hydroxylamine hydrochloride.

Selective ring-forming reactions are important with respect to construction of fused carbocyclic skeletons. The regio- and stereochemistry of the annulation in particular should be controlled. The Robinson annulation has been extensively studied and is now well-established.[1] The analogous synthetic problem for five-membered ring annulation[2] still remains unsolved in spite of the development of efficient three-carbon annulation process.[3–5] In view of the stereospecificity of electrocyclic reactions, the ring-closure of pentadienyl cation intermediates was utilized.[6] Characteristic procedures have been developed for cyclopentannulation,[7,8] but though highly efficient for simple cyclic ketones, the method[7b] involving dichloroallyllithium–ketone adducts is not applicable to a moderately hindered ketone such as 2-methylcyclohexanone. Having made efforts to elaborate access to 2-substituted cycloalkanones, we have found a process noted briefly by Islam and Raphael[9a] and others[9b,c] which is effective as regards to regio- and stereoselectivity. Details are reported herein.[10]

Cyclopentannulation of 2-Methylcyclohexanones. In order to disclose the regioselectivity of the Raphael process, 2-octanone was allowed to react with the dilithium salt of propargyl alcohol, and the resulting adduct was treated with sulfuric acid–methanol (1:1) at 0 °C to give 2-methyl-3-pentyl-2-cyclopentenone (**1**) as a sole product. Starting with 2-methylcycloheptanone, we obtained **2** as the major product. Thus, the more substituted α-carbon of these ketones is preferentially incorporated into the five-membered ring. This selectivity may be attributed to the thermodynamically most stable intermediates of types A and B, respectively, showing a sharp contrast to the exclusive production of **3** from 2-methylcycloheptanone by the dichloroallyllithium method.[7b]

Remarkable selective annulation was observed in 2-methylcyclohexanone derivatives (Table 1). The propargyl alcohol adduct **5** of 2-methylcyclohexanone (**4**) was cyclized under acidic conditions to give the hexahydroindenone derivative **6** exclusively. The electrocyclic ring-closure of the intermediate C followed by deprotonation should be responsible for selective annulation.

When 3-butyn-2-ol was added to **4** and the adduct **7** treated with sulfuric acid and methanol, *cis*-3,3a-dimethylhexahydroindenone **8** was produced along with its isomer **9**. The stereochemistry of **8** was unambiguously established by transforming **8** into the known octalone **28** (Scheme 1). Thus, dibromomethyllithium[11] was allowed to react with **8**, and the adduct **26** was then treated with 2 mol of butyllithium to give **27**. One methylene unit is selectively insert-

Table 1. Cyclopentannulation of 2-methylcyclohexanone derivatives

Entry	Cyclohexanone	Propargyl alcohol derivative	Adduct (% yield)	Annulated product (% yield)
1	 **4**	$CH{\equiv}CCH_2OH$	**5** (88) [a]	 **6** (70)
2		$CH{\equiv}CCHOH$ $\vert$ CH_3	**7** (84) [b]	 **8** (67)  **9** (10)
3	 **10**	$CH{\equiv}CCH_2OH$	**11** (89) [c]	 **12** (60)
4	 **13**	$CH{\equiv}CCHOH$ $\vert$ CH_3	**14** (87) [b]	 **15**  **16** (64% yield, **15** : **16** 83-85:17-15)
5	 **17**	$CH{\equiv}CCHOH$ $\vert$ CH_3	**18** (71) [b]	 **19** (55)

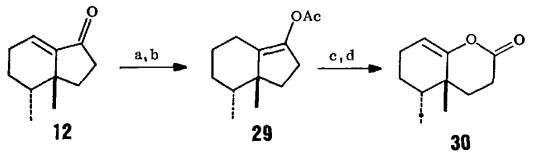
Scheme 1.

ed between the carbonyl and olefinic carbon of **8**. Treatment with aqueous sulfuric acid gave **28** having a ^{1}H-NMR absorption at δ 1.08 (singlet for the bridgehead methyl) consistent with the *cis* isomer **28** (*cf.* the *trans* isomer, δ 1.27).[12] The sole formation of **8** is ascribed to the conrotatory ring-closure of the intermediate D wherein the steric interaction between the two methyl groups is most reduced.

Using 2,3-dimethylcyclohexanone and propargyl alcohol, we attempted to cyclize the adduct **11** with sulfuric acid–methanol mixture as above and obtained an intractable mixture of products. The result was improved by converting the diol **11** into a monoacetate with acetic anhydride in pyridine and by employing 2,2,2-trifluoroethanol in place of methanol, a single product **12** being formed whose stereochemistry was established by transformation into the known enol lactone **30**[13] (Scheme 2). The enone moiety of **12** was reduced with lithium in anhydrous ammonia and the resulting enolate was trapped with acetic anhydride to give **29**. Ozonolysis of **29** fol-

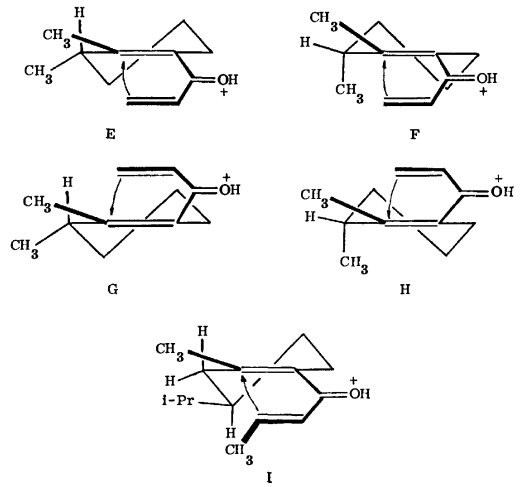
lowed by lactone formation with acetic anhydride and sodium acetate gave **30** which exhibited a ^{1}H-NMR absorption at δ 1.20 (singlet for bridgehead methyl) pertinent to the *trans* isomer (*cf.* δ 1.03 for the *cis* isomer).[13]



a: Li/NH_3, b: Ac_2O, c: O_3, Me_2S, d: Ac_2O, AcONa

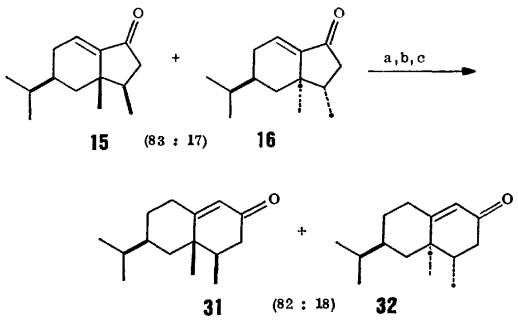
Scheme 2.

Let us consider the factors governing the transformation of **11** into **12**. *A priori*, four intermediates E—H are conceivable precursors for the five-membered ring annulation. The intermediate E or F gives **12** while G or H affords the *cis* isomer of **12**. Examination of molecular models suggests that in G or H severe interaction between the two methyl groups takes place as new C–C bond formation proceeds. However, such an interaction is not crucial in E or F since the two methyl groups are further apart during the course of C–C bond formation. Of the two favorable intermediates E and F, E seems to be the responsible one since the methyl group on the six-membered ring takes a pseudoequatorial position and C–C bond formation takes place from the antiperiplanar direction of a pseudoaxial C–H bond under orbital control.[14]



Provided that such orbital control is operative during the course of cyclization, we can take advantage of this effect by starting with 4-isopropyl-2-methylcyclohexanone (**13**) and 3-butyn-2-ol. The intermediate postulated here would be I whose isopropyl group should prefer an equatorial position; C–C bonding should occur from the antiperiplanar direction of the pseudoaxial C–H bond to produce a hexahydroindenone derivative with all *cis* substituents predominantly. This was found to be the case.

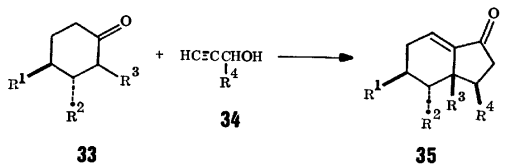
Addition of 3-butyn-2-ol to **13** gave an acetylenic diol **14** as a mixture of eight possible diastereomers. Without separation of the diastereomers, **14** was treated with sulfuric acid and methanol (1:1) at 0 °C to afford two products **15** and **16** in a ratio of 83:17 or 85:15 as revealed by ^{1}H-NMR or GLC respectively. The stereochemical outcome was secured by converting the mixture of products into an 82:18 (^{1}H-NMR) mixture of **31** and **32** by the sequence shown in Scheme 3 and by comparison of the retention time on capillary column GLC as well as ^{1}H-NMR spectra with those of each authentic sample. The authentic samples of **31** and **32** were prepared by the hydrogenation of 7-*epi*-nootkatone[15] and nootkatone,[16] respectively, with the aid of the catalyst chlorotris(triphenylphosphine)rhodium(I).



a: $LiCHBr_2$, b: n-BuLi, c: 5% H_2SO_4-THF

Scheme 3.

The results of entries 1—4 in Table 1 can be summarized as follows. A cyclohexanone **33** is converted by attaching a three-carbon unit of **34** into **35** in which the alkyl substituent R^3 on the bridgehead carbon comes invariably *cis* to R^4, *trans* to R^2 and selectively *cis* to R^1.



Synthesis of dl-*Nootkatone.* Scheme 3 shows that the annulation process is effective for stereoselective synthesis of an eremophilane-type sesquiterpene. We have applied this process to the synthesis of *dl*-nootkatone,[16,17] a component of the taste and flavor of grapefruit (*Citrus paradisi* Macfayden). Its carbon framework is characterized by the C(7)-epimer of eremophilane, *vis.*, valencane. An attempt using the adduct **18** of **17** and 3-butyn-2-ol resulted in the isomerization of the isopropenyl C=C bond to the conjugated one to give **19**. Taking account of the required epimerization at C(7), we started with **20** and obtained apossible precursor of nootkatone, **22**, in 34% yield. Because of the relative inefficiency of the annulation as well as the difficulty to obtain the starting material in large amount, we abandoned this route.

An ester group is found to be the appropriate functional group equivalent to isopropenyl group. The starting cyclohexanone **23**[18] was synthesized by the Diels-Alder reaction of methyl acrylate and 2-methyl-

Scheme 4.

3-trimethylsilyloxybutadiene[19] followed by hydrolysis. Subsequent addition of 3-butyn-2-ol was effected with concomitant hydrolysis of the ester group to give the adduct **24** as a stereoisomeric mixture, which was then treated with sulfuric acid–methanol (1:1) at 50 °C. The annulation product **25** was found to be a 3:2 mixture of epimers as evidenced by GLC and ^{13}C-NMR. Subsequent steps toward the target **43** are illustrated in Scheme 4.

In order to convert the methoxycarbonyl group of **25** into isopropenyl moiety of the correct configuration, we first transformed **25** into the ethylene dithioacetal **36** whose methoxycarbonyl group was transformed into isopropenyl group by standard methods. The final product **37** exhibited a ^1H-NMR spectrum revealing at least 97% stereochemical purity although one of its precursors, the methyl ketone, was a *ca.* 7:3 mixture of epimers. Probably epimerization took place before the Wittig olefiniation to yield a thermodynamically favorable product and/or the thermodynamically favorable isomer reacted more rapidly. Deprotection of the dithioacetal group was accomplished with isopentyl nitrite[20] to give the desired intermediate **38**. The configuration at C(5) turned out to be the correct one (purity >97%) as evidenced by hydrogenation of **38** to **16** with chlorotris(triphenylphosphine)rhodium(I) as a catalyst[16a] and by comparison of the spectrometric and chromatographic feature of **38** with those of the authentic specimen. Although the stereochemical outcome of **38** prepared by this route is acceptable, both formation and removal of the dithioacetal group were relatively inefficient (57% and 48% yield respectively), and hence another route from **25** to **38** was explored.

The enone **25** was reduced with sodium borohydride–cerium(III) chloride[21] in methanol to give an allyl alcohol **39** which was converted into a methyl ketone **40** as above. The Wittig reaction of **40** followed by oxidation with pyridinium chlorochromate gave **38** of >88% stereochemical purity at C(5) in 78% overall yield.

TABLE 2. CYCLOPENTANNULATION OF 2-CYCLOALKENONES

2-Cycloalkenone	Propargyl alcohol adduct (% yield)	Annulated product (% yield)
 44	**45** (92)	 **46**(65)
 47	**48** (51[a], 76[b])	 **49**(42)
 50	**51** (65)	 **52**(49)

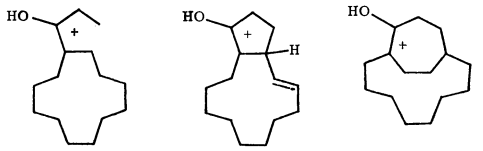
a) Cyclooctenone (30%) recovered. b) Yield based on the consumed starting enone.

Final ring-enlargement was effected by the β-oxido carbenoid procedure.[11] The hexahydroindenone **38** was allowed to react with dibromomethyllithium at −78 °C to give the adduct **41** which in turn was treated with 3 equivalents of butyllithium at −95 °C for 1.6 h to give an octalone **42**. The IR of **42** showed the presence of a cyclohexanone moiety with no contamination of a conjugated enone. Subsequently, **42** was isomerized to *dl*-nootkatone in 5% sulfuric acid–THF (1:1). The synthetic sample thus prepared was of more than 93% purity and chromatographically and spectrometrically identical with the authentic specimen.[16a]

Cyclopentannulation of 2-Cycloalkenones. Having disclosed the salient feature of the cyclopentannula-

tion using 2-methylcycloalkanones and propargyl alcohol we extended the concept to 2-functionalized cycloalkanones such as 2-phenylthiocyclohexanone, 2-chloro-2-methylcyclohexanone, and 2-propargylcyclohexanone. Although the addition of propargyl alcohol dianion occurred with no trouble, the next acid-catalyzed cyclization turned out futile. We eventually found that 2-cycloalkenones undergo regioselective annulation (Table 2).

2-Cyclododecenone (**44**) was allowed to react with propargyl alcohol and the adduct **45** was treated with a 1:2 mixture of sulfuric acid and methanol at −20 to −3 °C to give the conjugated dienone **46**. The spectral data of **46** (see Experimental) are fully consistent with the given structure. In particular, the configuration of the newly produced C=C bond was found to be (*E*) based on the ^{1}H-NMR and IR spectra. The formation of the conjugated dienone is explained in terms of the conrotatory ring-closure of a heptatrienyl cation J to a vinylcyclopentenyl cation K,[22] since the disrotatory ring-closure of J to a cycloheptadienyl cation L is sterically hindered by the octamethylene chain. It is worthy to note that the C(1) and C(2) solely of **44** are incorporated into the five-membered ring. In this sense the annulation is regioselective.

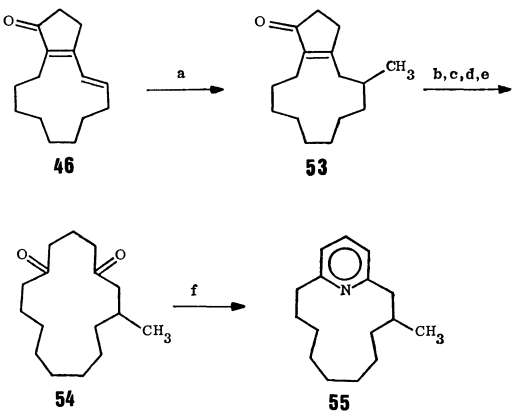


J K L

This two-step annulation was applied to lower homologs (Table 2) with less satisfactory results. The major obstacle was low efficiency in the addition of propargyl alcohol dianion to enones to induce enolization of the enones. The next cyclization is best performed by using the monoacetates of the adducts and by dissolving the monoacetates in sulfuric acid–methanol. Thus, bicyclic conjugated dienones **46**—**52** are now easily available which are otherwise hardly accessible.

Synthesis of dl-*Muscopyridine.* With the dienone **46** in hand, we planned to synthesize *dl*-muscopyridine (**55**).[23] A logical precursor of **55** should be 7-methyl-1,5-cyclopentadecanedione (**54**, Scheme 5). However, the introduction of methyl group into the parent diketone at the desired position is apparently difficult. We anticipated that diketone **54** would be derived from the bicyclic cyclopentenone **53**.

Selective 1,6-conjugated addition of the methyl group across the dienone moiety of **46** was best carried out using methylmagnesium iodide in the presence of copper(I) chloride,[24] **53** being obtained as the sole product. Dimethylcopperlithium turned out futile to give an intractable mixture of products with no trace of the desired one. Subsequent transformation into the diketone **54** was carried out according to the procedure of Gray and Dreiding.[25] Thus, **53** was reduced with sodium borohydride to an allyl alcohol which was then oxidized to an epoxy alcohol with *m*-chloroperoxybenzoic acid. Tosylation followed by solvolysis



a: CH_3MgI, CuCl, THF, b: $NaBH_4$, c: m-$ClC_6H_4CO_3H$, d: p-$CH_3C_6H_4SO_2Cl$, pyridine, e: aq dioxane, $CaCO_3$, f: $NH_2OH{\cdot}HCl$

Scheme 5.

in aqueous dioxane gave the diketone, which was finally heated with hydroxylamine hydrochloride in ethanol at 160 °C.[26] *dl*-Muscopyridine (**55**) thus prepared exhibited correct spectra.

Experimental

Distillation was carried out by use of Kugelrohr (Büchi) and boiling points were determined by measuring the bath temperature. All temperatures are uncorrected. ^{1}H-NMR spectra (tetramethylsilane as an internal standard) were obtained on a Varian EM 390 spectrometer, chemical shifts being given in ppm unit, ^{13}C-NMR spectra on a Varian CMR-20 spectrometer, IR spectra on a Shimadzu IR-27G spectrometer in neat liquid film unless otherwise stated, MS on a Hitachi RMU-6L spectrometer, exact mass on a JEOL-JMS-D 300 spectrometer and UV on a Hitachi 124 spectrophotometer. Propargyl alcohol was distilled before use. 3-Butyn-2-ol (Tokyo Kasei-Kogyo Co. or Nakarai Chemicals Ltd., 55% aqueous solution) was used. Commercial sulfuric acid (95%) was used for cyclization. Preparative TLC plates (20 cm×20 cm) were prepared with Merck Kiesel-gel PF_{254}. Column chromatography was carried out with silica gel (Wakogel C-100) at atmospheric pressure.

Synthesis of 2-Methyl-3-pentyl-2-cyclopentenone (1) from 2-Octanone. Under a nitrogen atmosphere at −78 °C, butyllithium (1.50 M† hexane solution, 6.0 ml, 9.0 mmol) was added dropwise to a tetrahydrofuran (THF, 15 ml) solution of propargyl alcohol (0.25 g, 4.5 mmol). After stirring for 70 min, 2-octanone (0.39 g, 3.0 mmol) in THF (5 ml) was added and the reaction mixture was warmed to room temperature and stirred for 30 min. Work-up followed by preparative TLC purification (ether, R_f 0.68—0.84) gave 4-methyl-2-decyne-1,4-diol (0.42 g, 75% yield) as a viscous oil. IR: 3324, 1038, 1000 cm^{-1}; ^{1}H-NMR (CCl_4): δ 0.7—1.8 (m, 13H), 1.43 (s, 3H, CH_3), 4.20 (s, 2H, $C\underline{H}_2OH$), 3.9—4.5 (br s, 2H, OH); MS: *m/e* (rel intensity) 169 (M^+-CH_3, 4), 99 (100, $M^+-C_6H_{13}$), 81 (24). Found: C, 71.73; H, 11.22%. Calcd for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94%.

Sulfuric acid (1.5 ml) was added dropwise over a period of 20 min to a methanol solution (1.5 ml) of 4-methyl-2-

† 1 M=1 mol dm^{-3}.

decyne-1,4-diol (172 mg, 0.93 mmol) at 0 °C. After stirring for 1.7 h, the reaction mixture was diluted with ether (10 ml) and neutralized with aqueous sodium hydrogencarbonate solution. The organic phase was separated, and the aqueous phase was extracted thoroughly with ether, the combined ethereal extracts being dried (Na_2SO_4) and concentrated *in vacuo*. Preparative TLC (hexane–ether 1:1, R_f 0.34—0.53) of the residue gave **1**[7b] (90 mg, 58% yield).

Cyclopentannulation of 2-Methylcycloheptanone. Butyllithium (1.81 M hexane solution, 8.3 ml, 15 mmol) was added at −78 °C under a nitrogen atmosphere to propargyl alcohol (0.40 g, 7.1 mmol) in THF (30 ml) in 5 min. The resulting viscous solution was stirred for 1 h and admixed with 2-methylcycloheptanone (0.60 g, 4.8 mmol) in THF (5 ml) during a period of 10 min. Stirring at −78 °C for 3 h, at room temperature for 0.5 h, followed by work-up, gave an oil (1.15 g). Purification by column chromatography (hexane–ether 1:1) gave the desired diol (TLC, hexane–ether 10:3, R_f 0.28, single spot, 0.67 g, 77% yield; 87% based on the consumed ketone) along with the recovered 2-methylcycloheptanone (68 mg, 10% recovery). The diol, mp 68.0—68.1 °C (hexane), showed the following spectra. ^{1}H-NMR (CCl_4): δ 1.08 (d, J=6.0 Hz, 3H, CH_3), 1.2—2.2 (m, 11H, methylenes and methine), 3.95 (br s, 1H, OH), 4.20 (s, 2H, $C\underline{H}_2OH$), 4.60 (br s, 1H, OH); IR: 3340, 1090 cm^{-1}; MS: *m/e* (rel intensity) 182 (M^+, 5), 164 (7), 151 (29), 111 (64), 79 (80), 55 (100). Found: C, 72.54; H, 10.09%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96%.

Sulfuric acid (1.0 ml) was added dropwise over a period of 10 min at 0 °C to a methanol (0.1 ml) solution of the diol (17 mg, 0.093 mmol). The reaction mixture turned dark reddish purple. After 4 h the reaction was quenched by dilution with ether (10 ml) and neutralization with sodium hydrogencarbonate aqueous solution. TLC purification of the crude product (hexane–ether 2:1) gave 1-methylbicyclo[5.3.0]dec-6-en-8-one (**2**) (10.0 mg, 67% yield, R_f 0.41—0.50) and 6-methylbicyclo[5.3.0]dec-1(7)-en-8-one (**3**)[7b] (2.1 mg, 14% yield, R_f 0.22—0.26). Physical properties of **2**: bp 97—103 °C (bath temp)/0.06 Torr††. ^{1}H-NMR (CCl_4): δ 1.11 (s, 3H, CH_3), 1.3—2.8 (m, 12H, methylenes), 6.57 (dd, J=7.0, 5.0 Hz, 1H, olefinic H); IR: 1716, 1643 cm^{-1}; MS: *m/e* (rel intensity) 164 (M^+, 70), 149 (67), 122 (100), 107 (91), 93 (98), 79 (93). Found: C, 80.57; H, 10.08%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%.

The regioselectivity of the annulation at 0 °C was dependent on the acidic conditions. Conditions, yield(%), ratio of **2** to **3** were as follows: sulfuric acid–methanol (1:1), 61%, 77:23; sulfuric acid–methanol (1:10), 90, 40:60; sulfuric acid–acetic acid (1:1), 59, 84:16; sulfuric acid–2,2,2-trifluoroethanol (1:1), 55, 75:25; sulfuric acid only, 62, 88:12; sulfuric acid–methanol (1:1) and 1 mol of mercury(II) sulfate, 97%, 82:18.

*Cyclopentannulation of 2-Methylcyclohexanone (**4**) with Propargyl Alcohol.* Propargyl alcohol dianion solution was prepared at −78 °C under a nitrogen atmosphere by adding butyllithium hexane solution (2.0 M, 15.8 ml, 32 mmol) to propargyl alcohol (0.85 g, 15.1 mmol) in THF (40 ml), and stirring for 3 h. Addition of 2-methylcyclohexanone (1.12 g, 10.0 mmol) dissolved in THF (10 ml) followed by stirring at −78 °C for 1 h, at room temperature for 0.5 h, and then work-up gave an oil which was purified by column chromatography to give the adduct **5** (1.48 g, 88% yield) as *ca.* 3:2 diastereomeric mixture (TLC, hexane–ether 1:2, R_f 0.14 and 0.22). ^{1}H-NMR (CCl_4): δ 1.01 (d, J=5.0 Hz, 3H), 1.2—2.2 (m, 9H), 3.67 (br s, 1H), 4.19 (s, 2H), 4.50 (br s, 1H); IR: 3340, 1012, 968 cm^{-1}; MS: *m/e* 168 (M^+). Each diastereomer was separated by careful column chromatography. The less polar isomer: colorless needles, mp 36.2—37.0 °C (hexane). Found: C, 71.29; H, 9.66%. The more polar isomer: bp 126—128 °C (bath temp)/0.06 Torr; Found: C, 71.44; H, 9.71%. The mixture was used for the subsequent cyclization.

Sulfuric acid (1.5 ml) was added dropwise at 0 °C over a period of 15 min to a methanol (1.5 ml) solution of the adduct **5** (162 mg, 0.96 mmol). Stirring for 1.5 h at 0 °C, followed by extractive work-up as before and preparative TLC (dichloromethane), gave 1-methylbicyclo[4.3.0]non-5-en-7-one (**6**) (101 mg, 70% yield, R_f 0.35—0.49). GLC assay of the reaction mixture showed the presence of a trace amount (less than 5%) of the regioisomer corresponding to **3**. Physical properties of **6** are: bp 78—80 °C (bath temp)/0.04 Torr; ^{1}H-NMR (CCl_4): δ 1.08 (s, 3H, CH_3), 1.2—2.5 (m, 10H), 6.37 (t, 1H, J=3.6 Hz); IR: 1716, 1646 cm^{-1}; MS: *m/e* (rel intensity) 151 (M^++1, 8), 150 (M^+, 42), 135 (32), 122 (33), 108 (75), 93 (88), 79 (100). Found: C, 79.69; H, 9.33%. Calcd for $C_{10}H_{14}O$: C, 79.95; H, 9.39%.

Each diastereomer of **5** was separated by preparative TLC and subjected to cyclization under similar conditions. The more polar isomer gave **6** in 66% isolated yield, and the less polar one in 62% isolated yield.

*Annulation of 2-Methylcyclohexanone (**4**) with 3-Butyn-2-ol.* Potassium hydroxide (6.80 g, 121 mmol) was dissolved in 55% aqueous solution (5.7 g, 45 mmol) of 3-butyn-2-ol and the resulting solution was warmed at 40 °C. To this mixture was added dropwise 2-methylcyclohexanone (3.4 g, 30 mmol) over a period of 2 h, and the whole was stirred for 24 h at 40 °C, then diluted with water (10 ml) and extracted with ether (20 ml×4 times). The ethereal extracts were dried with anhydrous sodium sulfate and concentrated *in vacuo*. Column chromatography of the residue (hexane–ether 1:2) gave 1-(3-hydroxy-1-butynyl)-2-methylcyclohexanol (**7**) as a diastereomeric mixture (R_f 0.24 and 0.35 on TLC with hexane–ether 1:2) (4.6 g, 84% yield), bp 110—118 °C (bath temp)/0.08 Torr. ^{1}H-NMR (CCl_4): δ 0.91 (d, J=6.0 Hz, 3H), 1.02 (d, J=6.0 Hz, 3H), 1.1—2.1 (m, 9H), 3.5—4.3 (br s, 2H, OH), 4.3—4.7 (m, 1H, C$\underline{H}$–OH); IR: 3344, 1116, 1062, 1024 cm^{-1}; MS: *m/e* 182 (M^+). Found: C, 72.20; H, 10.15%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96%.

Sulfuric acid (1.0 ml) was added at 0 °C over a period of 10 min to **7** (106 mg, 0.58 mmol) dissolved in methanol (1.0 ml). After 30 min the reaction was stopped by dilution with ether (10 ml) and neutralization with aqueous sodium hydrogencarbonate solution. The ethereal extracts were dried (Na_2SO_4), concentrated *in vacuo* to give an oil (107 mg). Preparative TLC purification (hexane–ether 1:1) gave 1,9-*cis*-dimethylbicyclo[4.3.0]non-5-en-7-one (**8**) (63 mg, 67% yield, R_f 0.58—0.71) and 1,9-dimethylbicyclo-[4.3.0]non-8-en-7-one (**9**) (10 mg, 10% yield, R_f 0.47—0.58). GLC assay of the crude product gave the **8**:**9** ratio to be 86:14. Physical properties of **8** were as follows. Bp 105—112 °C (bath temp)/0.07 Torr; ^{1}H-NMR (CCl_4): δ 0.95 (s, 3H, C–CH_3), 1.07 (d, J=6.0 Hz, 3H, CH–C$\underline{H}_3$), 1.5—2.3 (m, 9H), 6.37 (t, 1H, J=3.0 Hz, olefinic H); IR: 1723, 1653 cm^{-1}; MS: *m/e* (rel intensity) 164 (M^+, 50), 149 (23), 136 (15), 122 (95), 79 (100). Found: C, 80.65; H, 10.04%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%. Physical properties of **9**: bp 110—118 °C (bath temp)/0.09 Torr; ^{1}H-NMR (CCl_4): δ 1.23 (s, 3H), 1.0—2.3 (m+d (J=1.7 Hz) at δ 1.99, 12H), 5.70 (q, J=1.7 Hz, 1H); IR: 1700, 1619 cm^{-1}; MS: *m/e* (rel intensity) 164 (M^+, 46), 149

†† 1 Torr=133.322 Pa.

(100), 135 (22), 122 (27). Exact mass, found: *m/e* 164.1213 (M^+). Calcd for $C_{11}H_{16}O$: *m/e* 164.1201.

Transformation of ***8*** *to an Octalone* ***28***. Lithium dicyclohexylamide, prepared by addition of butyllithium (1.81 M hexane solution, 1.70 ml, 3.1 mmol) to a THF (2 ml) solution of dicyclohexylamine (0.56 g, 3.1 mmol) at 0 °C and by stirring the solution at 0 °C for 15 min, was added dropwise over a period of 2.3 h to a mixture of **8** (0.163 g, 1.0 mmol) and dibromomethane (0.37 g, 2.1 mmol) dissolved in THF (3 ml) at −78 °C under an argon atmosphere. The reaction mixture was stirred at −78 °C for 40 min and quenched by adding methanol (1.0 ml) at −78 °C. The reaction mixture was then warmed to room temperature, diluted with water (10 ml) and then treated with 5% hydrochloric acid. The precipitated insoluble material was filtered and washed with ether thoroughly. The aqueous phase of the filtrate was separated from the ethereal one and extracted with ether (20 ml×4 times). The combined ethereal extracts were dried (Na_2SO_4), and concentrated under reduced pressure to give an oil (0.45 g). Preparative TLC purification (benzene) gave the adduct **26** (R_f 0.34—0.46, 0.20 g, 60% yield; 83% yield based on the consumed starting material) along with the recovered **8** (R_f 0.08—0.21, 46 mg). ^{1}H-NMR (CCl_4) of **26**: δ 0.94 (d, J=7.5 Hz, 3H), 1.00 (s, 3H), 1.0—2.7 (m, 9H), 5.63 (t, J=3.3 Hz, 1H), 5.80 (s, 1H, $CHBr_2$); IR: 3440 cm^{-1}.

The adduct **26** (168 mg, 0.50 mmol) was dissolved in THF (4 ml) under an argon atmosphere, and a butyllithium hexane solution (1.83 M, 0.60 ml, 1.1 mmol) was added dropwise over a period of 12 min to the solution cooled at −95 °C. The reaction mixture was stirred at −95 °C for 2 h, then warmed to 0 °C, stirred for 5 min, and quenched with water (10 ml). Ether extraction (20 ml×4 times) followed by drying (Na_2SO_4) and concentration gave a crude product (115 mg) which was purified by preparative TLC (benzene) to give the octalone **27** (R_f 0.32—0.43, 36 mg, 41% yield). IR: 1715 cm^{-1}; ^{1}H-NMR (CCl_4): δ 0.94 (d, J=6.0 Hz, 3H), 1.10 (s, 3H), 1.1—2.5 (m, 9H), 1.73 (d, J=15.6 Hz, 1H), 3.10 (dm, J=15.6 Hz, 1H), 5.3—5.5 (m, 1H); MS: *m/e* (rel intensity) 178 (M^+, 50), 163 (23), 150 (23), 136 (56), 108 (76), 93 (100).

The octalone **27** (15 mg, 0.08 mmol) was dissolved in THF (0.5 ml) and 5% aqueous sulfuric acid (0.5 ml) and stirred for 2 h at room temperature. Work-up and TLC purification (hexane–ether 1:1) gave the octalone **28**[12] (R_f 0.23—0.31, 11 mg, 73% yield). ^{1}H-NMR (CCl_4): δ 0.94 (d, J=6.0 Hz, 3H), 1.08 (s, 3H), 1.1—2.5 (m, 11H), 5.60 (br s, 1H); IR: 3129, 1663, 1614 cm^{-1}; MS: *m/e* (rel intensity) 178 (M^+, 44), 163 (15), 150 (12), 136 (100), 121 (56). The recorded chemical shifts (CCl_4) of **28**:[12] δ 1.08 (s, 3H), and its *trans* isomer δ 1.27 (s, 3H).

*Cyclopentannulation of 2,3-Dimethylcyclohexanone (****10****) with Propargyl Alcohol.* Propargyl alcohol dianion was prepared by adding butyllithium hexane solution (1.92 M, 7.8 ml, 15.0 mmol) to propargyl alcohol (0.39 g, 7.0 mmol) in THF (35 ml) at −78 °C and allowed to react with 2,3-dimethylcyclohexanone (0.57 g, 4.5 mmol) dissolved in THF (10 ml) at −78 °C for 2.5 h, and at room temperature for 40 min. Work-up followed by column chromatography (hexane–ether 1:2) gave 1-(3-hydroxy-1-propynyl)-2,3-dimethylcyclohexanol (**11**) (0.74 g, 89% yield). Bp 118—126 °C (bath temp)/0.06 Torr; ^{1}H-NMR ($CDCl_3$): δ 0.8—1.0 (d, 6H), 1.0—2.3 (m, 8H), 3.08 (s, 2H), 4.26 (s, 2H); IR: 3340, 1008 cm^{-1}; MS: *m/e* (rel intensity) 182 (M^+, trace), 164 (M^+-H_2O, 8), 149 (33), 135 (42), 93 (44), 55 (100). Found: C, 72.42; H, 10.11%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96%.

The diol **11** (0.28 g, 1.5 mmol) was admixed with acetic anhydride (1 ml) and pyridine (0.1 ml) at room temperature for 50 min, all volatile material being evaporated with the aid of a vacuum pump. The residue was dissolved in 2,2,2-trifluoroethanol (1 ml). To the resulting solution was added dropwise at 0 °C a mixture of sulfuric acid (1 ml) and 2,2,2-trifluoroethanol (1 ml). The reaction mixture was stirred overnight and warmed up to room temperature. Work-up gave an oil (0.37 g) which was purified by preparative TLC (benzene–ether 10:1) to give *trans*-1,2-dimethylbicyclo[4.3.0]non-5-en-7-one (**12**) (R_f 0.40—0.52, 150 mg, 60% yield), bp 95—102 °C (bath temp)/0.06 Torr. The homogeneity of the sample was confirmed by GLC assay as well as ^{1}H-NMR assay using shift reagent, Eu(fod)$_3$. ^{1}H-NMR (CCl_4): δ 0.87 (d, J=7.2 Hz, 3H, CH-C$\underline{H}_3$), 1.19 (s, 3H, C-CH_3), 1.2—2.5 (m, 9H), 6.46 (t, J=3.6 Hz, 1H); IR: 1718, 1712, 1654, 1649 cm^{-1}; MS: *m/e* (rel intensity) 165 (M^++1, 11), 164 (M^+, 29), 149 (18), 122 (100), 107 (50), 93 (59), 79 (95). Found: C, 80.59; H, 9.93%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%.

Transformation of ***12*** *into* ***30***. Lithium metal (18 mg, 2.6 mmol) was dissolved at −78 °C in anhydrous liquid ammonia (distilled over sodium). To this blue solution was added dropwise the enone **12** (0.21 g, 1.29 mmol) dissolved in THF (12 ml). The blue color vanished at the completion of addition. After 4 min the cooling bath was removed and ammonia was allowed to evaporate over a period of 2 h. The residue was then treated with acetic anhydride (1 ml) in THF (6 ml) and stirred at room temperature for 45 min. Work-up followed by column chromatography (hexane–ether 15:1) gave the enol acetate **29** (178 mg, 66% yield). ^{1}H-NMR (CCl_4): δ 0.95 (d, J=7.0 Hz), 1.18 (s), 2.03 (s, $OCOCH_3$).

The dichloromethane (5 ml) solution of **29** (101 mg, 0.49 mmol) was allowed to react with ozone at −78 °C until the solution turned slightly blue. Quenching with dimethyl sulfide (0.5 ml) at −78 °C, warming to room temperature followed by concentration and purification on preparative TLC plate (hexane–ether 1:1) gave a keto carboxylic acid (R_f 0.05—0.27, 29 mg, 31% yield), IR ($CHCl_3$): 3600—2400, 1710 cm^{-1}.

The keto carboxylic acid (28 mg, 0.14 mmol) was heated with sodium acetate (30 mg, 0.37 mmol) in acetic anhydride (3 ml) at reflux temperature for 2.3 h. Work-up followed by preparative TLC (hexane–ether 1:1, R_f 0.38—0.49) gave the enol lactone **30**[13] (8 mg, 32% yield) having ^{1}H-NMR ($CDCl_3$): δ 0.95 (d, J=6.8 Hz, 3H, CHC$\underline{H}_3$), 1.20 (s, 3H, C-CH_3), 1.2—2.3 (m, 7H), 2.62 (dd, J=8.5, 6.0 Hz, 2H), 5.30 (quintet, J=3.0 Hz, 1H); IR (CCl_4): 1758, 1680, 1132 cm^{-1}; MS: *m/e* 180 (M^+). The reported chemical shift ($CDCl_3$) of **30**:[13] δ 0.96 (d, 3H, J=6.5 Hz), 1.21 (s, 3H), and its *cis* isomer: δ 0.96 (d, 3H, J=6.0 Hz), 1.03 (s, 3H).

*Cyclopentannulation of 4-Isopropyl-2-methylcyclohexanone (****13****) with 3-Butyn-2-ol.* **13** (0.33 g, 2.1 mmol) was added at 40 °C over a period of 2 h to a solution of potassium hydroxide (0.62 g, 11.0 mmol) dissolved in 55% aqueous solution of 3-butyn-2-ol (0.58 g, 4.5 mmol). After 16 h, the reaction mixture was worked up to give an oil (580 mg) which was purified by column chromatography (hexane–ether 1:1) to give 4-isopropyl-1-(3-hydroxy-1-butynyl)-2-methylcyclohexanol (**14**) as a viscous oil (0.42 g, 87% yield). TLC (hexane–ether 1:1) showed roughly two spots at R_f 0.09 and 0.14, but these were not separated. Bp 118—126 °C (bath temp)/0.08 Torr. ^{1}H-NMR (CCl_4): δ 0.87 (d, J=6.0 Hz, 6H, CH(C$\underline{H}_3$)$_2$), 1.02 (d, J=6.0 Hz, 3H, CHC$\underline{H}_3$), 1.1—2.2 (m+d (δ 1.43 J=6.0 Hz), 12H), 3.9—4.3 (br s, 2H, OH),

4.3—4.7 (m, 1H, CH(OH)); IR: 3346, 1120, 1071 cm^{-1}; MS: *m/e* (rel intensity) 224 (M^+, trace), 206 (8), 191 (15), 163 (16), 107 (24), 57 (72), 43 (100). Found: C, 75.18; H, 10.55%. Calcd for $C_{14}H_{24}O_4$: C, 74.95; H, 10.78%.

Sulfuric acid (1.5 ml) was added to a methanol (1.5 ml) solution of **14** (0.34 g, 1.5 mmol) at 0 °C over a period of 15 min and the resulting solution was stirred at 0 °C for 30 min and then worked up to give an oil (0.33 g) which was purified by preparative TLC (hexane–ether 1:1), giving a mixture of 3-isopropyl-*cis*-1,9-dimethylbicyclo[4.3.0]non-5-en-7-one (**15** and **16**) (R_f 0.60—0.71, 196 mg, 64% yield), bp 123—127 °C (bath temp)/0.05 Torr. The ratio of **15** to **16** was estimated by GLC (PEG 20 M, 10% on Celite 545, 2 m, 170 °C, N_2 carrier gas 0.8 kg/cm^2, FID detector) to be 85:15, R_t being 18.4 min and 19.7 min respectively. The ratio was alternatively estimated to be 83:17 by ^{1}H-NMR (CCl_4): δ 0.91 (s, 3H, CCH_3), 0.92 (d, J=6.2 Hz, 6H, $CH(CH_3)_2$), 1.03 (d, J=5.7 Hz, 3H, $CHCH_3$), 1.1—2.4 (m, 9H), 6.36 (t, J=3.3 Hz, 0.17 H), 6.53 (dd, J=7.7, 3.0 Hz, 0.83H). IR: 1715, 1652 cm^{-1}; MS: *m/e* (rel intensity) 206 (M^+, 31), 191 (9), 178 (6), 164 (87), 121 (100). Found: C, 81.55; H, 10.98%. Calcd for $C_{14}H_{22}O$: C, 81.50; H, 10.75%.

*Transformation of a Mixture of **15** and **16** into a Mixture of **31** and **32**.* Lithium dicyclohexylamide generated from butyllithium hexane solution (1.79 M, 2.5 ml, 4.4 mmol) and dicyclohexylamine (0.79 g, 4.4 mmol) in THF (3 ml) at 0 °C was added dropwise at −78 °C over a period of 1.5 h to a mixture of dibromomethane (0.76 g, 4.4 mmol), **15** and **16** (0.36 g, 1.76 mmol) in THF (7 ml) under an argon atmosphere. Stirring was continued for 1.5 h, and the reaction was stopped by addition of methanol (1 ml) at −78 °C. The reaction mixture was then allowed to warm to room temperature and treated with saturated aqueous ammonium chloride solution (20 ml). The precipitated material was filtered off and the filtrate was extracted with ether (20 ml×4 times). The ethereal phase was dried with anhydrous sodium sulfate, and concentrated *in vacuo* to give an oil (1.00 g) which was purified by column chromatography (hexane–benzene 1:1) to give the adduct (R_f 0.47—0.56, 0.45 g, 67% yield; 74% yield based on the consumed starting material) along with the starting material (36 mg, 10%). ^{1}H-NMR (CCl_4) of the adduct: δ 0.91 (d, J=6.0 Hz, 6H), 0.95 (d, J=6.4 Hz, 3H), 1.00 (s, 3H, CCH_3), 1.1—2.7 (m, 9H), 5.76 (s, 1H, $CHBr_2$), 5.6—6.1 (m, 1H); IR: 3435, 1120 cm^{-1}.

Butyllithium hexane solution (1.79 M, 1.40 ml, 2.5 mmol) was added at −95 °C over a period of 20 min to the above adduct (0.39 g, 1.0 mmol) in THF (8 ml) under an argon atmosphere. The reaction mixture was stirred at −95 °C for 1.7 h, at 0 °C for 5 min and then quenched with water (10 ml). Work-up followed by preparative TLC (benzene) gave an octalone (R_f 0.24—0.36, 186 mg, 83% yield). Bp 120—125 °C (bath temp)/0.06 Torr. IR: 1721, 1661 cm^{-1}; ^{1}H-NMR (CCl_4): δ 0.90 (d, J=6.3 Hz, 6H, $CH(CH_3)_2$), 0.91 (d, J=6.3 Hz, 3H, $CHCH_3$), 1.09 (s, 3H, CCH_3), 1.1—2.3 (m, 9H), 2.69 (dm, J=15.0 Hz, 1H, one of C(7) methylene), 3.20 (dm, J=15.0 Hz, 1H, the other of C(7) methylene), 5.3—5.5 (m, 1H); MS: *m/e* (rel intensity) 220 (M^+, 30), 178 (19), 177 (29), 107 (100), 93 (49), 91 (38), 79 (35), 77 (24), 69 (30). Exact mass, found: *m/e* 220.1827 (M^+). Calcd for $C_{15}H_{24}O$: *m/e* 220.1827.

A mixture of the octalone (103 mg, 0.47 mmol), THF (1.5 ml), and 5% sulfuric acid (1.5 ml) was stirred overnight vigorously. Work-up and preparative TLC separation gave a mixture of the conjugated octalones **31** and **32** (R_f 0.55—0.67, 48 mg, 47% yield, 79% yield based on the recovered octalone) along with the starting unconjugated octalone (42 mg, 41%). The bp of **31** and **32**: 121—123 °C (bath temp)/0.06 Torr; ^{1}H-NMR (CCl_4): δ 0.87 (d, J=6.0 Hz, 6H, $CH(CH_3)_2$), 0.97 (d, J=6.0 Hz, 3H, $CHCH_3$), 1.05 (s, 3H, CCH_3), 1.1—2.6 (m, 11H), 5.59 (br s, 0.18 H), 5.65 (br s, 0.82 H); ^{1}H-NMR ($CDCl_3$): δ 5.75 (br s, 0.18H), 5.80 (br s, 0.82H). IR: 3030, 1663, 1627 cm^{-1}; MS: *m/e* (rel intensity) 220 (M^+, 22), 178 (39), 177 (24), 135 (48), 108 (28), 107 (28), 91 (24), 79 (27), 55 (22), 40 (100). Found: C, 81.49; H, 11.23%. Calcd for $C_{15}H_{24}O$: C, 81.76; H, 10.98%.

GLC retention times of these samples (glass capillary column, 30 m×0.3 mm, SF-96 at 180 °C) were 27.4 min and 28.0 min, respectively, identical with those of the authentic samples (*vide infra*).

*An Authentic Sample of 11,12-Dihydro-7-*epi*-nootkatone (**31**).* A mixture of 7-*epi*-nootkatone[15] (43 mg, 0.2 mmol) and chlorotris(triphenylphosphine)rhodium(I) (20 mg) in benzene (2 ml) was stirred under a hydrogen atmosphere at room temperature for 19 h. Concentration followed by preparative TLC (benzene–ether 5:1, R_f 0.40—0.52) gave **31** (35 mg, 81% yield). ^{1}H-NMR (CCl_4): δ 0.86 (d, J=6.3 Hz, 6H, $CH(CH_3)_2$), 0.96 (d, J=6.5 Hz, 3H, $CHCH_3$), 1.046 (s, 3H, CCH_3), 1.1—2.6 (m, 11H), 5.65 (br s, 1H); IR: 1665, 1617 cm^{-1}. A *ca.* 1:1 mixture of 7-*epi*-nootkatone and nootkatone was also hydrogenated under similar conditions to give the corresponding dihydro derivatives of *ca.* 1:1 mixture which showed ^{1}H-NMR (CCl_4) absorptions: two broad singlets at δ 5.59, 5.65, and two singlets at 1.046 and 1.066.

*An Authentic Sample of 11,12-Dihydronootkatone (**32**)*[16a] exhibited ^{1}H-NMR (90 MHz) peaks at δ 5.75 (br s) and 1.066 (s) in $CDCl_3$, and 5.60 (br s) in CCl_4. GLC coinjection experiments revealed an identical R_t to that of the minor product, **32**.

*Cyclopentannulation of 4-Isopropenyl-2-methylcyclohexanone (**17**) with 3-Butyn-2-ol.* **17** (149 mg, 0.98 mmol) was added at 40 °C to a mixture of potassium hydroxide (0.24 g, 4.3 mmol) and 55% aqueous solution of 3-butyn-2-ol (193 mg, 1.50 mmol), and the resulting mixture was stirred at 40 °C overnight. Work-up followed by preparative TLC gave the adduct **18** (154 mg, 71% yield). ^{1}H-NMR (CCl_4): δ 1.01 (d, J=7.2 Hz, 3H), 1.44 (d, J=6.5 Hz, 3H), 1.1—2.3 (m, 8H), 1.71 (s, 3H), 4.1 (br s, 2H, OH), 4.4—4.7 (m+br s at δ 4.63, 2H); IR: 3355, 1642, 1040, 889 cm^{-1}; MS: *m/e* (rel intensity) 222 (M^+, trace), 204 (M^+-H_2O, 6), 189 (13), 107 (51), 79 (42), 55 (56), 43 (100). Exact mass, found: *m/e* 204.1500 (M^+-H_2O). Calcd for $C_{14}H_{20}O$: *m/e* 204.1512 (M^+-H_2O).

Sulfuric acid (0.5 ml) was added at 0 °C to a methanol (0.5 ml) solution of **18** (43 mg, 0.19 mmol) over a period of 15 min. After 30 min the reaction mixture was worked up and the crude product purified by preparative TLC (hexane–ether 1:1, R_f 0.66—0.76) to give 3-isopropyl-*cis*-1,9-dimethylbicyclo[4.3.0]nona-3,5-dien-7-one (**19**) (22 mg, 55% yield). ^{1}H-NMR (CCl_4): δ 0.91 (s, 3H, CH_3), 1.07 (d, J=6.6 Hz, 6H, $CH(CH_3)_2$), 1.09 (d, J=6.6 Hz, 3H, $CHCH_3$), 1.8—2.6 (m, 6H), 5.85 (dm, J=5.4 Hz, 1H), 6.53 (d, J=5.4 Hz, 1H); IR: 1702, 1644, 1574, 835 cm^{-1}; MS: *m/e* (rel intensity) 204 (M^+, 23), 161 (21), 147 (70), 119 (100), 91 (28). Exact mass, found: *m/e* 204.1493 (M^+). Calcd for $C_{14}H_{20}O$: *m/e* 204.1513.

*Cyclopentannulation of 4-(2-Methyl-1,3-dioxolan-2-yl)-2-methylcyclohexanone (**20**) with 3-Butyn-2-ol.* The keto acetal **20**[27] (0.60 g, 3.0 mmol) was added over a period of 2 h to a solution of potassium hydroxide (0.65 g, 11.6 mmol) in 55% aqueous 3-butyn-2-ol (0.64 g, 5.0 mmol) at 40 °C and the resulting mixture was stirred overnight. Work-up

followed by column chromatography (ether) gave the adduct **21** (0.40 g, 48% yield; 84% yield based on the consumed **20**) along with the recovered **20** (0.25 g, 42%). The adduct showed ^{1}H-NMR (CCl_4): δ 1.18 (s, 3H), 0.9—1.3 (m, 6H), 1.3—2.3 (m, 8H), 3.87 (br s, 6H), 4.4—4.7 (m, 1H); IR: 3420, 1038 cm^{-1}; MS: *m/e* (rel intensity) 253 (M^+-CH_3, 4), 87 (100). Exact mass, found: *m/e* 253.1312 (M^+-CH_3). Calcd for $C_{14}H_{21}O_4$: *m/e* 253.1332.

Sulfuric acid (1.0 ml) was added at 0 °C over a period of 15 min to **21** (92 mg, 0.34 mmol) dissolved in methanol (1.0 ml), and the reaction mixture was stirred for 30 min. Work-up followed by preparative TLC (hexane–ether, 1:1, R_f 0.21—0.35) gave 3-acetyl-*cis*-1,9-dimethylbicyclo[4.3.0]-non-5-en-7-one (**22**, 24 mg, 34% yield). Bp 120—128 °C (bath temp)/0.05 Torr. ^{1}H-NMR (CCl_4): δ 0.99 (s, 3H), 1.09 (d, J=6.5 Hz, 3H), 1.1—3.0 (m, 8H), 2.16 (s, 3H), 6.42 (t, J=3.0 Hz, 1H); IR (CH_2Cl_2): 1708, 1654, 1249, 894 cm^{-1}; MS: *m/e* (rel intensity) 206 (M^+, 1), 204 (11), 163 (100), 121 (59). Exact mass, found: *m/e* 206.1324 (M^+). Calcd for $C_{13}H_{18}O_2$: *m/e* 206.1307.

*Synthesis of Methyl 3-Methyl-4-oxocyclohexanecarboxylate (**23**).* A mixture of 2-methyl-3-trimethylsilyloxy-1,3-butadiene[19] (158 mg, 1.0 mmol) and methyl acrylate (175 mg, 2.0 mmol) dissolved in benzene (1 ml) was heated in a sealed tube at 160—180 °C for 4 h. After cooling to room temperature the volatile material was evaporated with a water-aspirator, and the residue was dissolved in 90% methanol (20 ml) containing potassium fluoride (*ca.* 0.2 g). After 4 h the reaction mixture was diluted with water (10 ml) and extracted with ether (20 ml×4 times). The ethereal extracts were dried (Na_2SO_4) and concentrated *in vacuo* to give a crude product (172 mg) which was purified by preparative TLC. The desired product **23**[18] at R_f 0.10—0.23 weighed 134 mg, 78% yield.

A large scale synthesis was carried out by using the diene (15.5 g, 0.10 mol), methyl acrylate (17.2 g, 0.20 mol) in benzene (10 ml) at 184—191 °C for 4 h and by hydrolyzing the resulting enol silyl ether with 20% acetic acid (30 ml) and methanol (30 ml) at room temperature for 1 h. The product (13.1 g, 77% yield) was collected by distillation at 140—142 °C/18 Torr. ^{1}H-NMR (CCl_4): δ 0.99 (d, J= 6.0 Hz, 3H), 1.1—2.9 (m, 8H), 3.66 (s, 3H); IR: 1735, 1710, 1195 cm^{-1}; (Found: C, 63.42; H, 8.26%).

*Synthesis of 3-Methoxycarbonyl-*cis*-1,9-dimethylbicyclo[4.3.0]non-5-en-7-one (**25**).* The keto ester **23** (0.39 g, 2.3 mmol) was added at 40 °C over a period of 1 h to potassium hydroxide (0.84 g, 14.9 mmol) dissolved in 55% aqueous solution (0.67 g, 5.3 mmol) of 3-butyn-2-ol and the mixture was allowed to react overnight. Dilution with water (10 ml), acidification with 10% hydrochloric acid, extraction with ether (20 ml×4 times), followed by drying (Na_2SO_4), and concentration gave a viscous oil (0.68 g) which was purified by column chromatography (ether) to give 4-hydroxy-4-(3-hydroxy-1-butynyl)-3-methylcyclohexanecarboxylic acid (**24**) (0.45 g, 86% yield). IR: 3650—2400, 1704 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 1.0—1.2 (d, 3H, $CHC\underline{H}_3$), 1.2—2.7 (m+2d (δ 1.43 and 1.47 each J=6.0 Hz), 11H), 4.4—4.9 (m, 3H, $\underline{H}O-C\underline{H}$ and OH). No peak due to the carboxyl group was observable. However, treatment of **24** with diazomethane gave the methyl ester (δ 3.68, s).

A large scale experiment using **23** (7.3 g, 43 mmol), potassium hydroxide (13.5 g, 0.24 mol) and 55% aqueous solution 3-butyn-2-ol (10.4 g, 82 mmol), afforded 8.9 g of **24** (91% yield).

Sulfuric acid (0.3 ml) was added at room temperature to **24** (24 mg, 0.11 mmol) dissolved in methanol (0.3 ml). The mixture was then heated at 50 °C for 30 min. Work-up followed by preparative TLC (hexane–ether 1:1, R_f 0.27—0.41) gave 3-methoxycarbonyl-*cis*-1,9-dimethylbicyclo-[4.3.0]non-5-en-7-one (**25**) (15 mg, 60% yield), bp 139—145 °C (bath temp)/0.05 Torr. ^{1}H-NMR (CCl_4): δ 0.84 and 0.98 (2s, 3H, CCH_3), 1.07, 1.09 (2d, J=6.0 Hz, 3H), 1.1—2.9 (m, 8H), 3.83 (s, 3H, CH_3COO), 6.3—6.6 (m, 1H). ^{13}C-NMR ($CDCl_3$) showed two peaks at δ 128.72 and 129.09 ($\underline{C}H_3O\underline{C}O$), with the ratio 1.9:1. IR: 1735, 1719, 1654, 1200 cm^{-1}; MS: *m/e* (rel intensity) 222 (M^+, 23), 207 (12), 180 (14), 163 (39), 121 (100), 93 (57), 77 (24). Found: C, 70.15; H, 8.40%. Calcd for $C_{15}H_{18}O_3$: C, 70.24; H, 8.16%.

A large scale experiment using **24** (8.9 g), methanol (25 ml), sulfuric acid (25 ml) resulted in 49% yield (4.3 g) of **25**.

Synthesis of t-*3-Isopropenyl-*r-*1,*c*-9-dimethylbicyclo[4.3.0]non-5-en-7-one (**38**).* A methanol (2 ml) solution of sodium borohydride (76 mg, 2.0 mmol) was added at room temperature to a mixture of **25** (0.45 g, 2.0 mmol) and cerium-(III) chloride heptahydrate (0.30 g, 0.80 mmol) in methanol (5 ml). After 20 min the reaction mixture was worked up to give a crude allyl alcohol **39** (0.50 g), which was dissolved in methanol (5 ml), treated with potassium hydroxide (0.23 g, 4.1 mmol) in water (5 ml) at room temperature and heated at 80 °C for 30 min. The reaction mixture was acidified with 5% hydrochloric acid and then extracted with ethyl acetate. The crude product thus obtained was dissolved in ether (5 ml) and methyllithium (1.14 M ether solution, 7.9 ml, 9.0 mmol) was added at 0 °C under an argon atmosphere and allowed to react for 2 h. Work-up followed by column chromatography (hexane–ethyl acetate 2:1) gave **40** (0.20 g, 49% yield, 97% yield based on the recovered **39**) along with **39** (0.21 g, 50%). The methyl ketone **40** showed IR: 3210, 1705 cm^{-1}; ^{1}H-NMR (CCl_4): δ 0.7—1.0 (m, 6H), 1.0—2.9 (m, 8H), 2.15 (s, 3H), 3.4—3.8 (br s, 1H), 4.2—4.7 (m, 1H), 5.5—5.7 (m, 1H).

Sodium hydride (50% in oil, 0.24 g, 5.0 mmol) was added to DMSO (2 ml) under an argon atmosphere and heated at 80 °C for 30 min. The resulting solution was cooled with a water bath and admixed with a DMSO (2 ml) solution of triphenylmethylphosphonium bromide (2.7 g, 4.8 mmol). After 15 min **40** (0.25 g, 1.20 mmol) in DMSO (5 ml) was added to the resulting red solution. After 1 h the reaction mixture was worked up. The crude product was dissolved in dichloromethane (2 ml) and added to pyridinium chlorochromate (1.33 g, 5.0 mmol) in dichloromethane (5 ml) at room temperature and allowed to react for 1. 5h. Work-up and preparative TLC purification (hexane–ether 1:1) gave **38** (0.20 g, 80% yield), bp 128—135 °C (bath temp)/0.3 Torr. ^{1}H-NMR (CCl_4): δ 1.00 (s, 3H, CCH_3), 1.07, 1.10 (2d, J=6.0 Hz, 3H, $CHC\underline{H}_3$), 1.5—2.7 (m, 8H), 1.76 (s, 3H, $C\underline{H}_3C=CH_2$), 4.72 (br s, 2H, $CH_2=C$), 6.39 (t, J=3.6 Hz, 0.88H), 6.53 (m, 0.12 H); IR: 3086, 1718, 1654, 886 cm^{-1}; MS: *m/e* (rel intensity) 204 (M^+, 61), 189 (31), 161 (28), 147 (41), 136 (30), 133 (32), 119 (100), 105 (50), 93 (53), 91 (48), 77 (43). Found: C, 82.21; H, 9.73%. Calcd for $C_{14}H_{20}O$: C, 82.30; H, 9.87%.

*Alternative Route from **25** to **38**.* A mixture of **25** (0.68 g, 3.0 mmol), 1,2-ethanedithiol (0.43 g, 4.5 mmol), chloroform (10 ml) and boron trifluoride etherate (40 mg) was stirred at room temperature under an argon atmosphere. After 16 h boron trifluoride ethereate catalyst (5 drops, *ca.* 50 mg) was added and the reaction mixture was stirred for 24 h. Work-up followed by preparative TLC (hexane–ether 3:1) gave **36** (R_f 0.64—0.76, 0.51 g, 57% yield). ^{1}H-NMR (CCl_4): δ 0.8—1.1 (m, 6H), 1.1—3.0 (m, 8H), 3.0—3.5 (m, 4H, SCH_2CH_2S), 3.65 (s, 3H, CH_3OCO), 5.9—6.2

(m, 1H); IR: 1728, 1195, 1167 cm^{-1}; MS: *m/e* 298 (M^+).

A mixture of **36** (126 mg, 0.42 mmol), methanol (2 ml), potassium hydroxide (53 mg, 0.95 mmol) dissolved in water (2 ml) was heated to reflux for 1 h. The reaction mixture was extracted once with ether and acidified with 10% hydrochloric acid. Extractive work-up with ether (20 ml×4 times) gave the carboxylic acid (120 mg) which was dissolved in ether (2 ml) at 0 °C. To this solution was added methyllithium (1.66 M ether solution, 0.76 ml, 1.26 mmol) over a period of 5 min and the resulting solution was stirred at 0 °C for 4.5 h. Work-up followed by preparative TLC (hexane–ether 2:1) gave the corresponding methyl ketone (78 mg, 66% yield). IR: 1707 cm^{-1}; ^{1}H-NMR (CCl_4, * refers to the major isomer): δ 0.79, 0.97 (s, 3H, CCH_3), 0.93*, 0.97 (d, J=7.0*, 7.5 Hz respectively, 3H), 1.1—2.9 (m, 8H), 2.13*, 2.10 (s, 3H, CH_3CO), 3.0—3.5 (m, 4H, SCH_2CH_2S), 5.97 (t, J=3.0 Hz, 0.29 H), 6.06* (dd, J=6.0, 3.0 Hz, 0.71 H); MS: *m/e* 282 (M^+).

The methyl ketone (73 mg, 0.26 mmol) was allowed to react with triphenylphosphonium methylide (0.52 mmol) in DMSO (7 ml) at room temperature for 2.3 h. Work-up followed by preparative TLC (hexane–ether 5:1) gave the corresponding isopropenyl derivative **37** (69 mg, 96% yield). ^{1}H-NMR (CCl_4): δ 0.91 (d, J=6.0 Hz, 3H), 0.97 (s, 3H, CCH_3), 1.0—2.7 (m, 8H), 1.73 (s, 3H, CH_3C=), 3.0—3.5 (m, 4H, SCH_2CH_2S), 4.67 (br s, 2H, CH_2=C), 5.96 (t, J=3.6 Hz, 1H). Careful examination of the olefinic region confirmed purity >97%. IR: 3090, 1642, 887 cm^{-1}; MS: *m/e* 280 (M^+).

Hydrolysis of the dithioacetal group was carried out by mixing **37** (40 mg, 0.14 mmol) in dichloromethane (1 ml) with isopentyl nitrite (19 mg, 0.16 mmol) and 30 min after with water (9 mg, 0.5 mmol). After 1.5 h isopentyl nitrite (0.5 ml) was added to complete the reaction and the entire mixture was stirred for 14.3 h. Work-up and preparative TLC purification (hexane–ether 1:1) gave the key intermediate **38** (14 mg, 48% yield) having the correct spectra. ^{1}H-NMR (CCl_4) gave olefinic absorption at δ 6.41 (t, J=3.6 Hz, 1H) only, thus indicating the purity higher than 97%.

Synthesis of dl-*Nootkatone.* A THF (2 ml)–hexane (1.6 ml) solution of lithium dicyclohexylamide (2.6 mmol) was added dropwise at −78 °C over a period of 2 h to **38** (88% purity) (177 mg, 0.87 mmol), dibromomethane (0.31 g, 1.77 mmol) dissolved in THF (5 ml) under an argon atmosphere, and the reaction mixture was stirred for 1 h, and then quenched with methanol (1.0 ml) at −78 °C. Work-up and preparative TLC (benzene) gave the adduct **41** (198 mg, 60% yield; 84% yield based on the consumed **38**) along with the recovered **38** (50 mg, 28%). ^{1}H-NMR (CCl_4): δ 0.98 (d, J=4.5 Hz, 3H, $CHC\underline{H}_3$), 1.07 (s, 3H, CCH_3), 1.1—2.7 (m, 8H), 1.74 (s, 3H, $C\underline{H}_3$-C=), 4.69 (s, 2H, CH_2=C), 5.66 (t, J=3.6 Hz, 1H), 5.81 (s, 1H, $CHBr_2$); IR: 3450, 3085, 1643, 888 cm^{-1}; MS: *m/e* 205 (M^+-CHBr_2).

A butyllithium hexane solution (1.57 M, 0.94 ml, 1.47 mmol) was added over a period of 20 min to the adduct **41** (185 mg, 0.49 mmol) in THF (10 ml) at −95 °C under an argon atmosphere. Stirring was continued at −95 °C for 100 min, and then at room temperature for 5 min. Work-up and preparative TLC (benzene) gave *t*-8-isopropenyl-*r*-5,*c*-6-dimethylbicyclo[4.4.0]dec-10(1)-en-3-one (**42**) (89 mg, 83% yield). ^{1}H-NMR (CCl_4): δ 0.97 (d, J=6.5 Hz, 3H, CH-C$\underline{H}_3$), 1.17 (s, 3H, CCH_3), 1.1—2.5 (m+s (δ 1.75), 11H), 2.73 d, J=16.5 Hz, 1H), 3.10 (dm, J=16.5 Hz, 1H), 4.70 (br s, 2H, CH_2=C), 5.3—5.5 (m, 1H); IR: 3090, 1721, 1644, 887 cm^{-1}; MS: *m/e* 218 (M^+).

The octalone **42** (78 mg, 0.36 mmol) was stirred at room temperature in THF (3 ml) and 5% sulfuric acid (3 ml) for 4 h. Work-up followed by preparative TLC (hexane–ethyl acetate 5:1) gave *dl*-nootkatone (**43**) (45 mg, 58% yield; 74% yield based on the recovered **42** (17 mg, 22%)). The synthesized sample had IR absorptions at 3080, 1671, 1619, 887 cm^{-1}, and ^{1}H-NMR (CCl_4) at δ 0.97 (d, J=6.5 Hz, 3H), 1.13 (s, 3H), 1.1—2.6 (m, 10H), 4.67 (s, 2H), 5.61 (s, 1H) identical exactly with the spectra of the authentic specimen. Careful integration around δ 5.9—5.5 revealed that the sample has purity higher than 93%. The 7-*epi*-nootkatone should give a peak at δ 5.68.[15]

*Cyclopentannulation of 2-Cyclododecenone (**44**).* A butyllithium hexane solution (1.49 M, 8.8 ml, 13.1 mmol) was added dropwise at −78 °C to a THF (90 ml) solution of propargyl alcohol (0.37 g, 6.5 mmol) under an argon atmosphere, and the reaction mixture was stirred for 2 h. To this solution was added a THF (5 ml) solution of 2-cyclododecenone (0.78 g, 4.4 mmol) over 8 min, and the whole was stirred at −78 °C for 2 h, then allowed to warm to room temperature and stirred for 16 min. Work-up followed by column chromatography (hexane–ethyl acetate 2:1 to 1:1) gave 1-(3-hydroxy-1-propynyl)-2-cyclododecenol (**45**) (0.95 g, 92% yield) as colorless needles, mp 71.5—72.5 °C (hexane–dichloromethane, *ca.* 2:1). ^{1}H-NMR (CCl_4): δ 1.0—2.3 (m, 18H), 2.93 (br s, 2H), 4.22 (s, 2H), 5.40 (d, J=16.1 Hz, 1H), 5.80 (dt, J=16.1, 6.3 Hz, 1H); IR: 3300, 785, 760 cm^{-1}; MS: *m/e* (rel intensity): 236 (M^+, 1), 218 (30), 205 (13), 187 (11), 175 (11), 161 (16), 147 (21), 125 (47), 117 (100), 95 (100), 91 (87), 79 (63), 67 (53), 55 (89). Found: C, 76.24; H, 10.46%. Calcd for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%.

The adduct **45** (1.20 g, 5.1 mmol) was dissolved in methanol (80 ml) and cooled at −20 °C. To this solution was added sulfuric acid (40 ml) over a period of 40 min. The resulting mixture was stirred for 14 h, being allowed to warm to room temperature. The reaction mixture was diluted successively with ether (100 ml) and satd. aq sodium chloride solution (100 ml), and shaken vigorously. The ethereal layer was separated, neutralized with aq sodium hydrogencarbonate solution, dried with anhydrous sodium sulfate and concentrated. The residue purified by column chromatography (hexane–ethyl acetate 5:1) gave *trans*-bicyclo-[10.3.0]pentadeca-1(12),2-dien-13-one (**46**) (0.72 g, 65% yield) as a colorless needles, mp 87—87.5 °C (hexane–dichloromethane *ca.* 1:1). ^{1}H-NMR (CCl_4): δ 0.8—1.9 (m, 12H), 2.1—2.4 (m, 6H), 2.4—2.7 (m, 2H), 6.17 (dt, J=16.5, 4.5 Hz, 1H), 6.68 (d, J=16.5 Hz, 1H); IR (CCl_4): 1693, 1643, 1596, 972 cm^{-1}; UV (EtOH); λ_{max} 281 nm (log ε 4.3); MS: *m/e* (rel intensity) 218 (M^+, 38), 203 (4), 189 (6), 175 (8), 161 (10), 147 (17), 133 (100), 122 (35), 105 (17), 91 (33). Found: C, 82.37; H, 9.8%. Calcd for $C_{15}H_{22}O$: C, 82.51; H, 10.16%.

*3-Methylbicyclo[10.3.0]pentadec-1(12)-en-13-one (**53**).* A methylmagnesium iodide ether solution (4.6 ml, 3.7 mmol), THF (10 ml) and then copper(I) chloride (29 mg, 0.29 mmol) were added successively at 0 °C over a period of 11 min to a THF (5 ml) solution of the dienone **46** (0.40 g, 1.83 mmol) and copper(I) chloride (14 mg, 0.14 mmol) under an argon atmosphere. The mixture was stirred for 1.4 h, treated with ice–hydrochloric acid mixture and then extracted successively with ether and ethyl acetate. The combined organic phase was dried (Na_2SO_4), concentrated *in vacuo*, and the residue was purified by preparative TLC (hexane–ethyl acetate 3:1) to give **53** (0.29 g, R_f 0.6—0.68, 68% yield; 74% yield based on the consumed **46**) along with the recovered dienone **46** (28 mg, R_f 0.55—0.60). Bp 157—159 °C (bath temp)/0.04 Torr. ^{1}H-NMR

(CCl_4): δ 0.9—3.0 (m+d (δ 1.08, J=6.6 Hz), 26H); IR: 1692, 1630 cm^{-1}; MS: *m/e* (rel intensity) 234 (M^+, 100), 219 (60), 191 (28), 177 (52), 163 (73), 149 (63), 135 (52), 121 (34), 110 (45), 79 (45), 155 (59). Found: C, 81.70; H, 11.45%. Calcd for $C_{16}H_{26}O$: C, 81.99; H, 11.18%.

*7-Methylcyclopentadecane-1,5-dione (**54**).* Sodium borohydride (0.56 g, 14.7 mmol) was added portionwise at 0 °C to the cyclopentenone **53** (0.29 g, 1.25 mmol) dissolved in a 5:1 mixture of methanol and water (17 ml) and the reaction mixture was stirred for 2.5 h. Work-up gave an allyl alcohol (0.32 g) which was dissolved in dichloromethane (14 ml) and treated at 0 °C with *m*-chloroperoxybenzoic acid (0.26 g, 1.5 mmol) dissolved in dichloromethane (14 ml). The reaction mixture was stirred at 0 °C for 1.2 h, quenched with satd. aq sodium sulfite solution and neutralized with aq satd. sodium hydrogencarbonate solution. Extraction with dichloromethane followed by concentration gave an epoxy alcohol (0.34 g) which was dissolved in pyridine (4 ml) and treated with *p*-toluenesulfonyl chloride (0.36 g, 1.87 mmol) at 0 °C under an argon atmosphere, and the whole was left at 0 °C for 21 h, then poured into 2 M hydrochloric acid solution, and extracted with ether. The usual work-up gave a crude epoxy tosylate (0.47 g) which was dissolved in a 3:2 mixture of dioxane–water (10 ml) and heated at reflux in the presence of calcium carbonate (185 mg, 1.85 mmol) for 24 h. Work-up followed by preparative TLC (hexane–ethyl acetate 2.5:1) afforded the desired diketone **54** (0.22 g, R_f 0.47—0.60, 71% overall yield). Bp 156—158 °C (bath temp)/0.05 Torr, ^{1}H-NMR (CCl_4): δ 0.8—2.9 (m+d (δ 0.91, J=5.7 Hz), 28H); IR: 1709 cm^{-1}; MS: *m/e* (rel intensity) 252 (M^+, 24), 195 (15), 167 (22), 128 (39), 97 (54), 69 (42), 55 (100). Found: C, 76.00; H, 11.39%. Calcd for $C_{16}H_{28}O_2$: C, 76.14; H, 11.18%.

dl-*Muscopyridine (**55**).* A mixture of the diketone (**54**) (90 mg, 0.36 mmol), ethanol (20 ml), and hydroxylamine hydrochloride (0.55 g, 0.79 mmol) was heated under an argon atmosphere at 150—160 °C in an autoclave (capacity 100 ml) for 17.6 h. After cooling the reaction mixture was taken in ether, and the ethereal solution was washed with aq satd. hydrogencarbonate solution, then dried (Na_2SO_4), and concentrated. The residue was purified by preparative TLC (hexane–ethyl acetate 5:1) to give *dl*-muscopyridine (**55**) (54 mg, R_f 0.65—0.75, 65% yield). The synthetic sample exhibited the following spectra identical with those of the authentic chiral specimen. ^{1}H-NMR (CCl_4): δ 0.6—2.3 (m+d (δ 1.11, J=7.5 Hz), 18H), 2.3—3.0 (m, 4H), 6.83 (d, J=7.8 Hz, 2H), 7.42 (t, J=7.8 Hz, 1H), IR: 3065, 1589, 1575, 1453, 763, 743 cm^{-1}; MS: *m/e* (rel intensity) 231 (M^+, 88), 188 (38), 160 (41), 147 (31), 146 (41), 134 (59), 133 (34), 120 (100), 107 (97).

*Cyclopentannulation of 2-Cyclooctenone (**47**).* A butyllithium hexane solution (1.49 M, 20.1 ml, 30.0 mmol) was added to a THF (170 ml) solution of propargyl alcohol (0.84 g, 15.0 mmol) at −78 °C under an argon atmosphere, and the reaction mixture was stirred for 2.7 h. The solution was warmed to −55 °C, and to this was added a THF (6 ml) solution of 2-cyclooctenone (**47**) (1.24 g, 10.0 mmol) over a period of 10 min. The reaction mixture was stirred for 10.7 h, and warmed to 20 °C. Work-up gave an oil (2.2 g) which was purified by column chromatography to give 1-(3-hydroxy-1-propynyl)-2-cycloocten-1-ol (**48**) (0.92 g, 51% yield; 76% yield based on the consumed enone **47**) along with the recovered **47** (0.37 g, 30%). Physical properties of **48**: bp 170—173 °C (bath temp)/0.07 Torr; ^{1}H-NMR (CCl_4): δ 1.2—2.8 (m, 10H), 3.17 (br s, 2H), 4.24 (s, 2H), 5.25—5.7 (m, 2H); IR: 3350, 1063, 1035, 708 cm^{-1}; MS: *m/e* (rel intensity) 180 (M^+, 2), 106 (51), 91 (100), 77 (51), 55 (60). Found: C, 73.55; H, 8.95%. Calcd for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%.

The adduct **48** (68 mg, 0.38 mmol) was stirred with acetic anhydride (0.5 ml) and pyridine (0.05 ml) at room temperature for 1 h. All the volatile material was evaporated *in vacuo*. The residue was dissolved in methanol (1 ml) and to this was added sulfuric acid (1 ml) dropwise at −15 °C over a period of 10 min. The solution was stirred for 25 min, and warmed up to −5 °C. Work-up followed by preparative TLC (hexane–ethyl acetate 2:1) gave bicyclo[6.3.0]undeca-1(8),2-dien-9-one (**49**) (26 mg, 42% yield). Bp 114—118 °C (bath temp)/0.08 Torr; ^{1}H-NMR (CCl_4): δ 1.3—1.9 (m, 4H), 1.9—2.7 (m, 8H), 5.7—6.4 (m, 2H); IR: 1693, 1620, 741 cm^{-1}; MS: *m/e* (rel intensity) 162 (M^+, 100), 133 (87), 115 (56), 91 (77). Found: C, 81.65; H, 8.98%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

*Cyclopentannulation of 2-Cycloheptenone (**50**).* Butyllithium (1.49 M hexane solution, 8.4 ml, 12.5 mmol) was added dropwise to a THF (70 ml) solution of propargyl alcohol (0.35 g, 6.3 mmol) at −78 °C under an argon atmosphere and the resulting solution was stirred for 4.5 h and warmed to −25 °C. At this temperature 2-cycloheptenone (**50**) (0.46 g, 4.2 mmol) dissolved in THF (5 ml) was added in 3 min and the reaction mixture was stirred for 15 h and allowed to warm to room temperature. Work-up followed by column chromatography (hexane–ethyl acetate 1:1) gave 1-(3-hydroxy-1-propynyl)-2-cyclohepten-1-ol (**51**) (0.45 g, 65% yield); bp 169—172 °C (bath temp)/0.07 Torr; ^{1}H-NMR (CCl_4): δ 1.2—2.9 (m, 8H), 4.29 (s, 2H), 4.42 (br s, 2H), 5.7—5.9 (m, 2H); IR: 3330, 1072, 1015, 686 cm^{-1}; MS: *m/e* (rel intensity) 166 (M^+, 14), 148 (24), 119 (43), 115 (48), 98 (33), 92 (43), 91 (100), 79 (52), 78 (48), 77 (52), 47 (43), 65 (43), 55 (67). Found: C, 72.06; H, 8.78%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%.

The diol **51** (68 mg, 0.41 mmol) was stirred with acetic anhydride (0.5 ml) and pyridine (0.05 ml) at room temperature for 1.5 h. The volatile material was evaporated off and the residue was dissolved in methanol (4 ml). To the solution was added sulfuric acid (2 ml) at −15 °C over a period of 5 min. Stirring was continued for 2.5 h and the reaction mixture was diluted with dichloromethane (5 ml), poured onto crushed ice (*ca.* 10 g), and the extracted with dichloromethane. The usual work-up followed by preparative TLC (hexane–ethyl acetate 2:1) gave bicyclo[5.3.0]deca-1(7),2-dien-8-one (**52**) (30 mg, 49% yield); bp 124—126 °C (bath temp)/0.06 Torr; ^{1}H-NMR (CCl_4): δ 1.7—2.1 (m, 2H), 2.2—2.7 (m, 8H), 5.90 (d, J=11.6 Hz, 1H), 6.20 (dt, J=11.6, 5.0 Hz, 1H); IR: 1689, 1639, 1607, 726 cm^{-1}; MS: *m/e* (rel intensity) 148 (M^+, 65), 133 (26), 116 (58), 115 (65), 92 (35), 91 (100), 79 (25), 78 (35), 77 (25), 65 (21). Found: *m/e* 148.0876 (M^+). Calcd for $C_{10}H_{12}O$: *m/e* 148.0888.

This work was financially supported by the Ministry of Education, Science and Culture (Grant-in-Aid Nos. 311702, 375462, 411102, and 475665).

Synthesis of Oligoinosinates with 2′–5′ Internucleotide Linkage in Aqueous Solution Using Pb^{2+} Ion

Hiroaki SAWAI* and Masaji OHNO

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received January 28, 1981)

Oligoinosinates up to a pentamer were synthesized by the polymerization of inosine-5′-phosphorimidazolide in aqueous solution using Pb^{2+} ion. 2′–5′ Internucleotide linkage was preferentially formed. The yields of the 2′–5′ linked dimer, trimer, and tetramer were 14.8, 4.5, and 1.6%, respectively. A small amount of linkage isomers of oligoinosinates with 3′–5′ linkage was obtained. The products were characterized by sequential enzyme tests.

Recently 2′–5′ linked oligoadenylate ($pppA^{2'}p^{5'}A^{2'}p^{5'}A$) was isolated from interferon-treated cell and has attracted widespread interest because of its strong biological activity and unusual structure.[1-3] The availability of various oligonucleotides with 2′–5′ linkage would facilitate further study of their biological action. As a part of our program in the synthetic approach to oligonucleotides, attention was focused on the selective synthesis of short chained oligonucleotides containing 2′–5′ linkage without using any protecting group.

Reports were given on the synthesis of 2′–5′ linked oligoadenylates from adenosine-5′-phosphorimidazolide in aqueous solution using Pb^{2+} ion.[4,5] The method employs no protecting group, various oligoadenylates being obtained in the one step reaction. We have attempted the synthesis of other homooligonucleotides with 2′–5′ linkage by a similar procedure.[6] This paper describes the oligoinosinates synthesis from inosine·5′·phosphorimidazolide in aqueous solution using Pb^{2+} ion. The products were separated by ion exchange column chromatography and characterized by sequential enzyme and alkaline digestion.

Results and Discussion

Inosine-5′-phosphorimidazolide (ImpI) was prepared from inosine-5′-monophosphate (pI) and imidazole using di-2-pyridyl disulfide and triphenylphosphine as a condensing agent. Phosphorimidazolide bond is labile, hydrolyzing in aqueous solution spontaneously in the absence of divalent metal ion catalyst. The Pb^{2+} ion promoted the internucleotide linkage formation from ImpI. Addition of lead nitrate to a neutral aqueous solution of ImpI caused precipitation, suggesting formation of Pb^{2+}–ImpI complex. The ImpI was allowed to react in a neutral aqueous mixture for 3 d with stirring in the presence of the Pb^{2+} ion for polymerization. Treatment of the reaction mixture with *N*·(2-hydroxyethyl)-ethylenediamine-*N*,*N*′,*N*′·triacetic acid trisodium (Versenol) buffer turned the mixture homogeneous. The Pb^{2+} ion formed a complex with Versenol completely. The formation of the oligoinosinates and Pb^{2+}–Versenol complex was checked by high pressure liquid chromatography (HPLC). The products were separated on a QAE·Sephadex A·25 anion exchange column. The separated products were further purified by paper chromatography when necessary. The elution pattern obtained on column chromatography is shown in Fig. 1. The composition and the yields of the products are given in Table 1 along with the hyperchromicity of the main products.

Oligoinosinates up to a pentamer were formed in addition to the hydrolyzed product pI. The internucleotide linkage formation took place as the following Scheme 1. The 2′–5′ internucleotide linkage was preferentially formed in the reaction.

The oligoinosinates thus obtained were characterized by enzymatic tests, paper chromatography and HPLC. The 2′–5′ internucleotide linkage is not degraded

Table 1. Oligoinosinates obtained from ImpI

Peak No.	ODU_{248}	h[a]	Structure identification	Yield/%[b]
1	36		I	1.0
2	12		3′,5′-Cyclic IMP	0.3
3	231		ImpI	5.5
4	1558		pI	41
5	72		ImpIpI	1.0
			-pIpI- (2′–5′, 2′–5′)	0.9[c]
6	51		IppI	1.3[c]
7+8	770		-pIpI- (2′–5′, 3′–5′)	1.8[c]
		1.04	-pIpI- (3′–5′, 3′–5′)	5.0
		1.08	$pI^{2'}p^{5'}I$	14.8
9	130	1.06	$pI^{3'}p^{5'}I$	2.6
			$IppI^{2'}p^{5'}I$	0.6[c]
10	146	1.15	$pI^{2'}p^{5'}I^{2'}p^{5'}I$	4.5
11	116	1.18	$pI^{2'}p^{5'}I^{3'}p^{5'}I$	2.6
			Unidentified	0.8[c]
12	66	1.15	$pI^{3'}p^{5'}I^{2'}p^{5'}I$	1.5
			Unidentified	0.5[c]
13	120	1.15	$pI^{3'}p^{5'}I^{3'}p^{5'}I$	1.6
		1.20	$pI^{2'}p^{5'}I^{2'}p^{5'}I^{2'}p^{5'}I$	1.5
			Unidentified	0.4[c]
14	33	1.24	$pI^{2'}p^{5'}I^{3'}p^{5'}I^{2'}p^{5'}I$	0.7
			$pI^{2'}p^{5'}I^{2'}p^{5'}I^{3'}p^{5'}I$	0.4
15	30		$(pI)_4$ (Mixtures of isomers)	0.8[c]
16	72	1.31	$pI^{2'}p^{5'}I^{2'}p^{5'}I^{2'}p^{5'}I^{2'}p^{5'}I$	0.6
			$(pI)_4$ and $(pI)_5$ (Mixture of isomers)	1.3[c]

a) Hyperchromicity calculated from alkaline hydrolysis. b) Yield obtained from UV_{248} after allowing for hyperchromicity of each oligoinosinate. Total ODU_{248} of starting ImpI is 3800 (0.31 mmol). c) Hyperchromicity correction was not carried out.

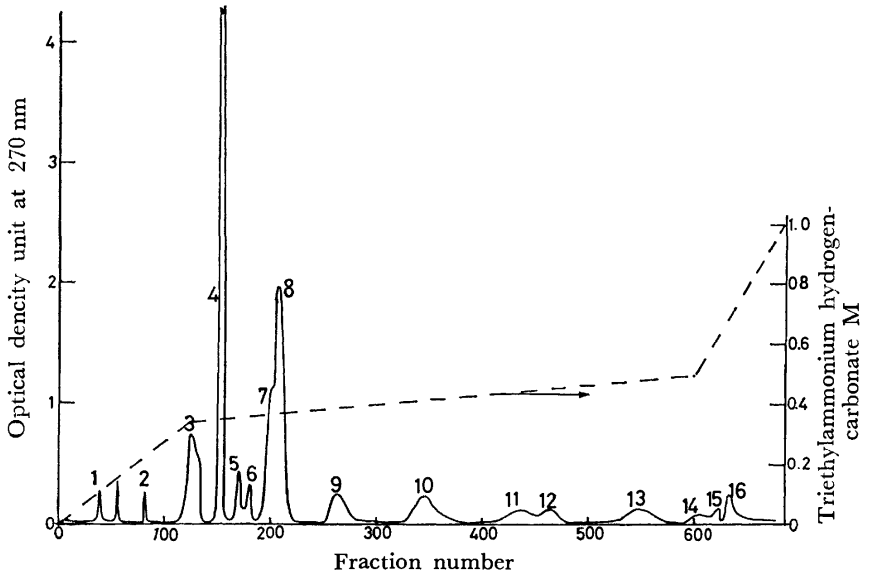

Fig. 1. Chromatography of the oligoinosinates on a QAE-Sephadex A-25 (hydrogen carbonate) column. A linear gradient of triethylammonium hydrogencarbonate was used for elution (dotted line). The characterization of the several peaks is listed in Table 1.

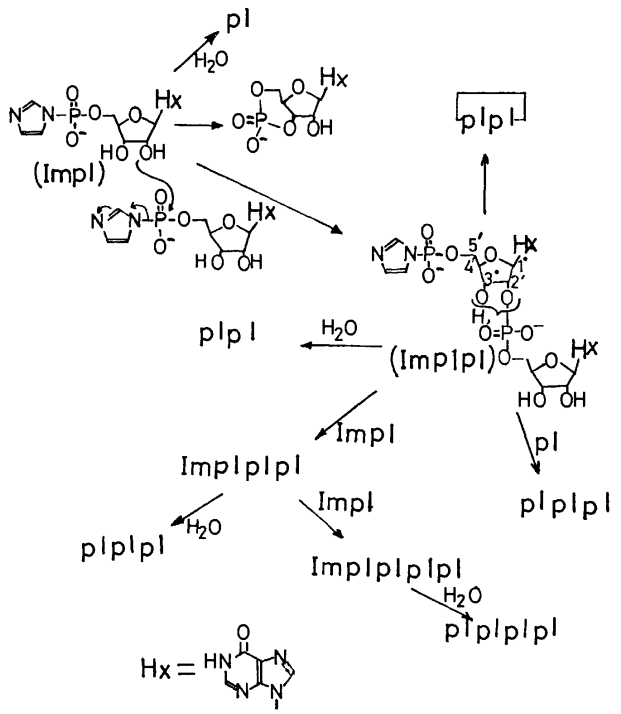

Scheme 1.

with nuclease P_1 (N. P_1) and ribonuclease T_2, while 3′–5′ linkage is degraded. Both 2′–5′ and 3′–5′ internucleotide linkages are hydrolyzed with venom phosphodiesterase (VPD) and by alkaline digestion. Thus, the internucleotide linkage and the chain length of the oligoinosinates were determined by sequential enzyme digestion using bacterial alkaline phosphatase (BAP), N. P_1, and VPD and by alkaline hydrolysis.

The 2′–5′ linked dimer, 5′-phosphoinosinyl-[2′–5′]-inosine ($pI^{2'}p^{5'}I$) and the trimer, 5′-phosphoinosinyl-[2′–5′]-inosinyl-[2′–5′]-inosine ($pI^{2'}p^{5'}I^{2'}p^{5'}I$) were degraded with the enzymes as follows. Digestion of $pI^{2'}p^{5'}I$ with BAP gave inosinyl-[2′–5′]-inosine. $pI^{2'}p^{5'}I$ and $I^{2'}p^{5'}I$ were insensitive to N. P_1. On the other hand, alkaline hydrolysis of $pI^{2'}p^{5'}I$ yielded to inosine (I) and inosine-2′(3′),5′-diphosphate (pIp), and $I^{2'}p^{5'}I$ to I and inosine-2′(3′)-monophosphate (Ip). $I^{2'}p^{5'}I$ was degraded with VPD to I and pI. The tetramer ($pI^{2'}p^{5'}I^{2'}p^{5'}I^{2'}p^{5'}I$) and pentamer ($pI^{2'}p^{5'}\cdot I^{2'}p^{5'}I^{2'}p^{5'}I^{2'}p^{5'}I$) were degraded in a similar way. The yields of the 2′–5′ linked dimer, trimer, tetramer, and pentamer were 14.8, 4.5, 1.5, and 0.5%, respectively.

$$pI^{2'}p^{5'}I \xrightarrow{\text{N. P}_1} \not\rightarrow$$

$$pI^{2'}p^{5'}I \xrightarrow{\text{NaOH}} pIp + I \quad (1:1)$$

$$pI^{2'}p^{5'}I \xrightarrow{\text{BAP}} I^{2'}p^{5'}I \xrightarrow{\text{N. P}_1} \not\rightarrow$$

$$I^{2'}p^{5'}I \xrightarrow{\text{NaOH}} Ip + I \quad (1:1)$$

$$I^{2'}p^{5'}I \xrightarrow{\text{VPD}} I + pI \quad (1:1)$$

$$pI^{2'}p^{5'}I^{2'}p^{5'}I \xrightarrow{\text{N. P}_1} \not\rightarrow$$

$$pI^{2'}p^{5'}I^{2'}p^{5'}I \xrightarrow{\text{NaOH}} pIp + Ip + I \quad (1:1:1)$$

$$pI^{2'}p^{5'}I^{2'}p^{5'}I \xrightarrow{\text{BAP}} I^{2'}p^{5'}I^{2'}p^{5'}I \xrightarrow{\text{N. P}_1} \not\rightarrow$$

$$I^{2'}p^{5'}I^{2'}p^{5'}I \xrightarrow{\text{NaOH}} Ip + I \quad (2:1)$$

$$I^{2'}p^{5'}I^{2'}p^{5'}I \xrightarrow{\text{VPD}} I + pI \quad (1:2)$$

The 3′–5′ linked dimer, 5′-phosphoinosinyl-[3′–5′]-inosine ($pI^{3'}p^{5'}I$), and the trimer, 5′-phosphoinosinyl-[3′–5′]-inosinyl-[3′–5′]-inosine ($pI^{3'}p^{5'}I^{3'}p^{5'}I$), were isolated in 2.6 and 1.4% yield, respectively. These compounds were hydrolyzed by the enzymes as illustrated below.

$$pI^{3'}p^{5'}I \xrightarrow{N.P_1} pI$$

$$pI^{3'}p^{5'}I \xrightarrow{BAP} I^{3'}p^{5'}I \xrightarrow{N.P_1} I + pI \ (1:1)$$

$$I^{3'}p^{5'}I \xrightarrow{NaOH} Ip + I \ (1:1)$$

$$pI^{3'}p^{5'}I^{3'}p^{5'}I \xrightarrow{N.P_1} pI$$

$$pI^{3'}p^{5'}I^{3'}p^{5'}I \xrightarrow{BAP} I^{3'}p^{5'}I^{3'}p^{5'}I \xrightarrow{N.P_1} I + pI \ (1:2)$$

$$I^{3'}p^{5'}I^{3'}p^{5'}I \xrightarrow{NaOH} Ip + I \ (2:1)$$

Two linkage isomers, $pI^{3'}p^{5'}I^{2'}p^{5'}I$ and $pI^{2'}p^{5'}I^{3'}p^{5'}I$, were present in peaks 11 and 12, respectively. Their characterization was accomplished by the following enzyme digestion.

$$pI^{3'}p^{5'}I^{2'}p^{5'}I \xrightarrow{N.P_1} pI + pI^{2'}p^{5'}I \ (1:1)$$

$$pI^{3'}p^{5'}I^{2'}p^{5'}I \xrightarrow{BAP}$$

$$I^{3'}p^{5'}I^{2'}p^{5'}I \xrightarrow{N.P_1} I + pI^{2'}p^{5'}I \ (1:1)$$

$$\downarrow NaOH$$

$$pIp + I \ (1:1)$$

$$pI^{2'}p^{5'}I^{3'}p^{5'}I \xrightarrow{N.P_1} pI^{2'}p^{5'}I + pI \ (1:1)$$

$$pI^{2'}p^{5'}I^{3'}p^{5'}I \xrightarrow{BAP}$$

$$I^{2'}p^{5'}I^{3'}p^{5'}I \xrightarrow{N.P_1} I^{2'}p^{5'}I + pI \ (1:1)$$

$$\downarrow NaOH$$

$$Ip + I \ (1:1)$$

Two tetramers containing one 3′–5′ and two 2′–5′ internucleotide linkages in a different position, $pI^{2'}p^{5'}I^{3'}p^{5'}I^{2'}p^{5'}I$ and $pI^{2'}p^{5'}I^{2'}p^{5'}I^{3'}p^{5'}I$, were isolated in a small amount. They were degraded with the enzymes as follows.

$$pI^{2'}p^{5'}I^{3'}p^{5'}I^{2'}p^{5'}I \xrightarrow{N.P_1} pI^{2'}p^{5'}I$$

$$pI^{2'}p^{5'}I^{3'}p^{5'}I^{2'}p^{5'}I \xrightarrow{BAP}$$

$$I^{2'}p^{5'}I^{3'}p^{5'}I^{2'}p^{5'}I \xrightarrow{N.P_1} I^{2'}p^{5'}I + pI^{2'}p^{5'}I \ (1:1)$$

$$pI^{2'}p^{5'}I^{2'}p^{5'}I^{3'}p^{5'}I \xrightarrow{N.P_1} pI + pI^{2'}p^{5'}I^{2'}p^{5'}I$$

$$pI^{2'}p^{5'}I^{2'}p^{5'}I^{3'}p^{5'}I \xrightarrow{BAP}$$

$$I^{2'}p^{5'}I^{2'}p^{5'}I^{3'}p^{5'}I \xrightarrow{N.P_1} I^{2'}p^{5'}I^{2'}p^{5'}I + pI \ (1:1)$$

$$\downarrow NaOH$$

$$Ip + I \ (2:1)$$

Linkage isomers of the tetramer and pentamer were present in peaks 15 and 16 in a small amount. They remain unidentified.

Contrary to the oligoadenylate formation,[5] appreciable amounts of cyclic diinosinates were obtained in peaks 6 and 7. They were characterized by resistance to BAP and by their chromatographic mobilities. The internucleotide linkage of the cyclic diinosinates was determined by susceptibility to N. P_1. N. P_1 degraded 3′–5′, 3′–5′, and 3′–5′, 2′–5′ linked isomers to pI and $pI^{2'}p^{5'}I$, respectively. 2′–5′,2′–5′ Linked cyclic diinosinate was insensitive to N. P_1, being degraded to pI with VPD. The degradation rate of the cyclic diinosinates with the enzymes was lower than that of the linear dimer. Of the three linkage isomers, the 3′–5′, 3′–5′ linked cyclic diinosinate was predominant. A molecular model indicates that the cyclic dinucleotide prefers 3′–5′ linkage to 2′–5′ linkage conformationally.

The side products containing pyrophosphate bond were characterized as 5,5′-diinosine diphosphate (IppI) and 5′-inosine-5′-inosinyl-[2′–5′]-inosine diphosphate ($IppI^{2'}p^{5'}I$) by resistance to BAP and mobility on paper chromatograms. Both IppI and $IppI^{2'}p^{5'}I$ were degraded with VPD giving pI. Alkaline hydrolysis of $IppI^{2'}p^{5'}I$ followed by incubation with BAP gave IppI.

Peaks 1, 2, 3, and 4 were identified as I, 3′,5′-cyclic IMP, ImpI, and pI, respectively, by comparison of paper chromatogram mobility and HPLC with those of authentic samples.

The selective formation of 2′–5′ linked oligoinosinates was established in this polymerization reaction. Yield and regioselectivity of internucleotide linkage were lower than those for the oligoadenylates.[5] This procedure employs no protecting group, condensation reaction taking place in an aqueous solution. It provides a simple preparative method for the 2′–5′ linked oligoinosinates, though the yield is not satisfactory.

Experimental

Materials. Inosine-5′-monophosphate sodium salt (Yamasa) and commercial imidazole, triethylamine, triphenylphosphine, Versenol trisodium salt, and lead nitrate were used. Di-2-pyridyl disulfide was prepared by a modification of the procedure of Jones and Katrizky.[7] Inosine-5′-phosphorimidazolide was prepared from pI and imidazole using triphenylphosphine and di-2-pyridyl disulfide as a condensing agent in a similar way to that of Lohrmann and Orgel.[8] Bacterial alkaline phosphatase, (BAPF) and venom phosphodiesterase (VPD) from Worthington, nuclease P_1 (N. P_1) from Yamasa and QAE-Sephadex A-25 from Pharmacia Fine Chemicals were used.

Paper Chromatography and HPLC. Paper chromatography was carried out by a descending technique on Whatman 3MM paper. The solvent systems were (**1**), 1-propanol–concentrated ammonia–water (55:10:35 v/v), and (**2**), saturated ammonium sulfate–0.1 M sodium acetate (pH 6.5)–2-propanol (79:19:2 v/v). R_f values of various oligoinosinates are given in Table 2.

HPLC was performed with a Hitachi 538 apparatus using a RPC-5 column (4 mmϕ × 25 cm). RPC-5 was prepared according to the method of Pearson *et al.*[9] The elution of the HPLC column was carried out with a linear gradient of aqueous $NaClO_4$ solution (H_2O–0.025 M $NaClO_4$) containing 0.0025 M Tris-acetate buffer (pH 7.5). The compounds were monitored by UV absorption at 260 nm.

Preparation of Oligoinosinate. Lead nitrate solution (0.25 M 0.3 ml) was added to a 5.7 ml aqueous solution of ImpI (150 mg, 3800 optical density unit at 248 nm, 0.3 mmol) containing 0.2 M imidazole buffer at pH 7.0 with stirring. White precipitates were formed. The solution was kept at 20 °C for 3 d with stirring. The reaction mixture was treated with 0.5 ml of 0.25 M Versenol buffer to complex the Pb^{2+} ion. A small portion (10 μl)

TABLE 2. R_f VALUES OF THE COMPOUNDS

Compound	R_f values relative to pI	
	Solvent 1	Solvent 2
I	1.57	0.80
3′,5′-Cyclic IMP	1.43	0.87
ImpI	1.56	
pI	1.00	1.00
IppI	0.91	0.86
ImpIpI	1.12	
[pIpI] - [3′–5′, 3′–5′ / 3′–5′, 2′–5′ / 2′–5′, 2′–5′]	1.05	0.30—0.50
$pI^{2'}p^{5'}I$	0.78	0.92
$pI^{3'}p^{5'}I$	0.76	0.81
$I^{2'}p^{5'}I$	1.17	
$I^{3'}p^{5'}I$	1.14	
$IppI^{2'}p^{5'}I$	0.60	0.80
$pI^{2'}p^{5'}I^{2'}p^{5'}I$	0.53	0.83
$pI^{2'}p^{5'}I^{3'}p^{5'}I$	0.48	0.77
$pI^{3'}p^{5'}I^{2'}p^{5'}I$	0.50	0.75
$pI^{3'}p^{5'}I^{3'}p^{5'}I$	0.49	0.64
$pI^{2'}p^{5'}I^{2'}p^{5'}I^{2'}p^{5'}I$	0.37	0.79
$pI^{2'}p^{5'}I^{3'}p^{5'}I^{2'}p^{5'}I$	0.35	0.67
$pI^{2'}p^{5'}I^{2'}p^{5'}I^{2'}p^{5'}I^{2'}p^{5'}I$	0.23	0.64

of the resulting homogeneous solution was analyzed with HPLC. The bulk of the solution was applied to the top of a QAE-Sephadex A-25 (hydrogencarbonate form) column, 25 mmϕ × 36 cm. After washing with water, elution was carried out by a stepwise linear gradient of triethylammonium hydrogencarbonate buffer (pH 7.5); (1) H_2O (0.75 l)–1/3 M (0.75 l); (2) 1/3 M (3 l)–1/2 M (3 l); 1/2 M (1 l)–1 M (1 l). *Ca.* 14 ml fractions were collected every 10 min. UV absorption of each fraction was measured at 270 nm. The fractions containing the UV absorbing compound were pooled and evaporated *in vacuo* below 30 °C. The excess of triethylammonium hydrogencarbonate was removed by repeated evaporation after addition of water. UV absorption of the oligoinosinates was measured at 248 nm. The yield was calculated from ODU_{248} after allowing for the hyperchromicity of each oligoinosinate. The hyperchromicity was obtained by the ratio of UV absorption at 248 nm after and before alkaline hydrolysis of the oligoinosinate.

Characterization of Products. Characterization of the products was carried out by means of sequential enzymes and alkaline digestion. The structure was confirmed by comparing the paper chromatograms and HPLC with those of authentic samples. The separated products were subjected to paper chromatography in solvent systems **1** and **2**. The UV active spot on the paper developed with system **1** was eluted with water, and then incubated with BAP. The incubated mixture was chromatographed on the paper using system **1**. The spot on the paper was elute with water. The eluate was evaporated *in vacuo* and incubated with N. P_1. The mixture was analyzed with HPLC, and applied to paper chromatography in system **1**. The UV absorbing spot was eluted with water and divided into two portions. One was digested with VPD and the other was degraded in a 0.5 M alkaline solution. The digested solution was analyzed with HPLC. The molar ratio of inosine and inosine nucleotides was determined with HPLC.

Digestion of the Products with Enzymes. Digestion with BAP was carried out by incubating a mixture of 0.5—1.5 μmol of nucleotidic material in a 50 μl solution containing 0.1 M Tris-HCl (pH 8.05), 0.001 M $MgCl_2$ and 0.1 unit of enzyme, at 37 °C for 2.5 h. The mixture was spotted directly on a Whatman 3MM paper and developed in system **1**.

Degradation with N. P_1 was performed at 37 °C for 2.5 h in a mixture (50 μl) containing the nucleotidic material (0.5—1.5 μmol), 0.006 M Veronal-acetate buffer (pH 5.75) and an enzyme solution (5 μg in 5 μl).

Degradation with VPD was carried out at 37 °C for 2.5 h in a mixture (50 μl) containing the substrate (0.2—0.4 μmol), 0.01 M Tris-acetate (pH 8.8), 0.01 M $MgCl_2$ and enzyme solution (0.01 unit).

Alkaline hydrolysis was carried out at room temperature for 1 d in a mixture (50 μl) containing the substrate (0.2—0.5 μmol) in a 0.5 M NaOH solution.

The Biosynthesis of Monoterpenoids in Higher Plants. The Biosynthetic Pathway Leading to the Monoterpenoids from Amino Acids with a Carbon-skeleton Similar to Mevalonic Acid

Keiji TANGE†

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received January 31, 1981)

Radioisotopically labeled L-leucine, L-valine, DL-alanine, sodium acetate, and DL-mevalonic acid were incorporated into linalool by the intact plant of *Cinnamomum camphora* Sieb. var. *linalooliferum* Fujita and into geraniol and citronellol by that of *Pelargonium roseum* Bourbon. The uptake of leucine and valine resulted in the preferential location of the radioactivity on the 3,3-dimethylallyl pyrophosphate-derived moiety of these acyclic monoterpenoids, whereas the uptake of alanine resulted in the preferential location on the isopentenyl pyrophosphate-derived moiety, much as in the cases of mevalonic acid and sodium acetate. A biosynthetic pathway leading to the monoterpenoids from the amino acids is discussed.

The biosynthesis of monoterpenoids is believed to involve the conversion of mevalonic acid (MVA)[1] into isopentenyl pyrophosphate (IPP)[1] and 3,3-dimethylallyl pyrophosphate (DMAPP),[1] followed by the condensation of IPP with DMAPP directed toward the formation of monoterpenoids.[2] The predominant location of the radioactivity on the IPP-derived moiety has been observed for the biosynthesis of monoterpenoids from MVA-2-^{14}C by the leaves of higher plants,[3–6] in contrast to the equal distribution in the IPP- and DMAPP-derived moieties of squalene and triterpenoids biosynthesized from MVA-2-^{14}C by *Pisum sativum*.[7] The unbalanced distribution of the labeling in the monoterpenoids has been explained in terms of the operation of several factors, which involve the participation of some other pathway or intermediates in the DMAPP formation. No incorporation, or only a slight one, of leucine and valine into monoterpenoids by higher plants has been reported,[3,8,9] but the biosynthetic pathway of steroids from leucine *via* MVA has been established in animal tissues,[10–13] and it is highly probable that such a pathway takes part in higher plants, also.

We have performed the feeding experiments of radioisotopically labeled leucine, valine, and alanine into linalool (**1**) with the intact plant of *Cinnamomum camphora* Sieb. var. *linalooliferum* Fujita, and into geraniol (**2**) and citronellol (**3**) with that of *Pelargonium roseum* Bourbon, and then compared the distribution of the radioactivity originating from these precursors in the IPP- and DMAPP-derived moieties of the monoterpenoids with its distribution in the moieties of the monoterpenoids biosynthesized from ^{14}C-labeled MVA and acetate. The results have been partly outlined in the preliminary communications.[14–17] We here wish to report, *en bloc*, details of the results.

Results

*The Incorporation of the Radioisotopically Labeled Precursors into Linalool (**1**), Geraniol (**2**), and Citronellol (**3**).* Feeding experiments were carried out on sprigs of *C. camphora* and *P. roseum*. The radioisotopically labeled precursors used for the incorporation were L-leucine-U-^{14}C,[18] L-valine-U-^{14}C, DL-alanine-2-^{14}C, sodium acetate-2-^{14}C, and DL-mevalonic-2-^{14}C acid. A phosphate-buffered solution (pH 7 4) of each precursor was fed through the cut stem to the leaves of the plants. The leaves and stems were subsequently steam-distilled to give an essential oil, which was then subjected to preparative TLC to isolate **1** from *C. camphora* and **2** and **3** from *P. roseum*. The radioactivities of **1**, **2**, and **3** were measured in Bray's scintillation solvent[19] with a liquid scintillation spectrometer; they are shown in Tables 1 and 2. Leucine and valine were incorporated into **1**, **2**, and **3** in the range of 0.0002—0.0055%. The incorporation of alanine into these monoterpenoids was at a considerably high level (0.014—0.076%), whereas that of acetate was at a low level (0.004—0.027%).

*The Distribution of Radioactivity in Linalool (**1**) Biosynthesized from ^{14}C-Labeled Leucine, Valine, and MVA by* C. camphora. Linalool (**1**), biosynthesized from leucine-U-^{14}C, valine-U-^{14}C, and MVA-2-^{14}C, was subjected to degradation to determine the labeling pattern. The radioactive linalool (**1**) isolated was hydrogenated in the presence of platinum dioxide to give 1,2-dihydrolinalool (**4**), which was subsequently degraded to 4-methyl-4-hexanolide (**5**) containing the C-1—C-6 and C-9 carbon atoms of **1**, and to acetone containing the C-7, C-8, and C-10 carbon atoms of **1**, by permanganate-periodate oxidation.[20] The hexanolide (**5**) and acetone were then converted to the *S*-benzylthiouronium salt[21] and the thiosemicarbazone

derivative respectively; these products were purified to a constant specific radioactivity by recrystallization. Table 3 shows the radioactivities of these degradation products. In the uptake of leucine-U-^{14}C and valine-U-^{14}C, the atoms of their tracer element are uniformly located on all the carbon atoms of DMAPP and IPP; therefore, the 5/3 of the total radioactivity of acetone resides on the DMAPP-derived moiety (C-5—C-8 and C-10), and the radioactivity of the IPP-derived moiety (C-1—C-4 and C-9) must be the difference between the radioactivity of **5** and 2/3 that of acetone. On the other hand, it has been established that the C-4 and C-8 carbon atoms of the monoterpenoids are labeled with the tracer from MVA-2-^{14}C.[22,23] In this

a) "Exptl No." correspond to the numbers in Tables 1 and 2. b) Refer to a) in Table 1. c) IPP-M. and DMAPP-M. denote the IPP- and DMAPP-derived moieties respectively.

case, therefore, all the radioactivity located on the DMAPP- and IPP-derived moieties would appear in acetone and **5**.

On the basis of the radioactivity of acetone and **5**, the distributions of radioactivity in the IPP- and DMAPP-derived moieties of **1** were determined by proportional allotment; they are shown in Table 4. The DMAPP-derived moiety of **1** was labeled with 81—84% of the total radioactivity incorporated into **1** in the administration of leucine-U-^{14}C and with 64—70% of it in the case of valine-U-^{14}C, whereas the DMAPP-derived moiety of **1** biosynthesized from MVA-2-^{14}C was labeled with less than 32% of the total activity.

In order to confirm the contrasted localization of the radioactivity on the IPP- and DMAPP-derived moieties between the incorporations of leucine and mevalonate, a mixture of leucine-4,5-^{3}H and MVA-2-^{14}C was fed to the plant to give a ^{3}H- and ^{14}C-labeled sample of **1**. The linalool (**1**) was then degraded to levulinic acid and acetone in the same manner as above. The tracer originating from leucine-4,5-^{3}H would be located on the C-4 and C-9 and the C-8 and C-10 carbon atoms; the former pair of carbon atoms constitutes a part of the IPP-derived moiety, and the latter, a part of the DMAPP-derived moiety. On the other hand, the tracer originating from MVA-2-^{14}C is located at the C-4 and the C-8 carbon atoms, which reside on the IPP- and DMAPP-derived moieties respectively. In the incorporation of the mixture of ^{3}H-labeled leucine and ^{14}C-labeled MVA, therefore, all the radioactivities located on the DMAPP- and IPP-derived moieties would appear in molecules of acetone and levulinic acid respectively. The distributions of the radioactivity of these tracers and the ^{3}H/^{14}C ratio of the radioactivity in molecules of the degradation products are shown in Table 5. Although the ^{3}H/^{14}C ratio in the whole molecule of **1** was 0.77, the ratios in the IPP- and DMAPP-derived moieties were 0.45 and 1.18 respectively. This fact indicates that the distribution of ^{3}H originating from leucine was greater in the DMAPP-derived moiety than in the IPP-derived moiety, whereas the distribution of ^{14}C originating from MVA was greater in the IPP-derived moiety than in the DMAPP-derived moiety. Thus, the experiment of the simultaneous feeding of ^{3}H-labeled leucine and ^{14}C-labeled MVA has firmly established the occurrence of the contrasted unbalanced distribution of radioactivity in the IPP- and DMAPP-derived moieties of the monoterpenoids when leucine and MVA are separately incorporated into the monoterpenoids.[3-6,14-17]

Table 5. Radioactivity in linalool (**1**) and its degradation products after uptake of a mixture of dl-leucine-4,5-^{3}H and dl-MVA-2-^{14}C to *C. camphora*

Compound (carbons originating from **1**)	Specific radioactivity		^{3}H/^{14}C ratio
	^{3}H dpm/mmol	^{14}C dpm/mmol	
Linalool (**1**) (C-1—C-10)	2.18×10^{3}	2.85×10^{3}	0.77
Levulinic acid (C-3—C-6 and C-9)	0.74×10^{3}	1.66×10^{3}	0.45
Acetone (C-7, C-8, and C-10)	1.43×10^{3}	1.21×10^{3}	1.18

*The Distribution of Radioactivity in Geraniol (**2**) and Citronellol (**3**) Biosynthesized from ^{14}C-Labeled Leucine, Valine, and MVA.* Radioactive samples of geraniol (**2**) and citronellol (**3**), resulting from the uptake of leucine-U-^{14}C, valine-U-^{14}C, and MVA-2-^{14}C, were subjected to permanganate-periodate oxidation. Geraniol (**2**) was degraded to levulinic acid containing the C-3—C-6 and C-9 carbon atoms and to acetone containing the C-7, C-8, and C-10 carbon atoms. Citronellol (**3**) was degraded to 6-hydroxy-4-methylhexanoic acid (**6**) containing the C-1—C-6 and C-9 carbon atoms and to acetone containing the C-7, C-8, and C-10 carbon atoms. The radioactivities of these compounds are listed in Tables 6 and 7. The distribution of the radioactivity of the ^{14}C-tracer in the IPP- and DMAPP-derived moieties of **2** and **3** were determined by the proportional allotment in the same manner as in the case of **1**; they are shown in Table 4. The uptake of the radioisotopically labeled amino acids resulted in the location of 72—88% of the total radioactivities on the DMAPP-derived moiety, whereas the predominant radioactivity resided on the IPP-derived moiety in the uptake of the ^{14}C-labeled MVA.

*The Distribution of Radioactivity in Linalool (**1**), Geraniol (**2**), and Citronellol (**3**) Biosynthesized from ^{14}C-Labeled Alanine, Acetate, and MVA.* The distribution of radioactivity in the IPP- and DMAPP-derived moieties of **1**, **2**, and **3**, biosynthesized from alanine-2-^{14}C,

acetate-2-^{14}C, and MVA-2-^{14}C, was determined by subjecting them to degradation as follows. The oxidation of **1** with permanganate-periodate gave levulinic acid, acetone, and formaldehyde, which contain the C-3—C-6 and C-9 carbon atoms, the C-7, C-8, and C-10 carbon atoms, and the C-1 carbon atom respectively. A part of the sample of levulinic acid was further degraded by an iodoform reaction to iodoform containing the C-9 carbon atom and to succinic acid containing the C-3—C-6 carbon atoms. Also, **1** was, on partial hydrogenation, converted to 1,2-dihydrolinalool (**4**), which was then degraded to 4-methyl-4-hexanolide (**5**) and acetone by permanganate-periodate oxidation. Table 8 shows the radioactivities of **1** and these degradation products. By oxidation with this reagent, geraniol (**2**) was degraded to levulinic acid and acetone, and citronellol (**3**), to 6-hydroxy-4-methylhexanoic acid (**6**) and acetone. The radioactivities of **2** and **3** and the degradation products are shown in Tables 6 and 7.

Table 8 indicates that 22% of the radioactivity due to the tracer originating from alanine-2-^{14}C is located on the C-1 carbon atom of **1** and 26% on the portion composed of the C-7, C-8, and C-10 carbon atoms, while the C-9 carbon atom is unlabeled. These results indicate that the tracer from alanine-2-^{14}C resides on the C-1, C-3, C-5, and C-7 carbon atoms. Tables 6 and 7 indicate that the labeling pattern of

2 and **3** is the same as that of **1**. In the uptake of alanine-2-^{14}C, therefore, the radioactivity of the DMAPP-derived moiety (C-5—C-8 and C-10) of **1**, **2**, and **3** is double that of acetone. On the other hand, the radioactivity of the IPP-derived moiety (C-1—C-4 and C-9) of **1** and **2** was evaluated by doubling the difference between the radioactivities of levulinic acid and acetone; in addition, the radioactivity of the IPP moiety of **1** was evaluated by deducting the radioactivity of acetone from that of 4-methyl-4-hexanolide (**5**). With respect to **3**, the radioactivity of its IPP-derived moiety was evaluated by deducting the radioactivity of acetone from that of 6-hydroxy-4-methylhexanoic acid (**6**). In the uptake of acetate-2-^{14}C, it has been well established that the tracer resides on the C-2, C-4, C-6, and C-8—C-10 carbon atoms of the acyclic monoterpenoids.[24-27] Taking this labeling pattern into consideration, the distribution of radioactivity in the IPP- and DMAPP-derived moieties of **1**, **2**, and **3** was evaluated by the proportional allotment of the radioactivities of acetone and levulinic acid in a manner similar to that described above.

On the basis of the specific radioactivities of the IPP- and DMAPP-derived moieties determined as above, the distribution of radioactivity in these moieties was evaluated; it is shown in Table 4. The incorporation of ^{14}C-labeled alanine and acetate into geraniol (**2**) and citronellol (**3**) resulted in the preferential location of radioactivity on the IPP-derived moiety, similarly to the incorporation of ^{14}C-labeled MVA, but in opposition to the incorporation of ^{14}C-labeled leucine and valine. The localization of radioactivity in linalool (**1**) biosynthesized from ^{14}C-labeled alanine was predominant on its IPP-derived moiety, but when **1** was biosynthesized from ^{14}C-labeled acetate, the imbalance of the distribution of radioactivity on the IPP- and DMAPP-derived moieties was very small.

Discussion

The previous reports[3,9] described that leucine and valine are not precursors for the monoterpenoid biosynthesis in higher plants because of their negligible incorporation into monoterpenoids. However, it has been found that the radioisotopically labeled leucine and valine are surely incorporated into monoterpenoids, though the incorporation is at a low level, as is shown in Tables 1 and 2. The low incorporation of the amino acids may be explained in terms of the operation of several factors: (i) the radioactivity of the amino acids is scattered into other metabolites rather than the monoterpenoids, (ii) there is a great pool of the amino acids, so that their radioactivity is diluted, and (iii) the low permeation of the amino acids into the biosynthetic site of monoterpenoids causes the low incorporation.

The DMAPP-derived moiety of the monoterpenoids, **1**, **2**, and **3**, biosynthesized from leucine-U-^{14}C and valine-U-^{14}C was labeled with more than 64% of the incorporated tracers, whereas this moiety of the monoterpenoids biosynthesized from MVA-2-^{14}C contained less than 32% of the tracers, as is shown in Table 4. If the monoterpenoids are biosynthesized from the amino acids *via* MVA, the distribution pattern will be similar to the pattern in the monoterpenoids biosynthesized from MVA-2-^{14}C. This indicates that, although leucine and valine have a carbon-skeleton similar to that of MVA, these amino acids are incorporated into the monoterpenoids, not *via* MVA, but by an alternate route. On the other hand, the distribution pattern in the monoterpenoids biosynthesized from alanine-2-^{14}C was similar to that in the monoterpenoids biosynthesized from MVA-2-^{14}C and acetate-2-^{14}C. This indicates that alanine is incorporated into the monoterpenoids by a route *via* MVA. Thus, it is likely that administered leucine and valine participate in the biosynthesis of the monoterpenoids by their direct conversion to DMAPP through an alternate route rather than through the mevalonate pathway, whereas administered alanine is first metabolized to acetyl-CoA, which then constructs preferentially the IPP-derived moiety of the monoterpenoids *via* MVA.

Experimental

The radioisotopically labeled monoterpenoids and their degradation products were purified to a constant specific radioactivity by a combination of preparative TLC and/or repeated recrystallization of the crystalline derivatives in every case that these could be prepared. The melting points and spectral data of all the products agreed with those of authentic samples.[22,23] The TLC analyses were carried out using silica-gel plates (Kieselgel 60 G; 0.25 mm thick) and the following five kinds of solvents: (i) hexane/EtOAc=9/1, (ii) hexane/EtOAc=4/1, (iii) hexane/EtOAc=1/1, (iv) $CHCl_3$, and (V) MeOH/acetone/formic acid=70/10/1. Spots on the plates were visualized by vaniline-H_2SO_4 spraying and subsequent heating to 120 °C. The preparative TLC was performed on silica-gel plates (Kieselgel 60 G; 0.75 mm thick) or on 3% $AgNO_3$–silica-gel plates (Kieselgel 60 G; 0.75 mm thick) with the above-described solvents. The GLC analyses were performed on an instrument equipped with FID and a glass column (2.0 m×3 mm) packed with either 2% OV-17, 15% DEGS, or 10% PEG-20M on Chromosorb W (80—100 mesh). The radioactivity was measured on a liquid-scintillation spectrometer using Bray's scintillation solvent.[19] The counting error was within 2%.

Plant Materials and Labeled Precursors. The leaves of *Cinnamomum camphora* Sieb. var. *linalooliferum* Fujita, which had been grown outdoors on the campus of Hiroshima University, produced an essential oil containing up to 90% (wt) of linalool (**1**) in August. The linalool (**1**) isolated showed $[\alpha]_D^{25}$ −19.3° (*c* 13.3, $CHCl_3$) and n_D^{25} 1.4603. Each top branch used for the feeding experiments was *ca.* 10 cm in length and *ca.* 5 g in fresh wt. The leaves of *Pelargonium roseum* Bourbon, which had been wintered indoors and grown outdoors from spring to autumn, produced an essential oil containing 35—40% of geraniol (**2**) and 25—30% of citronellol (**3**) in August. The isolated geraniol (**2**) and citronellol (**3**) showed n_D^{25} values of 1.4760 and 1.4551 respectively. Each top branch of the plant used for feeding experiments was *ca.* 15 cm long and *ca.* 10 g in fresh wt.

DL-Mevalonic-2-^{14}C acid (MVA-2-^{14}C) (7.16 mCi/mmol), L-leucine-U-^{14}C (Leu-U-^{14}C) (251 mCi/mmol), L-valine-U-^{14}C (Val-U-^{14}C) (225 mCi/mmol), DL-alanine-2-^{14}C (Ala-2-^{14}C) (12 mCi/mmol), and sodium acetate-2-^{14}C (58 mCi/

mmol) used for the feeding experiments were products of the Daiichi Pure Chemicals Co., Ltd., Tokyo.

Administration of the Labeled Precursors and Isolation of the Radioisotopically Labeled Monoterpenoids. The labeled precursor, dissolved in a phosphate-buffered solution (0.5 cm^3; pH 7.4), was fed to the fresh cuttings (50 g in total wt) through their cut-stem in a glass tube, and then distilled water was soaked into the cuttings several times to complete the uptake of the labeled precursor. At the end of the metabolic periods shown in Tables 1 and 2, the cuttings were steam-distilled. The distillate was extracted with four 50-cm^3 portions of ether. The combined ether layer was washed with two 50-cm^3 portions of a 5% sodium hydrogencarbonate solution and water, and then dried over anhydrous sodium sulfate. The removal of the solvent from the ether layer at temperature below 40 °C afforded a crude essential oil. The essential oil (0.6—1.0 g) obtained from *C. camphora* was subjected to preparative TLC with solvent (i) to give linalool (**1**), which was then further purified by TLC. The essential oil (0.15—0.2 g) obtained from *P. roseum* was separated on $AgNO_3$–silica-gel plates with solvent (ii) to give geraniol (**2**) and citronellol (**3**), which were subsequently further purified by TLC with silica-gel plates and solvent (i). The homogeneity of these monoterpene alcohols was confirmed by GLC analyses using a 2% OV-17 column at 100 °C, a 15% DEGS column at 120 °C, and a 10% PEG 20 M column at 120—180 °C, in addition to the examination of the constant specific radioactivity.

For time-course studies of the incorporation of the tracers into the monoterpene alcohols, each precursor was fed to the cuttings of the plant in the same manner as above, and then the cuttings were steam-distilled at appropriate time intervals to give the essential oil. This oil was subjected to isolation of the monoterpene alcohol in the same way as above.

Degradation of Linalool (1). Following the reported procedure of the $KMnO_4$–$NaIO_4$ oxidation,[20] a suspension of linalool (**1**) (350 mg) in a solution of $NaIO_4 \cdot H_2O$ (2.6 g) in water (260 cm^3) was stirred for 10 min at room temp. The mixture was neutralized with sodium carbonate under cooling to 0—10 °C. To the neutralized solution, $KMnO_4$ (250 mg) dissolved in water (15 cm^3) was added drop by drop, and, after which, the mixture was stirred overnight below 10 °C. The mixture, after the reduction of the remaining oxidant with sodium hydrogensulfite, was steam-distilled. The distillate (5 cm^3) was divided into two portions. One portion (2.5 cm^3) was treated with thiosemicarbazide as usual to give acetone thiosemicarbazone (64 mg), which was then purified by a combination of preparative TLC with silica gel and solvent (iii) and repeated recrystallizations; it showed mp and mixed mp 179.0—179.5 °C. The other portion (2.5 cm^3) was added to a solution of dimedone in water to give the bisdimedone derivative of formaldehyde (23 mg; mp and mixed mp 187—188 °C).[28]

The steam-distillation residue was concentrated to 100 cm^3, acidified with diluted H_2SO_4, and extracted, after the reduction of the remaining oxidant with sodium hydrogensulfite, with ether using a liquid-liquid continuous extractor to give an acidic product. This acidic product was subjected to preparative TLC with silica gel and solvent (v) to give levulinic acid (79 mg). This acid, on methylation with CH_2N_2, was converted to methyl levulinate (75 mg), which was subsequently further purified by TLC with silica gel and solvent (ii). The purified levulinate was divided into two portions. One portion (25 mg) was treated with an aqueous solution of thiosemicarbazide to give methyl levulinate thiosemicarbazone (38 mg; mp and mixed mp 140—141 °C). The other portion (25 mg) was subjected to hypoiodite oxidation to give iodoform (17 mg; mp and mixed mp 119—120 °C) and succinic acid (7 mg; mp and mixed mp 186—188 °C). The radioactivities of these products are shown in Tables 5 and 8.

Degradation of Geraniol (2). Radioactive geraniol (**2**) (20 mg) isolated was diluted with the carrier (280 mg) and then degraded to acetone and levulinic acid with $KMnO_4$–$NaIO_4$ in the same manner as above. The acetone was converted to the thiosemicarbazone derivative (72 mg; mp and mixed mp 179—180 °C). The levulinic acid (110 mg) was converted to methyl levulinate (86 mg), which was then transformed to the thiosemicarbazone derivative (116 mg; mp and mixed mp 140—141 °C). Table 6 shows the radioactivities of geraniol and these products.

Degradation of Citronellol (3). Radioactive citronellol (**3**) (20 mg) isolated was diluted with the carrier (300 mg) and degraded to acetone and 4-methyl-6-hydroxyhexanoic acid (**6**) by $KMnO_4$–$NaIO_4$ oxidation in the same manner as above. The acetone was converted to the thiosemicarbazone derivative (68 mg; mp and mixed mp 179—180 °C). The 4-methyl-6-hydroxyhexanoic acid (**6**)[22] [110 mg; IR (liq.) 3500—2900 and 1710 cm^{-1} (COOH)] was, on treatment with CH_2N_2, converted to its methyl ester [IR (liq.) 3450 (OH) and 1741 cm^{-1} (ester C=O); ^{1}H-NMR δ=0.93 (3H, d, J=5.8 Hz, CH_3), 2.33 (2H, bt, J=6.0 Hz, $-\underline{CH_2}-COOCH_3$), 3.65 (3H, s, $COOCH_3$), and 3.67 (2H, t, J=6.1 Hz, $-\underline{CH_2}OH$); MS (70 eV), m/z (rel intensity), 160 (M^+, 22), 142 (12), 129 (23), 87 (88), 74 (83), 69 (84), 55 (100), 43 (73), and 41 (95)]. The specific radioactivities of citronellol and the degradation products are shown in Table 7.

Degradation of Dihydrolinalool (4). Purified, radioactive linalool (**1**) (350 mg), dissolved in absolute MeOH (3 cm^3), was selectively hydrogenated in the presence of Adams PtO_2 (4 mg). The purification of the reaction mixture by preparative TLC, using $AgNO_3$–silica-gel plates and solvent (i), gave 1,2-dihydrolinalool (**4**) (300 mg), which was then subjected to $KMnO_4$–$NaIO_4$ oxidation as described above. The reaction mixture was steam-distilled. The distillate (5 cm^3) was divided into two portions. One portion (2.5 cm^3) was treated with an aqueous solution of thiosemicarbazide as usual to give acetone thiosemicarbazone (105 mg; mp and mixed mp 179—180 °C). Another portion (2.5 cm^3) was subjected to hypoiodite oxidation to give iodoform (80 mg; mp and mixed mp 119—120 °C). On the other hand, a steam-distillation residue was concentrated to 100 cm^3, acidified with 5% HCl, and extracted with ether to give 4-methyl-4-hexanolide (**5**)[23] [80 mg; IR (liq.) 1765 (C=O of γ-lactone) and 1238 and 1161 cm^{-1} (C–O of the lactone); ^{1}H-NMR ($CDCl_3$) δ=0.97 (3H, t, J=7.0 Hz, CH_3), 1.38 (3H, s, CH_3), and 1.73 (2H, q, J=7.0 Hz, $-CH_2-$)]. The hexanolide (**5**), dissolved in EtOH (1 cm^3), was refluxed with 1 M† NaOH (1.5 cm^3) for 1 h. To this reaction mixture, after neutralization, we added *S*-benzylthiouronium urea (160 mg) dissolved in EtOH (1 cm^3) to give the *S*-benzylthiouronium salt (150 mg; mp 132—133 °C). The radioactivities of linalool and its degradation products are shown in Tables 3 and 8.

The author wishes to express his thanks to Professor Takayuki Suga for his continuing guidance and encouragement, to Dr. Toshifumi Hirata for his useful discussions, and to Messrs. Yoshitaka Nakao and Hitoshi Okita for their co-work in the experiment. The author also would like to thank the Takasago

† 1 M=1 mol dm^{-3}.

Perfumery Co., Ltd., for a gift of the samples of linalool, geraniol, and citronellol, and the Soda Perfumery Co., Ltd., for a gift of the plants of *C. camphora* and *P. roseum*.

Synthesis of 7-Alkylidene-5-oxadispiro[2.0.4.4]dodecan-6-ones

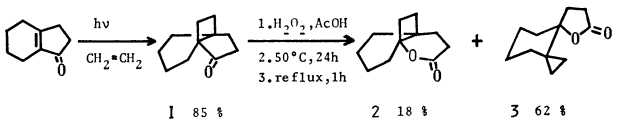
Kiyomi KAKIUCHI,* Takehito YONEI, Yoshito TOBE, and Yoshinobu ODAIRA
Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received February 9, 1981)

7-Alkylidene-5-oxadispiro[2.0.4.4]dodecan-6-ones, having a cyclopropane ring, were synthesized by the α-alkylidenation of easily available 5-oxadispiro[2.0.4.4]dodecan-6-one. Also, α-alkylidene-γ-butyrolactones, containing an additional hydroxyl group, were prepared. The screening of the biological activities of these γ-lactones gave the interesting results. For instance, α-isopropylidene-γ-lactone exhibited the antiarrhythmia activity *in vivo*.

Recently, α-methylene-γ-butyrolactones have been the subject of extensive research because a large number of sesquiterpene lactones, containing α-methylene-γ-butyrolactone moiety, have been shown to exhibit marked antitumor, cytotoxic, and other biological activities attributed to this moiety.[1a,b] The biological activities of these lactones are apparently driven from significant chemical affinity of this moiety for the thiol groups of sulfhydryl enzymes.[1c-f] In particular, interest in α-methylene-γ-butyrolactones as medical agents has been stimulated by the possibility that some of these might show enough selective toxicity against neoplastic cells to be of the therapeutic value as anticancer agents.[1b,c,g] Although the enone component is essential for the biological activities, there are additional factors which may enhance these properties. These enhancement factors include the presence of some substituents such as hydroxyl group or epoxy ring which may facilitate the addition of sulfide anion or proton transfer at some intermediate stage in the addition involving the thiol groups of enzymes.[1a,h] On the other hand, it has been well known that some natural products, having a cyclopropane ring, display remarkable biological activities.[2] For example, illudin S, containing a spiro cyclopropane ring, is well examined about antitumor activity.[2b] Previously, we reported on the synthesis of 5-oxadispiro-[2.0.4.4]dodecan-6-one (**3**) (γ-lactone), containing a spiro cyclopropane ring, by the acid catalyzed or thermally induced cyclobutyl-cyclopropylcarbinyl rearrangement of 2-oxatricyclo[4.4.2.0^{1,6}]dodecan-3-one (**2**) (δ-lactone).[3] From the above point of view, the γ-lactone **3** may be advantageously taken as a useful intermediate for the synthesis of a new type of α-alkylidene-γ-butyrolactones. As part of the studies on the structure-biochemical activity relationship,[4] we wish to describe here the synthesis of several 7-alkylidene-5-oxadispiro[2.0.4.4]dodecan-6-ones (**4a**—**h**) from the γ-lactone **3** and the interesting results on the screening of the biological activities of the α-alkylidene-γ-lactones *in vivo*.

Results and Discussion

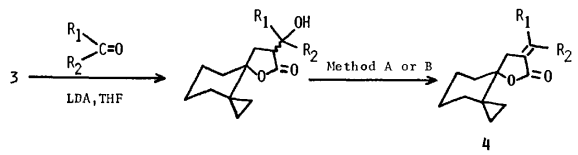
Propellalactone **2** was prepared by the Baeyer-Villiger oxidation of tricyclo[4.3.2.0^{1,6}]undecan-7-one (**1**), easily derived from the photocycloaddition of bicyclo[4.3.0]non-1(6)-en-7-one to ethylene as described previously.[6] In practice, however, the reaction mixture after the above oxidation without isolation of propellalactone **2** was heated at 50 °C for 1 d and then refluxed gently for 1 h to give a 78:22 ratio of dispiro-γ-lactone **3** and propellalactone **2** in 80% yield. The γ-lactone **3** was readily isolated from the reaction mixture by column chromatography on silica gel (Scheme 1).



1 85 % 2 18 % 3 62 %

Scheme 1.

α-Alkylidenation of the γ-lactone **3** was carried out according to the usual method[7] comprised of α-hydroxyalkylation and subsequent dehydration as shown in Scheme 2. To a solution of lithium diisopropylamide (LDA) in anhydrous tetrahydrofuran (THF) at −78 °C was slowly added a solution of the γ-lactone **3** in anhydrous THF and hexamethylphosphoric triamide (HMPT). After stirring at −78 °C for 30 min, the carbonyl compound was added and the mixture was stirred for 2 h. In the case of α-hydroxymethylation, gaseous formaldehyde was passed into the reaction mixture at −20 °C under nitrogen stream. In every case, α-hydroxyalkylation proceeded smoothly to afford the desired products in 80—100% yields. The crude products of α-hydroxyalkyl-γ-lactones were subjected to the next reaction without isolation. Next, the dehydration of the α-hydroxyalkyl-γ-lactones was carried out by means of two methods, depending upon the type of the hydroxyl group. Namely, when the hydroxyl group was primary or secondary, a solution of the alcohol in dry pyridine was treated with methanesulfonyl (Ms) chloride at 5 °C for 9 h, and the obtainable mesylate was dissolved in dry benzene containing 1.4 equivalent of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and then stirred at room temperature for 6 h (method A).[7b] On the other hand, when the hydroxyl group was tertiary, thionyl chloride was added to a solution of the alcohol in dry pyridine and dry dichloromethane and the reaction mixture was stirred at 0 °C for 30 min and then at room temperature for 4 h (method B).[8] After usual work-up, the crude product of 7-alkylidene-5-oxadispiro[2.0.4.4]dodecan-6-ones (**4a**—**f**) was obtained and purified by column chromatography on silica gel. The use of aldehydes as the carbonyl compound in the α-hydroxyalkylation resulted in the formation of *E*/*Z* stereoisomers of the γ-lactones (**4b**—**e**). They were, however, separated successfully by the careful chromatography. The results are summarized in Table 1.



Method A: 1. MsCl, Pyridine, 2. DBU, PhH.
Method B: $SOCl_2$, Pyridine, CH_2Cl_2.

Scheme 2.

TABLE 1. SYNTHESIS OF α-ALKYLIDENE-γ-BUTYROLACTONES

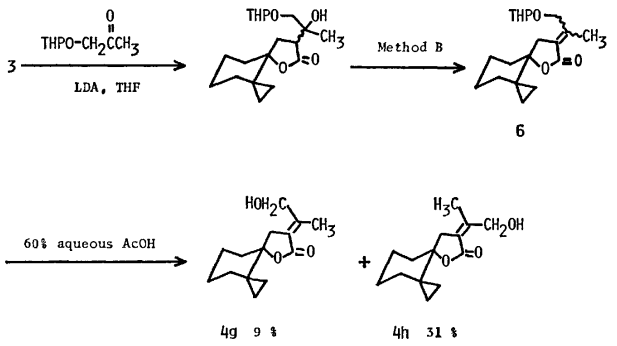
Carbonyl compd	α-Alkylidene-γ-butyrolactone	R_1	R_2		Yield/%[a]
Formaldehyde	**4a**	H	H		77[b]
Acetaldehyde	**4b**	CH_3	H	(*E*)	54
	4c	H	CH_3	(*Z*)	7
Propionaldehyde	**4d**	C_2H_5	H	(*E*)	30
	4e	H	C_2H_5	(*Z*)	20
Acetone	**4f**	CH_3	CH_3		52

a) Isolated yield based on **3**. b) Determined by ^1H NMR analysis.

It was easy to establish the stereochemistry around the olefinic part of the γ-lactones **4b**—**e** by the comparison of the ^1H NMR chemical shifts of the vinyl protons of **4b**—**e** with those of α-alkylidene-γ-butyrolactones described in literature.[9] The chemical shifts of the olefinic protons (6.57 and 6.11 ppm for *E* and *Z* isomers, respectively) were the most remarkable point to descriminate between the geometrical isomers of α-ethylidene-γ-lactones (**4b**) and (**4c**). Similarly, the observed values of the olefinic protons (6.48 and 6.00 ppm) of α-propylidene-γ-lactones (**4d**) and (**4e**) distinguished one from the other.

Furthermore, we tried to synthesize the α-alkylidene-γ-lactones having a hydroxyl group which was expected to enhance the reactivity of the conjugated lactone toward biological nucleophiles as mentioned earlier. The tetrahydropyran-2-yl (THP) ether of hydroxyacetone (**5**) was used for α-hydroxyalkylation of the γ-lactone **3**. Dehydration by the method B gave the mixture of *E*/*Z* isomers of the THP–ether (**6**), which was treated with 60% aqueous acetic acid at 45 °C for 3 h. After usual work-up followed by purification by column chromatography on silica gel, (*E*)- and (*Z*)-α-(2-hydroxy-1-methylethylidene)-γ-lactones (**4g**) and (**4h**) were obtained in 9% and 31% overall yields from the γ-lactone **3**, respectively (Scheme 3). The distinction in stereochemistry between two isomers was accomplished by the comparison of the chemical shifts of the methyl groups in ^1H NMR spectra (2.16 and 1.90 ppm for *E* and *Z* isomers, respectively) with those of α-isopropylidene-γ-lactone (**4f**), since the methyl groups of **4f** located in *syn*- and *anti*-positions toward the carbonyl group show resonances at 2.20 and 1.84 ppm, respectively.

The screening of biological activities of a series of the present α-alkylidene-γ-butyrolactones **4a**, **4b**, **4d**—**f**, and **4h** gave attractive results. Concerning the antitumor activity of these γ-lactones against Sarcoma 180 A *in vivo*, all of them were less active than the famous antitumor antibiotic, Mitomycin C. Interestingly, the other biological activities of these γ-lactones *in vivo*, however, were found out: the antihistamine activity of (*E*)-α-propylidene-γ-lactone **4d**, the antihistamine and the anticholine activities of (*Z*)-α-propylidene-γ-lactone **4e**, the antiarrhythmia activity of α-isopropylidene-γ-lactone **4f**, and the platelet aggregation inhibition activity of (*Z*)-α-(2-hydroxy-1-methylethylidene)-γ-lactone **4h**.



Scheme 3.

In this way, 7-alkylidene-5-oxadispiro[2.0.4.4]dodecan-7-ones **4a**—**h**, having a spiro cyclopropane ring, were synthesized and the interesting results relating to the biological activities of these lactones were given.

Experimental

All melting and boiling points are uncorrected. IR spectra were recorded with a JASCO IR-G spectrometer as liquid film unless otherwise stated. ^1H NMR spectra were obtained on a JEOL JNM-PS-100 instrument using Me_4Si as an internal standard and CCl_4 as a solvent. Mass spectra were measured with a Hitachi RMU-6E spectrometer. Analytical GLC was carried out on a Hitachi 163 gas chromatograph and preparative GLC separation was conducted on a Varian Aerograph 920 gas chromatograph.

Acetaldehyde, propionaldehyde, and hydroxyacetone were distilled prior to use. Acetone was distilled from potassium carbonate before use. Tricyclo[4.3.2.$0^{1,6}$]undecan-7-one (**1**) was prepared in 85% yield by the photocycloaddition of bicyclo[4.3.0]non-1(6)-en-7-one[10] to ethylene in ether (0.4 M†) at −70 °C as described previously.[6]

5-Oxadispiro[2.0.4.4]dodecan-6-one (3). To a solution of 40.7 g (0.248 mol) of **1** in 500 ml of acetic acid was added 20-fold excess of 30% aqueous hydrogen peroxide. The mixture was stirred at room temperature for 7 d and at 50 °C for 1 d, then at gentle reflux for 1 h. The solution was poured into water and extracted with ether. The ethereal extracts were washed with saturated sodium carbonate (Na_2CO_3) solution, brine, and dried over anhydrous sodium sulfate (Na_2SO_4). The solvent was evaporated *in vacuo* to give 35.7 g of 2-oxatricyclo[4.4.2.$0^{1,6}$]dodecan-3-one (**2**) and γ-lactone **3** in a ratio 22:78 (by GLC analysis) (80%). The γ-lactone **3** was isolated by column chromatography (SiO_2, 8% ether–petroleum ether). Spectral and analytical data were already described.[3b]

General Procedure for Synthesis of α-Alkylidene-γ-butyrolactones (4a—f). *α-Hydroxyalkylation*: A solution of diisopropylamine (2 mmol) in dry THF (1.5 ml) cooled to −78 °C was treated dropwise with butyllithium (1.5 mmol) in hexane under nitrogen atmosphere. After stirring at −78 °C for 1 h, a solution of the γ-lactone **3** (1 mmol) in dry THF (0.2 ml) and dry HMPT (0.1 ml) was added dropwise *via* a

† 1 M = 1 mol dm^{-3}.

syringe. After addition was complete, stirring was continued at −78 °C for 30 min, then a carbonyl compound (1 mmol) was added *via* a syringe and the mixture was stirred for 2 h. The reaction was quenched by saturated ammonium chloride solution and the mixture was extracted with ether. The organic extracts were washed with 5% HCl, saturated sodium hydrogencarbonate ($NaHCO_3$) solution, brine, and dried (Na_2SO_4). The solvent was removed *in vacuo* to give the crude alcohol product.

Dehydration: *Method A.* The above alcohol (1 mmol) was dissolved in dry pyridine (2 ml) and treated at 0—5 °C with methanesulfonyl chloride (3 mmol). After stirring at 5 °C for 9 h, an ice-water was added and the mixture was extracted with ether. The ethereal extracts were washed with 5% HCl, saturated $NaHCO_3$ solution, and brine. After drying (Na_2SO_4), the solvent was evaporated under reduced pressure to give the crude mesylate. The crude mesylate (1 mmol) was dissolved in dry benzene (2.0 ml) containing DBU (1.4 mmol) and the mixture was stirred at room temperature for 6 h. Water was added and the product was extracted with ether. The organic layer was washed with 5% HCl, saturated $NaHCO_3$ solution, and brine. After drying (Na_2SO_4), the solvent was removed *in vacuo* leaving the crude α-alkylidene-γ-lactones.

Method B. Thionyl chloride (1.2 mmol) was added dropwise to a solution of the crude alcohol (1 mmol) in dry pyridine (0.5 ml) and dry CH_2Cl_2 (1.5 ml). The reaction mixture was stirred at 0 °C for 30 min and then at room temperature for 4 h. After addition of a few pieces of ice, the mixture was extracted with CH_2Cl_2. The extracts were washed with 5% HCl, water, and dried (Na_2SO_4). The solvent was evaporated under reduced pressure to give the crude α-alkylidene-γ-lactones. Analytical samples of the γ-lactones were obtained by preparative GLC.

*7-Methylene-5-oxadispiro[2.0.4.4]dodecan-6-one (**4a**).* The reaction of **3** (829 mg, 4.6 mmol) and formaldehyde, generated by depolymerization of paraformaldehyde (3.5 g) at 160 °C (bath temperature) and passed into the reaction mixture at −20 °C under nitrogen stream, gave the crude α-hydroxymethyl-γ-lactone (873 mg, 90%: IR 3450, 1750 cm^{-1}). Dehydration of the alcohol by method A (the mesylate: IR 1750, 1350, 1160 cm^{-1}) gave α-methylene-γ-lactone **4a** (684 mg). Overall yield based on **3** was 77% (determined by ^1H NMR analysis). **4a**: IR 3050, 1750, 1660 cm^{-1}; NMR δ 0.10—1.00 (m, 4H), 1.23—2.00 (m, 8H), 2.68 (t, J=2.8 Hz, 2H), 5.50 (t, J=2.6 Hz, 1H), 6.10 (t, J=2.6 Hz, 1H); MS *m/e* 192 (M^+). Found: C, 74.59; H, 8.56%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%.

*(E)- and (Z)-7-Ethylidene-5-oxadispiro[2.0.4.4]dodecan-6-one (**4b**) and (**4c**).* The reaction of **3** (5.7 g, 31.6 mmol) and acetaldehyde (1.4 g, 31.6 mmol) gave the crude α-(1-hydroxyethyl)-γ-lactone (7.3 g, quantitatively: IR 3450, 1740 cm^{-1}). Dehydration of the alcohol by method A (the mesylate: IR 1750, 1350, 1160 cm^{-1}) gave the mixture of *E*-isomer **4b** and *Z*-isomer **4c** which were separated by column chromatography (SiO_2, 3% ether–petroleum ether). **4b** (54% from **3**): IR 3050, 1750, 1670 cm^{-1}; NMR δ 0.10—1.00 (m, 4H), 1.12—2.04 (m, 11H), 2.55 (m, 2H), 6.57 (m, 1H); MS *m/e* 206 (M^+). Found: C, 75.43; H, 8.76%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%. **4c** (7% from **3**): IR 3050, 1740, 1660 cm^{-1}; NMR δ 0.10—1.00 (m, 4H), 1.12—2.00 (m, 8H), 2.10 (m, 3H), 2.62 (m, 2H), 6.11 (m, 1H); MS *m/e* 206 (M^+). Found: C, 75.37; H, 8.89%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%.

*(E)- and (Z)-7-Propylidene-5-oxadispiro[2.0.4.4]dodecan-6-one (**4d**) and (**4e**).* The reaction of **3** (6.0 g, 33.3 mmol) and propionaldehyde (2.3 g, 33.3 mmol) gave the crude α-(1-hydroxypropyl)-γ-lactone (6.4 g, 80%: IR 3450, 1740 cm^{-1}). Dehydration of the alcohol by method A (the mesylate: IR 1740, 1350, 1160 cm^{-1}) gave the mixture of *E*-isomer **4d** and *Z*-isomer **4e** which were separated by column chromatography (SiO_2, 3% ether–petroleum ether). **4d** (30% from **3**): IR 3050, 1740, 1670 cm^{-1}; NMR δ 0.10—1.00 (m, 4H), 1.10 (t, 3H), 1.28—2.00 (m, 8H), 2.18 (m, 2H), 2.56 (m, 2H), 6.48 (m, 1H); MS *m/e* 220 (M^+). Found: C, 76.03; H, 9.21%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%. **4e** (20% from **3**): IR 3050, 1735, 1660 cm^{-1}; NMR δ 0.10—1.00 (m, 4H), 1.03 (t, 3H), 1.16—2.00 (m, 8H), 2.64 (m, 4H), 6.00 (m, 1H); MS *m/e* 220 (M^+). Found: C, 76.14; H, 9.24%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

*7-Isopropylidene-5-oxadispiro[2.0.4.4]dodecan-6-one (**4f**).* The reaction of **3** (5.0 g, 27.8 mmol) and acetone (1.6 g, 27.8 mmol) gave the crude α-(1-hydroxy-1-methylethyl)-γ-lactone (6.4 g, 97%: IR 3450, 1735 cm^{-1}). Dehydration of the alcohol by method B gave the crude α-isopropylidene-γ-lactone **4f** which was purified by column chromatography (SiO_2, 5% ether–petroleum ether) to afford 3.2 g of **4f** (52% from **3**): mp 70—71 °C (recrystallized from petroleum ether); IR (KBr) 3050, 1730, 1650 cm^{-1}; NMR δ 0.10—1.00 (m, 4H), 1.15—1.80 (m, 8H), 1.84 (m, 3H), 2.20 (m, 3H), 2.58 (m, 2H); MS *m/e* 220 (M^+). Found: C, 76.11; H, 9.28%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

*Tetrahydropyran-2-yl Acetonyl Ether (**5**).* A solution of hydroxyacetone (10 g, 0.135 mol) in 200 ml of dry CH_2Cl_2 containing 1.0 g of *p*-toluenesulfonic acid was treated at 0 °C with 3,4-dihydro-2*H*-pyran (13.6 g, 0.162 mol). After stirring at 0 °C for 3.5 h, the reaction was quenched by the addition of saturated $NaHCO_3$ solution and the mixture was extracted with CH_2Cl_2. The organic layer was washed with water, dried (Na_2SO_4), and concentrated *in vacuo* leaving the crude THP-ether **5**. Column chromatography (SiO_2, 20% ether–petroleum ether) followed by distillation gave 12.0 g of pure **5** in 57% yield: bp 64—66 °C/267 Pa; IR 1710, 1110, 1060, 1010 cm^{-1}; NMR δ 1.36—2.00 (m, 6H), 2.10 (s, 3H), 3.52 (m, 1H), 3.80 (m, 1H), 4.00 (m, 2H), 4.58 (t, 1H); MS *m/e* 156 (M^+−2). Found: C, 60.56; H, 8.99%. Calcd for $C_8H_{14}O_3$: C, 60.74; H, 8.92%.

*(E)- and (Z)-7-(2-hydroxyisopropylidene)-5-oxadispiro[2.0.4.4]dodecan-6-one (**4g**) and (**4h**).* The reaction of **3** (6.0 g 33.3 mmol) and **5** (5.3 g, 33.3 mmol) gave the crude alcohol (11.2 g, quantitatively: IR 3450, 1750, 1010 cm^{-1}). Dehydration of the alcohol by method B afforded the crude THP-ether (**6**) (10.1 g, 95% from **3**: IR 3050, 1720, 1650, 1010 cm^{-1}). The above ether **6** was dissolved in 100 ml of 60% aqueous acetic acid and the solution was stirred at 45 °C for 3 h. The reaction mixture was neutralized with saturated $NaHCO_3$ solution and the mixture was extracted with CH_2Cl_2. The organic layer was washed with water, dried (Na_2SO_4), and concentrated *in vacuo* leaving the mixture of *E*-isomer **4g** and *Z*-isomer **4h**. Separation by column chromatography (SiO_2, 20% ether–petroleum ether) gave 0.7 g of **4g** and 2.4 g of **4h** (9% and 31% from **3**, respectively). **4g**: IR 3400, 3050, 1730, 1650 cm^{-1}; NMR δ 0.10—0.90 (m, 4H), 1.08—2.04 (m, 8H), 2.16 (m, 3H), 2.64 (m, 2H), 2.74 (broad s, 1H), 4.10 (s, 2H); MS *m/e* 236 (M^+). Found: C, 70.94; H, 8.58%. Calcd for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53%. **4h**: IR 3400, 3050, 1720, 1650 cm^{-1}; NMR δ 0.10—0.95 (m, 4H), 1.08—1.85 (m, 8H), 1.90 (m, 3H), 2.62 (m, 2H), 3.48 (broad s, 1H), 4.36 (s, 2H); MS *m/e* 236 (M^+). Found: C, 70.95; H, 8.57%. Calcd for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53%.

