All the voltammetric measurements were made under potentiostatic conditions with a three-electrode system consisting of a hanging mercury drop working electrode, a coiled platinum wire auxiliary electrode, and a saturated calomel reference electrode(SCE). The HMDE was a Metrohm drop electrode E 410, the surface area of which was 0.0187 ± 0.0003 cm^2. Buffer solutions (0.2 mol dm^{-3} acetic acid–sodium acetate for pH 4.9 and 0.2 mol dm^{-3} sodium dihydrogenphosphate–disodium hydrogenphosphate for pH 6.9) were used as the base solutions. The ionic strength of a base solution was adjusted to 0.5 mol dm^{-3} with potassium nitrate. A fresh mercury drop from the HMDE was exposed to the electrolysis solution for a given period of time, to be referred to as the exposure time, t_{exp}, below, while the potential of the HMDE was controlled at a constant d.c. potential(E_i). Then the d.c. voltage scan was started from E_i, with scan rates of $v=0.091$ V s^{-1} for cyclic d.c. voltammetry and of $v=0.036$ V s^{-1} for a.c. voltammetry, unless otherwise stated. In a.c. voltammetry, the amplitude of the superimposed a.c. voltage was adjusted to 10 mV (peak to peak) throughout the frequency range of 100—500 Hz. To avoid possible photochemical decomposition of FMN, electrochemical measurements were performed in a dark box at 25 °C under a nitrogen atmosphere.

Results

In order to study the surface redox reaction of FMN, electrochemical measurements were performed at concentrations of FMN lower than 4×10^{-6} mol dm^{-3}, at which the current resulting from unadsorbed, diffusing FMN will be negligibly small.

Figure 1 shows a linear potential sweep voltammogram of 1.5×10^{-6} mol dm^{-3} FMN in a pH 6.9 phosphate buffer, which was recorded after $t_{exp}=2$ min at $E_i=+0.15$ V. At such a low concentration, FMN gave two peaked-shaped waves centered at +0.05 V and −0.41 V, but no ordinary diffusion wave was observed. According to Senda *et al.*[8] and Breyer and Biegler,[11] the reduction wave observed at +0.05 V may be due to the dissolution of the mercury electrode by FMN. Thus, in this study, the electrochemical behavior of the wave observed at −0.41 V was investigated in detail.

pH 6.9, which was recorded after $t_{exp}=1$ min at $E_i=-0.2$ V with the HMDE. A pair of cathodic and anodic waves was observed at −0.41 V. The shapes and heights of these two waves were practically identical expect for the opposite current sign. The waves grew to a certain limit, the maximum peak height I_{pc}^{max} or I_{pa}^{max}, with an increase in the concentration of FMN at a constant exposure time or with

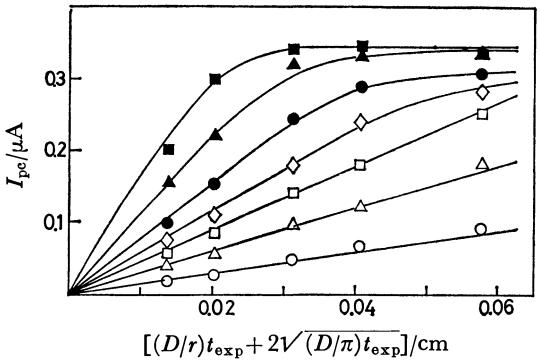

Fig. 3. Plot of I_{pc} against $[(D/r)t_{exp}+2(D/\pi)^{1/2}t_{exp}^{1/2}]$ in pH 6.9 phosphate buffer. FMN concentrations are: (○) 3×10^{-7} mol dm^{-3}; (△) 6×10^{-7} mol dm^{-3}; (□) 9×10^{-7} mol dm^{-3}; (◇) 1.2×10^{-6} mol dm^{-3}; (●) 1.8×10^{-6} mol dm^{-3}; (▲) 3×10^{-6} mol dm^{-3}; (■) 4×10^{-6} mol dm^{-3}.

an increase in the exposure time at a constant concentration of FMN, indicating that the waves are due to the FMN accumulated on the HMDE surface. The t_{exp} dependence of the cathodic peak height, I_{pc}, obtained with $E_i=-0.2$ V is shown in Fig. 3 for different FMN concentrations at pH 6.9. At lower concentrations, I_{pc} was proportional to the $[(D/r)t_{exp}+2(D/\pi)^{1/2}t_{exp}^{1/2}]$ function, where D is the diffusion coefficient of FMN, which was estimated by means of the Ilkovič equation to be 3.2×10^{-6} cm^2 s^{-1} in the pH range of 4.9—6.9, and where r is the radius of the HMDE, which was determined to be 0.038 cm. The slope of the plot was also proportional to the concentration of FMN. These results indicate the diffusion-controlled adsorption of FMN at the electrode surface.[5,13)] A similar dependence of the peak height on t_{exp} was observed also for the anodic wave. However, the maximum value of the anodic peak height, I_{pa}^{max}, was slightly larger than that of the cathodic peak height, I_{pc}^{max}; *i.e.*, $I_{pa}^{max}/I_{pc}^{max}\simeq1.1$ (see Fig. 5A).

Table 1 summarizes the peak heights, I_{pc} and I_{pa}; the peak potentials, E_{pc}^{DC} and E_{pa}^{DC}, and the half-peak widths, $\Delta E_{p/2,c}^{DC}$ and $\Delta E_{p/2,a}^{DC}$, of the cathodic and anodic waves respectively, which were recorded with various scan rates after $t_{exp}=3$ min at $E_i=-0.2$ V in a pH 6.9 phosphate buffer containing 9×10^{-7} mol dm^{-3} of FMN. Both I_{pc} and I_{pa} were proportional to the voltage scan rate, v. The I_{pa}/I_{pc} ratio was unity when corrected for the difference between the amounts of the adsorbed FMN at E_{pc}^{DC} and E_{pa}^{DC} due to the different t_{exp} values. E_{pc}^{DC} and E_{pa}^{DC} coincided with each other and are independent

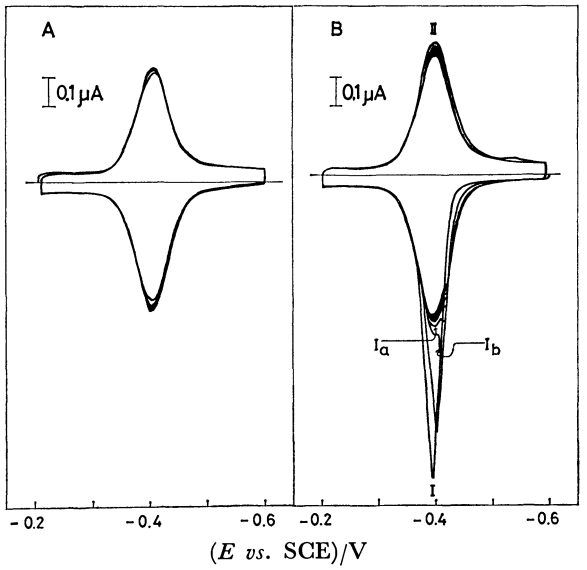

Fig. 5. Cyclic d.c. voltammograms of 4×10^{-6} mol dm^{-3} FMN in pH 6.9 phosphate buffer. Voltage scan was started after $t_{exp}=3$ min from (A) $E_i=-0.2$ V *vs.* SCE and (B) $E_i=-0.6$ V *vs.* SCE.

of the v. The half-peak widths were 68 mV over the scan rate range of 34 mV s^{-1} to 181 mV s^{-1}. The peak height of either wave was proportional to the electricity, Q, required to reduce or oxidize the FMN adsorbed on the electrode surface, which was estimated from the area under the wave, as is shown in Fig. 4. This indicates that the peak height is directly proportional to the amount of the FMN adsorbed on the electrode surface until the peak height reaches a maximum value. On the other hand, the peak potentials and half-peak widths were practically independent of the amount of the adsorbed FMN. These results indicate that the reaction corresponding to the waves is a reversible surface redox reaction.[4]

When the electrode was exposed to the FMN solution at potentials much more negative than the redox potential of the adsorbed FMN, *e.g.*, −0.6 V at pH

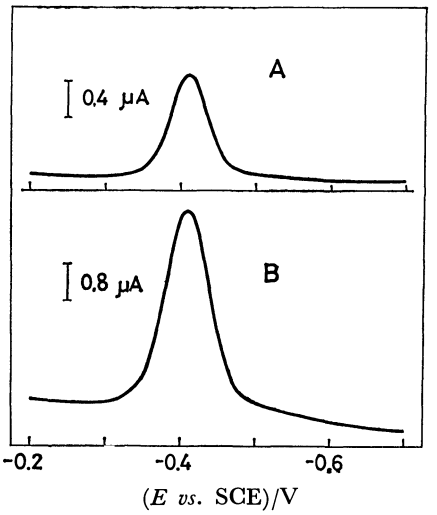

Fig. 6. A.c. voltammograms of 3×10^{-7} mol dm^{-3} FMN in pH 6.9 phosphate buffer at 300 Hz. D.c. voltage scan was started from $E_i=-0.2$ V *vs.* SCE after $t_{exp}=5$ min. (A): Real component, (B): imaginary component.

6.9, the adsorbed FMN was reduced to form an adsorbed layer of leuco-FMN on the electrode surface. The cyclic voltammetric behavior of this adsorbed leuco-FMN was the same as that of adsorbed FMN, provided that the surface coverage was low, as is shown in Fig. 2. However, as the surface coverage increased, the cyclic voltammograms observed were remarkably different in shape and height from that of the adsorbed FMN. Figure 5 shows the cyclic voltammograms of FMN at pH 6.9, which were recorded after the electrode had been exposed to a solution containing 4×10^{-6} mol dm^{-3} of FMN for $t_{exp}=3$ min at $E_i=-0.2$ V (Fig. 5A) and at $E_i=-0.6$ V (Fig. 5B). When FMN was adsorbed at $E_i=-0.2$ V, a symmetrical voltammogram was obtained as has been stated above; in succeeding cycles of the voltage scan between −0.2 V and −0.6 V, the peak heights and shapes of the cathodic and anodic waves remained practically unchanged (Fig. 5A). On the contrary, when FMN was adsorbed at $E_i=-0.6$ V, in the first voltage scan from −0.6 V to −0.2 V an asymmetric anodic wave was observed at −0.39 V (Wave I); its peak height was about three times that of the anodic wave in Fig. 5A. Upon the reversal of the voltage scan at −0.2 V, a symmetrical cathodic wave (Wave II) was observed at −0.40 V; its peak height was slightly larger than that of the cathodic wave in Fig. 5A. In the successive cycles of the voltage scan, Wave I decreased in height and split into two peaks, I_a and I_b, while Waves I_a, I_b, and II decreased in height until a steady state was attained. The steady-state cyclic voltammograms were nearly symmetric, and their peak heights were, though dependent on the bulk concentration of FMN, slightly higher than that of the wave in Fig. 5A, *i.e.*, the maximum peak height of the voltammogram produced by FMN adsorbed at $E_i=-0.2$ V. Similar behavior was observed also in the pH 4.9 acetate buffer.

a) $C_{FMN}=9\times10^{-7}$ mol dm^{-3}, $t_{exp}=2$ min at $E_1=-0.20$ V *vs.* SCE. b) V *vs.* SCE. c) Calculated by using $K=1.1$, $k_{sap}=4.9\times10^3$ s^{-1}, and $\theta_t=0.40$.

of FMN adsorbed at $E_1=-0.2$ V, the a.c. voltammogram of the cathodic scan was practically identical in height and shape with that of the anodic scan. Accordingly, the a.c. voltammetric behavior was studied only for the cathodic scan. Figure 6 shows a.c. voltammograms for FMN adsorbed on the HMDE at pH 6.9; the voltammograms were recorded after the electrode had been exposed to a solution containing 3×10^{-7} mol dm^{-3} FMN at $E_1=-0.2$ V for $t_{exp}=5$ min. In all the a.c. voltammograms recorded in this study, the peak potentials of the real and imaginary components, E_p^{real} and E_p^{imag}, were independent of the a.c. frequency between 100 and 500 Hz and independent of the amount of the adsorbed FMN; they coincided with each other and with the peak potentials of the corresponding cyclic d.c. waves, as is shown in Table 2. On the other hand, the peak currents, $\delta_1 I_p^{real}$ and $\delta_1 I_p^{imag}$, and the half-peak widths, $\Delta E_{p/2}^{real}$ and $\Delta E_{p/2}^{imag}$, of the real and imaginary components depended on the a.c. frequency and also on the amount of the adsorbed FMN, as may be seen in Fig. 8 and Table 2.

Discussion

Adsorption of FMN on the Mercury Electrode Surface. The present study has revealed that both the oxidized and reduced forms of FMN are strongly adsorbed on the HMDE surface; this finding is consistent with those of previous works.[8–10] The d.c. voltammetric data indicate that the adsorption of FMN is controlled by diffusion; at lower FMN concentrations, the peak height of the cyclic d.c. voltammogram is given by $I_p=kA\Gamma=kA[(D/r)t_{exp}+2(D/\pi)^{1/2}t_{exp}^{1/2}]C_{FMN}$, where k is the proportionality constant; A, the surface area of the HMDE; Γ, the surface concentration of FMN per unit of area; and C_{FMN}, the concentration of FMN in a bulk solution. At high concentrations, when the maximum current is attained, it is given by $I_p^{max}=kA\Gamma^{max}$, where Γ^{max} is the maximum value of Γ. By applying these two equations to such plots as are shown in Fig. 3, we estimated the maximum surface concentration of FMN adsorbed at -0.2 V, Γ_0^{max}, as $(6.7\pm0.1)\times10^{-11}$ mol cm^{-2} at pH 6.9 and $(9.5\pm0.4)\times10^{-11}$ mol cm^{-2} at pH 4.9. The Γ or Γ^{max} value can also be estimated from the area under the d.c. voltammetric wave, provided that m_1/n_1 and m_2/n_2 are assumed as unity;[3,4] $Q=nFA\Gamma$ and $Q_{max}=nFA\Gamma^{max}$, where n is the number of electrons transferred per molecule of FMN. For the cathodic wave this gave $\Gamma_0^{max}=(8.0\pm0.2)\times10^{-11}$ mole cm^{-2} at pH 6.9 and $(8.8\pm0.2)\times10^{-11}$ mol cm^{-2} at pH 4.9, by assuming $n=2$. The Γ_0^{max} values estimated by these two methods agree well with each other at either pH. When we assume that FMN is adsorbed on the electrode surface with its alloxazine-ring plane oriented parallel to the electrode surface, a CPK molecular model[14] gives $\Gamma_0^{max}=7.5\times10^{-11}$ mol cm^{-2}. On the other hand, when FMN was adsorbed at $E_1=-0.6$ V, the area under the anodic wave obtained with the first voltage scan increased with an increase in C_{FMN} and/or t_{exp} and did not attain a maximum value even at $C_{FMN}=4\times10^{-6}$ mol dm^{-3} and $t_{exp}=5$ min, at which the Γ_R estimated by $Q=nFA\Gamma$ was already larger than Γ_0^{max}. Accordingly, the maximum surface concentration of leuco-FMN, Γ_R^{max}, should be larger than Γ_0^{max}, but it could not be accurately estimated from the present d.c. voltammetric data.

The cyclic d.c. voltammetric behavior of FMN and leuco-FMN at high surface concentrations, shown in Fig. 5, should be interpreted as follows. Since $\Gamma_0^{max}<\Gamma_R^{max}$, the reduction of a complete monolayer of FMN would be followed by the further adsorption of FMN at potentials more negative than the redox potential of the adsorbed FMN, resulting in a higher surface concentration of leuco-FMN than the initial Γ_0^{max}. This would be explain why the anodic peak height is slightly larger than the preceding cathodic one for a complete monolayer of adsorbed FMN (see Fig. 5A). When the initial surface concentration of leuco-FMN, Γ_R, is larger than Γ_0^{max}, the oxidation of the monolayer of leuco-FMN should cause an immediate desorption of a part of the adsorbed FMN molecules. The distortion of the anodic wave (Wave I) and the appearance of Wave I_b, shown in Fig. 5B, may reflect the desorption process associated with the oxidation of the adsorbed leuco-FMN. Cyclic voltammograms of the repeated scans, illustrated in Fig. 5B, suggest that the desorption and adsorption processes are slow.

Surface Redox Reaction of FMN Adsorbed on HMDE. The cyclic d.c. and a.c. voltammetry behavior of FMN adsorbed on the electrode surface should be interpreted in terms of a two-step surface redox reaction:[7–10,12]

$$\begin{aligned} O_{ad} + n_1 e &\rightleftharpoons S_{ad} \\ S_{ad} + n_2 e &\rightleftharpoons R_{ad}. \end{aligned} \qquad (I)$$

When these two steps are d.c. reversible, the simplified equations (Case (I) in Ref. 4) of the cyclic d.c. voltammogram, I^{DC}, and the real and imaginary components of the a.c. current, $\delta_1 I_{corr}^{imag}$ and $\delta_1 I_{obsd}^{real}$, can be written, for $n_1=n_2=m_1=m_2=1$, as:

$$I^{DC} = I_F^{rev} = (F^2/RT)Av\Gamma_t \frac{[\rho^2(\sqrt{K}\rho+2)+\rho(\sqrt{K}+2\rho)]}{(1+\sqrt{K}\rho+\rho^2)^2}, \tag{1}$$

$$\delta_1 I_{obsd}^{real} = \delta_1 I_F^{real} = (F^2/RT)A\omega\Gamma_t\delta_1 E \frac{\sqrt{K}\rho\rho^{1/2}}{(1+\sqrt{K}\rho+\rho^2)} \times \frac{\lambda(\sqrt{K})^{1/2}(1+\rho)\{\sqrt{K}[\lambda^2\rho-(1+\sqrt{K}\rho+\rho^2)]+(\sqrt{K}+4\rho+\sqrt{K}\rho^2)(1+\sqrt{K})\}}{\{K[\lambda^2\rho-(1+\sqrt{K}\rho+\rho^2)]^2+\lambda^2(\sqrt{K})(1+\sqrt{K})^2(1+\rho)^2\rho\}}, \tag{2}$$

$$\delta_1 I_{corr}^{imag} = \delta_1 I_F^{imag} = (F^2/RT)A\omega\Gamma_t\delta_1 E \frac{\sqrt{K}\rho}{(1+\sqrt{K}\rho+\rho^2)} \times \frac{\{\rho\lambda^2(\sqrt{K})(1+\sqrt{K})(1+\rho)^2-\sqrt{K}[\lambda^2\rho-(1+\sqrt{K}\rho+\rho^2)](\sqrt{K}+4\rho+\sqrt{K}\rho^2)\}}{\{K[\lambda^2\rho-(1+\sqrt{K}\rho+\rho^2)]^2+\lambda^2(\sqrt{K})(1+\sqrt{K})^2(1+\rho)^2\rho\}}, \tag{3}$$

with:

$$K = \exp[(F/RT)(E'_{o1}-E'_{o2})]$$
$$\rho = \exp[(F/RT)(E-E'_o)]$$
$$E'_o = (E'_{o1}+E'_{o2})/2$$
$$\lambda = \omega/k_{sap}.$$

Here, it is further assumed that $\alpha_1=\alpha_2=\beta_1=\beta_2=0.5$ and $k_{sap}(1)=k_{sap}(2)=k_{sap}$, where α_i, β_i, and $k_{sap}(i)$ are the cathodic and anodic transfer coefficients and the apparent rate constant of the i-th charge transfer step respectively. In these equations, Γ_t is the total surface concentration per unit of area defined by $\Gamma_t=\Gamma_O+\Gamma_S+\Gamma_R$; E'_{o1} and E'_{o2} are the formal standard potentials of the first and second redox steps respectively, and ω and $\delta_1 E$ are the angular frequency and amplitude of the superimposed a.c. voltage respectively. E'_o corresponds to the formal standard potential of the adsorbed redox couple, O_{ad}/R_{ad}. The parameter K corresponds to the formation constant of the adsorbed semiquinone form, S_{ad}. The apparent rate constant, k_{sap}, depends on the adsorption parameters and on the total surface coverage, $\theta_t(\equiv\Gamma_t/\Gamma^{max})$; *i.e.*,

$$k_{sap} = k_{sap}(\theta_t\to 0)\exp(-a\theta_t), \tag{4}$$

where $k_{sap}(\theta_t\to 0)$ is the apparent rate constant at $\theta_t=0$.

When K is less than 16, Eq. 1 predicts that the cathodic and anodic d.c. voltammograms will have a maximum at E'_o, independently of v and Γ_t, *i.e.*, $E_{pc}^{DC}=E_{pa}^{DC}=E'_o$, and that the half-peak widths, $\Delta E_{p/2,c}^{DC}$ and $\Delta E_{p/2,a}^{DC}$, will have the same value, which is independent of v and Γ_t and which depends only on the K parameter:

$$\Delta E_{p/2,c}^{DC} = \Delta E_{p/2,a}^{DC} = (2RT/F)|\ln\xi|, \tag{5}$$

where ξ is the solution of the equation: $\xi^4-K\xi^3+(K-\sqrt{K}-6)\xi^2-K\xi+1=0$, and that the cathodic and anodic peak heights will be proportional to v and Γ_t:

$$I_{pc} = I_{pa} = 2(F^2/RT)A\Gamma_t v(2+\sqrt{K})^{-1} = (F/RT)vQ(2+\sqrt{K})^{-1}. \tag{6}$$

All the experimental results obtained in this work agreed well with these theoretical predictions (see Table 1 and Fig. 4). Thus, we determined the semiquinone formation constant, K, from the half-peak widths (Eq. 5) and from the slope of the I_p *vs.* Q plot (Eq. 6). The results are summarized in Table 3. The K values estimated by these two methods agreed well with each other at either pH.

Table 3. Semiquinone formation constants of FMN adsorbed on a mercury electrode at pH 6.9 and 4.9

pH	K	Method
6.9	1.2	$\Delta E_{p/2}^{DC}$
	1.0	I_{pc} *vs.* Q plot
4.9	0.82	$\Delta E_{p/2}^{DC}$
	0.62	I_{pc} *vs.* Q plot

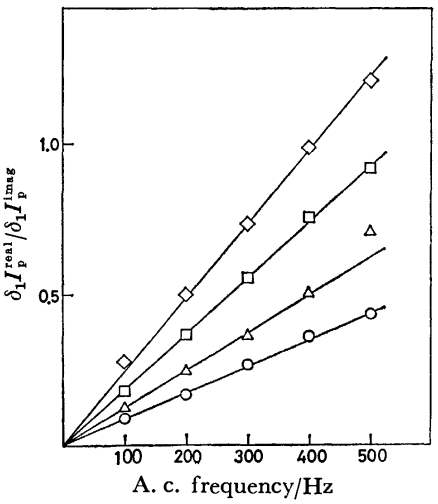

Fig. 7. Frequency dependence of the ratio of a.c. peak current, $(\delta_1 I_p^{real}/\delta_1 I_p^{imag})$, at various total surface coverages of FMN, θ_t, in pH 6.9 phosphate buffer. θ_t: (○) 0.24; (△) 0.40; (□) 0.84; (◇) 1.0.

According to Eqs. 2 and 3, the peak potentials of a.c. voltammograms, E_p^{real} and E_p^{imag}, should be independent of the a.c. frequency and should coincide with each other and with E'_o within a certain limited range of values of K and λ. Table 2 shows that the experimental results agree well with this prediction. In addition, the ratio of $\delta_1 I_F^{real}$ to $\delta_1 I_F^{imag}$ at $E=E'_o$ is given by:

$$(\delta_1 I_F^{real}/\delta_1 I_F^{imag})_{E=E'_o} = \omega/k_{sap}(K)^{1/4}. \tag{7}$$

Such a linear dependence of the current ratio on the a.c. frequency was proved for various total surface coverages, as is shown in Fig. 7, where θ_t was cal-

culated from the peak height of the corresponding cathodic d.c. voltammogram, *i.e.*, $\theta_t=(I_{pc}/I_{pc}^{max})$. The slope of this plot allows us to estimate the apparent rate constant, k_{sap}, provided that K is known. Table 4 summarizes the k_{sap} values estimated from such plots at various surface coverages using K values determined by d.c. voltammetry, *i.e.*, $K=1.1$ at pH 6.9 and $K=0.72$ at pH 4.9. Table 2 gives the experimental values of $\Delta E_{p/2}^{real}$ and $\Delta E_{p/2}^{imag}$ and the theoretical values calculated by using these values of K and k_{sap} at $\theta_t=0.4$. The a.c. peak currents are plotted against the a.c. frequency in Fig. 8, in which the solid lines are drawn by the use of Eqs. 2 and 3. The agreement between the experimental results and theoretical predictions is good. A good agreement between theory and experimental results was also obtained at other θ_t's. As may be seen from Eq. 4, a plot of ln k_{sap} against θ_t should yield a straight line with a slope of $-a$; this was experimentally verified, as is shown in Fig. 9. In conclusion, we can state that the cyclic d.c. and a.c. voltammetric behavior of the adsorbed FMN can be explained by the two-step surface redox mechanism (I). From E'_o and K, we can estimate the formal standard redox potentials of the first and second redox steps, E'_{o1} and E'_{o2}. Table 5 summarizes the values of $k_{sap}(\theta_t\rightarrow\theta)$ and a as well as the K, E'_o, E'_{o1} and E'_{o2} values determined above. For comparison, the standard redox potentials, E'_o(bulk), E'_{o1}(bulk), and E'_{o2}(bulk), and the semiquinone formation constant, K(bulk), for the redox reaction of FMN in a bulk solution[12] are given in Table 5. A comparison of the formal standard potentials of the surface redox reaction with those of the redox reaction in a bulk solution gives $\Delta E_1=E'_{o1}-E'_{o1}(\text{bulk})\simeq+70$ mV and $\Delta E_2=E'_{o2}-E'_{o2}(\text{bulk})\simeq+10$ mV at pH 6.9 and $\Delta E_1\simeq+60$ mV and $\Delta E_2\simeq0$ at pH 4.9. These results suggest that[4] the increasing adsorbability of FMN on the mercury electrode surface is in the order of the oxidized form<the semiquinone form≃the reduced form; this order is consistent with the findings of previous works.[7-10]

The Crystal and Molecular Structures of Paracyclophadiynes

Hideo UEDA,† Chuji KATAYAMA, and Jiro TANAKA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received March 27, 1980)

The molecular structures of tetramethyl[3.3]paracyclophadine(I) and [3.4]paracyclophadiyne(II) have been determined by X-ray analysis. Both crystals are monoclinic, with the space group of $P2_1/c$. The crystal data are: $a=9.170(4)$, $b=9.208(3)$, $c=18.232(7)$ Å, $\beta=94.0(1)°$, $Z=4$ for (I) and $a=10.938(3)$, $b=9.173(2)$, $c=14.988(4)$ Å, $\beta=116.1(1)°$, $Z=4$ for (II). In both molecules, consisting of benzene and diacetylene groups linked by two methylene-bridges, the diacetylene chain is bent into a bow shape. The (I) molecule has Cs symmetry, and the distances (3.019—3.256 Å) between the atoms of the diacetylene group and the benzene plane are smaller than those of [3.3]paracyclophadiyne(Aono, Sakabe, Sakabe, Katayama, and Tanaka, 1975). The methylene-bridge of [3.4]paracyclophadiyne has a disordered structure.

Misumi and his collaborators[1] have synthesized a series of paracyclophadiyne derivatives, and the chemical and spectral properties[1-3] and the crystal structures[4,5] have been investigated. We have ourselves now determined the structures of tetramethyl[3.3]-paracyclophadiyne(I) and [3.4]paracyclophadiyne(II) in order to study the interactions between the diacetylene group and the benzene ring in more detail.

Experimental

The space group of the two colorless crystals were determined as $P2_1/c$ from the systematic absences on the oscillation and Weissenberg photographs. The unit-cell parameters were determined by the least-squares method, using twelve reflections measured on a Hilger & Watts four-circle diffractometer with Zr-filtered Mo $K\alpha$ radiation for (I) and Ni-filtered Cu $K\alpha$ radiation for (II). In order to confirm the stability of the crystal and counting systems, the intensities of three standard reflections were monitored after every 100 reflections. The standard reflections were stable within a 1% fluctuation in both crystals. Neither absorption nor extinction correction was made. The crystal data and their experimental conditions are shown in Table 1.

Table 1. Crystal data and experimental conditions

Maximum 2θ	54°	144°

Determination and Refinement of the Structure

Tetramethyl[3.3]paracyclophadiyne. The structure was determined by the direct method with the MULTAN program,[12] using 188 reflections with $|E|\geqq 1.40$. An E map computed from the phase set with the highest figure of merit ($FOM=1.65$) revealed the locations of all the non-hydrogen atoms. The hydrogen atoms were found on a difference Fourier map computed after the refinement of the carbon atoms. The refinement was performed by the block-diagonal least-squares method with 1508 independent reflections of $|F_o|>3\sigma(F_o)$. The R index converged to 0.058 with an equal weight for each reflection.

[3.4]Paracyclophadiyne. The unit-cell parameters and the relative magnitude of the structure factors are very similar to those of [3.3]paracyclophadiyne-(III);[4] therefore, the two molecules seemed to take a similar structure in the crystals. All the non-hydrogen atoms were located on a Fourier map computed with the phases calculated for the crystal of (III), the structure was found to be disordered. The structure was refined by the block-diagonal least-squares method, with several different occupancies for the atoms of disordered trimethylene-bridge. The minimum R value of 0.083 was obtained when the occupancy factors of 0.55 and 0.45 were assigned to C(8a) and C(8b) respectively, while the R value calculated by the equal occupancy factors was 0.085. The hydrogen atoms of the aromatic ring and tetramethylene-bridge were found on a difference Fourier map after the anisotropic refinement for the non-hydrogen atoms, those of the disordered trimetylene-bridge were also located after the refinement of the other atoms. The refinement was carried out with an equal weight for 1504 independent reflections of $|F_o|\geqq 3\sigma(F_o)$.

The atomic scattering factors were taken from the "International Tables for X-Ray Crystallography."[13] The least-squares program used for the refinement was written by one of the present authors (C.K.). The

positional and thermal parameters of the non-hydrogen atoms are given in Tables 4 and 5.[15] The coordinates and isotropic thermal parameters of hydrogen atoms are given in Table 6.[15] The bond lengths and angles are listed in Tables 7 and 8 respectively.

Molecular Structure of Tetramethyl[3.3]paracyclophadiyne. The bond lengths in the benzene ring are 1.396—1.405 Å (mean 1.401 Å), somewhat longer than the value found for other paracyclophadiynes and close to those found for some cyclophanes[11] in which electron-donor-acceptor(EDA) interaction is considerable and for a complex of hexamethylbenzene with TCNE.[16] These results are reasonable, since some electrons in the bonding MO of the benzene ring are transfered to the vacant MO of the acceptor.

It has been reported that in the cyclophanes[6-11] and [3.3]paracyclophadiyne(III),[4] an angle of the carbon replaced by a methylene group is smaller by a few degree than the value of 120°, but the bond angles of C(2)–C(1)–C(6) and C(3)–C(4)–C(5) are very close to that of the normal sp^2 carbon. Therefore, it seems that the deformation of the benzene ring from the hexagonal shape is restricted by the repulsive forces between the methylene and methyl groups in the molecule. Although the substituent on the benzene ring has been reported to shrink the internal angle at the position of substitution,[17] the present molecule has substituent for all the atoms in the ring; therefore, the above effect might be cancelled.

The deviations of the atoms from the least-squares plane of the benzene ring are listed in Table 9. The C(1) and C(4) atoms in the ring deviate toward the diacetylene group, and the other atoms, C(2), C(3), C(5), and C(6), are displaced in the opposite direction. The deviations of the C(7) and C(16) atoms, which are the atoms of methylene groups substituted into the ring, are also displaced toward the diacetylene group. The dihedral angles between the least-squares plane composed of C(2), C(3), C(5), and C(6) and the planes through C(1), C(2), and C(6) and C(3), C(4), and C(5) are 4.3 and 4.0 °, respectively. The angles are greater than the value of 1.8° of (III).

A characteristic feature of the methyl groups attached to the benzene ring is the deviation from the benzene plane to the outer side of the molecule, not toward the center, as with the hydrogen of many paracyclophanes; this is perhaps due to the repulsion of the methyl and methylene groups. A similar displacement of the methyl group is found in tetramethyl quandruple-layered cyclophane.[10]

The bond lengths of the diacetylene group are almost the same as those of other paracyclophadiynes. The diacetylene chain is bent into a bow shape, which is characterized by the mean bond angle of 171.1° in the C(10), C(11), C(12), and C(13) atoms.

The molecular structures projected onto the benzene plane and from a trimethylene-bridge are shown in Figs. 3 and 4 respectively. The molecule has Cs symmetry, and the diacetylene group is nearly overlapped on the atoms of C(2) and C(3). The features of this molecules are distinct compared with those of (II) and (III), in which the diacetylene chaines are located on the mirror plane containing the C(1) and C(4) atoms.

It has been reported that the interaction between a methyl-substituted benzene and TCNE increases in

response to a number of methyl groups.[18] In the molecule of (I), the distances of the atoms in the diacetylene group from the benzene plane are in the range from 3.019 to 3.256 Å, as is shown in Table 9, smaller than those of (III) by 0.01—0.04 Å. Some of the short intramolecular contacts are 3.203 of C(1)···C(10), 3.288 of C(2)···C(11), 3.259 of C(3)···C(12), and 3.153 Å of C(4)···C(13).

Since the methyl substituents on the benzene ring enhance the electron-donor property of the ring by reducing the I_p of the ring (7.86 eV in hexamethylbenzene as compared to 9.24 eV of benzene), the EDA interaction is apparently stronger for this molecule than for unsubstituted [3.3]paracyclophadiyne. For instance, the peak of the first electronic-absorption band appears at 34200 cm^{-1}, while it is 35300 cm^{-1} in the unsubstituted one, and the red shift of about 1100 cm^{-1} means that the inter-ring interaction is enhanced. The CT transition from the benzene ring to the diacetylene group was found in (III) at 42700 cm^{-1}, while it is observed in this molecule at 40500 cm^{-1}. The lowering of the transition energy by 2200 cm^{-1} is an indication of the stronger EDA interaction. The analysis of the MO involved in EDA interaction would seem to be of interest. As is shown in Fig. 8, the phase of the HOMO of hexamethylbenzene (which is degenerated) matches the LUMO of diacetylene. The HOMO-LUMO interaction which is necessary for the EDA complex is considerable for this system, while in other cyclophadiynes without methyl substituents, the EDA interaction is less favourable.

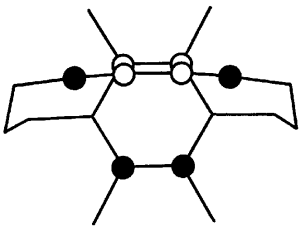

Fig. 8. Symmetries of MO. One of the HOMO of hexamethylbenzene and the LUMO of diacetylene groups are illustrated.