We thank the Kyowa Hakko Co., Ltd for the

screening of the biological activities.

Dynamic NMR as a Nondestructive Method for the Determination of Rates of Dissociation. III. Ionic Dissociation of α-Chlorodibenzyl Sulfide[1)]

Atsushi Shimizu, Yoshitaka Sakamaki, Kazufumi Azuma, Hiroshi Kihara, Nobuo Nakamura, and Michinori Ōki*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 10, 1981)

Rates of dissociation of α-chlorodibenzyl sulfide have been determined by dynamic NMR technique. Examination of the rates at various concentrations of chloroform-*d* solutions has confirmed that the rates are not dependent on concentration, thus establishing that the NMR measurement affords data of unimolecular dissociation. The salt effect seems to be very small since addition of tetraethylammonium bromide hardly affects the rates of dissociation. Rates of dissociation in *o*-dichlorobenzene are smaller than in chloroform-*d*. The main contribution to the decrease in rates is given by the increase in enthalpy of activation, indicating that the hydrogen-bonding ability of chloroform is favorable for ionic dissociation.

Ionization of organic halides is an important process, since it is regarded as the first and rate-determining step in S_N1 type reactions.[2)] Winstein *et al.* were able to analyze the dissociation process into at least three steps: formation of intimate ion pair, solvent-separated ion pair, and free ions.[3)] In solvolytic reactions, any of the ionic species can produce products depending on concentration,[4)] making it difficult to study the earlier stages of ionization by solvolysis.

$$RX \rightleftharpoons R^+X^- \rightleftharpoons R^+ /\!/ X^- \rightleftharpoons R^+ + X^-$$

products products products

Various methods have been worked out in order to clarify the early stages. One is the exchange of a halogen (or a sulfonyloxyl) group which is labeled by an isotope.[5,6)] However, it has a handicap intrinsically in that the rates are measured in the presence of salts, giving rise to the salt effect. Other methods involve racemization of an optically active halide (or sulfonate)[7)] or scrambling or retention of oxygen-18 isotopes in carboxylates[8)] and sulfonates.[9)] These techniques apparently require optical resolution of the substrate and preparation of the isotopically labeled compounds. If a facile method is available, it would help clarify the initial stages of ionization of organic halide to a considerable extent.

We have found that easily ionizable compounds such as 2-chloro-1,3,5-trithiane exhibit a drastic change in line shapes of their NMR spectra, indicating the ionization process of the compounds.[10)] The method has been applied to substituted α-chlorodibenzyl sulfide to show that it is possible to extend the method to ionic dissociation if the compound in question carries diastereotopic protons and a chiral center which is lost on ionization.[11)]

Since the process was followed by the coalescence temperature method[12)] of NMR spectroscopy, only the free energies of activation have been available. Kinetic data at various temperatures would enable us to get further insight into the early stages of ionization; most of earlier works provided kinetic data only at a certain temperature. The concentration *ca.* 0.5 mol L^{-1} utilized in the routine measurements of ^1H NMR spectroscopy might be too high to observe S_N1 type ionization; in the classical methods a lower concentration was used. It is necessary to examine the usual concentration in NMR measurements as regards S_N1 reactions.

We have carried out dynamic NMR measurements of α-chlorodibenzyl sulfide solutions in various concentrations. The line shapes were simulated and activation parameters, ΔH^* and ΔS^*, were obtained. This paper reports the results. The effects of the salts added as well as the solvents on ionic dissociation are discussed.

Experimental

Materials and Solutions. α-Chlorodibenzyl sulfide was prepared by the chlorination of dibenzyl sulfide with *N*-chlorosuccinimide.[11)] Chloroform-*d* or *o*-dichlorobenzene was dried over Molecular Sieves 4A and solutions were prepared in a dry box desiccated with diphosphorus pentaoxide. The solutions were made directly by weighing the sample and the solvent. The concentrations were calculated by using the density of the solvent. Substance to be added to chloroform-*d* solutions was carefully dried either in a vacuum or by means of Molecular Sieves.

^1H NMR Measurements. The spectra were obtained on a Hitachi R-20B spectrometer equipped with a temperature variation accessory for solutions with high concentration, and on a JEOL FX-60 spectrometer equipped with a temperature variation accessory and FT-facilities for solutions with low concentration. Both instruments were operated at 60 MHz. The temperature of the solution was determined by the chemical shift differences of methanol and ethylene glycol protons, at low and high temperatures, respectively, when not directly read by a thermocouple.

Acquisition and Processing of Data. The ^1H NMR spectral line shapes were simulated with a modified Binsch program,[13)] the process being treated as an AB⇌BA exchange. $\Delta\delta_{AB}$ and J_{AB} were obtained by simulating the spectra at temperatures low enough where the rate of exchange is considered to be zero. They were treated as constant throughout the temperature range examined. The T_2 values were obtained from the half band widths of the methine proton signals at given temperatures. The calculated spectra were compared with the observed by visual fitting. The rates of proton spin exchange thus obtained were put into the Eyring equation and activation parameters, ΔH^* and ΔS^*, were obtained.

The free energies of activation for the spin exchange at the coalescence temperatures were obtained by putting the observed data into[14)]

$$k_c = \frac{\pi}{\sqrt{2}}\sqrt{6J_{AB}^2 + \Delta\delta_{AB}^2}. \quad (1)$$

Results and Discussion

Since the diastereotopic protons in α-chlorodibenzyl sulfide is connected to the chiral center *via* two single bonds, there are various conformations possible in solution. The distribution of the conformations and consequently chemical shift difference might change with temperature. This is serious in total line shape analysis, since the chemical shift difference cannot be directly read from the line shapes at near-by coalescence temperatures. The difficulty is usually overcome by assuming the linearity of the change in the chemical shift difference due to temperature. We have measured the chemical shift differences at various temperature by observing the spectra at a temperature where the exchange of proton spins is slow, and also at several lower temperatures. The results are shown in Fig. 1. We see that the chemical shifts change with temperature. The difference in chemical shifts between protons A and B remains almost constant, enabling us to assume that the chemical shift differences are constant througout the temperature range examined. Coupling constants of the AB protons were invariant as well.

The agreement between the calculated and the observed spectra is satisfactory. A set of typical data is given in Fig. 2. The data obtained with chloroform-*d* solutions are summarized in Table 1. The kinetic parameters obtained with various concentrations agree within the error limit, although the concentrations have been changed by an order of magnitude. The calculated free energies of activation from the enthalpies and entropies of activation, obtained by line shape analyses, are in good agreement with those obtained by the coalescence temperature method. This may be taken as evidence that the line shape analysis affords reliable data since the principles of the two methods differ.

The activation parameters are independent of concentration. It is assumed in the NMR theory of exchange of proton spins that the process is unimolecular. If the reaction is multimolecular, its treatment would be as follows. If the actual reaction is of *n*-th order, the rates of the reaction is expressed by

$$v = k[x]^n. \quad (2)$$

Since, in the NMR treatment, the reaction is taken to be of the first order, the rate expression becomes

$$v = k[x]^{n-1}[x] = k'[x]. \quad (3)$$

Putting the k' value into the Eyring equation, we obtain

Table 2. AB proton exchange in α-chlorodibenzyl sulfide in *o*-dichlorobenzene: ^{1}H NMR spectral data at 60 MHz and kinetic parameters

	Run 5	Run 6	Run 7
Concentration/mol L^{-1}	0.214	0.197	0.167

T_c/°C	92.5	105.3	96.0
k_c/s^{-1}	75.3	75.4	75.3

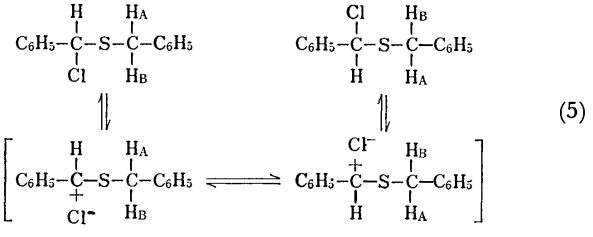
a) Obtained by the coalescence temperature method. b) Calculated from the enthalpy and the entropy of activation.

$$\ln\frac{k'}{T} = \frac{\Delta H^*}{R}\times\frac{1}{T} + \ln[x]^{n-1} + \frac{\Delta S^*}{R} + \ln\frac{k_B}{h}. \quad (4)$$

Thus correct ΔH^* can be obtained from the slope of the straight line by the plot. However, the intercept contains a $\ln[x]^{n-1}$ term, indicating that if the reaction is not unimolecular but multimolecular, the apparent ΔS^* should change with concentration. Since the actual values of ΔS^* are invariant throughout the concentration range examined, the constancy assures that we are measuring the unimolecular dissociation process of the α-halo sulfide.

The enthalpy of activation is very small whereas the entropy of activation is very large negative (Table 1). Easily ionizable organic halides give very large negative entropy of activation for solvolysis. For example, triphenylmethyl chloride gives ΔH^* 12.5 kcal mol^{-1} (1 cal=4.18 J) and ΔS^* −17 e.u. (1 e.u.= 4.18 J K^{-1} mol^{-1}) in aqueous acetone.[15] The entropy of activation for the exchange of chloride ion between an ammonium salt and triphenylmethyl chloride is even larger: ΔH^* and ΔS^* are 12.4 kcal mol^{-1} and −39 e.u. at 50 °C, respectively.[6] It is suggested that a large negative entropy of activation is associated with an ionization process in a medium of low dielectric constant.[16] The loss of freedom in motion of solvent molecules by ionization should cause the phenomenon.

The present results are the consequence of racemization of the compound which should be derived by the motion of ionic species. If the ion pair collapses from the side where the chloride ion departs, it does not cause racemization: it is not observed as the exchange of proton spins and the situation is apparent from Eq. 5.



(5)

Instead, either the rotation of the planar cation or the motion of chloride ion from one side to another of the cation plane is necessary to cause racemization, *i.e.* exchange of AB proton spins. This motion requires some freedom of the ionic species. This process does not seem possible in the intimate ion pair as suggested by Winstein and Robinson[17] for the attack by a solvent molecule, but it is possible in a loose, solvent-separated ion pair. It is not clear whether the formation of the intimate ion pair is the rate determining step of the observed change: the second step, intervention of solvent molecule(s), might be the rate determining as well. However, the above discussion indicates that the solvent-separated ion pairs are formed in nonpolar solvents like chloroform.

As a preliminary test of the salt effect on the ionization in this system, tetraethylammonium bromide was added. A solution containing 0.115 mol L^{-1} of α-chlorodibenzyl sulfide and 0.112 mol L^{-1} of the salt in chloroform-*d* showed the coalescence of the signals AB due to the methylene protons at 32.2 °C which differ little from those in Table 1. Since lowering in solution temperature caused precipitation of the salt, it was not possible to obtain the chemical shift difference and the coupling constant of the AB protons for calculation of the free energy of activation at the coalescence temperature. By using the data of Run 2, Table 1, which are not considered to be affected much by the salt added, the rate constant at 32.2 °C is calculated to be 74.8 s^{-1}. The presence or absence of the salt effect should be discussed carefully,[4] but the results suggest that the salt effect[18] is practically absent, since high concentration of the salt should affect the rates of ionization to some extent.[19] The salt effect is larger in less polar media.[20] Winstein *et al.* suggested that it is mostly caused by ion pairs in less polar media because the concentration of free ions is too low.[21] Although sodium tetraethylaluminate becomes solvent-separated ion pairs in benzene on addition of polar solvents,[22] it is not possible to utilize this in our case. However, it is almost certain that there are solvent-separated ion pairs in our system because of the low polarity of the medium. Further elaboration to fill the gap between the solvents, such as acetone and diethyl ether used by Winstein *et al.*,[20] and chloroform is apparently needed.

Pyridine reacts almost instantaneously with chloride to form a salt on addition to a solution in chloroform, but we could detect no ^{1}H NMR signals attributable

to α-bromodibenzyl sulfide which could be formed by exchange of the anion, after leaving a solution of tetraethylammonium bromide and α-chlorodibenzyl sulfide in chloroform to stand overnight. Swain and Kreevoy[6] found that the chloride-exchange could occur in benzene with measurable rates.

In order to examine the solvent effect on the enthalpy and entropy of activation for ionization, *o*-dichlorobenzene was used as a solvent. The results are given in Table 2. The dissociation of the halide in *o*-dichlorobenzene is slower in this solvent than in chloroform.[11] The main factor which decreases the rates of dissociation is the enthalpy term. Entropy of activation is large negative, the absolute value decreasing to some extent.

The larger enthalpy of activation indicates that the ionic species are less stabilized by the solvation of *o*-dichlorobenzene than by that of chloroform. This is contrary to expectation from the dielectric constants; 4.81 and 9.93 for chloroform and *o*-dichlorobenzene, respectively. Donor numbers and acceptor numbers are often used for the ionic species,[23] but they are unknown for these solvents except for the acceptor number of chloroform. *Z* values[24] may be useful because they are obtained from the UV spectra of salts (ion pairs) in various solvents; 63.2 and 60.0 for chloroform and *o*-dichlorobenzene, respectively. The Z values correspond to energy (kcal mol^{-1}) of the light absorbed by the ion pairs and ions and the difference is correlated with the difference in energy of the ground and the excited states,[25] not being directly connected with the freedom of ion pairs. Nonetheless, among other solvent parameters the *Z* values give best results for correlating the rates of dissociation of α-chlorodibenzyl sulfide in the two solvents. From the microscopic stand point, chloroform, which is capable of forming hydrogen bond,[26] can stabilize anions[27] and this ability is responsible for the observed results. The observed decrease in the enthalpy of activation should include this stabilization.

Conclusion. Dynamic NMR technique has been used for the investigation of ionic dissociation of α-chlorodibenzyl sulfide, which has a pair of diastereotopic protons; their diastereotopicity is lost on ionization. The process involves the ionization of the halide into intimate ion pairs and then solvent-separated ion pairs. Racemization may take place at this stage and the racemized solvent-separated ion pairs lose the solvent molecule(s) to give racemized intimate ion pairs which then collapse into the inverted covalent species.

$$RX \rightleftharpoons R^+X^- \rightleftharpoons R^+ /\!/ X^- \rightleftharpoons X^- /\!/ R^+ \rightleftharpoons X^-R^+ \rightleftharpoons XR$$

In this technique we do not have to see the presence of ionic species. The usual dynamic NMR technique makes use of the coalescence of the two signals ascribable to the respective species to estimate the rates of exchange. Kessler *et al.* investigated the rates of ionization of triarylmethyl derivatives by observing both the covalent and ionic species.[28] The rates of dissociation are obtained in relatively nonpolar solvents. The rates of ionization can be obtained at various temperatures without prior optical resolution of the substrate, affording activation parameters of ionization. The technique affords information on unimolecular dissociation at concentration of *ca.* 0.2 mol L^{-1}, which gives insight into the early stages of the S_N1 reactions.

The only shortcoming of this technique is that the substrate should possess diastereotopic protons whose diastereotopicity is lost on ionization. This may limit utilization of the technique to some extent and may require modification of a molecule which is conveniently studied by the classical method. The rates of exchange of proton spins should be 10^0—10^{-5} s^{-1} as in the usual dynamic NMR technique.[29] This will not hamper the usefulness of the technique because this kind of limitation is always present for other techniques as well. It is difficult to obtain reliable data by the classical method if the rates exceed 10^{-3} s^{-1}. The compound we used is very easily ionizable, thus reacting with atmospheric moisture. Although this may cause some errors, but it is the main reason why we were able to carry out the studies in relatively nonpolar aprotic solvents.

It is not possible to identify by this method how much of the solvent-separated ion pairs return to the covalent species without racemization, but this is unavoidable in the ionization of organic halides. Combination with isotopic labeling and subsequent observation of scrambling will afford useful data in this context.

The work was carried out with a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

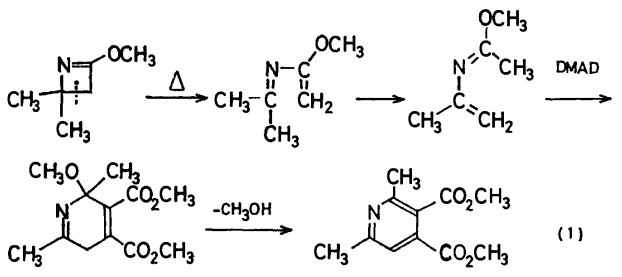
5-Amino-1-vinyl-4,5-dihydro-1*H*-1,2,3-triazoles as a Source of 1-Amino-2-aza-1,3-butadiene[1)]

Yujiro NOMURA,* Yoshito TAKEUCHI, Shuji TOMODA, and Masato M. ITO
Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received February 19, 1981)

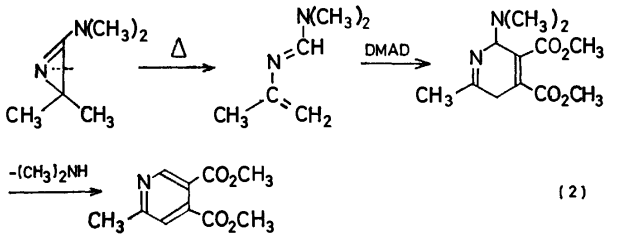
Thermolysis of 4,4-dimethyl-1-(1-phenylvinyl)-5-(1-pyrrolidinyl)-4,5-dihydro-1*H*-1,2,3-triazole gave 2-methyl-*N*-(1-phenylvinyl)-1-(1-pyrrolidinyl)-1-propanimine, which reacted as a 2-azabutadiene with electron-deficient dienophiles to afford the corresponding [4+2] cycloadducts. Reactivity and regioselectivity of the cycloaddition reactions were rationalized with the frontier molecular orbital treatment.

In the numerous examples cummulated previously for the Diels-Alder type [4+2] cycloaddition reaction of heterodienes[2)] the cases of 2-aza-1,3-butadienes are few, and in most of the few cases the azadiene system is a part of the ring system.[3)] To the best of our knowledge, three examples have been reported concerning the [4+2] cycloaddition reaction of *acyclic* 2-azabutadienes. Aue and Thomas have trapped methyl *N*-isopropenylacetimidate formed by thermolysis of 2-methoxy-4,4-dimethyl-1-azetine with dimethyl acetylenedicarboxylate (DMAD) (Eq. 1).[4)] Ghosez



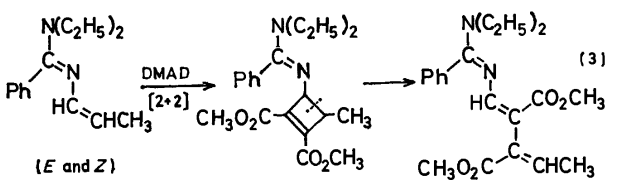
(1)

and coworkers have reported the [4+2] cycloaddition reaction of N^2-isopropenyl-N^1,N^1-dimethylformamidine formed by thermolysis of 3-dimethylamino-2,2-dimethyl-2*H*-azirine with electron-deficient dienophiles (Eq. 2).[5)] On the other hand, Taylor and coworkers have



(2)

reported that the reaction of N^1,N^1-diethyl-N^2-(1-propenyl)benzamidine with DMAD gave N^1,N^1-diethyl-N^2-[2,3-bis(methoxycarbonyl)-1,3-pentadienyl]benzamidine *via* [2+2] cycloaddition reaction and that no [4+2] adduct was formed (Eq. 3).[6)]

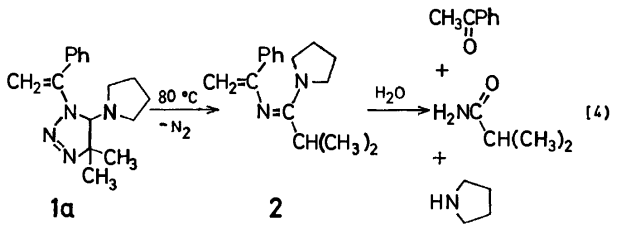


(3)

In the course of our studies on the reaction of 5-amino-1-vinyl-4,5-dihydro-1*H*-1,2,3-triazoles (**1**), which were prepared by the 1,3-dipolar cycloaddition reaction of vinyl azides with enamines,[7)] we noticed that the N^2-vinylamidine (**2**) formed by thermolysis of **1a** acted as a 2-aza-1,3-butadiene to form the [4+2] cycloadduct with some dienophiles.

Results and Discussion

*Thermolysis of 4,4-Dimethyl-1-(1-phenylvinyl)-5-(1-pyrrolidinyl)-4,5-dihydro-1*H*-1,2,3-triazole (**1a**).* 4,4-Dimethyl-1-(1-phenylvinyl)-5-(1-pyrrolidinyl)-4,5-dihydro-1*H*-1,2,3-triazole (**1a**) was thermolyzed at 80 °C in DMSO-d_6 for 22 h in a sealed NMR tube. The NMR spectra of the solution showed that 2-methyl-*N*-(1-phenylvinyl)-1-(1-pyrrolidinyl)-1-propanimine (**2**) was formed in quantitative yield (Eq. 4).



(4)

Since **2** was rapidly hydrolyzed into acetophenone and isobutyramide upon exposure to air, the isolation in pure form or combustion analysis of **2** was unsuccessful.

Table 1 collects the ^{1}H and ^{13}C NMR data pertinent to the structural confirmation of **2**. In addition to a phenyl and 1-pyrrolidinyl group, the presence of newly formed isopropyl group was indicated in its characteristic ^{1}H NMR peak pattern (a doublet at δ 1.04 and a septet at δ 3.01). The two low field singlets were assigned to the terminal olefinic protons at C-5. The structure was further supported by the ^{13}C NMR spectra. The presence of three singlets at low field, one of which corresponds to the *ipso* carbon of the phenyl group, and a triplet at δ 93.0 suggested a trisubstituted 2-aza-1,3-butadiene skeleton. The location of the three substituents was appropriately explained by the hydrolysis products, acetophenone and isobutyramide.

In other solvents (cyclohexane, benzene, diglyme, *etc.*) the amidine **2** was formed in much lower yields accompanied by 2,2-dimethyl-5-phenyl-2*H*-pyrrole (**3a**) (Scheme 1). The compound **3a** was separated with alumina column chromatography, and its structure was determined by spectral and analytical results.

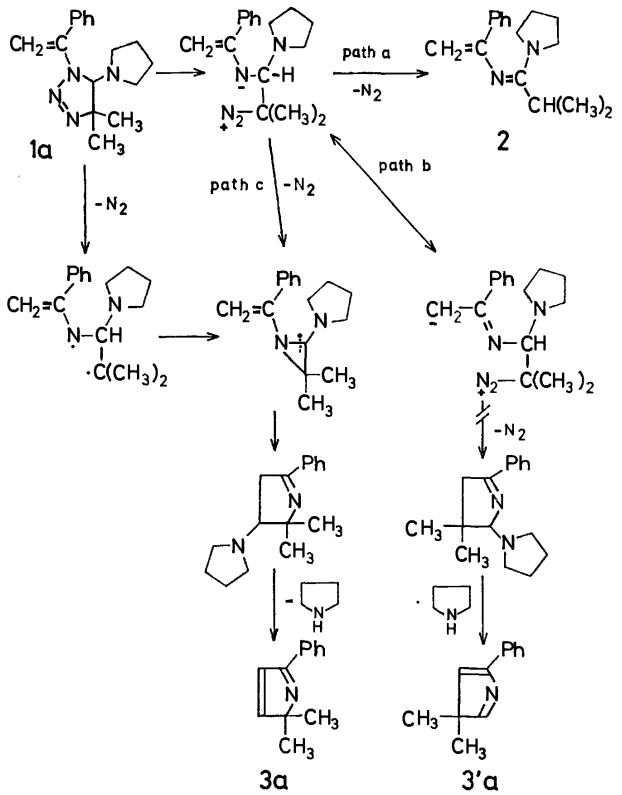


Scheme 1. Formation of the N^2-vinylamidine (**2**) and the 2*H*-pyrrole (**3a**) by thermolysis of the vinyltriazoline (**1a**).

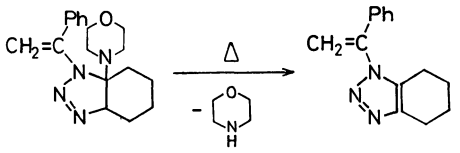
In ^{1}H NMR the singlet at δ 1.45 corresponds to the two methyl groups and the doublet at δ 6.73 (J= 4.5 Hz) corresponds to the proton at C-4. In ^{13}C NMR the two doublets at δ 162.6 and 123.1 correspond to the C-3 and C-4 of the 2*H*-pyrrole ring, and the singlets at δ 169.6 and 79.5 correspond to the C-5 and C-2 of the pyrrole ring, respectively.[8a] The alternative structure of the 3*H*-pyrrole (**3'a**) is eliminated because the signal at δ 79.5 should be assigned to the quaternary sp^3 carbon adjacent to one nitrogen atom.[8b]

The formation of the N^2-vinylamidine (**2**) and the 2*H*-pyrrole (**3a**) was most simply explained by the tentative routes shown in Scheme 1. In the thermolysis of 5-amino-4,5-dihydro-1*H*-1,2,3-triazoles, it is generally accepted that the heterolytic cleavage of the bond between N-1 and N-2 occurs first,[9-11] and that the loss of nitrogen followed by 1,2-hydride (or carbanion) shift gives amidines.[10-12] In the present case the N^2-vinylamidine (**2**) would be formed *via* the similar path (path a). Since the ring closure *via* path b would lead to the 3*H*-pyrrole (**3'a**), which was not actually formed, the 2*H*-pyrrole (**3a**) should be formed *via* another path. A plausible path involves the formation of aziridine, followed by the subsequent ring conversion to the pyrroline and elimination of pyrrolidine to the 2*H*-pyrrole (**3a**) (path c).[12] The homolytic extrusion of nitrogen from **1a** can also lead to the aziridine as was the case of thermolysis and photolysis of other 4,5-dihydro-1*H*-1,2,3-triazoles.[13] The fact that **3a** was not formed by thermolysis in DMSO but was formed in the less polar solvents may be suggestive of the homolytic mechanism for the aziridine formation (and the heterolytic one for the amidine), although no example of homolytic extrusion of nitrogen by thermolysis of 5-amino-4,5-dihydro-1*H*-1,2,3-triazoles has been reported.

Thermolysis of Other Vinyltriazolines. In contrast with the quantitative formation of the N^2-vinylamidine (**2**) from **1a** in DMSO, 4-ethyl-1-(1-phenylvinyl)-5-

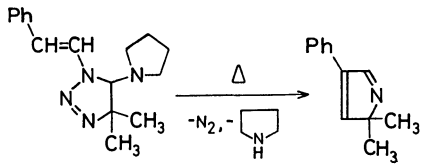
(1-pyrrolidinyl)-4,5-dihydro-1*H*-1,2,3-triazole (**1b**) was stable at 80 °C. Thermolysis at 100 °C in DMSO-d_6, diglyme-d_{14}, or pyridine-d_5 caused decomposition with evolution of nitrogen, but the NMR spectra of the resulting solution showed that neither amidine nor pyrrole was formed.

Thermolysis of 7a-morpholino-1-(1-phenylvinyl)-3a,4,5,6,7,7a-hexahydro-1*H*-1,2,3-benzotriazole (**1c**) also gave neither amidine nor pyrrole. Chromatographic separation of the reaction mixture gave faint yellow oil, whose spectral data were identical with those of previously reported 1-(1-phenylvinyl)-4,5,6,7-tetrahydro-1*H*-1,2,3-benzotriazole (**4**; 36% yield) (Eq. 5).[7]



(5)

1c **4**



(6)

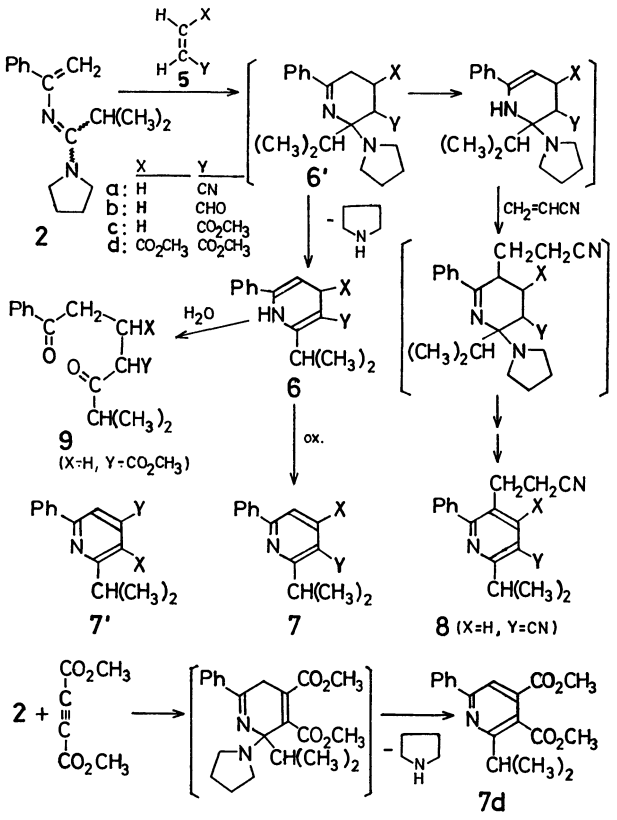
1d **3d**

Thermolysis of 4,4-dimethyl-5-(1-pyrrolidinyl)-1-styryl-4,5-dihydro-1*H*-1,2,3-triazole (**1d**) was carried out at 80 °C in DMSO and in benzene to give the corresponding 2,2-dimethyl-4-phenyl-2*H*-pyrrole (**3d**) in 38 and 80% yields, respectively (Eq. 6). No amidine was detected in the crude solution. The 2*H*-pyrrole (**3d**) seems to be formed *via* aziridine as in the case of **3a**.

These results were in sharp contrast with the Fusco's results of thermolysis of 1-aryl-5-amino-1,2,3-triazolines, in which the corresponding N^2-arylamidines were the sole products.[10-12]

[4+2] Cycloaddition Reaction of the 2-Aza-1,3-butadiene (2). In order to examine the reactivity of 2-methyl-*N*-(1-phenylvinyl)-1-(1-pyrrolidinyl)-1-propanimine (**2**) as a 2-aza-1,3-butadiene, **2** prepared by heating **1a** in DMSO at 80 °C for 1 d was allowed to react with an appropriate dienophile (**5**) at room temperature.

The results were summarized in Scheme 2 and Table 2. In the case of some electron-deficient dienophiles (**5a—d**, and DMAD), the corresponding dihydropyridines (**6**) and pyridines (**7**) were formed at room temperature for 1—5 d, but reaction with *p*-benzoquinone (**5e**) or *N*-phenylmaleimide (**5f**) gave only polymeric substances. With 3,4-dihydro-2*H*-pyran (**5g**), an olefin with a π-donating group, no reaction occurred even at 110 °C and **5g** remained unchanged.



Scheme 2. Cycloaddition reaction of the 2-azabutadiene (**2**) with electron-deficient dienophiles.

In the case of the reaction with acrylonitrile (**5a**) or acrylaldehyde (**5b**), the initially formed dihydropyridine (**6a,b**) was gradually oxidized to the pyridine (**7a,b**) upon exposure to air. In the case of **5a**, the reaction at 80 °C for 36 h or at room temperature for 30 d gave the 1:2 adduct **8** besides **6a** and **7a**. In the case of methyl acrylate (**5c**), dihydropyridine was not isolated but considerable amount of methyl 2-isobutyryl-5-oxo-5-phenylpentanoate (**9**) was isolated. The dioxo ester **9** was identified by spectral comparison with the authentic sample prepared according to the route shown in Eq. 7.

a) Carried out at room temperature, unless otherwise noted. b) Carried out at 80 °C. c) Initial crude products were oxidized with *p*-benzoquinone prior to work up. d) Only polymeric products were formed. e) Carried out at 80—110 °C, but dienophile remained unchanged.

A plausible mechanism for the formation of these products was depicted in Scheme 2. The [4+2] cycloaddition reaction of **2** with a dienophile would give the cyclic imine intermediate **6'**, which is deaminated to the dihydropyridine **6**. The Michael addition of acrylonitrile to the isomeric enamine form of **6'a** would lead to **8**.[14)] Formation of **9** would indicate the initial formation of dihydropyridine **6c**, which was hydrolyzed into **9** on silica gel. This was prevented by oxidation of **6c** to **7c** with *p*-benzoquinone prior to work up.

An intriguing aspect of these cycloaddition reactions involving **5a**—**c** is the formation of only one of the possible regioisomers. Two regioisomeric structures **7** and **7'** were expected, but only **7** was actually formed in all cases. In the case of **7a**, for instance, the two doublets at δ 7.68 and 7.92 in ^{1}H NMR spectra can be assigned to the two adjacent pyridine ring protons at C-5 and C-4. The large coupling constant between these protons (8 Hz) precluded the possibility of isomer **7'a** in which only a small *meta* coupling should be observed. This assignment was further supported by the general observation that the coupling constant between 4-H and 5(or 3)-H is the largest (about 8 Hz) in ordinary pyridine derivatives.[15)] These structural assignments were further confirmed by ^{13}C NMR data (see Experimental).

Taylor and coworkers suggested that the preference of [2+2] to [4+2] cycloaddition in the case of N^1,N^1-diethyl-N^2-(1-propenyl)benzamidine (Eq. 3) could be caused by the inaccessibility of the *s-cis* conformation in the 2-aza-1,3-butadiene system.[6)] In the present case *s-cis* conformation is not sterically unfavorable due to the presence of phenyl group at 3-position of the 2-aza-1,3-butadiene system of **2**, so that the preference of the [4+2] cycloaddition is in accord with the Taylor's postulate. But further experimental results about the cycloaddition reactions of various 2-aza-1,3-butadienes are necessary to examine the validity of his postulate. Useful synthetic methods of 2-aza-1,3-butadienes are awaited.

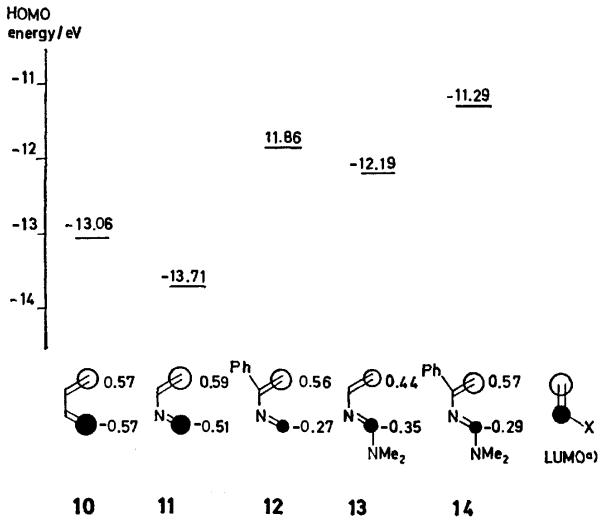

Fig. 1. Energies and coefficients of HOMO of 2-azabutadienes estimated with CNDO/2 method.
a) LUMO of a typical electron-deficient dienophile.

Frontier Molecular Orbital Treatment. Frontier molecular orbital treatment was successfully applied to rationalize the reactivity and regioselectivity of cycloaddition reactions such as Diels-Alder reactions and 1,3-dipolar cycloaddition reactions.[16)] We found that this treatment also rationalized the rather high reactivity and high regioselectivity in the [4+2] cycloaddition reactions of the 2-aza-1,3-butadiene (**2**).

Frontier orbital energies and coefficients of various 2-azabutadienes were estimated with CNDO/2 method (Fig. 1).

In Diels-Alder reaction with electron-deficient dienophiles, the interaction between HOMO (highest occupied molecular orbital) of the diene and LUMO (lowest unoccupied molecular orbital) of the dienophile is important.[16)] As shown in Fig. 1, the HOMO of 2-azabutadiene (**11**) is lower than that of butadiene (**10**), suggesting the lower reactivity of **11** compared with **10**. However, the HOMO of 3-phenyl-2-aza-

butadiene (**12**) or 1-amino-2-azabutadiene (**13**) is raised by their substituents (phenyl and amino groups), so that the HOMO of the 2-azabutadiene **14** (a model of **2**) is much higher in energy than that of **10** or **11**. The higher energy of HOMO would increase the interaction with LUMO of dienophiles, resulting the rather high reactivity in cycloaddition reaction of **2** with electron-deficient dienophiles.

On the other hand, the LUMO of enol ethers is higher in energy so that the interaction would be too small to cause the reaction with **2** in spite of the high energy of HOMO of **2**.

The magnitude of coefficients of HOMO of 2-azabutadienes were also in accord with the observed regioselectivity in the reactions of non-symmetrical dienophiles (**5a**—**c**). The coefficient of HOMO of **11** was larger at 4-position than at 1-position, and this trend was enhanced by the substitution of the phenyl and amino groups (**12**, **13**). Consequently the coefficients of HOMO of **14** was much larger at 4-position than at 1-position, so that the high regioselectivity in the [4+2] cycloaddition reaction of **2** would be induced.

Experimental

General. Melting points were determined on a Mitamura Riken hot-stage melting point apparatus and were uncorrected. Infrared spectra were determined on a JASCO DS-403G grating infrared spectrophotometer. Nuclear magnetic resonance spectra were determined on a JEOL MH-100, FX-90Q, and Varian FT-80A NMR spectrometer (splitting pattern in ^{13}C NMR data was obtained by off-resonance decoupling). Ultraviolet spectra were determined on a Hitachi EPS-3T recording spectrophotometer. Mass spectra were determined on a Hitachi RMU-6MG mass spectrometer. The vinyltriazolines (**1**) were prepared by the previously described method.[7] Solvents were distilled under anhydrous conditions before use.

*Thermolysis of 4,4-Dimethyl-1-(1-phenylvinyl)-5-(1-pyrrolidinyl)-4,5-dihydro-1*H*-1,2,3-triazole (**1a**).* *Method A*: In 0.5 ml of an appropriate solvent was dissolved 71—118 mg (0.26—0.44 mmol) of **1a** with 3.8—5.7 mg of 2,2,3,3-tetramethylbutane as an internal standard in a 5 mm diameter NMR sample tube. The tube was then sealed *in vacuo*, and was heated in an 80 °C bath until **1a** was completely consumed.

Method B: In 100 ml of an appropriate solvent was dissolved 1.0 g (3.7 mmol) of **1a** and the solution was heated to reflux under nitrogen until **1a** was completely consumed.

In Dimethyl-d_6 *Sulfoxide (DMSO-*d_6*, Method A)*: Thermolysis of **1a** was carried out in DMSO-d_6 at 80 °C for 22 h. NMR spectra of the resulting solution showed that 2-methyl-*N*-(1-phenylvinyl)-1-(1-pyrrolidinyl)-1-propanimine (**2**) (see Table 1) was formed in quantitative yield.

In Toluene (Method B): Thermolysis of **1a** (1.0 g, 3.7 mmol) was carried out in refluxing toluene (110 °C) for 75 min. Removal of the solvent *in vacuo* gave 700 mg of the residue, whose ^{1}H NMR spectra showed the existence of **2** and 2,2-dimethyl-5-phenyl-2*H*-pyrrole (**3a**) in 6:7 ratio. Chromatographic separation of 220 mg of the residue afforded 40 mg (28% yield) of acetophenone and 62 mg (37% yield) of **3a**, respectively. Analytically pure sample of **3a** was obtained by distillation with the Kugelrohr apparatus at 55 °C/3 mmHg†: mp 19—20 °C; MS *m/e* 171 (M^+); IR (neat) 1605, 1446, 1358, 1198, 1020, 760, and 694 cm^{-1}; UV_{max} (methanol) 212.5 (ε, 12000), 217.5 (12000), and 249 nm (10000); ^{1}H NMR ($CDCl_3$) δ 1.45 (6H, s), 6.73 (1H, d, J=4.5 Hz), 7.3—7.5 (4H, m), and 7.8—8.0 (2H, m); ^{13}C NMR ($CDCl_3$) δ 23.4 (q), 79.5 (s), 123.1 (d), 127.6 (d), 128.6 (d), 130.2 (d), 134.3 (s), 162.6 (d), and 169.6 (s, C=N).

Found: C, 84.04; H, 7.63; N, 8.27%. Calcd for $C_{12}H_{13}N$: C, 84.17; H, 7.65; N, 8.18%.

The rest of the residue (480 mg) was left at room temperature for 3 d. Then 1 ml of diethyl ether was added, and the precipitates of isobutyramide was collected by filtration and washed three times with 1 ml of diethyl ether (yield, 30 mg, 14%).

In Toluene-d_8 *(Method A)*: Thermolysis of **1a** was carried out in toluene-d_8 at 80 °C for 21 h. The ^{1}H NMR spectra of the resulting solution showed the formation of **2** and **3a** in 58 and 23% yields, respectively.

In Diglyme-d_{14} *(Method A)*: Thermolysis of **1a** was carried out in diglyme-d_{14} at 80 °C for 20 h. The ^{1}H NMR spectra of the resulting solution showed the formation of **2** and **3a** in 31 and 8% yields, respectively.

In Benzene (Method B): Thermolysis of **1a** was carried out in refluxing benzene (80 °C) for 1 d. The ^{1}H NMR spectra of the residue after removal of the solvent showed the formation of **2** and **3a** in 42 and 11% yields, respectively.

In Cyclohexane (Method B): Thermolysis of **1a** was carried out in refluxing cyclohexane (80 °C) for 1 d. The ^{1}H NMR spectra of the residue after removal of the solvent showed the formation of **2** and **3a** in 50 and 20% yields, respectively.

*Thermolysis of 7a-Morpholino-1-(1-phenylvinyl)-3a,4,5,6,7,7a-hexahydro-1*H*-1,2,3-benzotriazole (**1c**).* Toluene (20 ml) solution of **1c** (92 mg, 0.29 mmol) was heated to reflux for 16 h under nitrogen until **1c** was completely consumed. The toluene was removed *in vacuo* at room temperature. The ^{1}H NMR spectra of the residue showed that no N^2-vinylamidine was formed. Chromatographic separation of the residue through silica-gel column eluting with diethyl ether gave 1-(1-phenylvinyl)-4,5,6,7-tetrahydro-1*H*-1,2,3-benzotriazole (**4**)[7] in 36% yield.

*Thermolysis of 4,4-Dimethyl-5-(1-pyrrolidinyl)-1-styryl-4,5-dihydro-1*H*-1,2,3-triazole (**1d**).* *In DMSO-*d_6: The DMSO-d_6 (0.5 ml) solution of **1d** (0.16 g, 0.60 mmol) was heated at 80 °C according to Method A for 2 d. The ^{1}H NMR spectra of the resulting solution showed that N^2-vinylamidine was not formed. Diethyl ether (50 ml) was added to the solution, and the ether solution was washed four times with water (50 ml) and once with saturated aqueous solution of sodium chloride (50 ml) and dried over anhydrous magnesium sulfate. The ether was removed *in vacuo* and the residue was purified with silica gel preparative thin layer chromatography (Merck Art. 7747) developing with dichloromethane to give 38 mg (38% yield) of 2,2-dimethyl-4-phenyl-2*H*-pyrrole (**3d**). Analytically pure sample was obtained by distillation with the Kugelrohr apparatus at 65 °C/4 mmHg): mp 16.5—17.5 °C; MS *m/e* 171 (M^+); IR (neat) 1620, 1600, 1530, 1490, 1450, 925, 765, and 695 cm^{-1}; UV_{max} (methanol) 224 (ε, 15000), 268 (5000), 287 (sh), and 296 nm (sh); ^{1}H NMR ($CDCl_3$) δ 1.43 (6H, s), 7.4—7.8 (6H, m), and 8.55 (1H, s); ^{13}C NMR ($CDCl_3$) δ 23.2 (q), 80.3 (s), 126.3 (d), 128.1 (d), 128.8 (d), 132.4 (s), 138.1 (s), 153.6 (d), and 161.3 (d, C=N).

Found: C, 84.04; H, 7.65; N, 8.10%. Calcd for $C_{12}H_{13}N$: C, 84.17; H, 7.65; N, 8.18%.

In Benzene: The benzene (40 ml) solution of **1d** (0.68 g, 2.5 mmol) was heated to reflux for 42 h under nitrogen

† 1 mmHg≈133.322 Pa.

until **1d** was completely consumed. After removal of the benzene *in vacuo*, the residue was purified with alumina dry column chromatography (Woelm 04511) eluting with dichloromethane to give 0.35 g (80% yield) of **3d**.

Cycloaddition Reaction of 2 with Dienophiles. Method A: The N^2-vinylamidine (**2**) was prepared by heating the DMSO solution of the vinyltriazoline (**1a**, 1.0 g, 3.7 mmol) at 80 °C for 24 h under nitrogen atmosphere. After it was cooled to room temperature, an appropriate dienophile (molar ratio described in Table 2) was added to the solution with a micro syringe, and the solution was stirred at room temperature for 1—5 d. Then diethyl ether (50 ml) was added, and the ether layer was washed four times with water (50 ml) and once with saturated aqueous solution of sodium chloride (50 ml) successively, and dried over anhydrous magnesium sulfate. After removal of the ether *in vacuo*, the residue was purified with silica gel dry column chromatography (Woelm 04526, eluting with hexane–dichloromethane (1:1)) and/or with silica gel preparative thin layer chromatography (developing with dichloromethane).

Method B: The reaction procedure and the method of purification were similar to Method A, but *p*-benzoquinone (0.40 g, 3.7 mmol) was added to the DMSO solution in order to oxidize the initial products after the cycloaddition was completed.

Reaction with Acrylonitrile (5a): (*i*) Reaction of **2** with 2.0 molar amount of **5a** according to Method A for 2 d gave 3-cyano-1,4-dihydro-2-isopropyl-6-phenylpyridine (**6a**) and 3-cyano-2-isopropyl-6-phenylpyridine (**7a**) in 37 and 25% yields, respectively. Analytically pure samples of **6a** and **7a** were obtained respectively by recrystallization from methanol as colorless crystals: 3-cyano-1,4-dihydro-2-isopropyl-6-phenylpyridine (**6a**): mp 107—108 °C; MS *m/e* 224 (M^+); IR (KBr) 3330 (N–H), 2270 (C≡N), 1665 (C=C), 1610, 1495, 1290, 1110, 760, and 705 cm^{-1}; UV_{max} (methanol) 243 (ε 14000) and 335 nm (3000); ^1H NMR ($CDCl_3$) δ 2.21 (6H, d, J=7 Hz), 3.15 (1H, septet, J=7 Hz), 3.26 (2H, d, J=3.5 Hz), 4.90 (1H, td, J=3.5 and 1.7 Hz), 5.4 (1H, NH), and 7.32 (5H, C_6H_5).

Found: C, 80.19; H, 7.16; N, 12.20%. Calcd for $C_{15}H_{16}N_2$: C, 80.32; H, 7.19; N, 12.49%.

3-Cyano-2-isopropyl-6-phenylpyridine (**7a**): mp 75.5—76.5 °C; MS *m/e* 222 (M^+); IR (KBr) 2305 (C≡N), 1580, 1445, 1380, 860, 840, 770, and 695 cm^{-1}; UV_{max} (methanol) 260 (sh), 266 (ε, 15000), and 297 nm (20000); ^1H NMR ($CDCl_3$) δ 1.47 (6H, d, J=7 Hz), 3.64 (1H, septet, J=7 Hz), 7.4—7.6 (3H, m), 7.68 (1H, d, J=8 Hz), 7.92 (1H, d, J=8 Hz), and 8.0—8.2 (2H, m); ^{13}C NMR ($CDCl_3$) δ 21.7 (q), 34.8 (d), 105.8 (s), 116.9 (d), 117.1 (s, C≡N), 127.3 (d), 128.8 (d), 130.3 (d), 137.7 (s), 140.9 (d), 158.9 (s), and 169.1 (s).

Found: C, 80.96; H, 6.59; N, 12.69%. Calcd for $C_{15}H_{14}N_2$: C. 81.05; H, 6.35; N, 12.60%.

(*ii*) Reaction of **2** with 2.0 molar amount of **5a** according to Method A for 30 d gave **6a**, **7a**, and 3-cyano-5-(2-cyanoethyl)-2-isopropyl-6-phenylpyridine (**8**) in 16, 7, and 24% yields, respectively. Analytically pure sample of **8** was obtained by recrystallization from methanol as colorless crystals: mp 111.5—112 °C; MS *m/e* 275 (M^+); IR (KBr) 2235 (C≡N), 2230 (C≡N), 1590, 1435, 1070, 980, 785, 750, 715, and 700 cm^{-1}; UV_{max} (ethanol) 254 (ε, 10100) and 289 nm (10300); ^1H NMR ($CDCl_3$) δ 1.38 (6H, d, J=6.5 Hz), 2.24 (2H, t, J=7.5 Hz), 3.11 (2H, t, J=7.5 Hz), 3.58 (1H, septet, J=6.5 Hz), 7.48 (5H, C_6H_5), and 7.81 (1H, s). ^{13}C NMR ($CDCl_3$) δ 17.5 (t), 21.7 (q), 27.6 (t), 34.5 (d), 106.4 (s), 116.8 (s, C≡N), 118.4 (s, C≡N), 128.6 (s), 128.8 (d), 128.9 (s), 129.1 (d), 138.8 (s), 141.5 (d), 161.6 (s), and 167.7 (s).

Found: C, 78.50; H, 6.52; N, 15.11%. Calcd for $C_{18}H_{17}N_3$: C, 78.52; H, 6.22; N, 15.26%.

(*iii*) The vinyltriazoline (**1a**, 0.87 g, 3.2 mmol) and **5a** (0.34 g, 6.4 mmol) was dissolved in DMSO (20 ml) and stirred at 80 °C for 36 h under nitrogen atmosphere. After removal of excess **5a** and DMSO *in vacuo* at about 60 °C, the residue was dissolved in dichloromethane (50 ml) and the solution was washed with water (3×50 ml) and saturated aqueous solution of sodium chloride (50 ml) successively, and was dried over anhydrous magnesium sulfate. After removal of the solvent, the residue was purified according to Method A to give 90 mg of **7a** (13% yield) and 0.18 g of **8** (20% yield).

Reaction with Acrylaldehyde (5b): Reaction of **2** with 1.3 molar amount of **5b** according to Method A for 3 d gave 1,4-dihydro-2-isopropyl-6-phenylnicotinaldehyde (**6b**) and 2-isopropyl-6-phenylnicotinaldehyde (**7b**) in 24 and 22% yields, respectively. Analytically pure sample of **6b** was obtained by recrystallization from benzene as faint yellow crystals: mp 105—106.5 °C; MS *m/e* 227 (M^+); IR (KBr) 3230 (N–H), 1680 (C=C), 1595, 1505, 1390, 1365, 1290, 1240, 1110, 765, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.28 (6H, d, J=7.5 Hz), 3.17 (2H, d, J=3 Hz), 3.60 (1H, septet, J=7.5 Hz), 5.11, (1H, m), 5.81 (1H, NH), 7.34 (5H, C_6H_5), and 9.83 (1H, s, CHO).

Found: C, 79.21; H, 7.58; N, 6.21%. Calcd for $C_{15}H_{17}NO$: C, 79.26; H, 7.54; N, 6.16%.

The compound **7b** was obtained as colorless oil: MS *m/e* 225 (M^+); IR (CH_2Cl_2) 1685 (C=O), 1580, and 1370 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.44 (6H, d, J=7 Hz), 3.97 (1H, septet, J=7 Hz), 7.4—7.7 (3H, m), 7.77 (1H, d, J=8.5 Hz), 8.1—8.4 (3H, m), and 10.50 (1H, s, CHO). *p*-Nitrophenylhydrazone of **7b**: mp 248.5—249.5 °C.

Found: C, 70.12; H, 5.33; N, 15.60%. Calcd for $C_{21}H_{20}N_4O_2$: C, 69.98; H, 5.59; N, 15.55%.

Reaction with Methyl Acrylate (5c): (*i*) Reaction of **2** with 1.1 molar amount of **5c** according to Method A for 5 d gave methyl 2-isopropyl-6-phenylnicotinate (**7c**) and methyl 2-isobutyryl-5-oxo-5-phenylpentanoate (**9**) in 21 and 24% yields, respectively. Analytically pure sample of **7c** was obtained by recrystallization from methanol as colorless crystals: mp 88.5—89.5 °C; MS *m/e* 255 (M^+); IR (KBr) 1720 (C=O), 1580, 1270, 1080, 760, and 688 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.42 (6H, d, J=7 Hz), 3.92 (3H, s), 4.02 (1H, septet, J=7 Hz), 7.3—7.5 (3H, m), 7.52 (1H, d, J=7.5 Hz), and 8.0—8.2 (3H, m); ^{13}C NMR ($CDCl_3$) δ 22.4 (q), 32.6 (d), 52.2 (q, OCH_3), 116.8 (d), 123.1 (s), 127.4 (d), 128.8 (d), 129.8 (d), 138.3 (s), 139.3 (d), 158.4 (s), and 167.3 (s).

Found: C, 75.45; H, 6.81; N, 5.70%. Calcd for $C_{16}H_{17}NO_2$: C, 75.27; H, 6.71; N, 5.99%.

The dioxo ester **9** was obtained as faint yellow oil: IR (neat) 1740 (C=O), 1710 (C=O), 1680 (C=O), 1595, 1580, 1450, 755, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.13 (3H, d, J=6 Hz), 1.17 (3H, d, J=6 Hz), 2.28 (2H, q, J=7 Hz), 2.89 (1H, septet, J=6 Hz), 3.07 (2H, t, J=7 Hz), 3.74 (3H, s), 3.91 (1H, t, J=7 Hz), 7.3—7.6 (3H, m), and 7.8—8.1 (2H, m).

(*ii*) Reaction of **2** with 1.1 molar amount of **5c** according to Method B for 5 d gave **7c** in 44% yield.

Reaction with Dimethyl Maleate (5d): (*i*) Reaction of **2** with 2.1 molar amount of **5d** according to Method A for 2 d gave dimethyl 2-isopropyl-6-phenylpyridine-3,4-dicarboxylate (**7d**) in 11% yield. Analytically pure sample was obtained by recrystallization from methanol as colorless crystals: mp 75.5—76.5 °C; MS *m/e* 313 (M^+); IR (KBr)

1730 (C=O), 1580, 1330, 1275, 1250, 1085, 990, 755, 740, and 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.40 (6H, d, $J=7$ Hz), 3.09 (1H, septet, $J=7$ Hz), 3.92 (3H, s), 3.95 (3H, s), 7.3—7.5 (3H, m), 7.9—8.1 (3H, m); ^{13}C NMR ($CDCl_3$) δ 22.5 (q), 33.8 (d), 52.7 (q, OCH_3), 52.9 (q, OCH_3), 116.7 (d), 125.8 (s), 127.1 (d), 128.8 (d), 136.6 (s), 138.2 (s), 157.9 (s), 164.3 (s, C=O), 165.5 (s), and 168.9 (s).

Found: C, 69.16; H, 6.11; N, 4.52%. Calcd for $C_{18}H_{19}NO_4$: C, 69.00; H, 6.11; N, 4.47%.

(*ii*) Reaction of **2** with 2.1 molar amount of **5d** according to Method B for 2 d gave **7d** in 23% yield.

Reaction with Dimethyl Acetylenedicarboxylate (DMAD): Reaction of **2** with 2.1 molar amount of DMAD according to Method A for 1 d gave **7d** in 37% yield.

*Synthesis of an Authentic Sample of Methyl 2-isobutyryl-5-oxo-5-phenylpentanoate (**9**).* Methyl 4-methyl-3-oxopentanoate was prepared from 3-methyl-2-butanone and dimethyl carbonate according to Corey's method.[17] 3-Dimethylamino-1-phenyl-1-propanone was prepared from acetophenone, formaldehyde, and dimethylamine hydrochloride by Mannich reaction,[18] quaternized with methyl iodide, and it was condensed with the 3-oxo ester in methanol at 0 °C by means of sodium methoxide.[19] The dioxo ester **9** formed was purified with alumina (Woelm 04511) dry column chromatography eluting with hexane–dichloromethane (1:1). Its IR and ^1H NMR spectra were identical with the dioxo ester formed in the reaction of **2** with methyl acrylate (**5c**). Analytically pure sample was obtained by distillation with the Kugelrohr apparatus at 140 °C/0.1 mmHg.

Found: C, 69.58; H, 7.51%. Calcd for $C_{16}H_{20}O_4$: C, 69.55; H, 7.29%.

Method for CNDO/2 Calculation. The CNDO/2 calculation programme used was made by Professor Nozomu Ebara and members in his laboratory of College of General Education of The University of Tokyo, based mainly on the Pople's method.[20] Calculation was carried out at The Computer Center of The University of Tokyo.

(Received March 2, 1981)

Three new bitter diterpenoids, rabdosianin A, B, and C, have been isolated from the leaves of *Rabdosia shikokianus* Hara, and their structures, determined by spectroscopic and chemical methods. Complete assignments of the ^{1}H and ^{13}C NMR data are described.

The isolation of four diterpenoids: oridonin (**1**),[1] shikokianin (**2**),[1] shikokianidin (**3**),[2] and shikodonin (**4**),[3] from the leaves of *Rabdosia shikokianus* Hara[4] has already been reported. Further investigation of the bitter principles from this plant has led to the isolation of five additional diterpenoids: effusanin B (**5**),[5] longikaurin E (**6**),[6] and three new *ent*-kaurenoids. In this paper, we will deal with the isolation and structures of these new compounds, designated as rabdosianin A, B, andC.

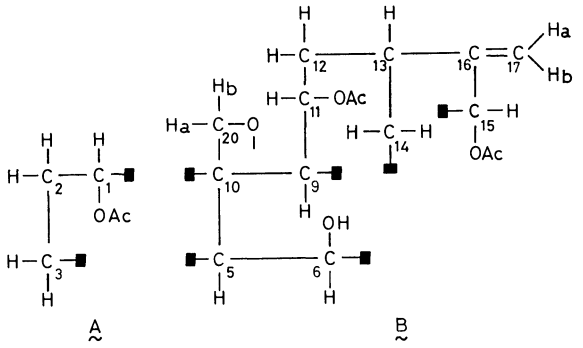
6 R_1=H, R_2=OAc

Rabdosianin A (**7**), $C_{26}H_{36}O_9$, mp 150—153 °C, $[\alpha]_D^{20}$ −50° (*c* 0.21, $CHCl_3$), was isolated as white needles in 0.053% yield from the ether extract of the dried leaves by extensive column chromatography. It had IR absorptions indicative of hydroxyl (3540, 3440), acetoxyl (1740, 1235), and *exo*-methylene (1660 and 902 cm^{-1}) groups. The ^{1}H NMR spectrum at 400 MHz showed signals due to two tertiary methyl groups at δ 1.08 and 1.14, three acetyl groups at δ 1.94, 2.10, and 2.11, one secondary hydroxyl group at δ 2.48 (d, J=2.4 Hz), one tertiary hydroxyl group at δ 3.17, one methine proton on an oxygenated carbon atom at δ 3.96 (dd, J=7.8 and 2.4 Hz), one ether type methylene group at δ 4.12 (dd, J=8.9 and 1.0 Hz) and 4.50 (dd, J=8.9 and 1.6 Hz), three methine protons attached to carbon atoms bearing an acetoxyl group at δ 4.82 (dd, J=4.1 and 3.5 Hz), 4.87 (dd, J=10.7 and 4.6 Hz), and 5.63 (dd, J=1.9 and 1.0 Hz), and one terminal methylene group at δ 4.86 (br s) and 5.03 (dd, J=1.9 and 1.0 Hz). In addition, extensive ^{1}H NMDR studies, summarized in Table 1, revealed the presence of the partial structures (**A**) and (**B**), the latter showing the following long-range couplings: $J_{H_5,H_{20b}}$=1.6 Hz, $J_{H_9,H_{20a}}$=1.0 Hz, $J_{H_{13},H_{17a}}$=1.9 Hz, $J_{H_{13},H_{17b}}$=1.0 Hz, $J_{H_{15},H_{17a}}$=1.0 Hz, and $J_{H_{15},H_{17b}}$=1.9 Hz.



A B

The spectral data and the analogy with the congeners isolated from *Rabdosia* species[1,2] suggested the structure **7** for rabdosianin A. The proposed structure was also supported by the ^{13}C NMR data at 100 MHz (Table 2), which showed the presence of one hemiacetal group (δ 96.5), four methylene groups, three methine groups, and three quaternary carbon atoms. The α-configuration of two acetoxyl groups at C_1 and C_{11} was evident from the J values of H_1 and H_{11} signals. Namely, the large axial-axial coupling (J=10.7 Hz) and the small axial-equatorial coupling (J=4.6 Hz) of the former signal indicated the axial nature of the corresponding proton. Hence, the acetoxyl group at C_1 must be α-oriented. The small J values of the latter signal ($J_{H_9,H_{11}}$=4.1 Hz, $J_{H_{11},H_{12\beta}}$= 3.5 Hz, and $J_{H_{11},H_{12\alpha}}\approx$0 Hz) revealed that the di-

OAc	2.11, 2.10, 1.94	2.16, 2.09, 2.06, 1.94	2.18

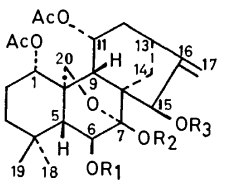
a) The spectra were determined at 25 °C in $CDCl_3$ solutions with TMS as an internal standard. Multiplicity and J values (in Hz) are in parentheses. b) These signals disappeared on addition of D_2O.

hedral angles between H_9 and H_{11}, and H_{11} and $H_{12\beta}$, are both close to 45°, and that between H_{11} and $H_{12\alpha}$ is roughly 90°. Thus, the acetoxyl group at C_{11} is α-oriented.

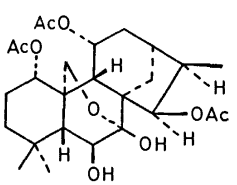
The catalytic hydrogenation of **7** afforded a dihydro compound (**8**), $C_{26}H_{38}O_9$, mp 252—253 °C, as the major product. Since the hydrogenation of the C_{16} double bond is assumed to occur from the less hindered α-side, the newly introduced secondary methyl group must be β-oriented.[2] The ^{1}H NMR spectrum of **8** displayed a signal of H_{15} as a doublet at δ 5.20 (J=10.4 Hz), the large J value of which defined the configuration of the acetoxyl group at C_{15} as β.[2] The β-configuration for the secondary hydroxyl group at C_6 is common to all *ent*-kaurenoids from *Rabdosia* species which have the same functional groups in the B-ring as **7**.

Finally, the structure was confirmed by the chemical correlation of **7** with **2**. Thus, the partial hydrolysis of **7** with methanol–0.1 M (1M=1 mol dm^{-3}) sodium hydroxide solution (1:1) gave a triol (**9**), $C_{24}H_{34}O_8$, mp 254—256 °C, which was found to be identical with the compound derived from **2** by the reduction with sodium borohydride.

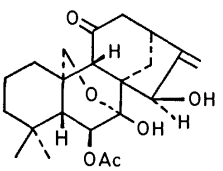
Rabdosianin B (**10**), $C_{28}H_{38}O_{10}$, mp 215 °C (dec), $[\alpha]_D^{20}$ −70° (c 0.39, $CHCl_3$), was isolated as colorless prisms in 0.004% yield and exhibited spectral data quite similar to those of **7**, except for the following



7 R_1=R_2=H, R_3=Ac
9 R_1=R_2=R_3=H
10 R_1=R_3=Ac, R_2=H
11 R_1=R_2=R_3=Ac



8



12

observation: the IR spectrum did not show the presence of a secondary hydroxyl group and, instead, the ^{1}H NMR spectrum (Table 1) revealed the signals due to four acetoxyl groups, one more than those of **7**. These facts, and the appearance of the H_6 signal at a lower field (δ 5.33) as a doublet (J=8.4 Hz) suggested that an acetoxyl group took the place of the secondary hydroxyl group at C_6 of **7**. From the evidence outlined above and the pertinent ^{13}C NMR data (Table 2), we assigned the structure **10**

Table 2. ^{13}C chemical shifts of rabdosianin A (**7**), B (**10**), and C (**12**)[a)]

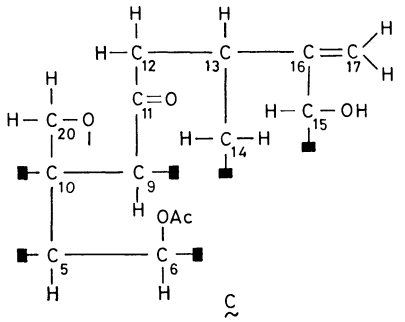
a) The spectra were measured at 100.61 MHz in $CDCl_3$ solutions and the shifts are given in ppm (δ) relative to the internal TMS. Assignments were made by off-resonance and selective proton-noise decouping technique.

for rabdosianin B.

Final confirmation of the structure was achieved by the chemical correlation of **10** with **7**. The acetylation of **10** with acetic anhydride–boron trifluoride etherate gave a pentaacetate (**11**), $C_{30}H_{40}O_{11}$, mp 182—183 °C, which was also obtained by a similar treatment from **7**.

Rabdosianin C (**12**), $C_{22}H_{30}O_6$, mp 222—225 °C, $[\alpha]_D^{20}$ −170° (*c* 0.15, $CHCl_3$), was obtained as colorless flakes in 0.003% yield and showed IR absorptions attributable to hydroxyl (3520, 3320), carbonyl (1755), and *exo*-methylene (3080, 1660, and 905 cm^{-1}) groups. The ^1H NMR spectrum exhibited signals due to two tertiary methyl groups at δ 0.85 and 1.14, one acetyl group at δ 2.18, one tertiary hydroxyl group at δ 3.19, one secondary hydroxyl group at δ 3.30 (d, J=1.9 Hz), one ether type methylene group at δ 4.03 (dd, J=9.5 and 2.2 Hz) and 4.16 (dd, J=9.5 and 1.1 Hz), one methine proton on an oxygenated carbon atom at δ 4.53 (ddd, J=1.9, 1.9, and 1.1 Hz), one methine proton attached to a carbon atom bearing an acetoxyl group at δ 5.17 (d, J=4.6 Hz), and one terminal methylene group at δ 5.18 and 5.25 (each br s). The ^{13}C NMR data (Table 2) revealed the presence of one acetal group (δ 96.1) and one ketonic carbon atom (δ 199.0) together with five methylene groups, three methine groups, and three quaternary carbon atoms. In addition, the presence of the partial structure (**C**) was revealed by extensive ^1H NMDR studies, the results of which are tabulated in Table 1. A long-range coupling across a ketonic group ($J_{H_9,H_{12\beta}}$=2.4 Hz) was observed in this system. Thus, all of the ten oxygen atoms in **12** can be characterized by the functional groups in the partial sturcture (**C**) and a hemiacetal group.



From the aforementioned data, it would be quite reasonable to assign the *ent*-kaurenoid structure for rabdosianin C, in which the partial structure (**C**) would form the B, C, and D-rings. Observation of about 10% N. O. E. on H_{15}, upon irradiation of $H_{14\beta}$, defined the configuration of the secondary hydroxyl group at C_{15} as β. The magnitude of the coupling constant between H_6 and H_5 (J=4.6 Hz) indicated that the acetoxyl group at C_6 is β-oriented.[2)] From this evidence, we propose the structure **12** for rabdosianin C.

Experimental

All mps were determined on a Mitamura micro melting point apparatus and are uncorrected. The IR spectra were recorded on a JASCO model IRA-1 spectrophotometer. The ^1H and ^{13}C NMR spectra were taken on a Bruker WH-400 instrument in $CDCl_3$ solutions with TMS as an internal standard unless otherwise stated. A Union Gikken apparatus, model PM-101, was used for the measurement of the rotations.

Isolation. The dried leaves (5.2 kg) of *Rabdosia shikokianus* Hara were extracted with ether (50 l). The ether solution was treated with activated charcoal (50 g) and evaporated to dryness. The residue (210 g) was subjected to chromatography over silicic acid (1.5 kg) eluting with $CHCl_3$–MeOH mixtures, with MeOH increasing from 0 to 10%. Elution with 2% MeOH in $CHCl_3$ gave a fraction (15 g) which was rechromatographed over silicic acid (300 g), using 40% ethyl acetate in petroleum ether as eluent, to yield rabdosianin C (**12**) (115 mg) and B (**10**) (250 mg). The material (28 g) which was eluted with 5% MeOH in $CHCl_3$ was rechromatographed over silicic acid (600 g), using 50% ethyl acetate in petroleum ether as eluent, to give effusanin B (**5**) (203 mg) and longikaurin E (**6**) (71 mg). The material (22 g) eluted with 10% MeOH in $CHCl_3$ was rechromatographed over silicic acid (600 g), using 70% ethyl acetate in petroleum ether as eluent, to afford rabdosianin A (**7**) (2.70 g).

Rabdosianin A (7). The crude material was recrystallized from ether to give fine needles (1.60 g), mp 150—153 °C; $[\alpha]_D^{20}$ −50° (*c* 0.21, $CHCl_3$); IR (Nujol) 3540, 3440, 1740, 1660, 1235, and 902 cm^{-1}; ^1H NMR (see Table 1); ^{13}C NMR (see Table 2); MS *m/e* 492 (M^+), 450, 432 (M^+—AcOH), 390, 372 (M^+—2AcOH), 330, and 312 (M^+—3AcOH). Found: C, 62.91; H, 7.21%. Calcd for $C_{26}H_{36}O_9$: C, 63.40; H, 7.37%.

Rabdosianin B (10). The crude solid was recrystallized from ether to yield colorless prisms (156 mg), mp 215 °C (dec); $[\alpha]_D^{20}$ −70° (*c* 0.39, $CHCl_3$); IR (Nujol) 3530, 3080, 1740, 1720, 1660, 1240, and 895 cm^{-1}; ^1H NMR (see Table 1); ^{13}C NMR (see Table 2); MS *m/e* 534 (M^+), 474 (M^+—AcOH), 432, 414 (M^+—2AcOH), 372, 354 (M^+—3AcOH), 312, and 294 (M^+—4AcOH). Found: C, 62.52; H, 7.06%. Calcd for $C_{28}H_{38}O_{10}$: C, 62.91; H, 7.17%.

Rabdosianin C (12). The crude substance was recrystallized from EtOH to afford colorless flakes (75 mg), mp 222—225 °C; $[\alpha]_D^{20}$ −170° (*c* 0.15, $CHCl_3$); IR (Nujol) 3520, 3320, 3080, 1755, 1660, 1245, and 905 cm^{-1}; ^1H NMR (see Table 1); ^{13}C NMR (see Table 2); MS *m/e* 372 (M^+—H_2O), 330 (M^+—AcOH), 312, 284, and 266. Found: C, 67.58; H, 7.79%. Calcd for $C_{22}H_{30}O_6$: C, 67.67; H, 7.74%.

Hydrogenation of **7**. **7** (100 mg) and 10% Pd–C (40 mg) were stirred in EtOH (10 ml) under a hydrogen atmosphere at room temperature for 16 h. The catalyst was removed by filtration, and the filtrate was evaporated. The residue was subjected to chromatography over silicic acid (10 g). Elution with ether gave dihydrorabdosianin A (**8**) (50 mg) which was recrystallized from aqueous MeOH to yield colorless plates (30 mg), mp 252—253 °C; IR (Nujol) 3570, 3460, 1740, 1735, 1720, and 1255 cm^{-1}; ^1H NMR δ 0.75 (3H, d, J=7.6 Hz, 17-Me), 1.05 and 1.12 (3H each, s, 18- and 19-Me), 1.95, 2.06, and 2.09 (3H each, s, 3Ac), 2.30 (1H, d, J=2.1 Hz, 6-OH), 2.87 (1H, s, 7-OH), 3.87 (1H, dd, J=7.3 and 2.1 Hz, H_6), 4.10 (1H, br d, J=8.9 Hz, H_{20a}), 4.51 (1H, dd, J=8.9 and 1.5 Hz, H_{20b}), 4.81 (1H, dd, J=3.6 and 3.4 Hz, H_{11}), 4.87 (1H, dd, J=10.7 and 4.6 Hz, H_1), and 5.20 (1H, d, J=10.4 Hz, H_{15}). Found: C, 63.08; H, 7.57%. Calcd for $C_{26}H_{38}O_9$: C, 63.14; H, 7.75%.

Partial Hydrolysis of **7**. A solution of **7** (150 mg) in MeOH (30 ml) and 0.1 M NaOH solution (30 ml) was allowed to stand in a refrigerator for 14 h to yield a crystalline precipitate (50 mg). The crude precipitate was recrystallized from EtOH to give a triol (**9**) as fine needles (33 mg), mp 254—256 °C; $[\alpha]_D^{20}$ +2° (*c* 0.11, $CHCl_3$); IR (Nujol) 3470, 3390, 1735, 1255, and 890 cm^{-1}; ^1H NMR (C_5D_5N) δ 1.14 and 1.24 (3H each, s, 18- and 19-Me), 2.09 and 2.13 (3H each, s, 2Ac), 4.31 (1H, dd, J=8.9 and 1.0 Hz, H_{20a}), 4.40 (1H, dd, J=7.6 and 4.3 Hz, H_6), 4.85 (1H, dd, J=8.9 and 1.4 Hz, H_{20b}), 5.07 (1H, ddd, J=3.0, 2.7, and 1.0 Hz, H_{15}), 5.11 (1H, dd, J=11.3 and 5.6 Hz, H_1), 5.15 (1H, br s, H_{17a}), 5.17 (1H, dd, J=5.4 and 4.6 Hz, H_{11}), 5.48 (1H, br s, H_{17b}), 6.65 (1H, d, J=3.0 Hz, 15-OH), 8.03 (1H, s, 7-OH), and 8.26 (1H, d, J=4.3 Hz, 6-OH); MS *m/e* 450 (M^+), 432 (M^+—H_2O), 390 (M^+—AcOH), 372, and 330 (M^+—2AcOH). Found: C, 63.62; H, 7.47%. Calcd for $C_{24}H_{34}O_8$: C, 63.98; H, 7.61%.

Reduction of **2** *with* $NaBH_4$. To a solution of **2** (100 mg) in MeOH (4 ml) and THF (4 ml) were added excess amounts of $NaBH_4$ (40 mg) with ice cooling. The mixture was stirred for 8 h at 0 °C. The solution was then concentrated, diluted with water (10 ml), and extracted with ethyl acetate. The organic layer was washed with water, dried over Na_2SO_4, and evaporated to dryness. The residue was recrystallized from EtOH to afford a triol (62 mg) which was identified by mixed mp, IR, and ^1H NMR comparison with **9**.

Acetylation of **10**. To a solution of **10** (50 mg) in acetic anhydride (6 ml) was added one drop of BF_3–etherate at −60 °C; the mixture was kept for 3 h below −20 °C, then poured into ice–water and extracted with $CHCl_3$. The $CHCl_3$ layer was washed with water, dried over Na_2SO_4, and evaporated to dryness. The residue was crystallized from ether–petroleum ether to yield a pentaacetate (**11**) as colorless prisms (33 mg), mp 182—183 °C; IR (Nujol) 1740, 1720, and 1235 cm^{-1}; ^1H NMR δ 1.94, 1.97, 1.99, 2.03, and 2.23 (3H each, s, 5Ac); MS *m/e* 516 (M^+—AcOH), 474, 456 (M^+—2AcOH), 432, 414, 396 (M^+—3AcOH), 372, 354, 336 (M^+—4AcOH), 312, 294, and 281. Found: C, 62.79; H, 6.92%. Calcd for $C_{30}H_{40}O_{11}$: C, 62.48; H, 6.99%. **11** was also obtained by the treatment of **7** with acetic anhydride and BF_3–etherate in a similar manner to that described.

We are grateful to Mr. Hideo Mori, Laboratories of Natural Products Chemistry, Otsuka Pharmaceutical Co. Ltd., for recording the mass spectra.

Chiroptical Properties of 10,11-Dihydro-5,10-methano-5*H*-dibenzo[*a*,*d*]cycloheptene Derivatives

Sanji HAGISHITA* and Kaoru KURIYAMA

Shionogi Research Laboratories, Shionogi & Co. Ltd., Fukushima-ku, Osaka 553

(Received April 4, 1981)

The titled compounds have been prepared from (+)-(9*R*,10*R*)-dimethyl 11-oxo-9,10-dihydro-9,10-ethanoanthracene-1,5-dicarboxylate. Their absolute configurations were determined by chemical reaction, and by IR and CD spectra. Although the CD spectra of **2** and **3** (R=NH_2) were expected to show an antipodal pattern from analysis of the simple coupling mechanism, they showed approximately the same magnitude of the positive Cotton effect in both regions of the ^1L_b and ^1L_a benzenoid transitions. Their CD spectra were calculated by the point-dipole exciton treatment and by the π-SCF approximation using the dipole velocity procedure with and without the charge transfer transition between the aromatic chromophores. Thus, the electric transition dipole moment should not be treated as a point dipole at any place and the rotational strength should be calculated by the dipole velocity procedure since a local magnetic transition dipole moment was produced perpendicular to the benzene ring in the region of the ^1L_b transition. The charge transfer transition can not be neglected in the calculation of the MO, though it does not cause the alteration of the sequence of the coupling mode.

In our previous report,[1] we pointed out that the chiroptical properties of C_2-symmetrical (+)-2,6-disubstituted 9,10-dihydro-9,10-ethanoanthracene (DEA) **1** should not be analyzed with a dipole-dipole coupling mechanism,[2] but should be calculated with the dipole velocity method using the molecular orbital calculations, which take into consideration an electron exchange effect between the two aromatic chromophores. Mixing of the charge transfer transition may change the sequence of the A- and B-coupling mode of local transitions into the opposite one and thus result in wrong assignment of the configuration.

In order to estimate the limitation of the electron exchange effect in changing the energy sequence, we synthesized optically active 10,11-dihydro-5,10-methano-5*H*-dibenzo[*a*,*d*]cycloheptene (DMDC) derivatives. They have two aromatic chromophores linked with ethylene and methylene chains and are rigid in conformation. Thus they would have a smaller electron exchange effect than DEA.

The skeletons of compounds **2** and **3** are antipodal to each other but they are not antipodes owing to the substituents at the 1,6- and 4,9-positions. But if the substituents are the same in both compounds and the direction of the electric transition dipole moment of the aromatic chromophores does not change, the CD curves of the two compounds can be expected to be quasi mirror images of each other from a simple coupling mechanism. Therefore the deviation from the antipodal pattern of their CD spectra may be a key to clarify the following factors; the contributions of the charge transfer effect, and a local magnetic transition moment produced perpendicular to the plane of the benzene ring, and a treatment of the electric transition dipole moment as a point dipole, and selection of its position (Fig. 1).[1,3]

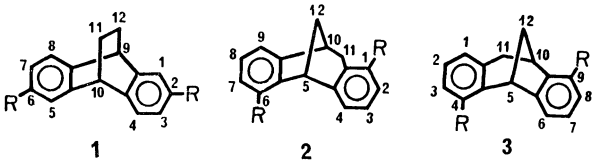

Fig. 1.

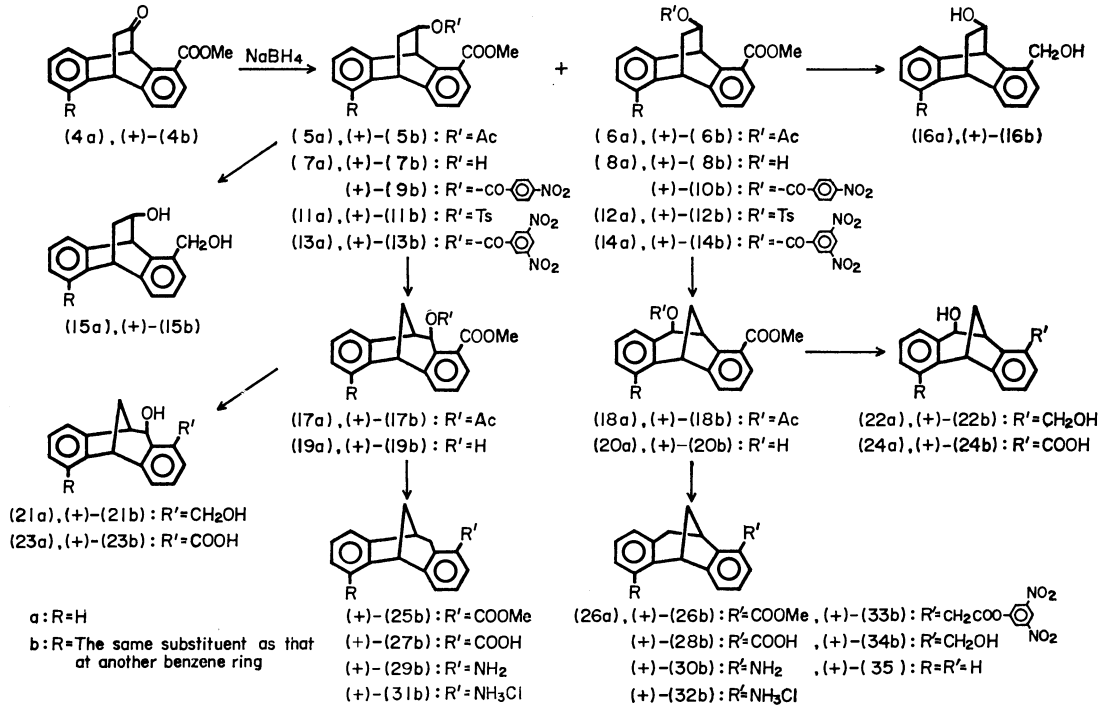
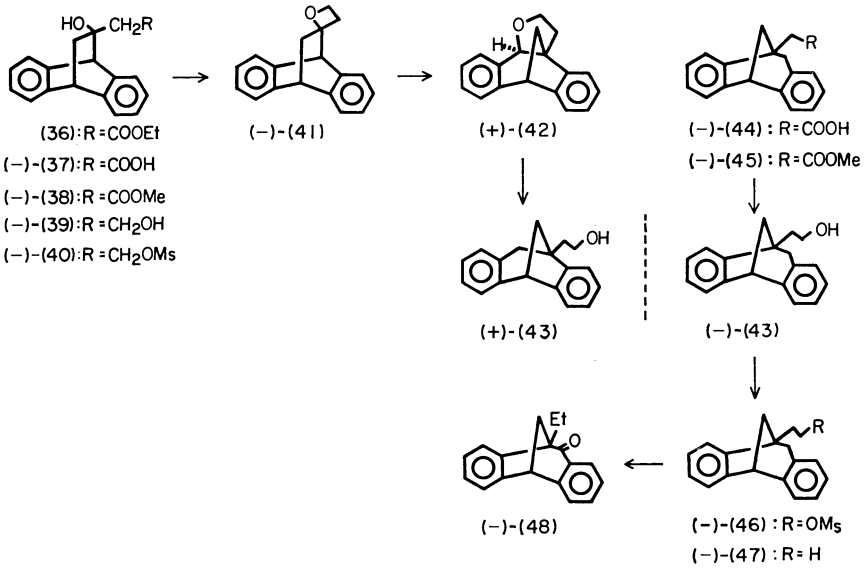
Synthesis. (+)-Dimethyl 12-oxo-DEA-1,5-dicarboxylate, (+)-**4b**, with an absolute configuration determined by us to be 9*R*,10*R*,**,[4] was reduced with sodium borohydride to give a 1:2 mixture of the diols, (+)-**7b** and (+)-**8b**, with a configuration determined by analysis of the NMR spectra of their acetates, (+)-**5b** and (+)-**6b**. The minor product (+)-**7b** was isolated by conversion into the *p*-nitrobenzoyl derivative (+)-**9b** and reduced to the triol (+)-**15b**. Its IR spectrum showed the band attributable to the intramolecular hydrogen bonding at 3483 cm^{-1}, CH_2OH/OH for the dilute chloroform solution, 1.495 mmol/l. Then an *endo*-configuration could be assigned to (+)-**15b** from the model consideration. The solvolysis of the tosylate **11b** took place by Wagner-Meerwein rearrangement giving the rearranged compound, (+)-**17b**, together with less than 5% of other rearranged DMDC, (+)-**18b**. The former could be purified by conversion into the alcohol (+)-**19b**, followed by TLC. The latter was obtained from the crude alcohol (+)-**8b** by the same procedure. The acetate group was assigned the *exo*-configuration in both rearranged products (+)-**17b** and (+)-**18b** by analysis of the NMR spectra.[5] The triol (+)-**21b** obtained from the former acetate showed intramolecular hydrogen bonding at 3439 cm^{-1}, CH_2OH/OH. On the other hand, (+)-**22b** from the latter acetate lacked the corresponding absorption. Thus, from both the NMR and IR spectra, the configurations of the rearranged products (+)-**17b** and (+)-**18b** were assigned as shown in Scheme 1 and coincided with the stereochemical outcome reported by Cristol *et al.*, that is, solvolysis rearrangement brought about migration of the *anti*- to the leaving group.[6] Since the configuration at C-10 of DEA does not change by the rearrangement, the configuration at C-5 of DMDC must possess the (*R*)-configuration. The absolute configurations of (+)-**17b** and (+)-**18b** can therefore be assigned as being (5*R*,10*R*) and (5*R*,10*S*), respectively.

Hydrogenolysis of the hydroxy diesters (+)-**19b** and

** The notation of the absolute configuration of (+)-1,5-disubstituted 11-oxo-DEA in Ref. 4 should be 9*R*,10*R*.



Scheme 1.



Scheme 2.

(+)-**20b** furnished the desired DMDC compounds (+)-**25b** and (+)-**26b** with absolute configurations of 10*S*,5*R* and 10*R*,5*R*, respectively. Other DMDC derivatives (+)-**27b**—**34b** and (+)-**35** could be prepared according to Scheme 1. The same procedure was applied to (±)-methyl 12-oxo-DEA-1-carboxylate **4a**.

11-Hydroxy-DEA-11-acetic acid,*** **37** was resolved with cinchonidine to the (−)-isomer, and (−)-oxetane (−)-**41** was obtained from (−)-**37** as shown in Scheme 2 according to literature[7] cited for the racemate. Rearrangement of the (−)-oxetane (−)-**41** of 94.4% optical purity took place at once with a catalytic amount of *p*-toluenesulfonic acid to give (+)-**42** in quantitative yield. The rearrangement occurred at the asymmetric center. Then in order to determine the optical yield of the reaction, the enantiomer of the hydrogenolyzed alcohol (−)-**43**, was prepared by a different route from optically pure (−)-DMDC-10-acetic acid, (−)-**44** which was obtained from cinchonidine salt. Comparing the optical rotations, $[\alpha]_D$ +180.0° and $[\alpha]_D$ −190.6°, the optical purity of 94.4% was obtained for the alcohol (+)-**43** and was the same as that of the starting carboxylic acid (−)-**37**. Therefore the rearrangement is a completely stereoselective process.

In the NMR spectrum of the rearranged compound

*** This was obtained from the ethyl ester[7] and was very sensitive to acid.

sh; Shoulder, !; lowest recorded value, not a maximum.

(+)-**42** in benzene-d_6, the signal at the C-11 proton appeared in lower field than other methylene and bridgehead protons and exhibited W-letter long-range coupling, J=1.0 Hz, with the C-12 *exo*-proton. This led us to decide upon an α-configuration for the hydrogen at C-11.

(−)-10-Ethyl-DMDC (−)-**47** was prepared from the (−)-alcohol, (−)-**43**, and showed an almost antipodal CD spectrum to (+)-**35**, (Fig. 2). Since the ethyl group at the bridgehead did not have a significant effect on the CD spectrum, the absolute configuration of (−)-**47** assigned was 5*R*,10*S*. This assignment was also supported by the negative Cotton effect attributable to the n-π^* transition of (−)-**48** (Table 1), since Tatemitsu *et al.*[8] have reported that in the structurally similar compound (+)-**49**, the contribution of β,γ-unsaturation is predominant and that of α,β-unsaturation is negligibly small in this region of the CD spectrum (Fig. 3).

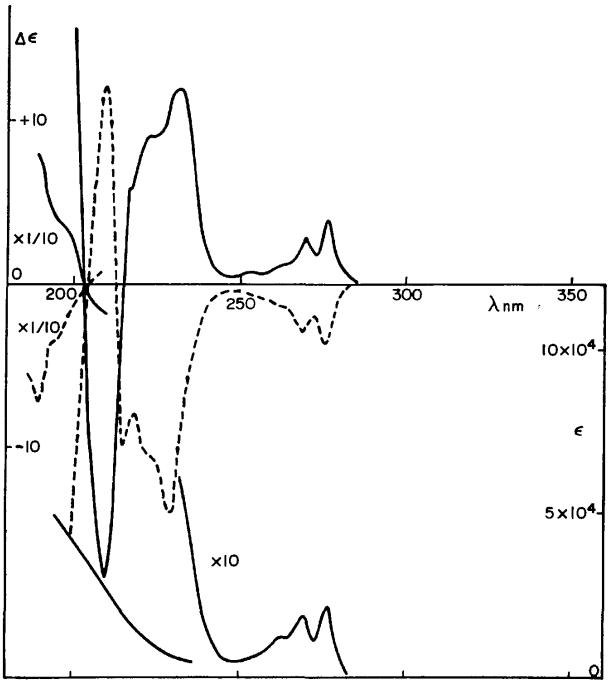

Fig. 2. UV and CD spectra of (+)-**35**, (——), and CD spectrum of (−)-**47**, (- - -).

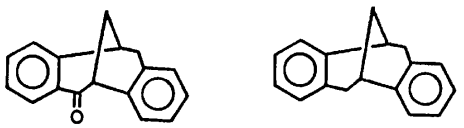

(+)-**49** (+)-**50**

Fig. 3.

Results and Discussion

Figure 4 shows temperature-dependent CD spectra of (−)-**47** in M.I.† Though the vibrational structure became fine for the ^1L_b transition with a decrease in temperature, the rotational strengths, -5.18×10^{-40} cgs at 25 °C, -5.08×10^{-40} cgs at −68 °C, and -5.16×10^{-40} cgs at −190 °C, were invariable within the experimental error. The DMDC skeleton proved to be rigid in conformation, as was expected from the model consideration.

Table 1 shows the UV and CD spectra. (+)-DMDC, (+)-**35**, did not exhibit the couplet pattern but did show a positive Cotton effect with fine structure in the region of the ^1L_b transition. We tried to apply the sector rule[9] to (+)-**35**, assuming the presence of two chromophores with CD spectra that were merely additive. Figure 5 shows two projections along the C_2-axis of the A and B benzene chromophores. In projection A, the rule predicts a negative CD within the ^1L_b band, while projection B predicts that contributions from the second benzene ring should be strongly positive. As they have op-

† Methylcyclohexane isopentane, 4:1,

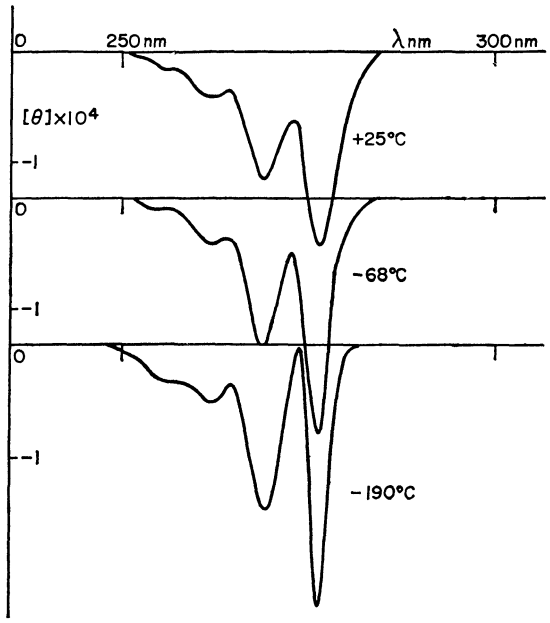

Fig. 4. Temperature-dependent CD spectra of (−)-**47**.

posite signs, a small positive value is expected and this agrees with the measurements.

In the 210—231 nm region, four Cotton effects were detected, three positive CD band followed by one negative CD band at shorter wavelength, with the last two CD bands looking like a couplet. Compound (−)-**50**, with two benzene rings linked with two ethylene chains, has been reported to have four Cotton effects in the 214—226 nm region.[8] Presumably, the couplet centered around 224 nm of (−)-**50** corresponds to the couplet at about 213 nm of (+)-**35** by the nature of the transition, owing to the similarity of the couplet pattern. In this region, besides the ^1L_a transition, the charge transfer transition between two aromatic chromophores are predicted to play an important role, and the positive CD bands at 231 and 224 nm of (+)-**35** and the negative CD bands at 218 and 214 nm of (−)-**50** seem to be assignable to the charge transfer transition by nature. The energy sequences seem likely to displace each other in (+)-**35** and (−)-**50** by their geometrical change.

In the ^1B transition region, two positive Cotton effects were observed but not the couplet pattern.

Compounds (−)-**43**—(−)-**47** have the opposite configuration in the DMDC skeleton to (+)-**35** and showed almost antipodal CD spectra to that of (+)-**35**, though their couplet was clearer in the region of 222—210 nm. Thus the substituent at the bridgehead has only a minor effect on the CD spectrum of DMDC.

Compound (+)-**42** showed a larger magnitude of the positive Cotton effect in the ^1L_b transition than (+)-**35** and only two Cotton effects were observed in the region of 221—230 nm, unlike the case of (+)-**35**. The tetrahydrofuran ring seems to produce little strain on the DMDC skeleton from model inspection. From another point of view, one of the aromatic chromophores is perturbed by oxygen of the ring or

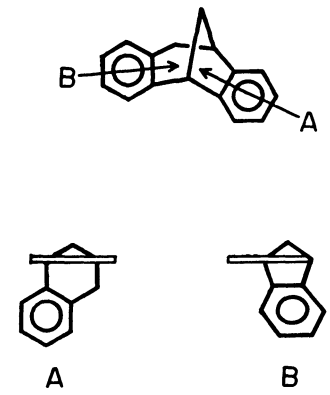

Fig. 5. Stereoformula of (+)-**35** and projection diagrams in the directions A and B.

the ring itself, though the sector rule[9] could not predict their contributions because the oxygen is situated in the negative sector while the ring is in the positive one. The contribution of the hydroxyl group at C-11 to the ^1L_b band CD was found to be positive from comparison of the CD spectra of (+)-**22b** with that of (+)-**34b**. Though this disagrees with the sector rule, it may suggest the predominance of the effect of the oxygen rather than the tetrahydrofuran ring in (+)-**42**.

Compounds (+)-**29b** and (+)-**31b** are antipodal to compounds (+)-**30b** and (+)-**32b** in the skeleton itself, respectively. The substituents, NH_2 or NH_3Cl do not change the direction of electric transition dipole moment of the aromatic chromophores. We would expect from the simple exciton coupling mechanism that they show CD spectra antipodal to each other. In fact, compounds (+)-**29b** and (+)-**30b** showed oppositely signed CD spectra in the wavelength region shorter than 230 nm. However, they showed almost the same magnitude of the positive Cotton effects in the region of the ^1L_b and ^1L_a transition. On the other hand, compounds (+)-**31b** and (+)-**32b** showed antipodal CD spectra in the region of the ^1L_b and ^1L_a transitions but the same signed Cotton effects in the shorter wavelength region.

Compounds (+)-**31b** and (+)-**32b** are not suitable for detailed treatments of the chiroptical properties, because of the uncertainty of the molecular orbitals of the chromophores or the direction of the transition dipoles. Therefore we will later describe the results of theoretical treatments of the optical activity of (+)-**29b** and (+)-**30b**.

In spite of the (+)-DMDC skeleton being rigid in conformation as previously described, the CD spectra of (+)-**25b** and (+)-**26b** were found to vary with temperature as shown in Table 2. For (+)-**25b**, assuming the equilibrium between two conformers, we estimated the free energy difference (ΔG^0) and the $\Delta\varepsilon$ values of two conformers by a simple method described by Moscowitz *et al.*[10]: $\Delta G^0 = 1.0$ kcal/mol; 298 nm ($\Delta\varepsilon$, +11.9 and −7.64); 235 nm ($\Delta\varepsilon$, +31.3 and −6.15).

With compound (+)-**26b**, the magnitude also increased for positive Cotton effects at 295—298 nm and at 230 nm and the negative Cotton effect at 254—

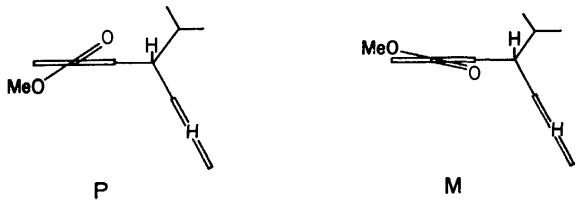

Fig. 6. Projective diagram of the rotamers P and M from the methoxycarbonyl group.

257 nm with the decrease in temperature. But the change could not be analyzed by assuming it to be an equilibrium between two kinds of species.

The methoxycarbonyl group at C-6 of (+)-**25b** and those at C-4 and C-19 of (+)-**26b** are not coplanar with the benzene ring judging from the steric interaction with the bridgehead proton (Fig. 6). But that at C-1 of (+)-**25b** can be coplanar with the benzene ring. Therefore, we deduced that (+)-**25b** had two rotamers. On the other hand, (+)-**26b** had more than two rotamers and showed complex temperature-dependent CD spectra.

The sign of the Cotton effect of the conjugation band in the 270 nm region is correlated with chirality of the conjugated system in some lactonic aromatic compounds, the absolute configurations of which have been determined. The P (right-handed) and M (left-handed) helicity produced positive and negative Cotton effects, respectively, as found with lycorenine alkaloids[11] (Table 3), ochracin derivatives[12] and dihydroisocoumarin compounds.[13]

This empirical rule predicts that the rotamer P will show a positive Cotton effect and the rotamer M, a negative one. Rotamer P would be more stable than rotamer M owing to an additional steric interaction of the methoxycarbonyl group with the proton at C-4. The experimental results of (+)-**25b** support the preference of the rotamer P.

A methoxycarbonyl group will change the direction of the electric transition dipole moment of the benzenoid chromophore, if it is fixed. But the CD spectra of (+)-**25b** and (+)-**26b** are quite similar to those of (+)-**29b** and (+)-**30b**, respectively. This may indicate that the CD spectra of DMDC are not altered very much by the minor change of direction of the local electric transition dipole moment.

Theoretical Consideration. For insight into the contribution of various factors to the chiroptical properties of (+)-**29b** and (+)-**30b**, we tried the following calculations.

1) The rotational strength was obtained by a coupling theory[14] using a point dipole approximation located at the center of the benzene ring. The local transition energy and intensity were taken from the experimental value of the four transitions of 5-aminotetralin.††,4) Structural parameters required for the calculation were derived from idealized geometry as follows: aromatic C-alkyl C bond length=1.52 Å, aromatic C–C=1.40 Å, alkyl C–C=1.54 Å, C–N=1.38 Å, C_{1l}–C_{1a}–C_{4a} and C_{1a}–C_{4a}–C_5 bond angles=122°, C_5–C_{5a}–C_9 and C_{5a}–C_{9a}–C_{10}=110°, and atoms C_5, C_{4a}, C_{1a}, C_{11}, and C_{10} in a plane.

2) The point dipole moment was displaced from the center of the benzene ring according to the calculation by the dipole velocity procedure[15] as follows: ^1L_b, −0.093 Å; ^1L_a, 0.375 Å; ^1B_b, −0.050 Å and ^1B_a, −0.038 Å toward the nitrogen atom.

3) The calculation of the molecular orbital and the rotational strength was as described in Ref. 1. The resonance energies between the two aromatic chromophores were evaluated by proportion to the overlap integrals.

4) All of the charge transfer (c.t.) transitions were neglected in calculating the rotational strength in the above treatment, though the MO contained the c.t. transition.

5) All of the c.t. transitions were neglected in obtaining the MO, and the rotational strength was calculated as in method 3.

Figure 7 shows the results of the calculations by methods 1—5. The CD spectra calculated by method 1 are completely antipodal to each other for (+)-**29b** and (+)-**30b**. The displacement of the point dipole moment does not seem to improve the rotational strength. Thus the disagreement between the calculated and the observed CD spectra may be caused by the assumption of the local electric transition dipole moment as a point dipole and the neglect of the c.t. transition. The results calculated by method 3 reproduce the qualitative features of the CD spectra quite well, with the exception of the transition energy (Figs. 7 and 8). The shift, *ca.* 10 nm, is mainly caused by the direct use of the value of the π-SCF-MO of aniline as a local transition energy. Even if the contribution of the c.t. transition is neglected in calculating the rotational strength by the same MO in method 4, the difference from the results by method 3 is not very large. This similarity indicates that the rotational strength is mainly produced by the coupling of the local transition dipole moments and not very much by the c.t. transition.

When the c.t. transition is completely neglected in obtaining the MO, by method 5, the calculated CD spectra do not reproduce the experimental one. Though the couplet pattern around 230 nm in method

†† The unit should be corrected to 10^{19} cgs in Ref. 4.

56

5 is shared by six transitions in method 3, the sequence of the coupling mode does not change and method 3 gives good agreement with the experimental results in this region. Thus the c.t. transition must be taken into consideration in the calculation of the MO.

In method 5, the local electric transition dipole moment is not assumed to be a point dipole and the rotational strength is calculated by the dipole velocity method.

Also, in method 5 a local magnetic transition dipole moment is produced perpendicular to the benzene ring,[16] which distinguishes this method from methods 1 and 2. The result from method 5 agrees better with the experimental one than those from methods 1 and 2, especially in the region of the ^1L_b transition. This indicates that the induced magnetic transition dipole moment can not be neglected in the transition of small rotational strength.

In summary, the electric transition dipole moment should not treated as a point dipole at any place and the rotational strength should be calculated with a dipole velocity method. The c.t. transition continues

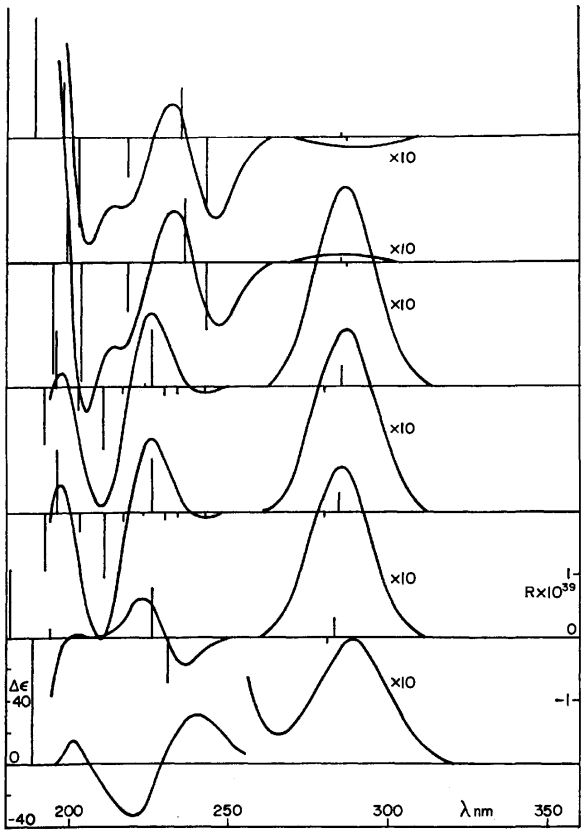

Fig. 7. CD spectra of (+)-**29b**. The theoretical spectra refer to calculations by methods 1 to 5 from the top. The experimental spectrum in cyclohexane is at the bottom.

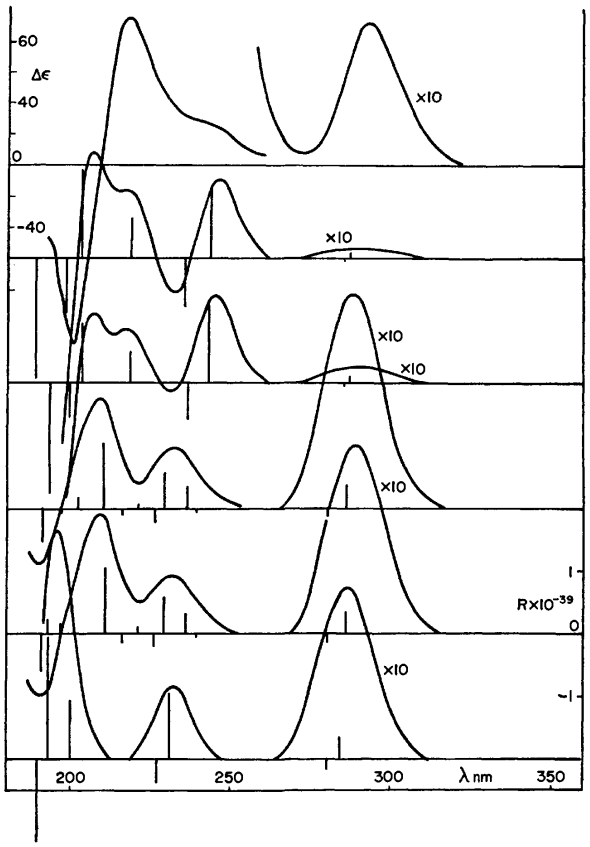

Fig. 8. CD spectra of (+)-**30b**. The experimental spectrum in cyclohexane is at the top. The theoretical spectra refer to calculations by methods 1—5 from the upper part.

to function in the chiroptical properties of the DMDC compounds and can not be neglected in the calculation of the MO, though it does not cause alteration of the coupling mode sequence. The rotational strength is mainly produced by the coupling of the local electric transition dipole moments without much contribution from the c.t. transition.

Experimental

IR spectra were recorded on a JASCO-DS-402G grating spectrophotometer. Optical rotations were determined with a Perkin-Elmer Model 141 polarimeter using a 1-dm microcell. Circular dichroism curves were obtained using a JASCO Model J-40C spectropolarimeter. ^{1}H NMR spectra were measured with a Varian A56/60 D spectrometer using tetramethylsilane as an internal standard. UV spectra were obtained with a Hitachi Model 323 spectrometer.

*Methyl 12-Hydroxy-DEA-1-carboxylate (**7a**) and (**8a**).* $NaBH_4$ (0.42 g) was added in small portions to a solution of methyl 12-oxo-DEA-1-carboxylate (**4a**) (1.03 g) in dry diglyme (20 ml) with ice cooling. The mixture was stirred for 3 h and dilute HCl was added dropwise at 0 °C. The mixture was extracted with ether. The solution was washed with water, dried (Na_2SO_4) and concentrated *in vacuo* to 1.05 g.

A small portion of the residue (53 mg) treated with acetic anhydride and pyridine gave the acetate. Its NMR showed it to be a 1:2 mixture of the epimers.

*(+)-Dimethyl 12-Hydroxy-DEA-1,5-dicarboxylate [(+)-(**7b**) and (+)-(**8b**)].* Dimethyl 12-oxo-DEA-1,5-dicarboxylate [(+)-(**4b**)] (10.1 g) was reduced as above to obtain the desired mixture, 11.0 g.

*Methyl 12-(3,5-Dinitrobenzoyloxy)-DEA-1-carboxylate (**13a**).* 3,5-Dinitrobenzoyl chloride (3.0 g) was added to a solution of a mixture of the alcohols **7a** and **8a** (1.0 g) in pyridine (15 ml) with ice cooling. The mixture was stirred for 1 h and allowed to stand overnight, poured into water and allowed to stand for 1 h. The mixture was extracted with chloroform. The solution was washed with dilute HCl, water, aqueous Na_2CO_3, and water, then dried (Na_2SO_4) and concentrated *in vacuo*. The oily residue was crystallized from benzene–ether and recrystallized twice from the same solvent, giving a colorless powder (113 mg): mp 216—217 °C; IR (Nujol) 1735, 1713, 1340 cm^{-1}; NMR ($CDCl_3$) δ 1.72 (1H, ddd, J=3, 3, 14 Hz), 2.59 (1H, ddd, J=3, 8, 14 Hz), 3.88 (3H, s), 4.45 (1H, t, J=3 Hz), 5.49 (1H, m), 6.02 (1H, d, J=2 Hz), 7.1—7.9 (7H, m), 8.90 (2H, d, J=2 Hz), 9.13 (1H, t, J=2 Hz). Found: C, 63.65; H, 3.75; N, 5.78%. Calcd for $C_{25}H_{18}N_2O_8$: C, 63.29; H, 3.82; N, 5.90%.

The epimer could not be isolated in pure form.

*(+)- and (±)-Dimethyl 11-(3,5-Dinitrobenzoyloxy)-DEA-1,5-dicarboxylate [(+)- and (±)-(**13a**) and (**13b**)].* The (+)- and (±)-alcohols (+)- and (±)-**7b** and **8b** were treated as above but both of the products could not be crystallized. The NMR spectrum showed a mixture of *ca.* 1:2 of the epimers.

*(+)-Dimethyl 11-(4-Nitrobenzoyloxy)-DEA-1,5-dicarboxylate [(+)-(**9b**)].* The (+)-alcohol (+)-**7b** and (+)-**8b**

(11.0 g) was treated with *p*-nitrobenzoyl chloride in the same manner as above. The residue was crystallized and recrystallized from ether, giving colorless prisms (1.5 g): mp 189—191 °C (racemic mp 189—190 °C) $[\alpha]_D^{21}$ +246.3°± 3.5° (*c* 0.709, $CHCl_3$); $\Delta\varepsilon$ +0.065 (333 nm), −0.036 (312), +7.12 (290), +15.9$_{sh}$ (235), +20.9$_{sh}$ (219), +26.6 (208); IR (Nujol) 1715, 1526, 1280 cm^{-1}; NMR ($CDCl_3$) δ 1.72 (1H, ddd, J=3, 3, 13 Hz), 2.52 (1H, ddd, J=13, 9, 3 Hz), 3.78 (3H, s), 4.96 (3H, s), 5.46 (1H, ddd, J=10, 3, 3 Hz), 5.78 (1H, t, J=3 Hz), 6.02 (1H, d, J=3 Hz), 7.0—8.4 (10H, m). Found: C, 66.27; H, 4.31; N, 2.81%. Calcd for $C_{27}H_{21}NO_8$: C, 66.53; H, 4.34; N, 2.87%.

The epimer could not be purified.

(+)-Dimethyl endo-*11-hydroxy-DEA-1,5-dicarboxylate [(+)-(**7b**)]*. A suspension of the (+)-ester (+)-**9b** (1.5 g) in a solution of sodium methoxide in methanol [Na metal (0.05 g) and methanol (25 mg)] was heated under reflux for 18 h and concentrated *in vacuo*. Water was added. The mixture was extracted with ethyl acetate. The solution was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed on thick silica gel plate [Merck, pre-coated plate; benzene–ethyl acetate (3:1)]. The residue (0.7 g) could not be crystallized (racemic mp 142—145 °C).

(+)-Dimethyl exo-*11-hydroxy-DEA-1,5-dicarboxylate [(+)-(**8b**)]*. The crude ester (+)-**10b**, obtained from the mother liquor, was treated as above and gave the crude product (5.5 g).

Methyl endo-*12-hydroxy-DEA-1-carboxylate (**7a**)*. The ester **13a** was treated as above and gave an oily product.

Methyl exo-*12-hydroxy-DEA-1-carboxylate (**8a**)*. *1)* The crude ester **14a**, obtained from the mother liquor was treated as above and gave an oily product. *2)* A mixture of the ester **14a** (657 mg), obtained from the mother liquor, in a solution of 5% KOH in methanol (12 ml) was heated under reflux for 2 h, poured into water, acidified with dilute HCl and extracted with ether. The solution was washed with water, dried (Na_2SO_4) and concentrated *in vacuo*. The crystalline residue could not be fractionally recrystallized and was heated under reflux in methanol (20 ml) and concentrated H_2SO_4 (1 ml) for 15 h. The mixture was poured into water and extracted with ether. The solution was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed on alumina (23 g, Merck, grade *2)* in benzene to obtain methyl 3,5-dinitrobenzoate and in ethyl acetate to obtain the oily product **8a** (402 mg).

*(±)- and (+)-Dimethyl 11-Acetoxy-DMDC-1,6-dicarboxylate [(±) (**17b**) and (+)-(**17b**)]*. A solution of *p*-toluenesulfonyl chloride (0.9 g) in pyridine (8 ml) was added dropwise to a solution of the alcohol (±) **7b** (0.45 g) in pyridine (15 ml) at −5—−7 °C over a period of 1.5 h. The mixture was allowed to stand at 4 °C for 40 h, poured into ice water and extracted with ether. The solution was washed with dilute HCl and water, dried (Na_2SO_4), and concentrated *in vacuo*.

A solution of the crude tosylate (0.423 g) in a solution of anhydrous sodium acetate (0.5 g) in glacial acetic acid (20 ml) was heated at 105 °C for 3 d, concentrated *in vacuo* and dissolved in a mixture of ether and aqueous $NaHCO_3$. The organic phases were washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The NMR spectrum of the crude product was contaminated with less than 5% of dimethyl 11-acetoxy-DMDC-4,9-dicarboxylate (**18b**). The residue was crystallized from hexane and recrystallized from ether, giving a powder (152 mg): mp 173—175 °C; IR (Nujol) 1743, 1722 cm^{-1}; NMR ($CDCl_3$) δ 2.06 (3H, s), 2.40 (2H, m), 3.63 (2H, m), 3.75 (3H, m), 3.89 (3H, m), 4.90 (1H, m), 6.29 (1H, d, J=2 Hz), 7.0—7.4 (2H, m), 7.6—7.9 (4H, m). Found: C, 69.29; H, 5.29%. Calcd for $C_{22}H_{20}O_6$: C, 69.46; H, 5.30%.

The (+)-isomer (+)-**17b** could not be crystallized.

*(+)-Dimethyl 11-Acetoxy-DMDC-4,9-dicarboxylate [(+)-(**18b**)]*. The alcohol (+)-**8b** (5.5 g) was treated as above and gave an oily product (4.1 g).

*Methyl 11-Acetoxy-DMDC-1-carboxylate (**17a**)*. The alcohol **7a** (0.3 g) gave an oily product **17a** by the same treatment.

*Methyl 11-Acetoxy-DMDC-9-carboxylate (**18a**)*. The alcohol **8a** (0.402 g) gave the rearranged compound **18a** (0.286 g).

*(+)-Dimethyl 11-Hydroxy-DMDC-1,6-dicarboxylate [(+)-(**19b**)]*. The crude acetate (+)-**17b** obtained above was treated as in the solvolysis of **9b** and gave the crude product, which was chromatographed on thin silica gel plate [Merck, pre-coated; benzene–ethyl acetate (2:1)] and gave an oily material: $[\alpha]_D^{26}$ +310.4°±5.5° (*c* 0.714, $CHCl_3$); IR ($CHCl_3$) 3465, 1714 cm^{-1}; NMR ($CDCl_3$) δ 2.2—2.9 (2H, m), 3.68 (1H, broad s), 3.83 (3H, s), 3.90 (3H, s), 4.88 (1H, broad s), 4.91 (1H, d, J=4 Hz), 6.9—7.9 (6H, m).

*(+)-Dimethyl 11-Hydroxy-DMDC-4,9-dicarboxylate [(+)-(**20b**)]*. Oil, $[\alpha]_D^{22}$ +433.5°±9.9° (*c* 0.480, MeOH); IR ($CHCl_3$) 3610, 1717 cm^{-1}; NMR ($CDCl_3$) δ 2.43 (2H, m), 3.90 (3H, s), 3.95 (3H, s), 4.16 (1H, broad s), 4.85 (1H, d, J=2 Hz), 4.98 (1H, broad s), 6.9—7.9 (6H, m); (racemic compound, mp 152—153 °C).

*Methyl 11-Hydroxy-DMDC-1-carboxylate (**19a**)*. Oil; IR (film) 3480, 1700 cm^{-1}; NMR ($CDCl_3$) δ 2.2—2.8 (2H, m), 3.65 (1H, m), 3.78 (1H, s), 3.94 (1H, m), 4.88 (1H, d, J=3 Hz), 6.9—7.5 (1H, m), 7.71 (1H, dd, J=7, 2 Hz).

*Methyl 11-Hydroxy-DMDC-9-carboxylate (**20a**)*. Mp 159—161 °C; IR (Nujol) 3503, 1698, 1024, 1012 cm^{-1}; NMR ($CDCl_3$) δ 2.40 (2H, m), 3.89 (3H, s), 3.90 (1H, s), 4.17 (1H, m), 4.82 (1H, d, J=2 Hz), 6.9—7.5 (6H, m), 7.72 (1H, dd, J=7.2 Hz). Found: C, 76.77; H, 5.64%. Calcd for $C_{18}H_{16}O_3$: C, 77.12; H, 5.75%.

1-Hydroxymethyl-endo-*12-hydroxy-DEA and 1-Hydroxymethyl*-exo-*1-hydroxy-DEA [(**15a**) and (**16a**)]*. A solution of the keto ester **4a** (193 mg) in dry tetrahydrofuran (5 ml) was added to a slurry of $LiAlH_4$ (100 mg) in tetrahydrofuran (5 ml) with ice cooling. This mixture was heated under reflux for 2 h. Excess $LiAlH_4$ was decomposed with a solution of methanol in ether then dilute HCl with ice cooling. The organic phase was separated and the aqueous phase was extracted with ether. The combined organic phases were washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The oily residue was chromatographed on thin silica gel plate [Merck, pre-coated; benzene–ethyl acetate (1:3)].

Fraction 1, 54.3 mg, was recrystallized from benzene: mp 169—170 °C; IR ($CHCl_3$) 3611, 3482 cm^{-1} (8.565×10^{-3} M/l); NMR ($CDCl_3$) δ 1.36 (1H, ddd, J=3, 3, 13 Hz), 2.28 (1H, ddd, J=3, 9, 13 Hz), 4.30 (1H, t, J=3 Hz), 4.30 (1H, m), 4.52 (1H, d, J=12 Hz), 4.80 (1H, d, J=3 Hz), 5.01 (1H, d, J=11 Hz), 7.0—7.5 (7H, m), Found: C, 80.45; H, 6.30%. Calcd for $C_{17}H_{16}O_2$: C, 80.93; H, 6.39%.

Fraction 2, 76.1 mg, was recrystallized from benzene: mp 142—143 °C; IR ($CHCl_3$) 3606, 3576 cm^{-1} (7.525×10^{-3} M/l); NMR ($CDCl_3$) δ 1.30 (1H, ddd, J=3, 3, 13 Hz), 2.21 (1H, ddd, J=3, 9, 13 Hz), 4.10 (1H, m), 4.20 (1H, t, J=3 Hz), 4.66 (3H, d, J=3 Hz), 6.9—7.4 (7H, m). Found: C, 81.89; H, 6.47%. Calcd for $C_{17}H_{16}O_2\cdot1/2C_6H_6$: C, 82.44; H, 6.57%.

Reduction of the diesters **5a** and **6a** gave the same product.

(+)-11-Hydroxy-1,6-bis(hydroxymethyl)-DMDC [*(+)-(**21b**)*]. The ester (+)-**19b** (80 mg) was reduced as described above and recrystallized from ethyl acetate: mp 194—196 °C, (31.6 mg), $[\alpha]_D^{22}$ +47.9°±1.6° (*c* 0.553, MeOH); IR ($CHCl_3$) 3595, 3439 cm^{-1} (a supernatant of 3.09 mg/5 ml); NMR (CD_3OD) δ 2.1—2.8 (2H, m), 3.47 (1H, broad s), 4.78 (1H, m), 4.44 (1H, d, J=13 Hz), 4.60 (2H, s), 4.78 (1H, d, J=13 Hz), 4.82 (s), 6.9—7.4 (6H, m). Found: C, 76.04; H, 6.44%. Calcd for $C_{18}H_{18}O_3$: C, 76.57; H, 6.43%.

(+)-11-Hydroxy-4,9-bis(hydroxymethyl)-DMDC [*(+)-(**22b**)*]. The ester (+)-**20b** (101 mg) was reduced as described above to give a powder (24.5 mg): mp 155—156 °C, $[\alpha]_D^{22}$ +357.8°±7.0° (*c* 0.573, MeOH); IR ($CHCl_3$) 3603 cm^{-1} (supernatant of 3.26 mg/5 ml); NMR (CD_3OD) δ 2.42 (2H, m), 3.62 (1H, broad s), 4.35 (1H, broad s), 4.65 (2H, s), 6.8—7.4 (6H, m). Found: C, 76.34; H, 6.53%. Calcd for $C_{18}H_{18}O_3$: C, 76.57; H, 6.43%.

*11-Hydroxy-1-hydroxymethyl-DMDC (**21a**).* The ester **19a** (87 mg) was reduced in the same manner to give a powder (48 mg): mp 155 °C; IR ($CHCl_3$) 3590, 3440 cm^{-1} (8.52×10^{-3} M/l); NMR ($CDCl_3$) δ 2.2—2.7 (2H, m), 3.52 (1H, broad s), 3.93 (1H, m), 4.23 (1H, d, J=12 Hz), 4.64 (1H, d, J=12 Hz), 4.80 (1H, d, J=2 Hz), 6.9—7.5 (7H, m). Found: C, 80.65; H, 6.51%. Calcd for $C_{17}H_{16}O_2$: C, 80.93; H, 6.39%.

*11-Hydroxy-9-hydroxymethyl-DMDC (**22a**).* The ester **20a** (24 mg) was reduced as described above to give a powder (6.5 mg): mp 129—130 °C; IR ($CHCl_3$) 3604 cm^{-1} (8.53×10^{-3} M/l); NMR ($CDCl_3$) δ 2.40 (2H, m), 3.63 (1H, m), 3.87 (1H, t, J=2 Hz), 4.62 (2H, s), 4.72 (1H, d, J=2 Hz), 6.9—7.3 (7H, m). Found: C, 80.78; H, 6.34%. Calcd for $C_{17}H_{16}O_2$: C, 80.93; H, 6.39%.

(+)-Dimethyl DMDC-4,9-dicarboxylate [*(+)-(**26b**)*]. A mixture of the hydroxy ester (+)-**20b** (2.8 g), 30% palladium charcoal (0.9 g) and a few drops of 70% perchloric acid in methanol (130 ml) was stirred in a hydrogen atmosphere for 6 d. The catalyst was filtered then washed with methanol. The filtrate was concentrated *in vacuo*. The residue was dissolved in dichloromethane, washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was distilled at 220 °C (bath temperature) at 0.05 mmHg through a short-path distillation apparatus and gave a viscous oil (2.4 g).

A solution of the (+)-diester (2.25 g) in a solution of 5% KOH in methanol (60 ml) was heated under reflux for 2 h and concentrated to the half volume *in vacuo*. Ice-cold dilute HCl was added. The crystals were collected by filtration, washed with water and dissolved in ethyl acetate. The solution was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was recrystallized from acetone, ethyl acetate then methanol and gave (+)-**28b**: mp 258—262 °C, $[\alpha]_D^{21}$ +575.4°±9.4° (*c* 0.349, MeOH); IR (Nujol) 1692 cm^{-1}; NMR (CD_3OD) δ 2.00 (1H, d, J=11 Hz), 2.42 (1H, ddd, J=11, 6, 1 Hz), 2.84 (1H, dd, J=4 Hz), 3.33 (1H, dd, J=18, 6 Hz), 4.18 (1H, broad t, J=4 Hz), 4.98 (1H, d, J=4 Hz), 6.9—7.8 (6H, m). Found: C, 73.37; H, 4.91%. Calcd for $C_{18}H_{14}O_4$: C, 73.46; H, 4.79%.

The (+)-dicarboxylic acid (55.3 mg) was esterified with excess diazomethane to give the diester (60 mg), which was crystallized from hexane: mp 92.5—93.5 °C; $[\alpha]_D^{21}$ +547.4°±9.6° (*c* 0.327, $CHCl_3$); IR ($CHCl_3$) 1716 cm^{-1}; NMR ($CDCl_3$) δ 2.04 (1H, d, J=13 Hz), 2.46 (1H, ddd, J=10, 6, 1 Hz), 2.92 (1H, dd, J=16, 1 Hz), 3.38 (1H, dd, J=16, 5 Hz), 3.88 (3H, s), 3.93 (3H, s), 4.15 (1H, broad t, J=4 Hz), 4.91 (1H, d, 5 Hz), 6.9—7.8 (6H, m), Found: C, 73.84; H, 5.49%. Calcd for $C_{20}H_{18}O_4$: C, 74.51; H, 5.63%.

(+)-Dimethyl DMDC-1,6-dicarboxylate [*(+)-(**25b**)*]. The same hydrogenolysis was carried out on the alcohol (+)-**19b** (110 mg) giving the desired product (44 mg): mp 113 °C; $[\alpha]_D^{22}$ +315.3°±2.0° (*c* 0.275, $CHCl_3$); IR (film) 1719 cm^{-1}; NMR ($CDCl_3$) δ 1.9—2.8 (2H, m), 2.9—3.3 (1H, m), 3.3—3.7 (2H, m), 3.77 (3H, s), 3.90 (3H, s), 4.82 (1H, d, J=5 Hz), 6.9—7.9 (6H, m). Found: C, 74.65; H, 5.57%. Calcd for $C_{20}H_{18}O_4$: C, 74.51; H, 5.63%.

*Methyl DMDC-9-carboxylate (**26a**).* The acetate **20a** (238 mg) was hydrogenolyzed according to the procedure cited above and gave prisms (53.3 mg): mp 80—81 °C; IR 1713 cm^{-1}; NMR ($CDCl_3$) δ 2.12 (1H, d, J=13 Hz), 2.47 (1H, broad dd, J=13, 6 Hz), 2.85 (1H, d, J=16 Hz), 3.32 (1H, dd, J=16, 6 Hz), 6.8—7.3 (6H, m), 7.73 (1H, dd, J=8, 2 Hz). Found: C, 81.43; H, 5.97%. Calcd for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10%.

(+)-DMDC-1,6-dicarboxylic Acid [*(+)-(**27b**)*]. Mp 259—260 °C; $[\alpha]_D^{22}$ ±315.3°±5.7° (*c* 0.347, MeOH).

(+)-1,6-Diamino-DMDC [*(+)-(**29b**)*]. NaN_3 (1.11 g) was added in small portions to a solution of the (+)-dicarboxylic acid [(+)-(**27b**)] (612 mg) in concentrated H_2SO_4 (33 ml) at 40—45 °C over a period of 1 h with vigorous stirring. The mixture was then heated at 50 °C for 6 h, allowed to stand overnight, poured onto ice, made alkaline with 40% aqueous NaOH and extracted with benzene. The solution was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The crystalline residue was recrystallized from benzene and gave prisms (368 mg) (74.9%): mp 178—179 °C; $[\alpha]_D^{22}$ +736.1°±11.4° (*c* 0.357, MeOH); IR (Nujol) 3355 cm^{-1}; NMR ($CDCl_3$) δ 1.97 (1H, d, J=10 Hz), 2.41 (1H, dd, J=5, 10 Hz), 2.63 (1H, d, J=14 Hz), 3.12 (1H, dd, J=5, 14 Hz), 3.31 (1H, d, J=4 Hz), 3.51 (4H, s), 3.90 (1H, d, J=5 Hz), 6.2—7.4 (6H, m). Found: C, 81.29; H, 6.76; N, 11.78%. Calcd for $C_{16}H_{16}N_2$: C, 81.32; H, 6.82; N, 11.85%.

(+)-4,9-Diamino-DMDC [*(+)-(**30b**)*]. The (+)-dicarboxylic acid [(+)-(**28b**)] (45 mg) was treated as above and gave prisms (21.5 mg): mp 224—225 °C; $[\alpha]_D^{23}$ +212.9°±4.1° (*c* 0.364, $CHCl_3$); IR (Nujol) 3465, 3375 cm^{-1}; NMR ($CDCl_3$–a drop of CD_3OD) δ 2.07 (1H, d, J=11 Hz), 2.42 (1H, dd, J=5, 11 Hz), 2.66 (1H, dd, J=5, 16 Hz), 3.15 (1H, dd, J=5, 16 Hz), 3.5 (1H, m), 3.81 (1H, d, J=5 Hz), 6.3—7.3 (6H, m). Found: C, 80.99; H, 6.66; N, 12.04%. Calcd for $C_{16}H_{16}N_2$: C, 81.32; H, 6.82; N, 11.85%.

*1,5-bis(hydroxymethyl)-11-*endo*-hydroxy-DEA (**15b**).* A solution of the ester **9b** (99 mg) in dry tetrahydrofuran (3 ml) was added to a slurry of $LiAlH_4$ (0.1 g) in tetrahydrofuran (3 ml) with cooling in ice. The mixture was then heated under reflux for 2 h and treated as usual. The residue was chromatographed on thin silica gel plate [Merck, pre-coated plate; ethyl acetate] and recrystallized from chloroform, giving a powder (31.2 mg): mp 153—154 °C; IR ($CHCl_3$) 3607, 3484 cm^{-1} (1.495 M/l); NMR (CD_3OD) δ 1.33 (1H, ddd, J=3, 3, 13 Hz), 2.22 (1H, ddd, J=3, 9, 13 Hz), 4.13 (1H, m), 4.5—4.8 (m), 6.8—7.4 (6H, m). Found: C, 75.67; H, 5.41%. Calcd for $C_{18}H_{18}O_4$: C, 76.57; H, 6.43%.

(+)-4,9-Bis(hydroxymethyl)-DMDC [*(+)-(**34b**)*]. The (+)-diester (+)-**26b** (91 mg) was reduced as above. The product could not be crystallized and was converted into the bis(3,5-dinitrobenzoyl) ester according to the above procedure, giving crystals (109 mg): mp 176—178 °C; $[\alpha]_D^{22}$ +179.8°±2.5° (*c* 0.511, $CHCl_3$); IR (Nujol) 1720, 1550,

1288 cm^{-1}; NMR ($CDCl_3$) δ 2.20 (1H, d, J=11 Hz), 2.64 (1H, dd, J=5, 11 Hz), 2.86 (1H, d, J=16 Hz), 3.43 (1H, dd, J=5, 16 Hz), 3.78 (1H, m), 4.42 (1H, m), 5.55 (1H, s), 5.57 (1H, d, J=12 Hz), 5.82 (1H, d, J=12 Hz), 6.9—7.4 (6H, m), 9.1—9.3 (6H, m). Found: C, 58.63; H, 3.54; N, 8.18%. Calcd for $C_{32}H_{22}N_4O_{12}$: C, 58.72; H, 3.39; N, 8.56%.

The ester was hydrolyzed with a 5% KOH solution in methanol by refluxing for 3 h giving an oily residue: $[\alpha]_D^{23}$ +407.5°±6.1° (c 0.402, MeOH); NMR ($CDCl_3$) δ 2.06 (1H, d, J=11 Hz), 2.48 (1H, dd, J=11Hz), 2.77 (1H, d, J=16 Hz), 3.28 (1H, dd, J=16, 5 Hz), 3.63 (1H, m), 4.34 (1H, d, J=5 Hz), 4.68 (2H, s), 4.80 (2H, s), 6.8—7.3 (6H, m). Found: C, 79.96; H, 6.79%. Calcd for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%.

*(+)-11-Hydroxy-DMDC-4,9-dicarboxylic Acid (**24b**).* A crude rearranged compound **18b** (4.1 g) was hydrolyzed with a solution of 5% KOH in methanol (60 ml) by heating under reflux for 3 h. The product could not be purified by recrystallization and was esterified with methanol in the presence of concentrated H_2SO_4 by heating under reflux for 16 h. The crude ester was chromatographed on a thick silica gel plate [Merck, pre-coated plate; benzene–ethyl acetate (5:2)]. The residue was crystallized from benzene–hexane giving a powder (1.0 g): mp 152—153 °C. Found: C, 71.32; H, 5.51%. Calcd for $C_{20}H_{18}O_5$: C, 70.99; H, 5.36%.

The ester was hydrolyzed as above. Mp 286 °C (dec); IR (Nujol) 1692 cm^{-1}; NMR (CD_3OD) δ 2.30 (2H, m), 4.32 (2H, broad s), 5.00 (1H, broad s), 6.9—7.9 (6H, m). Found: C, 70.22; H, 4.72%. Calcd for $C_{18}H_{14}O_5$: C, 69.67; H, 4.55%.

*(+)-DMDC [(+)-(**35**)].* A mixture of the (+)-dicaboxylic acid [(+)-(**28b**)] (163 mg), copper chromite (220 mg) and quinoline, which was distilled over copper chromite, was heated under reflux for 1.5 h, poured into water and extracted with ether. The solution was washed with dilute HCl, aqueous $NaHCO_3$ and water, dried (Na_2SO_4) and concentrated *in vacuo*. The residue was chromatographed on thin silica gel plate [Merck, pre-coated; hexane] and distilled at 140 °C (bath temperature) at 0.05 mmHg (1mmHg=133.322 Pa). $[\alpha]_D^{23}$ +206.5°±2.0° (c 0.3056, $CHCl_3$); IR (film) 750 cm^{-1}; NMR ($CDCl_3$) δ 2.08 (1H, d, J=11 Hz), 3.23 (1H, dd, J=15, 5 Hz), 3.46 (1H, m), 3.85 (1H, d, J=4 Hz), 7.8—7.4 (8H, m). Found: C, 92.92; H, 6.61%. Calcd for $C_{16}H_{14}$: C, 93.16; H, 6.84%.

*Ethyl 11-Hydroxy-DEA-11-acetate (**36**).* The procedure used was a modification of a reported method.[7] A solution of 11-oxo-DEA (10.3 g) and ethyl bromoacetate (10 ml) in dry tetrahydrofuran (70 ml) was added dropwise to a mixture of activated Zn powder (20 g) in tetrahydrofuran (80 ml) with vigorous stirring at refluxing temperature. The reaction was started by addition of a small piece of iodine. After completion of the addition, the mixture was heated for 1 h. Activated Zn powder (20 g) and a small piece of iodine was added together. The mixture was again heated for 30 min. A solution of ethyl bromoacetate (2 ml) in tetrahydrofuran (5 ml) and activated Zn powder (20 g) were added. Heating of the solution was continued for 1 h. Acetic acid (20 ml) was added with cooling in ice then water was added. The organic phase was separated and the aqueous phase was extracted with ether. The combined organic phases were washed with dilute NH_4OH and water, dried (Na_2SO_4) and concentrated *in vacuo*. The oily residue was crystallized from ether giving colorless crystals, 9.8 g (68.0%). All of the physicochemical properties were identical with those of the authentic samples.

*11-Hydroxy-DEA-11-acetic Acid (**37**).* A solution of the ester **36** (1.0 g) in 5% KOH solution of methanol (20 ml) was heated under reflux for 2 h then poured into ice-cold dilute HCl (1.8 ml of concentrated HCl in 80 ml of ice water). The mixture was extracted with ethyl acetate. The solution was washed with water, dried (Na_2SO_4) and concentrated *in vacuo*. The crystalline residue, 0.877 g (96.4%), was washed with ether. Mp 211 °C.

*Optical Resolution of the Carboxylic Acid **37**.* A solution of the acid **37** (0.877 g) in methanol (5 ml) was added to a solution of cinchonidine (0.925 g) in methanol (10 ml). The solvent was changed to ethyl acetate. The crystals were collected by filtration and recrystallized from methanol four times to give a pure diastereomer (0.34 g): $[\alpha]_D^{25}$ −89.5°±1.7° (c 0.784, MeOH).

The salt was shaken with ethyl acetate and dilute HCl. The organic phase was separated and the aqueous phase was extracted with ethyl acetate. The combined organic phases were washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was crystallized from methanol–water giving crystals (0.15 g): mp 139—140 °C, 158—159 °C (dimorphism), $[\alpha]_D^{27}$ −21.6°±0.6° (c 1.060, MeOH); IR (Nujol) 3330, 1708 cm^{-1}. Found: C, 75.83; H, 6.04%. Calcd for $C_{18}H_{16}O_3 \cdot 1/2H_2O$: C, 74.72; H, 5.92%.

*(−)-Methyl 11-Hydroxy-DEA-11-acetate [(−)-(**38**)].* A solution of the (−)-carboxylic acid (−)-**37** (0.685 g) in ether (10 ml) was added to a solution of excess diazomethane in ether. The solution was allowed to stand at 5 °C for 30 min and concentrated *in vacuo*. The crystalline residue was recrystallized from ether–hexane giving crystals (0.707 g): mp 117—118 °C; IR (Nujol) 3520, 3490, 1726, 1715 cm^{-1}; $[\alpha]_D^{24}$ +15.2°±0.5° (c 1.246, $CHCl_3$), CD $\Delta\varepsilon$ −0.175 (272.5 nm), +0.04 (270), −0.10 (267), +0.09 (262), +5.33 (232) (94.4% optical purity). Found: C, 77.82; H, 6.42%. Calcd for $C_{19}H_{18}O_3$: C, 77.53; H, 6.16%.

*(−)-11-Hydroxy-11-(2-hydroxymethyl)-DEA [(−)-(**39**)].* The (−)-ester (−)-**38** was reduced with $LiAlH_4$ by the same method reported for the reduction of the racemic ethyl ester **36**.[7] Mp 131—132 °C; $[\alpha]_D^{24}$ −21.4°±0.6° (c 1.027, MeOH), CD $\Delta\varepsilon$ −0.118 (273 nm), +0.023 (270), +0.052 (266), +6.33 (231), −7.78 (213) (94.4% optical purity).

*(−)-Monomesylate [(−)-(**40**)] of (−)-11-Hydroxy-11-(2-hydroxyethyl)-DEA.* The optically active compound (0.427 g, 95.3%) was synthesized from (−)-**39** (0.347 g) by the same procedure cited for the racemic compound.[7] The oily residue was used for the next preparation without further purification.

*(−)-Spiro[9,10-dihydro-9,10-ethanoanthracene-11,2′-oxetane] [(−)-(**41**)].* The optically active compound was also prepared by the same method cited for the racemic one. Mp 136—138 °C, $[\alpha]_D^{24}$ −67.0°±1.0° (c 1.119, $CHCl_3$), CD $\Delta\varepsilon$ +0.03 (276.5 nm), −0.16 (273), +0.087 (269.5), −0.12 (266), +0.056 (263), +2.20 (228) (94.4% optical purity).

*2,3,3a,12b-Tetrahydro-3a,8-methano-8H-dibenzo[3,4:6,7]cyclohepta[b]furan [(+)-(**42**)].* 1) The (−)-oxetane (−)-**41** (9.51 mg) was dissolved in chloroform (1 ml) containing *p*-toluenesulfonic acid (10 mg). After 3 min, $[\alpha]_D^{24}$ +145.8°±2.0°. The value did not change after 6 h.

2) The (−)-oxetane (−)-**41** (0.15 g) was dissolved in a solution of *p*-toluenesulfonic acid (0.1 g) in chloroform (10 ml). The solution was shaken for 10 min, washed with aqueous $NaHCO_3$ and water, dried (Na_2SO_4) and concentrated *in vacuo*. The oily residue (0.137 g) was distilled at 180 °C (bath temp) at 0.4 mmHg through a short path distillation apparatus. $[\alpha]_D^{24}$ +132.2°±3.6° (c 0.481, $CHCl_3$).

*(+)-10-(2-Hydroxyethyl)-DMDC [(+)-(**43**)].* A

mixture of the rearranged material (+)-**42** (63 mg, 94.4% e.e.), 30% palladium charcoal (0.4 g), a drop of 70% perchloric acid, and ethanol (4 ml) was stirred in a hydrogen atmosphere for 5 d. The catalyst was removed by filtration. The filtrate was concentrated *in vacuo*. The residue was chromatographed on florisil (5 g) in dichloromethane and crystallized from ether. Mp 131—134 °C; $[\alpha]_D^{25}$ +180.0° ±2.6° (*c* 0.845, MeOH).

*DMDC-10-Acetic Acid (**44**).* A Jones' reagent was added to a solution of the alcohol **39** (3.3 g) in acetone (50 ml) with cooling in ice until the characteristic brown color persisted. After 10 min, the mixture was diluted with water and extracted with ether. The solution was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The oily residue was crystallized from benzene–hexane giving a powder, 2.5 g (71.7%): mp 155—156 °C; IR (Nujol) 1700 cm^{-1}. Found: C, 82.70; H, 6.21%. Calcd for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10%.

*Optical Resolution of **44**.* Cinchonidine (2.60 g) was added to a solution of the carboxylic acid **44** (2.33 g) in methanol (40 ml). The mixture was warmed to a clean solution then allowed to stand at room temperature overnight. The crystals were collected by filtration and recrystallized from methanol three times to give the pure diastereomer (1.25 g): $[\alpha]_D^{24}$ −163.8°±5.6° (*c* 0.469, MeOH).

The salt was shaken with dilute HCl and ether. The organic phase was separated and the aqueous phase was extracted with ether. The combined organic phases were washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The oily residue, 0.578 g, could not be crystallized. $[\alpha]_D^{24}$ −170.0°±1.6° (*c* 1.329, MeOH).

*(−)-Methyl DMDC-10-Acetate [(−)-(**45**)].* A solution of the (−)-carboxylic acid (−)-**44** (0.157 g) in ether (3 ml) was added dropwise to a solution of excess diazomethane in ether with ice cooling. The mixture was stirred for 30 min and concentrated *in vacuo*. The residue was distilled at 200 °C (bath temperature) at 0.4 mmHg giving a viscous oil, 0.162 g (98.0%): $[\alpha]_D^{23}$ −158.4°±2.4° (*c* 0.826, $CHCl_3$); IR (film) 1738 cm^{-1}. Found: C, 81.82; H, 6.48%. Calcd for $C_{19}H_{18}O_2$: C, 81.99; H, 6.52%.

*(−)-1-(2-Hydroxyethyl)-DMDC [(−)-(**43**)].* The ester (−)-**45** (0.148 g) was reduced with $LiAlH_4$ as for (−)-**38**. The residue was distilled at 180 °C at 0.4 mmHg. The distillate (0.113 g) crystallized quickly and then was recrystallized from ether giving a powder (0.088 g): mp 133—134 °C; $[\alpha]_D^{23}$ −190.6°±3.1° (*c* 0.745, MeOH). Found: C, 86.51; H, 7.25%. Calcd for $C_{18}H_{18}O$: C, 86.36; H, 7.25%.

*Mesylate (−)-**46** of (−)-1-(β-Hydroxyethyl)-DMDC.* (−)-**43** (0.341 g) was mesylated as usual. The residue crystallized on standing and was used for the next preparation.

*(−)-10-Ethyl-DMDC [(−)-(**47**)].* A solution of the (−)-mesylate (−)-**46** (0.40 g) in dry tetrahydrofuran (5 ml) was added to a slurry of $LiAlH_4$ (0.3 g) in tetrahydrofuran (10 ml) with ice cooling. The mixture was then heated under reflux for 6 h. Excess $LiAlH_4$ was decomposed with a solution of methanol in ether then dilute HCl with ice cooling. The mixture was extracted with ether. The solution was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed on alumina (Merck grade 2, 7 g) in hexane. The elute was recrystallized from hexane: mp 81—82 °C, $[\alpha]_D^{25}$ −187.1°±2.0° (*c* 1.150, $CHCl_3$) (0.175 g); IR (Nujol) 755 cm^{-1}; NMR ($CDCl_3$) δ 1.00 (3H, t, *J*=7.0 Hz), 1.7—2.1 (2H, m), 2.34 (1H, ddd, *J*=1, 5, 10 Hz), 2.50 (1H, dd, *J*=1, 16 Hz), 3.10 (1H, d, *J*=16 Hz), 3.92 (1H, d, *J*=5 Hz), 6.8—7.3 (8H, m). Found: C, 92.47; H, 7.70%. Calcd for $C_{18}H_{18}$: C, 92.26; H, 7.74%.

*Oxidation of (−)-10-Ethyl-DMDC [(−)-(**47**)].* A mixture of the (−)-hydrocarbon (−)-**47** (0.325 g), *N*-bromosuccinimide (0.3 g), *m*-chloroperbenzoic acid (10 mg), and dry carbon tetrachloride (10 ml) was heated under reflux for 8 h. After cooling, the mixture was filtered and the solid was washed with carbon tetrachloride. The filtrate was concentrated *in vacuo*. The residue was chromatographed on thin silica gel plate [Merck, pre-coated plate; benzene]. The fraction of the larger R_f value was recrystallized from ether giving colorless crystals (62.5 mg): $[\alpha]_D^{25}$ 0°, $[\alpha]_{365}^{25}$ 0° (*c* 0.727, $CHCl_3$): mp 173—175 °C; IR (Nujol) 810, 770, 753 cm^{-1}; NMR ($CDCl_3$) δ 1.41 (3H, d, t, *J*=7, 1 Hz), 2.31 (2H, m), 4.40 (1H, t, *J*=3 Hz), 4.63 (1H, s), 5.56 (1H, m), 6.9—7.4 (8H, m). Found: C, 92.45; H, 6.82%. Calcd for $C_{18}H_{16}$: C, 93.05; H, 6.94%. The fraction with the smaller R_f value was recrystallized from hexane and gave (−)-**48** (46.4 mg): mp 130—134 °C; $[\alpha]_D^{23}$ −111.0° ±1.7° (*c* 0.928, $CHCl_3$); IR 1687, 763 cm^{-1}; δ ($CDCl_3$) 0.95 (3H, t, *J*=7 Hz), 1.87 (1H, q, *J*=7 Hz), 2.45 (1H, q, *J*=7 Hz), 2.72 (2H, d, *J*=3 Hz), 4.17 (1H, t, *J*=3 Hz), 6.9—7.4 (7H, m), 7.8—8.0 (1H, m). Found: C, 86.87; H, 6.49%. Calcd for $C_{18}H_{16}O$: C, 87.06; H, 6.49%.

We thank Dr. Kazuo Tori for the NMR measurement, Mr. Mamoru Takasuka for the IR measurements, and Mr. Tatsuo Iwata for assistance in performing the variable-temperature CD measurement.

Electronic Properties and π-π^* Absorption Spectrum of 2-Pyridone

Akira FUJIMOTO, Kozo INUZUKA,* and Ryuichi SHIBA
Department of Applied Science, Faculty of Technology, Tokyo Denki University, Kanda, Chiyoda-ku, Tokyo 101
(Received April 28, 1980)

The IR and UV absorption spectra as well as the Raman spectra of monomer and dimer of 2-pyridone were studied. The molecular weight of 2-pyridone in benzene and dimethyl sulfoxide was determined in order to examine the association. 2-Pyridone in nonpolar solvents shows two types of carbonyl stretching vibration bands due to the coexistence of the monomer and dimer. The highest wavelength UV absorption of 2-pyridone in isooctane (2,2,4-trimethylpentane) is ascribed to π-π^* electronic transitions of the monomer and dimer. The dimer absorption band appears at a higher wavenumber than that of the monomer by *ca.* 830 cm^{-1}. The dimer band corresponds to the π-π^* transition from the ground ^1A_g state to the excited ^1B_u state. No π-π^* transition absorption from the ground ^1A_g state to the excited ^1A_g state could be observed because of the g-g Laporte forbiddance in the transition under an assumption of the molecular C_{2h} symmetry.

Equilibrium between the monomer and dimer of 2-pyridone, investigated by ultrasonic[1] and dipole moment[2] measurements, is attained in certain solvents. As regards the solvent effect on the absorption and fluorescence spectra of 1-methyl-2-pyridone, the π-π^* absorption spectra were found to shift toward short-wavelengths on the hydrogen-bonding formation of 1-methyl-2-pyridone with ethanol, this being attributed to the decrease of dipole moment in the excited states.[3]

We have observed the C=O stretching vibration bands and π-π^* absorption bands of 2-pyridone, the band assignment for the monomer and dimer of 2-pyridone being made from the results for 1-methyl-2-pyridone.[3]

Experimental

2-Pyridone was recrystallized several times from ethanol and sublimed *in vacuo* at *ca.* 120 °C. 1-Methyl-2-pyridone was purified in the same way as described previously.[3] Purification of benzene, dioxane, isooctane (2,2,4-trimethylpentane), chloroform, and ethanol was carried out by conventional methods.[4] Dimethyl sulfoxide (DMSO) was dried over a calcium chloride-calcium hydride mixture and distilled in a stream of nitrogen. The distilled DMSO was further dehydrated with a mixture of calcium hydride and molecular sieves 3A. The dehydrated DMSO was distilled at 56—57 °C in a nitrogen atmosphere of 667 Pa.

Measurement of IR and UV absorption spectra were carried out with the spectrophotometers reported.[3] The molecular weight of 2-pyridone was measured in benzene and DMSO solvents with a modified Shibayama freezing point depression equipment (SS-50_c-KM). The measurement was carried out six times, the concentration of 2-pyridone being in the range 10^{-3}—10^{-2} mol dm^{-3}. The errors inherent to the measurement were $\pm 0.1\%$.

Methods of Calculation and Molecular Models

The dipole moments, π-bond orders, and charge densities of 2-pyridone and 1-methyl-2-pyridone in the ground state were calculated by the CNDO/2 method using the parameter given by Pople, Santry, and Segal.[5,6] The values of the bond distance and bond angle of 2-pyridone measured by Penfold[7] were used. The data were also used for the ring framework of 1-methyl-2-pyridone. For the methyl group the following values were used:

C-N: 1.48 Å, C-H: 1.096 Å, ∠HCH: 109°28′.

The P-P-P SCF-MO-CI method[8,9] was employed for calculated molecular properties such as the π-π^* transition energies, π-π^* transition oscillator strengths, π-charge densities, and π-bond orders in the lower excited states, and π-dipole moments of the monomer of 2-pyridone in the lower excited and ground states. The following empirical parameters were used:

Atom, μ	I_μ/eV	A_μ/eV
C	11.42	0.58
-NH-	27.50	11.20
=O	17.30	2.60

The value −2.50 eV was taken for all the resonance integrals of 2-pyridone. The Mataga-Nishimoto approximation[10] was used for the calculation of two-center Coulomb integrals. All singly excited configuration interactions were taken into account for the monomer.

Results and Discussion

Electronic Properties in the Ground State. The charge densities and π-bond orders of the two compounds calculated by the CNDO/2 method are given in Fig. 1. There is little difference in the charge density distributions of 2-pyridone and 1-methyl-2-pyridone except for the charge density on each nitrogen atom. The π-bond orders of the two molecules are also similar to each other.

The calculated dipole moments of 2-pyridone and 1-methyl-2-pyridone are 4.385 and 4.305 D, respectively. The observed dipole moments[2] of the latter molecule are 4.04 D in benzene and 4.07 D in dioxane. It seems that the dipole moment of 1-methyl-2-pyridone is independent of solvent. The calculated value (4.305 D) of 1-methyl-2-pyridone is in fairly good agreement with the observed values. The calculation shows that the dipole moment of 2-pyridone is close to that of 1-methyl-2-pyridone. However, the observed dipole moment of 2-pyridone is 1.73 D in benzene and 2.94 D in dioxane,[2] showing that the dipole moment of 2-pyridone changes with solvent. A large discrepancy between the values of the calculated and observed dipole moments and the dependence of the values

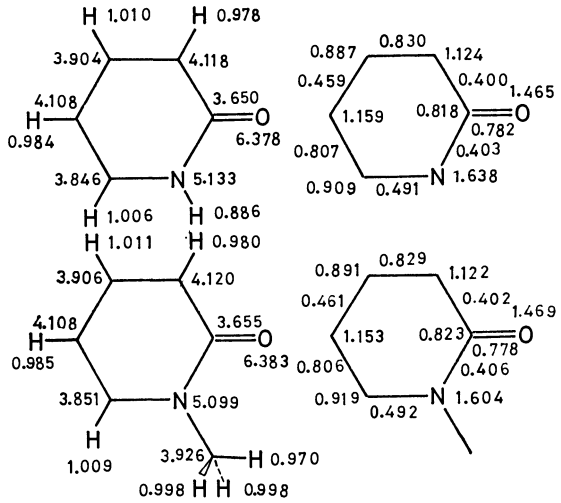

Fig. 1. Several molecular properties of 2-pyridone and 1-methyl-2-pyridone calculated by the CNDO/2 method; the total charge densities of valence electron, π-charge densities, and π-bond orders in the ground state.

of dipole moment on solvents are due to the coexistence of 2-pyridone dimer in such solutions.[1,2]

On the other hand, the IR absorption spectra of 2-pyridone and 1-methyl-2-pyridone were measured both in benzene and dioxane. The spectra in the range 1650—1700 cm^{-1} are shown in Fig. 2. 2-Pyridone shows two strong bands and 1-methyl-2-pyridone only one. The 1667 cm^{-1} IR band of 1-methyl-2-pyridone in carbon tetrachloride was assigned to the C=O stretching vibration on the basis of the band intensity and frequency-shift to the low frequency side taking place on addition of ethanol to carbon tetrachloride solution of 1-methyl-2-pyridone (Fig. 1, Ref. 3). The two bands of 2-pyridone are related to the C=O stretching vibrations of monomer and dimer as seen from their intensities and band positions. The higher-frequency band of 2-pyridone was assigned to the C=O stretching vibration of the monomer and the other to that of the dimer. The C=O stretching frequency of the monomer of 2-pyridone is thus higher than that of 1-methyl-2-pyridone. This is in line with the calculated π-bond orders of the carbonyl groups of 2-pyridone and 1-methyl-2-pyridone (Fig. 1). The IR band intensity of the monomer relative to that of the dimer increases with change of solvent from benzene to dioxane. On the assumption that the molar absorption coefficient of the C=O group of the dimer is approximately equal to that of the monomer, we conclude that the concentration of dimer is higher than that of monomer in benzene, and *vice versa* in dioxane. This is in line with the change of dipole moments observed in these solvents.[2] For the sake of comparison we have measured the bands of 2-pyridone in the range 1650—1700 cm^{-1} in isooctane and chloroform. The result in each case is similar to that of benzene (Figs. 2(1), (3), and (6)).