The mean value of the torsion angles around the methylene bridge is 70.5°, this indicates that the conformation are *gauche* as regards the internal rotation around the carbon-carbon bonds.

average of the bond lengths of the benzene ring is 1.382 Å, which is shorter than the normal value (1.392—1.397 Å) and similar to that of (III). As in cyclophanes, it is observed that a benzene ring is distorted from a normal hexagon, with the endocyclic angle of C(1) and C(4) being 117.6 and 116.7° respectively, smaller than the rest by 4.3°. The carbon atoms of the benzene ring are almost coplanar, and no deviation of the hydrogen atoms toward the center of the molecule is found. The dihedral angles between the benzene plane and the planes through C(1), C(2), and C(6) and C(3), C(4), and C(5) are 0.6 and 0.2° respectively. The displacements of the carbon of para-substituted methylene are 0.004 Å for C(1) of the tetramethylene and 0.055 Å for C(17) of the trimethylene-bridge. These values are smaller than those of (III), and the benzene ring keeps a good planarity.

The bond lengths of the diacetylene group are the same as those of the other paracyclophadiynes. The bow-shape deformation, the mean bond angle of the carbon atoms of diacetylene, is 174.1°, smaller than in the case of (I) and (III) because of a less repulsive interaction due to a longer methylene-bridge and a larger spatial distances between the two groups. The larger bow-shape deformation compared to the benzene ring is due to the difference between the length and shapes in these two groups. The distances between the benzene ring and the C(10) and C(11) atoms of the moiety of the diacetylene group are 3.185 and 3.473 Å, and the shortest interatomic distance is 3.250 Å of C(4)···C(10). For the other moeity, the short intramolecular distances are 3.729 of C(1)···C(13), 3.747 of C(1)···C(12), and 3.769 Å of C(6)···C(12). As may be seen from the projection of the diacetylene group onto the benzene plane, the diacetylene group is nearly parallel to the direction of C(1)···C(4) of the benzene ring, the inclination being only 4°, similar to (III).

An unexpected feature of the structure is the disordered arrangement of the trimethylene-bridge. It is interesting that the disordered arrangement is found only on the trimethylene-bridge of the molecules of (II) and (III). The bond distances of this disordered methylene-bridge are 1.4—1.7 Å. The values of the bond lengths and angles, including those of the atoms of the disordered part, are less reliable. The average of the torsion angles of the two methylene-bridges is 67.2°, and it is apparent that the conformations are *gauche*, similar to those of other paracyclophadiynes.

The stereoscopic views of the crystal structure projected along the b-axis are shown in Fig. 7. All the intermolecular contacts are normal.

The authors are grateful to Professor Soichi Misumi and Drs. Yoshiteru Sakata and Takehiro Matsuoka of Osaka University for the gift of the samples.

(Received August 30, 1980)

The ν_4 fundamental of fluoroform has been measured with a tunable diode-laser source spectrometer. The following molecular constants were determined: $\nu_0=1377.8458\ cm^{-1}$, $B_4=0.344788\ cm^{-1}$, $C_4=0.189134\ cm^{-1}$ $(C\zeta)_4=0.18619\ cm^{-1}$, $D_4^J=3.78\times10^{-7}\ cm^{-1}$, $D_4^{JK}=-5.73\times10^{-7}\ cm^{-1}$, $D_4^K=2.94\times10^{-7}\ cm^{-1}$, $\eta_4^J=1.44\times10^{-6}$ cm^{-1}, and $\eta_4^K=-8.2\times10^{-7}\ cm^{-1}$. Using the molecular constants of the $2\nu_3$, the Coriolis x-y interaction constant between the ν_4 fundamental and $2\nu_3$, $|\zeta_{334}|$, was estimated to be 0.065.

Although fluoroform is one of the most simple molecules belonging to the point group C_{3v}, only a few studies of its rotation-vibration spectra have been reported.[1-4] This is largely due to the deficiency in the resolving power of the spectrometers. Graner *et al.*[1] have observed the infrared spectra for the ν_6 and ν_3 fundamentals with an approximate resolution of 0.03 cm^{-1}. As for the ν_4 fundamental, the observations have been done under rather poor resolution. The molecular constants have been obtained from the analyses of the heads of the successive Q's in these works,[2-4] because the resolving power was not quite enough to resolve the successive Q branches into their fine structures. The present report concerns itself with the measurement of the rotation-vibration spectra for the ν_4 fundamental of fluoroform by the use of a tunable diode laser-source spectrometer and with the analysis of the rotation-vibration spectra.

Experimental

The sample used in this study was a commercial product and was used without further purification. The survey spectrum of the ν_4 band of fluoroform was recorded from 1350 to 1410 cm^{-1} using a Nicolet 7199A Fourier transform infrared spectrometer at a resolution of 0.06 cm^{-1}. The observation was made at room temperature using a 10 cm gas cell. The sample pressure was about 9 Torr.

The high resolution spectra were recorded from 1361 to 1385 cm^{-1} by the use of a tunable diode laser-source spectrometer (Laser Analytics, model LS 3). The sample pressure was 0.5—1.5 Torr. As the resolution of the instrument was estimated to be 10^{-4}—10^{-3} cm^{-1}, the line-width of the observed spectrum was governed by the Doppler broadening. About ten modes could be oscillated in the region cited above. In order to determine an accurate frequency value, the wavelengths of a few lines for each mode were measured by the use of a Michelson interferometer-type wavelength meter which was designed and constructed by Nagai *et al.*[5] The wavelengths of the other lines were determined relative to these frequencies by observing the interference fringes arising from a confocal germanium etalon. The free spectral range was calibrated to be $0.009929\pm0.000008\ cm^{-1}$ by the use of the OCS lines in the 870 cm^{-1} region. The precision of the wavelength measurement was about 0.0015 cm^{-1}. The accuracy of the wavelength measurement was restricted by the incomplete alignment of the reference He–Ne laser beam in parallel with the diode laser source.[5] It is believed to be better than 0.001 cm^{-1}.

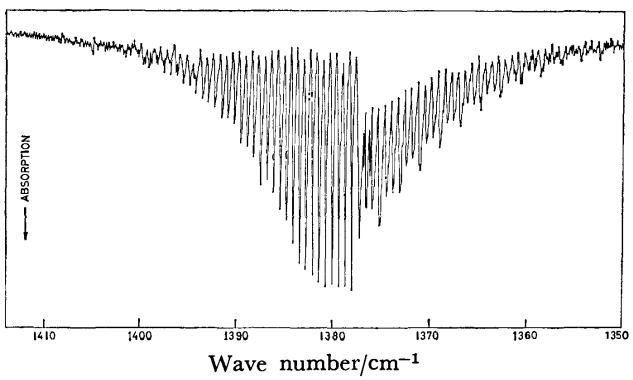

Fig. 1. The infrared absorption spectra for the ν_4 band of fluoroform recorded by the Fourier transform spectrometer.

Results and Discussion

Observed Spectra. The spectra for the ν_4 band recorded by the Fourier transform spectrometer is shown in Fig. 1. We can see the usual intensity alternation due to the three-fold symmetry for the sub-bands on the low frequency side (the 1377—1350 cm^{-1} region). These sub-bands may therefore be assigned to the successive ^RQ lines. In the high frequency region (the 1377—1400 cm^{-1} region), on the other hand, we cannot recognize any clear intensity alternations. This happens because these sub-bands on the high frequency side are mainly composed from

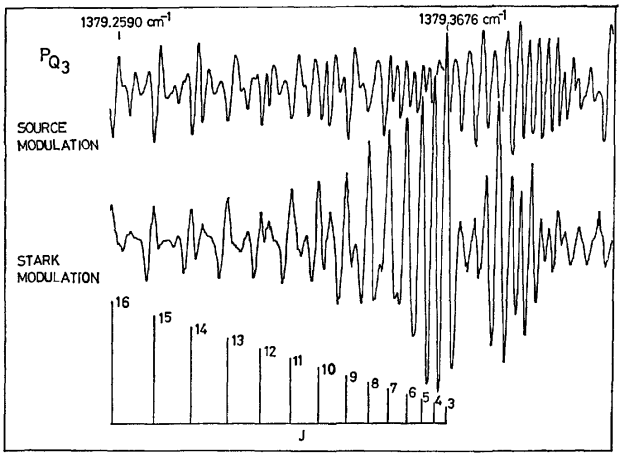

Fig. 2. The high resolution spectra observed by the diode laser-source spectrometer (upper: source modulation, lower: Stark modulation).

the ^{R}R lines instead of ^{P}Q lines. The ^{P}Q lines form only a background of the high frequency side.

Figure 2 shows the part of the high resolution spectra observed by the diode laser-source spectrometer which may be assigned to the $^{P}Q_3$ line series. The upper spectra were recorded by modulating the source diode by a sine wave of 5 kHz and detecting the absorption signal at 10 kHz by the use of a phase-sensitive detection method. The lower spectra were recorded by the use of the usual Stark modulation method. The modulation frequency and the electric field were 100 kHz and 200 V_{p-p}/cm (being superposed on the 200 V/cm DC field), respectively. The lower spectra were used for the J-number assignment.

The observed frequency values are summarized in Table 2, together with the assignments.

Assignment of the Observed Spectra. First, we calculated the synthetic spectra corresponding to the ν_4 fundamental by using the approximate molecular constants given in the references.[1,4] The spectral simulation showed that a group of lines having the same K value forms a localized sub-band, ^{P}Q or ^{R}Q, and that a group of lines having the same $(J-K)$ value form a localized sub-band, ^{P}P or ^{R}R. The comparison between the observed and the calculated frequencies leads to the rigorous assignments of K and $(J-K)$ numbers to the sub-bands ^{P}Q, ^{R}Q, ^{P}P, and ^{R}R. The sub-bands ^{P}P and ^{R}R can be identified from the sub-bands ^{P}Q and ^{R}Q, because the component lines of ^{P}P and ^{R}R show the intensity alternation due to the three-fold symmetry. The assignments of K numbers to the ^{P}Q and ^{R}Q sub-bands are confirmed by the low-resolution spectra of Fig. 1.

The assignment of J numbers to the component fine structure lines of each sub-bands can be done without ambiguity by using the Stark modulated spectra and the missing lines rule $(J \geq K)$. As the apparent intensity of a Stark modulated spectrum is observed to be stronger for lower J, the lines of the smallest J number in a sub-band is easily found. Therefore, the J number is rigorously assigned to the individual component lines in consideration of the missing lines rule and the already determined K and $(J-K)$ values. In this way we could identify about 100 lines and make a rigorous assignment of J and K numbers. Using these lines, trial molecular constants were obtained by least-squares method; these in turn were used in the spectral simulation to make further assignments.

Determination of the Molecular Constants. The vibration-rotation energy of a symmetric top in an E-vibrational state can be written in the form (for $v_4=1$):

$$\begin{aligned} E(J,k,l) = {} & \nu_0 + (C_4 - B_4)k^2 + B_4 J(J+1) - 2(C\zeta)_4 kl \\ & - D_4^J J^2(J+1)^2 - D_4^{JK} J(J+1)k^2 \\ & - D_4^K k^4 + \eta_4^J J(J+1)kl + \eta_4^K k^3 l, \end{aligned} \tag{1}$$

where ν_0 is the vibrational energy, C_4 and B_4 are the rotational constants, ζ is the Coriolis coupling constant, D_4^J, D_4^{JK}, and D_4^K are the centrifugal distortion constants, and η_4^J and η_4^K express the dependence of the Coriolis coupling on J and K.

From the selection rules for a perpendicular band ($\Delta k=+1$, $\Delta l=+1$, and $\Delta J=0, \pm 1$; or $\Delta k=-1$, $\Delta l=-1$, and $\Delta J=0, \pm 1$), the transition frequencies can be calculated as the differences between the energy levels of the upper and lower states. The energy of the ground state can be given by this formula:

$$\begin{aligned} E(J,k) = {} & (C_0 - B_0)k^2 + B_0 J(J+1) \\ & - D_0^J J^2(J+1)^2 - D_0^{JK} J(J+1)k^2 - D_0^K k^4. \end{aligned} \tag{2}$$

The B_0, D_0^J, D_0^{JK}, and C_0 values were obtained by the microwave studies[6,7] and/or by the analysis of the infrared spectra.[3,4,8] The D_0^K value was calculated from the harmonic force field.[7] After fixing all these molecular constants related with the ground state, the molecular constants of the excited state were determined by the least-squares method. The constants thus obtained are listed in Table 1 together with the fixed ground state values. The observed frequencies are listed in Table 2 with their assignments and the calculated frequencies.

Table 1. MOLECULAR CONSTANTS OF THE ν_4 BAND OF CHF_3 (cm^{-1})

ν_0	1377.84576(33)	η_4^J	$1.436(35)\times10^{-6}$
B_4	0.3447884(12)	η_4^K	$-8.20(28)\times10^{-7}$
C_4	0.18913390(54)		Ground State
$(C\zeta)_4$	0.186195(10)	B_0	0.34520105(7)
D_4^J	$3.7774(85)\times10^{-7}$	C_0	0.18925(10)
D_4^{JK}	$-5.735(18)\times10^{-7}$	D_0^J	3.779×10^{-7}
D_4^K	$2.941(12)\times10^{-7}$	D_0^{JK}	$-6.0375(134)\times10^{-7}$
q_4	$-1.115(12)\times10^{-4}$	D_0^K	3.72×10^{-7}

Numbers in parentheses denote the standard deviation σ.

l-type Doubling. In the case of the ν_4 fundamental, the effect of the l-type resonance is not so drastic as was observed for the ν_6 fundamental.[1] This is because the Coriolis coupling constant ζ_4 takes a positive value, which produces a repulsive effect on the interacting pair. As the precision of the frequency measurement exceeds the order of 10^{-3} cm^{-1}, it is possible to determine the l-type doubling constant, q_4. In our analysis, we take l-type resonace into account as well as l-type doubling.

The perturbed energies can be obtained from the diagonalization of a 2×2 matrix of this form:

$$\begin{bmatrix} E(K-1,\ l=-1) & W \\ W & E(K+1,\ l=+1) \end{bmatrix}, \tag{3}$$

where K is the absolute value of k. The off-diagonal element, W, has this form:

$$W = -\frac{q_4}{2}[J(J+1)-K(K+1)]^{1/2}[J(J+1)-K(K-1)]^{1/2}. \tag{4}$$

The explicit expression for the perturbed energy level can be written as

$$\begin{aligned} 2E_{\pm}(J,K\pm1,\pm1) = {} & E(J,K-1,-1) + E(J,K+1,+1) \\ & \pm \{E[(J,K-1,-1) - E(J,K+1,1)]^2 \\ & + q_4^2[J(J+1)-K(K+1)][J(J+1) \\ & - K(K-1)]\}^{1/2}, \end{aligned} \tag{5}$$

where E_+ and E_- correspond to the perturbed states of the upper and lower levels of the interacting pair, respectively. In order to determine the sign of q_4, the twelve lines which are definitely assigned to the

The standard deviation of the residuals $\sigma = 0.0023\ cm^{-1}$.

a) For example, PQ 3(3) denotes $^{P}Q_3(3)$.

$^{R}Q_0$ were carefully observed. The standard deviation arising in the least-squares fitting has shown that the negative sign was definitely preferable to the positive sign. The final result for q_4 is included in Table 1.[9]

x-y Type Coriolis Interaction. The standard deviation of $0.0023\ cm^{-1}$ for the overall least-squares fit is somewhat too large if we consider the precision of the wavelength measurement. This may hint at the existence of an x-y type Coriolis interaction between ν_4 and $2\nu_3$, because the band origin of $2\nu_3$ is expected to be about $1400\ cm^{-1}$. The intensity of the $2\nu_3$ band is so weak, in comparison with the ν_4 band, that we failed to pick up the lines of $2\nu_3$ in the $1400\ cm^{-1}$ region. Therefore, we attempted to consider the effect of such an x-y type Coriolis interaction by using the frequencies calculated for $2\nu_3$. The molecular constants were estimated from the results obtained for the $2\nu_3-\nu_3$.[1] The details are:

$$\nu = 700.1009 + 699.310 = 1399.411\ cm^{-1}$$

$$B = B_0 - 0.641\times10^{-3} - 0.6463\times10^{-3} = 0.343914\ cm^{-1}$$

$$C \simeq C_0 - 2\times1.700\times10^{-4} = 0.18852\ cm^{-1}$$

$$D^J = 3.52\times10^{-7}\ cm^{-1}$$

$$D^{JK} \simeq D_0^{JK} - 2\times(0.28\times10^{-8}) = -6.0935\times10^{-7}\ cm^{-1}$$

and

$$D^K \simeq D_0^K = 3.27\times10^{-7}\ cm^{-1}.$$

The matrix elements of the Hamiltonian for the Coriolis interaction between ν_4 and $2\nu_3$ are expressed as

$$\langle v_3 = 2, J, K|H_c|\ v_4 = 1,\ l = \pm1,\ J, K\pm1\rangle = \pm\xi_{334}[J(J+1)-K(K\pm1)]^{1/2}.$$

The ζ_{334} value is obtained from the ξ_{334} value by this relation:[10]

$$\xi_{334} = \left(\frac{1}{\sqrt{2}}\right)[(\nu_4/\nu_{33})^{1/2} + (\nu_{33}/\nu_4)^{1/2}]B\zeta_{334}.$$

By considering the x-y Coriolis interaction, the standard deviation value was reduced from $0.0024\ cm^{-1}$ to $0.0012\ cm^{-1}$. The final interaction parameters obtained are: $|\xi_{334}| = 0.03185\pm0.00054\ cm^{-1}$ and $|\zeta_{334}| = 0.065$. Other molecular constants did not change their magnitude very much, except for η_4^J and η_4^K. These values were obtained to be $(6.94\pm0.32)\times10^{-7}\ cm^{-1}$ and $(-1.30\pm0.24)\times10^{-7}\ cm^{-1}$, respectively. As this treatment of the x-y type Coriolis interaction is not complete, we have listed the molecular constant values which were obtained without considering this interaction in Table 1. However it must be concluded that the interaction parameter $|\zeta_{334}|$ takes the value of about 0.065 and that the molecular constants given in Table 1 are not affected much by the neglect of this type of interaction.

The authors are grateful to Dr. Jun Nakagawa of Hiroshima University for his helpful suggestions about the computer program.

Phase Transition in Ammonium-d_4 Sulfate as Studied by Heat Capacity Measurements between 3 and 300 K†

Yoshiyuki HIGASHIGAKI†† and Hideaki CHIHARA*

Department of Chemistry and Chemical Thermodynamics Laboratory, Faculty of Science, Osaka University, Toyonaka 560

(Received September 17, 1980)

Molar heat capacities were determined of $(ND_4)_2SO_4$ between 2.8 and 301 K. The phase transition at 223.94±0.03 K is of the first-order with a long tail extending down to 160 K. The overall heat and entropy of transition are 4270 J mol^{-1} and 20.35 J K^{-1} mol^{-1}, respectively, the first-order portion contributing only 40%. The contraction of the molar volume at the transition was evaluated as 0.33 cm^3 mol^{-1}. The enthaply to misorient ions in an otherwise perfectly ordered lattice was derived from the low-temperature tail of the anomalous heat capacity. It was 12.0 kJ/mol of $(ND_4)_2SO_4$, in reasonable agreement with 16 kJ mol^{-1} derived from O'Reilly-Tsang's mean field theory. The present results support the order-disorder mechanism of the transition.

Ammonium sulfate is probably one of the most extensively studied ferroelectric crystals. Its phase transition had been known to exist at about −50 °C by calorimetric investigations[1-3] before the ferroelectricity was discovered by Matthias and Remeika[4] in 1956. Since then reports have been published on its properties by such measurements as dielectric,[5,6] calorimetric,[5] X-ray[7] and electron[8] diffractions, neutron diffraction,[9] infrared[10,11] and far-infrared absorption,[12] neutron[13,14] and Raman[12] scattering, proton[10,15-18] and deuteron[17,19] magnetic resonance.

In spite of these studies, the nature of the phase transition has not been established; the neutron diffraction studies and the deuteron resonance studies gave conflicting interpretations. Thus, Schlemper and Hamilton[9] stated that both the high- and low-temperature phases were ordered from their neutron diffraction experiments on a single crystal of $(NH_4)_2SO_4$ whereas O'Reilly and Tsang[17] proposed that the transition is of an order-disorder type from their deuteron resonance. Both techniques indicate that there are two crystallographically inequivalent ammonium ions but the main issue is that whereas the neutron diffraction results can be interpreted by static distortion of the hydrogen-bonded ammonium tetrahedra, the deuteron resonance has to show a double minimum potential on each ammonium across the mirror plane in the high-temperature phase. O'Reilly and Tsang[20] then developed a molecular field theory based on a three-sublattice model involving disorder of sulfate ions. High resolution inelastic neutron scattering experiments[14] also support the dynamic order-disorder model.

More recently, an X-ray diffraction study[21] suggested strongly that the low-temperature phase of $(NH_4)_2SO_4$ was more properly described as a ferrielectric state in which the two types of inequivalent ammonium ions might assume separate order parameters. Peculiarity of the spontaneous polarization[26] at low temperatures and smallness of the Curie-Weiss constant in the high-temperature phase were also the reason to suspect the crystal to be ferrielectric at low temperatures.

Previous heat capacity results[2,5] are not sufficiently accurate for detailed examination of the transition; the measurements reported in this paper are consistent with the order-disorder model of the transition.

Experimental

Material. Ammonium sulfate (Nakarai Chemicals, Ltd., stated purity better than 99.5%) was recrystallized from distilled water and dried in vacuo. Ammonium-d_4 sulfate was prepared by deuterium substitution of the recrystallized $(NH_4)_2SO_4$ in heavy water. Thus, the degassed heavy water with various deuterium concentrations (48.1—99.8%) was transfered onto solid in a vacuum apparatus to prevent pick-up of atmospheric water and then the aqueous solution was evaporated to dryness. The deuterium content of water which was distilled in vacuo was monitored with the integral proton intensity of the high resolution NMR at each substitution step. Water thus distilled at the final stage was found to have an isotopic purity of 99.6%. The $(ND_4)_2SO_4$ crystals thus obtained, however, showed a small thermal anomaly at about 250 K on DTA thermogram, which was likely to be due to D_2O occluded in the $(ND_4)_2SO_4$ specimen. These crystals were then pulverized and heated to 80 °C under vacuum but this small DTA peak did not

disappear completely. Therefore, the $(ND_4)_2SO_4$ crystals were dissolved in D_2O again, recrystallized by slow cooling, separated from the solution by filtration, and dried *in vacuo*. Crystals thus prepared still showed a smaller heat anomaly at the same temperature as before, which disappeared after several thermal cycles between room temperature and liquid nitrogen temperature in a vacuum. Deuterium content of this sample was determined to be 99.3% from the deuterium content of the water distilled from the last mother liquor. Found: N, 19.90; S, 22.95%. Calcd for: N, 19.98; S, 22.87%.

The powder samples were put into the gold-plated copper calorimeter vessel which will be described below, in a conventional dry-box to reject atmospheric moisture. Weight of specimen used for calorimetry was 48.668 g (*in vacuo*), amounting to 0.34717 mol.

Calorimeter and Cryostat. The apparatus used was a newly constructed cryostat of a design similar to the one reported in the literature.[22] Some modifications were made to permit continuous operation from 2.5 K to 300 K using both liquid helium and liquid nitrogen. Once charged fully in the lower refrigerant tank, the liquid helium lasted for 6 to 10 h according as the upper tank contained solid nitrogen or solid hydrogen.

The calorimeter vessel is made of copper (0.3 mm in wall thickness) with 12 vertical vanes of copper (0.2 mm thick) as shown in Fig. 1. Both outside and inside were gold-plated. The platinum resistance thermometer D (Minco Products, Inc., Model S1055-1, Laboratory designation α) was fitted to the copper holder E with soft solder around which the heater G (double-nylon insulated KARMA wire, Driver-Harris Co., B.S. #36) was wound non-inductively and fixed with G.E. 7031 adhesive. This thermometer/heater assembly was cast into the re-entrant well of the calorimeter vessel with Wood's alloy. Gold-plated radiation shield I covers most of the bottom to reduce direct heat exchange between the thermometer and the adiabatic shield that surrounds the calorimeter vessel. The germanium resistance thermometer J (CryoCal, Inc., Model CR 1000, Laboratory designation ε) was fitted into a copper sheath snugly with small amounts of silicone grease. The calorimeter vessel thus weighed 91 g including the attachments and its inside volume was 76 cm^3. In measurements of the heat capacity of the $(ND_4)_2SO_4$ sample, helium exchange gas less than 3.6×10^{-5} mol was used for Series from I to XII and 1.5×10^{-5} mol for Series from XIII to XV. Equilibration rates of the vessel containing $(ND_4)_2SO_4$ varied greatly. At temperatures below 20 K, the sample reached equilibrium in ten seconds to a few minutes. At higher temperatures it took about 15 min for equilibrium, except near the ferroelectric transition temperature where it was much longer. The sample contributed 23% to the total heat capacity at 3 K: the contribution increased to more than 60% above 100 K.

Temperature Scales. The platinum thermometer (α) was used above 14 K and the germanium thermometer (ε) below 15 K. They were calibrated prior to the measurements of heat capacity.

The temperature scale of the thermometer α was fixed based on the 1968 International Practical Temperature Scale (IPTS 68). The necessary resistance values at the eight defining fixed points from 13.81 to 373.15 K were obtained by comparison with the Leeds & Northrup platinum thermometer (Model 8164) whose scale was determined at the U.S. National Bureau of Standards on IPTS 68. The thermometer α proved to satisfy the condition for the SPRT; $R(100\ °C)/R(0\ °C)\geqq1.3925$. The necessary coefficients for the IPTS 68 scale below 0 °C were calculated according to the standard procedure.[23] To obtain the scale between 0 and 100 °C, the resistance values were measured from 255 to 380 K at intervals of 5 K instead of determining the value at the freezing point of tin or zinc. Observed values of temperatures based on the IPTS 68 and the resistances were fitted to the following empirical formula;

$$R(t) = R(0)\{1+At+Bt^2+C(t-100)t^3\},$$

where $t=T_{68}-273.15$.

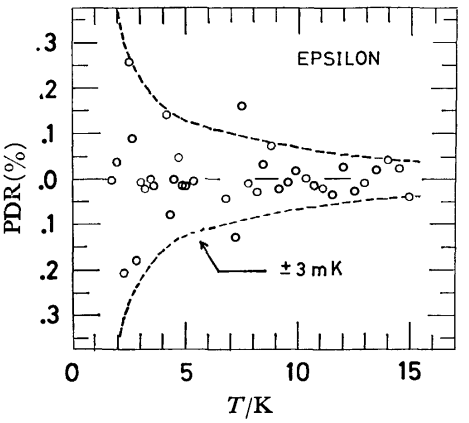

Fig. 2. Percent deviation (PDR) of calibration points from the smooth values of the germanium temperature scale.

The germanium thermometer ε was compared with the germanium thermometer (the same model, laboratory designation γ) which had been calibrated in our laboratory using the helium vapor pressures and gas thermometry on the IPTS 68. Resistance value of the thermometer ε was about 1 kΩ at 4.2 K and the calibration current of 5.7 μA was chosen to avoid the adverse effect of self-heating. To obtain the interpolation formula, a series expansion of the type

$$\log R = \sum_i A_i(\log T)^{k+i}$$

was used to fit the calibration data. The variance V given by

$$(M-1)V^2 = \sum_{j=1}^{M}\{R_j(\text{observed})-R_j(\text{smoothed})\}^2,$$

where M (=38) is the number of calibration points, and the temperature dependences of the first and second derivatives of log R with respect to log T were employed as a measure of fitting. The best fit was obtained when the power $k+i$ of the first term was taken as -2 and the number of the series expansion terms as 10. The temperature determined by the thermometer ε deviated less than 5 mK from the thermodynamic temperature between 1.8 and 15 K as shown in Fig. 2.

Results and Discussion

The experimental molar heat capacity is given in Table 1 in chronological sequence at the mean temperatures of determination. The temperature increment in each measurement was small as seen from the differences in the adjacent mean temperatures and hence no curvature correction was made. Corrections were not made either for the contribution from the helium exchange gas in calculating the heat capacity values because of negligible contribution. Scattering

of results was within 15% below 8 K, decreasing to 2% between 8 and 15 K, within 1% between 15 and 50 K, and 0.5% above 50 K. When our results are compared with the data by Nitta and Suenaga,[2] their values are found systematically larger than ours by 13% in the low-temperature phase and by 8% in the high-temperature phase. Hoshino *et al.*[5] also reports values too large by 24% at 200 K and 15% at 250 K in a similar manner to the case of NH_4HSO_4.[24] The entire heat capacity curve is shown in Fig. 3.

The thermodynamic functions were evaluated from the smoothed values of the heat capacity and are summarized in Table 2 at rounded temperatures, including the contributions from the heat capacity below 3 K and near the transition region which will be discussed later.

Low Temperature Heat Capacity. From the C_pT^{-3} *versus* T^2 plot, the heat capacity values below 5 K were estimated by using the formula,

$$10^4\, C_pT^{-3} = 4.28 \pm 0.04 + 0.003\, T^2,$$

where C_p is in the units of J K^{-1} mol^{-1} and the coefficient of the second term has an uncertainty of about 20%. This coefficient is smaller by a factor of 25 than that of $(NH_4)_2SO_4$ for which it is 0.08. The Debye temperature at 0 K was found to be 238.8±0.7 K for $9N$ degrees of freedom and 165.6±0.5 K for $3N$ degrees of freedom.

'Normal' Behavior. We now attempt to separate the 'normal' portion of the observed heat capacity in order to assess the 'abnormal' portion associated with the phase transition and to see to what extent the normal portion may be rationalized in terms of harmonic vibrational spectrum. The best practical way in which to find the temperature at which the abnormal contribution begins to be seen is to plot the equivalent Debye temperature θ_D as a function of temperature (see Fig. 4) and then draw a smooth curve ignoring the transition region. The normal por-

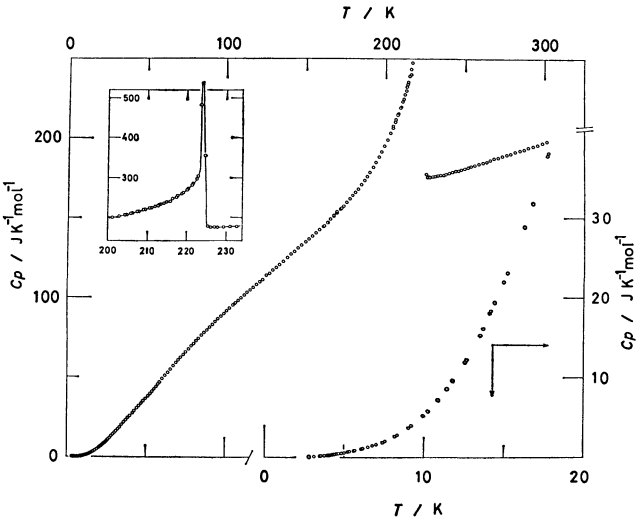

Fig. 3. Measured heat capacities of $(ND_4)_2SO_4$.

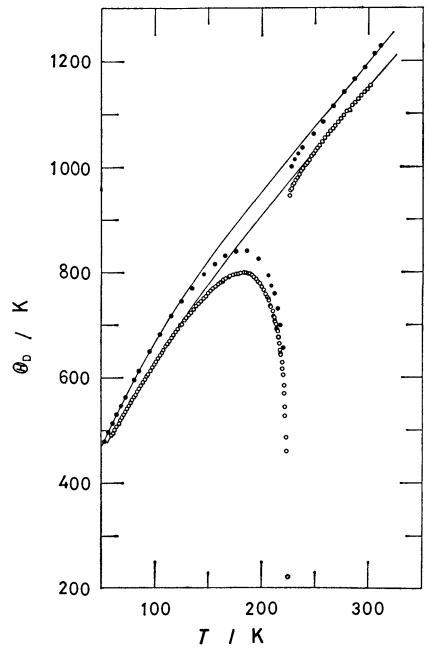

Fig. 4. Assessment of 'normal' heat capacities by the use of Debye temperature θ_D. Open circles for $(ND_4)_2SO_4$ and filled circles for $(NH_4)_2SO_4$.

tion of the heat capacity thus obtained is given in Table 3.

We may divide a total of $45N$ degrees of freedom into the $9N$ lattice vibrational modes, $3N$ librational modes of SO_4^{2-}, $6N$ librational modes of ND_4^+, $9N$ internal modes of SO_4^{2-} and 18 internal modes of ND_4^+, assuming that the intermolecular interactions are much weaker than the intramolecular interaction. The lattice vibrational contributions to the normal heat capacity may be derived from a Debye function with $\theta_D(0\,K)=238$ K. Other contributions can be estimated from the fundamental frequencies observed in the infrared and far infrared absorption spectra and also the Raman scattering; that is, for ND_4^+, $\nu_1(A_1)=2220$, $\nu_2(E)=1215$, $\nu_3(F_2)=2390$, $\nu_4(F_2)=1032$, $\nu_L=260$ and for SO_4^{2-}, $\nu_1(A_1)=973$, $\nu_2(E)=452$ and 464, $\nu_3(F_2)=1110$, $\nu_4(F_2)=614$ and 626, $\nu_L=102$ and 130 in units of cm^{-1}. Assuming that the librational modes of cations and anions are dispersion-less, the sum total of their modes accounts for most of the normal heat capacity above 120 K. However, such estimation exceeds the observed by about 10 J K^{-1} mol^{-1} at 80 K, which is outside of the experimental error. The anharmonic effects are usually too small to be seen at this temperature and, therefore, the discrepancy probably comes from inadequacy of the Debye approximation for the $9N$ degrees of freedom. The $9N$ degrees of 'lattice' freedom can further be divided into $3N$ acoustic modes and $6N$ optical modes. Since the translational optical mode frequencies are nearly independent of their wave vectors, compared with the acoustic modes, we tried to fix the average frequency of these optical modes by means of an Einstein function. As to the acoustic modes the value of $\theta_D(0\,K)=165.6$ K was used in the Debye approximation for $3N$ degrees of freedom. The best fit was obtained when the average optical frequency was chosen to be 185 ± 5 cm^{-1}. This value is consistent with the broad far infrared bands centering at 180 and 200 cm^{-1} which are assigned as the translational modes of ND_4^+ by our preliminary study[25] shown in Fig. 5. This value also shows a good agreement with the broad peak at 200 ± 16 cm^{-1} in the neutron inelastic scattering experiment,[13] the assignment of which is

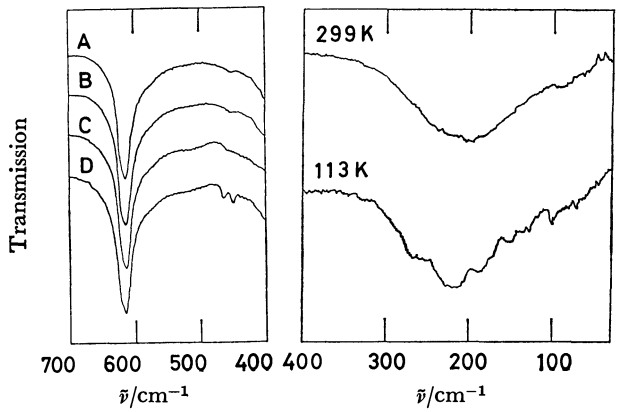

Fig. 5. Infrared and far infrared spectra of $(ND_4)_2SO_4$.