When the dimer of 2-pyridone belongs to the point group of the C_{2h} symmetry, its 66 normal vibrations are grouped into the following four species.

$$\Gamma = 23A_g + 10B_g + 11A_u + 22B_u$$

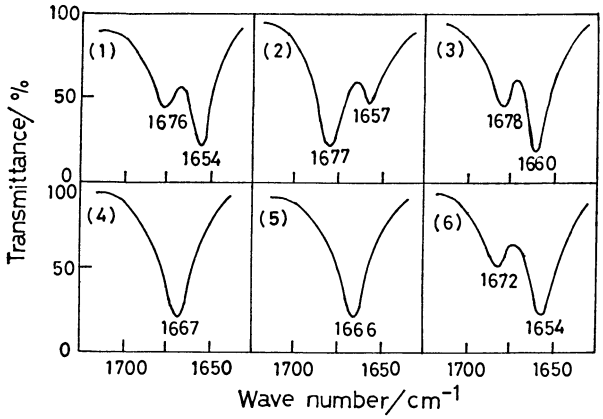

Fig. 2. The IR C=O absorption bands of 2-pyridone (1.2×10^{-2} mol dm^{-3}) and 1-methyl-2-pyridone (1.1×10^{-2} mol dm^{-3}) in various solvents:
(1) 2-Pyridone in benzene, (2) 2-pyridone in dioxane, (3) 2-pyridone in isooctane, (4) 1-methyl-2-pyridone in benzene, (5) 1-methyl-2-pyridone in dioxane, (6) 2-pyridone in chloroform. A cell of 0.5 mm path length was used.

a) s, Strong; m, medium; w, weak. b) 4.6×10^{-2} mol dm^{-3} in chloroform, c) 1 mol dm^{-3} in chloroform.

The vibrations with species A_g and B_u belong to the in-plane vibration and the others to the out-of-plane vibration. The vibrations with species A_g and B_g are Raman-active, the others being infrared-active.

In order to ascertain whether the dimer belongs to the point group of C_{2h} or not, we measured the Raman spectrum of 2-pyridone† in chloroform. The results are given in Table 1. Both the IR band at 1654 cm^{-1} and the Raman band at 1625 cm^{-1} were assigned to the stretching vibration of the C=O groups of the dimer, the former being strong and the latter

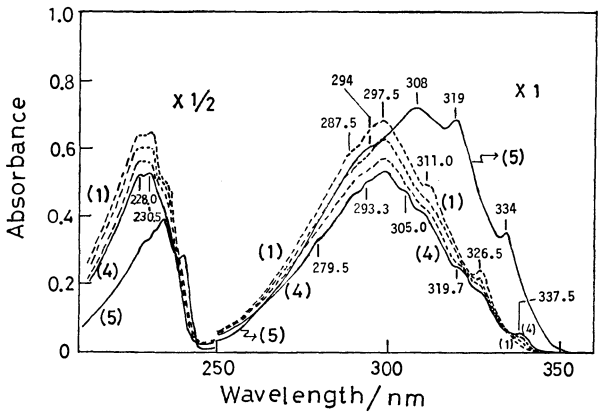

Fig. 3. The UV absorption spectra of 2-pyridone in isooctane solution with UV absorption spectrum of 1-methyl-2-pyridone in isooctane solution: (1) 1.68×10^{-3} mol dm^{-3} 2-pyridone, 1 mm cell, (2) 1.68×10^{-4} mol dm^{-3} 2-pyridone, 10 mm cell, (3) 3.36×10^{-5} mol dm^{-3} 2-pyridone, 50 mm cell, (4) 1.68×10^{-5} mol dm^{-3} 2-pyridone, 100 mm cell, (5) 1.0×10^{-4} mol dm^{-3} 1-methyl-2-pyridone, 10 mm cell.

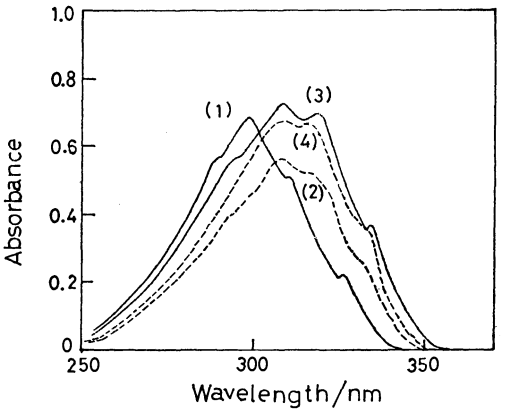

Fig. 4. The UV absorption spectra of 2-pyridone (1.6×10^{-3} mol dm^{-3}) and 1-methyl-2-pyridone (1.0×10^{-3} mol dm^{-3}): (1) 2-pyridone in isooctane, (2) 2-pyridone in DMSO, (3) 1-methyl-2-pyridone in isooctane, (4) 1-methyl-2-pyridone in DMSO. A cell of 1 mm path length was used.

weak. If the 2-pyridone dimer has the C_{2h} symmetry, the former should be assigned to the B_u species and the latter to the A_g species. No band was found in the Raman spectrum near 1672 cm^{-1} at which the carbonyl stretching band of the monomer was observed in the IR spectrum. The C=O band of the monomer might be too weak to be observed in the Raman spectrum, since the concentration of monomer is smaller than that of the dimer in chloroform. The 2-pyridone dimer seems to belong to the point group of C_{2h}. The fact that the dipole moment of 2-pyridone decreases with the change of solvent from dioxane to benzene also seems to support the interpretation that the 2-pyridone dimer belongs to the point group of C_{2h}.

π-π^* Absorption Spectrum of 2-Pyridone. The UV spectrum of 2-pyridone in isooctane in the concentration range 10^{-5}—10^{-3} mol dm^{-3} is shown in Fig. 3. In spectrum (1), the first π-π^* absorption system of 2-pyridone in the range 355—250 nm consists mainly of four vibrational bands. The first one appears at 326.5 nm, the second at 311.0 nm, the third at 297.5 nm corresponding to the band maximum, and the fourth at near 288 nm. Let us call these vibrational bands band system A. The concentration of 2-pyridone in spectrum (4) is 10^{-2} times lower than that of 2-pyridone in spectrum (1). In spectrum (4) band system A appears clearly, the other vibrational bands being observed at 337.5, 319.7, 305.0, 293.3, and 279.5 nm. Let us call these new vibrational bands band system B.

On the other hand, the first π-π^* absorption system of 1-methyl-2-pyridone shows the vibrational bands at 334, 319, 308, and 294 nm (Fig. 3(5)). The vibrational band at 308 nm is the band maximum of this system. The four bands seem to be related with the respective vibrational bands of 2-pyridone in isooctane, *i.e.*, the bands at 337.5, 319.7, 305.0, and 293.3 nm. The absorption spectra of 2-pyridone and 1-methyl-2-pyridone may be expected to be similar in their spectral features, since the π-charge densities and π-bond orders of 2-pyridone and 1-methyl-2-pyridone calculated by the CNDO/2 method are approximately equal to each other (Fig. 1). Good correspondence is seen between band system B of 2-pyridone and the vibrational bands of the first π-π^* absorption of 1-methyl-2-pyridone (Fig. 3).

In order to confirm which of the two molecular species of 2-pyridone is responsible for the appearance of band system B, we measured the absorption spectra of 2-pyridone and 1-methyl-2-pyridone in DMSO (Fig. 4). Each vibrational band position/intensity of 1-methyl-2-pyridone in isooctane solution is close to that in DMSO solution. The vibrational band features of 2-pyridone in DMSO are close to those of band system B (spectrum (4), Fig. 3). For the sake of comparison the molecular weight of 2-pyridone was determined by means of freezing point depression, benzene and DMSO being used as solvent. The observed values in benzene and DMSO are 217.1 and 96.3, respectively. The former is 2.28 times greater than the calculated molecular weight 95.1 and the latter almost equal to it, suggesting that 2-pyridone exists mainly as a dimer in the benzene soild solution although some associated complexes larger than a dimer may be formed, while 2-pyridone exists mainly as a monomer in the DMSO solid solution. The UV spectrum of 2-pyridone in DMSO is related to the monomer species of 2-pyridone. Band system B may be due to the monomer species, since its vibrational band position is close to that of 2-pyridone in DMSO (spectrum (4), Fig. 3). Band system A may thus be ascribed to the dimer species (Fig. 3). The band at 305.0 nm seems to be the maximum of the monomer band (Fig. 4). The energy difference of the maxima of the monomer and dimer

† The measurement, made at the laboratory of Prof. M. Ito, Tohoku University, was carried out in chloroform since the solubility of 2-pyridone in carbon tetrachloride is low.

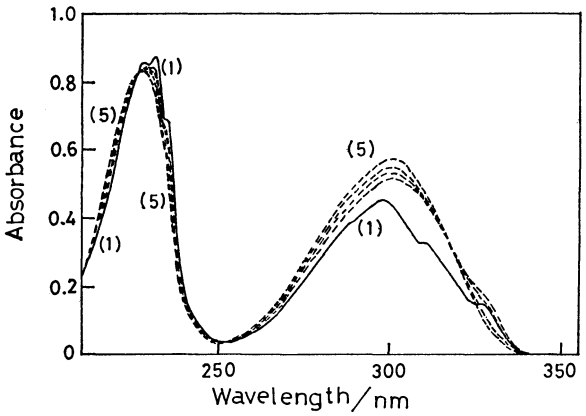

Fig. 5. The UV absorption spectra of 2-pyridone in isooctane-ethanol mixed solvents at room temperature.
Concentration of 2-pyridone: 2.19×10^{-4} mol dm^{-3}.
Concentrations of ethanol (mol dm^{-3}): (1) 0, (2) 7.0×10^{-2}, (3) 1.5×10^{-1}, (4) 5.0×10^{-1}, (5) 2.0.

absorptions is *ca.* 830 cm^{-1}.

The second π-π^* absorption system of 2-pyridone appears near 230 nm (Fig. 3). The concentration effect on the system is not so clear as the first one. As shown in spectrum (4) of Fig. 3, the band maximum of the second system apparently splits into two (228.0 and 230.5 nm), although a similar splitting is also observed in spectrum (1). The splitting energy is *ca.* 480 cm^{-1}.

The UV spectrum of 2-pyridone changes with a change in the concentration of ethanol (Fig. 5). The band maximum of the first π-π^* absorption system shifts toward longer-wavelengths with increase in the amount of ethanol, the second π-π^* absorption system, *e.g.*, the peak at 228.0 nm, shifting toward shorter-wavelengths accompanied by intensity decrease. When ethanol is added to an isooctane solution of 2-pyridone, the shift direction of the first band is opposite that of the first band of 1-methyl-2-pyridone.[3]

The π-π^* transition of the monomer is related to the excited state of A′ symmetry under the point group of the symmetry C_s, and that of dimer to the excited states of the A_g and B_u symmetries under the point group of the C_{2h} symmetry. Transition from the ground to the excited A_g state of the dimer is symmetry-forbidden, whereas transition to the excited B_u state is allowed by the dipole selection rule. Dimer formation gives rise to the paired excited states essentially based on the monomer electronic state. One of the states is lower in energy than the original monomer state and the other is higher if there is no remarkable difference between the solvent effects on the two molecular species. We have tentatively assigned the vibrational band at 337.5 nm to the 0-0 band of the first π-π^* absorption band of the 2-pyridone monomer, since the vibrational band at 337.5 nm is a member of system B which appears in DMSO solution. 2-Pyridone exists in DMSO almost as a monomer. The observed band maximum of the 2-pyridone dimer at 297.5 nm seems to correspond to the second π-π^* absorption band of the dimer with

Table 2. Calculated transition energies (E), oscillator strength (f), and π-dipole moments (μ) of the singlet π,π^* excited states of 2-pyridone monomer with π-dipole moment in the ground state

4	6.703	185	0.664	4.905	

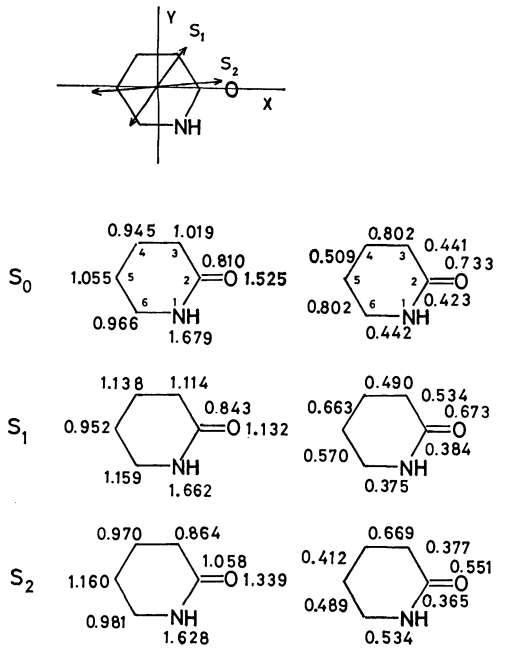

Fig. 6. The calculated π-charge densities and π-bond orders of 2-pyridone in S_0, S_1, and S_2. These calculations are based on the P-P-P SCF-MO-CI method. The uppermost drawing of this figure denotes the direction and the magnitude of the predicted dipole moments.

the B_u symmetry which is produced by the splitting of the monomer states on the formation of the dimer. The first π-π^* absorption band of the dimer would thus correspond to the electronic transition to the ^1A_g state. However, it might be difficult to observe the first π-π^* absorption band of the dimer due to the symmetry-forbidden band by a dipole selection rule. It is hard to decide which of the peaks at 230.5 and 228.0 nm in the second absorption band belongs to the vibrational band of the dimer; one belongs to the peak of the monomer band and the other to that of the dimer as judged by the experimental results.

The transition energies, oscillator strengths and π-dipole moments in the excited states calculated by the P-P-P SCF-MO-CI method for the monomer of 2-pyridone are given in Table 2. The π-dipole moment of the monomer is larger in the ground state than in the excited states except for the fourth-excited state. The calculated results suggest that the first

and second π-π^* absorption bands of the 2-pyridone monomer might move toward the shorter-wavelength side on the hydrogen-bonding formation with ethanol. This might be reasonable from the solvent effect on the absorption and fluorescence spectra of 1-methyl-2-pyridone.[3] However, the first absorption band maximum of the 2-pyridone–ethanol system shifts to the longer-wavelength side (Fig. 5). This is opposite the shift of the first absorption band of the 1-methyl-2-pyridone–ethanol system, the band maximum of the 2-pyridone–ethanol complex being located at a longer-wavelength than that of the 2-pyridone dimer, and the former at a shorter-wavelength side than the band maximum of the monomer. Addition of ethanol to the isooctane solution of 2-pyridone disturbs the equilibrium between the monomer and dimer of 2-pyridone. The hydrogen-bonded monomer of 2-pyridone with ethanol may increase and the dimer may decrease in concentration with an increase of ethanol. Thus, the band maximum of 2-pyridone moves to the longer-wavelength side, but the shift of the band maximum depends on the concentration of the dimer, monomer, and monomer–ethanol complex.

The directions of transition moment for the first and second excited states, π-charge densities, and π-bond orders calculated by the P-P-P. SCF-MO-CI method for the ground and excited states of the 2-pyridone monomer are shown in Fig. 6. There is a large difference in the π-bond order and π-charge density of the ground and first excited states. The calculated π-bond orders suggest that there is a large change in bond length between the ground and first-excited states, which is similar to the result for polyenals. A large deformation of the ring framework between the ground and first excited states may give rise to the band broadening of 2-pyridone (Fig. 3) as shown in polyenal[11] and fulvene spectra.[12]

The photochemical dimerization property[13] of 2-pyridone in the first-excited state can be attributed to an increase in π-charge density at the C_3 and C_6 atoms and in π-bond order between the C_4 and C_5 atoms.

The authors are grateful to Prof. M. Ito, Tohoku University, for his cooperation in the measurement of the Raman spectrum of 2-pyridone and for his valuable suggestions. The work was supported by grants from the Tokyo Denki University Research Fund. One of the authors (K. I) acknowledges the assistance of the staff of Tokyo Denki University Computing Center.

The Correlation between the Electron-capture Detector Response and the Chemical Structure for Polychlorinated Biphenyls†

Yukikazu HATTORI,* Yoshio KUGE, and Masao NAKAMOTO
Environmental Pollution Control Center of Osaka Prefecture,
1-3-62, Nakamichi, Higashinari-ku, Osaka, Osaka 537
(Received November 12, 1980)

The relative sensitivities of an electron-capture detector for various polychlorinated biphenyls were measured at different temperatures. Generally, the sensitivities of these compounds become larger as the number of the chloro substituent increases. The temperature dependence of the electron-capture coefficients(K) for these compounds was also determined. These results show that the electron-capture reactions of polychlorinated biphenyls containing less than four chlorine atoms proceed dissociatively, while for four chlorine atoms the reactions proceed either dissociatively or non-dissociatively. For more than five chlorine atoms, the reactions almost always proceed non-dissociatively.

The electron-capture detector (ECD) which exhibits a highly sensitive response to various organic compounds containing halogen, oxygen, and sulfur atoms is used for the analyses of environmental pollutants. Many reports about ECD sensitivities for various compounds have been published,[1-4] but the temperature dependence of the sensitivity has not been considered in these studies.

Wentworth *et al.*[5-7] and Kojima *et al.*[8-11] studied the electron-capture phenomena by using the pulse-sampling technique. From the temperature dependence of the electron-capture coefficient (K) for various compounds, the activation energies and electron affinities were calculated. The present authors[12-15] have also previously studied the ECD sensitivities and the temperature dependence for various environmental pollutants using the D.C. mode.

In this work, the ECD sensitivities and the temperature dependence for various polychlorinated biphenyl (PCB) isomers were determined. The correlation between the ECD response and the chemical structure for these compounds was also studied.

Experimental

Apparatus and Materials. A Varian aerograph, 2100-type gas chromatograph with an ECD (^{63}Ni, 8.5 mCi) was used in this experiment. The applied voltage was supplied using the D.C. mode. A glass column (2 mmϕ × 1.8 m) was packed with Gaschrom Q (100—120 mesh) coated with 2% Silicone OV-1. The extra pure nitrogen gas (Teikoku Sanso Co., Ltd.) used as a carrier gas was purified by passing it through two tubes (20 cm) packed with Molecular Sieve 5A and an Oxy-trap tube (Alltech Associate Co., Ltd., 4002 type); the flow rate was 30 cm^3/min. The injector temperature was kept at 200 °C. The column temperature was set at 150 °C (1—3 chlorinated biphenyls) and at 180 °C (4—6 chlorinated biphenyls). The detector temperature was varied from 210 °C to 340 °C.

The PCB isomers (Analytical Standard, Analab Co., Ltd.), hexachlorobenzene (HCB) (special grade from Wako Pure Chemical Co., Ltd.) and pentachlorobenzene (PTCB) (guranteed grade from Tokyo Chemical Co., Ltd.) were used without further purification. All the substances were used as hexane (pesticide analytical grade from Wako Pure Chemical Co., Ltd.) solutions and were checked by gas chromatography.

Procedure. The relative sensitivity (*R.S.*) was calculated from the relative peak area per mole of the compound, using HCB as a standard. The relative retention time (*R.R.T.*) was obtained at a column temperature of 150 or 180 °C by using HCB as a standard. The sample size was chosen so as to keep the peak area within a linear range on the calibration curve. The K values, the electron affinities (EA'), and the *R.S.* values were calculated by the method reported in a previous paper.[12] The temperature dependence of the K values was shown by plotting the logarithm values of K or $KT^{3/2}$ against $1/T$, where T was the absolute temperature of the detector cell, which had been predetermined by inserting a Fe-Constantan thermocouple into a vacant ECD cell.

Results and Discussion

Relative Sensitivities of ECD and Relative Retention Times for PCBs. For various PCBs containing 1—6 chlorine atoms, the *R.S.*s of ECD at the detector temperatures of 230 °C, 290 °C and 320 °C and the *R.R.T.*s are tabulated in Table 1. The *R.S.*s of PCBs ordinarily become larger as the number of chloro substituents increases. These results agreed with the reports by Zitko *et al.*[16] and Gregory *et al.*[17] The *R.S.* of PCBs containing the same number of chlorine atoms are not equal, but they depend upon the position of the chlorine substituents. The *R.S.*s of monochlorinated biphenyls (Cl-PCB) were in the order of: 2-chlorobiphenyl>4-chlorobiphenyl>3-chlorobiphenyl; the *R.S.* of 3-chlorobiphenyl was especially small. The *R.S.*s of dichlorinated biphenyls (2Cl-PCB) were in the order of: 4,4′-dichlorobiphenyl> 3,3′-dichlorobiphenyl > 2,2′-dichlorobiphenyl. These orders of the *R.S.*s for mono- and dichlorobiphenyls are in accordance with the report by Gregory *et al.*[17] The *R.S.*s of tri- and tetrachlorobiphenyl were increased by one order of magnitude over those of dichlorobiphenyls. Among the pentachlorobiphenyls, the ECD sensitivity of 2,3,4,5,6-pentachlorobiphenyl was the highest. This compound has five chloro substituents and one phenyl substituent on a benzene ring. The *R.S.* of the compound was on the same level as that of pentachlorobenzene. The *R.S.* value of 2,2′3,5′6-pentachlorobiphenyl, which has three chloro substituents on the 2- or 6- position, was the

smallest.

As the number of chloro substituents increases, the *R.R.T.* value of PCB become larger, much as with the *R.S.* values of PCB. As to the PCB containing the same number of chlorine atoms, when the compound has fewer chlorine atoms on the 2- or 6- position, the value of *R.R.T.* is larger than those of the other compounds.

The Temperature Dependence of the ECD Response for PCBs. The temperature dependence of the K values of PCBs was examined in order to obtain some information about the electron-capture reactions of PCBs. Figures 1, 2(a), and 2(b) show the temperature dependence of the K values of the PCB isomers. The values of electron affinities (EA') and/or the activation energies (E^*) were calculated; they are tabulated in Table 2. The K values of the PCBs which contain fewer chloro substituents, such as mono-, di-, and trichlorinated biphenyls, become larger as the detector temperature increases. Therefore, the reaction of these PCBs appears proceeds dissociatively. The E^* values of Cl–PCBs were in the order of: 3-chlorobiphenyl>4-chlorobiphenyl>2-chlorobiphenyl. This order seems to be consistent with the degree of difficulty in eliminating chloro substituents. On the other hand, the *R.S.*s of Cl–PCB were in the order of: 2-chlorobiphenyl>4-chlorobiphenyl>3-chlorobiphenyl; this order agrees with that of the ease of eliminating chloro substituents. However, the order of the E^* values of 2Cl-PCBs was 4,4′-dichlorobiphenyl>3,3′-dichlorobiphenyl>2,2′-dichlorobiphenyl, the same as that of the *R.S.*s.

The temperature dependence of the K values of tetra-, penta-, and hexachlorinated biphenyl are shown in Figs. 2(a) and (b). The K values of 2,2′,3,3′-, 2,2′,4,5′-, and 2,2′,3,5′-tetrachlorobiphenyl become

larger as the detector temperature increases; therefore, the EC reactions of these tetrachlorinated biphenyls seem to proceed dissociatively. On the contrary, the K value of 2,3′,4′,5-tetrachlorobiphenyl become smaller as the detector temperature increases, so the EC reaction of this PCB isomer seems to proceed non-dissociatively. From Fig. 1, the EC reaction of 2,3′,5-trichlorobiphenyl seems to proceed dissociatively. The

2,2′,3,5′,6-Pentachlorobiphenyl	1.7 (510—463)	16.6 (463—435)
2,2′,3′4,5-Pentachlorobiphenyl	6.5 (510—489)	
	22.6 (489—435)	
2,2′,4,5,5′-Pentachlorobiphenyl		31.5 (510—435)
2,3,4,5,6-Pentachlorobiphenyl		12.2 (510—436)
2,2′,3,4,5′-Pentachlorobiphenyl		15.7 (510—435)
2,2′,3,3′,4,4′-Hexachlorobiphenyl		17.5 (510—476)
2,2′,3,4,4′,5′-Hexachlorobiphenyl		8.2 (510—449)
Pentachlorobenzene		30.5 (510—463)
Hexachlorobenzene		13.0 (510—463)

The values of E^* and EA' for the compounds were determined at the ranges of detector temperatures(K) which are shown in parentheses.

EC reaction of 2,2′,3,5′-tetrachlorobiphenyl(2,2′3′,5-tetrachlorobiphenyl), with one more chloro substituent added on the 2′-position to 2,3′,5-trichlorobiphenyl, is of the dissociative-reaction type, but 2,3′,4′,5-tetrachlorobiphenyl, with one more chloro substituent added on the 4′-position to 2,3′,5-trichlorobiphenyl, is of the non-dissociative-reaction type.

These phenomena can be explained in the following way. The latter compound is able to form a stable negative ion by catching an electron, and so the EC reaction proceeds non-dissociatively, but it is difficult for the former compound, containing more chloro substituents on the 2- or 2′-position, to form a stable negative molecular ion because of steric hindrance. The EC reactions of penta- and hexachlorinated biphenyls seem to proceed non-dissociatively. These are of the same reaction type as the PTCB, HCB, and BHC isomers which contain five six chloro substituents. These compounds seems to be able to form stable negative ions by catching electrons.

Karasek[18] studied the EC reaction of PCB compounds by means of plasma chromatography. He reported that the peaks corresponding to PCB-ion complexes appeared in negative plasmagrams for tetra- to decachlorobiphenyl compounds. On the other hand, as to mono- and dichlorobiphenyl compounds, no peak corresponding to the negative PCB-ion complex was observed in negative plasmagram; only positive-ion peaks corresponding to the PCB molecule with an added water molecule introduced into the carrier gas were observed. These phenomena are considered to show that these higher-chlorinated biphenyl compounds form stable negative ions, while lower-chlorinated biphenyl compounds do not. This supports our experimental results. Therefore, it is considered that the EC reactions of lower-chlorinated biphenyls proceed dissociatively, while those of higher-chlorinated biphenyls proceed non-dissociatively.

Molecular Deformation Caused by Hydrogen Bonding. 1,3-Dimethylurea

Kunio FUKUSHIMA* and Takeshi KAWAI

Department of Chemistry, Faculty of Science, Shizuoka University, 836 Oya, Shizuoka 422

(Received October 16, 1980)

Synopsis. Raman spectra of 1,3-dimethylurea were measured for the crystalline state, acetone (proton acceptor) solution and water and methanol (proton donors) solutions. Remarkable differences were observed among the spectra of the aqueous solution and those of the acetone solution and the crystal. The difference is interpreted as due to the molecular deformation caused by hydrogen bonding.

Urea dissolves almost freely into water to form a solution similar to an ideal solution.[1] It is expected that the interaction of urea molecule with water molecules in an aqueous solution is strong enough to cause deformation of some parts of molecules associated with a change of the valence state of nitrogen atom (sp^2 state→sp^3 type state) by hydrogen bonding to the atom. This deformation in aqueous solutions, if it exists, may be found most effectively by Raman spectroscopy. A recent unpublished study of Raman spectra of urea in aqueous solutions by one of the present authors suggested the presence of the deformation, but the experimental results were not clear enough to be certain about it. In the present study, a related molecule, 1,3-dimethylurea, which is expected to show considerable frequency changes of its skeletal deformation vibrations associated with molecular deformation, was examined by Raman spectroscopy.

Experimental

Commercial 1,3-dimethylurea (grade EP, wako Chemicals Co., Ltd.) was used for preparation of the sample solutions: aqueous solution (x=0.065); acetone solution (x=0.096); methanol solution (x=0.176); water-heavy water solution (x=0.151, x_{D_2O}=0.412, x_{H_2O}=0.437), heavy water solution of 1,3-dimethylurea-d_2 (x=0.113), where x denotes mol fraction of 1,3-dimethylurea or 1,3-dimethylurea-d_2. The heavy water was purchased from Merck Co., Ltd. (99.75%). Raman spectra were recorded on a Model 800T Raman Spectrophotometer (Japan Spectroscopic Co., Ltd.) using the excitation line of 514.5 nm (300 mW) of a Spectra Physics argon ion laser (model 165). Spectra of solutions were obtained by use of 0.3 ml Raman cells, while those of the crystal were obtained with a sample disc. The spectra were obtained under four time accumulations and with the resolution of 5 cm^{-1}.

Results and Discussion

In the following discussion, refer to Table 1 and Fig. 1. Observed Raman bands of crystalline 1,3-dimethylurea are consistent with previous works.[2-4] These bands persist in the spectrum of the compound in acetone (proton acceptor), while a new band having lower intensity appears at 875 cm^{-1}. Since the Raman bands of the crystal of 1,3-dimethylurea in the region below 1000 cm^{-1} are due to skeletal vibrations,[3] the presence of the band at 875 cm^{-1} suggests

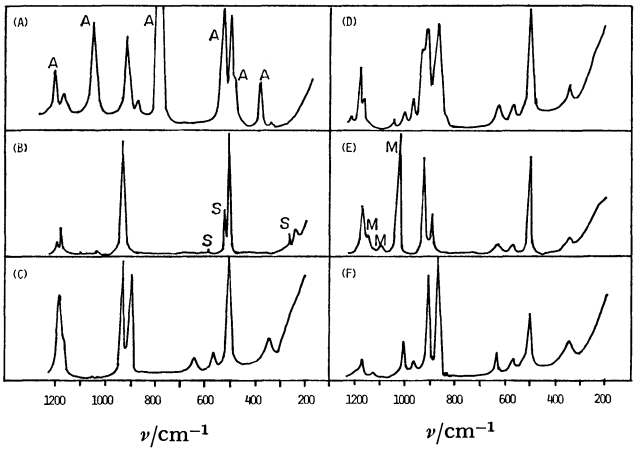

Fig. 1. Raman spectra ($I_{//}$) of 1,3-dimethylurea and 1,3-dimethylurea-d_2.
(A) Acetone solution, A: acetone band, (B) crystal, s: spontaneous emission line, (C) aqueous solution, (D) water–heavy water solution, (E) methanol solution, M: methanol band, (F) 1,3-dimethylurea-d_2 in heavy water.

that another species, having a molecular skeleton different from that in the crystal, is generated in the solution. However, the abundance of the species is very low, because the relative intensity of the band is very weak. For the aqueous solution, a very intense band at 891 cm^{-1} and three other bands at 353 cm^{-1}, 573 cm^{-1}, and 643 cm^{-1} appear, and the same is the case for the methanol solution. Moreover, it was confirmed that the relative intensities of the four bands increase as the mol fraction of water or methanol (proton donor) in the solutions increases. Considering the remarkable spectrum change associated with solution, these four bands may be due to molecules deformed by being hydrogen bonded or due to the skeletal vibrations of non-deformed molecules, which include NH deformation modes and, therefore, are expected to change their frequencies considerably by hydrogen bond formation. The latter explanation is not reasonable, because the spectra of 1,3-dimethylurea in water–heavy water solution show that the frequencies of these four bands do not change much by N-deuteration. The band at 891 cm^{-1} forms a pair with the band of the crystal at 932 cm^{-1}, which is assigned to a coupled vibration of the CH_3–N stretching mode and the CH_3 rocking mode.[3] The band at 643 cm^{-1} and 573 cm^{-1} exist in the spectra of aqueous solutions instead of the band of the crystal at 510 cm^{-1}, which is assigned to a skeletal deformation vibration of the CH_3–NH–CO–N skeleton.[3] The band at 353 cm^{-1} forms a pair with the band of the crystal at 244 cm^{-1}, which is assigned to a skel-

etal vibration of CH_3–NH–C skeleton.[3] Thus, these four bands are interpreted as generated by deformation of the CH_3–NH–C skeleton. Therefore, it is most probable that 1,3-dimethylurea undergoes molecular deformation when it acts as a proton acceptor at its nitrogen atom. But the presence of the band at 875 cm^{-1} in the spectrum of acetone (proton acceptor) solution seems to be contradictory with our explanation, even though it is very weak. However, this band may be ascribed to the molecules whose CH_3–NH–C skeletons are deformed by the N–H..N hydrogen bonding between 1,3-dimethylurea molecules.

The Far-infrared Absorption Intensities and the Dipole Moments of Acetone and Dimethyl Sulfoxide in Solutions

Yusei OHKUBO* and Masao KIMURA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received November 12, 1980)

Synopsis. The effective dipole moments of acetone and dimethyl sulfoxide in nonpolar solutions were obtained from the far-infrared absorption intensities on the basis of an extended Onsager model with an eccentric point dipole.

Dipolar molecules in the liquid phase have absorptions in the far-infrared region[1-5] due to the rotational motion of the molecules and the temporary dipole moments induced by collision. However, the collision-induced absorption is generally much weaker than the dipolar absorption.[6] If the far-infrared absorption is attributed solely to the rotational motion of the molecule, the effective dipole moment can be obtained using Gordon's sum rule[7] after correcting for the internal-field effect.[8,9] In a previous study of CH_3I, $CHCl_3$, CH_2Cl_2, and CH_3CN in solutions,[5] the far-infrared absorption intensities were explained successfully by taking into account the internal-field effect and the internal moment[10] based upon Onsager's model. In the present study, far-infrared absorption intensities were measured for acetone and dimethyl sulfoxide (DMSO) in dilute C_6H_6, CCl_4, C_2Cl_4, and n-C_6H_{14} solutions. The observed intensities, however, cannot be interpreted by the same model as was employed in the previous study. Therefore, the model for the reaction field has been extended to a model with an eccentric dipole-location.

Experimental

The far-infrared spectra were measured at room temperature by means of an apparatus described previously.[5] Solutions were prepared from spectroscopic-grade reagents except for the deuterated compounds, which were already more than 99.6% pure when obtained from CEA and Merck. The concentration range was 0.06—0.17 M.

Results and Discussion

The absorption coefficients, $\sigma(\nu)$, of the solutes in nonpolar solvents are given by:

$$\sigma(\nu) = (1/\rho l)\ln(T_0/T)_\nu, \quad (1)$$

where ρ is the concentration (molecules cm^{-3}); l, the sample thickness (cm), and T_0 and T, the transmittances of the solvent and the solution respectively. The observed results are shown in Fig. 1, where the fine broken lines indicate the spectra profiles assumed in order to obtain the intensities, $A=\int\sigma(\nu)d\nu$. The value of A for each solution was determined by measurements at four concentrations. The results obeyed Beer's law. The A values were estimated, from the fluctuation of the four measurements, to be within ±3%. The systematic errors are due mainly to uncertainties in the assumed curves. The area of the assumed portion is 3—4% of the total area. Thus, the total experimental errors in A were estimated to be ±5% at most.

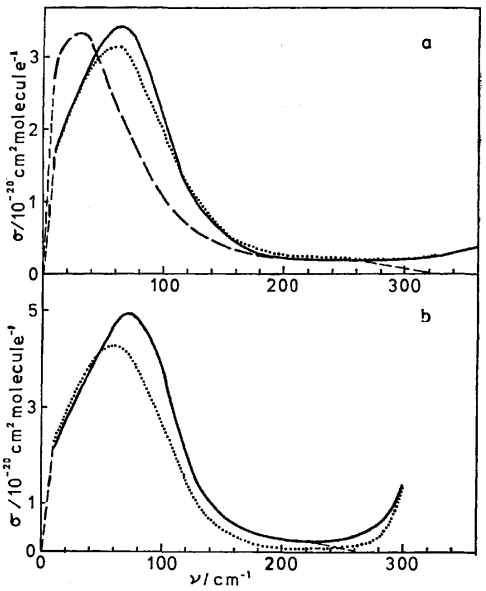

Fig. 1. a) Far-infrared absorption bands of $(CH_3)_2CO$ dissolved in CCl_4(——), in C_6H_6(……), and n-C_6H_{14} (----). b) Far-infrared absorption bands of $(CH_3)_2SO$ dissolved in CCl_4(——), and in C_6H_6(……).

The intensities, as corrected for the internal field effect, A_c, are given as:[8,9]

$$A_c = xA, \quad x = n_s\{[(n/n_s)^2+2]/(n^2+2)\}^2, \quad (2)$$

where n and n_s are the refractive indices of the solute and the solvent respectively. For C_{2v} symmetric molecules, Gordon's sum rule is expressed by:[7]

$$A_c = (\pi\mu^2/3c^2)(1/I_x+1/I_y), \quad (3)$$

where c is the velocity of light; μ, the effective dipole moment taken along the z axis, and I_x and I_y, the moments of inertia about the x and y axes respectively. The μ values, μ_I, obtained from Eq. 3 are shown in the fourth column of Table 1, together with the values of the moments of inertia and the permanent dipole moments in the gas phase, μ_0. The μ_I values for the H-compounds are in good agreement with those for the D-compounds, which have different moments of inertia. Furthermore, the μ_I values are about 10—30% larger than the μ_0 values for all the solutions.

In Onsager's model, the internal moment, μ^*_I, is expressed as:[10,11]

$$\mu^*_I = \mu_0(n^2+2)(2\varepsilon+1)/3(2\varepsilon+n^2), \quad (4)$$

where ε is the dielectric constant of the uniform medium and can be replaced by n_s^2 to a good approximation. The μ^*_I values calculated from μ_0 are listed in the fifth column of Table 1. However, the μ_I

values are larger by about 10% or more than the μ^*_I values except for that of DMSO in the C_6H_6 solutions. Onsager's model was extended to a model with an ellipsoidal cavity and an eccentric point dipole.[11] It turned out that, in nonpolar solvents, the magnitude of the reaction-field effect was almost independent of the cavity shape, but was significantly dependent on the position of the dipole in the cavity. For a molecule with an eccentric point dipole in a spherical cavity, the internal-field correction factor, x, and the internal moment, μ^*, are given by:[11]

$$x = n_s[3\varepsilon/(2\varepsilon+1)(1-f\cdot\alpha)]^{-2}, \quad (5)$$

$$\mu^* = \mu_0/(1-f\cdot\alpha), \quad (6)$$

where:

$$f = (1/a^3)\sum_{m=1}^{\infty}[m^2(m+1)(\varepsilon-1)/(m+m\varepsilon+\varepsilon)](s/a)^{2m-2}, \quad (7)$$

and where α is the average polarizability of the molecule, a is the radius of the cavity, and s is the distance from the center of the cavity to the point dipole. The parameter, s/a, is a measure of the eccentricity of the position of the dipole. α and a are related in a good approximation by:[10]

$$\alpha = a^3(n^2-1)/(n^2+2). \quad (8)$$

If $s=0$, Eqs. 5 and 6 reduce to Eqs. 2 and 4. The μ and μ^* values thus calculated with $s/a=0.3$, μ_{II} and μ^*_{II}, are shown in Table 1. There is no other means to confirm the propriety of the s/a value. However, a good agreement between μ_{II} and μ^*_{II} is obtained except for the C_6H_6 solutions of DMSO. For acetone, the internal moments are the least in the hexane solutions and almost the same in the other solutions, reflecting the dielectric constants of the solvents. Unlike as in the results for acetone, the μ_{II} value in the C_6H_6 solutions of DMSO is distinctly smaller not only than that in the CCl_4 solutions, but also than the μ^*_{II} value. There seems to exist a short-range ordering of C_6H_6 molecules around a DMSO molecule, such as the alignment of benzene rings perpendicular to the direction of the dipole moment of DMSO. The reaction field becomes weak because the axial polarizability of benzene molecules is smaller than the average polarizability, and so a μ_{II} value smaller than the μ^*_{II} value is obtained.

The authors wish to thank Dr. Shun-ichi Ikawa for his valuable suggestions and discussions.

Effects of β-Cyclodextrin on Fluorescence Quenching of Sodium 1-Pyrenesulfonate by Aniline in Aqueous Media

Harumichi KOBASHI,* Masatoshi TAKAHASHI, Yasuyoshi MURAMATSU, and Toshifumi MORITA

Department of Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received December 24, 1980)

Synopsis. β-Cyclodextrin added to the fluorescence quenching system of the title compounds has two effect, depression on dynamic quenching and binding between the fluorescer and quencher causing rapid quenching.

Catalytic actions of cyclodextrins on various chemical reactions are well known.[1] Inclusion effects on excited state properties of organic molecules, such as fluorescence enhancement, have been investigated by several workers,[2] but studies of the effects on intermolecular interactions from photophysical view points are still scarce.[3]

This paper gives results of addition effects of β-cyclodextrin (CD) on fluorescence quenching of sodium 1-pyrenesulfonate (PS) by aniline (A) in aqueous solutions. It is concluded that CD acts as a mediator for ground state association between the fluorescer and the quencher as well as acting as a retarder for dynamic quenching. Immediately after this work had been completed, a similar effect of CD was reported by Kano *et al.*[4] for fluorescence quenching of pyrene and PS by diethylamine. The enhancement of the quenching induced by CD was very small because of a higher ionization potential of the aliphatic amine (8.51 eV) than that of the aromatic amine (7.68 eV) we used. A more efficient quenching induced by such association together with retardation for the dynamic quenching has been revealed from a general consideration of the intensities and lifetimes of fluorescence consisting of two components.

Experimental

After measurements of absorption and fluorescence spectra, fluorescence lifetimes were measured with a Hitachi time resolved photometer and an apparatus for ns flash photolysis.[5] All measurements were carried out at 22 °C unless otherwise stated. Concentrations of CD and A were $\leq 1.0\times10^{-2}$ and $\leq 6.0\times10^{-3}$ M (1 M=1 mol dm^{-3}), respectively. The PS was fixed at 2.0×10^{-5} M. Degassed solutions of these concentrations were stable.

Results and Discussion

The absorption and fluorescence spectra of PS alone agreed with those obtained by Klein *et al.*[6] Addition of CD caused a slight red shift in the L_a absorption band. This shift, similar to that in micellar systems[6,7] originates from the hydrophobic property of a central void of CD. It gives an evidence for inclusion by CD.

In order to study the inclusion further, the difference absorption spectra between PS with and without CD were measured (Fig. 1). With an increase in the amount of CD the positive (d_+) and negative (d_-) absorptions increase their amplitudes. No changes

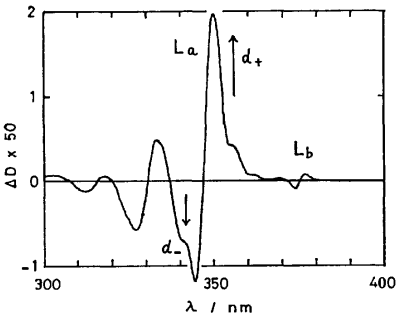

Fig. 1. Difference Spectrum of PS+CD against PS in aqueous solution at 15 °C.
[PS]=2.0×10^{-5} M, [CD]=6.0×10^{-3} M.

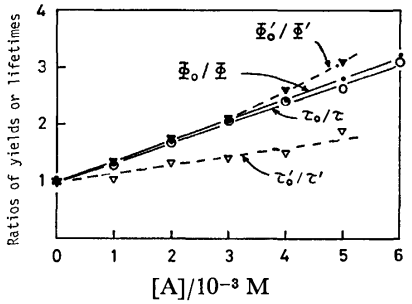

Fig. 2. Stern-Volmer plots for fluorescence yields and life-times of PS in the absence and presence of CD.
[PS]=2.0×10^{-5} M, [CD]=1.0×10^{-2} M.

were observed in positions and shapes of the absorption bands. This indicates that PS included by CD has a characteristic absorption differing from that of the free PS. The separation of wavelength between d_- and d_+ of the maximum amplitudes are ≈460 cm^{-1} for the L_a band and ≈180 cm^{-1} for the L_b band, respectively. The dependence of d_+ and d_- on [CD] was analyzed by means of a modified Ketelaar equation, $a/d_\pm = 1/(b^n K\varepsilon_\lambda) + 1/\varepsilon_\lambda$, where a and b are the initial concentrations of PS and CD, respectively, K is the association constant between PS and CD, ε_λ the difference of molar extinction coefficients between complexed PS and free PS at a wavelength λ, $d_\pm$ denotes d_+ or d_-, and n is the number of CD concerning the complex formation. The equation with $n=1$ corresponds to the observed dependence, the K value for the 1:1 complex between PS and CD being obtained to be 46±9 M^{-1} at 15 °C.

Fluorescence spectra with and without CD are very similar, their quantum yields being almost the same. The Stern-Volmer plots for the fluorescence quenching by A are shown in Fig. 2. In the case with no CD, both plots of Φ_0/Φ and τ_0/τ, where Φ_0/Φ and τ_0/τ have their usual meanings, are in good agreement with each other. The quenching rate con-

a) Obtained from the plots for Φ_0/Φ and Φ'_0/Φ'. b) Obtained from the plots for τ_0/τ and τ'_0/τ'.

stants (k_q) were obtained to be $4.7\times10^9\ M^{-1}\ s^{-1}$ from the Φ_0/Φ plot and $4.4\times10^9\ M^{-1}\ s^{-1}$ from the τ_0/τ plot. In the case with CD, however, each plot for Φ'_0/Φ' and τ'_0/τ' (the prime is used to distinguish the quantities from those in the former case) splits with increase in A. The difference in the Stern-Volmer constants (K_{SV}) estimated approximately from Φ'_0/Φ' and τ'_0/τ' is larger than that given by Kano *et al.*[4] For the purpose of comparison apparent quenching parameters and lifetimes in the presence and absence of CD are given in Table 1.

The τ'_0 and τ' have been calculated according to the statistical definition of the lifetime, $\tau_s=\int_0^\infty t\phi(t)\mathrm{d}t\Big/\int_0^\infty \phi(t)\mathrm{d}t$, where $\phi(t)$ is an observed decay function of the fluorescence. The decay function in the absence of the quencher is nearly exponential in both cases with and without CD. This might be due to a slight change between the fluorescence lifetimes of the free and the complexed PS. However, the non-exponential feature of the decay in the presence of CD becomes remarkable with increase of quencher. This indicates that at least these two kinds of fluorescers, the free PS and the (PS···CD) complex, are quenched by A with a different rate. Since the complex (the long life component) decays more slowly than the free PS, the excited PS in the complex has been protected to some extent from quenching. When the decay is non-exponential it is not correct to regard the discrepancy between Φ'_0/Φ' and τ'_0/τ' (Fig. 2) as being due to the static quenching. In the present case the following consideration may be possible. Since the inclusion rate constants (k_a) in the ground state are of an order less than $10^7\ M^{-1}\ s^{-1}$ in many cases,[1b] the excited state equilibrium between PS and the complex would not be attained within the lifetime ($k_a\tau_0[CD]\ll1$ for $\tau_0=79$ ns and $[CD]=10^{-2}$ M). The excited species might decay independently of each other. If the observed decay functions can be expressed approximately by $\phi'(t)=A\ \exp(-\alpha' t)+B\ \exp(-\beta' t)$ and $\phi'_0(t)=C\ \exp(\alpha'_0 t)$ in the presence and absence of the quencher, respectively, we have

$$\frac{\Phi'_0}{\Phi'}=\frac{\int_0^\infty \phi'_0(t)\mathrm{d}t/C}{\int_0^\infty \phi'(t)\mathrm{d}t/(A+B)}=\frac{\alpha'}{\alpha'_0}\cdot\frac{A+B}{A+(\alpha'/\beta')B},\qquad(1)$$

$$\frac{\tau'_0}{\tau'}=\frac{\int_0^\infty t\phi'_0(t)\mathrm{d}t\Big/\int_0^\infty \phi'_0(t)\mathrm{d}t}{\int_0^\infty t\phi'(t)\mathrm{d}t\Big/\int_0^\infty \phi'(t)\mathrm{d}t}=\frac{\alpha'}{\alpha'_0}\cdot\frac{A+(\alpha'/\beta')B}{A+(\alpha'/\beta')^2B},\qquad(2)$$

where α' and β' denote the rate parameters of the free and the complexed PS depending on [A], respectively, and α'_0 the one observed at [A]=0. A, B, and C are coefficients depending on [CD] and excitation wavelength. Since we can put $\alpha'=\alpha$, $\alpha'_0\approx\alpha_0$, $\alpha'>\beta'$, and $\alpha/\alpha_0=\Phi_0/\Phi=\tau_0/\tau$, the relations, $\tau'_0/\tau'<\tau_0/\tau$ (Eq. 3), $\tau'_0/\tau'<\Phi'_0/\Phi'$ (Eq. 4), and $\Phi'_0/\Phi'<\Phi_0/\Phi$ (Eq. 5), are obtained from Eqs. 1 and 2 at a certain concentration of the quencher. We see from Fig. 2 that Eqs. 3 and 4 fit the observed results, but not Eq. 5. The results obtained from fluorescence intensity give the relation, $\Phi'_0/\Phi'\gtrsim\Phi_0/\Phi$. There is a discrepancy between the yield (Φ') obtained by the intensity measurements and the one calculated from the decay functions, the former being smaller than the latter. This suggests that there exists an additional quenching so rapid that it is impossible to detect by decay experiments. It would be reasonable to take into account the ground state association between the fluorescer and the quencher induced by CD, because such quenching occurs only with the coexistence of CD. A 1:1:1 complex among PS, CD, and A is plausible as suggested by Kano *et al.*[4] Such a three component complex has also been suggested by Hamai in the system of 2-methoxynaphthalene and *p*-dicyanobenzene in the presence of CD.[8]

The effects of CD on the intermolecular quenching are summarized as follows. (1) Inclusion of the fluorescer and the quencher[9] depresses the dynamic quenching by diffusive collision. (2) Mutual association of the quenching pairs mediated by CD gives rise to rapid quenching. The second effect appears to be important as one of catalytic functions of CD in relation to the association between biological substances under a very low concentration.

The authors are grateful to Mr. Noriaki Ikeda and Prof. Noboru Mataga, Osaka University for their advice and the supply of purified PS.

(Received January 14, 1981)

Synopsis. The photoelectrochemical behavior of *p*-type semiconducting *trans*-$(CH)_x$ film in the presence of *N,N'*-dimethyl-4,4'-bipyridinium as the solution species is described. The spectral response of the photocurrent shows a mismatch with the absorption spectrum, and the quantum yield ($\approx 10^{-3}$) of the charge flow is extremely low. It is assumed that $(CH)_x$ film has a high trap density and that the lifetime of the photogenerated hole is limited by trapping and recombination in the space-charge region.

In recent years, there has been a considerable interest in the electrical and optical properties of polyacetylene, $(CH)_x$, film as a new class of semiconducting material.[1-6] A $(CH)_x$-sodium polysulfide solution photovoltaic cell has been fabricated as an active photoelectrode for a photoelectrochemical cell.[7] Although Chen *et al.* mentioned that the $(CH)_x$ photocathode exhibited significant photoresponse with an open circuit voltage, $V_{oc} \approx 0.3$ V, and a short circuit current, $I_{sc} \approx 40$ μA/cm², under illumination of approximately 1 sun,[7] the photoresponse ($V_{oc} \approx 60$ mV, $I_{sc} \approx 1$ μA/cm²) in our work was very low. These results suggest that, in order to use the $(CH)_x$ as an active photoelectrode for a photoelectrochemical cell, it is of primary importance to characterize its general photoelectrochemical behavior before any modification experiments are performed. The studies reported here concern the basic photoelectrochemical properties of the *trans*-$(CH)_x$ film in the presence of *N,N'*-dimethyl-4,4'-bipyridinium (MV^{2+}) as the solution species.

Experimental

The preparation of the *trans*-$(CH)_x$ film has been described elsewhere.[8] The film was about 0.1 mm thick. The conductivity of the film was found to be about 10^{-6} Ω^{-1} cm^{-1}, as determined by the standard four-probe van der Pauw technique.[9] The ohmic contact with a thin copper sheet was obtained by the use of Electrodag on the shiny side of the $(CH)_x$ film. The preparation of the $(CH)_x$ working electrode was done according to Chen's method.[7]

Photocurrent measurements were performed under potentiostatic conditions with a home-made potentiostat.

The light source used in the study of the photoelectrochemical effect was a 100-W high-pressure mercury lamp with a glass filter ($\lambda \leq 430$ nm cut-off). A water filter with a 10-cm optical pathlength as a heat-absorbing filter was employed. Chemical actinometry for 436-nm-wavelength light, obtained by combination with a KL-43 filter, was carried out using the potassium ferrioxalate system. The measurement of the action spectrum of the photocurrent was done by the lock-in (NF Model LI-574) technique using a modulation of the light beam with 8 Hz. As a light source in this case, a Xe 500-W lamp was used, while a grating monochrometer (Nikon G-250) was employed for the wavelength selection.

Reagent-grade chemicals were used without further purification. All the solutions were deoxygenated for at least 30 min with purified nitrogen before each experiment. All the experiments were carried out with the solution under nitrogen without stirring.

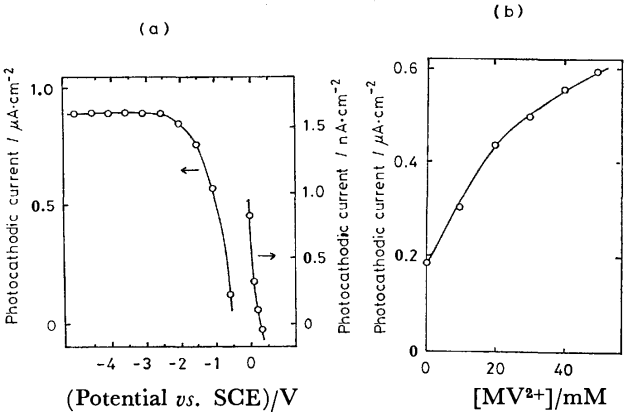

Fig. 1. (a) Steady-state photocurrent *vs.* electrode potential for 20 mM MV^{2+} in 1 M KCl (pH 5) at *trans*-$(CH)_x$ electrode; (b) Steady-state photocurrent as a function of concentration of MV^{2+} (1 M KCl, pH 5, $U_{SCE} = -1.0$ V).

Results and Discussion

Cyclic-voltammetric curve revealed that the $(CH)_x$ film did not react with MV^{2+} in the dark at all. Figures 1(a) and (b) show the steady-state photocurrent-voltage characteristic and the dependence of the signal on the MV^{2+} concentration respectively. The results can be qualitatively explained in terms of the p-type semiconducting properties of the $(CH)_x$ film. The cathodic photocurrent indicates that MV^{2+} acts as a primary acceptor of the electron as the minority carrier ejected from the $(CH)_x$ into the solution and can be attributed to the reduction of MV^{2+} to the purple $MV^{\cdot+}$, as evidenced by the blue-purple color streaming from the $(CH)_x$ film surface at $U_{SCE} \leq -1.5$ V. This fact suggests that the lower edge of the $(CH)_x$ conduction band is positioned at energies above the standard redox potential (−0.7 V *vs.* SCE) of $MV^{2+}/MV^{\cdot+}$.[10] Figure 1(b) shows the observation of the signal in the absence of MV^{2+} as well. The electron acceptor in this case remains unidentified, but dissolved oxygen gas as an impurity is a possible candidate, because O_2 can mediate the transfer of the conduction-band electron across the $(CH)_x$ film-solution interface. The onset potential ($U_{SCE} \approx 0.4$ V) of the photocurrent, which approximately corresponded to the flat-band potential for the $(CH)_x$ electrode, was almost independent of the solution pH (1—13), and the signal decreased with the solution acidity when U_{SCE} was kept constant. When a solution containing sodium polysulfide (20 mM as Na_2S_2) and 1 M (mol dm^{-3}) KCl at pH 11.6 was used,[7] the photo-

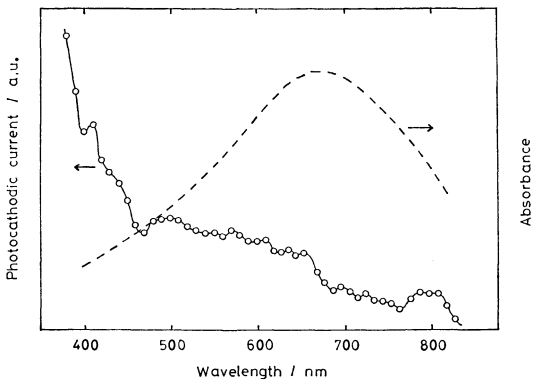

Fig. 2. Spectral response (in arbitrary units) of *trans*-$(CH)_x$ electrode in 20 mM MV^{2+}+1 M KCl aqueous solution (pH 5).
Dashed curve indicates absorption spectrum of *trans*-$(CH)_x$ with about 1 μm in thickness.

current was lower (≈0.27 μA/cm² at $U_{SCE}=-1.0$ V) than that of the 20 mM MV^{2+} system at pH 5 (≈0.45 μA/cm² at $U_{SCE}=-1.0$ V). This lower photocurrent may be mainly caused by an absorbance of the polysulfide solution used, and we may conclude that, in the polysulfide electrolyte, $(CH)_x$ does not exhibit the significant photoresponse previously reported.[7]

In Figure 2 the spectral response of the $(CH)_x$ electrode is shown. The data on the vertical axis were obtained by dividing the photocurrent at a certain wavelength by the number of photons incident on the electrode. It can be seen that the spectral response of the photocurrent shows a mismatch with the absorption spectrum of the $(CH)_x$ film, which exhibits an absorption maximum at 670 nm.[11] Similar behavior has been observed for the solid-state $(CH)_x$ Schottky junction.[12] The threshold of the photocurrent response is observed at about 830 nm (≈1.5 eV), in agreement with the direct-band gap calculated from the optical studies of the $(CH)_x$ film.[1] The anticorrelation between the action and the absorption spectrum indicates that the light absorbed on the front suface of the $(CH)_x$ film is not effective in creating free-charge carriers. In effect, most holes generated on the front surface are not long-lived enough to diffuse into the space-charge layer, while holes generated within the bulk have a finite probability of transiting the space-charge layer to be registered as carriers in the external circuit. The rate of charge generation at a certain distance, x, from the front surface is proportional to $\exp(-kx)$, where k is the absorption coefficient of the $(CH)_x$ film (for example, $k_{670}\approx 2\times 10^5$ cm^{-1} [1]). Detailed studies of the photovoltaic response for *p*-$(CH)_x$: *n*-CdS heterojunction have implied the existence of a meta-stable trapping state 0.9 eV below the conduction band of the $(CH)_x$ film.[6] Therefore, the anticorrelation may be explained by assuming that the $(CH)_x$ film has an excessively high trap density; if the penetration depth of the light ($\lambda\leq 600$ nm) is large, the trapping of the photogenerated holes may be insignificant compared to the case of about a 670 nm-wavelength light corresponding to the absorption maximum of the $(CH)_x$ film. The quantum yield of the charge flow under the 436-nm-light irradiation was extremely low, being 1×10^{-3} at $U_{SCE}=-1.0$ V in the 20 mM MV^{2+} +1 M KCl aqueous solution (pH 5). Furthermore, the light-intensity dependence of the photocurrent varied with the applied potential; the light-intensity exponent for the photocurrent was less than unity and increased from 0.8 to 0.9 as $-U_{SCE}$ increased from 0.5 to 3.0 V. These results may be related to the recombination or trapping of the photogenerated holes in the bulk of the $(CH)_x$ film, which arises from the high trap density and which well limits the photocurrent to a significant level, if we consider that an increase in the electric field in the space-charge layer would cause the photogenerated holes to have an increasing chance of transiting the space-charge layer before being trapped.[13]

13) The AsF_5-doped *trans*-$(CH)_x$ film with 8.4×10^{-3} Ω^{-1} cm^{-1} exhibited 5×10^{16} and 2.5×10^{18} cm^{-3} as the ionized acceptor concentration (N_A) and the trap density (N_T), respectively.[14] Accordingly, it may be reasonable to assume $N_A\approx 10^{15}$ cm^{-3} for the present $(CH)_x$ film with 10^{-6} Ω^{-1} cm^{-1}. Then, about 10^4 Å as the space-charge layer width under the band bending of about 1 eV can be calculated, when $\varepsilon\approx 10$ is taken as the dielectric constant. In this case, most of the absorption maximum-photons ($k_{670}\approx 2\times 10^5$ cm^{-1}) incident on the $(CH)_x$ film would be absorbed within 10^3 Å of the front surface, and most of the photogenerated holes would be not long-lived enough to transit the space-charge layer with a 10^4 Å width, due to the trapping by the high-trap density (probably $N_T>2.5\times 10^{18}$ cm^{-3}). This may lead to the absence of any parallel effect for the photocurrent signal, as is shown in Fig. 2.

***Society for Activated Carbon Research, Ogimachi, Kita-ku, Osaka 530*
(Received January 22, 1981)

Synopsis. An adsorption equation is postulated for predicting the adsorption isotherms of organic compounds from water on activated carbons.

It is known that the prediction of adsorption isotherms for a given adsorbent from the physical properties of the adsorbate is important for adsorbent-adsorbate interaction. For gas-phase adsorption, Dubinin[1] showed that the physical constants such as molar volume and parachor are useful for predicting the isotherms. Reucroft *et al.*[2] studied the relationship between the adsorbability and physical constants and concluded that the molecular refraction gives a good correlation. In liquid-phase adsorption, Abe *et al.*[3] have calculated partition coefficient of 93 organic compounds between the solution and the adsorbed phases at an infinite dilution and examined the correlation with various physical constants. We present the following adsorption equation for predicting the adsorption isotherms of organic compounds from water on activated carbons in terms of a physical constant.

$$\log X = \alpha\Phi + \beta + \gamma \log C, \quad (1)$$

where X is the weight of solute adsorbed (mg/g), C the equilibrium concentration of the solute (mg/l), and α, β, γ are constants. The constant Φ represents the adsorbability of the adsorbate and is independent of the nature of adsorbent. We have tried to replace the Φ value with a physical constant such as molecular refraction or parachor.

Equation 1 was applied to the adsorption isotherms of 22 aliphatic monofunctional compounds from water on an activated carbon at 25 °C,[4] the data of 122 plots being given to a HITAC 10—II computer to determine the α, β, γ values by means of multiple regression analysis. The constants and statistic analysis for several physical constants are given in Table 1. High correlation coefficients have been obtained for molecular refraction and parachor. The result resembles that in gas-phase adsorption. Standard deviations, the t values in the Student test and the overall goodness of fit expressed by means of the F values indicate that Eq. 1 in which the Φ value is replaced with molecular refraction or parachor provides a satisfactory approximation. Figure 1 shows a plot of log X observed *vs.* log X calculated by means of

$$\log X_{\text{calcd}} = 0.08111R - 1.230 + 0.4895 \log C. \quad (2)$$

We see from Fig. 1 that the molecular refraction gives a good prediction of the isotherms as shown by

$$\log X_{\text{obsd}} = 0.99998 \log X_{\text{calcd}} - 0.000066. \quad (3)$$

(r=0.9685, s=0.09400, F=1018, t=42.63)

[T]	0.06926	−0.8454	0.5206	13	0.9836	0.06853	149.2	17.26	6.775

$F(2, 9; 0.001)=16.4$, $t(9, 0.001)=4.781$, $t(9, 0.01)=3.250$.

In order to examine whether Eq. 1 is applicable to the other activated carbons with different adsorption capacities, the adsorption experiments were carried out for 20 different activated carbons and 7 aliphatic monofunctional compounds (1-pentanol, butyric acid, hexanoic acid, 2-butanone, 2-pentanone, methyl acetate, butyl acetate). The results of multiple regression analysis for Eq. 1 with molecular refraction are given in Table 2. The high muliple correlation coefficients indicate that Eq. 1 is applicable to all the carbons.

If the α, β, and γ constants for a given activated carbon are determined from the adsorption data of several compounds, the adsorption isotherms of many other aliphatic monofunctional compounds can be predicted from only the molecular refraction constant.

The Measurement of the Distribution Equilibrium Constant of Metallic Mercury for $Hg_{(aq)} \rightleftharpoons Hg_{(gas)}$

Shoichi Okouchi* and Sokichi Sasaki

Chemical Laboratory, Faculty of Engineering, Hosei University, Kajino, Koganei, Tokyo 184

(Received May 10, 1980)

Synopsis. The gas-aqueous distribution equilibrium constant of mercury(0) was determined in the temperature range from 5 to 45 °C. The experiment was made by volatilizing metallic mercury dissolved in water to the gas phase, which was connected with the absorption cell in a cold-vapor atomic absorption spectrophotometer, and by measuring the absorbance under gas-aqueous distribution equilibrium conditions. The distribution equilibrium constant, $[Hg]_{gas}/[Hg]_{aq}$, was found, *e.g.*, to be 0.40 ± 0.02 at 25 °C. The effect of the concentration of NaCl on the distribution equilibrium constant was measured at 25 °C. The salting-out effect was found to be expressed by the Setschenow equation, and the salting-out coefficient was found to be 0.105.

The behavior of mercury in an environment is interesting, although rather complicated and still not entirely explainable. The most distinct difference between mercury and the other metals is the high vapor pressure of mercury, so that the mercury volatilizes[1,2] from water surfaces, such as seas and rivers, to the atmosphere. The most important factor[3] in the mercury volatilization is the gas-aqueous distribution equilibrium constant of mercury, although the distribution equilibrium constant has not yet been measured, to our knowledge.

In this work, the distribution equilibrium constant was measured by volatilizing metallic mercury dissolved in water to the gas phase, which was connected with the absorption cell in a cold-vapor atomic absorption spectrophotometer.

Experimental

Doubly distilled water was used throughout this work. All the chemicals were of an analytical reagent grade. Analytical-grade metallic mercury was further purified in the usual manner.[4]

By shaking the distilled water containing a few drops of the purified metallic mercury and 0.001 mol dm^{-3} of phosphinic acid[5,6] as a reducing agent to prevent the mercury oxidation, the mercury was dissolved in the water. The solution with the dissolved free mercury was prepared in the vessel shown in Fig. 1, and stirred by means of a magnetic stirrer. The mercury in the solution was equilibrated with the gas phase,[7,8] which was connected with the absorption cell in a cold-vapor atomic absorption spectrophotometer (Hiranuma, HG-1). The absorbance became constant under the gas-aqueous distribution equilibrium conditions of mercury (first equilibrium conditions). The absorbance at equilibrium was measured, the stirring was stopped, and then the mercury vapor in the gas phase was swept by nitrogen gas into a ($KMnO_4+H_2SO_4$) absorber without disturbing the aqueous phase. When the absorbance had returned to zero level (base line), the same procedure was repeated and a second absorbance was measured (second equilibrium conditions). The variation in the absorbance with the time is shown in Fig. 2. The experiment was made in the temperature range from 5 to 45 °C, the precision of the temperature in the aqueous and the gas phases being ±0.1 °C and ±0.5 °C respectively.

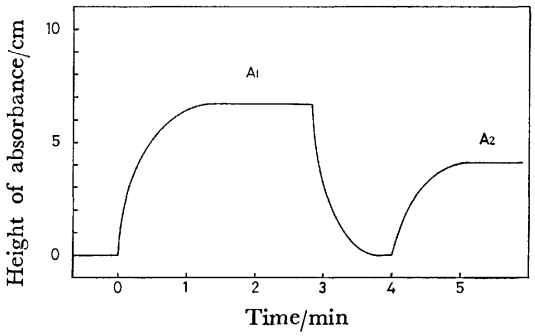

Fig. 2. Variation in absorbance with time at 25 °C. $[Hg]_0 = 1.32 \times 10^{-8}$ mol dm^{-3}, $V_L = 250$ cm^3, $V_G = 395$ cm^3.

Results and Discussion

The distribution equilibrium constant, K, for $Hg_{(aq)} \rightleftharpoons Hg_{(gas)}$ is expressed as follows:

$$K = [Hg]_{gas}/[Hg]_{aq}, \quad (1)$$

where $[Hg]_{gas}$ and $[Hg]_{aq}$ are the mercury concentrations in the gas and aqueous phases respectively. Assuming that $[Hg]_0$ is an initial mercury concentration, V_G and V_L are the volumes in the gas and aqueous phases respectively under the first equilibrium conditions:

$$K = \frac{[Hg]_{gas\,1}\, V_L}{[Hg]_0\, V_L - [Hg]_{gas\,1}\, V_G} \quad (2)$$

and under the second equilibrium conditions:

$$K = \frac{[Hg]_{gas\,2}\, V_L}{[Hg]_0\, V_L - \{[Hg]_{gas\,1} + [Hg]_{gas\,2}\} V_G}, \quad (3)$$

where the subscript numbers 1 and 2 indicate the

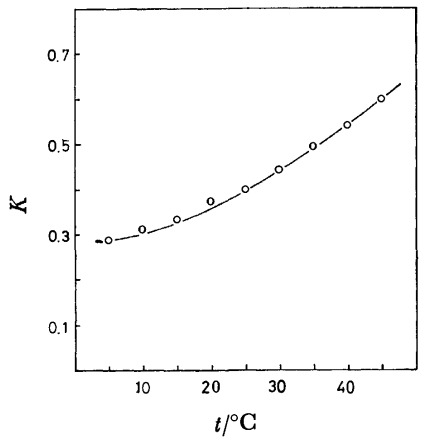

Fig. 3. Temperature dependence of K.

first and the second equilibrium conditions respectively. The relation between the mercury concentration in the gas phase and the absorbance is expressed as follows:

$$[\mathrm{Hg}]_{\mathrm{gas}\,1} = A_1\,a$$
$$[\mathrm{Hg}]_{\mathrm{gas}\,2} = A_2\,a, \qquad (4)$$

where a is the mercury concentration in the gas phase per unit absorbance; it indicates a constant value if the temperature and the operating conditions of the spectrophotometer are fixed. Therefore, from Eqs. 2, 3, and 4, Eq. 5 is obtained:

$$K = \frac{A_1 - A_2}{A_2} \times \frac{V_L}{V_G}. \qquad (5)$$

The distribution equilibrium constant, K, can be determined by measuring the absorbances, A_1 and A_2, under the gas-aqueous equilibrium conditions. In case of Fig. 2, A_1=6.7 cm** and A_2=4.1 cm** were measured. Therefore, the value of K=0.40 was calculated from Eq. 5. The value of K obtained at 25 °C is found to be 0.40±0.02 by measurements in the various cases of V_1 from 100 to 500 cm^3 and of $[\mathrm{Hg}]_0$ from (0.35 to 1.64)×10^{-8} mol dm^{-3}. The constant was found to be unaffected by the reducing-agent concentrations of phosphinic acid between 0.0005 and 0.02 mol dm^{-3}.

The standard Gibbs energies of the formation and the solution for the mercury element at 25 °C are 31.853[9] and 39 K J/mol[10] respectively. Using these values, K=0.74 is calculated. Compared with the K measured in this work, the calculated value is larger, though the ±2 K J/mol differences of $\Delta G°$ give about a 5-fold change of K in the calculating method of the free-energy change. The calculation of K by using the mercury solubility in water previously reported gives K=0.79 with Pariaud's data (1.3×10^{-7} mol dm^{-3})[11] and K=0.34 with Moser's data (3.0×10^{-7} mol dm^{-3}).[5] According to recent solubility studies,[4,12,13] the latter value is preferable. The distribution equilibrium constant in this work is reasonable in view of the above discussion and the dilution of the mercury. The temperature dependence of K is shown in Fig. 3.

** The absorbances, A_1 and A_2, were expressed by the height of the absorbance (cm) on the recorder chart in the cold-vapor atomic absorption spectrophotometer.

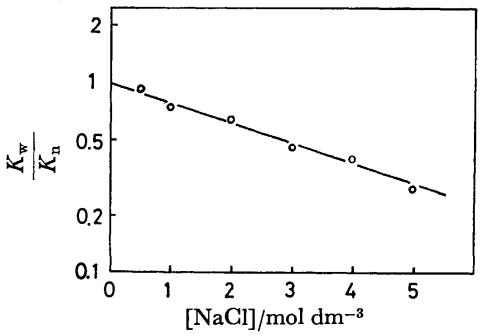

Fig. 4. Salting-out effect at 25 °C.
K_w:K for water (0.40), K_n:K for NaCl solution.

Instead of distilled water, sodium chloride solutions were used under the same distribution equilibrium experiments. The effect of the concentration of NaCl on the distribution equilibrium constant is shown in Fig. 4. A salting-out effect was observed; it could be explained by the Setshenow equation[14] for an aqueous electrolyte solution. The salting-out coefficient was found to be 0.105 at 25 °C.

Conclusion

The distribution equilibrium constant of metallic mercury between the aqueous and the gas phases was determined in the temperature range from 5 to 45 °C by using a cold-vapor atomic absorption spectrophotometer and the equation derived from the material balance of the mercury.

The effect of the concentration of NaCl on the distribution equilibrium constant was investigated at 25 °C, and the salting-out coefficient was determined in the concentration range from 0 to 5 mol dm^{-3}.

We gratefully acknowledge the valuable suggestions of Professor Yuhbun Tsutsumi, Hosei University.

Isomers of the Diamminebis(trimethylenediamine)cobalt(III) Complex

Mitsuru SANO, Miho FUJITA,† Ken-ichi SASAKI, Yuzo YOSHIKAWA, and Hideo YAMATERA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

†*Department of Chemistry, Nagoya City University, Mizuho-ku, Nagoya 467*

(Received January 5, 1981)

Synopsis. The isomers of $[Co(NH_3)_2(tn)_2]^{3+}$ were separated by recycling chromatography. The CD spectra of cis isomers were obtained and are compared with the spectra of the corresponding tris complexes. The magnitude of CD intensity of bisdiamine complex is roughly one-third of the corresponding trisdiamine complex.

A number of studies have been made on the stereochemistry of cobalt(III) complexes with five-membered diamine chelate rings. However, this has not been the case for those complexes including six-membered diamine chelate rings, probably because many of their isomers can be hardly separated and/or resolved.

The circular dichroism (CD) intensity of cobalt(III) complexes with six-membered diamine chelate rings is known to be much weaker than the corresponding cobalt(III) complexes with five-membered rings. The purpose of the present work was to separate *cis*-$[Co(NH_3)_2(tn)_2]^{3+}$, which had not yet been separated, to resolve it into antipodes, and to assign the configuration by comparing their CD spectra with those of known $[Co(NH_3)_2(diamine)_2]^{3+}$- and $[Co(diamine)_3]^{3+}$-type complexes (diamine=en, tn, and RR-ptn**).

Experimental

To about 10 ml of liquid ammonia cooled in a Dry Ice–acetone bath was added 350 mg of *trans*-$[CoCl_2(tn)_2]Cl$ prepared according to the literature.[1] The mixture was stirred for one hour and allowed to stand overnight, while the temperature of the solution gradually increased up to room temperature and finally all the solvent ammonia evaporated.

The orange-red product obtained as residue was subjected to recycling chromatography[2,3] on an SP-Sephadex column (4.1 dia.×96 cm) using an aqueous 0.18 M (1 M= 1 mol dm^{-3}) sodium $(+)_{589}$-tartrate solution as eluent. The flow rate of elution was about 2.0 ml per minute. The elution after the sixth recycling gave two well-separated bands, which are denoted by A and B in the order of effluence (Fig. 1a).

The CD spectral measurements of each fraction of the effluent showed that the complex contained in the B band was partially resolved. The combined solution of B-band fractions was rechromatographed on the same column with a different eluent, 0.15 M sodium $(+)_{589}$-tartratoantimonate(III) solution. The elution after the tenth recycling resulted in two well-separated bands, B-I and B-II, with an area ratio of about 1:1 (Fig. 1b). The notations, A, B-I, and B-II, will hereafter be used to designate the isomer contained in each band.

The chlorides of A, B-I, and B-II were obtained from the eluates of the corresponding bands with the method described previously.[4] Found for the isomer A: C, 19.62; H, 7.65; N, 22.61%. Found for the isomer B-I: C, 19.32; H, 7.65; N, 22.61%. Calcd for $[Co(NH_3)_2(tn)_2]Cl_3 \cdot H_2O$: C, 19.72; H, 7.72; N, 22.99%.

** Ethylenediamine, trimethylenediamine, and (2*R*,4*R*)-2,4-pentanediamine, respectively.

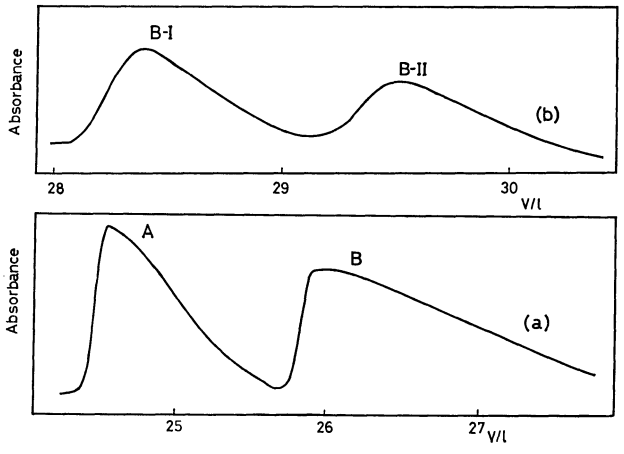

Fig. 1. The elution curves of the recycling chromatography of (a) $[Co(NH_3)_2(tn)_2]^{3+}$ by the 0.18 M sodium $(+)_{589}$-tartrate and (b) *cis*-$[Co(NH_3)_2(tn)_2]^{3+}$ by the 0.15 M sodium $(+)_{589}$-tartratoantimonate(III).

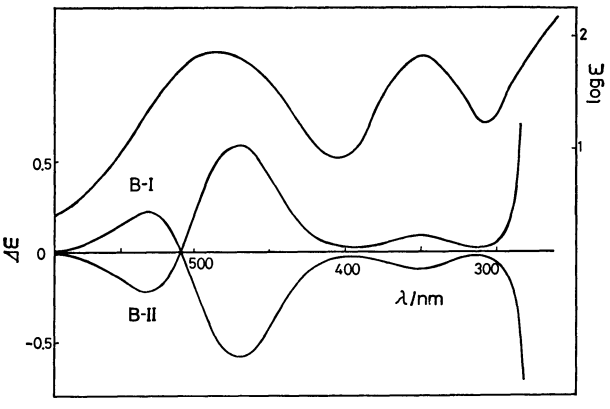

Fig. 2. Visible absorption and CD spectra of isomers of *cis*-$[Co(NH_3)_2(tn)_2]^{3+}$.

The ^{13}C NMR spectra were obtained with a JEOL JNM FX-60 spectrometer, using dioxane as an external reference. Absorption spectra were recorded on a Hitachi EPS-3T spectrophotometer and CD curves on a JASCO J-20 spectrophotometer.

Results and Discussion

The ^{13}C NMR spectra of $[Co(NH_3)_2(tn)_2]Cl_3$ isomers have a broader signal at 25.5 ppm and a more intense signal at 39—40 ppm, the latter being split into two peaks for the B isomer. The signals, in the order mentioned, are assigned to β- and α-methylene carbons according to the literature.[5]

The α-methylene carbon atoms are all equivalent in the trans complex, but are divided into two groups in the *cis* complex. Therefore, the A and B isomers

a) Ref. 8. b) Present work. c) Ref. 6. d) Ref. 9. e) This ligand holds the *ob* form of chelate rings in both the bis and tris complexes.

are assigned to the trans and cis isomers of $[Co(NH_3)_2(tn)_2]^{3+}$, respectively. These assignments are supported also from the fact that the B isomer has been resolved into catoptromers, as described below.

The CD spectra of the B-I and B-II isomers are shown in Fig. 2 with the absorption spectrum of *cis* (B) isomer. Their CD spectra are enantiomeric to each other and resemble those of Λ- and Δ-$[Co(en)_3]^{3+}$, respectively, in their Cotton effects and their shapes.[6] Thus, the B-I and B-II isomers are the optical antipodes of pure *cis*-$[Co(NH_3)_2(tn)_2]^{3+}$, and were assigned to the Λ and Δ forms, respectively.

Table 1 shows the maximum CD intensities and positions in the first and second absorption region of the Λ-$[Co(NH_3)_2(diamine)_2]^{3+}$ and $[Co(diamine)_3]^{3+}$ spectra. The CD spectra of each bisdiamine and the corresponding trisdiamine complex are similar to each other with respect to peak positions and signs, as mentioned above for the tn complexes.

If the number of chelate rings contributes to CD intensity of a bisdiamine complex, the intensity would be expected to be two-thirds of that of the corresponding trisdiamine complex. However, as seen from the last column of Table 1, the observed ratio is roughly one-third or less, particularly with regard to the dominant CD peaks in the first absorption region. Therefore, the number of asymmetric pairs of chelate rings is considered to be more important in determining the CD intensity at least in the first absorption region of the spectra of $[Co(NH_3)_2(diamine)_2]^{3+}$ and $[Co(diamine)_3]^{3+}$, in which the diamine forms either five-membered or six-membered chelate ring. This is consistent with the previous results for the CD intensity of $[Co(en)_x(tn)_y(tmd)_z]^{3+}$ isomers.[7]

The Synthesis of Purpurosamine B Derivatives

Yutaka HONDA and Tetsuo SUAMI*

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received June 7, 1980)

Synopsis. Purpurosamine B and its 6-epimer have been found in antibiotic gentamicin C_2 and fortimicin A respectively. Methyl 2,6-di-*N*-acetyl-α-purpurosaminide B and its corresponding 6-epimer have been synthesized from methyl 2-acetamido-2,3,4-trideoxy-α-D-*erythro*-hexodialdo-1,5-pyranoside.

In a continuation of preceding papers,[1,2] the synthesis of methyl 2,6-di-*N*-acetyl-α-purpurosaminide B (**6**) and its 6-epimer (**8**) will be described in the present paper. The nitromethane addition of methyl 2-acetamido-2,3,4-trideoxy-α-D-*erythro*-hexodialdo-1,5-pyranoside[2] (**1**) gave a mixture of two diastereomers, methyl 2-acetamido-2,3,4,7-tetradeoxy-7-nitro-α-D-*ribo*- and -β-L-*lyxo*-heptopyranosides, in a yield of 49%. The catalytic hydrogenation of the mixture, followed by treatment with benzyloxycarbonyl chloride in pyridine afforded 7-benzyloxycarbonylamino derivatives in a yield of 69%. The mesylation of the derivatives gave a mixture of 6-*O*-mesyl derivatives (**2**) in a yield of 89%.

Compound **2** was converted to aziridine derivatives by treatment with sodium isopropoxide. When the derivatives reacted with benzyloxycarbonyl chloride in dioxane and subsequently treated with HCl in dioxane, methyl 2-acetamido-6-(benzyloxycarbonylamino)-7-chloro-2,3,4,6,7-pentadeoxy-α-D-*ribo*-heptopyranoside (**3**) and the corresponding β-L-*lyxo* derivative (**4**) were obtained in 23 and 35% yields respectively.

The dehalogenation of **3** with tributylstannane gave methyl 2-acetamido-6-(benzyloxycarbonylamino)-2,3,4,6,7-pentadeoxy-α-D-*ribo*-heptopyranoside (**5**) in a yield of 84%; this was then converted to methyl 2,6-di-*N*-acetyl-α-purpurosaminide B (**6**), which was found to be identical with an authentic sample.[3]

Analogous reaction sequences of **4** gave methyl 2,6-di-*N*-acetyl-6-*epi*-α-purpurosaminide B (**8**).

Experimental[4]

A Mixture of Methyl 2-Acetamido-7-(benzyloxycarbonylamino)-2,3,4,7-tetradeoxy-6-O-mesyl-α-D-ribo- and -β-L-lyxo-heptopyranosides (2). A 1.34-g portion of methyl 2-acetamido-2,3,4-trideoxy-α-D-*erythro*-hexodialdo-1,5-pyranoside[2] (**1**) was treated with nitromethane (0.62 ml) in the presence of sodium methoxide at an ambient temperature for 40 h, as has been described in the preceding paper,[2] without recrystallization, to give 845 mg (49%) of a mixture of the two diastereomers.

The product was catalytically hydrogenated and subsequently treated with benzyloxycarbonyl chloride to give 805 mg (69%) of 7-*N*-benzyloxycarbonyl derivatives. The derivatives were mesylated analogously to the method described in the preceding paper[2] to give 872 mg (89%) of **2**: mp 123—126 °C.

Found: C, 51.25; H, 6.27; N, 6.34; S, 6.90%. Calcd for $C_{19}H_{28}N_2SO_8$: C, 51.34; H, 6.35; N, 6.30; S, 7.21%.

Methyl 2-Acetamido-6-(benzyloxycarbonylamino)-7-chloro-2,3,4,6,7-pentadeoxy-α-D-ribo-heptopyranoside (3) and -β-L-lyxo-heptopyranoside (4). To a solution of sodium isopropoxide (0.11 g of Na in 10 ml of isopropyl alcohol) in dioxane (5 ml), **2** (780 mg) was added, and the mixture was heated under reflux for 2 h. The solution was then concentrated, and benzyloxycarbonyl chloride (1.4 ml of 30% toluene solution) was added to a solution of the residue in dioxane (10 ml). After 3 h, dioxane (5 ml) containing 3% HCl was added to the mixture. After 1 h, the mixture was neutralized with Amberlite IRA-400(OH^-) and concentrated. The residue was purified on a silica-gel column using 3:2 (v/v) 2-butanone–toluene. Fractions homogeneous on TLC (R_f 0.43) in the same solvent were combined and concentrated. The residue was recrystallized from $CHCl_3$–

Photochemical Isomerization of 6,7-Dicyano- and 6,7-Bis(methoxycarbonyl)-3-phenylsulfonyl-(2,4-*exo*)-3-azatricyclo[3.2.1.$0^{2,4}$]oct-6-ene

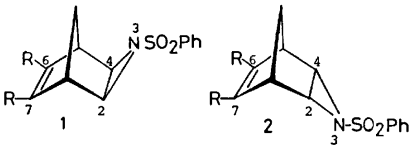
Katsumi UMANO,* Hiroto KOURA, and Hiroo INOUE

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received November 4, 1980)

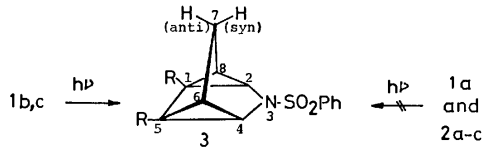
Synopsis. The photochemical reactions of 6,7-bis(methoxycarbonyl)- and 6,7-dicyano-3-phenylsulfonyl-(2,4-exo)-3-azatricyclo[3.2.1.$0^{2,4}$]oct-6-ene afford the corresponding tetracyclic compounds (**3b** and **3c**) by the skeletal isomerization, but those of their endo isomers do not result in the formation of **3b** and **3c**.

Recently we have reported that 3-phenylsulfonyl-(2,4-*exo*)-3-azatricyclo[3.2.1.$0^{2,4}$]oct-6-enes **1a—c** undergo thermal rearrangement to afford the corresponding 2-phenylsulfonyl-2-azabicyclo[3.2.1]oct-3,6-dienes in high yields under moderate conditions.[1] Our interest in the reactivity of these tricyclic aziridines prompted us to examine the photochemical isomerization of compounds **1a—c** and their endo isomers **2a—c**. The photochemical isomerization of tricyclo[3.2.1.-$0^{2,4}$]oct-6-enes[2] and their 3-oxa[3] and 3-aza[4] analogs has been known to afford tetracyclo[3.3.0.$0^{2,8}$.$0^{4,6}$]-octanes by a $[2\pi+2\sigma]$ cycloaddition pathway. Herein, we wish to report several results on the photochemical reaction of the tricyclic aziridines.



(a; R = H, b; R = CO_2Me, c; R = CN)

A solution of compounds **1a—c** and **2a—c** in acetonitrile was degassed in a Pyrex or quartz tube and irradiated with a high-pressure mercury lamp (300 W); the products were isolated in the usual manner. The results are summarized in Table 1. The irradiation of the unsubstituted *exo* and *endo* compounds **1a** and **2a** afforded no tetracyclic product. On the other hand, the 6,7-disubstituted *exo* compounds **1b** and **1c** were converted into the corresponding tetracyclic compounds **3b** and **3c** together with an unidentifiable polymeric material, as Table 1 shows.



(b; R = CO_2Me, c; R = CN)

The cyano and methoxycarbonyl groups made possible the intramolecular photocyclization of the *exo* tricyclic aziridines, although in the thermal rearrangements of **1a—c** such substituents caused a decrease in their reactivity.[1] Furthermore, the cyano group brought about a higher yield of a tetracyclic compound than that in the case of the methoxycarbonyl group. The use of a quartz tube as a reaction vessel or a low-pressure mercury lamp as a light source resulted in the increase of the amount of the polymeric material produced.

TABLE 1. THE YIELDS OF THE TETRACYCLIC COMPOUNDS IN THE PHOTOCHEMICAL REACTIONS OF AZIRIDINES **1a—c** AND **2a—c**[a]

Compound	Tube[b]	Time/h	Yield/%	Recovery/%
1b	P	96	11	56
1b	Q	12	24	41
2b	P	96	0	96
2b	Q	12	0	53
1c	P	96	76	5
1c	Q	6	54	0
2c	P	96	0	78
2c	Q	6	0	64

a) Solvent: acetonitrile. Concentration of compound: 6.1×10^{-2} mol/l (Pyrex) and 1.3×10^{-1} mol/l (quartz). In the cases of **1a** and **2a**, the tetracyclic compounds were not obtained at all. The unreacted **1a** (*ca.* 90%) was isolated as 2-phenylsulfonyl-2-azabicyclo[3.2.1]oct-3,6-diene, which was produced by the thermal rearrangement on silica gel chromatography. The compound **2a** was recovered in *ca.* 90% yield. b) P= Pyrex and Q=quartz.

Contrary to the results in the cases of the *exo* compounds **1b** and **1c**, it was found that the 6,7-disubstituted *endo* compounds **2b** and **2c** undergo no isomerization under the similar conditions, as Table 1 shows. Thus, this result demonstrates that the bent C_2–C_4 bond directed toward the *endo* side is necessary for the photochemical isomerization of the tricyclic aziridines. A similar phenomenon has been observed in the thermal reactions of **1a—c** and **2a—c** described previously.[1]

Experimental

Melting points were uncorrected. Acetonitrile was distilled under nitrogen from CaH_2. IR, ^{1}H- and ^{13}C-NMR, and mass spectra were obtained on a Hitachi 216 grating infrared spectrometer, a Hitachi R-24A spectrometer, a JEOL FX 90Q Fourier transform NMR spectrometer, and a Hitachi RMU-6E mass spectrometer, respectively.

Material. The compounds, **1a—c** and **2b,c**, were prepared by the reactions of the corresponding norbornadienes with benzenesulfonyl azide. The ^{1}H-NMR, IR, and mass spectral data of their compounds are summarized in Table 2. The **2a** was prepared according to the methods described in the literature.[5]

General Procedure for Photochemical Reaction. All reactions were performed similarly in a pyrex or quartz tube (72 cm^3 total capacity). A reaction tube was charged with 0.61—0.65 mmol of **1a—c** and **2a—c** and 5—10 ml of dry

The Photochemical Reaction of Benzo[c]cinnoline. IV. Comments on the Mechanism of 2,2′-Diaminobiphenyl Formation

Hiroyasu Inoue,* Yukimi Hiroshima, Toshihiko Sakai, Tadamitsu Sakurai, and Norio Fukuda

Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama 221

(Received November 20, 1980)

Synopsis. In order to determine the mechanism of 2,2′-diaminobiphenyl formation from benzo[*c*]cinnoline, effect of aldehyde on the reaction was examined. It is proposed that ethanal, which was generated from ethanol in the initial photoreduction, formed an adduct with 5,6-dihydrobenzo[*c*]cinnoline, and that the resulting adduct participated in the subsequent photo-induced 2,2′-diaminobiphenyl formation.

Photochemical reactions of benzo[*c*]cinnoline (hereafter referred to as BCC) show a dependence on excitation wavelengths and solvents. In a previous paper,[1] BCC found to give 2,2′-diaminobiphenyl (referred to as DAB) under irradiation of light of wavelength longer than 400 nm in an acidic aqueous ethanol. In the DAB formation, 5,6-dihydroBCC, which is monoprotonated in the acidic solution, is initially produced as an intermediate. On the other hand, when 2-propanol is used in the place of ethanol, the visible light irradiation does not afford DAB, although the photoreduction to 5,6-dihydroBCC occurs.[2] Therefore, there is a distinct difference in the DAB formation between these alcohols. Such solvent dependence is a problem to be solved.

Protonated 5,6-dihydroBCC itself can not be excited electronically by visible light; it has been shown that the excitation of 5,6-dihydroBCC with ultraviolet light causes the photoelimination to afford carbazole in an acidic 2-propanol as well as in an acidic ethanol.[3]

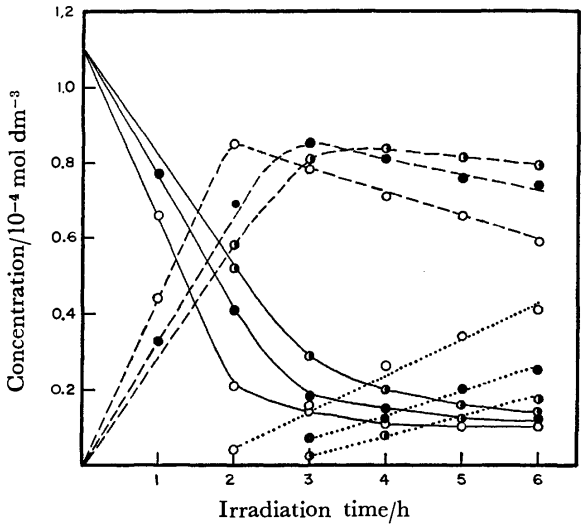

Fig. 1. Rate of the reaction under the visible light irradiation upon a 3.6 mol dm^{-3} HCl ethanol solution of BCC (1.1×10^{-4} mol dm^{-3}).
Concentrations of BCC(——), 5,6-dihydroBCC(- - -), and DAB(·····). Relative light intensity; ○: 3.1; ●: 1.6; ◑: 1.0.

The present paper is concerned with the mechanism of the photo-induced DAB formation from 5,6-dihydroBCC.

Experimental

BCC and 2-propanol were the same as those used previously.[2] Aldehydes used here were ethanal, propanal, butanal, and 2-methylpropanal and were purified by distillation.

A 500 W high pressure mercury arc lamp (Ushio USH-500), with a glass filter (Corning CS-3—73), which cut off light of wavelength shorter than 400 nm, was used as a visible light source. The quantitative conversion of BCC (5.0×10^{-5} mol dm^{-3}) into 5,6-dihydroBCC was attained by the visible light irradiation for 3 h upon an acidic (4 mol dm^{-3} HCl) 2-propanol solution of BCC. In order to examine the effects of some added compounds, further irradiation were carried out in the same manner after the addition of additives into the reactant solution. All irradiations were carried out at room temperature under nitrogen. The intensity of incident light was determined by actinometry, using a potassium trioxalatoferrate(III) solution.

Results and Discussion

Figure 1 shows the rates of reaction under the visible light irradiation upon a 3.6 mol dm^{-3} HCl aqueous ethanol solution of BCC (1.1×10^{-4} mol dm^{-3}). The concentrations of BCC, 5,6-dihydroBCC, and 2,2′-diaminobiphenyl were determined spectrophotometrically as reported earlier.[1] The DAB formation was initiated after about 80% of the initial amount of BCC was converted into 5,6-dihydroBCC, irrespective of light intensities. Moreover, as seen from Fig. 1, the amount of DAB produced is related linearly to the irradiation time, and is dependent on light intensities. Since 5,6-dihydroBCC itself has no absorption in the visible region, these results suggest that a certain species, which can be excited electronically with the visible light, may play an essential role in the subsequent DAB formation.

Effects of aldehyde and ketone on the reaction were examined, because these compounds were generally produced from primary and secondary alcohols, respectively, in photo-induced hydrogen abstraction reactions by substrates.[4,5] When ethanal was added into an acidic 2-propanol solution of 5,6-dihydroBCC prepared previously[2] and the irradiation was allowed to continue, the DAB formation was observed without the induction period. On the other hand, acetone was shown to have no effect on the reaction. Therefore, the solvent dependence of the photo-induced DAB formation can be interpreted in terms of the

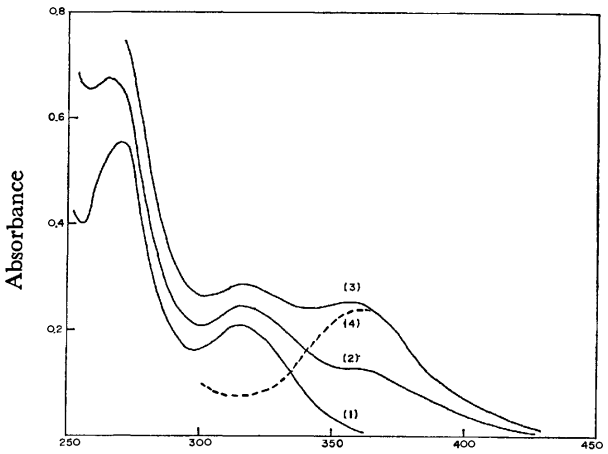

Fig. 2. Spectral change caused by the addition of butanal into an acidic 2-propanol solution of 5,6-dihydroBCC(5.0×10^{-5} mol dm^{-3}).
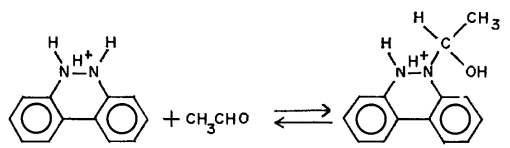
Concentration of butanal; (1): 0 mol dm^{-3}, (2): 2.2×10^{-3} mol dm^{-3}, (3): 8.9×10^{-3} mol dm^{-3}, (4): difference spectrum (3)—(1).

difference of the products from alcohols in the initial photoreduction.

Figure 2 shows the spectral change caused by the addition of butanal into an acidic 2-propanol solution of 5,6-dihydroBCC. As seen from this figure, a new absorption band appears around 360 nm on the addition of the aldehyde, thus indicating that there is interaction between 5,6-dihydroBCC and the aldehyde giving a certain species. The resulting species can absorb the irradiation light. On the other hand, no spectral change was observed when acetone was added.

The species formed is so unstable that it gives BCC quantitatively after being allowed to stand for several hours under nitrogen, although 5,6-dihydroBCC itself is relatively stable in the acidic solution. Here it should be noted that this aldehyde is known to form an adduct with amine, and the resulting adduct (carbinolamine) is usually unstable.[6-8] In the present case, therefore, the following equilibrium can be considered to be established, and the adduct may participate in the DAB formation through the visible light absorption. The adduct converts spontaneously



5*H*-6-(1-Hydroxyethyl)-benzo[*c*]cinnoline

to BCC, as described above. This conversion may be expected to be accompanied by the generation of a primary alcohol, RCH_2OH. In order to detect the alcohol generated from the adduct, an acidic tetrahydrofuran solution of 5,6-dihydroBCC in concentration of 1.2×10^{-1} mol dm^{-3} was prepared using $LiAlH_4$ as reported earlier.[2] Propanal was added into the 5,6-dihydroBCC solution to form the adduct,[9] and then the solution was allowed to stand for enough time for the conversion of the adduct to BCC. Gas chromatography showed that propanol was present in the tetrahydrofuran solution.

Table 1. Equilibrium constants (K) of the adduct formation and rates of the conversion of BCC into DAB[a]

Aldehyde[b]	K/mol dm^{-3} at 21 °C	DAB produced (%)
Ethanal	322	67
Butanal	243	39
Propanal	110	31
2-Methylpropanal	25	14

a) Initial concentration of BCC: 2.0×10^{-5} mol dm^{-3}, Irradiation time: 30 min. b) Concentration of aldehyde: 4.0×10^{-4} mol dm^{-3}.

For several aldehydes the same new absorption band was observed around 360 nm. The alkyl groups in the aldehydes did not affect the position of the band. The equilibrium constants for the adduct formation were determined by applying the Benesi-Hildebrand equation.[10] The results are presented in Table 1, in which the rates of the DAB formation are also shown. The equilibrium constant is dependent on the alkyl groups in the aldehydes. The observed correlation between the equilibrium constant and the product yield indicates that the carbinolamine adduct serves as a precursor of DAB.

(Received January 12, 1981)

Synopsis. The cross-coupling reactions of 2-(1,3-butadienyl)magnesium chloride (1) with aryl and alkyl iodides were investigated in the presence of transition metal catalysts. Tetrakis(triphenylphosphine)palladium(0) catalyzes the cross-coupling reactions of **1** with aryl iodides, and copper(I) iodide catalyzes the reaction with alkyl iodides. These cross-coupling reactions offer convenient routes for the synthesis of 2-substituted 1,3-butadienes.

It has been reported that the cross-coupling reactions of Grignard reagents with allyl or alkenyl halides occurred in the presence of nickel or palladium complexes under mild conditions.[1-5]

Allyl Grignard reagent was reported to be alkylated by alkyl iodides or tosylates in the presence of copper(I) iodide.[6,7]

The authors carried out the synthesis of 2-substituted 1,3-butadienes by the cross-coupling reactions of **1** with aryl iodides in benzene–tetrahydrofuran (THF) catalyzed by tetrakis(triphenylphosphine)palladium(O) (**4**) or alkyl iodides in THF by copper(I) iodide (**5**) (Eqs. 1 and 2), and wish to report the results.

$$\underset{\text{MgCl}}{\underset{|}{\text{CH}_2{=}\text{CH}{-}\text{C}{=}\text{CH}_2}} + \text{ArI} \xrightarrow[\text{C}_6\text{H}_6\text{-THF}]{\text{Pd(pph}_3)_4} \underset{\text{Ar}}{\underset{|}{\text{CH}_2{=}\text{CH}{-}\text{C}{=}\text{CH}_2}} \quad (1)$$

1 **2**

$$\underset{\text{MgCl}}{\underset{|}{\text{CH}_2{=}\text{CH}{-}\text{C}{=}\text{CH}_2}} + \text{RI} \xrightarrow[-30\,^\circ\text{C, THF}]{\text{CuI}} \underset{\text{R}}{\underset{|}{\text{CH}_2{=}\text{CH}{-}\text{C}{=}\text{CH}_2}} \quad (2)$$

1 **3**

The results of cross-coupling reactions of **1** with iodobenzene are shown in Table 1. Only **4** is highly active among the transition metal complex catalysts examined, and 2-phenyl-1,3-butadiene (**2**) was obtained in increasing yield with an increase in the amount of the catalyst. Nickel(II) acetylacetonate was inactive for the reaction. As **4** showed a high activity, the cross-coupling reactions of **1** with aryl and alkyl halides were investigated in the presence of **4**. However, **4** was not an effective catalyst for the cross-coupling reaction of **1** with bromobenzene, alkyl iodide, or iodocyclohexane, as shown in Table 2.

Only aryl iodides gave the cross-coupling products

in reasonably good yield. In order to overcome the low activity of **4** in the reaction, **5**, which is known to form an ate complex with a Grignard reagent, was used as a catalyst and the results with aryl and alkyl halides are shown in Table 3.

Although **5** was not active for iodobenzene, iodocyclohexane, or alkyl bromides, reasonable yields could be obtained with linear alkyl iodides, giving 2-alkyl-1,3-butadienes. These selectivities can be applied to the chemoselective cross-coupling reaction (Table 2 No. 11 and Table 3 No. 27) for the synthesis of functionalized 1,3-butadienes.

Experimental

Reagents. **1** was prepared as described in the previous report.[8] **4** and **5** were prepared by the procedures described elsewhere.[9,10]

*Cross-coupling Reaction of **1** with Aryl Iodides.* To a mixture of an aryl iodide (0.1 mol), **4** (1—3 mol% to an aryl iodide) and dry benzene (50 ml) in a 300 ml four-necked flask, **1** (0.1 mol) in THF (100 ml) was added dropwise with stirring under nitrogen atmosphere.

An exothermic reaction occurred during the addition, and the color of the contents gradually changed from yellowish green to black. After the completion of the addition, stirring was continued for 30 min at the refluxing temperature of the reaction system.

The organic layer was separated after hydrolyzing with 6 mol dm^{-3}-HCl, and the aqueous layer was extracted with two portions of diethyl ether (80 ml). The combined organic layer was washed first with 5% aqueous sodium hydrogencarbonate, then with water, then dried (Na_2SO_4) and distilled.

*Cross-coupling Reaction of **1** with Alkyl Iodides.* To a mixture of an alkyl iodide (0.1 mol), 5 (10—20 mol% to an alkyl iodide) and THF (50 ml) in a 300 ml four-necked flask cooled to −30 °C, **1** was added dropwise with stirring under nitrogen atmosphere.

The color of the contents gradually changed from light yellow to black. After the completion of the addition, stirring was continued for 2 h at 0 °C. The products were isolated by the work-up used for aryl iodides. The reaction products were identified by comparing their IR and NMR spectra with the reported data.

Facile Dehydrogenative Dimerization of Indolizine Derivatives

Akikazu KAKEHI,* Suketaka ITO, Akihiro HAMAGUCHI, and Tsutomu OKANO

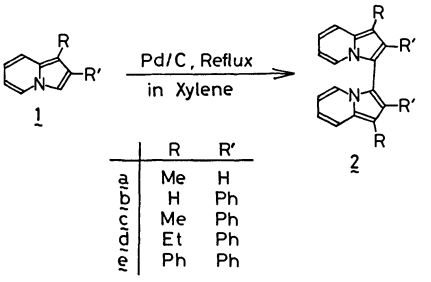
Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received January 28, 1981)

Synopsis. Treatment of 3-unsubstituted indolizines with a dehydrogenating agent such as palladium on carbon in refluxing xylene gave the corresponding 3,3′-biindolizine derivatives in 19—74% yields.

It is well known that indolizines react smoothly at the 3-position with various electrophiles, as observed, for example, in the cycloaddition and the Michael addition with electron-poor olefins[1-3] and substitution with diazonium salts[4] or an acylating agent.[5] In order to study nitrogen-bridged heterocycles, a method for direct functionalization of indolizine derivatives was required. Attempts to obtain the corresponding adducts by the reactions of an indolizine with electron-poor olefins such as diethyl fumarate and ethyl cinnamate under various conditions were unsuccessful. However, in the reaction in the presence of a dehydrogenating agent, an unexpected product, *i.e.* a dimer of the indolizine was obtained. In this note we wish to report a facile dehydrogenative dimerization of some 3-unsubstituted indolizine derivatives and the structural assignment of the resulting biindolizines.

When the reaction of 1-methylindolizine (**1a**) with diethyl fumarate or ethyl cinnamate was carried out in refluxing xylene in the presence of palladium on carbon (Pd/C), a product (**2a**, pale yellow needles), mp 144—145 °C, was separated as the only isolable compound. Elementary analysis (Table 1), and the mass spectrum (M^+ 260) of the product show that **2a** is a bimolecular dehydrogenative coupling product from **1a**. The same product (**2a**) was also formed by the reaction of **1a** with Pd/C in the absence of the olefin in 38% yield. In order to confirm the generality of this reaction, we carried out the reactions of some indolizines with Pd/C. As expected, the corresponding pale yellow products (**2b—e**) were formed from 2-phenyl- (**1b**), 1-methyl-2-phenyl- (**1c**), 1-ethyl-2-phenyl- (**1d**), and 1,2-diphenyl-indolizine (**1e**), respectively. Elementary analyses and mass spectra (Table 1) of **2b—e** were also in accord with the expected structures. The site of the coupling in these biindolizines (**2a—e**) was determined mainly by means of their NMR spectral data (Table 2): For example, the NMR spectrum of **2a** exhibited signals at δ 6.40 (2H, dt, J=7.0, 7.0, and 1.5 Hz, 6-H and 6′-H), 6.71 (2H, br t, J=9.0 and 7.0 Hz, 7-H and 7′-H), 7.46 (2H, br d, J=9.0 Hz, 8-H and 8′-H), and 7.72 (2H, br d, J=7.0 Hz, 5-H and 5′-H) due to the protons on the pyridine rings, and at δ 2.43 (6H, s, 1-Me and 1′-Me) and 6.86 (2H, s, 2-H and 2′-H) due to the methyl groups and the protons on the pyrrole rings. As compared with the original 1-methylindolizine (**1a**),[6] in particular, the disappearance of the 3- and 3′-protons and the absence of the coupling of the 2- and 2′-protons (δ 6.86, singlet) in **2a** are ultimate evidences that **2a** is 3,3′-biindolizine derivative. Furthermore, distinct symmetrical structures of **2a—e** were also suggested by their IR spectra in which only a few weakened absorption bands appear in contrast with those of **1a—e**. From these results we conclude the structures of **2a—e** to be 3,3′-biindolizines.



Scheme 1.

Similar reactions of aromatic substrates by the action of palladium(II) compounds[7,8] are well established, but that with Pd(O) as described above is unprecedent. The dehydrogenative dimerization with Pd/C is of interest and high synthetic value because of its simplicity and low cost, though the yields were not satisfactory.

Experimental

Melting points were measured with a Yanagimoto micromelting point apparatus and are uncorrected. Microanalysis was carried out in a Perkin-Elmer 240 Elemental Analyzer. NMR spectra were determined with a Varian EM360A NMR spectrometer in deuteriochloroform with tetramethylsilan as an internal standard, chemical shifts being expressed in terms of δ, mass spectra with a JEOL LMS-01SG-2 mass spectrometer with a JEC-6 spectrocom-

puter attached, and IR spectra with a Hitachi 260—10 Infrared spectrophotometer.

Materials. Indolizines (**1b—2e**) were synthesized by the Tschitschibabin reaction of the corresponding 1-phenacylpyridinium bromides.[9-11] 1-Methylindolizine (**1a**)[12] was prepared in overall 45% yield by the reaction of 1-(ethoxycarbonylmethyl)-2-ethylpyridinium bromide with ethyl (ethoxymethylene)cyanoacetate in ethanol in the presence of potassium carbonate at 40—50 °C followed by acidic hydrolysis of the resulting ethyl 1-methylindolizine-3-carboxylate.

Preparation of 3,3′-Biindolizines (2a—e). General Method. A mixture of indolizine (2 mmol), palladium on carbon (5%, 0.8—1.0 g), and dry xylene (50 ml) was heated under reflux in a 100 ml round flask equipped with a condenser for 20—25 h and then cooled. Insoluble substances were removed from the reaction solution by filtration and the filtrate was concentrated at reduced pressure. The residue was separated carefully by column chromatography (alumina) using hexane and then ether as eluents. Recrystallization several times from ether–hexane gave the corresponding 3,3′-biindolizine derivatives as pale yellow needles (**2a**) or prisms (**2b—e**).

Similar treatment of the parent indolizine with Pd/C did not afford the expected 3,3′-biindolizine because of its instability.

These results and some properties of **2a—e** are given in Tables 1 and 2.

An Improved Oxidation Method of Pyridoxine

Masaaki IWATA

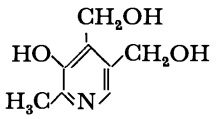
The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received January 28, 1981)

Synopsis. Manganese dioxide oxidation in the presence of primary amine was found to be an efficient oxidation system for pyridoxine.

Prevalent method to synthesize pyridoxal and its congeners from the corresponding pyridoxines has been carried out by use of "active" manganese dioxide as an effective oxidant in aqueous solution of restricted pH ranges or in chloroform.[1] The efficiency of the oxidation method seems to depend on activity of manganese dioxide, which is reported to be dependent on the preparation method,[2] and on solvent choice and reaction temperature which are proved to affect product yield as much as or more than the activity of manganese dioxide.[2,3]

In connection with our study directed toward devised molecular construction from pyridoxine to pyridinophanes with pyridoxal-like activity,[4] it was inevitably required to develop a new oxidation system by use of manganese dioxide.[5] With those above in mind and through several attempts employing pyridoxine (**1**) as a substrate model, we eventually found



1

a new oxidation system by use of manganese dioxide[7] in the presence of amine. The present method has been successfully applied to pyridinophane congeners without exception or reduction in yield.[4]

The fundamental reaction system consisted of **1**, manganese dioxide,[7] and an amine in the molar ratio of 1:10:2 in benzene. Pyridine was added to dissolve **1**. The mixture was heated under reflux with azeotropic removal of the resulting water. The resulting imine was subjected to transimination for isolation (path A). For the purpose of comparison of amine effect on the reaction, path C was examined as well.

$$\mathbf{1} \xrightarrow[R'\text{-}NH_2]{MnO_2} \underset{\mathbf{2}}{R\text{-}CH{=}N\text{-}R'} \xrightarrow{R''\text{-}NH_2} \underset{\mathbf{3}}{R\text{-}CH{=}N\text{-}R''} \quad \text{(path A)}$$

$$\mathbf{1} \xrightarrow[R''\text{-}NH_2]{MnO_2} \underset{\mathbf{3}}{R\text{-}CH{=}N\text{-}R''} \quad \text{(path B)}$$

$$\mathbf{1} \xrightarrow{MnO_2} \underset{\mathbf{4}}{R\text{-}CHO} \xrightarrow{R''\text{-}NH_2} \underset{\mathbf{3}}{R\text{-}CH{=}N\text{-}R''} \quad \text{(path C)}$$

R′=$-CH_2CH_2NH_2$, $-CH_3\cdot HCl$, or $-CH_2CH_2CH_2N(CH_3)_2$
R″=$-C_6H_4$-*p*-$OC_2H_5\cdot HCl$

The results obtained are listed in Table 1. Each primary amine has a positive effect on the oxidation. Especially, 3-(dimethylamino)propylamine was the most effective of amines used.

Although we have no substantial evidence for the bimolecular oxidation mechanism,[9] the primary amino group might participate in the oxidation process by forming a transient manganese dioxide complex. The previous work on the oxidation of β-amino alcohols[10] could be mechanistically related to the present work.

The present method will provide "an oxidant substitute" for "active" manganese dioxide and, thus, seems to be a useful tool for the synthesis of unstable aldehydes, protected directly by coexisting primary amine to form a relatively stable Schiff base during oxidation.

Experimental

The melting point is uncorrected. The IR spectra were recorded on a Shimadzu IR-27 instrument. The UV spectra were measured with Hitachi 124 spectrophotometer. The ^{1}H-NMR spectra were recorded on a Varian HA-100D apparatus, with TMS as the internal standard and the chemical shift and coupling constant were represented by δ and Hz, respectively. Merck silica gel 60 (Art. 7734, 0.063—0.20 mm) was used for the column chromatography and Wakogel B-5 FM (Wako Pure Chem. Co., Ltd.) for analytical thin layer chromatography. The elemental analyses were performed by this Institute. All the reagents used were commercially available and employed without further purification.

Oxidation Method. The mixture consisting of **1**, manganese dioxide,[7] and an amine in the molar ratio of 1:10:2 in benzene (150 ml/g of **1**) was heated under reflux for the mentioned time with azeotropic removal of the resulting

water by the Dean-Stark apparatus until no more water came out. Pyridine was mixed to dissolve **1** up to fifty volume percent of benzene. The reaction mixture was then filtered, while hot, through celite (No. 545) to remove excess amount of manganese dioxide and the resulting manganese oxide, washed several times with hot pyridine. The combined filtrate was treated, after removal of the solvents under reduced pressure, with one of the following ways.

For transimination[8] (path A), the residue was dissolved into small amount of benzene–ethyl acetate (1:1 v/v), and equal weight of *p*-ethoxyaniline hydrochloride to the amine initially used was mixed, followed by addition of equal volume of water to the organic layer. By magnetic stirring, immediately, the brown solution resulted in orange-red precipitate which was recrystallized from methanol after collection by filtration. Spectral data supported that the orange red crystals are 4-(*p*-ethoxyphenyliminomethyl)-5-hydroxy-6-methylpyridine-3-methanol (**3**); mp 211—212.5 °C (decomp), needles. Found: C, 66.62; H, 6.35, N, 9.66%. Calcd for $C_{16}H_{20}O_3N_2$: C, 66.64; H, 6.99; N, 9.72%. UV (EtOH): λ_{max} (ε) 210 (19200), 224 (sh, 17700), 253 (sh, 8400), 297 (sh, 7100), 305 (sh, 7500), 350 (14700), 366 (15000), and 384 (sh, 11800) nm. UV (EtOH–0.1 M NaOH): λ_{max} (ε) 239 (18800), 310 (7000), and 410 (3400) nm. ^{1}H-NMR (DMSO-d_6): 1.34 (3H, t, J=7.0, OCH_2–$C\underline{H}_3$), 2.41 (3H, s, $C\underline{H}_3$ on the pyridine ring), 4.07 (2H, q, J=7.0, $OC\underline{H}_2CH_3$), 4.75 (2H, broad d, J=5.0, $C\underline{H}_2$–OH on the pyridine ring), 5.38 (1H, broad t, J=5.0, CH_2–$O\underline{H}$), 7.10 and 7.46 (2H each, d, J=9.0, protons on the benzene ring), 7.83 (1H, s, proton on the pyridine ring), 9.10 (1H, s, –$C\underline{H}$=N–), and 15.10 (1H, broad s, phenolic proton on the pyridine ring). IR (KBr disc): ν_{C-O-C} 1250; $\nu_{C=N}$ 1615; ν_s 1500, 1406, 1385, 1298, 1020, and 818; ν_m 1582, 1475, 1310, 1265, 1198, 1163, 1118, 1019, 860, 789, 572, and 535 cm^{-1}.

For direct isolation of **3** (path B), the residue was triturated with benzene. The precipitate was collected by filtration and recrystallized from methanol.

For (indirect) Schiff base (**3**) formation (path C), the residue was dissolved into *ca.* 20 ml of benzene followed by addition of equal weight of *p*-ethoxyaniline hydrochloride to **1** and the mixture was stirred for the mentioned time. **3** was isolated by silica gel chromatography eluted with chloroform–methanol (9 : 1 v/v).

The author would like to express appreciation to Dr. Haruo Homma and his staff for elemental analyses, to Dr. Jun Uzawa and Mrs. Tamiko Chijimatsu for ^{1}H-NMR measurement, and to Drs. Sakae Emoto and Hiroyoshi Kuzuhara for encouragement through this work.

A Simple Regioselective Partial Hydrolysis of Di-*O*-isopropylidene Monosaccharides with Copper(II) Ion

Masaaki IWATA* and Hiroshi OHRUI

The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received January 30, 1981)

Synopsis. Copper(II) ion was found to be effective for regioselective removal of the 5,6-O-isopropylidene group of α-D-mannose and α-D-glucose derivatives in alcohols at ambient temperature.

In connection with a series of reactions promoted by copper(II) ion in organic solvent,[1] a convenient method was developed for the preparation of 1-*O*-benzoyl-2,3-*O*-isopropylidene-α-D-mannofuranose (**3**), benzyl 2,3-*O*-isopropylidene-α-D-mannofuranoside (**4**), 3-*O*-benzoyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**6**), and 6-*O*-benzoyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**7**) from the corresponding diisopropylidene monosaccharides.

Monoisopropylidene-D-mannose and -D-glucose are useful starting materials for the preparation of numerous derivatives and chiral natural products.[2] Monoisopropylidene derivatives of monosaccharides are usually prepared from the corresponding diisopropylidene derivatives by preferential partial hydrolysis of the more acid labile 5,6-*O*-isopropylidene group. Methods reported so far[3] have employed acetic acid or mineral acids as promoters, thus making it necessary to control pH, temperature, and/or reaction time, and evaporate a large quantity of solvent occasionally giving rise to further hydrolysis. The present method is easy, giving quantitative yield under mild conditions and not requiring certain manipulation required in other procedures.

The 5,6-*O*-isopropylidene group was regioselectively hydrolyzed by stirring a mixture of 1-*O*-benzoyl-2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose (**1**), benzyl 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranoside (**2**), or 3-*O*-benzoyl-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**5**) and five molar equivalents[4] of copper(II) chloride dihydrate in ethanol or 2-propanol[5] at room temperature to give **3**, **4**, or **6** in 97, 99, or 99% yields, respectively, after neutralization by sodium hydrogencarbonate. The prolonged reaction time and scale-up of the preparation from 0.5 to 40 g can be achieved without reduction in the yield.

Interestingly, however, when the reaction mixture of **5** was neutralized by sodium carbonate, the product was solely 6-*O*-benzoyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**7**). On the other hand, when an ethanol solution of **6** was stirred in the presence of 1 M—Na_2CO_3 at room temperature for 10—30 min, quantitative transformation of **6** into **7** was observed by measurement of the specific rotation change before and after the reaction.[6] Thus, it was confirmed that the benzoyl group is labilized and easily migrates to the C_6-position by subtle pH change.[7]

The β-anomer of **2** was more acid-sensitive than **2**. When a mixture of the β-anomer of **2** and a molar equivalent[9] of copper(II) chloride dihydrate in 2-propanol was stirred at room temperature for 44 h, silica gel chromatographic separation ($CHCl_3$–MeOH 9:1 v/v) of the product after work-up provided benzyl 2,3-*O*-isopropylidene-β-D-mannofuranoside (**8**) in 30% yield, benzyl β-D-mannofuranoside (**9**) in 12% yield, and benzyl 5,6-*O*-isopropylidene-β-D-mannofuranoside (**10**) in 20% yield, along with 34% recovery of the starting diisopropylidenemannoside. The formation of **10** was rationalized by the isopropylidenation of **9** with liberated acetone *in situ*.[10]

The copper(II)-ion promoted partial hydrolysis was inhibited in the presence of pyridine; thus, a copper complex of sugar may be a possible intermediate in this reaction which could be supported by other circumstantial evidence.[4,5]

Experimental

Merck silica gel 60 (Art. 7734, 0.063—0.20 mm) was used for the column chromatography and Wakogel B-5 FM (Wako Pure Chem. Co., Ltd.), for the analytical TLC. TLC plates were visualized by spraying *p*-methoxybenzaldehyde–concd sulfuric acid–methanol (5:10:85 v/v) followed by heating. The optical rotations were measured with Perkin-Elmer model 241 MC polarimeter. The IR spectra were recorded on a Shimadzu IR 27 instrument. Elemental analyses were carried out in this Institute. The mp is uncorrected.

*Preparation of 1-O-Benzoyl-2,3-O-isopropylidene-α-D-mannofuranose (**3**).* A mixture of 20 g (0.055 mol) of **1** and 48 g (0.28 mol) of copper(II) chloride dihydrate in 500 ml of ethanol was magnetically stirred at room temperature for 14 h (overnight). The reaction was terminated by addition of 48 g of sodium hydrogencarbonate crystals and the mixture was stirred (mostly for 0.5—1 h) until no more carbon dioxide was evolved. Then 100 ml of water was added, further amount of carbon dioxide being evolved, and the mixture was diluted with 400 ml of water to promote precipitation. The pale blue precipitate was filtered off through celite (No. 545). The filtrate was extracted with *ca.* 500 ml of chloroform and dried over $MgSO_4$ followed by filtration. After removal of the solvent, the residue was chromatographed on a silica gel column eluted with chloroform and then with chloroform–methanol (9:1 v/v) to give 17.2 g (97% yield based on **1**, colorless amorphous powder) of **3**; $[\alpha]_D^{20}$ 37.4° (*c* 0.968, $CHCl_3$) (lit,[11] $[\alpha]_D^{20}$ 52.5° (*c* 1.7, ethanol); IR (KBr disc) $\nu_{C=O}$ 1724 cm^{-1}.

*Preparation of Benzyl 2,3-O-Isopropylidene-α-D-mannofuranoside (**4**).* A mixture of 40.54 g (0.116 mol) of **2** and 98.7 g (0.58 mol) of copper(II) chloride dehydrate in 400 ml of 2-propanol was stirred overnight (*ca.* 14 h). A similar work-up to that for **1** afforded 35.5 g (99% yield, syrup) of **4**; $[\alpha]_D^{30}$ 71.1° (*c* 0.771, $CHCl_3$) (lit,[12] mp 60—61 °C, $[\alpha]_D^{30}$ 90° (*c* 1, $CHCl_3$)).

*Preparation of 3-O-Benzoyl-1,2-O-isopropylidene-α-D-glucofuranose (**6**).* A mixture of 0.5 g (1.37 mmol) of **5** and 1.2 g (7 mmol) of copper(II) chloride dihydrate in 20 ml of ethanol was stirred overnight (*ca.* 15 h). The reaction mixture was neutralized with 1.2 g of sodium hydrogencarbonate followed by a similar work-up to that for **1** to

give 0.441 g (99% yield) of **6** (syrup); $[\alpha]_D^{25}$ −26.5° (*c* 0.941, ethanol) (lit,[3d] −26° (ethanol); lit,[13] −26.5° (*c* 0.859, ethanol)).

Preparation of 6-O-Benzoyl-1,2-O-isopropylidene-α-D-glucofuranose (7). A mixture of 0.5 g (1.37 mmol) of **5** and 1.2 g (7 mmol) of copper(II) chloride dihydrate in 20 ml of ethanol was stirred at room temperature for 19 h followed by neutralization with 1.2 g of sodium carbonate. A similar work-up to that for **1** afforded 0.43 g (97% yield) of **7**; recryst. from ethanol (minor)–chloroform (major); mp 195—196 °C (lit,[7] 195—197 °C); $[\alpha]_D^{26.5}$ 4.71° (*c* 0.488, ethanol) (lit,[8] 7.4° (*c* 0.535, ethanol)).

The authors are grateful to Dr. Haruo Homma and his staff for carrying out elemental analyses, and to Drs. Hiroyoshi Kuzuhara and Masajiro Kawana for their valuable discussions.

Dickhauser, *ibid.*, **58**, 2601 (1925); K. Freudenberg, W. Dürr, and H. v. Hochstetter, *ibid.*, **61**, 1735 (1928); H. W. Coles, L. D. Goodhue, and R. M. Hixon, *J. Am. Chem. Soc.*, **51**, 523 (1929); A. S. Meyer and T. Reichstein, *Helv. Chim. Acta*, **29**, 139 (1946); F. Blindenbacher and T. Reichstein, *ibid.*, **31**, 1669 (1948). C. L. Mehltretter, B. H. Alexander, R. L. Mellies, and C. E. Rist, *J. Am. Chem. Soc.*, **73**, 2424 (1951); S. G. Land, *Acta Chim. Scand.*, **8**, 866 (1954); R. E. Gramera, A. Park, and R. L. Whistler, *J. Org. Chem.*, **28**, 3230 (1963).

4) The molar ratio was not optimized. However, it was found by changing the ratio of copper(II) ion quantity to diisopropylidene monosaccharide that when one molar equivalent of copper(II) ion is used in ethanol at room temperature, **2** is obtained in 79% yield in 46 h along with 20% recovery of **1**. When two molar equivalents of copper(II) ion was employed under the same conditions, **2** was obtained in 85% yield with 14% recovery of **1** in 43 h.

5) Qualitatively, the relative reaction rate was greater in ethanol than in 2-propanol. Aprotic solvents such as benzene, dioxane, *N,N*-dimethylformamide, and dimethyl sulfoxide were found to be unsuitable for the hydrolysis due to insolubility of copper(II) ion or the formation of copper(II) ion–solvent complex.

6) When the reaction mixture was divided into two equal parts and neutralized by sodium hydrogencarbonate and sodium carbonate, respectively, both chloroform extracts showed $[\alpha]_D^{25}$ −23° (*c* 1.12, ethanol) (lit,[3d] −26° (*c* 0.94 ethanol)) and 1.3° (*c* 0.547, ethanol) (lit,[8] 7.4° (*c* 0.535, ethanol)), respectively.

7) The migration of the acetyl group in a glucose derivative from C_3 to C_6 induced by ammonium hydroxide (pH *ca.* 9) has been reported by K. Josephson, *Justus Liebigs Ann. Chem.*, **472**, 217 (1929).

8) E. Fischer and H. Noth, *Ber.*, **51**, 321 (1918).

9) When molar ratio of copper(II) ion was increased up to five, yield of **8** decreased and that of **9** increased. When the β-anomer of **2** was hydrolyzed by 90% acetic acid at around 50 °C for 1 h, **9** was obtained quantitatively.

10) When **9** was acetonated in acetone in the presence of one molar equivalent of copper(II) chloride dihydrate at room temperature, **9** was lost in 2 h accompanied by the formation of **10** and the diisopropylidenemannoside in equal ratio on TLC, **10** being converted into the diisopropylidenemannoside in 18 h.

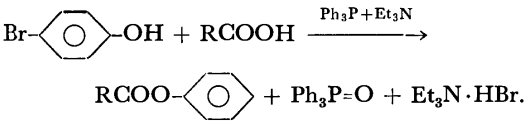
The Synthesis of Phenyl Carboxylates from *p*-Bromophenol and Carboxylic Acids

Shizunobu HASHIMOTO and Isao FURUKAWA*
Department of Applied Chemistry, Doshisha University, Karasuma-imadegawa, Kamigyo-ku, Kyoto 602
(Received February 2, 1981)

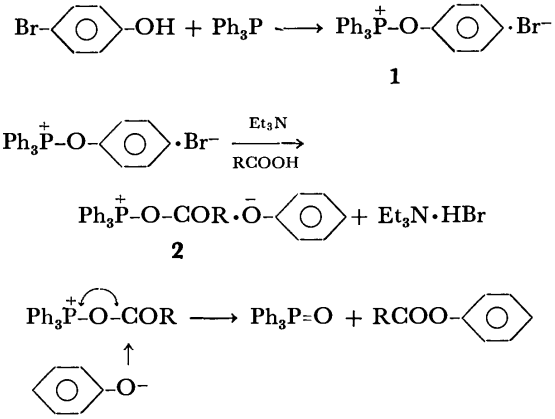
Synopsis. The reaction of *p*-bromophenol with carboxylic acids in the presence of triphenylphosphine and triethylamine proceeded at a high temperature, with the elimination of hydrogen bromide, to give phenyl carboxylates and small amounts of *p*-bromophenyl carboxylates.

We have recently reported that the direct esterification of phenols (ArOH) with carboxylic acids proceeds easily at room temperature by the use of both triphenylphosphine and carbon tetrachloride as dehydrating agents in the presence of triethylamine, giving only the corresponding aryl carboxylates (RCOOAr) such as *p*-bromophenyl benzoate from *p*-bromophenol and benzoic acid in a high yield.[1] From our further investigation into the esterification of *p*-bromophenol, we have found that the esterification in the presence of triphenylphosphine and triethylamine gives phenyl carboxylates, with the elimination of hydrogen bromide:



The results are shown in Table 1. The reaction proceeds at a high temperature to give, simultaneously, phenyl carboxylate and small amounts of *p*-bromophenyl carboxylates. The yield of the phenyl carboxylates increased with an increase in the reaction temperature, but the yield of *p*-bromophenyl carboxylates decreased conversely. A black-colored, tarry product was produced in the absence of triethylamine, and the use of pyridine instead of triethylamine gave phenyl carboxylate in a poor yield. Also, the esterification with carboxylic acid having a nitro group resulted in the formation of a tarry product in contrast to the expected ester.

It is concluded that the esterification of *p*-bromophenol with carboxylic acids in the presence of triphenylphosphine and triethylamine proceeds through the process shown in the following scheme:



It has been reported by Hoffmann that the phosphonium salt (**1**) assumed as an intermediate is formed by the elimination of bromine from *p*-bromophenol with triphenylphosphine at a high temperature.[2] The resulting salt **1** is converted to acyloxytriphenyl-

phosphonium phenoxide (**2**) by the nucleophilic attack of the acyloxy anion onto the phosphorus atom of **1**, followed by the attack of the phenoxy anion onto the carbonyl carbon of **2**, giving phenyl carboxylate with the elimination of triphenylphosphine oxide. Otherwise, it is considered that the formation of *p*-bromophenyl carboxylate is by the attack of *p*-bromophenol on **2**.

Experimental

All the melting and boiling points are uncorrected. All the chemicals used were of an analytical reagent-grade. The thin-layer chromotography (TLC) was performed on Merck's silica gel 60 (70—230 mesh). The IR spectra were recorded in KBr on a Shimadzu IR-27C spectrometer, and the MS, on a Hitachi RM-50GC spectrometer with 60 eV.

General Procedure. A mixture of triphenylphosphine (5.5 mmol), triethylamine (5.5 mmol), carboxylic acid (5.5 mmol), and *p*-bromophenol (5.0 mmol) was heated at 200 °C for 4 h in the absence of a solvent. After hexane has been poured into the resulting mixture, the insoluble triphenylphosphine oxide and triethylamine hydrobromide were filtered off. The filtrate was washed with an aqueous sodium hydroxide solution, dried over anhydrous sodium sulfate, and concentrated, thus giving an ester. The pure ester was obtained by recrystallization from hexane or methanol, or by chromatography on silica gel, and was determined by infrared and mass-spectral analysis.

Effects of Crown Ethers on the Critical Micelle Concentration and the Micellar Catalysis of Sodium and Potassium Dodecyl Sulfates in Aqueous Solutions

Manabu Senō, Tomiyuki Namba, and Hideo Kise*

Institute of Industrial Science, The University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106

(Received February 12, 1981)

Synopsis. The catalytic micellar effects of potassium dodecyl sulfate on the hydrolysis of trimethyl orthobenzoate were found to be much retarded by 15-crown-5 or 18-crown-6.

It has been reported that complex-forming crown ethers lower the critical micelle concentration and increase the partial molal volumes and compressibilities of sodium decanoate in aqueous solutions.[1] The results have been interpreted in terms of the formation and association of Na^+–crown ether complexes with micelles, reducing the repulsion between the ionic groups at the micelle surface.

This article describes the effects of crown ethers on the critical micelle concentration (cmc) of sodium dodecyl sulfate (SDS) and potassium dodecyl sulfate (PDS) in aqueous solutions, and their effects on the rate of hydrolysis of methyl orthobenzoate in the PDS micellar systems.

When 15-crown-5 or 18-crown-6 was added to an aqueous SDS or PDS solution, an appreciable decrease in the specific conductivity of the solution was observed, and, as summarized in Table 1, the cmc, which was determined by the plot of conductivity against surfactant concentration, was found to decrease. The apparent enhancement of the micelle formation by the crown ethers is quite similar to that of sodium decanoate.[1] The magnitude of the decrease in cmc seems to have a correlation with the association constant of the crown ethers with alkali metal ions of the surfactants as shown in Table 1. 18-Crown-6 has higher association constants both with K^+ and Na^+ and gives lower cmc of PDS and SDS than 15-crown-5. The plot of cmc against the ratio of 18-crown-6 to PDS is shown in Fig. 1.

It is known that organic compounds often increase the cmc of surfactants, as is the case of urea in an aqueous SDS solution.[2] The effects of crown ethers described above may be the consequence of the formation of crown ether–metal ion complexes and their incorporation into the micelles, which leads to the decrease in the electrostatic repulsion between the anionic head groups of the micelles.

Table 1. Critical micelle concentration of SDS and PDS in the absence and presence of equimolar amounts of crown ethers

Surfactant	Crown ether	Cmc/mM 35 °C	Cmc/mM 23 °C	Association const (log K) of crown ether[a]
SDS	None	8.0	8.1	—
	15-Crown-5	6.7	7.2	0.70(Na^+)
	18-Crown-6	6.6	6.7	0.80(Na^+)
PDS	None	8.0		—
	15-Crown-5	6.5		0.74(K^+)
	18-Crown-6	4.1		2.03(K^+)

a) From Ref. 4 (at 25 °C).

A kinetic study was made to clarify the effects of crown ethers on the hydrolysis of methyl orthobenzoate in aqueous PDS solutions. The hydrolysis was followed by the change in absorbance of the product methyl benzoate at 228 nm at 35 °C and pH 3.41, which was adjusted by acetic acid. As shown in Fig. 2, the first order rate constant in PDS solution in the absence of crown ethers increases markedly above cmc. In the presence of a crown ether, however, the rate enhancement by the surfactant micelle is much decreased; 18-crown-6 has a larger inhibitory effect than 15-crown-5. Since the effects of crown ethers on the hydrolysis rate below cmc are small

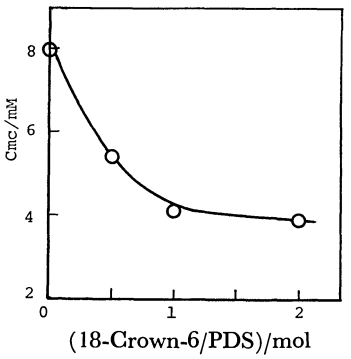

Fig. 1. The effect of 18-crown-6 on the cmc of PDS in aqueous solutions.

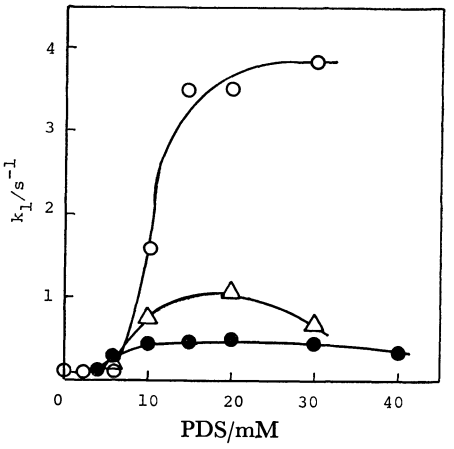

Fig. 2. First order rate constant for the hydrolysis of trimethyl orthobenzoate in the absence and presence of equimolar crown ethers (35 °C, pH 3.41). ○: PDS only, △: PDS-15-crown-5, ●: PDS-18-crown-6.

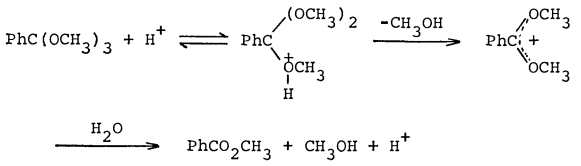
(first order rate constants are 0.052 and 0.054 s^{-1} for PDS concentrations of 2.0 and 4.0 mM, respectively, while those for PDS-18-crown-6 systems are 0.052 and 0.064 s^{-1} at the same concentrations, respectively), the rate retardation is obviously the consequence of the change of the nature of the micelles.

The reaction is considered to proceed by general acid catalysis, involving the proton transfer to the substrate followed by the formation of a carbenium ion by the elimination of methyl alcohol as shown in Scheme 1.[3] The catalytic effects of anionic micelles have been interpreted by the solubilization of the substrate in the Stern layer of the micelle where the proton concentration is higher than in the bulk water phase. The rate retardation by the crown ethers may be interpreted by the decrease in the charge density and hence the lower hydrogen ion concentrations on the surface of the micelles as implied by the decrease in the cmc by the addition of the crown ethers. A larger inhibitory effect of 18-crown-6 which has stronger complex-forming ability than 15-crown-5 seems to support the above consideration.



Scheme 1.

Since the complexation with crown ethers is considered to enhance the hydrophobic nature of potassium ion, the inclusion of the complexes into the micelle is likely to occur in the present systems, which would result in the decrease in the fraction of micelle charge.

It is interesting to note that, as shown in Fig. 2, in the presence of the crown ethers, the hydrolysis rate decreases at higher concentrations of the surfactant–crown ethers. Since no maximum rate is observed in the absence of the crown ethers, the interaction of the free crown ethers with hydroxonium ions may be responsible for the rate retardation.

The formation of crown ether–metal ion complexes and their interaction with micelles described above may serve as an experimental model system of biological ionophore-mediated metal ion-protein interactions.

Chlorination of Acetylenes with Sulfuryl Chloride

Sakae UEMURA,* Chiaki MASAKI,** Akio TOSHIMITSU, and Seiji SAWADA**

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

***Department of Chemistry, Kyoto University of Education, Kyoto 612*

(Received March 9, 1981)

Synopsis. The reactions of some acetylenes with sulfuryl chloride in benzene and carbon tetrachloride at the reflux temperature afford the corresponding (*E*)- and (*Z*)-dichloroalkenes in good to moderate yields *via* homolytic pathway. The kinetically controlled isomer ratios(*E*/*Z*) depended very much on the kind of acetylenes employed; *i.e.*, 93/7 for 1-octyne to 14/86 for 3,3-dimethyl-1-phenyl-1-butyne in benzene.

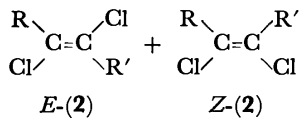
Sulfuryl chloride has long been known to chlorinate olefin homolytically, both chlorine atoms and chlorosulfonyl radicals acting as chain carriers.[1] To our knowledge, however, the application to acetylenes seems to be so far limited only to divinylacetylene,[2] 2-butyne,[3] and phenylpropiolic acid and its methyl ester.[4] In the last case where sulfuryl chloride itself was used as solvent, the products were the complex mixture and, interestingly, the stereoisomeric ratios (*E*:*Z*) of the produced dichloroalkenes (one of the main products) were 1:4 and 4:1 for the acid and its methyl ester, respectively. Since a systematic study on the stereoisomeric ratios in radical chlorination of acetylenes has been reported only for (dichloroiodo)-benzene,[5] we undertook the chlorination of some acetylenes with sulfuryl chloride in nonpolar solvent to know whether the reaction proceeds homolytically and what the isomer ratios of dichloroalkenes are. As one of a series of our studies of halogenation of acetylenes by molecular halogen and metal halides,[6] we wish here to describe the details of the reaction.

Results and Discussion

The reactions of some acetylenes with equimolar amount of sulfuryl chloride in carbon tetrachloride or benzene at the reflux temperature gave a mixture of the corresponding *E*- and *Z*-dichloroalkenes in good to moderate yields [Scheme (1)]. Typical results are shown in Table 1 together with the reported isomer

$$\mathrm{R{-}C{\equiv}C{-}R' + SO_2Cl_2 \longrightarrow}$$

(1)



E-(**2**) *Z*-(**2**) (1)

ratios of the chlorination with $PhICl_2$ and of thermodynamic equilibrium. A use of excess sulfuryl chloride resulted in an increase of tetrachloroalkanes with a slight increase of (**2**), the isomer ratio being almost constant. As exemplified from the product yield in the table, the reactions proceeded more smoothly in benzene than in carbon tetrachloride, the isomer ratio being nearly the same in both solvents. Since prolonged reaction time had little effect on the isomer ratios of the products, the reactions must be almost entirely kinetically controlled. We confirmed independently that interconversion between the isomers of (**2**; R=Ph, R′=H or Me) did not occur in both solvents at the reflux temperature for 1—2 h in the presence of 1 equiv. of sulfuryl chloride. The observed kinetically controlled ratio is much different with the ratio of thermodynamic equilibrium and slightly different with the one of radical chlorination using $PhICl_2$. In the case of (**1**; R=Ph, R′=*t*-Bu) the *Z*-isomer was the major product, as has been observed in the chlorination with several chlorinating agents such as Cl_2,[6b] $CuCl_2$,[6a] and $SbCl_5$.[6d]

In order to know whether the reaction is homolytic, we have carried out the chlorination of (**1**; R=Ph, R′=H or Me) in the presence of a radical scavenger such as *t*-butylcatechol or phenol and found that the product yield decreased profoundly and the isomer ratio of *E*/*Z* became low. For example, *E*- and *Z*-(**2**; R=Ph, R′=H) were obtained from (**1**; R=Ph, R′=H) in a yield of 11% (*E*/*Z*=76/24) and 17% (*E*/*Z*=63/37) in chloroform (0.5 mmol of *t*-butylcatechol added) and in benzene (0.2 mmol of the catechol added) at reflux for 2 h, respectively. Similarly, the yield of (**2**) in the reaction of (**1**; R=Ph, R′=Me) in benzene at reflux for 2 h decreased to 27% (*E*/*Z*=66/34) by addition of 0.2 mmol of the catechol. On the other hand, when the reaction of (**1**; R=Ph, R′=H) in carbon tetrachloride was carried out by the addition of benzoyl peroxide, a radical initiator, the product yield of (**2**) increased to 58% from 34% without it. This finding also supports the radical nature of the reaction. An ionic chlorination of (**1**; R=Ph, R′=H or Me) with chlorine gas has been reported to give (**2**) in a ratio (*E*/*Z*) of 51/49 or 67/33 respectively. Therefore, a slight increase for the *Z*-isomer in the isomer ratio obtained in the presence of the radical inhibitor may be explained by assuming that this radical chlorination is slightly accompanied with an ionic one with chlorine which may be formed by dissociation of sulfuryl chloride. In fact, when the chlorination of (**2**; R=Ph, R′=Me) with sulfuryl chloride in benzene was carried out at 30 °C for 30 min under UV irradiation, *E*- and *Z*-(**2**; R=Ph, R′=Me) were obtained in a yield of 20%, *E*/*Z* being 91/9. Under similar conditions without irradiation almost no products were obtained. This fact shows that under completely radical condition the formation of the *E*-isomer is much favored.

Considering from the proposed mechanism for olefin chlorination with sulfuryl chloride,[1] the reaction scheme for the chlorination of phenyl-substituted acetylene seems to be as that shown in Scheme 2 where both chlorine atom and chlorosulfonyl radical act as chain carriers (R· may be derived from organic peroxides). The *E*/*Z* isomer ratio of (**2**) may be determined by the step of sulfuryl chloride attack on the intermediate linear α-phenylvinyl radical [A][7] where

a) Carried out at reflux temperature (78 °C for CCl_4 and 81 °C for benzene) with **1** (2 mmol), SO_2Cl_2 (2 mmol), and solvent (4 ml). b) Determined by GLC. c) Ref. 5. d) The ratio of thermodynamic equilibrium; Ref. 5.

$$\left.\begin{array}{l} R\cdot + SO_2Cl_2 \longrightarrow RCl + SO_2Cl\cdot \\ SO_2Cl\cdot \longrightarrow SO_2 + Cl\cdot \\ SO_2Cl_2 \xrightarrow{h\nu} SO_2Cl\cdot + Cl\cdot \\ Cl\cdot + (\mathbf{1};\ R=Ph) \longrightarrow Ph\text{-}\dot{C}\text{=}C(Cl)(R') \quad [A] \\ \downarrow \\ Ph\text{-}\dot{C}\text{=}C(Cl)(R') + SO_2Cl_2 \longrightarrow (\mathbf{2};\ R=Ph) + SO_2Cl\cdot \end{array}\right\} \quad (2)$$

the attack by sulfuryl chloride should occur in the plane containing both Cl and R groups.[6b)] When R is sterically smaller than Cl (like H or Me), the *E*-isomer would be favored, while the *Z*-isomer should be the major one when R is a large substituent like *t*-Bu. This assumption is consistent with the experimental results.

Experimental

1-Phenyl-1-alkynes and authentic samples of (**2**) for GLC analyses were prepared as previously described.[6a)] Phenylacetylene, diphenylacetylene, 1-octyne, and other organic materials were commercial products and used without further purification. Sulfuryl chloride was distilled before use. The GLC analyses were carried out on Shimadzu 4BMPF apparatus using EGSS-X(1 or 3 m)-Chromosorb-W columns (N_2 as the carrier gas); the *E*-isomer has a shorter retention time than the *Z*-isomer in all cases except (**2**; R=R′=Ph). The internal standards were ethyl cinnamate for (**2**; R=Ph, R′=H, alkyl, Ph) and *cis*-1,2-dichlorocyclohexane for (**2**; R=*n*-C_6H_{13}, R′=H). The NMR spectra were recorded with a Varian EM-360 and a JEOL JNM-MH-100 apparatus using CCl_4 solvent (TMS as an internal standard). The UV irradiations were carried out with a high-pressure mercury lamp(Ushio UM-103).

Wittig Reaction of 1,3-Benzodithiol-2-ylidenetriphenylphosphorane with Carbon Disulfide

Juzo NAKAYAMA,* Sanae MARUYAMA, and Masamatsu HOSHINO
Department of Chemistry, Faculty of Science, Saitama University, Urawa, Saitama 338

(Received March 10, 1981)

Synopsis. 1,3-Benzodithiol-2-ylidenetriphenylphosphorane reacted with carbon disulfide to give 1,3-benzodithiole-2-thione, dibenzotetrathiafulvalene, and an unidentified crystalline red compound in addition to triphenylphosphine sulfide. The same products were also obtained by treatment of 1,3-benzodithiol-2-ylthiocarbonyl chloride with base.

Recent findings concerning the highly-conductive charge transfer salt of tetrathiafulvalene (TTF) with tetracyanoquinodimethan (TCNQ) have created a wide and extensive interest in the design of organic donors and acceptors.[1] Thus, the syntheses of compounds of types **1**[2] and **2**[3] have appeared recently; in compounds **1**, TTF system is extended by insertion of a quinonoid unit and compound **2** is isoelectronic with TCNQ. In this connection, the synthesis of organic donor like **3** is of current interest. We report here some findings found during the attempted synthesis of **3**.

There are abundant examples of dimerization of thioketenes which yield 1,3-dithietans.[4] Therefore, dimerization of the thioketene **4**, which would be produced by the Wittig reaction of carbon disulfide with 1,3-benzodithiol-2-ylidenetriphenylphosphorane (**5**) (conveniently obtainable by treatment of **6** with butyllithium),[5] was chosen as our synthetic strategy to **3**.

A stirred suspension of **6** in tetrahydrofuran was treated with a slight excess of butyllithium and then carbon disulfide was added at −78 °C. The mixture was gradually warmed to room temperature and then refluxed. Chromatographic purifications gave 1,3-benzodithiole-2-thione (**7**) (9—25%), dibenzotetrathiafulvalene (**8**) (15—20%), and a red crystalline compound **9** (5—9%) in addition to triphenylphosphine sulfide (44—65%). The reaction was repeated several times and gave reproducible results. Although the occurrence of triphenylphosphine sulfide is suggestive of the formation of the expected thioketene **4**, no products, which correspond to the dimer of **4**, were isolated. The red compound **9** has a molecular formula of $C_{15}H_8S_5$ on the basis of mass spectrum and elemental analysis (a tentative structure is given in the Experimental section).

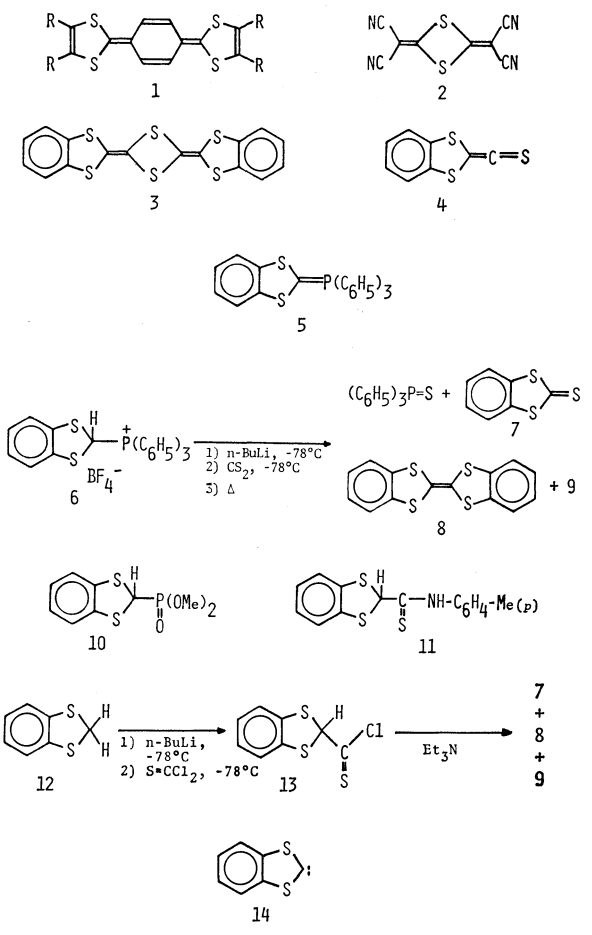
The use of compound **10**[5] instead of **6** gave an intractable mixture.