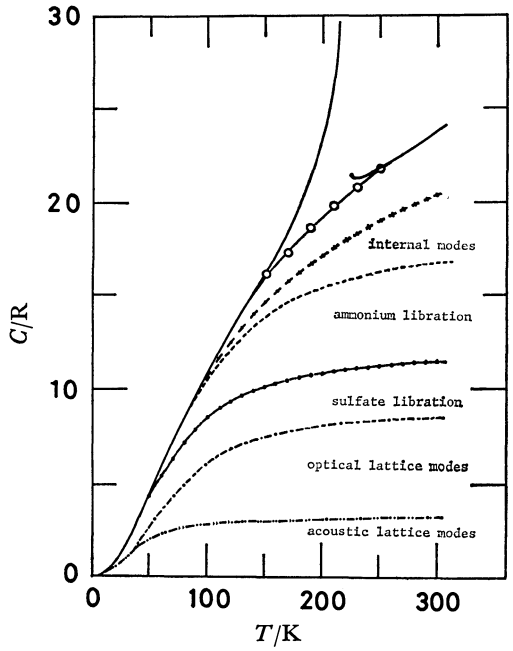

Fig. 6. Breakdown of the normal heat capacity into contributions.

the same as ours. Figure 6 shows the final result of the present analysis on the normal heat capacity of $(ND_4)_2SO_4$. Remaining discrepancy of about 10% of the normal C_p value at 200 K (14% at 300 K) is partly due to neglected C_p-C_V correction and partly due to the onset of anharmonic effects.

Ferroelectric (Ferrielectric) Phase Transition. The transition temperature of $(ND_4)_2SO_4$ was determined from the position of maximum heat capacity as 223.94± 0.03 K and is compared with previous determinations and with the results for $(NH_4)_2SO_4$ in Table 4. There is virtually no effect of deuterium substitution on the transition temperature. This fact indicates that the Gibbs energies on both sides of the transition change by the same magnitude upon deuteration. Because the modes of motion that suffer from the largest influence are those related to libration of ammonium ions, the potential energy surface which an ammonium ion sees when it rotates changes little on passing through the transition. In other words, there is little difference in the libration frequency between the low- and high-

temperature phases. This is consistent with the fact it was possible to draw a continuous smooth curve between the normal portions on the θ_D *vs.* T plot (Fig. 4). This also leads to an important notion that the transition mechanism can not be such as to accompany a substantial change in the librational state of the ammonium ions. If the ammonium ions are to play a leading role in the transition, it will be either order-disorder between almost equivalent orientations or translational displacement.

The transition is of first order with a long tail on the low-temperature side (down to $0.6T_c$). Other properties also show the first-order characteristics, like thermal hysteresis,[2] molar volume,[5] spin-lattice relaxation time of NMR,[17,19] and spontaneous polarization.[5] The present calorimetric study showed that the time for equilibration was extremely long in the transition region, as long as three hours. However, the latent heat and its corresponding entropy change account for only 40% of the overall heat and entropy of the transition (1.8 kJ mol^{-1} and 8.1 J K^{-1} mol^{-1}). The overall shape of the heat capacity anomaly is shown in Fig. 7. The inset of Fig. 3 depicts how the latent heat portion begins abruptly after very gradual rise of the heat capacity. The temperature

dependence between $0.6T_c$ and T_c is very much like that of dielectric anomaly[5,6]. Table 5 lists the thermodynamic quantities of the transition in comparison with corresponding results for $(NH_4)_2SO_4$. These are large, perhaps one of the largest among the ferroelectric transitions. Shomate[3] reported a value of 16.7 J K^{-1} mol^{-1} for the 'excess' entropy of $(NH_4)_2SO_4$ which is smaller than our value of 20.4 for $(ND_4)_2SO_4$ by as much as 18%. His value is based on an arbitrary assessment of the 'normal' curve and it is not possible to deduce from his published primary results a quantity which may be compared with our ΔS value. However, the θ_D curve calculated by using the Shomate's results for $(NH_4)_2SO_4$ is superimposable on the θ_D curve for $(ND_4)_2SO_4$ by slight vertical displacement (Fig. 4), which fact strongly suggests that what is occurring in $(ND_4)_2SO_4$ is also occurring in $(NH_4)_2SO_4$ in the same way.

If we formally apply the Clapeyron-Clausius equation to the transition excluding the gradual part, we obtain a value of 0.33 cm^3 mol^{-1} for the volume decrease from the low-temperature to the high-temperature phase by using the value[27] of $dT_c/dp = -4.0 \times 10^{-3}$ K kg^{-1} cm^2. There is no other data to compare with this figure but the almost corresponding quantity[5] for $(NH_4)_2SO_4$ is 0.69 cm^3 mol^{-1}.

Now, we will consider the mechanism of the transition. From neutron diffraction studies,[9] there are two kinds of inequivalent ammonium ions, types I and II, in both phases, each of which changes the hydrogen bond arrangements as well as the extent of distortion from regular tetrahedral structure. The most eminent structural feature of the transition is the replacement of the mirror symmetry (the ab plane of the high-temperature phase) with the two-fold screw axis (low-temperature phase). O'Reilly and Tsang[20] developed a molecular field treatment of the transition using three-sublattice model on the basis of their experimental results of deuteron magnetic resonance[17]. The theory assumes essentially an order-disorder mechanism in which the two types of ammonium ions assume random distribution of two orientations separated by $\pm 30°$ from the mirror plane in the high-temperature phase. They also assumed that sulfate ions, which occupy the third sublattice, are also disordered in a similar manner. They derived two energy parameters ε and $d\varepsilon/dn_\pm$ by fitting the theory to the temperature dependence of the crystal volume[5] in the low-temperature phase. Here ε is the energy of a misoriented (antiparallel) pair relative to a parallel pair and $d\varepsilon/dn_\pm$ is its dependence on the number of the antiparallel pairs. The values they

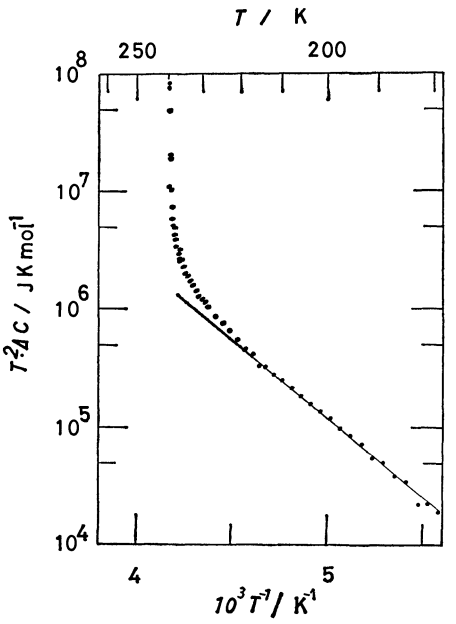

Fig. 8. Plot according to Eq. 1 for determination of enthalpy to form defects.

obtained were $\varepsilon = 0.92$ kJ mol^{-1} and $d\varepsilon/dn_\pm = 0.10$ kJ mol^{-1} for the case of six nearest neighbors.

The present thermodynamic results may be compared with the O'Reilly-Tsang theory in two ways. In the first place, the overall entropy of the transition is expected to be $\Delta S = 3R\ln 2 = 17.3$ J K^{-1} mol^{-1} according to the three-sublattice, order-disorder model in comparison with the experimental 20.4 J K^{-1} mol^{-1}. The difference is outside of the experimental error; although there is small uncertainty in the evaluation of the 'normal' portion of the heat capacity, it can not account for the difference. Therefore, there must be some other small contributions to the entropy such as coupling of translational modes of motion with librational degrees of the ions.

The other quantity that can be compared with the theoretical model is the enthalpy to form a defect in the otherwise perfectly ordered structure. Suppose an ammonium ion is misoriented to create six 'wrong' pairs in the ordered lattice. This process requires an additional enthalpy of 6ε per ion. Since there are three such ions a formula unit, the total enthalpy per mole would be $h = 18\varepsilon$. Let n be the number of such defects and the excess heat capacity due to this process of defect formation is given by

$$\Delta C_p = (\partial \Delta H/\partial T)_p = \partial(nh)/\partial T = (n_0 h^2/kT^2)\exp(-h/kT), \quad (1)$$

where the Boltzmann relation,

$$n = n_0 \exp(-h/kT),$$

has been used. Thus, a plot of $\ln(T^2\Delta C_p)$ *vs.* T^{-1} should give a straight line whose slope yields a value of h. Figure 8 shows such a plot for $(ND_4)_2SO_4$ and the straight line corresponds to

$$n/N = 88 \exp(-1451/T),$$

which gives $h = 12.0$ kJ mol^{-1} or $\varepsilon = 0.67$ kJ mol^{-1}. This is comparable in magnitude with 0.92 kJ mol^{-1} which O'Reilly and Tsang derived. The observed

points in Fig. 8 begin to deviate from the straight line at about 173 K where the fraction of the defects reaches 2%. The deviation reflects the cooperative nature of the defect formation, in other words h or ε depends on the number of defects already present.

A similar analysis on the Shomate's data on $(NH_4)_2SO_4$ gave $h=12.2$ kJ mol^{-1}, indicating that one sees the same phenomenon in the two crystals.

An attempt to find the critical index was not successful because a plot of $\ln\Delta C_p$ against $\ln(T-T_c)/T_c$ did not give any straight line region.

In conclusion, the phase transition, whether ferroelectric or otherwise, in $(ND_4)_2SO_4$ consists of a second-order portion and a first-order portion, the former contributing 60% to the total entropy of transition. The thermal properties are consistent with the three-sublattice, order-disorder model proposed by O'Reilly and Tsang including disordering of the sulfate ions. It will help understand the mechanism better if the quadrupole effects of ^{17}O resonance may be studied in the two phases.

A Method of Estimating the Diffusion Coefficient of Disperse Dyes into Hydrophobic Fibers from the Initial Sorption Data of Dyeing by Means of the Polynomial Least-squares Method[1)]

Takao SHIBUSAWA

College of Technology, Gunma University, Kiryu, Gunma 376

(Received January 17, 1980)

For the initial and the medium stage of diffusion, Hill's equation was approximated by the simple polynomial in the form of $M_t/M_\infty \approx P_1(Dt/r^2)^{1/2} - P_2(Dt/r^2)$, where P_1 and P_2 are constants depending on the interval in which the approximation is used, while the other symbols have a usual meanings. On the other hand, several experimental M_t's were plotted against square root of t, and an experimental formula describing the regression curve passing through a discrete set of experimental points, $M_t = A_0 + A_1 t^{1/2} - A_2 t$, was obtained by means of curve fitting with a polynomial of degree 2. From the polynomial approximation and the experimental formula, the following equations which are capable of calculating the approximate value of M_∞ and D were obtained.

$$(D/r^2)^{1/2} \approx (A_2P_1)/(A_1P_2), \quad M_\infty \approx (A_1^2P_2)/(A_2P_1^2)$$

Then the method for obtaining more probable values of D and M_∞ was described, in this method the approximations to inverse function of Hill's equation and the curve fitting with polynomial of degree 2 were used.

The diffusion coefficient of a dye into a fiber is frequently calculated from the kinetic data of dyeing obtained in an infinite bath using Eq. 1 (Hill's equation)[2)] or its approximations.[3)]

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=1}^{\infty} \frac{4}{q_n^2} \exp\left(-q_n^2 \frac{Dt}{r^2}\right) \tag{1}$$

where M_t and M_∞ are the quantities of dye taken up by a fiber of radius r at time t and equilibrium respectively, D is concentration independent diffusion coefficient and q_n's are positive roots of the Bessel function of the first kind of order zero, $J_0(q_n)=0$.

However, it is often difficult to determine a reasonable value of M_∞ experimentally, since the decomposition of dye and the degradation of polymer substrate are apt to occur during a long period of the dyeing. Therefore, several studies have been made regarding the method of estimating D without using M_∞.[4-7)]

In this paper, we propose a polynomial least-squares method which is capable of estimating the probable value of D and M_∞ from several values of M_t determined at the early stage of dyeing.

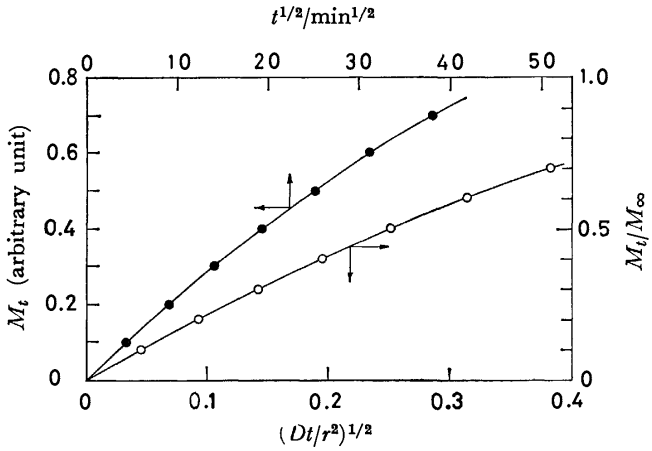

Fig. 1. Curve fitting by least squares with a polynomial of degree 2.
—●—: $M_t = A_0 + A_1 t^{1/2} - A_2 t$, —○—: $M_t/M_\infty = Q_0 + Q_1(Dt/r^2)^{1/2} - Q_2(Dt/r^2)$.

Theoretical

For the small and medium values of Dt/r^2, Eq. 1 can be approximated by simple polynomials in the form of Eq. 2.

$$\frac{M_t}{M_\infty} \approx P_1\left(\frac{Dt}{r^2}\right)^{1/2} - P_2\left(\frac{Dt}{r^2}\right) \tag{2}$$

P_1 and P_2, the coefficients of the polynomial, depend on the interval in which Eq. 2 is used as an approximation to Eq. 1. The values of the coefficients were determined by the minimum maximum error techniques as follows:

Interval	P_1	P_2	$\Delta\left(\frac{M_t}{M_\infty}\right)$
$0 < \frac{M_t}{M_\infty} < 0.6$	2.271	1.122	±0.0005
$0 < \frac{M_t}{M_\infty} < 0.7$	2.277	1.150	±0.001
$0 < \frac{M_t}{M_\infty} < 0.8$	2.297	1.222	±0.002
$0 < \frac{M_t}{M_\infty} < 0.9$	2.331	1.352	±0.005

where $\Delta(M_t/M_\infty)$ is the maximum deviation of Eq. 2 from Eq. 1 in M_t/M_∞ in the interval.

On the other hand, if the plot of the experimental M_t value *vs.* $t^{1/2}$ is made as is shown by the solid circles in Fig. 1, we can obtain Eq. 3 as an experimental formula expressing the rate of diffusion by the curve-fitting technique:

$$M_t \approx A_0 + A_1 t^{1/2} - A_2 t \tag{3}$$

empirical constants, A_0, A_1, and A_2, are determined in order to minimize S:

$$S = \sum_{i=0}^{n} \{M_{ti} - (A_0 + A_1 t_i^{1/2} - A_2 t_i)\}^2 \tag{4}$$

where, the data at origin ($t=0$, $M_t/M_\infty=0$) are weighted by a factor of ten. This weighting makes A_0 negligible and reduces the effect of the experimental error in the M_t determined at the early stage of dyeing

a) Calculated by Eq. 1 using $M_\infty=1.0000$ and $(D/r^2)^{1/2}=0.01\ \text{min}^{-1/2}$. b) Calculated by using $M_\infty=0.9975_4$. c) Calculated using the M_t/M_∞ given in the fourth column by Eq. 7. d) Calculated by Eq. 6 using $P_1=2.277$ and $P_2=1.150$.

on the value of D estimated by this method.

A comparison of Eqs. 2 and 3 gives:

$$\left(\frac{D}{r^2}\right)^{1/2} \approx \frac{A_2P_1}{A_1P_2} \tag{5}$$

$$M_\infty \approx \frac{A_1^2P_2}{A_2P_1^2}. \tag{6}$$

Equation 5 enables us to estimate an approximate value of D without using M_∞. The appropriate P_1 and P_2 values in Eq. 5 are selected as follows. The rate of dyeing data given in the columns from the first to the third of Table 1 were calculated by Eq. 1 using $(D/r^2)^{1/2}=0.01000\ \text{min}^{-1/2}$ and $M_\infty=1.000$ (arbitrary unit) in order to examine the accuracy of D, estimated by this method. From the data given in the second and the third columns of Table 1, $A_0=0.000095$, $A_1=0.022785$, and $A_2=0.00011544$ are obtained as the empirical constants in Eq. 3 by means of curve fitting with a polynomial of degree 2. For this case, if we use $P_1=2.271$ and $P_2=1.122$(suitable for $M_t/M_\infty=0$—0.6), we get $M_\infty=0.9784$ by Eq. 6. By dividing the values of M_t by the M_∞ value obtained above, we can estimate that the M_t's range about $M_t/M_\infty=0$—0.715 and that the appropriate P_1 and P_2 values are that for $M_t/M_\infty=0$—0.7. Similarly, if $P_1=2.297$ and $P_2=1.222$(suitable for $M_t/M_\infty=0$—0.8) are used at first, we get $M_\infty\approx1.0416$ and find that P_1 and P_2 for $M_t/M_\infty=0$—0.7 are suitable for this case. The appropriate P_1 and P_2 values are thus determined. By using $P_1=2.277$ and $P_2=1.150$ which are suitable for $M_t/M_\infty=0$—0.7, approximate values, $(D/r^2)^{1/2}=0.01003\ \text{min}^{-1/2}$ and $M_\infty=0.9975$, are obtained by the use of Eqs. 5 and 6 respectively. This result shows that the use of appropriate P_1 and P_2 values gives an accurate value of D in Eq. 5. However, we can not always use values of P_1 and P_2 as appropriate as in the case of simulation described above, so that, in most cases, further calculations are required to get a more probable value of D, as will be described below.

An accurate value of $(Dt/r^2)^{1/2}$ yielding a given value of M_t/M_∞ in Eq. 1 can be obtained by the use of Eq. 7 or 8, which were derived by means of the method described by Hastings[8] as the approximations to the inverse function of Eq. 1.

For $M_t/M_\infty<0.855$,

$$\left(\frac{Dt}{r^2}\right)^{1/2} \approx \frac{0.44292M-0.480014M^2+0.069127M^3}{1-1.282686M+0.31912M^2}. \tag{7}$$

For $0.855<M_t/M_\infty<0.998$,

$$\left(\frac{Dt}{r^2}\right)^{1/2} \approx \left\{-\frac{0.36839+\ln(1-M)}{5.7836}\right\}^{1/2} \tag{8}$$

where $M\equiv M_t/M_\infty$; the maximum deviation of Eqs. 7 and 8 from the inverse function of Eq. 1 in $(Dt/r^2)^{1/2}$ are within ±0.000015 at the each interval.

By dividing the experimental M_t values by the M_∞ estimated by Eq. 6, we can get the series of M_t/M_∞ values given in the fourth column of Table 1. The value of $(Dt/r^2)^{1/2}$ yielding each M_t/M_∞ in Eq. 1 is obtained by the use of Eq. 7 or 8 as is shown in the fifth column of Table 1. The set of data: $\{(Dt_i/r^2),\ M_{t_i}/M_\infty,\ i=0,1,2,\cdots n\}$ is thus obtained. If the data are plotted as is shown by the empty circles in Fig. 1, we can get Eq. 9 as a regression equation passing through these points by means of the curve-fitting with polynomial of degree 2, where the data at origin, $\{(Dt/r^2)^{1/2}=0,\ M_t/M_\infty=0\}$, are also weighted by a factor of ten.

$$\frac{M_t}{M_\infty} = Q_0 + Q_1\left(\frac{Dt}{r^2}\right)^{1/2} - Q_2\left(\frac{Dt}{r^2}\right) \tag{9}$$

Q_1, Q_2, and Q_0 are the regression coefficients and constant respectively.

A comparison of Eqs. 3 and 9 gives:

$$\left(\frac{D}{r^2}\right)^{1/2} \approx \frac{A_2Q_1}{A_1Q_2} \tag{10}$$

and:

$$M_\infty \approx \frac{A_1^2Q_2}{A_2Q_1^2}. \tag{11}$$

More probable values of D and M_∞ are obtained by the use of Eqs. 10 and 11 respectively. For example, from the data given in the fourth and fifth columns of Table 1, the regression coefficients, $Q_1=2.2786$ and $Q_2=1.1549$, are obtained by means of the curve-fitting with polynomial of degree 2. By inserting this values into Eqs. 10 and 11, we get $(D/r^2)^{1/2}=0.009996\ \text{min}^{-1/2}$ and $M_\infty=1.0003$ respectively.

If we repeat the calculations described above using the M_∞ value obtained by means of Eq. 11 and the experimental M_t's, we can get a far more probable value of D, *e.g.*, in the case of the M_t's given the third column of Table 1, $Q_1=2.2784$, $Q_2=1.1540$ and $(D/r^2)^{1/2}=0.010003$ and $M_\infty=0.99979$. However, taking into account the precision with which the experimental M_t's can be obtained, repeated calculations are not required in most cases if the appropriate P_1 and P_2

values are used in Eq. 6.

The results of simulations using M_t's including experimental error show that the value of D estimated by this method is insensitive to the error in M_t at the early stage of diffusion, but relatively sensitive to that at the later stage. Therefore, by increasing the accuracy of the M_t determined at the last two or three points of measurement, we can get an accurate value of D without using M_∞.

Experimental

Materials. The dye used was purified C.I. Disperse Violet 1 (1,4-diaminoanthraquinone, mp: 271—272 °C, Found: N, 11.9%, Calcd for: N, 11.8%). The crystal of the dye was grounded in a ball mill with a dispersing agent for 48 h and then dispersed in water. The dispersing agent was thus removed from the dispersion by the use of a membrane filter (average pore size: 0.65 μm). The dispersion containing 0.5 g/l pure dye was used for dyeing.

The fiber used poly(ethylene terephthalate) spun yarn (40 s, pretreated in boiling water for 2 h, $r = 6.79 \times 10^{-4}$ cm).

Determination of Rate of Dyeing. About 10 mg of the fiber was dyed in the dye dispersion of one liter for a certain period at 95 °C using an apparatus similar to that used by Peters *et al.*[9] The dyed fiber was rinsed with cold acetone to remove the surface dye. Then the dye on the fiber was extracted with hot chlorobenzene, and the amount of dye in the fiber was determined colorimetrically using a Hitachi 101 spectrophotometer.

All the calculations were made using a Canon SX 110 programmable calculator.

Results and Discussion

The kinetic data of the dyeing were determined to be as given in the first three columns of Table 2. From the set of data given in the second and third columns of the table, the values of the empirical constants in Eq. 3 were calculated to be $A_1 = 0.050109$ and $A_2 = 0.0001234$ respectively by means of the polynomial least-squares method. Consequently, approximate values of $(D/r^2)^{1/2} \approx 0.00498_4$ $min^{-1/2}$, and $M_\infty \approx 4.42_7 \times 10^{-2}$ mol/kg were obtained by the use of Eqs. 5 and 6, where $P_1 = 2.271$ and $P_2 = 1.122$ were used. If we use $P_1 = 2.297$ and $P_2 = 1.222$, which are suitable for $M_t/M_\infty = 0$—0.8, we get $M_\infty \approx 4.71_3 \times 10^{-2}$ mol/kg from Eq. 6. However, by dividing the experimental M_t's by the M_∞ obtained above, we find that the values of M_t/M_∞ range about 0—0.58 and that the appropriate P_1 and P_2 values for this case are 2.271 and 1.122 respectively.

Therefore, the values of M_t/M_∞ were calculated using $M_\infty = 4.42_7 \times 10^{-2}$ mol/kg and the experimental M_t values given in the fourth column of Table 2. The values of $(Dt/r^2)^{1/2}$ yielding these M_t/M_∞ in Eq. 1 were calculated by the use of Eqs. 7 or 8, as listed in the fifth column. The application of the polynomial least-squares method to the set of data listed in the fourth and fifth columns of Table 2 gave these regression coefficients: $Q_1 = 2.2697$ and $Q_2 = 1.116_4$. The substitution of these values into Eqs. 10 and 11 gave $(D/r^2)^{1/2} \approx 0.00500_7$ $min^{-1/2}$, $D = 1.15_4 \times 10^{-11}$ $cm^2 \cdot min^{-1}$ and $M_\infty \approx 4.41_0 \times 10^{-2}$ mol/kg respectively.

If we use the M_t obtained at $t = 409$ h as M_∞, we get the values of D given in the last column of Table 2 by means of the standard method, which gives an average value of $D = 1.18 \times 10^{-11}$ $cm^2 \cdot min^{-1}$. This value agrees well with the value of D estimated by the polynomial least-squares method proposed in this paper.

Conclusions

Since the numerical calculations of Eqs. 7 and 8 and the curve-fitting with a polynomial of degree 2 can easily be carried out using one of the programmable pocket calculator commercially available today, the method of estimating D and M_∞ from the initial sorption data by the polynomial least squares-method is relatively simple. The values of D and M_∞ estimated by this method are accurate enough when the several experimental M_t's fall in the range wider

than $M_t/M_\infty=0$—0.6 and each M_t's are equally spaced within the range.

(Received July 2, 1980)

Synopsis. The X-ray photoelectron spectrum of the powder of Cr_2O_5 was measured and compared with those of the related chromium compounds. It is concluded that Cr_2O_5 is a mixed-valence compound having Cr^{3+} and Cr^{6+} ions, possibly with the ratio of 1:2.

We have previously studied the X-ray photoelectron spectra of CrO_2, and related Cr compounds which contain Cr^{3+}, Cr^{4+} and Cr^{6+}.[1] One of the present authors (T. N.)[2] found that the powder of Cr_2O_5 can be obtained as an intermediate product in the process of preparing the ferromagnetic fine powder of CrO_2 by the hydrothermal decomposition of CrO_3 under a high oxygen pressure. The chemical composition of this oxide suggests the possibility that Cr ions in this oxide are in the valency state of Cr^{5+}. Thus it seemed of great interest to see if Cr ions are actually in the state of Cr^{5+} or in a mixed-valence state. We examined the X-ray photoelectron spectrum of the powder of Cr_2O_5 and found that this oxide is a mixed-valence compound having Cr^{6+} and Cr^{3+} ions with a ratio of 2:1.

Experimental

The powder of Cr_2O_5 was prepared by the following method. The powder of CrO_3 was heated at 350 °C for 2 h in the ordinary atmosphere, and, after cooled, the product was suspended in water to remove water-soluble components and ferromagnetic component, the latter being removed by applying a magnetic field to the suspension. The resultant product Cr_2O_5 was filtered off from the suspension and dried. The powder thus obtained was confirmed to be Cr_2O_5 by means of X-ray diffraction.

In the present study, we also measured the X-ray photoelectron spectra of Cr_2O_3, $K_2Cr_2O_7$, and KCr_3O_8. The first two compounds were commercially obtained and the last one was synthesized according to the literature.[3]

X-Ray photoelectron spectra were measured with a McPherson ESCA 36 photoelectron spectrometer using Mg $K\alpha$ (1253.6 eV) as the stimulating radiation. All measurements were done on the powder samples pressed onto aluminium plates. Binding energies of photoelectron peaks were calibrated by using Au $4f_{7/2}$ peak (84.0 eV) of gold deposited on the sample.

In the case of Cr_2O_5, the X-ray photoelectron spectrum was found to change gradually with X-ray irradiation. Thus, we collected the photoelectron data only within a short measuring time on each fresh sample, and, repeating such measurements on many fresh samples, we summed up the data to obtain the spectrum which can be regarded as the one having been little affected by X-ray irradiation.

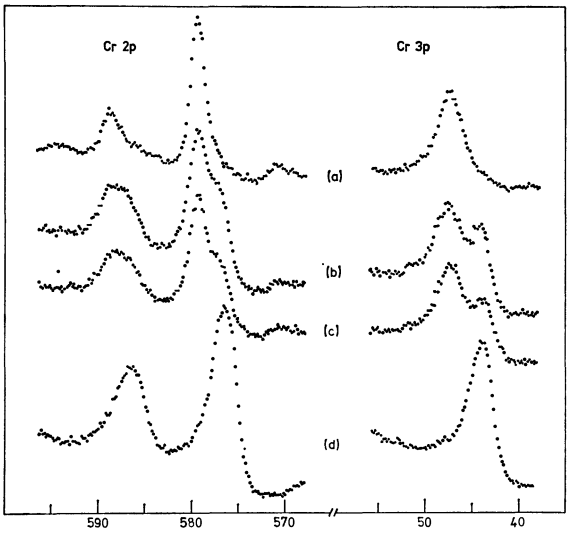

Fig. 1. The X-ray photoelectron spectra of Cr 2p and 3p peaks of (a) $K_2Cr_2O_7$, (b) Cr_2O_5, (c) KCr_3O_8, and (d) Cr_2O_3.

Results and Discussion

The Cr 2p and Cr 3p regions of the XPS spectrum of Cr_2O_5 are shown in Fig. 1 together with those of KCr_3O_8, $K_2Cr_2O_7$, and Cr_2O_3. The observed spectra are very much similar between Cr_2O_5 and KCr_3O_8. In these two cases, the Cr 3p peak exhibits a shape composed of two component peaks, the Cr $2p_{3/2}$ peak exhibits a shoulder at the low binding energy side of the main peak, again suggesting that two peaks are superimposed on each other, and the Cr $2p_{1/2}$ peak is very broad. All these facts indicate that Cr ions of two different valency states are contained in Cr_2O_5 as well as in KCr_3O_8, in other words, these materials are mixed-valence compounds. In effect, it is known from the X-ray crystal structure analysis that there are Cr^{6+} and Cr^{3+} sites with the ratio of 2:1 in the crystal lattice of KCr_3O_8.[4] Thus one can regard that, in the XPS spectrum of KCr_3O_8, each core electron peak associated with Cr ions, is a superposition of the peaks due to Cr^{6+} and Cr^{3+}, respectively. This can be seen in Fig. 1 by comparing the spectrum of KCr_3O_8 with those of Cr_2O_3 and $K_2Cr_2O_7$: Cr_2O_3 contains only Cr^{3+} and $K_2Cr_2O_7$ contains only Cr^{6+}. The fact that the profiles of the Cr 2p and Cr 3p peaks of Cr_2O_5 are very much similar to those of the corresponding peaks of KCr_3O_8, suggests that Cr_2O_5 is also a mixed-valence compound having Cr^{6+} and Cr^{3+} sites with a ratio roughly the same as that

Table 1. XPS Core-level binding energies of chromium compounds

	Binding energy/eV			
	$K_2Cr_2O_7$	Cr_2O_5	KCr_3O_8	Cr_2O_3
Cr $2p_{1/2}$	588.9	588.6	588.3	
		587.1	586.7	586.5
Cr $2p_{3/2}$	579.6	579.3	579.4	
		577.0	577.2	576.6
Cr 3p	47.4	47.7	47.3	
		44.1	43.5	43.8
O 1s	530.3	529.8	530.2	530.6

in KCr_3O_8.

Using the profiles of the Cr 2p and Cr 3p peaks of Cr_2O_3 as those characteristic of Cr^{3+} ion, and the profiles of the corresponding peaks of $K_2Cr_2O_7$ as those characteristic of Cr^{6+} ion, we tried to decompose the observed Cr 2p and Cr 3p peaks of KCr_3O_8 and Cr_2O_5 into the component peaks due to Cr^{6+} and Cr^{3+} ions, respectively. The procedure used here is the same as the one which we have adopted in the XPS study of organic mixed-valence compounds.[5]

The binding energies of the decomposed peaks are listed in Table 1 together with those of the corresponding peaks of Cr_2O_3 and $K_2Cr_2O_7$. In principle, one could determine the Cr^{6+}/Cr^{3+} ratio from this peak profile analysis. The analysis of the Cr 3p peak profile of KCr_3O_8 gave the Cr^{6+}/Cr^{3+} ratio as 2:1 in agreement with the ratio known from the crystal structure. In comparison with this, the Cr^{6+}/Cr^{3+} ratio obtained from the analysis of the Cr $2p_{3/2}$ peak of KCr_3O_8 was found to be rather anomalous, it being 1:1 in significant disagreement with the expected ratio. It should be noted that, in the obtained Cr $2p_{3/2}$ peak, the main peak corresponds to Cr^{6+} and its low-binding-energy shoulder correspond to Cr^{3+}, and the intensity ratio of the Cr^{6+} component to the Cr^{3+} component will be estimated to be 2—2.5 if we decompose the observed peak into the two components naively assuming the same peak width for the two components. On the other hand, it becomes 1:1 as we have mentioned when we use the Cr $2p_{3/2}$ peak profile of $K_2Cr_2O_7$ for the Cr^{6+} component and that of Cr_2O_3 for the Cr^{3+} component, the peak width of the former being significantly smaller than the latter. Seemingly it is inadequate to use the peak shapes of $K_2Cr_2O_7$ and Cr_2O_3 for decomposing the observed peak profile of a mixed valence compound. Probably we should better assume that the peaks of the Cr^{6+} and Cr^{3+} components are of nearly the same width. The situation will be the same in the case of Cr_2O_5. Since the observed profile of the Cr $2p_{3/2}$ peak of Cr_2O_5 is almost exactly the same as that of KCr_3O_8, one may conclude that the Cr^{6+}/Cr^{3+} ratio in Cr_2O_5 is also 2:1 as in KCr_3O_8. The observed profile of the Cr 3p peak of Cr_2O_5 is slightly different from that of KCr_3O_8 although they should be the same if the Cr^{6+}/Cr^{3+} ratio is identical between the two compounds as we have concluded from the Cr $2p_{3/2}$ peak shape. This may be due to the situation that, in the case of Cr_2O_5, it is rather hard to obtain the true Cr 3p peak profile without having been affected by X-ray irradiation since a considerably long measuring time is necessary to record Cr 3p peak while Cr_2O_5 is damaged with X-ray irradiation. Since Cr $2p_{3/2}$ peak is much stronger than Cr 3p peak, the observed 2p peak of Cr_2O_5 is likely to be more free from the radiation damage as compared with the Cr 3p peak.

In conclusion, the XPS data of Cr_2O_5 indicate that the chromium ions in Cr_2O_5 is not in the state of Cr^{5+} but in a mixed-valence state consisting of Cr^{6+} and Cr^{3+}, presumably with the ratio of 2:1.