As to the mechanism of the formation of **7** and **8**, initial formation of **7** from **5** and carbon disulfide followed by reaction of **7** and **5** which yields **8**, was ruled out since control experiment showed that compound **7** is unreactive toward **5**.

Attempted trapping of **4** with amine was fruitless. The Wittig reagent **5**, prepared as above, was allowed to react with carbon disulfide and then a solution of *p*-toluidine in tetrahydrofuran was added at −78 °C. Workup of the mixture by column chromatography did not give the expected adduct **11**, but afforded compounds **7**, **8**, and **9** in decreased yields. The result indicates that either the final products, **7**, **8**, and **9**, are produced by a mechanism which does not involve **4** as the intermediate or **4** fails to react with *p*-toluidine and is readily converted to the final products under the conditions.

Generation of **4** by other method was next tried. 1,3-Benzodithiole (**12**) was lithiated by butyllithium[6] and allowed to react with thiophosgene at −78 °C, and then the resulting **13** was dehydrochlorinated by triethylamine. Purification of the mixture by column chromatography yielded **7** (2%), **8** (28%), and **9** (2%). The use of DBU as the base gave a similar result. The formation of the same products, **7**, **8**, and **9**, by two different reactions is strongly suggestive of the presence of the common intermediate **4**.

One of possibilities as to the mechanism of the formation of the final products is the decomposition of **4** to the carbene **14** and carbon monosulfide since **14**, generated by addition of carbon disulfide to benzyne, is known to give **8** by dimerization and **7** by an uncertain mechanism.[7]



Experimental

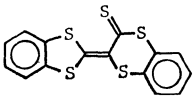
Reaction of 1,3-Benzodithiol-2-ylidenetriphenylphosphorane (5) with Carbon Disulfide. To a stirred suspension of 4.02 g (8 mmol) of **6**[5] in 200 ml of anhydrous tetrahydrofuran (THF) was added a 15% solution of butyllithium in hexane (6.0 ml, 9.2 mmol) under nitrogen at −78 °C. After stirring of 1.5 h, 0.76 g (10 mmol) of carbon disulfide in 7 ml of THF was added at −78 °C. The mixture was stirred for 0.5 h at −78 °C, gradually warmed to room temperature, and then refluxed for 2 h. The solvent was removed under reduced pressure and the residue was extracted with 200 ml of dichloromethane, washed with water, dried on sodium sulfate, and evaporated. The resulting reddish brown mass was chromatographed on a silica-gel column (Merck, Art 7734, 100 g). Elution with carbon tetrachloride gave 0.26 g (21.5%) of dibenzotetrathiafulvalene (**8**), mp 244—246 °C (lit,[8] mp 235—236 °C), 0.36 g (24.5%) of 1,3-benzodithiole-2-thione (**7**), mp 165—166 °C (lit,[9] mp 164 °C), and 82 mg (6%) of a dark red compound (**9**), mp 220—221 °C (from benzene). Elution of the column with benzene gave 1.03 g (44%) of triphenylphosphine sulfide, mp 158—159 °C.

The reaction was repeated several times and the yields of **7**, **8**, and **9** varied in the range of 15—25%, 9—25%, and 5—9%, respectively.

The red compound **9** has the following properties: ^{1}H NMR (CS_2) δ 5.94—6.35 (complex m); UV ($CHCl_3$) λ_{max} (log ε) 242 (4.4), 261sh (4.3), 287sh (4.0), 383 (3.7), and 480 nm (4.3); IR (KBr) 1450, 1380, 1270, 990, 960, and 740 cm^{-1}; MS *m/e* 348 ($C_{15}H_8S_5$, M^+, 100%), 304 (M^+—CS), 283, 208, 196, 164, 152, 120, 108, 96, and 69. Found: C, 51.68; H, 2.31; S, 45.79%. Calcd for $C_{15}H_8S_5$: C, 51.74; H, 2,32; S, 45.95%.

When compound **9** was heated at 200—220 °C for 2 h without solvent, it was converted into a mixture of compounds **7** and **8**. Attempted reduction with sodium borohydride resulted in the decolorization of **9**.

On the basis of these results, the following tentative structure was given for **9**.



Attempted Reaction of 5 with 7. To a stirred solution of **5**, prepared from 1.51 g (3 mmol) of **6** as described above, was added a solution of 0.55 g (3 mmol) of **7** in 25 ml of THF at −78 °C. The mixture was stirred for 0.5 h at −78 °C, gradually warmed to room temperature, and then refluxed for 3 h. Chromatographic purification gave 23 mg (5%) of **8** and a nearly quantitative yield of **7**.

When a solution of **5**, prepared at −78 °C in THF, was gradually warmed and then refluxed without any additive, a 10% yield of **8** was obtained.

It is therefore concluded that **8**, formed by attempted reaction of **5** with **7**, is produced by decomposition of **5**, but not by reaction of **5** with **7**, and thus the phosphorane **5** is unreactive toward **7**.

Attempted Trapping of 4 by p-Toluidine. The phosphorane **5**, prepared from 1.51 g (3 mmol) of **6** in THF, was allowed to react with carbon disulfide (0.28 g, 3.75 mmol) at −78 °C. After stirring of 2 h, a solution of *p*-toluidine (0.32 g, 3 mmol) in THF (5 ml) was added at −78 °C under nitrogen. The mixture was stirred for 2 h at −78 °C and then gradually warmed to room temperature. Chromatographic purification gave 43 mg (2.8%) of **8**, 23 mg (1.3%) of **7**, 82 mg (4.7%) of **9**, and 0.57 g (64%) of triphenylphosphine sulfide. *p*-Toluidine was recovered nearly quantitatively.

Attempted Generation of 4 from 1,3-Benzodithiole (12). Compound **12** was conveniently prepared by reduction of 1,3-benzodithiolylium tetrafluoroborate[10] with sodium borohydride in THF. A 15% solution of butyllithium in hexane (7.8 ml, 12 mmol) was added through a syringe to a stirred solution of **12** (1.54 g, 10 mmol) in THF (120 ml) under nitrogen at −78 °C.[6] Stirring was continued for 2 h and then a solution of thiophosgene (1.15 g, 10 mmol) in THF (1 ml) was added all at once. The mixture was stirred for 1 h at −78 °C and then 2 ml of triethylamine was added. After 0.5 h of stirring, the mixture was warmed to room temperature and then evaporated. The resulting dark red residue was extracted with dichloromethane (200 ml), washed with water, dried, and evaporated. Chromatographic purification of the residue gave 0.42 g (28%) of **8**, 40 mg (2%) of **7**, and 30 mg (2%) of **9**.

The use of DBU as the base instead of triethylamine yielded **7** (3%), **8** (0.3%), and **9** (4%).

A Mild and Convenient Procedure for Conversion of Aromatic Compounds into Their Iodides Using Ammonium Hexanitratocerate(IV)

Takashi SUGIYAMA

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

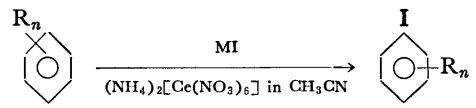
(Received March 12, 1981)

Synopsis. Polymethylbenzenes, polymethoxybenzenes, and naphthalene are iodinated with tetrabutylammonium iodide, alkali metal iodides, or molecular iodine in the presence of ammonium hexanitratocerate(IV). Ammonium hexanitratocerate(IV) behaves as a catalyst in the latter system, whereas it is a reagent in the fomer two.

Although there are some reports on direct iodination of aromatic compounds, it presents rather complicated problems; molecular iodine is the least reactive of the halogens in aromatic substitution; the reaction is reversible and hydrogen iodide produced in the reaction must be removed to allow the reaction to be completed.[1)]

During the course of a study on one-electron-transfer reaction, the author found a novel and regioselective iodination of aromatic compounds using ammonium hexanitratocerate(IV) (CAN), a potential one electron oxidizing agent.

The results from iodination of some polymethylbenzenes are summarized in Table 1.



$R=CH_3$ ($n=2$, 3, 4, 6) or OCH_3 ($n=1$, 2, 3)
$M=n\text{-}Bu_4N$, Li, Na, K, I

There are two remarkable feautures in the present iodination. First, the reaction takes place only on the aromatic ring. It is noteworthy that, even hexamethylbenzene affords iodopentamethylbenzene as the sole iodinated product. This is a marked contrast with the oxidation of polymethylbenzenes promoted by CAN in acetic acid where the reaction on side-chains are predominated.[2)] Secondary, the iodination proceeds with ortho-para orientation with respect to methyl substituents. In particular, the result from *o*-xylene shows that para substitution occurs in preference to ortho substitution (the ortho:para-ratio being 1:6).

The present reaction proceeds under mild conditions. The yield, however, decreases as the number of methyl groups increases probably because of some side reactions.

Alkali metal iodides and molecular iodine as well as tetrabutylammonium iodide can be used as iodinating agents (Table 2).

In the case of iodination with molecular iodine, 0.5 mmol of iodine for 1.0 mmol of substrate is enough to complete the reaction in 80% yield based on aromatics. In general, one-half part of the molecule is discarded when molecular iodine is used as an iodinating agent. However, this economical disadvantage is overcome in the present reaction.

The substrate can be extended to polymethoxybenzenes and fused-ring aromatic as shown in Table 3. Evidentry, as the number of methoxyl groups attached on benzene ring increases, the reactant is consumed more rapidly. However, the yield of iodinated compounds are not parallel with the number of methoxyl groups.

Attempts to iodinate aromatic compounds bearing an electron-withdrawing substituent such as nitro- and chlorobenzenes, were unsuccessful, and these unchanged reactants were recovered from the reaction mixture. On the other hand, phenols and anilines were not iodinated, although they were consumed completely.

Among several possible reaction mechanisms, the author favors the one which involves the reaction of aromatic compound with a cationic halogen species, which is produced by the interaction between the halogen source and CAN. The argument is based on the facts that; (1) the only aromatics bearing electron donating substituents react with halogen species, (2) the iodination shows an ortho-para orientation, and (3) the reaction occurs only on an aromatic ring.

a) Isolated yield based on the substrates used. Numerical values in parentheses are the yields determined by GLC.

Experimental

General Procedure. Into a solution of 4.0 mmol of an aromatic compound and 4.0 mmol of tetrabutylammonium iodide in 40 ml of acetonitrile was added a solution of 8.0 mmol of CAN (dried at 90—100 °C for 2 h) in 40 ml of acetonitrile. The mixture was stirred for 24 h at 60 °C, poured into 80 ml of water, and extracted with benzene (4×30 ml). The combined benzene layers were treated with sodium thiosulfate, washed with water, dried over $CaCl_2$, and the benzene was removed, carefully, under reduced pressure. The residue was purified by distillation, column chromatography (Woelm Akt I: hexane–benzene), and/or preparative gas chromatography (10% silicon OV-17). The isolated product was weighed and identified by comparing their IR, MS, and ^{1}H-NMR spectra with those of corresponding authentic samples. Elemental analyses also gave satisfactory results. The yield was, also, determined by analytical gas chromatography.

The author thanks Professor S. Oka and Dr. A. Ohno for useful discussions.

Reaction of μ-Peroxo Complexes of Palladium with Alcohols, Amines, and Thiols

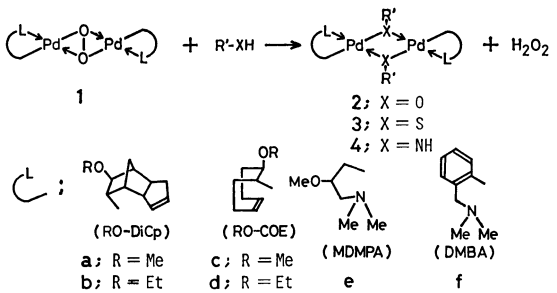
Ryuichi SUGIMOTO, Hajime EIKAWA, Hiroharu SUZUKI,* Yoshihiko MORO-OKA,* and Tsuneo IKAWA
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta 4259, Midori-ku, Yokohama 227
(Received March 18, 1981)

Synopsis. Reactions of μ-peroxo complexes of palladium with alcohols, amines, and thiols proceed at room temperature to afford hydrogen peroxide and alkoxo-, amido-, and alkylthio-bridged complexes of palladium, respectively.

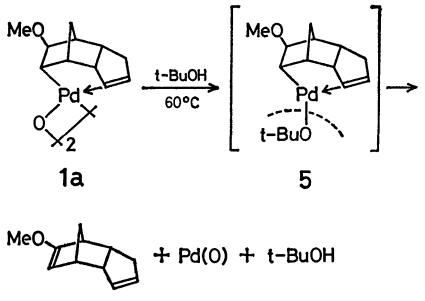
In the previous papers we reported a novel preparation method of μ-peroxo complexes of palladium, platinum and rhodium having olefinic ligands *via* an anion exchange reaction of μ,μ'-dihalo complexes with potassium superoxide in dichloromethane and suggested that μ-peroxo ligand in the complexes behaved as a base and did not participate in the oxygenation of the olefinic ligands.[1-3] Such basic nature of dioxygen ligands was also reported for the mononuclear peroxo complexes of transition metal elements.[4-6] Important role of the basic nature of the coordinated dioxygen of the cobalt Schiff base complex was demonstrated by Nishinaga *et al.* in the catalytic oxidation of substituted phenols.[7] In the present investigation, reactions of μ-peroxo ligand with a series of alcohols, amines, and thiols have been examined in order to clarify the nature of μ-peroxo complexes of palladium.

Results and Discussion

Reactions of dioxygen complexes **1** with alcohols, thiols and amines were carried out in dry benzene at room temperature under dry nitrogen atmosphere. Treatment of **1a** with methanol gave μ,μ'-bis(methoxo) complex **2a-Me** in a 50% yield accompained with liberation of hydrogen peroxide. Formation of hydrogen peroxide was confirmed by the iodometry. Methoxy-bridged complex **2d-Me** was prepared in a similar manner. Methoxy-bridged complexes **2a-Me**



and **2d-Me** were unstable in benzene solution and decomposed immediately with heating at 30—40 °C to deposit metallic palladium. Even in the solid state, they decomposed after standing for one day at ambient temperature under dry nitrogen atmosphere. Ethoxy-bridged complexes **2a-Et** and **2c-Et** were also prepared by the reaction of **1** with ethanol. It was found that they were less stable than the corresponding methoxy-bridged ones. Further attempts to prepare the alkoxy-bridged complexes of bulky alcohols were resulted in vain. The starting μ-peroxo complex was recovered in the reaction of **1a** with 2-propanol (pK_a 18) or *t*-butyl alcohol (pK_a 19) at room temperature. Decomposition of complex **1a** in *t*-butyl alcohol proceeded giving a cyclic diene **6** at higher reaction temperatures (40—60 °C). Abstraction of proton from such alcohols is well supported by the fact that **1a** is basic enough to abstract active hydrogen from acetone (pK_a 20). Steric repulsion between Me-DiCp ligand and bulky alkoxo groups may force the β-elimination of Pd–H from a coordinatively unsaturated intermediate **5**. Yoshida *et al.* reported that treatment of $[Ni(CCl{=}CCl_2)(\mu\text{-}OMe)(PPh_3)]_2$ in alkaline solution gave $[Ni(CCl{=}CCl_2)(\mu\text{-}OH)(PPh_3)]_2$ *via* an anion exchange reaction.[8] In the present work, the bridging methoxy group was readily exchanged with ethoxy group by treatment of **2a-Me** with a large excess of ethanol in benzene at room temperature, and *vice versa*.



μ-Peroxo complexes also reacted with thiols to yield the corresponding alkylthio-bridged complexes. Alkylthio-bridged complex **3a-Et** was obtained by the dropwise addition of a diluted solution of ethanethiol to a rigorously stirred solution of **1a** in benzene. Analogous alkylthio complex **3e-Et** and phenylthio-bridged complexes **3a-Ph** and **3f-Ph** were prepared similarly. All these alkylthio-bridged complexes were stable sufficiently so that decomposition was not observed after standing for several months without special care. The reaction of the μ-peroxo complexes with benzylamine or acrylamide also gave the corresponding amido-bridged complex **4** and hydrogen peroxide at room temperature. A similar reaction of mononuclear peroxo complex of platinum with phenylenediamine was previously studied by Pizzotti *et al.* and they reported that the reaction afforded an amido complex with hydrogen peroxide.[9] Since an ordinary μ-peroxo complex does not react with compounds hav-

a) For all products, satisfactory ^{1}H-NMR and IR spectra were obtained.

ing pK_a values higher than 20, the reaction observed in this strudy is not explicable by the direct interaction of the coordinated dioxygen with amines. A zwitter ionic transition state **7** resulted from the coordination of amine to the μ-peroxo complex may assist the abstraction of proton to form amido-bridged complex **4** and hydrogen peroxide.

Experimental

General. All reactions were run under a pressure of dry nitrogen. ^{1}H-NMR spectra were determined in $CDCl_3$ on a Hitachi R-24B instrument. Chemical shifts are reported in the δ unit, parts per million (ppm) downfield from tetramethylsilane and coupling constants are reported in hertz. Melting points were obtained on a Yanagimoto MP-apparatus and are uncorrected.

Diethyl ether and benzene for the solvent were distilled from sodium benzophenone ketyl. Pentane was distilled from sodium. Dichloromethane was purified by washing with water and dried over calcium hydride and then distilled from phosphorous pentoxide under a pressure of dry nitrogen. Methanol and ethanol were distilled from magnesium turnings. Isopropanol and *t*-butyl alcohol were dried over molecular sieve 3A and distilled prior to use. Benzylamine was dried over potassium hydroxide pellets. Acrylamide, ethanethiol, and thiophenol were used without further purification. Dioxygen complexes (**1a**—**f**) were prepared according to the procedure reported previously.[1-3]

*Reaction of **1a** with Methanol.* To a solution of 0.176 g (0.38 mmol) of **1a** in 5 cm^3 of dry benzene was added 0.2 cm^3 of dry methanol followed by 3 cm^3 of dry diethyl ether at room temperature. The solution was stirred for a few minutes and was allowed to stand for 20 h in a refrigerator. Pale yellow prisms precipitated in the solution were collected by suction and washed with dry pentane, then dried *in vacuo* to give 0.115 g (50%) of di-μ-methoxybis(8-*exo*-methoxytricyclo[5.2.1.0^{2,6}]dec-3-en-9-yl)dipalladium. Mp (dec.) 155 °C; IR (KBr) ν(C–O) 1082, 1053 (bridging) cm^{-1}; NMR ($CDCl_3$) δ 3.18 (6H, s, OCH_3), 3.40 (6H, s, OCH_3), 5.16 (2H, m, olefinic), 5.63 (2H, m, olefinic); Mol wt (cryoscopy in benzene) calcd 600.8, found 645.

In a similar procedure, alkoxo-bridged complexes were prepared and characterized. Yields, mps, and results of elemental analyses are summarized in Table 1.

*Reaction of **1a** with Ethanethiol.* To a suspension of 0.329 g (0.58 mmol) of **1a** in 25 cm^3 of dry diethyl ether was added dropwise 1.63 cm^3 of a solution of ethanethiol in benzene (0.7 mmol/cm^3). The solution was stirred for 6 h at room temperature. The resulting orange solution was filtered and filtrate was dried in vacuo to give red powder. Recrystallization from a mixed solvent of benzene, diethyl ether and pentane (1:1:1 vol ratio) gave di-μ-ethylthiobis(8-*exo*-methoxytricyclo[5.2.1.0^{2,6}]dec-3-en-9-yl)dipalladium (**3a-Et**) as yellowish orange prisms (0.259 g, 58%). Mp (dec.) 114 °C; IR (KBr) ν(C–S) 1250, ν(C–O) 1080 cm^{-1}; NMR ($CDCl_3$) δ 1.41 (6H, t, J=7, S–CH_2–CH_3), 2.53 (4H, q, J=7, S–CH_2–), 3.26 (6H, s, OCH_3), 5.87 (2H, m, olefinic), 6.35 (2H, m, olefinic).

*Reaction of **1c** with Benzylamine.* To a suspension of 0.174 g (0.33 mmol) of **1c** in 25 cm^3 of dry diethyl ether was added slowly 1.4 cm^3 of a solution of benzylamine in benzene (0.47 mmol/cm^3). The solution was stirred for 10 h at ambient temperature. The resulting yellow solution was filtered and the filtrate was concentrated under a reduced pressure. Addition of dry pentane and storage in a refrigerator for 40 h yielded di-μ-benzylaminobis(8-*exo*-methoxy-4-cyclooctenyl)dipalladium (**4c-Bz**) as pale yellow precipitates (0.152 g, 67%). Mp (dec.) 135 °C; IR (KBr) ν(N–H) 3450, ν(C–O) 1090 cm^{-1}. NMR ($CDCl_3$) δ 3.10 (3H, s, OCH_3), 4.13 (2H, d, Ph–CH_2–), 5.25 (2H, br, olefinic), 7.0—7.5 (5H, aromatic). Mol wt (cryoscopy in benzene) Calcd 702.8; Found 714.

The Reaction of 2-Methylfuran with Methyl Acrylate. Unusual Formation of 1,1′-Bis(5-methyl-2-furyl)ethane and Methyl 3,3′-Bis(5-methyl-2-furyl)propionate

Osamu MARUYAMA, Yuzo FUJIWARA,* and Hiroshi TANIGUCHI

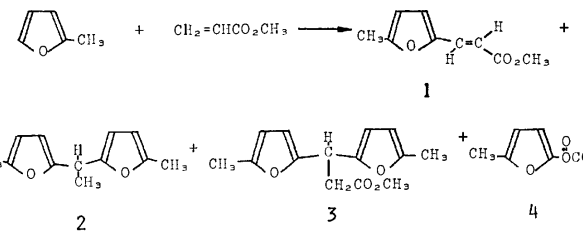
Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Higashi-ku, Fukuoka 812

(Received March 23, 1981)

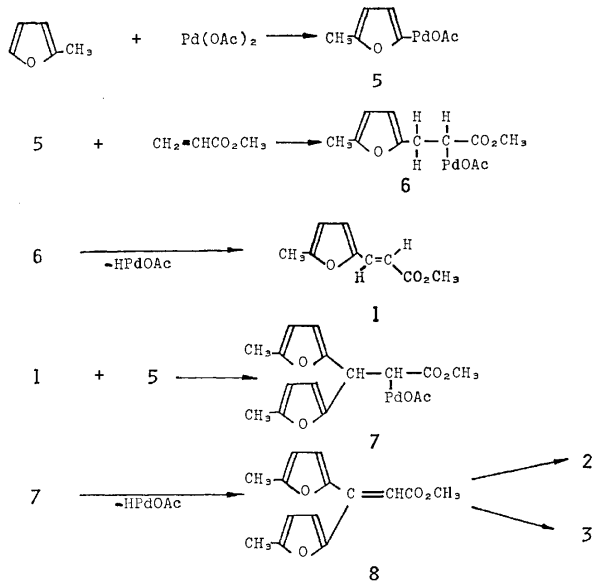
Synopsis. The reaction of 2-methylfuran with methyl acrylate in the presence of $Pd(OAc)_2$ gave unusual products such as 1,1′-bis(5-methyl-2-furyl)ethane (22%) and methyl 3,3′-bis(5-methyl-2-furyl)propionate (10%) along with the usual aromatic substitution product. This is a marked contrast to the reaction of furan with olefins.

In our previous paper we reported the palladium-assisted one-step alkenylation reactions of heterocycles.[1,2] These reactions afford both the 2-mono- and 2,5-dialkenylated products when the five-membered aromatic heterocycles such as furan, thiophene, or pyrrole are allowed to react with olefins. In subsequent related studies, we attempted 2-methylfuran to react with methyl acrylate, and obtained some unusual products such as 1,1′-bis(5-methyl-2-furyl)-ethane (**2**) and methyl 3,3′-bis(5-methyl-2-furyl)propionate (**3**).

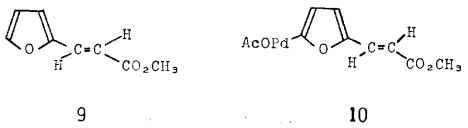
The reaction of 2-methylfuran with methyl acrylate was carried out with stirring at 100 °C for 8 h. After the usual work-up, there were obtained 27%[3] of methyl 3-(5-methyl-2-furyl)acrylate (**1**), the usual aromatic substitution product, 22% of **2** of which identity was proved by comparison of NMR and IR spectra with those of an authentic sample prepared from 2-methylfuran and acetaldehyde,[4] 10% of **3**, and 5% of 5-methyl-2-furyl acetate (**4**). The formation of **2** and **3** in considerable amounts is of particular interest since no such products are obtained in the case of unsubstituted five-membered heterocycles.[1,2]



The formation of **2** and **3** may be explained in the following way (Scheme 1). First, palladium(II) attackes at the 5-position of 2-methylfuran electrophilically to give a furyl-Pd σ complex **5**. Then **5** adds to methyl acrylate affording a σ complex **6**. Elimination of a PdH species gives **1**. Then the furyl-Pd σ complex adds to **1** giving an intermediate complex **7**. Elimination of HPdOAc from **7** gives an olefin **8** which may be transformed into **2** and **3** by hydrogenation[5] and/or decarboxylation.[6] In the case of furan, Pd(II) can attack further at the 5-position of the furan ring of **9** to produce a furyl-Pd σ complex **10** which reacts with the olefin yielding the dialkenylated products.[1,2] However, in the present case, there is no reactive 5-position available since the 5-position is occupied with a methyl group.



Scheme 1.



Experimental

NMR spectra were obtained with a Hitachi R-24S spectrometer using Me_4Si as an internal standard. Materials used were prepared and purified as described already.[2]

Reaction of 2-Methylfuran with Methyl Acrylate. The reaction was performed with stirring at reflux for 8 h using 2-methylfuran (2 mmol), methyl acrylate (2 mmol), palladium(II) acetate (2 mmol), dioxane (20 ml), and acetic acid (5 ml). After work-up as described already,[2] the residue was chromatographed on a column of silica gel. Elution with hexane–ether (9:1) yielded **2** (22% yield) which was assigned by comparison of the IR and NMR spectra with those of an authentic sample prepared from 2-methylfuran and acetaldehyde.[4] **2**: bp 130 °C/15 mmHg†; IR (neat) 2960, 1562, 1015, and 790 cm^{-1}; NMR (CCl_4) δ 1.50 (d, 3H, J=7 Hz), 2.23 (s, 6H), 3.84 (q, 1H, J=7 Hz), and 5.69 (4H). Further elution gave a 1:5 mixture of **3** and **1**. The products were isolated by preparative glc (OV-17, 0.5 m, 118 °C). **1**: 27% yield; IR (Nujol) 1724 and 974 cm^{-1}; NMR ($CDCl_3$) δ 2.36 (s, 3H), 3.81 (s, 3H), 6.0—6.7 (3H), and 7.44 (d, 1H, J=17 Hz). **3**: 10% yield; IR (neat) 1725 cm^{-1}; NMR ($CDCl_3$) δ 2.22 (s, 6H), 2.91 (d, 2H, J=8 Hz), 3.60 (s, 3H), 4.48 (t, 1H, J=9 Hz), and 5.7—6.0 (m, 4H). Further elution with hexane–ether (3:2)

† 1 mmHg≈133.322 Pa

gave 5-methyl-2-furyl acetate (**4**). **4**: 5% yield; IR (neat) 1770 cm^{-1}; NMR ($CDCl_3$) δ 1.84 (s, 3H), 2.07 (s, 3H), 6.20 (d, 1H, J=6 Hz), and 7.17 (d, 1H, J=6 Hz).

Possibility of the Intramolecularity of Triazene Rearrangement[1)]

Yoshiro OGATA,* Yoshiaki NAKAGAWA, and Morio INAISHI
Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received September 29, 1980)

Synopsis. The mechanism for the ortho-rearrangement of diaryltriazenes still remains equivocal. An interesting result suggesting an intramolecular nature of the triazene rearrangement was obtained on the basis of the effect of concentration of added *N,N*-dimethylaniline in the ortho-rearrangement of 1,3-bis(4-methylphenyl)triazene (**1**). The ortho/para ratio for the rearrangement of 1,3-diphenyltriazene (**4**) tends to increase with an increase of the viscosity. The results are discussed on the basis of increasing nucleophilicity of free amine by H-bonding with dimethylaniline and favoring ortho-migration with viscosity, respectively.

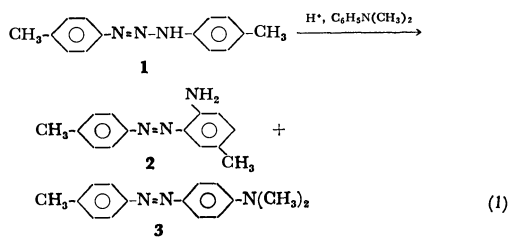
It is known that acid-catalyzed rearrangement of 1,3-diphenyltriazene to *p*-aminoazobenzene, accompanied by a small amount of *o*-isomer[2)] (Eq. 2), is intermolecular based on the trap of intermediary diazonium ion with phenols and dialkylanilines.[3)] However, as to the ortho-rearrangement at least, the possibility of intramolecular mechanism cannot be excluded.

Berezovskii *et al.*[4)] suggested that the ortho-rearrangement has an intramolecular character based on analogous yields for the rearrangement of 1,3-bis(3,4-dimethylphenyl)triazene in *p*-toluidine and in chlorobenzene, but their evidence is not definitive.

We attempted to clarify the mechanism of triazene rearrangement by the examination of the effects of the addition of *N,N*-dimethylaniline as a trapping agent for the intermediary diazonium ion during the rearrangement and also of the solvent effect on the ortho/para ratio of 1,3-diphenyltriazene. The results suggest the partial intramolecularity of the rearrangement.

Results and Discussion

Effect of N,N-*Dimethylaniline on 1,3-Bis(4-methylphenyl)-triazene Rearrangement.* 1,3-Bis(4-methylphenyl)-triazene (**1**) was rearranged in acidic ethanol, affording 2-amino-5,4′-dimethylazobenzene (**2**). In the presence of *N,N*-dimethylaniline (DMA) as a scavenger of diazonium ion, **1** gave 4-dimethylamino-4′-methylazobenzene (**3**) as well as the rearrangement product **2**.



(1)

A plot of the reciprocal of the initial concentration of added DMA ($1/[DMA]_0$) *vs.* a ratio of the yields of **2** to **3** (**2/3**) is shown in Fig. 1.

Assuming this rearrangement to be completely intermolecular, the ratio (**2/3**) must be zero, when

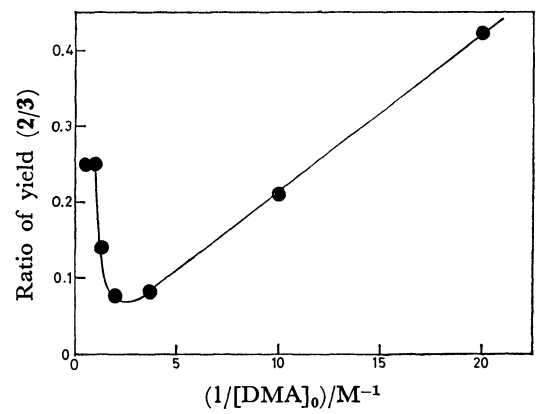


Fig. 1. Effect of *N,N*-dimethylaniline on the rearrangement of **1** in ethanol at room temperature. The initial concentrations of reagents were: $[\mathbf{1}]_0$= 0.05 M, $[HCl]_0$=0.011 M.

$[DMA]_0$ is extrapolated to infinity. As shown in Fig. 1, the ratio decreases really until $[DMA]_0$ of 0.75 M (1 M=1 mol dm^{-3}), but with increasing $[DMA]_0$ over 0.75 M, the ratio increases to 0.25, which suggests an increase of intramolecular nature of the rearrangement at very high concentration of DMA.

The Goldschmidt mechanism[5)] in which protonated triazene reacts with anilines might explain the observed plot of the **2/3** ratio *vs.* $1/[DMA]_0$ (Fig. 1), but the mechanism requires that the analogous DMA-catalyses should operate with both rearrangement and DMA-coupling at high $[DMA]_0$. Hence the higher ratio of **2/3** at low $1/[DMA]_0$ cannot be explained.

The increase of intramolecular nature by increasing $[DMA]_0$ may be caused by increasing the nucleophilicity of $ArNH_2$ of intermediary $[ArNH_2 \cdot N\equiv \overset{+}{N}Ar]$ *via* hydrogen bonding $Ar\overset{\delta-}{N}H\cdots H\cdots \overset{\delta+}{N}Me_2Ph$. The diazo coupling reaction takes place between diazonium ion and free amine[6)] which exist in neutral and even weakly acidic media. In fact, the yield of **2** for the rearrangement of **1** ($[\mathbf{1}]_0$=0.05 M) in ethanol with $[HCl]_0$=0.005 M (37%) in the absence of DMA was found to be higher than those with $[HCl]_0$=

Table 1. Effect of *N,N*-dimethylaniline (DMA) on the rearrangement of 1,3-bis(4-methylphenyl)-triazene (**1**) in ethanol at room temperature[a)]

$[\mathbf{1}]_0$ (M)	$[DMA]_0$ (M)	Yield/%		Ratio of yields
		2	**3**	**2/3**
0.051	0	23	—	—
0.045	0.050	19	48	0.39
0.046	0.10	13	65	0.21
0.046	0.27	3.7	45	0.083

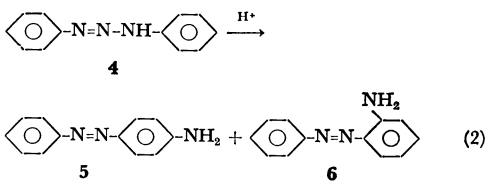
1-Butanol	2.27	3.87	17.7	75	12	0.16	4[f]
2-Butanol	3.18	—	16.6	55	—[e]	—	33
t-Butyl alcohol	3.32	—	12.5	61	14	0.23	34
DG[d]	30[g]	—	31.7[h]	18	1.8[i]	0.10	3

a) Initial concentration; $[4]_0=0.051$—0.052 M, $[HCl]_0=0.0054$ M. Reaction temp.; 30 °C. b) Initial concentration; $[1]_0=0.046$—0.051 M, $[HCl]_0=0.011$ M. Reaction temp.; room temp. c) Duplicates gave similar results on the trend with viscosity effect, so that the average yields were shown here. d) Diethylene glycol. e) These yields could not be estimated because of the overlapping of the HPLC peaks of **6** and unknown product. f) A large amount of **1** was recovered. g) At 25 °C. h) At 20 °C. i) This yield was estimated after concentration of the solution of products by evaporating the solvent. However, the yield for DG is low because of the decomposition of triazene giving aniline and benzene (GLC analysis) so that the data are little reliable.

0.01 M (25%) and 0.02 M (15%). Ethanol, as in the case of HCl, may deactivate $ArNH_2$ by hydrogen bonding. The increase of nucleophilicity of $ArNH_2$ lowers the selectivity and raises the *o*/*p* ratio.

Solvent Effect in 1,3-Diphenyltriazene Rearrangement. 1,3-Diphenyltriazene (**4**) gives *p*- (**5**) and *o*-aminoazobenzene (**6**).[2] As shown in Table 2, satisfactory yields of rearrangement products were obtained except with 1-butanol and diethylene glycol. We expected that the ortho-rearrangement may occur *via* intramolecular process, especially in viscous solvents. Hence, **4** was rearranged in various solvents under



(2)

acidic conditions. The effect of viscosity on the ratio of ortho/para-was examined by estimating the ratio of the yields of ortho *vs.* para (**6**/**5**) (Table 2).

The ratio, **6**/**5**, or the trend for ortho migration tends to increase slightly with increasing viscosity of the solvent in going from methanol to *t*-butyl alcohol. The same tendency was also observed with the rearrangement of **1**, where the yield of **2** increased in going from methanol to **2**-propanol (Table 2).

This tendency for the ratio **6**/**5** and yields of **2** suggests that the triazene rearrangement has at least a partial contribution of intramolecularity. The increase of the ratio **6**/**5** and the yield of **2** may be caused by an increase of viscosity. In the reaction of diethylene glycol, the decomposition of triazene to aniline and benzene is remarkable; the yields of rearrangement products are so poor. Also the yield of rearrangement of **1** in 1-butanol was poor, a considerable amount of **1** being recovered.

Experimental

Melting points were measured by a Yanagimoto micro melting point apparatus and uncorrected. NMR spectra were recorded on a Hitachi R-24B NMR spectrometer using Me_4Si as an internal standard. The HPLC analysis was performed with a Yanagimoto L-1030 high pressure liquid chromatograph.

Materials. Triazenes were prepared from corresponding anilines by the method of Hartman *et al*;[7] 1,3-diphenyltriazene: mp 95—97.5 °C (lit,[7] 94—96 °C); NMR (CCl_4) δ 7.3 (m, 10H, ArH), 9.9 (s, 1H, NH); UV (EtOH) λ_{max} 353 nm (ε 1.98×10^4), 294 nm (0.74×10^4), 236 nm (1.69×10^4). 1,3-bis(4-methylphenyl)triazene: mp 119—120 °C (lit,[8] 118 °C); NMR (CCl_4) δ 2.28 (s, 6H, CH_3), 7.1 (dd, 8H, ArH), 9.5 (s, 1H, NH); UV (EtOH) λ_{max} 357 nm (ε 2.03×10^4), 292 nm (1.02×10^4), 238 nm (1.73×10^4). Solvents were of commercial guaranteed grade and purified by fractional distillation.

Effect of N,N-*Dimethylaniline on the Rearrangement of 1,3-Bis(4-methylphenyl)triazene (1).* An ethanolic solution (10 ml) of **1** (0.05 M) and *N*,*N*-dimethylaniline containing HCl (0.011 M) was allowed to stand at room temperature for 3 d, until **1** was consumed. One ml of the resulting solution was pipetted out and ethanol was added for dilution to a suitable concentration for HPLC analysis. The HPLC analysis was performed under the following conditions using Yanaco SA-I as a packing. A carrier solvent of hexane/THF (9 1 in vol.) was used at a flow rate of 40 ml/h. The products were identified by HPLC peaks in comparison with the authentic specimens.

Solvent Effect in 1,3-Diphenyltriazene (4) Rearrangement. Various solutions (10 ml) of **4** (0.05 M) containing HCl (0.005 M) were allowed to stand at 30 °C in a thermostat for 2 d, until **4** was consumed. In a similar manner as above, the products were identified and estimated by HPLC under the following conditions. Yanaco SA-I was used as a packing, and hexane/THF (7/3) was used at a flow rate of 90 ml/h. Products from propanol and 2-butanol contained a small amount of unknown product, which showed UV peaks (334 nm) different from *o*-aminoazobenzene, 4-(phenyldiazoamino)azobenzene (C_6H_5–N=N–NH–C_6H_4–N=N–C_6H_5) and *p*-[*p*-(phenylazo)phenylazoaniline (C_6H_5–N=N–C_6H_4–N=N–$C_6H_4NH_2$).

Cyclodehydrogenation of 3-Cinnamoyltropolones with 2,3-Dichloro-5,6-dicyanobenzoquinone

Kimiaki IMAFUKU* and Kazuko YAMAGUCHI†

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received April 15, 1981)

Synopsis. 3-Cinnamoyltropolone and 3-(3-methoxycinnamoyl)tropolone were oxidized with 2,3-dichloro-5,6-dicyanobenzoquinone to give 2-phenyl- and 2-(3-methoxyphenyl)-4,9-dihydrocyclohepta[*b*]pyran-4,9-diones, while 2′- and/or 4′-methoxy-substituted 3-cinnamoyltropolones gave 2-arylmethylene-2*H*-3,8-dihydrocyclohepta[*b*]furan-3,8-diones.

2,3-Dichloro-5,6-dicyanobenzoquinone (DDQ) is recently used for synthetic organic chemistry as a dehydrogenating or cyclodehydrogenating agent.[1a-c] In connection with our studies on cyclization reactions of 3-cinnamoyltropolones,[2-4] which have a 2′-hydroxychalcone-like structure, we have been interested in the use of DDQ for their cyclization reaction. Little is known about the DDQ cyclization of 2′-hydroxychalcones except for 2′-hydroxy-5′-prenyl-4,4′-diphenylchalcone, which gave the corresponding flavone.[5]

A mixture of 3-cinnamoyltropolones (**1a—i**) (1 mmol) and DDQ (2 mmol) in dry benzene was refluxed for 20 h. Thus, the reactions of 3-cinnamoyltropolone (**1a**) and 3-(3-methoxycinnamoyl)tropolone (**1c**) gave flavone-like compounds, 2-aryl-4,9-dihydrocyclohepta[*b*]pyran-4,9-diones, while the other 3-cinnamoyltropolones (**1b**, **d—i**) which have the methoxyl group at 2′- and/or 4′-position gave selectively aurone-like compounds, 2-arylmethylene-2*H*-3,8-dihydrocyclohepta[*b*]furan-3,8-diones (**3b**, **d—i**). Each of the products was identified with comparison of its mp and IR and NMR spectra with those of the product from selenium dioxide oxidation[2] and alkaline hydrogen peroxide oxidation[3] of the corresponding 3-cinnamoyltropolones. The results are summarized in Table 1.

These results show that the DDQ is a useful cyclodehydrogenating reagent of 3-cinnamoyltropolones. This reaction might be extended to the oxidative cyclization of 2′-hydroxychalcones.

Experimental

Measurement. The melting points were determined with a Yanagimoto melting-point measuring apparatus and are uncorrected. The IR spectra were taken on a JASCO IRA-1 spectrophotometer. The NMR spectra were recorded with a Hitachi R-24 spectrometer (60 MHz).

*Oxidative Cyclization of 3-Cinnamoyltropolones (**1a—i**).* A mixture of 3-cinnamoyltropolone (**1a—i**) (1 mmol, 252—343 mg) and DDQ (2 mmol, 454 mg) in dry benzene (20 ml) was refluxed for 20 h. The reaction mixture was poured into a saturated sodium carbonate solution (100 ml) and extracted with chloroform. The extract was washed with water, dried over anhydrous sodium sulfate, and brought to dryness by evaporation of the solvent. The residue was recrystallized from benzene to afford 2-aryl-4,9-dihydro-

Use of Propagators in the Hückel Model. III. Stability and Reactivity

Takayuki Ohmae, Kiyoshi Nishikawa, Kisaburo Deguchi, and Shigeyuki Aono*
Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920
(Received December 20, 1980)

The propagator approach is applied to the problems of chemical reactivity and stability. Subjects discussed are the ring closure and opening reactions, the Diels-Alder reaction and sigmatropic reaction for reactivity; the aromaticity, two ring compounds (such as naphthalene and azulene), and benzenoid hydrocarbons (such as anthracene and phenanthrene) for stability. Results are given in analytical formulas.

The Hückel model or the tight-binding approximation is of great use because of its mathematical simplicity in analysis of molecular electronic states and chemical reactivities. Coulson and Longuet-Higgins[1] emphasized that once the Hückel determinant is given for a system all its physical properties are derived by making analysis of the determinant, not *via* wave functions as has been done in the usual theories. The charge density, bond order and total energy are expressed by the corresponding contour integrals closely related to the Hückel determinant. The perturbation theory has been developed in terms of mutual polarizability, which are also given by similar expressions. They applied their theory to the conjugated molecules and successfully derived many rules. Recent trials of Hosoya *et al.*[2] with topological aspects seem to be inherently related to the treatment of Coulson and Longuet-Higgins.

On the other hand Fukui[3] discussed chemical reactivity and stability in view of frontier electron. In this theory, the specified orbitals called LUMO and HOMO play dominant roles in the chemical reactions, and their mutual phases qualitatively decide whether the reaction takes place or not. The last is known as the Woodward-Hoffmann rule.[4]

In the first paper[5] of this series, the Hückel theory is reformulated in terms of propagators. This is a Green's function version of Coulson's work, and has merit of giving results beyond the elementary perturbation theory. Our theory is not so easy as the usual LCAO theory, but sometimes successfully reveals physical concepts hidden in the latter. The bond order between the r-th and s-th sites, $q(r,s)$ is usually inferred to the overlap charge or the charge density at the bond. This might not be feasible if the r-th and s-th sites are far from each other. By use of a propagator the bond order is defined by

$$q(r, s) = \frac{1}{2\pi i}\int_c dz G(r, s; z). \quad (1)$$

What this means is as follows: consider the probability amplitude which an electron at the r-th site transfers to the s-th site in any one-electron state. If we sum up such amplitude with respect to the levels occupied in the ground state, the result is $q(r, s)$. Moreover, $q(r, s)$ is divided into the contributions arising from several independent paths.[6] The bond order between the nearest sites in benzene is composed of two components which refer the shorter and longer paths in a way from the one site to the other.

Any chemical bond produced by the chemical reaction under consideration is due to the propagations of interactions. Thus the bond order plays a leading role in the following investigations, showing quantitatively what kind of route of propagation is important.

Interaction Energy

In order to investigate the stability condition in the ground state and the chemical reactivity, *i.e.*, selection of the reaction path of the chemical reaction, we derive the expression of energy stabilization due to perturbation. In the case of reactivity, we estimate the stabilization energy due to perturbation at some point along the reaction path, then at the corresponding point along the other path. Comparing these two, we can decide which one is favorable. Calculations will be performed following those in I, but are limited to the second order with respect to the perturbation. This suffices for the present case.

The total energy of the system is

$$E = \mathrm{Tr}\frac{1}{2\pi i}\int_c dz\, z\mathbf{G}(z), \quad (2)$$

where $\mathbf{G}$ is the matrix of Green's function represented by the site indices, z the energy parameter and Tr the trace with respect to the site indices. Integration contour c is the so-called Coulson contour shown in Fig. 1. Note that the integration in Eq. 2 includes the spin sum.

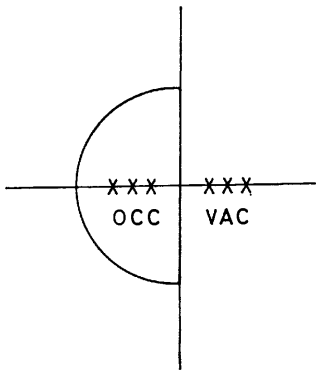

Fig. 1. Coulson's contour.

Let us consider the perturbation $\mathbf{v}$, which is a matrix represented by the site indices. The interaction energy caused by the perturbation is

$$\Delta E = \mathrm{Tr}\frac{1}{2\pi i}\int_c dz\, z[\mathbf{G}_0\mathbf{v}\mathbf{G}_0+\mathbf{G}_0\mathbf{v}\mathbf{G}_0\mathbf{v}\mathbf{G}_0+\cdots]$$
$$= \mathrm{Tr}\frac{1}{2\pi i}\int_c dz\, z\mathbf{G}_0\sum_n(\mathbf{v}\mathbf{G}_0)^n$$
$$= \sum_n\frac{1}{n}\mathrm{Tr}\frac{1}{2\pi i}\int_c dz(\mathbf{G}_0\mathbf{v})^n. \quad (3)$$

The final result is as follows:

$$\frac{1}{2}\mathrm{Tr}\frac{1}{2\pi i}\int_c dz\mathbf{G}_0\mathbf{v}\mathbf{G}_0\mathbf{v}$$
$$=\frac{1}{2}\mathrm{Tr}\frac{1}{2\pi i}\int_c dz\frac{1}{z-\mathbf{H}_0}\mathbf{v}\frac{1}{z-\mathbf{H}_0}\mathbf{v}$$
$$=\frac{1}{2}\mathrm{Tr}\frac{1}{2\pi i}\int_c dz\, z\left[\frac{1}{(z-\mathbf{H}_0)^2}\mathbf{v}\frac{1}{z-\mathbf{H}_0}\mathbf{v}\right.$$
$$\left.+\frac{1}{z-\mathbf{H}_0}\mathbf{v}\frac{1}{(z-\mathbf{H}_0)^2}\mathbf{v}\right]$$
$$= \mathrm{Tr}\frac{1}{2\pi i}\int_c dz\, z\frac{1}{z-\mathbf{H}_0}\mathbf{v}\frac{1}{z-\mathbf{H}_0}\mathbf{v}\frac{1}{z-\mathbf{H}_0}$$
$$= \mathrm{Tr}\frac{1}{2\pi i}\int_c dz\, z\mathbf{G}_0\mathbf{v}\mathbf{G}_0\mathbf{v}\mathbf{G}_0, \quad (4)$$

where the second equality arises from the partial integration and the third one from the permutation invariability in Tr.

Illustrative Example Provided that the perturbation is applied to the site a, say $v_{aa}=\varepsilon$, it follows that

$$\Delta E = \sum_n\frac{1}{n}\frac{1}{2\pi i}\int_c dz[G_0(a)\varepsilon]^n$$
$$= \frac{1}{2\pi i}\int_c dz\ln(1-G_0(a)\varepsilon)^{-1} \quad (5a)$$
$$\simeq \frac{1}{2\pi i}\int_c dz\, G_0(a)\varepsilon+\frac{1}{2}\frac{1}{2\pi i}\int_c dz\, G_0(a)^2\varepsilon^2$$
$$\equiv q(a)\varepsilon+\frac{1}{2}\Pi_{a,a}\varepsilon^2. \quad (5b)$$

Here $q(a)$ is the charge density at the a-th site and $\Pi_{a,a}$ is the atom-atom polarizability defined by Coulson and Longuet-Higgins.[1)]

Ring Closure and Ring Opening

Let us first consider the ring closure reaction of conjugated chain. Figure 2a shows the transition state where the chain begins the ring closure reaction. The arrows at both ends stand for the basis functions, $2p\pi$ together with the phases. Note that we can put the phases in this way without loss of generality. We need not worry about one-electron state, *i.e.*, the shape of MO and its energy.

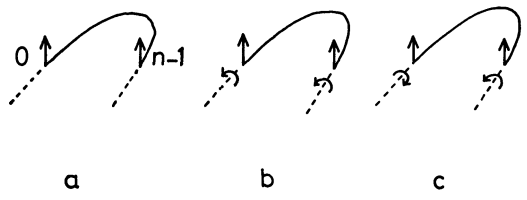

Fig. 2. Ring closure reaction.
a: Transition state, b: con-rotatory, c: dis-rotatory.

For the sake of simplicity, let us consider the case in which the chain is composed of n sites and n electrons. If the ring closure begins in the con-rotatory mode or in the dis-rotatory mode, the interaction arises between sites 0-th and (n-1)-th.

$$v_{0,n-1}=v_{n-1,0}=v\begin{cases}\text{positive for the con-rotatory}\\ \text{negative for the dis-rotatory.}\end{cases} \quad (6)$$

The extra energy due to this is given by Eq. 3. If one mode works to stabilize the system, *i.e.*, $\Delta E<0$, we can choose this mode as the desired reaction path.

Let us consider the ring opening reaction. The σ-bond in the transition state slightly rotates (Fig. 3a) in a con-rotatory mode (Fig. 3b) or in the dis-rotatory mode (Fig. 3c) to yield a small fraction of π-bond. The extra energy due to this determines which mode is preferable. Since the perturbation energy arising in these motion is classified entirely in the same way as that of ring closure reaction, *i.e.*, as Eq. 6, we see that the mathematical procedures are the same, *viz.*, if in any system the con-rotatory mode is desirable for the ring closure reaction, the same mode is also desirable for the ring opening reaction for the system in which transition state is similar to that of the previous system.

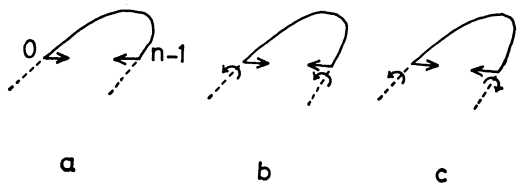

Fig. 3. Ring opening reaction.
a: Transition state, b: con-rotatory, c: dis-rotatory.

In both cases, the extra energy ΔE in Eq. 3 due to perturbation to the second order is

$$\Delta E = \frac{1}{2\pi i}\int_c dz[G_n(0,n-1)v_{n-1,0}+G_n(n-1,0)v_{0,n-1}]$$
$$+\frac{1}{2}\frac{1}{2\pi i}\int_c dz[G_n(0,n-1)v_{n-1,0}G_n(0,n-1)v_{n-1,0}$$
$$+G_n(n-1,0)v_{0,n-1}G(n-1,0)v_{0,n-1}]$$
$$+\frac{1}{2}\frac{1}{2\pi i}\int_c dz[G_n(0)v_{0,n-1}G_n(n-1)v_{n-1,0}$$
$$+G_n(n-1)v_{n-1,0}G_n(0)v_{0,n-1}] \quad (7a)$$
$$= \frac{1}{2\pi i}\int_c dz[2vG_n(0,n-1)+v^2G_n(0,n-1)G(n-1,0)$$
$$+v^2G_n(0)G_n(n-1)]. \quad (7b)$$

Each term in Eq. 7b, shown in detail in Eq. 7a, has its own structure: the first order term indicates a path going round the system once, the path indicated by the second terms in Eq. 7a goes round the system twice, and the final second order term corresponds to the interaction going back and forth between the ends. Let us examine each term in detail.

The matrix elements of Green's function in Eq. 7a are given in the second paper[7)] of this series, as

$$G_n(0) = G_n(n-1) = \frac{\sin n\theta}{\sin(n+1)\theta}, \tag{8}$$

$$G_n(0, n-1) = G_n(n-1, 0) = \frac{\sin\theta}{\sin(n+1)\theta}, \tag{9}$$

$$z = 2\cos\theta. \tag{10}$$

If we map the Coulson contour in z-plane onto θ-plane by means of the relation (10), the contour in θ-plane turns round twice the corresponding points in z-plane. This is why we introduced the factor, 1/2.[7]

As an example, let us take the system with n sites and n electrons, n being even. The first order energy in Eq. 7b is

$$\Delta E^{(1)} = -4\frac{1}{4\pi i}\int_c d\theta \frac{\sin^2\theta}{\sin(n+1)\theta} v. \tag{11}$$

The poles of the propagator are given by

$$\theta_r = \frac{\pi r}{n+1}, \quad r = \pm 1, \pm 2, \cdots, \pm(n+1), \tag{12}$$

in which the single particle states from $r=\pm 1$ to $r=\pm n/2$ are doubly occupied. The result of calculation is

$$\begin{aligned}\Delta E^{(1)} &= -\frac{8v}{(n+1)}\sum_{r=1}^{n/2}(-1)^r \sin^2\theta_r \\ &= -\frac{4v}{(n+1)}\left\{\sum_{r=1}^{n/2}(-1)^r + 1/2 \right. \\ &\quad \left. + \frac{(-1)^{n/2}}{2}\sec\pi/(n+1)\right\}. \end{aligned} \tag{13}$$

The second order energy arising from the path going round the system twice is

$$\begin{aligned}\Delta E^{(2,q)} &= -2\frac{1}{4\pi i}\int_c d\theta \frac{\sin^3\theta}{\sin^2(n+1)\theta}\frac{v^2}{\beta} \\ &= \frac{-3}{2(n+1)^2}\left\{\operatorname{cosec}\pi/2(n+1)\right. \\ &\quad \left. + \operatorname{cosec} 3\pi/2(n+1)\right\}\frac{v^2}{\beta}. \end{aligned} \tag{14}$$

The resonance integral β which was scaled to unity in evaluating G, is recovered by dimensional analysis. The resonance integral β is negative. Another second order term is

$$\begin{aligned}\Delta E^{(2,c)} &= -2\frac{1}{4\pi i}\int_c d\theta \frac{\sin\theta\sin^2 n\theta}{\sin^2(n+1)\theta}\frac{v^2}{\beta} \\ &= \frac{(2n-1)}{2(n+1)^2}\left\{\operatorname{cosec}\pi/2(n+1)\right. \\ &\quad \left. + \operatorname{cosec} 3\pi/2(n+1)\right\}\frac{v^2}{\beta}. \end{aligned} \tag{15}$$

Thus we get

$$\begin{aligned}\Delta E &= \Delta E^{(1)} + \Delta E^{(2,q)} + \Delta E^{(2,c)} \\ &= \frac{-4}{n+1}\left\{\sum_{r=1}^{n/2}(-1)^r + 1/2 + \frac{(-1)^{n/2}}{2}\sec\pi/(n+1)\right\}v \\ &\quad + \frac{n-2}{(n+1)^2}\left\{\operatorname{cosec}\pi/2(n+1) + \operatorname{cosec} 3\pi/2(n+1)\right\}\frac{v^2}{\beta}. \end{aligned} \tag{16}$$

Due to the fact that $n>2$ in the actual molecules the second order terms in Eqs. 16 and 20 are negative, irrespective of the sign of v. The second order term has nothing to do with the determination of the reaction path, except for slight stabilization of the system as regards energy. The first order term should dominantly affect the progress of the reaction. The reaction proceeds if the quantity in the curly bracket has the same sign as that of v in the first order term.

Let us examine the case with odd n sites and n electrons. In this case, the single particle states, $r=\pm 1$ to $\pm(n-1)/2$, are doubly occupied and those with $n=\pm(n+1)/2$ are singly occupied. The spin summation should be carefully done. Terms corresponding to the previous ones are

$$\Delta E^{(1)} = \frac{-4}{n+1}\left\{\sum_{r=1}^{(n+1)/2}(-1)^r + \frac{1}{2} - \frac{(-1)^{(n+1)/2}}{2}\right\}v = 0, \tag{17}$$

$$\Delta E^{(2,q)} = \frac{-3}{2(n+1)^2}\left\{\cot\frac{\pi}{2(n+1)} + \cot\frac{3\pi}{2(n+1)}\right\}\frac{v^2}{\beta}, \tag{18}$$

$$\Delta E^{(2,c)} = \frac{2n-1}{2(n+1)^2}\left\{\cot\frac{\pi}{2(n+1)} + \cot\frac{3\pi}{2(n+1)}\right\}\frac{v^2}{\beta}. \tag{19}$$

Thus

$$\begin{aligned}\Delta E &= \Delta E^{(1)} + \Delta E^{(2,q)} + \Delta E^{(2,c)} \\ &= \frac{n-2}{(n+1)^2}\left\{\cot\frac{\pi}{2(n+1)} + \cot\frac{3\pi}{2(n+1)}\right\}\frac{v^2}{\beta}. \end{aligned} \tag{20}$$

The first order term vanished identically, the second order term having a similar character as previous ones.

Since the first order term predominantly affects the electrocyclic interaction, we will reexamine this more carefully. Denote the number of sites by n, which is even or odd, and the number of electrons by M, which is less than $2n$. Let us investigate the cases where M is $4m$, $4m+2$, $4m+1$, and $4m+3$.

(i) $M = 4m$

$$\begin{aligned}\Delta E^{(1)} &= -\frac{8v}{n+1}\sum_{r=1}^{2m}(-1)^r \sin^2\theta_r \\ &= \frac{4v}{n+1}\sum_{r=1}^{2m}(-1)^r \cos 2\pi r/(n+1) \\ &= -\frac{2v}{n+1}\left\{1 - \frac{\cos(4m+1)\pi/(n+1)}{\cos\pi/(n+1)}\right\}. \end{aligned} \tag{21a}$$

Note that

$$1 - \frac{\cos(4m+1)\pi/(n+1)}{\cos\pi/(n+1)} > 0. \tag{21b}$$

(ii) $M=4m+2$ Similar calculation yields

$$\Delta E^{(1)} = \frac{2v}{n+1}\left\{1 - \frac{\cos(4m+3)\pi/(n+1)}{\cos\pi/(n+1)}\right\}. \tag{22a}$$

Note that

$$1 - \frac{\cos(4m+3)\pi/(n+1)}{\cos\pi/(n+1)} > 0. \tag{22b}$$

(iii) $M = 4m+1$

$$\begin{aligned}\Delta E^{(1)} &= \frac{v}{(n+1)\cos\pi/(n+1)} \\ &\quad \times [\cos(4m+1)\pi/(n+1) - \cos(4m+3)\pi/(n+1)] \\ &= \frac{2v}{n+1}\tan\pi/(n+1)\sin(4m+2)\pi(n+1). \end{aligned} \tag{23a}$$

Note that $\tan\pi/(n+1)>0$, but

$$\sin(4m+2)\pi/(n+1)\begin{cases} >0 & \text{for } 1 < M < n \\ =0 & \text{for } M = n \\ <0 & \text{for } n < M < 2n. \end{cases} \tag{23b}$$

$(iv) M = 4m+3$

$$\Delta E^{(1)} = \frac{-2v}{n+1} \tan \pi/(n+1) \sin(4m+4)\pi/(n+1) \quad (24a)$$

with

$$\sin(4m+4)\pi/(n+1) \begin{cases} >0 & \text{for } 1 < M < n \\ =0 & \text{for } M = n \\ <0 & \text{for } n < M < 2n. \end{cases} \quad (24b)$$

It is desirable to clarify the fact that in the ring closure and ring opening reactions, it is not the number of sites but the number of electrons which control the reactivity of these reactions.[8] The results obtained are summarized in Table 1.

Table 1. Conditions for $\Delta E^{(1)} < 0$

M[a]	[b]	Sign of v	Reaction path[c]
$4m$		+	con
$4m+2$		−	dis
	$0<M<n$	−	dis
$4m+1$	$M=n$		
	$n<M<2n$	+	con
	$0<M<n$	+	con
$4m+3$	$M=n$		
	$n<M<2n$	−	dis

a) Number of electrons. b) Relation between M and the number of sites, n. c) con: con-rotatory, dis: dis-rotatory.

In order to confirm the previous general results the details of small systems are given in Table 2. Care should be taken on signs of $\Delta E^{(1)}$ and $\Delta E^{(2)}$, remembering that β is negative. Our predictions as to whether the reactions is con-rotatory or dis-rotatory are made only from the first order term, $\Delta E^{(1)}$. Agreements with those from the Woodward-Hoffmann rule are almost satisfactory. For cases written as non-selective or that indicating disagreements between two predictions, there has been no experimental result,[4] so far we are aware of.

Diels-Alder Reaction

The simplest Diels-Alder reaction is shown in Fig. 4. As transition states for this sort of reaction, we adopt two types (Fig. 5a). In both models, the phases of basic orbitals can be chosen, without a loss of generality, such that the perturbing interactions are negative (attractive).

Let us investigate the case in which two interactions

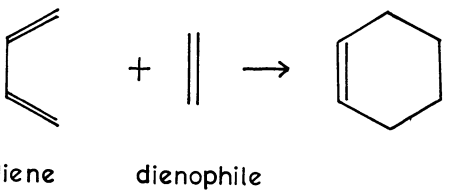

Fig. 4.

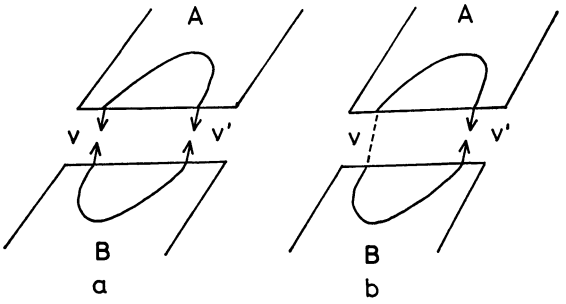

Fig. 5. Diels-Alder reaction.
a: Two interactions, b: single interaction.

v and v' coexist (Fig. 5a). We will show that this is not acceptable. For the sake of simplicity, we assume that the combining two species A and B are the same consisting of n sites and n electrons.

The extra energy due to perturbation Eq. 3, up to the second order is

$$\begin{aligned} \Delta E &= (v^2+v'^2)\frac{1}{2\pi i}\int_c dz\, G_n(0) G_n(n-1) \\ &\quad + 2vv' \frac{1}{2\pi i}\int_c dz\, G_n^2(0, n-1) \\ &= (v^2+v'^2)\frac{-2}{4\pi i}\int_c d\theta \frac{\sin\theta \sin^2 n\theta}{\sin^2(n+1)\theta} \\ &\quad + 2vv' \frac{-2}{4\pi i}\int_c d\theta \frac{\sin^3\theta}{\sin^2(n+1)\theta}. \end{aligned} \quad (25)$$

Calculations are carried out in a similar way to that for the second order terms $\Delta E^{(2)}$.

If n is even, the levels up to $n/2$ are doubly occupied, so that

$$\begin{aligned} \Delta E = \frac{1}{2(n+1)^2\beta} &[\operatorname{cosec} \pi/2(n+1) + \operatorname{cosec} 3\pi/2(n+1)] \\ &\times [(2n-1)(v^2+v'^2) - 6vv'], \end{aligned} \quad (26a)$$

Table 2. Ring closure and ring opening reaction

n[a]	M[b]	Species	$\Delta E^{(1)}$	$\Delta E^{(2)}$	Prediction	W-H rule[c]
	2	+ion	v	$\sqrt{2}v^2/8\beta$	dis	dis
3	3	neutral	0	$\sqrt{2}v^2/8\beta$	non-selective	con
	4	−ion	$-v$	$\sqrt{2}v^2/8\beta$	con	con
	3	+ion	$(5-3\sqrt{5})v/10$	$3\sqrt{5}v^2/25\beta$	con	con
4	4	neutral	$-\sqrt{5}v/5$	$4\sqrt{5}v^2/25\beta$	con	con
	5	−ion	$(5-3\sqrt{5}v/10$	$3\sqrt{5}v^2/25\beta$	con	dis
	4	+ion	$-2v/3$	$(3+\sqrt{3})v^2/12\beta$	con	con
5	5	neutral	0	$(3+\sqrt{3})v^2/12\beta$	non-selecitve	dis
	6	−ion	$2v/3$	$(3+\sqrt{3})v^2/12\beta$	dis	dis

a) Number of sites. b) Number of electrons. c) Predictions from the Woodward-Hoffmann rule.

and for $v=v'$

$$\Delta E = \frac{2(n-2)}{(n+1)^2}[\text{cosec}\,\pi/2(n+1) + \text{cosec}\,3\pi/2(n+1)]\frac{v^2}{\beta}. \tag{26b}$$

By means of dimensional analysis, we write explicitly β put to unity in evaluating propagators of the original system.

If n is odd, the levels up to $(n-1)/2$ are doubly occupied and the $(n+1)/2$-th is singly occupied, thus

$$\Delta E = \frac{1}{2(n+1)^2\beta}[\cot\pi/2(n+1) + \cot 3\pi/2(n+1)] \times [(2n-1)(v^2+v'^2) - 6vv']. \tag{27a}$$

For $v=v'$ we have

$$\Delta E = \frac{2(n-2)}{(n+1)^2}[\cot\pi/2(n+1) + \cot 3\pi/2(n+1)]\frac{v^2}{\beta}. \tag{27b}$$

Since β is negative, ΔE given by Eqs. 26b and 27b are negative, indicating that the Diels-Alder reaction is possible if two species are like those given in Fig. 5a. The result shows that the combined system is more stable than the original, not explaining the selection rule of Diels-Alder reaction.

Let us consider the model in Fig. 5b. Simultaneous interactions considered in Fig. 5a hardly seem to happen, instead a two step process like Fig. 5b is more probable. In the first step, A and B combine, due to v, yielding a long chain. In the second step, the chain starts the ring closure interaction due to the v' interaction. Note that in this model v' has always negative sign.

If we assume that the first step is rate-determining, the rules investigated for the ring closure reaction can be applied. Only the cases with negative v in Table 1 are allowed:

1) The case $M=4m$ is forbidden.
2) The case $M=4m+2$ is allowed.
3) For the case $M=4m+1$
   if $0<M<n$, the reaction is allowed,
   if $n<M<2n$, the reaction is forbidden,
   where n is the number of sites.
4) For the case of $M=4m+3$
   if $0<M<n$, the reaction is forbidden,
   if $n<M<2n$, the reaction is allowed.

The Cope and Claisen rearrangements are also treated in a similar way.

Sigmatropic Reaction

Let us consider the reaction shown in Fig. 6. This has been pointed out by Berson[9] as an example that the Woodward-Hoffman rule does not hold exactly. The Woodward-Hoffmann rule suggests the reaction path shown in Fig. 6a rather than that in Fig. 6b. In view of symmetry, the highest occupied orbital of the allyl type radical is described by displaying the phases of the atomic orbitals of both ends.

As has been done in the Diels-Alder reaction, we make use of the models shown in Figs. 7a and 7b for the transition states in Figs. 6a and 6b, respectively. v_a and v_b are examined since v_a' and v_b' have no significant contribution. The interactions, v_a and v_b are split

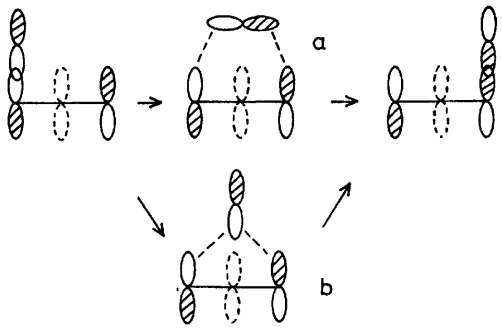

Fig. 6. Sigmatropic reaction.
The highest occupied orbital of the allyl type radical is described by displaying the phases of the atomic orbitals at the both ends.

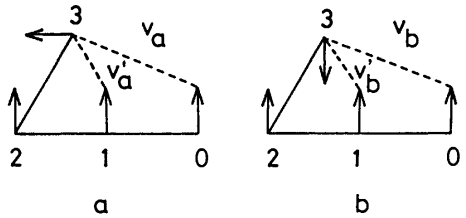

Fig. 7. Models for the transition states of the sigmatropic reaction.
Figures 7a and 7b correspond to the Figs. 6a and 6b respectively, but here arrows indicate the phases of the basic atomic orbitals.

into σ- and π-components, the parallel or perpendicular components with respect to the binding axis. Both components of v_a are positive, v_a being repulsive. The σ-component of v_b is negative and the π-one is positive. The migrating radical in the reaction is the methyl type one. This suggests that if we consider the steric effect, the methyl type radical might migrate above the allyl radical considerably nearer in the case of Fig. 7b than in the case of Fig. 7a. If this is the case, it is possible that the π-component becomes predominant and v_b is repulsive. Thus i) $v_a>0$, ii) $v_b>0$, if the migrating radical moves considerably close to the allyl radical.

For the cases of Figs. 7a and 7b, we obtain ΔE in Eq. 3 in the first order approximation;

$$\Delta E = \text{Tr}\frac{1}{2\pi i}\int_c dz\,\mathbf{Gv} = 2\left\{\frac{v_a}{2\pi i}\int_c dz\,G_4(0,3) + \frac{v_a'}{2\pi i}\int_c dz\,G_4(1,3)\right\}, \tag{28}$$

for the cases of Fig. 7a. Replacing v_a and v_a' by v_b and v_b', respectively, we get the expression for Fig. 7b. $G_4(0,3)$ is the 0-3 matrix element of the chain propagator with four sites. In Eq. 28, the second integral is the bond order between the starred sites of the conjugated chain, vanishing identically. The remaining term gives

$$\Delta E_a(\Delta E_b) = \frac{2\sqrt{5}}{5}v_a(v_b),\ v_a(v_b) > 0. \tag{29}$$

The reaction mechanism infers the first case in Table 1, in other words, the formation of the Möbius ring

presented in the next section. Accordingly our theory explains the possibility of two reaction paths.

Aromaticity

Let us examine the stability conditions in the ground state of the conjugated systems. The question what aromaticity is has been discussed for a long time. We consider it as a problem of energy stabilization when the conjugated chain becomes a ring by connection of both ends.[10]

Let the interaction between two ends be v. The following conclusions are obtained from Table 1.

A. The ring with the negative v or the Hückel ring is more stable than the original chain, under the conditions where

i) $M=4m+2$
ii) $M=4m+1$ and $0<M<n$
iii) $M=4m+3$ and $n<M<2n$,

where n is the number of sites.

B. The ring with positive v or the Möbius ring is preferable under the conditions that

i) $M=4m$
ii) $M=4m+1$ and $n<M<2n$
iii) $M=4m+3$ and $0<M<n$.

Naphthalene and Azulene

The stability of compounds consisting of two rings is of interest. Naphthalene and azulene are well-known examples. Two ring compounds consisting of ten atoms are presented (Fig. 8).

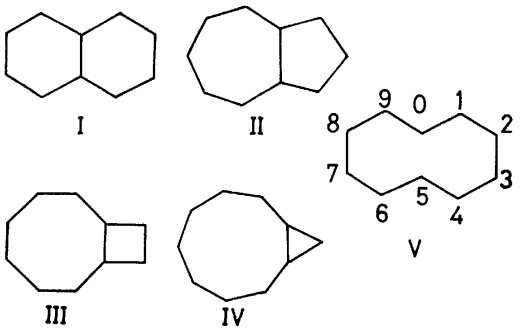

Fig. 8. Two ring compounds (I—IV) composed of cyclodecapentaene (V).

Compounds I—IV are derived from various perturbations put in cyclodekapentaene V as follows:

$$v' = \begin{cases} v'_{05} \text{ for I} \\ v'_{04} \text{ for II} \\ v'_{03} \text{ for III} \\ v'_{02} \text{ for IV.} \end{cases} \tag{30}$$

The stabilization energies in these cases are mainly due to the first order term:

$$\left.\begin{matrix} \Delta E(\mathrm{I}) \\ \Delta E(\mathrm{II}) \\ \Delta E(\mathrm{III}) \\ \Delta E(\mathrm{IV}) \end{matrix}\right\} = 2v' \frac{1}{2\pi i}\int_c dz \begin{Bmatrix} G_{10}(0,5) \\ G_{10}(0,4) \\ G_{10}(0,3) \\ G_{10}(0,2) \end{Bmatrix} = 2v' \begin{Bmatrix} q_{10}(0,5) \\ q_{10}(0,4) \\ q_{10}(0,3) \\ q_{10}(0,2). \end{Bmatrix} \tag{31}$$

The problems are reduced to the evaluation of the corresponding bond orders. The bond order $q_n(0, k)$ in this case is

$$q_n(0,k) = \frac{2}{n}\frac{\sin(k\pi/2)}{\sin(k\pi/n)}, \tag{32}$$

from which it follows that

$$\begin{aligned} q_{10}(0,5) &= 1/5 \\ q_{10}(0,4) &= 0 \\ p_{10}(0,3) &= -(\sqrt{5}-1)/5 \\ q_{10}(0,2) &= 0. \end{aligned} \tag{33}$$

Naphthalene is the most stable, azulene and IV next, III being the most unstable.

Anthracene and Phenanthrene

In order to clarify the distinction between anthracene and phenanthrene in view of stabilization, a simple method has been worked out for generalization to larger benzenoid hydrocarbons.

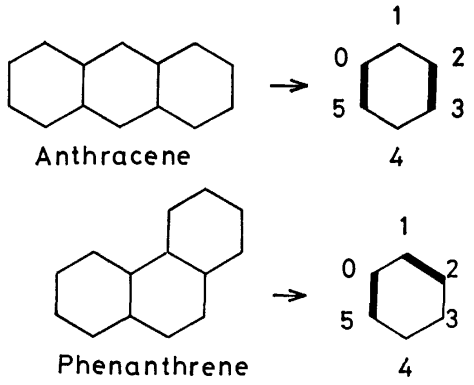

Fig. 9.

We rewrite anthracene and phenanthrene, as in Fig. 9, by means of structures with bold bonds which indicate the adjacent benzene rings in each compound. Anthracene is considered as a fictitious benzene in which the 0-5 and 2-3 bonds have the effective resonance integrals, β_{eff}, instead of the original β. If we put

$$v = \beta_{\mathrm{eff}} - \beta, \tag{34}$$

and use Eq. 3 up to the second order, ΔE for anthracene is given by

$$\begin{aligned} \Delta E_{\mathrm{A}} = \frac{1}{2\pi i}\int_c dz \{ & 2v[G(0,5)+G(2,3)]+v^2[G(0)G(5) \\ & +G(2)G(3)+G(0,5)G(5,0) \\ & +G(2,3)G(3,2)]+2v^2[G(0,2)G(3,5) \\ & +G(0,3)G(2,5)]\}. \end{aligned} \tag{35}$$

In a similar way, ΔE for phenanthrene is given by

$$\begin{aligned} \Delta E_{\mathrm{P}} = \int_c dz \{ & 2v[G(0,5)+G(1,2)]+v^2[G(0)G(5) \\ & +G(1)G(2)+G(0,5)G(5,0) \\ & +G(1,2)G(2,1)]+2v^2[G(0,1)G(2,5) \\ & +G(0,2)G(1,5)]\}. \end{aligned} \tag{36}$$

The difference between ΔE_A and ΔE_P arises from the second order terms,

$$\Delta E_A - \Delta E_P = \frac{1}{2\pi i}\int_c dz\, 2v^2[G(0,2)G(3,5)+G(0,3)G(2,5) - G(0,1)G(2,5)-G(0,2)G(1,5)]. \quad (37)$$

It is instructive to trace the routes indicated by combining propagators and v of Eq. 37. We can easily evaluate this and find

$$\Delta E_A - \Delta E_P = -(0.17+0.35)v^2/\beta = -0.25v^2/\beta. \quad (38)$$

Because of the negative sign of β, the value of Eq. 38 is positive, with a small magnitude. Thus phenanthrene should be more stable than anthracene. This is in line with the observation. The result is independent of the sign of v. Generalization to a larger system is straigtforward (Fig. 10).

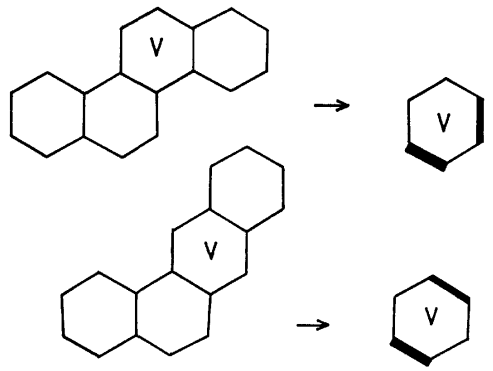

Fig. 10. Shorthand display of the benzenoid.

β_{eff} in Eq. 34 is interpreted as an average of the operator, $|s><\beta_{st}<t|$, with respect to the ground state of the system in question,

$$|0> = \prod_i^{\text{occ}} |i>. \quad (39)$$

Namely

$$\beta_{\text{st:eff}} = \beta_{\text{st}} \sum_i <s|i><i|t> = \beta_{\text{st}} \frac{1}{2\pi i}\int_c dz\, G(s,t;z). \quad (40)$$

This relation reproduces the original β_{st} in the diatomic chain. Using Eq. 40 in the benzene ring, we obtain

$$\beta_{\text{eff}} = 0.667\beta. \quad (41)$$

This is in line with the fact that in anthracene or phenanthrene, the corresponding bond length is slightly greater than that of benzene.

Concluding Remarks

Propagator theory has been successfully applied to the problems of chemical reactivity and stability. No use was made of wave functions or LCAO coefficients. Even if the concept of orbital is established, the orbital is not a physical quantity. The final result should be presented only in terms of the coupling constants in the Hamiltonian. In this respect our theory is nearer to that of Coulson than that of Fukui and Woodward-Hoffmann.

Electron Spin-Spin Interaction in Excited Triplet States of Aromatic Hydrocarbons with a Trigonal Symmetry Axis

Jiro Higuchi

Department of Chemistry, Faculty of Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240

(Received December 20, 1980)

Zero-field splitting (ZFS) parameters of benzene, triphenylene, and coronene molecules in their lowest and second excited triplet states are calculated from the electron spin-spin interaction using semi-empirical self-consistent-field π-electron molecular orbitals. The results show that in obtaining a good agreement of the evaluated ZFS parameters with the experimental values the selection of the basis functions in LCAO-MO's with zero-differential overlap is actually important. The ZFS parameters in some distorted structures are also calculated.

Since the detection of electron spin resonance (ESR) signals for the phosphorescent naphthalene molecule by Hutchison and Mangum,[1] many theoretical works on the zero-field splittings (ZFS) of aromatic molecules in their triplet states have been carried out with various degrees of approximations.[2-8] Nevertheless, the progress in such a calculation has essentially been slow in spite of the development in the theory of electronic structures of molecules. For large molecules, *ab initio* studies have scarcely been done except a work of benzene by Langhoff, Davidson, and Kern.[3] On the other hand, semi-empirical calculations have usually been concerned with the explanation of experimental values without careful reexamination of points in question. In most of these works, the electron spin-spin interactions were evaluated by using Slater-type or Gaussian-type atomic orbitals (AO's) as the AO bases and adopting the zero differential overlap (ZDO) approximation. The spin-orbit interactions were ignored in expecting their minor influence.[9]

As the basis functions of semi-empirical LCAO-MO's cannot pertinently be approximated by AO's of the corresponding free atoms, these calculations usually include some adjustable parameters although they are not always explicitly specified. That is, for obtaining a good agreement between the calculated values and the experimental ones, many works employed one of the following modifications: (1) use of partly adjusted values of spin-spin interaction integrals;[4] (2) use of adjusted orbital exponent of Slater-type 2p AO;[6,7] (3) inclusion of unsuitable approximation in exchange-type spin-spin interaction integrals,[8] and so on. In these works, the meanings of modified points were not distinctly explained.

With the recent development of accurate measurements in magnetic resonance experiments, detailed experimental data on the phosphorescent triplet states of aromatic molecules have been accumulated using methods such as conventional ESR and the optically detected magnetic resonance. From the standpoint of theoretical calculation, however, instructive information on ZFS parameters is still insufficient in discussing the values evaluated, except the case of benzene.[3,5] Under these circumstances, it may be desirable to reexamine the semi-empirical calculations of ZFS parameters on the basis of the works of benzene. Besides, there are many interesting experiments on the lowest triplet states of aromatic molecules with trigonal symmetry.[10-16] For these molecules, a relatively simple approximation with only Coulomb-type spin-spin interaction integrals is fairly satisfactory, since the other integrals have minor influence upon the ZFS parameters when the E value is very small.[5] Especially for benzene, the ratios among coefficients of AO's in the π-electron LCAO-MO's are uniquely determined from only the molecular symmetry and the calculated ZFS parameters may not largely be affected by the selection of semi-empirical parameters. In the present work, therefore, ZFS parameters of benzene, triphenylene, and coronene in the lowest and second excited triplet states were evaluated from the electron spin-spin interactions:

$$\begin{aligned}\mathcal{H}_{ss} &= \frac{\mu_0 g^2\beta^2}{4\pi}\left[\frac{(\boldsymbol{s}_1\cdot\boldsymbol{s}_2)}{r_{12}^3}-\frac{3(\boldsymbol{s}_1\cdot\boldsymbol{r}_{12})(\boldsymbol{s}_2\cdot\boldsymbol{r}_{12})}{r_{12}^5}\right]\\ &= \frac{\mu_0 g^2\beta^2}{8\pi}\left[s_x^2\left(\frac{r_{12}^2-3x_{12}^2}{r_{12}^5}\right)+s_y^2\left(\frac{r_{12}^2-3y_{12}^2}{r_{12}^5}\right)\right.\\ &\quad + s_z^2\left(\frac{r_{12}^2-3z_{12}^2}{r_{12}^5}\right)-(s_ys_z+s_zs_y)\frac{3y_{12}z_{12}}{r_{12}^5}\\ &\quad \left.-(s_zs_x+s_xs_z)\frac{3z_{12}x_{12}}{r_{12}^5}-(s_xs_y+s_ys_x)\frac{3x_{12}y_{12}}{r_{12}^5}\right] \qquad (1)\end{aligned}$$

(μ_0: vacuum permeability; $\boldsymbol{S}=\boldsymbol{s}_1+\boldsymbol{s}_2$: total spin)

using a standard and simple approximation with only Coulomb-type integrals.[8,17] In terms of the principal magnetic axes shown in Figs. 1—3, the ZFS parameters can be expressed as

$$D = \frac{3\mu_0 g^2\beta^2}{16\pi hc}\left\langle\frac{r_{12}^2-3z_{12}^2}{r_{12}^5}\right\rangle \qquad (2)$$

$$E = \frac{3\mu_0 g^2\beta^2}{16\pi hc}\left\langle\frac{y_{12}^2-x_{12}^2}{r_{12}^5}\right\rangle. \qquad (3)$$

Calculation

The wavefunctions (WF's) used were constructed from Pariser-Parr-Pople-type (PPP) LCAO-MO's[18,19] by including configurations arising from all the single excitations relative to the ground state. ZFS parameters were calculated by adopting one of the following three kinds of treatments:

(A) The basis AO used was a double-zeta SCF-AO of carbon atom by Clementi.[20] This treatment corresponds to the conventional standard calculations except the used AO instead of a single Slater-type AO (STAO). A similar work with all the spin-spin interaction integrals evaluated with single STAO's has been carried out for benzene and naphthalene by Godfrey,

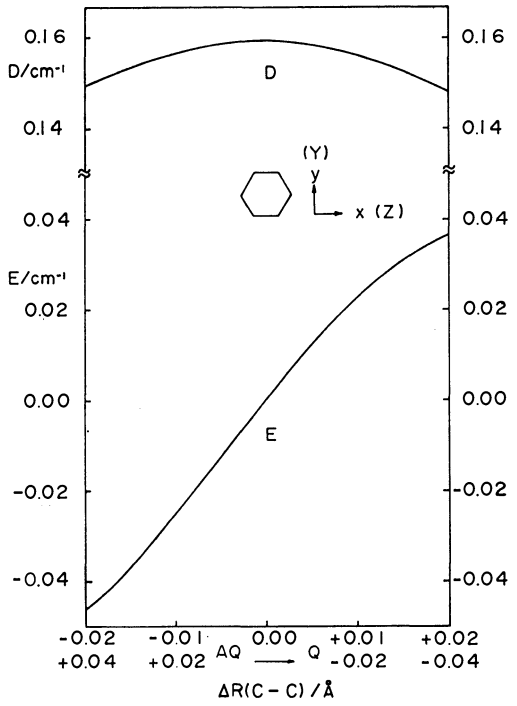

Fig. 1. Variation of the calculated zero-field splitting parameters of benzene with antiquinonoidal (AQ) and quinonoidal (Q) forms. The lower and the upper value in ΔR(C–C) are the change of length in two C–C bonds which are parallel to the x axis and that for the other four C–C bonds, respectively. The axis system for D_{2h} symmetry is indicated in parentheses.

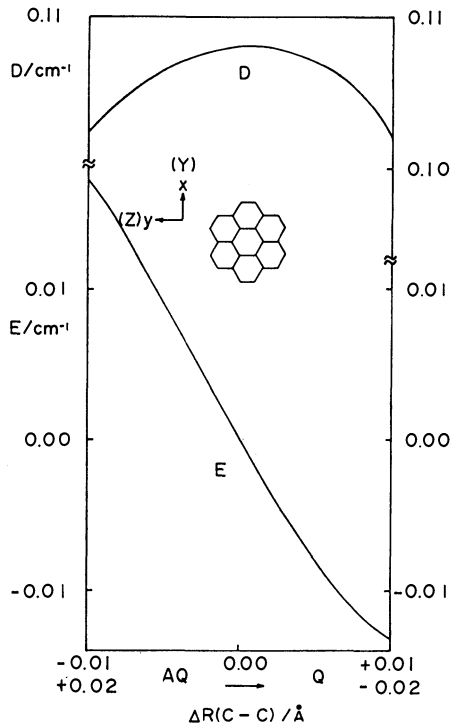

Fig. 3. Variation of the calculated zero-field splitting parameters of coronene with antiquinonoidal (AQ) and quinonoidal (Q) forms. The lower and the upper value in ΔR(C–C) are the change of length in C–C bonds which are parallel to the y axis and that for the other C–C bonds, respectively. The axis system for D_{2h} symmetry is indicated in parentheses.

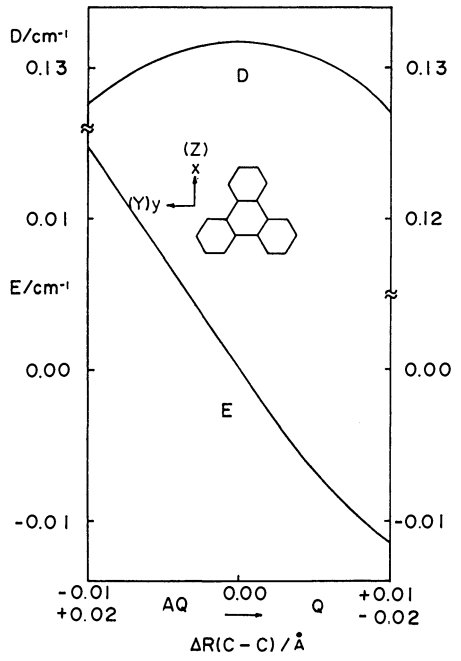

Fig. 2. Variation of the calculated zero-field splitting parameters of triphenylene with antiquinonoidal (AQ) and quinonoidal (Q) forms. The lower and the upper value in ΔR(C–C) are the change of length in C–C bonds which are parallel to the y axis and that for the other C–C bonds, respectively. The axis system for C_{2v} symmetry is indicated in parentheses.

Kern, and Karplus.[5]

(B) The basis AO used was an adjusted single STAO, the orbital exponent of which was chosen to give the experimental D value of benzene [D=0.1593 cm^{-1}].[12] The value of δ=1.5055 thus obtained is considerably different from that of Capello-Pullman's improved AO (δ=1.37)[6] which was determined from the SCF-AO of carbon atom. In any case, such AO's should not generally be better than the double-zeta AO used in Treatment (A).

(C) Since the usual AO's χ_p's do not satisfy the orthogonal relation in the PPP LCAO-MO's, approximate orthogonalized AO's were taken as the basis functions. In reality, the calculation was carried out as described below. As the AO bases of PPP MO's should essentially be different from the usual AO's χ_p's in the valence state of constituent atoms, the following orthogonalized AO's ϕ_p's proposed by Löwdin[21] may be chosen as one of suitable bases:

$$\boldsymbol{\phi} = \boldsymbol{\chi}(\boldsymbol{1}+\boldsymbol{S})^{-1/2}, \tag{4}$$

where $\boldsymbol{S}$ is a matrix with elements

$$S_{pq} = \int \chi_p^* \chi_q d\tau - \delta_{pq}. \tag{5}$$

Since the π-electron MO's of benzene are essentially unique as described above, the PPP MO's taking the orthogonalized AO's ϕ_p's as the bases are exactly identical with those in which the nonorthogonality between the AO's χ_p's is strictly included.[22] For

alternant hydrocarbons, the PPP MO's with basis functions of the orthogonalized AO's ϕ_p's may semi-empirically be good approximations of the SCF-MO's with inclusion of all overlap integrals as pointed out by Parr,[22] although this relation should not exactly be valid. In Treatment (C), the ZFS parameters were simply calculated by using LCAO-MO's which the coefficients of AO's χ_p's are in the same ratios as those of the PPP MO's, and by including the nonorthogonality between the nearest neighboring AO's χ_p's, as a first step of approximation with orthogonalized AO's. In this case, the overlap integrals were evaluated by using the aforementioned double-zeta AO's.[20]

In the present work, molecular structures of benzene, triphenylene, and coronene were assumed to be planar with symmetry D_{6h}, D_{3h}, and D_{6h}, respectively.[23-25] Since triphenylene and coronene are deformed in crystals,[24-26] structures with symmetry C_{2v} and D_{2h}, respectively, were taken as typical examples of such conformations. The internuclear distances and bond angles used were obtained by averaging the observed values in each ground state[23-26] for each equivalent bond and angle. A similar study was carried out by assuming hypothetical structures with which all the benzene rings involved are the same size as in the ground state of benzene. As the observed E values are nonzero for these molecules,[10,12-15] the influence of distortion from hexagonal or trigonal symmetry upon the ZFS parameters was also examined for conformations in which the benzene rings of the system are all antiquinonoidal (AQ) or all quinonoidal (Q) forms. Such a calculation was carried out under the following assumptions: (i) the sum of the six nearest C–C bond lengths of each benzene ring and all the bond angles are unchanged from those of the ground state with symmetry D_{6h}, D_{3h}, and D_{6h} for benzene, triphenylene, and coronene, respectively; (ii) the changes of the lengths in a pair of parallel C–C bonds [ΔR(C–C)] are taken to be identical with each other and twice as large as the change in each of the other four C–C bond lengths [$-\Delta R$(C–C)/2]. The coordinate system used for ZFS parameters of each molecule is indicated by small letters in Figs. 1—3.

When the SCF π-electron MO's were calculated for each ground state with the PPP approximation,[18,19] the Coulomb integrals were evaluated by using Ohno-Klopman-type (OK) approximation:[27]

$$J_{pq} = e^2/(k^2a^2+r_{pq}^2)^{1/2}, \quad (6)$$

where $a=e^2/(I_p-A_p)$, $I_p(C)=11.16$ eV, $A_p(C)=0.03$ eV[28] and r_{pq} is an internuclear distance between atoms p and q. The parameter k is chosen as 1.0 and 0.7[29] for electron repulsion and electron-core attraction integrals, respectively. The resonance integrals were evaluated by adopting Wolfsberg-Helmholz-type approximation[30] in which β_{cc} for benzene was assumed to be -2.60 eV[31] and the overlap integrals were calculated by using the double-zeta AO by Clementi.[19]

Results and Discussion

For the lowest triplet state of benzene with symmetry D_{6h}, the D value in Treatment (A) is fairly small [$D=0.1341$ cm^{-1}], while a rather larger value is obtained, if a single STAO with conventional orbital exponent of $\delta=1.59$ (or 1.625) is used [$D=0.1770$ (or 0.1842) cm^{-1} with the present approximation and 0.1671 cm^{-1} with all the spin-spin interaction integrals[5]]. Also, if one use Capello-Pullman's improved STAO with $\delta=1.37$,[6] the D value becomes 0.1295 cm^{-1} still smaller than that obtained in Treatment (A). Further, a fairly good agreement with the observed value cannot be obtained, if only the C–C distances are varied within their permissible limits of the bond lengths. In Treatment (C), however, the evaluated D value [0.1594 cm^{-1}] is very close to the experimental one, in spite of the fact that orthogonalized AO's used were not strictly obtained.

For triphenylene and coronene, the D and E values by Treatment (C) are surprisingly close to those by Treatment (B) and in fair agreement with the experimental values as compared with the case of Treatment (A). These results are listed in Table 1. For the cases where the structures for the lowest triplet states were changed

from hexagonal and/or trigonal symmetry, therefore, only the ZFS parameters obtained in Treatment (C) are shown in Figs. 1-3.

In general, the D-type spin-spin interaction integrals except the Coulomb-type ones are relatively small compared with those of the E-type ones.[5] Since such integrals were disregarded here, the D values obtained may possibly be more reliable than the E values. Comparing with the observed E value, the calculated E value of benzene shown in Fig. 1 is relatively large at a distorted structure where the change of bond lengths from the equilibrium ones are nearly the same as those obtained by the SCF-MO-CI calculation.[4,32] This result is quite similar with those of the previous works.[4,5] Under the present circumstances, therefore, the quantitative estimation of the distorted structures in crystals is actually difficult from the calculated ZFS parameters, even if all the spin-spin interaction integrals were included.[3,5]

As can be seen in Figs. 2 and 3, the change of the ZFS parameters of triphenylene and coronene with the molecular distortion have a similar trend with that of benzene, although the influence on the E value is fairly small compared with the case of benzene. The calculated E value of triphenylene assuming the aforementioned C_{2v} structure in a crystal is not much different from the observed value. On the other hand, the experimental E value of coronene changes slightly according to the host crystal,[15,16] as is seen in benzene.[12,13] This makes it very difficult to infer whether the intramolecular pseudo-Jahn-Teller instability significantly affects the E value or not.

As a preliminary step, the ZFS parameters of these molecules were also calculated by using Nishimoto-Mataga-type (NM) two-center integrals:[33]

$$J_{pq} = e^2/(ka+r_{pq}). \quad (7)$$

In this case, Treatments (A) and (B) were adopted by using the traditional parameters: $I_p(C)=11.22$ eV, $A_p(C)=0.62$ eV,[34] and $\beta_{cc}(\text{Benzene})=-2.39$ eV.[18] As given in Table 1,[35] the OK approximation does not always give a better result for the ZFS parameters than the NM one, while the former formula may yield better electronic energies for the triplet state rather than the latter one.[31] Actually, the present results with the use of OK approximation are in general satisfactory compared with the previous works on these molecules used various different treatments.[36]

For the second excited triplet state of these molecules, the ZFS parameters were similarly calculated as is given in Table 2. These values may have some theoretical interest, although the experimental values have not yet been available. The E value of benzene might apparently be zero because of its D_{6h} symmetry and can be obtained to be zero using complex WF's of $\Psi(^3E_{1u\pm})=2^{-1/2}[\Psi(^3B_{1u})\pm i\Psi(^3B_{2u})]$.[37] However, if the real WF's of $\Psi(^3B_{1u})$ and $\Psi(^3B_{2u})$ were separately used as the limit forms of D_{2h} symmetery, the E values so obtained are negative and positive, respectively, as given in Table 2 and both the ZFS levels obtained are still degenerate. This might appear the fact that each of such real WF's does not seemingly satisfy the condition of symmetry D_{6h}. For D_{2h} structures which are slightly deformed from D_{6h}, the influence of the off-diagonal element of $\langle\Psi(^3B_{1u})|-2x_{12}y_{12}/r_{12}^5|\Psi(^3B_{2u})\rangle$ upon E values should be considerable if the separation between the $^3B_{1u}$ and $^3B_{2u}$ states is the same order as their E values. Similar results were obtained by using real WF's of $\Psi(^3B_2)$ and $\Psi(^3A_1)$ for triphenylene[38] and those of $\Psi(^3B_{2u})$ and $\Psi(^3B_{1u})$ for coronene[39] (see Table 2). With the OK approximation, the $^3E_{1u}$ state of coronene is calculated to be located slightly lower than the $^3B_{2u}$ state. Because of the perturbation from this state, the D value becomes fairly small as compared with that obtained with the NM approximation where the $^3B_{2u}$ state is not much close to the $^3E_{1u}$ state. This is a rather different type of interaction than the above-mentioned slightly deformed case. To examine these points, further studies are necessary from the viewpoint of both theory and experiment. In near future, it is hoped to observe fine structures of the second excited triplet state using some new refined technique.

In previous studies, ZFS parameters were evaluated by using various treatments which do not always give

a satisfactory D value for benzene without some modifications. Concerning this point, however, no detailed explanation was made in such publications, except a paper in which the effect of overlap integrals was non-empirically pointed out.[3] In the present work, such a difficulty is partly reduced by using the approximate orthogonalized AO's which are given by a linear combination of SCF-AO's. Although the present work includes various points to be improved such as spin-spin interaction integrals, orthogonalized AO's, configuration interactions, and so on, the general trend for the calculated D value should not significantly be changed. In view of these facts, the present results may show the fact that for evaluating physical constants such as ZFS parameters using semi-empirical LCAO-MO's with ZDO approximation their basis functions should carefully be chosen without use of the usual AO's.

This work was undertaken in collaborating with Professor M. Kinoshita, The University of Tokyo, in connection with the work on the triplet state of triphenylene.[14] At several stages, the author is indebted to him for his suggestion and discussions. The author also wished to thank Professor Y. Gondo, Kyushu University, for informing the error in a formula of spin-spin interaction integrals appeared in Ref. 17, and Dr. S. Iwata, The Institute of Physical and Chemical Research, for his helpful suggestion. The numerical calculations were carried out on HITAC 8700/8800 at Computer Centre, The University of Tokyo.

The Formation of Amino Acids by the Reactions of Singlet NH with Several Carboxylic Acids

Shigeru TSUNASHIMA,* Takashi KITAMURA, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 3, 1981)

The photolysis of hydrogen azide was studied in liquid acetic acid, propionic acid, and isobutyric acid at room temperature. The formation of amino acids was confirmed by the color reactions with ninhydrin and with chromotropic acid and by the NMR spectra. From the propionic acid, α- and β-alanine were formed in the ratio of 1.5. In the case of isobutyric acid, α- and β-aminoisobutyric acids were formed in the ratio of about 5. These results are explained by the insertion reaction of NH($a^1\Delta$) into the C–H bonds of carboxylic acids.

The formation of NH($a^1\Delta$) has been observed in the photolysis of hydrogen azide with light of wavelengths between 250 and 320 nm.[1] Since NH radicals are isoelectronic with O or CH_2 radicals, it is expected that the reactions of the singlet NH radicals are similar to those of O(^{1}D) and $CH_2(^1A_1)$. Recently, we photolyzed hydrogen azide in liquid paraffin at the temperature of Dry Ice–methanol and found the formation of amines: ethylamine from the ethane solution, propyl- and isopropylamine from the propane solution, and isobutyl- and *t*-butylamine from the isobutane solution.[2,3] These amine formations were explained by the insertion reaction of the singlet NH into the C–H bonds of paraffins.

If the singlet NH inserts into the C–H bonds of hydrocarbons, the singlet NH will insert into the C–H bonds of carboxylic acid to form amino acids. The formation of amino acids on the primitive earth is an interesting problem in the study of prebiotic molecular evolution. The formation of singlet NH has been found in the discharge and vacuum ultraviolet photolysis of ammonia.[4] Since ammonia is known to have been an important component of the primordial atmosphere, the insertion reaction of the singlet NH into the C–H bonds of carboxylic acid, if it occurred, might have been important for the formation of amino acids on the primitive earth.

For these reasons, the photolysis of hydrogen azide was studied in liquid propionic acid, as was shown in a previous letter, and the formation of α- and β-alanine was observed.[5] The present paper will report the details of the previous letter, together with new results obtained with acetic acid and isobutyric acid.

Experimental

The methods of the preparation and purification of hydrogen azide have already been described.[2,3] Acetic acid, propionic acid, and isobutyric acid (Tokyo Kasei Co.) were used after distillation *in vacuo*.

The reaction cell was a Pyrex tube, 10 mm o.d., in which about 2 cm^3 of carboxylic acid and a small amount of hydrogen azide were introduced *in vacuo*. A medium pressure mercury lamp (Toshiba HP 400) was used to illuminate the reaction cell through a transparent quartz Dewar flask filled with distilled water. Since a Pyrex tube was used as a reaction cell, the effective wavelengths absorbed by hydrogen azide were limited within about 280—320 nm.

After the irradiation, non-condensable products at −196 °C were collected with a Toepler pump and their amount was measured with a gas burette. Unreacted hydrogen azide and carboxylic acid were evacuated *in vacuo* at about 50—90 °C. The residue in the cell was dissolved in water and subjected to the analysis by color reactions.[6] A D_2O solution of the residue was analyzed with an NMR spectrometer (JEOL FX 100). The NMR spectra were compared with those obtained with D_2O solutions of glycine, α- and β-alanine, and α- and β-aminoisobutyric acid (Tokyo Kasei Co.). To measure the amount of the products, a known amount of maleic acid was added to the NMR sample, and the integrated intensities were compared.

Results

The non-condensable product at −196 °C was nitrogen. The mass spectrometric analysis showed neither methane nor hydrogen. The yield of nitrogen increased with the increase in the concentration of hydrogen azide and in the irradiation time.

When the solvent was evacuated together with unreacted hydrogen azide, a white solid was left on the

wall of the reaction cell in the cases of acetic acid and propionic acid. In the case of isobutyric acid, the residue was a yellowish liquid. When methanol was added to this liquid, the white solid remained undissolved. The white solid was soluble in water.

In the case of acetic acid solution, the formation of glycine was confirmed by the color reactions with ninhydrin and with chromotropic acid. The color observed for the products agreed well with that observed with an authentic glycine.

The D_2O solution of the residue was subjected to the NMR analysis. The NMR spectra of the products coincided with those obtained with a mixture of amino acids and the reactant acid: glycine with acetic acid, α- and β-alanine with propionic acid, and α- and β-aminoisobutyric acid with isobutyric acid. An attempt to eliminate the reactant acid from the products was not successful. The ratios of the yield of amino acid to that of nitrogen are summarized in Table 1, as functions of the concentration of hydrogen azide and of the irradiation time.

Discussion

As shown in Table 1, the ratios of the yield of amino acid to that of nitrogen were independent of the changes in the concentration of hydrogen azide and in the irradiation time for every case examined. The trend observed is similar to that observed in the photolysis of hydrogen azide in liquid ethylene or propene at the temperature of Dry Ice–methanol.[7] The following mechanism can be considered to explain the results:

$$NH_3 + h\nu \rightarrow NH(a^1\Delta) + N_2 \quad (1)$$

$$NH(a^1\Delta) + CA \rightarrow \text{Amino acids} \quad (2)$$

$$\rightarrow NH(X^3\Sigma^-) + CA \quad (3)$$

$$NH(X^3\Sigma^-) + NH_3 \rightarrow NH_2 + N_3 \quad (4)$$

$$NH_2 + HN_3 \rightarrow NH_3 + N_3 \quad (5)$$

$$2\,N_3 \rightarrow 3\,N_2, \quad (6)$$

where CA is carboxylic acid. Reaction 2 is the insertion reaction of the singlet NH into the C–H bond of carboxylic acid. In the cases of propionic acid and isobutyric acid, α- and β-amino acids are formed, which correspond to the two types of the C–H bonds involved in the carboxylic acid. As shown in Table 1, the β/α ratios in alanine and in aminoisobutyric acid produced were 1.5 and 5.0 respectively; these are very close to the ratios of the numbers of the C–H bonds in the two types. These results agree well with the assumption that the amino acids are formed by the insertion reaction.

Reaction 3 is the quenching of the singlet NH by carboxylic acid. In the above mechanism, the triplet NH is assumed to abstract a hydrogen atom from hydrogen azide. The triplet NH might abstract a hydrogen atom from carboxylic acid:

$$NH(X^3\Sigma^-) + CA \rightarrow NH_2 + R. \quad (7)$$

When the resultant radical, R, was assumed to abstract a hydrogen atom from hydrogen azide:

$$R + HN_3 \rightarrow CA + N_3. \quad (8)$$

Reaction 7 followed by Reaction 8 is indistinguishable from Reaction 4.

In the present experiment, ammonia could not be analyzed, since it was difficult to isolate it from the reactant. If ammonia is formed, an ammonium salt will be formed by the reactions with acid. The ammonium salt may be evacuated together with the reactant and/or will give $RCOO^-$ in the D_2O solution. Thus the NMR spectra of the ammonium salt in D_2O are the same as those of the reactant acid.

According to the above mechanism, (1)—(6), the quantum yields of amino acid (ϕ_a) and of nitrogen (ϕ_n) should have the following relation:

$$\phi_n = 4 - 3\phi_a. \quad (9)$$

Using the values of relative yields (ϕ_a/ϕ_n) shown in Table 1, the quantum yields of amino acid formation can be calculated. The results are shown in Table 2. As are shown in Table 2, the quantum yield of amino acid increased with an increase in the number of C–H bonds in the reactant acid.

TABLE 2. THE QUANTUM YIELDS OF AMINO ACID FORMATION

Reactant	α-Amino acid	β-Amino acid	Total
CH_3COOH	0.52	—	0.52
CH_3CH_2COOH	0.29	0.43	0.72
$(CH_3)_2CHCOOH$	0.13	0.67	0.80

Miller found the formation of amino acids in the electric discharge of a mixture of methane, ammonia, hydrogen, and water.[8] This mixture is considered to be the primordial atmosphere of earth. He considered that α-amino acids are formed by the hydrolysis of cyanohydrin:

$$RCHO + NH_3 + HCN \rightarrow RCH(NH_2)CN + H_2O \quad (10)$$

$$RCH(NH_2)CN + 2H_2O \rightarrow RCH(NH_2)COOH + NH_3. \quad (11)$$

For the formation of β-alanine, he assumed acrylonitrile as the intermediate:

$$CH_2{=}CHCN + NH_3 \rightarrow NH_2CH_2CH_2CN \quad (12)$$

$$NH_2CH_2CH_2CN + 2H_2O \rightarrow NH_2CH_2CH_2COOH + NH_3. \quad (13)$$

Miller also found the formation of carboxylic acids such as formic acid, acetic acid, and propionic acid.[8] Since it is known that the singlet NH radicals are formed in the electric discharge of ammonia,[9] the insertion reaction of the singlet NH into the C–H bond of carboxylic acid might explain the formation of amino acids in Miller's study.

The present study suggests a new possibility of the prebiotic synthesis of amino acids on the primordial earth.

The authers are much obliged to Professors Takeshi Nakai and Yoshihiko Morooka of Tokyo Institute of Technology for the NMR measurements.

Temperature Dependence of the Rate Constants of H and D-Atom Additions to C_2H_4, C_2H_3D, C_2D_4, C_2H_2, and C_2D_2

Ko-ichi SUGAWARA, Kiyoshi OKAZAKI, and Shin SATO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 7, 1981)

The high pressure limiting rate constants of H and D-atom additions to C_2H_4, C_2H_3D, C_2D_4, C_2H_2, and C_2D_2 have been measured in the temperature range from 206 to 461 K by means of the pulse radiolysis-resonance absorption method. Practically no isotope effects due to the deuteration of ethylene and acetylene could be observed. The rate constants were compared with those calculated by the activated complex theory using the potential energy surfaces provided by the *ab initio* calculations. Concerning the isotope effects, very poor agreement was obtained between theory and experiment. This seems to suggest that the assumptions on which the activated complex theory is based have to be reconsidered when it is applied to such reactions as $H+C_2H_4 \rightarrow C_2H_5$ and $H+C_2H_2 \rightarrow C_2H_3$.

The reaction of H-atoms with ethylene has been extensively studied for the last 50 years.[1] The following reaction mechanism is now established:

$$H + C_2H_4 \rightleftharpoons C_2H_5^* \xrightarrow{+M} C_2H_5. \quad (1)$$

Here M stands for the third body for the deactivation of the energized ethyl radicals, $C_2H_5^*$. When H_2 is used as the third body, 200 Torr (1 Torr=133.3 Pa) is probably high enough to suppress the decomposition of $C_2H_5^*$.[2] The reaction of H-atoms with acetylene has also been studied for many years and a similar reaction mechanism has been proposed:

$$H + C_2H_2 \rightleftharpoons C_2H_3^* \xrightarrow{+M} C_2H_3. \quad (2)$$

Recently, we studied the unimolecular decomposition of $C_2H_3^*$[3] and showed that 500 Torr of He is high enough to suppress the decomposition of $C_2H_3^*$. If H_2 is used, 300 Torr may be high enough. In the present paper, we report the high pressure limiting rate constants of these addition reactions in the temperature range 206—461 K. Such measurements were made by Lee *et al.* on the reaction $H+C_2H_4 \rightarrow C_2H_5$[4] and by Payne and Stief on the reaction $H+C_2H_2 \rightarrow C_2H_3$.[5]

Since these addition reactions are relatively simple, the *ab initio* calculations have been carried out for drawing the potential energy surfaces.[6-9] Nagase and Kern predicted the structure of the activated complex for the $H+C_2H_2$ reaction[6] and Nagase *et al.* for the $H+C_2H_4$ reaction.[9] Using this calculated potential energy surface, Nagase *et al.* predicted the kinetic isotope effects in the $H+C_2H_4$ reaction on the basis of the activated complex theory (ACT). We therefore extended our measurement to the reactions with D-atoms and to those with isotopic ethylenes and acetylene, C_2H_3D, C_2D_4, and C_2D_2. A short communication on the $H+C_2H_4$ reaction has already been published.[10]

The kinetic isotope effect is one of the key points when the rate theory of chemical reactions is discussed. The potential energy surfaces calculated for any reactions are not accurate enough to estimate the absolute rate constants;[11] an error of 0.1 kcal/mol (1 kcal=4.184 kJ) introduces a crucial effect on the estimation of the rate constant. For the discussion on the isotope effect, however, such an accurate potential energy surface is not considered necessary.

Experimental

The details of the apparatus and experimental procedures were given in previous papers.[2,12]

The main modification of the apparatus is that the temperature of the reaction system can be controlled in the range from 200 to 500 K. The temperatures lower than room temperature were obtained by letting chilled nitrogen gas flow in a box made of Styroform which surrounds the cell. Higher temperatures were attained by winding the cell with flexible insulated heating tapes. The gas temperature was measured with an accuracy of ±2 K with a copper-constantan thermocouple at the center of the cell prior to each pulse irradiation. Because of the small capacity of the reaction cell and of the simple technique of temperature control, some temperature deviation during a series of measurements (2—3 h) could not be avoided; however, since the rate measurement is finished within 0.1 s, the temperature fluctuation during each measurement may be ignored.

The H_2, D_2 (Takachiho Shoji Co.), and He (Nihon Helium Co.) were used after having been passed through traps filled with molecular sive 4A at 77 K. The C_2H_4, C_2H_2 (Takachiho Shoji Co.), C_2H_3D, C_2D_4, and C_2D_2 (Merck Sharp and Dohme, Canada Ltd.) were used as received. The nominal purities of the last three compounds are 98, 99, and 99%, respectively; these values have been confirmed by gas chromatographic and mass spectrometric analyses.

Results

With a system containing only H_2 or D_2, a very slow decay of H or D-atoms was observed at every temperature. The decay rate increased from 2 to 10 s^{-1} with increasing temperature. This decay may be attributable to the diffusion of the atoms from the optical path. In the presence of a small amount of ethylene or acetylene, the decay of H or D-atoms was far more rapid (10^2—10^4 s^{-1}). A typical oscillogram is shown in Fig. 1. The mixture of 0.212 Torr† C_2D_2 and 595 Torr D_2 was irradiated at 273 K. The lower figure is the first order decay plot of the optical density at 121.6 nm against the reaction time. From this first order decay plot, we can calculate a bimolecular rate constant. All data thus obtained for the reaction of $D+C_2D_2$ are listed in Table 1. When the average of rate constants in each group of measurements is estimated, the deviation due to a small difference of temperature is corrected by using the following formula:

† 1 Torr ≈ 133.322 Pa.

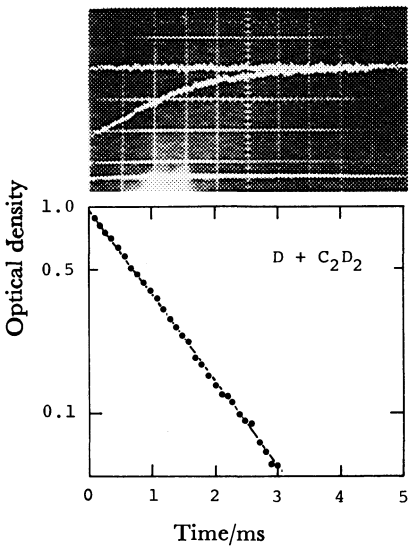

Fig. 1. The oscillogram for the decay of D-atoms in the system of 0.212 Torr C_2D_2 and 595 Torr D_2 at 273 K.

$$k(T+\Delta T) = k(T)[1+(E/R)(\Delta T/T^2)].$$

Here, $k(T)$ is the rate constant at temperature T, E is the activation energy, and R is the gas constant. For the reaction with ethylene, E was assumed to be 2.2

kcal/mol, and for acetylene, 3.0 kcal/mol was used.

For the other nine reactions, similar measurements and calculations were carried out. The rate constants thus obtained are summarized in Table 2 and in Fig. 2 in the form of an Arrhenius plot, together with the results of Lee *et al.* and Payne and Stief. The results of Lee *et al.* are in good agreement with the present ones, while those of Payne and Stief on the $H+C_2H_2$ reaction are in serious disagreement with ours. This discrepancy will be discussed later.

At high temperatures, the total pressure used might not be high enough to obtain the high pressure limiting rate constant. Figure 3 shows the result of this check.

Table 3 summarizes the Arrhenius parameters calculated from Fig. 2 by the least-squares method, in which the weights resulting both from the experimental errors and from the calculation of the logarithms of

rate constants are included. This calculating method was recently discussed by Cvetanovic *et al.*[13] In the previous communication,[10] we did not use this procedure. The Arrhenius parameters reported in the previous communication should be read as those shown in Table 3 of this paper, although the discrepancy is not substantial. It should be noted in this table that practically no isotope effects due to the deuteration of ethylene and acetylene could be observed.

Discussion

Effect of Product Radicals on the Decay of Atoms. One of the most difficult problems in the present experiment is whether or not the produced ethyl or vinyl radicals affect the measurement of the decay of the reacting atoms. It is established that, if the concentration of hydrogen atoms is higher than or comparable to that of the reactant, ethylene or acetylene, the produced ethyl or vinyl radicals participate into the decay of the reacting atoms, and the decay rate of the atoms is thus overestimated.

As Fig. 2 shows, the temperature dependence of the rate constant of the $H+C_2H_4$ reaction obtained is in good agreement with that obtained by Lee *et al.*, but in the case of the $H+C_2H_2$ reaction, the agreement between the present measurement and that by Payne and Stief is very poor; our data is twice as large as theirs at low temperatures and three times larger at high temperatures. This discrepancy has been discussed in a previous paper;[3] its final conclusion was retained because, when the resonance absorption method is used, the concentration of atoms cannot be reduced to lower than 10^{11} cm^{-3}. In the measurement of the rate constant of the $H+C_2H_4$ reaction, Lee *et al.* used the resonance fluorescence method, by which the atomic concentration can be reduced to 10^{10} cm^{-3}. In fact they obtained the rate constants shown in Fig. 2 by using this low concentration of H-atoms.

When we discussed the participation of vinyl radicals in the $H+C_2H_2$ system, the Runge-Kutta integration method was used to estimate the concentration of vinyl radicals. It was concluded that the participation of this radical in the decay of hydrogen atoms is negligibly small at room temperature; however, since the rate constant $k(H+C_2H_2)$ at room temperature is about 3 times slower than $k(H+C_2H_4)$ at room temperature, there remains a small suspicion about the calculation. As is shown in Fig. 2, $k(H+C_2H_2)$ at 400 K is almost in the same order as $k(H+C_2H_4)$ at room temperature; therefore, if the value for k $(H+C_2H_4)$ at room temperature is reliable, the same thing may be said to that for k $(H+C_2H_2)$ at 400 K. On the other hand, all Arrhenius plots obtained in the present experiments are nicely linear. Consequently, we believe that the rate constants obtained here do not suffer from any disturbance due to the participation of product radicals, although we have no proper explanation for the discrepancy between our results and those of Payne and Stief.

The ACT Calculations. In order to calculate the absolute rate constant of an elementary reaction by the ACT, we need the geometrical structure and the normal mode frequencies of the activated complex. For the reactions of $H+C_2H_4$ and $H+C_2H_2$, we have two sets of data for each reaction. The one is that somewhat arbitrarily constructed for the discussion of the uni-

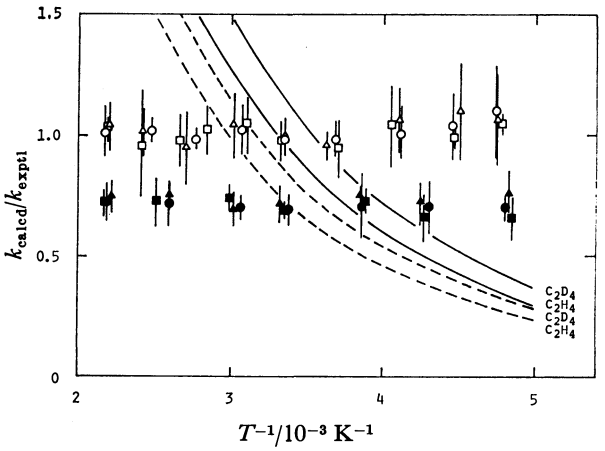

Fig. 4. Comparison of the experimental results with the theoretical calculations, in which the data of Cowfer and Michael are used. For symbols, see the caption of Fig. 2. Solid lines for H-atom reactions and dashed lines for the D-atom reactions.

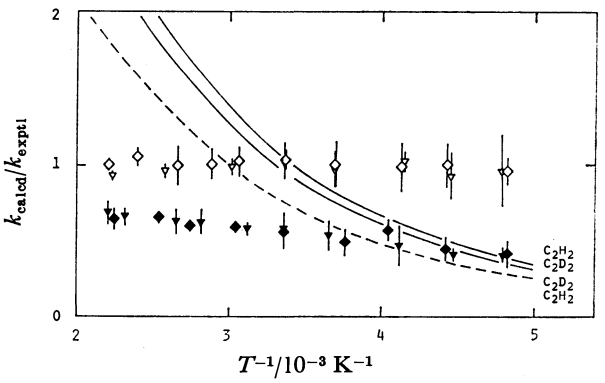

Fig. 5. Comparison of the experimental results with the theoretical calculations, in which the data of Keil *et al.* are used. For symbols, see the caption of Fig. 2. The experimentally obtained rate constant for reaction, $H+C_2H_2$, $k_{exptl}=3.8\times10^{-11}\exp(-2.73/RT)$, is taken as the standard. Solid lines for the H-atom reactions and dashed lines for the D-atom reactions.

molecular decomposition of energized ethyl[14] and vinyl radicals,[15] and the other is the results of the *ab initio* calculations.[6,9]

Figures 4 and 5 compare the experimental results with those calculated by using the parameters estimated for the discussion of the unimolecular decomposition of energized radicals. Here, the experimental rate constants for the $H+C_2H_4$ and $H+C_2H_2$ reactions, $k_{exptl}=4.7\times10^{-11}\exp(-2.18/RT)$ and $k_{exptl}=3.8\times10^{-11}\exp(-2.73/RT)$ respectively, are taken as the standard for each group of reactions, and the k_{calcd}/k_{exptl} ratios are plotted as a function of $1/T$. In these calculations, the barrier heights for the two groups of reactions are adjusted so as to fit the room temperature rate constants for the $H+C_2H_4$ and $H+C_2H_2$ reactions to the experimental ones.

For the convenience of the following discussions, we give the formula used for the calculation of the rate constant:

$$k_{calcd}=\kappa\frac{kT}{h}\frac{F^{\dagger}_{tr}}{F_{atom}F^{1}_{tr}}\frac{f^{\dagger}_{rot}}{f^{1}_{rot}}\frac{f^{\dagger}_{vib}}{f^{1}_{vib}}\exp(-E/RT) \quad (3)$$

$$E=V+\frac{1}{2}\Sigma h\nu_{\dagger}-\frac{1}{2}\Sigma h\nu_{1}. \quad (4)$$

Here V is the barrier height and the other symbols are the same as those appearing in a textbook of reaction kinetics.[16]

In the calculation of the theoretical curves shown in Figs. 4 and 5, the V values are adjusted and found to be 2.83 kcal/mol for the $H+C_2H_4$ reaction and 3.56 kcal/mol for the $H+C_2H_2$ reaction. The transmission coefficient κ is assumed to be unity. As both figures show, the agreement between calculation and experiment is very poor, especially for the temperature dependence.

In the treatment of the unimolecular decomposition of ethyl and vinyl radicals, the activated complexes were assumed to be loose, in order to explain the fall-off pressure.[14,15] In the "loose activated complex," most of the normal mode frequencies are very close to those in the reactants, except for the vibrations newly formed in the activated complex, and their frequencies are considered to be small compared with those in stable compounds. In fact, Cowfer and Michael estimated 120 cm^{-1} for the frequency of the two newly formed vibrations in the activated complex of the $H+C_2H_4$ reaction. The substitution of this value into the vibrational partition function, $f^{\dagger}_{vib}=(1-e^{-h\nu/kT})^{-1}$, gives 2.29 at 300 K. Small vibrational frequencies thus increase the preexponential factor and result in the increase of the adjustable barrier height. This seems to be the main reason for the disagreement between calculation and experiment in Figs. 4 and 5. If the frequencies of the newly formed vibrations in the activated complex could be estimated to be more than 400 cm^{-1} with no effect on the other vibrations, the agreement between calculation and experiment would be much improved.

On the other hand, the recent *ab initio* calculations have suggested that the activated complexes for the reactions of $H+C_2H_4$ and $H+C_2H_2$ have more "tight" structures than those discussed above. The structure

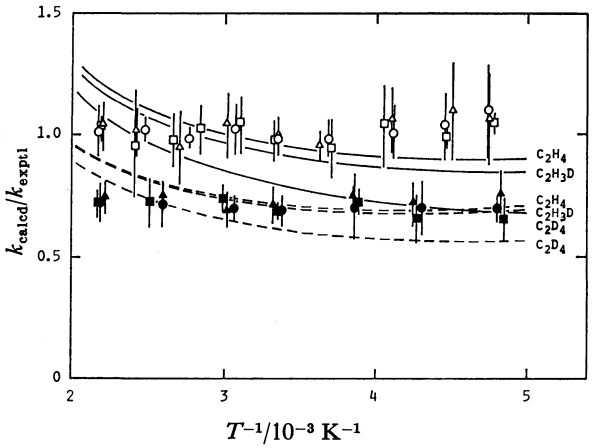

Fig. 6. Comparison of the experimental results with the theoretical calculations, in which the results of the *ab initio* calculations by Nagase *et al.* are used. For the details, see the caption of Fig. 4.

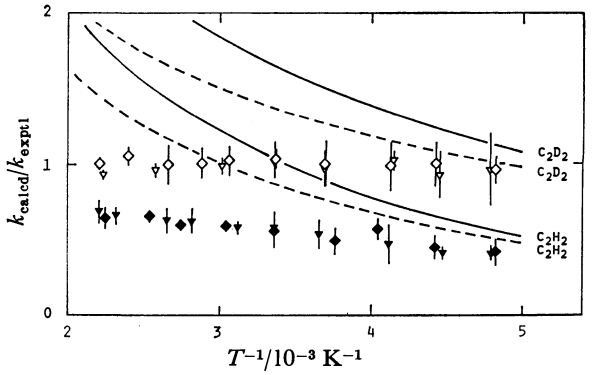

Fig. 7. Comparison of the experimental results with the theoretical calculations, in which the results of the *ab initio* calculations by Nagase and Kern are used. For the details, see the caption of Fig. 5.

and the normal mode frequencies calculated have already been published in previous papers;[3,10] therefore it will not be necessary to restate them. According to these data, the frequencies of the newly formed vibrations in the activated complexes are larger than 400 cm^{-1}, but, along with this increase, other vibrational frequencies are changed and the isotope effects strongly appear. Figures 6 and 7 show the calculated results. In these calculations, the transmission coefficients are estimated by using Wigner's approximation:

$$\kappa=1+\frac{1}{24}(h|\nu|/kT)^2. \quad (5)$$

Here, ν is the imaginary frequency along the reaction coordinate at the top of the barrier. The adjustable V values used in the calculation of the theoretical curves in Figs. 6 and 7 are 2.43 and 2.46 kcal/mol, respectively.

Comparing these figures with Figs. 4 and 5, we can say that the agreement for the temperature dependence between calculation and experiment in Figs. 6 and 7 is better than that in Figs. 4 and 5; however, concerning the isotope effects due to the deuteration of the reactants, C_2H_4 and C_2H_2, the agreement seems to get worse. Another method for the estimation of the transmission

coefficient using an inverted parabola[17] does not improve the situation.

Recently Kupperman and Truhlar developed the generalized transition state theory, in which they stressed that the real activated complex is not necessarily situated on the top of the barrier of the reaction coordinate.[18] This concept was discussed by Horiuchi years ago.[19] This treatment might improve the agreement between the theoretical calculation and experiment; however, as Figs. 6 and 7 show, the isotope effects between C_2H_4 and C_2D_4, and between C_2H_2 and C_2D_2 are so remarkable that filling the gap would be a difficult task.

In 1938, Wigner classified the assumptions on which the ACT is based into three categories:[20] 1) adiabatic condition, 2) quantum effects, and 3) return at the saddle point. The second and third categories have been discussed by many investigators. The transmission coefficient discussed above belongs to the second category. The problem in the third category has been discussed in connection with the trajectory calculation on the atom-diatomic molecule reaction.[21] In the present case, the overshoot of the theoretical curves at high temperatures may be explained by this effect.

Our present impression is that any corrections belonging to the second and third categories cannot improve the agreement between calculation and experiment, especially for the isotope effects due to the deuteration of reactants, and that the first category—adiabatic condition—has to be reconsidered when the ACT is applied to such reactions as $H+C_2H_4$ and $H+C_2H_2$.

On the Continuous Slowing Down Approximation for the Degradation Spectra of Secondary Electrons

Ken-ichi KOWARI and Shin SATO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 28, 1981)

The degradation spectra of secondary electrons produced in helium irradiated with high energy electrons have been calculated by two methods. In the first method, the direct integration of the basic formula was carried out and in the second one, the continuous-slowing-down-approximation (CSDA) was used. When the energy of incident electrons is 1 keV (1 eV=9.648×10⁴ J/mol), the second method gave a *G*-value of ionization, 2.17, while the first method gave 2.29. With the decrease in the energy of incident electrons, the CSDA was found to become less reliable. With the incident electrons of 100 eV, the error in the *G*-value of ionization exceeded 15%. The implication of these calculations to the theoretical treatment of the initial process of radiation chemistry is discussed. As an example, the spatial distribution of ion-pairs in γ-irradiated water has been recalculated.

The degradation spectrum of secondary electrons produced in a material irradiated with ionizing radiations is a useful concept for discussing physical and chemical changes induced by these secondary electrons in the material. However, the numerical calculation of the degradation spectrum is not a simple problem, even when all the inelastic collision cross sections of electrons are known. Consequently, the continuous-slowing-down-approximation (CSDA) has often been used for the calculation.

In the previous papers,[1-4] the theoretical estimation of *G*-values of ionization and excitation has been made on many atoms and molecules by using the CSDA. The calculated *G*-values were found to be in fair agreement with those obtained experimentally. However, we were not confident of these calculated *G*-values, partly because of the CSDA.

The accuracy of CSDA has been discussed by many investigators,[5,6] but few numerical checks have been made.[7,8] Klots and Wright carried out Monte Carlo calculations to obtain accurate degradation spectra in some physical model systems and compared them with those calculated under CSDA. Both spectra apparently coincided with each other, but the implication of these calculations to the theoretical treatment of radiation chemistry was not given. The Monte Carlo calculation is very laborious and time-consuming.

The basic formula for the degradation spectrum has been originally proposed by Fano.[9] The numerical calculation of this formula is not a difficult problem, if the energy of incident electrons is not extremely high and if the material consists of simple atoms or molecules.

In the present paper, we will calculate the exact degradation spectra of secondary electrons in helium irradiated with less than 1 keV electrons and estimate the *G*-values of ionization and excitation. These spectra and the *G*-values will be compared with those calculated by using CSDA. Since all the collision cross sections used in the present calculations are obtained by the classical binary-encounter-collision theory, "the exact degradation spectrum" does not mean the true one but the mathematically exact one.

Theory

The basic form of the degradation equation for secondary electrons is expressed as follows:

$$y(T)\int_{E_0}^{T} k(T,E)\,\mathrm{d}E = \int_{E_0}^{\lambda} y(T+E)k(T+E,E)\mathrm{d}E + \int_{2T+I}^{T_0} y(T')k(T',T+I)\,\mathrm{d}T' + S(T). \quad (1)$$

Here, $y(T)$ is the degradation spectrum at the electron energy T, and $k(T, E)$ is the probability per unit path length that an electron of energy T experiences an energy loss between E and $E+\mathrm{d}E$. This probability is the product of the differential cross section by the number density of molecules in the medium. $S(T)$ is the energy distribution of source electrons. In the present calculations, $S(T)=\delta(T_0-T)$. When an electron induces ionization, we cannot distinguish which electron is the incident electron or the electron originally attached to the medium. In the formulation, we define the electron carrying the larger energy after collision to be the incident one; therefore, the upper limit of the integration range of the first term in the right hand side of Eq. 1, λ, is the lesser of T_0-T and $T+I$, where I is the ionization energy, and the lower limit of the second term is $2T+I$. E_0 is the lowest energy loss resulted from the collision.

It is mathematically possible to obtain the degradation spectrum $y(T)$ by numerically solving Eq. 1, if all inelastic collision cross sections are known; however, since the lowest energy loss E_0 is usually much smaller than that of the incident electron T_0, numerous reiterations for integration are necessary and consume a long time for the calculation even by the use of an electronic computer. In the present calculations, the T_0 is limited to 1 keV. If its energy is increased, the calculation time is increased exponentially.

Continuous-slowing-down-approximation. In 1954, Spencer and Fano showed that, if the inelastic collision cross section is proportional to $(\pi e^4/T)(1/E^2)$ and the lowest energy loss E_0 can be assumed to be much smaller than T, the degradation spectrum for the incident particle is expressed as the reciprocal of the stopping power of the medium for that particle.

The exact degradation equation for the incident particle may be written as follows:

$$y_1(T)\int_{E_0}^{T} k(T,E)\mathrm{d}E = \int_{E_0}^{\lambda} y_1(T+E)k(T+E,E)\mathrm{d}E + S(T). \quad (2)$$

This equation is similar to Eq. 1 except for the second term of the right hand side of Eq. 1, the term which corresponds to the generation of new particles. The result of Spencer-Fano's derivation may be expressed as follows:

$$y_1(T) \approx 1/s(T) = \left[\int_{E_0}^{T} k(T,E)E\mathrm{d}E\right]^{-1}, \quad (3)$$

where, $s(T)$ is the stopping power. Now let us consider that the incident particle is an electron, then $y_1(T)$ calculated above corresponds to the degradation spectrum of the incident electron. Once $y_1(T)$ is calculated, the degradation spectrum of the second generation $y_2(T)$ can be calculated as follows:

$$y_2(T) = \frac{N}{s(T)}\int_{T}^{I/2(T_0-T)}\int_{2T_2+I}^{T_0} y_1(T)\sigma(T_1,T_2)\,\mathrm{d}T_1\mathrm{d}T_2. \quad (4)$$

Here, N is the number density of electrons in the medium and $\sigma(T_1, T_2)$ is the cross section for the formation of electrons with energy T_2 in the collision of electrons with energy T_1. A similar equation for the degradation spectrum of the third generation can be constructed:

$$y_3(T) = \frac{N}{s(T)}\int_{T}^{I/4(T_0-3I)}\int_{2T_2+I}^{T_0} y_2(T)\sigma(T_1,T_2)\,\mathrm{d}T_1\mathrm{d}T_2. \quad (5)$$

The degradation spectrum of all electrons is thus calculated by summing up those of all generations:

$$y(T) = \sum_m y_m(T). \quad (6)$$

Collision-cross-section. All the inelastic collision cross sections used in the present calculations are derived by the classical binary-encounter-collision-theory. These cross sections have been fully discussed in a previous paper.[1] For example, $\sigma(T_1, T_2)$ is expressed as follows:

$$\sigma(T_1,T_2) = \frac{\pi e^4}{T_1+I_1+E_1}\left[\frac{1}{(T_2+I_1)^2} + \frac{4E_1}{3(T_2+I_1)^2} + \frac{1}{(T_1-T_2)^2} + \frac{4E_1}{3(T_1-T_2)^3}\right]. \quad (7)$$

Here I_i and E_i are the binding energy and the average kinetic energy of i-th shell.

G-Values of Ionization and Excitation. Once $y(T)$ is obtained, we can calculate the G-values of ionization and excitation.

$$G_n = \frac{1}{100\ T_0}\int_{E_n}^{T_0} Ty(T)Q_n(T)\,\mathrm{d}\ln T. \quad (8)$$

Here Q_n and E_n are the total cross section and the threshold energy for the excitation process n.

Subexcitation Electrons. In order to discuss the behavior of secondary electrons in the medium, the initial energy distribution of subexcitation electrons is indispensable, which can be calculated by using $y(T)$:

$$N(T)_{T<E_0} = \int_{E_0}^{T+I} y(T+E)k(T+E,E)\mathrm{d}E + \int_{2T+I}^{T_0} y(T')k(T',T+I)\mathrm{d}T'. \quad (9)$$

Results and Discussion

The Degradation Spectra near the Energy of Incident Electrons. Figure 1 shows the $y(T)$ near the source energy, 1 keV. The solid line shows the result of the direct integration of Eq. 1 and the dashed line shows the result calculated under the CSDA. Table 1 summarizes necessary in-put data.

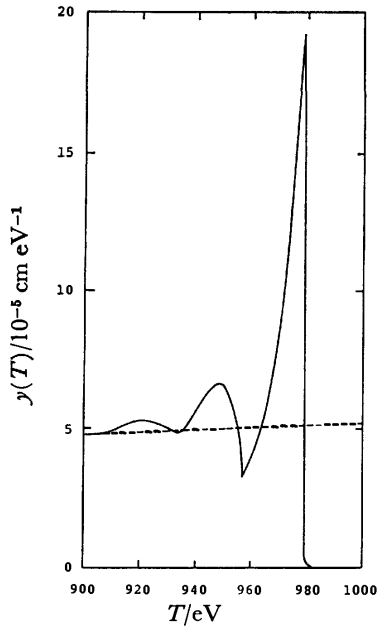

Fig. 1. The degradation spectra of secondary electrons near the energy of incident electrons.
——: Direct integration, – – – –: CSDA calculation.

Table 1. The binding energy (I_i) and the average kinetic energy(E_1) of electrons in helium, and the singlet(E_s) and triplet(E_t) excitation energies of helium in units of eV

I_i	E_1	E_s	E_t
24.581	38.74	21.2	19.8

Since the lowest energy loss accompanying the inelastic collision in helium is the triplet excitation energy, E_t=19.8 eV, no electrons can be produced having energy in the range 980.2 to 999.9 eV. The solid line correctly expresses this transient effect. The oscillations of $y(T)$ for energies near the source energy, which is known as the Lewis effect,[10] is also correctly expressed by the solid line. The spacing between maxima is about 30 eV. On the other hand, the $y(T)$ obtained by using the CSDA does not show such effects. If the detailed structure of $y(T)$ near the source energy is to be included, CSDA cannot be used.

The numerical calculation of such oscillations of $y(T)$ has been carried out by Douthat, who used a different approximate method named SF-2 cord.[6] The general trend of the degradation spectrum he reported is in fair agreement with that obtained here.

The Degradation Spectra and the G-Values of Ionization and Excitation. In Fig. 2 two degradation spectra calculated by the two methods are compared: the solid curve is the result of the direct integration and the dashed one is that calculated under CSDA. Both curves are apparently in good agreement. In the range from 900 to 80 eV, the difference is within a few %, but below 80 eV, the difference increases to about

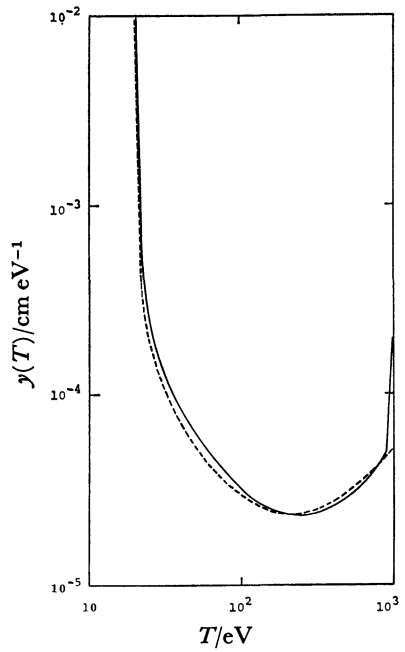

Fig. 2. The degradation spectra of secondary electrons produced in helium irradiated with 1 keV electrons.
——: Direct integration, ----: CSDA calculation.

20%. These calculations depend upon the mesh with which the numerical integration is carried out. For the solid curve, the smallest mesh used was 0.1 eV; with this mesh, the curve obtained was nearly completely converged. For the CSDA calculation, the logarithmic mesh was used; the curve shown in Fig. 2 was obtained with log $(\Delta T/T)=0.01$. With this mesh, the convergion was nearly complete.

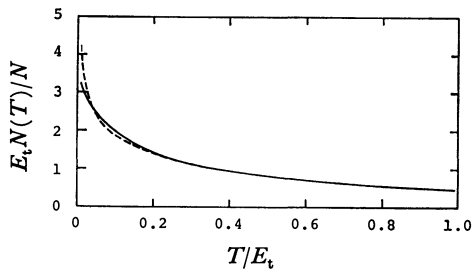

Fig. 3. The initial energy distribution of subexcitation electrons produced in helium irradiated with 1 keV electrons.
——: Direct integration, ----: CSDA calculation.

TABLE 2. THE G-VALUES OF IONIZATION AND SINGLET AND TRIPLET EXCITATIONS CALCULATED BY THE TWO METHODS: DIRECT INTEGRATION (DI) AND THE APPROXIMATE METHOD USING CSDA[a)]

	DI	CSDA
G_{ion}	2.29	2.17
$G_{singlet}$	0.91	0.82
$G_{triplet}$	0.17	0.14

a) Comparison of the calculated G_{ion} with experiment has been made in Ref. 2.

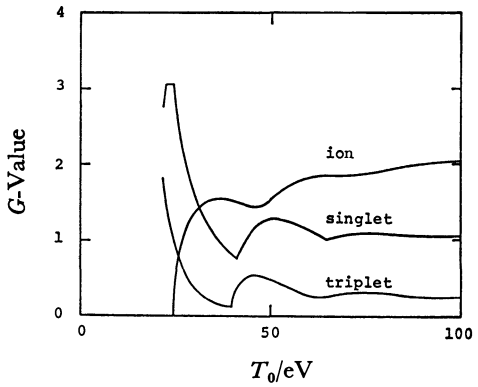

Fig. 4. The source energy dependence of the G-values of ionization and singlet and triplet excitations calculated by the direct integration.

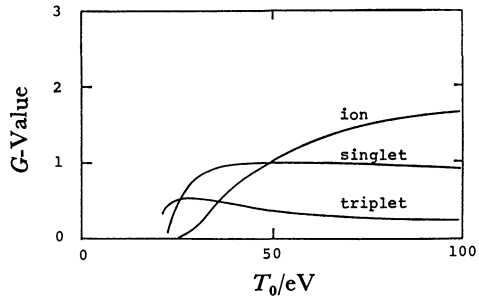

Fig. 5. The source energy dependence of the G-values of ionization and singlet and triplet excitations calculated under the CSDA.

Using these two degradation spectra, we calculated the initial energy distribution of subexcitation electrons and the G-values of ionization and singlet and triplet excitations. The results are shown in Fig. 3 and Table 2. The discrepancy between the CSDA calculation and the direct integration was found in the G-values. The CSDA calculation gave G-values smaller than the direct integration of Eq. 1. This is probably due to the underestimation by the CSDA calculation of $y(T)$ near the threshold energy E_t.

In order to clarify this discrepancy, we calculated the dependence of the G-values of ionization and excitation on the source energy T_0 in the range of 20—100 eV. Figures 4 and 5 show the results. A comparison of these two figures clearly shows that the CSDA calculation underestimates the G-values and that, with the decrease in the source energy, the discrepancy increases. At $T_0=1$ keV, the discrepancy is 6%, while at 100 eV, it increases to 15%.

In a previous paper,[2)] the source energy dependence of the G-values of ionization and excitations of helium was calculated by using the Fowler equation, and curves similar to those in Fig. 4 were obtained. In fact, these two sets of curves coincide exactly with each other. In the actual calculations, the Fowler equation is solved from lower energies, while Eq. 1 is solved from higher energies. The agreement of these sets of curves probably means that the mesh used in these calculations is small enough for the numerical integrations. Incidentally,

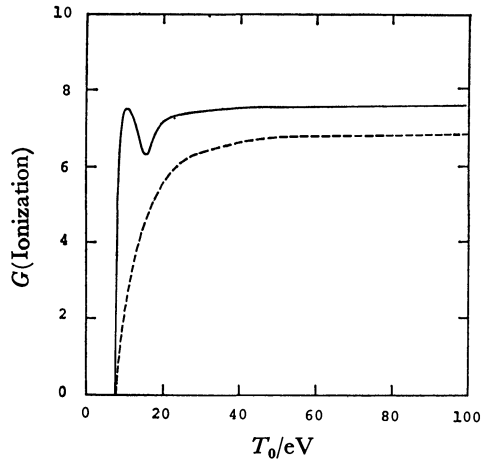

Fig. 6. The source energy dependence of the G-value of ionization in water.
——: Direct integration, ----: CSDA calculation.

it has been proved that the Fowler equation is mathematically equivalent to the Spencer-Fano equation, Eq. 1.[11]

In summary of the above calculations, it may be said that, if the energy of incident electrons is higher than 1 keV, CSDA is accurate enough to estimate the G-value of ionization and excitation; the error limit caused by the use of CSDA is within 6%.

Relative Numbers of Ion-pairs in Different Spurs Generated in the γ-Irradiated Water. In a previous paper,[4] we calculated the spatial distribution of ion-pairs produced in water irradiated with ^{60}Co-γ rays. About 27% of ion-pairs were found to be produced in isolated spurs and another 27% were found in the condensed spurs consisting of more than 100 ion-pairs. In that estimation, we used the source energy dependence of the G-value of ionization calculated under CSDA. As has been discussed above, when the source energy is small, the G-value of ionization is underestimated by the CSDA calculation. We calculated the source energy dependence of the G-value of ionization in water by the direct integration of the Spencer-Fano equation. The result is shown in Fig. 6. By using this result, we recalculated the relative frequencies of spurs in water and the relative numbers of ion-pairs in different spurs. The results are shown in Tables 3 and 4, together with those previously reported. It is noticeable that the agreement between calculation and experiment has been improved.

Table 3. Calculated relative frequencies of spurs in water and relative frequencies of clusters observed in a cloud chamber

Ion-pairs per spur	1	2	3	4	>4
Relative frequency/%	65.7	18.6	6.0	3.1	6.6
(Previously reported)	(73.6)	(11.7)	(5.0)	(3.1)	(6.6)
Ion-pairs per cluster	1	2	3	4	>4
Relative frequency/%					
Source: 25 keV[12]	42.6	22.5	12.4	10.1	12.4

(Received February 16, 1981)

The formation mechanism of spherical particles of various metal oxides through O_2–H_2 flame fusion was investigated. Molten droplets of Al_2O_3 are solidified to form spherical particles having the structure of δ- and θ-Al_2O_3 in the surface layer and α-Al_2O_3 inside. Heat treatment of the spherical particles of Al_2O_3 at temperatures higher than 1573 K gave rise to the transition from δ- and θ-Al_2O_3 to α-Al_2O_3 and made the crystal growth, but no change in the smooth surface structure was observed, contrary to the case of TiO_2 where facetting of the surface occurred on heating. In the cases of NiO and Cr_2O_3, particles bigger than 2—3 μm in diameter are spherical, but smaller ones are apt to form single crystals. With ZnO, SnO_2, and MgO, no spherical particles were formed. It is suggested that amorphous or polymorphous substances easily form spherical particles but monomorphous ones do not. Substances, which can sublime or have higher melting point, do not give pherical particles but only single crystals.

Spherical particles having homogeneous size and smooth surface are important for research on surface and colloidal chemical properties of materials. Recent developments in the preparation of spherical latex particles promoted progress in researches in this field.[1,2] The present authors are interested in the interaction of water molecules with the surface of metal oxides, using samples with a homogeneous surface.[3–6] Recently, we have investigated the surface properties of spherical metal oxides produced by melting the particles in the O_2–H_2 flame,[7,8] as such surfaces may be expected to be homogeneous. It has been found that SiO_2 particles[7] produced by this method have excellent sphericity with smooth surfaces and a dense internal phase. Water adsorption experiments on the SiO_2 particles manifested an improvement of surface homogeneity compared to that of raw Aerosil SiO_2. In the case of TiO_2[8] it has been found that the outer layer of the spherical particles has an anatase structure and the inner part a rutile one; in contrast to SiO_2 there are many cavities inside the particles. Heat treatment of TiO_2 spheres at temperatures higher than 1073 K not only changes the anatase structure in the surface layer into a rutile one, but also promotes facetting of the spherical particle surface and finally splitting of the particles into a few rutile single crystals.

The present paper will deal with high temperature treatment of such metal oxides as SiO_2, TiO_2, SnO_2, Al_2O_3, Cr_2O_3, MgO, NiO, and ZnO in the O_2–H_2 flame and with the formation mechanism of spherical particles.

Experimental

Materials. Two kinds of raw alumina, Al_2O_3-I and Al_2O_3-II were used for the preparation of spherical particles. Al_2O_3-I is the sample pulverized from an α-Al_2O_3 ingot to give a mean particle size of 7 μm. Al_2O_3-II is aluminium oxide-C produced by Degussa; its particles are ultrafine with a particle diameter of about 20 nm; it gives broad X-ray diffraction peaks characteristic of γ-Al_2O_3. MgO powder was produced by Tokyo Electro-Chemical Industry. Both NiO and ZnO were formed by heating each metal oxalate at 873 K in air. Cr_2O_3 was formed by pyrolizing $(NH_4)_2Cr_2O_7$ at 573 K in an N_2 stream. The SnO_2 used was a commercial sample provided by Wako Pure Chemicals. These metal oxide samples were confirmed to contain only one type of crystal structure by X-ray diffraction. In the present work these materials were used without any additional treatment.

Apparatus for Preparing Spherical Particles. The facilities used for the O_2–H_2 flame treatment of metal oxides were the same as those used previously.[7] Metal oxide particles were introduced into the O_2–H_2 flame through the O_2 stream, the flame being generated by burning the mixture of 13 L·min^{-1} O_2 and 20 L·min^{-1} H_2 gases. The temperature of the flame in the furnace was determined to be higher than 2300 K over a 10 cm length from a point 7 cm below the gas nozzle by use of an optical pyrometer together with a siliconit rod. Fused particles were drawn and cooled by pumping through a 3 m duct, which is constructed from duct-1, duct-2, duct-3 of 1 m each (D_1, D_2, and D_3), stainless steel net of 100 mesh (N) and cotten gauze (G). The particles produced were collected at several positions along the flight path.

Examination of Particles. Particles treated in the O_2–H_2 flame were examined by electron microscopic observation by use of a scanning electron microscope JEOL-JSM 35, Au–Pd alloy being deposited in advance on all the samples to avoid the electrification during bonbardment by the electron beam. The particles size distribution histogram was determined by investigating more than 500 particles in electron micrographs. The crystal structure of both the raw and the product particles was established by a powder X-ray diffraction method using Cu $K\alpha$ radiation as well as with a polarizing microscope.

Results and Discussion

Formation of Spherical Al_2O_3 Particles. Figure 1 shows electron micrographs of spherical particles of Al_2O_3-I and Al_2O_3-II. The size of spherical Al_2O_3-I particles captured at any collection point is closely similar to that (6—9 μm) of non-spherical particles of the raw material; this indicates that each raw particle has been sphered individually, *i.e.*, no coalescence has occurred between them. It was also found that no cavity was present in a spherical partcle. On the contrary, spherical particles of Al_2O_3-II were very much larger than raw material particles, *i.e.*, larger than 1 μm (Fig. 1b), indicating the wide particle size distribu-

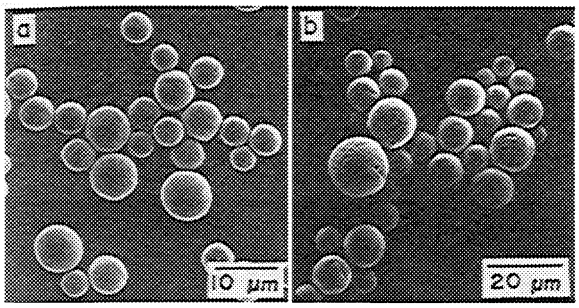

Fig. 1. Scanning electron micrographs for spherical particles of Al_2O_3-I (a) and Al_2O_3-II (b) captured at duct.

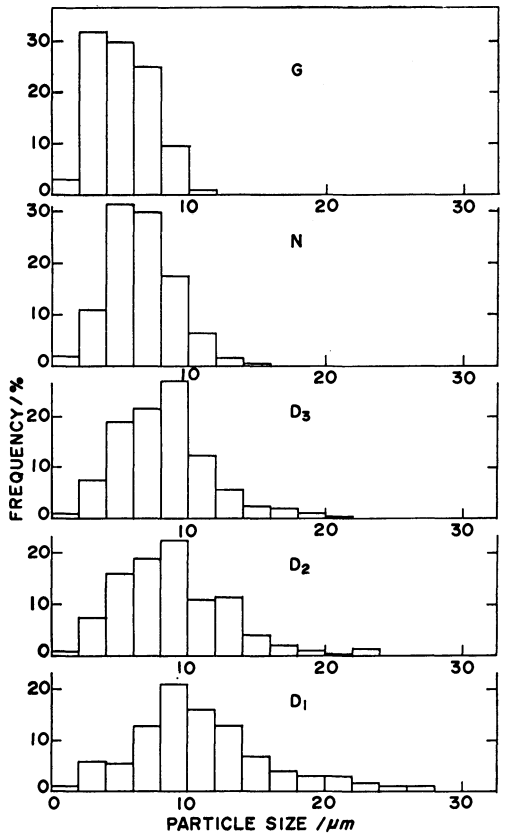

Fig. 2. Dependence of size distribution of Al_2O_3-II spherical particles on the flight distance from the furnace.

tion (Fig. 2). It is also found that the further the collection point, the smaller the mean particle size. Though the Al_2O_3-II particles look perfectly spherical, the inside of the particle is not perfectly fused and has much empty space.