On the NMR Spectra of Some Substituted Pyridinium 2-Pyridylcarbonylmethylides

Gen-etsu MATSUBAYASHI

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received June 7, 1980)

Synopsis. The partial double-bond character of the ylide carbon–pyridinium nitrogen bond is discussed on the basis of the ^1H and ^{13}C NMR spectra of 4-cyano- (Y_{CN}), 4-methyl- (Y_{pic}), and 3,5-dimethylpyridinium 2-pyridylcarbonylmethylide (Y_{lut}). The α-proton signals of the 4-cyanopyridinium ring of Y_{CN} have been separately observed at low temperatures, indicating a hindered rotation around the ylide carbon-pyridinium nitrogen bond.

Sulfur and phosphorus ylides can be stabilized by the carbanion delocalization to d-orbitals of the sulfur and phosphorus atoms.[1,2] On the other hand, the same effect is usually unexpected in nitrogen ylides, because nitrogen has no d-orbitals available for bond formation. Pyridinium ylides, however, are unique in being stabilized by the carbanion participation in the resonance of the pyridinium ring.[3] In the course of an investigation of the nucleophilic reactivity of several 2-pyridylcarbonylmethylides, $C_5H_4NC(O)\bar{C}H\overset{+}{Z}$ ($\overset{+}{Z}=\overset{+}{S}Me_2$, $\overset{+}{P}Ph_3$, and $\overset{+}{N}C_5H_4CH_3$-4), toward metal ions,[4–7] we have recently found some unique NMR spectral behavior of the substituted pyridinium 2-pyridylcarbonylmethylides. This paper will discuss the configurations of 4-cyano-(Y_{CN}), 4-methyl-(Y_{pic}), and 3,5-dimethylpyridinium 2-pyridylcarbonylmethylide (Y_{lut}) and the carbanion delocalization on the basis of the IR frequencies and the ^1H and ^{13}C NMR parameters.

The IR spectra of the 2-pyridylcarbonylmethylides gave ν(C=O) bands at fairly low frequencies compared with those of common organic carbonyl compounds: 1529, 1530, and 1530 cm^{-1} for Y_{pic}, Y_{lut}, and Y_{CN} respectively, indicating a considerable contribution of the canonical structure, **B**, besides **A**. Furthermore,

A **B**

X=4-CH_3, 3,5-$(CH_3)_2$, and 4-CN

assuming that the 2-pyridylcarbonyl group is almost planar, the ylides are likely to adopt a configuration avoiding some electronic repulsion between the negatively polarized pyridine–nitrogen and carbonyl–oxygen atoms.

The ^1H and ^{13}C NMR spectra of Y_{pic} in chloroform-*d* are depicted in Fig. 1. The proton signals have easily been assigned by comparison with the spectra of *N*-substituted 2-pyridylmethanimines[8] and 2,2′-bipyridine.[9] The ^{13}C-signal assignment has been performed by comparing the chemical shifts with those of 2-substituted pyridines[10] and the coupling constants between ^{13}C and directly bonded hydrogen atoms ($^1J(^{13}C–H)$).

The ylide-carbon signal is observed at an extremely low field (99.1 δ) compared with those of other

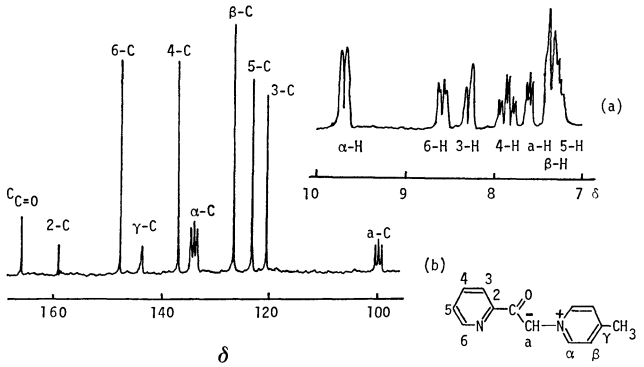

Fig. 1. The ^1H (a) and ^{13}C NMR (b) spectra of Y_{pic} in chloroform-*d*.

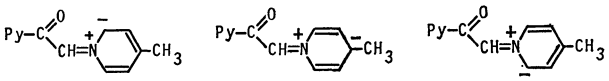
related phenacylides and 2-pyridylcarbonylmethylides: $PhC(O)\bar{C}H\overset{+}{P}Ph_3$ (50.4 δ),[11] $PhC(O)\bar{C}H\overset{+}{A}sPh_3$ (53.13 δ),[12] and $PyC(O)\bar{C}H\overset{+}{S}Me_2$ (53.8 δ).[13] This may be due to the strongly electron-withdrawing property of the 4-methylpyridinium group, as is shown in the resonance contributions, **C**—**E**.



C **D** **E**

The ylide-proton signal of Y_{pic} appears at a fairly low field compared with that of 4-methylpyridinium phenacylide (6.64 δ);[14] this is because of the paramagnetic anisotropy effect of the lone-pair electrons of the pyridine nitrogen in the configurations, **A** and **B**, with the almost planar 2-pyridylcarbonyl group. Essentially the same situation was noticed in Y_{lut} (7.46 δ) and 3,5-dimethylpyridinium phenacylide (6.56 δ).

A characteristic feature is the clear appearance of a triplet signal of the ylide proton resulting from spin-spin coupling with the ^{14}N nucleus ($^2J(^{14}N–H_{ylide})$= 2.5 Hz). Furthermore, it is notable that the α-carbon signal, as well as the ylide-carbon signal, appears as a well-resolved triplet because of the ^{14}N coupling. In Y_{lut} and 3,5-dimethylpyridinium phenacylide, these carbon signals have also been observed as triplets ($^1J(^{14}N–^{13}C)$=8.8 and 8.3 Hz respectively). The relevant ^1H and ^{13}C NMR parameters of the ylides are summarized in Table 1.

Previously Phillips and Ratts[15] showed that the signals of the α-protons of the pyridinium ring of 4-substituted pyridinium phenacylides are shifted fairly downfield compared to those of the α-protons of the HBr salts of the phenacylides. These downfield shifts were attributed to the deshielding of α-H by the carbonyl function, as is depicted in **F**. This explanation may be based on the planarity of both the pyridinium ring and the phenacyl group. However, no separated

Table 1. Relevant NMR chemical shifts (δ) of the ylides[a)]

	6-H	a-H	α-H	6-C	a-C	α-C
Y_{pic}	8.52	7.50[b)]	9.61	147.2[c)] (178)	99.1[c)] (183)	133.4 (189)

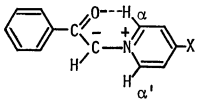
a) Measured in chloroform-d at 24 °C (^{1}H NMR) and at 34 °C (^{13}C NMR). The spin-spin couplings ($^1J(^{13}C-^1H)$, Hz) are shown in parentheses. b) $^2J(^{14}N-^1H) = 2.5$ Hz. c) $^1J(^{14}N-^{13}C) = 8.8$ Hz. d) Not measured because of its poor solubility.



F

signals due to α-H and α′-H were observed, and only one signal occurred at an averaged field, because of the fast rotation around the ylide carbon-pyridinium nitrogen bond. This is the same as with the α-H signals of the pyridinium rings of both Y_{pic} and Y_{lut}, which exhibited the averaged chemical shifts of the α-H and α′-H signals at approximately 9.5 δ even at −70 °C in dichloromethane.

In Y_{CN} broad α-H signals are observed at 9.39 δ in chloroform-*d* at room temperature. At −50 °C, two widely separated α-H signals are noticed, as is illustrated in Fig. 2. This indicates the magnetic non-equivalence of the two α-protons, which seems to be attributable to the slow hindered rotation around the ylide carbon-pyridinium nitrogen bond on the NMR time scale. The Gibbs energy of activation (ΔG_{Tc}^{*}) for the rotation at the coalescence temperature (−20±5 °C) has been estimated to be 11.4(±0.3) kcal/mol using the approximate equation.[16)] The hindered rotation may be caused by the partial double-bond character of the ylide carbon-pyridinium nitrogen bond, which is ascribed to the contribution of the canonical structures, **C**—**E**.

Experimental

Preparation of 4-Cyanopyridinium 2-Pyridylcarbonylmethylide (Y_{CN}). 4-Cyanopyridine (1.25 g, 12 mmol) was added to a benzene (50 ml) solution of 2-(bromoacetyl)pyridine[17)] (2.0 g, 10 mmol), and the mixture was refluxed for 10 h to give white precipitates of Y_{CN}·HBr, which were subsequently collected by filtration (1.98 g, 66% yield). To an aqueous solution (10 ml) of the product was added a 30% K_2CO_3 aqueous solution (50 ml) to separate out red solids immediately. They were collected and recrystallized from a mixture of dichloromethane/diethyl ether (1/1 vol. ratio) to afford red crystals of Y_{CN} (0.59 g, 26% yield); mp 168 °C (dec). Found: C, 69.95; H, 4.06; N, 18.82%. Calcd for $C_{13}H_9N_3O$: C, 70.28; H, 3.77; N, 18.65%.

The preparation of Y_{pic} and Y_{lut} is described elsewhere.[5)]

Spectral Measurements. The IR and ^{1}H NMR spectra were measured as has been described previously.[14)] The ^{13}C NMR spectra were recorded in chloroform-*d* at 15.03 MHz, using the pulse Fourier transform technique on a JEOL FX 60 spectrometer at 34 °C. The chemical shifts were measured relative to TMS as the internal standard.

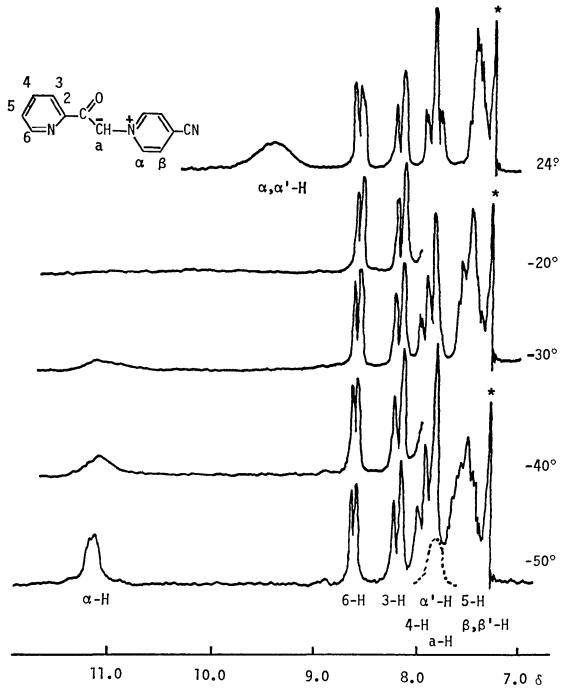


Fig. 2. Temperature-dependent ^{1}H NMR spectra of Y_{CN} in chloroform-*d* (*; $CHCl_3$).

The author wishes to express his hearty thanks to Professor Toshio Tanaka for his continuous encouragement throughout this study.

A Molecular Orbital Study of the Conformation and *g*-Factors of the $H_2SSH_2^+$ and H_2SSH Radicals

Osamu KIKUCHI

Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305

(Received June 16, 1980)

Synopsis. The conformation and *g*-factors of the $H_2SSH_2^+$ and H_2SSH radicals were analyzed by means of a restricted open-shell SCF MO method with the semi-empirical MINDO/3 and INDO approximations, and the observed *g*-factors of the family of radicals consisting of $R_2SSR_2^+$, R_2SSR, and $RSSR^-$ were compared on the basis of their molecular and electronic structures.

Since the principal values of *g*-factors correlate strongly with the molecular structure of a radical, the theoretical analysis of the *g*-factors can clarify the molecular and electronic structure of the radical. We have elucidated the observed *g*-factors of the $HSSH^-$ radical anion in a previous paper.[1] Recently, much attention has been paid to the structure and stability of the S–S cation radicals.[2-4] In the present study, the *g*-factors of the $H_2SSH_2^+$ and H_2SSH radicals were examined, and the $H_2SSH_2^+$, H_2SSH, and $HSSH^-$ radicals are compared in terms of their molecular and electronic structures.

The MO's of the restricted doublet state were obtained by the use of the approximate SCF version proposed by Longuet-Higgins and Pople.[5] In the previous study of the $HSSH^-$ anion,[1] the MINDO/3 approximation was used. It is, however, uncertain whether MINDO/3 correctly predicts the *g*-factors of all of the neutral, anion, and cation radicals. Both the MINDO/3[6] and INDO[7] approximations were, thus, employed independently for the present calculation of $H_2SSH_2^+$ and H_2SSH. A more detailed description of the calculation of the *g*-factors has been reported elsewhere.[8-9]

$H_2SSH_2^+$ Radical. The observed $g_{av}(=(g_1+g_2+g_3)/3)$ values for the $R_2SSR_2^+$ radicals are $\simeq 2.01$;[2-3,10-11] no principal value has been reported. Since the 12 protons in $Me_2SSMe_2^+$ have equivalent hyperfine coupling constants,[10] the symmetric structures are examined. The MINDO/3 optimized $H_2SSH_2^+$ structures are I—IV. In all of the I—IV structures, the singly-occupied MO (SOMO) is the S–S antibonding σ^* orbital. The large g_y value of the planar structure, I, comes from the contribution of the π(S–S) bonding orbital; the highest occupied π^*(S–S) orbital makes no contribution because of its symmetry property. The other two principal values of I, g_x and g_z, are close to the free-spin value, g_f. The skewed structure, II, has two lone-pair orbitals at the sulfur atoms; these 3p lone-pair orbitals contribute to the large g_y and g_z values of II. These electronic structure and *g*-factors of II are very similar to those of the $HSSH^-$ anion radical.[1] In the bent structures, III and IV, mixing occurs among the σ^* SOMO and the π orbitals. This mixing reduces the g_y value and gives smaller g_{av} values for III and IV.

The INDO optimized structures are shown in Fig. 2, while their *g*-factors are listed in Table 2. The trend observed in the INDO *g*-factors of I'—IV' is similar to that in the MINDO/3 *g*-factors.

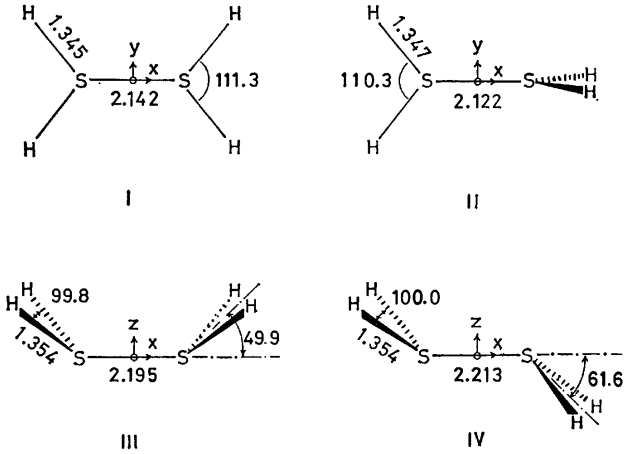

Fig. 1. The MINDO/3 optimized structures of the $H_2SSH_2^+$ radical. Bond lengths are in Å, and angles are in degrees.

TABLE 1. THE MINDO/3 *g*-FACTORS FOR FOUR OPTIMIZED STRUCTURES OF THE $H_2SSH_2^+$ RADICAL[a]

	I	II	III	IV
E_{total}/eV	−515.377	−515.483	−515.907	−515.903
g_x	2.0023	2.0023	2.0022	2.0023
g_y	2.0156	2.0125	2.0067	2.0071
g_z	2.0031	2.0125	2.0018	2.0017
g_{av}	2.0070	2.0091	2.0036	2.0037

a) The coordinate axes are shown in the optimized structures in Fig. 1.

The electronic structure of the $H_2SSH_2^+$ radical described above indicates that the g_y and g_{av} values depend largely on the S–S distance. The calculation showed that the increase in the g_{av} values of the planar and skewed structures, I and II, with an increase in the S–S distance was larger than that of the bent structures. The bent structure III with $R_{S-S}=2.542$ has $g_{av}=2.0118$. Since the principal values have not been reported for the $R_2SSR_2^+$ radical, it is difficult to derive any ultimate conclusion for the structure of the $H_2SSH_2^+$ radical from the present *g*-factor calculation. However, the present analysis of the *g*-factors suggests that the planar or skewed structure may correspond to the observed $R_2SSR_2^+$ structures. The present calculation shows a large difference in the principal values of the planar and skewed structures; the conformation of the $R_2SSR_2^+$ radicals may be determined if three principal values are determined experimentally.

H_2SSH Radical. The MINDO/3 optimized structure of H_2SSH is V. The calculated principal values of this structure are 2.036, 2.002, and 2.002.

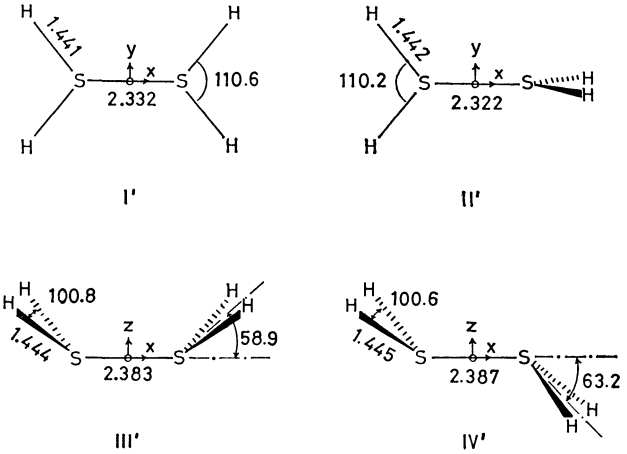

Fig. 2. The INDO optimized structures of the $H_2SSH_2^+$ radical.
Bond lengths are in Å, and angles are in degrees.

Table 2. The INDO g-factors for four optimized structures of the $H_2SSH_2^+$ radical[a)]

	I'	II'	III'	IV'
E_{total}/eV	−609.657	−609.713	−610.136	−610.153
g_x	2.0023	2.0023	2.0023	2.0023
g_y	2.0119	2.0080	2.0068	2.0074
g_z	2.0022	2.0080	2.0010	2.0010
g_{av}	2.0055	2.0061	2.0034	2.0036

a) The coordinate axes are shown in the optimized structures in Fig. 2.

Similar results were obtained by the INDO calculation; the optimized structure is V', and its g-factors are 2.053, 2.002, and 2.002. The radicals attributed to R_2SSR are H_2SSH (g_1=2.066, g_2=2.025, g_3=2.003),[12] EtHSSEt (g_1=2.063, g_2=2.027, g_3=1.999),[13] and RCH_2SSHCH_2R (g_1=2.063, g_2=2.010, g_3=2.000).[12,14] The two principal values are very large, while only one principal value is close to g_f. Since the two principal values of V and V' are very close to g_f, the V and V' structures can not explain the observed g-factors of the R_2SSR radicals. In the solid state, the environment effect may cause a deformation of the molecular structure of the radical. Thus, the dependence of the g-factors upon the conformation of H_2SSH was examined by means of MINDO/3. The g-factors were calculated by changing the S–S distance from 2.05 Å to 2.25 Å, the rotation angle about the S–S bond from −90° to +90°, the S–S–H angle from 100° to 140°, or the bending angle of the H_2S group from 0° to 60°. In all the conformations considered, the second largest principal values was less than 2.007. The results of this examination suggest that the observed principal values are possibly reproduced by the conformation with a very large SSH angle. The structures in Fig. 4 are the conformations for which the best agreement between the calculated and observed values was obtained. The g-factors of VI are 2.066, 2.023, and 2.000. The g-factors of VI' are 2.067, 2.021, and 2.002. Although the VI and VI' structures are more unstable than the optimized structures by 80 and 130 kJ mol^{-1} respectively, the present analysis of the g-factors suggests that the SSR* angle of the R_2SSR^* radical would be much larger than those to be expected for the $R_2SSR_2^+$ and $RSSR^-$ radicals.

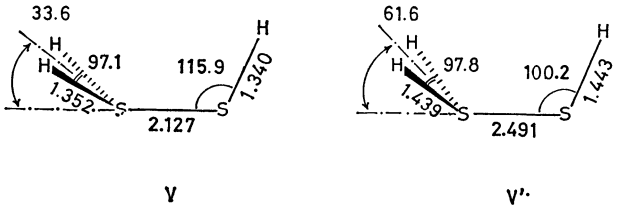

Fig. 3. The MINDO/3(V) and INDO(V') optimized structures of the H_2SSH radical.

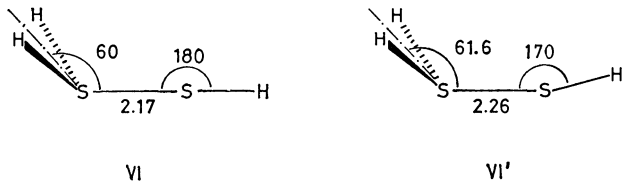

Fig. 4. The MINDO/3(VI) and INDO(VI') structures of the H_2SSH radical which give the best agreement between the calculated and observed g-factors.

Near-infrared Magnetic Circular Dichroism Studies on Iron(III) Horse Heart Cytochrome c

Nagao KOBAYASHI,** Tsunenori NOZAWA, and Masahiro HATANO*
Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980
(Received June 30, 1980)

Synopsis. Magnetic circular dichroism (MCD) spectra in the near-infrared region reported first for oxidized cytochrome c in its neutral (pH 5.58), alkaline (pH 11.62), and acidic (pH 1.88) forms exhibit temperature dependence, indicating that they are composed of Faraday C terms, except for the acidic form. The relation between the near-infrared MCD and the heme vicinity is discussed in terms of the structures for the heme chromophore of cytochrome c.

Near-infrared MCD spectra for heme chromophores are very sensitive to the oxidation, spin and ligand states of hemoproteins.[1,2] This is due to the fact that the bands ascribable to the charge-transfer transitions among iron, porphyrin and axial ligand, and d-d transitions of the iron ion can be easily resolved because of the absence of strong π-π^* transitions.[3,4] However, only a few studies[1,2,5-7] have been reported on the observation of near-infrared MCD, especially its temperature dependence, because of technical difficulties. The difficulties were overcome by use of a near-infrared MCD spectropolarimeter and deuterated solvents. We wish to report the accurate temperature dependence of near-infrared MCD for several forms of iron(III) cytochrome c.

Experimental

Materials. Cytochrome c from horse heart (Sigma type VI) was dissolved in deuterium oxide without further purification. Complete oxidation was attained by adding slight excess of freshly prepared deuterium oxide solution of potassium hexacyanoferrate(III). For the temperature variation experiments, an appropriate solution was diluted with hexadeutrated ethylene glycol at 60 (v/v) percent. The pH was adjusted by adding the least amount of concentrated sodium hydroxide or hydrochloric acid solution with stirring. The concentrations were determined on the basis of the heme molar concentrations from the visible absorption spectra.

Measurements. Absorption spectra were measured with a Hitachi EPS-3T spectrophotometer, MCD being recorded on a JASCO J-200 spectropolarimeter equipped with an electromagnet which affords up to 1.47 T magnetic field. MCD magnitude is expressed by the 10^{-4} molar ellipticity per Tesla ($[\theta]_M/10^{-4}$ °mol^{-1} dm^3 m^{-1} T^{-1} or 10^{-7} °m^2 mol^{-1} T^{-1}). Temperature was controlled by means of a stream of cold nitrogen gas. The path lengths of cells were 10 mm for the measurement at ambient temperature and 3 mm for that at cryogenic temperature.

Results and Discussion

MCD and absorption spectra are shown for iron (III) cytochrome c at neutral and at alkaline pH solutions in Figs. 1 and 2, respectively. The general spectral patterns of MCD are similar to those of absorption spectra, being characteristic for iron(III) low-spin heme complexes such as metmyoglobin cyanide.[1,6] The MCD spectra show the largest absorption peak. The positions of the strongest MCD peaks for neutral cytochrome c and alkaline cytochrome c are at 1720 and 1460 nm, respectively. The cyanide derivatives of metmyoglobin[1] and peroxidase[2] reveal MCD peaks at 1530 and 1680 nm, respectively. Since the iron (III) heme bands in the near-infrared region have been assigned as charge-transfer transitions from porphyrin a_{1u}, $a_{2u}(\pi)$ to $e_g(d\pi)$ orbitals ($E_u \leftarrow A_{1g}$) in D_{4h} symmetry, the energy differences in the peak positions for these low-spin species depend mostly on the energy levels of $e_g(d\pi)$ orbitals which vary more sensitively with the axial ligation mode than those of the porphyrin π orbitals. Theoretical consideration

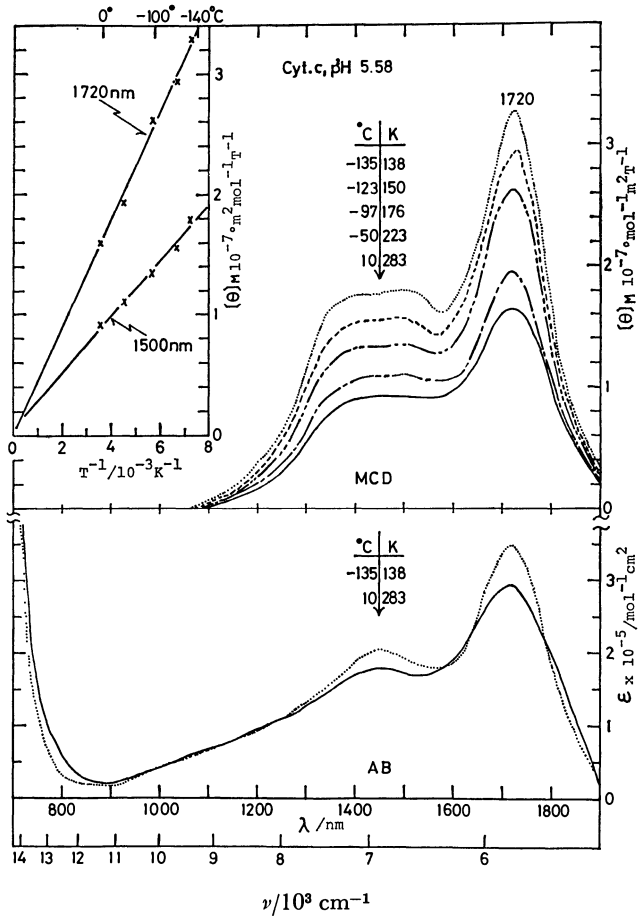

Fig. 1. MCD and absorption spectra of iron(III) cytochrome c at p^{2}H 5.58. Cell length; 0.3 cm, concentration; 4.5×10^{-3} mol dm^{-3}, field; 1.47 T. The inset shows plots of the MCD magnitudes at 1720 and 1500 nm *vs.* the reciprocal of the absolute temperature.

**Present address: Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980.

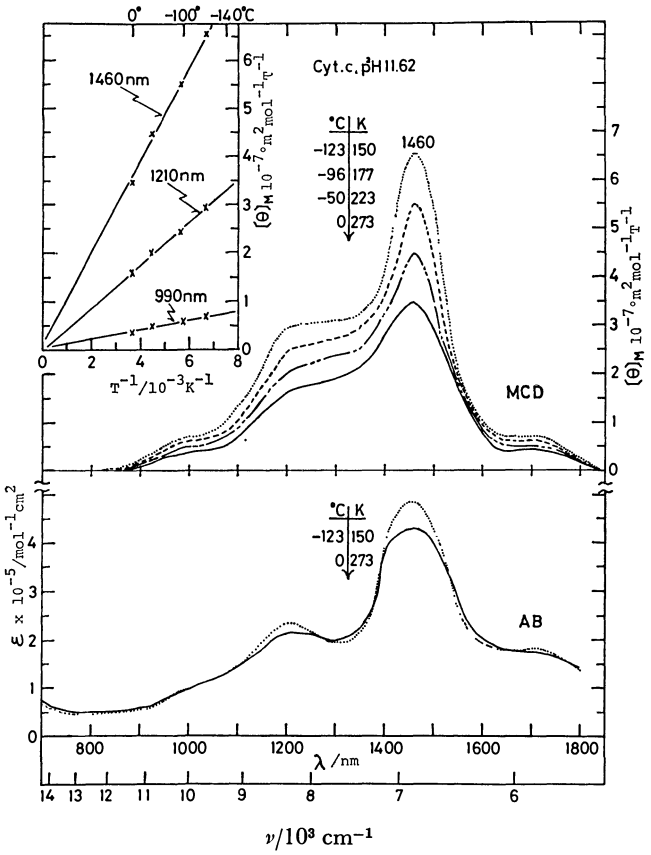

Fig. 2. MCD and absorption spectra of iron(III) cytochrome c at p²H 11.62. Other conditions are the same as for Fig. 1. The inset shows the MCD magnitudes of the peaks at 1460, 1210, and 990 nm *vs.* the reciprocal of the absolute temperature.

on the spectra of iron(III) low-spin heme derivatives[8] indicates that these peaks are composed mainly of the vibrational overtones superposed on the two electronic (charge-transfer) transitions.

The effect of wider temperature range on the near-infrared MCD of iron(III) cytochrome c is shown in Figs. 1 and 2. For metmyoglobin cyanide,[1] the shape of MCD did not change with lowering in temperature as in the Soret bands, while the MCD magnitude increased linearly with the reciprocal of absolute temperature. The extrapolation of temperature dependence at the peaks around 1720, 1500, 1460, 1210, and 990 nm approaches zero at infinite temperature, indicating that these bands are composed of pure Faraday C terms.

Figure 3 shows the MCD and absorption spectra of iron(III) cytochrome c in an acidic solution. A dispersion type MCD, characteristic of iron(III) high-spin heme, was obtained corresponding to the absorption peak at 1000 nm. For native metmyoglobin the

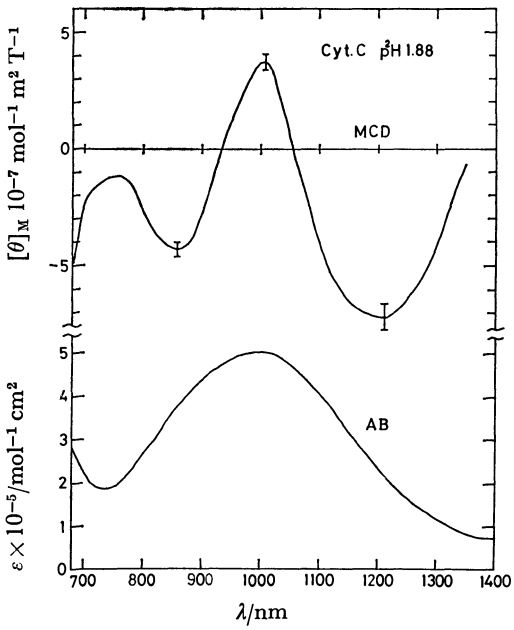

Fig. 3. MCD and absorption spectra of iron(III) cytochrome c at p²H 1.88. Cell length 1.0 cm. Concentration; 0.6×10^{-3} mol dm^{-3}. Temperature; 20 °C.

curve is non-symmetrical with respect to the line of $[\theta]_M=0$, differing from metmyoglobin fluoride which displays a clear S-shaped dispersion.[1] The MCD spectrum showed a slight change in magnitude with lowering in temperature. The band was confirmed to consist predominantly of Faraday A terms plus B terms. A similar spin state is suggested between this species and metmyoglobin from the near coincidence of the crossover points and relative intensities of the MCD peak (1010 nm) and trough (1210 nm).

Charge-transfer Interaction and Ground-state Energy Stabilization in Crystalline Complex Ion Radical Salts

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 2, 1980)

Synopsis. Although predominant cohesive energy is Madelung energy, the ground state of crystalline complex ion radical salt is further stabilized by the charge-transfer interaction between neutral molecule and ion radical, together with that between ion radicals. The magnitude of this stabilization energy was estimated with (Phenothiazine)$_2^{+\cdot}$ Br$^-$.

In crystalline simple ion radical salts, the planar ion radical molecules are known to form, in themselves, a segregated stacking into columns so as to make a large overlap between their half-occupied molecular orbitals.[1] Much attention has been paid to the prominent optical and magnetic properties of such ion radical salts.[1-6] In their optical properties, charge-transfer absorption due to the transition of unpaired electron between ion radical molecules appear in the low-energy region. As for the magnetic properties, antiferromagnetic spin exchange interaction acts between adjacent ion radicals, so that such a salt is considered as one-dimensional Heisenberg antifferomagnet. In previous papers,[2,3] we applied one-dimensional half-occupied Hubbard model to the segregated stack of ion radical molecules. This model is a simplification of the real crystal and is described by two parameters I and T. $T(<0)$ is the transfer matrix element of an unpaired electron which describes hopping between adjacent molecular ion radical sites, while I is the on-site Coulomb repulsion between two electrons with up and down spins on the same molecule. This model could well explain the reason why the charge-transfer absorption is observable in such ion radical salts.[2] The applicability of the Hubbard model is further justified by the fact that the one-dimensional half-occupied Hubbard model with $I \gg |T|$ becomes equivalent to one-dimensional Heisenberg antiferromagnet with exchange interaction $J=2T^2/I$.[7] Then, the ground-state energy of the one-dimensional system of ion radicals can be given by $E=-2NJ\ln 2=-(4NT^2/I)\ln 2$, where $N\to\infty$ is the number of ion radical molecules in the one-dimensional system.[3] This energy stabilization is caused by the charge-transfer interaction between unpaired electrons of adjacent ion radicals through non-zero $|T|$ value in segregated stack of ion radicals.

So far, we have considered simple ion radical salts, where each ion radical carries one unpaired electron. In the case of crystalline complex ion radical salts, the ion-radical and parent neutral molecules are known to stack together to form regular one-dimensional column, where each molecular site is occupied by less-than-one electron.[4-6] Then, we can apply regular one-dimensional less-than-half occupied Hubbard model to the segregated stack composed of ion-radical and neutral molecules in crystalline complex ion radical salts. Shiba and Klein-Seitz have shown that the magnetic susceptibility of a uniform stack of less-than-half occupied molecules (average number of unpaired electrons per site is $\rho<1$) is related to the magnetic susceptibility of a uniform stack of half-occupied molecules ($\rho=1$) in simple ion radical salt.[8,9] If the value of I is much larger than that of $|T|$, the less-than-half occupied one-dimensional Hubbard model becomes equivalent to an antiferromagnetic Heisenberg chain with exchange interaction,[10]

$$J=\frac{2T^2\rho}{I}\left(1-\frac{\sin 2\pi\rho}{2\pi\rho}\right). \tag{1}$$

Under the same condition, the lowest energy was also given by Shiba.[8] If we denote total number of molecular sites as N, the number of unpaired electrons is given by $N\rho$, and the lowest energy of the system, E, is expressed by

$$E/N|T| = -\left\{\frac{2}{\pi}\sin\pi\rho+\frac{4|T|\rho^2\ln 2}{I}\left(1-\frac{\sin 2\pi\rho}{2\pi\rho}\right)\right\}. \tag{2}$$

In the case of $\rho<1$, the E value of Eq. 2 is composed of two factors; one is the term, $E_1=-(2/\pi)N|T|\sin\pi\rho$, and the other, $E_2=-(4NT^2\rho^2/I)\ln 2\ (1-\sin 2\pi\rho/(2\pi\rho))$. The E_2 term is regarded as the stabilization energy due to the charge-transfer interaction between unpaired electrons. In terms of J in Eq. 1, E_2 is written as $-2NJ\rho\ln 2$. On the other hand, the E_1 term is characteristic of less-than-half occupied system. It becomes zero at $\rho=0$ or 1, but has the most negative value of $-(2/\pi)N|T|$ at $\rho=1/2$. E_1 is not a function of I, but is related only to $|T|$ and ρ. Therefore, E_1 corresponds to the stabilization energy due to the charge-transfer interaction between neutral and ion-radical molecules in one-dimensional system. If we consider the case of $\rho=1$, Eq. 1 is simply $J=2T^2/I$, and Eq. 2 is reduced to $E=E_2=-(4NT^2/I)\ln 2$ and $E_1=0$. As our model requires, the J and E values are found to be identical with those described previously in simple ion radical salt. In the case of half-occupied Hubbard model with $\rho=1$, each molecular site is occupied by one unpaired electron and there remains no neutral molecular site, so that there acts no charge-transfer interaction between neutral and ion-radical molecules in simple ion radical salts. This is the reason why $E_1=0$ at $\rho=1$. Therefore, the energy stabilization due to E_1 appears only in complex ion radical salts.

Next, we shall apply the above-mentioned approach to certain crystalline complex ion radical salt and estimate its ground-state stabilization energy. For purposes of comparison, we shall also examine the corresponding simple salt. For this purpose, we take simple cation radical salt of (Phenothiazine)$^{+\cdot}$ Br$^-$ and complex salt of (Phenothiazine)$_2^{+\cdot}$ Br$^-$. In pre-

vious papers,[6] we reported that the optical and magnetic properties of those phenothiazine (PT) cation radical salts were well explained by applying regular one-dimensional Hubbard model to the segregated stack of phenothiazines, and estimated the values of $I=12900\ cm^{-1}$ and $T\approx-2500\ cm^{-1}$ for the one-dimensional system of the simple salt of $PT^{+\cdot}\ Br^-$. Moreover, these parameter values could be commonly used for the one-dimensional system of the complex salt of $(PT)_2^{+\cdot}\ Br^-$. Then, the average number of unpaired electrons per site and the number of phenothiazine sites are $\rho=1$ and $N=N_A$ (Avogadro number) for one mole of $PT^{+\cdot}\ Br^-$, respectively, while they are $\rho=1/2$ and $N=2N_A$ for one mol of $(PT)_2^{+\cdot}\ Br^-$, respectively. In the case of the simple salt, by the use of $E=-(4NT^2/I)$ ln 2 together with the estimated I and T values, the stabilization energy due to the charge-transfer interaction between phenothiazine cation radicals was calculated to be $E=-16.0\ kJ\ mol^{-1}$. As for the complex salt, the stabilization energy, E, is given by two factors, E_1 and E_2. By using the E_2 equation together with $N=2N_A$, $\rho=1/2$, $I=12900\ cm^{-1}$ and $T\approx-2500\ cm^{-1}$, the value of E_2 was determined to be $-8.0\ kJ\ mol^{-1}$, whose magnitude was found to be just half of that of E in the simple salt. In the complex salt, however, the E_1 term due to the charge-transfer interaction between neutral and cation-radical phenothiazines was estimated to be $-38.0\ kJ\ mol^{-1}$ by the use of the E_1 equation. By summing E_1 and E_2, the ground-state stabilization energy of the complex salt was $E=-46.0\ kJ\ mol^{-1}$. We can see that, although the stabilization due to the charge-transfer interaction between phenothiazine cation radicals decreases, the total stabilization energy of the complex salt greatly increases in comparison with that of the simple salt. The reason for this is that the interaction between neutral and cation-radical phenothiazines plays an important role in the complex salt.

Since every ion radical salt belongs to a kind of ionic crystals, Madelung energy is the most important factor for the cohesive energy.[11] However, the ground-state energy stabilization due to the charge-transfer interactions between ion-radical molecules and between neutral and ion-radical molecules will be the next important factor for the total cohesive energy in crystalline ion radical salts.

(Received August 28, 1980)

Synopsis. The effect of added sodium chloride on the metachromatic interaction between cationic dyes (Crystal Violet, Trypaflavine, and 9-aminoacridinium chloride) and sodium polyphosphate and poly(ethylenesulfonate) was studied in aqueous solutions by measuring the visible absorption spectra and by determining the bound-dye spectra and the equilibrium constants with the principal component analysis.

Previous reports have shown that metachromatic changes of the absorption spectra of Crystal Violet (CV) and Trypaflavine (TF) in the presence of sodium polyphosphate (NaPP) are affected by addition of simple electrolytes.[2-4)] The degree of metachromasy was decreased with the increase of ionic strength, *i.e.*, the absorption spectra of dye–NaPP solutions returned to the original spectra of the NaPP-free dye solutions. On the basis of the ultrafiltration of dye–NaPP solutions, this result was attributed to the dissociation of bound-dye species from NaPP by competition with Na^+ ions.[3,4)]

Recent applications of the extended-principal-component-analysis (EPCA) procedure to a variety of dye–polymer solutions demonstrated that it is possible to determine the number of light-absorbing components, the equilibrium constant, the pure spectra of dye species bound to polymer, and the fraction of the bound-dye species from a family of experimental absorption spectra of a dye–polymer system.[5-8)] By utilizing this EPCA procedure, therefore, the amount of dye species dissociated from the polymer site by an increase of ionic strength can now be estimated on a precise and quantitative basis. In this Note, the effect of added NaCl on the metachromatic behavior of four different dye–polymer systems will be reported. In all dye–polymer combinations, the fractions of bound-dye species indeed decrease with an increase of added NaCl but, surprisingly, the spectra of the bound-dye species remain unchanged.

Experimental

Materials. Samples were sodium polyphosphate (NaPP)[5)] and sodium poly(ethylenesulfonate) (NaPES),[5)] and the chlorides of Crystal Violet (CV),[5)] Trypaflavine (TF),[5)] and 9-aminoacridinium chloride (AA).[8)]

Measurements and the Procedure for Data Analysis. Absorption spectra were measured at 25 °C.[8)] Optical titration of a dye solution, which contains either 1 mM ($=10^{-3}$ mol/dm^3) or 0.1 mM NaCl, was carried out by the dropwise addition of a polymer solution which contains the same amount of NaCl. The observed series of spectra of each dye–polymer system were analyzed by the EPCA procedure, which has been described together with other precautions.[5-9)] The molar absorption coefficient, ε, was defined as before.[5,8)]

Results and Discussion

Pure Spectra of Bound-dye Species and Equilibrium Constants. Figures 1a—d show the typical absorption spectra of dyes in the presence and the absence of polymers. In each dye–polymer system, optical titrations were carried out to obtain eight to nine experimental spectra over the P/D range 0—*ca.* 1, where P and D are the concentrations of a polymer in the residue unit and a dye respectively.[3)] (Not all spectra were drawn in each figure, but details are the same as were shown in Refs. 5—8.) Each family of spectra shows the presence of isosbestic points, which are independent of the concentration of added NaCl (*cf.* caption of Fig. 1), indicating that the dye–polymer solution consists of two light-absorbing components, probably, free- and bound-dye species. The result of the EPCA procedure applied to the experimental spectra revealed that each dye–polymer system, which contains either 1 mM or 0.1 mM NaCl, is composed

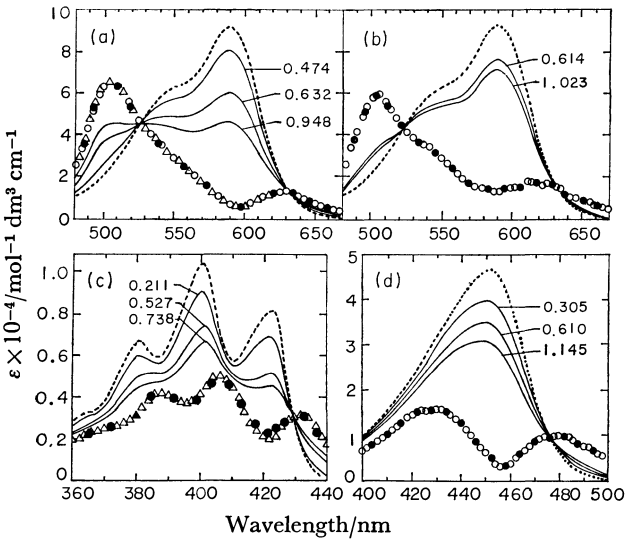

Fig. 1. Absorption spectra of CV–, AA–, and TF–polymer systems in the presence of NaCl and the corresponding pure spectra of dye species bound to the polymers. The experimental conditions are: (a) CV–NaPP with P/D 0—1.26 in 0.1 mM NaCl, (b) CV–NaPES with P/D 0—1.023 in 0.1 mM NaCl, (c) AA–NaPP with P/D 0—0.738 in 1 mM NaCl (precipitates appeared at the concentration of added NaCl higher than 5 mM), and (d) TF–NaPES with P/D 0—1.145 in 0.1 mM NaCl. The initial dye concentrations in μM are (a) 8.13, (b) 7.04, (c) 44.3, and (d) 9.43. Isosbestic points in nm are: (a) 639 and 529, (b) 641 and 526, (c) 429, (d) 476. In each figure, the spectrum of the polymer-free dye solution is shown by the dotted curve and the numerals indicate the P/D values. The bound spectra are denoted by either (○) in 0.1 mM or (△) in 1 mM NaCl and by (●) in NaCl-free solutions, the latter being cited from Ref. 5 for (a), (b), and (d) and from Ref. 8 for (c) for comparison.

Table 1. Effect of added NaCl on the empirical parameter α and the equilibrium constant K of dye-polymer systems at 25 °C

Dye-polymer	NaCl[a]	α	K[b]	K'[c]
CV-NaPP	0.1	2.1(1.5)[d]	1.0×10^{11}	1.4×10^{5}
CV-NaPP	1.0	1.9(1.5)	1.8×10^{9}	4.7×10^{4}
CV-NaPES	0.1	1.5(0.6)	5.2×10^{7}	1.4×10^{5}
AA-NaPP	1.0	1.6(1.2)	1.2×10^{8}	2.8×10^{5}
TF-NaPES	0.1	1.2(0.9)	1.5×10^{6}	1.5×10^{5}

a) The concentration in 10^{-3} mol/dm^3. b) The dimension in $[\mathrm{dm^3/mol}]^{\alpha}$. c) $K'=K[\mathrm{P}]^{\alpha-1}$ at $P/D=1$. d) The α values in parentheses are for NaCl-free systems and are taken from Ref. 5 or 8 for comparison.

of two absorbing species. The pure spectra of dye species bound to NaPP and NaPES were thus evaluated and are shown in Figs. 1a—d, together with those in NaCl-free solutions. Interestingly, the bound-dye spectra in the presence or the absence of added NaCl are essentially identical with each other.

Fractions of Bound-dye Species. The scheme for the binding reaction includes an empirical parameter, α, in such a way that $K=[\mathrm{DP^*}]([\mathrm{D}][\mathrm{P}]^{\alpha})^{-1}$. The notations are all the same as before.[5,8] Both α and K were estimated by the EPCA procedure and are given in Table 1. The values of α are larger than unity in all cases where NaCl is added, indicating that the optical titration curves change sigmoidally with P/D.[5,6] The values of α are also larger in the presence of NaCl than in its absence. It is thus clear that the empirical parameter α reflects the effect of ionic strength on the binding reaction.

The fraction of bound-dye species in each solution, f_b, may be calculated with the estimated α and K values and also directly from the EPCA method.[5-8] The results are shown in Fig. 2, where the fraction of free-dye species remaining in solution, $1-f_b$, is plotted against P/D. The amount of CV bound to NaPP decreases most markedly with the increase in NaCl (Fig. 2a), *i.e.*, only 20% of CV remain bound even at $P/D=1$ in 1 mM NaCl, while 50% of CV are bound in the salt-free solution. In contrast, the effect of added NaCl was negligible for the AA–NaPP system (Fig. 2c), *i.e.*, 75% of AA remain bound at $P/D=1$ in 1 mM NaCl. Similarly, CV bound to NaPES is affected more than TF by added NaCl (Figs. 2b and d). It is clear that, as compared with acridine dyes (TF and AA), CV dissociates from the polymer to a remarkable extent, probably as a result of competitive inhibition by Na^+ ions.[10] Our result is in accord with the cases of Proflavine–poly(glutamic acid),[10] CV–poly(methacrylic acid),[11] and Acridine Orange–poly(*p*-styrenesulfonate).[12]

In summary, we have clearly shown that the spectra of bound-dye species are not affected by added NaCl but the Na^+ ion competes with the bound dye for the polymer site from which the dye is forced to dissociate. These results imply several possibilities to be resolved: (1) If the dye molecules are stacked on a polymer chain, they remain so even when over

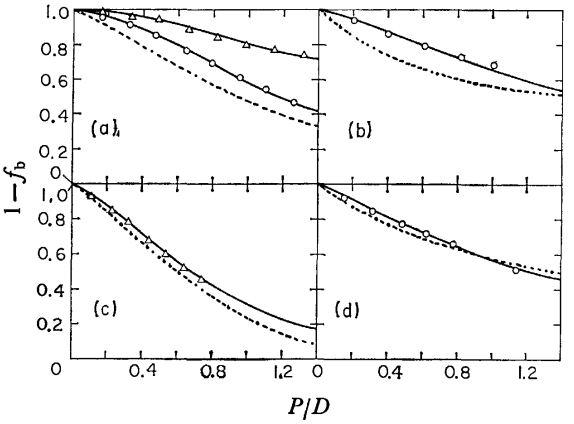

Fig. 2. The P/D dependence of the fraction of free-dye species remaining in solution, $1-f_b$, for four dye–polymer systems. (a) CV–NaPP, (b) CV–NaPES, (c) AA–NaPP, and (d) TF–NaPES. The solid curves were calculated from the values of α and K in Table 1 (*cf.* Eq. 2 in Ref. 6), while each point [(○) in 0.1 mM NaCl or (△) in 1 mM NaCl] was calculated by the EPCA method with 56 to 40 selected wavelengths (*cf.* Eq. 4 in Ref. 6). The dotted curves are the binding curves for NaCl-free systems for comparison (taken from Ref. 5 for (a), (b), and (d) and from Ref. 8 for (c)).

80% of them are liberated into the solution as free dye. (2) If the added salt enhances the degree of stacking[12] or aggregation of dye,[13] the bound-dye spectra may be so insensitive as not to reflect such changes of the bound-dye species. (3) The bound-dye species may exist in an unstacked state regardless of the amount of NaCl present in a solution.

We thank Mr. Kinya Nakata for his technical assistance.

Vibrational Spectra and Normal Coordinate Calculations for Trimethylsilane

Yoshika IMAI* and Koyo AIDA

Department of Applied Science, Faculty of Engineering, Tohoku University, Sendai 980

(Received September 19, 1980)

Synopsis. Vibrational spectra of trimethylsilane-d_0, -d_1, -d_9, and -d_{10} have been obtained. Assignments for all the fundamentals have been made assuming C_{3v} molecular symmetry. Normal coordinate calculations have been carried out to confirm the assignments.

The vibrational studies of trimethylsilane have been made extensively.[1] For instance, Ball *et al.*[2] have reported the vibrational spectra of $(CH_3)_3SiH$ and $(CH_3)_3SiD$, and based on their data, Tenisheva *et al.*[3] have carried out the normal coordinate calculations. From these studies, it was found that there is a considerable coupling between the SiH bending and the methyl rocking vibrations, thus remaining some ambiguities in these assignments. Therefore, it is desirable to obtain the vibrational spectra of its methyl-d_9 homologues, $(CD_3)_3SiH$ and $(CD_3)_3SiD$, and to achieve the normal coordinate calculations using the data of these four isotopic species.

Experimental

The compounds were prepared by reduction of bromotrimethylsilane-d_0 or -d_9 with $LiAlH_4$ or $LiAlD_4$ and purified by vacuum distillation.

Infrared spectra (4000—300 cm^{-1}) were obtained on a Hitachi 345 spectrophotometer in the gas phase and in the solid films at liquid nitrogen temperature. Far-infrared spectra (400—80 cm^{-1}) were recorded on a Hitachi FIS-III spectrophotometer in the solid films at liquid nitrogen temperature. Raman spectra were recorded in the liquid state on a JEOL JRS S-1 laser Raman spectrophotometer equipped with a 50 mW NEC GLS 5800 He-Ne laser. Qualitative polarizations were also measured.

Results and Discussion

With C_{3v} symmetry, 24 normal vibrations are expected to distribute as $8A_1+4A_2+12E$. The A_1 and E modes are both infrared and Raman active, and the A_2 modes are inactive in both spectra. The observed frequencies for $(CD_3)_3SiH$ and $(CD_3)_3SiD$ are listed in Table 1. Those for $(CH_3)_3SiH$ and $(CH_3)_3SiD$ are nearly equal with those given by the previous authors.[2] The Raman spectra below 1000 cm^{-1} are shown in Fig. 1.

a) The stretching force constants are given in mdyn/Å, the deformation force constants in mdyn·Å, the stretching-deformation interaction constants in mdyn.

The observed spectra and the assignments for $(CH_3)_3SiH$ and $(CH_3)_3SiD$ are almost identical with those given by the previous authors.[2)] However, a discrepancy is found in the assignments for the methyl rocking vibrations. They have reported two Raman bands at 853 and 831 cm^{-1}, of which the latter was assigned to the A_1 mode from the polarization measurements. In agreement in frequency with their results, we have observed two bands at 850 and 830 cm^{-1}, but the former band, not the latter, is found to be polarized (Fig. 1. (A)). Therefore, the band at 850 cm^{-1} should be assigned to the A_1 methyl rocking mode and the latter to the E mode. This mis-assignments were probably caused by the fact that the polarization measurements were difficult in a photographic method with a Hg-arc as an excitation, especially in the case of closely separated bands.

For $(CD_3)_3SiH$ and $(CD_3)_3SiD$, the assignments can be easily made except the range between 1000 and 400 cm^{-1}. In the case of $(CD_3)_3SiD$, two polarized Raman bands are observed at 705 and 552 cm^{-1} in this region (Fig. 1. (D)) and can be assigned to the CD_3 rock(A_1) and to the SiC_3 stretch(A_1), respectively. These bands are observed nearly at the same frequencies in $(CD_3)_3SiH$, but the band at 704 cm^{-1} is now only partly polarized (Fig. 1. (C)). This suggests that some vibrations other than the CD_3 rock(A_1) coincide on this band. The most probable candidate is the asymmetric SiC_3 stretch, for this mode has been observed at *ca.* 700 cm^{-1} in $(CD_3)_3SiX$.[4)] This asymmetric SiC_3 stretch is found at 730 cm^{-1} in $(CD_3)_3SiD$.

The Raman band at 858 cm^{-1} in $(CD_3)_3SiH$ can be assigned to the SiH bending vibration, for it disappears in $(CD_3)_3SiD$. However, as a considerable coupling is expected between this mode and the methyl rock, the exact assignments can only be made with the aid of the normal coordinate calculations.

The normal coordinate calculations were carried out by Wilson's GF-matrix method on an ACOS 77/900 computer at the Computer Center, Tohoku University, using the iterative least-squares procedure in the usual manner. The G matrix was calculated by use of the molecular parameters determined from microwave study.[5)] The least-squares refinement[6)] was carried out in terms of the symmetry force constants, which were fitted to the Raman frequencies observed in the liquid, for the four isotopes simultaneously. The torsional mode was neglected in the E class. The symmetry force constants, together with uncertainties from the last cycle are given in Table 2. The average errors were 0.41 and 0.66% for the A_1 and E vibrations, respectively. The sum of the weighted squares of errors $\Sigma(\lambda_{obsd}-\lambda_{calcd})^2/\lambda_{obsd}$ was 1.8×10^{-3} for the A_1 and 4.9×10^{-3} for the E vibrations. The potential energy distributions are also given in Table 1.

The results of the calculations clearly indicate that the methyl rock, the SiH bending and the asymmetric SiC_3 stretch strongly couple with each other, especially in $(CD_3)_3SiD$.

The valuence force constant f(Si–C), derived from the symmetry force constants, is 2.97 mdyn/Å. This value is equal to that of CH_3SiH_3(2.97 mdyn/Å)[7)] and is slightly larger than that of $(CH_3)_4Si$(2.88 mdyn/Å).[8)] This is in agreement with what might be expected from their Si–C bond lengths; 1.868 Å in $(CH_3)_3SiH$,[5)] 1.867 Å in CH_3SiH_3,[9)] and 1.875 Å in $(CH_3)_4Si$.[10)]

This work was partly supported by a grant from the Asahi Glass Foundation for Industrial Technology to which our thanks are due. One of the authors (Y. I.) wishes to his thanks to Assist. Prof. Fumio Watari for the computer programs used in calculations.

(Received June 12, 1980)

Synopsis. The distribution coefficients of several metal ions have been measured on sulfonated diphenyl phosphonate–formaldehyde resin in HCl–water miscible organic solvent solutions. Differences in the distribution coefficients are large enough to develop multicomponent separations. Particularly in HCl–propanone systems the separation of a complex mixture, Cd(II)–Zn(II)–Pb(II)–Cu(II)–Co(II)–Mn(II)–Mg(II), can be carried out chromatographically by sequential elution.

In a previous paper,[1] a report was given on the cation exchange behavior of metal ions on sulfonated diphenyl phosphonate–formaldehyde resin (abbreviated to DFS resin) in an aqueous HCl system.

The numerous studies to improve the cation exchange separation of metal ion by addition of a water miscible organic solvent have been reported. Fritz and Rettig[2] studied the separation of metal ions using Dowex 50W-X8 resin by elution with 0.10—1.0 mol dm^{-3} HCl–60—92 vol% propanone systems. Strelow *et al.*[3] presented a procedure for the separation of metal ions using Bio-Rad AG 50W-X8 resin by elution with 0.20—1.0 mol dm^{-3} HCl–30—90 vol% propanone systems. However, the separation of Pb(II) has not been achieved. Kawazu *et al.*[4] performed the separation of Pb(II) from bivalent metal ions by elution with 1.2—1.4 mol dm^{-3} HCl–90 vol% 2 propanol system using Amberyst 15 cation exchanger.

We have selected ethanol, propanone and acetonitrile as water miscible organic solvent and examined the separation of several metal ions. In the HCl–propanone systems seven elements could be separated successfully from each other, the separation of Pb(II) being achieved. In the HCl–acetonitrile and –ethanol systems, neither Zn(II)–Pb(II) or Co(II)–Mn(II) could be separated. In both systems Pb(II) could be separated from bivalent metal ions except Zn(II).

Experimental

The DFS resin was prepared as described previously.[1] 1 cm^3 of sample solution containing 5 mg of metal as nitrate was used. The concentration of organic solvent is expressed in volume percentage and that of HCl in molarity. Procedures for the separation of metal ion mixtures are shown in Figs. 2—4. Metal ions were determined by atomic adsorption spectrometry and are given in mmol/25 cm^3.

Results and Discussion

Distribution Coefficient. The distribution coefficients of metal ions were measured in HCl–organic solvent media in the acid concentration range 0.10—0.40 mol dm^{-3} and solvent concentration range 20—80 vol% (Table 1). The coefficients of Cd(II), Zn(II), and Pb(II) decreased in the HCl concentration range 0.10—0.30 mol dm^{-3} with increase in solvent concentration. The coefficient of Cu(II) in 0.40 mol dm^{-3} HCl decreased with increase in solvent concentration. The coefficients of Mn(II) and Mg(II) gave the lowest value in 20 vol% organic solvent at 0.40 mol dm^{-3} HCl. The coefficients of Co(II), Ni(II), and Ca(II) were higher than under the conditions given in Table 1.

For the organic solvent concentration of 95 vol%, the coefficients of Cd(II), Zn(II), and Pb(II) were nearly 0 in 0.025 mol dm^{-3} HCl. On the other hand, in the HCl–propanone and –acetonitrile systems the coefficients of Cu(II), Co(II), and Mn(II) decreased sharply from 0.025 to 1.0 mol dm^{-3} HCl. In the HCl–ethanol system only the adsorption of Cu(II) decreased significantly from 0.10 to 0.30 mol dm^{-3} HCl. The results for Cu(II), Co(II), and Mn(II) in propanone and ethanol systems are given in Fig. 1.

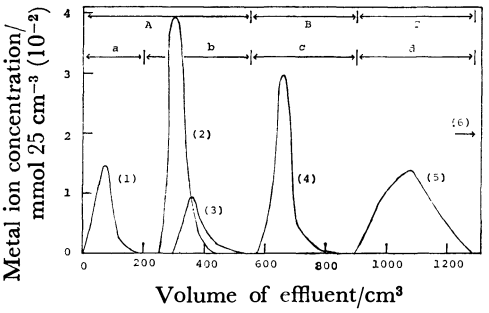

Fig. 4. Elution curves for a seven-component mixture in HCl–ethanol system.
Ethanol(vol%); A: 80, B: 95, C: 20, HCl(mol dm^{-3}); a: 0.10, b: 0.20, c: 0.30, d: 0.40, (1): Cd(II), (2): Zn(II), (3): Pb(II), (4): Cu(II), (5): Mg(II), (6): Co(II) and Mn(II), yield of metal ion: over 99.0 wt%, column: 8ϕ×250 mm, flow rate: 2.5 cm³/min.

Separation of Mixtures. Based on the relevant distribution coefficients, several procedures for the separation of Cd(II)–Zn(II)–Pb(II)–Cu(II)–Co(II)–Mn(II)–Mg(II) were developed. Cd(II)–Zn(II)–Pb(II) were stripped consecutively by elution with 0.10—0.20 mol dm^{-3} HCl–60—80 vol% organic solvent systems, then Cu(II)–Co(II)–Mn(II) with 0.025—0.30 mol dm^{-3} 95 vol%, and Mg(II) with 0.40 mol dm^{-3} —20 vol%. The elution curves with HCl–propanone, –acetonitrile, and –ethanol systems are shown in Figs. 2, 3, and 4, respectively.

The ^{1}H NMR Spectra of $[(CH_3)_2SbCl_2(oxine)]$ in Several Solvents

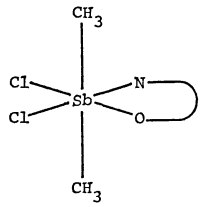
Yoshikane KAWASAKI* and Masahiro KINOSHITA

Department of Petroleum Chemistry, Osaka University, Yamadakami, Suita, Osaka 565

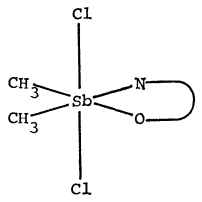
(Received June 19, 1980)

Synopsis. The ^{1}H NMR spectra of dichlorodimethyl(8-quinolinolato)antimony(V), $[(CH_3)_2SbCl_2(oxine)]$, were measured in several solvents. Two methyl signals were observed in some aromatic and aliphatic solvents, although only one signal was detected in dichloromethane. The results were explained by the presence of two isomers in solution.

The structure of dichlorodimethyl(8-quinolinolato)-antimony(V), $[(CH_3)_2SbCl_2(oxine)]$, was studied by Meinema, Rivalora, and Noltes.[1] They reported that the IR spectrum of this compound shows one Sb–C and two Sb–Cl stretching bands in the solid state, while the ^{1}H NMR spectra in chloroform-*d* and dichloromethane give only one methyl signal, and no broadening of this signal is observed even at −100 °C. From these facts and the UV spectral data, they concluded that the compound has a hexacoordinate structure with a distorted *trans*-dimethyl configuration(**1**).[1]



1



2

As we have been interested in the solvent dependence of the ^{1}H NMR spectra of several organometallic compounds,[2,3] we measured the ^{1}H NMR spectra of $[(CH_3)_2SbCl_2(oxine)]$ in several solvents in order to elucidate the solute-solvent interaction and structure in solution.

The ^{1}H NMR data of the compound are shown in Table 1. The chemical shifts of the 2-, 3-, and 4-protons of the 8-quinolinolato ligand move to a higher field in benzene as compared with those in nonaromatic solvents. Especially, the upfield shift of the 2-proton in a benzene solution has been explained in terms of the coordination of the nitrogen atom of the 8-quinolinolato ligand to the antimony atom.[3] This result is consistent with the UV spectral data of the compound.[1]

One of the most remarkable results of the solvent dependence of the ^{1}H NMR spectra of the compound is that two methyl proton signals were observed in some solvents (see Table 1). These results are different from those obtained by Meinema *et al.* in chloroform-*d* and dichloromethane.[1] The signal intensity at the higher field(I_h) is larger than that of the lower field(I_l) in nonpolar solvents. However, the opposite results were obtained in polar solvents. The signal contour and the intensity ratio(I_h/I_l) do not show any appreciable change upon a change in the temperature from the ambient temperature to −24 °C in carbon disulfide and to 58 °C in 1-chloronaphthalene. Figure 1 shows the methyl-proton chemical shifts and relative intensities of the higher-field methyl signal($I_h/(I_h+I_l)$) in mixed solvents of benzene and dichloromethane. The methyl-proton chemical sihfts move to a higher field as the relative volume of benzene ($V_b/(V_b+V_m)$) increases, but the intensity ratio is almost insensitive to the volume fraction of benzene in the 0.1—0.9 range. The relative intensity of the higher-field methyl signal, extrapolated to pure dichloro-

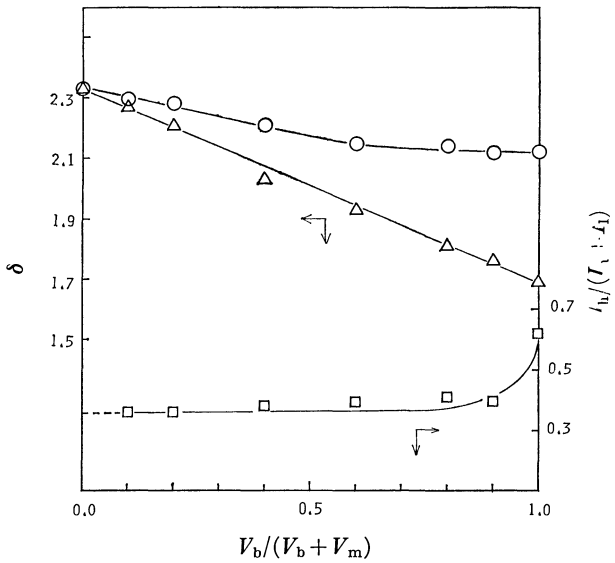


Fig. 1. Methyl proton chemical shifts and relative intensities of higher field methyl signal in mixed solvents of benzene and methylene chloride.

a) Intensity ratio of high-field signal to low-field signal. b) Ref. 1. c) Extrapolated value.

methane, is found to be 0.35. This value is similar to that obtained in 1-chloronaphthalene. The observation of only one signal of the methyl protons of $[(CH_3)_2SbCl_2(oxine)]$ in dichloromethane, therefore, may be an accidental coincidence of the two methyl-proton signals.

The observation of the two methyl signals in the ^1H NMR spectra with unequal signal intensities seems to suggest that the compound has two isometic structures, probably **1** and **2**, in solution. The presence of two isomers in solution has also been reported for some hexacoordinate (acethylacetonato)diaryldihaloantimony(V) compounds,[4,5] although only one isomer with a *trans*-dimethyl configuration corresponding to **1** has been reported for (acetylacetonato)dihalodimethylantimony(V).[6,7]

Experimental

The compound, $[(CH_3)_2SbCl_2(oxine)]$, was prepared and purified by the method reported in the litarature.[1] The solvents used was purified by distillation. The ^1H NMR spectra were measured by using a JEOL JNM PS-100 spectrometer. The chemical shift was measured relative to the internal TMS.

Synopsis. The title compounds, orange, diamagnetic four-coordinate complexes, $[NiL]X_2 \cdot 2H_2O$ (X=Cl, Br, I for *meso*-L and X=Cl, Br for *rac*-L) were converted, upon dehydration by heating in the solid state, to violet, paramagnetic six-coordinate complexes, $[NiX_2L]$. The enthalpies of the dehydration reactions were close to those for many simple inorganic hydrates and that for the ice-water vapor equilibrium in spite of the presence of the large organic ligand.

Nickel(II) halides (Cl, Br, and I) and the *meso*-form of the title macrocyclic ligand ((7*RS*,14*SR*)-form) form orange low-spin complexes, $[Ni(meso\text{-}L)]X_2 \cdot 2H_2O$, and violet high-spin complexes, $[NiX_2(meso\text{-}L)]$.[1] The macrocyclic ligand is constrained by the steric requirements to coordinate in a single plane. From their electronic spectra and magnetic properties,[1] and the X-ray analyses of $[Ni(meso\text{-}L)]Cl_2 \cdot 2H_2O$,[2] $[NiCl_2(meso\text{-}L)]$,[2] and $[Ni(meso\text{-}L)]Br_2 \cdot 2H_2O$,[3] it has been shown that the orange dihydrate is a square-planar four-coordinate complex having a singlet ground state, whereas the violet paramagnetic anhydride is a *trans*-dihalogeno six-coordinate complex having a triplet ground state. The solid, violet, paramagnetic anhydrous complex readily reverts to $[Ni(meso\text{-}L)]X_2 \cdot 2H_2O$ when moisture is available.[1]

In the present study, the orange four-coordinate dihydrate was found to be converted to $[NiX_2(meso\text{-}L)]$ upon dehydration by heating in the solid state. The isomeric complex containing the racemic ligand ((7*RS*,14*RS*)-form),[4] $[Ni(rac\text{-}L)]X_2 \cdot 2H_2O$ (X=Cl and Br)[5] underwent exactly the same reaction, yielding the anhydrous six-coordinate complex, *trans*-$[NiX_2(rac\text{-}L)]$. In the present note, the enthalpies of the dehydration reactions are reported.

Figure 1 shows a typical example of the thermogravimetry (TG) and the differential scanning calorimetry (DSC). When $[Ni(meso\text{-}L)]Cl_2 \cdot 2H_2O$ was heated at a heating rate of 3 °C min^{-1}, the weight loss due to the dehydration began at 58 °C and constant weight attained at 110 °C. The weight loss of 8.2±0.2% was in accord with the calculated value for the loss of two mols of water (8.00%). Corresponding to the weight loss, an endothermic peak appeared on a DSC curve. The heat of dehydration was estimated to be 100±1 kJ mol^{-1} by comparing the peak area with that for melting of naphthalene crystals (ΔH=18.98 kJ mol^{-1}).[6] Experiments for other systems were carried out similarly. The results are summarized in Table 1. Values given in Table 1 are mean values for at least four experimental runs. The product was identified by elemental analysis, electronic spectrum,[1,7,8] and infrared spectrum.[8] All the results indicated that the reaction proceeds as follows:

$$[NiL]X_2 \cdot 2H_2O \xrightarrow{\Delta} [NiX_2L] + 2H_2O.$$

This is the reverse reaction reported by Busch[1] and involves the change in the coordination number from four to six, *viz.*, the singlet to triplet spin-state change.