The crystal structure of so formed spherical particles of Al_2O_3-I was examined by X-ray diffraction analysis. Spherical particles formed by passing through O_2–H_2 flame consist of δ- and θ-Al_2O_3, which are stable at lower temperatures, together with small portion of α-Al_2O_3, though the raw material is α-Al_2O_3 (Fig. 3). In the case Al_2O_3-II, these three structures are also observed, but their ratio varies with the collection point of the sample in the duct, α-Al_2O_3 content being much more

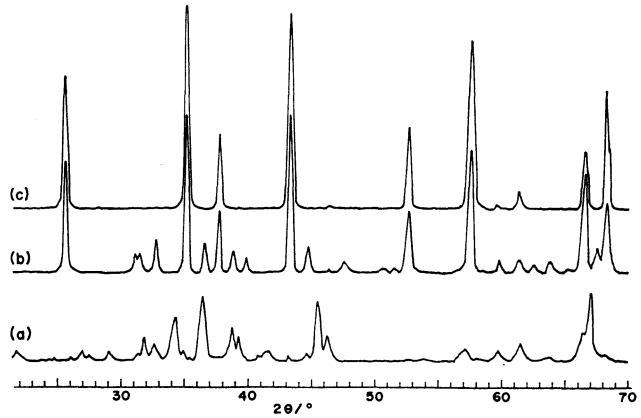

Fig. 3. X-Ray diffraction spectra of spherical Al_2O_3-II particles determined by using the radiation of Cu $K\alpha$.
a: As-grown sample including the crystal structures of α-, δ-, and θ-Al_2O_3, b: 1473 K-treated, α- and θ-Al_2O_3, c: 1573 K-treated, α-Al_2O_3.

than δ- and θ-Al_2O_3 when the particles are collected at duct-1, and less when collected at points far from the furnace, where the ratio of δ-Al_2O_3 to θ-Al_2O_3 was constant throughout the collection points. A similar situation holds also for the sample of TiO_2,[8] where the concentration of rutile exceeds that of anatase in the larger particles. These results can be interpreted as follows. Smaller particles having smaller heat capacity can be quenched so rapidly that crystal forms of δ- and θ-Al_2O_3 appeared in a large amount in the surface layer, while that of α-Al_2O_3 appeared in inner part of particles. On the bigger particles with larger heat capacity the inner part of the spherical particle is rich in α-Al_2O_3.

When the spherical particles of Al_2O_3 are heated for 4 h up to 1373 K, the X-ray diffraction spectrum remains almost unchanged. Upon calcination at 1473 K δ-Al_2O_3 disappeared, θ- and α-Al_2O_3 being left (Fig. 3b). Treatment of the sample at temperatures higher than K led to the complete transition of crystal structure from θ-Al_2O_3 to α-Al_2O_3 (Fig. 3c). Contrary to the TiO_2 particles, however, no facetting of the particle surface was observed upon heat treatment, even at higher temperatures, in spite of the drastic changes in crystal structure. What appeared here was merely a smoothing of the particle surface and charging up of the particle during SEM observation. This might have stemmed from the increased insulation upon dehydration by heat treatment. Polarizing microscope observation of so grown spherical Al_2O_3 particles under crossed nicols showed small spots in a vague back ground, probably because of the polycrystallinity of the particles. After the crystal structures were changed into α-Al_2O_3 by heat treatment, the small spots decreased in number and became brilliant, which indicates that the heated spherical particle has mosaic structure of a few well grown α-Al_2O_3 crystallites, as reported by Nelson *et al.*[9] on Al_2O_3 spheres.

Formation of Spherical Particles of Metal Oxides by Means of O_2–H_2 Flame Treatment. Like SiO_2 and TiO_2 particles, it has been ascertained that spherical particles of Al_2O_3 can be produced through O_2–H_2 flame fusion

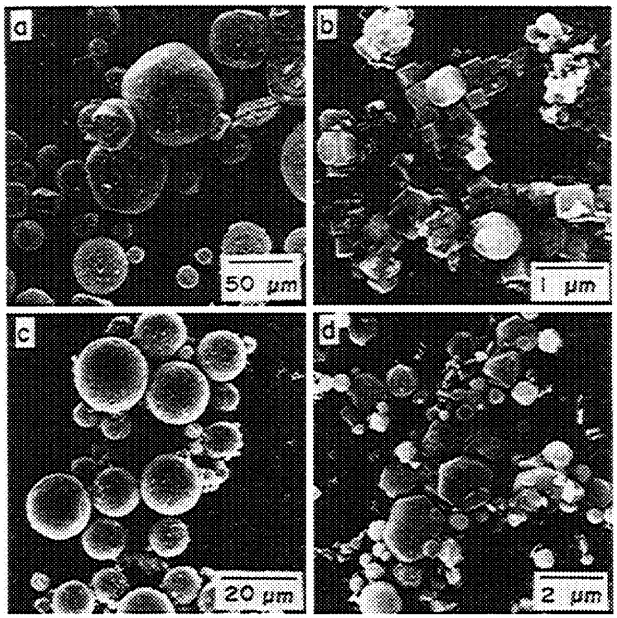

Fig. 4. Scanning electron micrographs for NiO and Cr_2O_3 particles treated through O_2–H_2 flame.
a: NiO at D_1, b: NiO at G, c: Cr_2O_3 at D_1, d: Cr_2O_3 at G.

irrespective of the preparation method of raw materials. However, there are some metal oxide samples that it is difficult or impossible to make spherical. Figure 4 demonstrates electron micrographs for NiO and Cr_2O_3 particles treated in the O_2–H_2 flame. Larger particles of both metal oxides are almost spherical have wrinkles in the surface, but those of NiO having a smooth surface are cubic. With larger particles of NiO, a small amount of contamination by Ni metal was detected by X-ray diffration; this indicates partial dissociation of NiO at higher temperatures. Smaller NiO particles collected on gauze have a characteristic cubic shape; some of them are lacking corners. In the case of Cr_2O_3 particles the shape changed from sphere, through short hexagonal rod, to hexagonal platelet as the size decreased. Inner structure of spheres of metal oxides is similar to that of Al_2O_3 and includes many cavities. It is interesting here that despite the presence of cavities, the NiO particles obtained near the furnace are apt to become cubic. By considering this fact together with the result that apparently spherical having cavities approach the cubic particle by heating at 1473 K (Fig. 5a), it can be understood that a molten NiO particle is apt to take up an ordered arrangement of atoms and to form almost a single crystal sphere. On the other hand, change in the surface structure of Cr_2O_3 spheres upon calcination is very similar to that of TiO_2:[8] heat treatment results in facetting to split a particle into single crystals (Fig. 5b).

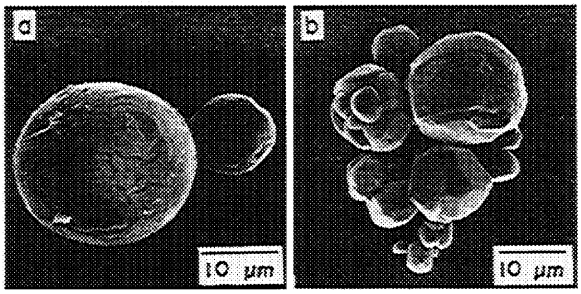

Fig. 5. Scanning electron micrographs for spherical particles of NiO (a) Cr_2O_3 (b) heated at 1573 K for 4 h.

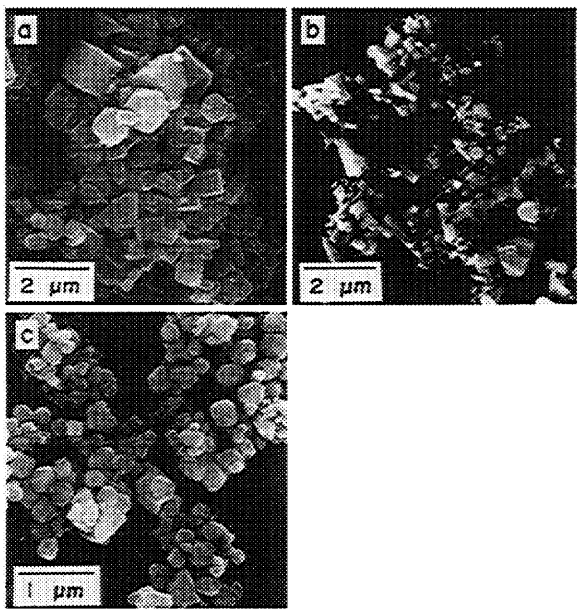

Fig. 6. Scanning electron micrographs for MgO (a), ZnO (b), and SnO_2 (c) particles treated through O_2–H_2 flame and captured at gauze.

When metal oxides such as MgO, ZnO, and SnO_2 were passed through the O_2–H_2 flame, the particles obtained were not spherical but polyhedral, having well defined crystal planes. As shown in Fig. 6, smaller particles collected by gauze are single crystals of each crystal structure of the metal oxides: cubes for MgO, needlelike single crystals with well defined prism planes $(10\bar{1}0)$ for ZnO, similar to those produced by burning Zn metal in air,[4] and polyhedra for SnO_2 in which some particles are octahedral, that is trigonal planes are exposed. Similar particles have been formed by oxidizing SnO vapour at 1423 K in air,[10] where the trigonal face was identified to be the (111) plane by electron diffraction.

As has been discussed above, the possibility whether metal oxide particles formed by the O_2–H_2 flame fusion are spherical or not seems to depend upon the nature of metal oxide. Next, let us consider the reason for this phenomenon on the basis of data shown in Table 1. Using our technique for producing spherical particles, to produce a decrease in the surface free energy of a molten metal oxide particle on sphering, it is necessary that the temperature of the O_2–H_2 flame is higher than the melting point of the sample. With SiO_2, TiO_2, and Al_2O_3, as can be expected from data in Table 1, this condition is found to be satisfied, since spherical particles were obtained.

It would be anticipated that smaller particles would be more easily liquified to give spherical particles than larger ones. With TiO_2 and Al_2O_3, this expectation is

Table 1. Physical properties and sphericity of metal oxides

Metal oxide	$\frac{Mp}{K}$	Crystal structure	Sphericity
Al_2O_3	2320	α-, δ-, θ-Al_2O_3	Yes
TiO_2	2143	Rutile, Anatase	Yes
SiO_2	1883 (quartz)	Amorphous	Yes
NiO	2230	NaCl	Difficult (spheres, single crystallites)
Cr_2O_3	2607 2530 (sublimate)	α-Al_2O_3	Difficult (spheres, single crystallites)
ZnO	2073 (sublimate)	Wurtzite	No (single crystallites)
SnO_2	1898 (sublimate)	Rutile	No (single crystallites)
MgO	3073	NaCl	No (single crystallites)

valid, but with NiO and Cr_2O_3, the inverse is truth. The larger particles are spheres and the smaller ones fine single crystals, though the flame temperature exceeds the melting point. The data in Table 1 lead to a conclusion that one simple rule is involved in the present phenomena. Namely, such metal oxides as SiO_2, TiO_2, and Al_2O_3 which easily form spheres have amorphous or polymorphous structures, while NiO and Cr_2O_3, which have lower ability to produce spheres, are crystallized monomorphously. This interrelationship can be interpreted as follows. First, NiO forms cubic particles not only of the smaller ones but also for the larger ones sedimented in duct 1. Cr_2O_3 particles with fairly large size (4—7 μm) are hexagonal prisms (almost spheres) with about the same length of the diagonal distance and height. That is, these two molten oxides have a strong tendency to form single crystal particles. It is well known that the liquid, at temperatures not much higher than the melting point, is composed of a number of small domains which retain the ordered structures of the solid even below the melting point. In the case of small molten particles of monomorphous metal oxides, it may be considered that the liquid domains of the same quasi-crystal structure unite to control the shape of the particle. Barry *et al.*[11] obtained fine spherical particles of Cr_2O_3 (<0.1 μm) besides hexagonal platelets from CrO_2Cl_2 by the induction plasma torch method. The ease of formation of fine spheres in their experiments seems to differ from that reported here, but this may be explained as follows. They raised the temperature of the furnace to 5000 K which is much higher than that in the present case; the spherical liquid droplets formed would have lost any ordered structure and would be quenched as spherical particles.

Secondly, the molten particles of Al_2O_3 or TiO_2, which are polymorphous, will possibly have a number of domains with different crystal structures just like polycrystalline particles from time to time and from place to place, in contrast to the case of monomorphous oxides. Such a molten particles should be isotropic to form spherical particles due to surface tension. It will easily be understood that the spherical glassy SiO_2 droplet has been solidified as it stands in a liquid state.

ZnO and SnO_2, have sublimation temperatures lower than the flame temperature and therefore no liquid phase is present under our conditions. Thus, it will be reasonable to conclude that particles of these two oxides sublimed to recrystallize as fine single crystallites at relatively lower temperatures. For MgO, the melting point is much higher than the flame temperature; accordingly spherical particles were not formed but the crystal growth of well defined cubic particles proceeded during the O_2–H_2 flame treatment.

(Received February 19, 1981)

The amination of chloromethylated polystyrene (CMPS) and benzyl chloride (BC) with amino alcohols was investigated kinetically in dioxane, *N,N*-dimethylformamide (DMF), and dimethyl sulfoxide (DMSO). The amination rate was related mainly to the branching structure and partly to the pK of amino alcohols; $\Delta G^{\ddagger}$ and $\Delta H^{\ddagger}$ increased in the following order: 2-aminobutanol<1-amino-2-propanol<2-amino-1-butanol<2-amino-2-methyl-1-propanol<tris(hydroxymethyl)methanamine<triethanolamine. The rate was also related to the polarity of the solvent; $\Delta G^{\ddagger}$ and $\Delta H^{\ddagger}$ decreased in the following order: dioxane>DMF>DMSO. The difference in the amination rate between CMPS and BC is also discussed in terms of the activation parameters. The amination rate of the polymer partly containing quaternary ammonium groups (QCMPS) in DMSO was found to be greater than that of CMPS probably owing to the ion-dipole interaction.

The amination kinetics of chloromethylated polystyrene conforms to a second-order rate equation in many cases. However, there are cases where the rate constant increases or decreases during the course of the amination. The reaction of CMPS with 2-amino-1-butanol (AB), for example, followed second-order kinetics in *N,N*-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO).[2)] However, it exhibited self-acceleration in dioxane.[3)] The reactions of CMPS with various amino alcohols containing a primary amino group in the above-mentioned solvents have been investigated in the present study and the same kinetic behavior as that in the reaction with AB is found. Dragan *et al.*[4)] found a self-accelerating effect in the amination of CMPS with such *N*-(hydroxyalkyl) tertiary amines as 1-dimethylamino-3-propanol and 3-dimethylamino-1-propanol in dioxane and *N,N*-dimethylacetamide. The same kind of acceleration was also observed by Luca *et al.*[5)] in the amination of CMPS with *N,N*-dimethyl-2-hydroxyethylamine and *N,N*-bis-(2-hydroxyethyl)methylamine in DMF. Kawabe[1)] noted an example of self-deceleration in the reaction of CMPS with triethylamine (TEA) in DMSO, although the usual second-order kinetics was observed in the reaction in DMF. The reaction of CMPS with triethanolamine (TEOA) in the present study, however, has been shown to exhibit a different kinetic behavior from that with TEA; it follows the second-order kinetics in DMSO and exhibits the self-acceleration in DMF. The amination of benzyl chloride (BC), a low molecular weight species having a chloromethyl group, follows second-order kinetics in all cases. The author has determined the activation parameters of the aminations of CMPS and BC with a view to discussing the dependence of the reaction rate on the species of the amino alcohols, the solvents, and the chlorides (CMPS or BC). The acid-base equilibria of the polyelectrolytes produced by the reactions of CMPS with the amino alcohols have also been investigated.

Experimental

Materials. The chloromethylated polystyrene (CMPS) was prepared and purified as previously reported;[3,6)] chlorine contents of the samples: 22.38—22.89%, degrees of chloromethylation: 0.979—0.984, and mol wts.: 9.65—11.43×10^4. The (*R*)-2-amino-1-butanol was prepared and purified as previously reported.[3)] The triethanolamine used was of analtical grade. The other amino alcohols, triethylamine (TEA), and benzyl chloride (BC) were of reagent grade. Except for tris(hydroxymethyl)methanamine (TRIS), the amino alcohols, TEA, BC, and the solvents were distilled before use and proved to be pure by their refractive indices.

Kinetic Measurements. In the reactions of CMPS and BC with the amino alcohols in dioxane, the initial concentration of chloromethyl groups (b) was 0.040 mol dm^{-3}, while that of the amino alcohol (a) was 0.8000 mol dm^{-3}. It was not possible to examine the reactions with TRIS in dioxane and DMF because of its insolubility. The author also examined the reactions in DMSO of QCMPS, the chloromethylated polystyrene with half of its chloromethyl groups being converted to quaternary ammonium groups. In practice, CMPS (b=0.040 mol dm^{-3}) was first treated with TEA (a=0.020 mol dm^{-3}) in DMSO at 318 K until 48% of chloromethyl group was converted to quaternary ammonium groups, and QCMPS thus obtained was then aminated with the amino alcohols in DMSO at 318 K on the conditions that the initial concentrations of the remaining chloromethyl groups and amino alcohol were 0.017 and 0.170 mol dm^{-3} respectively. In all the kinetic measurements, temperature was kept constant within ±0.1 K and aliquots of a reaction mixture were removed at appropriate intervals, poured into dilute nitric acid, and titrated potentiometrically with a standard silver nitrated solution (1/10 mol dm^{-3}) to determine the concentration of chloride ions produced by the reaction.

Purification of the Polyelectrolytes Produced by the Reactions of CMPS and the Amino Alcohols. The reaction of CMPS (degree of chloromethylation: 0.979) with amino alcohols was carried out in DMSO until the conversion rose to 99%, and each reaction mixture was dialysed in dilute hydrochloric acid (pH 2.0) and lypophilized. Deionized water was used throughout. The polyelectrolytes produced by the reactions of QCMPS with the amino alcohols were also purified by the same procedure.

Acid-Base Titrations of the Amino Alcohols and the Polyelectrolytes. An aqueous solution containing 0.2—0.5 mmol of an amino alcohol was titrated with a standard hydrochloric acid (0.1006 mol dm^{-3}) to determine the pK_a value of the amino alcohol on the basis of the pH value at the midpoint of the titration curve. The acid-base titrations of the polyelectrolytes were carried out with and without the addition of salt. A 50 ml acidic solution of each purified polyelectrolyte, containing about 0.15 mmol of amino alcohol residues and about 0.30 mmol of hydrogen chloride, was titrated with a standard sodium hydroxide solution (0.1007 mol dm^{-3}). To aother

solution containing the same amount of polyelectrolyte and hydrogen chloride (50 ml) 0.1 mol of sodium chloride and 20 ml of DMSO were added; the mixture was diluted with water to 100 ml and was also titrated with the standard sodium hydroxide solution. The addition of DMSO was intended to avoid the deposition of the polymer in a higher pH range. In the foregoing process, deionized and decarbonized water was used, and nitrogen gas was bubbled through the solution during the titration.

Results and Discussion

The reactions of chloromethylated polystyrene (CMPS) and benzyl chloride (BC) with amino alcohols such as 2-aminoethanol (AE), 1-amino-2-propanol (AP), 2-amino-2-methyl-1-propanol (AMP), tris(hydroxymethyl)methanamine (TRIS), and triethanolamine (TEOA) were investigated in dioxane, *N,N*-dimethylformamide (DMF), and dimethyl sufoxide (DMSO).

Reactions in Dioxane. The reactions of BC with AE and AP in dioxane stopped at low fractional conversions. Since the maximum fractional conversion in the reaction with AE was only 0.1, it was difficult to determine the reaction rate exactly. It was proved, however, that the reaction rates of BC with AP and AMP in dioxane conformed to the following second-order rate equation:

$$kt = \frac{1}{a-b}\ln\frac{b(a-x)}{a(b-x)} = \frac{1}{a-b}\ln\frac{1-\alpha}{1-\beta} \equiv kt, \qquad (1)$$

where a and b are initial concentrations of an amine and the chloromethyl group respectively, while x is the concentration of the chloride ions produced at time t, and $\alpha=x/a$ and $\beta=x/b$. On the other hand, the reactions of CMPS with AE, AP, and AMP, which proceeded nearly to completion, were found to conform to Eq. 2:

$$k = k_0(1+m\beta), \qquad (1)$$

where k is the apparent rate constant obtained by Eq. 1, and where k_0 and m are constants. Kawabe and Yanagita[3] found similar self-acceleration with respect to the reaction of CMPS with 2-amino-1-butanol (AB) in dioxane, and the author attributed such acceleration to the intramolecular hydrogen bonding between the hydroxyl group of the already-aminated neighbor and the chlorine of the chloromethyl group in the transition state.[1] The observed value of m were 2.0 for AE, 1.9 for AP and 0.9 for AMP, whereas the m value for AB was 1.2. The m value decreases in the following order; AE>AP>AB>AMP, and this order conforms to the branching structures of the amino alcohols. Since the m value is a measure of the acceleration, the foregoing suggests that the more complex the branching structure, the more the formation of the hydrogen bond is sterically obstructed.

The k values of BC and the k_0 values of CMPS are listed in Table 1. No further kinetical analysis was performed for the reactions of CMPS with AE and AP because of the deposition of the polymer beyond $\beta=0.5$. The process of the reaction of CMPS with AMP which proceeded in a homogeneous system was found to be represented by Eq. 3:

$$\beta = 1 - A'\exp(-3k_1at) - B'\exp(-k_2at), \qquad (3)$$

where $A'=(k_1-k_2)/(3k_1-k_2)$ and $B'=2k_1/(3k_1-k_2)$. The author[1] found the reaction of CTPS with AB in dioxane to follow closely the same equation. The exact values of k_1 and k_2 are determined by correcting the approximate values of k_1 and k_2 obtained as slopes of the plot of kt against t, which is represented approximately by two lines intersecting at the point corresponding to $\beta=1/3$; the correction of the k_1 and k_2 values was made by means of the repeated computation of the equations:[1]

$$k_2t = -\ln X'/a \equiv \overline{k_2t}$$
$$X' \equiv [(1-\beta)-A'\exp(-3k_1at)]/B' \qquad (4)$$
$$k_1t = -\ln Y'/3a \equiv \overline{k_1t}$$
$$Y' \equiv [(1-\beta)-B'\exp(-k_2at)]/A'. \qquad (5)$$

The observed β values of the reaction of CMPS with AMP fall exactly on the line computed on the basis of Eq. 3 as shown in Fig. 1. This suggests that the self-acceleration in the reaction of CMPS with AMP can be explained by the same mechanism as in the case of the reaction with AB. Table 1 indicates that the k_1 value agrees with the k_0 value (for AMP) with the k_0 values being equal to the k values of BC (for AP and AMP). In Table 1 are also listed the activation energies (E_a) and the frequency factors (A) which are computed by means of the least-squares method on the basis of the equation:

$$\ln k = \ln A - E_a/RT. \qquad (6)$$

The k_0 value decreases and the E_a value increases in the following order: AE, AP, (AB),[1] AMP. Arrhenius plots for the amination of CMPS are shown in Fig. 2, where dotted lines are calculated in accordance with Eq. 6.

Reactions in DMF and DMSO. The reactions of CMPS, with AE, AP, AMP, and TRIS in DMF and DMSO all comformed to the second-order rate equation, Eq. 1, as in the case of BC. The values of the rate constant (k), E_a and A are tabulated in Tables 2 and 3. Arrhenius plots for the amination of CMPS are shown in Figs. 2 and 3, where solid lines are calculated in accordance with Eq. 6.

○: Observed values, ——: calculated values.

The reactions of BC with TEOA in DMF and DMSO and that of CMPS with TEOA in DMSO, all of which proceeded in a homogeneous system, conformed to Eq. 1. The reaction of CMPS with TEOA in DMF exhibited the self-acceleration represented in the form of Eq. 2 up to $\beta=0.5$ with the m value of 0.8. In the process, deposition of the polymer was observed with the progress of the reaction due to cross-linking as reported by Luca *et al.*[7] and Drăgan *et al.*[8] The values of k or k_0, E_a, and A are listed in Table 4. Arrhenius plots for the amination of CMPS are shown in Figs. 2 and 3.

The reaction of CMPS with triethylamine (TEA) was found by the author to follow second-order kinetics in DMF and self-decelerate in DMSO.[1] The difference

in kinetic behavior between TEOA and TEA, which are both tertiary amines, may be due to the presence of hydroxyl groups in TEOA. The self-acceleration in the reactions of CMPS with amino alcohols in dioxane may be attributed to the formation of the intramolecular hydrogen bond between the hydroxyl group of the already aminated neighbor and the chlorine of the chloromethyl group at the transition state. The formation of the bond does not take place in DMF and DMSO which are much more polar solvents than dioxane. This does not preclude the possibility of the bond formation in DMF in the case of TEOA with three hydroxyl groups. The author suggested that the deceleration during the reaction of CMPS with TEA in DMSO can be ascribed to the electrostatic effect of the quaternary ammonium groups formed in the polymer.[1] In the case of TEOA, pK_a of the quaternary ammonium groups is made to decrease by the hydroxyl groups as described later, so that their electrostatic effect must be insufficient to cause the deceleration.

Reactions of QCMPS in DMSO. The treatment of CMPS with a limited amount of TEOA (equivalent to half the chloromethyl groups) in DMSO yielded the polymer composed of 48 mol% quaternary ammonium groups and 52 mol% chloromethyl groups (QCMPS). QCMPS thus obtained was made to react with the amino alcohols in DMSO at 318 K. The reaction proceeded to completion (β=0.99) in conformity with Eq. 1. The reaction rate constants of QCMPS are compared with those of CMPS in Table 5, which indicates that k of QCMPS (k_{QCMPS}) is two or three times as large as k of CMPS (k_{CMPS}). This may be because the positive charges of the quaternary ammonium groups in QCMPS attract amino alcohol molecules by an ion-dipole interaction thereby increasing the local concentration of amino alcohol and hence increasing the reaction rate.

Table 5. Comparison of amination rate constants, k, in DMSO at 318.2 K between QCMPS and CMPS

TRIS	5.53	1.87	3.0

a) The k values at 318.2 K computed on the basis of the equation $k=A\exp(-E_a/RT)$, by the use of the E_a and A values given in Table 3. b) E_a=51.08 kJ mol^{-1} and log A=5.350.[2]

Activation Parameters. The activation parameters, ΔH^*, ΔS^*, and ΔG^*, of the reactions of CMPS and BC with the amino alcohols are summarized in Tables 6—8. The difference in ΔG^* between CMPS and BC is generally small. In each solvent, the magnitude of ΔG^* of CMPS or BC depends on the species of amino alcohols, increasing in the following order:

$$\text{AE} < \text{AP} < \text{AB} < \text{AMP} < \text{TRIS} < \text{TEOA}.$$

This order of ΔG^* in each solvent corresponds to the order of ΔH^*; the difference in ΔG^* among the amino alcohols is mainly ascribed to the difference in ΔH^*, since the difference in ΔS^* is slight. It seems that the difference in ΔG^* or ΔH^* is largely due to the structural differences of the amino alcohols in question. Since the pK_a of the amino alcohols composed of monohydric alcohol (AE, PA, AB, and AMP) are similar to each other (refer to the pK_a values in Table 10), the difference in ΔG^* among the amino alcohols is ascribed to the difference in their structures. That is to say, the differ-

ence in the branching structure of the hydroxyalkyl group may produce the difference in the steric hindrance of the benzene ring to the group in the transition state. Kawabe and Yanagita[9] reported on this kind of structural effect on $\Delta G^{\ddagger}$ in regard to the reactions of CMPS and BC with butylamine isomers in DMF; $\Delta G^{\ddagger}$ increases in the following order: butylamine< isobutylamine<*s*-butylamine<*t*-butylamine. The higher $\Delta G^{\ddagger}$ values for TRIS and TEOA may be ascribed not only to their increased steric hindrance but also to their decreased basicity, as indicated by the lower pK_a values (refer to the pK_a values in Table 10). Both $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values of CMPS are lower than those of BC for the amino alcohols composed of a monohydric alcohol, while the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values of CMPS are higher than those of BC for the amino alcohols with three hydroxyl groups, TRIS and TEQA.

Review of Tables 6—8 with respect to the solvent effect on the activation parameters reveals that for each amino alcohols examined, $\Delta G^{\ddagger}$ is higher in dioxane than in DMF due to higher $\Delta H^{\ddagger}$ and lower $\Delta S^{\ddagger}$ in the former. The fact that $\Delta G^{\ddagger}$ is higher in DMF than in DMSO is mainly due to the higher $\Delta H^{\ddagger}$ in the former. The author reported a similar solvent effect for primary alkylamines such as butylamines[9,10] and for amino alcohols such as AB[2] and diethanolamine.[11]

It is to be noted that $\Delta G^{\ddagger}$ is a linear function of the electrostatic factor of the solvent, EF, for the amination of CMPS and BC with AE, AP, AB, and AMP, and the slopes of the lines range (−0.52)—(−0.61); EF is the product of dielectric constant, ε, and dipole moment, μ. It takes on values of 1 for dioxane, 140 for DMF, and 209 for DMSO.[12] The plots of $\Delta G^{\ddagger}$ against the Hildebrand solubility parameter, δ, or against δ^2, are also approximately linear; the δ values were calculated on the basis of the equation, $\delta=[(\Delta H^{v}-RT)\rho/M]^{1/2}$, where ΔH^{v} is the heat of vaporization of a solvent with molecular weight M and density ρ, taken to be 40.3 for dioxane, 49.3 for DMF and 54.4 kJ$^{1/2}$ dm$^{-3/2}$ for DMSO at T=298.2 K.[13] However, the plot of $\Delta G^{\ddagger}$ against $1/\varepsilon$ or $(\varepsilon-1)/(2\varepsilon+1)$ is not linear. These results, in addition to the dependence of the change in $\Delta G^{\ddagger}$ on the change in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ mentioned above, suggest that the solute-solvent interactions, notably the solvation of the activated complex, are controlling factor of the rate of the amination of CMPS or BC.

Comparison of the activation parameters of CMPS with those of BC in Tables 6—8 shows the polymer effects described below, where the difference in the activation parameters ($\Delta X^{\ddagger}$: $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, $\Delta G^{\ddagger}$) between CMPS and BC is represented by $\delta\Delta X^{\ddagger}(=\Delta X_{\mathrm{CMPS}}-\Delta X_{\mathrm{BC}})$:

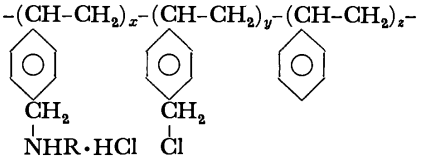
(1) $\delta\Delta H^{\ddagger}$ are negative for the reactions with the amino alcohols composed of a monohydric alcohol (AE, AP, AB, and AMP) in dioxane, DMF and DMSO ($-\delta\Delta H^{\ddagger}$=1—2 kJ). This is also the case with the reactions with primary, secondary, and tertiary alkylamines such as butylamines,[9,10] diethylamine,[11] and TEA.[1] Negative $\delta\Delta H^{\ddagger}$ values may due to some energetic interactions between the polymer skeleton and the alkyl or hydroxyalkyl group of the amine or amino alcohol molecule at the transition state.

(2) The reactions with the amino alcohols and alkylamines described in paragraph (1) above all exhibit negative values of $\delta\Delta S^{\ddagger}$ in DMF and DMSO ($-T\delta\Delta S^{\ddagger}$=1—3 kJ). In DMF and DMSO, the solvation of the activated complex is an important factor in determining the amination rate of CMPS or BC, and this solvation works to decrease $\Delta G^{\ddagger}$ in DMF and DMSO. The negative value of $\delta\Delta S^{\ddagger}$ in DMF and

DMSO appears to have resulted from the steric hindrance to the solvation in the polymer. This is evident from the results of the author's study[10,14] on the reactions with AB and the butylamines, isobutylamine and *s*-butylamine, in DMF-dioxane binary system, which showed that $T\Delta S^{*solv}$ (ΔS^{*solv}: the entropy of the solvation of the activated complex) of CMPS was lower some 2 kJ than that of BC. The $\delta\Delta G^*$ values of all these reactions in DMF and DMSO are slightly positive, since the $T\delta\Delta S^*$ values are lower than the $\delta\Delta H^*$ values. On the other hand, the $\delta\Delta G^*$ are zero or otherwise slightly on the negative side in dioxane, since its solvation effect is much smaller than that of DMF or DMSO.

(3) The reactions with TEOA and TRIS in DMSO and the one with TEOA in DMF are characterized by the positive values of both $\delta\Delta H^*$ and $\delta\Delta S^*$; the magnitudes of $\delta\Delta H^*$ and $\delta\Delta S^*$ in DMSO are greater than those in DMF. Both amino alcohols contain three hydroxyl groups and it is expected that they are strongly solvated in DMF and DMSO. Considering that both ΔH^* and ΔS^* of CMPS are higher than the respective values of BC, it is quite reasonable to assume that the desolvation is required for the activated complex to form in the polymer.

Elementary Analysis of the Polyelectrolytes. The polymers obtained by the reaction of CMPS with the amino alcohols (AMPS) were dialysed in diluted hydrochloric acid and lypophylized. The composition of AMPS is represented by:



where –NHR represents the amino alcohol residue composed of secondary amino group and the residue is assumed to form monohydrochloride. The reaction of CMPS with TEOA produces the quaternary ammonium chloride residue ($-NR_3Cl$). The mole fractions, x, y, and z, were determined by the following equations:

$$\left.\begin{aligned} x &= r_c r_a \\ y &= r_c(1-r_a) \\ z &= 1-r_c \end{aligned}\right\}, \qquad (7)$$

where r_c is a fractional conversion in the chloromethylation of polystyrene and r_a that in the amination of CMPS. The mole fractions were $x=0.97$, $y=0.01$, and $z=0.02$ for all the AMPS polymers shown in Table 9, in which the data of elementary analysis are listed.

The best agreement of the found and calculated values in Table 9 is shown for the reaction product from TEOA. The agreement is fairly good for the other AMPS polymers, though the found nitrogen content is a little lower than the calculated one for the AMPS polymers from EA and PA. The result suggests that the reaction of CMPS with the amino alcohols scarcely induce such a side reaction as an intramolecular reaction of the chloromethyl groups with the neighboring amino alcohol residues in the polymer.

Acid-Base Equilibria of the Polyelectrolytes. A 50 ml acidic solution of AMPS containing about 0.15 mmol amino alcohol residues was titrated with a standard sodium hydroxide solution (1/10 mol dm^{-3}). The titration curves of the AMPS polymers containing AB, AMP, TRIS, and TEOA residues are shown in Fig. 4. The titration curve of the AMPS polymer containing AB residues in the absence of salt gives an inflection point at a higher pH range, and another inflection point is observed in a lower pH range in the presence of salt (Fig. 4A). The acid-base equilibria of the AB residues are represented by the titration curves in a region between the two inflection points. Similar titration curves were obtained for the AMPS polymers

TABLE. 9 ELEMENTARY ANALYSIS OF THE POLYELECTROLYTES PRODUCED BY THE AMINATION OF CMPS[a,b]

Amine		C(%)	H(%)	N(%)	Cl(%)	O(%)
AE	Found	61.88	6.95	5.40	19.61	6.16
	Calcd	62.21	7.54	6.43	16.47	7.35

a) The found values are the ones corrected for water contents. b) The calculated values are the ones calculated on the basis of the fractional conversions by means of Eq. 7.

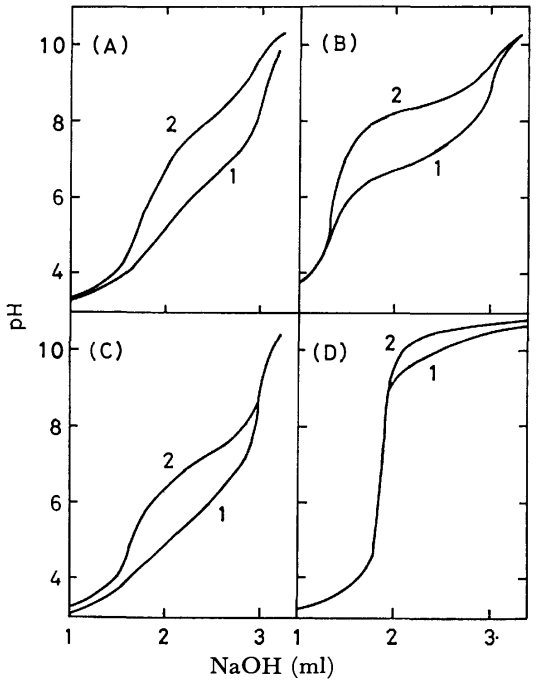

Fig. 4. Titration curves of the polyelectrolytes (AMPS) produced by the amination of CMPS with (A) AB, (B) AMP, (C) TRIS, and (D) TEOA.
Curve 1: In the absence of salt, Curve 2: in the presence of NaCl (1 mol dm^{-3}).

prepared from AE and AP. Since the pK_a of AMP residue is higher than that of AB residue, the titration curve in the absence of salt in Fig. 4B has two inflection points. In contrast, the curve in the presence of salt in Fig. 4C has two inflection points due to the fact that the pK_a of TRIS residue is lower than that of the AB residue. On the other hand, the inflection point does not appear in Fig. 4D in a higher pH range, as expected from the fact that TEOA produces a strong basic quaternary ammonium residue.

The acid-base equilibria of these AMPS polymers, except for the one from TEOA, can be described by the modified Henderson-Hasselbach equation:

$$pH = pK_m - n'(1-\alpha_i)/\alpha_i, \quad (8)$$

where α_i is the degree of dissociation of the conjugated acid of the amino alcohol residue, n' is a constant, and pK_m is the pK_a value at $\alpha_i=0.5$. The results are summarized in Table 10, where the pK_a values of the amino alcohols are also listed. The values of n' were 1.8—2.0 in the absence of salt and 1.5—1.7 in the presence of salt, except for the polymer from AMP (n' was close to unity). The addition of sodium chloride (1 mol dm^{-3} concentration) weakens the electrostatic field effect and pK_m becomes higher ($\Delta pK_m=1.1$—1.6). The difference between the pK_a value of an amino alcohol and the pK_m value of the corresponding AMPS in the presence of the salt becomes smaller in the following order: AE>AP>AB>AMP>TRIS ($\Delta pK=pK_a-pK_m=1.7$—1.2). Since this order is related to the branching structure of the amino alcohol residue, it may be that the branching structure has the shielding effect on the electrostatic interaction or that it lowers the local dielectric constant around the amino group thereby decreasing the effective charge of the the charged group. The reason that the pK_m value of AMPS does not agree with the pK_a value of the corresponding amino alcohol is to certain extent explained by the amino alcohol residue being combined with the benzyl group. pK_a are found in certain cases to decrease by about unity due to the effect of the benzyl group.[15] The pK_m of the TEOA residue is greater than the pK_a value of TEOA, because TEOA combines with the benzyl group to form the strong basic quaternary ammonium group. Neverthless, the pK_a of the TEOA quaternary ammonium residue is lower than that of the TEA quaternary ammonium residue ($pK_m>11$) because of the inductive effect of the hydroxyl groups in the former residue. Table 10 also lists the pK_m values of QAMPS or the amino alcohol residues of the reaction products of QCMPS and the amino alcohols in the presence of salt. They are found to be practically identical with those of AMPS.

TABLE 10. THE pK VALUES OF THE AMINO ALCOHOLS AND THE POLYELECTROLYTES

Effect of Pressure on Charge-transfer Spectra and Equilibria in Solutions of Tetracyanoethylene and Styrene Derivatives

Yasuhiro UOSAKI, Masaru NAKAHARA,* Muneo SASAKI, and Jiro OSUGI

Department of Chemistry, Faculty of Science, Kyoto University, Oiwake-cho, Kitashirakawa, Sakyo-ku, Kyoto 606

(Received May 11, 1981)

Charge-transfer spectra of *trans*-stilbene–, *cis*-stilbene–, 1,1-diphenylethylene–, and α-methylstyrene–TCNE mixtures in chloroform and in 1,2-dichloroethane have been measured at high pressures at 25 °C. The spectra shifted to a lower energy (red shift) with increasing pressure, the two bands in each complex shifting almost in parallel to each other. The shifts are qualitatively interpreted by McRae's theory. The spectral changes in intensity with pressure was analyzed taking account of reversible formation of the EDA complex and 1,4-cycloadduct; only the complex was formed in the stilbene systems. Volume changes for the complex formation are in the range of −4 to −7 $cm^3\ mol^{-1}$ and those for the cycloaddtion are in the range of −23 to −30 $cm^3\ mol^{-1}$. The latter slightly increase in magnitude when solvent is changed from chloroform to a more polar solvent, 1,2-dichloroethane.

Disappearance of red color in dichloromethane solution of styrene and tetracyanoethylene (TCNE) was discovered at a high pressure of about 8 kbar (1 bar=0.1 MPa) half a decade ago.[1] The observation has led to finding a new 1,4-cycloaddition between styrene and TCNE with the aid of the quenching method; the electron-donor-acceptor (EDA) complex is transformed to the cycloadduct by the application of pressure.[2,3] Effects of substituents in styrene, solvent polarity, and temperature on the found 1,4-cycloaddition have been investigated to elucidate the reaction mechanism from a kinetic point of view in a series of papers.[4-6] A short paper has been published where effect of pressure on the 1,4-cycloaddition between α-methylstyrene and TCNE in 1,2-dichloroethane is studied.[7] In the present paper, charge-transfer (CT) spectra of *trans*-stilbene–, *cis*-stilbene–, 1,1-diphenylethylene–, and α-methylstyrene–TCNE mixtures in chloroform and in 1,2-dichloroethane have been taken at high pressures and spectral changes in intensity are analyzed by taking account of chemical equilibria involved in each system. The pressure effect allows us to know the volume change accompanying the reversible 1,4-cycloaddition without measuring the partial molal volumes of the reactants and product; in this case, direct density measurements can not be carried out on the product because it is not isolated. The large effect of pressure on the 1,4-cycloaddition is well established here; a decrease of 10—12% in volume accompanies the cycloaddition where two bonds are formed between the component molecules.

Experimental

TCNE, α-methylstyrene, 1,1-diphenylethylene, and *trans*- and *cis*-stilbenes were purified by the method described elsewhere.[3] Solvents were purified by the standard method.

Electronic absorption spectra were recorded on a Shimadzu UV-200S spectrophotometer at 1 bar and on a Union Giken RA-405 spectrophotometer at high pressure. All the other apparatuses and procedures for spectroscopic measurements at high pressure were the same as those in the previous work.[3]

The formation constants for the EDA complex and 1,4-cycloadduct were determined from absorbance of the EDA complex at the first charge-transfer band at each pressure at 25°C. The temperature was regulated to ±0.1 °C and the pressure was measured within ±1%. The concentration of the donor was always much larger than that of TCNE. The concentrations of the donor and the acceptor at high pressure were corrected for compression by using the Tait equation for the solvents.[8]

The partial molal volumes of α-methylstyrene in several solvents were determined by the method described in the previous work.[6]

Results and Discussion

Charge-transfer Spectra. Some typical electronic absorption spectra of the complexes studied here in the visible region are shown in Figs. 1—4 as a function of pressure. Two kinds of intermolecular charge-transfer transitions occur in each complex, while in Figs. 2 and 3, the second transition band lying at a higher energy is markedly obscured by the absorption due to the donor. The band multiplicity can arise from electron donation from the two highest occupied levels in the donor or from electron acceptance at the two lowest unoccupied levels in the acceptor.[9] The latter is not the case in the complexes of TCNE with these styrenes, because the difference in energy between the maxima ($\tilde{\nu}_{max,1}$ and $\tilde{\nu}_{max,2}$) of the first and second bands is dependent on the

donors.[10,11] Each band maximum shifts toward a lower energy (red shift) with increasing pressure, as found in other EDA complexes.[12] The frequency shifts between 1 and 1500 bar are in the range of −200 to −400 cm^{-1} kbar^{-1}. Causes for the red shift are pressure-induced increases in the refractive index and dielectric constant of the solvent according to McRae's theory.[13] The excited state much polar than the ground state is stabilized more at higher pressures, and as a result, the energy gap between the ground and excited states is reduced to some extent by pressure. The difference between $\tilde{\nu}_{max,1}$ and $\tilde{\nu}_{max,2}$ is independent of pressure within an experimental uncertainty of 10^2 cm^{-1} as follows; $(\tilde{\nu}_{max,2}-\tilde{\nu}_{max,1})/10^2$ cm^{-1} in chloroform at 1, 500, 1000, and 1500 bar are 68.3, 68.4, 69.4, and 69.8 for the *cis*-stilbene complex and 50.3, 49.7, 50.6, and 50.5 for α-methylstyrene complex, respectively. A similar behavior is found for the biphenyl–TCNE complex, while the two bands of the naphthalene–TCNE complex are reported to behave differently from each other.[14] In that case, existence of isomeric forms of the complex is proposed on the basis of the nonparallel shifts, but the present result of the parallel shifts of the two bands suggest some similarity in polarity between the excited states of the first and second bands.[15]

Spectral Intensities and Chemical Equilibria. An increase, a decrease, and a complicated variation in absorbance with increasing pressure are observed in the solutions of stilbenes (Figs. 1 and 2), α-methylstyrene (Fig. 4), and 1,1-diphenylethylene (Fig. 3), respectively. The increase is due to the formation of the EDA complex promoted by pressure and the decrease is caused by the transformation of the complex to the 1,4-cycloadduct which is promoted by pressure more than the complex formation. Thus, the following reversible reactions,

$$D + A \overset{K_c}{\rightleftharpoons} \text{EDA Complex} \qquad (1)$$

and

$$D + A \overset{K_c}{\rightleftharpoons} \text{EDA Complex} \overset{K_1}{\rightleftharpoons} P \qquad (2)$$

occur in solutions of TCNE with stilbenes and in those with α-methylstyrene and 1,1-diphenylethylene, respectively.[4] Here, D, A, and P denote the donor, the acceptor, and the 1,4-cycloadduct, respectively, and K_c and K_1 are, respectively, expressed by

$$K_c = \frac{[EDA]}{[D][A]} \qquad (3)$$

and

$$K_1 = \frac{[P]}{[EDA]}, \qquad (4)$$

where the square brackets indicate the concentration of each species. The equilibrium constants in Eqs. 3 and 4 can be determined, respectively, by the Scott equations

$$\frac{[D]_0[A]_0 l}{A_e} = \frac{1}{K_c\varepsilon_{max}} + \frac{1}{\varepsilon_{max}}[D]_0 \qquad (5)$$

and

$$\frac{[D]_0[A]_0 l}{A_e} = \frac{1}{K_c\varepsilon_{max}} + \frac{1+K_1}{\varepsilon_{max}}[D]_0, \qquad (6)$$

where $[D]_0$ and $[A]_0$ are the initial concentration of the

Table 1. Formation constants (K_c/mol^{-1} dm^3) of EDA complexes in chloroform at 25 °C at various pressures

Donor	P/bar			
	1	500	1000	1500
trans-Stilbene[a]	1.16	1.23	1.34	1.42
cis-Stilbene[b]	0.415	0.424	0.467	0.493
α-Methylstyrene[c]	0.422	0.443	0.452	0.466
1,1-Diphenylethylene[d]	0.312	0.329	0.353	0.369

a) ε_{max} is 1880, 1940, 1960, and 2040 mol^{-1} dm^3 cm^{-1} at 1, 500, 1000, and 1500 bar, respectively. b) ε_{max} is 1950, 2090,2050, and 2100 mol^{-1} dm^3 cm^{-1} at 1, 500, 1000, and 1500 bar, respectively. c) ε_{max} is taken to be 1760 mol^{-1} dm^3 cm^{-1} from Ref. 4. d) ε_{max} is taken to be 1660 mol^{-1} dm^3 cm^{-1} from Ref. 4.

donor and acceptor, respectively, l is the path length (0.5—0.6 cm), A_e is the equilibrium absorbance at $\tilde{\nu}_{max.1}$, and ε_{max} is the molar absorption coefficient.

When spectra in the *trans*-stilbene–TCNE system like those in Fig. 2 are measured at high pressures over a wide range of $[D]_0$, the left-hand side of Eq. 5 can be plotted against $[D]_0$ as shown in Fig. 5. The plots are linear at each pressure and provide K_c and ε_{max} from their slopes and intercepts (see Eq. 5). Similar plots are obtained in the *cis*-stilbene–TCNE system. The results are summarized in Table 1 as a function of pressure; actually, the formation constants increase with increasing pressure.

Figure 6 illustrates plots of the left-hand side of Eq. 6 against $[D]_0$ for the α-methylstyrene–TCNE system in chloroform; the intercept, $1/(K_c\varepsilon_{max})$ becomes smaller and the slope, $(1+K_1)/\varepsilon_{max}$ becomes larger as pressure increases, both K_c and K_1 increasing with pressure. Similar plots are obtained for the α-methylstyrene–TCNE system in 1,2-dichloroethane and for the 1,1-diphenylethylene–TCNE system in chloroform and in 1,2-dichloroethane. We can not determine the pressure dependence of ε_{max} in the present case where the two kinds of equilibria are involved. Hence, we use the values of ε_{max} at 1 bar[4,6] to determine the values of K_c and K_1 at high pressures. The determined values of K_c and K_1 are listed in Tables 1 and 2 and 3 and 4, respectively. The values of K_c/mol^{-1} dm^3 and K_1 at 1 bar for the α-methylstyrene–TCNE system in chloroform are comparable with those obtained by a kinetic method,[4] 0.436 and 4.12, respectively, and the values in 1,2-dichloroethane with 0.084 and 11.6,[6] respectively. The values of K_c/mol^{-1} dm^3 at 1 bar for the 1,1-diphenylethylene–TCNE system in chloroform is in reasonable agreement with the kinetically determined one, 0.306, whereas the K_1 value is smaller than that determined kinetically, 3.51 for some unknown reason.[4]

(ΔV_c) accompanying the EDA-complex formation and that (ΔV_1) for the 1,4-cycloaddition are determined from the thermodynamic relation,

$$\left(\frac{\partial \ln K}{\partial P}\right)_T = -\frac{\Delta V}{RT} + \Delta m \cdot \kappa, \qquad (7)$$

where R, K, P, T, ΔV, Δm, and κ are the gas constant, the equilibrium constant (K_c or K_1), the pressure, the temperature, the volume change (ΔV_c or ΔV_1), the change in the molecular number for the reaction ($\Delta m = -1$ for K_c and 0 for K_1), and the isothermal compressibility of the solvent, respectively. Plots of ln K *vs.* P are linear within the experimental error in every case. Typical plots for α-methylstyrene–TCNE system in chloroform are shown in Fig. 7. The values of ΔV_c and ΔV_1 obtained thus are given in Table 5, where the volume changes, $\Delta V_R = \Delta V_c + \Delta V_1$, for the overall reactions from the donor and the acceptor in the two solvents are included.

The volume changes accompanying the complex formation are in the range of −4 to −7 cm³ mol⁻¹.

a) In 1,2-dichloroethane.

The relatively small negative values are found also for other TCNE complexes.[12,16] There is no general correlation between ΔV_c and $-RT \ln K_c$ in the series of donors studied here.

The reaction volumes(ΔV_R) for the 1,4-cycloadditions studied in the present work are comparable with those reported so far for many other 1,4-cycloadditions (−30 to −40 cm³ mol⁻¹).[17] The difference (4—7 cm³ mol⁻¹) in ΔV_R between chloroform and 1,2-dichloroethane is probably due to the polarity of the adduct for the following reason. The partial molal volume of α-methylstyrene varies little in the solvent used here; its value at 25 °C is 132.5±0.3, 132.3±0.3, 131.3±0.3, and 130.8±0.1 cm³ mol⁻¹ in 1,2-dichloroethane, dichloromethane, chloroform, and carbon tetrachloride, respectively. The partial molal volume of TCNE sparlingly soluble in these solvents are 107, 107, and 106 cm³ mol⁻¹ in 1,2-dichloroethane, dichloromethane, and carbon tetrachloride, respectively.[6,18] Thus, the partial molal volumes of the donor and the acceptor depend little on solvent polarity in these solvents. It is clarified in the previous paper[6] that the cycloadduct has a relatively large dipole moment as a result of the symmetry breakdown in the TCNE moiety. In consequence, the partial molal volume of the polar adduct is expected to be smaller in 1,2-dichloroethane than in chloroform. If this is the case, the reaction volume becomes larger in magnitude in 1,2-dichloroethane than in chloroform as observed.

15) When we apply McRae's theory[13] to the two bands under the same conditions, we can expect cancellation of the dispersion term *etc.* and also neglect of the dipole moment of the ground state much smaller than the dipole moment (μ_E) of the excited state. In the present case, therefore, McRae's formula is simplified as

$$\{\tilde{\nu}_{max,2}(P)-\tilde{\nu}_{max,1}(P)\} - \{\tilde{\nu}_{max,2}(1)-\tilde{\nu}_{max,1}(1)\} = -\frac{\mu_{E,2}^2-\mu_{E,1}^2}{hca^3}\cdot\frac{n(P)^2-n(1)^2}{\{2n(P)^2+1\}\{2n(1)^2+1\}},$$

where $n(P)$ is the refractive index of the solvent at pressure P, h is Planck's constant, c is the velocity of light, and a is the effective radius of the complex. The above equation shows that if the left-hand side is zero, $\mu_{E,2}$ is equal to $\mu_{E,1}$.

The DV-Xα MO Study of the Electronic Structures of $[M(CN)_6]^{3-}$ (M=Cr, Mn, Fe, and Co) and $[Fe(CN)_6]^{4-}$

Mitsuru SANO,** Hirohiko ADACHI,† and Hideo YAMATERA*

(Received August 5, 1980)

The discrete-variational Xα (DV-Xα) calculations are used for the hexacyano transition-metal complexes, $[M(CN)_6]^{3-}$ (M=Cr, Mn, Fe, and Co) and $[Fe(CN)_6]^{4-}$. The calculated values of the core- and valence-orbital energies can be correlated with the XPS results. The Mulliken populations are presented. The calculated d-d excitation energies are in good agreement with the Δ (ligand-field parameter) values obtained from the spectra.

The Hartree-Fock-Slater (HFS) model[1] has recently been applied to the molecular orbital (MO) calculation of the electronic structures of molecules, clusters, and crystals. Three methods have been developed for the application of this model to the MO calculation: the multiple-scattering Xα (MS-Xα) method,[2] the discrete-variational Xα (DV-Xα) method,[3] and the LCAO-Xα method.[4] The MS-Xα method developed by Johnson and his co-workers seems to be oversimplified for use in the calculation of a metal complex which contains heteropolar covalent bonds. The LCAO-Xα method is an attractive approximation,[5] but it does not seem to meet the present purpose because of the incompatibility of a satisfactory basis set and a reasonable computer time. Most suitable to the present case, therefore, is the DV-Xα method, which has the following advantages: any type of functions, including numerical functions, can be used as the basis functions and as the potential functions, mathematical difficulties are eliminated, and a large system can be calculated in a relatively short computer time. On the other hand, this method is not suitable for the calculation of accurate total energies. The DV-Xα calculations for the ionization and excitation energies have shown an excellent agreement with the experimental results for small molecules[6,7] and metal clusters.[8,9]

However, only a few reports[9,10] have so far appeared concerning the systematical application of the DV-Xα method to a series of transition-metal complexes. It still remains uncertain how far the DV-Xα method can be relied on for the calculation of the orbital energy, the atomic charge, the bond-overlap population, and the d-d excitation energy of a transition-metal complex.

The present study is concerned with the application of the DV-Xα method to a series of hexacyano transition-metal complexes, which have been of special interest for both inorganic and theoretical chemists.[11] Cyanide ions are coordinated to a metal ion with both σ- and π-type bondings, and cyano complexes are typical of the complexes in which the π back-donation of electrons possibly takes place.

The main purpose of the present study is to obtain a deeper understanding of the coordinate bond by comparing the electronic structures of hexacyano complexes. For this purpose, an HFS MO calculation with the numerical-basis DV-Xα method has been made of $[M(CN)_6]^{3-}$ (M=Cr, Mn, Fe, and Co) and $[Fe(CN)_6]^{4-}$. The results are compared with the experimental results in order to confirm their reliability, and comparisons are made between the results for different complexes of the series. A comparison is also made with the recent results of the *ab initio* MO calculation of $[Co(CN)_6]^{3-}$ by Sano *et al.*[12,13]

Computational Method

The computational details of the spin-polarized DV-Xα method and the relation between the DV-Xα treatment and ligand-field theory have been sufficiently described elsewhere.[9]

In the HFS model,[1] the exchange-correlation term is given by:

$$V_{xc}^{\uparrow}(1) = -3\alpha[(3/4\pi)\rho^{\uparrow}(1)]^{1/3}$$

where $\rho^{\uparrow}(1)$ is the local charge density with up-spin and α is the exchange scaling parameter; α=0.70 is used for all atoms throughout the present calculation.[6] The spin-polarized DV-Xα self-consistent-charge (SCC) procedure[9] has been performed for both up and down spins, where an approximate self-consistent molecular potential is determined from the Mulliken gross orbital populations. The up- and down-spin numerical basis functions are generated as the solutions of the atomic HFS equations in which an atom-like potential is constructed by spherically averaging the molecular potential around the nucleus for the region inside each atomic sphere.[8] The basis sets including the metal 1s-4p and C and N 1s-2p are utilized for most of the present calculations.

The molecular geometries for the complexes are taken from the experimental results.[14] In the present calculation, the complexes are regarded as having the O_h symmetry.

Results and Discussion

The MO's of the Cyanide Ion and Its Coordination to a Metal Ion. The eigenvalues and charge distributions calculated for free CN^- are tabulated in Table 1.

The 1σ and 2σ MO's are N1s and C1s orbitals respectively. On the basis of the orbital components and the bond-overlap populations, each orbital may be characterized as follows: 3σ is the N2s-C2s bonding

orbital, the major part of the population of nonbonding 4σ and that of antibonding 5σ reside at N and C respectively, and 1π is bonding. These features are similar to previous results[12,13] derived from the *ab initio* MO calculation. However, the results of the population analysis in the present calculation (−0.59 on N and −0.41 on C) are in contrast with the previous results (−0.454 on N and −0.546 on C).[13] The present results are more reasonable for the reason that they are consistent with the higher electronegativity of the nitrogen atom. The *ab initio* calculation with double-zeta basis functions sometimes gives unreasonable results for Mulliken populations due to a diffuse component of the double-zeta function extending to the neighboring atom.[15] Thus, one of the merits of the DV-Xα SCC method seems to be that it gives reasonable populations.

In spite of the higher negative charge located on the nitrogen atom, the cyanide ion is coordinated to the metal at the carbon atom. This can be expected from the frontier-electron theory,[16] according to which an electrophilic reaction tends to takes place on the atom that has the highest electron density in the highest occupied MO (HOMO) of the ground state of the nucleophile. The HOMO of the free CN^- ion is 5σ, the population of which is greater on the carbon atom (62%) than on the nitrogen atom (38%); this is consistent with the tendency of CN^- to coordinate at the carbon atom.

Orbital Energies and Ionization Potentials of the Metal Complexes. The core-electron binding energies for N1s and C1s are first discussed. The orbital-energy values calculated by the Xα method cannot be directly compared with the experimental values obtained from X-ray photoelectron spectroscopy (XPS), since the relaxation effect is disregarded in the calculation. However, the relaxation energies for C and N core orbitals do not change appreciably from one cyano complex to another; thus, the relative changes in core levels may be meaningful. In Table 2, the differences between the N1s and C1s orbital energies of the complexes are compared with the corresponding XPS results. The calculated N1s−C1s difference, ΔE(N1s−C1s), decreases from $[Cr(CN)_6]^{3-}$ (110.0 eV) to $[Co(CN)_6]^{3-}$ (109.6 eV) and from $[Fe(CN)_6]^{3-}$ (109.9 eV) to $[Fe(CN)_6]^{4-}$ (109.8 eV), showing a trend similar

to that observed in the XPS data. Detailed discussions of the XPS results have been given elsewhere.[17]

Table 3 shows the energies and symmetries of the filled outer-shell MO's of $[Co(CN)_6]^{3-}$, along with their atomic components. The energies of orbitals with up- and down-spins are schematically shown in Fig. 1 for all the complexes of the series. In all cases, the HOMO is $2t_{2g}$, consisting mainly of metal $d\pi$ with a small contribution of ligand π orbitals. This is different from the previous results of a simple Hartree-Fock (HF) calculation,[12] which showed that $2t_{2g}$ consists mainly of ligand orbitals, but it is consistent with the results of the HF calculation with the ΔSCF procedure,[13] according to which the ionization potential of $2t_{2g}$ (a mainly ligand orbital) is larger than that of $1t_{2g}$ (a mainly metal orbital) and the latter may therefore be regarded as HOMO. The XPS results[19,20] also show that the electron of the smallest binding energy is of a mainly metal-d character, in agreement with the present and the ΔSCF results. Figure 2 shows a comparison of the calculated orbital-energy levels and the XPS spectra of the valence regions of $[Fe(CN)_6]^{4-}$ and $[Co(CN)_6]^{3-}$.[20] For easy comparison, the position of the calculated energy level of $2t_{2g}$ ($d\pi$, HOMO) was arbitrarily taken as the reference to be fitted to the corresponding XPS peak in Fig. 2. The relative positions of the calculated orbital-energy levels appear to show a good correlation with the spectra, in spite of the fact that the reorganization energy is neglected in the calculation. A more detailed discussion, including the calculation by the transition-state method and an estimation of the relative intensities, will be given elsewhere.[21]

In the valence levels, the $6a_{1g}$, $5t_{1u}$, and $3e_g$ MO's of the complexes are predominantly composed of CN^- 3σ orbitals (see Tables 1 and 3). The $7a_{1g}$, $4e_g$, and $6t_{1u}$ MO's are CN^- σ orbitals mixed with metal σ orbitals. The $1t_{2g}$ MO is composed of CN^- π and metal $d\pi$. The $8a_{1g}$, $7t_{1u}$, and $5e_g$ MO's are CN^- σ orbitals located mainly on N. The $1t_{1g}$ and $1t_{2u}$ MO's are CN^- π orbitals, while $8t_{1u}$ MO is predominantly CN^- π orbitals slightly mixed with the metal 4p orbital.

We shall compare the orderings of MO's in the free and coordinated CN^- ions. Although the 5σ orbital

is the HOMO in the free CN^- ion, the ordering of the σ and π orbitals is reversed by the coordination of CN^- with a metal ion. Thus, the ordering is

$5\sigma > 1\pi > 4\sigma$ in the free CN^- ion

and;

metal $d\pi > \pi(CN^-) > \sigma(CN^-)$ in the complex ion.

Since the cyanide ion is a good σ-electron donor, the 5σ orbital energy is greatly decreased by the bonding interaction with the metal dσ orbital.

Bond-overlap Population and Bond Strength. The calculation has been done by the procedure of SCC. The numerical basis set generated by iterative SCC[8] gave adequate wavefunctions suitable to the Mulliken population analysis. The bond-overlap population and charge distributions thus obtained are given in Tables 4 and 5. The metal-carbon bond strength is related to both the σ- and π-overlap populations for the M–C bond. The σ-bond-overlap populations of the $[M(CN)_6]^{3-}$-type complexes gradually increase with an increase in the atomic number of the metal (from Cr to Co). This is consistent with the tendency for the effective nuclear charge of the metal ion to increase in the order of $Cr^{3+}<Mn^{3+}<Fe^{3+}<Co^{3+}$. The increase in the nuclear charge is only incompletely screened by the increase in the number of metal dπ electrons. Thus, the ligand-to-metal donation of σ electrons is expected to increase with an increase in the atomic number of the metal. On the other hand, the π-bond-overlap population remains almost unchanged, probably because of the counterbalancing effects of the π+dπ bonding and dπ—π antibonding interactions. The total bond-overlap population and, consequently, the M–C-bond strength increase in the order of Cr–C<Mn–C<Fe–C< Co–C. As regards the C–N bond, the bond-overlap population is 1.43 in the free CN^- ion and 1.44—1.51 in the complexes. The C–N-overlap population consists of two components, the σ- and π-overlap populations, which are, respectively, 0.32 and 1.11 in the free CN^- and 0.42—0.45 and 1.07—1.10 in the complexes (except for the Fe^{2+} complex, to be discussed below). The formation of the M–C bond results in a decrease in the antibonding character of 5σ (HOMO) and, consequently, in an increase in the C–N bond-overlap population from 0.32 to 0.42—0.45. This suggests that a stronger metal–carbon σ bond is associated with a stronger C–N σ bond. On the other hand, the formation of metal–ligand π bonds with π back-donation slightly weakens the C–N bond, as is shown by the descrease in the C–N π-overlap population from 1.11 to 1.07—1.10. The σ and π effects partially compensate for each other, resulting in a slight increase in the C–N bond strength. When Fe^{3+} in the hexacyano complex is reduced to Fe^{2+}, an electron is added to the dπ orbital. Thus, in $[Fe(CN)_6]^{4-}$ the π back-donation of iron dπ electrons to the cyanide antibonding π orbitals occurs to a greater extent, resulting in a weakening of the C–N π bond. The increase in the number of dπ electrons will only indirectly affect the Fe–C σ bonding and the C–N σ bonding. Consistent with this argument, Table 5 shows that the π-overlap population decreases from 1.07 to 1.01 and that the σ-overlap population changes very little in going from the Fe^{3+} to the Fe^{2+} complex.

Charge Distribution. The differences in the charge distribution between the free CN^- ion and the CN^- ligand in the complexes are seen mainly in the carbon charges as a result of the σ donation to metal. A fraction (0.3—0.4) of electron flows into the metal ion from each carbon atom, partially neutralizing the positive charge of the metal ion. The 3dσ population increases from 1.28 to 1.89 with the increase in the carbon-to-metal σ donation in going from Cr^{3+} to Co^{3+}. The 3dπ population, of course, increases with the increase in the atomic number. The net population of 3dπ, however, is lower than the formal population, and the deficiency increases from 0.12 to 0.52, showing an increase in the π back-donation with an increase in the atomic number. The population of 4s changes only slightly, while that of 4p increases from 0.38 to 0.53 across the series (due to ligand-to-metal donation). The metal positive charge thus decreases with the increase in the 3dσ population in going from Cr^{3+} to Co^{3+}. On carbon, the C2s and C2pσ populations decrease from 1.28 and 1.15 for $[Cr(CN)_6]^{3-}$ to 1.20 and 1.10 for $[Co(CN)_6]^{3-}$ respectively with an increase in the σ donation from carbon to metal, while the C2pπ population remains approximately constant. As for the nitrogen charge, the population remains unchanged for 2s, slightly decreases for 2pσ, and increases for 2pπ, in going from Cr^{3+} to Co^{3+}. As a result, the negative charge of nitrogen increases from −0.53 to −0.60, in contrast to the

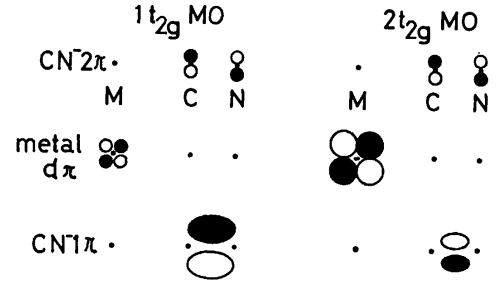

Fig. 3. Orbital interaction of metal dπ and cyanide π orbitals of T_{2g} symmetry. Sizes of circles and ellipses roughly indicate the magnitudes of orbital components. Signs of orbital wavefunctions, namely positive or negative, are shown by white and black area.

decrease in that of carbon from −0.17 to −0.04.

The changes in the cyanide π populations will now be briefly discussed. According to the orbital-mixing rule,[22] the $1t_{2g}$ and $2t_{2g}$ MO's consist of linear combinations of the $(1\pi+2\pi+d\pi)$- and $(d\pi-1\pi+2\pi)$-types respectively. These combinations are schematically summarized in Fig. 3. In the formation of the bonding $1t_{2g}$ MO, the CN^- 1π and 2π amplitudes intensify each other at the carbon atom and compensate for each other at the nitrogen atom to result in increased and decreased populations on the carbon and nitrogen atoms respectively. On the other hand, in the $2t_{2g}$ MO, a compensation and an intensification of the amplitudes occur at the carbon and nitrogen atoms respectively. The mixing of 2π (antibonding cyanide orbital) into $d\pi$ with bonding combination strengthens the M–C bond, but weakens the C–N bond.

In the cyano complexes of Fe^{2+} and Fe^{3+}, the metal charges are +0.83 and +0.98, respectively, and the difference results mainly from different 3d populations. The $3d\sigma$ population for Fe^{3+} (1.70) is greater than that for Fe^{2+} (1.52) in agreement with a greater σ donation to Fe^{3+}, while the difference in the $3d\pi$ population between Fe^{2+} (4.99) and Fe^{3+} (4.62) is much less than unity (or the difference in the formal charge) indicating a greater π back-donation from Fe^{2+}. The charges on the two kinds of iron atoms differ from each other only by 0.15, which is much smaller than the difference in the oxidation number.

As has been shown in previous papers,[12,15] the charge distribution derived from the Mulliken population analysis strongly depends on the basis set of orbitals used in the calculation. Thus, the cobalt charge in $[Co(CN)_6]^{3-}$ was estimated to be +3.138 and +1.301 by two *ab initio* MO calculations with only slightly different basis sets. On the other hand, the atomic charge derived from the analysis of the spatial charge distribution naturally depends on the atomic radius assumed. Our previous analysis[13] gave +0.3 or +2.3 for the cobalt charge in the same complex, depending on the radius: 1.22 Å, in accordance with the results of an X-ray analysis,[23] or 0.95 Å, which is the distance of minimum electron density on the calculated distribution curve. As has previously been discussed,[12,15] the diversity of the calculated charges results from the fact that the allocation of charge to each atom is artificial. Nevertheless, the atomic charges are one of the important clues for elucidating the electronic structure of metal complexes, provided that an appropriate method is used consistently to calculate the charge distributions for the complexes to be compared. In this sense, the present results for charge distribution give useful information on the electronic state of the complexes. The resonable numerical values obtained for atomic charges may indicate that the iterative SCC procedure would give suitable wavefunctions for the purpose of population analysis.

The Excitation Energies. One of the main purposes of the present work is to examine the extent to which the experimental values of the ligand field parameter, Δ, can be reproduced by the DV-Xα SCC scheme. The theory has been thoroughly described by Adachi *et al.*[9] The Δ values are obtained as the weighted averages of the energy differences between the vacant $6e_g$ and occupied $2t_{2g}$ orbitals with the same spin:

$$\Delta = [n^{\uparrow}\{E(6e_g^{\uparrow})-E(2t_{2g}^{\uparrow})\}+n^{\downarrow}\{E(6e_g^{\downarrow}) -E(2t_{2g}^{\downarrow})\}]/(n^{\uparrow}+n^{\downarrow}),$$

where the superscripts $\uparrow$ and $\downarrow$ indicate the up- and down-spins, and n, the occupation number of the $2t_{2g}$ orbital with the designated spin. In Table 6, the calculated Δ values are compared with the experimental values reported by Alexander and Gray.[24]

The agreement is reasonably good if the difficulties associated with the estimation of the experimental Δ values are taken into consideration. For some complexes such as $[Fe(CN)_6]^{3-}$, the d-d bands are not clearly observed due to the overlap of strong charge-transfer bands. The estimation of the Δ values from the observed wavenumbers of the absorption bands may be more or less dependent on the values assumed for Racah's B and C parameters. A good agreement between the calculated and experimental values of Δ for metal fluorides has been reported by Larsson and Connolly,[25] who used the SW-Xα method to obtain the Δ values as the difference between the two d-orbital energies. More careful DV-Xα treatments of the same compounds made by Adachi *et al.*[9] gave an excellent agreement. Along with their results, our present results illustrate the usefulness of the Xα method for the estimation of the Δ values.

The Δ values calculated for the $[M(CN)_6]^{3-}$-type complexes increase with the increase in the atomic number of the metal. Though not fully consistent with the existing experimental data, this trend can be expected from the following reasoning: in going from Cr^{3+} to Co^{3+}, the effective charge of the metal ion increases, the σ donation from CN^- σ to metal $d\sigma$

TABLE 6. CALCULATED VALUES OF THE LIGAND-FIELD PARAMETER, Δ, AND THE EXPERIMENTAL VALUES[24]

Orbital	Cr^{3+}	Mn^{3+}	Fe^{3+}	Co^{3+}	Fe^{2+}	
$6e_g^{\downarrow}$	11.11	10.61	10.43	9.46	16.50	(eV)
$6e_g^{\uparrow}$	8.89	9.17	9.73	9.46	16.50	(eV)
$2t_{2g}^{\downarrow}$	7.71	6.95	6.57	5.35	12.35	(eV)
$2t_{2g}^{\uparrow}$	5.42	5.40	5.76	5.35	12.35	(eV)
Δ (calcd)	28000	30200	31600	33200	33500	(cm^{-1})
Δ (exptl)	26600	34000[a]	34950	34500	33800	(cm^{-1})

a) 30000 cm^{-1} in Ref. 26.

occurs to a greater extent, and metal dσ is more strongly destabilized by the increased antibonding interaction. The π back-donation is small in these complexes; thus, the change in π back-donation makes a minor contribution to the change in the Δ values.

The calculated Δ value for $[Fe(CN)_6]^{4-}$ is greater than that for $[Fe(CN)_6]^{3-}$. This is contrary to the above reasoning, according to which $[Fe(CN)_6]^{4-}$ with Fe^{2+}, with a lower effective charge, would have a lower Δ value. In this case, however, a change in the π back-donation makes a significant contribution to the change of the Δ value. The increase in the stabilization of Fe dπ due to the stronger π-bonding effect overbalances the decrease in the destabilization of Fe dσ due to the weaker σ-antibonding effect in going from the Fe^{3+} to the Fe^{2+} complex. Calculation showed that the σ donation decreased from 42.3% to 37.7%, while the π back-donation increased from 8.5% to 16.8% correspondingly.

Conclusions

The spin-polarized DV-Xα method has been applied to the calculation of the electronic structures of transition-metal cyano complexes. This leads to the following conclusions:

(1) The calculated orbital energies give a good correlation with the XPS results.

(2) The calculated atomic charges and bond-overlap populations due to Mulliken population analysis show a trend that can be satisfactorily elucidated by a qualitative molecular-orbital consideration using the orbital mixing rule.

(3) The Δ value, as expressed by the difference between dσ ($6e_g$) and dπ ($2t_{2g}$) orbital energies, shows a good agreement with the spectroscopic Δ values.

(4) The conclusions described under (1)—(3) suggest that the DV-Xα MO method gives an adequate description of the electronic structures of transition-metal complexes.

The numerical calculations were performed with a HITAC M-180 system at the Computer Center of the Institute for Molecular Science and a FACOM 230-75 system at the Nagoya University Computation Center. The authors are grateful to the staffs of the computer centers for their assistance in the calculation.

Preparation and Analytical Evaluation of Liquid Membrane Electrodes Based on Solid-solvents

Hirokazu HARA, Satoshi OKAZAKI, and Taitiro FUJINAGA*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received September 16, 1980)

A new type of liquid membrane electrode has been developed in which organic compounds solidified at room temperature were used as solvents of an ion-sensing membrane. The electrode performance of a *p*-toluenesulfonate ion-sensitive electrode was examined and compared with that of a corresponding liquid membrane electrode, no remarkable difference being observed in sensitivity and response time. However, a distinct difference in selectivity was observed between the 1-octadecanol (solid) and 1-decanol (liquid) membranes. The difference was interpreted on the basis of the solvation energy of interfering anions. The effects of ion-pair concentration, membrane thickness, and pH on the electrode potentials of the 1-octadecanol membrane were investigated in comparison to those of the 1-decanol membrane. The electrodes responsive to various anions such as iodide, nitrate, bromide, and chloride were prepared with an 1-octadecanol membrane.

Liquid membrane electrodes (LME) have the advantage of a wide variety in their ion-exchanger as regards solvent extraction systems. However, they have disadvantages in practical use in comparison with solid membrane electrodes. The potentiometric response of LME is liable to be disturbed by hydrostatic pressure or stirring of the sample solution, or its ion-exchanging liquid tends to leak into the sample. In order to overcome these difficulties studies have been made resulting in the development of an LME based on plastic matrices,[1,2] carbon paste,[3] and the solidification of ion-exchanging liquid by addition of naphthalene to a nitrobenzene membrane.[4]

Organic sulfonate selective electrodes were developed by use of a coated wire type electrode.[5] We have developed a *p*-toluenesulfonate selective electrode (solid-solvent membrane electrode, SSME) using organic compounds having a high melting point, which solidify at room temperature. The effects of the membrane components, such as ion-pair concentration, membrane thickness, and pH on the response behavior of SSME with an 1-octadecanol membrane were also studied in comparison to LME with a 1-decanol membrane. The electrode performance of SSME was examined and compared with that of the corresponding LME. A distinct difference in the selectivity patterns between the 1-octadecanol (SSME) and 1-decanol (LME) membranes was observed.

Experimental

Reagents. Reagent grade solid-solvents, 1-octadecanol, 1-docosanol, *m*-dinitrobenzene, 1,2,4,5-tetrachlorobenzene and triphenyl phosphate, and liquid-solvents, 1-octanol, 1-decanol, nitrobenzene, *o*-dichlorobenzene, and tributyl phosphate were used without further purification. An ion-pair of methyltrioctylammonium *p*-toluenesulfonate (TOMA·pTS) was prepared with methyltrioctylammonium chloride (Capriquat, from Dojin Research Laboratories Co.) by the extraction method[5] and recrystallized from ethyl acetate. Capriquat salts of perchlorate, iodide, nitrate, and bromide were similarly prepared. These salts of iodide, nitrate, and bromide are hygroscopic and they were dehydrated under reduced pressure before use. The pH of the sample solution was adjusted with hydrochloric acid or sodium hydroxide solutions.

Preparation of Membranes. An ion-pair was dissolved into solid-solvent molten at elevated Temperature. After cooling at room temperature, the solidified ion-exchanger was ground into powder and pressed on a polished silver disk 1 cm in diameter at *ca.* 300 MPa to form a thin film of ion-sensing membrane. The thickness of the membranes was in the range 0.2—0.4 mm unless otherwise stated. The impedance of these membranes was several mega-ohms.

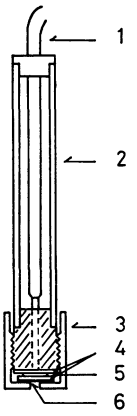

Fig. 1. Configuration of solid-solvent membrane electrode.
(1) Coaxial wire, (2) glass tube, (3) Teflon cap, (4) silver plate, (5) metal for electric conduction, and (6) pressed ion-exchanger.

Electrode Assembly and Potential Measurements. For the potentiometric test of the pressed membranes, SSME was constructed as shown in Fig. 1. For LME, a Corning type liquid membrane electrode was used. The membrane potentials were measured *versus* SCE with an Orion Digital Ionalyzer Model 601 connected to a Matsushita pen recorder Model VP654A.

Results and Discussion

The membrane conditions which affect the electrode response of SSME with an 1-octadecanol membrane responsive to *p*-toluenesulfonate ion (pTS) were investigated in comparison to those of LME with a 1-decanol membrane as follows:

Effect of the Ion-pair Concentration. Dependence of the sensitivity of the SSME on the concentration of the ion-pair is illustrated in Fig. 2. The optimum concen-

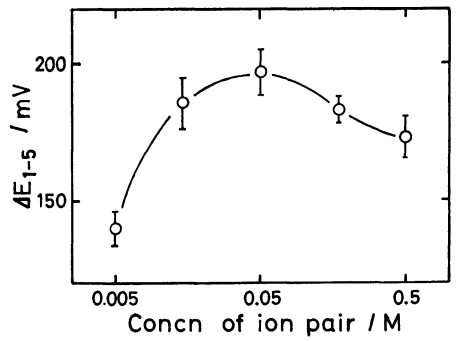

Fig. 2. Effect of ion-pair concentration on the potential difference between 10^{-1} M and 10^{-5} M.

The mean value of four measurements with its standard deviation is given.

tration of the ion-pair is *ca.* 0.05 M†. As in LME,[6] the sensitivity decreased in a very high concentration region due to the elution of the membrane solute. The sensitivity decreased also in low concentration range, the membrane potential becoming unstable below 0.005 M because of the increase of membrane impedance. The potential reproducibility of SSME was not very good, ± 5 mV, in comparison to the conventional liquid membrane electrode.

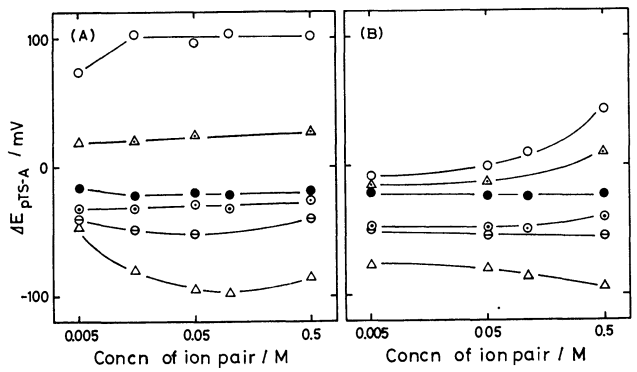

Fig. 3. Effect of ion-pair concentration on SPD of (A) SSME and (B) LME.
Interfering ions: (○) ClO_4^-, (△) I^-, (●) $PhSO_3^-$, (⊙) NO_3^-, (⊖) Br^-, and (△) Cl^-.

The selectivity of SSME changes slightly with the concentration of the ion-pair (Fig. 3A). Selective potential difference (SPD, ΔE_{pTS-A}) was defined in order to study the selectivity characteristic of the membrane as follows. The membrane potentials of 0.01 M objective pTS ion (E_{pTS}) and each interfering anion (E_A) were measured separately. The potential difference, $\Delta E_{pTS-A}=E_{pTS}-E_A$, was used instead of the conventional selectivity factor because of its super-Nernstian responses. The decrease in selectivity at 0.005 M resulted from the poor response to the objective ions. On the other hand, the range of the selectivity of LME widened somewhat with increase in concentration of the ion-pair (Fig. 3B).

Ion-exchanger: 0.05 M TOMA·pTS in 1-octadecanol.

Effect of the Membrane Thickness. As shown in Fig. 4, the sensitivity of the SSME is not influenced much by the membrane thickness, little effect of the membrane thickness on selectivity and response time being observed.

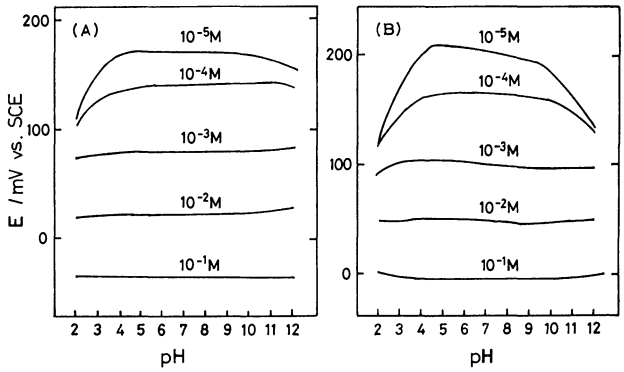

Fig. 5. Effect of pH on the membrane potentials of (A) SSME and (B) LME.
Ion-exchanger: 0.05 M TOMA·pTS in (A) 1-octadecanol and (B) 1-decanol.

Effect of pH. The effects of pH on the membrane potential of SSME (A) and LME (B) were examined (Fig. 5). In the low pH range, the interference of chloride ion could not be ignored in both membranes, the interference of hydroxide ion in an alkaline solution being much larger in LME than in SSME.

Comparison of the Potentiometric Behavior of SSME with That of LME. The response behavior of SSME and LME is summarized in Table 1, four pairs of the pressed membranes and the corresponding liquid membranes being compared. Super-Nernst slopes were observed for both liquid and pressed membranes. This might be attributed to the malfunction of the reference electrode as reported by Moody and Thomas.[7] SSME gave a slightly better result in the linear response ranges in comparison to the corresponding LME except in the case of a pair of 1-alkanols. Since the linear response range of LME depends not only on the membrane solvent but also on the ion-pair species,[6] the most appropriate solvent for a given ion-pair should be selected in order to obtain a highly sensitive electrode. In view of the wide linear response range, 1-decanol

was found to be the best liquid-solvent of those tested for a long chain tetraalkylammonium as a counter ion. However, in case of SSME, the linear response range was independent of the kind of solid-solvent used. The sensitivity of SSME seems to be determined mainly by the solubility of the ion-pair.[8] Shorter response time was needed for SSME than the corresponding LME, especially in the high concentration range of pTS^-.

The selectivity characteristics of SSME and LME based on various solvents are shown in Figs. 6 and 7. Hardly any difference was observed among the solid-solvents in the selectivity patterns of SSME (Fig. 6A), while an exceptional pattern was found among LME for 1-decanol membrane (Fig. 6B).

The selectivity patterns of SSME with solid 1-alkanols were compared with those of LME with liquid 1-alkanols (Fig. 7). A distinct difference in patterns was observed. The solvent effects of the solid-solvents on the selectivity pattern were small in contrast to the liquid-solvents examined. The potentials of SSME seem to be governed mainly by the direct ion-exchange reaction at the membrane-solution interface, being hardly affected at all by the inner-membrane phenomena. The selectivity of SSME was anticipated to be

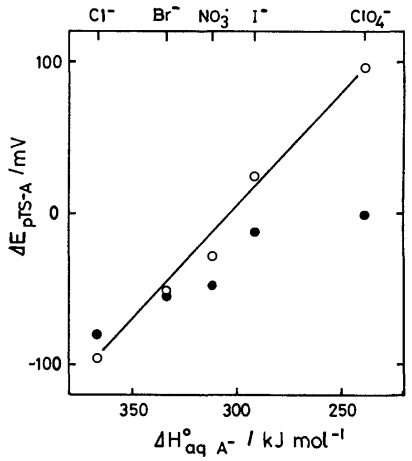

Fig. 8. Relationship between standard hydration enthalpy and SPD. (○) 1-Octadecanol and (●) 1-decanol membranes.

determined mainly by the hydration energy of the interfering ions. A linear relationship is seen between hydration energy and the SPD for an 1-octadecanol membrane, no such correlation being observed for a 1-decanol membrane (Fig. 8). The SPD of the 1-decanol membrane seems to be determined not only by the hydration energy of interfering anions but also

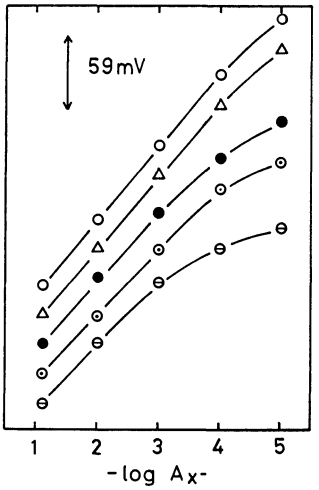

Fig. 9. Calibration curves of solid-solvent membranes. Ion-exchanger: 0.05 M TOMA·X^- in 1-octadecanol (20 mg).
X^-: (○) ClO_4^-, (△) I^-, (●) NO_3^-, (⊙) Br^-, and (⊖) Cl^-.

by the solvation energy in the solvent, as reported by Reinsfelder and Schults for the $Fe(bphen)_3^{2+}$–*t*-pentyl alcohol electrode.[9]

SSMEs Responsive to Other Anions. Figure 9 shows the calibration curves of each electrode sensitive to the respective anions. The sensitivity to ions having a smaller hydration energy is better than that having a larger one.[8,10] SSME with 1-octadecanol membrane has several merits over LME with common aromatic compounds; 1) it is insoluble in water, 2) it does not sublime, and 3) it can be use as the matrix of a coated-wire type electrode in place of the conventional PVC matrix.

An SSME with an inner reference electrode showed reproducibility to be better than ±2 mV. This type of pressed membrane should be *ca.* 0.5 mm thick or else it will break easily. A coated-wire type SSME, prepared by dipping a platinum tip into the extract of the ion-pair in molten 1-octadecanol, also showed good response.

SSME has advantages of both solid and liquid membranes; it shows fast response and can be used as a sensor of a flowing system.[11] The contamination of the sample solution with the eluted solvent from the membrane can be minimized. It is widely applicable to most LME-systems. A highly selective organic sulfonate ion selective electrode with alkylphenol derivative has been developed.[12]

The Decomposition of Hydrogen Iodide and Separation of the Products by the Combination of an Adsorbent with Catalytic Activity and a Temperature-swing Method

Yoshinao Oosawa

National Chemical Laboratory for Industry, Higashi, Yatabe-cho, Tsukuba-gun, Ibaraki 305

(Received October 29, 1980)

The decomposition of hydrogen iodide and the separation of the products by the combination of a column packed with an adsorbent with catalytic activity (platinum-supported active carbon, 2.3 wt%) and a temperature-swing method (450—900 K) are carried out, and the features and the problems of the method are examined. A one-step conversion of hydrogen iodide, 70%, is obtained at 450 K, where the equilibrium conversion is 13%. It is shown that the products of the decomposition of hydrogen iodide containing water are separated from each other.

The decomposition of hydrogen iodide serves as the hydrogen-evolution step in several thermochemical water-splitting cycles,[1-3] including the Magnesium–Iodine cycle[4,5] previously proposed by Kondo *et al.* Suitable catalysts for the catalytic decomposition of hydrogen iodide were searched for,[6] and the kinetic analysis of the reaction over a platinum-supported active carbon catalyst and an active carbon catalyst which had been found effective was carried out.[7] The results showed that hydrogen iodide could be decomposed rapidly enough by the use of those catalysts in the range of comparatively low temperatures (500—700 K) and in the presence of water vapor that might coexist in the actual cycle. However, the equilibrium conversion of hydrogen iodide is low (0.13—0.20 at 450—700 K)[6] when all the components, including the products, are in the gaseous phase. Therefore, the separation of the product mixture into its components, *i.e.*, hydrogen, iodine, undecomposed hydrogen iodide, and water, is necessary. However, iodine and undecomposed hydrogen iodide cannot be separated from each other easily, since iodine readily dissolves in the hydriodic acid formed from hydrogen iodide and water. On the other hand, the amount of undecomposed hydrogen iodide which has to be recirculated should be minimzied in order to increase the thermal efficiency of the whole cycle.

Therefore, from the standpoint of the thermochemical water splitting, the problems in the decomposition of hydrogen iodide can be summarized as follows: the elevation of a one-step coversion, and the development of an effective separation method of the product mixture. Various decomposition-separation methods have been proposed, *i.e.*, methods in which hydrogen iodide is decomposed, when iodine is in the liquid phase[8] or hydrogen iodide is in the liquid phase,[8] a method with porous membrane,[9] a method with MgO,[10] *etc.* However, each method has its own problems. Therefore, the present author considered that the development of a new method was necessary.

Principle

An adsorbent with catalytic activity is prepared by the addition of catalytic activity to an adsorbent which has very different adsorption characteristics toward the reactant, hydrogen iodide, and the products, hydrogen and iodine. Under the conditions that a column packed with the adsorbent with catalytic activity is heated in the temperature range where hydrogen iodide is decomposed rapidly, and that hydrogen iodide is fed in intermittently, there is a possibility that a one-step conversion higher than the equilibrium one can be obtained.

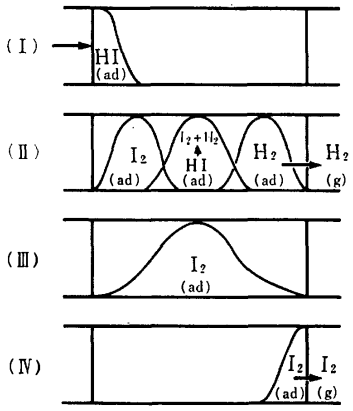

Fig. 1. Conceptual drawing of the decomposition of hydrogen iodide and the separation of the products by the use of a column packed with an adsorbent with catalytic activity.

Figure 1 is the conceptual drawing of the method. As a certain amount of hydrogen iodide fed intermittently proceeds in the column, it decomposes on the surface of the adsorbent, thus forming hydrogen and iodine. If it is hard for the adsorbent to adsorb hydrogen, while it readily adsorbs iodine, the hydrogen formed on the surface of the adsorbent desorbs into the gaseous phase, while the iodine formed remains adsorbed. Since the iodine formed is continuously removed from the reaction system, the undecomposed hydrogen iodide is decomposed further as it proceeds in the column (Figs. 1-I, II). Thus, if the decomposition of hydrogen iodide is rapid enough, a one-step conversion higher than the equilibrium one is obtained. The iodine remaining in the adsorbent is desorbed, and the adsorbent is regenerated (III, IV). In the present method, the one-step conversion of hydrogen iodide will be dependent

on both the catalytic activity of the adsorbent and the difference in the adsorption characteristics of the adsorbent toward hydrogen iodide, hydrogen, and iodine. If a higher one-step conversion is obtained, the thermal efficiency of the whole cycle is expected to become higher, since the amount of the undecomposed hydrogen iodide which has to be recirculated decreases. This method may be divided into two kinds of procedures. One is a procedure in which the decomposition of hydrogen iodide and the desorption of iodine are carried out at a constant temperature (Pressure-swing Method). The other is one in which they are carried out at different temperatures (Temperature-swing Method).

As has been mentioned above, the platinum-supported active carbon catalyst has been found to reveal high catalytic activity for the decomposition of hydrogen iodide. On the other hand, active carbon, which is the support of the catalyst, is known to exhibit markedly different adsorption characteristics toward hydrogen, iodine, and hydrogen iodide.[11,12] Therefore, it seems that it is possible for the platinum-supported active carbon (abbreviated as Pt/C) to behave as the adsorbent with catalytic activity mentioned above. With this in view, the present author has attempted the decomposition of hydrogen iodide and the separation of the products by the combination of a column packed with a Pt/C and a temperature-swing method; he has also examined the features and the problems of the present decomposition-separation method.

Experimental

Materials. The Pt/C's (1.1 wt%, 2.3 wt%) were prepared by an impregnation-calcination method (1000 K, 6 h, in an argon stream) from $H_2PtCl_6 \cdot 6H_2O$ (WAKO, Sp. Gr.) and active carbon (PITTSBURG ACTIVATED CARBON, BPL, 12-30 U. S. Sieve Series). Six grams of the Pt/C (2.3 wt%) was used in each run, unless otherwise stated. One ml of hydriodic acid (WAKO, Sp. Gr., 7.52 mol dm^{-3}, $d=1.70$) was fed in in each run.

Apparatus. Figure 2 shows the experimental apparatus. The inside diameter of the quartz reaction tube (b) was 12 mm. The length of the quartz wool layer (c) was 20 mm, while that of the adsorbent layer (d) was 165 mm.

Procedure. The quartz reaction tube was heated in an argon stream at 900 K for 2—3 h, after which the water, oxygen, and so on adsorbed on the quartz wool and the Pt/C were desorbed. After the reaction tube had been cooled, it was set up and 1 ml of hydriodic acid was added to the quartz-wool layer by means of a transfer pipet from the end. After the Pt/C layer only had been heated at the reaction temperature in an electric furnace, the quartz-wool layer also was moved into the electric furnace. The hydriodic acid contained in the quartz-wool layer was evaporated in an argon stream within 10 (450 K) —0.5 min (900 K) and fed into the Pt/C layer. The step of the iodine desorption followed the step of the decomposition of hydrogen iodide. The flow rate of argon in both the steps was usually 27 ml/min.

Thermogravimetry. The Pt/C (2.3 wt%, 100 mg, ground into a diameter less than 0.3 mm and heated at 1000 K for 6 h in an argon stream) and the samples prepared from the Pt/C by the addition of a certain amount of water, hydriodic acid, or iodine were used in the measurements. The sample containing iodine was prepared by the adsorption of iodine into the Pt/C at 373 K in a glass ampoule. After a reduced-pressure treatment (660 Pa, 30 min) of the samples in the sample chamber, argon was introduced and the samples were analyzed by means of thermogravimetry (CHYO, TRDA3-L). The flow rate of argon was 100 ml/min, while the heating rate was 5 K/min.

Analyses. All the components of the product-gas mixture except for hydrogen and argon were condensed at the back part of the reaction tube or trapped in the scrubber. The hydrogen concentration of the exhaust gas was determined by means of gas-chromatography (YANACO 180G, Molecular Sieve 13A). The amount of hydrogen iodide or iodide, condensed or trapped, was determined by titration.[13,14]

Results and Discussion

Thermogravimetry. Figure 3 shows the results of the thermogravimetric analyses of the Pt/C samples. The weight of the Pt/C itself which had been treated at 1000 K remained almost constant up to 1000 K. The water added desorbed almost completely in the pre-measurement operation composed of a reduced-pressure treatment and an argon introduction at room temperature. The iodine added began to desorb around 450 K and finished its desorption at 900 K. In the case of hydriodic acid, about 40% of the weight of the hydriodic acid added was reduced in the pre-measurement operation, after which the residue was reduced in weight in a manner similar to that of the iodine added. The weight loss in the pre-measurement

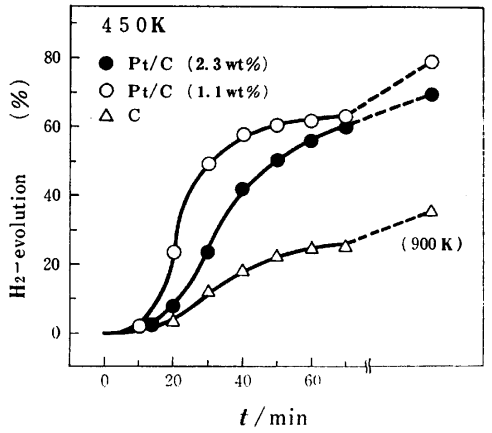

Fig. 4. Influence of the addition of platinum to active carbon on the hydrogen evolution. Six grams of the adsorben twas used. The points above (900 K) corres ponds tothe sum of the amount of hydrogen evolved in the course of the reaction at 450K and that evolved in the hightemperature after-treatment at 900 K for 30 min.

operation was almost equal to the weight of the water contained in the hydriodic acid. This fact suggested the possibility of a selective removal of water from hydriodic acid.

Influence of the Addition of Platinum to Active Carbon on the Hydrogen Evolution. Figure 4 shows the hydrogen evolution (equals the conversion of hydrogen iodide; 100% corresponds to 84 ml (STP) of hydrogen). The points above (900 K) correspond to the sum of the amount of the hydrogen evolved in the course of the reaction at 450 K and that evolved in the high-temperature after-treatment (iodine desorption) at 900 K for 30 min. The amount of hydrogen evolved after the after-treatment was negligibly small, even at 1000 K. The hydrogen evolution obtained with the active carbon itself was remarkably lower than that obtained with the two kinds of Pt/C. This fact indicates that the catalytic activity of the adsorbent is one of the important factors that affect the hydrogen evolution.

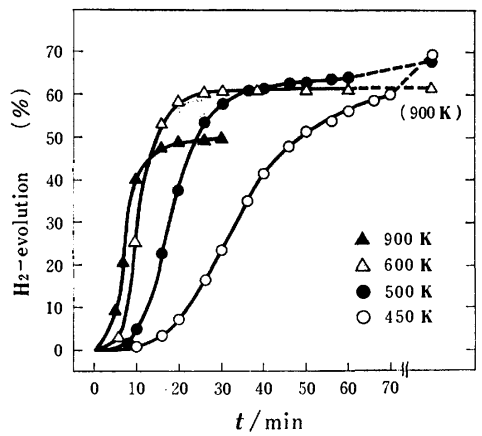

Fig. 5. Influence of the reaction temperature on the hydrogen evolution. The points above (900 K) corresponds to the sum of the amount of hydrogen evolved in the course of the reaction at each temperature and that in the high temperature after-treatment at 900 K for 30 min.

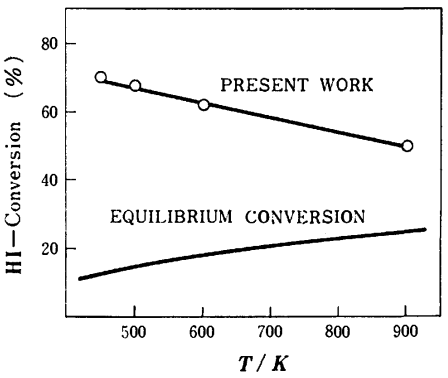

Fig. 6. Comparison of the one-path conversion with the equilibrium one.[6]

Influence of the Reaction Temperature on the Hydrogen Evolution. Figure 5 shows the hydrogen evolution at various temperatures. In the case of the reaction temperature of 900 K, the hydrogen evolution stopped within 30 min. Figure 6 shows that a one-step conversion fairly higher than the equilibrium one was obtained at each temperature. In the temperature region employed in the present experiment, lower temperatures gave higher hydrogen evolutions. This fact may be explained as follows. When the reaction temperature was low, the hydrogen formed was easily desorbed, while the iodine remained adsorbed and the reaction conditions favorable for the elevation of one-step conversion which have been mentioned in the "Principle" section were satisfied. However, as the reaction temperature increased, the desorption of the iodine became easier, as is shown in Figs. 3 and 7. Thus, the removal of the iodine formed from the reaction system by the adsorption became more difficult. Therefore, the one-step conversion decreased as the reaction temperature increased. At higher temperatures, the one-step conversion is expected to approach the equilibrium conversion. However, of course, higher temperatures required a shorter re ction time.

There was a reproducibility for each hydrogen evolution when fresh (not used) Pt/C was used. On the other hand, the hydrogen evolution obtained with a used Pt/C was lower than that obtained with a fresh Pt/C, even if the adsorbates had been fully desorbed from the used Pt/C: for example, the hydrogen evolutions were 61.5% for the first use, 58.6% for the second use, and 54.1% for the third use at 600 K. This fact suggests that the Pt/C gradually deteriorates on repeated runs through the interaction with hydrogen iodide, hydrogen, iodine, and water.

Influence of the Desorption Temperature on the Recoveries of Iodine and Hydrogen Iodide. As Fig. 7 shows, the undecomposed hydrogen iodide began desorbing at 500 K, the iodine formed did so at 600 K, and the total iodine ($HI+I_2$) finished desorption at 900 K. This is in fairly good agreement with the results of the thermogravimetric analyses (Figs. 3-c and d). The maximum temperature available in the thermochemical water splitting is expected to be around 1200 K (High Temperature Gas Cooled Reactor). The fact that the

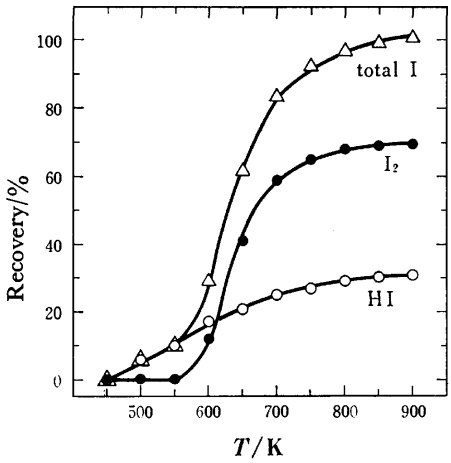

Fig. 7. Influence of the desorption temperature on the recoveries of iodine and hydrogen iodide. Column was kept at each temperature (in the direction of higher temperature) for 30 min: total $I=HI+I_2$.

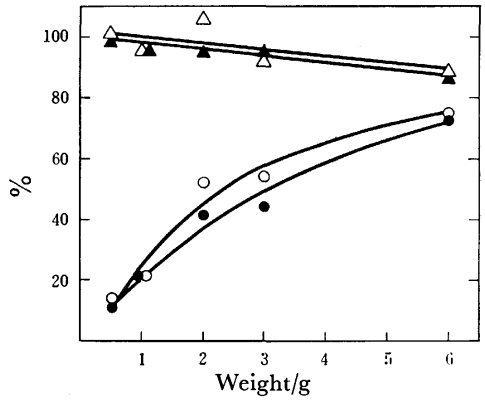

Fig. 8. Influence of the amount of the Pt/C on the hydrogen evolution, the iodine evolution, the total H recovery, and the total I recovery. Each value was obtained in one hour's reaction and thirty minutes' after-treatment at 900 K.
H_2 evolution (○), I_2 evolution (●), total H recovery (△), total I recovery (▲).

iodine desorption, which requires the maximum temperature of this method, is completed around 900 K indicates that this method may be used in the thermochemical water-splitting cycles.

Selective Removal of Water from Hydriodic Acid. As Fig. 7 shows, the undecomposed hydrogen iodide began desorbing around 500 K. On the other hand, a colorless and transparent liquid was already found to condense in the back part of the reaction tube at 450 K. As has been mentioned in the "Thermogravimetry" section, it may be suggested that the liquid was water and that the amount of it corresponded to that of the water contained in the hydriodic acid initially added on the basis of the behavior of the sample D in Fig. 3. The following experiments were carried out in order to confirm this idea. A Teflon tube packed with about 10 g of calcium chloride was attached to the back part of the reaction tube. After 1 ml of hydriodic acid had been added to Part c and the reaction tube had been maintained at 450 K for one hour in an argon stream, the weight of the Teflon tube (kept at room temperature) increased 0.72—0.73 g, with a good reproducibility. The results of titration showed that the total iodine ($HI+I_2$) present in the calcium chloride after the reaction was negligibly small. As no other colorless and transparent liquid except for water and hydriodic acid was included in the system, the liquid was confirmed to be pure water. The amount of 0.72—0.73 g corresponds to 97—98% of the amount of water (0.739 g) contained in 1 ml of the hydriodic acid. On the basis of these experiments, it was found that the water in the hydriodic acid could be removed selectively and almost completely by the use of the Pt/C.

It is well known that active carbon is consumed through the water-gas reaction with water vapor at elevated temperatures. The amounts of hydrogen evolved in the reaction of the Pt/C (2.3 wt%, 6.0 g) with water vapor (0.738 g, corresponding to the amount of the water contained in 1 ml of hydriodic acid) were as follows: 0 mmol(450 K), 0(600 K), 0(700 K), and 0.0982(900 K). On the basis of these results, it is concluded that the consumption of active carbon attributable to the water-gas reaction can be prevented when the water in the hydriodic acid is desorbed at temperatures below 750 K.

Influence of the Amount of the Pt/C on the Hydrogen Evolution. Figure 8 shows the dependence of the hydrogen evolution, the iodine evolution, the total H recovery (H_2+HI), and the total I recovery (I_2+HI) on the amount of the Pt/C. When the amount of the Pt/C was large, a high hydrogen evolution and a high iodine evolution were obtained. On the other hand, the total H recovery and the total I recovery were low in that case, since the time devoted to the desorption was not long enough. As Fig. 7 shows, if enough long time is devoted to the desorption, a total I recovery of almost 100% will be obtained. The optimum amount should be found to obtain a high hydrogen evolution, a high iodine evolution, a high total H recovery, and a high total I recovery, all at the same time.

As has been described above, it was confirmed that a fairly higher one-step conversion of hydrogen iodide than the equilibrium one could be obtained by the combination of the adsorbent with the catalytic activity, namely, the platinum-supported active carbon, and the tempreature-swing method. By the use of this method, the hydrogen formed and almost all the water contained in hydriodic acid could be separated from the product mixture through the operation at 450 K. By removing the water completely from the product mixture, the iodine and the undecomposed hydrogen iodide that desorbs below 900 K can be separated from each other easily. Therefore, the author could show the possibility of the solution of both the subjects mentioned in the introduction; the elevation of the one-step conversion and the development of an effective separation method. However, the method proposed above has two problems which remain unsolved: the rate of the process is low in the temperature region employed; and the process must be driven between the two separated temperatures. It remains necessary to undertake the research

and development of new adsorbents which do not deteriorate, their activation, and that of the pressure-swing method at elevated temperatures, where the rate of the decomposition of hydrogen iodide and the desorption of the adsorbates are high enough, from the standpoint of thermochemical water splitting.

(Received November 25, 1980)

Reversible thermochromism of a Zn(II) complex with 3,3′-bis[bis(carboxymethyl)aminomethyl]-*o*-cresolsulfonphthalein (Xylenol Orange, XO) was studied in D_2O by means of the ^{13}C NMR method with reference to the data of spectrophotometric and temperature-jump measurements. ^{13}C NMR spectra of XO were measured in the pD range between 2.0 and 11.0 and the signals were assigned. π-Electron conjugations in XO and Zn(II)–XO spread on phenol- and quinonoid-rings through the central carbon atom, but the phenyl ring having an SO_3^- substituent is not involved in the π-conjugated system. The temperature- and the pD-dependences of ^{13}C NMR spectra of the Zn(II)–XO complex show that the thermochromism is caused by the temperature-dependence of a protolytic equilibrium of a phenolic hydroxyl group of the Zn(II)–XO complex.

In previous papers, thermochromisms observed for the Cu(II) complexes with triphenylmethane complexons (TPMC), Xylenol Orange (XO),[1] Methylthymol Blue (MTB),[2] and Methylxylenol Blue (MXB),[2] were interpreted in terms of the temperature-dependence of a protolytic equilibrium between a complex species AH having an uncoordinated free phenolic hydroxyl group and a complex species A having a coordinated phenolate group:

$$AH \rightleftharpoons A + H. \quad (1)$$

In the present paper, we aimed at studying thermochromism of metal chelates with TPMC by the ^{13}C NMR method. We chose a diamagnetic Zn(II) complex of XO, which is remarkably thermochromic.[1] The ^1H NMR spectrum of XO[3,4] is too complicated for the present purpose. Since the ^{13}C NMR spectrum of XO has not been reported, the related compounds were also examined for ^{13}C signal assignments of XO.

Experimental

Materials. XO was synthesized by Mannich condensation from *o*-Cresol Red (*o*-CR), iminodiacetic acid (IDA), and formaldehyde.[5] A crude sample of the synthesized XO purified beforehand through a cellulose column was finally purified by means of high-performance liquid chromatography (HPLC).[6] The purified XO was used as a free acid form. Anhydrous zinc(II) chloride[7] was used for the NMR measurements. Zinc(II) perchlorate was used for equilibrium and kinetic measurements. Reagent grade Aurin, Phenol Red (PR), *o*-CR, and IDA were used. The purity of these triphenylmethane derivatives was checked by analytical HPLC with a column of Microbondapak C_{18} (4×300 mm) and water–methanol (50/50, v/v) as a solvent. Deuterium oxide (99.7%), *ca.* 37% DCl in D_2O, and *ca.* 40% NaOD in D_2O were purchased from E. Merck, Ltd.

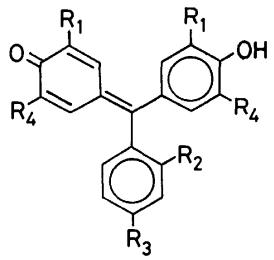
Measurements. The carbon-13 Fourier transform NMR spectra were measured in D_2O solutions at 25.0 MHz with a JEOL JNM-FX-100/PFT-100 spectrometer at various temperatures. The sample was held in a 5 mm tube. The sample concentration was adjusted to 200 mg cm^{-3} for $ZnCl_2$, 100 mg cm^{-3} for IDA and XO, and 40 mg cm^{-3} for Aurin, *o*-CR, and PR. Dioxane was used as an internal reference. Chemical shifts are expressed by δ as δ(dioxane)=67.4.[8] The spectral width was 5000 Hz covered by 4096 addresses in the Fourier transform spectrum and the pulse width was 6 μs. Pulse repetition times ranged from 1.0 to 4.0 s with delay times of 200 μs. The number of scans ranged from 5000 to 20000.

Details on the equilibrium and kinetic measurements were described in the previous papers.[1,2]

The pD values (= pH-meter readings + 0.40)[9] of D_2O solutions were adjusted with DCl and NaOD, and measured with a Hitachi-Horiba pH-meter Model F-7SS equipped with a micro combined pH electrode. Phthalate and phosphate buffers were used for ^{13}C NMR measurements. Acetate buffers were used for equilibrium and kinetic measurements.

Results and Discussion

^{13}C NMR Spectra of XO and Related Compounds in D_2O. In order to assign ^{13}C signals of XO and Zn(II)–XO, we measured ^{13}C NMR spectra of related compounds of XO, Aurin, PR, *o*-CR, and IDA, at various pD. The structures and the abbreviated nomenclatures of those compounds are shown in Fig. 1. The ^{13}C NMR



Compound	R_1	R_2	R_3	R_4
Aurin	H	H	OH	H
PR	H	SO_3H	H	H
o-CR	CH_3	SO_3H	H	H
XO	CH_3	SO_3H	H	A[a]

a) $A=CH_2N(CH_2COOH)_2$.

Fig. 1. The structures of the triphenylmethanes.

† Presented in part at the 30th Annual Meeting on Coordination Chemistry, Tokyo, October 9, 1980, Abstracts, p. 382.

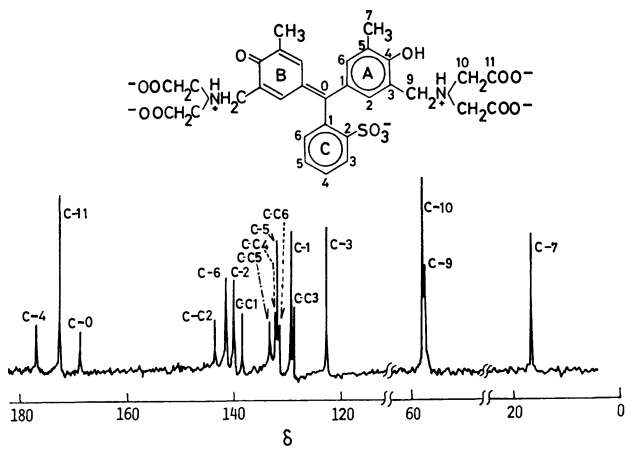


Fig. 2. The ^{13}C NMR spectrum of XO in D_2O at 29°C and pD 6.59.

spectrum of XO is given in Fig. 2.

The central carbon atom of a triphenylmethane skeleton is designated as C-0. The carbon atoms in the A, B, and C ring moieties are designated as C-A*i*, C-B*i*, and C-C*i* ($i=1, 2, \cdots, n$), respectively. In the case of the structural equivalence of the ring moieties, the carbon atoms in these ring moieties are written simply as C-*i*. The ^{13}C signals of the compounds described above were assigned by the peak intensities, the single-frequency off-resonance ^1H decoupling technique, and comparisons of their chemical shifts with those of analogous compounds.[10-12] Data on chemical shifts are summarized in Table 1.

The ^{13}C NMR spectra of Aurin, PR, and *o*-CR show the equivalence between a phenol and a quinonoid ring in neutral and alkaline solutions.[13] Machida *et al.* reported data on the structure of phenolsulfonphthalein dyes, PR, *o*-CR, *etc.*, based on laser-induced Raman spectroscopy. They suggested that phenolsulfonphthalein dyes exist in alkaline solutions as a resonance hybrid of quinonoid and phenolate structures.[14] In the ^{13}C NMR spectra of XO, seventeen peaks were observed in the range of pD 2.0—11.0. This indicates that the A- and the B-ring moieties are equivalent on the NMR time scale irrespective of the existence of a phenolic proton. High intensities of peaks of C-10 and C-11 show the existence of four identical acetate moieties. Ray *et al.* reported that the chemical shifts of the central carbon atom are in the ranges from δ 80 to 82 for para-substituted triphenylmethanols, $(p\text{-}XC_6H_4)_3COH$, and from δ 194 to 212 for the corresponding carbonium ions, $(p\text{-}XC_6H_4)_3C^+$.[15] The central carbon atoms in triphenylmethanols have the tetrahedral configuration, while those in triphenylmethyl cations are reported to be coplanar to the three adjacent ring carbons.[16] For Aurin, PR, *o*-CR, and XO, the signals of C-0 appear in the range from δ 165 to 180, which are comparable to the chemical shifts of C-0 in triphenylmethyl cations.

pD-Dependence of ^{13}C Chemical Shifts for XO. Figure 3 shows plots of values of ^{13}C chemical shifts for seventeen carbon atoms in XO *versus* pD between pD 2.0 and 11.0. C-0, C-1, C-3, C-4, and C-11 undergo significant changes in chemical shifts. Upfield signal shifts for C-0 and C-4, and a small downfield shift for C-10 with an increase in pD observed between pD 2.0 and 4.0 are attributed to the deprotonation at the carboxyl groups. Downfield signal shifts for C-0 and C-4, and an upfield shift for C-1 with an increase in pD observed between pD 5.0 and 8.0 are caused by deprotonation at the phenolic hydroxyl group. Downfield signal shifts for C-3, C-10, and C-11, and an upfield shift for C-0 with an increase in pD observed between pD 9.0 and 11.0 are caused by the deprotonation at $-NH^+-$ groups.[17] For triphenylmethane derivatives, delocalization of charge throughout the π-electron system of the molecule was suggested by Ray *et al.* on the basis of ^{13}C NMR measurements[15] and by

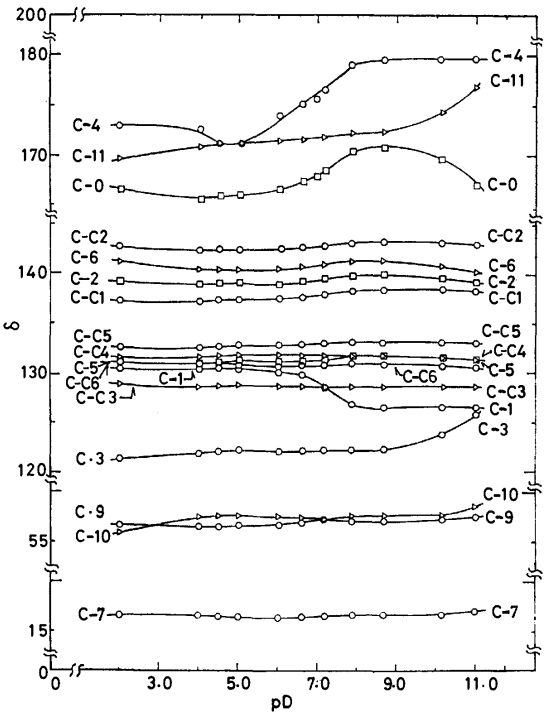

Fig. 3. pD-Dependence of the ^{13}C chemical shifts of XO.

Machida *et al.* from resonance Raman spectroscopic measurements.[14] The large pD-dependence of the chemical shift for C-0 could be explained in terms of the localization-delocalization effect of the π-electron in the molecule.

The chemical shifts of the C-ring carbon atoms were not sensitive to the pD change. In view of this fact, π-electron conjugation in the XO molecule does not spread on the C-ring.

Unexpected distinct pD-dependence of the chemical shift was observed for C-11 in the pD region 9.0—11.0. ^{1}H and ^{13}C chemical shifts are usually influenced by the formation of an intramolecular hydrogen bond.[8] Chapman *et al.* reported in their infrared and ^{1}H NMR studies of ethylenediaminetetraacetic acid and related substances the existence of doubly hydrogen-bonded rings, $-COO^{-}\cdots(NH)^{+}\cdots{}^{-}OOC-$.[19] We infer that the above pD-dependence observed in the chemical shift of C-11 should reflect the existence of such intramolecular hydrogen bonds $-COO^{-}\cdots(NH)^{+}\cdots{}^{-}OOC-$ in XO. A downfield signal shift for C-11 with an increase in pD observed between pD 9.0 and 11.0 would be attributed to the rupture of the hydrogen bonds at the protonated amino groups. Furthermore, a small upfield signal shift for C-4 observed in the pD region 2.5—4.5 would be attributed to the formation of a doubly hydrogen-bonded ring structure, $-COO^{-}\cdots(OH)\cdots{}^{-}OOC-$. Murakami *et al.* suggested the existence of a hydrogen bond between the phenolate oxygen and the proton attached to the amino nitrogen in Semi-Xylenol Orange by spectrophotometric method.[20] However, no pD-dependence was observed in the chemical shift of C-4 for XO in the pD range 9.0—11.0. This result suggests the absence of the hydrogen bond between the phenolate oxygen and the proton attached to the amino nitrogen. From the pD-dependence of chemical shifts of C-0 and C-4, the pK_a value of the phenolic hydroxyl group was determined to be 6.55 at 29 °C. This value is in good agreement with the value derived from the spectrophotometric measurements.[1]

Temperature-dependence of ^{13}C Chemical Shifts for XO. Upon heating a solution of XO buffered at pD 6.93 from 1 to 88 °C, the signals of C-0 and C-4 moved downfield by +0.7 and +1.6 ppm (Table 2). The feature of the temperature-dependence of the chemical shifts of C-0 and C-4 was similar to that of the pD-dependence of the chemical shifts of the same carbon atoms in the pD range 5.0—8.0. Since the pD-dependence of the chemical shifts of C-0 and C-4 is caused by the protonation-deprotonation equilibrium of the phenolic hydroxyl group, we conclude that the temperature-dependence of the chemical shifts for the free ligand XO is also caused by temperature-dependent protonation-deprotonation at the phenolic hydroxyl group.

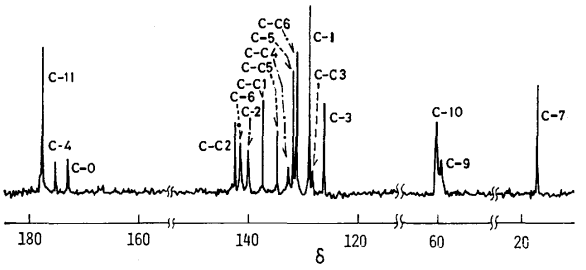

Fig. 4. The ^{13}C NMR spectrum of the Zn(II)–XO in D_2O at 29 °C and at pD 3.88. $[Zn(II)]_0=1.7$ mol dm^{-3}. $[XO]_0=0.17$ mol dm^{-3}.

^{13}C NMR Spectrum of Zn(II)–XO Complex and its pD-Dependence. ^{13}C NMR spectra of Zn(II)–XO complex were measured in the pD range 1.9—5.5 and at 29 °C using D_2O solutions containing a ten-fold excess of Zn(II) ion over the ligand. Figure 4 shows ^{13}C NMR spectrum at pD 3.88. Around pD 2.0 the signals of the carbon atoms, except for the C-ring carbon atoms, were broadened. Seventeen peaks resulting from the predominance of 2 : 1 Zn(II)–XO complex having coordinated carboxylate and amino groups were

		C-4		179.5	

a) δ Values; δ(dioxane)=67.4. b) At 29 °C. c) Phthalate buffers were used. d) Phosphate buffers were used.

observed at pD 3.88 (Fig. 4). At pD 5.46, more than nineteen peaks were observed, indicating that the formation of 1 : 1 Zn(II)–XO complex is not negligible.[21] Signals of C-0 and C-4 were observed at δ 174.0 and 176.3 at pD 3.88, and δ 176.0 and 182.5 at pD 5.46, respectively (Table 2). Both signals of C-0 and C-4 were shifted to lower fields with an increase in pD of the solution. The features of pD-dependence of chemical shifts of C-0 and C-4 for Zn(II)–XO in the pD range 3.8—5.5 were quite similar to those for the free ligand XO in the pD range 5.0—8.0. Therefore, the pD-dependence of chemical shifts of C-0 and C-4 observed for Zn(II)–XO was ascribed to the deprotonation of a phenolic hydroxyl group accompanied with coordination to the central Zn(II).

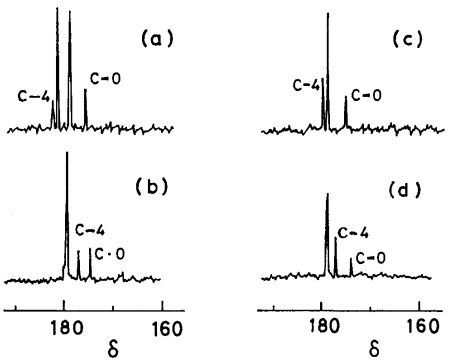

Fig. 5. pD- and temperature-dependence of the chemical shifts of C-0 and C-4 for Zn(II)–XO in D_2O. At 29 °C and at pD 5.46 (a) and 3.88 (b). At pD 3.88 and at 88 (c) and 1 °C (d). Phthalate buffres were used for (c) and (d).

Temperature-dependence of ^{13}C Chemical Shifts for Zn(II)–XO. ^{13}C NMR spectra of Zn(II)–XO were measured at various temperatures in the pD region where remarkable pD-dependences of the chemical shifts of C-0 and C-4 were observed.[22] Signals of C-0 and C-4 moved downfields by +1.7 and +3.2 ppm upon heating a solution of Zn(II)–XO buffered at pD 3.88 from 1 to 88 °C (Table 2). The feature of the temperature-dependences of chemical shifts of C-0 and C-4 (Figs. 5(a) and (b)) was similar to that of the pD-dependences of chemical shifts of the same carbon (Figs. 5(c) and (d)). This fact indicates that the temperature-dependences of the chemical shifts of C-0 and C-4 for Zn(II)–XO is caused by temperature-dependent protonation-deprotonation of a phenolic hydroxyl group in the coordinated ligand.

Spectrophotometric and Temperature-jump Studies. Figure 6 shows the temperature-dependence of the visible absorption spectra of an aqueous solution of Zn(II)–XO at pH 3.97 in the presence of a ten-fold excess of the metal ion over the ligand. The absorption spectrum changes reversibly with a distinct isosbestic point at 492 nm. As the temperature rises the absorbance at 450 nm decreases accompanied with a large increase in the absorbance at 572 nm. The feature of the temperature-dependence of the absorption spectra at a constant pH was quite similar to that of the pH-dependence of the absorption spectra at a constant temperature. These facts clearly indicate that the observed thermochromism of Zn(II)–XO is primarily due to the temperature-dependence of the protolytic equilibrium (1).

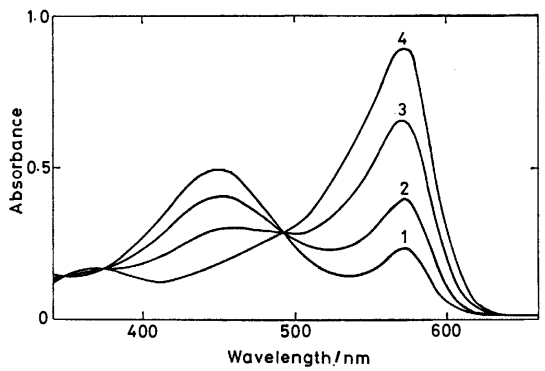

Fig. 6. Temperature-dependence of the absorption spectra of the Zn(II)–XO. At 5 (1), 24 (2), 45 (3), and 69 °C (4). $[Zn(II)]_0=2.0\times10^{-4}$ mol dm^{-3}. $[XO]_0=2.0\times10^{-5}$ mol dm^{-3}. $I=0.1$ mol dm^{-3} ($NaClO_4$). At pH = 3.97 ± 0.02.

Upon heating a solution of Zn(II)–XO complex at pH 3.97 from 15 to 35 °C, the absorbance at 572 nm increased by so large as 40%, whereas the absorbance at 580 nm of the free ligand at pH 6.40, near the pK_a value of the phenolic proton of the free ligand XO, increased only by 19% for the same temperature-rise. The increments in the chemical shifts of C-0 and C-4 for Zn(II)–XO at pD 3.88 were 1.0 and 1.9%, respectively, for temperature-rise from 1 to 88 °C, and those for the free ligand at pD 6.93 were 0.4% and 0.9% for the same temperature-rise.[23] In both spectrophotometric and ^{13}C NMR measurements, the increments of the quantities measured for the Zn(II) complex were twice as large as those for the free ligand upon heating the solutions.

Temperature-jump studies were carried out for Zn(II)–XO. A relaxation signal of an increasing absorbance at 572 nm observed in 5—10 μs region is attributed to the protolytic reaction of a phenolic hydroxyl group. The value of the rate constant for the dissociation of a phenolic proton in the complex was estimated to be 2.3×10^5 s^{-1}. This value was in the same order of magnitude as that for Cu(II)–XO.[1]

Considering the equilibrium and the kinetic data, we concluded that the temperature-dependence of the chemical shifts of C-0 and C-4 for Zn(II)–XO is primarily ascribed to the temperature-dependence of protolytic equilibrium (1).

22) Changes in all chemical shift values upon heating unbuffered solutions of both XO and Zn(II)–XO were similar to the changes in chemical shifts with a decrease in pD of the same solutions. At 88 °C the spectrum of an unbuffered XO solution at pD 6.42 showed two new peaks assigned to C-10 and C-11 of free IDA (Table 2) in the same pD region.
23) Increases in ^{13}C chemical shifts were smaller than those expected because of the incomplete buffer action in the solutions. Upon heating from 1 to 75 °C the pH-meter reading decreased from 3.75 to 3.10 for Zn(II)–XO and from 6.51 to 6.06 for the free ligand XO.

Metal Complexes of Peptides. II.[1] Circular Dichroism Spectra and Absolute Configuration of Bis(dipeptidato)cobalt(III) Complexes

Takaji YASUI,* Hiroshi KAWAGUCHI, and Tomoharu AMA

Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780

(Received December 3, 1980)

Type $[Co(dipeptidato)_2]^-$ complexes (dipeptidato denotes dianions of glycylglycine, -β-alanine, -L-alanine, and -L-leucine, β-alanylglycine and -L-alanine, L-alanylglycine and -β-alanine, L-leucylglycine, and L-prolylglycine) and the complex $[Co(gly\text{-}gly)(L\text{-}pro\text{-}gly)]^-$ were prepared by a method using lead dioxide as an oxidizing agent, and these complexes were separated into two diastereomers or enantiomers by column chromatography. The absolute configurations of the optical isomers were determined on the basis of their circular dichroism patterns in the ligand transition region.

A great number of metal complexes with various peptides have been studied as enzymatic metal complexes.[2-14] However, coordination behaviors of peptides to metal ions are delicately different among metals and peptides. It is very interesting to characterize systematically metal complexes with various peptides. It is well-known that cobalt(III) ion produces stable peptide complexes.[1,3,13-20]

According to X-ray crystallographic studies of bis(glycylglycinato)cobalt(III) complex,[21,22] two glycylglycinates are coordinated to cobalt(III) in the meridional (mer) configuration as terdentate ligand. In our previous studies concerning mixed-ligand complexes containing both dipeptidate and iminodiacetate or *N*-methyliminodiacetate,[1,23] it was demonstrated by ^1H and ^{13}C NMR data that the dipeptidate coordinates to cobalt(III) in mer disposition.

Recently, Boas *et al.*[20] studied several preparative methods for type $[Co(\alpha_1\text{-}\alpha_2)_2]^-$ complexes ($\alpha_1\text{-}\alpha_2$ denotes dianion of dipeptide) and their configurations by ^1H NMR, circular dichroism (CD) spectroscopy in the d-d transition region, and column chromatography.

In the present paper, we will describe the preparation of new type bis(dipeptidato)cobalt(III) complexes containing L-proline or β-alanine residue and discuss their absolute configurations on the basis of absorption and CD spectral data.

Experimental

Ligands. Glycyl-β-alanine (H_2gly-β-ala), β-alanylglycine (H_2β-ala-gly), L-alanyl-β-alanine (H_2L-ala-β-ala), and β-alanyl-L-alanine (H_2β-ala-L-ala) were prepared by the method described in our previous paper.[1] Glycylglycine (H_2gly-gly), glycyl-L-leucine (H_2gly-L-leu), L-leucylglycine (H_2L-leu-gly) were obtained commercially from Protein Research Foundation, glycyl-L-alanine (H_2gly-L-ala) and L-alanylglycine (H_2L-ala-gly) from Fluka Chemical Company, and L-prolylglycine (H_2L-pro-gly) from Sigma Chemical Company. These purchased dipeptides were used without further purification.

Preparation of Complexes. Two Diastereomers of Potassium Bis(L-prolylglycinato)cobaltate(III), K[Co(L-pro-gly)$_2$]: L-Prolylglycine (3.44 g, 0.02 mol) was dissolved in 20 cm^3 of water, and the solution was adjusted to pH 9—9.5 with a 1 M† NaOH solution. An aqueous solution containing cobalt(II) chloride hexahydrate (2.37 g, 0.01 mol) in 10 cm^3 of water was added drop by drop to the above peptide solution, keeping the pH of the solution at *ca.* 9 with a NaOH solution. The mixed solution was oxidized with lead dioxide (5 g) at 40 °C for 1 h with stirring. The resulting solution was filtered to remove insoluble materials, and the purple filtrate was chromatographed on a QAE-Sephadex A-25 column (4.7 cm × 90 cm, Cl^- form). The positively charged and neutral complexes were removed by flushing the column with water. The adsorbed band was separated into violet and purple bands by elution with an 0.05 M KCl solution. Each eluted solution was concentrated to a small volume by a rotary evaporator at 35—40 °C. A large amount of methanol was added to the concentrated solution, and then potassium chloride which deposited was removed by filtration. The filtrate was concentrated again to a few milliliters, and the residual KCl in the solution was removed completely by using a Sephadex G-10 column. The early eluted isomer ($R(C_2)$-K[Co(L-pro-gly)$_2$]·3H_2O) was crystallized by addition of ethanol to the concentrated aqueous solution and by keeping the solution in a refrigerator for a few days. The crystals were filtered and washed with 90% ethanol, 99.5% ethanol, and then acetone. The late eluted isomer ($S(C_2)$-K[Co(L-pro-gly)$_2$]·3.5H_2O) was isolated as needle crystals by addition of acetone to the methanolic solution and by keeping the solution in a refrigerator for a few days. The crystals were filtered and washed with acetone. Both complexes were dried over calcium chloride in a desiccator under reduced pressure.

The diastereomers of other bis(dipeptidato)cobalt(III) complexes with L-alanyl-β-alaninate, β-alanyl-L-alaninate, glycyl-L-leucinate, L-leucylglycinate, glycyl-L-alaninate, or L-alanylglycinate were prepared and separated by the same procedure as that used for the complex K[Co(L-pro-gly)$_2$] described above, except that the pH of the reaction solutions containing the dipeptide ligands with β-alanyl or β-alanine residue was adjusted to 8—8.5. Crystallization of these complexes was carried out from the concentrated aqueous solutions by addition of methanol or acetone.

Two Diastereomers of Potassium(glycylglycinato)(L-prolylglycinato)cobaltate(III), K[Co(gly-gly)(L-pro-gly)]: The preparation and chromatographic separation for the diastereomers of this mixed ligand complex were carried out by the method similar to that used for the complex K[Co(L-pro-gly)$_2$], except that a mixture of glycylglycine (1.32 g, 0.01 mol) and L-prolylglycine (1.72 g, 0.01 mol) was used instead of L-prolylglycine. However, in this case an adsorbed band was separated into five ($[Co(L\text{-}pro\text{-}gly)_2]^-$ ($R(C_2)$-isomer), $[Co(gly\text{-}gly)(L\text{-}pro\text{-}gly)]^-$ ($R(C_2)$-isomer), $[Co(gly\text{-}gly)_2]^-$, $[Co(gly\text{-}gly)(L\text{-}pro\text{-}gly)]^-$ ($S(C_2)$-isomer), and $[Co(L\text{-}pro\text{-}gly)_2]^-$ ($S(C_2)$-isomer)) by continuous development using six QAE-Sephadex columns (4.7 cm × 90 cm, Cl^- form). Two diastereomers (second and forth eluates) of the mixed ligand complex were

† 1 M = 1 mol dm^{-3}.

isolated as needle crystals of reddish-purple color.

Barium Bis(glycyl-β-alaninato)cobaltate(III) Tetrahydrate and Potassium Bis(β-alanylglycinato)cobaltate(III) Monohydrate, $Ba[Co(gly\text{-}\beta\text{-}ala)_2)]_2\cdot 4H_2O$ and $K[Co(\beta\text{-}ala\text{-}gly)_2]\cdot H_2O$:[1] These complexes were obtained by the method similar to that used for $K[Co(L\text{-}pro\text{-}gly)_2]$. However, since the potassium salt of bis(glycyl-β-alaninato)cobaltate(III) complex was hygroscopic, it was converted to the barium salt using a small SP-Sephadex C-25 column (Ba^{2+} form).

The analytical data of the newly prepared complexes are listed in Table 1.

Partial Resolution of $[Co(gly\text{-}\beta\text{-}ala)_2]^-$. Racemic $Ba[Co(gly\text{-}\beta\text{-}ala)_2]_2\cdot 4H_2O$ (*ca.* 0.2 g) was dissolved in a small amount of water and loaded on a QAE-Sephadex column (4.7 cm × 90 cm, Cl^- form). An adsorbed band was developed with an 0.1 M L-histidinium chloride solution. After the development had been repeated about twenty-five times using a circulating micropump, the broadened band was eluted fractionally. The first and last fractions exhibited optical rotations of (−) and (+) signs at 589 nm, respectively. Each fraction was concentrated by a rotary evaporator until crystals of L-histidinium chloride appeared. The L-histidinium chloride was removed by filtration, and methanol was added to the filtrate to deposit out the residual L-histidinium chloride. After the removal of L-histidinium chloride, the methanolic solution was evaporated again almost to dryness. The resulting residue was dissolved in a small amount of water and chromatographed to remove completely the L-histidinium chloride and to convert the complex to the potassium salt using a small SP-Sephadex column (K^+ form). The crude complex was purified using a Sephadex G-10 column. The CD spectra of the optically active complexes were measured without isolating them as crystals, and the $\Delta\varepsilon$ values of the complexes were calculated from the absorption spectral data of the racemic complexes. The main CD band in the first absorption region showed negative and positive signs for the two isomers from the first and last fractions, respectively.

Partial resolution of racemic $[Co(\beta\text{-}ala\text{-}gly)_2]^-$ and $[Co(gly\text{-}gly)_2]^-$ was also carried out by the method similar to that used for the complex $[Co(gly\text{-}\beta\text{-}ala)_2]^-$. However, in the case of the complex $[Co(\beta\text{-}ala\text{-}gly)_2]^-$ the $(+)_{589}$- and $(-)_{589}$-isomers were obtained from the first and last fractions, respectively, and the elution order of the enantiomers was opposite to the cases of the complexes $[Co(gly\text{-}\beta\text{-}ala)_2]^-$ and $[Co(gly\text{-}gly)_2]^-$.

Measurements. The absorption and CD spectra were measured by a Hitachi 557-type spectrophotometer and a JASCO J-22 spectropolarimeter, respectively.

Results and Discussion

Boas *et al.*,[20] trying seven preparative methods for type $[Co(dipeptidato)_2]^-$ complexes, adopted the method starting from cobalt(III) hydroxide oxide. In the present study, however, we used the preparative method based on oxidizing cobalt(II) by lead dioxide, which is not included in the above seven methods. The present method is featured by rapid reaction, minor by-products, comparable yields of two diastereomeric complexes, and prevention of the hydrolysis of dipeptide.

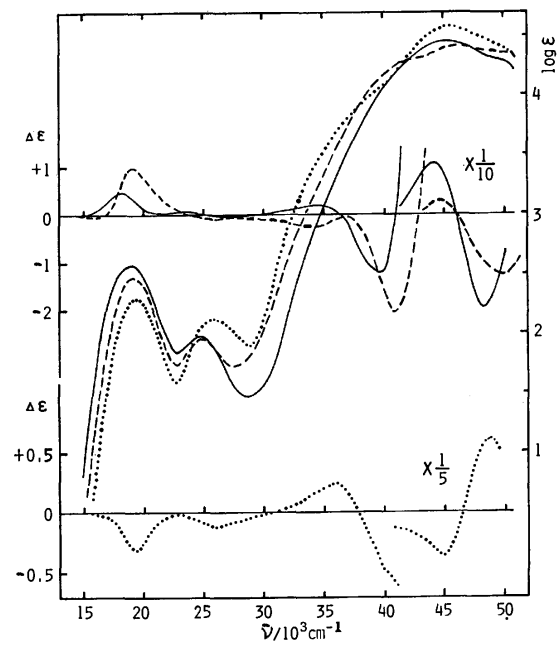

Fig. 1. Absorption (racemate) and CD (last fraction resolved by column chromatography) spectra: $[Co(gly\text{-}gly)_2]^-$ (——), $[Co(gly\text{-}\beta\text{-}ala)_2]^-$ (------), and $[Co(\beta\text{-}ala\text{-}gly)_2]^-$ (····).

Absorption Spectra. Absorption spectral data of the complexes bis(dipeptidato)cobalt(III) examined are summarized in Table 2. These complexes show a slight difference in their spectral behaviors. Figure 1 shows a comparison of absorption curves among the complexes $[Co(gly\text{-}gly)_2]^-$, $[Co(gly\text{-}\beta\text{-}ala)_2]^-$, and $[Co(\beta\text{-}ala\text{-}gly)_2]^-$. The first and second absorption maxima shift to the higher energy side in the order of gly-gly, gly-β-ala,

a) In the unit of 10^3 cm^{-1}. b) Molar extinction coefficient ratio of the first and second absorption maxima.

and β-ala-gly complexes. Such a shift of the maximum positions may be attributed to a delicate difference in the ligand field strength of coordinated dipeptidates or in the stability of dipeptidato complexes; it follows that the six-membered chelate ring (β-alanyl ring) in the N-terminal side is less strained than the five-membered chelate ring (glycyl ring). The order of the stability of these dipeptidato complexes quite agrees with that established by Nakahara *et al.* for copper(II) complexes of dipeptides[24] and tripeptides[25] containing glycine and/or β-alanine residues.

Difference between the type [Co(β-ala-α_2)$_2$]$^-$ and [Co(α_1-β-ala)$_2$]$^-$ or [Co(α_1-α_2)$_2$]$^-$ (α denotes α-amino acid residue) complexes is also observed in the intensity ratio of the first to second absorption maximum ($\varepsilon_I/\varepsilon_{II}$) (Table 2). It is interesting that the $\varepsilon_I/\varepsilon_{II}$ ratios of the diastereomeric complexes indicate higher values for the early eluted isomers ($S(C_2)$-isomers) than for the late eluted ones ($R(C_2)$-isomers), except for the [Co(L-pro-gly)$_2$]$^-$ complexes.

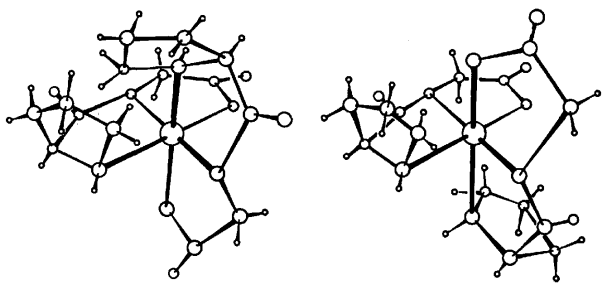

Fig. 2. Possible structures of two diastereomers in [Co(L-pro-gly)$_2$]$^-$ complex.

Figure 2 shows the two diastereomeric structures of the complex [Co(L-pro-gly)$_2$]$^-$. With the notation, proposed by Boas *et al.*[20] for the bis(dipeptidato)cobalt(III) type complexes, applied to the case of complex [Co(L-pro-gly)$_2$]$^-$, a diastereomer assuming the $R(C_2)$ configuration has a larger steric compression between the two pyrrolidine rings in the complex molecule than the other assuming the $S(C_2)$ configuration. As shown in Table 2, the first and second absorption maxima of the early eluted isomer (violet isomer) locate toward the longer wavelength side by as much as 300 and 290 cm^{-1}, respectively, than those of the late eluted isomer (purple isomer). Consequently, it is expected from these spectral behaviors that the former isomer assumes a structure of larger steric compression than the latter isomer, hence the configurations of the early and late eluted isomers can be assigned to R(C$_2$) and S(C$_2$), respectively.

Circular Dichroism Spectra and Absolute Configurations. The CD spectral data of all the complexes are listed in Table 3, and their absolute configurations and the elution order of the diastereomers are shown in Table 2. The CD spectra of the complexes examined may be divided into three band regions in the d-d transition range 15000—30000 cm^{-1}, the charge transfer range 30000—40000 cm^{-1}, and the ligand transition range 40000—50000 cm^{-1}. Figure 3 shows the CD curves of the two pairs of diastereomers in the complexes [Co(L-pro-gly)$_2$]$^-$ and [Co(gly-gly)(L-pro-gly)]$^-$. These diastereomers exhibit quite similar CD patterns in the first and second absorption regions. Therefore, in these cases it is difficult to assign their absolute configurations from their CD patterns only for the d-d transition region. On the other hand, the CD curves of the pair of diastereomers in the range of

a) In the unit of 10^{-3} cm^{-1}. b) The isomer was obtained from the last fraction when the complex was chromatographed on a QAE-Sephadex C-25 column with an 0.1 M L-histidinium chloride solution.

40000—50000 cm^{-1} show antipodal CD patterns with opposite signs, which may be related to the absolute configurations of the diastereomeric complexes. Namely, in the complex [Co(L-pro-gly)$_2$]$^-$ the CD curve of the early eluted isomer assigned to the R(C$_2$) shows plus and minus peaks at 42190 and 46510 cm^{-1}, respectively, and that of the late eluted isomer assigned to the S(C$_2$) shows minus and plus peaks at 42920 and 47170 cm^{-1}, respectively. Quite similar CD patterns are observed also for the pair of the diastereomers of the complex [Co(gly-gly)(L-pro-gly)]$^-$ (Fig. 3). Therefore, we can assign the early and late eluted isomers the configurations R(C$_2$) and S(C$_2$), respectively.

However, the observed CD spectra of the present diastereomers are produced as a sum of the configurational and vicinal contributions. Figure 4 shows only the configurational CD curves (obtained through subtraction of values for the early eluted diastereomer from those for the late eluted) for the diastereomeric complexes. The configurational CD curves in the d-d transition region exhibit quite similar patterns to each other for the L-ala-gly and L-leu-gly complexes of the gly-L-ala and gly-L-leu complexes, but those of the L-pro-gly, L-ala-β-ala, and β-ala-L-ala complexes do not indicate such a similarity among them. On the other hand, the configurational CD curves in the region of 40000—50000 cm^{-1} show the same patterns (plus and minus signs from the longer wavelength side) for

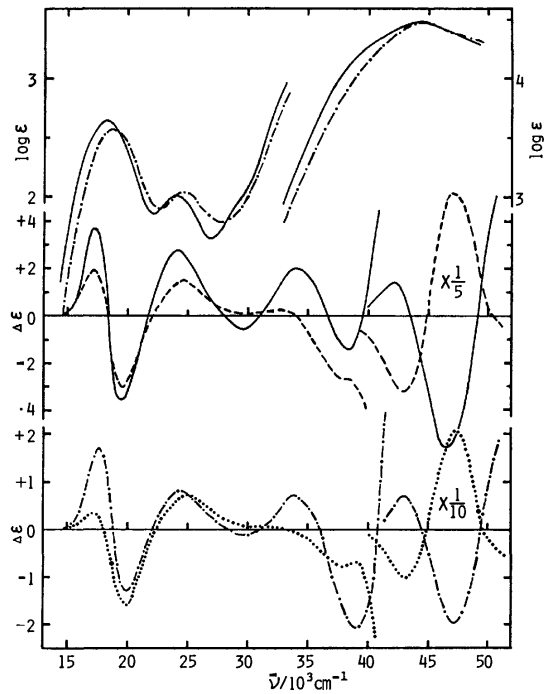

Fig. 3. Absorption and CD spectra of the dipeptidato complexes: early (——) and late (------) eluted diastereomers of [Co(L-pro-gly)$_2$]$^-$; early (·····) and late (·····) eluted diastereomers of [Co(gly-gly)(L-progly)]$^{-1}$.

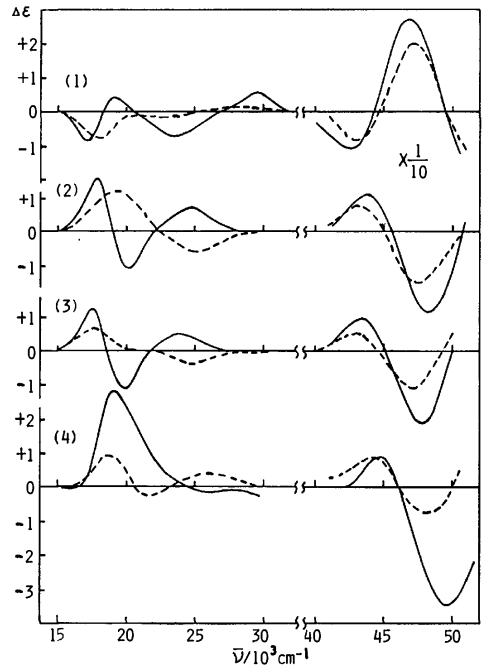

Fig. 4. Configurational CD curves calculated for the dipeptidato complexes: [(late eluted diastereomer)—(early eluted diastereomer)]/2. (1) [Co(L-pro-gly)$_2$]$^-$ (——) and [Co(gly-gly)(L-pro-gly)]$^-$ (------), (2) [Co(L-ala-gly)$_2$]$^-$ (——) and [Co(gly-L-ala)$_2$]$^-$ (------), (3) [Co(L-leu-gly)$_2$]$^-$ (——) and [Co(gly-L-leu)$_2$]$^-$ (------), (4) [Co(L-ala-β-ala)$_2$]$^-$ (——) and [Co(β-ala-L-ala)$_2$]$^-$ (------).

complexes (2)—(4) in Fig. 4. From a comparison of these CD patterns with those of the L-pro-gly and (gly-gly)(L-pro-gly) complexes one can assign the absolute configurations to the paired diastereomers in complexes (2)—(4). Namely, the R(C_2) and S(C_2) configurations can be assigned to the late and early eluted diastereomers of complexes (2)—(4), respectively, as shown in Table 2. These configurational assignments for the gly-L-ala, L-ala-gly, gly-L-leu, and L-leu-gly complexes are quite in agreement with those by Boas *et al.*[20]

An analogous discussion can be made for the complexes [Co(gly-gly)$_2$]$^-$, [Co(gly-β-ala)$_2$]$^-$, and [Co(β-ala-gly)$_2$]$^-$ which were partially resolved by column chromatography[26] using an 0.1 M L-histidinium chloride solution. Figure 1 shows the CD spectra of their first fractions ((+)$_{589}$-[Co(gly-gly)$_2$]$^-$, (+)$_{589}$-[Co(gly-β-ala)$_2$]$^-$, and (—)$_{589}$-[Co(β-ala-gly)$_2$]$^-$). The CD patterns in the ligand transition region exhibit plus and minus signs in the range 40000—50000 cm^{-1} for the gly-gly and gly-β-ala complexes. Therefore, the R(C_2) configuration can be assigned to the first fractions ((+)$_{589}$-isomer) of these complexes. The elution order of the two enantiomers in the complex [Co(gly-gly)$_2$]$^-$ was the same as that Gillard *et al.*[15,20] obtained with a starch column. On the other hand, the first fraction ((—)$_{589}$-isomer) of the complex [Co(β-ala-gly)$_2$]$^-$ shows the CD pattern with opposite (minus and plus) signs which can be assigned to the S(C_2) configuration.

Metal Complexes Coordinating Pyridine Derivatives. III.[1] Stereoselective Formation of Chromium(III) Complexes of Chiral Quadridentate Ligands

Yukihiro YAMAMOTO* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received December 22, 1980)

Dichloro mononuclear and di-μ-hydroxo dinuclear chromium(III) complexes were prepared with the following three ligands, (*S*)-*N*,*N*′-bis(2-pyridylmethyl)propylenediamine (abbrev. *S*-picpn), (*S*,*S*)-*N*,*N*′-bis(2-pyridylmethyl)-2,3-butanediamine (abbrev. *SS*-picbn), and (*S*,*S*)-*N*,*N*′-bis(2-pyridylmethyl)-1,2-cyclohexanediamine (abbrev. *SS*-picchxn). The *SS*-picbn and *SS*-picchxn ligands produce novel *Λ*(*SS*)-*cis*-α diastereomer of dichloro complex, in which the terminal chelate ring is formed by coordination of equatorially-oriented substituent on the secondary nitrogen atom. An explanation from the viewpoint of steric repulsion is given for the stereoselective formation of *Λ*(*SS*) diastereomers for the *cis*-α dichloro complexes of *SS*-picchxn and *SS*-picbn. A similar explanation is also given for stereoselective formation of a limited number of isomers of dinuclear μ-hydroxo complexes of *S*-picpn, *SS*-picbn, and *SS*-picchxn.

In a previous paper,[2] two diastereomers *Δ*(*S*) and *Λ*(*S*) were prepared for a *cis*-α-dichloro or dibromo chromium(III) complex of a quadridentate ligand (*S*)-*N*,*N*′-bis(2-pyridylmethyl)propylenediamine (abbrev. *S*-picpn). In the *Δ*(*S*)-*cis*-α diastereomer, the quadridentate ligand takes the most stable conformation, the aminomethylpyridine chelate ring being formed by coordination of an axially-oriented substituent on the secondary nitrogen atom. This fact was confirmed from the X-ray crystal structure analysis of *Δ*-*cis*-α-[$CrCl_2$(*S*-picpn)]Cl.[3] On the other hand, the *Λ*(*S*)-*cis*-α diastereomer belongs to a rather rare type, in which the terminal chelate ring is formed by coordination of an equatorially-oriented substituent on the secondary nitrogen (Fig. 1). Another example of this type found in literature is a *Δ*-*cis*-α diastereomer of (oxalato or ethylenediamine) {(*R*,*R*)-*N*,*N*′-dimethyl-1,2-cyclohexanediamine(diacetato)}cobalt(III).[4]

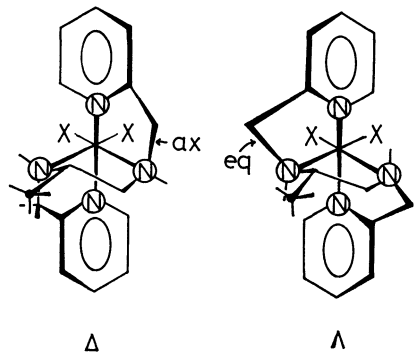

Fig. 1. Two *cis*-α diastereomers of $[CrX_2$(*S*-picpn)]$^+$, "ax" showing the axial orientation of the pyridylmethyl substituent on the secondary nitrogen atoms and "eq" the equatorial orientation.

In this paper, two kinds of chiral ligands, (*R*,*R*)-*N*,*N*′-bis(2-pyridylmethyl)-1,2-cyclohexanediamine (abbrev. *RR*-picchxn) and (*S*,*S*)-*N*,*N*′-bis(2-pyridylmethyl)-2,3-butanediamine (abbrev. *SS*-picbn), were used for preparation of dichloro and di-μ-hydroxo type chromium(III) complexes, turning our attention to the *cis*-α structure. For convenience, the explanation is made in Results and Discussion using *SS*-picchxn, actually *RR*-picchxn being used in Experimental.

Experimental

Ligands. *(S,S)-2,3-Butanediamine*: This was prepared and resolved by the method in the literature.[5] The absolute configuration is considered to be (*S*, *S*) from the literature.[6]

(R,R)-1,2-Cyclohexanediamine: This was resolved by the method in the literature.[7]

The quadridentate ligands *S*-picpn, *SS*-picbn, and *RR*-picchxn were prepared from (*S*)-propylenediamine, (*S*, *S*)-2,3-butanediamine, or (*R*,*R*)-1,2-cyclohexanediamine and 2-pyridinecarbaldehyde by the method of Goodwin and Lions.[8]

Mononuclear Complexes. *Preparation I*: Anhydrous chromium(III) chloride (1.0 g) was suspended in 0.1 cm^3 of dimethyl sulfoxide, the equimolar amount (1.79 g) of *SS*-picbn (1.8 g in the case of *RR*-picchxn) being added slowly with stirring. After thirty minutes, unreacted material was filtered off and the filtered solution was poured onto an SP-Sephadex C-25 column ($\phi 30 \times 700$ mm) and the adsorbed band was eluted with 0.1 mol dm^{-3} NaCl aqueous solution. Three bands were eluted, a purple one (i), a red-violet one (ii), and a violet one (iii). The first band proved to contain only one diastereomer by examining circular dichroism (CD) spectra of the fractions of this band collected with a fraction collector. To the concentrated solution of the eluate was added sodium perchlorate and obtained precipitates were recrystallized from warm water. For the *SS*-picbn complex: Found; C, 38.24; H, 4.56; N, 10.97%. Calcd for $[CrCl_2$(*SS*-picbn)]$ClO_4 \cdot 0.5H_2O = C_{16}H_{22}N_4O_4Cl_3Cr \cdot 0.5H_2O$: C, 38.30; H, 4.62; N, 11.17%. For the *RR*-picchxn complex: Found; C, 41.24; H, 4.68; N, 10.68%. Calcd for $[CrCl_2$(*RR*-picchxn)]$ClO_4 \cdot 0.5H_2O = C_{18}H_{24}N_4O_4Cl_3Cr \cdot 0.5H_2O$: C, 40.96; H, 4.77; H, 10.62%. The band (ii) contained two species but decomposed during the concentration procedure even below 25 °C. The band (iii) seemed to be a di-μ-hydroxo complex, but its yield was very low. In the same way the *S*-picpn dichloro complex has been prepared, both *Δ* and *Λ* diastereomers being isolated.[2]

Preparation II: Chromium shot (0.50 g) was crushed and dissolved in hydrochloric acid under nitrogen atmosphere. the blue solution was evaporated to dryness, to which was added 2.56 g of *SS*-picbn (2.86 g in the case of *RR*-picchxn) in 4 cm^3 of pyridine. While refluxing for ten minutes, a pyridine solution (10 cm^3) of iodine (2.44 g) was added. The deposited product was dissolved in water and passed through the Dowex 1-X8 column (Cl^- form). After concentrating the eluate, 60% perchloric acid was added. The precipitate was recrystallized from hot water. Only one diastereomer was obtained, the CD spectrum being the same as the band

(i) in Preparation I. For the *SS*-picbn complex: Found; C, 38.65; H, 4.57; N, 11.24%. Calcd for $[CrCl_2(SS\text{-picbn})]ClO_4 \cdot 0.5H_2O = C_{16}H_{22}N_4O_4Cl_3Cr \cdot 0.5H_2O$: C, 38.30; H, 4.62; N, 11.17%. For the *RR*-picchxn complex: Found; C, 40.88; H, 4.72; N, 10.54%. Calcd for $[CrCl_2(RR\text{-picchxn})]ClO_4 \cdot 0.5H_2O = C_{18}H_{24}N_4O_4Cl_3Cr \cdot 0.5H_2O$: C, 40.96; H, 4.77; N, 10.62%. This method of preparation gave only the more stable diastereomer (*Λ*) in the case of the *S*-picpn ligand.[2]

Di-μ-hydroxo Dinuclear Complexes. Chromium(III) bromide hexahydrate (2.0 g) was dissolved in 2-methoxyethanol (15 cm^3). After adding zinc powder, *S*-picpn (1.28 g) was added with stirring. After ten minutes, the zinc powder and violet precipitate were filtered off, and the filtrate was poured onto an SP-Sephadex C-25 column ($\phi 30 \times 700$ mm). Eluting with 0.5 mol dm^{-3} NaCl aqueous solution, three bands were obtained, a brown one (i), and two violet ones (ii) and (iii). Pure crystalline product was obtained by concentrating the eluate (ii) and adding an aqueous solution of sodium perchlorate. For the *S*-picpn complex: Found; C, 32.44; H, 4.24; N, 9.95%. Calcd for $[\{Cr(OH)(S\text{-picpn})\}_2](ClO_4)_4 \cdot 3.5H_2O = C_{30}H_{42}N_8O_{18}Cl_4Cr_2 \cdot 3.5H_2O$: C, 32.42; H, 4.44; N, 10.08%. For the *SS*-picbn complex: Found; C, 33.32; H, 4.52; N, 9.59%. Calcd for $[\{Cr(OH)(SS\text{-picbn})\}_2](ClO_4)_4 \cdot 3H_2O = C_{32}H_{46}N_8O_{18}Cl_4Cr_2 \cdot 3H_2O$; C, 33.99; H, 4.64; N, 9.91%. For the *RR*-picchxn complex: Found; C, 35.92; H, 4.83; N, 9.24%. Calcd for $[\{Cr(OH)(RR\text{-picchxn})\}_2](ClO_4)_4 \cdot 4H_2O = C_{36}H_{50}N_8O_{18}Cl_4Cr_2 \cdot 4H_2O$: C, 36.01; H, 4.87; N, 9.33%. The eluate (i) seemed to be a mononuclear species. From (iii) pure crystals could not be obtained in spite of repeated crystallizations. This may be a polynuclear complex.

The dinuclear complex $[\{Cr(OH)(RR\text{-picchxn})\}_2](ClO_4)_4$ was dissolved in concd hydrochloric acid. After 6 d, 30% perchloric acid was added to it and the obtained perchlorate salt was recrystallized from water. Found: C, 40.41; H, 4.68; N, 10.40%. Calcd for $[CrCl_2(RR\text{-picchxn})]ClO_4 \cdot H_2O = C_{18}H_{24}N_4O_4Cl_3Cr \cdot H_2O$: C, 40.28; H, 4.88; N, 10.44%. The CD spectrum of this mononuclear complex was the same as those of the samples prepared in Preparations I and II.

Other Complexes. The dinuclear complexes $[\{Cr(OH)(picen)\}_2](ClO_4)_4$, $[\{Cr(OH)(pma)_2\}_2](ClO_4)_4$ (pma=2-pyridylmethylamine), and *meso*-$[\{Cr(OH)(en)_2\}_2]Cl_4$ were prepared by the methods in the literatures.[9-12]

ΛΛ-trans(py)*trans*(py)-$[\{Cr(OH)(S\text{-pea})_2\}_2]I_4$ (*S*-pea=(*S*)-1-(2-pyridyl)ethylamine) was prepared in a previous paper.[1]

Measurements. The visible and ultraviolet absorption spectra were measured with a Shimadzu UV-200 and a Hitachi 330 spectrophotometer. The CD spectra were measured on a JASCO MOE-1 spectropolarimeter. The dichloro complexes were measured in 0.1 mol dm^{-3} HCl and the dinuclear ones in water.

Results and Discussion

Structure Assignments. The absorption and CD spectra of the mononuclear dichloro complexes of *SS*-picbn and *SS*-picchxn are shown in Fig. 2. The geometries and absolute configurations were determined from the CD spectra in the first d-d absorption band region. As stated in a previous paper,[2] the CD of *Λ-cis-α* complex of chromium(III) or cobalt(III) coordinated with pcen derivative shows a typical (+, −) dispersion pattern from the lower energy side and that of *Λ-cis-α* (−, +), the $|\Delta\varepsilon|$ value at the each extremum being larger than 1.0. From this criterion, the present complexes of *SS*-picbn and *SS*-picchxn are assigned *Λ-cis-α* form. The absorption and CD spectra of di-*μ*-hydroxo dinuclear complexes of *S*-picpn, *SS*-picbn, and *SS*-picchxn are shown in Figs. 3 and 4 together with those of *ΔΔ-trans*(py)*trans*(py)-$[\{Cr(OH)(picen)\}_2](ClO_4)_4$ (picen=*N,N'*-bis(2-pyridylmethyl)ethylenediamine)(each parts linked by two hydroxyl groups take *trans*(py)*trans*(py) structure(cis-α structure)), which takes the *trans*(py)*trans*(py) structure stereoselectively because of the steric hindrance between pyridine rings.[10] The CD curve of *S*-picpn complex is nearly a mirror image to that of the picen complex of *ΔΔ* configuration. Thus the configuration of the *S*-picpn complex is assigned

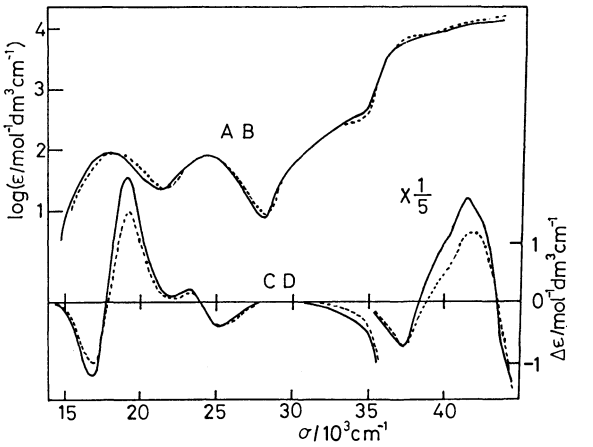

Fig. 2. The absorption (AB) and CD spectra of *Λ-cis-α*-$[CrCl_2(SS\text{-picchxn})]ClO_4$ (——) and *Λ-cis-α*-$[CrCl_2(SS\text{-picbn})]ClO_4$ (------).

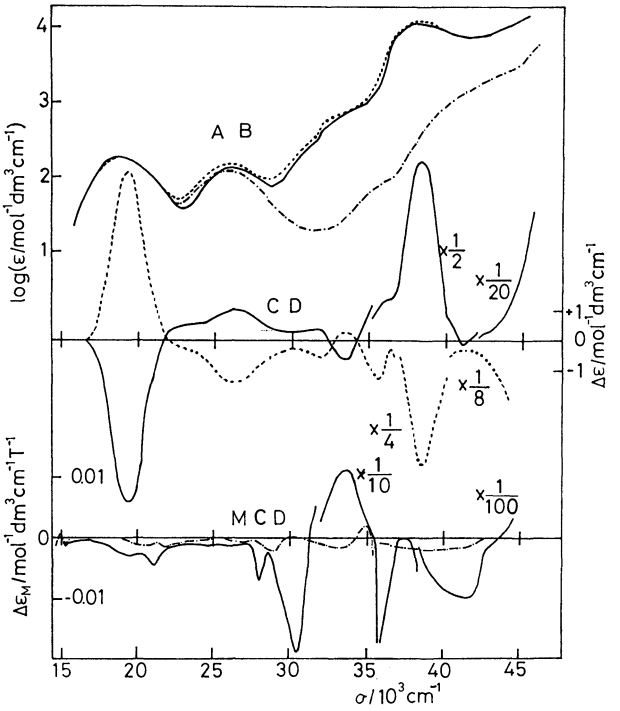

Fig. 3. The absorption (AB) and CD spectra of *ΔΔ-trans*-(py)*trans*(py)$[\{Cr(OH)(picen)\}_2](ClO_4)_4$ (——) and *ΔΔ-trans*(py)*trans*(py)$[\{Cr(OH)(S\text{-picpn})\}_2](ClO_4)_4$ (------). The AB and MCD spectra of *meso*-$[\{Cr(OH)(en)_2\}_2]Cl_4$ (·····) and MCD of *trans*(py)*trans*(py)$[\{Cr(OH)(picen)\}_2](ClO_4)_4$ (——) are also presented.

a) ε is given in mol^{-1} dm^3 cm^{-1}.

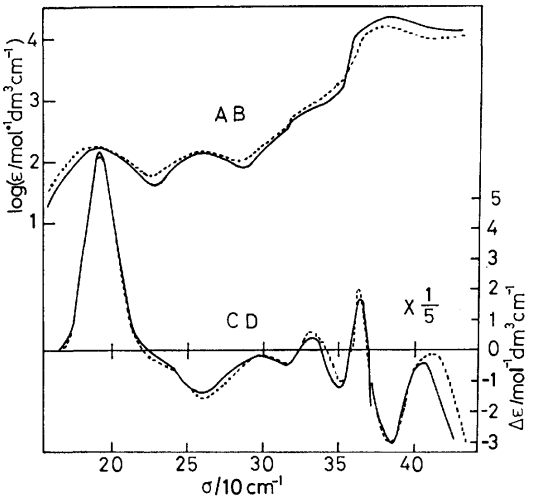

Fig. 4. The absorption (AB) and CD spectra of *ΔΔ-trans*-(py)*trans*(py)-[{Cr(OH)(*SS*-picchxn)}$_2$](ClO$_4$)$_4$ (——) and *ΔΔ-trans*(py)*trans*(py)-[{Cr(OH)(*SS*-picbn)}$_2$]-(ClO$_4$)$_4$ (------).

ΔΔ-trans(py)*trans*(py). From the CD spectra in Fig. 4, the *SS*-picbn and *SS*-picchxn complexes are assigned *ΔΔ-trans*(py)*trans*(py). These assignments are supported by the decomposition experiment of the dinuclear complex into the mononuclear complex. The numerical data for the absorption and CD spectra are collected in Table 1.

Stereoselective Formation of Diastereomers. The *Δ* and *ΔΔ* diastereomers of the mononuclear and dinuclear complexes were prepared, respectively, for the ligands, *S*-picpn, *SS*-picbn, and *SS*-picchxn, in this study. They belong to the type in which the terminal chelate ring are formed by coordination of the equatorially-oriented substituents on the secondary nitrogen atoms (Fig. 1). Both *Δ* and *Λ* diastereomers of *S*-picpn dichloro mononuclear complex were obtained by the method of Preparation I, but only the more stable *Δ* one in Preparation II. On the other hand, only one isomer was obtained in the case of *SS*-picchxn and *SS*-picbn in either method of preparation. In Fig. 5 the two diastereomers, *Δ-cis-α* and *Λ-cis-α* of mononuclear *SS*-picchxn complex are shown. The central chelate ring takes the most stable *δ* conformation for the *SS*-picchxn ligand. In the *Δ* form, there is a steric repulsion between one of the methylene proton (1 in Fig. 5) of the terminal chelate ring and the proton (2 in Fig. 5) attached to the cyclohexane carbon atom adjacent to the asymmetric one. In this form the terminal chelate ring is less strained than that of the *Λ* form. On the other hand, in the *Λ* form there is no such steric repulsion as in the *Δ* form, though the terminal chelate ring in the *Λ* form is more strained than that in *Δ* form. If the steric hindrance predominates, only the *Λ* form will be formed. A preliminary X-ray crystal structure analysis revealed that the *Λ-cis-α*-[CrCl$_2$(*SS*-picchxn)]ClO$_4$ has in fact the terminal chelate rings of equatorially-oriented pyridylmethyl groups on the secondary nitrogen atoms.[13] In the case of *SS*-picbn ligands, the steric repulsion between the methylene proton and the methyl group on the central chelate ring is considered to be similar to the case of *SS*-picchxn ligand. Thus the *Λ* form was actually isolated.

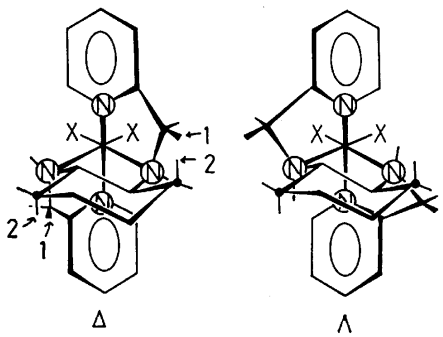

Fig. 5. The two diastereomers of *cis*-α-[CrX$_2$(*SS*-picchxn)]$^+$.

For the dinuclear complexes of *SS*-picchxn and *SS*-picbn, the stereoselective formation of diastereomers can be explained by the same way as in the mononuclear ones. For the *S*-picpn ligand, only the *ΔΔ* form was formed. One more factor must be taken into account. From the X-ray structure analyses of *meso*-[{Cr(OH)-(en)$_2$}$_2$](S$_2$O$_6$)$_2$[14] and racemic [{Cr(OH)(phen)$_2$}$_2$]I$_4$-4H$_2$O[15] (phen=1,10-phenanthroline), the in-plane <NCrN angle of di-*μ*-hydroxo dinuclear complexes is larger than 90° ("in-plane" means that the N atoms are in the plane defined by two chromium and two hydroxo-oxygen atoms). On the other hand, the

	41670	−100	

a) $\Delta\varepsilon_M$ is given in $mol^{-1}\ dm^3\ cm^{-1}\ T^{-1}$.

∠NCrN angle of the mononuclear complexes is less than 90°. For example, that of *Δ-cis*-α-$[CrCl_2(S\text{-picpn})]^+$ is 83.9°.[3] Accordingly, the central chelate ring of the present dinuclear complexes approaches near planar, and the strain energy becomes not so different between the *ΔΔ* and the *ΛΛ* forms, so the strain of the terminal chelate ring has a less important contribution. ("strain" means the deviation from the picen (=*N,N'*-bis(2-pyridylmethyl)ethylenediamine) chelate rings of the complex $[\{Cr(OH)(picen)\}_2]^{4+}$.) The steric repulsion between the methyl group and the terminal chelate ring is the main factor of the stereoselective formation of diastereomers. Thus only the *ΛΛ* form which has no such steric repulsion is considered to be isolated.

Spectral Properties. A shoulder is observed in the region of 33000—34000 cm^{-1} for the dinuclear complexes, overlapping to the spin-forbidden band[1] or pyridine ring band (Figs. 3 and 4). The CD pattern in this region is identical for all the dinuclear complexes treated here, three (+, −, +) or (−, +, −) bands are observed in 32500—37000 cm^{-1}. The absorption and CD spectra of di-μ-hydroxo dinuclear complexes of bidentate ligands are shown in Fig. 6 in which the same shoulder and CD pattern are also observed for $[\{Cr(OH)(pma)_2\}_2]^{4+}$ and $[\{Cr(OH)(S\text{-pea})_2\}_2]^{4+}$. The MCD spectra in this region are shown for $[\{Cr(OH)(picen)\}_2]^{4+}$ and $[\{Cr(OH)(pma)_2\}_2]^{4+}$ (Figs. 3 and 6). The two complexes show only a large positive MCD band in this region. The mononuclear complexes also display a large positive MCD band in this region.[1] The weak absorption band observed in this region for the di-μ-hydroxo en complex has been assigned tentatively to the weak exchange interaction between the two chromium(III) ions.[16] The MCD spectrum (Fig. 3) shows a small (−, +) dispersion in this region, which is a clear indication of existence of a band. The MCD spectral data are shown in Table 2 for $[\{Cr(OH)(en)_2\}_2]^{4+}$, $[\{Cr(OH)(pma)_2\}_2]^{4+}$, and $[\{Cr(OH)(picen)\}_2]^{4+}$. For the di-μ-hydroxo cobalt(III) complex, a strong band has been observed in the same region and assigned to be a hydroxo-to-cobalt charge transfer band, characteristic of this type complexes.[16] In view of the optical electronegativities of chromium(III) and cobalt(III), 1.9 and 2.3, respectively,[17] the shoulders found for the di-μ-hydroxo chromium(III) complexes seem to be due to some another origin than that for the cobalt(III) complexes.

Studies on the Solvent Extraction of Metal Perchlorates III. Extraction Equilibria of Alkaline Earth Ions with Trioctylphosphine Oxide as Perchlorate and Thiocyanate

Satoshi KUSAKABE and Tatsuya SEKINE*

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received January 23, 1981)

Solvent extraction of alkaline earth metal ions in 1 mol dm^{-3} sodium perchlorate or thiocyanate aqueous solution with trioctylphosphine oxide (TOPO) in hexane was studied at 25 °C. The extraction in both systems improved in the order: beryllium(II)>calcium(II)>strontium(II)≃magnesium(II)≃barium(II). When the TOPO concentration was the same, the extraction of beryllium or calcium thiocyanate was better than that of the perchlorate, that of magnesium or strontium thiocyanate was nearly similar to that of the perchlorate, while barium perchlorate was extracted better than its thiocyanate. From these results it was concluded that these five perchlorates and strontium and barium thiocyanates were extracted as ion-pairs, $[M(topo)_4]^{2+}(X^-)_2$, ($X^- = ClO_4^-$ or SCN^-), while beryllium thiocyanate was extracted as solvates of noncharged complexes, $M(SCN)_2(topo)_n$, ($n=2$ and 3), and that magnesium and calcium thiocyanates in the organic phase ($n=3$ and 4) should have both ionic and coordinative properties. The poor extraction of magnesium salts was assumed to be due to their strong hydration.

In the previous study, the authors observed that the solvent extraction of alkali metal ions with trioctylphosphine oxide (TOPO) in hexane as perchlorate improved in the order lithium(I)>sodium(I)>potassium(I)>rubidium(I)>caesium(I). This was explained by suggesting that the extraction is mainly dependent on the stability of the TOPO solvates, which is higher when the ionic size is smaller.[1] In the present reseach we studied the solvent extraction of alkaline earth ions as perchlorate and thiocyanate with TOPO in hexane and have considered the effect of possible coordination of these metal ions with the anions on their solvent extraction with solvating type extractants.

Experimental

Materials. The materials were the same as reported previously.[1,2] The beryllium perchlorate stock solution was prepared by dissolving its hydroxide, obtained by precipitation from sulfate solutions. The other alkaline earth stock solutions were prepared by dissolving their chloride in sodium perchlorate or thiocyanate solutions.

The content of beryllium(II) was analyzed by gravimetry of its 2-methyl-8-quinolinolate;[3] that of the other alkaline earths was determined by titration with a standard EDTA or silver nitrate solution.

Procedures. Experiments were carried out in a thermostated room at 25 °C. The metal stock solution and 1 mol dm^{-3} sodium perchlorate or thiocyanate solution were placed in a stoppered glass tube. The initial metal concentration of barium was 5×10^{-3} mol dm^{-3} and that of the other metal ions was 1×10^{-3} mol dm^{-3}. For the experiments with beryllium, the hydrogen-ion concentration was adjusted at 1×10^{-3} mol dm^{-3} by perchloric acid or hydrochloric acid. The same volume of a hexane solution of TOPO was then added and the two solutions were agitated mechanically for half an hour and then centrifuged. A portion of the organic phase was transferred into another glass tube and the metal ions contained were back-extracted into diluted nitric or hydrochloric acid. The concentrations of strontium(II) and barium(II) in this solution and those in the aqueous phase were determined by flame spectrophotometry and those of the other metals by an atomic absorption method.

Statistical. Distribution ratio of the metal, M(II), is defined as

$$D = [M(II)]_{org}/[M(II)], \quad (1)$$

where the subscript "org" denotes the species in the organic phase and the absence of a subscript denotes that in the aqueous phase. The extraction equilibrium of the metal with TOPO can be written as

$$M^{2+} + 2X^- + n\text{topo(org)} \rightleftharpoons MX_2(topo)_n(org)$$

$$K_{ex,n} = [MX_2(topo)_n]_{org}[M^{2+}]^{-1}[X^-]^{-2}[topo]_{org}^{-n}, \quad (2)$$

$$D = \sum K_{ex,n}[topo]_{org}^{n}, \quad (3)$$

where X^- denotes a perchlorate or thiocyanate ion. The concentration of free TOPO in the organic phase is reduced by the solvation of the metal ions and sodium ions co-existing in the organic phase. (Both sodium perchlorate and thiocyanate are extracted as tri-solvates into hexane and the extraction constants $K_{ex,NaX}(=[NaX)topo)_3]_{org}[Na^+]^{-1}[X^-]^{-1}[topo]_{org}^{-3})$ are $10^{1.01}$ and $10^{0.38}$, respectively.[2]) Since the concentration of both sodium ions and X^- in the aqueous phase are nearly equal to 1 mol dm^{-3}, the equilibrium concentration of TOPO can be related to its total concentration by the following equation;

$$\begin{aligned}[topo]_{org,total} &= [topo]_{org} + \sum n[MX_2(topo)_n]_{org} \\ &\quad + 3[NaX(topo)_3]_{org} \\ &= [topo]_{org} + \sum nK_{ex,n}[M^{2+}][topo]_{org}^{n} \\ &\quad + 3K_{ex,NaX}[topo]_{org}^{3}. \end{aligned} \quad (4)$$

The constants which fit best with the experimental data, and the equilibrium TOPO concentration, were calculated using a least squares program.

Results

Figures 1a—c give the extraction curves from 1 mol dm^{-3} $NaClO_4$ and Figs. 2a—c from 1 mol dm^{-3} NaSCN, both as a function of the TOPO concentration in the organic phase at equilibrium. These results may be summarized as follows: (i) The perchlorate extractions of magnesium(II), strontium(II), and barium(II) are nearly the same, that of calcium(II) is about one and half orders better than the extraction of these metal

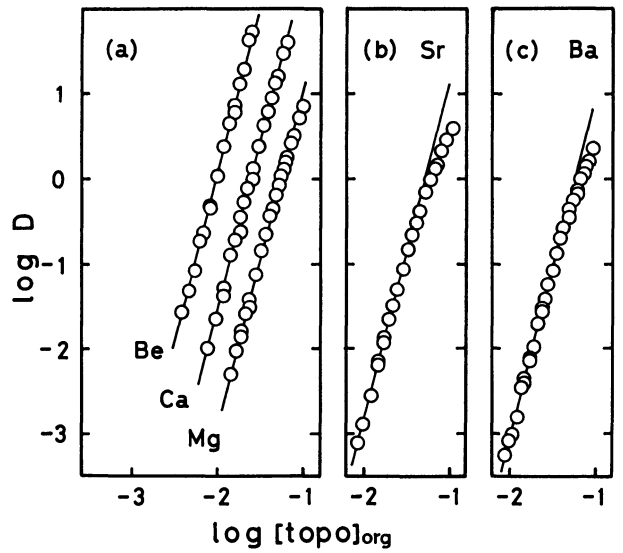

Fig. 1. Extraction of alkaline earth metal ions from 1 mol dm^{-3} $NaClO_4$ with TOPO in hexane. The TOPO concentrations are the values at equilibrium. Some data at higher TOPO concentrations in Figs. b and c were not used for the calculation of the constants (see text). The solid lines were calculated by introducing the constants in Table 1 into Eq. 3.

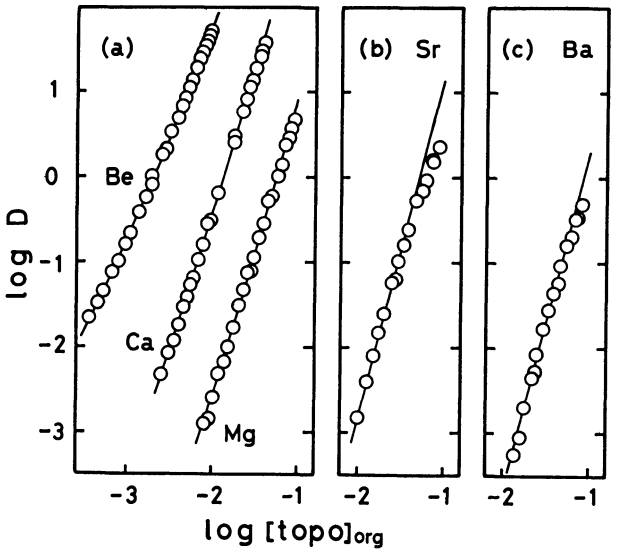

Fig. 2. Extraction of alkaline earth metal ions from 1 mol dm^{-3} NaSCN with TOPO in hexane. The TOPO concentrations are the values at equilibrium . Some data at higher TOPO concentrations in Figs. b and c were not used for the calculation of the constants (see text). The solid lines were calculated by introducing the constants in Table 1 into Eq. 3.

ions and that of beryllium(II) is better still: one and half orders better than calcium(II). (ii) The differences of the extraction curves of the thiocyanates are greater than those of the perchlorates. (iii) The extraction of magnesium(II) and strontium(II) as perchlorate and the thiocyanate is nearly the same. The extraction of barium thiocyanate is somewhat inferior to that of its perchlorate, while the opposite is found with calcium(II). The extraction of beryllium thiocyanate is much better than its perchlorate.

The data were analyzed by using a least squares computer program. As is seen from the figures, the slope of the extraction curve of strontium(II) and barium(II) decreased in the higher TOPO concentration region both in the perchlorate and thiocyanate extraction systems. Since this trend could not be explained stoichiometrically, those data were eliminated from the least squares calculation. Beryllium(II) was reported to form thiocyanate complexes in aqueous solutions[4] and corrections for them are necessary in order to obtain accurate extraction constants from the data in the figures. It is assumed from the stability constants ($\beta_1=10^{-0.16}$ and $\beta_2=10^{-0.60}$ in 4 mol dm^{-3} $NaClO_4$) that the total concentration of the complexes is approximately equivalent to Be^{2+} in the 1 mol dm^{-3} thiocyanate solution. Thus the constants $K_{ex,n}$ obtained in the present study, assuming no complexes in the aqueous phase should be a little lower than the values defined by Eq. 2. The formation of thiocyanate complexes in the aqueous phase of the other alkaline earths should be slight[5] and no correction for that may be necessary.

Solvation of the alkaline earth salts and of the co-extracted sodium perchlorate or thiocyanate should decrease the free TOPO concentration. In the higher concentration region, this was not negligible. For example, in the extraction of barium perchlorate from the 1 mol dm^{-3} $NaClO_4$ medium with 0.14 mol dm^{-3} of initial TOPO in hexane, it is calculated by Eq. 4 by introducing the values in Table 1 that about 20% of this TOPO combines with sodium perchlorate and 10% combines with barium perchlorate. Correction for this decrease in the free TOPO concentration by successive approximation was included in the computer program.

All of the extraction data of the perchlorates were found to be well explained in terms of solvation with four TOPO molecules in the organic phase. The $K_{ex,4}$ values obtained by the least squares calculation are listed in Table 1. In the extraction of thiocyanates, a solvation number of four well explained the data of strontium(II) and barium(II), but two types of solvates

Table 1. Extraction constants[a] of alkaline earth metal perchlorates and thiocyanates with TOPO in hexane at 25°C[b]

Metal	Perchlorate	Thiocyanate		
	log $K_{ex,4}$	log $K_{ex,2}$	log $K_{ex,3}$	log $K_{ex,4}$
Be(II)	8.01±0.20	5.18±0.16	7.73±0.19	
Mg(II)	4.99±0.21		3.32±0.39	4.86±0.41
Ca(II)	6.39±0.17		5.45±0.14	7.12±0.32
Sr(II)[c]	5.13±0.10			5.17±0.18
Ba(II)[c]	4.92±0.13			4.29±0.21

a) The limit of error is 3σ. b) Aq phase: 1 mol dm^{-3} $NaClO_4$ or NaSCN. Org. phase: hexane containing TOPO. c) Some of the data for these ions in the higher TOPO concentration region in Figs. 1b, 1c, 2b, and 2c were eliminated in the calculation of these constants. See text.

were necessary in order to explaine the extraction of the other metal ions; solvation numbers of two and three for beryllium(II) and of three and four for magnesium(II) and calcium(II) were found to give a better fit of the calculated values with the experimental data than only one solvation number. The extraction constants thus computed are listed in Table 1.

Discussion

As is seen from Fig. 1 and Table 1, the solvent extraction of alkaline earth perchlorates with TOPO is much better than that of alkali perchlorates[1] under identical conditions. The solvation number is four in the former extraction, but three in the latter one. The extraction of alkaline earth thiocyanates with TOPO is also much better than that of alkali metals.

The smaller the ionic size, the better the TOPO extraction which was found among the alkali perchlorates.[1] This tendency is also found among the alkaline earth perchlorates, except magnesium(II): the extraction of magnesium(II) is nearly similar to that of barium(II). The extraction order of the alkaline earth thiocyanates is also similar to that of their perchlorates, again except magnesium(II).

If we omit magnesium(II), this extraction order may be explained in terms of the higher ability of solvation with TOPO of smaller ions and of the difference in the nature of the chemical bonds between the anion and the metal ion. The solvation reduces hydrating water and also increases the molar volume of the cation; these effects are favorable for its extraction. A smaller ion tends to form more stable solvates than a larger one, although the former tends to be hydrated more strongly. On the other hand, since the metal ions combine with four molecules of TOPO in their extraction as perchlorates, the molar volumes of the resulting solvates should be rather similar even when the size of the central metal ion is different. For this reason, smaller metal ions are extracted better than larger ones. It is generally true that when the bond between the anion and the metal is coordinative the extraction is better than when it is ionic. The better extraction of beryllium thiocyanate than of its perchlorate indicates that the thiocyanate ions in the extracts coordinate with the central metal ion. The smaller solvation numbers of beryllium thiocyanate with TOPO than of its perchlorate also indicate that the thiocyanate ions occupy the coordination sphere of the metal ion in the extracts. As is seen from the stability of the alkaline earth thiocyanates in the aqueous phase, the coordination with thiocyanate ions should be weaker when the ionic size is larger. The extraction of thiocyanates of strontium(II) and barium(II) is rather similar to their perchlorates. The somewhat poorer extraction of barium thiocyanate than of its perchlorate may indicate that this thiocyanate is essentially an ion-pair; the same tendency was observed in the TOPO extraction of sodium(I)[2] and this was explained in this previous paper in terms of the larger molar size and the less polar nature of the perchlorate ion than of the thiocyanate ion, these factors make the extraction of the ion-pairs containing the former more favorable.

The poorer extraction of magnesium(II), both as perchlorate and thiocyanate, than of calcium(II) seems to suggest a stronger hydration for the magnesium(II) ion than for the calcium(II) ion. The same tendency has been pointed out before: the extraction of magnesium(II) with tributyl phosphate (TBP) as nitrate[6] and as halides[7] was also poorer than calcium(II). This was explained by a higher tendency of hydration of magnesium(II). Similar reasoning was also proposed for the poor extraction of nickel perchlorate and thiocyanate than of cobalt(II).[8] However, in order to continue discussion about this problem, much comparative work on the extractability of magnesium(II) and calcium(II) in several liquid-liquid systems seems to be necessary.

The extraction of ion-pairs into polar solvents is very often better when the metal ion is larger.[9] However, although the extracted perchlorates are ion-pairs in the present study, the magnitude of the extraction is mainly dependent on the ability to form the solvate with TOPO. The tendency of extraction is similar to that of coordination complexes: the smaller the metal ion, the better the extraction.

The differences among the extraction of the alkaline earth thiocyanates are larger than those of their perchlorates. This is especially marked with beryllium(II); the thiocyanate in the organic phase should be coordinative. As is described above, barium thiocyanate in the organic phase may be essentially ion-paired and the other thiocyanates may have both of these characters.

The extraction of alkaline earths as perchlorates[10,11] and thiocyanates[12-15] with TBP has been reported. The observations such as the order of extraction and the solvation numbers of extracts are similar with our results for the extraction with TOPO.

The authors are grateful to Mr. Kenji Ohira for his experimental aid.

(Received January 28, 1981)

A sensitive technique for determination of germanium was investigated by atomic absorption spectrometry following volatile hydride generation. Of the three types of hydride generator and atomizer systems tested, direct transfer of the generated hydride into nitrogen–hydrogen flame for atomization was found to be suitable. The sensitivity was enhanced more than 40—60% in phosphoric acid medium as compared to hydrochloric acid, malic acid, or tartaric acid media. Interference of nickel(II), gold(III), and cobalt(II) in hydrochloric acid medium was reduced by adding ethylenediaminetetraacetate as a masking reagent or replacing the acid medium by malic acid. Detection limit and relative standard deviation of ten determinations of 0.5 μg germanium(IV) in 20 ml of 0.20 M** phosphoric acid were 7 ng (S/N=2) and 4.3%, respectively, with 3 ml of 8 w/v % sodium tetrahydroborate solution. The method was applied to the determination of germanium in standard rocks, concentrations of germanium in JB-1 and JG-1 being evaluated as 1.3_1 and 1.3_2 ppm, respectively.

In the determination of germanium by atomic absorption spectrometry (AAS), it is difficult to attain high sensitivity because of production of highly stable oxide species in the flame. Dinitrogen oxide–acetylene flame is often used in combination with solvent extraction. The highest sensitivity so far reported is 0.13 ppm for 1% absorption by means of nebulizer effect.[1] Indirect AAS based on the formation of molybdogermanic acid complex has also been used because of chemical amplification.[2]

Volatile hydride generation technique has been applied to the determination of germanium by AAS,[3–6] but the sensitivity and reproducibility are inferior to those of elements such as arsenic, selenium, and antimony.[3,5] This technique was also extended to plasma emission spectrometry,[7–10] and thermal conductivity detection systems.[11]

Investigation was carried out to find suitable conditions for the determination of germanium by AAS by means of three types of hydride generation and atomization systems. Chapman and Dale[12] suggested the use of dinitrogen oxide–acetylene flame for the atomization following hydride generation. However, it was found that nitrogen–hydrogen (entrained air) flame is suitable when combined with a direct transfer type hydride generator, enabling us to use a large amount of sodium tetrahydroborate as a reductant.

The method was applied to the determination of germanium in rock samples (JB-1 and JG-1). Samples were decomposed with acid mixture; germanium was extracted into carbon tetrachloride from 9 M hydrochloric acid, and then back-extracted into water, the aqueous solutions being subjected to analysis.

Experimental

Apparatus. A Hitachi Model 170-50 type atomic absorption spectrophotometer equipped with deuterium background corrector and germanium hollow-cathode lamp (Hamamatsu TV) were used. Atomic absorption signals were recorded with a Hitachi 056 type recroder, peak height signals being used for the determination. Hydride generator and atomizer systems were used as follows.

I: Collection type hydride generator connected to nitrogen–hydrogen flame. Volatile hydride was generated with Nippon Jarrel-Ash Model ASD-1A and introduced into a nitrogen–hydrogen flame (one slot burner with 10 cm).

II: Direct transfer type hydride generator connected to heated silica tube. The hydride generator system reported by Thompson and Thomerson[5] was slightly modified, the gas being introduced into a heated silica tube (14φ×114 mm) mounted on 10 cm path air–acetylene flame burner.

III: Direct transfer type generator connected to nitrogen-hydrogen flame. A modified Hitachi hydride generator connected to a nitrogen–hydrogen flame system described in a previous paper[13] was used, the dispenser (REBURET) being replaced by another one (HANSEN 500 ml).

Conditions for the nitrogen–hydrogen flame: wavelength 256.1 nm, nitrogen flow rate 8 l min^{-1}, hydrogen flow rate 7 l min^{-1}, height of beam above burner tip 12.5 mm.

Reagents. All the reagents were of analytical grade. Deionized water was distilled twice.

Germanium(IV) stock solution (0.5 mg/ml): 0.360 g of soluble germaniumdioxide prepared by the method of Shimomura *et al.*[14] was dissolved in hot water, cooled, and diluted with water to 500 ml.

Sodium tetrahydroborate solution (8 w/v %): Sodium tetrahydrobolate(powder, Aldrich Chemical Company, Inc) was dissolved in 0.5% sodium hydroxide and filtered with 1 μm glass filter.

Sodium tetrahydroborate tablet (*ca.* 0.13 g $NaBH_4$): Thirty tablets were prepared from 2 g of caoline (Fisher Scientific Co.,) and 4 g of sodium tetrahydroborate by addition of 2.5 ml of 2 M aqueous ammonia.[15] The tablet was wrapped in wafer sheet when added to the I type hydride generation vessel.

Procedure. *I*: Pipet the prescribed volume of sample solution into the reaction vessel, add an appropriate volume of acid and dilute the solution to 20 ml with water. Put a teflon coated spin bar into the vessel and set it up on the hydride generation unit. Pass nitrogen into the vessel for 20 s, turn the four-way stopcock to collection mode. Remove the cap of the reaction vessel, put sodium tetrahydroborate tablet into the vessel and replace the cap immediately. Collect the gas for 30 s, then sweep it to the nitrogen–hydrogen flame.

II: Pipet 1 ml of 8 w/v% sodium tetrahydroborate solution into the reaction vessel and set it up on the hydride

** 1M=1 mol dm^{-3}

generation unit. A plastic syringe containing 1 ml of the sample solution is inserted into the side-arm seal of the vessel. Pass nitrogen through the reaction vessel to replace air with nitrogen for 15-20 s, then inject the sample solution into the reaction vessel and carry the gas into heated silica tube with nitrogen flow rate of 2 l min^{-1}.

III: The procedure reported[13] was carried out with modification: 3 ml of 8 w/v% sodium tetrahydroborate solution was used and nitrogen was passed through the vessel with flow rate of 2 l min^{-1}.

Results and Discussion

Stability of Germanium Hydride. The stability of volatile hydride should be considered at first in the hydride generation method.[4,12,15] The effect of germanium hydride collection time in system I was examined. Figure 1 shows effect of collection time 15—300 s for 5.0 μg of germanium. Collection time 20—300 s causes no fall in sensitivity, showing that germanium hydride is stable during the course of collection. The precision of the method is not improved by altering the collection time to 30—300 s.

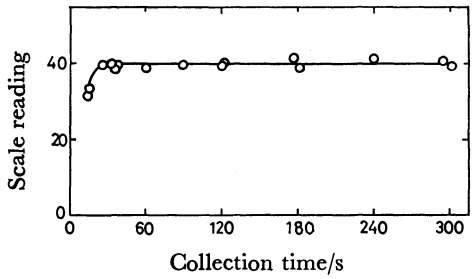

Fig. 1. Effect of collection time on the generation of germanium hydride, in system I.
Ge(IV): 5.0 μg/20 ml, acidity: 0.2 M HCl.

Atomization of Germanium Hydride. A comparison was made between nitrogen-hydrogen and argon-hydrogen flames. The former was found to be superior by *ca.* 20—30% in sensitivity of systems I and III. Sensitivity of the germanium determination by heated silica tube atomization with system II is inferior to that of flame atomization.

Effect of Acids and Acidity. Effect of acids and acidity on the relative sensitivity of germanium determination was investigated by system I for 5.0 μg germanium(IV) and system III for 0.5 μg germanium(IV); the results are shown in Figs. 2 and 3, respectively. Concentration of acids seriously affects peak height of the signals in both types of hydride generator systems, giving maximum peak height at 0.1—0.2 M, at which acids are almost neutralized by the alkaline sodium tetrahydroborate solution. In addition to hydrochloric acid reaction medium used in volatile hydride generation with sodium tetrahydroborate, various acids can be used as reaction media, *i.e.* malic acid, tartaric acid, acetic acid, and oxalic acid (Fig. 2). Nitric acid, sulfuric acid, and phosphoric acid are also useful, but not citric acid (Fig. 2).

In system III, the effect of acid is differs somewhat from that of system I. A large difference in sensitivity

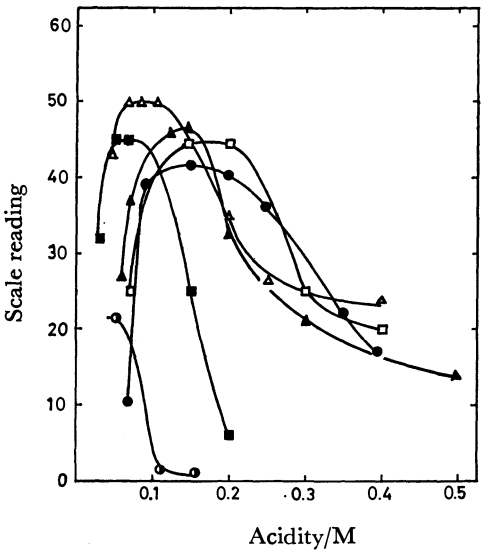

Fig. 2. Effect of acidity on the determination of germanium, in system I.
Ge(IV): 5.0 μg/20 ml, collection: 30 s, —●—: HCl, —△—: malic acid, —▲—: tartaric acid, —□—: acetic acid, —■—: oxalic acid, —◑—: citric acid.

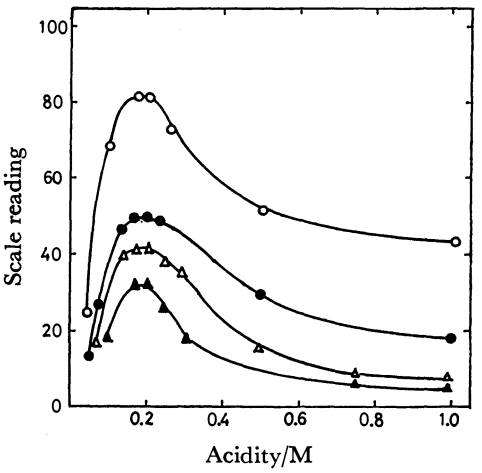

Fig. 3. Effect of acidity on the determination of germanium, in system III.
Ge(IV): 0.5 μg/20 ml, 8 w/v % $NaBH_4$: 3 ml, —○—: H_3PO_4, —●—: HCl, —△—: malic acid, —▲—: tartaric acid.

is observed with use of these acids (Fig. 3). About 40% enhancement in sensitivity is attained in 0.20 M phosphoric acid medium as compared with hydrochloric acid. The difference seems to originate from the change in reaction rate of germanium(IV) to germanium hydride.

The utility of nitric acid is different from the result of Thompson and Pahlavanpour;[10] the results of hydrochloric acid also differ. The peak height does not increase at 2—5 M hydrochloric acid.

Amount of Sodium Tetrahydroborate. In system I, the best sensitivity is attained with 0.13 g of sodium tetrahydroborate. Because of the limitation of the internal gas pressure during the course of collection, more than 0.13 g of the reductant could not be used.

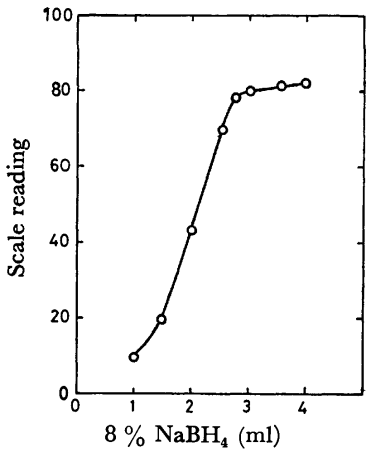

Fig. 4. Effect of the volume of tetrahydroborate solution, in system III.
Ge(IV): 0.5 μg in 20 ml of 0.2 M H_3PO_4.

Effects of the amount of sodium tetrahydroborate on germanium determination examined in system III are shown in Fig. 4, high senistivity being attained with 3—4 ml of 8 w/v% sodium tetrahydroborate solution. A relatively large amount of sodium tetrahydroborate can be treated as compared with system I. However, the use of more than 3.5 ml of 8 w/v% sodium tetrahydroborate solution sometimes caused overflow of the reaction medium. The reductant volume was fixed at 3 ml.

TABLE 1. REPRODUCIBILITY AND DETECTION LIMIT OF THE METHOD

System[a)]	Matrix	RSD[b)] %	Detection limit (S/N=2)
I	0.15 M HCl	8.3[c)]	140 ng/20 ml
	0.1 M Malic acid	7.7[c)]	
II	0.20 M HCl	4.6[d)]	
	0.20 M H_3PO_4	2.7[d)]	200 ng/ml
III	0.20 M HCl	4.5[e)]	10 ng/20 ml
	0.20 M H_3PO_4	4.3[e)]	7 ng/20 ml

a) Described in Experimental. b) Relative standard deviation calculated from ten determinations. c) Germanium taken: 5.0 μg/20 ml. d) Germanium taken: 5.0 μg/ml. e) Germanium taken: 0.5 μg/20 ml.

Precision and Sensitivity. Precision and sensitivity of germanium determination in system I—III were compared. The results are given in Table 1. System I is conventional, but its precision and sensitivity are not so good as that of system III. Precision is improved in system II as compared with system I, but not sensitivity. The highest sensitivity was attained in system III; detection limit of 7 ng/20 ml (=0.35 ppb) is more sensitive than 50 ng/13 ml (=4 ppb) reported by Smith,[6] the highest sensitivity so far reported by AAS.

Influence of Foreign Ions. The influence of various foreign ions on the determination of germanium(IV) (0.5 μg) were examined in system III. The results are shown in Table 2. The ions showing strong suppression in 0.2 M hydrochloric acid medium were paradium(II), nickel(II), gold(III), and cobalt(II). Suppression was also observed in the presence of 50 μg of volatile hydride forming elements such as arsenic(III), antimony(III), and selenium(IV) in the same medium, 250 μg of bismuth(III) not interfering. The interference was not eliminated significantly except selenium(IV) by addition of potassium iodide; coexistence of 100 μg of selenium(IV) was tolerable by addition of 1 ml of 40% potassium iodide solution in hydrochloric acid.

TABLE 2. EFFECTS OF FOREIGN IONS ON THE DETERMINATION OF GERMANIUM
(Results given are percentage changes in absorbance for 0.5 μg of germanium(IV) in systemIII.)

Ion	Added (μg)	Acid reaction matrix[a)] 0.2 M-HCl[b)]	0.2 M-H_3PO_4	0.2 M-H_3PO_4 +EDTA[c)]	0.2 M-Malic acid
Ni(II)	20	−74	−60	0	0
	100	−97	—	0	0
Pd(II)	3	−66	−90	−90	−11
Au(III)	20	−55	−27	0	−19
	60	−70	—	−30	−34
Co(II)	60	−24	0	0	0
	250	−65	0	0	0
Cd(II)	125	−35	−30	−5	−40
Fe(III)	1400	−20	0	0	0
	2800	−37	0	0	0
As(III)	50	−9	−15	−15	−9
Sb(III)	50	−30	−30	−30	—
	250	−50	—	−54	−56
Se(IV)	50	—	−25	−25	—
	125	−31	—	—	−11

a) Volume of test solution, 20 ml; 3 ml of 8 w/v % sodium tetrahydroborate solution was added as a reductant. b) The following are tolerable: Sn(II), Pb(II), Te(IV) (50 μg coexistence); Bi(III)(250 μg coexistence); Hg(II), Ca(II), Mg(II), Mn(II, VII), Ru(III), Mo(VI), V(V), Cr(III, VI), Al(III) (500 μg coexistence); Cl^-, Br^-, NO_3^-, SO_4^{2-}, CH_3COO^-, SiO_3^{2-}, BO_3^{3-}, IO_3^-, ClO_4^-, Na^+, K^+ (2500 μg coexistence). c) 0.25 M EDTA2Na 1 ml was added.

The influence of foreign ions on the determinations in phosphoric acid medium was almost the same as that of hydrochloric acid, but the interference by cobalt(II) and iron(III) is much more reduced than that of hydrochloric acid medium (Table 2).

In malic acid reaction medium, interference caused by nickel(II), gold(III), cobalt(II), zinc(II), or iron(III) is less than that of hydrochloric acid medium as shown in Table 2. Malic acid is superior to other organic acids such as tartaric acid and lactic acid as regards the influence of nickel(II); coexistence of 100 μg of nickel(II) caused no loss of sensitity in 0.2 M malic acid. However, 70% sensitivity suppression took place in 0.2 M tartaric acid, and 95% in 0.2 M ractic acid.

Addition of EDTA to reaction medium is effective for eliminating the interference of nickel(II), gold(III), cadmium(II), and zinc(II) as shown in Table 2. Addition of EDTA to phosphoric acid medium is suitable for the determination of germanium(IV) in

view of sensitivity and influence of foreign ions.

Determination of Germanium in Standard Rocks. The method was applied to the determination of germanium in standard rocks JB-1 and JG-1. Samples were decomposed by the following methods.

Procedure A: Germanium separation process developed by Schneider and Sandell,[16] Onishi,[17] Argollo and Schilling[18] was appleid with a slight modification: Weigh 0.5 g of rock samples in Uniseal decomposition vessel. Add 2 ml of 9 M sulfuric acid, 1 ml of concentrated nitric acid, and 5 ml of 46% hydrogen fluoride. Seal the vessel immediately, put the vessel in air bath for 2 h at 100 °C. After cooling, take off the cap of the decomposition vessel and heat it on a hot plate until fuming of sulfuric acid begins. Transfer the contents into the separation funnel, add 15 ml of 9 M hydrochloric acid and shake for 10 min with an electric shaker. Add 10 ml of carbon tetrachloride and shake for 3 min. Separate each phase and transfer the carbon tetrachloride phase to another separation funnel. Repeat the procedure by adding another 10 ml of carbon tetrachloride into the first separation funnel. Add second carbon tetrachloride phase to previous carbon tetrachloride phase, and wash the phase with 5 ml of hydrochloric acid. Separate each phase, transfer the carbon tetrachloride phase to another separation funnel and add 10 ml of water. Shake for 5 min, then separate each phase. The aqueous solutions were subjected to germanium determination by the proposed method (system III, phosphoric acid matrix). Blank solution was prepared by the same preparation as above. Recovery of germanium was checked by adding standard germanium(IV) solution into Uniseal vessel with sample and carrying out the same procedure described above.

Procedure B: Procedure without germanium separation as in Procedure A was carried out until the decomposition step of the sample in air bath. After cooling the reaction vessel, add 80 ml of 4% boric acid in order to mask excess fluoride ion and transfer the solution to a 100 ml volumetric flask, and add water to the mark. The prescribed volume of the sample solution was subjected to germanium determination by means of standard addition technique (in phosphoric acid containing EDTA). Blank solution was also prepared by the same procedure as above.

The analytical results are given in Table 3. Recovery of 85—95% germanium in Procedure A (both for JB-1 and JG-1) agreed with that of other rock samples.[17] The germanium contents of JB-1 and JG-1 corrected with recovery percent agreed with those by Argollo and Scilling[18] attained by neutron activation analysis. Results obtained by Procedure B were somewhat inaccurate. However, the technique is very simple, rapid, and an average of two or three multiple sample determinations gives almost the same result as that by Procedure A (Table 3). A large discrepancy of germa-

Circular Dichroism Spectra and Absolute Configurations of *cis,cis,cis*-(*C,N,O*)-Dicyanobis(glycinato)cobaltate(III) and Dicyanobis-(β-alaninato)cobaltate(III) Complexes

Shuhei FUJINAMI* and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received February 9, 1981)

The $[Co(CN)_2(NO)_2]^-$-type complexes (NO: gly^- and β-ala^-), which have *cis,cis,cis* geometry with respect to the donor atoms C, N, and O, have been prepared by a new method, and resolved into their optical antipodes. The CD spectra of the resolved complexes have been measured, and compared with that of $(-)_{589}[Co(CN)_2(ox)(en)]^-$ complex which has the same chromophore with the bis(glycinato) complex. It is found that the optical activity of the *cis,cis,cis*-$[Co(C)_2(N)_2(O)_2]^-$-type complex mainly arises from the arrangement of the donor atoms; the non-ligating atoms of NO ligand make minor contribution to the optical activity.

Recent years have seen dramatic development in CD spectral studies of transition metal complexes, on account of development of theoretical treatment. In particular, many investigations have been carried out on tris(diamine)-type complexes, and the optical rotatory strength of a d-d transition has been connected in detail with the structure of a given complex.[1] Evans *et al.*[2] have calculated the optical activity of $[Co(en)_3]^{3+}$ complex by a molecular orbital method, and obtained good coincidence with the experimental values. Mason and Seal[3] have applied the dynamic coupling model to the complexes of this type, and given numerical evaluations of the optical activities, differentiating between the contribution from donor atoms and that from non-ligating atoms.

In contrast to the above complexes whose absolute configurations are designated with *Λ* and *Δ* notation, a few studies of optically active complexes such as *cis,cis*-$[Co(CN)_2(CO_3)(NH_3)_2]^-$,[4] $[Co(Br)(CN)(NH_3)(tacn)]^+$[5] and $[Co(NO_2)(gly)(tacn)]^+$[6](tacn represents 1,4,7-triazacyclononane), whose absolute configurations cannot be defined in *Λ* and *Δ* notation, have been reported in our laboratory. We have expressed the absolute configurations of those complexes in the *R* and *S* notation proposed by Cahn *et al.*[7] and it has been found that the arrangement of donor atoms plays an important role in the optical activity of these complexes. However, an apparent role of the non-ligating atoms in the chelate rings has not been examined.

On the other hand, the CD spectrum of a $(-)_{589}$-$[Co(CN)_2(ox)(en)]^-$ complex[4] is interesting, because the optical activity of the complex is considered to be derived from two origins; one is due to the arrangement of the donor atoms of the ligands as in the *cis,cis,cis*-$[Co(CN)_2(NH_3)_2(H_2O)_2]^+$,[4] and another due to the helical distribution of the two bidentate ligands. If the deviation of the donor atoms from the octahedral sites due to the chelations does not have a large influence on the optical activity, the contribution to the optical activity from the non-ligating atoms is intimately associated with the "*Λ* or *Δ*" configuration, and that from the donor atoms, with "*R* or *S*" configuration. It is significant to elucidate with contribution is dominant in the complex. In order to clarify this problem, we attempted to prepare a *cis,cis,cis*(*C,N,O*)-$[Co(CN)_2(gly)_2]^-$ complex, whose chromophore was the same as the $[Co(CN)_2(ox)(en)]^-$ complex, and then to resolve it into a pair of enantiomers. The absolute configuration of an enantiomer in the bis(glycinato) complex is represented with either *Δ*(*R*) or *Λ*(*S*). Since the absolute configuration of the $(-)_{589}[Co(CN)_2(ox)(en)]^-$ isomer is known to be *Λ*(*R*),[4] the comparison between the CD spectra of the two dicyano complexes will be helpful to determine the origin of the optical activities of the complexes. We also attempted to determine the absolute configuration of a diastereoisomeric salt $(-)_{589}[Co(ox)(en)_2]\cdot cis,cis,cis(C,N,O)\text{-}(+)^{CD}_{500}[Co(CN)_2(gly)_2]\cdot 3H_2O$ by X-ray analysis, in order to facilitate the analyses of the CD spectra.

There are five possible geometrical isomers for the $[Co(CN)_2(gly)_2]^-$ complex. Poznjak and Pawlowski[8] have isolated three isomers with *cis*(*CN*) geometry, modifying the method devised in our laboratory.[9] In this paper, a new method to prepare the dicyano complex will be reported.

Experimental

Preparation of $[Co(CN)_2(gly)_2]^-$ *Complex.* The complex has been prepared from $[Co(gly)_3]$ by reaction with KCN in the presence of activated charcoal,[8] but this method yields a poor product. We devised a new method: To a cold green solution of the so-called tricarbonato solution ($Co(NO_3)_2\cdot 6H_2O$, 29 g, 0.1 mol scale),[10] potassium cyanide (16.3 g, 0.25 mol) was added, and the mixed solution was stirred for 1 h at room temperature in order to prepare *cis*-$[Co(CN)_2(CO_3)_2]^{3-}$.[11] The solution was slowly neutralized by 30% $HClO_4$ in an ice bath. After the precipitated $KClO_4$ was filtered off, glycine (18.8 g, 0.25 mol) was added to the filtrate. With occasional neutralization by 30% $HClO_4$, the reaction mixture was stirred for 10 h. The dominant species in the solution was considered to be $[Co(CN)_2(gly)(CO_3)]^{2-}$. The solution was adjusted to pH 1 with 30% $HClO_4$, and stirred again for 1 h to complete the acid hydrolysis. The solution was adjusted to pH 9 with 6 mol/dm³ KOH and then the precipitated material was filtered off. The filtrate was stirred for 2 h at 40 °C. The reaction mixture was sufficiently diluted with water (3—4 dm³) and poured onto a column of Dowex 1-X8 resin (Cl^- form, 4×25 cm). By elution with 0.2 mol/dm³ KCl solution, complex species of univalent anion were collected in a fraction . After concentration and removal of the eluent, the filtrate was diluted with 2 dm³ of water and rechromatographed on a column of Dowex 1-X8 (Cl^- form, 4×30 cm). When the adsorbed band was eluted with 0.1

mol/dm³ $CaCl_2$ solution, nine bands were distinguished (labeled A1-A9 in the order of elution). The yellow A4, orange A8 and rose A9 bands were the main products. Hereafter, the notations A1—A9 will be used to designate the isomer contained in each band. A4, A8 and A9 were identified with the *trans(N)-cis(C)*, *cis,cis,cis(C, N, O)*, and *trans(O)-cis(C)* isomers, respectively, on the basis of the absorption spectral data.[8] The other bands contained no dicyano complex species.

Preparation of the $[Co(CN)_2(\beta\text{-}ala)_2]^-$ *Complex.* This complex was prepared in the same way as the bis(glycinato) complex except for the use of β-alanine in the place of glycine. Upon rechromatography, three bands were obtained as univalent species (B1—B3 in the order of elution), by elution with 0.1 mol/dm³ $CaCl_2$ solution, After removal of the eluting agent from each fraction, the counter ions were converted to sodium ions by means of column chromatography. The effluents were concentrated and then kept in a refrigerator. Found for B2: C, 28.54; H, 4.50; N, 16.62%. Found for B3: C, 28.67; H, 4.30; N, 16.89%. Calcd for $Na[Co(CN)_2(\beta\text{-ala})_2]\cdot 1.5H_2O$: C, 28.50; H, 4.48; N, 16.62%. B1 was not a sought complex species.

Resolution. The crystals of *cis,cis,cis(C,N,O)*-$Na[Co(CN)_2(gly)_2]\cdot 2H_2O$ (3.2 g, 0.01 mol) were dissolved in a minimum amount of warm water (60 °C). The solution was mixed with a warm solution of $(-)_{589}[Co(ox)(en)_2](CH_3COO)$, which had been prepared using $(-)_{589}[Co(ox)(en)_2]I$ (1.7 g, 0.005 mol) and CH_3COOAg (0.84 g, 0.005 mol). The mixed solution was mechanically stirred and cooled in an ice bath. The diastereoisomeric salt obtained was recrystallized several times, until the Δε values became constant. Found: C, 24.79; H, 5.41; N, 19.47%. Calcd for $(-)_{589}[Cn(ox)(en)_2]\cdot(+)^{CD}_{500}[Co(CN)_2(gly)_2]\cdot 3H_2O$: C, 24.84; H, 5.21; N, 19.31%.

The *trans(N)-cis(C)*- and *trans(O)-cis(C)*-$[Co(CN)_2(gly)_2]^-$ complexes were resolved into each optical antipodes in a similar way as the *cis,cis,cis(C,N,O)*-$[Co(CN)_2(gly)_2]^-$ complex, by using $(-)_{589}[Co(ox)(en)_2](CH_3COO)$ as resolving agent. The *trans(N)-cis(C)*- (B2) and *cis,cis,cis(C,N,O)*-$[Co(CN)_2(\beta\text{-ala})_2]^-$ (B3) complexes were also resolved by use of $(-)_{589}[Co(NO_2)_2(en)_2](CH_3COO)$.

Measurements. The absorption spectra in aqueous solution were measured with a Hitachi 323 recording spectrophotometer. The CD spectra were recorded on a JASCO J-40C automatic recording spectropolarimeter equipped with a JASCO Model J-DPZ data processor for CD. The less-soluble diastereoisomeric salts obtained were passed through columns of cation exchanger in sodium form, and the effluents were submitted to the measurements of CD spectra. The Δε values were evaluated from the absorption spectral data.

Results and Discussion

Absorption and CD Spectra. Absorption spectral data of the complexes obtained are listed in Table 1. Absorption spectra of the isomers of the bis(glycinato) complex coincided with those of the literature.[8] Therefore, A4 is identified as *trans(N)-cis(C)* isomer, A8 as *cis,cis,cis(C,N,O)* one, and A9 as *trans(O)-cis(C)* one. As for the bis(β-alaninato) complex, B2 exhibited a narrow absorption band in the first absorption band region, and B3 two maxima in the region. By comparison with the spectra of the bis(glycinato) complex, B2 is assignable to *trans(N)-cis(C)* isomer and B3 to *cis,cis,cis(C,N,O)* isomer. As shown in Fig. 1, the absorption spectrum of the *cis, cis,cis(C,N,O)*-bis(glycinato) complex resembles that of the $[Co(CN)_2(ox)(en)]^-$ complex in shape and intensity, that is, two maxima in the first absorption band region have comparable intensity to each other. However, an intense band is observed at a lower frequency in the *cis,cis,cis(C,N,O)*-bis(β-alaninato) complex, and at a higher frequency in the *cis,cis*-$[Co(CN)_2(ox)(NH_3)_2]^-$ complex. These phenomena are considered to be associated with the rigidity of the chelate rings in terms of the vibronic mechanism of an intensity borrowing.[12] The absorption maxima of the bis(β-alaninato) isomers appear at a lower frequency than those of the corresponding bis(glycinato) isomers.

The CD spectral data are also collected in Table 1. The CD spectrum of the *trans(N)-cis(C)*-$[Co(CN)_2(gly)_2]^-$ exhibits a single Cotton peak at the maximum position of the first absorption band. An attempt to isolate an enantiomer of the *trans(N)-cis(C)*-bis(β-

alaninato) isomer using $(-)_{589}[Co(ox)(en)_2]^+$ and $(-)_{589}[Co(CO_3)(en)_2]^+$, *etc.* as resolving agents failed. However, when $(-)_{589}[Co(NO_2)_2(en)_2]^+$ was used, an extremely weak Cotton peak with a negative sign was observed at 22700 cm^{-1} for an enantiomer obtained in the form of the less-soluble diastereomer. The *trans(O)-cis*(C)-$[Co(CN)_2(gly)_2]^-$ complex could be resolved by using $(-)_{589}[Co(ox)(en)_2]^+$, however, the optical purity of the diastereoisomeric salt obtained was very low. The CD spectrum of *trans(O)-cis(C)*-$[Co(CN)_2(gly)_2]$ exhibits two extrema with opposite signs in the region of the absorption band at 19200 cm^{-1} which is assigned to $^1A_{1g}\rightarrow{}^1E_g$ in a holohedrized symmetry[13] D_{4h}. A Cotton peak corresponding to $^1A_{1g}\rightarrow{}^1A_{2g}$ is observed as a shoulder at *ca.* 25000 cm^{-1}. As shown in Fig. 1, the CD spectrum of *cis,cis,cis(C,N,O)*-$[Co(CN)_2(gly)_2]^-$ exhibits two extrema with opposite signs in the first absorption band region, and a shoulder, observed at *ca.* 27000 cm^{-1}, is considered to be a splitting component of the second absorption band. The spectra of *cis,cis,cis(C,N,O)*-bis-(β-alaninato) isomer also exhibits two extrema in the first absorption band region; the Cotton peak at the lower frequency is dominant.

Optical Activity of cis,cis,cis-$[Co(C)_2(N)_2(O)_2]^-$ *Complexes.* The CD spectra of *cis,cis*-$[Co(CN)_2(OO)(NH_3)_2]^-$ and *cis*-$[Co(CN)_2(OO)(en)]^-$ complexes (OO: CO_3^{2-} and ox^{2-}) have been reported.[4] The optical activities of the former complexes are mainly derived from the chiral arrangement of three kinds of donor atoms. However, the chirality of the latter complexes are considered to have two origins; one is the arrangement of the donor atoms, and another is a chiral distribution of the chelate rings. The absolute configurations of these dicyano complexes have been predicted in terms of the sign of the Cotton peak observed at the higher frequency in the first absorption band region. For example, the absolute configuration of $(-)_{589}[Co(CN)_2(ox)(en)]^-$ complex, which exhibits three Cotton peaks with alternating signs, has been assigned as shown in Fig. 2, being denoted as $\Lambda(R)$ according to the two origins of the chirality. The *cis,cis,cis(C,N,O)*-$[Co(CN)_2(gly)_2]^-$ complex has also two chiral origins as for *cis*-$[Co(CN)_2(ox)(en)]^-$, however, the absolute configuration is denoted with either $\Lambda(R)$ or $\Lambda(S)$.

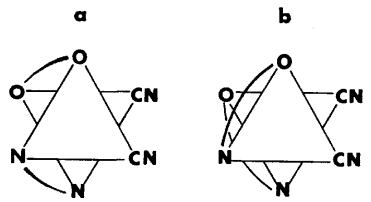

Fig. 2. Absolute configurations of;
a. *cis*-$\Lambda(R)$-$(-)_{589}[Co(CN)_2(ox)(en)]^-$, b. *cis, cis, cis(C, N, O)*-$\Lambda(R)$-$(+)^{500}_{CD}$ $[Co(CN)_2(gly)_2]^-$.

Mason and Seal[3] have applied a dynamic coupling model to the $[Co(en)_3]^{3+}$ and $[Co(tn)_3]^{3+}$ complexes. In their treatment, the contribution to the optical activity from the donor atoms was separated from that of the non-ligating atoms. It is possible to apply such a treatment in the present complexes. If the deviation of the donor atoms from the octahedral sites due to chelations can be disregarded, the contribution from the donor atoms intimately associates with the *R* (or *S*) configuration, while the contribution from the non-ligating atoms associates with the Λ (or Λ) configuration. The CD spectrum of the *cis,cis,cis(C,N,O)*-$(+)^{CD}_{500}[Co(CN)_2(gly)_2]^-$ isomer roughly resembles that of the $(-)_{589}[Co(CN)_2(ox)(en)]^-$ isomer. This suggests that either the donor atoms or the non-ligating atoms mainly contribute to the optical activity of the complexes. The resemblance between the CD spectrum of *cis,cis,cis-(C,N,O)*-$(+)^{CD}_{500}[Co(CN)_2(gly)_2]^-$ and that of *cis,cis-R*$(+)_{589}[Co(CN)_2(ox)(NH_3)_2]^-$ (shown in Fig. 1) suggests the larger contribution from the donor atoms, and predicts the absolute configuration of the bis(glycinato) isomer as $\Lambda(R)$, since the chirality of the *cis,cis*-$[Co(CN)_2(ox)(NH_3)_2]^-$ complex is considered to be derived from the arrangement of the donor atoms.

In order to confirm the above suggestion, an X-ray crystal analysis of $(-)_{589}[Co(ox)(en)_2]\cdot$*cis,cis,cis(C,N,O)*-$(+)^{CD}_{500}[Co(CN)_2(gly)_2]\cdot 3H_2O$ was attempted, and the detailed data will be presented elsewhere. The absolute configuration of the bis(glycinato) isomer was determined as $\Lambda(R)$, as illustrated in Fig. 2. This result shows that the optical activity of the *cis,cis,cis*-$[Co(C)_2(N)_2(O)_2]^-$-type complexes mainly arises from the chiral arrangement of the donor atoms and the non-ligating atoms cause auxiliary optical activity. It is found that the deviation of the donor atoms from the octahedral sites due to the chelations also makes a minor contribution to the optical activity. The results supports the

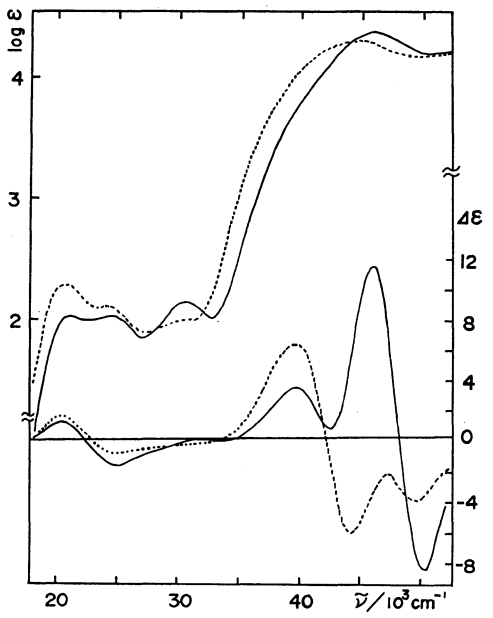

Fig. 3. Visible and ultra-violet absorption and CD spectra of;
——: *cis*, *cis*, *cis*(*C*, *N*, *O*)-(+)$^{CD}_{500}$ [Co(CN)$_2$(gly)$_2$]$^-$,
……: *cis*, *cis*, *cis*(*C*, *N*, *O*)-(+)$^{CD}_{500}$ [Co(CN)$_2$(*β*-ala)$_2$]$^-$.

evaluation of the absolute configurations of the *cis,cis*-[Co(CN)$_2$(OO)(NH$_3$)$_2$]$^-$ and *cis*-[Co(CN)$_2$(OO)(en)]$^-$ complexes reported in the previous paper,[4] by the CD spectral comparison.

At a glance, the results obtained are incompatible with those for the tris(diamine) complexes, where the non-ligating atoms play an important role in the optical activities of the complexes. As to the tris(diamine) complexes, if the existence of the non-ligating atoms and the deviation of the donor atoms from the octahedral sites be disregarded, the distribution of the donor atoms around a metal ion creates no optical activity. On the contrary, as to the *cis,cis,cis*-[Co(C)$_2$(N)$_2$(O)$_2$]$^-$ complexes, such a distribution is considered to generate large optical activity, because the ligand field strengths of the C, N, and O donors are very different from each other.

The isomer (+)$^{CD}_{500}$[Co(CN)$_2$(*β*-ala)$_2$]$^-$ is also assignable to *Δ*(*R*) configuration by comparison with the CD spectrum of the bis(glycinato) complex in the first absorption band region, since the change from gly to *β*-ala chelate rings results in a slight change of the intensities of the Cotton peaks. This is supported by the comparison with the spectra in the ultra-violet region, illustrated in Fig. 3. Since several transitions lie closely in the same region, the CD spectra of the isomers are complicated. However, both isomers exhibit the positive Cotton peaks at *ca.* 40000 cm^{-1} which correspond to the lowest lying allowed-transition.

The authors wish to express thanks to Mr. T. Katahara for his aid in the experiment.

Binuclear Metal Complexes. XL.[1] Synthesis and Magnetic and Spectral Properties of Alkoxo-bridged Copper(II) Complexes with 2-(Alkylthio)ethanols

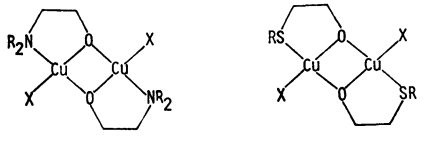
Masahiro MIKURIYA, Hisashi OKAWA, and Sigeo KIDA*

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received February 12, 1981)

Alkoxo-bridged copper(II) complexes with 2-(alkylthio)ethanols, $Cu(RSCH_2CH_2O)X$ ($R=CH_3$, C_2H_5, n-C_3H_7, i-C_3H_7, s-C_4H_9, t-C_4H_9; X=Br, Cl), have been prepared and characterized by elemental analyses, infrared and electronic spectra and magnetic susceptibilities (80—300 K). Based on the magnetic properties, these complexes were divided into three types, A, B, and C. Type A complexes show a strong antiferromagnetic interaction and exhibit a distinct absorption band characteristic of alkoxo-bridged structure in the 22—24$\times 10^3$ cm^{-1} region. Type B and C complexes follow the Curie-Weiss law. The former complexes show a ferromagnetic behavior, whereas the latter complexes show a weak antiferromagnetism. The results were compared with those of the complexes with 2-(dialkylamino)ethanols, $Cu(R_2NCH_2CH_2O)X$.

A great number of copper(II) complexes with 2-(dialkylamino)ethanols (abbreviated as HR-no) with the general formula Cu(R-no)X were reported and their structures and magnetic properties have been extensively studied.[2-5] However, there has been no study on copper(II) complexes with 2-(alkylthio)ethanols so far. This may partly be due to the poor coordinating ability of both thioether sulfur and alcoholic oxygen atoms.[6] As a continuing project for binuclear copper(II) complexes of sulfur-containing ligands, we recently reported the synthesis, crystal structures and spectral and magnetic properties of alkoxo-bridged copper(II) complexes with tridentate ligands having sulfur, nitrogen and oxygen as donor atoms (SNO and NSO donor sets). The results were discussed in relation to those of the alkoxo-bridged copper(II) complexes with NNO tridentate ligands.[7,8] In this study, we have prepared a series of alkoxo-bridged copper(II) complexes with 2-(alkylthio)ethanols, $Cu(RSCH_2CH_2O)X$ (abbreviated as Cu(R-so)X, $R=CH_3$, C_2H_5, n-C_3H_7, i-C_3H_7, s-C_4H_9, t-C_4H_9; X=Br, Cl), and investigated their magnetic and spectral properties in comparison with those of the complexes with 2-(dialkylamino)ethanols, Cu(R-no)X (Fig. 1).



(a) (b)

Fig. 1. Structures of complexes. (a) Cu(R-no)X, (b) Cu(R-so)X.

Experimental

Preparation of the Complexes. The ligands, $RSCH_2CH_2OH$ ($R=CH_3$, C_2H_5, n-C_3H_7, i-C_3H_7, s-C_4H_9, t-C_4H_9), were prepared after the method described in the literature.[9] Preparation of the complexes is exemplified by $Cu(CH_3$-so)Cl. To an absolute ethanol solution of 2-(methylthio)ethanol (370 mg) and triethylamine (143 mg) was added an absolute ethanol solution of copper(II) chloride (135 mg). A dark green precipitate was yielded in the solution. This precipitate was separated by filtration, washed with ethanol and dried *in vacuo* over P_2O_5. Yield: 125 mg.

t-C_4H_9	Br	25.85(26.05)	4.81(4.74)

The bromides, Cu(R-so)Br, were prepared by a method similar to that for the chlorides except for using copper(II) bromide instead of copper(II) chloride.

Carbon and hydrogen analyses were carried out at the Service Center of Elemental Analysis, Kyushu University. The results of elemental analyses are listed in Table 1.

Measurements. Infrared spectra were measured with a Hitachi Grating Infrared Spectrophotometer Model 215 in the region 4000—650 cm^{-1} on a KBr disk. Electronic spectra were measured with a Shimadzu Multipurpose Spectrophotometer Model MSP-5000 at room temperature. Magnetic susceptibilities were measured by the Faraday method over the range 80—300 K. The apparatus was callibrated by the use of $[Ni(en)_3]S_2O_8$.[10] All the susceptibilities were corrected for the diamagnetism of the constituting atoms by the use of Pascal's constants.[11] Effective magnetic moments were calculated from the equation, $\mu_{eff}=2.828\sqrt{(\chi_A-N\alpha)T}$, where χ_A is atomic magnetic susceptibility and $N\alpha$ is temperature-independent paramagnetism in cgs emu. (1 BM=9.274$\times 10^{-24}$ A m^2, 1 cm^3 mol^{-1} (cgs emu)=$4\pi\times 10^{-6}$ m^3 mol^{-1}.)

Results and Discussion

Infrared spectra of the free ligands show a strong band around 3370 cm^{-1}, which is attributed to the OH stretching vibration. In the case of 2-(methylthio)-ethanol, the OH deformation vibration was assigned

a) For all the complexes $g=2.10$ was assumed.

to the band at 1160 or 1010 cm^{-1}.[12] All these bands are absent in the spectra of the copper(II) complexes. This indicates that the alcoholic proton is lost upon complexation.

Based on the temperature dependence of the magnetic susceptibilities, we classified the complexes into three types: type A; complexes whose magnetic behavior can be interpreted in terms of the Bleaney-Bowers equation[13] with considerably large J values, type B; complexes which obey the Curie-Weiss law with positive Weiss constants in the temperature range studied, and type C; complexes which obey the Curie-Weiss law with negative Weiss constants. These types exactly correspond to the types A, B, and C(a) of Nishida and Kida's classification,[5] respectively.

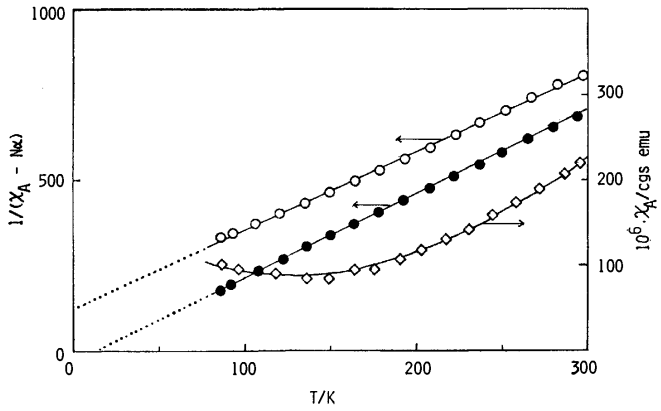

Fig. 2. Temperature dependence of magnetic susceptibilities of Cu(s-C_4H_9-so)Br (type A) (◇), Cu(i-C_3H_7-so)Cl (type B) (●), and Cu(n-C_3H_7-so)Cl (type C) (○). The solid curve was calculated from Eq. 1 using the parameters listed in Table 2.

Type A Complexes. The magnetic moments are very low at room temperature, indicating the existence of a strong antiferromagnetic interaction in these complexes. An example of the temperature dependence of magnetic susceptibilities of type A complexes is shown in Fig. 2. The temperature dependence of magnetic susceptibilities can be interpreted by the modified Bleaney-Bowers equation[14]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1}(1-P) + \frac{0.45P}{T} + N\alpha, \quad (1)$$

where χ_A is susceptibility per copper atom, P is the mole fraction of the mononuclear copper(II) impurity, and other symbols have the usual meanings. The second term in Eq. 1 was added to account for the presence of the small amount of a paramagnetic impurity which was found in some samples of type A complexes. The parameters, $-2J$, $N\alpha$, and P were evaluated from the best fit of the experimental data to Eq. 1 and are listed in Table 2. The $-2J$ values, the energy separation between the spin-singlet ground state and the lowest spin-triplet state, is comparable to those of type A complexes of Cu(R-no)X,[4,5] indicating that a strong antiferromagnetic interaction is operating between the copper(II) ions.

The electronic absorption spectra in nujol mull of type A complexes are shown in Fig. 3. The band maxima of the absorption spectra in nujol mull and in 1,2-dichloroethane solutions are given in Table 3. Both spectra display a broad band centered at about 14—15$\times10^3$ cm^{-1} which is attributable to d-d transitions. In the higher frequency region 22—24$\times10^3$ cm^{-1}, a

a) 1,2-Dichloroethane solution. b) sh=Shoulder.

distinct absorption band with higher intensity ($\log \varepsilon =$ *ca.* 3) was observed. This band should correspond to the band in the 24—25$\times 10^3$ cm^{-1} region observed for type A complexes of Cu(R-no)X,[4,5] and may be assigned to p_π(O)→d(Cu) charge transfer transition.[5] The lowering of the transition energy for Cu(R-so)X relative to that of Cu(R-no)X may be interpreted in terms of lowering of optical electronegativity[15] of copper ion of Cu(R-so)X on the assumption that the energies of p_π electrons of alkoxo oxygen are nearly constant.[7]

Type B Complexes. The room-temperature magnetic moments of type B complexes fall in the range of the value generally observed for mononuclear copper(II) complexes. As shown in Fig. 2, the magnetic susceptibilities of type B complexes follow the Curie-Weiss law, $\chi_A = C/(T-\theta) + N\alpha$, in the temperature range 80—300 K. Since the ground states of these complexes are orbitally nondegenerate, the positive Weiss constants indicate that a ferromagnetic interaction is operative between the copper ions (Table 2), as was so in the case of type B complexes of Cu(R-no)X.[4,5] The X-ray structure analyses showed that type B complexes of Cu(R-no)X have tetranuclear structures with a cubane type Cu_4O_4 core.[3] Therefore, it can be presumed that type B complexes of Cu(R-no)X have similar cubane tetranuclear structures.

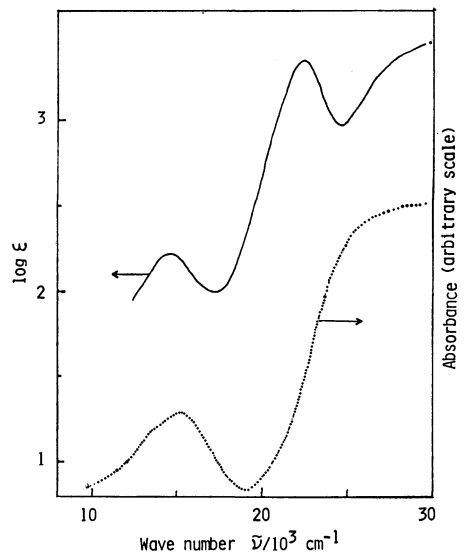

Fig. 4. Absorption spectra of Cu(n-C_3H_7-so)Br in Nujol mull (·····) and in 1,2-dichloroethane solution (——).

As shown in Fig. 4, type B complexes show no distinct absorption band at 22—24$\times 10^3$ cm^{-1} in the nujol mull spectra, whereas in the solution a distinct absorption in that region. This fact suggests that type B complexes are likely to dissociate in solution to form a binuclear species similar to type A complexes.[16]

Type C Complexes. The effective magnetic moments at room temperature of type C complexes are slightly lower than the spin-only value for one unpaired electron per copper atom. The cryomagnetic data follow the Curie-Weiss law with a negative Weiss constant, indicating the existence of a weak antiferromagnetic interaction in this type of complexes (Fig. 2).

The band maxima of the electronic absorption spectra of type C complexes are given in Table 3. In both the solid state and the solution spectra, type C complexes show a distinct absorption band at 22—24$\times 10^3$ cm^{-1}, as observed for type A complexes. These magnetic and spectral properties are similar to those of type C(a) complexes of Cu(R-no)X.[4,5]

Preparation and Spectroscopic Studies of Cobalt(III) Complexes Containing Optically Active Seven-membered Chelate Ligands

Masaaki KOJIMA, Ken'ichi MORITA, and Junnosuke FUJITA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 16, 1981)

New cobalt(III) complexes of the types, *trans*-$[CoCl_2L_2]^+$, $[Co(NH_3)_4L]^{3+}$, *cis*-$[Co(NH_3)_2L_2]^{3+}$, and $[Co(en)_2L]^{3+}$, where L denotes a seven-membered chelate diamine ligand, (*R*)-2-methyl-1,4-butanediamine or *meso*- and (*R* or *S*)-2,5-hexanediamine, have been prepared. The dichloro complexes decompose gradually even in the solid state, and rapidly in methanol. The ammine and ethylenediamine complexes are stable in acidic water, but decompose gradually in neutral water. The absorption and circular dichroism spectra of all the complexes have been recorded in aqueous or acetone solutions. The circular dichroism spectra in the first absorption band region are changed by the addition of sulfate ions, and the variation has been discussed in terms of the structure of isomers and the conformational instability of the seven-membered chelate rings.

A six-membered chelate ring has been shown to be conformationally flexible and to interchange easily its conformation between two forms, the chair and the skew depending on environment. In the previous papers,[1-3] we reported that spectral changes in absorption and circular dichroism (CD) of some 1,3-diamine cobalt(III) complexes caused by the addition of sulfate ions can be interpreted in terms of such conformational instability of six-membered chelate rings.

Studies with molecular models suggest that a seven-membered diamine chelate ring is also conformationally labile and can interchange among some conformers (Fig. 1). In fact, two 1,4-butanediamine (tetramethylenediamine, tmd) chelate rings in *trans*-$[CoCl_2(tmd)_2]Cl\cdot H_2O$ have been shown by X-ray analysis to have different conformations, *skew*(*h*) and *skew*(*v*),[4] while those in *Δ*-$[Co(tmd)_3]Br_3$ have the *λ*-*skew*(*h*) conformation.[5] In [Pd{(*S*)-ornithinato}$_2$], two seven-membered chelate (*N*,*N*) rings are in the *twist-chair* conformation, which can be regarded as the distorted *chair* form.[6] Thus, seven-membered chelate rings are stabilized in various conformations in crystals of metal complexes. In solution, however, these conformations might be changed by different factors such as solvation and ion-pair formation. In order to elucidate the conformation of seven-membered chelate rings in solution, we have prepared cobalt(III) complexes containing tmd, (*R*)-2-methyl-1,4-butanediamine (*R*-mtmd), and 2,5-hexanediamine (dmtmd), and measured their absorption and CD spectra in the absence and presence of sulfate ions.

Experimental

Measurements. Absorption spectra were recorded on a Hitachi 323 spectrophotometer, and CD spectra on JASCO model J-20 and J-40CS spectropolarimeters. Optical rotation at 589 nm were measured with a JASCO DIP-4 polarimeter. All the measurements were made at 25±1 °C.

Preparation. *2-Methyl-1,4-butanediamine(mtmd).* Dimethyl 2-methylbutanedioate prepared by the method of Jeffery and Vogel[7] was dissolved in methanol which had been saturated with ammonia. The solution was stirred for 6 days at room temperature to give 2-methyl-1,4-butanediamide. 2-Methyl-1,4-butanediamine (mtmd) was prepared by reducing the diamide with $LiAlH_4$ in dry tetrahydrofuran (THF). To a suspension of $LiAlH_4$ (11.4 g, 0.3 mol) in dry THF (280 cm^3) was added the diamide (7.6 g, 0.056 mol) in small portions. The mixture was refluxed for 27 h, and then cooled in an ice-bath. A mixture of water–THF (1:1) was added dropwise with vigorous stirring. The slurry was filtered by suction, the residue was extracted with THF (*ca.* 100 cm^3) under reflux for 1 h, and filtered again. The extraction was repeated once more. The combined filtrate and extracts were mixed with hydrochloric acid to adjust the pH to *ca.* 2, and then evaporated to dryness under reduced pressure. The residue was dissolved in a small amount of water, and a concd sodium hydroxide solution was added. The separated amine layer was extracted three times with chloroform. The extracts were dried over potassium hydroxide pellets, and the chloroform was removed under atmospheric pressure. The remaining oily liquid was distilled under reduced pressure. Bp 88—91 °C/5.3 kPa (lit,[8] 172—173 °C/101 kPa). Yield: 10 g. The diamine was also prepared by reducing 1,2-dicyanopropane[9] in ethanol with sodium.[8] The *rac*-diamine thus obtained was resolved by the following method. To a hot ethanol solution (90 cm^3) of (*R*,*R*)-2,3-bis(benzoyloxy)succinic acid monohydrate (10 g, 0.027 mol) was slowly added an ethanol solution (27 cm^3) of *rac*-mtmd (2.8 g, 0.027 mol). White crystals (4.5 g, crude (*R*,*R*)-2,3-bis(benzoyloxy)-succinate) which formed were collected, washed with ethanol, recrystallized seven times from water, and then converted to the dihydrochloride ((+)-mtmd·2HCl) by a method similar to that for (*R*,*R*)-2,4-pentanediamine dihydrochloride.[10] Yield: *ca.* 30%. $[\alpha]=+5.6°$ (*c* 0.01, H_2O). The (+)-isomer is known to have the (*R*) configuration.[11]

2,5-Hexanediamine (dmtmd). This diamine was prepared by reducing 2,5-hexanedione dioxime[12] with sodium in ethanol according to the known method,[13] or with Raney-Ni in water. The dioxime (50 g, 0.35 mol) was dissolved in an aqueous solution (1 dm^3) of sodium hydroxide (150 g, 3.75 mol). To this solution was added Raney-Ni alloy (100 g) in small portions while the solution was vigorously stirred and cooled to keep the reaction temperature between 25 and 30 °C. After the addition had been completed (*ca.* 1.5 h), the mixture was allowed to stand overnight at room temperature. The residual nickel was filtered off and washed with water. The combined filtrate and washings were steam distilled until no further amine was detected. The distillate was acidified with hydrochloric acid (pH *ca.* 2) and evaporated to dryness to give the diamine hydrochloride. The free diamine was obtained from the hydrochloride by extracting and distilling according to a method similar to that for mtmd, for extraction ether being used instead of chloroform. Bp 80 °C/3.3 kPa (lit,[13] 175 °C/101 kPa). Yield: 12 g. The meso and active diamines were obtained by the following method. To a

hot ethanol solution (240 cm^3) of (*R,R*)-2,3-bis(benzoyloxy)-succinic acid monohydrate (24.3 g, 0.065 mol) was added an ethanol solution (70 cm^3) of the diamine (7.5 g, 0.065 mol). The solution was allowed to stand overnight at room temperature. Colorless crystals which formed were filtered, and recrystallized three times from water–ethanol (1:3). Yield: 6.7 g. $[\alpha]=-86.4°$ (*c* 0.033, H_2O). No change in the rotation was observed with further recrystallizations. This product was converted to the dihydrochloride ((+)-dmtmd·2HCl) by a method similar to that for (+)-mtmd·2HCl. Yield: 1.7 g. $[\alpha]=+11.4°$ (*c* 0.051, H_2O). The free diamine prepared from this dihydrochloride showed negative rotation. The *meso*-diamine dihydrochloride was obtained from the most soluble fraction of the (*R,R*)-2,3-bis-(benzoyloxy)succinate salt by a method similar to that for the active diamine.

trans-$[CoCl_2(R\text{-}mtmd)_2]ClO_4$. A mixture of *R*-mtmd·2HCl (2.0 g, 11.4 mmol) and sodium methoxide (1.08 g, 20 mmol) in methanol (15 cm^3) was stirred for *ca.* 1 h. Sodium chloride which deposited was filtered off and washed with a small amount of methanol. The combined filtrate and washings were diluted with dimethyl sulfoxide (DMSO, 200 cm^3). This solution of *R*-mtmd and a DMSO solution (200 cm^3) of $Co(NO_3)_2\cdot 6H_2O$ (1.02 g, 3.5 mmol) were simultaneously added dropwise to vigorously stirred DMSO (500 cm^3). Air was bubbled through the resulting solution for 6 d in the presence of active charcoal (2 g). After removal of the active charcoal, the dark red solution was diluted with 4 dm^3 of 10^{-2} M HCl (1 M=1 mol/dm^3), and passed through a column (ϕ 2.7×7 cm) of SP-Sephadex. The Sephadex charged with the product was placed on the top of a column (ϕ 7×30 cm) of the same resin, and the adsorbed complexes were eluted with 0.2 M Na_2SO_4 adjusted to pH 2 with $HClO_4$. The effluent of the fastest moving violet band, which was presumed from the absorption spectrum to involve $[Co(R\text{-}mtmd)_2(H_2O)_2]^{3+}$, was collected, diluted with water, and passed again through an SP-Sephadex column (ϕ 2.7×5 cm). After the column had been washed with water, the adsorbed band was eluted with 1 M HCl. Perchloric acid (70%, 0.5 cm^3) was added to the eluate, and the solution was concentrated in a vacuum desiccator over P_2O_5 and NaOH to yield green needles. They were filtered and washed with water. Yield: 0.05 g. The complex is unstable even in the solid state, decomposing at room temperature in 2 months. It is much more unstable in solution; a methanol solution became turbid in 5 min, while an acetone solution was stable enough to record absorption and CD spectra, although it decomposed in a day.

trans-$[CoCl_2\{(-)\text{-}dmtmd\}_2]ClO_4\cdot 0.5H_2O$. This complex was prepared from (+)-dmtmd·2HCl (dihydrochloride of (−)-dmtmd) and $Co(NO_3)_2\cdot 6H_2O$ by a method similar to that for the corresponding *R*-mtmd complex. The complex is as unstable as the *R*-mtmd complex.

$[Co(NH_3)_4(tmd)]Cl_3\cdot 1.5H_2O$. This complex was prepared by a method similar to that reported.[14] To a DMSO solution (380 cm^3) of tmd (1.0 g, 11 mmol) was slowly added a DMSO solution (380 cm^3) of $[Co(NH_3)_5(H_2O)](ClO_4)_3$ (5.3 g, 11 mmol). The solution was stirred for 2 days at room temperature. The resulting orange-red solution was diluted with water, adjusted to pH 2 with HCl, and poured onto a column (ϕ 2.7×4 cm) of SP-Sephadex. A small portion of the Sephadex charged with the product was placed on the top of a column (ϕ 2.7×120 cm) of SP-Sephadex, and the adsorbed complexes were eluted with 0.2 M Na_2SO_4 adjusted the pH to 2 with HCl. The column showed several bands. The effluent of the third orange band was diluted ten times with 10^{-2} M HCl and passed again through an SP-Sephadex column (ϕ 2×3 cm). After the column had been washed with 10^{-2} M HCl (10 dm^3), the adsorbed band was eluted with 1 M HCl. The effluent was evaporated to almost dryness in a vacuum desiccator over P_2O_5 and NaOH. Orange crystals which formed by the addition of ethanol were filtered and washed with ethanol. Yield: 0.5 g.

$[Co(NH_3)_4(R\text{- }or\text{ }S\text{-}mtmd)](ClO_4)_3$. This complex was prepared from *rac*-mtmd and $[Co(NH_3)_5(H_2O)](ClO_4)_3$ by a method similar to that for the corresponding tmd complex. The effluent containing $[Co(NH_3)_4(mtmd)]^{3+}$ was diluted with 10^{-2} M HCl, and passed through a column (ϕ 2×3 cm) of SP-Sephadex. The adsorbed band was eluted with 1.5 M $NaClO_4$ adjusted to pH 2 with $HClO_4$. On concentration with a rotary evaporator, the effluent yielded orange crystals, which were collected and washed with ethanol. Yield: 10%. This racemate was resolved by SP-Sephadex column chromatography. The complex (*ca.* 50 mg) adsorbed on a column of SP-Sephadex (ϕ 2.7×120 cm) was eluted with 0.15 M sodium (+)-tartratoantimonate(III). A good separation between the enantiomers was observed. From the fast and the slowly eluted fractions, $[Co(NH_3)_4(S\text{-}mtmd)](ClO_4)_3$ and $[Co(NH_3)_4(R\text{-}mtmd)](ClO_4)_3$ were isolated, respectively, by a method similar to that for the racemate. The assignment of the isomers was made by comparing the CD spectra with that of the complex prepared from the active *R*-mtmd and $[Co(NH_3)_5(H_2O)](ClO_4)_3$.

$[Co(NH_3)_4(meso\text{-}dmtmd)]Cl_3\cdot 2.5H_2O$, $[Co(NH_3)_4\{(+)\text{-}dmtmd\}](ClO_4)_3\cdot H_2O$, *and* $[Co(NH_3)_4\{(-)\text{-}dmtmd\}](ClO_4)_3\cdot H_2O$. These complexes were prepared from a mixture of *meso*- and *rac*-dmtmd and $[Co(NH_3)_5(H_2O)](ClO_4)_3$ by a method similar to that for $[Co(NH_3)_4(tmd)]^{3+}$. By elution with 0.2 M Na_2SO_4 adjusted to pH 2 with HCl, the column showed five bands; orange-red ($[Co(NH_3)_5(H_2O)]^{3+}$), purple ($[Co(NH_3)_5(DMSO)]^{3+}$), yellow-orange ($[Co(NH_3)_6]^{3+}$) and two orange ($[Co(NH_3)_4(dmtmd)]^{3+}$) bands in the order of elution. From the fourth band, $[Co(NH_3)_4(meso\text{-}dmtmd)]Cl_3\cdot 2.5H_2O$ was obtained by the same method as that for the corresponding tmd complex. The complex corresponding to the fifth band ($[Co(NH_3)_4(rac\text{-}dmtmd)]^{3+}$) was resolved into a pair of enantiomers by the same method as that for $[Co(NH_3)_4(mtmd)]^{3+}$. The fast and the slowly moving bands were assigned to the (−)-dmtmd and the (+)-dmtmd complexes, respectively, by comparing their CD spectra with that of the complex prepared by use of (+)-dmtmd·2HCl ((−)-dmtmd). The enantiomers were isolated as perchlorates by a method similar to that for $[Co(NH_3)_4(mtmd)](ClO_4)_3$ using an eluent of 1 M $HClO_4$ instead of 1.5 M $NaClO_4$. Attempts to obtain the crystalline chlorides were unsuccessful.

Λ-$[Co(en)_2(R\text{-}mtmd)](ClO_4)_3\cdot 0.5H_2O$ *and* Δ-$[Co(en)_2(R\text{-}mtmd)](ClO_4)_3\cdot 2H_2O$. To a DMSOsolution (200 cm^3) of *trans*-$[CoCl_2(en)_2]ClO_4$ (0.7 g, 2 mmol) was slowly added a DMSO solution (50 cm^3) of *rac*-mtmd (0.2 g, 2 mmol). The solution was stirred for 2 d at room temperature. The resulting solution was subjected to SP-Sephadex column chromatography by a method similar to that for the corresponding tetraammine complex. By elution with 0.2 M Na_2SO_4 adjusted to pH 2 with HCl, the column showed four bands; two pink (small amount) and two orange (nearly the same amount) bands; M-I and M-II, in the order of elution. M-I and M-II are racemates of a pair of diastereomers, *Λ*(*R*) and *Δ*(*S*), and *Λ*(*S*) and *Δ*(*R*), respectively. The racemates were resolved without isolation by the same method as that for $[Co(NH_3)_4(mtmd)]^{3+}$. The faster eluted enantiomers of M-I and M-II are *Λ*-$[Co(en)_2(R\text{-}mtmd)]^{3+}$ (M-I-1) and *Λ*-$[Co(en)_2(S\text{-}mtmd)]^{3+}$(M-II-1). respectively. The isomers obtained from the slower eluted bands are thus *Δ*-$[Co(en)_2(S\text{-}mtmd)]^{3+}$ (M-I-2) and *Δ*-$[Co(en)_2(R\text{-}mtmd)]^{3+}$ (M-II-2).

The absolute configurations of these isomers were assigned by comparing the CD spectra with those of the isomers prepared by use of active *R*-mtmd which was obtained by neutralizing *R*-mtmd·2HCl with sodium methoxide in methanol. When excess sodium methoxide was used to neutralize the (*R*)-dihydrochloride, *Δ*-[Co(en)$_2$(*R*-mtmd)]$^{3+}$ (M-II-2) was not yielded, giving only *Λ*-[Co(en)$_2$(*R*-mtmd)]$^{3+}$ (M-I-1) stereoselectively. All the isomers were isolated as perchlorates by the same method as that for [Co(NH$_3$)$_4$(mtmd)](ClO$_4$)$_3$·H$_2$O.

Preparation and Resolution of [*Co(en)$_2$(dmtmd)*]$^{3+}$. The isomers of this complex were prepared from dmtmd·2HCl (a mixture of *meso* and *rac* forms)and *trans*-[CoCl$_2$(en)$_2$]ClO$_4$ in *N,N*-dimethylformamide (DMF) by a method similar to that for the corresponding mtmd complex. By elution with 0.2 M Na$_2$SO$_4$ adjusted to pH 2 with HCl, the column gave four bands; orange-yellow ([Co(en)$_3$]$^{3+}$) and three orange bands, D-I, D-II, and D-III named in the order of elution. From the effluent of D-II, *rac*-[Co(en)$_2$(*meso*-dmtmd)]Cl$_3$·1.5H$_2$O was isolated by the same method as that for [Co(NH$_3$)$_4$(tmd)]-Cl$_3$·1.5H$_2$O. In a similar way one racemate (*Λ*-[Co(en)$_2$-{(+)-dmtmd}]$^{3+}$ and *Δ*-[Co(en)$_2${(−)-dmtmd}]$^{3+}$) was isolated as perchlorate from the effluent of D-III. The racemate in D-I (*Λ*-[Co(en)$_2${(−)-dmtmd}]$^{3+}$ and *Δ*-[Co(en)$_2${(+)-dmtmd}]$^{3+}$) was not isolated because of a small amount. The formation ratio of the racemates, D-I: D-II: D-III was 1 : 4 : 2. Each of the racemates was resolved into a pair of enantiomers by the same method as that for [Co(NH$_3$)$_4$-(mtmd)]$^{3+}$. In all cases, the column showed two separate bands (D-I-1, D-I-2, *etc.*), the *Λ* isomer (D-I-1, *etc.*) being eluted faster. The optically active chlorides were obtained by the same method as that for [Co(NH$_3$)$_4$(tmd)]Cl$_3$·1.5H$_2$O. To assign the isomers, the (−)-dmtmd complex was prepared from (+)-dmtmd·2HCl ((−)-dmtmd). A pair of diastereomers, *Λ*(−) and *Δ*(−) corresponding to D-I-1 and D-III-2, respectively, were obtained.

Preparation and Resolution of cis-[*Co(NH$_3$)$_2$(tmd)$_2$*]$^{3+}$. The *trans*-[CoCl$_2$(tmd)$_2$]ClO$_4$[15] complex was dissolved in liquid ammonia to give an orange solution. After evaporation of ammonia, the crude complex remained was dissolved in 10^{-2} M HCl and column-chromatographed by the same method as that for [Co(NH$_3$)$_4$(tmd)]$^{3+}$. The column showed two orange bands. From the slower moving band, *cis*-[Co(NH$_3$)$_2$-(tmd)$_2$](ClO$_4$)$_3$ was obtained by the same method as that for [Co(NH$_3$)$_4$(mtmd)](ClO$_4$)$_3$·H$_2$O. Yield: 70%. The trans isomer (the faster moving band) was not isolated because of the very small amount. The cis isomer was resolved by the same method as that for [Co(NH$_3$)$_4$(mtmd)]$^{3+}$, the (+)-*Δ* isomer being eluted first. The enatiomers were isolated as perchlorates by the method described.

cis-*Δ*-[*Co(NH$_3$)$_2$*{(−)-*dmtmd*}$_2$]*Cl$_3$*·*2H$_2$O*. This complex was prepared from *trans*-[CoCl$_2${(−)-dmtmd}$_2$]ClO$_4$·H$_2$O and liquid ammonia by the same method as that for the corresponding tmd complex, and isolated as chloride by the method described. Yield: 10%. The other diastereomer was not yielded under the conditions given.

Analytical data of the new complexes are given in Table 1.

Results and Discussion

Preparation and Stability of the Complexes. The *trans*-[CoCl$_2$(*R*-mtmd)$_2$]$^+$ and [CoCl$_2${(−)-dmtmd}$_2$]$^+$ complexes were prepared by oxidizing a DMSO solution of the diamine and cobalt(II) ions with air and by treating with hydrochloric acid. The air-oxidation in aqueous solution resulted in only the formation of insoluble cobalt hydroxide. The DMSO solution was prepared by slowly mixing fairly dilute solutions of the reactants in order to avoid the formation of polymeric complexes.[16] The yields are still very poor, *ca.* 3%. The complexes isolated as perchlorate decompose gradually even in the solid state, and rapidly in methanol (Experimental). The *trans*-[CoCl$_2$(*R*-mtmd)$_2$]$^+$ complex can have two geometrical isomers, *trans-trans* and *trans-cis*, by the alignment of the two methyl groups. However, no attempt to separate them was made because of instability of the complex. The tetraammine and bis-(ethylenediamine) complexes of the diamines were prepared from [Co(NH$_3$)$_5$(H$_2$O)]$^{3+}$ and *trans*-[CoCl$_2$-(en)$_2$]$^+$, respectively by mixing with the diamine in a large amount of DMSO or DMF. Such reactions are

known to be useful in obtaining complexes containing a large chelate ring.[16] Similar reactions with 1,2- or 1,3-diamines are usually accompanied by disproportionation to yield complexes of other bis- and tris-diamine than the desired mono-diamine. In the present study, however, the formation of bis or tris(1,4-diamine) complexes are *seldom* observed. These complexes would be unstable because of crowding due to the bulky seven-membered chelate rings. The $[Co(en)_2(R\text{-mtmd})]^{3+}$ complex yielded only the *Λ* isomer when excess sodium methoxide was used for neutralizing *R*-mtmd·2HCl. However, when distilled free *R*-mtmd was used, such selectivity was not observed, forming the *Λ* and *Δ* isomers in nearly the same amount. The di- and tetraammine and bis(ethylenediamine) complexes with the 1,4-diamines are stable in acidic water, but decom-

a) Solvent: acetone, sh: shoulder.

pose gradually in neutral water. Thus, care was taken to maintain solutions acidic in the course of preparation. The chelate coordination of 1,4-diamines in all the complexes is supported by elution behavior in column chromatography.[16]

Absorption and CD Spectra. As seen in Table 2, the first absorption maxima of $[Co(NH_3)_4(R\text{-mtmd})]^{3+}$, $[Co(NH_3)_4(tmd)]^{3+}$, $[Co(NH_3)_4\{(-)\text{-dmtmd}\}]^{3+}$, and $[Co(NH_3)_4(meso\text{-dmtmd})]^{3+}$ appear at 20720, 20700, 20620, and 20450 cm^{-1}, respectively. Thus the order of these 1,4-diamines in the spectrochemical series can be determined as *R*-mtmd$\gtrsim$tmd$>$(−)-dmtmd$>$*meso*-dmtmd. Since the basicities of (−)-dmtmd and *meso*-dmtmd ligands will be similar, the red shift of the first absorption band of the *meso*-dmtmd complex can be attributed to the strained structure of the complex (*vide infra*). It is reported that cobalt(III) complexes with a strained structure show the red shift in the first absorption band.[17] In the ultraviolet region, the *meso*-dmtmd complex shows a shoulder (46100 cm^{-1}) and a strong band (49500 cm^{-1}), which can be assigned to charge transfer transitions from the *meso*-dmtmd and ammonia ligands, respectively to the cobalt(III) ion. No shoulders are observed for the other tetraammine complexes. The appearance of the shoulder in the *meso*-dmtmd complex indicates that there is a fairly large energy difference between those two kinds of charge transfer transitions. For the other complexes, the charge transfer bands from the 1,4-diamines to the cobalt(III) ion might be hidden by that from the ammonia to the cobalt(III) ion owing to small energy differences between them. The $[Co(NH_3)_6]^{3+}$ complex gives the charge transfer band at 51150 cm^{-1}.[18] Thus the strained $[Co(NH_3)_4(meso\text{-dmtmd})]^{3+}$ complex shows the red shift in both the d-d and charge transfer bands.

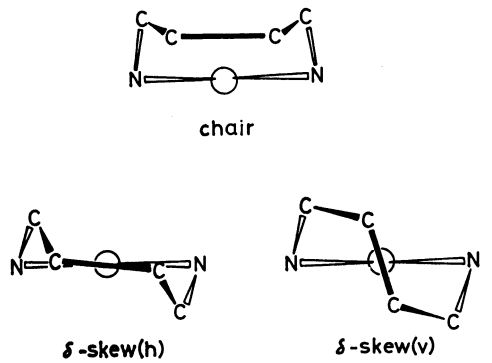

Fig. 1. Possible conformations of a seven-membered 1,4-diamine chelate ring.

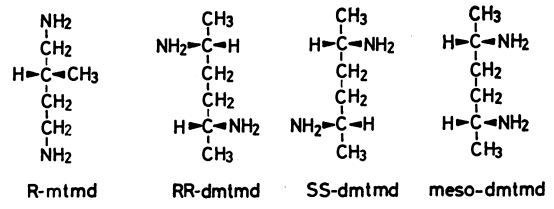
Figure 1 shows three typical conformations of a 1,4-diamine chelate ring. Each of the skew conformations is chiral and has its antipode. The chair conformation seems to be unstable because big steric hindrance is involved among the axial hydrogens of 1- and 4-carbon atoms of the 1,4-diamine chelate ring and an apical ligand. However, the *meso*-dmtmd chelate ring might take the chair conformation, since both methyl groups can have equatorial positions in only this form. In any skew conformation one of the two methyl groups is forced to take the axial position. Molecular models indicate that for 1,4-diamine chelate rings, conformations with an axial methyl group do not seem to be plausible. Thus the $[Co(NH_3)_4(meso\text{-dmtmd})]^{3+}$ complex would be strained and shows the red shift in the absorption spectrum. The conformations of the *R*-mtmd and *RR*-dmtmd chelate rings with the equatorial methyl group(s) are either *δ-skew(h)* or *λ-skew(v)*, and *λ-skew(h)* or *λ-skew(v)*, respectively (Figs. 1 and 2).



Conformation

Ligand	δ-skew(h)	λ-skew(h)	δ-skew(v)	λ-skew(v)	chair
R-mtmd	e	a	a	e	e(a)
RR-dmtmd	aa	ee	aa	ee	ae
SS-dmtmd	ee	aa	ee	aa	ae
meso-dmtmd	ae	ae	ae	ae	ee(aa)

e: methyl equatorial a: methyl axial

Fig. 2. Absolute configurations of *R*-mtmd and three isomers of dmtmd, and their conformations in chelates.

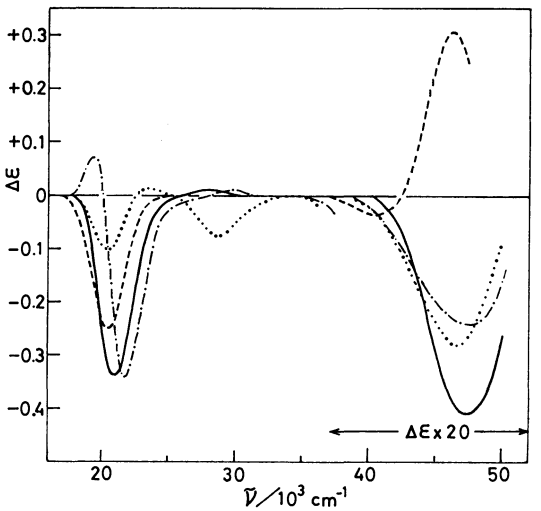


Fig. 3. CD spectra of $[Co(NH_3)_4(diamine)]^{3+}$ in water. Diamine: *R*-mtmd (——), (−)-dmtmd (------), *SS*-2,3-bn (·····), and *SS*-ptn (·····).

Figure 3 compares CD spectra of some tetraamine complexes of a chiral diamine. Except for the (−)-dmtmd complex, all the complexes show negative CD in both the first and the charge transfer absorption band regions. Since the (*S,S*)-2,3-butanediamine (*SS*-2,3-bn)[18] and (*S,S*)-2,4-pentanediamine (*SS*-ptn)[1] chelate rings are stabilized in the *δ-gauche* and *δ-skew* forms, respectively, the *R*-mtmd chelate ring can also be assigned to have the same chirality, *δ-skew(h)*. The *R*-mtmd complex increases the CD strength in the first absorption band region in DMSO ($\Delta\varepsilon=-0.48$ at

21000 cm^{-1}). The same trend is observed for the *SS*-2,3-bn and *SS*-ptn complexes. In the (−)-dmtmd complex, on the other hand, the CD sign in the first absorption band region differs from that in the charge transfer absorption band region. In addition, the complex decreases the CD strength in the first absorption band region in DMSO ($\Delta\varepsilon = -0.18$ at 20300 cm^{-1}), which is opposite to those of the other tetraammine complexes. The results make the assignment for the chirality of the (−)-dmtmd chelate ring difficult. Thus the *trans*-$[CoCl_2\{(-)\text{-dmtmd}\}_2]^+$ complex was prepared and the CD spectrum was compared with those of the related complexes. The relationship between CD patterns and conformational chirality in complexes of this type has also been studied extensively.[10,19]

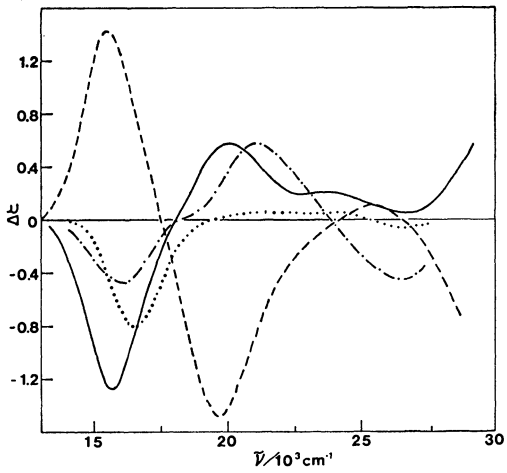

Fig. 4. CD spectra of *trans*-$[CoCl_2(\text{diamine})_2]^+$. Diamine: *R*-mtmd(——, in acetone), (−)-dmtmd (------, in acetone), *SS*-2,3-bn (·····, in methanol), and *SS*-ptn (-·-·-, in methanol).

The *R*-mtmd complex shows a CD pattern similar to those of the *SS*-2,3-bn[10,18] and *SS*-ptn[20] complexes; negative and positive CD bands corresponding to the Ia ($^1E_g \leftarrow {}^1A_{1g}$) and Ib ($^1A_{2g} \leftarrow {}^1A_{1g}$) bands,[21] respectively (Fig. 4). Thus the R-mtmd chelate ring can be assigned to have the *δ-skew(h)* conformation. This assignment agrees with that based on the CD spectrum of the tetraammine complex. On the other hand, the CD pattern of the (−)-dmtmd complex is opposite to those of the other dichloro complexes, indicating the conformation of *λ* chirality. When the *λ*-(−)-dmtmd chelate ring has two equatorial methyl groups, the two chiral carbon atoms are determined to have the (*R*,*R*) configuration, regardless of two kinds of conformations, *skew(h)* or *skew(v)*. This assignment is supported by CD spectra of a pair of diastereomers of $[Co(en)_2\{(-)\text{-dmtmd}\}]^{3+}$ discussed later. The reason why the $[Co(NH_3)_4\{(-)\text{-dmtmd}\}]^{3+}$ complex, in which the chelate ring has *λ* chirality, shows the negative CD band in the first absorption band region is unknown. Similar anomalous CD has been reported for the tetraammine complexes of (*S*,*S*)-1,3-diphenyl-1,3-propanediamine[22] and (*S*)-1,3-butanediamine.[2]

In Fig. 5 are shown CD spectra of M-I-1 and M-II-2

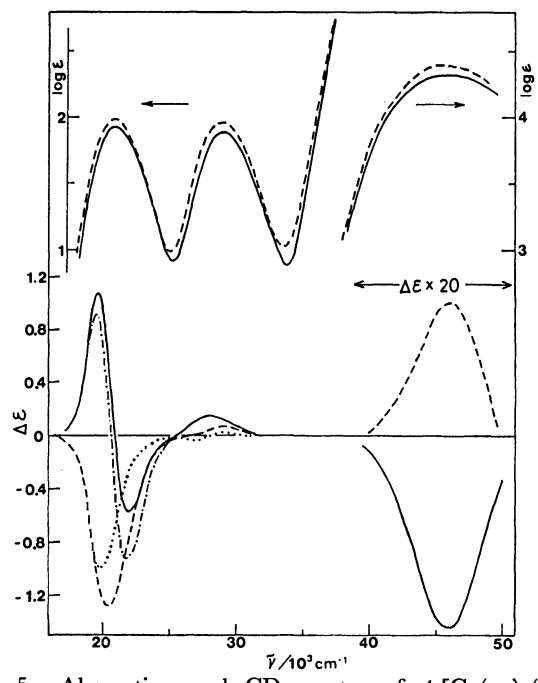

Fig. 5. Absorption and CD spectra of *Λ*-$[Co(en)_2(R\text{-mtmd})]^{3+}$ (M-I-1) in water (——) and in 0.2 mol/dm^3 Na_2SO_4 (·····), and *Δ*-$[Co(en)_2(R\text{-mtmd})]^{3+}$ (M-II-2) in water (------) and in 0.2 mol/dm^3 Na_2SO_4 (·····).

isomers of the $[Co(en)_2(R\text{-mtmd})]^{3+}$ complex in aqueous solutions in the absence or the presence of sulfate ions. The complexes give a typical CD pattern for a tris(diamine) complex, and their absolute configurations can be assigned on the basis of the CD spectra in the first absorption band region; M-I-1 and M-II-2 are assigned to the *Λ*(*R*) and *Δ*(*R*) isomers, respectively. The line connecting 1- and 4-carbon atoms of the *R*-mtmd chelate ring in the *δ-skew(h)* (or *λ-skew(v)*) or *λ-skew(v)* (or *δ-skew(h)*) form is nearly parallel or oblique to the pseudo C_3 axis of the *Λ* (or *Δ*)-$[Co(en)_2(R\text{-mtmd})]^{3+}$ complex, respectively. Thus *Λ* and *Δ* isomers of the *R*-mtmd complex in the *δ-skew(h)* conformation are designated as "*lel*" and "*ob*" isomers, respectively, as in the case of $[Co(en)_3]^{3+}$.[23] The CD patterns of *Λ*- and *Δ*-$[Co(en)_2(R\text{-mtmd})]^{3+}$ in aqueous solutions are characteristic of the "*lel*" and "*ob*" isomers, respectively; the former gives two CD bands with different signs in the first absorption band region, while the latter only one band in this region. Thus the *R*-mtmd chelate rings in these complexes are also stabilized in the *δ-skew(h)* conformation. In the presence of sulfate ions, the *Λ*(*R*) isomer diminishes the CD strength of the major positive component, and complementarily enhances that of the minor component. Such a phenomenon is known to be brought about by an increase in the amount of the lel_3 conformer of a tris(diamine) complex stabilized by ion-association with a sulfate ion.[24] The ion-pair is formed through hydrogen bonding between the three amino protons nearly parallel to the C_3 axis of a tris(diamine) complex and a sulfate ion, and the lel_3 structure affords such amino protons. Thus the *Λ*-$[Co(en)_2(R\text{-mtmd})]^{3+}$ complex will be stabilized in the *Λ*(*δ-gauche*$_2$, *δ-skew(h)*)(lel_3) confor-

mer to increase the amount of δ-diamines in the presence of sulfate ions, and increases the negative CD strength in the first absorption band region. It is known that the vicinal effect of a δ-diamine chelate ring in the $[CoN_6]$-type complex is negative in this region.[25] The Δ-$[Co(en)_2(R\text{-mtmd})]^{3+}$ complex also shows a CD change on addition of sulfate ions, decreasing considerably the negative strength. According to the previous discussion, the decrease in the negative CD strength indicates an increase in the amount of λ-diamines in order to form the $\Delta(lel_3)$ conformer. The complex can afford the lel_3 conformer when the R-mtmd chelate ring forms the λ-*skew*(v) structure, in which the methyl group is disposed equatorially.

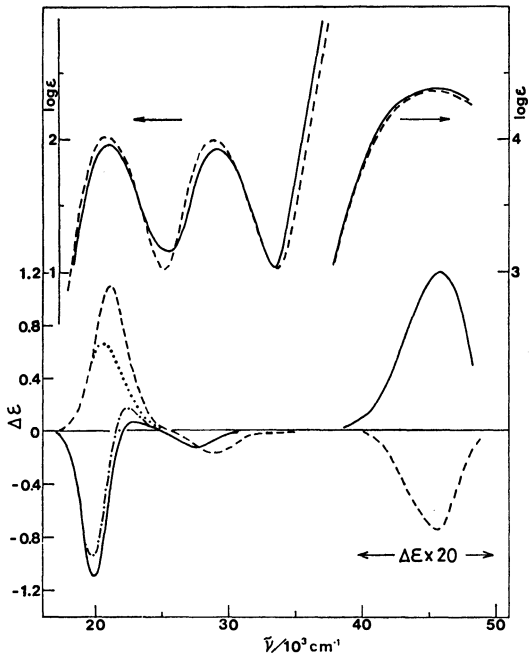

Fig. 6. Absorption and CD spectra of Δ-$[Co(en)_2\{(-)\text{-dmtmd}\}]^{3+}$ (D-III-2) in water (——) and in 0.2 mol/dm³ Na_2SO_4 (·····), and Λ-$[Co(en)_2\{(-)\text{-dmtmd}\}]^{3+}$ (D-I-1) in water (------) and in 0.2 mol/dm³ Na_2SO_4 (·····).

The D-I-1 and D-III-2 isomers of $[Co(en)_2\{(-)\text{-dmtmd}\}]^{3+}$ can be assigned to the Λ and Δ configurations, respectively from the sign of the main CD band in the first absorption band region (Fig. 6). The Λ and Δ isomers show CD patterns characteristic of the "*ob*" and "*lel*" isomers, respectively. This indicates that the (—)-dmtmd ligand has the (R,R) carbon atoms, forming the λ-*skew*(h) or λ-*skew*(v) conformation with the two equatorial methyl groups. The assignment for (—)-dmtmd agrees with that given previously from the CD spectrum of *trans*-$[CoCl_2\{(-)\text{-dmtmd}\}_2]^+$. The CD change for the $\Delta(lel)$ isomer caused by the addition of sulfate ions is characteristic of the "*lel*" isomer, but the magnitude of the change is fairly small as compared with that of $\Lambda(lel)$-$[Co(en)_2(R\text{-mtmd})]^{3+}$. The smaller CD change in the (—)-dmtmd complex seems to be related with difficulty in forming an ion-pair with a sulfate ion. The Δ-$[Co(en)_2\{(-)\text{-dmtmd}\}]^{3+}$ complex can form the lel_3 conformer (λ-*gauche*$_2$, λ-*skew*(h) or λ-*skew*(v)), and provides two sets of three N–H bonds for the ion-pair formation with a sulfate ion. In the lel_3 conformer, however, the two methyl groups on 1- and 4-carbons of the (—)-dmtmd ligand stick out in nearly parallel with the pseudo C_3 axis of the complex ion, and hinder a sulfate ion from approaching the complex ion along this axis. On the other hand, the methyl group on 2-carbon of the R-mtmd complex is disposed far from the pseudo C_3 axis to involve no such hindrance to a sulfate ion. Thus $\Delta(lel)$-$[Co(en)_2\{(-)\text{-dmtmd}\}]^{3+}$ might have weaker affinity in ion-association with sulfate ions than the R-mtmd complex, and shows the smaller CD change in the presence of sulfate ions. On the other hand, the CD change of $\Lambda(ob)$-$[Co(en)_2\{(-)\text{-dmtmd}\}]^{3+}$ in the presence of sulfate ions is as large as that of $\Lambda(ob)$-$[Co(en)_2(R\text{-mtmd})]^{3+}$ (Fig. 6). The two methyl groups in $\Lambda(ob)$-$[Co(en)_2\{(-)\text{-dmtmd}\}]^{3+}$ are disposed far from the pseudo C_3 axis, differing from those in the $\Delta(lel)$-(—)-dmtmd complex. However, the complex should not form the lel_3 conformer, since the conversion of the (—)-dmtmd chelate ring to the *lel* form (δ-*skew*(h or v)) with the two axial methyl groups is very unlikely. The reason for the large CD change is not clear. However, molecular models indicate that the large and flexible (—)-dmtmd chelate ring can form rather easily an intermediate conformation suitable for ion-association with a sulfate ion by a slight distortion from the typical skew form. The $\Lambda(ob)$ isomer comprising such a conformer might form an ion-pair with a sulfate ion to cause the large CD change. The suggestion that the $\Lambda(ob)$ isomer has stronger affinity for a sulfate ion than the $\Delta(lel)$ isomer is supported by the elution order in column chromatography. By elution with 0.2 M Na_2SO_4, the former is eluted faster than the latter (Experimental). In similar column chromatographic separation for a pair of diastereomers, it has been observed that a *lel* isomer is always eluted faster than an *ob* isomer.[26] The $[Co(en)_2(R\text{-mtmd})]^{3+}$ complex in this study is the case. The elution order of such a pair of diastereomeric complexes is reported to depend on the ion-association constant between a complex ion and an anion;[27] a complex with the larger value is eluted faster. In the ion-association between $[Co(R\text{-pn})_3]^{3+}$ (R-pn=(R)-1,2-propanediamine) and a sulfate ion, the constant for the $\Delta(lel_3)$ isomer is larger than that for the $\Lambda(ob_3)$ isomer.[28] Thus the $\Lambda(ob)$ isomer of $[Co(en)_2\{(-)\text{-dmtmd}\}]^{3+}$ which is eluted faster than the other $\Delta(lel)$ isomer should have a larger constant in association with a sulfate ion, and causes a larger CD change than the other isomer does in the presence of sulfate ions.

In Fig. 7 are shown the CD spectra of Δ-$[Co(en)_2(meso\text{-dmtmd})]^{3+}$ (D-II-2) in the absence and presence of sulfate ions, the absolute configuration of which is assigned on the basis of the CD sign in the first absorption band region. In the presence of sulfate ions, the complex shows a CD change as small as that in $\Delta(lel)$-$[Co(en)_2\{(-)\text{-dmtmd}\}]^{3+}$. The small CD change of the *meso*-dmtmd complex would also be attributable to weak association with a sulfate ion as stated for the

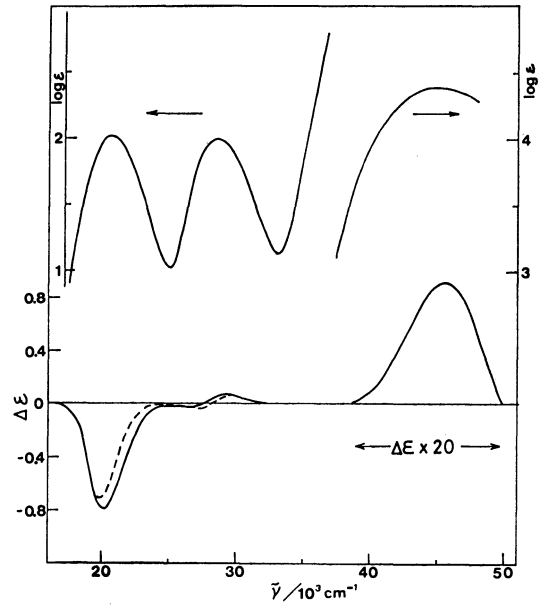

Fig. 7. Absorption and CD spectra of Δ-[Co(en)$_2$(*meso*-dmtmd)]$^{3+}$ (D-II-2) in water (——) and in 0.2 mol/dm^3 Na_2SO_4 (------).

$\Delta(lel)$-(−)-dmtmd complex. When the *meso*-dmtmd chelate ring is in the same chair form as that in the tetraammine complex, one methyl group is disposed near one set of three N–H bonds to hinder the ion-association, but the other methyl group is located away from the other set of three N–H bonds, a sulfate ion being able to approach the complex ion. However, the amino protons of the *meso*-dmtmd ligand are oblique to the C_3 axis of the complex ion, and unfavorable for association of the lel_3-SO_4^{2-} type. The *meso*-dmtmd chelate ring would be less flexible than the (−)-dmtmd chelate one because of the strained structure as stated previously. Thus the [Co(en)$_2$(*meso*-dmtmd)]$^{3+}$ complex would have weak affinity for a sulfate ion to cause the small CD change.

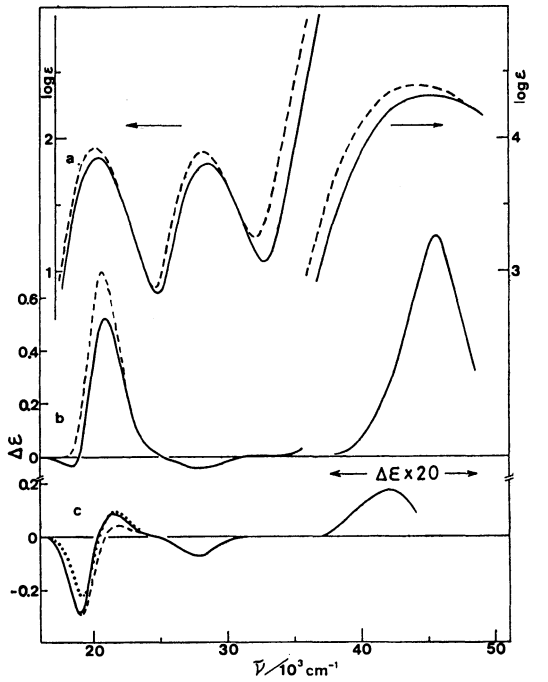

Fig. 8. a. Absorption spectra of *cis*-Δ-[Co(NH$_3$)$_2$(tmd)$_2$]$^{3+}$ (——) and *cis*-Δ-[Co(NH$_3$)$_2${(−)-dmtmd}$_2$]$^{3+}$ (------) in water.
b. CD spectra of *cis*-Δ-[Co(NH$_3$)$_2$(tmd)$_2$]$^{3+}$ in water (——) and in 0.2 mol/dm^3 Na_2SO_4 (------).
c. CD spectra of *cis*-Δ-[Co(NH$_3$)$_2${(−)-dmtmd}$_2$]$^{3+}$ in water (——) and in 0.2 mol/dm^3 Na_2SO_4 (------), and the calculate dCD curve, $2\times\Delta\varepsilon$([Co(NH$_3$)$_4${(−)-dmtmd}]$^{3+}$)$+\Delta\varepsilon$(*cis*-Δ-[Co(NH$_3$)$_2$(tmd)$_2$]$^{3+}$) (·····).

In Fig. 8 are compared CD spectra of the Δ isomers of $(+)_{589}$-[Co(NH$_3$)$_2$(tmd)$_2$]$^{3+}$ and $(-)_{589}$-[Co(NH$_3$)$_2$-{(−)-dmtmd}$_2$]$^{3+}$ in the absence and presence of sulfate ions. The main CD bands of these complexes exhibit different signs in the first absorption band region. The absolute configuration of the tmd complex was assigned from a comparison of CD patterns of Δ-[Co(en)-(tmd)$_2$]$^{3+}$[29] and Δ-[Co(tmd)$_3$]$^{3+}$,[29] and that of the(−)-dmtmd complex was done on the basis of the stereoselective complex formation {$\Delta(lel_2)$}brought about by the ligand of *R,R*-configuration. The $\Lambda(ob_2)$ isomer involves severe steric hindrance between the two chelate ligands. Both Δ isomers of the tmd and (−)-dmtmd complexes show a negative CD component in the small wavenumber side in the first absorption band region, and a strong positive CD band in the ultraviolet region. The features agree with those observed for other related complexes of the Δ configuration. The Δ-[Co(NH$_3$)$_2$-{(−)-dmtmd}$_2$]$^{3+}$ complex involves two chiral sources, the Δ configuration and the *RR*-dmtmd chelate ligand of λ-*skew*(*h* or *v*). When the additive law[25,30] for the configurational and vicinal CD effects holds in the CD spectrum of Δ-[Co(NH$_3$)$_2${(−)-dmtmd}$_2$]$^{3+}$, it can be approximated by the sum of the CD spectrum of Δ-[Co(NH$_3$)$_2$(tmd)$_2$]$^{3+}$ and the curve doubled the CD strength of [Co(NH$_3$)$_4${(−)-dmtmd}]$^{3+}$. The CD curve calculated in the first absorption band region resembles

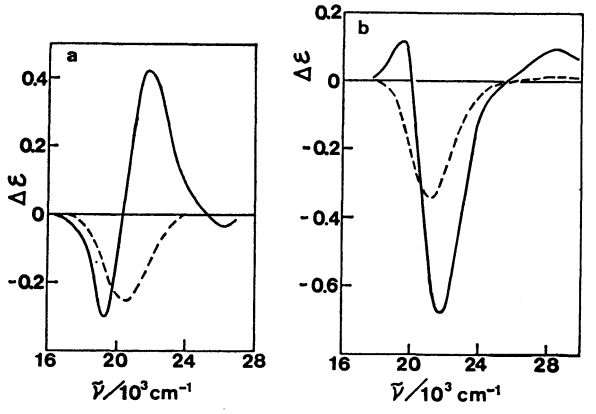

Fig. 9. a. Vicinal effect CD of the (−)-dmtmd ligand. The calculated CD curve, $1/2\{\Delta\varepsilon(\Delta$-[Co(en)$_2${(−)-dmtmd}]$^{3+})$+\Delta\varepsilon(\Delta$-[Co(en)$_2${(−)-dmtmd}]$^{3+})\}$, (——). The observed CD spectrum of [Co(NH$_3$)$_4${(−)-dmtmd}]$^{3+}$ (------).
b. Vicinal effect CD of the *R*-mtmd ligand. The calculated CD curve, $1/2\{\Delta\varepsilon(\Delta$-[Co(en)$_2$(*R*-mtmd)]$^{3+})$ $+\Delta\varepsilon(\Delta$-[Co(en)$_2$(*R*-mtmd)]$^{3+})\}$, (——). The observed CD spectrum of [Co(NH$_3$)$_4$(*R*-mtmd)]$^{3+}$ (------).

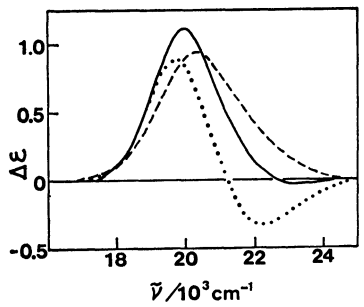

Fig. 10. Configurational effect CD ($\Delta\varepsilon(\Lambda)$) curves. The calculated CD curve, $1/2\{\Delta\varepsilon(\Lambda\text{-}[Co(en)_2(R\text{-mtmd})]^{3+}) - \Delta\varepsilon(\Lambda\text{-}[Co(en)_2(R\text{-mtmd})]^{3+})\}$, (——). The calculated CD curve, $1/2\{\Delta\varepsilon(\Lambda\text{-}[Co(en)_2\{(-)\text{dmtmd}\}]^{3+}) - \Delta\varepsilon(\Lambda\text{-}[Co(en)_2\{(-)\text{-dmtmd}\}]^{3+})\}$, (----). The observed CD spectrum of Λ-$[Co(en)_2(tmd)]^{3+}$(·····).

well the observed CD spectrum (Fig. 8). Thus the strong negative CD of Λ-$[Co(NH_3)_2\{(-)\text{-dmtmd}\}_2]^{3+}$ in the first absorption band region can be attributed to the strong negative vicinal effect of the *RR*-dmtmd chelate ligand.

In the presence of sulfate ions, the tmd complex shows fairly large CD change, but the (−)-dmtmd complex a little change. Such a difference might also be related with a difference in the flexibility and structure of the chelate rings. The more flexible tmd chelate ring would be stabilized in a certain conformation by forming an ion-pair between the complex ion and a sulfate ion. On the other hand, the (−)-dmtmd complex has four methyl groups, which hinder a sulfate ion from approaching the N–H protons of the chelate ligands to cause little change in the conformation of the chelate rings. Thus the complex would show the small CD change in the presence of sulfate ions.

Figures 9 and 10 show the configurational and vicinal effect CD curves obtained by the usual way[30] from CD spectra of the diastereomers of $[Co(en)_2(R\text{-mtmd})]^{3+}$ and $[Co(en)_2\{(-)\text{-dmtmd}\}]^{3+}$. These curves are compared with CD spectra of the related complexes in the Figures. The additive law for the configurational and vicinal effects does not hold among these complexes, although it works among the ammine complexes of tmd and (−)-dmtmd. The lack of the additivity might be related with crowded structures of those tris-chelate-type complexes involving a large seven-membered chelate ring. Some six-membered diamine complexes have also been reported to show lack of the additivity, and it has been interpreted as the results of flexible conformation of a six-membered chelate ring; the conformation of a six-membered chelate ring in one complex would differ from that in the other.[1] The same interpretation can be made on the complexes concerned. The stable conformation of a seven-membered chelate ring in the crowded bis-en complex would differ from that in the much less crowded tetra-ammine complex, and this might cause the lack of the additivity.

Pyrolytic Sulfurization Gas Chromatography. IX. Determination of the Atomic Ratio between C, H, O, N, Cl, Br, and I in an Organic Halogen Compound

Tadashi HARA,* Kaoru FUJINAGA, and Fujio OKUI

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received February 20, 1981)

The atomic ratio between C, H, O, N, Cl, Br, and I in an organic halogen compound was obtained satisfactorily by gas chromatography and ion chromatography. At first the atomic ratio between C, H, O, and N was determined simultaneously by PSGC and then the atomic ratio between a halogen atom and C, H, O, and N was obtained by estimating the amount of a halogen atom in the reaction residue and by calculating the weight percent in Eq. 4 by use of a correction factor and peak areas in gas and ion chromatograms.

Pyrolytic sulfurization gas chromatography (PSGC), which was originated by the present authors, has been successfully applied to the simultaneous determination of the atomic ratio between C, H, O, and N in a normal organic compound,[1] a metal organic chelate compound,[2] a polymer,[3] and an organic halogen compound.[4]

The present study has been further carried out with the objective of estimating the atomic ratio between C, H, O, N, and halogen atoms (Cl, Br, and I) (X) in an organic halogen compound. Since X in an organic halogen compound was fixed in the reaction residue as sodium halide (NaX) by PSGC,[4] determination of X in the NaX was separately investigated by (1) gas chromatography after conversion of the halide to hydrogen halide (HX) and (2) ion chromatography after dissolving the halide in water, and the results obtained were compared. In the former, HX was easily identified but its determination was difficult due to the incomplete conversion of the NaX to HX and the decomposition of HX. In the latter, a satisfactory result was obtained by dissolving the reaction residue with an aqueous solution of potassium hydrogen phthalate (KHP), by filtering S and quartz pieces off, and by introducing the filtrate to an ion chromatograph through a Teflon membrane filter. On the basis of the relationship between the peak of hydrogen sulfide (H_2S) in a gas chromatogram and that of halide ions (X^-) in an ion chromatogram for a definite composition of organic halogen compound, the atomic ratio of H to X for an unknown compound was obtained without weighting it.

Experimental

Apparatus and Samples. The same gas chromatograph was used as described in the previous paper. A HITACHI 634A liquid chromatograph fitted with a Wescan model 213 conductivity detector and Vydac 302 IC 4.6 column (250 mm), was operated at the flow rate of 1.7 cm³/min by use of a 0.004 mol/dm³-KHP as an eluent to monitor X^-.

The organic halogen compound samples were of analytical grade.

Procedure. The ampule containing an organic halogen compound, S, and sodium sulfide (Na_2S) was made to react by the previously described procedure.[4] It was placed in a 80 mm long, 4.22 mm i.d., 4.94 mm o.d. Teflon tube, and crushed in a gas sampler, the evolved gases being analyzed in accordance with the previous paper to determine the atomic ratio between C, H, O, and N. The pieces obtained by crushing the ampule was taken out of the sampler and treated with 0.004 mol/dm³-KHP, followed by filtration through a G4 glass filter. The filtrate was passed through a Teflon membrane filter (pore size 0.5 μm) and introduced into an ion chromatograph. According to the present procedure, well-defined and separated peaks were obtained for X^- and they were used for the determination of the atomic ratio between C, H, O, N, and X.

Results and Discussion

Analysis of X^- by Ion Chromatography. A mixed solution consisting of each 5×10^{-4} mol/dm³ sodium chloride, sodium bromide, and sodium iodide was analyzed by ion chromatography under the above-mentioned conditions. As can be seen from Fig. 1, the present procedure gives a satisfactory result for the

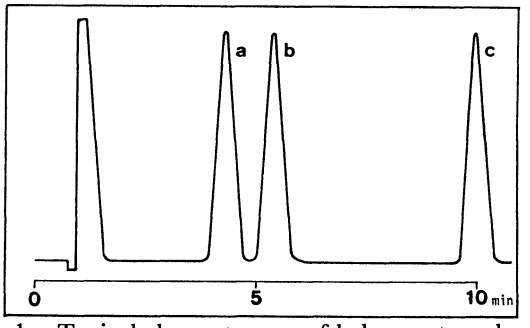

Fig. 1. Typical chromatogram of halogen atoms by the ion chromatography.
a): Cl^-, b) Br^-, c): I^-.
Conditions: Column Vydac 302 IC 4.6 (250 mm); detector conductivity (Wescan model 213); eluent 0.004 mol/dm³-KHP; flow rate 1.7 cm³/min.

Table 1. Precision[a] in the determination of halide ions by ion chromatography

separation of X^-. In order to examine the precision of the present procedure, each 5×10^{-4} mol/dm³ standard solution of X^- was analyzed 10 times and the results were shown in Table 1 by the coefficient of variation (C.V.). The values of C.V. in Table 1 are reasonable ones in comparison with those obtained by an ordinary ion chromatography.

Determination of X by Use of Calibration Curve. Three kinds of organic halogen compounds, that is, 0.112—0.350 mg *p*-chlorobenzoic acid, 0.188—0.416 mg *p*-bromoacetanilide, and 0.188—0.390 mg *o*-iodobenzoic acid were analyzed by the above-mentioned procedure and the relationship between sample weight and peak area in an ion chromatogram were plotted in Fig. 2. Judging from the linearity in Fig. 2, the present procedure is suitable for the determination of X in an organic halogen compound.

To examine the recovery of the present procedure, a definite amount of organic halogen compound was treated by PSGC and the absolute value of X in it was determined using a calibration curve which had been obtained with a standard solution of NaX (Tables 2 and 3). As can be seen from Tables 2 and 3, satisfactory results were obtained for X. This means that both

a) The upperline: theoretical values, the medium line: experimental values, and the lower line: error. b) The sulfur atom was neglected in the composition of the sample since it could not be determined.

area of Cl^- in an ion chromatogram and the atomic ratio of H to Cl in an organic chlorine compound, was plotted in Fig. 4. It was found to give a straight line regardless of the Cl content of the compound. The slope(a) of the straight line in Fig. 4 is shown by Eq.1.

$$a = \left(\frac{H}{Cl}\right) \times \frac{A(Cl^-)}{A(H_2S)} = \text{const.} \quad (1)$$

Equation 1 is rewritten by Eq. 2.

$$\frac{2}{a} = \left(\frac{Cl}{H}\right) \times \frac{2A(H_2S)}{A(Cl^-)} = \text{const.} \quad (2)$$

Equation 2 is also given by Eq. 3 for all halogen atoms.

$$\frac{2}{a} = \left(\frac{H}{X}\right) \times \frac{2A(H_2S)}{A(X^-)} = \text{const.} \quad (3)$$

The form of the $(H/X) \times 2A(H_2S)/A(X^-)$ in Eq. 3 is the same as that of the correction factor[1] which was used for the determination of the atomic ratio between C, H, O, and N. Therefore, the value of Eq. 3 can be replaced by $K(X^-)$ which is used for the determination of the atomic ratio between C, H, O, N, and X. The values of $K(X^-)$ were obtained by analyzing each standard sample (Table 4). They were consistent with a definite value of Eq. 3. Thus the atomic ratio between C, H, O, N, Cl, Br, and I is obtained by Eq. 4.

$$\alpha(wt\%) = \frac{\sum M(\gamma)K(\gamma)A(\gamma)}{\sum M'(\beta)K(\beta)A(\beta)} \times 100 \quad (4)$$

where α: C, H, O, N, Cl, Br, and I, β: the product obtained by the present method, γ: the product containing an element α, $M'(\beta)$: the value obtained by subtracting the amount of S from the formula weight of β, $M(\gamma)$: the formula weight of α in γ, $K(\gamma)$: correction factor of γ, and $A(\gamma)$: peak area of γ.

Determination of the Atomic Ratio between C, H, O, N, and X in an Organic Halogen Compound. Various organic halogen compounds were analyzed by the present method and the atomic ratio between C, H, O, N, and X was calculated by introducing both chromatographic data to Eq. 4 (Table 5). It can be seen from Table 5 that the atomic ratio between C, H, O, N, and X is obtained satisfactorily by the present method in which only one sample is used.

Formation of Anatase Precipitates Containing Fe(III) by the Air Oxidation at 95 °C of Strongly Acidic Solutions

Masao KIYAMA* and Toshio TAKADA
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received February 27, 1981)

Strongly acidic titanium(III) chloride solutions containing iron(II) sulfate were subjected to oxidation with air at 95 °C. The products consist of spheres, 0.5—1.0 μm in size, each composed of extremely fine particles, 100—150 Å in size. Fe(III) is incorporated up to about 6% of the total metal ions in the product, in spite of the strongly acidic solution. The products, containing H_2O and SO_4^{2-} besides Fe(III), are dehydrated in the temperature range 100—400 °C and the sulfate decomposition begins at about 750 °C in air. The SO_4^{2-} in the products can be easily removed by washing at room temperature with NaOH solution. No marked differences can be detected in color, magnetic properties, or in growth of the extremely fine particles before and after the dehydration by heat treatment at 500 °C; a change in such physical properties begins to occur at 550 °C. It is concluded that the Fe(III) in the product is interposed between the extremely fine particles, whereas the H_2O and SO_4^{2-} are adsorbed in the spherical polycrystalline particles formed with oxo and hydroxo combination of the extremely fine particles.

Titanium dioxide, TiO_2, can be formed in three kinds of crystalline modifications—brookite, rutile and anatase. Two of the three modifications—precipitates of anatase and rutile, can be prepared by selecting the conditions of hydrolysis of titanium(IV) salts—*i.e.*, kinds and concentrations of the acid anions present in acidic solutions and the hydrolysis temperature.[1-4] Precipitates consisting of any one of the three modifications can be prepared by selecting the conditions for allowing Ti(III) ions gradually to oxidize in an acidic solution at 65—90 °C.[5]

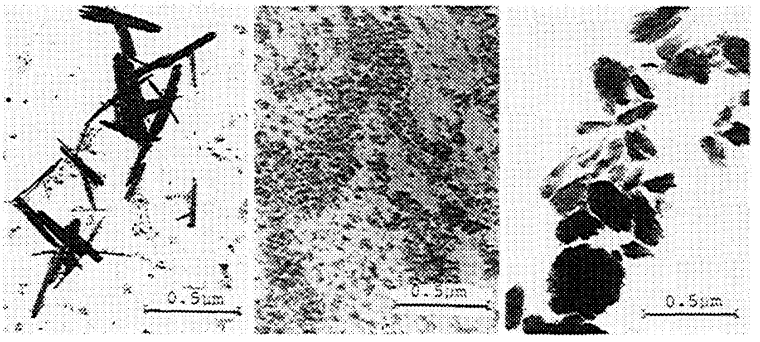
Ti(III) in HCl solution forms a precipitate of brookite or rutile according to the excess HCl concentration or oxidation temperature. Precipitates of brookite or rutile thus formed consist of fine needle-like(a) or extremely fine cubic(b) particles as shown in Fig. 1. The presence of SO_4^{2-} was found to promote the formation of a precipitate of anatase consisting of extremely fine particles, similar to the precipitates of brookite and rutile previously mentioned, as determined by X-ray diffraction examination.[5] Nevertheless, the BET surface area is much less than that of the precipitate of brookite or rutile, the anatase precipitate consisting of relatively large spherical or flat leaf polycrystalline particles as shown in Fig. 1(c). It has been found that in spite of a strongly acidic solution, Fe(III) is partly incorporated into the anatase precipitate in the presence of $FeSO_4$ in the starting solution. A clue to the elucidation of the mechanism of the formation of the polycrystalline particles of anatase would be obtained by clarifying the properties of the polycrystalline particles containing Fe(III).