As shown in Table 1, the ΔH values are not largely different from each other except for the iodide system of [Ni(*meso*-L)], though the difference in ΔH caused by the kind of halide ion and the ligand may be significant. It is worth while to mention that the enthalpies found in the present study can be compared to the calculated enthalpy value for sublimation of ice, where ΔH(sublimation)=51.9 kJ mol^{-1} at 25 °C.[9] (Note that the ΔH values given in Table 1 correspond to the loss of two mols of water.) Except for the iodide system, the enthalpy values found in the present study are significantly larger than those usually found for dehydration reactions of coordination compounds. For example, ΔH for dehydration of $[Ni(abi)_4]X_2 \cdot nH_2O$ (abi=2-aminobenzimidazole) has been reported to be 8.8 (X=Cl, n=3), 8.8 (X=Br, n=3), and 7.1

L	X	$\Delta H(-2H_2O)$ / kJ mol^{-1}	Temperature of incipient reaction/°C[a]
meso-L	Cl	100±1	58
	Br	104±3	75
	I	78±2	58
rac-L	Cl	99±4	76
	Br	96±4	65

a) Heating rate: 3 °C min^{-1}.

kJ mol^{-1} (X=NO_3, n=1).[10] Fogel *et al.* studied dehydration reactions of many simple inorganic hydrates[9,11,12] and reported that, for many reactions, ΔH=55.2x kJ mol^{-1} (x designates mol number of lost water), which is close to what is observed for the ice system.[12] They concluded on this basis that, when only small structural changes occur during dehydration reactions, the thermodynamic value is close to that for the vaporization of ice.[9]

It is striking that the ΔH values given in Table 1 are close to those reported by Fogel and that for the sublimation of ice, even though the present complexes bear the large organic ligand. This indicates that the water molecules in the dihydrates of the present complexes are involved in the strong hydrogen-bonds such as those in ice and many simple inorganic hydrates. It has been shown that, in the crystals of [Ni(*meso*-L)]$Cl_2\cdot 2H_2O$[2] and [Ni(*meso*-L)]$Br_2\cdot 2H_2O$,[3] all the water molecules are disposed above the hydrogen atoms of N–H groups and are involved in the strong hydrogen-bonds, N–H···OH_2 and OH_2···X, forming hydrogen-bonded chelate rings of the type Ni–N–H···O–H···X···H–N. The magnitude of ΔH seems to reflect at least qualitatively the strength of the hydrogen-bonds in the hydrate, although many other factors affect the magnitude of ΔH. The small ΔH value for the iodide system probably indicates the weaker hydrogen-bond in the crystal as expected. Busch pointed out the importance of the role played by water in the spin-state conversions such as the anhydrous spin-free–hydrate spin-paired type.[13] When the anhydrous [NiX_2L] takes up the two water molecules from the atmospheric moisture to produce [NiL]$X_2\cdot 2H_2O$, the incorporated water molecules displace the halogen ions from the coordination sites but are not involved in the coordination in the product. This is unexpected in the light of the fact that water has much higher coordinating ability as compared with the halide ion. In view of the crystal structures of [Ni(*meso*-L)]$Cl_2\cdot 2H_2O$[2] and [Ni(*meso*-L)]$Br_2\cdot 2H_2O$,[3] the dispositions of the water molecules above the N–H bonds would be much more favorable over the hypothetical occupation by the water molecules at the axial coordination sites. This situation could be explained by the larger ΔH values observed in the present study. The N–H···OH_2 and OH_2···X hydrogen-bond networks operating in the vicinity of the nickel(II) ion are strong enough to prevent the coordination of water.

Experimental

Materials. Orange dihydrates, [Ni(*meso*-L)]$X_2\cdot 2H_2O$ (X=Cl, Br, and I) and [Ni(*rac*-L)]$X_2\cdot 2H_2O$ (X=Cl and Br), were prepared from the corresponding perchlorates[4] by ion exchange (Dowex 1-X8). Elemental analyses gave satisfactory results.

Measurements. Thermal analyses were carried out on a Rigaku Denki differential scanning calorimeter, Model 8001 SL/C.

Elemental Analyses of the Reaction Products. (a) [NiX_2(*meso*-L)]=$NiC_{16}H_{36}N_4X_2$. Found: C, 46.35; H, 8.89; N, 13.44; Cl, 17.16%. Calcd for X=Cl: C, 46.41; H, 8.76; N, 13.53; Cl, 17.12%. Found: C, 38.08; H, 7.30; N, 11.30; Br, 31.96%. Calcd for X=Br: C, 38.20; H, 7.21; N, 11.14; Br, 31.77%. Found: C, 31.96; H, 6.16; N, 9.42; I, 42.69%. Calcd for X=I: C, 32.19; H, 6.08; N, 9.39; I, 42.51%. (b) [NiX_2(*rac*-L)]=$NiC_{16}H_{36}N_4X_2\cdot$ Found: C, 45.53; H, 8.81; N, 12.89; Cl, 16.83%. Calcd for X=Cl: C, 46.41; H, 8.76; N, 13.53; Cl, 17.12%. [$NiBr_2$(*rac*-L)] is very sensitive to moisture. Accurate data for the anhydrous complex could not be obtained because of rapid absorption of water vapor during weighing the sample.

The authors wish to thank Professor Yoshio Matsunage for the kindness in the DSC measurements.

Potential Gradient Detector for Capillary Type Isotachophoresis

Fumitaka NISHIYAMA, Takeshi HIROKAWA,* and Yoshiyuki KISO
Applied Physics and Chemistry, Faculty of Engineering, Hiroshima University, 3-8-2, Senda, Naka-ku, Hiroshima 730
(Received July 10, 1980)

Synopsis. The potential gradient detector previously reported has been improved as regards mechanical stability and the contaminated electrodes can be easily exchanged with new ones. The linearity of step-height holds below the electrode voltage of 1.2 V (0.005 mol dm^{-3} aq HCl). The detection limit was 2.5×10^{-10} mol for adipic acid.

In isotachophoresis, the ratio of potential gradients of sample zone (E_V) to leading zone (E_L) can be measured by means of a potential gradient detector (PGD). The ratio, R_E, correlates with the step-height (h) in the isotachopherogram and the effective mobility (m) of sample and leading ion as follows:

$$R_E = E_V/E_L = h_V/h_L = \bar{m}_L/\bar{m}_V, \quad (1)$$

where V and L denote the sample and leading zones, respectively.

The R_E values obtained are useful for the evaluation of aboslute mobility,[1,2] dissociation constants[2] and complex stability constants.[3] For the measurements of R_E, the drift of baseline in the isotachopherogram should be suppressed as little as possible. The drift might be due to the following: (A) Inadequate choice of electrolyte system and/or pH of leading electrolyte. (B) An undesirable electric pass among sensing electrodes and ground due to leak of electrolytes and/or high humidity. (C) The inactive electrodes of PGD contaminated by electrode reaction; An exchange of the damaged sensing electrodes is preferable, since the PGD once contaminated will not give a stable base line even when it is rinsed well. The defects due to acryl resin[2] were removed: The previous model was not strong mechanically; due to thermal melting on boring, it was difficult to pass electrolytes with a uniformed bore and no organic solvent could be used.

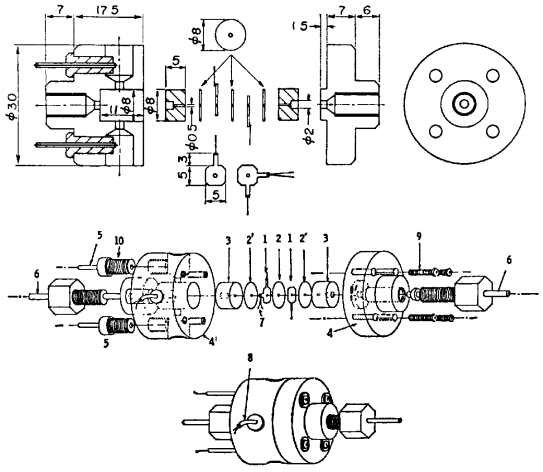

Fig. 1. Potential gradient detector.
1: Pt sensing electrodes, 2: PTFE insulator, 2′: PTFE gaskets, 3: PTFCE holders, 4 and 4′: Cell bodies (polycarbonate), 5: Lead wires, 6: PTFE capillary tube, 7 and 8: Cu-constantan thermocouple, 9: Fixing screws, 10: PTFE bushings.

Construction of PGD Cell. Figure 1 shows the mechanical construction and an exploded view of the PGD cell. The cell bodies (4,4′) are made of polycarbonate resin and turn on a rod, the holes in the bodies being for screws (9), and plugs to fit the capillary tube to the cell, and lead wires to the sensing electrodes (5). The sensing electrodes (1) are made of platinum disk of 20 μm thick. A copper-constantan thermocouple soldered to one of the electrodes (7) is to monitor the temperature of electrolyte. The holders (3) for sandwiching the electrodes are made of poly(trifluorochloroethylene) (PTFCE), which is harder than poly(tetrafluoroethylene) (PTFE). PTFE disks of 50 μm thick were used as an insulator of the electrodes (2) and gaskets (2′). The diameter of the pass of electrolyte is 0.5 mm. The bored electrodes were carefully trimmed with sandpaper (# 2000) and rinsed with water, 0.1 mol dm^{-3} HNO_3, distilled water and ethanol. The holders, insulators, and gaskets were also rinsed with ethanol and dried.

One of the holders (3) was inserted into the cell body (4′), a centering rod of 0.5 mmϕ being inserted into the holes. The gaskets, electrodes, insulator and the other holder were inserted and settled. The other body was then fixed tightly with the screws (9) and the rod was pulled out carefully. The lead wires, supported by PTFE bushings (10), were soldered to the sensing electrodes. When construction was complete, the pass was rinsed again.

Check on PGD. First, the linearity between the input voltage applied and the observed step-heights was checked using the recorder of an isotachophoretic analyzer (Shimadzu Seisakusho Ltd., IP-1B) and continuous voltage generator (0 to 2 V).

A 0.005 mol dm^{-3} aq HCl was used as an electrolyte in the pass of the capillary tube and the PGD. The pH was adjusted to 6 by addition of histidine. When there was no electric leakage and the sensing electrodes were clean, the base line of the electropherogram did not drift for 1 h with migration current of 50 μA (drift, less than a few percent of the step-height of base line). Sometimes, an upward drift due to electric leakage among the electrodes and ground, and a downward drift due to electric leakage between the electrodes or the contaminated electrodes were observed.

Since the electric resistance of the buffered electrolyte is constant in the thermostatted capillary tube, the migration current and the voltage detected should be linearly correlated until the sensing electrodes are polarised. The linearity of step-heights on migration was checked as follows. The migration current was varied from 25 to 200 μA at regular intervals of 25

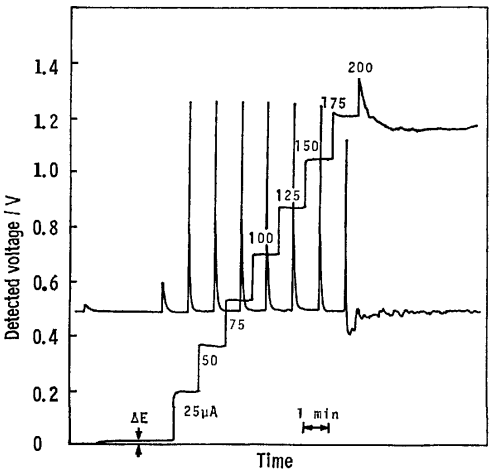

Fig. 2. Electropherogram for the check on linearity of step heights.

μA and the step-heights *vs.* time were recorded (Fig. 2). The irregular step-heights on migration due to polarisation of the electrodes were recorded at 200 μA. However, the linearity held below 175 μA, at which the electrode voltage corresponded to *ca.* 1.2 V. The value agrees with the decomposition voltage of aq HCl. If the electrodes were contaminated or the electric leakage took place in the pass of electrolyte, no normal linear relation could be obtained. Thus, the present PGD gives the correct R_E values of given samples, when the voltage between the sensing electrodes does not exceed the decomposition voltage of sample or solvent. ΔE in Fig. 2 shows an example of the asymmetrical potential which appears at the opening of a short-circuiting switch for PGD. Ideally, the value should be null, but sometimes a slight shift was observed. For estimation of the exact R_E value, the step-height of ΔE should be subtracted from the step-heights of leading, samples and terminating zones. Use of an internal standard will give more reliable R_E values.

Detection Limit. Adipic acid was used in order to check the quantitative limitation according to the procedure reported by Akiyama and Mizuno.[4] The leading electrolyte was 0.01 mol dm^{-3} aq HCl containing 0.2% Triton X-100, the pH of which was adjusted to 6.0 by adding histidine. The terminating electrolyte was 0.01 mol dm^{-3} glutamic acid. The pH was adjusted to *ca.* 6 by adding histidine. Figure 3 shows the differential curves of the isotachopherograms obtained for the injected sample. The quantitative limit was *ca.* 5×10^{-10} mol and the detection limit 2.5×10^{-10} mol.

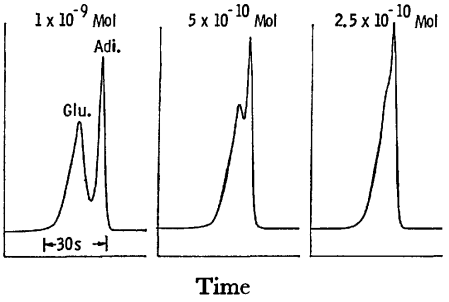

Fig. 3. Differential curves of isotachopherograms of adipic acid for the check on detection limit. Adi: adipic acid, Glu: glutamic acid.

According to a computer analysis of isotachophoresis for the injected sample of 1×10^{-9} mol, the total concentration in the sample zone and the zone length were estimated to be 0.00433 mol dm^{-3} and 0.1176 cm, respectively. The isotachophoretic velocity can be expressed as follows:

$$v = E_a\bar{m}_a = J\bar{m}_a/\kappa_a \text{ cm/s}, \quad (2)$$

where E_a is the potential gradient and $\bar{m}_a$ the effective mobility, J the current density and κ_a specific conductivity. When the current applied is 25 μA, J is 1.273×10^{-2} A/cm^2. The simulated $\bar{m}_a$ and κ_a were 42.96×10^{-5} cm^2/V s and $5.593\times10^{-4}/\Omega$ cm, respectively. Substitution of these values into Eq. 2 gives the isotachophoretic velocity 9.8×10^{-3} cm/s. The passing time of the zone through the detector expected was 12 seconds ($0.1176/9.8\times10^{-3}$). This agrees with the observed one (*ca.* 12 s.) as shown in Fig. 3. The maximum resolving power of 5×10^{-10} mol corresponds to the zone length of 588 μm, which is 8 times the effective gap of the electrodes of 70 μm.

The resolving power of 2.5×10^{-10} mol reported by Akiyama and Mizuno[4] for the same inner diameter and thickness of insulator is twice as large as that of our result. The difference may be due to the thickness of our electrodes (20 μm), since it would affect the degree of sharpness of differential curves. A better resolution might be obtained using thinner eletrodes, a smaller inner diameter of PGD, and lower concentration of leading electrolyte than those in the present experiment.

The Core-level Binding Energies and the Structures of Nickel Complexes

Tooru YOSHIDA* and Kiyoshi YAMASAKI

Osaka Prefectural Industrial Research Institute, 2-1-35, Enokojima, Nishi-ku, Osaka 550

(Received July 28, 1980)

Synopsis. The X-ray photoelectron spectra of thirty-two nickel complexes were measured in order to examine the relation between the structures and the core-level binding energies of the complexes. The differences between the energies of Ni(2p) and Ni(3p) electrons for the complexes with an octahedral structure were about 1 eV larger than for those with a square planar one.

There have been many reports on X-ray photoelectron spectroscopic studies of nickel compounds.[1] It has been established that paramagnetic complexes show intense shake-up satellites on the higher energy side of the primary peaks in the Ni(2p) electron region, but that diamagnetic ones do not. However, there have been few studies of the relationship between the binding energy and the stereochemistry.[1d] The purpose of this study is to examine the relation between the structure of nickel complex, square planar or octahedral, and the binding energies of its core-electrons.

The X-ray photoelectron spectra were measured on an AEI ES200 spectrometer. Al $K\alpha$ (1486.6 eV) X-ray radiation was used as the excitation source. The samples were ground to powder and then dusted onto double-backed adhesive tape. The measurements were run at room temperature under a vacuum of about 10^{-7} Torr. The binding energy of the C(1 s) electron peak was used as the energy standard throughout the present experiments; it was taken to be 285.0 eV. The reproducibilities of the values thus obtained were ±0.1 eV. All the complexes used and their binding energies are given in Table 1. All the complexes were prepared based upon the literature.

The spectra in the Ni(2p)- and Ni(3p)-electron regions for the nickel complexes of 2-pyridinecarboxylic acid and dimethylglyoxime are shown in Fig. 1. E_b in the figure indicates the binding energy. The spectra of the 2-pyridinecarboxylic acid complex, like those of the complexes of Nos. 1—16 in Table 1, showed intense satellites on the higher energy side of each primary peak originating in the $2p_{1/2}$, $2p_{3/2}$, and 3p electrons, but the spectra of the dimetylglyoxime complex, like those of the complexes of Nos. 17—32, did not show such satellites. This suggests that the complexes of Nos. 1—16 are paramagnetic, while those of Nos. 17—32 are diamagnetic.

In general, the Ni(3p) spectrum does not show clear doublet peaks because of the small difference (about 2 eV)[2] between the binding energies of the Ni($3p_{1/2}$) and Ni($3p_{3/2}$) electrons. Therefore, the 3p binding energies in Table 1 correspond to the top of a main peak, as is shown in Fig. 1b.

On the basis of the results of X-ray structural analysis, IR, UV, and magnetic measurements, it has been proved that the structures of the complexes of Nos. 1,[3] 2,[4] 4,[5] 5,[5] 6,[5] 7,[6] 9,[7] 11,[8] 12,[8] 13,[8] 14,[9] 15,[8] and 16[10] are octahedral, while those of Nos. 18,[11] 23,[12] 24,[13] 25,[14] 26,[15] 27,[16] 29,[10] 30,[17] 31,[18]

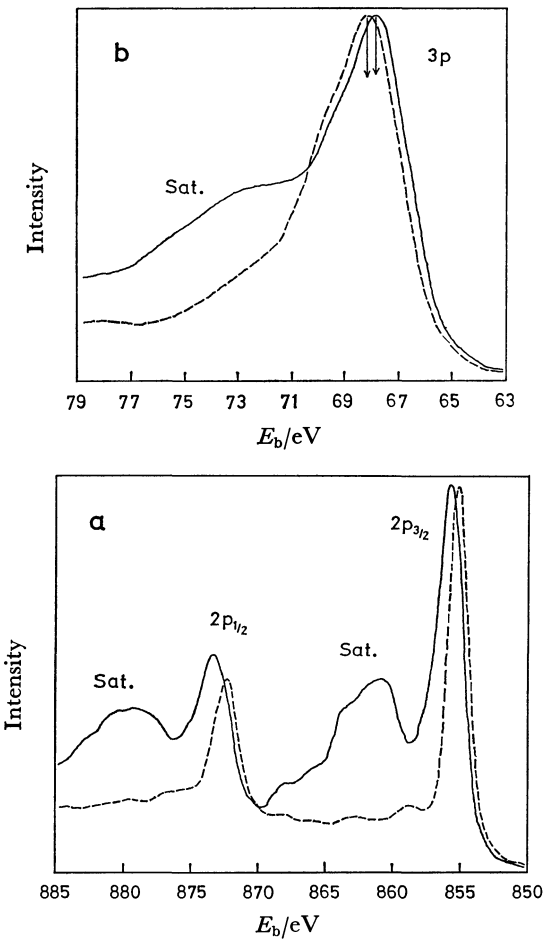

Fig. 1. XPS spectra of a: Ni(2p) and b: Ni(3p) electron regions. Solid line: *trans*-diaquabis(2-pyridinecarboxylato)Ni(II), broken line: bis(dimethylglyoximato)Ni(II).

and 32[19] are square planar. The structure of the No. 3 complex may be considered to be octahedral in view of the structures of the corresponding copper and zinc complexes.[20] It seems reasonable to consider that the structures of the complexes of Nos. 8 and 10 are octahedral, because 1-(2-pyridylazo)- and 1-(8-quinolylazo)-naphthols as well as 1-(2-thiazolylazo)-2-naphthol are tridentate ligands. Furthermore, it seems that the structures of the complexes of Nos. 17, 19—21, and 28 are square planar in view of the structures of the complexes of Nos. 18 and 25—27. The structure of the No. 22 complex seems to be square planar. The square planar structure for the complexes of Nos. 17—32 are supported by the absence of intense satellites in their Ni(2p) and Ni(3p) electron spectra.

It has been reported that, for the nickel complexes of NCS^- ligand, the Ni(2p) binding energies of octahedral compounds are a little higher than those of the square planar ones.[1d] Such a tendency was

a) A: $Ni(L\text{-}4H)Na_2 \cdot 2H_2O$, B: $Ni(L\text{-}H)_2 \cdot 2H_2O$, C: $Ni(L\text{-}H)_2 \cdot 4H_2O$, D: $Ni(L\text{-}H)_2$, E: $NiL_3Cl_2 \cdot 2H_2O$, F: NiL_2Cl_2, G: $NiL_3(ClO_4)_2$, H: Ni(L-H)Cl, I: $K_2Ni(L\text{-}2H)_2$, J: Ni(L-2H). L, L-H, L-2H, and L-4H in the above formulas indicate a free ligand and mono-, di-, and tetra-deprotonated ligands respectively. b) The binding energy of a main peak. c) ΔE_1 and ΔE_2 indicate the binding energy differences, $2p_{1/2}-3p$ and $2p_{3/2}-3p$ respectively.

not observed in this study. This is probably due to the comparison among the complexes of a variety of ligands. Therefore, in this study the differences between the binding energies of core-electrons for each complex were compared in order to reduce the effect of the variety of ligand on the binding energies.

Two kinds of differences, $\Delta E_1 = Ni(2p_{1/2}) - Ni(3p)$ and $\Delta E_2 = Ni(2p_{3/2}) - Ni(3p)$, are given in Table 1. The ΔE_1 and ΔE_2 values for Nos. 1—16 were 805.0—805.6 eV and 787.6—788.0 eV respectively. Those for Nos. 17—32 were 804.0—804.4 eV and 786.9—787.1 eV respectively. That is, the ΔE_1 and ΔE_2 values for the complexes of the former group were about 1 eV larger than those of the latter. This indicates that the differences between the binding energies of core-electrons give valuable information on the stereostructures of nickel complexes.

Synthesis and Absorption Spectra of Annelated 5-Amino-1,4-diazaanthraquinones and Related Compounds

Hiroyuki NAKAZUMI,* Kazuyoshi KONDO, and Teijiro KITAO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received February 20, 1980)

Synopsis. New annelated 5-amino-1,4-diazaanthraquinones and related derivatives were prepared from 2,3,5-triamino-1,4-naphthoquinone or 5-amino-2,3-dichloro-1,4-naphthoquinone. Their visible absorption spectra were examined by the PPP-SCF-MO calculation with a variable β approximation.

1-Amino- and 1,4-diaminoanthraquinones are of great value as coloring matter. We have attempted to prepare new diazaanthraquinones for dyes. The visible absorption maximum of 5-amino-1,4-diazaanthraquinone **2** prepared from 2,3,5-triamino-1,4-naphthoquinone **1** is found at a longer wavelength than that of its carbon analogue.[1)]

In this paper, we wish to report the preparation and visible absorption spectra of annelated derivatives of **2** and related compounds. Annelated 5-amino-1,4-diazaanthraquinones **5**—**7** were prepared by the reaction of 1,2-quinones (1,2-naphthoquinone, acenaphthenequinone and 9,10-phenanthrenequinone) with **1** in 50—86% yields. Benzo derivative **4** was prepared from 5-amino-2(or 3)-chloro-3(or 2)-anilino-1,4-naphthoquinone **3** and sodium azide. Bromination of **2** afforded 5-amino-6,8-dibromo-1,4-diazaanthraquinone **8**. No monobromo derivative[1)] was isolated under the same conditions. 5-Amino-8-anilino derivative **9** was prepared by the Ullmann amination of **8** with aniline, along with 6(or 8)-bromo-5-amino derivative **10**, debrominated product of **8** in trace amounts.

The observed and calculated absorption maxima of new annelated compounds and **9** are summarized in Table 1. All the annelated compounds showed a pronounced bathochromic shift of λ_{max} in polar solvents. In this PPP calculation, the parameters for the solvent effect were not included. Annelation to 6,7-positions of some 1,4-disubstituted anthraquinones produces a small hypsochromic shift.[2)] The hypsochromic shifts of 4—8 nm are accurately predicted by the PPP calculation.[3)] The observed absorption

a) Oscillator strength. b) The values of ε could not be measured due to the poor solubility. c) This structure was presumed by the comparison with the calculated λ_{max} of **5** and its isomer (2X =  : 426 nm (f = 0.343).

maxima of annelated derivatives **4**—**6** were found at wavelengths somewhat shorter than those of the parent compound **2**. The calculated values of all annelated compounds were very close to the value of **2**. The calculated changes in π-electron density accompanying electronic excitation to the first excited state for **4**—**6** were mainly from aniline moiety to two carbonyl groups. The changes were similar to those for **2**.[1)]

On the other hand, the λ_{max} of **7** was observed at a longer wavelength than that of **2**. The absorption band corresponds to changes in π-electron density away from aniline moiety to an acenaphthene ring. Thus, it is predicted that the character of charge transfer for the first excitation for **7** differs from that of the other 5-amino-1,4-diazaanthraquinones.

The absorption maximum of 5-amino-8-anilino derivative **9** was found at the same wavelength as that of its carbon analogue (1-amino-2-bromo-4-anilinoanthraquinone: λ_{max} (benzene) 634 nm (ε, 1.35×10^4)).[4)] It is suggested that the substitution of a pyrazine ring for 1,4-disubstituted anthraquinone series produces no bathochromic shift.

Experimental

Most melting points of 1,4-diazaanthraquinones were not measured owing to the fact that no melting takes place below 300 °C. The absorption spectra were recorded on a Hitachi EPS-3T spectrophotometer, IR spectra on a Hitachi EPI-S_2 spectrophotometer, and mass spectra on a Hitachi RMU-6E mass spectrometer operating at 80 eV. Elemental analyses were recorded on a YANACO CHN recorder MT-2.

Method of SCF-MO Calculation. The calculations were carried out by the PPP-SCF-CI method with a variable β approximation, using the parameters reported,[1)] except for the core resonance integrals (β). The following β_{rs}'s were used for all the annelated compounds.

$$\beta_{CC}/\text{eV} = -1.81 - 0.51\,P_{CC}$$
$$\beta_{CN}/\text{eV} = -1.98 - 0.53\,P_{CN}$$
$$\beta_{CO}/\text{eV} = -2.17 - 0.56\,P_{CO}$$

5-Amino-2,3-benzo-1,4-diazaanthraquinone (4). A solution of aniline (3.5 g) in EtOH (8.3 ml) was added dropwise to a solution of 5-amino-2,3-dichloro-1,4-naphthoquinone (3.7 g)[5)] in EtOH (160 ml) at 75 °C. After the mixture had been refluxed for 3 h, the solid was separated. The filtrate was evaporated, and the combined solids were dissolved in pyridine and filtered. Water was added to the filtrate and the resulting solid was separated. The crude product was purified by dissolution in a minimum quantity of pyridine and reprecipitating with water to give **3**; yield 48%, mp 213—216 °C (dec), Found: C, 64.61; H, 3.76; N, 10.11%. Calcd for $C_{16}H_{11}N_2O_2Cl$: C, 64.32; H, 3.69; N, 9.38%. *m/e* (rel intensity), 300 (M+2, 30), 298 (M, 86), 264 (23), and 263 (100). A solution of NaN_3 (0.7 g) in water (2.2 ml) was added dropwise to a solution of **3** (2.2 g) in DMF (17 ml) at room temperature. The mixture was stirred at 120 °C for 4 h. After cooling, the resulting solid was separated, water being added to the first filtrate to precipitate crude product. The combined crude products were dissolved in EtOH and filtered. The filtrate was evaporated, and the residue was washed with hot xylene. Recrystallization from *o*-dichlorobenzene gave **4**; yield 18%, *m/e* (rel intensity), 275 (M, 100), 247 (35), 219 (35), and 192 (7), IR: 3400 and 3290 cm^{-1} (NH_2), 1670 and 1648 cm^{-1} (CO): Found, C, 69.17; H, 3.59; N, 14.39%. Calcd for $C_{16}H_9N_3O_2$: C, 69.82; H, 3.27; N, 15.27%.

Preparation of Annelated 5-Amino-1,4-diazaanthraquinones (5—7). 1,2-Naphthoquinone (0.93 g, 5.9 mmol) was added to a suspension of 2,3,5-triamino-1,4-naphthoquinone (1.0 g, 4.9 mmol) in 10% acetic acid (50 ml) at 80 °C. The mixture was stirred at 90 °C for 2.5 h. After cooling, the solid was separated and recrystallized from xylene to give **5**. No other isomer was observed by means of TLC. The other annelated compounds **6** and **7** were similarly prepared and recrystallized from DMF. **5**: yield 86%, *m/e* 325 (M, 100), 297 (27), and 269 (27), IR (KBr): 3420 and 3300 cm^{-1} (NH_2), 1689 and 1645 cm^{-1} (CO), Found: C, 74.20; H, 3.72; N, 11.69%. Calcd for $C_{20}H_{11}N_3O_2$: C, 73.85; H, 3.38; N, 12.92%. **6**: yield 51%, *m/e* 375 (M, 100), 347 (17), 319 (15), and 318 (10), IR (KBr): 3440 and 3325 cm^{-1} (NH_2), 1678 and 1650 cm^{-1} (CO), Found: C, 76.65; H, 3.36; N, 11.08%. Calcd for $C_{24}H_{13}N_3O_2$: C, 76.80; H, 3.47; N, 11.20%. **7**: yield 56%, *m/e* 349 (M, 100), 321 (22), and 293 (17), IR (KBr): 3430 and 3300 cm^{-1} (NH_2), 1670 and 1645 cm^{-1} (CO), Found: C, 75.51; H, 3.20; N, 11.60%. Calcd for $C_{22}H_{11}N_3O_2$: C, 75.64; H, 3.15; N, 12.03%.

5-Amino-6,8-dibromo-1,4-diazaanthraquinone (8). To a suspension of **2** (0.91 g) in *o*-dichlorobenzene (46 ml) was added bromine (1.62 g) dropwise at 130 °C for 1 h. The mixture was heated at 140—145 °C for 5 h. After cooling, the solid was separated and washed with benzene, methanol, and water. The crude product was suspended in water (150 ml) and treated with aqueous sodium sulfite, and recrystallized from xylene to give **8**; yield 47%, *m/e* 385 (M+4, 52), 383 (M+2, 100), 381 (M, 52), 357 (8), 355 (16), 353 (9), 286 (23), and 284 (28), IR (KBr): 3400 and 3280 cm^{-1} (NH_2), 1680 and 1640 cm^{-1} (CO), λ_{max} (EtOH): 492 nm (ε, 6.6×10^3), Found: C, 37.58; H, 1.52; N, 10.93%. Calcd for $C_{12}H_5N_3O_2Br_2$: C, 37.62; H, 1.31; N, 10.97%.

5-Amino-6-bromo-8-anilino-1,4-diazaanthraquinone (9). A mixture of **8** (0.94 g), $CuCO_3$ (0.06 g), potassium acetate (1.3 g), and aniline (8.0 g) was stirred at 130—140 °C for 1 h. After being cooled to 80—90 °C, methanol (8 ml) was added to the mixture. The resulting solid was separated, washed with water and methanol, and recrystallized from benzene. The crude product was separated by column-chromatography on silica gel (developing solvent: benzene–acetone (1:2)) to give **9** and **10** in yields of 31% and $\approx$0.1%, respectively. Compound **9** was again recrystallized from benzene. The first filtrate was steam distilled, and the residue solution evaporated. The crude product was recrystallized from water to give **10** (yield 0.3%). **9**: *m/e* 396 (M+2, 100) 394 (M, 100) 379 (43), 377 (47), and 298 (38), Found: C, 54.87; H, 3.01; N, 12.94%. Calcd for $C_{18}H_{11}N_4O_2Br$: C, 54.70; H, 2.79; N, 14.18%, mp 254 °C (sublimed). **10**: λ_{max} (EtOH): 488 nm (ε, 6.8×10^3), *m/e* 305 (M+2, 100), 303 (M, 100), 277 (24), 275 (25), 249 (14), 248 (12), 247 (12), 197 (13), and 196 (20), Found: C, 47.85; H, 2.20; N, 13.12%. Calcd for $C_{12}H_6N_3O_2Br$: C, 47.38; H, 1.97; N, 13.82%.

Phenalenones. III. The Anomalous Diazotization of 3-Substituted 2-Aminophenalenones

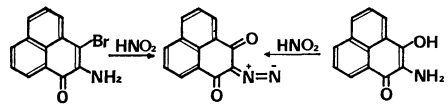
Masatane KUROKI* and Yutaka TSUNASHIMA

Department of Chemistry, Shibaura Institute of Technology, Fukasaku, Ohmiya, Saitama 330

(Received July 9, 1980)

Synopsis. The diazotization of 3-substituted 2-amino-1*H*-phenalen-1-ones (substituents=Cl, Br, PhS, or OH) gave 2-diazo-1*H*-phenalene-1,3(2*H*)-dione. It is most probable that the reaction involves the intramolecular rearrangement of a transient diazohydroxide intermediate and the consequent elimination of the substituent at the 3-position.

When 2-amino-3-bromo-1*H*-phenalen-1-one (**1a**) was treated with nitrous acid in concentrated hydrochloric acid, 2-diazo-1*H*-phenalen-1,3(2*H*)-dione (**2**) was unexpectedly obtained. Although the diazo diketone **2** had previously been prepared by the diazotization of 2-amino-3-hydroxy-1*H*-phenalen-1-one (**1e**),[1] the reaction of **1a** seemed to be different from that of **1e**. A bromine atom at the 3-position of **1a** is replaced by a carbonyl oxygen, whereas a hydrogen atom of the hydroxyl group is apparently eliminated in the case of **1e**. However, the reaction of **1e** may be understood similarly, if the hydroxyl group is considered to be a leaving group.



1a **2** **1e**

Scheme 1.

In order to clarify this, the diazotization of several 3-substituted 2-amino-1*H*-phenalen-1-ones was investigated.