This paper is an account of the formation of the anatase precipitates containing Fe(III) and the properties of such precipitates.

Experimental

The starting titanium(III) chloride solution (Wako Pure Chemical Industries Ltd.) contained 2.0 M (1 M=1 mol dm^{-3}) $TiCl_3$, 1.6 M $ZnCl_2$, and 1.2 M HCl. To this the required amount of either $FeSO_4 \cdot 7H_2O$ or Na_2SO_4 (analytical grade) was added in various mole ratios of Fe(II) or SO_4^{2-} to Ti(III). Each mixed solution was diluted with water to 3 L (dm^3) in a 4 L flask. The oxidation of the mixed solutions was carried out at 95 °C by bubbling air into them at a constant rate of 200 L/h. The construction of the flask for the air-oxidation experiments has been previously described.[6] After a time lapse of 20 h, Ti(III) ions in the solutions changed completely to Ti(IV) and the solutions, originally colored bluish black, turned to yellowish white suspensions of various hues depending on the Fe(II) concentrations in the starting solutions.

The sedimentation velocities of most oxidation products consiting of anatase particles were extremely fast and they



(a) (b) (c)

Fig. 1. Electronmicrographs of rutile (a), brookite (b), and anatase (c) precipitates. Preparation conditions for samples (a), (b), and (c) correspond respectively to those for sample Nos. 4, 6, and 5 shown in Ref. 5.

could easily be separated from the solutions by filtration. After filtration, the products were washed with water, treated with acetone, and then dried in air at 100 °C. All powdery samples thus obtained were examined by X-ray diffraction using Ni filtered Cu $K\alpha$ radiation; some were further examined by electronmicroscopic observation, magnetic measurement using a magnetic torsion balance, BET surface area determination using nitrogen gas, and, thermal and chemical analyses.

The mean size of the extremely fine particles was estimated from the line broadening of the X-ray diffraction peak for the (101) plane of the anatase crystal structure. Thermogravimetry (TG) and differential thermal analysis (DTA) were carried out each with 40 mg samples at a heating rate of 5 °C/min in air using a Shimadzu Dt-TG simultaneous recording apparatus, Model DTG 30 M.

After the samples had been fused with Na_2CO_3 and then dissolved into water, the SO_4^{2-} content was gravimetrically determined as $BaSO_4$. The Cl^- content was determined by nephelometry for a mixture of $AgNO_3$ solution and the solution prepared by the dissolution of the samples in a HF solution by heating. The metal ion contents were determined by atomic absorption after the samples had been dissolved in a mixed solution of HF and HCl.

Results and Discussion

Four typical oxidation products of anatase are given in Table 1. These products were found to consist of spherical particles, 0.5—1.0 μm in size, each composed of a number of extremely fine anatase particles, 100—150 Å in size, as a result of electronmicroscopic and X-ray diffraction examination.

Table 1. Anatase precipitates containing Fe(III)

Sample	Starting solution Concn/mol dm^{-3}		Oxidation product	
	Ti(III)	Fe(II)	Fe(III) content(At%)	S ($m^2 g^{-1}$)
A[a)]	0.166	0		1.34
B	0.166	0.166	1.8	2.17
C	0.166	0.333	4.2	3.49
D	0.083	0.333	5.9	4.34
E[b)]	0.166	0.333	1.3	

a) Sample prepared in the presence of 0.166 mol dm^{-3} Na_2SO_4. b) Rutile prepared by the use of $FeCl_2$ in place of $FeSO_4$.

As evident from the table, the mean size of the polycrystalline particles, as estimated from the BET surface area, slightly decreases with increasing Fe ion content; at the same time, the color changes from white to yellowish white. These samples contained 4—5 wt% SO_4^{2-}, about 10 wt% H_2O and less than 0.1 wt% Cl^-. It is noteworthy that in spite of being products from strongly acidic solutions, these samples contain Fe(III) to the extent of nearly 6% of the total metal ions. However they contained less than 0.02% Zn(II). Increasing the Fe(II) concentration in the starting solution yielded a whitish yellow product containing more than 6% Fe(III). In the whitish yellow products thus prepared, however, extremely fine particles of α-FeO(OH) were intermingled with the anatase particles.

Similar experiments were also conducted using iron(II) chloride in place of the sulfate. Whitish products consisting of rutile particles with or without brookite could be obtained int he absence of SO_4^{2-}. Their sedimentation velocities were extremely slow and the suspended particles could not easily be filtered off. The Fe(III) content was much smaller than would be obtained in the presence of SO_4^{2-} as will be evident from sample E in the table containing less than 0.02 wt% Zn(II).

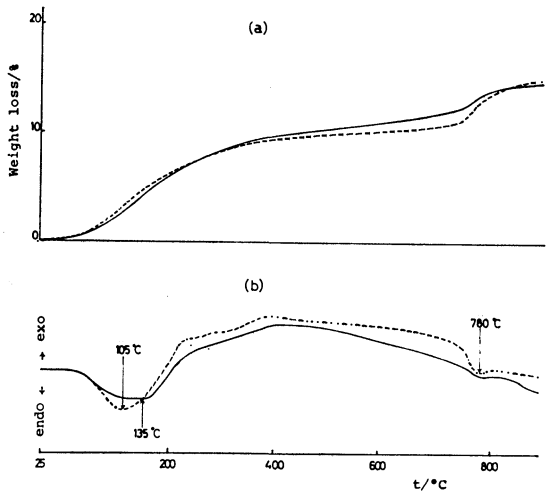


Fig. 2. TG (a) and DTA (b) curves for samples A (——) and D (------).

As shown by the TG and DTA curves in Fig. 2 for samples A and D, these samples are dehydrated in the temperature range 100—400 °C and the sulfate decomposition begins at about 750 °C. The fact that dehydration for the samples takes place continuously from 100°C to temperatures as high as 400 °C indicates that part of the OH^- is interposed between the extremely fine particles. Sample D was divided into several parts and introduced into separate furnaces for heat treatment in air at temperatures between 400 and 750 °C for 20 h. Afterwards they were taken out from the furnaces and allowed to cool to room temperature.

For the sample heat-treated at 500 °C, a decrease in the BET surface area to 3.3 $m^2 g^{-1}$ was observed, but no appreciable differences in color, half broadening of X-ray diffraction peaks and magnetic properties could be detected before and after the dehydration by heat treatment. The samples heat-treated at 550—700 °C became more yellowish and at the same time, their X-ray diffraction peaks became sharper with increasing heat treatment temperature as seen in Fig. 3.

As shown in Fig. 4, no particle growth due to sintering between the spherical polycrystalline particles at 700 °C could be detected, but the BET surface area decreased to 2.2 $m^2 g^{-1}$ because of the decrease in fine projections. The SO_4^{2-} content of this sample still remained at 2.6 wt%. Part of the anatase changes to rutile on heat treatment at 750 °C (Fig. 3(d)).

Magnetic susceptibilities, χ, were measured with the original sample D and its heat treated samples in a

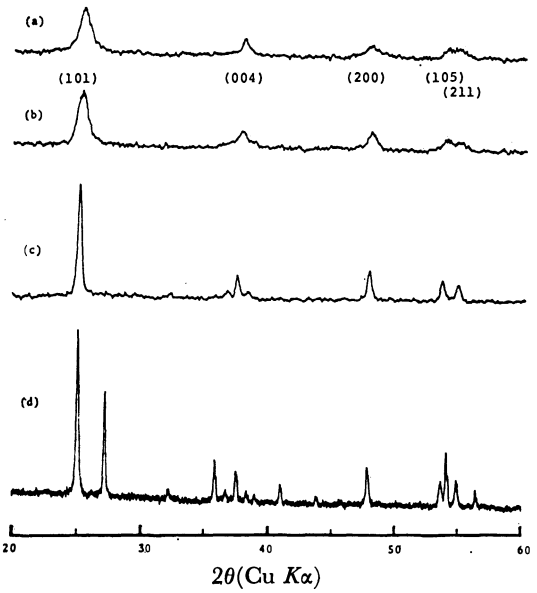

Fig. 3. X-Ray diffraction patterns of the original sample D (a) and its 500 (b), 700 (c), and 750°C (d) heat treated samples.

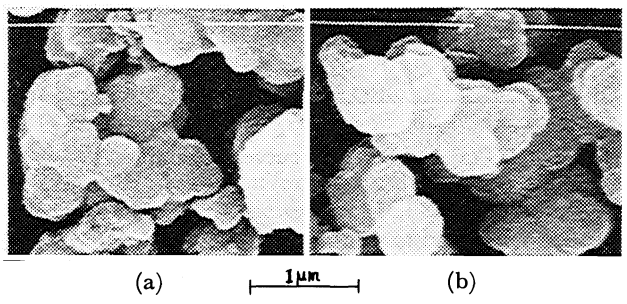

Fig. 4. Scanning electronmicrographs of sample D before (a) and after heat treatment at 700 °C in air.

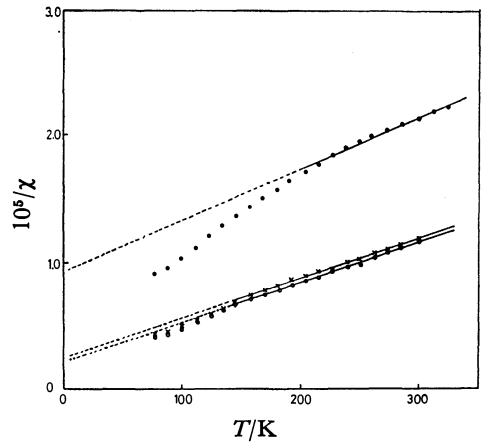

Fig. 5. A plot of reciprocal of magnetic susceptibility, χ emu/g ($4\pi 10^{-3}$ m^3 kg^{-1}), as a function of temperatures T for the original sample D (○) taken after heat treatment in air at 500 (×) and 700 °C (●).

magnetic field range 2—9 kOe (1 Oe=1000/4 π A m^{-1}) at temperatures between 77 and 300 K. No magnetic field dependency of χ could be detected with any of these samples.

Figure 5 is a plot of χ^{-1} of typical samples as a function of T(K). An inspection of these curves readily reveals the following: χ values of sample D on the higher temperature side follow the Curie-Weiss equation

$$\chi = C(T-\theta)^{-1},$$

the paramagnetic Curie temperature θ is −60 K, and the Curie constant C is 31×10^{-4} emu. From the C value, sample D is estimated to contain 4.0 wt% Fe(III) with an effective magnetic moment of 5.9—that is, Fe(III) content is 6.6% in the total metal ions.

No marked differences in the values of C and θ can be observed before and after the heat treatment at 500 °C for sample D. The temperature range to follow the Curie-Weiss equation becomes narrow with the sample heat-treated at 700 °C, and its θ value is −230 K. A shift in θ to the lower temperature side is attributable to the greater magnetic interaction generated between the Fe (III) ions.

To clarify how SO_4^{2-} is intermingled within the polycrystalline particles, the following experiments were conducted. Samples A and D, each weighing 5 g, were immersed in separate 100 mL 1 M NaOH solutions and left at room temperature for 8 h. During this period, ultrasonic dispersion was applied several times, 5 min each time, to each of these suspensions. Precipitates were separated from alkaline solutions by filtration, thoroughly washed with water, treated with acetone, and dried at 100 °C to obtain white and yellowish white samples.

X-Ray diffraction and electron-microscopic examinations of these samples before and after the alkaline treatment, could detect no appreciable differences between the two samples. It was found, however, that the BET surface area increased to 4.0 (sample A) and to 7.9 m^2 g^{-1} (sample D), probably because of chipping of polycrystalline particles due to the ultrasonic dispersion,whereas the SO_4^{2-} content of the samples A and D decreased markedly to 0.38 and to 0.47 wt%, respectively, with the alkaline treatment. From these results, it can be concluded that the major portion of the SO_4^{2-} ions is adsorbed, similar to H_2O, in the polycrystalline particles, without being interposed between extremely fine anatase particles.

It is well known that since titanium(III) chloride solutions are powerful reducing agents, Ti(III) easily reduces Fe(III) in a strongly acidic solution. Accordingly, the oxidation with air of Ti(III) to Ti(IV) must take place before that of Fe(II) to Fe(III). The Ti(IV) in a HCl solution containing SO_4^{2-} will be present as sulfato complexes.[7] It is presumed, therefore, that the Ti(IV) in the strongly acidic solution formed by oxidation generates the polynuclear complexes, each consisting of the oxo, aqua, hydroxo, and sulfato groups where the Ti(IV) concentration is high. These complexes would form extremely fine particles of anatase with the oxo combining as a result of the dissociation by hydrolysis of the H_2O, OH^-, and SO_4^{2-}. The Ti(IV) ions present in the subsurfaces of extremely fine particles will be still combined with SO_4^{2-} besides OH^- and H_2O. With the desorption by further hydrolysis of these SO_4^{2-} and H_2O from the subsurfaces, the formation of polycrystalline particles will take place with oxo and

hydroxo combinings of the extremely fine particles in the absence of Fe(III). The oxidation into Fe(III) would begin to take place after most of the Ti(III) ions have been changed to Ti(IV). The Fe(III) ions formed by oxidation exist as monomers[8] and part of them must exist as hydroxo complexes.

Ramakrishna and Seneratyapa reported as a result of their spectrometric studies, that Fe(III) hydroxo complexes in strongly acidic solutions easily reacted with Ti(IV) hydroxo complexes to form mixed complexes, whose formation was governed by the nature of the dissolved acid anions.[9] This reaction suggests that under the existence of the Fe(III) hydroxo complexes, part of the Ti(IV) combined with H_2O, OH^-, or SO_4^{2-} in the subsurface of each extremely fine particle would be combined with the Fe(III) hydroxo complexes. Each polycrystalline particle, in which the Fe(III) ions are relatively evenly interposed between the extremely fine particles, would be formed and become greater in size with the oxo and hydroxo combination caused during the progress of hydrolysis.

The authors wish to thank Messrs T. Akita, N. Horiishi, and I. Sugano for their help in conducting numerous experiments.

^{1}H NMR Studies on the Interactions of Acyclic Polyethers with Dimethyltin Dichloride in Aromatic Solvents[1)]

Junzo OTERA,* Tadashi SHIOMI, Kazuhiko MURAKAMI, and Yoshikane KAWASAKI†

Okayama University of Science, Ridai-cho, Okayama 700

†*Department of Petroleum Chemistry, Osaka University, Yamadagaoka, Suita, Osaka 565*

(Received March 2, 1981)

The interactions between various acyclic polyethers, $RO(CH_2CH_2O)_nR'$(R, R'=CH_3, Ph), and dimethyltin dichloride (DMTC) in aromatic solvents have been studied by means of ^{1}H NMR spectroscopy. On the basis of a continuous variation method, the formation of the 1 : 1 complexes between glymes, $CH_3O(CH_2CH_2O)_nCH_3$ (n=2, 3, 4), and DMTC was revealed in benzene. The $^2J(^{119}Sn-CH_3)$ values suggested distorted *trans*-octahedral configurations for these complexes. From the statistical consideration of stability constants, it was found that the coordination occurred virtually through neighboring two oxygen atoms in these complexes. DMTC gave the complexes of both 1 : 1 and 1 : 2 glyme/DMTC stoichiometry with glymes (n=5, 6) in benzene and with all glymes employed here in toluene and 1-chloronaphthalene. Coexistence of 1 : 1 and 1 : 2 species was also encountered for $PhO(CH_2CH_2O)_nCH_3$ (n=3, 4, 5), whereas no appreciable interaction was observed between $PhO(CH_2CH_2O)_nPh$ (n=2, 3, 4) and DMTC. On the basis of these observations, the additional formation of the 1 : 2 complexes was assumed to be caused by the bulkiness of polyethers.

With recent development of the crown ether chemistry, much attention has also been paid on the metal complexes of acyclic polyethers.[2)] Structural analysis of these complexes in the solid state[2)] and their thermodynamic properties in solution[3)] have been extensively studied. However, it is rather limited to elucidate their behavior, especially their configuration, in solution, because metals employed in these studies were mostly inorganic ions. The structure of some fluorenyl metal complexes of polyethylene glycol dimethyl ethers (glymes) in solution has been investigated by means of ^{1}H NMR[4,5)] and optical spectroscopies.[5)] Coordinating abilities of glymes towards the Na^+ ion have been discussed from kinetical point of view using ^{23}Na NMR spectra.[6)] More recently, ^{1}H NMR spectra of metal complexes with polyethers containing aromatic terminal groups have been reported.[7)]

Molecular complexes of methyltin(IV) halides have been studied for a long time, since their configurations in solution can be deduced easily from their ^{1}H NMR spectra.[8)] Therefore, it seems probable that NMR studies on the polyether/methyltin(IV) halides systems afford various informations on these complexes in solution. In addition, methyltin(IV) halides, unlike the naked metal ions studied so far, possess four substituents attached to the central metal atom. Accordingly, the interactions of methyltin(IV) halides with polyethers are expected to be sterically different from those of inorganic metal ions.

In this paper are presented the results of ^{1}H NMR studies on the interactions of various acyclic polyethers, $RO(CH_2CH_2O)_nR'$ (R, R'=CH_3, Ph), with dimethyltin dichloride (DMTC) in some aromatic solvents.

Experimental

Commercially available DMTC was purified by sublimation. DiG, TrG, and TetG[9)] were of reagent grade and distilled from $LiAlH_4$ before use. The preparative methods for PeG,[10)] HeG,[10)] and $PhO(CH_2CH_2O)_nPh$[3)] have been reported.

Preparation of $PhO(CH_2CH_2O)_nCH_3$. n=*2*: The procedure for this compound is as follows;

$$(ClCH_2CH_2)_2O \xrightarrow{+\frac{1}{2}PhONa} Ph(OCH_2CH_2)_2Cl \xrightarrow[+NaI]{+CH_3ONa} PhO(CH_2CH_2O)_2CH_3.$$

To a suspension of NaH (4.8 g, 0.2 mol) in 150 cm^3 of DMF was added phenol (18.8 g, 0.2 mol) in DMF (27 cm^3) with stirring and the mixture was heated at 80 °C for 4 h. After cooling, the mixture was combined with $(ClCH_2CH_2)O$ (57.2 g, 0.4 mol) and heated at 80 °C for 6 h. The reaction mixture was combined with benzene and shaken twice with 0.2 mol dm^{-3} NaOH and with water for several times. The organic layer was dried over sodium sulfate. Evaporation of solvent and distillation gave $Ph(OCH_2CH_2)_2Cl$ (24.4 g, 61%); bp, 104—107 °C (27 Pa). $Ph(OCH_2CH_2)_2Cl$ (24.4 g, 122 mmol) and NaI (33.6 g, 224 mmol) in 100 cm^3 of acetone were heated under reflux for 41 h. After filtration of NaCl and evaporation of acetone, the product was treated with an ether–water mixture. Ether was evaporated and resulting crude $Ph(OCH_2CH_2)_2I$ (29.3 g, 82%) was used in the next reaction without further purification. To 50 cm^3 of methanol was added 1.4 g (60 mmol) of Na and subsequently $Ph(OCH_2CH_2)_2I$ (14.6 g, 50 mmol). The mixture was heated under reflux for 9 h, and combined with water and ether. The organic layer was dried over sodium sulfate and evaporated to leave a yellow oil which was chromatographed on a silica gel column (hexane–ether 10 : 1) to give $PhO(CH_2CH_2O)_2CH_3$ (4.0 g, 41%): ^{1}H NMR (CCl_4) δ=3.23 (s, 3H, CH_3), 3.40—4.07 (m, 8H, CH_2), and 6.58—7.23 (m, 5H, aromatic), high-resolution mass spectrum, 196.2437 (Calcd for $C_{11}H_{16}O_3$, 196.2456).

n=*3*: This compound was prepared by an analogous method for n=2 employing $CH_3OCH_2CH_2ONa$ in place of CH_3ONa: ^{1}H NMR (CCl_4) δ=3.23 (s, 3H, CH_3), 3.43—4.06 (m, 12H, CH_2), and 6.33—7.20 (m, 5H, aromatic), high-resolution mass spectrum, 240.2971 (Calcd for $C_{13}H_{20}O_4$, 240.2986).

n=*4*: This compound was prepared by an analogous method for n=3 employing $(ClCH_2CH_2OCH_2)_2$ in place of $(ClCH_2CH_2)_2O$: ^{1}H NMR (CCl_4) δ=3.23 (s, 3H, CH_3), 3.40—4.07 (m, 16H, CH_2), 6.60—7.20 (m, 5H, aromatic), high-resolution mass spectrum, 284.3511 (Calcd for $C_{15}H_{24}O_5$, 284.3516).

n=*5*: The procedure for this compound is as follows;

$$(HOCH_2CH_2OCH_2CH_2)_2O \xrightarrow{+PBr_3,\ C_5H_5N}$$

$$(BrCH_2CH_2OCH_2CH_2)_2O \xrightarrow{+\frac{1}{2}PhONa} Ph(OCH_2CH_2)_4Br$$

$$\xrightarrow{+CH_3OCH_2CH_2ONa} PhO(CH_2CH_2O)_5CH_3.$$

To 100 cm³ of benzene solution containing PBr_3 (189 g, 0.7 mol) and pyridine (32 g, 0.4 mol), tetraethylene glycol (194 g, 1.0 mol) was added with stirring at 0 °C for a period of 4 h. After completion of addition, the mixture was kept on stirring for 72 h at room temperature and extracted with a benzene–water mixture. Drying and evaporation of the organic layer gave crude $(BrCH_2CH_2OCH_2CH_2)_2O$ (206 g, 76%), which was subjected to the reaction with PhONa (0.38 mol) in 100 cm³ of DMF. After heating at 80 °C for 7 h, the product was poured into a benzene–water mixture. Benznene layer was shaken twice with 0.2 mol dm^{-3} NaOH and with water for several times. Drying and evaporation gave a crude mixture (103 g) of $Ph(OCH_2CH_2)_4Br$ and $PhO(CH_2CH_2O)_4$-Ph in *ca.* 8 : 2 ratio. This mixture (30 g) was treated with $CH_3OCH_2CH_2ONa$ prepared from $CH_3OCH_2CH_2OH$ (20.5 g, 270 mmol) and Na (3.1 g, 135 mmol) and heated at 120 °C for 30 h. Ether and water were added to the reaction product. The organic layer was dried over sodium sulfate and evaporated to yield 19.7 g of an oil. Column chromatography of this oil on silica gel (hexane–ether 5 : 1) gave 2.8 g of pure $PhO(CH_2CH_2O)_5CH_3$: ^1H NMR (CCl_4) δ=3.23 (s, 3H, CH_3), 3.42—4.10 (m, 20H, CH_2), and 6.63—7.22 (m, 5H, aromatic), high-resolution mass spectrum, 328.4011 (calcd for $C_{17}H_{28}O_6$, 328.4046).

Measurements of ^1H NMR spectra were carried out with a Hitachi R-24B spectrometer operating at 60 MHz at 35°C. The chemical shifts (δ) were referred to internal TMS and accurate to $\pm$0.01 ppm. Solvents were purified by standard methods.

Stability constants, K, for the equilibrium (1), $\delta^c(CH_3\text{–Sn})$, and $^2J^c$ ($^{119}Sn\text{–}CH_3$) were calculated by a least-squares method using Eqs. 2 and 3.[11]

$$(CH_3)_2SnCl_2 + Gly \overset{K}{\rightleftharpoons} (CH_3)_2SnCl_2\cdot Gly \quad (1)$$

$$\delta = \delta^\circ + \frac{\delta^c-\delta^\circ}{2}[(r+1+1/A_0K) - \sqrt{(r+1+1/A_0K)^2-4r}] \quad (2)$$

$$J = J^\circ + \frac{J^c-J^\circ}{2}[(r+1+1/A_0K) - \sqrt{(r+1+1/A_0K)^2-4r}]. \quad (3)$$

Gly: glyme.

δ, δ°, and δ^c: values of $\delta(CH_3\text{–Sn})$ for the observed, the uncomplexed, and the 1:1 complexed, respectively.

J, J°, and J^c: values of $^2J(^{119}Sn\text{–}CH_3)$ for the observed, the uncomplexed, and the 1:1 complexed, respectively.

A_0: concentration of DMTC.

r: Gly/DMTC mole ratio.

The calculations were made with a NEAC model 900 computer at the Calculation Center of Osaka University.

Results and Discussion

In Fig. 1 is illustrated the dependence of chemical shifts of methyl protons attached to tin, $\delta(CH_3\text{–Sn})$, on DiG/DMTC mole ratio (r) in some aromatic solvents

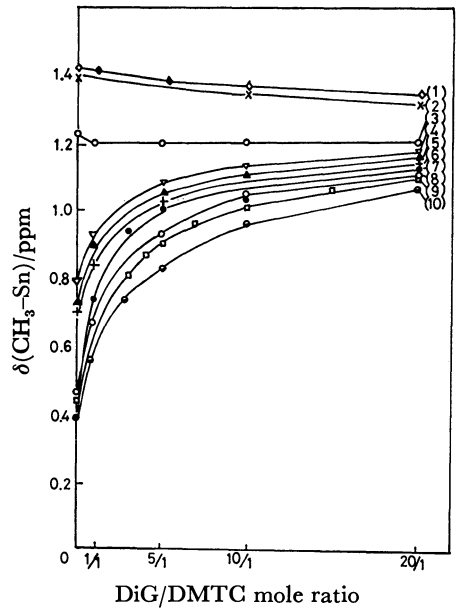

Fig. 1. Dependence of $\delta(CH_3\text{–Sn})$ on DiG/DMTC mole ratio at constant DMTC concentration (0.15 M) in various solvents.

and dichloromethane. Marked difference was observed for the change of $\delta(CH_3\text{–Sn})$ among these solvents; the first group giving rise to little change in $\delta(CH_3\text{–Sn})$ with r involves benzonitrile, nitrobenzene, and dichloromethane, the second group affecting some dependence on r involves chlorobenzene, bromobenzene, and anisole, and the third group involves benzene, toluene, *p*-xylene, and 1-chloronaphthalene in which the largest dependence of $\delta(CH_3\text{–Sn})$ on r was observed. In the solvents of the latter two groups, the solvent effect caused by aromatic rings disappeared upon coordination of DiG to tin. This change of $\delta(CH_3\text{–Sn})$ can be a

TetG	3.5±0.5	1.26	83.4

a) MoG was assumed to give 1 : 1 stoichiometry.

good measure for the interactions between glymes and DMTC. Therefore, we have studied, in detail, the ^1H NMR spectra of a series of Gly/DMTC system in benzene, toluene, and 1-chloronaphthalene.

First, the results obtained in benzene will be described. The stoichiometry of complexation was successfully disclosed by the Job's continuous variation method[12] as shown in Fig. 2. While no reliable curve could be drawn in the case of MoG, the evident 1 : 1 stoichiometry was found for DiG, TrG, and TetG. Figure 3 shows plots of $\delta(CH_3–Sn)$ and $^2J(^{119}Sn–CH_3)$ *vs.* r.[13] Stability constants, K, for the equilibrium (1), along with the values of $\delta^c(CH_3–Sn)$ and $^2J^c(^{119}Sn–CH_3)$ calculated by a least squares method using the above data are given in Table 1. The K values reveal a large gap of complexing ability between MoG and DiG. This trend is similar to the results obtained for some alkali metal salts in THF, in which the K value for DiG is larger by 10^2 times than that for MoG.[5a,b] The values of $^2J^c(^{119}Sn–CH_3)$ are comparable to those of *trans*-octahedral dimethyltin(IV) compounds with a slightly bent C–Sn–C moiety such as dimethyltin diacetate[14] and dikojate.[15] Since the benzene solutions containing Gly and DMTC in a 10 : 1 mole ratio at the DMTC concentration of 10^{-4} M (1 M=1 mol dm^{-3}) found to be nonelectrolytes by conductivity measurements indicative of nonionic structures, analogous distorted *trans*-octahedral configurations are suggested for the 1 : 1 complexes formed in this study.[16]

In the glyme complexes of inorganic metal ions, the coordination mode of the oxygen atoms has been the subject of considerable interest. While naked metal ions such as Li^+, Na^+, and K^+ can accommodate four to eight coordinating oxygen atoms on the interaction with glymes,[5,6] DMTC can accept two oxygen atoms at most due to the existence of four substituents. If we assume that all oxygen atoms are equivalent in coordinating ability and the coordination takes place virtually through neighboring two oxygen atoms in our 1 : 1 complexes, the total number of possible coordination modes should be 2, 3, and 4 for DiG, TrG, andTetG, respectively, leading to the increase in K values by the same factors. The observed K values of 2.0, 2.9, and 3.5 for these glymes are almost in accordance with the above statistical consideration.

For the complexes of PeG and HexG, unexpected Job's plots were encountered (Fig. 2). Appearance of two peaks at *ca.* 0.33 and 0.5 in mole fraction of Gly suggests the formation of the 1 : 2 and 1 : 1 complexes[17] as shown in the equilibrium (4).[18] An intramolecular chelation of glyme molecule resulting in a six-coordinate

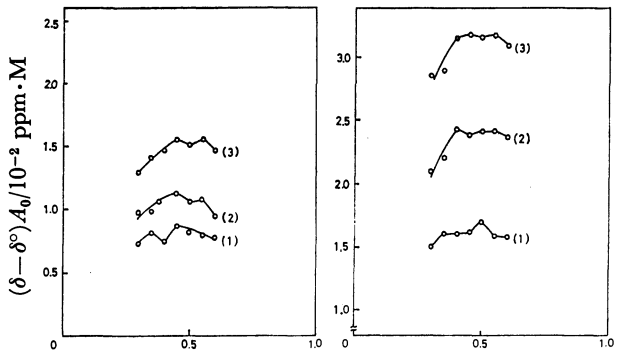
$$2(CH_3)_2SnCl_2 \underset{K_1}{\overset{Gly}{\rightleftharpoons}} [(CH_3)_2SnCl_2]_2\cdot Gly$$

$$\underset{K_2}{\overset{Gly}{\rightleftharpoons}} 2(CH_3)_2SnCl_2\cdot Gly \quad (4)$$

configuration obviously becomes sterically unfavored on increasing chain length of glymes. The additional formation of the 1 : 2 species was found for all glymes in toluene and 1-chloronaphthalene as shown in Fig. 4. On the basis of $(\delta-\delta^\circ)A_0$ values in the Job's plots which are proportional to stability constants,[12] overall stability constants in these solvents seem to be larger than those in benzene for respective glymes.



(a) Mole fraction of Gly (b) Mole fraction of Gly

(1): $n=3$, (2): $n=4$, (3): $n=5$.

Steric effect on stoichiometry and complexation was further confirmed with polyethers involving terminal phenoxy groups. As shown in Fig. 5, replacement of one of the methoxy groups in glymes by a bulkier phenoxy group resulted in the coexistence of 1 : 2 and 1 : 1 complexes in both benzene and 1-chloronaphthalene even for lower members of the polyethers. It should be noted that each $PhO(CH_2CH_2O)_nCH_3$ ($n=3$, 4, 5) shows a smaller $(\delta-\delta^\circ)A_0$ value than that of $CH_3O(CH_2CH_2O)_{n-1}CH_3$ and no reliable Job's plot could be obtained for $n=2$. When a series of $PhO(CH_2CH_2O)_nPh$ ($n=2$, 3, 4) was employed, no appreciable interaction was detected in all cases. It is rather unexpected that little interaction was observed even for $PhO(CH_2CH_2O)_4Ph$, since this polyether involves three oxygen atoms linked by ethylene units and accordingly should be equivalent to $CH_3O(CH_2CH_2O)_2CH_3$ or $PhO(CH_2CH_2O)_3CH_3$ in coordinating ability. These observations suggest that the coordination behavior of polyethers towards DMTC is affected to a considerable degree by the bulkiness of the terminal groups.

The Separation by Means of the Zone-melting Technique and the Spectrofluorometric Determination of Trace Amounts of Anthracene in Phenanthrene

Motohisa FURUSAWA* and Masaki TACHIBANA
Faculty of Engineering, Yamanashi University, Takeda, Kofu 400
(Received December 16, 1980)

Since ordinarily available phenanthrene contains interfering impurities, such as phenanthrenequinone and fluoranthene, it is difficult to determine anthracene by spectrofluorimetry directly. Trace amounts of anthracene in phenanthrene can, however, be selectively separated from the interfering impurities by means of the zone-melting technique, for the distribution coefficient of anthracene in phenanthrene is greater than unity. The anthracene thus separated is spectrofluorometrically measured using xylene as the solvent. The determination limit of anthracene is 0.05 ppm. In a glass tube with an i.d. of 4 mm, 4.0 g of the sample was charged to a length of about 27 cm, and then the zone-pass was repeated 20 times. The molten zones were set to travel at a speed of 100 mm/h under constant stirring. Exactly 2.5 g of the zone-molten sample was cut out and dissolved in 50 ml of xylene. The fluorescence intensity of the solution was measured at 403 nm with excitation at 378 nm. The recovery of anthracene was 95%, with a coefficient of variation of 0.6%. The incompleteness of the recovery was corrected for.

The fluorometric determination of trace amounts of anthracene in phenanthrene has been developed by Parker *et al.*[1] and Iwashima *et al.*[2] These methods, however, are difficult to apply to the determination of anthracene in ordinarily available samples of phenanthrene, for these samples contain interfering impurities, such as fluoranthene and phenanthrenequinone.

In the present paper, the separation of anthracene from the interfering impurities in phenanthrene by means of the zone-melting technique and its spectrofluorometric determination will be described. The distribution coefficient of anthracene in phenanthrene being greater than unity, anthracene is concentrated toward the beginning of the ingot by repeating the zone-melting process. On the contrary, the interfering impurities show an opposite behavior; they are accumulated toward the end of the ingot. Therefore, the anthracene can be separated. The anthracene thus separated is spectrofluorometrically measured, using xylene as the solvent. The determination limit of anthracene is 0.05 ppm.

Experimental

Reagent. Phenanthrene was purified in the following manner. Commercial phenanthrene was fused with maleic anhydride in the presence of chloranil at 170 °C for 1 h to remove the anthracene. After cooling, the solidified product was dissolved in acetone. Phenanthrene crystals were precipitated by the addition of water, collected, and dissolved in benzene. The solution was shaken with 85% sulfuric acid, and then the benzene was evaporated. After this process had been repeated once more, the phenanthrene thus obtained was further purified by repeating the zone refining according to the method of Matsumoto *et al.*[3] and finally by ordinary zone refining.

Apparatus. The fluorometric measurements were carried out using a Hitachi 204 fluorescence spectrophotometer. A 150-W xenon lamp was used as the exciting source. A 10 mm × 10 mm × 45 mm quartz cell was used.

Zone melting was performed using a Shibayama SS-950 high-speed zone refiner. In this apparatus, six zones are produced by six ring heaters placed at equal spacings on the charge, and each zone is set to travel by moving the heater along the charge. After traveling to the distance between the centers of the nearest neighbor zones, the heater assembly returns quickly to its initial position. In this cycle, each molten zone is transferred into its next one. The tube is rotated around its longitudinal axis with a reversal of the rotation direction.

Procedure. In a glass tube with an i.d. of 4 mm, 4.0 g of the sample was charged to a length of about 27 cm, and then the zone-pass was repeated 20 times. The molten zones about 30 mm in length were set to travel at a speed of 100 mm/h. During the travels, the zones were stirred by spinning the glass tube at 1200 rpm with a reversal of the rotation direction at intervals of 1.0 s. Exactly 2.5 g of the zone-molten sample was cut out from the beginning part of the ingot and dissolved in 50 ml of xylene. The fluorescence intensity of the solution was measured at 403 nm, with excitation at 378 nm. An anthracene solution (50 or 500 ng/ml) and xylene were used as the standard and the blank respectively. The quantity of anthracene was determined by using a calibration curve, which had been prepared by measuring the relative fluorescence intensities of anthracene solutions (0—50 or 0—500 ng/ml) containing phenanthrene (50 mg/ml). Since the recovery of anthracene was 95%, the incompleteness of the recovery was corrected for by using the reciprocal of 0.95 as the correction factor.

Results and Discussion

Solvent. Fluorometric methods for the determination of trace amounts of anthracene in phenanthrene[1,2] use ethanol as the solvent, and the lower limit of determination in these methods is approximately 1 ppm. For the determination of more minute amounts of anthracene in phenanthrene, it is desirable to measure the fluorescence intensity of anthracene using a concentrated solution of the sample. For the purpose of dissolving large amounts of phenanthrene, xylene was selected as the solvent.

Fluorescence Spectra. The fluorescence spectra of anthracene and phenanthrene were measured with excitation at 378 nm by means of an apparatus with the same sensitivity. The measurements were made on a

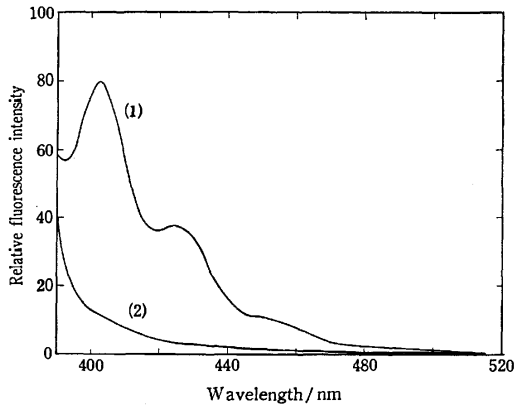

Fig. 1. Fluorescence emission spectra of anthracene and phenanthrene.
Excitation wavelength: 378 nm; solvent: xylene; (1): anthracene (uncorrected), 50 ng/ml; (2): Phenanthrene (uncorrected), 50 mg/ml.

solution containing 50 ng/ml of anthracene and on a concentrated phenanthrene solution containing a concentration 10^6 times as high as that of anthracene. These spectra are shown in Fig. 1. The fluorescence spectrum of anthracene exhibits a maximum at 403 nm. A concentrated solution of phenanthrene shows a weak fluorescence at this characteristic wavelength of anthracene.

Calibration Curves. For the determination of trace amounts of anthracene in phenanthrene, it is necessary to correct for the influence of phenanthrene. The fluorescence intensity of phenanthrene at the characteristic wavelength of anthracene is so weak that it seems to be correctable by using a calibration curve, which can be prepared by measuring the fluorescence intensities of anthracene solutions containing phenanthrene. The sensitivity of the fluorescence spectrophotometer was adjusted by setting the intensity of a standard anthracene solution (50 or 500 ng/ml) at 80 division; then, the relative fluorescence intensities of anthracene solutions (0—50 and 0—500 ng/ml) containing phenanthrene (50 mg/ml) were measured. The resultant calibration curves are shown in Figs. 2(1) and (2). For comparison, the fluorescence intensities of anthracene solutions were also measured in the absence of phenanthrene; the results are illustrated in Figs. 2(3) and (4). As a result of the influence of phenanthrene, the calibration curves shown in Figs. 2(1) and (2) do not intersect at the point of origin, and each gradient shows a slight decrease compared with the corresponding curve of anthracene alone. However, good linear relationships are observed between the fluorescence intensity and the concentration of anthracene. Therefore, the influence of phenanthrene is correctable by using the calibration curve, and anthracene in phenanthrene can be determined over the range from 0.05 to 10 ppm.

Separation of Anthracene. Since ordinarily available phenanthrene contains interfering impurities, such as phenanthrenequinone and fluoranthene, it is necessary to separate anthracene prior to its determination. For this purpose, the separation of anthracene by means of the zone-melting technique was studied. After the zone melting had been performed using phenanthrene samples containing 1.7 and 12.3 ppm of anthracene, each zone-molten ingot was divided into fifteen portions 1.5—2 cm in length, and then the anthracene was spectrofluorometrically measured. The resultant distribution profile of anthracene on the zone-molten ingot is shown in Fig. 3(1). The distribution profiles of phenanthrenequinone and fluoranthene, obtained in a manner similar to that used for anthracene, are shown in Figs. 3(2) and (3). The initial contents of phenanthrenequinone and fluoranthene were 0.1% and 0.2% respectively. The phenanthrenequinone was spectrophotometrically evaluated by employing the absorption at 416 nm, using a mixture of xylene and methanol (1 : 1) as the solvent. The presence of methanol was necessary to avoid a decrease in the absorbance. The fluoranthene was evaluated by measuring the fluores-

(1): C_0=1.7 ppm; (2): C_0=12.3 ppm.

cence intensity at 460 nm with excitation at 378 nm, using xylene as the solvent. Figure 3 indicates that anthracene is concentrated toward the beginning of the zone-molten ingot, and that both impurities are effectively removed from the beginning, and accumulated toward the end, of the ingot. Therefore, anthracene in phenanthrene can be effectively separated from these interfering impurities.

Recovery of Anthracene. After the zone melting of two phenanthrene samples containing 1.7 and 12.3 ppm of anthracene had been carried out, each zone-molten ingot was divided into 10—12 portions; the quantity of anthracene in each divided ingot was then spectrofluorometrically evaluated. From the results, the relation between the amounts of the ingot cut out from the beginning and the recovery of anthracene were calculated; they are illustrated in Fig. 4. Figures 3 and 4 show that it is the most suitable for the determination of anthracene to use 2.5 g of the sample cut out from the beginning of the ingot. In this case, about 95% of anthracene can be recovered. Under these conditions, the recovery of anthracene was measured more precisely. After the zone melting of the phenanthrene samples had been performed, exactly a 2.5 g portion of each zone-molten ingot was cut out and the quantity of the anthracene was evaluated. The results are shown in Table 1. Table 1 indicates that the recovery is 95%, with a coefficient of variation of 0.6%. Since a reproducible value is obtained, the incompleteness of the recovery can be corrected for by using the reciprocal of 0.95 as the correction factor.

Determination of Anthracene in Synthetic Mixtures. The analytical results for anthracene in synthetic mixtures of phenanthrene are shown in Table 2. Each synthetic mixture contains 200 ppm of phenanthrenequinone, carbazole, and fluorene, 100 ppm of acenaphthene, dibenzofuran, and naphthalene, 40 ppm of 9-fluorenone, and 10 ppm of fluoranthene, pyrene, and anthraquinone. Table 2 indicates that the analytical results agree closely with the individual contents of anthracene in synthetic mixtures. Therefore, trace amounts of anthracene in phenanthrene containing impurities can be determined by this proposed method.

Determination of Anthracene in Practical Samples. A commercial sample of phenanthrene containing about 300 ppm of anthracene was purified by treating it with sulfuric acid to remove the anthracene according to the

TABLE 2. ANALYTICAL RESULTS FOR ANTHRACENE IN SYNTHETIC MIXTURES

Nos. 1—3,6: as the standard, the fluorescence intensity of a 50 ng/ml anthracene solution in xylene was taken as 80 div.; Nos. 4, 5: a 500 ng/ml anthracene solution was used.

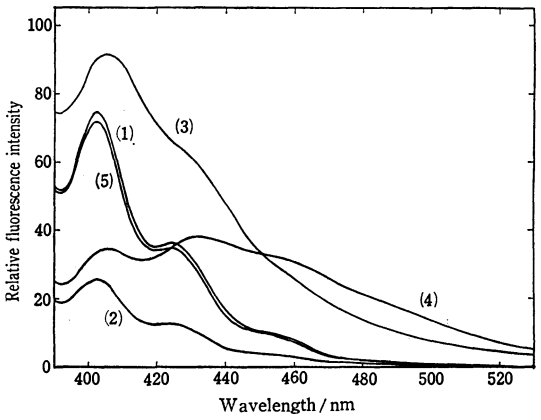

Fig. 5. Comparison of fluorescence emission spectra of practical or zone-molten samples with the spectrum of anthracene containing phenanthrene.
Standard: fluorescence intensity of 1 μg/ml anthracene solution was taken as 80 div; (1), (2): solutions employed for the determination (uncorrected), 50 mg/ml; (3), (4): solutions of practical samples (uncorrected), 100 mg/ml; (5): anthracene solution containing 50 mg/ml of phenanthrene (uncorrected); (1), (3): results of a sample purified with sulfuric acid; (2), (4): results of a sample purified with maleic anhydride and by recrystallization; excitation wavelength: 378 nm; solvent: xylene.

method of Lamey and Maloy.[4] Another commercial phenanthrene containing about 1200 ppm of anthracene was purified by a combination of the treatment with maleic anhydride and recrystallization. Trace amounts of anthracene in the two purified samples were determined by this proposed method. The analytical results were 13 ppm and 4.3 ppm respectively. The fluorescence spectra of the xylene solutions employed for the determination are shown in Figs. 5 (1) and (2). The spectra of the sample solutions were also measured; they are shown in Figs. 5 (3) and (4). The spectrum of an anthracene solution containing phenanthrene is shown in Fig. 5 (5). The shapes of the spectra shown in Figs. 5 (3)—(5) are not identical. However, the shapes of the spectra shown in Figs. 5 (1) and (2) agree closely with that of the spectrum shown in Fig. 5 (5). Therefore, this proposed method can be used in the determination of trace amounts of anthracene in practical samples of phenanthrene.

The Preparation and Properties of Ethylenediamine(8-quinolinolato)cobalt(III) Complexes

Yoshihisa YAMAMOTO,* Reiko KATAOKA, Shinji IMAHARA,† and Toshio AMANO††

Faculty of Pharmaceutical Science, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02

(Received March 16, 1981)

Bis(ethylenediamine)(8-quinolinolato)cobalt(III) chloride dihydrate and ethylenediaminebis(8-quinolinolato)-cobalt(III) chloride dihydrate have been isolated and characterized. The ^{1}H-NMR spectrum of the latter complex indicates that the two oxygen atoms of the coordinated 8-quinolinolato ligands are in the cis positions.

Previously, we have reported the preparation and properties of the ammine(8-quinolinolato)cobalt(III) complexes.[1] Among these complexes, the two oxygen atoms of the coordinated 8-quinolinolato ligands of diamminebis(8-quinolinolato)cobalt(III) chloride hydrate were found to be in the *trans* positions.

In the corresponding ethylenediamine complexes which have been obtained in the present research, the two oxygen atoms of the coordinated 8-quinolinolato ligands were found to be in the *cis* positions.

Results and Discussion

Bis(ethylenediamine)(8-quinolinolato)cobalt(III) chloride dihydrate, $[Co(C_9H_6NO)(en)_2]Cl_2\cdot 2H_2O$ (**1**) and ethylenediaminebis(8-quinolinolato)cobalt(III) chloride dihydrate, $[Co(C_9H_6NO)_2(en)]Cl\cdot 2H_2O$ (**2**) have been obtained by the chromatographic separation of the reaction mixture of *trans*- or *cis*-dichlorobis(ethylenediamine)cobalt(III) chloride,[2] Ag_2O and 8-quinolinol. Tris(8-quinolinolato)cobalt(III) complex[3,4] (**3**) and tris(ethylenediamine)cobalt(III) chloride[5] (**4**) are produced as by-products from the reaction mixture. Complex **1** is very soluble in water, soluble in methanol and slightly soluble in ethanol. Complex **2** is soluble in methanol and somewhat soluble in water and ethanol. These complexes are insoluble in most other organic solvents. The corresponding nitrate (**5**) has been prepared from the chloride (**1**) and silver nitrate. Also the corresponding picrate (**6**) has been prepared from the chloride (**2**) and picric acid. The possible geometrical structures of **2** are shown in Fig. 1. The NMR spectra and behavior in chromatography with Dowex 50W-X2[6,7] show that the complex **2** obtained has one of these structures and is not a mixture of isomers.

Fig. 1. The possible isomeric structures of $[Co(oxine)_2(en)]Cl\cdot 2H_2O$.

The absorption bands of 8-quinolinolato-metal complexes have already been reported by several researchers.[8-10] The absorption spectra of **1** and **2** have three absorption bands around 324, 338, and 407 nm in methanol. The bands around 407 nm are considered to be charge-transfer bands.[1] These bands shift to 383—388 nm in water.

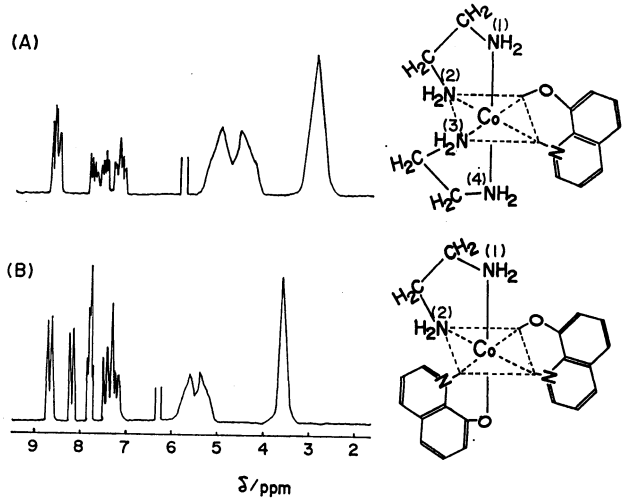

Fig. 2. The ^{1}H-NMR spectra of ethylenediamine-(8-quinolinolato)cobalt(III) chloride.
(A): $[Co(oxine)(en)_2]Cl_2\cdot 2H_2O$ in 1.8 mol dm^{-3} D_2SO_4, (B): $[Co(oxine)_2(en)]Cl\cdot 2H_2O$ in 2.5 mol dm^{-3} D_2SO_4

In the ^{1}H-NMR spectrum of **1** shown in Fig. 2, the signal at 2.92 ppm is assigned to the methylene protons of the coordinated ethylenediamine. The NH_2 protons of that ligand showed two singlet signals in the intensity ratio of 1 : 1. The singlet signal at 4.55 ppm (4H) is assigned to the protons of the two amines of $N(1)H_2$ and $N(4)H_2$ which are *cis*[1] to the coordinated 8-quinolinolato ligand, while the singlet signal at 5.0 ppm (4H) is assigned to the protons of $N(2)H_2$ and $N(3)H_2$ which are *trans* to the coordinated 8-quinolinolato ligand. Table 1. ^{1}H-NMR spectra of ethylenediamine(8-quinolinolato)cobalt(III) complexes

Complex No.	$NH_2CH_2CH_2NH_2$ δ/ppm					8-Quinolinolato δ/ppm	Picrate δ/ppm	Solvent and standard
	CH_2	$N(4)H_2$	$N(1)H_2$	$N(2)H_2$	$N(3)H_2$			
1	2.92 s(8H)	4.55 s(4H)		5.0 s(4H)		7.0—8.7 m(6H)		A-1
5	2.99 s(8H)	4.55 s(4H)		5.0 s(4H)		7.1—8.7 m(6H)		A-1
2	3.54 s(4H)		5.38 s(2H)	5.58 s(2H)		7.1—8.7 m(12H)		B-1
6	2.78 s(4H)		5.31 s(2H)	5.80 s(2H)		7.0—8.4 m(12H)	8.6 s(2H)	C-2
L						6.7—8.7 m		D-2

Solvents: A, 1.8 mol dm^{-3} D_2SO_4; B, 2.5 mol dm^{-3} D_2SO_4; C, DMSO-d_6; D, $CDCl_3$. Standard: 1, internal DSS; 2, internal TMS.

the ^{1}H-NMR spectrum of **2**, the signal (3.54 ppm) at the highest field is assigned to the methylene protons of the coordinated ethylenediamine. The NH_2 protons of that ligand showed two singlet signals in the intensity ratio of 1 : 1. The singlet signal at 5.38 ppm is assigned to the protons of $N(1)H_2$ which are *trans*[11,12] to the oxygen of the coordinated 8-quinolinolato ligand. Another singlet signal at 5.58 ppm is assigned to the protons of $N(2)H_2$ group which are *trans* to the nitrogen of that ligand, which is less electronegative than the 8-quinolinol oxygen. Thus, the structure of **2** is considered to be **2b**. The two oxygen atoms of the coordinated 8-quinolinolato ligands in **2b** are in the *cis* positions in contrast to most of the known cases where the two oxygen atoms of the coordinated 8-quinolinolato ligands in an octahedral configuration are in *trans*[13–15] positions. The diamminebis(8-quinolinolato)cobalt(III) chloride dihydrate, $[Co(C_9H_6NO)_2(NH_3)_2]Cl\cdot H_2O$ (**7**), reported previously,[1] is included among these cases. The complexes of **1**, **2**, **7**, and tetraammine(8-quinolinolato)cobalt(III) chloride monohydrate, $[Co(C_9H_6NO)(NH_3)_4]Cl_2\cdot H_2O$ (**8**),[1] are thermally stable compounds. Concerning decomposition of these complexes, their stabilities are arranged in the following order: **1** (247 °C), **7** (205 °C), **8** (177 °C), **2** (163 °C).

The ethylenediamine complex (**2**) is less stable than the corresponding ammine complex (**7**) and bis(ethylenediamine) complex (**1**). This is probably due to the positions of the two oxygen atoms of the coordinated 8-quinolinolato ligands of **2** in an octahedral configuration; in the ammine complexes, diammine complex **7** is more stable than the tetraammine complex (**8**). Tetraammine(8-quinolinolato)cobalt(III) nitrate, $[Co(C_9H_6NO)(NH_3)_4](NO_3)_2$ (**9**), and diamminebis(8-quinolinolato)cobalt(III) nitrate hydrate, $[Co(C_9H_6NO)_2(NH_3)_2]NO_3\cdot H_2O$ (**10**) have been prepared from the corresponding chloride[1] and silver nitrate. Also tetraammine(8-quinolinolato)cobalt(III) picrate, $[Co(C_9H_6NO)(NH_3)_4](pic)_2$ (**11**) and diamminebis(8-quinolinolato)cobalt(III) picrate, $[Co(C_9H_6NO)_2(NH_3)_2]pic$ (**12**) have been prepared from the corresponding chloride[1] and picric acid. ^{1}H-NMR spectral data of **1**, **2**, **5**, and **6** complexes are listed in Table 1.

In the ^{13}C-NMR spectra of **1** and **2** in D_2O, nine

signals have been observed for the coordinated 8-quinolinolato ligand in the regions 115—170 ppm. The assignment (Table 2) of that ligand has been tried by the means of a consideration of the assignments of quinoline[16] and 8-quinolinol. The chemical shifts of C-8 of quinoline move to lower field upon the substitution of a hydroxyl group[17] to form 8-quinolinol. The methylene carbons of the coordinated ethylenediamine in **1** have been observed at 44.1, 45.0, 45.8, and 46.2 ppm and those of **2** have been observed at 45.9 ppm as is shown in Fig. 3, but the chemical shifts of the methylene carbons of the coordinated ethylenediamine of **1** are difficult to assign to the individual carbon atom. The methylene carbon signals of **2** overlapped. An X-ray study is expected to give further information as to the structure of **2b** or **2c**.

The complexes **1**, **2**, **5**—**12** are diamgnetic compounds.

Experimental

Measurements. The NMR spectra were recorded with an FX-60 spectrometer (JEOL) for ^{13}C-NMR and R-40 (Hitachi) for ^{1}H-NMR. The visible absorption spectra were recorded with a Shimadzu MPS-5000 recording spectrophotometer. The magnetic susceptibilities were measured by Faraday's method using a magnetic balance (Shimadzu) at room temperature. The electric conductivities of aqueous solutions were determined by the use of a conductometer, CM-30 (Shimadzu) at room temperature.

Preparation of Complexes. Bis(ethylenediamine)(8-quinolinolato)cobalt(III) Chloride Dihydrate (1), and Ethylenediaminebis(8-quinolinolato)cobalt(III) Chloride Dihydrate (2) and Tris(8-quinolinolato)cobalt(III) Complex (3) and Tris(ethylenediamine)cobalt(III) Chloride (4): One hundred cubic centimeters of a methanol solution of 8-quinolinol (4.16 g, 28.66 mmol) were slowly added to 100 cm^3 of an aqueous solution of $[Co(OH)_2(en)_2]^+$, which was prepared from *trans*-$[CoCl_2(en)_2]Cl$ (4.0 g, 14.01 mmol) and Ag_2O which, in turn, was prepared from $AgNO_3$ (4.8 g, 28.26 mmol) and KOH (2.0 g, 35.65 mmol). They were stirred for 2 d at 60 °C. The precipitated yellow complex (**3**) was filtered. The filtrate was concentrated on a rotary evaporator and dried over silica gel. Complex **2** was extracted with dry ethanol from the dried reaction mixture. The purification (removal of **1**) of **2** from the ethanol solution was achieved by column chromatography on alumina. On elution with ethanol–acetone (3 : 1), the first band (complex **2**) was collected and concentrated. Complex **2** was recrystallized from ethanol–ether twice. Complex **1** was extracted with dry methanol from the dried reaction mixture. This complex was recrystallized from water-acetone twice. Complex **4** remaining to the last did not dissolve in dry methanol. Yield: 0.8 g (13.27%) for **1**, 2.9 g (43.23%) for **2**, 1.2 g (17.4%) for **3** and 0.5 g (10.3%) for **4**. Found **1**: C, 36.51; H, 6.19; N, 16.70; Cl, 16.98%. **2**: C, 49.95; H, 5.20; N, 11.39; Cl, 7.41%. Calcd for **1**: $CoC_{13}H_{26}N_5O_3Cl_2$ (M.W. 430.22) C, 36.29; H, 6.09; N, 16.28; Cl, 16.48%. **2**: $CoC_{20}H_{24}N_4O_4Cl$ (M.W. 478.82) C, 50.17; H, 5.05; N, 11.70; Cl, 7.40%. Dec 245—247 °C for **1**, 161—163 °C for **2**. Λ=270 S cm^2 for **1**, 130 S cm^2 for **2** in water. Absorption spectra, 320 nm (ε=910), 335 (1100), and 338 (2400) in water, 271 nm (ε=11000), 324 (1150), 338 ((1250), and 407 (2900) in methanol for **1**, 320 nm (ε=1070), 334 (1370), and 384 (4780) in water, 267 nm (ε=14800), 325 (2400), 339 (2960), and 404 (5730) in methanol for **2**. Color: brick-red for **1**, brown for **2**.

Bis(ethylenediamine)(8-quinolinolato)cobalt(III) Nitrate, $[Co($  $)(en)_2](NO_3)_2$ (**5**): To an aqueous solution of **1** (0.5 g, 1.16 mmol) was added an aqueous solution of silver nitrate (0.4 g, 2.35 mmol). The mixture was stirred, and the silver chloride precipitated was filtered. The filtrate was concentrated and recrystallized from water twice. Yield: 0.42 g (80.9%). Found: C, 34.91; H, 5.17; N, 21.43%. Calcd for $CoC_{13}H_{22}N_7O_7$ (M.W. 447.30) C, 34.91; H, 4.96; N, 21.92%. Dec 245—249 °C. Absorption spectrum: 322 nm (ε=860), 339 (1050) and 388 (2500) in water. Color: brick-red.

Ethylenediaminebis(8-quinolinolato)cobalt(III) Picrate, $[Co($  $)_2(en)]pic$ (**6**): An aqueous solution of **2** (0.30 g, 0.63 mmol) was added to a solution of picric acid (0.16 g, 0.7 mmol), the mixture was stirred, and the separated brown complex was filtered and recrystallized from methanol. Yield: 0.29 g (66.2%). Found: C, 48.76; H, 3.92; N, 15.50%. Calcd for $CoC_{26}H_{22}N_7O_9$ (M.W. 635.44) C, 49.14; H, 3.49; N, 15.43%. Dec 156—160 °C Absorption spectrum: 267 nm (ε=18300), 350 sh (15400), 362 (15700), and 393 (15100) in methanol. Color: brown.

Tetraammine(8-quinolinolato)cobalt(III) Nitrate (9). An aqueous solution of silver nitrate (0.90 g, 5.30 mmol) was added to an aqueous solution of tetraammine (8-quinolinolato)-cobalt(III) chloride dihydrate[1] (**8**) (1.0 g, 2.78 mmol). The mixture was stirred, and the precipitated silver chloride was filtered. The filtrate was concentrated and recrystallized from water twice. Yield: 0.92 g (83.7%). Found: C, 27.29; H, 4.87; N, 24.44%. Calcd for $CoC_9H_{18}N_7O_7$(M.W. 395.22) C, 27.35; H, 4.59; N, 24.81%. Dec 163—165 °C. Λ=240 S cm^2 in water. Absorption spectrum: 321 nm (ε=940), 337 (1170), and 384 (2450) in water. ^{1}H-NMR spectrum,[1] δ: 3.36 ppm (s, 6H) for N(4)H$_3$ and N(1)H$_3$, 3.99 (s, 3H) for N(2)H$_3$ and 3.59 (s, 3H) for N(3)H$_3$, 7.24—8.7 (m, 6H) for 8-quinolinol. Color: brown.

Diamminebis(8-quinolinolato)cobalt(III) Nitrate Monohydrate

(10). This complex was prepared from diamminebis-(8-quinolinolato)cobalt(III) chloride hydrate[1] (**7**) (1.0 g, 2.30 mmol) and silver nitrate (0.39 g, 2.30 mmol) according to the method of **9**, and recrystallized from methanol–water (1 : 1) twice. Yield: 0.81 g (76.4%). Found: C, 46.92; H, 4.61; N, 15.39%. Calcd for $CoC_{18}H_{20}N_5O_6$ (M.W. 461.33) C, 46.86; H, 4.37; N, 15.18%. Dec 193—195 °C. Absorption spectrum: 300 nm (ε=3600), 319 (3000), 337 (3100) and 408 (6100) in methanol. ^{1}H-NMR spectrum δ: 3.09 ppm (s, 6H) for NH_3, 7.0—9.1 (m, 12H) for 8-quinolinol. Color: yellowish brown.

Tetraammine(8-quinolinolato)cobalt(III) Picrate (11). An aqueous solution of **8** (0.5 g, 1.39 mmol) was added to a solution of picric acid (0.61 g, 2.65 mmol), the mixture was stirred, and the separated yellowish brown complex was filtered and recrystallized from methanol. Yield: 0.82 g (81.2%). Dec 156—159 °C. Found: C, 34.88; H, 3.09; N, 21.42%. Calcd for $CoC_{21}H_{22}N_{11}O_{15}$ (M.W. 727.41) C, 34.68; H, 3.05; N, 21.18%. Color: yellowish brown.

Diamminebis(8-quinolinolato)cobalt(III) Picrate (12). This complex was prepared from **7** (1 g, 2.30 mmol) and picric acid (0.053 g, 2.31 mmol) according to the method of **11**, and recrystallized from methanol. Yield: 1.1 g (78.6%). Dec 200—203 °C. Found: C, 47.57; H, 3.32; N, 15.97%. Calcd for $CoC_{24}H_{20}N_7O_9$ (M.W. 609.40) C, 47.30; H, 3.31; N, 16.09%. Color: yellow.

A Facile Reduction of Copper(II) Leading to Formation of Stable Copper(I) Complexes. Redox Properties of Four- and Five-coordinate Copper Complexes

Takeshi SAKURAI,* Masazo KIMURA, and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received March 17, 1981)

Schiff bases derived from 2-pyridinecarbaldehyde and 1,6-hexanediamine or bis(2-aminoethyl) disulfide gave stable Cu(I) complexes instead of Cu(II) complexes by reactions with copper(II) perchlorate. The facile reduction of copper(II) has been discussed on the basis of systematic comparisons of redox and ESR properties of about 20 complexes of similar structures.

In the course of our study on biological coppers[1] and model compounds,[2-4] we found that some Schiff base ligands derived from 2-pyridinecarbaldehyde (pca) and 1,6-hexanediamine (heda) or bis(2-aminoethyl) disulfide (baed) afford stable copper(I) complexes in spite of the use of divalent copper as starting material. We have systematically investigated redox and ESR properties of some four- and five-coordinate copper complexes in order to shed light on this novel phenomenon. Diamines employed in this study to derive Schiff bases with pca were as follows: heda, 1,5-pentanediamine (peda), 1,4-butanediamine (buda), 1,3-propanediamine (prda), 1,2-ethanediamine (etda), baed, bis(2-aminoethyl) sulfide (baes), 2-aminoethyl 3-aminopropyl sulfide (aeps), *N*-(2-aminoethyl)-1,3-propanediamine (aepd), *N*-(2-aminoethyl)-1,2-ethanediamine (aeed), and bis(2-aminoethyl) ether (baee).

Experimental

Materials. Copper(II) perchlorate hexahydrate, heda, peda, buda, prda, etda, and aeed were purchased from Nakarai Chemicals Ltd., and baed, aeps, and baee from Aldrich. Diamines with single thio group, baes and aeps, were prepared according to literatures.[3,5] All other reagents used were of the highest grade commercially available.

Preparation of Complexes. *Cu^{I}(pca=heda=pca)*:** To a 80 ml of neutral or basic aqueous ethanol (1 : 1 by volume) solution of heda (1.16 g) was added twice as much amount of pca (2.14 g) to give 2 : 1 pca: heda Schiff base, and was treated with 3.71 g of $Cu(ClO_4)_2 \cdot 6H_2O$. A brown complex precipitated very soon. On account of its poor solubility in most solvents, the precipitate was washed by aqueous ethanol instead of being recrystallized. Found: C, 46.57; H, 4.79; N, 12.39; Cu, 13.1%. Calcd for $C_{18}H_{22}N_4Cu(ClO_4) \cdot H_2O$: C, 46.25; H, 5.18; N, 11.99; Cu, 13.6%.

Cu^{I}(pca=baed=pca). This brown complex was prepared by the same method as that in Cu^{I}(pca=heda=pca). Found: C, 36.39; H, 3.55; N, 10.45; Cu, 11.5%. Calcd for $C_{16}H_{18}N_4S_2Cu(ClO_4) \cdot 2H_2O$: C, 36.29; H, 4.19; N, 10.58; Cu, 12.0%.

The other parent copper(II) complexes were prepared according to the methods in previous papers[3,6,7] as diperchlorate except Cu(pca=prda=pca), Cu(pca=baee=pca), Cu(pca-prda-pca) and Cu(pca-heda-pca) which were monochloride monoperchlorate. All these compounds were identified based on elemental analyses and IR spectra.

Measurements. Cyclic voltammetry was performed at 25 °C with a three electrode system consisting of platinum working and auxiliary electrodes and a standard calomel electrode. Voltammograms were generated using a Yanagimoto P-1000 voltammetric analyzer and an NF FG-121G function generator and recorded on a National VP-6421 X-Y recorder for *N,N*-dimethylformamide (DMF) solutions of complexes (*ca.* 5×10^{-3} mol·dm^{-3}, I=0.1 (tetrabutylammonium perchlorate)). $E°$ values were determined as the midpoints between the peak potentials. Absorption spectra were recorded in 1 cm- or 1 mm-path length quartz cell in the range 270—700 nm with a Hitachi 323 spectrophotometer at room temperature. Electron spin resonance spectra of copper(II) complexes were obtained using a JEOL JES-FEIX instrument at 77 K. Infrared spectra were measured using a Hitachi 260-10 grating infrared spectrophotometer by KBr disk method. Copper contents of complexes were determined by a Nippon Jarrell-Ash AA-1 atomic absorption spectrometer. DMF was used as solvent throughout measurements unless otherwise specified. The magnetic susceptibility was determined at room temperature by using a Gouy magnetic apparatus.

** The notation "pca=heda=pca" represents hereafter the 2 : 1 Schiff base derived from pca and heda, and "pca-heda-pca" the aorresponding reduced ligand.

Results and Discussion

Brown copper(I) complex, Cu^{I}(pca=heda=pca), unexpectedly precipitated immediately after addition of $Cu(ClO_4)_2$ to pca=heda=pca in aqueous ethanol, instead of producing green Cu^{II}(pca=heda=pca). Reduction of copper(II) to copper(I) was substantiated not only by elemental analysis but also by ESR and absorption spectroscopy. Copper(II) content was several percent, which was determined by double integration of ESR signals using $Cu(imidazole)_4$ as standard. Addition of H_2O_2 or permission to stand Cu^{I}(pca=heda=pca) in H_2O–DMF for several days presented full copper(II) ESR signal (Fig. 1), and the solution turned green.

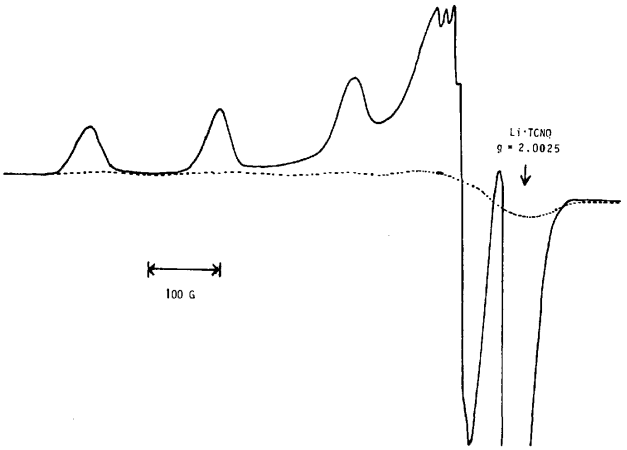

Fig. 1. ESR spectra of isolated Cu(pca=heda=pca) (------) and H_2O_2-treated Cu(pca=heda=pca) (——).

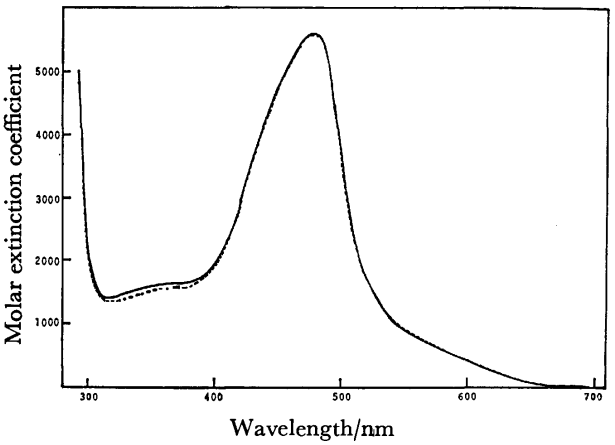

Fig. 2. Absorption spectra of authentic (——) and isolated (------) Cu(pca=heda=pca).

An authentic copper(I) complex solution prepared by using $Cu^{I}(CH_3CN)_4(ClO_4)$ as copper(I) source afforded a quite similar absorption spectrum as that of the isolated Cu(pca=heda=pca) (Fig. 2), exhibiting an intense MLCT band at 478 nm. Magnetic moment per copper atom was calculated from susceptibility to be 0.62 BM ($1\ BM = 9.274 \times 10^{-24}\ A\ m^2$) at room temperature, indicating that paramagnetic copper(II) was really a trivial contaminant. The present quite rapid reduction of copper, which occurs much readily in alkaline medium than in neutral aq ethanol, might be accompanied by generation of 2-pyridinecarboxylic acid from free 2-pyridinecarbaldehyde in the system. In fact, thin layer chromatography on silica gel plate has suggested the formation of 2-pyridinecarboxylic acid in the brown reaction mixture. A green copper(II) complex which was precipitated in acidic solution also gradually turned brown in DMF. Copper does not seem to be reduced by a concomitant oxidation of the coordinated ligand, since the IR spectrum of brown Cu^{I}(pca=heda=pca) is similar to green intact copper(II) complexes providing with various lengths of methylene chain.

In line with this, the quite similar reduction of copper(II) ligated by pca=baed=pca has been observed. However, pure Cu(I) complex has not been isolated: Cu(II) content determined by ESR spectrum was 35% and magnetic moment of this complex was evaluated as 1.55 BM at room temperature. The extremely delicate difference in stabilizing Cu(I) complex of the present kind might be interpreted on the basis of the greater size of sulfur over a methylene group. The dithio group would not bind copper, or if any, the interaction of the dithio group with copper will be rather weak. These examples suggest that the facile reduction of Cu(II) to Cu(I) may occur when providing the ligand with methylene chain of appropriate length. In the case of the present series of complexes, diamines having six methylene groups or equivalent length as half moiety of Schiff base are considered to best suit the condition.

In order to understand this phenomenon, redox potentials of copper have been compared for about 20 copper complexes. $E°$ values and ESR parameters to exhibit properties of parent copper(II) complexes are

Table 1. Redox potentials and ESR parameters of copper complexes

tabulated in Table 1. For Cu(pca=heda=pca) and Cu(pca=baed=pca) copper(I) complexes were used for determining $E°$ values since pure green Cu(II) complexes have not been isolated. As clearly seen from Table 1, Cu(pca=heda=pca) and Cu(pca=baed=pca) exhibited higher redox potentials over zero volt. In contrast to this, the analogues with shorter methylene chain lengths exhibited lower $E°$ values. This implies that the former two bear the favorable chain length adaptable to tetrahedral coordination around Cu(I). In addition, the present copper(II) complexes display a trend toward tetrahedral distortion, as visualized in $g_{//}$—$A_{//}$ profile for $Cu(N)_4$-type complexes as described by Peisach and Blumberg.[8]

The single thio group-containing five coordinate Schiff base complexes also exhibited higher redox potentials. These complexes, Cu(pca=baes=pca) and Cu(pca=aeps=pca) also tend to be reduced spontaneously in DMF, although Cu(I) complexes have not yet been isolated. Other five coordinate Schiff base complexes devoid of thio group display lower $E°$ values and favor a copper(II) state. The reduction of Schiff bases prominently lowered $E°$ values (0.2—0.3 V), hence the stabilization of copper(I) state cannot be realized even by pca–heda–pca and pca–baed–pca. Thus it can be considered that the aliphatic amine is not necessarily favorable for stabilizing the copper(I) state.

The present unexpected reduction of copper(II) and stabilization of Cu(I) in the presence of air is anticipated to afford a clue to appreciate the nature of biological coppers and to design model compounds.

Binuclear Metal Complexes. XLI.[1] Crystal Structure and Unusual Magnetic Property of Isothiocyanato{2-[2-(dimethylamino)-ethylthio]ethanolato}copper(II)

Masahiro MIKURIYA, Hisashi OKAWA, and Sigeo KIDA*

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received March 27, 1981)

A binuclear copper(II) complex, isothiocyanato{2-[2-(dimethylamino)ethylthio]ethanolato}copper(II), (Cu(CH_3-nso)NCS), was prepared and characterized by elemental analysis, infrared and electronic spectra, magnetic susceptibility (90—300 K), and single-crystal X-ray diffraction. The complex exhibits a band at 25×10^3 cm^{-1} characteristic of alkoxo-bridged structure. The temperature dependence of the magnetic susceptibility is unusual and shows a dramatic change in the temperature range 240—180 K. The magnetic data were fitted to the Bleaney-Browers equation separately in the two temperature ranges ($-2J=535$ cm^{-1} for $300\geq T\geq240$ K; $-2J=595$ cm^{-1} for $170\geq T\geq90$ K).

In the previous paper[2] of this series, we reported the synthesis, structure, spectra, and magnetic properties of binuclear copper(II) complexes with 2-[2-(dialkylamino)ethylthio]ethanols, Cu{$R_2N(CH_2)_2S(CH_2)_2O$}X (abbreviated as Cu(R-nso)X, where R=CH_3, C_2H_5, n-C_3H_7, n-C_4H_9; X=Br, Cl, NO_3). With Cu(CH_3-nso)-Br we found that its crystal consists of discrete binuclear units but that its magnetic susceptibility exhibits a temperature dependence which does not obey the Bleaney-Bowers equation[3] based on a binuclear structure; similar temperature dependence applies also to all the other Cu(R-nso)X but Cu(n-C_4H_9-nso)Cl. In order to elucidate this unusual magnetic behavior, we have continued collecting information on magnetic properties of similar complexes. In the course of this activity, we found that isothiocyanato{2-[2-(dimethylamino)ethylthio]ethanolato}copper(II), Cu(CH_3-nso)-NCS, exhibits a magnetic behavior suggestive of a phase transition between two binuclear structures at 240—180 K. The present investigation was undertaken to characterize Cu(CH_3-nso)NCS by means of elemental analysis, infrared and electronic spectra, magnetic susceptibility, and single-crystal X-ray diffraction, for the purpose of elucidating the unusual magnetic behavior.

Experimental

Preparation of the Complex. 2-[2-(Dimethylamino)ethylthio]ethanol was prepared by the method previously described.[2] To an ethanol solution (50 ml) of 2-[2-(dimethylamino)ethylthio]ethanol (298 mg) and copper(II) acetate monohydrate (200 mg) was added an ethanol solution (10 ml) of potassium thiocyanate (97 mg). On standing overnight, dark green crystals were formed, which were separated by filtration, washed with ethanol and dried *in vacuo* over P_2O_5.

Found: C, 31.16; H, 5.24; N, 10.33%. Calcd for $C_7H_{14}CuN_2OS_2$: C, 31.16; H, 5.23; N, 10.38%.

Measurements. Infrared spectra were measured with a Hitachi Grating Infrared Spectrophotometer Model 215 in the region 4000—650 cm^{-1} on a KBr disk. Electronic spectra were measured with a Shimadzu Multipurpose Spectrophotometer Model MSP-5000 at room temperature. Magnetic susceptibility was measured by the Faraday method in the temperature range from liquid nitrogen temperature to room temperature. The apparatus was calibrated by the use of $[Ni(en)_3]S_2O_3$.[4] The susceptibility was corrected for the diamagnetism of the constituent atoms by the use of Pascal's constants.[5] Effective magnetic moment was calculated from the equation, $\mu_{eff}=2.828\sqrt{(\chi_A-N\alpha)T}$, where χ_A is the atomic magnetic susceptibility and $N\alpha$ is the temperature-independent paramagnetism. For the present complex, $N\alpha$ is assumed to be 60×10^{-6} cgs emu.[6]

X-Ray Crystal Structure Analysis. A crystal with dimensions of 0.19 mm × 0.25 mm × 0.31 mm was used for the X-ray analysis. The unit-cell parameters and intensities were measured on a Rigaku AFC-5 automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation ($\lambda=0.71069$ Å) at 24 ± 1 °C. The unit-cell parameters were determined by the least-squares refinement based on the 15 reflections in the range of $23<2\theta<33°$.

Crystal Data: $C_{14}H_{28}N_4O_2S_4Cu_2$, F.W.=539.73; monoclinic; $P2_1/a$; $a=10.025(3)$, $b=14.421$ (3), and $c=8.595$ (2) Å; $\beta=110.49$ (2)°; $D_m=1.52$ (by floatation in n-C_6H_{14}–CCl_4); $D_c=1.54$ g cm^{-3}; $Z=2$; μ(Mo $K\alpha$)=21.7 cm^{-1}.

The intensity data were collected by the 2θ-ω scan technique with a scan rate of 8° min^{-1}. For weak reflections the peak scan was repeated up to four times depending on thier intensities. Three standard reflections were monitored every 100 reflections, and their intensities showed a good stability. A total of 2282 reflections with $2\theta<50°$ were collected. The intensity data were corrected for the Lorentz and the polarization effects, but not for absorption. Independent 1605 reflections with $|F_o|>3\sigma(|F_o|)$ were considered as "observed" and were used for the structure analysis.

The systematic absences observed, h odd for $h0l$ and k odd for $0k0$, uniquely define the space group as $P2_1/a$. The structure was solved by the heavy atom method. The position of the copper atom was obtained from a three-dimensional Patterson synthesis. Successive Fourier Synthesis revealed all the nonhydrogen atoms. Refinement was carried out by the block-diagonal least-squares method. Anisotropic thermal parameters being introduced, the block-diagonal least-squares refinement yielded discrepancy factors $R_1=\sum||F_o|-|F_c||/\sum|F_o|=0.068$ and $R_2=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}=0.103$. In the course of refinement, it became apparent that the carbon atom of the chelate ring, C(4), is subjected to disorder. The carbon atom was divided between two positions with an occupancy factor 0.5 on the basis of a difference Fourier map. Hydrogen atoms were inserted in their calculated positions and included in the refinement. Further refinement with anisotropic thermal parameters for nonhydrogen atoms and isotropic temperature factors for hydrogen atoms gave final values of 0.062 and 0.093 for R_1 and R_2, respectively. In the least-squares refinement the function

minimized was $\sum w(|F_o|-k|F_c|)^2$, and the weighting scheme was $w=(6.0+|F_o|+0.012|F_o|^2)^{-1}$.[7] The final difference Fourier synthesis showed no peaks higher than 0.65 e/Å^3.

The atomic scattering factors for Cu, S, O, N, and C_{val} and the anomalous dispersion corrections, $\Delta f'$ and $\Delta f''$ for Cu and S, were taken from the International Tables for X-Ray Crystallography.[8] For the hydrogen atom, the scattering factors were adopted from the tables of Stewart et al.[9] All the calculations were carried out on the FACOM M-200 computer in the Computer Center of Kyushu University by the use of a local version[10] of the UNICS-II[11] and the ORTEP[12] programs.

Lists of structure factors and anisotropic thermal parameters have been deposited at the Chemical Society of Japan as Document No. 8142. The final positional and thermal parameters with their estimated standard deviations are given in Table 1.

Results and Discussion

The molecular packing in the unit cell is shown in Fig. 1. As is evident from the packing diagram and the closest interdimer contact (C(4A)–C(7) 3.37(2)Å), the crystal consists of discrete binuclear units.

As shown in Fig. 2, the complex consists essentially of

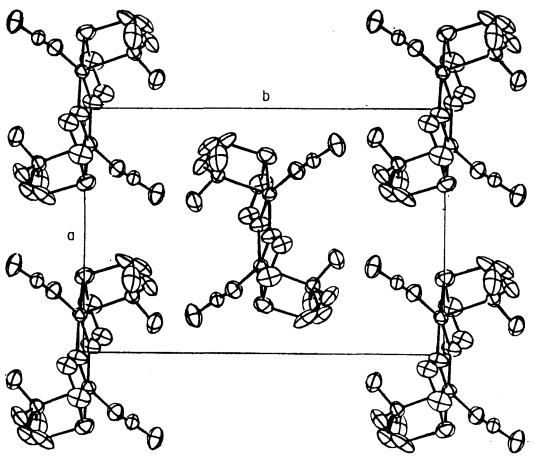

Fig. 1. Projection of the unit cell on the ab plane.

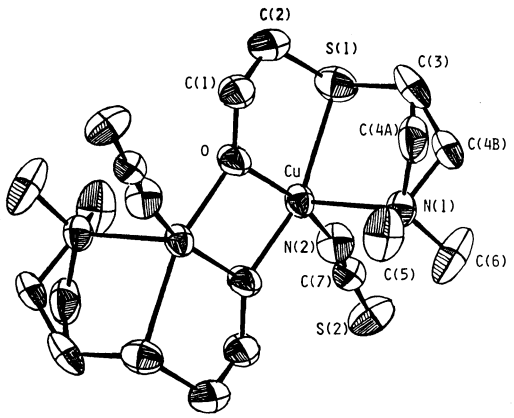

Fig. 2. Molecular structure of Cu(CH_3-nso)NCS. Thermal ellipsoids are drawn at 30% probability level.

alkoxo-bridged centrosymmetric binuclear units. The coordination geometry around each copper atom is best described as a distorted square pyramid with two alkoxo oxygen atoms, a thioether sulfur atom and an isothiocyanate nitrogen atom in the basal plane, and an amino nitrogen atom in the apical position. The copper atom deviates from the basal plane toward the apical N(1) atom by 0.233Å (Table 3). There is a tetrahedral distortion in the basal plane, because the deviations of the basal atoms from the least-squares plane are 0.088—0.129Å and the dihedral angle between the planes

a) The equation of the plane is expressed as $LX+MY+NZ=D$, where X, Y, and Z are in Å units refered to the crystallographic axes. b) Deviations (l/Å) of atoms from the planes are listed in square brackets. Superscript (i) refers to the equivalent position $(-x, -y, -z)$.

Cu–O–O^{i} and Cu–S(1)–N(2) is 21.5°. This distortion is smaller than that in Cu(CH_3-nso)Br.[2)] The bond distances and angles with their estimated standard deviations are listed in Table 2. The Cu–Cu^{i} distance (3.009(2)Å) agrees well with the value found for Cu(CH_3-nso)Br (3.004(2) Å), while the Cu–O–Cu^{i} angle (103.0(2)°) is larger than that found for Cu(CH_3-nso)Br (102.2(2)°).[2)]

The Cu–O and Cu–N(1) distances of Cu(CH_3-nso)-NCS are 1.902(7) and 2.296(7)Å, respectively, which are slightly shorter than those of Cu(CH_3-nso)Br (Cu–O 1.930(5), Cu–N 2.334(6)Å). On the other hand, the Cu–S(1) bond length (2.361(3)Å) is longer than that (2.316(2)Å) of Cu(CH_3-nso)Br. The shortening of the Cu–O and Cu–N bonds should bring about a considerable strain in the fused chelate ring, although the elongated Cu–S bond may contribute to the releasing of the strain. In fact, the carbon atom of the chelate ring, C(4), is disordered. This is probably due to the strain of two adjacent five-membered chelate rings.[2)] It is noteworthy that all the atoms of the complex have considerably large temperature factors. This fact suggests that the conformation of the complex easily fluctuates.

The isothiocyanate group coordinates to the copper atom with the nitrogen atom. The infrared spectrum (ν_{CN}=2075 cm^{-1}; ν_{CS}=760 cm^{-1}) is consistent with this coordination mode.[13)] The Cu–N(2) distance (1.940(9) Å) is in the range of the normal in-plane coordination. The NCS group is nearly linear (the N(2)–C(7)–S(2) angle 177.8(8)°) and of nearly the same structure as found for other alkoxo-bridged copper(II) complexes containing an NCS group.[14–17)]

The electronic absorption spectrum in 1,2-dichloroethane solution resembles the diffuse reflectance spectrum, indicating that the molecular structure is essentially the same in the solution as in the solid state. The absorption spectrum shows a band centered at 13.9×10^3 cm^{-1} (ε=130) with a shoulder at *ca.* 11.1×10^3 cm^{-1}. These bands can be assigned to the d-d transitions of a five-coordinate copper(II) complex.[18)] A more intence band (ε=2350) occurs at 24.9×10^3 cm^{-1}. This is the band characteristic of alkoxo-bridged structure assigned to a charge transfer from a p_π orbital of the bridging oxygen atom to the unfilled d orbital of the copper ion.[2)]

The magnetic susceptibility was measured over the temperature range 90—300 K. The magnetic moment per copper atom is 0.90 BM at 299 K. The temperature dependence of the magnetic susceptibility is shown in Fig. 3. The susceptibility decreases gradually with lowering temperature from 300 to 240 K and then

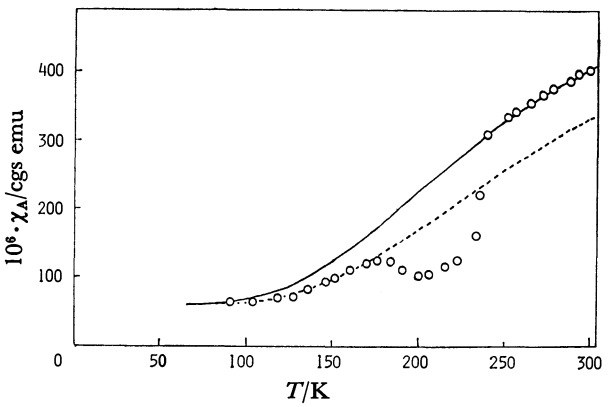

Fig. 3. Temperature dependence of magnetic susceptibility of Cu(CH_3-nso)NCS. The solid curve was calculated from Eq. 1 with g=2.10 and $-2J$=535 cm^{-1}; the bloken curve, from Eq. 1, using g=2.10 and $-2J$=595 cm^{-1}.

suddenly decreases in the range 240—230 K, reaching a minimum at 200 K. Below 200 K, the susceptibility increases to a maximum at about 180 K and finally decreases again. This fact suggests that a phase transition occurs in the temperature range 240—180 K. The susceptibility data were fitted to Eq. 1 (the Bleaney-Bowers equation[3]) separately in the two temperature ranges:

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1} + N\alpha, \qquad (1)$$

where $-2J$ is equal to the energy separation between the spin-singlet ground state and the lowest spin-triplet state and the other symbols have their usual meanings. Between 300 and 240 K, the experimental data fit Eq. 1 with $-2J=535$ cm^{-1} and $g=2.10$. Below 170 K, the susceptibility follows Eq. 1 with $-2J=595$ cm^{-1} and $g=2.10$. Although temperature dependence of J value was already noticed in some binuclear copper(II) complexes,[19-21] the present complex provides the most remarkable instance. Such a magnetic behavior may be attributed to the fact that the conformation of the chelate ring readily fluctuates with temperature variation. It is known that J values of binuclear copper(II) complexes depend sensitively on the Cu–O–Cu angle[22] or the tetrahedral distortion about the copper coordination.[23] Therefore, a slight variation in the conformation of the complex may lead to a marked change in the J value.

Tetrahedral Transition Metal Complexes of $[MW_{12}O_{40}]$-type ($M=Cu^{II}$, Fe^{III}, Co^{II}) with Dodecatungstate as Tetrahedral Ligand

Kenji Nomiya, Makoto Miwa,* Ryoichi Kobayashi, and Masahiro Aiso

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180

(Received March 30, 1981)

Tetrabutylammonium salts of 12-heteropolytungstates with central transition metal ions in a tetrahedral oxygen environment, $MW_{12}O_{40}$ ($M=Cu^{II}$, Fe^{III}, Co^{II}), have been prepared and their spectroscopic data (infrared (IR), near-infrared, UV-vis, and magnetic circular dichroism (MCD)) presented.

12-Tungstometallate, $MW_{12}O_{40}$, is a typical 12-heteropolytungstate with the central transition metal in a tetrahedral oxygen environment. The compound is also considered as a transition metal complex with quadridentate dodecatungstate "ligand," $W_{12}O_{40}$, having tetrahedral cavity. Therefore, the formula can be rewritten as $MO_4W_{12}O_{36}$.

12-Tungstocuprate(II) anion, first reported by Brown and Mair,[1] is not easily prepared because of the extremely low yield and the difficulty of controling experimental conditions, pH and temperature, into the very narrow range allowed. Subsequently, except for the polarographic study by Wexell and Pope,[2] no precedent has been reported. On the contrary, 12-tungstocobaltate(II) and 12-tungstoferrate(III) anions, although purification takes time and yields are not so high, are not so difficult to prepare,[3-6] and many investigations have been reported.[7-14] Nevertheless, little spectroscopic data, especially IR data, of these heteropoly compounds have been reported.

Heteropoly compounds have contained different numbers of solvated water molecules (18 to 1), because the degree of hydration of K^+, Na^+, and Cs^+ salts of the anion varies according to the temperature of crystallization and the humidity at which the crystals are stored. Furthermore, most of the studies have been limited to aqueous systems. However, these compounds sometimes undergo hydrolytic decomposition in aqueous solution, the electronic spectra being influenced by the pH of the aqueous solvent because of the protonation of the dodecatungstate framework. We isolated these anions as tetrabutylammonium salts and measured the optical spectra in nonaqueous solution.

In this work, from a structural point of view, IR spectra of tetrabutylammonium salts of heteropolyanions with $M=Cu^{II}$ **1**, Fe^{III} **2**, and Co^{II} **3**, as heteroatom have been studied both in the solid and in the solution. On the basis of the results, the near-infrared and UV-vis spectra have been interpreted; MCD spectra have been measured to aid the resolution of the overlapping visible spectra.

Experimental

Near-infrared and UV-vis absorption spectra were measured on a Hitachi 340-spectrophotmeter with an attached computer key-board. MCD spectra were recorded by a JASCO J-40AS spectropolarimeter mounted with 10.0 kG electromagnet. The MCD intensity is expressed in terms of $\Delta\varepsilon=\varepsilon_l-\varepsilon_r$. Measurements were made at room temperature. IR spectra in acetonitrile were measured using a KBr cell with 0.1 mm optical path.

Preparation. $H_2[(C_4H_9)_4N]_4[CuW_{12}O_{40}]$, (*1*): Preparation of 12-tungstocuprate(II) is mainly performed according to the Brown-Mair's method.[1] Instead of using copper(II) nitrate solution, we modified as follows: the pH of sodium tungstate solution ($Na_2WO_4\cdot 2H_2O$ 56.2 g, 0.170 mol, in 300 cm^3 water) was adjusted within 4.5—5.0 by 1 mol dm^{-3} nitric acid and the temperature was maintained at 68—70°C. To this solution, the dropwise addition throughout 6 h of copper(II) sulfate solution ($CuSO_4\cdot 5H_2O$ 6.2 g, 2.48×10^{-2} mol, in 300 cm^3 water) was made with continuous stirring. During the process of purification, the metatungstate by-product should be removed. The product was dried on a steam bath followed by extraction with water; the separation of 12-tungstocuprate(II) and metatungstate was monitored by the near-infrared spectrum at *ca.* 1340 nm, until the spectra of its aqueous solution become unchanged.

The aqueous solution, acidified with nitric acid, of excess tetrabutylammonium bromide was added to the aqueous solution of purified 12-tungstocupric acid. The precipitate formed was filtered, washed thoroughly with water, dried *in vacuo* and recrystallized twice from acetonitrile (yield 1%, yellow). Found: C, 19.41; H, 3.83; N, 1.48%. Calcd for $H_2[(C_4H_9)_4N]_4[CuW_{12}O_{40}]$: C, 19.79; H, 3.76; N, 1.44%.

$H[(C_4H_9)N]_4[FeW_{12}O_{40}]$ (*2*): The 12-tungstoferrate(III) is prepared by a modification of the method reported by Pope and Varga,[4] and purified by Mair's method.[3] The compound structure is confirmed by the absorption spectrum of an aqueous solution as reported by Brown.[8] The aqueous solution, acidified with nitric acid, of excess tetrabutylammonium bromide was added into the aqueous solution of the purified 12-tungstoferric acid. The precipitate was washed thoroughly with water and recrystallized three times from acetonitrile (yield 1%, pale yellow). Found: C, 19.87; H, 3.95; N, 1.52%. Calcd for $H[(C_4H_9)_4N]_4[FeW_{12}O_{40}]$: C, 19.84; H, 3.74; N, 1.45%.

$K_2[(C_4H_9)_4N]_4[CoW_{12}O_{40}]\cdot CH_3CN$ (*3*): Potassium 12-tungstocobaltate(II) is prepared and purified by the method of Baker and McCutcheon.[5,6] The structure of the potassium compound is confirmed by the absorption spectrum of the aqueous solution as reported by Rollins.[11] This compound is converted to tetrabutylammonium salts (yield 1%, blue-green). Found: C, 19.58; H, 3.87; N, 1.49%. Calcd for $K_2[(C_4H_9)_4N]_4[CoW_{12}O_{40}]\cdot CH_3CN$: C, 19.83; H, 3.68; N, 1.75%.

$Na_2[(C_4H_9)_4N]_4[H_2W_{12}O_{40}]$ (*4*): Tungsten(VI) oxide monohydrate, $WO_3\cdot H_2O$ (yellow), obtained by acidic decomposition of $Na_2WO_4\cdot 2H_2O$, is converted to the sodium metatungstate (white) by Freedman's method.[15] This compound is converted to tetrabutylammonium salts as described above. Found: C, 20.18; H, 3.94; N, 1.46%. Calcd for $Na_2[(C_4H_9)_4N]_4[H_2W_{12}O_{40}]$: C, 20.12; H, 3.83; H, 1.47%. $[(C_4H_9)_4N]_4[SiW_{12}O_{40}]$ (**5**) and $[(C_4H_9)_4N]_3[PW_{12}O_{40}]$, (**6**) were prepared by the usual manner.[16]

Results and Discussion

IR Spectra. The IR spectra of heteropoly-compounds of M=Cu^{II}, Fe^{III}, and Co^{II} and metatungstate, recorded in KBr disks, in the metal-oxygen stretching region are shown in Fig. 1. The vibrational frequencies are presented in Table 1, together with the data of the M=Si and P compounds.

Fig. 1. IR spectra of tetrabutylammonium salts of $MW_{12}O_{40}$ heteropolyanions in 1000—400 cm^{-1} region measured in KBr disk; semi-dashed line (-·-·-) for M=Cu^{II}, dashed line (------) for M=Fe^{III}, full line (——) for M=Co^{II} and dotted line (·····) for metatungstate.

Three prominent bands in the tungstate spectra of **1**—**3** were assigned by comparison with the spectra of tetrabutylammonium salts of metatungstate $H_2W_{12}O_{40}^{6-}$ **4**, which is considered to be metal-free ligand, α-$SiW_{12}O_{40}^{4-}$ **5** and $PW_{12}O_{40}^{3-}$ **6**; ≈940 cm^{-1}, ν(W–O, terminal); ≈870 cm^{-1}, ν(W–O–W, octahedral edge-sharing); ≈770 cm^{-1}, ν(W–O–W, octahedral corner-sharing).[17] The characteristics of **1**—**3** compounds are as follows; (1) new bands appear at *ca.* 440 cm^{-1} and (2) the corner-sharing bands at *ca.* 770 cm^{-1} are more asymmetric and broader than that of **4**, and have some shoulder peaks.

In general, for an undistorted tetrahedron (T_d symmetry) of the MO_4^{n-} type ion there are four fundamental vibrational modes (A_1+E+2F_2), only triply degenerated F_2 modes of which are IR active; one of the F_2 is predominantly the M–O stretching motion, $\nu_3(F_2)$ and the other F_2 is the deformation by O–M–O angle bending motion, $\nu_4(F_2)$. The asymmetric stretch ν_3 is normally very strong in the IR and $\nu_3 > \nu_4$.[18] In the heteropolyanions **1**—**3**, by analogy with ν_3 and ν_4 of **4**, **5**, and **6** compounds, the new bands at *ca.* 440 cm^{-1} may be assigned to $\nu_4(F_2)$, and $\nu_3(F_2)$ band to be overlapped with the W–O–W octahedral corner-sharing band at *ca.* 770 cm^{-1}.

Table 2. Numerical data of the vibrational mode $\nu_4(F_2)$ of tetrabutylammonium salts of $MW_{12}O_{40}$ anions

M	In the solid (KBr disk) Max. cm^{-1}	In the solution (in CH_3CN)	
		Max. cm^{-1}	Half-width cm^{-1}
Cu^{II}	437[a)]	444[a)]	68±4
Fe^{III}	440	447	18±4
Co^{II}	441	450	39±4
Si	528[a)]	530[a)]	34±13
P	505	513[b)]	46±4

a) Asymmetric triplet. b) Center of doublet.

The expected splitting of ν_3 and ν_4 for different site symmetries has been described.[19] When the effects of crystal packing and/or environment upon ν_3 and ν_4 are eliminated, the spectral envelopes of both bands will show whether the central site symmetry is regularly tetrahedral or distorted. Accordingly, we have examined the variation in the frequencies and the widths of these vibrational modes, especially ν_4, in acetonitrile solution. The results are presented in Table 2. It was observed that the positions of the ν_4 band are essentially insensitive to the crystalline state and the apparent features of the envelopes are not significantly varied, except for the P compound.

The very symmetrical envelope and small width of the ν_4 for the Fe^{III} compound may be indicative of the regular tetrahedron of the FeO_4 moiety of this compound. The envelope for the Co^{II} compound is also very symmetrical, although the width is rather broad. This compound can be expected to retain excellent tetrahedral symmetry. On the contrary, the envelopes for the Cu^{II} and Si compounds are asymmetric; there are actually splittings into three bands and significant broadenings, indicating that the MO_4 moieties of these compounds possess far from perfect tetrahedral site symmetry. Since these bands are also asymmetric and broadened in the solid state (KBr disk), the features will not be caused by the effect of crystal packing, but mainly by the intrinsic structure of the tetrahedral complexes surrounded by dodecatungstate ligand. The significant distortion of the SiO_4 moiety in α-$Ba_2[SiW_{12}O_{40}]$ has been established by X-ray structural analysis.[20] The Cu^{II} compound is considered to have an intrinsic distortion on account of the Jahn-Teller effect of the d^9 configuration. It may be anticipated that the distortion reflects plausibly on the spectral envelope of ν_4 band. In the case of the P compound, the envelope of ν_4 band is very sharp and symmetric in the solid, whereas there is a splitting to two bands and the width is more broadened in the solution. If the above-mentioned hypothesis is true, the data indicate some departure from regular tetrahedral symmetry in the PO_4 moiety occurs.

Regarding the two W–O–W stretchings of **4**, there

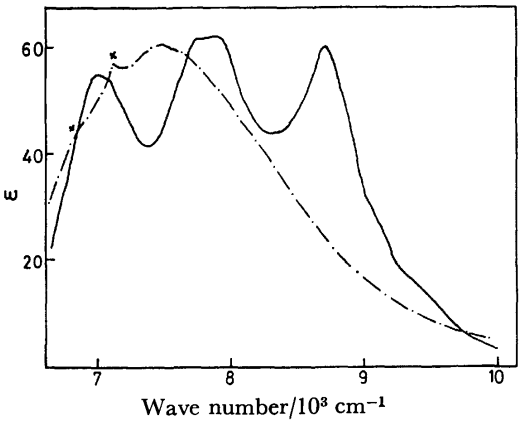

Fig. 2. Near-infrared spectra of tetrabutylammonium salts of $[Cu^{II}W_{12}O_{40}]^{6-}$ (-·-·-) and $[Co^{II}W_{12}O_{40}]^{6-}$ (——) in acetonitrile solution. The cross mark stands for the absorption of contaminated water.

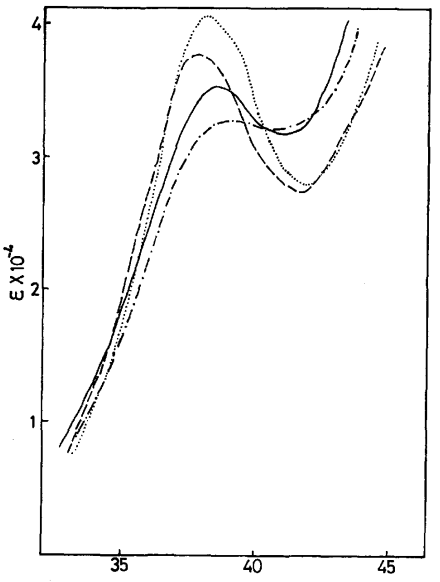

Fig. 3. UV spectra of tetrabutylammonium salts of $MW_{12}O_{40}$ heteropolyanions in acetonitrile solution; semidashed line (-·-·-) for $M=Cu^{II}$, dashed line (------) for $M=Fe^{III}$, full line (——) for $M=Co^{II}$ and dotted line (·····) for metatungstate.

are two cases as follows; where the heteroatom is a non-transition metal, those two bands are relatively unchanged or only slightly shifted to a higher frequency region, whereas if the heteroatom is a transition metal, the bands are shifted considerably to a low frequency region. Thus, the central transition metals may give rise to the strong electronic interaction with the dodecatungstate lattice.

Near-infrared, UV-vis, and MCD Spectra. The near-infrared and UV-vis spectra (Figs. 2 and 3) of an acetonitrile solution of 12-tungstocuprate(II) **1** shows a broad band at 7490 cm^{-1} (ε 60.1) and another at 39000 cm^{-1} (ε 32400). The former is slightly higher than that in water reported by Brown and Mair.[1] The former band is due to the d-d transition of Cu^{II} (d^9) displaced to this position in the tetrahedral oxygen lattice and is broadened by some components based on a Jahn-Teller effect in the ground state. Since the expected value should be around 4/9 of 12500 cm^{-1} (the value of 10 Dq for $Cu(H_2O)_6^{2+}$), *i.e.* around 5560 cm^{-1}, the ligand field strength by $W_{12}O_{40}$ "ligand" may be greater than the corresponding hypothetical four hydrate. A band at 39000 cm^{-1} is due to the charge transfer transition within the oxotungstate lattice and is observed in the spectra of other dodecatungstates of central nonmetals and transition metals.

The electronic and MCD spectra of 12-tungstoferrate(III) **2** in acetonitrile are shown in Figs. 3 and 4. This anion has perfect T_d symmetry; no distortion of the central FeO_4 tetrahedra would occur in solution. The three absorption bands observed at 20900 (ε 0.7), 24210 (ε 10.9) and 37590 cm^{-1} (ε 38400) are in good agreement with the results in aqueous solution, although the intensities of the visible absorptions are less than the halves of the previous data.[8] These have been assigned

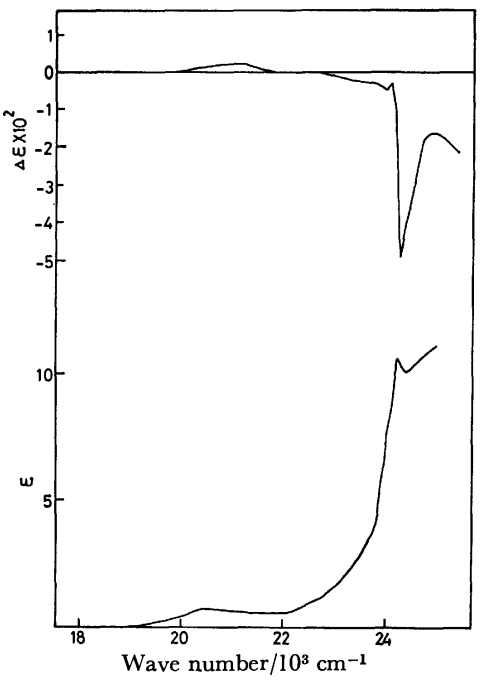

Fig. 4. Vis and MCD spectra of tetrabutylammonium salt of $[Fe^{III}W_{12}O_{40}]^{5-}$ in acetonitrile solution.

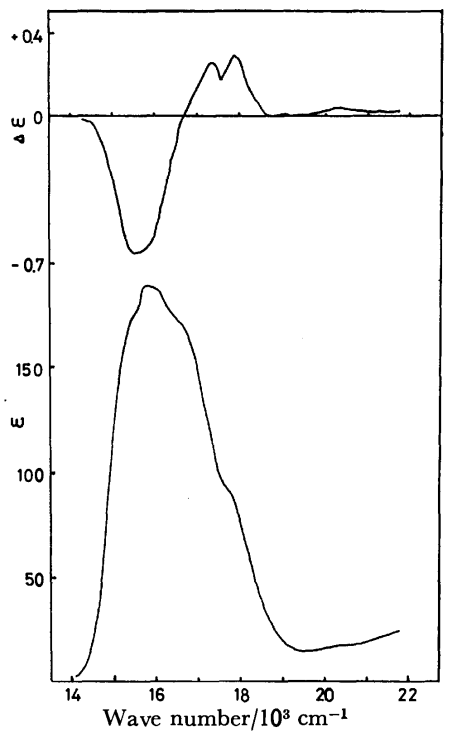

Fig. 5. Vis and MCD spectra of tetrabutylammonium salt of $[Co^{II}W_{12}O_{40}]^{6-}$ in acetonitrile solution.

to $^4T_1(G)\leftarrow{}^6A_1(S)$, $^4A_1(G)+{}^4E(G)\leftarrow{}^6A_1(S)$ and the charge transfer band, respectively. A very sharp band at 24210 cm^{-1} corresponds to a sharp band observed commonly in other high-spin d^5 ions such as $Mn(H_2O)_6^{2+}$ and $Fe(H_2O)_6^{3+}$, being on account of the independence of *Dq*. The negative MCD peak corresponding to this absorption is also very sharp. The very weak shoulder about 24×10^3 cm^{-1} which has been suggested as $^4T_2(G)\leftarrow{}^6A_1(S)$ from the spectral shape in the aqueous solution,[8] is obscure in this visible spectrum. However, the MCD spectrum shows such a band explicitly at 23950 cm^{-1}. The higher peaks due to d-d transitions of Fe(III) ion are swamped by the tail of the charge transfer band in both the electronic and the MCD spectra. These spectral data give us a 10 *Dq* value of 6200 cm^{-1} and a *B* value of 740 cm^{-1}, where the previously reported values are 6000 and 810 cm^{-1}, respectively. The 10 *Dq* value is in good agreement with the expected value, 4/9 of a 10 *Dq* value, 14200 cm^{-1}, for $Fe(H_2O)_6^{3+}$, *i.e.* about 6300 cm^{-1}.

The near-infrared, UV-vis absorption spectra, and the MCD spectrum in visible region of 12-tungstocobaltate(II) **3** are shown in Figs. 2, 3, and 5. The absorption spectrum shows the typical pattern of many common tetrahedral Co(II) complexes;[21] in the near-infrared region the spin-allowed transition to the excited quartet state, $^4T_1(F)\leftarrow{}^4A_2(F)$, at *ca.* 7.8×10^3 cm^{-1} and in the visible region $^4T_1(P)\leftarrow{}^4A_2(F)$ at *ca.* 16×10^3 cm^{-1}. In the UV region, there is a strong band at 38460 cm^{-1} (ε 35200) due to the charge transfer transition of the lattice. The near-infrared band exhibits much fine structure. Since many more peaks are observed than predicted by spin-orbit coupling, another causes must be sought; one may be a Jahn-Teller effect in the excited state.[21] The peak ($^4T_1(F)\leftarrow{}^4A_2$, 7.8×10^3 cm^{-1}) suggests a 10 *Dq* value of about 4100 cm^{-1}. This is estimated by using the energy level diagram for tetrahedrally coordinated Co(II), presented by Cotton and his coworkers.[21] The value is in good agreement with the expected values, 4/9 of 9200 cm^{-1} (the 10 *Dq* value of $Co(H_2O)_6^{2+}$), *i.e.* about 4090 cm^{-1} and the 10 *Dq* value of 4230 cm^{-1} for $Co(OH)_4^{2-}$.

The visible band is complicated because of a number of transitions to doublet excited states which occur in the same region, and these gain some of their intensity by means of spin-orbit coupling.[22] However, the corresponding MCD spectrum is much more resolved and suggests at least four different transitions; (1) intense and broad band with negative sign centered at *ca.* 15.6×10^3 cm^{-1}, (2) positive band at *ca.* 17.3×10^3 cm^{-1}, (3) positive band at *ca.* 17.9×10^3 cm^{-1}, and (4) weak and broad band with positive sign at *ca.* 20.4×10^3 cm^{-1}. There are further complications because each of (1), (2), and (3) includes some components. However, as suggested from the sign and the intensity of MCD, the band (1) will be mainly dominated by spin-allowed transition to a quartet excited state and the others (2)—(4) by transitions to doublet excited ones.

This type of heteropolyanions studied here is a real tetrahedral complex and stable even in dilute nonaqueous solution. These compounds lie in high-spin state, or paramagnetic state because of small 10 *Dq*. The crystal field theory and ligand field theory, which have been applied to the traditional octahedral coordination complexes, are acceptable to explain the spectral and magnetic properties.

(Received April 6, 1981)

The title ligand (L) has been resolved through its *d*-tartrato-nickel(II) complex. The X-ray analysis shows that the less-soluble $(-)_{589}$-diastereomer has a dimer structure with the folded macrocycles, [{NiL}$_2$(*d*-tart)(H$_2$O)]-(ClO$_4$)$_2$·2H$_2$O, and that the chiral carbon atoms have the absolute configuration of *S*. Axial methyl groups of geminal dimethyl pairs of each nickel(II) complex in the dimer provide stereoselective environment for the coordination site of the *d*-tartrate ion. Stereospecific hydrogen-bonds between a secondary amine group of the macrocyclic ligand or coordinated water and hydroxyl or carboxyl oxygens of the *d*-tartrate ion play also an important role in the optical resolution. Pairs of enantiomers of the free ligand and three isomers of the four-coordinate nickel(II) complex have been isolated. Circular dichroism spectra of various four- and six-coordinate complexes with the optically active ligand have been described.

Transition metal complexes of the tetraaza-fourteen membered macrocyclic ligand (L) **1** have been studied in depth.[1] However, the optically active form of the ligand has not been reported so far, although unsuccessful attempts of the optical resolution of its nickel(II) complex, [Ni(*rac*-L)]$^{2+}$, by column chromatography have been documented.[2] In this study, we aimed to resolve *rac*-L into the optically active form. The nickel(II) complex, [Ni(*rac*-L)]$^{2+}$, has been known to exist as three isomeric α-, β-, and γ-forms and their structures have been determined by X-ray analyses and ^{1}H NMR study as shown in structural formulae **2**—**4**.[3,4] The isomerism arises from a difference in conformations of six- and five-membered chelate rings associated with combination of chiralities of the four coordinated secondary amine nitrogens. Of these three isomers, only the α-isomer reacts readily with a bidentate ligand such as oxalate, acetylacetonate, acetate, or nitrate ion to form *cis*-type six-coordinate complexes with the macrocycle folded.[4-6] It was anticipated that optically active bidentate ligands such as (*R*)-1,2-propanediamine, (*S*)-amino acidate, and (*R*,*R*)-*d*-tartrate ions might react stereospecifically with the α-isomer to give sterically favored six-coordinate diastereomers and thereby the racemic ligand could be resolved into the enantiomers. The optical resolution of *rac*-L has been achieved successfully with *d*-tartrate ions. The absolute configurations of chiral centers have been determined by the X-ray crystallographic analysis of the less-soluble diastereomer. Preparations and circular dichroism spectra of various nickel(II) complexes with the optically active ligand are also described. Throughout this paper, abbreviations, *SS*-L and *RR*-L, are used for the ligand with the C(7)*S*,C(14)*S*- and C(7)*R*,C(14)*R*-configurations, respectively. The racemic mixture is designated as *rac*-L.

Experimental

Materials. The racemic complex, α-[Ni(*rac*-L)](ClO$_4$)$_2$, was prepared as reported previously.[4]

$(-)_{589}$-[{Ni(SS-L)}$_2$(d-tart)(H$_2$O)](ClO$_4$)·2H$_2$O. Addition of 7.2 g of tetrabutylammonium bromide to an acetonitrile solution of α-[Ni(*rac*-L)](ClO$_4$)$_2$ (4.0 g in 160 cm^3) gives green precipitate of the bromide salt (yield, 3.6 g). Found: C, 38.61; H, 7.43; N, 11.00%. Calcd for NiC$_{16}$H$_{36}$N$_4$Br$_2$: C, 38.20; H, 7.21; N, 11.14%. Four grams of the bromide (8.0 mmol) are dissolved in 160 cm^3 of water at room temperature and 0.50 g of sodium *d*-tartrate dihydrate (2.2 mmol) dissolved in a minimum amount of water are added portionwise. Color of the solution turns gradually greenish brown. After 30 min, 0.60 g of sodium perchlorate (4.0 mmol) dissolved in a minimum amount of water is added to this solution. Then the solution is chilled in an ice-bath for 1 h. The blue-violet precipitate is filtered and washed with chilled water, ethanol, and ether. Yield, 1.70 g. The filtrate (solution A) contains the other enantiomer and is used in the subsequent treatment (see below). The optical purity is checked by the *g*-value of the product in 1 mol dm^{-3} perchloric acid, where $g=|\Delta\varepsilon_{440}|/\varepsilon_{450}$ is 0.018 for the optically pure form. Judging from the *g*-value, the optical purity of the product at this stage is more than 90%. Recrystallization from acetonitrile gives blue-violet crystals. Found: C, 40.33; H, 7.71; N, 10.78%. Calcd for Ni$_2$C$_{36}$H$_{82}$N$_8$Cl$_2$O$_{17}$: C, 39.76; H, 7.60; N, 10.30%.

α-, β-, and γ-[Ni(SS-L)](ClO$_4$)$_2$. The optically active α-isomer is prepared by stirring 2.0 g of $(-)_{589}$-[{Ni(*SS*-L)}$_2$-(*d*-tart)(H$_2$O)](ClO$_4$)$_2$·2H$_2$O in 30 cm^3 of 70% perchloric acid at room temperature. Within a few min, the starting blue-violet complex decomposes to give a bright orange solution. A yellow product is obtained upon addition of cold water to the solution, and is recrystallized from 0.1 mol dm^{-3} perchloric acid. Found: C, 34.73; H, 6.73; N, 10.03%. Calcd for $NiC_{16}H_{36}N_4Cl_2O_8$: C, 35.45; H, 6.69; N, 10.34%. The β-derivative is prepared from the α-isomer following the reported procedure for the racemate[3] and recrystallized from 0.1 mol dm^{-3} perchloric acid. Found: C, 34.60; H, 6.53; N, 10.05%. Large red-orange crystals are obtained from a dilute solution of either α- or β-[Ni(*SS*-L)](ClO$_4$)$_2$ upon standing the solution for several days. These are identified with the ^{1}H NMR spectrum in CH$_3$CN-d_3 to be the γ-isomer. In contrast to the α- and β-isomers, the ^{1}H NMR spectrum of the γ-isomer shows that the six methyl groups are not pairwise equivalent.[3] Found: C, 34.88; H, 6.59; N, 10.32%.

(+)$_{589}$-[{Ni(RR-L)}$_2$ox](ClO$_4$)$_2$·H$_2$O. To the solution A (see above) is added 1.0 g of sodium oxalate and 1.0 g of sodium perchlorate. The solution is basified to pH ≈10 with aqueous sodium hydroxide to give a pale blue product. This is a well characterized racemic oxalate dimer, [{Ni(*rac*-L)}$_2$ox]-(ClO$_4$)$_2$,[1a,4] and is filtered off (*ca.* 1.3 g).[7] The pH of the blue filtrate is adjusted to ≈1 with dropwise addition of 60% perchloric acid in an ice-bath to yield a blue-violet product. This is almost optically pure $(+)_{589}$-[{Ni(*RR*-L)}$_2$ox](ClO$_4$)$_2$·H$_2$O (yield, 1.12 g) and is recrystallized from methanol. Found: C, 40.93; H, 7.54; N, 11.30%. Calcd for Ni_2C_{34}-$H_{74}N_8Cl_2O_{13}$: C, 41.12; H, 7.52; N, 11.30%. The structural formula is tentative. The addition of excess perchloric acid results in decomposition of the blue-violet product and formation of the yellow α-isomer.

α-, β-, and γ-[Ni(RR-L)](ClO$_4$)$_2$. α-, β-, and γ-Complexes of *RR*-L are obtained from $(+)_{589}$-[{Ni(*RR*-L)}$_2$ox]-(ClO$_4$)$_2$·H$_2$O in a manner similar to synthetic procedures for the *SS*-L complexes from $(-)_{589}$-[{Ni(*SS*-L)}$_2$(*d*-tart)(H$_2$O)]-(ClO$_4$)$_2$·2H$_2$O. Crude products are recrystallized from 0.1 mol dm^{-3} perchloric acid. Found for α: C, 34.65; H, 6.59; N, 10.09%. Found for β: C, 34.85; H, 6.60; N, 10.16%. Found for γ: C, 34.78; H, 6.63; N, 10.28%.

Optically Active Free Ligands. Following the reported procedures for the racemate,[8,9] the optically active free ligand is obtained from α-[Ni(*SS*- or *RR*-L)](ClO$_4$)$_2$ by sodium cyanide decomposition in strongly alkaline aqueous media (yield>90%). Found for *SS*-L: C, 66.03; H, 13.16; N, 19.18% (C/N=4.02). Found for *RR*-L: C, 66.14; H, 13.14; N, 19.43% (C/N=4.03). Calcd for $C_{16}H_{36}N_4$·0.5H$_2$O: C, 65.48; H, 12.70; N, 19.08% (C/N=4.00).

Measurements. The electronic absorption and circular dichroism spectra were recorded on a Hitachi 340 spectrophotometer and a JASCO J-40 spectropolarimeter, respectively. Optical rotations were measured with a JASCO DIP-4 polarimeter.

X-Ray Analysis. Blue-violet prismatic single crystals of the less-soluble diastereoisomer, $(-)_{589}$-[{Ni(*SS*-L)}$_2$(*d*-tart)-(H$_2$O)](ClO$_4$)$_2$·2H$_2$O, were obtained from an acetonitrile solution. A specimen with dimensions 0.28 mm × 0.32 mm × 0.36 mm was used for the X-ray study. Diffraction data were measured on a Rigaku AFC-5 diffractometer with graphite monochromatized Mo *Kα* radiation. Within the range $2\theta < 60°$, 5310 independent reflections with $|F_o| > 3\sigma(|F_o|)$ were obtained. Intensities were corrected for Lorentz and polarization factors but not for absorption.

Crystal data are: Monoclinic, P2$_1$, a=17.568 (3), b=11.482 (2), c=13.272 (2) Å, β=102.59 (1)°, U=2612.8 (6) Å^3, Z=2, D_m=1.39, D_x=1.39 g cm^{-3}, μ(Mo*Kα*)=8.95 cm^{-1}.

The structure was solved by the heavy atom method and refined by a block-diagonal least-squares method. The weighting scheme, $w=[\sigma_{count}{}^2+(0.015|F_o|)^2]^{-1}$, was employed. All hydrogen atoms except for those of water of crystallization and one of the methyl protons were located by the difference Fourier syntheses, and included in the final refinement with the isotropic temperature factors. The final R indicies were R=0.047 and R_w=0.057. Table 1 lists the final atomic coordinates.[10]

The calculations were carried out on the HITAC M-200H computer at the Computer Center of the Institute for Molecular Science with Universal Crystallographic Computation Program System UNICS III.[11]

Results and Discussion

Optical Resolution and Syntheses of the Nickel(II) Complexes with the Optically Active Ligand. The optical resolution of *rac*-L was performed by taking advantage of the characteristic nature of α-[Ni(*rac*-L)]$^{2+}$; this isomer readily forms *cis*-type six-coordinate complex with a bidentate chelate ligand. The use of *d*-tartrate has proved successful. But attempts by use of (*R*)-1,2-propanediamine and (*S*)-proline were ineffective, although they reacted with the α-complex to give six-coordinate complexes.

As has been well characterized, the α-isomer isomerizes in neutral or at much faster rate in basic media to the thermodynamically more stable β-isomer to give an equilibrium mixture.[4] Therefore, the perchlorate salt of the α-isomer was converted to the bromide salt so as to enhance the solubility and to dissolve quickly the racemic compound in the α-form in water. Reaction of α-[$NiBr_2$(*rac*-L)] with *d*-tartrate salt and subsequent addition of sodium perchlorate yielded the crystalline less-soluble diastereomer. Addition of excess sodium perchlorate gave less optically pure product. On account of the two facts mentioned above, the conversion of the perchlorate to the bromide is essential for the present synthetic procedures.

The less-soluble diastereomer was shown to be $(-)_{589}$-[{Ni(*SS*-L)}$_2$(*d*-tart)(H_2O)](ClO_4)$_2$·$2H_2O$ by the X-ray analysis (*vide infra*). The other enantiomer was isolated as the oxalate dimer, $(+)_{589}$-[{Ni(*RR*-L)}$_2$ox]-(ClO_4)$_2$·H_2O. When sodium oxalate is added to the filtrate obtained after the isolation of the less-soluble diastereomer, two kinds of oxalate dimers, optically active and racemic ones, are obtained. Since the perchlorate of the racemic compound is practically insoluble while the optically active one is fairly soluble in methanol, the separation of these two oxalate dimers are accomplished easily.

The optical purities of the diastereomer and the oxalate dimers were examined at each step of procedures by monitoring *g*-values ($\Delta\varepsilon_{440}/\varepsilon_{450}$) of the complexes dissolved in 1 mol dm^{-3} perchloric acid, where all the compounds are converted to four-coordinate complexes in the α-form.

The optically active four-coordinate complexes of α-, β-, and γ-[Ni(*SS*- or *RR*-L)](ClO_4)$_2$ were obtained from [{Ni(*SS*-L)}$_2$(*d*-tart)(H_2O)](ClO_4)$_2$·$2H_2O$ or [{Ni(*RR*-L)}$_2$ox](ClO_4)$_2$·H_2O in a way similar to the procedure for the isolation of the respective racemic complexes.

A pair of enantiomers of free ligand has been isolated successfully from the optically active nickel(II) complexes in a synthetic scale. Using these ligands, optically active complexes of other metal ions can be prepared.[12]

X-Ray Structure Analysis of $(-)_{589}$-[{*Ni*(SS-*L*)}$_2$(*d*-*tart*)(*H_2O*)](*ClO_4*)$_2$·*$2H_2O$*. The structure analysis revealed that the compound is a dimer of [Ni(*SS*-L)]$^{2+}$ with a bridged *d*-tartrate ion. A stereoscopic view of the dimer is shown in Fig. 1, in which only hydrogen atoms of NH groups and those bonded to chiral carbon atoms are depicted. Bond lengths and angles within the dimer are listed in Tables 2 and 3, respectively. Each Ni(II) in the dimer has a six-coordinate structure with

a folded macrocycle as anticipated. The bridged *d*-tartrate ion is coordinated to Ni(1) and Ni(2) unsymmetrically: one carboxyl group of the *d*-tartrate ion is coordinated to Ni(1) bidentately (O(1) and O(2)), while the other carboxyl group is coordinated to Ni(2) unidentately (O(3)). The sixth coordination site of Ni(2) is occupied by water (Ow(c)).

Each macrocycle (L) in the NiL dimer is folded about N(4)–Ni(1)–N(11) and N(4')–Ni(2)–N(11'). All these nitrogens are adjacent to the geminal dimethyl carbon atoms. A similar structural feature has been found in the crystal structure of [Ni(OAc)(*rac*-L)]$(ClO_4)_2$, where OAc is an acetate ion.[5] This is most likely owing to the following reason. When the macrocycle is folded from its coplanar nitrogen geometry, the nitrogen atom adjacent to the single methyl carbon is more easily lifted than that adjacent to the geminal dimethyl carbon atom is.[13] As a result, the more crowded side of the macrocycle, *i.e.*, that with the two geminal dimethyl groups, is directed toward the *d*-tartrate ion in each Ni(II) complex in the dimer. As a consequence, the axial methyl groups of the geminal dimethyl pairs in the folded macrocycle give stereoselective environments to the sites of *d*-tartrate coordination. Furthermore, stereospecific intramolecular hydrogen-bonds are observed between a secondary amine group of the macrocyclic ligand and hydroxyl oxygen of the *d*-tartrate ion and between a coordinated water molecule and the uncoordinated carboxyl oxygen : N(11')–H···O(5), 3.246(7) Å; Ow(c)···O(4), 2.605(6) Å (see Fig. 1). The preferred coordination of the *d*-tartrate ion to the *SS*-L complex over the *RR*-L complex is effected by the steric interactions with the axial methyl groups of the macrocyclic ligands and the stereospecific intramolecular hydrogen-bonds. In view of the fact that the use of (*S*)-prolinate ion or (*R*)-1,2-propanediamine as a resolving agent was not effective, the stereospecific hydrogen-bonds play more important roles in the optical resolution.

Each chelate ring adopts the most strain free conformation: all the six-membered rings take the chair form with the single methyl groups in equatorial positions; all the five-membered rings are in the gauche conformation. It should be noted that the macrocycle cannot adopt such a most strain free chelate ring conformation in the planar coordination.

The observed Ni–N and Ni–O distances are within the normal range for octahedral nickel(II) complexes. Chelation of the carboxyl group of the *d*-tartrate ion to Ni(1) results in a small angle of O(1)–Ni(1)–O(2) (61.0(2)°), giving a distorted octahedral geometry around the Ni(1) atom. The value is comparable to the corresponding angle of 62.4(3)° reported for [Ni(OAc)(*rac*-L)](ClO_4).[5]

Absolute configurations of the chiral centers were determined on the basis of that of the *d*-tartrate ion. All the chiral carbon atoms have the absolute configuration of *S* and all the chiral nitrogen atoms have *R*

configuration.

Intermolecular hydrogen-bonds are observed among water of crystallization (Ow), secondary amine groups of the macrocyclic ligands, hydroxyl oxygen atom of the *d*-tartrate ion (O(6)), a coordinated water molecule, and perchlorate oxygen atoms (Op).[14] Other intermolecular contacts appear to be normal.

Absorption and Circular Dichroism Spectra. Absorption (AB) and circular dichroism (CD) spectra of some four- and six-coordinate complexes are presented in Figs. 2 and 3, respectively. The spectral data are summarized in Table 4. As reported for other tetraazamacrocyclic nickel(II) complexes,[1] AB spectra of the present complexes in the d-d region consists of single bands for four-coordinate complexes and three main bands for six-coordinate complexes.

As for the spectra of four-coodinate complexes, perchlorates of the three isomers in acidic aqueous solutions show similar AB spectra but their CD spectra are significantly different from each other (Fig. 2). The difference in the CD spectra provides some informations on subtle solution behaviors of the compounds, which had not been detected from absorption spectral studies.

It has been reported that α-[Ni(*rac*-L)](ClO_4)$_2$ gives blue, green, and violet solutions when dissolved in *N*,*N*-dimethylformamide, dimethylsulphoxide, and acetonitrile, respectively, in spite of the yellow-orange color in the solid state.[4] This has been interpreted as equilibria between four-coordinate species having singlet ground states and six-coordinate triplet species with two solvent molecules in the first coordination sphere:

α-[Ni(*rac*-L)]$^{2+}$+2 solvent⇌α-[Ni(*rac*-L)(solvent)$_2$]$^{2+}$.

Absorption spectra of these solutions show the charac-

a) Data for the β- and γ-isomers of *RR*-L are not listed. They are enantiomeric to the data for the *SS*-L complexes. b) s: four-coordinate singlet species; t: six-coordinate triplet species. c) In this solvent, the compound exists as an equilibrium mixture. The apparent values for ε and Δε at 20 °C are given.

teristic absorptions both for four-coordinate singlet species and six-coordinate triplet species of nickel(II).[4] The AB and CD spectra in acetonitrile are shown in Fig. 3, the equilibrium being shifted toward the triplet form. In water, however, which should have strong coodinating ability, only an absorption band corresponding to the four-coordinate species has been reported.[4] This has been in contrast to the case with unsubstituted fully-saturated tetraaza-macrocyclic nickel(II) complexes, where such equilibria in water are clearly observed and the equilibrium constants and the thermodynamic parameters are studied in detail.[15-20] The CD spectrum of α-[Ni(*SS*-L)]$(ClO_4)_2$ in 0.01 mol dm^{-3} perchloric acid shows clearly a positive band ($\Delta\varepsilon=+0.12$) at 10400 cm^{-1} and a weak negative band ($\Delta\varepsilon=-0.03$) at 17400 cm^{-1} as well as strong bands due to the four-coordinate species. The exactly enantiomeric CD spectrum was observed with α-[Ni(*RR*-L)]$(ClO_4)_2$. These facts indicate an equilibrium between the four-coordinated and the diaquated six-coordinate species attains in water. It is difficult to detect the corresponding AB bands under usual experimental conditions because of the low solubility of the compound. But careful measurements revealed very weak AB bands at 10000 and 17100 cm^{-1} (see Table 4).

It is well known for analogous systems that the equilibria can be shifted toward the four-coordinate species by increasing the temperature and/or by increasing the concentration of perchlorate ions.[15-20] In 60% perchloric acid solution of the present α-complex, no AB and CD bands corresponding to the diaquated species were detected at 30 °C. From this spectrum, the molar extinction coefficient (ε) at the absorption maximum of the pure four-coordinate species was evaluated to be $\varepsilon_{447}=80$ dm^3 mol^{-1} cm^{-1}. Using this value, the equilibrium constant ($K=$[[α-Ni(*rac*-L)$(H_2O)_2$]$^{2+}$]/[α-[Ni(*rac*-L)]$^{2+}$]) in 0.01 mol dm^{-3} perchloric acid solution was determined to be 0.19 at 20 °C: the complexes in the solution consist of 16% six-coordinate and 84% four-coordinate species. The positions of the AB and CD bands due to the diaquated six-coordinate species are close to those observed for [{Ni(*SS*-L)}$_2$(*d*-tart)(H_2O)]$^{2+}$ and [{Ni(*RR*-L)}$_2$ox]$^{2+}$ (see Table 4). This indicates that the diaquated species of α-[Ni(*rac*-L)]$^{2+}$ has a *cis*-NiO_2N_4 structure. Compounds of the *trans*-NiO_2N_4 type show AB bands around 9000, 15000, and 29000—30000 cm^{-1}.[7,21,22]

The perchlorates of all the α-, β-, and γ-isomers give finally identical AB and CD spectra when dissolved in 10^{-3} mol dm^{-3} sodium hydroxide solution, where the compounds can isomerize to more stable forms. The resulting CD spectra are almost the same as that of the β-isomer in weakly acidic solution (Table 4). In the equilibrated solution, the predominant species is the β-form and the amounts of the α- and γ-forms are very small, if any. Nevertheless, the γ-isomer can easily be isolated as large crystals, because of the very low solubility, upon standing the equilibrated dilute solution for a long time.

As shown in Fig. 3, the AB spectra of $(-)_{589}$-[{Ni(*SS*-L)}$_2$(*d*-tart)(H_2O)]$^{2+}$ and $(+)_{589}$-[{Ni(*RR*-L)}$_2$-ox]$^{2+}$ are quite similar and their CD spectra are almost enantiomeric. This fact indicates that the CD patterns are determined by the chiralities associated with the coordinated macrocyclic ligand and that the effects of the *d*-tartrate ion on the CD pattern are small.

Figure 3 shows that the CD intensity of the α-isomer is stronger than those of the β- and γ-isomers. This is most likely because only the α-isomer has a skeletal chirality (see **2**—**4**). In view of the structure found in the crystal of the α-isomer of the racemic perchlorate **2**,[3] the optically active α-isomer containing *RR*-L would have six-membered rings in the λ twist conformation and five-membered rings in the δ gauche conformation.

Crystal Structure and Absolute Configuration of *d*-Tartaric Acid-(+)$^{CD}_{500}$-Tris(2-aminoethanesulfenato)cobalt(III)-Water (1/1/1)

Masakazu KITA,* Kazuaki YAMANARI, Katsuki KITAHAMA,† and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

†*The Institute of Scientific and Industrial Research, Osaka University, Yamadagaoka, Suita, Osaka 565*

(Received April 13, 1981)

The crystal structure and absolute configuration of diastereomeric molecular compound, *d*-$C_4H_6O_6\cdot(+)^{CD}_{500}$-$[Co\{S(O)CH_2CH_2NH_2\}_3]\cdot H_2O$, were determined by the X-ray diffraction method. The crystals are orthorhombic with space group $P2_12_12_1$, $Z=4$, and $a=13.034(4)$, $b=13.559(6)$, and $c=11.048(8)$ Å. The rifinement of 1724 reflections (Mo $K\alpha$ radiation) led to $R=0.068$. The complex molecule has the configuration *fac*(*S*)-*Λ*-(δ,δ,δ)-(*R*, *R*, *R*). All amino groups and the sulfenato oxygen atoms form hydrogen bonds with *d*-tartaric acid and/or water molecules three-dimensionally, which is responsible for the formation of the novel diastereomeric molecular compound.

Free sulfenic acids are recognized as important intermediates in reactions of many sulfur-containing organic compounds,[1,2] but a few ones have ever been isolated[1-3] because of the instability.[2,4,5] Some sulfenic acids which are S-coordinated to a cobalt(III) ion are stabler than their corresponding free acids,[6-11] their complexes providing a means for investigating the chemistry of sulfenic acids. Furthermore, sulfenato complexes are important for an understanding of redox reactions associated with metal-sulfur enzymes.[12]

The previous letter[11] reported the preparation and optical resolution for *fac*(*S*)-$[Co\{S(O)CH_2CH_2NH_2\}_n\{S(O)_2CH_2CH_2NH_2\}_{3-n}]$ type ($n=3$, 2, 1, and 0). In particular, one of the isomers of $[Co\{S(O)CH_2CH_2NH_2\}_3]$ was resolved by means of preferential crystallization of a diastereomeric molecular compound with *d*-tartaric acid, which is the first example of optical resolution by molecular compound formation in the field of metal complex chemistry. The crystal structure determination of this molecular compound, *d*-tartaric acid – (+)$^{CD}_{500}$-tris(2-aminoethanesulfenato)cobalt(III) – water (1/1/1), is especially of interest in connection with (1) the absolute stereochemistry of this complex (*i.e.*, the absolute configuration about the cobalt center (*Δ* or *Λ*) and those of the three asymmetric sulfur donor atoms (*R* or *S*)), (2) the intramolecular bond distances in comparison with those of monosulfenato complex $[Co\{S(O)CH_2CH_2NH_2\}(en)_2](SCN)_2$,[10] and (3) intermolecular interactions among the complex, *d*-tartaric acid, and water in the packing (en=ethylenediamine).

Experimental

Preparation of Compound. The diastereomeric molecular compound was prepared by the reported procedure.[11] Recrystallization of the compound from an ethanol-water (2 : 1) solution gave orange-red crystals in the form of rectangular prism. Found: C, 23.72; H, 5.22; N, 8.35%. Calcd for *d*-$C_4H_6O_6\cdot(+)^{D}_{500}$-$[Co\{S(O)CH_2CH_2NH_2\}_3]\cdot H_2O=C_{10}H_{26}N_3O_{10}S_3Co$: C, 23.86; H, 5.21; N, 8.35%.

Data Collection. Precession photographs exhibited systematic absences $h=$odd for $h00$, $k=$odd for $0k0$, and $l=$odd for $00l$, indicating the unique space group $P2_12_12_1$. An orange-red crystal, of approximate dimensions 0.18 mm × 0.20 mm × 0.30 mm, was mounted with its long dimension along the axis of a glass fiber to protect it from moisture. The diffraction intensities were measured using a Rigaku four-circle diffractometer, with a graphite monochromatized Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). Accurate lattice parameters were obtained by least-squares refinement of ten high angle reflections. The crystal data are summarized in Table 1. Three standard reflections fluctuated within 4% in intensity over the time of data collection. Within the sphere $2\theta<50°$, 1968 unique reflections were obtained. Among them 1724 reflections were $|F_o|>3\sigma_{cs}$ (σ_{cs} is the standard deviation of F in counting statistics). Only these reflections were used for the structure determination and refinement. No absorption correction was applied.

Table 1. Crystal data

$C_{10}H_{26}N_3O_{10}S_3Co$	$F.W.=503.44$
Orthorhombic	Space group $P2_12_12_1$
$a=13.034(4)$ Å	
$b=13.559(6)$ Å	
$c=11.048(8)$ Å	
$U=1952.49$ Å^3	
$D_m=1.70(5)$ g cm^{-3} (by flotation)	
$D_c=1.72$ g cm^{-3}	$Z=4$
μ(Mo $K\alpha$)$=13.44$ cm^{-1}	

Structure Solution and Refinement. The structure was solved by the usual heavy-atom method; the positions of cobalt and sulfur atoms were picked up by means of the Patterson synthesis, and all the nonhydrogen atoms were located by the subsequent Fourier synthesis. Absolute configurations of the two asymmetric carbon atoms of *d*-tartaric acid were fitted to those reported previously.[13] Therefore, the absolute configuration of the metal complex molecule, $[Co\{S(O)CH_2CH_2NH_2\}_3]$, was determined definitely. The structure was refined by the block-diagonal least-squares method with the positional and isotropic thermal parameters for all nonhydrogen atoms. Further subsequent refinement was carried out using anisotropic thermal parameters for all nonhydrogen atoms. In the last cycles of least-squares refinement, 245 parameters were varied including an overall thermal parameter, a scale factor, positional and anisotropic thermal parameters for all nonhydrogen atoms. Convergence was achieved with $R=0.075$ ($R=\sum||F_o|-|F_c||/\sum|F_o|$). Although no hydrogen position was detected from the difference electron density map, hydrogen positions except those of carboxyl and hydroxyl groups of *d*-tartaric acid and those of water were tentatively calculated based on the following conditions; N-H=0.87 Å, C-H=0.97 Å, and tetrahedral geometry. Postulating $B=4.0$ Å^3 for each H atom, these twenty H atoms were added to the least-squares refinement, which gave the final R value of 0.068.

Atomic scattering factors from International Tables for

X-Ray Crystallography[14] were used for Co, S, O, N, C, and H atoms. Anomalous dispersion correction was made for Co and S atoms.[14] All computations were performed on an ACOS-S700 at Crystallographic Research Center, Institute for Protein Research, Osaka University. The computer programs used were RSSFR-5,[15] HBLS V,[16] DAPH,[17] and ORTEP.[18]

Final positional parameters, the corresponding isotropic thermal parameters which were calculated from respective anisotropic ones by Hamilton's method,[19] and their estimated standard deviations for nonhydrogen atoms are given in Table 2. The calculated positional parameters of hydrogen atoms, the anisotropic thermal parameters for all nonhydrogen atoms, and the complete list of the $|F_o|$ and $|F_c|$ values have been preserved by the Chemical Society of Japan (Document No. 8143).

a) The estimated error in the last digit is shown in parentheses. This form is used throughout. b) O(10) is for the water of hydration; the rest of numberings are as shown in Fig. 1. c) B is evaluated from the corresponding anisotropic thermal parameters according to Ref. 17. Isotropic thermal parameters are of the form $\exp\{-B(\sin^2\theta/\lambda^2)\}$.

Results and Discussion

Figure 1 shows the notation of the complex, *d*-tartaric acid, and the oxygen atom of water. Nonhydrogen atom bond distances and angles are given in Tables 3 and 4, respectively. Table 5 lists several selected plane equations, sets of deviations of atoms from the plane, and dihedral angles between the pair of planes.

Structure of $(+)^{CD}_{500}$-$[Co\{S(O)CH_2CH_2NH_2\}_3]$. The perspective view of the complex projected down its threefold axis is shown in Fig. 2. The cobalt(III) center is six-coordinate in approximately octahedral configuration (Table 5). The bidentate 2-aminoethanesulfenate coordinates to a cobalt(III) ion through sulfur and nitrogen atoms and the complex has *fac*(*S*) geometry. The average coordination angles of S–Co–S, N–Co–N, and S–Co–N (the S and N atoms are in trans) are 89.4°, 90.7°, and 177.7°, respectively (Table 4). The values indicate that the CoS_3 parasol constituted of three facial S atoms and a Co atom at the top is less blown

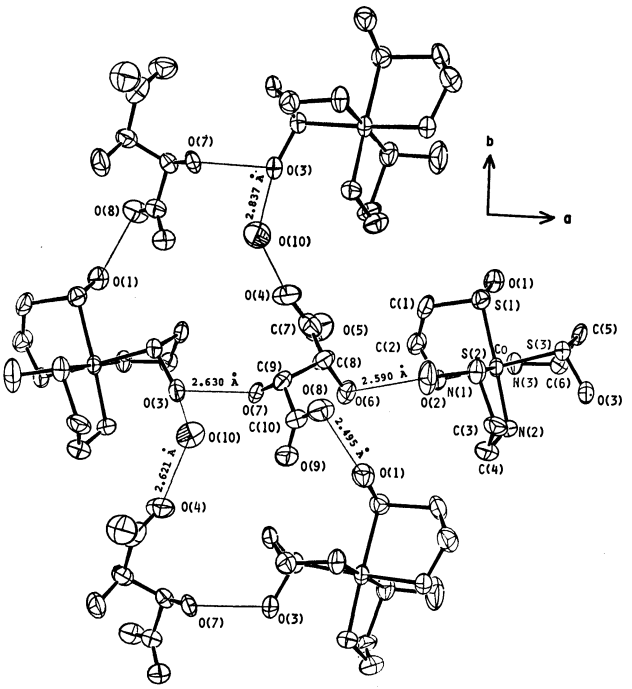

Fig. 1. A perspective view of a layer constituted by hydrogen bonds onto ab plane projected along c-axis, where line bonds denote hydrogen bonds within 3.10 Å. Thermal ellipsoids are drawn at the 50% probability level.

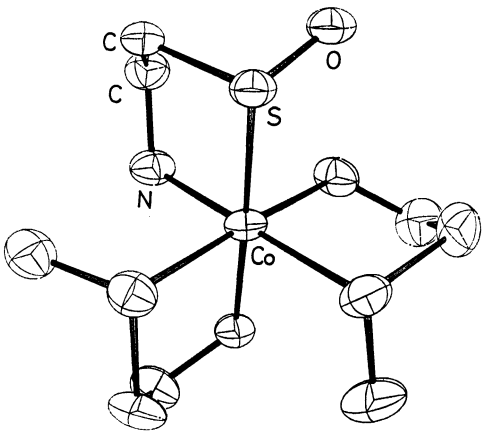

Fig. 2. A perspective drawing of the complex projected down the threefold axis of the complex (50% probability thermal ellipsoids).

than the corresponding CoN_3 parasol. The three sulfenato sulfur atoms are three-coordinate (to the cobalt atom, the carbon atom of chelate ring, and the oxygen atom) in an approximately tetrahedral configuration counting the sulfur lone pair of electrons as occupying the fourth site. The oxygen atoms of sulfenato groups occupy the least repulsive positions on the *fac*(*S*) plane to one another. Therefore, the oxygen atoms are on the plane perpendicular to the threefold axis of the complex.

Since the sulfur atom of sulfenato group becomes chiral on coordination, the stereochemical possibilities for this *fac*(*S*) complex are as follows: (1) the wrapping of the chelate rings about the cobalt center may be either Δ or Λ, (2) the conformations of the three chelate rings generate four sets of isomers (δ,δ,δ), (δ,δ,λ), (δ,λ,λ), and (λ,λ,λ), and (3) four configurations (*R*,*R*,*R*), (*R*,*R*,*S*), (*R*,*S*,*S*), and (*S*,*S*,*S*) are possible from the combination of three chiral sulfur atoms. Therefore, 32 configurations in all, *i.e.*, 16 enantiomeric pairs of diastereoisomers are expected. However, the crystal contains only the configuration *fac*(*S*)-Λ-(δ,δ,δ)-(*R*,*R*,*R*). The result is consistent with the previous assignment based on the absorption, CD, and ^{13}C NMR spectra.[11]

Table 6 shows the selected bond distances and angles of the complex in comparison with those of Δ-{$\lambda'(S)$, λ,δ}[Co{S(O)$CH_2CH_2NH_2$}$(en)_2$]$^{2+}$.[10] There are no large differences between the two complexes in the bond distance and angle. In the monosulfenato complex ion, the Co–N distance (2.048 Å) *trans* to the sulfur donor atom is significantly larger than the average *cis* Co–N one (1.976 Å) which is consistent with the ordinary Co–N distance. Such a phenomenon is referred to as *structural trans effect* (*STE*).[10] The present *fac*(*S*) complex has exclusively the *trans* Co–N bond. The average Co–N distance is longer than the ordinary Co–N one but trivially shorter than the *trans* Co–N distance of the monosulfenato cobalt(III) complex ion. The Co–S bond distance (2.226 Å) is also somewhat shorter than that (2.253 Å) of the reference complex. The XPS data of both complexes show the existence of a significant amount of electron-transfer from the sulfenato sulfur donor atom to cobalt(III) ion in comparison with the tris(ethylenediamine)cobalt(III) complex.[20] The Co-$2p_{3/2}$, S-$2p_{3/2}$, and N-1s binding energies of the present complex (779.0, 163.8, and 398.9 eV, respectively) are lower than those of the monosulfenato complex (781.0, 164.9, and 400.1 eV, respectively). The results indicate that the saturation on the electron-transfer to cobalt(III) ion occurs

according to the increase in number of sulfenato groups which lowers the S-$2p_{3/2}$ binding energy of the present complex. However, there is an apparent conflict between the XPS data and the Co–S bond distances: the present tris(sulfenato) complex with the more negative sulfur donor atoms has the shorter Co–S bond distance than the monosulfenato complex. This conflict may be interpreted as that the electron-transfer from sulfur to cobalt in sulfenato complex contains an antibonding character.

Structure of d-*Tartaric Acid.* The *d*-tartaric acid molecule has reasonable bond distances, angles, and dihedral angles as compared with other structure analyses[13] (Tables 3, 4, and 5). The carbon skelton C(7)–C(8)–C(9)–C(10) is planar, and the dihedral

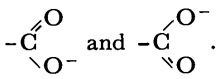
angle between the planes [O(4), O(5), C(7), and C(8)] and [O(8), O(9), C(9), and C(10)] is 56.6°.Furthermore, a proof of no dissociation of its two carboxyl groups can be given by two kinds of bond distances C–O(–H) (1.333 Å, 1.303 Å) and C=O (1.158 Å, 1.215 Å), that is, the *d*-tartaric acid being not in resonance structure between



Crystal Packing. As for the intermolecular bond, possible hydrogen bond distances and angles are listed in Table 7. The perspective view of a layer constituted of hydrogen bonds onto ab plane projected along the c-axis is given in Fig. 1, where line bonds denote hydrogen bonds within 3.10 Å. This layer further interacts with the upper and lower layers by hydrogen bonds between the hydrogen atoms of amino groups of the complex and oxygen atoms of *d*-tartaric acid onto bc plane (Fig. 3). Thus, seven hydrogen bonds are possible

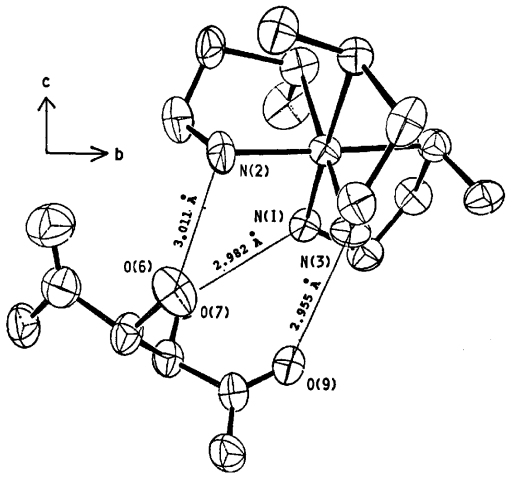


Fig. 3. The arrangement of the complex and *d*-tartaric acid molecule projected along a-axis (50% probability thermal ellipsoids). The line bonds represent possible hydrogen bonds (the distances within 3.10 Å).

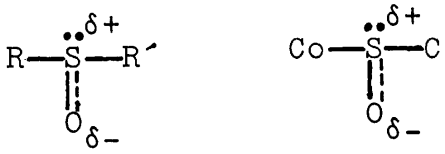
per one *d*-tartaric acid molecule. The hydrogen bond distances between oxygen atoms of sulfenato groups and hydrogen atoms of carboxyl groups, hydroxyl groups, or water are considerably short (2.495—2.837 Å), that is, the sulfenato oxygens have a significantly basic character. The S–O bond distance (1.548 Å) is rather longer than that of the sulfinato group of $[Co\{S(O)_2\text{-}CH_2CH_2NH_2\}(en)_2]^{2+}$ (1.456 Å, 1.476 Å).[21] The facts indicate that the sulfur-oxygen bond of sulfenato complex has a large polarity (*right*) in analogy with



that of sulfoxide (*left*).[22] Such a basic property of oxygen atoms in sulfenato groups is confirmed for the first time. The hydrogen bonding mode in Fig. 3 is similar to the so-call *face-to-face close contact* between a triangular face of the octahedral complex cation and the hydrogen *d*-tartrate or the *d*-tartrate anion.[23] The hydrogen bond interaction between the neutral complex and the *d*-tartaric acid molecule seems to be a key for the successful optical resolution of this molecular complex.

We wish to thank Mr. Yoshihisa Baba of our University for his technical assistance. We are also grateful to Professor Shichio Kawai of our University for his support to this work. This work was partly supported by a Grant-in-Aid for Scientific Research No. 547041 from the Ministry of Education, Science and Culture.

Cobalt(III) Complexes with Tripodlike Quadridentate Ligands. I. Circular Dichroism Spectra of Quasi-enantiomeric Geometrical Isomers of [Co(tripod)(chiral bidentate)]-type Complexes

Keiji Akamatsu,* Takashi Komorita, and Yoichi Shimura

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received April 23, 1981)

Cobalt(III) complexes containing a tripodlike quadridentate ligand, tris(2-aminoethyl)amine or nitrilotriacetate, and a chiral bidentate, L-amino carboxylate or (*R*)-propylenediamine, are prepared and separated into their respective geometrical isomers. The two geometrical isomers have mutually quasi-enantiomeric configurations. Circular dichroism spectra in the d-d absorption band region are discussed in connection with this novel type of geometrical isomerism.

Two geometrical isomers, *trans*(*N*) and *cis*(*N*), of (L-amino carboxylato)(nitrilotriacetato)cobaltate(III) ion [Co(L-am)(ata)]$^-$ [1] which has been prepared by Koine *et al.*[2] show vicinal CD (circular dichroism) due to the coordinated chiral amino carboxylate ligand in the d-d absorption band region. But it has remained puzzling why the intensity of vicinal CD is much stronger than those of other simple (L-amino carboxylato)cobalt(III) complexes which have no tripodlike quadridentate ligand.

The present paper deals with CD spectra of several mixed cobalt(III) complexes of a tripodlike quadridentate ligand, ata^{3-} or tren[1] and a chiral bidentate one, α-amino carboxylate or 1,2-diamine. For each of these complexes two geometrical isomers are possible, which are denoted as in Fig. 1.

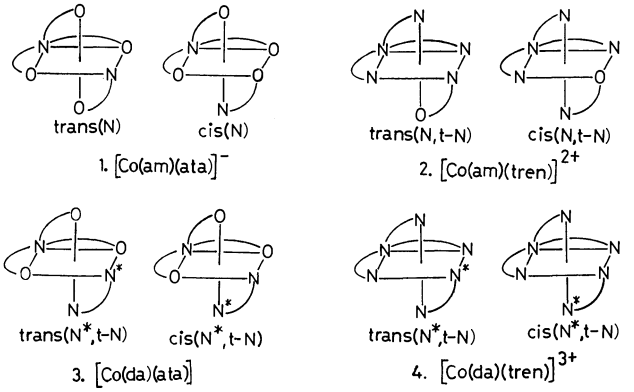

Fig. 1. Two geometrical isomers of [Co(tripod)(chiral bidentate)]type complex: tripod=ata^{3-} or tren, chiral bidentate=am$^-$ or da, and *N** and *t-N* mean the nitrogen atoms adjacent to the asymmetric carbon atom of the ligand and that of the tertiary amine of tripod ligand, respectively.

Experimental

Preparations. *(1) [Co(L-ala)(tren)]$^{2+}$ Salts*: To a solution of [$CoCl_2$(tren)]$ClO_4 \cdot 0.5H_2O$[3] (1 g) in 10 cm^3 of water was added an aqueous solution of L-alanine (0.3 g) neutralized with an equimolar amount of NaOH and the mixture was mechanically stirred for 2 h at 60 °C. The resulting red solution was poured into a cation-exchanger column (SP Sephadex C-25, Na^+ form) and the adsorbed band was eluted with a 0.07 M NaCl aqueous solution (1 M=1 mol dm^{-3}). The band split into three; orange, red, and purple one in the elution order. The third band turned out to be a trivalent complex cation, [Co(tren)$(H_2O)_2]^{3+}$, from the absorption spectrum and the column chromatographic behavior. The first and second eluates were evaporated almost to dryness on a rotary evaporator below 40 °C. A small amount of methanol was added to the residue to precipitate NaCl, which was filtered off. The repetition of this procedure enabled one to remove most of the sodium chloride. On addition of $NaClO_4$ to the solution the chloride perchlorate salt (orange isomer) or perchlorate (red isomer) deposited. They were recrystallized from warm water, washed with methanol and ether and dried in air. Found for the orange isomer: C, 24.98; H, 5.69; N, 16.50%. Calcd for [Co(L-ala)(tren)]Cl·ClO_4: C, 25.25; H, 5.66; N, 16.36%. Found for the red isomer: C, 21.71; H, 5.01; N, 14.37%. Calcd for [Co(L-ala)(tren)]$(ClO_4)_2$: C, 21.56; H, 5.04; N, 13.98%.

(2) Other tren Complexes with Amino Carboxylate: L-val, L-ser, L-phe, D-pgly, and L-cys complexes were prepared in the same way as that described in (1) using the corresponding amino carboxylate ligand instead of L-alaninate. Only orange isomer was isolated for these amino carboxylato complexes except for the L-cys one, for which only a brown isomer was isolated. Found for the L-val complex: C, 24.87; H, 5.50; N, 13.40%. Calcd for [Co(L-val)(tren)]$(ClO_4)_2$: C, 25.39; H, 5.44; N, 13.46%. Found for the L-ser complex: C, 20.67; H, 5.06; N, 13.34%. Calcd for [Co(L-ser)(tren)]$(ClO_4)_2$: C, 20.54; H, 4.99; N, 13.31%. Found for the L-phe complex: C, 31.80; H, 5.09; N, 12.51%. Calcd for [Co(L-phe)(tren)]$(ClO_4)_2$: C, 31.70; H, 4.98; N, 12.33%. Found for the D-pgly complex: C, 30.63; H, 4.67; N, 12.81%. Calcd for [Co(D-pgly)(tren)]$(ClO_4)_2$: C, 30.33; H, 4.74; N, 12.64%. Found for the L-cys complex: C, 25.04; H, 5.57; N, 16.10%. Calcd for [Co(L-cys)(tren)]ClO_4: C, 24.96; H, 5.60; N, 16.19%.

(3) [Co(ata)(en)] and [Co(ata)(R-pn)]: One gram of *cis*(*Cl*)-[$CoCl_2(NH_3)_2$(en)]Cl[4] was dissolved in 10 cm^3 of water and to this blue solution was added a solution (5 cm^3) containing nitrilotriacetic acid (1 g) and NaOH (0.46 g) with stirring. The mixture was stirred for 4 h at 70 °C until the evolution of gaseous ammonia ceased. The resulting red-violet solution was then poured into a cation-exchanger column (Dowex 50w-x8, Na^+ form) and after the adsorbed band had been eluted with water, the red-violet eluate obtained was evaporated on a rotary evaporator and to the residue was added methanol to precipitate the complex as a powder. It was recrystallized from water, washed with methanol and ether and air-dried. Found: C, 29.63; H, 4.92; N, 12.98%. Calcd for [Co(ata)(en)]·H_2O: C, 29.54; H, 4.97; N, 12.92%.

The corresponding *R*-pn complex was prepared using *cis*(*Cl*)-[$CoCl_2(NH_3)_2$(*R*-pn)]Cl[4] as a starting meterial. Found: C, 32.62; H, 5.18; N, 12.77%. Calcd for [Co(ata)-

(*R*-pn)]·0.5H_2O: C, 32.72; H, 5.20; N, 12.73%.

(4) [Co(en)(tren)]Br_3·0.5H_2O and [Co(R-pn)(tren)]Br_3: One gram of *cis(Cl)*-[$CoCl_2(NH_3)_2$(en)]Cl[4] was dissolved in 10 cm^3 of water and to the solution were added a small amount of activated charcoal and a solution (neutralized with NaOH) of tren·3HBr (1.4 g) in 10 cm^3 of water. The mixture was mechanically stirred for 3 h at 60 °C until the color of the solution turned orange. The resulting mixture was then diluted to 50 cm^3 with water and the activated charcoal was filtered off by suction. The filtrate was evaporated in a rotary evaporator almost to dryness. The residue was dissolved in 5 cm^3 of water and NaBr (0.5 g) was added to the solution. Yellow crystals deposited were filtered and recrystallized from warm water, washed with methanol and ether and dried in air. For the *R*-pn complex *cis(Cl)*-[$CoCl_2(NH_3)_2$-(*R*-pn)]Cl[4] was used as a starting material. Found for the en complex: C, 18.41; H, 5.05; N, 15.96%. Calcd for [Co(en)(tren)]Br_3·0.5H_2O: C, 18.69; H, 5.31; N, 16.35%. Found for the *R*-pn complex: C, 20.80; H, 5.50; N, 16.27%. Calcd for [Co(*R*-pn)(tren)]Br_3: C, 20.82; H, 5.45; N, 16.19%.

(5) Other Complexes: The [Co(L-ala)(ata)]$^-$ (*trans(N)* and *cis(N)*) and [Co(L-ala)$(NH_3)_4$]$^{2+}$ complexes were prepared in the same way as described in the literature.[2,5]

Measurements. The visible and ultraviolet absorption measurements were made by a Shimadzu UV-200 spectrophotometer in aqueous solutions. The CD spectra were recorded on a JASCO MOE-1 spectropolarimeter in aqueous solutions and the ^{1}H-NMR spectra were obtained in deuterium oxide on Varian XL-100-15 spectrometer using DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) as as internal standard.

Results and Discussion

(1) [Co(am)(ata)]$^-$ Complexes. The two isomers of [Co(L-ala)(ata)]$^-$, red-violet and blue-violet, have been assigned[2] to *trans(N)* and *cis(N)* structures, respectively, from the splitting pattern of the first d-d absorption band. A remarkable feature is observed in the CD curves of two isomers (Fig. 2); namely they are almost enantiomeric to each other in the d-d transition band region. This is probably related to the fact that the two geometrical isomers are mutually quasi-enantiomeric as is seen in Fig. 3. The CD curves in Fig. 2 are explained by the contributions from two kinds of chiralities, one being the (*S*) asymmetric carbon atom of the L-alaninate ligand and the other the quasi-enantiomeric orientation of substituent $-CH_3$ on the chelate ring.

On assumption that the CD contributions of both chiralities are additive, the following equations are obtained.

$$\text{CD[red-violet]} = \text{CD}[S] + \text{CD}[trans],$$

$$\text{CD[blue-violet]} = \text{CD}[S] + \text{CD}[cis],$$

and

$$\text{CD}[trans] = -\text{CD}[cis],$$

where CD[*S*] represents the contributions of (*S*) asymmetric carbon, and CD[*trans*] and CD[*cis*] those of the quasi-enantiomeric geometrical configuration. Two contributions, CD[*S*] and CD[*trans*] were calculated rom the equations,

$$\text{CD}[S] = 1/2\{\text{CD[red-violet]} + \text{CD[blue-violet]}\},$$

$$\text{CD}[trans] = -\text{CD}[cis]$$

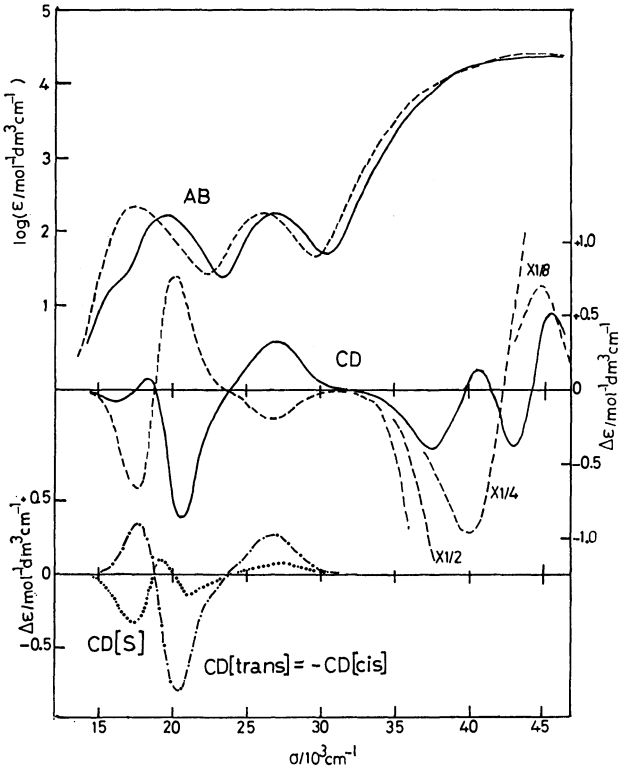

Fig. 2. Absorption (AB) and CD curves of *trans(N)* (——) and *cis(N)* (------) isomers of [Co(L-ala)(ata)]$^-$. Caclulated CD curves for asymmetric carbon (····) and quasi-enantiomeric (-···-) effects are also shown.

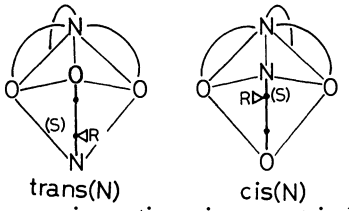

Fig. 3. Two quasi-enantiomeric geometrical isomers of [Co(am)(ata)]$^-$. (*S*) denotes absolute configuration of the asymmetric carbon.

$$= 1/2\{\text{CD[red-violet]} - \text{CD[blue-violet]}\}.$$

The obtained curves are also illustrated in Fig. 2. The CD[*S*] curve consists of three extrema (—, +, and —) from the longer wavelength side in the first d-d transition band region and the pattern and intensity are similar to the vicinal effect curve of the L-alaninate ligand in *trans(N)*-[Co(ox)(L-ala)$_2$]$^-$.[6] The CD[*trans*] curve shows two (+ and —) and one (+) component in the first and second d-d transition band region, respectively, and the contribution of CD[*trans*] or CD[*cis*] to the observed CD is larger than that of CD[*S*], the pattern of the observed CD being mainly determined by the quasi-enantiomeric effect.

(2) [Co(am)(tren)]$^{2+}$ Complexes. Kimura *et al.*[7] prepared tren complexes with amino carboxylate ligands and isolated two isomers, orange and red, of [Co(gly)(tren)]$^{2+}$. Recently it has been found from the X-ray crystal structure analyses that the orange isomer has *trans(N,t-N)* structure and the red one *cis(N,t-N)*.[8] Two isomers, orange and red, of the L-alaninato complex show absorption spectra analogous to those

of the corresponding orange and red isomers of the glycinato complex, respectively (Table 1). Therefore, the orange isomer is *trans*(*N*,*t*-*N*) and the red *cis*(*N*,*t*-*N*). Though a pair of isomers, red-violet and blue-violet, were also isolated for each ata complex with the other amino carboxylates,[2] only orange isomer was obtained for each tren complex with L-val, L-ser, L-phe, and D-pgly. A series of hydrolysis studies[9] on $[CoCl_2(tren)]^+$ suggested that steric hindrance of hydrogen atoms on the aminoethyl chelate ring makes the chloro ligand *cis*

to the tertiary amine more labile, and X-ray crystal structure analyses of the two isomers of $[Co(gly)(tren)]^{2+}$ showed that unfavorable non-bonded interactions between the amino protons of the glycinate ring and the adjacent protons on the carbon and nitrogen atoms of tren make the *cis*(*N*,*t*-*N*) structure (red isomer) unstable[8] In fact, the formation ratio of the red isomer to the orange one was rather low for the tren complex with L-alaninate. Instability of the red isomer seems to increase with an increase in the bulkiness of a substituent on the amino carboxylate chelate ring. All orange isomers obtained have *trans*(*N*,*t*-*N*) structure from the same reason as that described for the L-alaninate complex. All these *trans*(*N*,*t*-*N*) isomers have similar CD patterns (+ and −) from the longer wavelength side in the first d-d transition band region, except for the D-pgly isomer, which shows the opposite sign pattern (− and +) (Table 2).

The two isomers of $[Co(L\text{-ala})(tren)]^{2+}$ show almost enantiomeric CD in the d-d transition band region (Fig. 4). On the basis of the same assumption as that for the ata complex, the CD contributions of (*S*) asymmetric carbon and the quasi-enantiomeric chirality were separated. The calculated CD contribution of the latter chirality is comparable in intensity to that of the former (Fig. 4). The pattern of the CD[*trans*(*N*,*t*-*N*)] is analogous to that of the CD[*trans*] for the ata complex; *i.e.*, two (+ and −) and one (+) components are

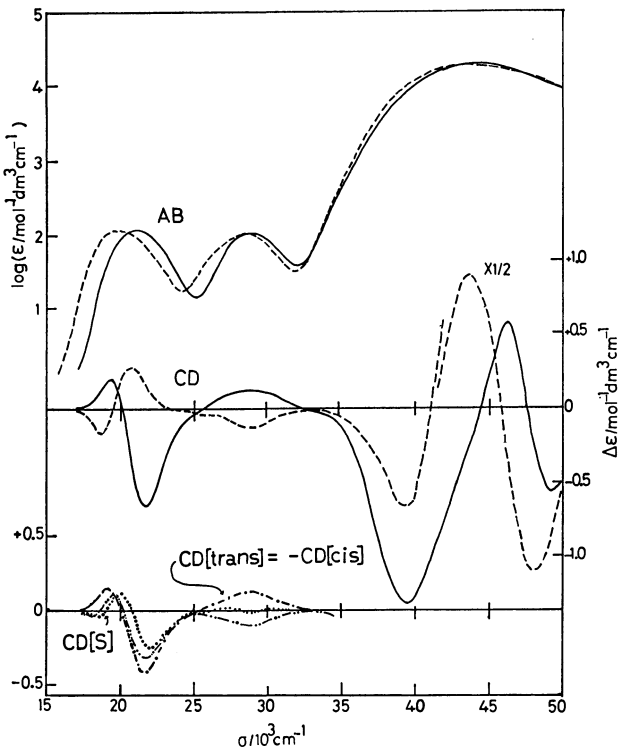

Fig. 4. Absorption (AB) and CD curves of *trans*(*N*,*t*-*N*) (——) and *cis*(*N*, *t*-*N*) (------) isomers of $[Co(L\text{-ala})(tren)]^{2+}$. Calculated CD curves for asymmetric carbon (····) and quasi-enantiomeric (-·-·-) effects are also shown. Another asymmetric carbon effect curve (-·-·-·-) is the observed one for $[Co(L\text{-ala})(NH_3)_4]^{2+}$ complex.

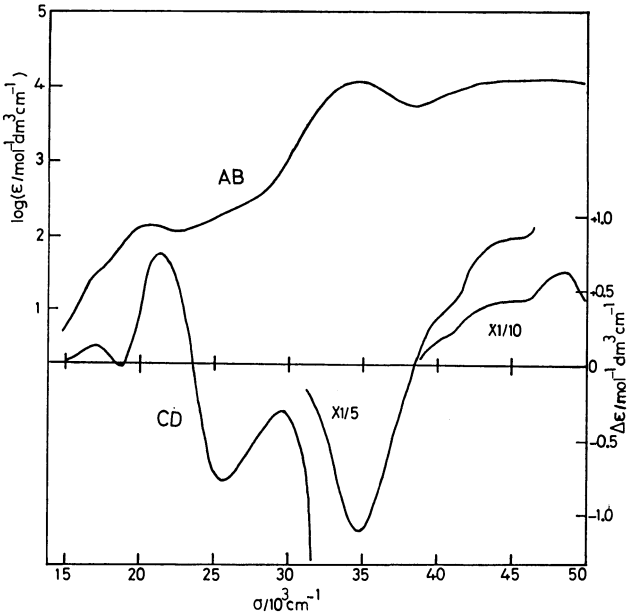

Fig. 5. Absorption (AB) and CD curves of *trans*(*N*, *t*-*N*)-$[Co(L\text{-cys})(tren)]^{+}$ complex.

present in the first and second d-d transition band region, respectively. The asymmetric carbon contribution CD[*S*] well coincides with the observed CD of the $[Co(L\text{-ala})(NH_3)_4]^{2+}$ in the first band region (Fig. 4).

The L-cysteinate complex is in a complicated situation. When L-cysteinate coordinates through the N and O donors, the α-substituent $-CH_2S^-$ is directed at the same side as in the other L-amino carboxylate complexes (Fig. 3), but when it does through N and S donors, the substituent $-CO_2^-$ is at the opposite side. Jackson *et al.*[10] first prepared two isomers, brown and ink-blue, of $[Co(L\text{-cys})(tren)]^{+}$ with N and S donors and assigned those to *trans*(*N*,*t*-*N*) and *cis*(*N*,*t*-*N*) structures, respectively, from their absorption, ^1H- and ^{13}C-nuclear magnetic resonance spectra. In the present work only the brown isomer, *trans*(*N*,*t*-*N*), was isolated, which showed a CD pattern enantiomeric to the L-alaninate complex of *trans*(*N*,*t*-*N*) structure in accordance with the *N*,*S*-coordination of L-cys ligand (Fig. 5).

(3) [Co(da)(ata)] Complexes. For en and *R*-pn, each only one complex of this type was prepared. The absorption spectrum of the *R*-pn complex was very similar to that of the en complex, having a broad first d-d band in agreement with the *mer*-CoN_3O_3 chromophore (Fig. 6 and Table 1). As the donor atoms at each end of *R*-pn have almost the same ligand-field strength, the discrimination of the two isomers, *trans*(*N**,*t*-*N*) and *cis*(*N**,*t*-*N*) in Fig. 1, is impossible only from the absorption spectra, in contrast to the case of amino carboxylate complex. In order to examine whether the isolated crystals contain only one isomer or both, the ^1H-NMR spectrum was measured.

It was found that the *R*-pn complex revealed two methyl doublets with about the same intensity (Fig. 7-a). Thus the complex is a 1 : 1 mixture of two isomers, *trans*(*N**,*t*-*N*) and *cis*(*N**,*t*-*N*), which are quasi-enantiomeric geometrical isomers (Fig. 8). If the same argument as that described for the L-ala complex is

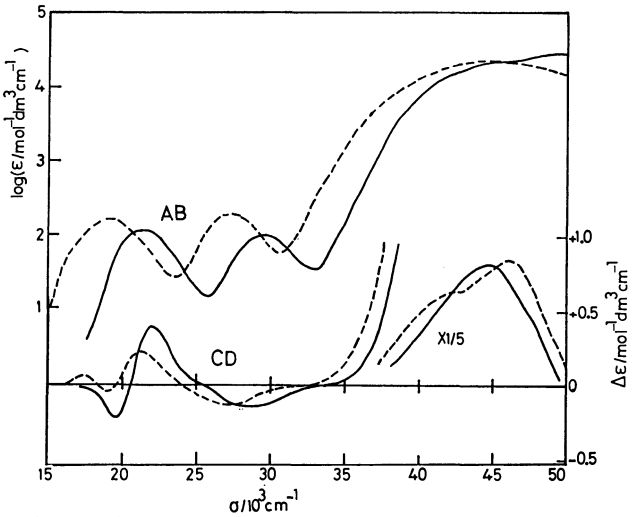

Fig. 6. Absorption (AB) and CD curves of [Co(ata)(*R*-pn)] (------) and [Co(*R*-pn)(tren)]$^{3+}$ (——).

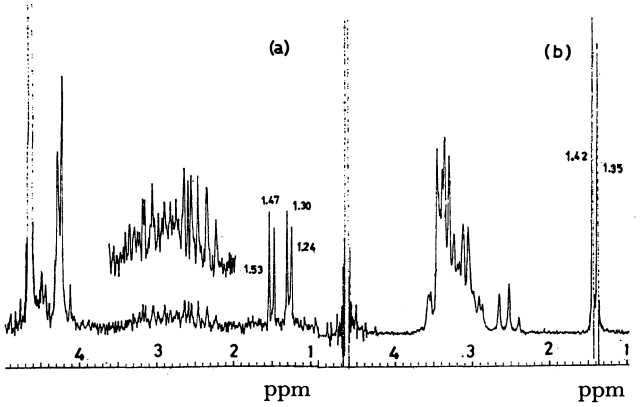

Fig. 7. ^{1}H-NMR spectra of (a) [Co(ata)(*R*-pn)] and (b) [Co(*R*-pn)(tren)]$^{3+}$.

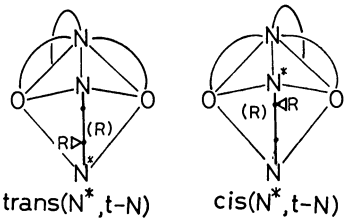

Fig. 8. Two quasi-enantiomeric geometrical isomers of [Co(ata)(*R*-pn)]. (*R*) denotes absolute configuration of the asymmetric carbon.

applicable to the *R*-pn complex, the observed CD curve (Fig. 6) should approximately correspond to a CD contribution CD[*R*], which contains two contributions, from (*R*) asymmetric carbon and λ-gauche conformation of the chelate ring.[11] In spite of a difference in the type of chromophore, the CD[*R*] contribution curve in Fig. 6 is roughly enantiomeric to the CD[*S*] curve of [Co(L-ala)(ata)]$^-$ (Fig. 2) or [Co(L-ala)(tren)]$^{2+}$ (Fig. 4) in the first and second d-d transition band region.

(4) [Co(da)(tren)]$^{3+}$ Complexes. Also in this case, only one complex was prepared for every 1,2-diamine (en or *R*-pn).

These complexes have a CoN_6 chromophore and their absorption spectra (Table 1) closely resembled that of [Co(en)$_3$]$^{3+}$ in regard to the position, intensity and half-width of the first d-d transition band. This indicates that the tripodlike ligand, tren, has about the same ligand-field strength as that of two en ligands. The ^{1}H-NMR spectrum of the [Co(*R*-pn)(tren)]$^{3+}$ complex showed only one methyl doublet (Fig. 7-b). Thus the complex consists of only one isomer, *trans(N*,t-N)* or *cis(N*,t-N)* in Fig. 1. Both isomers have unfavorable non-bonded interactions among the protons on the *R*-pn nitrogen atoms and on the carbon and nitrogen atoms of the tren. However, concerning the orientation of the substituent $-CH_3$, steric crowding in the *trans(N*,t-N)* structure is less unfavorable than that in *cis(N*,t-N)*; thus the only one isomer obtained is assigned to *trans-(N*,t-N)*. Therefore, its CD curve (Fig. 6) consists of two contributions, one from CD[*R*] and the other CD[*trans(N*,t-N)*]. Though the pattern of the observed CD for [Co(*R*-pn)(tren)]$^{3+}$ complex is similar to that for [Co(*R*-pn)$(NH_3)_4$]$^{3+}$, which has no quasi-enantiomeric effect and shows two (— and +) and one (—) component in the first and second d-d transition band region, respectively,[11] the intensity of the tren complex is much larger than that of the tetraammine complex. The subtraction of the CD curve for the tetraammine complex from that for the tren complex is expected to give an approximate CD[*trans(N*,t-N)*] contribution. The pattern of this CD contribution in the first and second d-d transition band region is analogous to that of CD[*R*] and the intensity for the CD[*trans(N*,t-N)*] is smaller than that for CD[*R*].

(5) Conclusion. The CD spectral data described above lead one to the following conclusion: 1. CD patterns of the [Co(L-am)(ata)]$^-$ or [Co(L-am)(tren)]$^{2+}$ complexes in the d-d band region are governed by the "vicinal effect" of amino carboxylate ligands, which consists of two contributions, the asymmetric carbon effect and the quasi-enantiomeric effect, the latter being dominant. 2. The *trans(N)* or *trans(N,t-N)* isomer shows two (+ and —) or three (—, + and —) CD components in the first d-d band region, and one (+) component in the second, while the *cis(N)* or *cis(N,t-N)* isomer shows two (— and +) and one (—) component in the first and second band region, respectively. 3. The CD patterns of this type of complex are not affected from the varieties of the first coordination spheres or chromophore (for example, the two isomers of the ata complex belong to *trans-* and *cis-*CoN_2O_4 chromophore and those of the tren complex CoN_5O). 4. For the corresponding *R*-pn complexes, the quasi-enantiomeric effect has a sign opposite to that for the L-ala complexes because the substituent $-CH_3$ is at the opposite side.

Synthesis and Structures of Steroidal Oxathiolanes

Shafiullah,* Hasrat Ali, Haruo Ogura,† and Hiroaki Takayanagi†

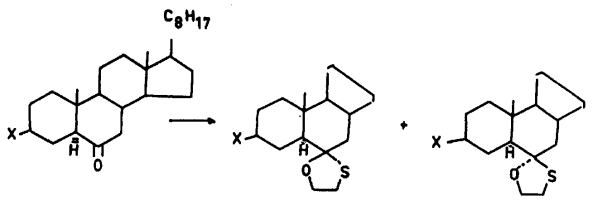
Steroid Research Laboratory, Department of Chemistry, Aligarh Muslim University, Aligarh-202001, India

†*School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108*

(Received July 25, 1980)

Synthesis of isomeric oxathiolanes from 6-oxosteroids is described. Configurations at spirocyclic carbon in these compounds have been established on the basis of CD and NMR spectra with the use of shift reagent [Eu(dpm)$_3$].

As an extension of a previous study,[1] the synthesis and spectrochemical studies of steroidal oxathiolanes have been carried out.



Results and Discussion

Reaction of ketone **1** with 2-mercaptoethanol in acetic acid ($BF_3 \cdot Et_2O$ as catalyst, room temperature) afforded a compound melting at 56 °C and a noncrystallizable oil. These compounds gave molecular ion peaks at *m/e* 446 ($C_{29}H_{50}OS$). The compound, mp 56 °C, showed characteristic bands at 1225 (–S–CH_2)[2] and 1065 cm^{-1} (monothioacetal group),[3] and the oil bands at 1220 (–S–CH_2) and 1070 cm^{-1} (monothioacetal group) in IR spectra. The NMR spectrum of the compound, mp 56°C, gave two distorted triplets at δ 4.32 and 3.92 (–O–CH_2) each integrating for 1 proton, and a double doublets at δ 2.78 (–S–CH_2; J=3.7 Hz) for 2 protons. The oil gave a distorted triplet for 2 protons at δ 4.03 (–O–CH_2) and a clean triplets for 2 protons at δ 2.93 (–S–CH_2).

The configuration of the –O–CH_2 and –S–CH_2 in the products could not be assigned with these spectral data, and [tris(dipivalomethanato) europium III] was employed as a shift reagent. Addition of the reagent to the compound, mp 56 °C, caused no significant change in the chemical shift of the signals in its NMR spectrum (Table 1), while its addition to the oily isomer showed a remarkable difference in the chemical shift of the NMR signals (Table 2). This confirmed that the –O–CH_2 group of monothioacetal ring attached to C(6) has an equatorial orientation in the oil, and an axial one in the compound, mp 56 °C.[4] Thus the compound is considered to be (6*S*)-6,6-oxyethylenethio-5α-cholestane **4** and the oil (6*R*)-6,6-oxyethylenethio-5α-cholestane **7**. CD data for compounds **4** (negative Cotton effect) and **7** (positive Cotton effect) (Fig. 1) further support configurational asignments for the monothioacetal ring in these compounds.[5]

By a similar treatment ketones **2** and **3** afforded oxathiolanes **5**, **8**, and **6**, **9** respectively. In NMR spectra, the splitting pattern of –O–CH_2 and –S–CH_2 protons of **5** and **6** was found identical with **4**, and oxathiolanes **8** and **9** provided similar NMR peaks for –O–CH_2 and –S–CH_2 protons as in **7**. On the basis of the NMR peak pattern the configurations at spirocyclic carbon in compounds **5**, **6**, and **8**, **9** were assigned similarly to **4** and **7**, respectively. This is supported by the negative Cotton effect (Figs. 2 and 3) for compounds **5** and **6** and positive Cotton effect (Figs. 2 and 3) for compounds **8** and **9**.

The parent ketones **1**—**3** were generated when monothioacetals **4**—**9** were treated with aqueous acetic acid.

Experimental

All melting points are uncorrected. IR spectra were recorded on a Perkin-Elmer 237 spectrophotometer, and ^{1}H-NMR spectra in $CDCl_3$ on a Varian A60 instrument (δ scale. TMS=0 ppm). CD curves were measured with a JASCO J-20 spectropolarimeter in dioxane. Mass spectra were measured on a Varian AJMS D100 mass spectrometer. TLC were performed with silica gel (BDH) and column chromatography with silica gel (BDH-60-120 mesh). NMR values in ppm (s=singlet; dd=double doublets; t=triplet; mc=multiplet centred at).

(6S)-6,6-Oxyethylenethio-5α-cholestane **4** *and (6R)-6,6-Oxyethylenethio-5α-cholestane* **7**. A solution of ketone **1**[6] (5.0 g) in AcOH (200 cm^3) was treated with 2-mercaptoethanol (10 cm^3) and $BF_3 \cdot Et_2O$ (2 cm^3) and left to stand at room temperature for 1 h. The solution was diluted with MeOH (25 cm^3), poured into water and extracted with ether. The ethereal layer was washed successively with water, $NaHCO_3$ solution (5%), water and dried (anhydrous Na_2SO_4). The oil (5.0 g) obtained after removal of ether under reduced pressure was chromatographed over silica gel (100 g). Elution with light petroleum ether afforded **4**; solidified on being left at room temperature (2.0 g); mp 56 °C; MS (70 eV) *m/e* 446 (30%) (M^+); Found: C, 78.03; H, 11.01%. Calcd for $C_{29}H_{50}OS$: C, 78.02; H, 11.20%; CD (dioxane) $[\theta]^{20}$(nm): −1380 (250). NMR ($CDCl_3$): δ 0.68, 0.82, 0.92, and 0.98 (C(10)−; C(13)− and side chain methyl protons).

Further elution with light petroleum ether afforded **7** (2.10 g) as an oil; MS (70 eV) *m/e* 446 (28.3%) (M^+); Found: C, 78.03; H, 11.01%. Calcd for $C_{29}H_{50}OS$: C, 78.02, H,11.20; CD (dioxane) $[\theta]^{20}$ (nm): +3170 (241). NMR ($CDCl_3$): δ 0.67, 0.70, 0.75, and 0.98 (C(10)−; C(13)− and side chain methyl protons).

3β-Acetoxy-(6S)-6,6-oxyethylenethio-5α-cholestane **5** *and 3β-Acetoxy(6R)-6,6-oxyethylenethio-5α-cholestane* **8**. The ketone **2**[7] (5.0 g) was treated with 2-mercaptoethanol (10 cm^3) and $BF_3 \cdot Et_2O$ (2 cm^3) in AcOH (200 cm^3) in the same way as for **1**. The oil obtained after removal of the solvent was chromatographed over silica gel (100 g). Elution with light petroleum ether–ether (22 : 1) afforded **5**, recrystallized from light petroleum ether (2.20 g); mp 142 °C, MS (70 eV) *m/e* 504 (12.5%) (M^+); Found: C, 73.81; H, 10.49%. Calcd for $C_{31}H_{52}O_3S$: C, 73.8; H, 10.51%; CD (dioxane) $[\theta]^{20}$ (nm): −860 (220) and −800 (250). IR (KBr): 1740 (CH_3–CO–O–), 1240 (C–O), and 1030 cm^{-1} (monothioacetal group); NMR ($CDCl_3$): δ 4.7 (mc, $W_{1/2}$=16 Hz, C(3)α-H), 4.28, 3.9 (distorted tripletes, –O–C$\underline{H}_2$–), 2.86 (dd, J=3.6 Hz, –S–C$\underline{H}_2$–), 2.03 (s, C(3)–O–CO–C$\underline{H}_3$), 0.70, 0.83, 0.93, and 1.0 (C(10)–, C(13)–, and side chain methyl protons).

Further elution with light petroleum ether-ether (20 : 1) yielded **8** recrystallized from light petroleum ether (2.0 g), mp 106°C; MS (70 eV) *m/e* 504 (11.4%) (M^+); Found: C, 73.80; H, 10.49%. (Received October 8, 1980)

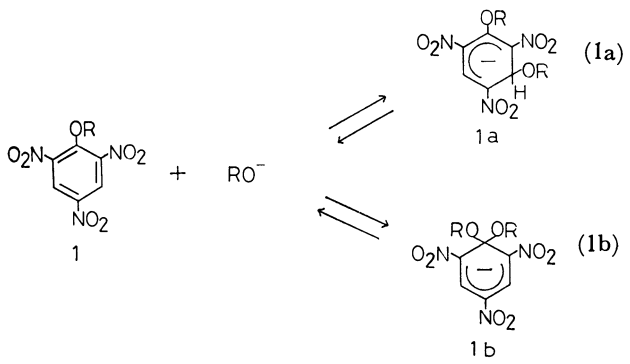
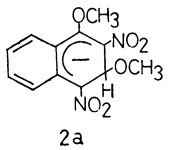
The formation of 1,3-disubstituted anionic σ complexes, followed by 1,1-disubstituted ones was confirmed by means of absorption and NMR spectra in the reactions of 1-dialkylamino-2,4-dinitronaphthalenes with potassium methoxide in DMSO–CH_3OH. The rates and activation parameters were determined by kinetic studies with use of stopped-flow and conventional spectrophotometers. The rate constants for the formation of 1,3-disubstituted one decreased in the order 1-dimethylamino-$>$1-(*N*-methylbutyl)amino-$>$1-piperidino-$>$1-diethylamino-2,4-dinitronaphthalenes, those for its decomposition being comparable with each other. On the other hand, the rate constant for the formation of 1,1-disubstituted one decreased in the same order as above while that for its decomposition decreased in the order 1-dimethylamino-$>$1-(*N*-methylbutyl)amino-$>$1-diethylamino-$>$1-piperidino-2,4-dinitronaphthalenes. The mechanism was discussed from activation parameters.

Many Jackson-Meisenheimer complexes (anionic σ complex) have been prepared by nucleophilic attack on polynitroaromatic compounds[2] as shown by



Especially in the reactions of 1-alkoxy- or 1-amino-substituted activated benzenes or heteroaromatics with alkoxides or amines, two anionic σ complexes, 1,3- and 1,1-disubstituted ones (**1a** and **1b**) are usually formed.[3–22] Upon addition of bases **1a** is formed at first, undergoing isomerization to **1b**; the former is said to be a kinetically controlled product and the latter an equilibrium-controlled one.[23,24]

However, with activated naphthalene derivatives 1,3-disubstituted complexes such as **1a** have hardly been found. As a few exceptional cases, Millot and Terrier testified the formation of **2a** by stopped-flow spectrophotometric technique,[14] although its evidence was considered to be somewhat uncertain. Fendler *et al.*[25] attempted the reaction of 1-methoxy-2,4-dinitronaphthalene (**2**) with alkoxide, but were unsuccessful in the identification of **2a**. Their failure is due to the insufficient stability of such complexes as **2a**, as compared with those formed from benzene derivatives.



2a

Thus, if the stability of **2b** (naphthalene analog corresponding to **1b**) could be reduced, the energy barrier between **2a** and **2b** would become smaller, elongating the life of **2a** and making the identification easier. Such attempts were successful in the reactions of 1-amino-2,4-dinitronaphthalenes with alkoxides.[26,27] Replacement of amino for alkoxyl groups clearly deactivates the C-1 position of a naphthalene moiety, necessitating the slower isomerization of **2a** to **2b**.

As a result, it would be interesting to investigate the kinetic and thermodynamic parameters of the reactions of 1-dialkylamino-2,4-dinitronaphthalenes with alkoxides.[28]

This paper reports the stopped-flow kinetics of the formation and decomposition of the 1,3- and 1,1-disubstituted anionic σ complexes in the reactions of various 1-dialkylamino-2,4-dinitronaphthalenes (**3**—**6**) with potassium methoxide in DMSO–CH_3OH (90/10 v/v).

Results

General Features. The reaction of 1-dimethylamino-2,4-dinitronaphthalene (**4**) with potassium methoxide in DMSO–CH_3OH afforded **4a** at first and then **4b** in quantitative yields (Fig. 1). Spectrum (b) obtained by stopped-flow spectrophotometry just after addition of methoxide is due to **4a**, absorbance scale being arbitrary; Spectrum (c), attributable to **4b**, was obtained in 12 min after addition.[29,30] From the results, the reaction is expected to proceed in a mode similar to that of Eq. 1.

NMR technique is considered useful for elucidating the structures of anionic σ complexes.[23] Just after addition of methanolic potassium methoxide (1.40×10^{-4} mol) to a DMSO solution (0.5 ml) of **4** (1.40×10^{-4} mol) at room temperature, the solution turned red at once, suggesting the formation of a complex. Just after addition, H_3 sharp singlet (δ 8.63) of **4** shifted upfield

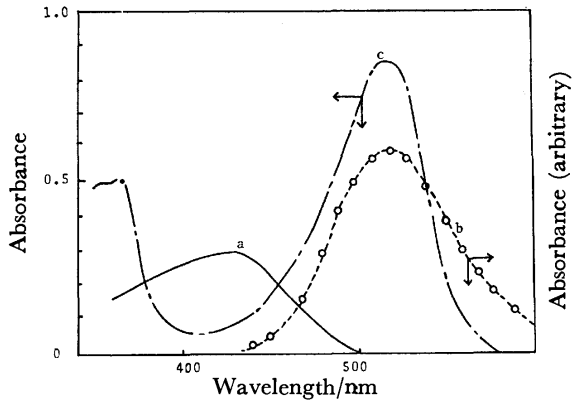


Fig. 1. Spectral changes relevant to the reaction of 1-dimethylamino-2,4-dinitronaphthalene (**4**) with CH_3OK in DMSO–CH_3OH (90 : 10, v/v); (a) **4** (3.25×10^{-5} M (1M=1 mol dm^{-3}) at room temperature; (b) obtained by means of a stopped-flow method (**4** 5.0×10^{-4} M and CH_3OK 4.5×10^{-3} M); (c) 12 min after addition of CH_3OK.

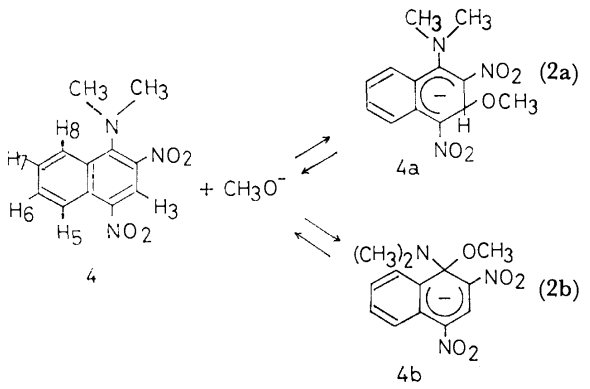

(δ 6.33, H_3 of **4a**). Fast sweep time (500 Hz/50 s) and fast procedure are indispensable for detecting spectral changes, 2.5 min after addition, a new singlet, due to H_3 of **4b** appeared at δ 9.31 at the expense of the singlet at δ 6.33 (measured at the normal sweep time, 250 Hz/50 s, in this case) which appeared faintly.

The results also support the reaction paths (Eq. 2). Similar results were obtained for **3**, **5**, and **6**.[31] It is thus expected that the discrete kinetics of formation and decomposition of **4a** and **4b** is possible.

Kinetic Runs. Let us rewrite Eq. 2 in a form convenient for quantitative discussion as Eq. 3. Stage I kinetics (**4**⇄**4a**, Eq. 3a) is much faster than Stage II

$$\mathbf{4} + {}^-OCH_3 \underset{k_{-1}}{\overset{k_1,\ K_1}{\rightleftharpoons}} \mathbf{4a} \quad (3a)$$

$$K_1 = \frac{k_1}{k_{-1}},\quad K_2 = \frac{k_2}{k_{-2}}$$

$$\mathbf{4a} \underset{k_{-2}}{\overset{k_2,\ K_2}{\rightleftharpoons}} \mathbf{4b} \quad (3b)$$

reaction (**4a**⇄**4b**, Eq. 3b). Thus, when Stage I kinetics is taken into account, Stage II reaction can be neglected, since the former reaction is completed in several thousandths seconds (Table 3), making the contamination by the latter negligible.

Stage I. The pseudo-first-order rate constant, k_ψ, for the attainment of an equilibrium is the sum of forward and reverse components. For the system (Eq. 3a) the following expression should hold:

$$k_\psi = k_1([CH_3O^-]+[4]) + k_{-1}. \quad (4)$$

Under the usual condition $[CH_3O^-]\gg[4]$, Eq. 4 is simplified to

$$k_\psi = k_1[CH_3O^-] + k_{-1}. \quad (5)$$

As a result, dependence of k_ψ on methoxide concentration would afford the linear relationship, and k_1 and k_{-1} are estimated from the slope and the intercept, respectively. The dependence of k_ψ on methoxide concentration is given in Table 1, involving estimated rate constants and equilibrium constants. The relationship between k_ψ and methoxide concentration at 15, 25, and 35 °C indicates that Eq. 5 holds fairly well (Fig. 2). The temperature dependence of K_1, k_1, and k_{-1} was determined at four temperatures. Kinetic and activation parameters obtained from the Arrhenius plot (not shown) are summarized in Table 3, which includes the results obtained for **3**, **5**, and **6**. The k_1 values decrease in the order **4**>**5**>**3**>**6** and the k_{-1} values in the order **3**>**6**>**4**>**5**. The enthalpy and entropy of activation for **3**, **4**, **5**, and **6** ($\Delta H_1^{\ddagger}$ and $\Delta S_1^{\ddagger}$) compensate with each other, and those ($\Delta H_{-1}^{\ddagger}$ and $\Delta S_{-1}^{\ddagger}$) also do the same except for **3**, in which the k_{-1} value depends upon $\Delta S_{-1}^{\ddagger}$ rather than $\Delta H_{-1}^{\ddagger}$.

Stage II. As shown in Fig. 1, the change from Spectrum a to Spectrum b (**4**⇄**4a**) obtained by stopped-flow spectrophotometry is instantaneous, whereas that from Spectrum b to Spectrum c (Stage II reaction) is relatively slow. As a result, Stage II reaction (**4a**⇄**4**⇄**4b**), in which Stage I process (**4**⇄**4a**) is involved as equilibrium, is much slower than Stage I reaction. Therefore, Stage I reaction can be treated as equilibrium, lying almost entirely on the right in the treatment of Stage II kinetics. Table 3 shows that Stage I reaction

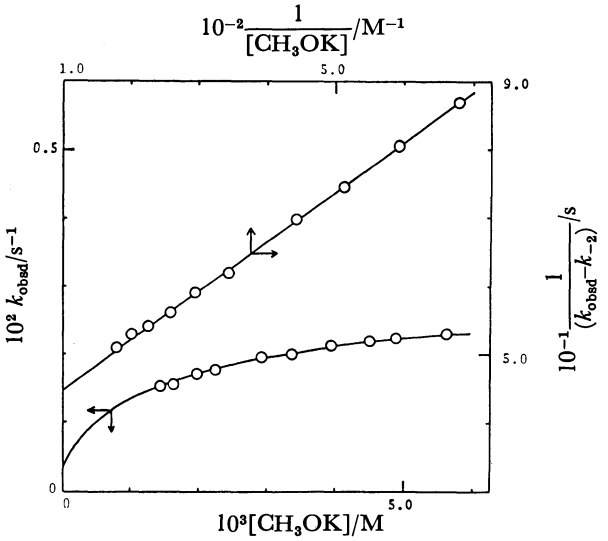

Fig. 2. Relationship between k_{obsd} and $[CH_3OK]$ and between $1/(k_{obsd}-k_{-2})$ and $1/[CH_3OK]$ in the reaction of 1-dimethylamino-2,4-dinitronaphthalene with CH_3OK in DMSO–CH_3OH (90 : 10, v/v) at 25 °C.

nearly completed in several thousandths of a second, very small in the time scale for Stage II reaction.

As to the rate of Stage II reaction, the general kinetic expression derivable from Eq. 3 should take account of the possibility that the substrate may be split between **4** and **4a**. Putting $[\mathbf{4}]_{st}=[\mathbf{4}]+[\mathbf{4a}]$, and K_1 the equilibrium constant for Stage I reaction, we obtain

$$k_{obsd}=k_{-2}+\frac{k_2[CH_3O^-]}{1+K_1[CH_3O^-]}, \quad (6)$$

where k_{obsd} is the pseudo-first-order rate coefficient for Stage II reaction, and k_2 and k_{-2} the rate coefficients for forward and reverse reactions. Consequently, dependence of k_{obsd} on methoxide concentration would afford a curvilinear relationship, in which the curve would not pass through the origin. If the k_{-2} value can be obtained by extrapolation from the relationship between k_{obsd} and methoxide concentration, we obtain the following equation by substituting the value into Eq. 6, and rearranging. Thus, k_2 and k_1 can be obtained from the slope and intercept in the plot of $1/(k_{obsd}-k_{-2})$ against $1/[CH_3O^-]$.

$$\frac{1}{k_{obsd}-k_{-2}}=\frac{1}{k_2[CH_3O^-]}+\frac{K_1}{k_2} \quad (7)$$

The dependence of k_{obsd} on methoxide concentration involves estimated rate and equilibrium constants (Table 4). Figure 2 shows the dependence of k_{obsd} on methoxide concentration and the inversion plot. Equation 6 and 7 are seen to hold. Objection might arise that the relation between k_{obsd} and methoxide concentration (Fig. 2) would afford a straight line within the range of methoxide concentration. This would be expected if $K_1[CH_3O^-]\ll1$ in Eq. 6. Although an increase in k_{obsd} with increasing methoxide concentration is much smaller at 25 °C, the plot of k_{obsd} against methoxide concentration were steeply convex upward at higher temperatures (*e.g.*, 35 and 40 °C), indicating that Eq. 6 holds. The k_{-2} value was so determined that the best linear relationship would be established in the inversion plot (Eq. 7). There might be some

ambiguity in the k_{-2} values. The temperature dependence of K_1, K_2, k_2, and k_{-2} at four temperatures is given in Table 5. The Arrhenius plot affords kinetic and activation parameters (Table 6), together with the results obtained for **3**, **5**, and **6**. Although there is some difference between the K_1 values obtained from Stage I and II kinetics, the agreement could be considered to be fairly good. Formation of 1,3-disubstituted anionic σ complex is kinetically controlled and that of 1,1-disubstituted one equilibrium-controlled, which is reflected in the K_1 and K_2 values (Tables 3 and 6).

Discussion

1,3-Disubstituted Anionic σ Complex. The rates and activation parameters (Table 3) do not differ much, since

methoxide ion attacking at the C-3 position does not get the direct effect of a dialkylamino group at the C-1 position. Some comments are given in the following. (a) The entropy of activation for k_{-1} is negative, as compared with that for k_1 with each substrate. This indicates that the entropy refers to unimolecular reactions in line with the view that part of the negative charge delocalized in the anionic σ complex becomes concentrated on the incipient methoxide ion in the transition state of decomposition, increasing the solvation of activated complexes and giving rise to negative entropy of activation.[33] (b) The enthalpy and entropy of activation for k_1 ($\Delta H_1^{\ddagger}$ and $\Delta S_1^{\ddagger}$) compensate each other, in line with the view that the solvation of methanol to the dialkylamino group of a substrate, in which the F- and B-strains proposed by Brown *et al.*[34–36] occur,

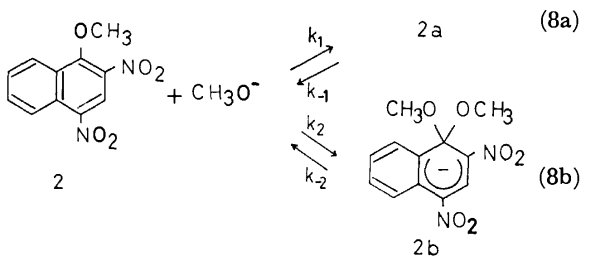
$\Delta S_{1.1}^{0}$/cal deg^{-1} mol^{-1}	0.4±11.7	39.1±13.4	21.0±11.2	36.8±12.5
$\Delta G_{1.1}^{0}$/kcal mol^{-1}	−15.1±12.2	−4.8±4.9	−4.6±9.0	−4.8±8.8

a) Only the substituent at C-1 of 2,4-dinitronaphthalene is indicated. b) $\Delta H_{1.1}^{0}=\Delta H_2^{\ddagger}-\Delta H_{-2}^{\ddagger}$. c) $\Delta H_{1.1}^{0}=\Delta H_2^{\ddagger}-\Delta H_{-2}^{\ddagger}$. d) $\Delta G_{1.1}^{0}=\Delta H_{1.1}^{0}-T\Delta S_{1.1}^{0}$.

would make amino nitrogen ammonium-nitrogen-like, which exerts the less electron-donating resonance contribution (due to the lone pair electrons of the amino nitrogen), giving rise to the reduced deactivation of the C-3 position indirectly. Naturally, the bulkier an amino group, the less it is solvated by methanol. Thus, the compensation would be evolved between the enthalpy and entropy of activation ($\Delta H_1^{\ddagger}$ and $\Delta S_1^{\ddagger}$). As regards the enthalpy and entropy of activation for k_{-1} ($\Delta H^{\ddagger}_{-1}$ and $\Delta S^{\ddagger}_{-1}$), those on **4**, **5**, and **6** linearly compensate each other except for **3**. With **3**, the compensation between $\Delta H^{\ddagger}_{-1}$ and $\Delta S^{\ddagger}_{-1}$ was found to deviate somewhat from the linear relationship. The conformation of **3** could be taken into account. In veiw of solvation ($-NR_2\cdots HOCH_3$), the 2,5-dinitro-1-naphthyl group should be put into an equatorial position at the nitrogen atom of piperidine. The same conformation could be held also in the anionic σ complex (**3a**). In the unimolecular decomposition of **3a**, the less solvation of methanol to the incipient methoxide ion at the C-3 position would be respon sible for the deviation to some extent, because 1-methoxy-2,6-dinitro-4,5-benzo-3-cyclohexadienylido group is very large.

It is of interest to compare our results with those of Millot and Terrier,[11] who carried out the kinetics of the reaction of **2** with potassium methoxide in DMSO–CH_3OH (90 : 10, v/v) at 20 °C, although their identification of the 1,3-disubstituted anionic σ complex was somewhat imcomplete (Eq. 8). Their values are as follows: k_1 7800 $M^{-1}\,s^{-1}$; k_{-1} 8.5 s^{-1}; K_1 916 M^{-1}.



2 2a (8a) 2b (8b)

Their reaction temperature is a little lower than ours, but the k_1 and k_{-1} values are considerably larger; the difference in the K_1 values is not large. The stronger inductive (−I) and weaker resonance (+R) effects, that is, the more electron-attracting effect of methoxyl group than those of dialkylamino group, activate the C-3 position more strongly, making the attack of methoxide ion faster (k_1). The effects of methoxyl group activate the C-1 position also more strongly, making the 3→1 migration of methoxyl group easier (k_{-1}).

1,1-Disubstituted Anionic σ Complex. The k_2 and k_{-2} values are expected to vary with the steric and activating effects of a substituent at the C-1 position (Table 6). The k_2 value increases in the order **6**<**5**<**4**, depending on the enthalpy of activation ($\Delta H_2^{\ddagger}$) rather than on the entropy of activation ($\Delta S_2^{\ddagger}$), in which the same effect ($-NR_2\cdots HOCH_3$) might function. However, in the case of **3**, the decrease in the k_2 value, seems to depend on the negative and large entropy of activation, which might occur from the steric interference of piperidyl group with the bimolecular attack of methoxide ion at the C-1 position.

Non-linear compensation takes place among the enthalpy and entropy of activation for the decomposition of complex. Especially in the case of **3**, the k_{-2} value depends on the enthalpy of activation rather than on the entropy of activation. The steric strain at the C-1 position of **3**, due to the bulkiness of piperidyl group would be relieved during the formation of complex. This might make the complex more stable, making the k_{-2} value smaller.

Millot and Terrier[11] reported the following constants for the formation and decomposition of 1,1-disubstituted anionic σ complex (Eq. 8b): k_2 2100 $M^{-1}\,s^{-1}$; k_{-2} too small to be decided.

In the case of **2**, the k_{-2} value is very small, and the K_2 value might be very large. The conpicuous constrast is the difference in the k_2 values, which indicates the steric and inductive advantageousness of methoxyl group. The k_1/k_2 ratios are *ca.* 40—380 in our case, whereas it is *ca.* 4 in the case of Millot and Terrier, which also represents the advantageousness.

In the reaction course of 1-dialkylamino-2,4-dinitronaphthalenes with potassium methoxide in DMSO–CH_3OH, the existance of 1,1- and 1,3-disubstituted anionic σ complexes was confirmed, the life of the latter being much shorter.

Experimental

NMR spectra were recorded on a Varian A-60D spectrometer and UV-VIS absorption spectra on a Hitachi Model 200-10 spectrophotometer.

Materials. The compounds (**3**, **4**, **5**, and **6**) were prepared according to the method described previously.[38] A small amount of calcium hydride was added to commercial dimethyl sulfoxide, which was then distilled under reduced pressure. Methanol was refluxed with magnesium for 1 h and distilled. Commercial potassium perchlorate of special grade was used without further purification.

Rate Measurement. As regards the kinetics of formation and decomposition of 1,3-disubstituted anionic σ complex, the transmittance of complex was measured in order to estimate the apparent rate constants(k_ψ) with a thermostatted stopped-flow spectrophotometer (Union RA-1300 Stopped-Flow Analyser). The kinetic measurements for the formation and decomposition of 1,1-disubstituted ones (k_{obsd}) were made with a thermostatted Hitachi Model 200-10 Spectrophotometer.

This research was supported in part by Grant-in-Aid for Scientific Research No. 455330 from the Ministry Education, Science and Culture.

Amino Sugars. XXXII. Ammonolysis and Azidolysis of Benzyl 2,3-Anhydro-4-azido-4-deoxypentopyranosides

Hironobu HASHIMOTO,* Koichi ARAKI, and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received December 23, 1980)

Ammonolysis and azidolysis of four benzyl 2,3-anhydro-4-azido-4-deoxypentopyranosides of α-D-*lyxo*, α-D-*ribo*, β-L-*lyxo*, and β-L-*ribo* configurations, were studied. Ratios of two ring-opening isomers and relative reaction rates were determined, factors controlling the direction of ring opening being discussed.

The ring-opening reaction of anhydro sugars with nucleophiles has been widely used not only for amino sugar synthesis by the reaction with ammonia or azide ion[1] but also for various kinds of carbohydrate derivatives.[2] In these reactions the formation of two kinds of *trans* α-hydroxy products is possible, depending on which carbon atom is attacked by the nucleophiles. Anhydropyranosides are well known to exist mainly in half-chair conformation.[3,4] When the conformation is fixed by a fused-ring such as in 4,6-*O*-benzylidene-2,3-anhydrohexopyranosides and 1,6 : 2,3-dianhydrohexopyranoses,[2] the predominant product is a *trans*-diaxial ring-opening product as postulated by the Fürst-Plattner rule.[5] On the other hand, the conformationally flexible anhydropyranoside like anhydropentopyranoside gives two ring-opening products in various ratios according to substituents on the pyranoside and to the character of nucleophiles. There is little systematic study on such ring-opening reaction, and the finding of the reversed ring-opening mode between ammonolysis and azidolysis of benzyl 2,3-anhydro-4-azido-4-deoxy-β-L-ribopyranoside (**4**)[6] prompted us to study the same reactions of all four stereochemical counterparts of benzyl 2,3-anhydro-4-azido-4-deoxypentopyranoside.

Results

All four stereochemical counterparts, namely, α-*lyxo* (**1**),[7] α-*ribo* (**2**),[7] β-*lyxo* (**3**),[8] and β-*ribo* (**4**)[6] isomers of benzyl 2,3-anhydro-4-azido-4-deoxypentopyranoside were prepared as reported previously. D-Enantiomer and L-enantiomer were used, for the α-anomers and β-anomers, respectively, because of availability of their starting materials.

Ammonolysis reactions of **1**,[6] **3**,[7] and **4**[8] in methanol at 90—95 °C gave 2-amino derivatives predominantly (40—70% yields of isolation). The ratios of two ring-opening isomers, 2-amino and 3-amino derivatives, were determined by means of densitometer (Method A) and optical rotational values (Method B). In method A the reaction mixture was developed on a silica gel TLC plate using benzene–pyridine as a solvent, the spots being detected by ninhydrin or sulfuric acid. In method B the ratio was calculated from the optical rotational value of the product mixture using that of each component. When the two isomers were well separated on TLC, the weights of products isolated by preparative TLC were also used for the estimation of the ratios of products (Method C). The results are summarized in Table 1. In each case the yield of the product mixture was over 90%. The ratios obtained by the different methods agreed with each other. In the case of **2**, closer mobility on TLC of two products may cause a slightly larger deviation of the ratios by method A. Thus, predominant formation of 2-amino derivatives could be ascertained for all four isomers.

Structures of newly obtained ammonolysis products of **2** were elucidated easily by NMR data, *viz.*, the

Table 1. Ratios of ammonolysis and azidolysis products

2,3-Anhydro sugars	Products[a]	Ratios of 2- and 3-substituted products/%							
		Ammonolysis				Azidolysis			
		NH_3/MeOH			NH_3/H_2O				
		A[b]	B[b]	C[b]	A	A	B	C	D[b]
1 (α-lyxo)	2-	64		60*	61	22[c]		15[c]*	16
	3-	36		40*	39	78[c]		85[c]*	84
2 (α-ribo)	2-	64	72*		55	44	52	51*	
	3-	36	28*		45	56	48	49*	
3 (β-lyxo)	2-	75	71*		73	57[c]		55[c]*	57
	3-	25	29*		27	43[c]		45[c]*	43
4 (β-ribo)	2-	60	66*		65	30	23	18*	
	3-	40	34*		35	70	77	82*	

a) 2- =2-Substituted product, 3-=3-substituted product. b) The following methods were used for estimation; A: densitometer, B: optical rotation, C: weight, D: NMR (see Experimental). c) Isolated as 3-acetates. *These values were used for the estimation of relative rates described in Discussion.

chemical shift of H_1 and the coupling constants of ring protons. H_1 signals of 2-amino (**7a**) and 3-amino (**8a**) derivatives appear at δ 4.17 ($J_{1,2}$=7.5 Hz) and δ 4.89 ($J_{1,2}$=3.5 Hz), indicating axial-axial and equatorial-axial orientations of H_1 and H_2, respectively. This and the coupling constants of other ring protons confirmed α-D-*arabino* (**7a**) and α-D-*xylo* (**8a**) configurations (Table 2).

Ammonolysis reaction in aqueous ammonia was also examined. In this reaction, the anhydro sugar did not dissolve at first, but went into solution with the progress of the reaction. Little difference was observed between the two solvents, methanol and water (third column, Table 1). The reason for the slightly different ratio for the products of **2** is not clear.

The 2,3-anhydro sugars was then treated with sodium azide in 2-methoxyethanol containing 5% water at 110 °C in the presence of ammonium chloride. The ratios of two ring-opening products, 2-azido and 3-azido derivatives, were determined by the same method as described above.

Estimation from NMR spectra was used as the fourth method (Method D) in the cases of azidolysis products of **2** and **3** because of poor separation on TLC. The reaction mixture could be separated on TLC after *O*-acetylation, the ratios being determined also by Methods A and C. As shown in Table 1 the results obtained from the various methods agree with each other. The error of these values was estimated to be about 5%, but the densitometric method may give a larger error since the difference of color development for each compound has

a) The suffixes 5a and 5e designate the axially and equatorially oriented protons on C-5, respectively, in the $^0H_5$ conformation. b) Analyzed as AB_2 and confirmed by simulation. c) Could not be obtained from the spectrum. d) The ratios estimated by $J_{1,2}$ and $J_{4,5a}$ are 50 : 50 and 89 : 11, respectively. e) The ratios estimated by $J_{1,2}$ and $J_{4,5a}$ are 18: 82 and 85 : 15, respectively. *These values were used for the estimation of relative rates (see Discussion).

not been considered.

Structures of these azidolysis products could be ascertained by their NMR data (Table 2). The products from **1** and **3** were characterized again as *O*-acetyl derivatives.

In order to elucidate the above result, *i.e.* the different regioselectivity in the ammonolysis and azidolysis reactions, the relative reaction rates and the conformations of these 2,3-anhydropentopyranosides were examined. The reactions were carried out in sealed tubes and followed by TLC. The conversion ratios determined densitometrically and the relative reaction rates estimated from the conversion ratios after the shortest reaction time examined are summarized in Table 3. The relative reaction rates are qualitative, but show a clear difference in the relative reactivities of the 2,3-anhydro sugars.

The pyranoside ring in 2,3-anhydropyranosides takes two half-chair forms, $^0H_5$ and $^5H_0$. The conformational equilibrium between these two forms was estimated by the coupling constants of vicinal ring protons, $J_{4,5}$ together with $J_{1,2}$ and $J_{3,4}$. The following standard values[4] were used for estimation: $J_{4a,5a}$ 9.9, $J_{4e,5e}$ 1.5; *cis*-$J_{1peq,2}$ 3.1, *cis*-$J_{1pax,2}$ 0.9; *cis*-$J_{3,4peq}$ 5.4, *cis*-$J_{3,4pax}$ 1.7 Hz.[9] Although the ratios estimated by $J_{4,5}$ should be more reliable considering the magnitude of difference in two conformers, those by $J_{1,2}$ and $J_{3,4}$ also indicate predominant conformers in the cases of the isomers having *cis*-relationship between H_1 and H_2, or H_3 and H_4. While the first-order analysis of H_4, H_5, and H_5, in **3**[8] and **4**[6] were possible, the NMR signals of the corresponding protons in **1** and **2** were not well separated. Coupling constants concerning these protons could be obtained in the aid of lanthanoid shift reagents or simulation (Table 4).

Predominance of $^0H_5$ conformation was confirmed in the cases of **1** and **2**, while **4** adopts $^0H_5$ conformation slightly preferentially than $^5H_0$ conformation (last column, Table 4). The use of lanthonoid shift reagents seems to cause no remarkable change of conformation[10] as supposed in the cases of **2** and **4**. In the case of **3** the ratios estimated by $J_{1,2}$ and $J_{4,5}$ are totally different, indicating a deviation from the half-chair conformation. The values of $J_{1,2}$, $J_{4,5a}$ and $J_{4,5e}$ are in line with the flattened half-chair conformation. The dihedral angles H-1–C-1/C-2–H-2, H-4–C-4/C-5–H-5a, and H-4–C-4/C-5–H-5e are 40°, 55°, and 65°, respectively. They were determined by assuming the Karplus-type dependence of coupling constants.[11,12] Thus, the predominant existence of $^0H_5$ conformation in **1**, **2**, and **4**, and also the flattened half-chair conformation of **3** confirm the importance of the anomeric effects on the conformational stability, observed in some 2,3-anhydropyranosides taking half-chair conformation.[13]

Discussion

In order to examine the factors affecting the regiospecificity of ring-opening reactions the results were analysed with the following assumptions.

1) The epoxides **1**, **2**, and **4** react with the nucleophiles in one of two half-chair conformations according to the Fürst-Plattner rule (Fig. 1).

2) The mutual conformational inversion is much faster than the reaction.

3) Epoxide **3** reacts in the flattened half-chair conformation, where the attack of nucleophiles can take place both at C-2 and C-3.

Although the deviation from the Fürst-Plattner rule, *i.e.*, *trans* diequatorial ring opening, was observed even in the conformationally rigid system especially when the favorable reaction site due to this rule is C-2, which is contrariwise the electronically unfavorable one[14] in the case of 2,3-anhydropyranosides such as 2,3-anhydro-4,6-*O*-benzylideneallopyranosides,[15] the contribution of such ring opening may be negligible as the first approximation. The expected relative small value of the free energy of conformational inversion in these epoxides also supports the assumption. The second assumption may be admitted for a reaction, whose activation energy is much higher than the free energy of conformational conversion. The reactions discussed here seem to

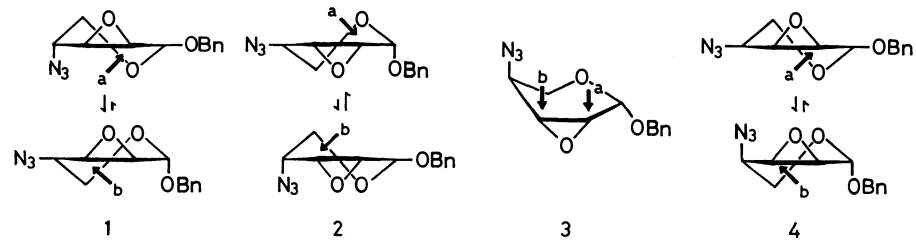

Fig. 1. Conformations and stereoelectronically preferred reaction sites of 2,3-anhydro-4-azido-4-deoxypentopyranosides.

correspond to this case, judging from those of substituted cyclohexene derivatives (25—30 kJ/mol),[16] which adopt a similar half-chair conformation to 2,3-anhydropentopyranoside.

The relative reaction rate of each conformer or site, K_a and K_b, were estimated by means of the equations,

$$K = N_a K_a + N_b K_b,$$

$$\frac{P_a}{P_b} = \frac{N_a K_a}{N_b K_b},$$

where N and P represent the mole fractions of two conformers (Table 4) and products (Table 1), respectively, and K is the relative reaction rate of each epoxide (Table 3). Suffixes a and b indicate the conformers or positions which give the 2- and 3-substituted products, respectively. The following relative reaction rates were obtained, where the standards are the same as in Table 3 and the comparison is significant only in the same reaction. In general the azidolysis reaction is faster than the ammonolysis. These results give useful informations for synthetic purpose.

	1a	**1b**	**2a**	**2b**	**3a**	**3b**	**4a**	**4b**
Ammonolysis	12	1.7	0.8	3.1	0.7	0.3	4.0	1.2
Azidolysis	0.8	1.0	1.1	10	0.6	0.5	0.75	1.9

(a) Among several possible interactions between the nucleophile and the reactant epoxide the dipole-dipole interaction between C_2---nucleophile and two C_1–O dipoles in the transition state may be the most effective factor as indicated in the cases of **1a** and **4a**. These conformers show higher reactivities than the other in ammonolysis, and lower reactivities in azidolysis. The differene ccould be explained by reverse direction of C_2---nucleophile diople as shown in Fig. 2.[17] A comparison of the reactivity between **2a** and **4a** shows the effect, which affects only **4a**. Thus the electronic character of the nucleophile controls the direction of ring opening.

(b) If the reactivity is not markedly increased or decreased by the dipole-dipole interaction, the attack of the nucleophile at the electronically favorable C-3 position predominates, as is well known in the reaction of 2,3-anhydro sugars.[1] In ammonolysis, **2b**, **1b**, and **4b** have higher reactivities except **1a** and **4a**, while in azidolysis **2b** and **4b** show the same tendency.

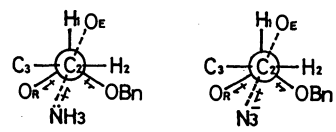

Fig. 2. Dipole-dipole interactions at the transition state of substitution on C-2 (O_E and O_R represent the oxygens in the epoxide and pyranoside rings, respectively.)

(c) The electronic or steric interactions between the nucleophile and the quasi-axial substituent (azido or benzyloxy group on the carbon adjacent to the epoxide) were also suggested by comparing **1a** with **4a** and **2b** with **4b**. There seems to be a little difference in the nature of the interactions between these groups and the nucleophiles. The axial azido group accerelates ammonolysis and retards azidolysis, while the axial benzyloxy group retards both reactions.

The evaluation of these interactions would be helpful for prediction of the ammonolysis and azidolysis products of 2,3-anhydropentopyranosides.

Experimental

General. Melting points were determined with a Beckmann Mel-temp melting point apparatus and are not corrected. Optical rotations were measured in methanol (M), unless otherwise stated, using a 0.5-dm tube with a Carl Zeiss LEP-Al or a JASCO DIP-4 polarimeter. IR spectra were recorded with a Hitachi EPI-G2 grating spectrometer, and NMR spectra with a JEOL JNM PS-100 spectrometer in chloroform-*d* containing tetramethylsilane as an internal reference. Chemical shifts and coupling constants are recorded in δ and Hz units, IR frequencies in cm^{-1}. All NMR data are summerized in Table 2. Evaporation was carried out in a rotary evaporator under reduced pressure. The products were recrystallized from ethanol unless otherwise stated. TLC was performed on silica gel (Merck Kieselgel H type 60) using the following developing solvent: A, benzene–pyridine (3 : 2); B, benzene–pyridine (7 : 3); C, benzene–methanol (200 : 1).

Benzyl 2,3-anhydro-4-azido-4-deoxypentopyranosides having α-D-*lyxo* (**1**), α-D-*ribo* (**2**), β-L-*lyxo* (**3**), and β-L-*ribo* (**4**) configurations were prepared according to published procedure.[6-8]

Ammonolysis of 2,3-Anhydropentopyranosides. A solution of 2,3-anhydro sugar (250 mg, 1 mmol) in methanol (20 ml) saturated with ammonia was heated in a sealed tube at 95 °C. After complete disappearance of the starting material the reaction solution was evaporated to give a crystalline mixture of products, which was separated on preparative TLC with the developing solvent A or B. Ammonolysis products of **1** (**5a** and **6a**),[6] **3** (**9a** and **10a**),[7] and **4** (**11a** and **12a**)[8] have been reported.

*Benzyl 2-Amino-4-azido-2,4-dideoxy-α-*D*-arabinopyranoside (**7a**) and Benzyl 3-Amino-4-azido-3,4-dideoxy-α-*D*-xylopyranoside (**8a**).* Ammonolysis of **2** was performed for 48 h, two isomeric products being separated as described above. **7a**: mp 119—121 °C, $[\alpha]_D$ +42.7° (*c* 1.1, M); IR (KBr): 3260 and 3330 (NH_2 and OH), 2100 (N_3), 700, and 730 (Phenyl). Found: C, 54.25; H, 5.97; N, 20.80%. Calcd for $C_{12}H_{16}N_4O_3$: C,

54.55; H, 6.10; N, 21.20%. **8a**: mp 122—124 °C, $[\alpha]_D$ +118° (*c* 0.75, M); IR(KBr): 3320 (NH_2 and OH), 2100 (N_3), 700 and 735 (Phenyl). Found: C, 54.41; H, 6.13; N, 20.95%. Calcd for $C_{12}H_{16}N_4O_3$: C, 54.55; H, 6.10; N, 21.20%. NMR data: see Table 2.

Azidolysis of 2,3-Anhydropentopyranosides. A suspension of 2,3-anhydro sugar (250 mg, 1 mmol), sodium azide (250 mg, 3.8 mmol), and ammonium chloride (100 mg, 1.9 mmol) in 2-methoxyethanol–water (14 : 1, 20 ml) was heated in a sealed tube at 110 °C. After the reaction had been completed, the insoluble material was filtered off, and the filtrate evaporated. The residue was extracted with methanol, the mixture of two isomeric products obtained by evaporation of the extract being separated by preparative TLC with multiple development using solvent C.

Benzyl 3-O-Acetyl-2,4-diazido-2,4-dideoxy-α-D-xylopyranoside (5c) and Benzyl 2-O-Acetyl-3,4-diazido-3,4-dideoxy-α-D-arabinopyranoside (6c). Azidolysis of **1** was performed for 4 h as described above. Since a mixture of two isomeric products (**5b** and **6b**) obtained could not be separated on TLC, it was acetylated with acetic anhydride in pyridine in the usual way to give **5c** and **6c**, which were separated by prepaprative TLC with developing solvent C. **5c**: sirup $[\alpha]_D$ +229° (*c* 0.6, M); IR(NaCl): 2100 (N_3), 1755 (OAc), 695, and 738 (Phenyl). Found: C, 50.66; H, 4.92; N, 24.89%. Calcd for $C_{14}H_{16}N_6O_4$: C, 50.60; H, 4.85; N, 25.29%. **6c**: sirup, $[\alpha]_D$ +49.9° (*c* 1.7, M); IR(NaCl): 2100 (N_3), 1745 (OAc), 695, and 740 (Phenyl). Found: C, 51.04; H. 4.86; N, 24.93%. Calcd for $C_{14}H_{16}N_6O_4$: C, 50.60; H, 4.85; N, 25.29%. NMR data: see Table 2.

Benzyl 2,4-Diazido-2,4-dideoxy-α-D-arabinopyranoside (7b) and Benzyl 3,4-Diazido-3,4-dideoxy-α-D-xylopyranoside (8b). Azidolysis of **2** as described for **1** gave **7b** and **8b**, which could be separated without acetylation. **7b**: sirup, $[\alpha]_D$ +26.5° (*c* 0.6, M); IR(NaCl): 3320 (OH), 2110 (N_3), 700, and 745 (Phenyl). Found: 49.30; H, 4.48; N, 28.68%. Calcd for $C_{12}H_{14}N_6O_3$: C, 49.65; H, 4.86; N, 28.95%. **8b**: sirup, $[\alpha]_D$ +259° (*c* 0.7, M); IR(NaCl): 3400 (OH), 2110 (N_3), 700, and 745 (Phenyl). Found: C, 49.27; H, 4.52; N, 28.67%. Calcd for $C_{12}H_{14}N_6O_3$: C, 49.65; H, 4.86; N, 28.95%. NMR data: see Table 2.

Benzyl 3-O-Acetyl-2,4-diazido-2,4-dideoxy-β-L-xylopyranoside (9c) and Benzyl 2-O-Acetyl-3,4-diazido-3,4-dideoxy-β-L-arabinopyranoside (10c). Azidolysis of **3** and separation of the isomeric products were carried out in the same way as described for **5c** and **6c**. **9c**: mp 107—110 °C, $[\alpha]_D$ +18.0° (*c* 0.6, M); IR(KBr): 2100 (N_3), 1755 (OAc), 715, and 750 (Phenyl). Found: C, 50.60; H, 4.64; N, 24.96%. Calcd for $C_{14}H_{16}N_6O_4$: C, 50.60; H, 4.85; N, 25.29%. **10c**: sirup, $[\alpha]_D$ +168° (*c* 0.9, M); IR(NaCl): 2105 (N_3), 1748 (OAc), 700, and 740 (Phenyl). Found: C, 50.24; H, 4.59; N, 24.91%. Calcd for $C_{14}H_{16}N_6O_4$: C, 50.60; H, 4.85; N, 25.29%. NMR data: see Table 2.

Benzyl 2,4-Diazido-2,4-dideoxy-β-L-arabinopyranoside (11b) and Benzyl 3,4-Diazido-3,4-dideoxy-β-L-xylopyranoside (12b). Azidolysis of **4** and separation of the isomeric products were carried out in the same way as described for **7a** and **8b**. **11b**: sirup, $[\alpha]_D$ +173° (*c* 0.7, M); IR(NaCl): 3380 (OH), 2100 (N_3), 700 and 740 (Phenyl). Found: C, 49.76; H, 4.60; N, 28.91%. Calcd for $C_{12}H_{14}N_6O_3$: C, 49.65; H, 4.86; N, 38.95. **12b**: reported.[8] NMR data: see Table 2.

Ratios of Ammonolysis and Azidolysis Products. Method A. In order to estimate the ratio with a densitometer, TLC was performed using Merck silica gel plate and self-made one, whose uniformity of thickness was checked densitometrically before use, with solvent A or B for the ammonolysis products and C for azidolysis ones. Each spot was detected by sulfuric acid and also by ninhydrin in the case of the ammonolysis products, and measured at 560 nm with an Atago Kemic densitometer. Each sample was developed, detected, and determined densitometrically three times separately, and the values were averaged. Method B. An analytically pure mixture of the products was obtained by preparative TLC with the same solvent system as described for Method A. Its rotational value compared with that of each component gave the desired ratio. Method C. In some cases, where the products could be well separated on TLC, the ratios were also obtained from the amount of isolated isomers by preparative TLC using the same solvents as described above. Method D. The ratio was estimated from the intensity of H_1 and H_{5a} signals in the NMR spectra of the analytically pure mixture of azidolysis products obtained by Method B.

This work was supported in part by a Grant-in-Aid for Scientific Research No. 554158 from the Ministry of Education, Science and Culture.

Reactions of 5,6-Dilithioacenaphthene-*N,N,N',N'*-Tetramethyl-1,2-ethanediamine Complex with α-Diketones. I. *cis*-Directing 1 : 1 Cyclic Additions with Acyclic and Cyclic α-Diketones and Related Compounds[1]

Norio TANAKA and Toshiyasu KASAI*

Department of Chemistry for Engineering, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received January 8, 1981)

The title complex (**3**) is readily generated from 5,6-dibromoacenaphthene with butyllithium and the diamine in ether at −10—0 °C. The reaction of **3** with biacetyl gave *cis*-1,2,5,6-tetrahydro-1,2-dimethylcyclopent[*fg*]-acenaphthylene-1,2-diol but no *trans*-isomer, whereas the reaction of pyracenequinone (PYQ) with methylmagnesium bromide gave both the *cis*- and *trans*-diols. The reactions of **3** with acenaphthenequinone and PYQ also gave *cis*-diols. On treatment with phenylboronic acid, these *cis*-diols quantitatively yielded the corresponding cyclic esters. The diols and their derivatives tend to form crystalline molecular compounds with solvent molecules. The stereoselectivity of the cyclic addition between **3** and the acyclic α-diketone can be best explained in terms of five-membered chelate-ring formation in a transition state.

5,6-Dilithioacenaphthene (**1**)[2,3] can be regarded as a nucleophile like 1,8-dilithionaphthalene (**2**)[4,5] which possesses two reaction sites at the peri positions of a naphthalene nucleus; thus, its synthetic conditions and reaction modes are of interest in connection with the peri interaction in naphthalene derivatives.[6] This paper describes an improved method for the generation of **1** as a *N,N,N',N'*-tetramethyl-1,2-ethanediamine (TMEDA) complex, and reports its *cis*-directing 1 : 1 cyclic additions with some α-diketones.

Results and Discussion

Generation of 5,6-Dilithioacenaphthene–TMEDA Complex (3).[7] The dihaloprecursor, 5,6-dibromoacenaphthene (**4**), can readily be prepared in a 15—20% yield from the reaction of acenaphthene (**5**) with *N*-bromosuccinimide by use of the procedure developed in our laboratory.[2]

An ethereal suspension of **4** was quantitatively converted into the solution of **3** by a 1 : 1 mixture of butyllithium (*n*-BuLi)[8] and TMEDA[9] at −10—0 °C within 15—30 min. Such mild conditions are preferable to those without TMEDA, in which case at least 1 h of refluxing is essential.[2] The substantially quantitative formations of 5,6-acenaphthenedicarboxylic anhydride (**6**) and 5,6-diiodoacenaphthene (**7**) confirm that the structure of **3** possesses two reaction sites at the peri positions (Eq. 1).[10]

cis-Directing 1 : 1 Cyclic Additions between 3 and α-Diketones. The reactions of **3** were investigated with three α-diketones: acenaphthenequinone (ACQ), pyracenequinone (5,6-dihydrocyclopent[*fg*]acenaphthylene-1,2-dione; PYQ), and biacetyl (Ac_2). Reaction conditions and results are summarized in Table 1.

The 1 : 1 cyclic additions of both ACQ and PYQ with **1** have been reported by Mitchell *et al.*[3] The reactions of the TMEDA complex (**3**) also gave the identical products (**8** and **9**) in almost the same yields

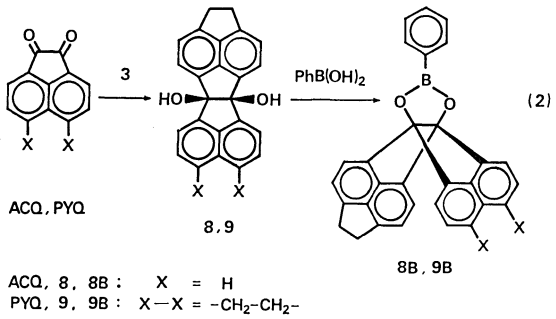
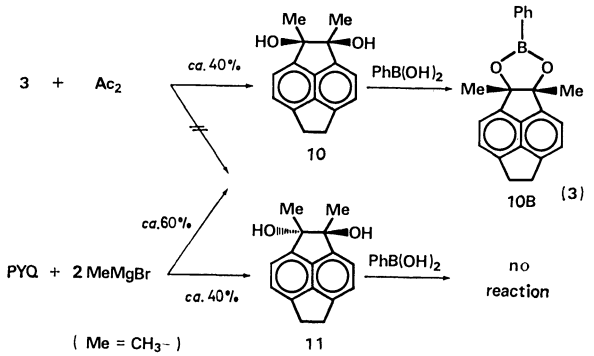
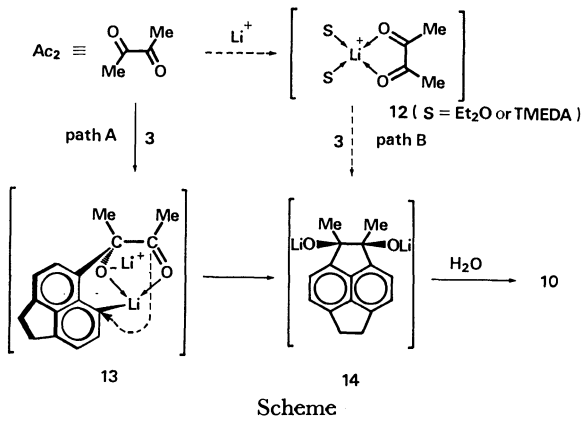
as those reported. The use of TMEDA considerably shortened each reaction-time (see Table 1) in comparison with that in the literature[3] (14 h at room temperature or 6 h on refluxing in ether). The reactions of **8** and **9** with phenylboronic acid (dihydroxyphenylborane; $PhB(OH)_2$)[5] quantitatively yielded cyclic esters **8B** and **9B**, respectively (Eq. 2). These facts prove the *cis*-conformation of the 1,2-diols.



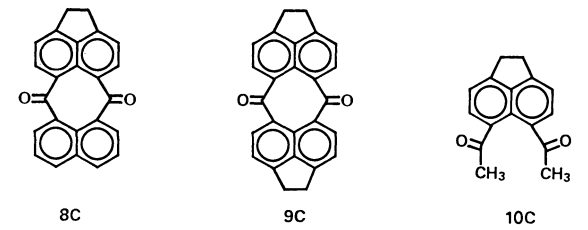


A 1 : 1 cyclic addition also took place between **3** and biacetyl and gave *cis*-diol **10** (mp 134—135 °C), which was quantitatively converted into cyclic ester **10B** with $PhB(OH)_2$. The *trans*-isomer (**11**; mp 171—172 °C) was separately synthesized from the reaction of PYQ with methylmagnesium bromide, and did not react with $PhB(OH)_2$. In this Grignard reaction, *cis*-diol **10** was also yielded in the *cis* : *trans* ratio of about 3 : 2 (Eq. 3). On the other hand, no **11** was detected in the reaction mixture of **3** with biacetyl. Hence, it is concluded that the cyclic addition of each of the three α-diketones to **3** proceeds in a completely *cis*-directing mode.

As Letsinger and Gilpin[5] have discussed in the case of **2** with ACQ, the five-membered *o*-quinone parts of ACQ and PYQ sterically require the *cis*-orientation of the addition product with **1** or **2**. But biacetyl itself, whose quasi-*trans*-conformation has been confirmed in the literature,[11] does not require the *cis*-directing cyclization. The possibility that biacetyl forms a chelate (**12**) and adopts a *cis*-conformation before the addition (Scheme, path B) has been disproved spectroscopically: The electron spectrum of biacetyl was uninfluenced by the presence of lithium cation.[12] The cyclic addition is, therefore, considered to be a two-step process that involves an α-oxide ketone intermediate (**13**) in which a five-membered chelate-ring permits only the *cis*-directing intramolecular cyclization (Scheme, path A). An analogous transition state has been proposed by Cram



Scheme



et al.[13] in order to explain the stereoselectivities in the reactions of α-hydroxy ketones and α-methoxy ketones with monofunctional organolithium compounds. In comparison with their results, the stereoselectivity of the present system is very high. This must be ascribed to the specific structure of **3** described before.

The reactions of *cis*-diols **8**, **9**, and **10** with lead(IV) acetate gave diketones **8C**, **9C**, and **10C** in 81, 84, and 92% yields, respectively, under the appropriate conditions described later. Because it has been confirmed that the reaction of **5** with acetyl chloride in the presence of aluminium chloride yields only 3,6-diacetylacenaphthene (mp 149 °C),[14] the cleavage of **10** is a new method for the synthesis of authentic 5,6-diacetylacenaphthene (**10C**; mp 156—157 °C).

It is worth noting that diols **8**, **9**, **10**, and **11**, cyclic esters **8B** and **9B**, and diketones **8C** and **9C** tend to form crystalline molecular compounds with some solvent molecules. Some of them are listed in Table 2. Notice that *cis*-diol **10** (mp 134—135 °C) formed a white molecular compound (mp 143—144 °C) with **5** (mp 94—95 °C). The solvent molecules in these crystals did not dissociate under an aspirator pressure at room temperature, whereas recrystallizations from suitable solvents separated their components, except in the case

Table 2. Crystalline molecular compounds

Component A	Component B	Composition (A : B)[a]	Mp/°C
10	Acenaphthene	2 : 1	143.0—144.0
10	Benzene	3 : 1	127.0—129.0
11	Cyclohexane	3 : 1	170.0—171.0
9B	Benzene	1 : 1	302.0—304.0[b]
9B	Cyclohexane	1 : 1	190[b]

a) Determined by elemental analysis and ^1H NMR spectrum. b) Dissociation in an argon-filled, sealed capillary.

of cyclohexane- or benzene-**9B** (see Experimental). "Solvated" crystals were also observed in the following systems: **8**/ethanol, **8**/acetone, **9**/benzene, **10**/cyclohexane, **11**/carbon tetrachloride, **8B**/cyclohexane, **8C**/acetic acid, and **9C**/acetic acid. By reference to analogous compounds known as "clathrate compounds,"[15] the three-dimensional bulkinesses of the diols and their derivatives seem to be related to the solvent inclusions.

The reactions of benzil and 9,10-phenanthrenequinone with **3** gave no 1 : 1 cyclic addition product, but rather gave unexpected, novel products. Their details will be reported separately.[16]

Experimental

General Procedures. All melting points except that over 360 °C are corrected; some of them were measured in argon-filled, sealed capillaries after degassing. Electron spectra were determined on a Shimadzu UV-200 double beam spectrophotometer. Fluorescence excitation- and emission-spectra were measured on a Shimadzu RF-501 recording spectrofluorophotometer. IR spectra were taken on a JASCO IRA-1 spectrophotometer, using KBr pressed discs. ^{1}H NMR spectra were recorded on a JEOL JNR-PS-100 (100 MHz) or a Hitachi R-40 (90 MHz) spectrometer. Chemical shifts are given in ppm relative to tetramethylsilane as an internal standard. In assignments, abbreviations PhH, NpH, ActH, and ArH mean benzene-, naphthalene-, and acenaphthene-ring protons and aromatic protons, respectively. Mass spectra were taken on a JEOL JMS-D-100 or a Hitachi RMU-7M mass spectrometer at an ion-source temperature of 200 °C and an ionizing voltage of 70 eV unless otherwise indicated. Analytical determinations by GLC were performed on a Shimadzu GC-3BT gas chromatograph operated at 220 °C with a 3 m×3 mm column of 10% SE-30 on Celite 545SK and with helium as carrier gas.

Pyracenequinone was prepared according to the reported method;[17] mp 304.0—306.0 °C (dec), (lit,[17a] mp 305—306 °C). All other chemicals were obtained commercially.[18] Acenaphthenequinone[18a] was recrystallized from toluene. Each of the quinones was ground down and degassed *in vacuo* before use. The biacetyl used was freshly distilled. Lithium perchlorate[18c] was dried at 200 °C/0.1 mmHg† for 2 h. Acetonitrile (Dotite Spectrosol)[18b] was dried with Molecular Sieves 5A. Under an argon atmosphere, "dry" solvents (diethyl ether and benzene) were distilled from sodium wire and then stored with Molecular Sieves 4A or 5A. TMEDA[18a] was refluxed with calcium hydride for 2—3 h and distilled.

All the reactions of **3** and of lead(IV) acetate were carried out under an argon atmosphere. All organic extracts were washed with aqueous concd sodium chloride and dried with anhydrous magnesium sulfate unless otherwise indicated. All evaporations were carried out under a reduced pressure on a rotary evaporator below *ca.* 50 °C.

5,6-Dibromoacenaphthene (4). This was prepared by the method of Yoshiwara[2] with modifications. To a *N,N*-dimethylformamide (DMF) suspension of acenaphthene (77.1 g, 0.50 mol in 250 cm^3), a DMF solution of *N*-bromosuccinimide (NBS)[18c] (89.0 g, 0.50 mol in 250 cm^3) was added dropwise over a period of 90 min at 30—40 °C. After the mixture had been stirred for 1 h at about 30 °C, additional NBS (133.5 g, 0.75 mol) was added in portions over a period of 90 min, the temperature being maintained at 30—40 °C. The dark mixture which formed was stirred for 2 h at about 30 °C and then allowed to stand overnight in a refrigerator. The pale yellow crystalline **4** which precipitated was filtered off, washed with a small amount of DMF and 100 cm^3 of methanol, and dried *in vacuo*. This crude product (mp 166.5—171.5 °C) was recrystallized from carbon tetrachloride,[19] giving 24—31 g (15—20%) of pure **4** as almost colorless needles: mp 174.0—176.0 °C, (lit,[3] mp 173—175 °C).

Generation of 3. All solutions of **3** were prepared just before use as follows. All glassware pieces were heated in a drying oven (*ca.* 100 °C) and then quickly assembled; **4** (1.560 g, 5.00 mmol) was introduced into a four-necked 500 cm^3-flask which was then equipped with a thermometer, a stopcock for sampling, a pressure-equalizing addition funnel joined with a stopcock, and a reflux condenser joined with a three-way stopcock for attachment to a vacuum-line and an argon-line. During a few repetitions of the pumping—argon-introducing cycle, the crystals of **4** were milled with a magnetic stirrer. Dry ether (300 cm^3 or 150 cm^3) was introduced into the flask with syringe-technique and then cooled on an ice–ethanol bath. During the period of cooling, *n*-BuLi (12.0 mmol in 5.5 cm^3 of hexane) was injected into the addition funnel and then mixed with TMEDA (2 cm^3, 13.3 mmol). After the yellow suspension which resulted had been allowed to stand for 15 min, it was added dropwise to the ethereal suspension over a period of 15 min with gentle stirring, and the pale red solution which formed was then stirred for 15 min. During these operations, the temperature was maintained at −10—0°C. A 0.5—1.0 cm^3 of sample of the solution was added to aqueous ammonium chloride and then analyzed gas-chromatographically. The relative peak-area of acenaphthene is usually≥99% within 5—12 min after the adding of *n*-BuLi–TMEDA. In case that a theoretical amount of *n*-BuLi was used, 5—10% of 5-bromoacenaphthene[20] was observed.

5,6-Acenaphthenedicarboxylic Anhydride (6). A solution of **3** (5.00 mmol in 150 cm^3 of ether) was cooled below −70 °C and poured onto crushed dry ice under an argon atmosphere. After the mixture had been allowed to come to room temperature, the white salt which formed was filtered off, washed with ether, and dried *in vacuo*. The quantitative yield of lithium salt (mp>340 °C) was extracted with 30 cm^3 of aqueous 5% sodium carbonate, and the extract was acidified with concd hydrochloric acid, giving 1.11 g (91.4%) of crude 5,6-acenaphthenedicarboxylic acid: mp 282.0—289.0 °C (dec/Ar); IR 3600—2400 (broad band) and 1670 cm^{-1} (C=O). Recrystallization from acetic acid gave anhydride **6**: mp 298.5—299.5 °C (under Ar), (lit,[21] mp 293—294 °C); $UV_{max}(C_2H_5OH)$ 213.5 (log ε 4.20), 237 (4.41), 247 (4.34), 332 (3.89), and 352 nm (3.88); IR 1790, 1765, and 1740 cm^{-1} (C=O).

(Found: C, 75.41; H, 3.26%).

5,6-Diiodoacenaphthene (7). To a solution of **3** (5.00 mmol in 300 cm^3 of ether), a solution of iodine (2.82 g, 11.1 mmol in 25 cm^3 of ether) was added dropwise over a period of 30 min at −10—0 °C. The dark mixture was stirred for 30 min with cooling and for 1 h without cooling. To the mixture 100 cm^3 of aqueous 5% sodium thiosulfate was added with vigorous stirring. The organic layer which separated was washed with aqueous sodium thiosulfate and then water, dried, and evaporated. The pale brown residue, 1.94 g (95.4%) of crude **7** (mp 144.0—148.5 °C), was recrystallized from hexane and then ethanol,[19] giving 1.26 g (62%) of pure **7**: mp 159.0—160.5 °C (dec), (lit,[22] mp 159—160 °C).

(Found: C, 35.44; H, 1.90; I, 62.24%).

cis-1,2-Dihydrocyclopenta[1,2-a: 3,4,5-f'g'] diacenaphthylene-4b,10b-diol (8). Acenaphthenequinone (0.900 g, 4.94 mmol)

† 1 mmHg≃133.3 Pa.

was added to a solution of **3** (5.13 mmol in 300 cm^3 of ether) with vigorous stirring over a period of 30 min at −10—0 °C. The deep violet suspension which resulted was stirred for 2 h with cooling and for 1 h without cooling. Aqueous ammonium chloride (30 g/100 cm^3) was added to the suspension with vigorous stirring. The dark yellow solid which precipitated was filtered off, washed with water and ether, and dried *in vacuo*; 87 mg (9.7%) of the quinone being recovered. The combined organic layer was washed, dried, and evaporated. The residue was washed with hot carbon tetrachloride and water and dried *in vacuo*, giving 326 mg (21.8%) of crude **8** (mp 280—283 °C (dec)). Recrystallization from benzene[19] gave 269 mg (16.2%) of pure **8** as white needles: mp 320.0—322.0 °C (dec/Ar), (lit,[3] mp 304—308 °C (dec)); UV_{max} (C_2H_5OH) 219 (log ε 4.89), 265 (3.54), 275 (3.75), 287 (3.88), 316 (4.13), and 330 nm (4.15); $Fluorescence_{max}$ (C_2H_5OH) 398 nm (excitation at 325 nm); IR 3500 and 3350 cm^{-1} (OH); MS (215 °C, 30 eV), *m/e* (rel intensity), 336 (100), 318 (34), 317 (21), and 290 (25).

(Found: C, 85.89; H, 4.58%).

cis-*1,2,7,8-Tetrahydropentaleno*[*1,2,3*-fg: *4,5,6*-f′g′]*diacenaphthylene-4b,10b-diol* (**9**). A solution of **3** (5.00 mmol in 300 cm^3 of ether) was treated with pyracenequinone (1.60 g, 7.67 mmol) as described above for **8**. After hydrolysis, the unreacted pyracenequinone was extracted with aqueous 10% sodium hydrogensulfite,[17] 499 mg (31.2%) of the quinone being recovered. Crude **9** (27.4%, mp 292—295 °C (dec)) was recrystallized from benzene[19] and then acetone, giving 386 mg (21.3%) of pure **9** as a white powder: mp 347.0—348.0 °C (dec/Ar), (lit,[3] mp 316—320 °C (dec)); UV_{max} (C_2H_5OH) 216 (log ε 4.80), 230 (4.87), 259 (3.28), 269 (3.51), 280 (3.78), 291 (3.96), 319 (4.19), and 333 nm (4.24); $Fluorescence_{max}$ (C_2H_5OH) 394 nm (excitation at 328 nm); IR 3435 and 3315 cm^{-1} (OH); MS, *m/e* (rel intensity), 362 (100), 361 (27), 360 (44), 359 (23), 345 (29), 344 (69), 343 (36), 334 (19), 333 (36), and 332 (16).

(Found: C, 86.22; H, 4.79%).

cis-*1,2,5,6-Tetrahydro-1,2-dimethylcyclopent*[fg]*acenaphthylene-1,2-diol* (**10**). To a solution of **3** (10.0 mmol in 300 cm^3 of ether), a solution of biacetyl (1.35 g, 15.6 mmol in 50 cm^3 of ether) was added over a period of 30 min at −10—0 °C. The pink suspension which resulted was stirred for 1 h with cooling and for 1 h without cooling, and then hydrolyzed with aqueous ammonium chloride (30 g/100 cm^3). The organic layer which separated was washed, dried, and evaporated. The dark residue was dissolved in 10 cm^3 of hot benzene and allowed to stand at room temperature for one day, giving 950 mg of a colorless crystal (mp 127.0—129.0 °C). This was spectrally identical with the molecular compound, benzene-**10**, prepared separately; the yield as $C_6H_6 \cdot 3C_{16}H_{16}O_2$ was 35.7%. The combined filtrate was evaporated and allowed to stand for four days, giving 162 mg of a pale brown crystal (mp 133.0—143.0 °C). This was spectrally identical with the molecular compound, acenaphthene-**10**, the yield as $C_{12}H_{10} \cdot 2C_{16}H_{16}O_2$ being 5.1%. Each of the molecular compounds was recrystallized from hexane,[19] giving a total of 914 mg (38.0%) of pure **10** as white needles: mp 134.0—135.0 °C; UV_{max} (*c*-C_6H_{12}) 226sh (log ε 4.71), 232 (4.87), 250 (2.83), 260sh (3.09), 273sh (3.58), 284 (3.84), 292sh (3.90), 296 (3.93), 305 (3.78), 311 (3.69), 319sh (3.12), and 325 nm (3.27); $Fluorescence_{max}$ (*c*-C_6H_{12}) 386 nm (excitation at 303 nm); IR 3350 (OH), 3035, 2975, 2930 sh, 2915, 2835, 1165, and 1090 cm^{-1}; NMR ($CDCl_3$) δ=7.33 (2H, d, *J*=7.0 Hz, *m*-CH_2-ActH), 7.26 (2H, broad d, *J*=7.0 Hz, *o*-CH_2-ActH), 3.42 (4H, s, $2CH_2$), 3.14 (2H, s, exch., 2OH), and 1.59 (6H, s, $2CH_3$); MS, *m/e* (rel intensity), 240 (14), 222 (12), 221 (16), 207 (48), 198 (17), 197 (100), and 179 (19).

Found: C, 79.95; H, 6.72%; M^+ 240.1121. Calcd for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%; M, 240.1150.

Molecular Compounds of **10**. *With Benzene*: A recrystallization of **10** from benzene gave benzene-**10** (1/3) as white needles; mp 127.0—129.0 °C. The IR spectrum and NMR spectrum were identical with those of pure **10**, except for the bands at 1485 and 680 cm^{-1} and δ 7.29 ppm, which are characteristic of benzene. The ratio of NMR peaks was ArH : CH_2 : OH : CH_3=6 : 4 : 2 : 6. The benzene molecule in the crystal did not dissociate at 20 °C/20 mmHg, but the crystal sublimed at 100 °C/0.1 mmHg, giving pure **10**.

Found: C, 81.18; H, 6.79%. Calcd for $C_6H_6 \cdot 3C_{16}H_{16}O_2$: C, 81.17; H, 6.81%.

With Acenaphthene: Acenaphthene (64 mg) and **10** (99 mg) were dissolved in 6 cm^3 of ether and allowed to stand for one day at −20 °C. A white precipitate formed (76 mg, mp 142—144 °C); this was filtered off and recrystallized once from ether, giving acenaphthene-**10** (1/2); mp 143.0—144.0 °C; UV_{max} (*c*-C_6H_{12}) 228 (log ε based on the assumption that the molecular weight is 317.40: 4.99), 250 sh (2.88), 286 (3.97), 292 (4.02), 296 (4.01), 305 (3.85), 310 (3.71), 320 (3.31), and 325 nm (3.26); IR 3350 and 3310 sh (OH), 3070, 3035, 2995, 2970, 2920, 2840, 1165, and 1090 cm^{-1}; NMR ($CDCl_3$) δ= 7.57—7.18 (7H, m, ArH), 3.42 (4H, s, CH_2 of **10**), 3.37 (2H, s, CH_2 of **5**), 3.00 (2H, s, exch., 2 OH), and 1.60 (6H, s, $2CH_3$).

Found: C, 82.87; H, 6.59%. Calcd for $C_{12}H_{10} \cdot 2C_{16}H_{16}O_2$: C, 83.25; H, 6.67%.

Reaction of Pyracenequinone with Methylmagnesium Bromide. Under an argon atmosphere, methylmagnesium bromide[18a] (16.8 mmol in 5.6 cm^3 of dibutyl ether) and 150 cm^3 of dry ether were introduced into a three-necked 300 cm^3-flask, and pyracenequinone (848 mg, 4.07 mmol) was added to the solution over a period of 30 min. After 2 h of refluxing, the mixture was cooled on an ice bath and hydrolyzed with aqueous ammonium chloride (15 g/50 cm^3). The organic layer which separated was washed, dried, and evaporated. The resulting dibutyl ether suspension was allowed to stand at −20 °C for 16 h. The pale yellow precipitate was then filtered off, washed with carbon tetrachloride, and dried *in vacuo*, giving 287 mg (29.3%) of crude *trans*-diol **11** (mp 168.5—170.0 °C). The combined filtrate was treated three times in a similar manner, giving 200 mg (20.4%) of crude *cis*-diol **10** (mp 130.0—132.5 °C) and 452 mg in total of a mixture of **10** and **11** (NMR spectral isomeric ratio *cis* : *trans*= 8 : 1—4 : 1). Averaged over repeated runs, the total yield of **10** and **11** was >95% and the total *cis* : *trans* ratio was approximately 3 : 2. The crude **10** and **11** on this run were individually recrystallized from hexane,[19] giving 123 mg (12.6%) of pure **10** and 237 mg (24.2%) of pure **11**: mp 171.0—172.0 °C; UV_{max} (*c*-C_6H_{12}) 224sh (log ε 4.63), 232 (4.89), 273sh (3.58), 284 (3.83), 295 (3.92), 305 (3.76), 310sh (3.65), 320sh (3.12), and 325 nm (3.18); $Fluorescence_{max}$ (*c*-C_6H_{12}) 387 nm (excitation at 304 nm); IR 3330 (OH), 3085, 3045, 2975, 2925, 2840, 1180, 1055, and 1025 cm^{-1}; NMR ($CDCl_3$) δ=7.34 (2H, d, *J*=7.5 Hz, *m*-CH_2-ActH), 7.28 (2H, broad d, *J*=7.5 Hz, *o*-CH_2-ActH), 3.44 (4H, s, $2CH_2$), 1.85 (2H, s, exch., 2OH), and 1.70 (6H, s, $2CH_3$); MS (150 °C, 75 eV), *m/e* (rel intensity), 240 (30), 222 (12), 221 (15), 207 (36), 198 (18), 197 (100), and 179 (11).

Found: C, 80.04; H, 6.70%; M^+ 240. Calcd for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%; M, 240.

Molecular Compound of **11** *with Cyclohexane*: A recrystallization of **11** from cyclohexane gave cyclohexane-**11** (1/3) as white hair-like crystals; mp 170.0—171.0 °C; IR 3340 (OH), 3085, 3040, 2980, 2925, 2840, 1180, 1055, and 1025 cm^{-1}.

The NMR spectrum was identical with a 1 : 3 mixture of cyclohexane and **11**. The cyclohexane molecule in the crystal did not dissociate at 20 °C/20 mmHg for 48 h, but did at 20 °C/0.1 mmHg, the weight-loss-ratio being 9.95% after 8 h (Calcd for: 10.45%).

Found: C, 80.07; H, 7.28%. Calcd for $C_6H_{12}\cdot 3C_{16}H_{16}O_2$: C, 80.56; H, 7.51%.

1,2-Dihydro-14-phenyl-4b,10b-(epoxyboroxy)cyclopenta[1,2-a : 3,4,5-f'g']diacenaphthylene (8B). A mixture of *cis*-diol **8** (168.25 mg, 0.5002 mmol) and phenylborenic acid[18a] (62.39 mg, 0.5116 mmol) in 50 cm³ of benzene was refluxed for 2 h. After a trace amount of suspended matter had been filtered off, the solution was evaporated to dryness, giving a quantitative yield of crude **8B** (mp 303—305 °C (under Ar)). Recrystallization from benzene gave 187.3 mg (88.7%) of pure **8B** as white needles: mp 307.0—308.0 °C (under Ar); UV_{max} (c-C_6H_{12}) 220sh (logε 4.79), 227 (4.81), 254 (3.50),264 (3.69), 274 (3.91), 280sh (3.75), 285 (4.01), 300sh (3.96), 313 (4.18), and 328 nm (4.22); $Fluorescence_{max}$ (c-C_6H_{12}) 390 nm (excitation at 322 nm); IR 3045, 2915, 2835, 1605, 1385, 1345 (-B-O-), and 1085 cm⁻¹; NMR ($CDCl_3$) δ=8.04—7.96 (2H, m, α-NpH), 7.89 (2H, d, J=7.1 Hz, m-CH_2-ActH), 7.89—7.78 (2H, m, o-B-PhH), 7.78—7,51 (4H, m, β-NpH), 7.43—7.17 (3H, m, m- and p-B-PhH), 7.27 (2H, d, J=7.1 Hz, o-CH_2-ActH), and 3.41 (4H, s, $2CH_2$); MS (220 °C, 75 eV), m/e (rel intensity), 422 (100), 421 (23), 318 (21), 300 (23), 288 (22), 262 (73), 186 (84), 149 (66), 104 (42), and 77 (30).

Found: C, 85.38; H, 4.44%; M⁺ 422 and 421. Calcd for $C_{30}H_{19}BO_2$: C, 85.33; H, 4.53%; M-^{11}B, 422 and M-^{10}B, 421.

1,2,7,8-Tetrahydro-14-phenyl-4b,10b-(epoxyboroxy)pentaleno[1,2,-3-fg : 4,5,6-f'g']diacenaphthylene (9B) and Its Molecular Compounds. *cis*-Diol **9** (181.44 mg, 0.5006 mmol) was treated with phenylboronic acid (62.41 mg, 0.5119 mmol) in 50 cm³ of benzene as described above for **8B**. The white crystalline residue was dried overnight under an aspirator pressure, giving 262.4 mg (99.6%) of crude benzene-**9B** (mp 299—302 °C (under Ar)). Recrystallization from benzene gave pure benzene-**9B** (1/1) as white needles: mp 302.0—304.0 °C (under Ar); MS (150 °C, 75 eV), m/e (rel intensity), 448 (100) and 78 (48). The λ_{max}'s of the UV spectrum in cyclohexane were identical with those of pure **9B** and the logε's, based on the assumption that the molecular weight is 526.44, were consistent with those of **9B** within ±0.03. The IR spectrum and NMR spectrum were identical with those of pure **9B**, except for the bands at 3090, 3075, 1485, and 680 cm⁻¹ and δ 7.33 (6H, s).

Found: C, 87.06; H, 5.00%. Calcd for $C_6H_6\cdot C_{32}H_{21}BO_2$: C, 86.70; H, 5.17%.

On recrystallization from cyclohexane, benzene-**9B** was converted into cyclohexane-**9B** (1/1). Under an argon atmosphere, these white needles melt at 190 °C with foaming and immediately solidify, and then re-melt at 300.0—301.0 °C. The UV spectrum, IR spectrum, NMR spectrum, and MS confirmed the composition to be the same as in the case of benzene-**9B**.

Found: C, 85.51; H, 5.87%. Calcd for $C_6H_{12}\cdot C_{32}H_{21}BO_2$: C, 85.71; H, 6.25%.

On heating at 100 °C/0.1 mmHg for 16 h and at 160 °C/0.1 mmHg for 8 h, 47.749 mg of cyclohexane-**9B** (1/1) gave 40.311 mg of pure **9B**: mp 306.0—307.0 °C; Weight loss, found: 15.58%, calcd: 15.81%; UV_{max} (c-C_6H_{12}) 224sh (logε 4.96), 230 (5.01), 258sh (3.01), 268 (3.56), 275sh (3.68), 278 (3.85), 286sh (3.81), 290 (4.04), 304sh (4.00), 315 (4.23), and 330 nm (4.30); $Fluorescence_{max}$ (c-C_6H_{12}) 390 nm (excitation at 326 nm); IR 3030, 2915, 2835, 1605, 1380, 1345 (-B-O-), 1115, and 1080 cm⁻¹; NMR ($CDCl_3$) δ=7.87 (4H, d, J=7.1 Hz, m-CH_2-ActH), 7.88—7.78 (2H, m, o-B-PhH), 7.36—7.22 (3H, m, m- and p-B-PhH), 7.27 (4H, d, J=7.1 Hz, o-CH_2-ActH), and 3.40 (8H, s, $4CH_2$); MS (150 °C, 75 eV), m/e (rel intensity), 448 (100), 447 (27), 420 (8), 344 (12), 343 (16), 326 (8), 316 (10), 315 (10), 313 (11), 262 (17), 186 (13), 149 (34), 104 (5), and 77 (25).

Found: C, 85.69; H, 4.65%; M⁺ 448 and 447. Calcd for $C_{32}H_{21}BO_2$: C, 85.73; H, 4.72%; M-^{11}B, 448 and M-^{10}B, 447.

1,2,4b,7a-Tetrahydro-4b,7a-dimethyl-6-phenylcyclopent[5,6]acenaphtho[1,2-d][1,3,2]dioxaborole (10B). *cis*-Diol **10** (240.76 mg, 1.002 mmol) was treated with phenylboronic acid (126.10 mg, 1.034 mmol) as described above for **8B**. A quantitative yield of crude **10B** (mp 164—168 °C) was recrystallized from hexane, giving 262.8 mg (80.4%) of pure **10B**: mp 169.5—171.0 °C; UV_{max} (c-C_6H_{12}) 227 (logε 4.83), 231 (4.93), 254 (3.21), 261sh (3.41), 269sh (3.62), 274 (3.72), 279sh (3.81), 283 (3.90), 291 (3.95), 295 (3.99), 304 (3.83), 310 (3.71), 319 (3.09), and 324 nm (3.13); $Fluorescence_{max}$ (c-C_6H_{12}) 387 nm (excitation at 303 nm); IR 3060, 2985, 2945, 2915, 1600, 1390, 1385, 1350 (-B-O-), and 1090 cm⁻¹; NMR ($CDCl_3$) δ=7.81—7.71 (2H, m, o-B-PhH), 7.49 (2H, d, J=7.1 Hz, m-CH_2-ActH), 7.43—7.14 (3H, m, m- and p-B-PhH), 7.29 (2H, broad d, J=7.1 Hz, o-CH_2-ActH), 3.43 (4H, s, $2CH_2$), and 1.86 (6H, s, $2CH_3$); MS (160 °C, 75 eV), m/e (rel intensity), 326 (100), 325 (24), 311 (4), 283 (66), 282 (17), 222 (22), 221 (19), 207 (15), 205 (12), 189 (10), 179 (18), 178 (13), 152 (12), 149 (8), 104 (16), and 77 (12).

Found: C, 81.24; H, 5.81%; M⁺ 326 and 325. Calcd for $C_{22}H_{19}BO_2$: C, 81.01; H, 5.87%; M-^{11}B, 326 and M-^{10}B, 325.

1,2-Dihydronaphtho[1',8': 5,6,7]cyclooct[1,2,3-fg]acenaphthylene-5,12-dione (8C). A mixture of diol **8** (132.5 mg, 0.3939 mmol) and lead(IV) acetate[18a] (291 mg, 1.50 molar ratio) in 30 cm³ of dry benzene was stirred at room temperature for 2 h, refluxed for 30 min, and allowed to come to room temperature. To the mixture 20 cm³ of dil hydrochloric acid was added dropwise. The pale yellow precipitate which formed was filtered off, washed with benzene, dil hydrochloric acid, and then water, and dried *in vacuo*, giving 106 mg (80.5%) of crude **8C**. Recrystallization from benzene gave pure **8C**: mp 343.0—345.0 °C (dec/Ar), (lit,[3] mp 330—334 °C (dec)); UV_{max} (C_6H_6) 320sh (logε 4.08) and 334 nm (4.13); $Fluorescence_{max}$ (C_6H_6) 401 nm (excitation at 333 nm); IR 1680 cm⁻¹ (C=O); MS, m/e (rel intensity), 334 (100), 333 (45), 306 (17), 278 (41), 277 (52), 276 (61), and 275 (12).

(Found: C, 85.84; H, 3.78%).

1,2,8,9-Tetrahydrocycloocta[1,2,3-fg : 5,6,7-f'g']diacenaphthylene-5,12-dione (9C). A mixture of diol **9** (135.0 mg, 0.3725 mmol) and lead(IV) acetate (300 mg, 1.63 molar ratio) in 20 cm³ of dry benzene was treated as described above for **8C**, giving 112.8 mg (84.0%) of almost pure **9C**. Recrystallization from benzene gave pure **9C** as pale yellow needles: mp 390—400 °C (uncorrected, dec/Ar), (lit,[3] mp >330 °C (dec)); UV_{max} (C_6H_6) 326sh (logε 4.04) and 341 nm (4.12); $Fluorescence_{max}$ (C_6H_6) 400 nm (excitation at 339 nm); IR 1680 cm⁻¹ (C=O); MS (240 °C, 35 eV), m/e (rel intensity), 360 (100), 359 (24), 332 (9), 331 (20), 304 (9), and 303 (13).

(Found: C, 86.63; H, 4.21%).

5,6-Diacetylacenaphthene (10C). A mixture of diol **10** (240.6 mg, 1.001 mmol) and lead(IV) acetate (600 mg, 1.22 molar ratio) in 25 cm³ of dry benzene was treated as described above for **8C**, except that the lead(II) acetate which precipitated was filtered off and the filtrate was chromatographed on a column of Wakogel C-200[18b] (40 g). After tarry matters (mainly silicone grease) had been extracted with benzene, the effluent with chloroform was collected and evaporated to dryness, giving 219 mg (91.8%) of crude **10C** (mp 153—155

°C). Recrystallization from cyclohexane gave 156 mg (65.4%) of pure **10C** as pale yellow plates: mp 156.0—157.0 °C; UV_{max} (c-C_6H_{12}) 230 (logε 4.60), 277sh (3.63), 310 (3.93), and 324sh nm (3.84); (Fluorescence was not detected.); IR 3045, 3015, 2940, 2910, 1670 (C=O), 1605, 1275, 1210, and 1115 cm^{-1}; NMR ($CDCl_3$) δ=7.80 (2H, d, J=7.1 Hz, o-CH_3CO-ActH), 7.35 (2H, broad d, J=7.1 Hz, o-CH_2-ActH), 3.44 (4H, s, $2CH_2$), and 2.70 (6H, s, $2CH_3CO$); MS (70 °C, 75 eV), m/e (rel intensity), 238 (29), 224 (19), 223 (100), 195 (14), 165 (22), 152 (21), 151 (10), 150 (5), and 149 (5).

Found: C, 80.53; H, 5.84%; M^+ 238. Calcd for $C_{16}H_{14}O_2$: C, 80.65; H, 5.92%; M, 238.

Reactions of 5,6-Dilithioacenaphthene-*N,N,N',N'*-Tetramethyl-1,2-ethanediamine Complex with α-Diketones. II.[1] Competitive Oxophilic and Carbophilic Additions and Redox Reactions

Norio TANAKA and Toshiyasu KASAI*

Department of Chemistry for Engineering, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received January 8, 1981)

The reaction of the title complex (**3**) with benzil did not give the 1 : 1 cyclic addition product expected, but gave 5,6-dibenzoylacenaphthene, 5-(1-hydroxy-2-oxo-1,2-diphenylethyl)-6-(2-oxo-1,2-diphenylethoxy)acenaphthene (**5**), 5-benzoyl-6-(1-hydroxy-2-oxo-1,2-diphenylethyl)acenaphthene, benzoin, and benzilic acid. Compound **5** suggests a new type of oxophilic addition accompanied by a carbophilic addition. The reaction of **3** with 9,10-phenanthrenequinone in a 1 : 1 molar ratio gave both the oxidative homo-coupling product of **3**, 1,2,7,8-tetrahydrodicyclopenta[*cd* : *lm*]perylene, and the hydroquinone dianion, which was converted into 9,10-diacetoxyphenanthrene on acetolysis. The differences in the reaction modes between **3** and α-diketones can basically be understood in terms of the redox potentials and the steric factors of the α-diketones.

5,6-Dilithioacenaphthene (**1**)[2,3] can be regarded as a nucleophile like 1,8-dilithionaphthalene (**2**)[4–8] which possesses two reaction sites at the peri positions of a naphthalene nucleus; thus, its synthetic conditions and reaction modes especially with bifunctional electrophiles are of interest in connection with the peri interaction in naphthalene derivatives.[9] A 1 : 1 cyclic condensation or addition is the most possible reaction path in the reaction systems of **1** and **2** with 1,2-dichlorodisilanes,[2,8] 1,3-dichlorodisiloxanes,[2] or acenaphthenequinone (ACQ),[3,5] **1** with pyracenequinone (5,6-dihydrocyclopent[*fg*]acenaphthylene-1,2-dione; PYQ),[3] and **2** with dialkyldichlorosilanes[6] or organotin dihalides.[7] No other reaction mode except a 2 : 2 cyclic condensation in the last case[7] has been reported.

In the course of studies on the synthetic conditions of **1**, the authors have found that the 5,6-dilithioacenaphthene-*N,N,N',N'*-tetramethyl-1,2-ethanediamine (TMEDA) complex (**3**)[1] reacts with some α-diketones in unexpected, novel modes which may illustrate new aspects of the peri interaction. This paper is chiefly concerned with the complicated reactions of **3** with benzil (Bz_2) and the redox reaction between **3** and 9,10-phenanthrenequinone (PQ). The factors that govern the reaction modes will also be discussed.

Results and Discussion

Competitive Complex Reactions of 3 with Benzil; Oxophilic Addition, Carbophilic Additions, and Reduction of Benzil. The *cis*-directing 1 : 1 cyclic additions of **3** with ACQ, PYQ, and biacetyl (Ac_2), reported separately,[1] prompted us to examine the reaction with benzil. The product expected, *cis*- or *trans*-1,2,5,6-tetrahydro-1,2-diphenylcyclopent[*fg*]acenaphthylene-1,2-diol (**4**), however, was not detected in the reaction mixture. Five products were isolated and identified as follows: 5-(1-hydroxy-2-oxo-1,2-diphenylethyl)-6-(2-oxo-1,2-diphenylethoxy)-acenaphthene (**5**), 5-benzoyl-6-(1-hydroxy-2-oxo-1,2-diphenylethyl)acenaphthene (**6**), 5,6-dibenzoylacenaphthene (**7**), benzoin (**8**), and benzilic acid (**9**). Typical yields are cited in Table 1. The structure of **5** was determined by means of a single-crystal X-ray analysis. The details of this analysis are reported elsewhere.[10] Figure 1 shows one of the two crystallographically independent molecules of **5**. Probably because of packing forces, their geometries are slightly different.[10]

The ^1H NMR spectrum of **5** shows some unusual features, one of which is that the signal assigned to the methine proton of the *O*-substituted benzoin moiety

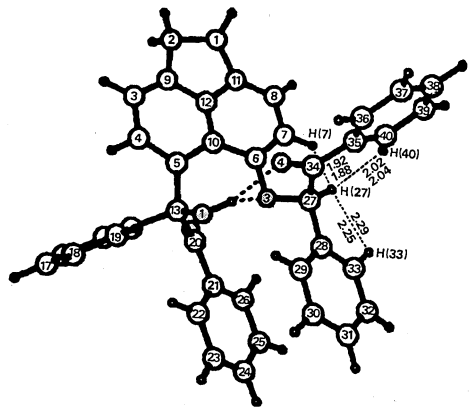

Fig. 1. Molecular structure of **5**. Some close H–H contacts (Å) are also shown, e.s.d.'s being 0.06—0.08 Å.

appears as a doublet (J=7.5 Hz) at δ 6.45 coupling with an aromatic proton, the signal of which appears as a multiplet at 7.00 (in $(CD_3)_2SO$).[13] This remarkably large long-range coupling-constant must ascribed to the specific conformation of **5** in which the methine H-atom, H(27), is in contact with three aromatic H-atoms: H(7), H(33), and H(40) (Fig. 1).[10,14]

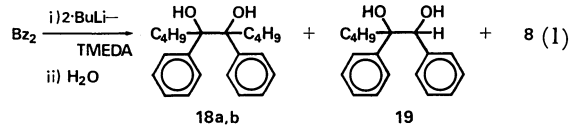
The structure of **5** suggests a new type of oxophilic addition which cooperates with a normal carbophilic addition. This is the first example of the heterophilic addition of an organolithium compound with an α-diketone; in the case of Grignard reagent, not a few instances of this type of reactions have been reported.[15] These heterophilic additions have shown the radical character of some Grignard reactions with certain carbonyl compounds.[16] As discussed below, products **5** and **8** also suggest strongly that the radical processes that involve the benzil radical anion ($Bz_2^{-\cdot}$) take an important part in the reaction with **3**.

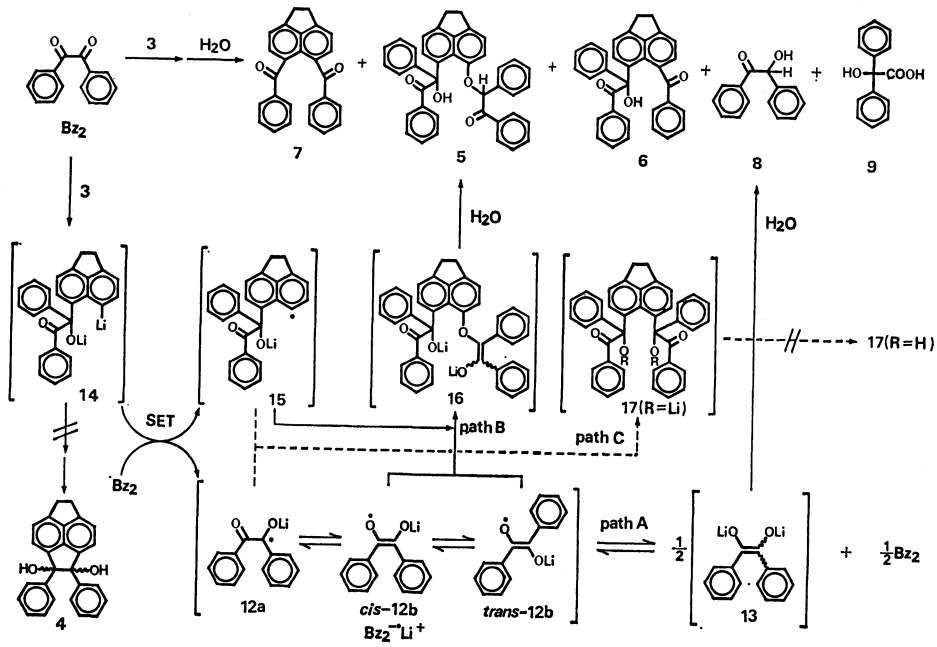
According to the reports published on the reduction of benzil,[17-21] $Bz_2^{-\cdot}$ generated *via* a single-electron-transfer (SET) in the presence of metal cation forms an ion pair, $Bz_2^{-\cdot}Li^+$ (≡**12a**⇌*cis*-**12b**⇌*trans*-**12b**), and disproportionates to benzil and dilithium stilbenediolate (**13**) which is converted into **8** on hydrolysis (Scheme 1, path A). The formation of **5** can most readily be accounted for when the redox reaction of benzil with a probable intermediate (**14**) is assumed: The SET between the two followed by the coupling of the resulting radicals, **15** and **12b**, will yield stilbene derivative **16**, which can be converted into **5** on hydrolysis[22] (Scheme 1, path B). The other coupling product (**17**), sterically unfavorable, was not detected in the reaction mixture.

Although **7** is the major product, no positive evidence that elucidates a mechanism for its formation has been obtained. However, a by-product expected for the oxidative fission of **17** (R=H), benzoic acid, was not detected in the reaction mixture. There is a possibility that 1 : 1 cyclic addition product **4** is formed but decomposes to yield **7**. This seems to be excluded because of the stabilities of *trans*-**4**,[11] *cis*-diaryl-1,2-acenaphthenediols,[23] and the methyl analogues, *cis*- and *trans*-1,2,5,6-tetrahydro-1,2-dimethylcyclopent[*fg*]-acenaphthylene-1,2-diols,[1] though the exact factor that prevents the formation of **4** is not yet clear.

An acidification of the aqueous layer after hydrolysis gave benzilic acid. On treatment of benzil in an ethereal solution with an aqueous lithium hydroxide in the presence of TMEDA, benzilic acid rearrangement[24] did not take place. Hence, the acid must be formed in the reaction system before hydrolysis.[25]

In order to evaluate the reducing potential of the butyllithium (*n*-BuLi)–TMEDA complex, it was allowed to react with benzil in a molar ratio of *n*-BuLi : Bz_2= 2 : 1 under the conditions similar to those in the case





Scheme 1.

of **3** with Bz_2. From the reaction mixture, *erythro*- or *threo*-5,6-diphenyl-5,6-decanediol (46% of **18a** and 22% of 1 : 4 mixture of **18a** and **18b**),[26] 5% of 1,2-diphenyl-1,2-hexanediol (**19**), and 2% of benzoin were isolated (Eq. 1). Thus, the reducing effect of an excess *n*-BuLi which may remain in the solution of **3**[27] is negligible.

Oxidative Homo-coupling of 3. Although the reactions of *o*-quinones ACQ and PYQ with **3** yield 1 : 1 cyclic addition products,[1] another *o*-quinone, 9,10-phenanthrenequinone (PQ), has not yielded such a product (**20**). The reaction of **3** with PQ in a 1 : 1 molar ratio gave both the oxidative homo-coupling product of **3**, 1,2,7,8-tetrahydrodicyclopenta[*cd* : *lm*]-perylene (**10**; 27%), and the hydroquinone dianion (PQ^{2-}), which was converted into 9,10-diacetoxy-phenanthrene (**11**; 48%) on acetolysis, as described below in detail. Thus, the redox reaction between **3** and PQ took place preferentially. This is a novel instance of the behavior of a bifunctional organolithium compound in the system with quinones, although the homo-coupling of monofunctional Grignard reagent or organolithium compound is often induced by certain quinones.[28] In the case of PQ, however, many normal additions with such organometals[29] and some oxophilic additions with aryl and allyl Grignard reagents[15] have been reported, but homo-coupling products are described only in the cases of *p*-tolyl-[29c] and *p*-methyl-benzyl-[29d] magnesium bromides.

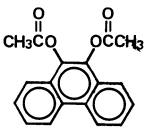
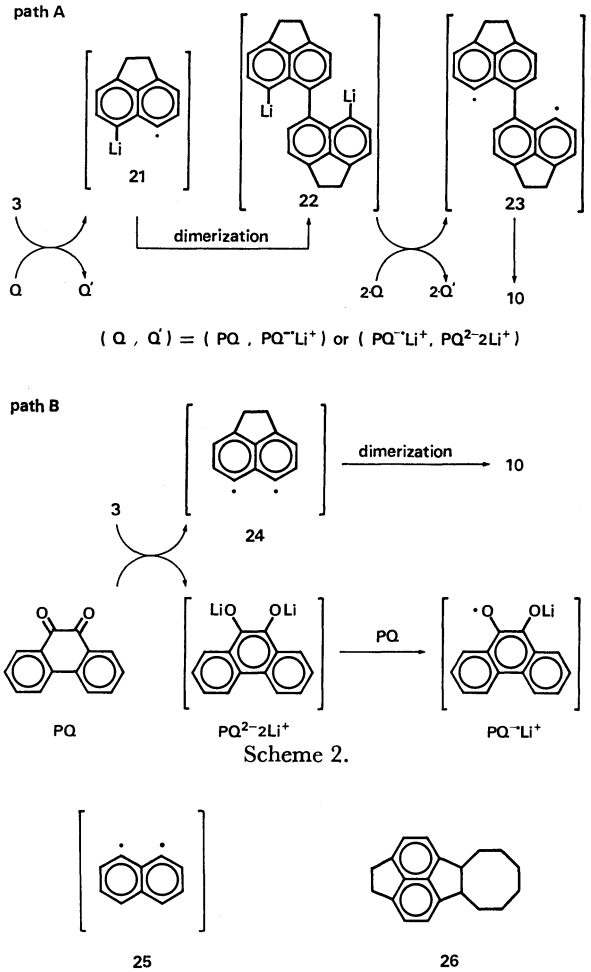
10



11

The molar ratio of PQ to **3** dramatically changed the appearance of the reaction. When an equivalent mol of PQ was added to a pale red solution of **3** over a period of 5 min, every portion of the yellow powder of PQ rapidly dissolved, the solution developed instantaneously a brilliant green color; just after the adding had been ended, the consumption-ratio of **3** was 50—60% and the reaction mixture became a dark green suspension involving a dark yellow powder of **10**. When the reaction was allowed to continue, the consumption-ratio increased and finaly reached to *ca.* 90%, and the suspension gradually changed to yellow. After a treatment with an aqueous iron(III) chloride, 60—70% of PQ was recovered, while a treatment with acetic anhydride gave a *ca.* 50% yield of 9,10-diacetoxy-phenanthrene and no PQ. When a 2 molar ratio of PQ was used, the consumption of **3** was approximately quantitative just after the adding and the dark green suspension which resulted did not change its color for at least 2 h. The maximum yield of **10** was 27% regardless of the molar ratio, but in the case of that of 1 : 1, the yield depended on the reaction-time (Table 1).

The reduction of PQ and the behavior of its radical anion ($PQ^{-\cdot}$) and dianion (PQ^{2-}) in the presence of metal cation have been well documented.[15a,30-32] On the bases of these reports, the observations described



Scheme 2.

above strongly suggest that a SET between PQ or $PQ^{-\cdot}Li^+$ and **3** or **22** (Scheme 2, path A) is more operative than a single two-electron-transfer between PQ and **3**, followed both by the homo-coupling of the resulting biradical (**24**) and by the redox reaction between PQ^{2-} and PQ[31] (Scheme 2, path B). This idea was further examined.

By reference to the trapping experiments of 1,8-dehydronaphthalene (**25**),[33] the reaction of **3** with PQ was investigated in the presence of a 77 molar ratio of cyclooctene,[34] but the yield of **10** was not decreased (26%) and no cyclooctene adduct (**26**) was detected. This may disprove the presence of the *free* biradical (**24**).[35]

The oxidative homo-coupling reactions of aromatic dilithium compounds by transition metal halides have been reported in the cases of **2**,[33] *o*-dilithiobenzene,[36] and 2,2'-dilithiobiphenyl,[37] and no evidence for the corresponding biradicals has been obtained. For comparison, the reaction of **3** with a 2 molar ratio of cobalt(II) chloride was investigated: complex **3** was readily decomposed by $CoCl_2$ above −30 °C, the consumption-ratio reached to ≥95% within 2 h, and **10** was isolated in a 28% yield.

The similarities between the reactions with PQ and $CoCl_2$ in the reaction rate and the yield of **10** are quite in agreement with the idea that oxidative homo-coupling of **3** proceeds in a step-wise SET pathway regardless of the oxidizing agent. In fact, the reactions of **3** with

Table 2. Cyclic voltammetric data for reduction of α-diketones (in CH_3CN, [diketone]=1.3 mmol dm^{-3}, $[Et_4NClO_4]$=0.2 mol dm^{-3}, at 20 °C)

some *p*-quinones also yielded **10** (see Experimental). On the other hand, detailed examinations confirmed that other α-diketones (ACQ, PYQ, Bz_2, and Ac_2) did not induce the homo-coupling of **3**. This indicates that the redox potential of α-diketone may be an important control-factor of the reaction modes.

Redox Potentials of α-Diketones. As Table 2 shows, the one- and two-electron reductions of the α-diketones are easier in the order of

$$PQ > ACQ > PYQ > Bz_2 > Ac_2, \quad (2)$$

under the conditions where the ion-pairing effect[17c,32] is negligible. Then, the effects of lithium cation and TMEDA, which may prevent the ion-pairing,[38] were examined.

All the cyclic voltammograms measured in the presence of lithium perchlorate in an acetonitrile solutions[39] are complex and correspond to irreversible steps; thus, quantitative discussions are difficult. In the case of PQ, however, the clear, positive shifts of the cathodic peaks were observed. This can be explained in terms of the formation of an ion pair $PQ^{-\cdot}Li^+$, as in the literature.[32] As expected, these positive shifts were reduced by adding TMEDA, but its effect was relatively slight. In the cases of ACQ, PYQ, and Bz_2, the positive shifts were not so clear as in the case of PQ, and no distinct effect of TMEDA was observed at any scan rate (<0.27 V s^{-1}). These findings suggest that the order of the reduction potentials (Eq. 2) may be unchanged in the ethereal solution containing Li^+–TMEDA. Thus, PQ is the most reducible α-diketone in those investigated regardless of the presence of Li^+. The relatively low reducibility of benzil even under the influence of ion-pairing supports the idea that only the sterically hindered intermediate, **14**, is able to reduce benzil in the reaction system with **3**, as discussed before. On the other hand, the difference between PQ and ACQ in redox potential seems to be too small to contribute to the distinct disparity in their reaction modes toward **3**. In fact, the reactions of these *o*-quinones with monofunctional organometals proceed in almost the same modes involving normal[23,29] and unusual[40] carbophilic additions and redox reactions.[15a] It is clear that the specific structure of **3** has revealed an unknown difference between the two *o*-quinones, though its exact nature can not yet be explained.

Experimental

General Procedures. Melting points, electron spectra, fluorescence excitation- and emission-spectra, IR spectra, ^1H NMR spectra, and mass spectra were recorded according to the methods given in the previous paper.[1] The solution of **3** was prepared from 5,6-dibromoacenaphthene, *n*-BuLi, and TMEDA in dry ether at −10—0 °C just before use, as in the previous paper.[1] All other chemicals were obtained commercially.[41] Benzil[41a] and 9,10-phenanthrenequinone[41a] were recrystallized from ethanol and benzene, respectively, and ground down and degassed *in vacuo* before use. Tetraethylammonium perchlorate[41b] was dried *in vacuo* at room temperature. Lithium perchlorate[41c] was dried at 200 °C/0.1 mmHg† for 2 h. Acetonitrile (Dotite Spectrosol)[41b] was dried with Molecular Sieves 5A and degassed with argon-bubbling. All reactions were performed under an argon atmosphere. All evaporations were carried out under a reduced pressure on a rotary evaporator below *ca.* 40 °C. Chromatographic separations were carried out on the columns (2.2 cm × 60—90 cm) of Wakogel C-200.[41b] Analytical determinations by GLC were carried out according to the previous paper.[1]

Reactions of 3 with Benzil. To a solution of **3** (10.0 mmol in 300 cm^3 of ether), a solution of benzil[42] (4.280 g, 20.36 mmol in 50 cm^3 of ether) was added with stirring over a period of 30 min at −10—0 °C. The solution became at first dark brown, changed to dark green, and finally to a brown purple suspension. This was stirred for 2 h at −10—0 °C and for 0.5 h without cooling, and then refluxed for 1 h. After the suspension was allowed to stand for 30 min, aqueous ammonium chloride (30 g/100 cm^3) was added to it with vigorous stirring. The hydrolysate was then cooled on an ice bath for 2 h. The pale yellow precipitate which formed was filtered off, washed with water and ether, and dried *in vacuo*, giving a mixture of **5** and **7**. This was chromatographed on a silica-gel column (150 g) with benzene and chloroform as successive eluents, giving 286 mg of crude **5** (mp 177—180 °C) and then 461 mg of crude **7** (mp 199—205 °C). The combined filtrate was separated and the organic layer was washed with 3 × 100 cm^3 of aqueous concd sodium chloride. The combined aqueous layer was acidified with concd hydrochloric acid and allowed to stand for a few days, giving 160 mg of pure benzilic acid (**9**). The acidic solution was then extracted with ether and gave additional **9** (39 mg); the total yield was 4.3%: mp and mixed mp 151.0—152.0 °C. The organic mother layer was dried ($MgSO_4$), concentrated to about 50 cm^3, and then cooled for one day at −15 °C, giving 167 mg of crude **5** (mp 174—176 °C). The filtrate was then evaporated and the residue was triturated with ether, giving 432 mg of crude **8** (mp 122—133 °C). The filtrate of this trituration was evaporated to dryness and chromatographed on a silica-gel column (150 g) with benzene as eluent. The dark brown solution became dark green on this column. The first green eluent was collected and evaporated, and the brown residue was dissolved in carbon tetrachloride. The solution was then diluted with hexane, giving 108 mg of crude **6** as a pale brown crystal (mp 194—205 °C (dec)). The second yellowish green eluent was treated as described above for the first, giving 159 mg (3.7%) of benzil. The filtrate of this treatment was evaporated to dryness and the residue was recrystallized from ethanol, giving 83 mg of crude **6** (mp 180—182 °C). After the third deep green eluent (unknown), extraction with chloro-

† 1 mmHg ≃ 133.3 Pa.

from gave the fourth pale yellow eluent. This was evaporated to dryness, giving 390 mg of crude **8** (mp 128—132 °C). The fifth dark green eluent with chloroform was evaporated to dryness and then recrystallized from benzene, giving 306 mg of crude **7** (mp 206.5—208.5 °C). The total of 822 mg (19%, based on benzil used) of crude benzoin was decolorized in a short benzene-silica-gel column and then recrystallized from ethanol,[43] giving 547 mg (12.7%) of pure **8**; mp and mixed mp 135.0—136.0 °C.

*5-(1-Hydroxy-2-oxo-1,2-diphenylethyl)-6-(2-oxo-1,2-diphenylethoxy)acenaphthene (**5**)*: A total of 453 mg (7.9%) of crude product was recrystallized from benzene,[43] giving 331 mg (5.8%) of pure **5** as white plates: mp 181.0—182.5 °C; UV_{max} (C_2H_5OH) 214 (logε 4.65), 240 (4.69), 300 (3.99), 318sh (3.87), and 334sh nm (3.66); $Fluorescence_{max}$ (C_2H_5OH) 402 nm (excitation at 341 nm); IR 3425 (OH),3065, 3035, 2920, 1670 (C=O), 1600, 1450, 1265, 1225, 1140, 965, 855, 770, 750, 720, 705, and 695 cm^{-1}; NMR $\delta(CDCl_3)=7.83$—7.73 (4H, m, ArH), 7.68—6.80 (20H, m, ArH), 6.64 (1H, d, $J=7.5$ Hz, CH), and 3.30 (4H, s, $2CH_2$), $\delta((CD_3)_2SO)=7.98$—7.91 (2H, m, ArH), 7.70—6.80 (22H, m, ArH), 6.45 (1H, d, $J=$ 7.5 Hz, CH), and 3.29 ((4H), s, $2CH_2$); MS (270 °C, 75 eV), *m/e* (rel intensity), 574 (2.6), 572 (2.7), 558 (2.1), 556 (2.1), 540 (3.2), 469 (5.3), 452 (9.2), 451 (23), 450 (6.5), 435 (5.0), 364 (4.0), 363 (4.9), 362 (3.1), 361 (4.0), 347 (5.4), 346 (4.3), 345 (3.6), 285 (4.0), 269 (4.4), 257 (5.9), 241 (4.4), 240 (3.7), 239 (5.1), 167 (5.4), 152 (4.2), 105 (100), and 77 (70).

*5,6-Dibenzoylacenaphthene (**7**)*: A total of 767 mg (21.2%) of crude product was recrystallized from ethanol,[43] giving 612 mg (16.9%) of pure **7** as white needles: mp 209.0—210.0 °C, (lit,[11] mp 207—208 °C); UV_{max} (c-C_6H_{12}) 236 (logε 4.74), 248sh (4.53), and 316 nm (3.99); (Fluorescence was not detected.); IR 3080, 3040, 2905, 1655 and 1645 (C=O), 1600, 1270, 1230, 940, and 710 cm^{-1}; NMR ($CDCl_3$) $\delta=7.80$—7.70 (4H, m, o-CO-PhH), 7.58 (2H, d, $J=7.1$ Hz, o-CO-ActH), 7.52—7.20 (6H, m, m- and p-CO-PhH), 7.35 (2H, broad d, $J=7.1$ Hz, o-CH_2-ActH), and 3.49 (4H, s, $2CH_2$); MS (225 °C, 75 eV), *m/e* (rel intensity), 362 (46), 286 (16), 285 (62), 258 (25), 257 (92), 256 (10), 255 (14), 228 (16), 227 (23), 226 (32), 186 (16), 151 (10), 105 (62), and 77 (100).

(Found: C, 86.62; H, 4.81%).

Reaction of Benzil with n-*BuLi–TMEDA Complex*. Under an argon atmosphere, n-BuLi (25.3 mmol in 11 cm^3 of hexane) and TMEDA (4 cm^3, 26.6 mmol) were introduced into a four-necked 200 cm^3-flask, the mixture was stirred for 15 min, and then 35 cm^3 of dry ether was added to the mixture . To this solution a solution of benzil (2.150 g, 10.23 mmol in 50 cm^3 of ether) was added dropwise over a period of 30 min at −10—0 °C. The yellowish orange solution which resulted was stirred at −10—0 °C for 1 h and for 0.5 h without cooling, and then refluxed for 0.5 h. After the solution was allowed to stand for 30 min, it was hydrolyzed with aqueous ammonium chloride (15 g/50 cm^3). The organic layer was separated, washed with aqueous concd sodium chloride, dried ($MgSO_4$), and evaporated to dryness. The residue was recrystallized from 10 cm^3 of hexane, giving 1.401 g (42.0%) of crude **18a** (mp 118—120 °C). The filtrate was chromatographed on a silica-gel column (100 g) with hexane, benzene, and chloroform as successive eluents, giving 1.387 g of a mixture of **18a** and **18b** as a yellow oil, 44 mg (2.0%) of almost pure benzoin (mp 130—133 °C), and then 213 mg (7.7%) of crude **19** (mp 108—118 °C). The oily mixture was dissolved in 3 cm^3 of hexane and allowed to stand; it gave 145 mg (4.3%) of crude **18a** (mp 119—121 °C). The filtrate of this operation was chromatographed on a silica-gel column (120 g) with hexane–benzene as eluent, giving 743 mg (22.3%) of 1 : 4 mixture of **18a** and **18b** as a colorless solid: mp 76.0—84.0 °C (found: C, 80.98; H, 9.36%); UV_{max} (c-C_6H_{12}) 253 (logε 2.50), 259 (2.59), and 265 nm (2.41); IR 3535 (OH), 3095, 3060, 3035, 2960, 2865, 1445, and 1150 cm^{-1}; NMR ($CDCl_3$) $\delta=7.14$ (10H, broad s, PhH), 2.55 (1.6H, s, exch., OH of **18b**), 2.22 (0.4H, s, exch., OH of **18a**), 2.32—1.43 (4H, m), and 1.30—0.64 (14H, m).

(5R, 6R*)- or (5R*, 6S*)-5,6-Diphenyl-5,6-decanediol (**18a**)*: A total of 1.546 g (46.3%) of crude product was recrystallized from hexane, giving 1.341 g (40.2%) of pure **18a** as colorless prisms: mp 121.0—122.0 °C; UV_{max} (c-C_6H_{12}) 218sh (logε 4.13), 253sh (2.47), 259 (2.62), and 265 nm (2.50); IR 3600 (OH), 3055, 3035, 2955, 2930, 2865, 1445, and 1160 cm^{-1}; NMR ($CDCl_3$) $\delta=7.19$ (10H, s, PhH), 2.22 (2H, s, exch., 2OH), 2.47—2.15 (2H, m), 1.77—1.48 (2H, m), and 1.36—0.70 (14H, m); MS (150 °C, 20 eV), *m/e* (rel intensity), 326 (1.5), 309 (0.9), 292 (0.8), 164 (14), 163 (100), 162 (58), 120 (5), 107 (5), 105 (3), 85 (5), 71 (1.3), 57 (6), and 43 (1.4).

*Oxidative Homo-coupling of **3**. 1,2,7,8-Tetrahydrodicyclopenta-[cd : lm]perylene (**10**). A) **3** : PQ (1/2)*: To a solution of **3** (5.00 mmol in 150 cm^3 of ether), 9,10-phenanthrenequinone (2.154 g, 10.3 mmol) was added with gentle stirring over a period of 5 min at −10—0 °C. The dark green suspension which resulted was stirred for 1 h at −10—0 °C and for 1 h without cooling. Aqueous iron(III) chloride (30 g/100 cm^3) was then added to the supension. After 0.5 h of stirring, the dark brown solid which had precipitated was filtered off with 10 g of Celite and washed with water and ether. The combined filtrate was separated and the organic layer was washed with aqueous concd sodium chloride, dried ($MgSO_4$), and evaporated. The residue was then chromatographed on a silica-gel column (150 g) with benzene as eluent, giving

472 mg of PQ. The residue containing Celite was exhaustively extracted with hot benzene. This extract was dried ($MgSO_4$), concentrated, and chromatographed on a silica-gel column (150 g) with benzene as eluent, giving 205 mg (26.9%) of crude **10** (mp 335—337 °C (dec/Ar)) and then 1.011 g of PQ. Total recovery of the quinone was 68.8%. The crude **10** was recrystallized from benzene, giving 180 mg (23.7%) of pure **10** as brilliant red rods: mp 345.0—346.0 °C (dec/Ar); UV_{max} (c-C_6H_{12}) 382 (logε 3.78), 402 (4.27), 426 (4.64), 443sh (4.41), 450sh (4.66), and 455 nm (4.82), (C_6H_6) 386 (3.70), 407 (4.18), 431 (4.56), and 460 nm (4.69); $Fluorescence_{max}$ (c-C_6H_{12}) 462 (rel intensity 100), 489 (87), 524 (20), and 565 nm (3) (excitation at 450 nm), (C_6H_6) 470 (100), 495 (100), and 530 nm (29) (excitation at 455 nm); IR 3065, 3030, 2905, 2830, 1620, 1585, 1395, 1375, 840, and 815 cm^{-1}; NMR (CS_2) δ= 7.76 (4H, d, J=7.5 Hz, m-CH_2-ArH), 7.09 (4H, broad d, J=7.5 Hz, o-CH_2-ArH), and 3.31 (8H, s, $4CH_2$); MS (200 °C, 70 eV), m/e (rel intensity), 304 (100), 303 (33), 302 (19), 301 (18), 300 (17), and 276 (6); $m/2e$, 152 (12), 151.5 (8), 151 (11), 150.5 (10), 150 (17), and 149.5 (3); $m/3e$, 101.7 (0.2), 101.3 (0.3), 101 (0.1), 100.7 (0.8), 100.3 (0.8), and 100 (1.8).

Found: C, 95.13; H, 5.15%; M^+ 304. Calcd for $C_{24}H_{16}$: C, 94.70; H, 5.30%; M, 304.

B) 3 : PQ (1/1): This was carried out exactly as described above for run *A*), except that 1.077 g (5.17 mmol) of PQ was used. The consumption-ratio of **3** changed as follows: 59% (5 min), 67% (50 min), and 76% (2 h). Column-chromatography gave 150 mg (19.7%) of **10** and 665 mg (61.7%) of PQ.

C) 3 : PQ (1/1) with Acetolysis: This was carried out exactly as described for run *A*), except that 1.070 g (5.14 mmol) of PQ was used and that the reaction mixture was treated with acetic anhydride (45 cm^3, 0.48 mol) and pyridine (5 cm^3), and then with 100 cm^3 of dil hydrochloric acid. After the addition of PQ, the consumption-ratio of **3** and the color of the reaction mixture changed as follows: 3—60 min, 65%, dark green; 2—4 h, 73—82%, dark green and partly dark yellow: 5—6 h, 86—87%, dark yellow. Column-chromatography gave 207 mg (27.2%) of **10** and then 703 mg (47.8%) of crude **11**. The latter was recrystallized from benzene, giving 619 mg (42.1%) of pure 9,10-diacetoxyphenanthrene (**11**); mp 203.0—204.0 °C, (lit,[12] mp 203—203.5 °C); IR 3075, 2930, and 1785 and 1770 cm^{-1} (C=O); NMR ($CDCl_3$) δ=8.75—8.56 (2H, m), 7.95—7.78 (2H, m), 7.78—7.50 (4H, m), and 2.46 (6H, s).

(Found: C, 73.20; H, 4.72%).

D) 3 : PQ (1/2) in the Presence of Cyclooctene: Freshly distilled cyclooctene (from sodium wire) (50 cm^3) was added to a solution of **3** (5.00 mmol in 150 cm^3 of ether) and the mixture was treated with PQ (2.195 g, 10.5 mmol) as described for run *A*). Column-chromatography gave 200 mg (26.3%) of **10** and 1.64 g (73.5%) of PQ.

E) 3 : $CoCl_2$ (1/2): Anhydrous cobalt(II) chloride[41b] (1.580 g, 12.2 mmol) was dried at 120 °C/0.1 mmHg for 4 h, and then added to a solution of **3** (5.00 mmol in 150 cm^3 of ether) over a period of 15 min at −78 °C . During 1 h of stirring, the solution became pale brown and *ca.* 10% of **3** was consumed. The reaction mixture was then allowed to come to room temperature gradually; after 2 h, ≥95% of **3** was consumed. The black suspension which resulted was treated as described for run *A*), giving 210 mg (27.6%) of **10**.

F) 3 : 2,3-Dibromo-1,4-naphthoquinone (1/1): This was carried out exactly as described for run *A*), except that 1.617 g (5.12 mmol) of the quinone[44] was used. The consumption-ratio of **3** and the color changed as follows: 3 min, 94%, brown purple; 20 min, 98%, blue green; 1—2 h, 98%, dark green. Column-chromatography gave 40 mg (5.2%) of **10**.

G) 3 : 2,3-Dichloro-5,6-dicyano-1,4-benzoqinone (1/1): This was carried out as described for run *A*), except that 1.160 g (5.11 mmol) of the quinone[41d] was used and that the reaction mixture was refluxed for additional 1 h. Finally, approximately 50% of **3** was consumed and 76 mg (10%) of **10** was obtained.

The authors wish to thank Professor S. Aoyagi (Tokyo Institute of Technology) for the measurements of the cyclic voltammograms. We also would like to thank Professor Y. Sasada and Dr. A. Takenaka (Tokyo Institute of Technology, Nagatsuta) for their helpful discussions.

13) Other features are that the signal of the methylene protons at the ethano bridge appears as a sharp singlet in spite of the different substituents at their opposite peri positions (*cf.* the corresponding signal of **6**), and that the signal of the hydroxy proton can not clearly be discerned in the solvents used.