Results and Discussion

The treatment of the amine **1a** with nitrous acid gave no clear solution, and no nitrogen gas evolved on the addition of phosphinic acid to the reaction mixture. In accordance with these observations, the reaction product was not the 3-bromo-1*H*-phenalen-1-one expected for a usual reductive deamination, but, rather, was diazo diketone **2**. The yields of **2** were independent of the presence of phosphinic acid.

Similarly, other 3-substituted 2-amino-1*H*-phenalen-1-ones (**1b**—**1e**) afforded the corresponding diazo diketones in good yields (Table 1).

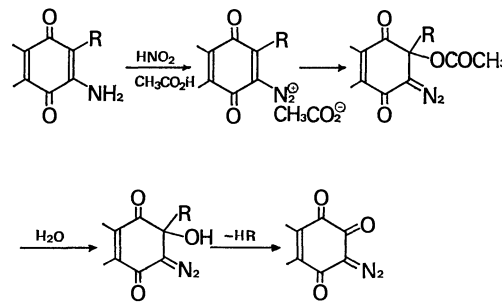
TABLE 1. YIELDS OF **2a** AND **2d**

	1		2	
	R^1	R^2	R^2	Yield/%
a	Br	H	H	96
b	Cl	H	H	62
c	SPh	H	H	44
d	Br	Br	Br	97
e	OH	H	H	74
f	H	H	H	0

Eistert *et al.*[1] carried out the diazotization of the 3-hydroxy derivative **1e** by using nitrosyl hydrogensulfate in a homogeneous solution. The present reactions proceeded sufficiently in a suspension of the amines in hydrochloric acid.

An exceptional case was the reaction of 2-amino-1*H*-phenalen-1-one (**1f**) (R^1=H), which gave an unworkable polymer (mp>330 °C, partly soluble in an aqueous sodium carbonate solution). The treatment of the diazotized solution with phosphinic acid led to a partial decomposition to give a small amount of phenalenone, although the main product was a complicatedly polymerized mass. The formation of phenalenone indicates that normal diazotization occurred in part.

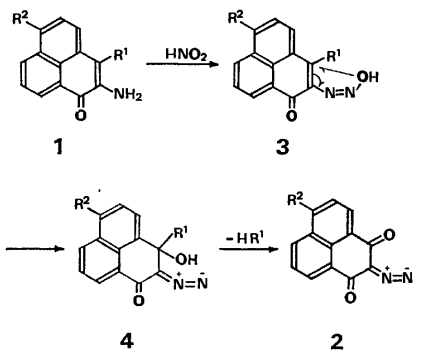
These reactions resemble those of 3-substituted 2-amino-1,4-naphthoquinones. Cajipe *et al.*[2] found that the diazotization of the amino quinones in acetic acid gave 3-diazo-1,2,4(3*H*)-naphthalenetrione. They postulated a reaction mechanism involving the nucleophilic attack of the acetate ion at the 3-position, followed by hydrolysis and the elimination of RH (R=Cl, CH_3O, N_3, and PhS), as is shown in Scheme 2.



Scheme 2.

However, the application of Cajipe's mechanism to the present reaction seems to be less probable, since we did not use acetic acid as a solvent, and even if the nucleophile is the hydroxide ion, the concentration of the hydroxide ion could be extremely low in concentrated hydrochloric acid.

For our reactions, the participation of the diazohydroxide intermediate **3** and a sequent intramolecular rearrangement seem probable, as is outlined in Scheme 3. The existence of a diazohydroxide compound as a transient intermediate has been widely accepted in the diazotization of primary amines.[3] The hydroxyl group of **3** migrates to the 3-position of the phenalene ring, then HR^1 is released to give the diazo diketone **2**. Consistently with the reaction sequences benzenethiol was obtained as another reaction product in the reaction of **1c**. On the same basis, it is understandable that the unsubstituted 2-amino-1*H*-phenalen-



Scheme 3.

1-one **1f** did not give **2**, since the hydroxyl group of the intermediate **3f** can migrate only with difficulty because of the less positive nature of the carbon atom at the 3-position. In addition, even if migration occurs, the intermediate **4f** can not be converted to **2** unless dehydrogenation takes place. There is no possibility of dehydrogenation under the present reaction conditions.

The authers are grateful to Mr. Toshikatsu Sekine and Mr. Minoru Matsuzawa for their technical support.

Experimental

All the melting points are uncorrected. The IR spectra were taken on a JASCO IRA-1 spectrophotometer, while the UV spectrum was recorded on a Hitachi EPS-3T spectrophotometer. The NMR spectra were recorded with a JEOL JNM-PS-100 spectrometer (100 MHz), with TMS as the internal standard. The mass spectra were obtained at 70 eV using a Hitachi RMU-7M spectrometer.

*2-Amino-3-bromo-1*H*-phenalen-1-one (**1a**)* (mp 187—188.5 °C) and *2-amino-3,6-dibromo-1*H*-phenalen-1-one (**1d**)* (mp 213—215 °C) were prepared by the methods described in a previous paper.[4]

*2-Amino-3-chloro-1*H*-phenalen-1-one (**1b**).* Into 30 ml of a vigorously stirred solution of 2-amino-1*H*-phenalen-1-one[4] (0.50 g) in chlorobenzene we added, portion by portion, a chlorine solution in carbon tetrachloride containing 0.20 g of chlorine at 50 °C. After 30 min, a yellow precipitate was collected and washed with carbon tetrachloride. The free base was obtained by the treatment of the solid salt with a sodium carbonate aqueous solution. Red crystals of mp 214 °C (methanol) was obtained in a 36% yield. IR (KBr) 3467, 3347 (N-H) and 1622 cm^{-1} (C=O); NMR (DMSO-d_6) δ=7.95—7.52 (4H, m), 8.32 (1H, d, J=8 Hz), 8.46 (1H, d, J=8 Hz). Found: C, 67.76; H, 3.49; N, 6.12; Cl, 15.82%. Calcd for $C_{13}H_8ONCl$: C, 67.98; H, 3.51; N, 6.10; Cl, 15.44%.

*2-Amino-3-(phenylthio)-1*H*-phenalen-1-one (**1c**).* The solution of 2-amino-3-bromo-1*H*-phenalen-1-one (1.37 g) in 80 ml of an ethanol–dioxane mixture (2:1) was added by an ethanolic solution of sodium benzenethiolate which had been prepared from 1.10 g of benzenethiol and sodium methoxide; the mixture was then refluxed for 4 h. After the removal of a small amount of dark powder by filtration, the solution was concentrated to give 0.96 g of reddish brown crystals (63%); mp 147.5—149 °C. MS *m/e* 303 (M^+); IR (KBr) 3470, 3360 (N-H), and 1635 cm^{-1} (C=O); NMR (DMSO-d_6) δ=7.07—7.14 (5H, m), 7.48 (1H, t, J=7 Hz), 7.77 (1H, t, J=6 Hz), 7.82 (1H, d, J=6 Hz), 7.98 (1H, d, J=6 Hz), 8.32 (1H, d, J=7 Hz), and 8.51 (1H, d, J=7 Hz).

Found: C, 75.68; H, 4.31; N, 4.54; S, 10.32%. Calcd for $C_{19}H_{13}ONS$: C, 75.22; H, 4.32; N, 4.62; S, 10.57%.

*2-Diazo-1*H*-phenalene-1,3(2*H*)-dione (**2**).* Finely ground 2-amino-3-bromo-1*H*-phenalen-1-one (2.00 g) was added, portion by portion, to 20 ml of concentrated hydrochloric acid, after which we added 2.00 g of sodium nitrite dissolved in minimum volume of water; the mixture was then stirred at 5 °C for 1 h and allowed stand overnight. A yellow-brown solid was collected and washed with dilute aqueous ammonia and then with water. Recrystallization from benzene gave 1.05 g (65%) of **2** as pale yellow crystals of mp 197—199 °C dec. (lit,[1] mp 191—195 °C). MS *m/e* 222.0434 (M^+, Δ=0.5 m mass unit), 194.0041 (M^+−28, $-N_2$), and 166.0418 (M^+−56, -CO) IR (KBr) 2230, 2160 (N_2), and 1635 cm^{-1} (C=O); NMR ($CDCl_3$) δ=7.66 (2H, t, J=7 Hz), 8.12 (2H, d, J=7 Hz), 8.48 (2H, d, J=7 Hz); UV (λ_{max}^{EtOH}, nm, log ε) 235.5 (4.82), 298 (4.08), and 338 (4.05). Found: C, 69.91 H, 2.55; N, 12.11%. Calcd for $C_{13}H_6O_2N_2$: C, 70.27; H, 2.72; N, 12.61%.

Similar reactions on **1b**, **1c**, and **1e** afforded **2**, as is shown in Table 1. The addition of the diazotized reaction mixture to phosphinic acid did not affect the yields of diazo diketone.

In a run of the reactions on **1c**, benzenethiol was obtained besides **2**. The reaction mixture was filtered and washed with diethyl ether. The filtrate and washings were combined, and the solution was extracted with diethyl ether. The subsequent removal of the solvent left an oil, which was determined to be benzenethiol by a comparison of its IR and GLC with those of an authentic specimen (15% crude yield).

*6-Bromo-2-diazo-1*H*-phenalene-1,3(2*H*)-dione (**2d**).* Orange yellow crystals (benzene); mp 194—195.5 °C dec; MS *m/e* 302 (M^+); IR (KBr) 2230, 2150 (N_2), and 1644 cm^{-1} (C=O); NMR (pyridine-d_5) δ=7.81 (1H, t, J=9 Hz), 8.07 (1H, d, J=9 Hz), 8.39 (1H, d, J=9 Hz), 8.50 (1H, d, J=8 Hz), and 8.56 (1H, d, J=8 Hz). Found: C, 51.53; H, 1.67; N, 9.01; Br, 25.95%. Calcd for $C_{13}H_5O_2N_2Br$: C, 51.85; H, 1.67; N, 9.31; Br, 26.54%.

Conversion of Quassin into 15β-[(*E*)-3,4-Dimethyl-2-pentenoyloxy]quassin. A *D*-Ring Analog of Bruceantin

Tatsushi MURAE and Takeyoshi TAKAHASHI*

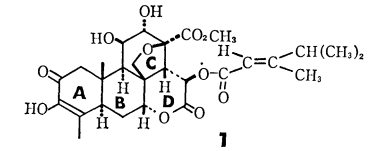
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 29, 1980)

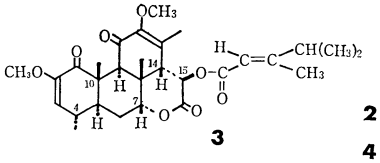
Synopsis. Quassin was transformed in five steps into 15β-[(*E*)-3,4-dimethyl-2-pentenoyloxy]quassin.

Bruceantin (**1**), a simaroubolide isolated from *Brucea antidysenterica* MILL., has been described to be a potent antileukemic tumor inhibitor, the importance of the α,β-unsaturated ester grouping for the antitumor activity of **1** being pointed out.[1] This paper deals with a conversion of quassin (**2**)[2] into its 15β-[(*E*)-3,4-dimethyl-2-pentenoyloxy] derivative (**3**), having the *D*-ring moiety of bruceantin (**1**).

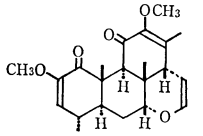
Quassin (**2**) has been transformed, *via* neoquassin (**4**)[2,3] and anhydroneoquassin (**5**),[4] into hydroxyneoquassin (**6**) and hydroxyquassin (**7**) both in low yields, the configuration of the hydroxyl group at C-15 being undetermined for **6** and **7**.[2a] Synthesis of **3** starting from **2** was carried out as follows.



1



3



5

	R^1	R^2
2	H_2	O
4	H_2	OH, H
6	ξ-OH, ξ-H	OH, H
6a	β-OH, α-H	OH, H
7	ξ-OH, ξ-H	O
7a	β-OH, α-H	O

When quassin (**2**) was reduced with 1 equivalent mole of sodium borohydride in ethanol or 3 equivalent moles of diisobutylaluminium hydride in benzene, neoquassin (**4**) was obtained almost quantitatively. Treatment of **4** with hexamethylphosphoric triamide under reflux gave anhydroneoquassin (**5**) in 80% yield. The unsaturated ether (**5**) was oxidized with osmium(VIII) oxide in pyridine and then treated with sodium hydrogensulfite to give 15β-hydroxyneoquassin (**6a**) in 91% yield. On oxidation with silver(I) oxide, **6a** gave 15β-hydroxyquassin (**7a**) in 55% yield. In the ^{1}H-NMR spectrum of **7a**, the coupling constant between the C-14 and C-15 protons was observed to be 11 Hz. Thus the C-15 hydroxyl group was shown to be in a β-configuration for both **6a** and **7a**. By the improved procedure described above, 15β-hydroxyquassin (**7a**) was prepared from quassin (**2**) in *ca.* 40% yield.

Finally, acylation of **7a** gave 15β-[(*E*)-3,4-dimethyl-2-pentenoyloxy]quassin (**3**) in 83% yield. Inhibitory effect (ID_{50}) against growth of HeLa cells was 150 μg/ml for **3**. Further modification of the quassin molecule would be required for exhibition of strong activity.

Experimental

Melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and are uncorrected. High resolution mass spectra were measured with a JEOL JMS-D300 mass spectrometer. Other details are the same as described previoulsy.[5]

Reduction of Quassin (2) with Sodium Borohydride or Diisobutylaluminium Hydride. Quassin (**2**)[2] was isolated from *Picrasma ailanthoides* PLANCHON according to the procedure of Murae *et al.*[6] Sodium borohydride (38 mg, 1 mmol) was added to a solution of quassin (**2**) (388 mg, 1 mmol) in ethanol (50 ml), and the mixture was stirred at room temperature for 3.5 h. After addition of a few drops of acetic acid, the solvent was removed to give a residue. This was extracted with dichloromethane after addition of water. The organic solution was washed with brine, dried (Na_2SO_4) and evaporated, giving **4** (386 mg) in 99% yield as a colorless solid. Crystallization from a mixture of dichloromethane and ether gave colorless needles, mp 230.5—231 °C, identical with an authentic specimen of neoquassin (**4**).[2a,7]

Diisobutylaluminium hydride (22 mg, 0.15 mmol) in dry tetrahydrofuran (0.5 ml) was added to a solution of quassin (**2**) (20 mg, 0.05 mmol) in dry benzene (2 ml), and the mixture was stirred under nitrogen atmosphere at room temperature for 1 h. The reaction mixture was treated in the usual way to give a product (19 mg) in 95% yield identical with neoquassin (**4**).

Dehydration of Neoquassin (4). A mixture of neoquassin (**4**) (67 mg) and hexamethylphosphoric triamide (0.9 ml) was heated under reflux for 5 min. The reaction mixture was poured into a mixture of chloroform (20 ml) and brine (30 ml). The chloroform solution was separated, and the aqueous layer was extracted twice with chloroform (each 20 ml). The combined chloroform solution was dried (Na_2SO_4) and evaporated to give a residue, which was chromatographed on a column of silica gel (50 g). Elution with ether gave **5** (51.3 mg) in 80% yield. Crystallization from a mixture of chloroform and ether gave **5** as colorless prisms, mp 191—192 °C, IR (Nujol) 1705, 1668, 1643, and 1630 cm^{-1}, no absorption due to hydroxyl group; ^{1}H-NMR ($CDCl_3$) δ 1.11 (3H, d, J=7 Hz), 1.17 (3H, s), 1.59 (3H, s), 1.88 (3H, s), 3.12 (1H, s), 3.59 (3H, s), 3.63 (3H, s), 3.81 (1H, t, J=2 Hz), 4.59 (1H, dd, J=6 and J=2 Hz), 5.30 (1H, d, J=2 Hz), and 6.45 (1H, dd, J=6 and J=3 Hz). Found: *m/e* 372.1927. Calcd for $C_{22}H_{28}O_5$: M, 372.1935. The product was found to be identical with an authentic sample of anhydroneoquassin (**5**).[2a]

15β-Hydroxyneoquassin (6a). A solution of anhydroneoquassin (**5**) (496 mg) in pyridine (20 ml) was treated with osmium(VIII) oxide (369 mg) at room temperature for 4 h. After addition of a solution of sodium hydrogensulfite (1 g) in a mixture of water (40 ml) and pyridine (30 ml), the reaction mixture was extracted with chloroform. The chloroform solution was washed with water (30 ml) and brine (30 ml), dried (Na_2SO_4) and evaporated to give

6a (495 mg) in 91% yield. 15β-Hydroxyneoquassin (**6a**): amorphous solid; IR (Nujol) 3450, 1680, and 1632 cm^{-1}; UV (EtOH) λ_{max} 258 nm (ε 10100); ^{1}H-NMR ($CDCl_3$) δ 1.06 (3H, s), 1.07 (3H, d, J=6 Hz), 1.43 (1.5H, s), 1.46 (1.5H, s), 1.51 (3H, s), 3.18 (0.5H, s), 3.23 (0.5H, s), 3.53 (1.5H, s), 3.55 (1.5H, s), 3.65 (3H, s), 4.50 (0.5H, broad d, J=7.5 Hz), 5.19 (0.5H, d, J=4 Hz), and 5.26 (1H, d, J=2 Hz). Found: *m/e* 406.1963. Calcd for $C_{22}H_{30}O_7$: M, 406.1990. The hemiacetal (**6a**) of a neoquassin type exists as a mixture of diastereomers at C-16.

Oxidation of **5** was attempted with potassium permanganate to form **6** and **7**,[2a] but no consistent result was obtained due to the complicatedness of the reaction. Direct comparison of **6a** with **6** was not carried out.

15β-Hydroxyquassin (7a). 15β-Hydroxyneoquassin (**6a**) (444 mg) was dissolved in ethanol (20 ml) and water (15 ml), and treated with freshly prepared silver(I) oxide (1.4 g) under reflux for 19 h. The warm mixture was filtered through Celite, the solid on Celite being washed with methanol (50 ml). The filtrate and washings were combined and concentrated to a volume of 20 ml. This was extracted with chloroform. The chloroform solution was treated in the usual way to give a residue (408 mg), which was chromatographed on a column of silica gel (50 g). Elution with a mixture of benzene and acetone (7:3) gave **7a** (241 mg) in 55% yield. 15β-Hydroxyquassin (**7a**): mp 256—258 °C (crystallized from a mixture of ethyl acetate and light petroleum); IR (Nujol) 3490, 1740, 1699, 1681, and 1632 cm^{-1}; UV (MeOH) λ_{max} 257 nm (ε 10500); ^{1}H-NMR ($CDCl_3$) δ 1.12 (3H, d, J=7 Hz), 1.21 (3H, s), 1.52 (3H, s), 2.09 (3H, s), 2.41 (1H, d, J=11 Hz), 3.05 (1H, s), 3.59 (3H, s), 3.69 (3H, s), 4.35 (1H, m), 4.49 (1H, d, J=11 Hz), and 5.31 (1H, d, J=2 Hz). Found: *m/e* 404.1813. Calcd for $C_{22}H_{28}O_7$: M, 404.1832. Direct comparison of **7a** with **7**[2a] was not carried out.

(E)-3,4-Dimethyl-2-pentenoyl Chloride. Ethyl (*E*)-3,4-dimethyl-2-pentenoate was prepared according to the procedure of Jorgenson and Leung.[8] Potassium hydroxide (1 g) was added to a solution of ethyl (*E*)-3,4-dimethyl-2-pentenoate (2 g) in ethanol (10 ml), and the mixture was treated in the usual way to give an acid (1.5 g) in 91% yield. (*E*)-3,4-Dimethyl-2-pentenoic acid: a colorless oil, bp 114 °C/2.4 kPa; IR (neat) 3050 (broad), 1690, and 1619 cm^{-1}; ^{1}H-NMR (CCl_4) δ 1.10 (6H, d, J=7 Hz), 2.13 (3H, broad s), and 5.67 (1H, broad s). Found: *m/e* 128.0845. Calcd for $C_7H_{12}O_2$: M, 128.0837.

A mixture of carboxylic acid (1.5 g) and thionyl chloride (2.4 g) was heated under reflux for 1 h. The reaction mixture was distilled under reduced pressure giving an acid chloride (0.89 g) in 52% yield. (*E*)-3,4-Dimethyl-2-pentenoyl chloride: bp 70—72 °C/2.7 kPa; IR (neat) 1780 cm^{-1}. The acid chloride was used immediately for the following acylation.

15β-[(E)-3,4-Dimethyl-2-pentenoyloxy]quassin (3). A mixture of 15β-hydroxyquassin (**7a**) (100 mg) and (*E*)-3,4-dimethyl-2-pentenoyl chloride (1.5 g) in the presence of potassium carbonate (450 mg) was heated with stirring at 100 °C for 30 min. After addition of dichloromethane (10 ml), the reaction mixture was filtered and evaporated to give a residue, which was subjected to purification by dry column chromatography [18 g of silica gel; eluted with a mixture of light petroleum and ether (1:1) (240 ml) and then ether (180 ml)]. The fractions eluted with ether were combined and the solvent was removed to afford an ester (**3**) (106 mg) as a colorless solid in 83% yield. 15β-[(*E*)-Dimethyl-2-pentenoyloxy]quassin (**3**): mp 219—223 °C (crystallized from a mixture of benzene and light petroleum), $[\alpha]_D^{28}$ +152° (*c* 0.73, $CHCl_3$), IR (Nujol) 1753, 1718, 1702, 1690, 1635, and 1628 cm^{-1}, no absorption due to hydroxyl group; UV λ_{max} (MeOH) 226 nm (ε 19300) and 252 nm (ε 14800; shoulder); ^{1}H-NMR ($CDCl_3$) δ 1.10 (6H, d, J=6 Hz), 1.13 (3H, d, J=6 Hz), 1.22 (3H, s), 1.56 (3H, s), 1.92 (3H, s), 2.17 (3H, d, J=1 Hz), 2.63 (1H, d, J=10 Hz), 3.05 (1H, s), 3.60 (3H, s), 3.70 (3H, s), 4.55 (1H, m), 5.15 (1H, d, J=10 Hz), 5.31 (1H, d, J=2.5 Hz), and 5.80 (1H, broad s). Found: *m/e* 514.2511. Calcd for $C_{29}H_{38}O_8$: M, 514.2566. The fragment ion peak due to a loss of 3,4-dimethyl-2-pentenoic acid was observed at *m/e* 386.1720 as a base peak. Calcd for $C_{22}H_{26}O_6$: M−$C_7H_{12}O_2$, 386.1727.

The authors wish to thank Dr. Wataru Tanaka, Nippon Kayaku Co., for the biological assay.

Synthesis of Thiol Esters by Carboxylic Trichlorobenzoic Anhydrides

Yasuhiro KAWANAMI, Yuichiro DAINOBU, Junji INANAGA, Tsutomu KATSUKI, and Masaru YAMAGUCHI*

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received August 27, 1980)

Synopsis. Thiocarboxylic S-esters were obtained rapidly and in high yields by treating the mixed anhydrides prepared from 2,4,6-trichlorobenzoyl chloride and carboxylic acid, with various types of thiols in the presence of 4-dimethylaminopyridine.

Because of the distinctive properties of thiocarboxylic S-esters as activated esters in synthetic as well as biological reactions, considerable attention has recently been called to the mild and facile preparation of these compounds.[1] Recently we have shown that the combination of carboxylic 2,4,6-trichlorobenzoic anhydrides (**2**) and 4-dimethylaminopyridine[2] are very useful for the preparation of esters from alcohols as well as for macrocyclic lactonizations.[3] Now we wish to describe the synthesis of thiol esters using the same mixed anhydrides.

When the solutions prepared by mixing 2,4,6-trichlorobenzoyl chloride (**1**),[4] carboxylic acid and triethylamine in dichloromethane, were treated with thiols under the presence of 4-dimethylaminopyridine, the corresponding thiol esters were obtained in good yields. The reaction proceeded rapidly, and was usually completed within 30 min at room temperature. The results are summarized in Table 1.

$$R^1COOH + 2,4,6\text{-}Cl_3C_6H_2COCl \xrightarrow{Et_3N} \underset{\mathbf{1}}{} \quad 2,4,6\text{-}Cl_3C_6H_2COOCOR^1 \quad \underset{\mathbf{2}}{}$$

$$\mathbf{2} + R^2SH \xrightarrow[CH_2Cl_2]{\text{4-dimethylaminopyridine}} R^1COSR^2$$

As can be seen from these results, aliphatic, aromatic or heterocyclic thiol esters could be smoothly prepared. The sterically crowded thiol esters such as *S-t*-butyl 2,2-dimethylpropanethioate (entry 3, Table 1) were also prepared in good yields. Methyl hydrogen meso-2,4-dimethylglutarate was converted into the corresponding 2-methyl-2-propanethiol ester without any detectable epimerization (GLPC, entry 7).

When dimethylaminopyridine was replaced by pyridine or triethylamine, the reaction became very slow and, for example, only 3—4% of *S-t*-butyl 2-methylpentanethioate was formed after 1 h (*cf.* entry 2). Though the aromatic hydrocarbons such as benzene or toluene, were the best solvent for the esterification by the same reagents,[3] dichloromethane was the most effective solvent in the present thiol esterification. Acetonitrile or DMF was much less satisfactory.

The possibility of nucleophilic attack on the undesired carboxyl site is inherent to the mixed anhydride method. For example, when carboxylic pivalic anhydrides which have been sometimes used in peptide[5] or ketone synthesis,[6] were treated with 2-methyl-2-propanethiol or benzenethiol in the presence of 4-dimethylaminopyridine under the similar conditions, both the carboxyl sites were attacked as shown in Eqs. 1, 2, and 3. In the present method, however, thiol attacked exclusively on the desired carboxyl carbon except for one case where sterically crowded pivalic acid was converted into its benzenethiol ester (entry 5, Table 1).[7]

$$\begin{array}{l} C_6H_5COOCOC(CH_3)_3 \\ + \\ HSC(CH_3)_3 \end{array} \xrightarrow[\text{rt, 10 h}]{\text{DMAP (1 eq)}} \begin{array}{ll} C_6H_5COSC(CH_3)_3 & 60\% \\ + & \\ (CH_3)_3CCOSC(CH_3)_3 & 15\% \end{array} \quad \text{(GLPC)} \qquad (1)$$

$$\begin{array}{l} CH_3(CH_2)_2COOCOC(CH_3)_3 \\ + \\ HSC_6H_5 \end{array} \xrightarrow[\text{rt, 10 min}]{\text{DMAP (1 eq)}} \begin{array}{ll} CH_3(CH_2)_2COSC_6H_5 & 48\% \\ + & \\ (CH_3)_3CCOSC_6H_5 & 43\% \end{array} \quad (^1\text{H-NMR}) \qquad (2)$$

$$\begin{array}{l} (CH_3)_2CHCOOCOC(CH_3)_3 \\ + \\ HSC_6H_5 \end{array} \xrightarrow[\text{rt, 10 min}]{\text{DMAP (1 eq)}} \begin{array}{ll} (CH_3)_2CHCOSC_6H_5 & 48\% \\ + & \\ (CH_3)_3CCOSC_6H_5 & 38\% \end{array} \quad (^1\text{H-NMR}) \qquad (3)$$

The use of symmetrical anhydrides[8] or mixed anhydrides with phosphoric acid derivatives[9] has been reported for the synthesis of thiol esters. The main advantage of the present method is the rapidness and the mildness of the reaction, high yields, and the wide applicability.

Experimental

The preparation of *S-t*-butyl 2-methylpentanethioate (entry 2, Table 1) is described below as a typical example of the present thiol esterifications.

2,4,6-Trichlorobenzoyl chloride (80 μl, 0.5 mmol) was added to a stirred mixture of 2-methylpentanoic acid (63 μl, 0.5 mmol), triethylamine (70 μl, 0.5 mmol), and dichloromethane (0.8 ml). After 1 h, the reaction mixture was filtered through a dry celite column. To the filtrate were added 2-methyl-2-propanethiol (56.4 μl, 0.5 mmol) and 4-dimethylaminopyridine (61 mg, 0.5 mmol) and the mixture was stirred at room temperature. GLPC analysis showed the quantitative formation of the thiol ester after 30 min. The reaction mixture was diluted with ether, washed successively with 5% aqueous phosphoric acid, a saturated sodium hydrogencarbonate solution, and brine, dried with sodium sulfate, and distilled at 80 °C/15 mmHg[10] (bath temperature) giving *S-t*-butyl 2-methylpentanethioate in 86.3% yield.

This work was partially supported by a Grant-in-Aid for Scientific Research No. 443008 from the Ministry of Education, Science and Culture.

7) The thiol esterification of pivalic acid with benzenethiol by the present method is peculiar in that the reaction with triethylamine or morphorine in place of dimethylaminopyridine gives a quite similar result as that with dimethylaminopyridine in rate, yield, and product distribution. This indicates that the reaction presumably involves the direct attack of thiolate ion formed by the bases, on the mixed anhydride. Benzenethiol is much more acidic than the aliphatic thiols.

A Simple Method for the Synthesis of Exaltolide

Toshio SATO, Tatsuo KAWARA, Yasuchika KOKUBU, and Tamotsu FUJISAWA*

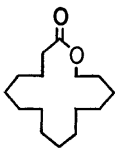
Chemistry Department of Resources, Mie University, Tsu, Mie 514

(Received September 8, 1980)

Synopsis. Copper-catalyzed reaction of β-propiolactone with 12-methoxydodecylmagnesium bromide, derived from 1,12-dodecanediol, gives 15-methoxypentadecanoic acid in a high yield, which is easily converted into exaltolide.

15-Pentadecanolide (exaltolide, **1**) is a component of the root oil of *Archangelica officianalis* Syn., which is known as a perfume of the most strong and elegant musk-like fragrance in the series of macrocyclic lactones. Among the numerous synthetic methods for exaltolide so far reported, the most common one is the cyclization of 15-hydroxy- or 15-bromopentadecanoic acid. These acids have been usually prepared from long-chain carboxylic acids arising from several plant oils, such as (*Z*)-13-docosenoic acid (erucic acid)[1] from rapeseed oil, 9,10,16-trihydroxyhexadecanoic acid (aleuritic acid)[2] from the resin of schellac, or 10-undecenoic acid from castor oil.[3] Recently cyclododecanone has been frequently used as a useful starting material of C_{12} unit because of easy availability from butadiene trimer, and various routes to exaltolide have been elaborated by C_3 extention of cyclododecanone.[4] A short-step synthesis of exaltolide (**1**) *via* 15-bromopentadecanoic acid (**4**) was investigated from easily available starting materials of β-propiolactone (**2**) and 1,12-dodecanediol (**3**).

In this route, the regioselective reaction of β-propiolactone with a Grignard reagent[5] containing an oxygen functionality was applied as a key step for the synthesis of exaltolide, *i.e.*, the three carbon homologation terminating in a carboxyl function was easily achieved by the copper catalyzed reaction of 12-methoxydodecylmagnesium bromide (**6**) with the lactone **2** to furnish 15-methoxypentadecanoic acid (**5**) which was smoothly converted into **4**. Thus, to a mixture of



1

$HO(CH_2)_{12}OH$

3

$X(CH_2)_{14}CO_2H$
4 X=Br
5 X=MeO

$MeO(CH_2)_{12}Y$
6 Y=MgBr
7 Y=OH
8 Y=Br

the lactone **2** (1 equiv) and copper(I) iodide (0.02 equiv) in THF–Me_2S (8:1) was added **6** (1 equiv) at 0 °C. After the reaction mixture was stirred at 0 °C for 3 h, the desired acid **5** was obtained in a yield of 99%. Treatment of **5** with excess boron tribromide in CH_2Cl_2 at −25 °C for 4 d gave 15-bromopentadecanoic acid (**4**) in 78% yield. Then, according to the method of Mandolini *et al.*,[6] the ω-bromo acid was treated with potassium carbonate in dimethyl sulfoxide at 75 °C to furnish exaltolide (**1**) in 78% yield.

The Grignard reagent **6** of C_{12} unit was easily derived from the diol **3**. Chipped sodium was slowly added to an excess of **3** at 100 °C and then dimethyl sulfate was added dropwise. After stirring for 2 h at 120 °C, 12-methoxy-1-dodecanol (**7**) was obtained quantitatively. Bromination of **7** with phosphorus tribromide and pyridine at room temperature for 2 d gave 1-bromo-12-methoxydodecane (**8**) in a yield of 65%, which was easily transformed into the Grignard reagent **6** by the reaction with magnesium metal in refluxing ether.

As mentioned above, by the use of the regioselective reaction of the Grignard reagent of an oxygen functionality with β-propiolactone in the presence of a copper(I) catalyst, exaltolide was conveniently synthesized from the easily available materials.

Experimental

The IR spectra were recorded on a Hitachi EPI-G2 spectrometer. The NMR spectra were taken with a Varian A-60 spectrometer using TMS as an internal standard. All boiling points and melting points are uncorrected.

12-Methoxy-1-dodecanol (7). Chipped sodium (0.744 g, 31 mg atom) was slowly added to 1,12-dodecanediol (25 g, 124 mmol) at 100 °C. After the sodium was dissolved, dimethyl sulfate (3.9 g, 31 mmol) was added dropwise at 120 °C and the mixture was stirred for 2 h. The reaction mixture was cooled to room temperature, quenched with water and extracted with chloroform. The extracts were dried over anhydrous $MgSO_4$. The solvent was removed and the residue was extracted with hexane. Distillation of the hexane solution gave **7** (6.9 g, quant.): bp 120—124 °C/0.8 mmHg; IR (KBr) 3300 (OH) and 1120 cm^{-1} (C-O); NMR (CCl_4) δ 1.10—1.78 (20H, broad), 3.12—3.60 (5H, m), and 3.20 (3H, s).

1-Bromo-12-methoxydodecane (8). To a mixture of phosphorus tribromide (3.10 g, 11.4 mmol) and pyridine (0.048 g, 0.61 mmol) in dry ether (5 ml) was added dropwise **7** (7.45 g, 34.4 mmol) in pyridine (0.160 g, 2.02 mmol) at −20 °C. The reaction mixture was stirred at room temperature for 2 d. Hydrochloric acid (1 M) was added and the mixture was extracted with ether. The extracts were washed with 5% sodium hydrogencarbonate solution and dried over anhydrous $MgSO_4$. After removal of the solvent, distillation afforded **8** (6.24 g, 65%): bp 114—119 °C/0.5 mmHg; IR (KBr) 1120 (C-O), 645 and 560 cm^{-1} (C-Br); NMR (CCl_4) δ 1.3 (20H, m) and 3.12—3.60 (4H, m), 3.20 (3H, s).

15-Methoxypentadecanoic Acid (5). 12-Methoxydodecylmagnesium bromide (**6**) was prepared from magnesium (1.17 g, 48 mmol) and **8** (6.19 g, 22 mmol) in ether (24 ml), which was titrated by Eastham's method[6] (0.547 M, 74%).

To a THF (4 ml) solution of copper(I) iodide (3.8 mg, 0.02 mmol), dimethyl sulfide (0.5 ml) and β-propiolactone (72.2 mg, 1.00 mmol) was added the Grignard reagent **6** (0.55 ml, 1.01 mmol) at 0 °C. The reaction mixture was

stirred for 3 h, quenched with water and then made basic with 3 M aqueous sodium hydroxide solution. The white precipitate was filtered and the filtrate was washed with ether. The water layer was acidified with 6 M hydrochloric acid. The solid was dissolved in this acidic solution, which was extracted with ether. The extracts were dried over anhydrous $MgSO_4$ and the solvent was evaporated to afford **5** (268 mg, 99%): mp 47—48 °C; IR (KBr) 3300—2500, 1700 (CO_2H), and 1125 cm^{-1} (C-O); NMR (CCl_4) δ 1.10—1.72 (24H, m), 2.20 (2H, t, J=7 Hz), 3.20 (3H, s), 3.23 (2H, t, J=7 Hz), 9.20 (1H, s).

15-Bromopentadecanoic Acid (4). To a solution of **5** (0.234 g, 0.86 mmol) in dry CH_2Cl_2 (4 ml) was added dropwise boron tribromide (0.870 g, 3.47 mmol) in dry CH_2Cl_2 at −78 °C and the reaction mixture was stirred for 30 min. The solution was warmed to −25 °C and allowed to stand for 4 d. Sodium hydrogencarbonate (2.60 g, 3.09 mmol) was added at −25 °C. The mixture was then acidified with 3 M hydrochloric acid and extracted with ether. The extracts were dried over anhydrous $MgSO_4$. Removal of the solvent gave **4** (0,215 g, 78%): mp 66—67 °C (lit,[8] 66 °C); IR (KBr) 3500—2400, 1700 (CO_2H) and 650 cm^{-1} (C-Br); NMR (CCl_4) δ 1.20—2.00 (24H, m), 2.30 (2H, t, J=7 Hz), and 9.50 (1H, s).

Exaltolide (1). To a suspension of powdered potassium carbonate (0.563 g, 4.08 mmol) in dimethyl sulfoxide (11 ml) was added dropwise **4** (0.321 g, 1.00 mmol) in dimethyl sulfoxide (5 ml) at 75 °C in 4 h under vigorous stirring. After the mixture was cooled to room temperature, cold water (10 ml) was added and resulting mixture was extracted with hexane. The extracts were dried over anhydrous $MgSO_4$ and the solvent was evaporated. The crude product was purified by TLC on silica gel (hexane:ether=8:1) to afford **1** (0.189 g, 78%): mp 32 °C (lit,[1] 32 °C); IR (KBr) 1735 cm^{-1} (C=O); NMR (CCl_4) δ 1.00—2.00 (26H, m), 2.17 (2H, t, J=7 Hz), and 3.93 (2H, t, J=5 Hz). The spectral data were identical with those of an authentic sample.

The present work was partially supported by a Grant-in-Aid for Scientic Research No. 554144 from the Ministry of Education, Sciene and Culture.

(Received September 26, 1980)

Synopsis. The convenient methods for the synthesis of 4-sydnonylmethyl acetates from *N*-(4-sydnonylmethyl)morpholines, 4-sydnonylmethanols, or bis(4-sydnonylmethyl) ethers are described.

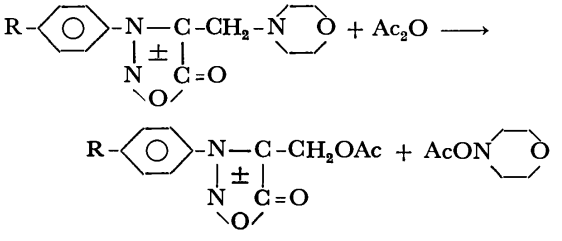
Sydnones are typical mesoionic compounds and their chemical, physical, and biological properties are peculiar.[1] Generally, a sydnone ring is unstable to acid, alkali, and heat. Therefore, reaction conditions for the synthesis of sydnone compounds are considerably limited. For instance, no method to introduce electron-releasing groups, such as amino, hydroxyl, and alkoxy groups, into the 4-position of the sydnone ring has been found. It seems to be possible to substitute the 4-position by these groups in interposition of a methylene group. Imashiro and Masuda[2] synthesized many kinds of 4-sydnonylmethylamines and found that some of them have a biological activity. We also found the synthetic method of 4-sydnonylmethanols and bis(4-sydnonylmethyl) ethers.[3] Screening tests of some biological activities of these 4-sydnonylmethyl compounds are in progress.

We aim at synthesizing new derivatives of 4-sydnonylmethyl compounds, especially 4-sydnonylmethyl acetates in this work. The 4-sydnonylmethyl acetates may have a characteristic biological activity different from those of the previously synthesized 4-sydnonylmethyl compounds. The expectation of such a biological activity and an interest in reactivities of the 4-sydnonylmethyl compounds inspired us to develop the synthetic method of 4-sydnonylmethyl acetates.

For this purpose, three kinds of 4-sydnonylmethyl compounds, of which preparative methods had been reported,[2,3] were examined as starting compounds for the 4-sydnonylmethyl acetates.

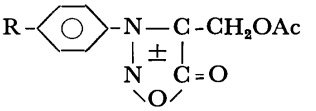
The first attempt to synthesize the 4-sydnonylmethyl acetates was led by the reaction of *N*-(4-sydnonylmethyl)morpholines, which were prepared by the modified method of Imashiro and Masuda,[2] with acetic anhydride(Method A).

Method A:



As shown in Table 1, though the desired 4-sydnonylmethyl acetates could be obtained, their yields were not high even in high reaction temperature and long reaction time. Since a sydnone ring is generally unstable as described above, mild conditions should be desirable in the synthesis of sydnone compounds.

Table 1. Synthesis of 4-sydnonylmethyl acetates

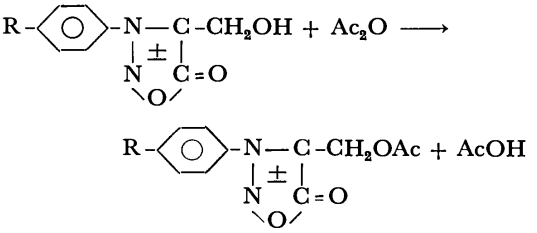


R	Method	Temp/°C	Time/min	Yield[a]/%
H	A	90—100	480	48
CH_3	A	90—100	480	42
Br	A	90—100	480	47
H	B	30	4	76
CH_3	B	30	4	81
Br	B	30	4	84
H	C	30	5	71
CH_3	C	30	5	80
Br	C	30	5	81

a) After purification.

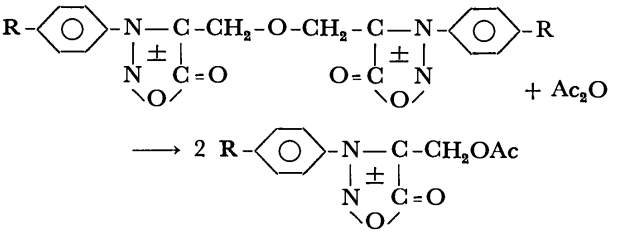
The second attempt was done by acetylating directly 4-sydnonylmethanols[3] with acetic anhydride in the presence of a catalytic amount of sulfuric acid and was successful as expected. The acetylation was completed within a few minutes at room temperature (about 30 °C) and the 4-sydnonylmethyl acetates could be obtained in high yields as shown in Table 1 (Method B).

Method B:



In the synthesis of the 4-sydnonylmethanols, considerable amounts of bis(4-sydnonylmethyl) ethers were formed as a by-product under a reaction condition.[3] The third attempt was the synthesis of the 4-sydnonylmethyl acetates from these ethers (Method C). The ethers also reacted with acetic anhydride in the presence of sulfuric acid to give the corresponding 4-sydnonylmethyl acetates in high yields comparable to those in Method B.

Method C:



The above fact may suggest that the 4-sydnonylmethyl acetates can be efficiently and conveniently obtained from a mixture of the 4-sydnonylmethanols and the bis(4-sydnonylmethyl) ethers, without separation of the each component from mixed products in their syntheses.

In all the methods, the yield of the 4-sydnonylmethyl acetates was not affected by both an electron-releasing group (*p*-CH_3) and an electron-withdrawing one (*p*-Br) attached to the benzene ring of the starting sydnone compounds. This fact may suggest a potentiality of the general application of these methods to the synthesis of a variety of 4-sydnonylmethyl acetates, though few examples were given in the present work.

Experimental

Starting Materials. N-*(4-Sydnonylmethyl)morpholines*: *N*-(3-Phenyl-4-sydnonylmethyl)morpholine was prepared by the method of Imashiro and Masuda.[2] *N*-[3-(*p*-methylphenyl)-4-sydnonylmethyl]morpholine and *N*-[3-(*p*-bromophenyl)-4-sydnonylmethyl]morpholine were newly synthesized according to a similar procedure. The former compound: yield, 72%; appearance, colorless needles; mp, 118—120 °C. IR (KBr): 2810, 1740, 1730, 1240, and 1110 cm^{-1}. MS (70 eV): *m/e* 275 (M^+). Found: C, 61.15; H, 6.24; N, 15.44%. Calcd for $C_{14}H_{17}N_3O_3$: C, 61.09; H, 6.22; N, 15.26%. The latter compound: yield, 77%; appearance, colorless needles: mp, 128—130 °C. IR (KBr): 2830, 1730, 1235, and 1110 cm^{-1}. MS (70 eV): *m/e* 339 (M^+) and 341 (M^+). Found: C, 45.85; H, 4.08; N, 12.54; Br, 23.61%. Calcd for $C_{13}H_{14}N_3BrO_3$: C, 45.90; H, 4.15; N, 12.35; Br, 23.49%.

4-Sydnonylmethanols and Bis(4-sydnonylmethyl) Ethers: 3-Phenyl-4-sydnonylmethanol, 3-(*p*-methylphenyl)-4-sydnonylmethanol, bis(3-phenyl-4-sydnonylmethyl) ether, and bis[3-(*p*-methylphenyl)-4-sydnonylmethyl] ether were prepared by the method of the previous work.[3] 3-(*p*-Bromophenyl)-4-sydnonylmethanol and bis[3-(*p*-bromophenyl)-4-sydnonylmethyl] ether were newly synthesized by a similar method. The former compound: yield, 67%; appearance, colorless powder; mp 161—163 °C. IR (KBr): 3395, 1710, 1245, and 1010 cm^{-1}. MS (70 eV): *m/e* 270 (M^+) and 272 (M^+). Found: C, 39.74; H, 2.62; N, 10.14%. Calcd for $C_9H_7N_2BrO_3$: C, 39.87; H, 2.60; N, 10.34%. The latter compound: yield, 23%, appearance, pale yellow needles; mp, 175—176 °C. IR (KBr): 3080, 1735, 1260, 1250, 1040, and 1000 cm^{-1}. MS (70 eV): *m/e* 253 [1/2(M^+−16)] and 255 [1/2(M^+−16)]. Found: C, 41.19; H, 2.10; N, 10,65%. Calcd for $C_{18}H_{12}N_4Br_2O_5$: C, 41.25; H, 2.31; N, 10.69%.

Synthesis of 4-Sydnonylmethyl Acetates. Typical procedures for the synthesis of the titled compounds are shown below. *Method A*: One gram (3.6 mmol) of *N*-[3-(p-methylphneyl)-4-sydnonylmethyl]morpholine was added into 3 ml of acetic anhydride and the reaction mixture was heated at 90—100 °C in a water bath. After 8 h, the reaction mixture was poured into crushed ice. Recrystallization of the resulting solid from ethanol afforded 0.38 g (1.5 mmol, 42%) of pure 3-(*p*-methylphenyl)-4-sydnonylmethyl acetate as colorless needles. Mp, 129—131 °C. IR (KBr): 3050, 1740, 1230, and 1030 cm^{-1}. MS (70 eV): *m/e* 248 (M^+). NMR (chloroform-*d*): δ 2.06 (s, 3H), 2.52 (s, 3H), 4.91 (s, 2H), and 7.42 (s, 4H) ppm. Found: C, 58.35; H, 4.97; N, 11.30%. Calcd for $C_{12}H_{12}N_2O_4$: C, 58.06; H, 4.87; N, 11.29%.

Method B: One gram (5.3 mmol) of 3-phenyl-4-sydnonylmethanol was added into 3 ml of acetic anhydride containing one drop of sulfuric acid. After 4 min at room temperature, the reaction mixture was poured into crushed ice. Recrystallization of the resulting pale yellow solid from ethanol afforded 0.92 g (4.0 mmol, 76%) of pure 3-phenyl-4-sydnonylmethyl acetate as colorless needles. Mp, 97—98 °C. IR (KBr): 3060, 1750, 1220, and 1020 cm^{-1}. MS (70 eV): *m/e* 234 (M^+). NMR (chloroform-*d*): δ 2.08 (s, 3H), 4.95 (s, 2H), and 7.65 (m, 5H) ppm. Found: C, 56.29; H, 4.19; N, 11.69%. Calcd for $C_{11}H_{10}N_2O_4$: C, 56.41; H, 4.30; N, 11.96%.

Method C: One gram (1.9 mmol) of bis[3-(*p*-bromophenyl)-4-sydnonylmethyl] ether was added into 3 ml of acetic anhydride containing one drop of sulfuric acid. After 5 min at room temperature, the reaction mixture was poured into crushed ice. Recrystallization of the resulting solid from ethanol afforded 0.97 g (3.1 mmol, 81%) of pure 3-(*p*-bromophenyl)-4-sydnonylmethyl acetate as colorless needles. Mp, 88—91 °C. IR (KBr): 3060, 1750, 1215, and 1010 cm^{-1}. MS (70 eV): *m/e* 312 (M^+) and 314 (M^+). NMR (chloroform-*d*): δ 2.10 (s, 3H), 4.95 (s, 2H), and 7.66 (m, 4H) ppm. Found: C, 42.21; H, 2.28; N, 8.84; Br, 25.43%. Calcd for $C_{11}H_9N_2BrO_4$: C, 42.19; H, 2.90; N, 8.95; Br, 25.52%.

(Received August 7, 1980)

Synopsis. Effects of ammonia pre-treatment on catalytic activities of metal halides for the reduction of nitrogen monoxide are investigated in order to obtain highly active catalysts at lower temperatures. By the pre-treatment with NH_3, some supported metal halide catalysts such as $CeCl_2$, $MnCl_2$, $TiCl_4$, $FeBr_3$, and $CuCl_2$, showed higher activities than untreated ones.

Among the various techniques proposed for reducing nitrogen oxides (NO_x) emitted from stationary combustion equipments, the catalytic reduction of nitrogen monoxide (NO) with ammonia (NH_3) has been considered to be one of the most favorable methods.[1-3] In this process, metal oxide supported catalysts such as V_2O_5, CuO, Fe_2O_3, and MoO_3 on γ-Al_2O_3 or TiO_2 have been applied for practical use. They are used at reaction temperatures over 300 °C in order to obtain effective reduction of NO_x. From economical point of view, catalysts active at lower temperatures are desirable since temperatures of flue gases emitted from a coke oven or sintering furnace are lower than 200 °C. The present authors have been trying to develope new type of catalysts having higher activities at temperatures as low as possible. Metal halide catalysts were found to show high activities at temperatures under 200 °C.[4] Another investigation showed that the most favorable electronic state of cations in the catalysts can be obtained by a proper combination of the cation with a counter anion and carrier for high activity.[5] In this work, it was found that supported metal halide catalysts pre-treated with NH_3 show higher activities than those of untreated ones.

Experimental

The catalyst used in this study were prepared by impregnating γ-Al_2O_3 spheres (diam. 1.5 mm, surface area 250 m^2/g, average pore radius 58 Å, alkali content 0.01 wt%) with aqueous solution of metal halides. After the impregnation, the catalysts were dried for 3 h at 120 °C and then for 2 h at 180 °C in air stream. The catalysts were then placed in a glass vessel containing gaseous ammonia for 10 h at room temperature. Activity measurements were carried out using a conventional flow reactor (stainless steel, length 200 mm, diam. 15 mm) under the space velocity of 15000 h^{-1}. As a standard feedstream, the gas mixture consisting of NO 300 ppm, NH_3 400 ppm, O_2 5 vol%, H_2O 9.2 vol%, SO_2 200 ppm, and N_2 balance was used. Analysis of NO and NH_3 were made by means of a chemiluminescence type NO_x analyzer and the chemical method (JIS-K-0099), respectively.

Results and Discussion

The effect of NH_3 pre-treatment on the activity of $CeCl_2$–Al_2O_3 catalyst for the reduction of NO is shown in Fig. 1. In the temperature region lower than 200 °C, $CeCl_2$–Al_2O_3 catalyst treated with ammonia showed higher activity than untreated ones. Figures 2 and 3 show results obtained on $MnCl_2$–Al_2O_3 and $TiCl_4$–Al_2O_3 catalyst, respectively. Though almost no activity was observed on untreated one on $TiCl_4$–Al_2O_3 catalyst, much higher activity was obtained after NH_3 pre-treatment. Similar effects were observed on some supported metal halide catalysts such as $FeBr_3$, and $CuCl_2$ on γ-Al_2O_3. These activities enhanced by NH_3 pre-treatment continued longer

than 3 h.

Metal halides are well known to form metal halide ammonium complexes. The color of each catalyst changed to that of metal halide ammonium complex by NH_3 pre-treatment, indicating that metal halide ammonium complexes were formed on the catalysts. It is also known, however, that ammonium complexes are unstable at temperatures over 100 °C. The activities of the present catalysts pre-treated with NH_3 disappeared when they were heated over 300 °C. A thermogravimetric analysis showed that although the amount of NH_3 in these complexes decreased with the temperature elevated, NH_3 were still remained at temperatures over than 200 °C. These results show that NH_3 coordinates to metal ions in metal halides at lower temperatures, indicating the increase of the concentration of NH_3 available for the reduction of NO on active sites. On the other hand, previous study showed that proper amount of NO adsorption on catalyst is also essential as well as that of NH_3 adsorption for producing highly active state, and that the most favorable electronic state of the cation in the catalyst is required for this purpose.[5] NH_3 coordination is considered to affect on the electronic state of the cation. In fact, the binding energy of Fe $2p_{3/2}$ photoelectron peak on $FeBr_3$–Al_2O_3 catalyst measured by a photoelectron spectrometer(XPS) changed from 711.6 to 711.1 eV after NH_3 pre-treatment. These results will indicate that the enhancement of the activity by NH_3 pre-treatment is mainly due to the improvement of the electronic state of the cation. More research is now needed on such metal halide ammonium complex catalysts to fully understand the mechanism of the enhancement of the catalysts.

Hydration of Quaternary Phosphonium Bromides, $Bu_{4-n}Ph_nPBr$, in Chloroform[1]

Toshiki WAKABAYASHI* and Katsuko TAKAIZUMI
The College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received January 5, 1980)

Studies have been carried out on the hydration of quaternary phosphonium bromides, $Bu_{4-n}Ph_nPBr$($n=0$—4), in the chloroform phase by means of distribution equilibrium and ^1H NMR spectroscopy, in order to clarify the difference between the alkyl- and aryl-substituted ions in ion–water interactions. The hydration constant for these bromides in the chloroform phase increases gradually from Bu_4PBr to Bu_2Ph_2PBr, and then rapidly to $BuPh_3PBr$ and to Ph_4PBr. The free energy of transfer from water to chloroform was evaluated for the non-hydrated species of the phosphonium bromides in the chloroform phase, the lowest being that for Bu_2Ph_2PBr. From ^1H NMR spectra for water in the chloroform phase, it is concluded that the hydrated water molecule is hydrogen bonded with the anion of the onium salts. In the case of phenyl-rich cations such as $BuPh_3P^+$, Ph_4P^+, and Ph_4As^+ the water molecule occupies a site so close to the central atoms that it undergoes diamagnetic effects of phenyl groups. With phenyl-rich cations such hydration will play a certain role in their aqueous solutions.

The ion–water interactions of the so-called hydrophobic ions, considerably large organic ions, have been widely investigated over the past two decades. Differences between the alkyl- and aryl-substituted ions in their interactions with water have been recognized.[2-4] In a similar way to those of hydrocarbons, the interactions of alkyl-substituted ions with water are tentatively explained by the concept of a structure-making effect on the solvent water, though not completely established so far.

On the other hand, with tetraphenyl ions such as Ph_4M^+ (M=P, As, Sb) and BPh_4^-, their interactions with water might be more complicated, due to some effects not present in the case of benzene such as the delocalized charges on the phenyl groups[8,9] and the hydration of the central atoms. Tetraphenyl borate is known to interact with water in a different way from Ph_4M^+ ions.[4-7] The penta-coordinate state of the central atom was suggested for Ph_4As^+ in water, but not for Ph_4P^+, by Orenberg *et al.*[10] who studied laser-Raman spectra. From a study of ^1H NMR for Ph_4M^+ and BPh_4^- ions in various solvents, Coetzee and Sharpe[7] concluded that the screening of the central atoms by essentially flat phenyl rings is not sufficient for elimination of the solvation effects. The effects are related to the failure to classify the ions as structure makers or structure breakers.[12]

An approach to the hydration of aryl-substituted ions would be to examine systematically the ions with mixed substituents of alkyl and aryl groups besides the tetraalkyl and tetraphenyl ions. Only tetraphenyl ions have been used as aryl-substituted ions, with only one exception.[11] A series of studies[13-15] deal with some quaternary phosphonium ions, $Bu_{4-n}Ph_nP^+$.

The hydration of these phosphonium ions might be influenced by two factors: (a) influence on the structure of the solvent water and (b) the interaction between the central atoms and water separated from the bulk of water. The effect of (b) might depend upon the nature of substituents as well as that of the central atom.

The present work was undertaken anticipating that the interaction with water separated from the bulk water would become conspicuous in a system containing water dissolved in a non-aqueous solvent. The methods used in this study are distribution equilibrium and ^1H NMR spectroscopy.

Experimental

Materials. All the phosphonium salts were synthesized from the phosphines except for commercial Ph_4PCl (DOTITE) and Ph_4AsCl. The synthesis, purification and purity of these salts are similar to those reported.[13] Water was redistilled after ion exchange. Chloroform was distilled just before use after being treated with aqueous solution of Na_2CO_3 and then with water. The other chemicals were all of G.R. grade.

Procedure. Distribution equilibria were attained by shaking chloroform solution of known concentration of phosphonium bromide with an equal volume of an aqueous solution of sodium bromide in an air-thermostat, the temperature being regulated to 25±0.5 °C. The concentration of NaBr was 0.08 and/or 0.125 mol dm^{-3}. The initial concentration of the phosphonium salts in chloroform phase was in the range 5×10^{-3}—2×10^{-1} mol dm^{-3}. The shaking time was 45 min, the same results being obtained by shaking for 20 min. The aliquots of the equilibrated chloroform phases were subjected to measurements for water content and ^1H NMR of water in the phase. The aqueous phases were analyzed for phosphonium salts. An aliquot of the aqueous phase was diluted and a part of it was transferred to a neutral aqueous solution containing sodium bromide (0.1 mol dm^{-3}) and Methyl Orange in a large excess in comparison with the phosphonium bromide (below 5×10^{-5} mol dm^{-3}). Phosphonium ion was then extracted into a fresh chloroform phase in a form of 1 : 1 ion-pair with the anion of Methyl Orange. The molar absorption coefficient of the ion-pair at 415 nm is around 2.6×10^5 dm^3 mol^{-1} cm^{-1} in chloroform for all the phosphonium salts examined. Lambert-Beer's law holds. All the phosphonium ions seemed to be almost quantitatively extracted into chloroform. For the sake of confirmation the standard solutions of each phosphonium salt were treated under the same conditions for calibration.

Measurement. The water contents in the chloroform phases were determined by Karl Fischer's method with a Hirama Rika recording automatic titrator.

The ^1H NMR spectra were obtained on a Hitachi R-20 (90MHz) spectrometer, equipped with a temperature controller. All the solutions were measured at 25±0.5 °C with the probe temperature established by a standard methanol calibration. Tetramethyl silane (TMS) was used as an internal standard at a concentration of 0.3% (v/v). The chemical shift for each solution is the mean from a minimum of three scannings for each solution.

Solubility of NaBr in Chloroform. The solubility of NaBr in chloroform was tested as follows: A 50 cm^3 volume

of chloroform was shaken with 0.125 mol dm^{-3} aqueous solution of NaBr, 30 cm^3 of the chloroform phase being separated and evaporated at room temperature in the dark, no residue remained. After adding of 10 cm^3 water titration was carried out with silver nitrate solution. No titrant was consumed.

Results

Water Content in Chloroform Phase. For all the onium salts examined, the water concentration in the organic phase increases linearly with increase in the analytical concentration of a given onium salt in the phase. Examples for Bu_2Ph_2PBr and Ph_4PBr, the ionic strength of aqueous phase being 0.125 (NaBr), are shown in Fig. 1. The linear relation between water concentration in the organic phase and the salt concentration indicates two kinds of water species, (a) free water dissolved in the solvent and (b) hydrated water accompanied by the onium salt. The average hydration number of the phosphonium salt is constant and nearly independent of its concentration in the organic phase. The average hydration number, α, for some onium salts (Table 1) was determined from the slopes of the straight lines in Fig. 1. For both aqueous phases of ionic strength of 0.08 and 0.125, the α values agree with each other within experimental error as expected, since the water activities for both ionic strengths are nearly the same, *i.e.*, 0.997 and 0.996 for aqueous solutions of NaBr of 0.08 and 0.125 mol dm^{-3}, respectively, evaluated from osmotic coefficients of NaBr at 25 °C in water.[16]

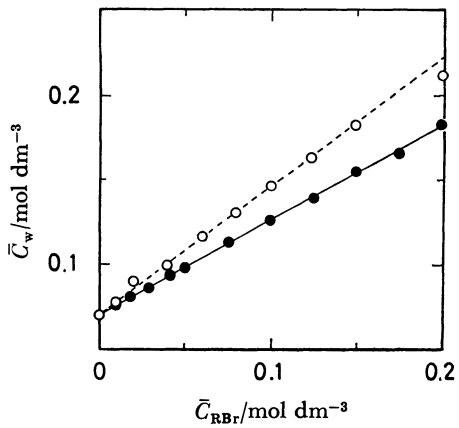

Fig. 1. The water concentration, $\bar{c}_w$, in chloroform phase equilibrated with aqueous phase of an ionic strength of 0.125 (NaBr), as a function of the analytical concentration of phosphonium bromide, $\bar{c}_{RBr}$, in the organic phase, at 25 °C. The open circles are for Ph_4PBr and closed circles, for Bu_2Ph_2Br.

Chemical Shift of Water Proton in Chloroform Phase. Single resonance of water proton is found in the ^{1}H NMR spectra of organic solutions of onium salts equilibrated with aqueous phase. Equilibrium is established in the organic phase between free water and hydrated water through a rapid exchange reaction in the NMR time scale. The observed chemical shifts are obtained for averaged proton by the process

$$H_2O(\text{hydrated}) \rightleftharpoons H_2O(\text{free})$$

and we thus have

$$\delta = x_f\delta_f + x_h\delta_h, \quad (1)$$

where δ is the observed chemical shift, x_f the fraction of the free water, δ_f the chemical shift of free water proton and subscript h refers to the hydrated water.

The chemical shift of free water proton in the presence of phosphonium salt would differ from that in the absence of the salt. The salt effect on the ^{1}H chemical shift can be expressed by

$$\delta_f = \delta_f^\circ + F(\bar{c}), \quad (2)$$

where $F(\bar{c})$ is a function of the gross concentration of a given salt and δ_f° the chemical shift of free water proton in the absence of the salt. In order to understand the F-function, the chemical shifts of water proton in chloroform phase were measured in the presence of hexane, butyl bromide, benzene, and chlorobenzene. The water concentration in these solutions was 0.0665 mol dm^{-3}, the same for all runs, the ratio to water solubility being *ca.* 0.9. The results are shown in Fig. 2.

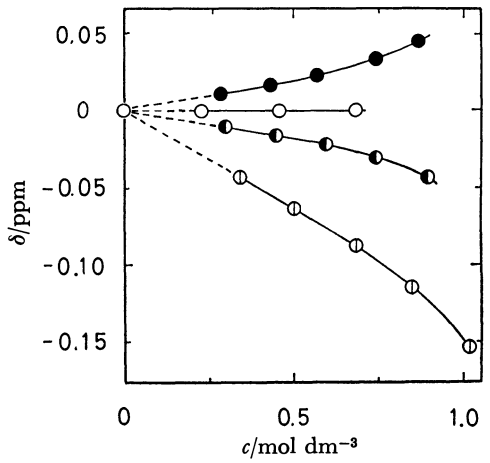

Fig. 2. Chemical shift of water proton in chloroform solutions of some solutes; butyl bromide (●), hexane (○), chlorobenzene (◐), and benzene (◑), as a function of solute concentration, at 25°C. The shifts are relative to that of water in pure chloroform at a concentration of 0.0665 mol dm^{-3}.

The ^{1}H chemical shifts of water are expressed by the relative value to that of water proton in pure chloroform measured against internal TMS. A linear relation with respect to the solute concentration holds for each solution, at least up to near 0.7 mol dm^{-3}. Equation 2 can thus be simplified to

$$\delta_f = \delta_f^\circ + \beta\bar{c}, \quad (3)$$

where β is a constant for a given salt. The hydrated water concentration is given by $\alpha\bar{c}$, x_h being equal to $(1-x_f)$ by definition. Combining Eqs. 1 and 3, we have

$$\delta = x_f\delta_f^\circ + (1-x_f)\left(\delta_h + \frac{\beta}{\alpha}\bar{c}_0\right), \quad (4)$$

where $\bar{c}_0$ is the solubility of water in chloroform (0.072 mol dm^{-3}, 25 °C). Since the last term in the second brackets is a constant for a given onium salt by the

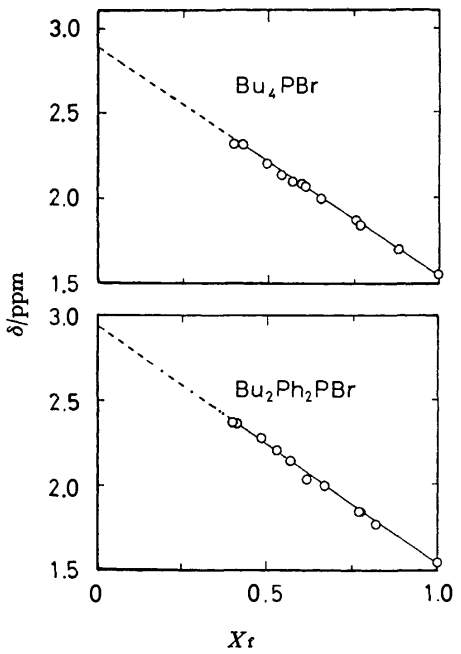

Fig. 3. ^1H chemical shifts of water in chloroform solutions of phosphonium bromides against internal TMS as a function of the fraction of free water to the total of water in the solution, at 25 °C.

Table 1. The ^1H chemical shifts of water solvated to phosphonium salts in chloroform, at 298 K

Salts	δ_h^f/ppm[a]	α[b]
Bu_4PBr	2.89	0.50
Bu_3PhPBr	2.90	0.52
Bu_2Ph_2PBr	2.92	0.55
$BuPh_3PBr$	2.85	0.67
Ph_4PBr	2.79	0.77
Ph_4PNO_3[c]	3.01	0.84
Ph_4PCl[d]	3.10	1.09
Ph_4AsBr	2.75	0.79

a) Average chemical shifts from protons of hydrated water, measured against internal TMS (see text). b) Average hydration number. c) Ionic strength of aqueous phase was adjusted by $NaNO_3$ (0.125). d) Ionic strength of aqueous phase was adjusted by NaCl(0.125).

above assumption, the plots of the observed chemical shifts against the free water fraction should give straight lines. Some of the plots are shown in Fig. 3, in which linearity holds. The values for the second brackets in Eq. 4 are obtained from the intercepts of these straight lines with the ordinate (Table 1).

The resonance of water proton, in the absence of salt in the chloroform phase, shifts gradually to high-field by dilution, *viz.*, 1.55, 1.54, and 1.51 ppm (relative to internal TMS) at water concentrations of 0.072, 0.036, and 0.014 mol dm^{-3}, respectively. It seems that the free water slightly associates in chloroform at the free water concentration of 0.072 mol dm^{-3}.

Distribution Ratios of Phosphonium Bromides at Zero Concentration. The distribution ratio, D, of a phosphonium bromide is defined by

$$D = \frac{\bar{c}_{RBr}}{c_{RBr}}, \quad (5)$$

where $\bar{c}_{RBr}$ and c_{RBr} are the analytical concentrations of the salt in the chloroform phase and in the aqueous phase, respectively. As an example, the distribution ratios of Bu_4PBr and Ph_4PBr are shown as a function of $\bar{c}_{RBr}$ in Fig. 4, where the ionic strength of aqueous phase is 0.125, adjusted by NaBr. From these curves the distribution ratios at zero concentration of the phos-

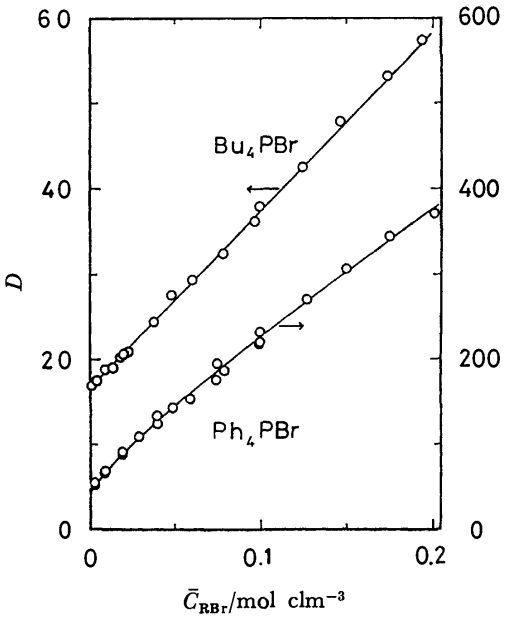

Fig. 4. Distribution ratios of phosphonium bromides between chloroform phase and aqueous phase of an ionic strength of 0.125 (NaBr) as functions of the analytical concentration of the salts in the organic phase, $\bar{c}_{RBr}$, at 25 °C.

Table 2. Hydration constants of phosphonium bromides in chloroform phase and distribution constants between chloroform and water at 298 K

		Hydration constant	Distribution constant				
			I=0.125(NaBr)		I=0.08(NaBr)		Mean value
Salts	α	K_h	D_o	$K_D\times10^{-2}$	D_o	$K_D\times10^{-2}$	$K_D\times10^{-2}$
Bu_4PBr	0.50	1.0_0	16.5	1.3	11.5	1.3	1.3
Bu_3PhPBr	0.52	1.0_8	28	2.1	18	1.9	2.0
Bu_2Ph_2PBr	0.55	1.2_2	42	3.0	30	3.0	3.0
$BuPh_3PBr$	0.67	2.0_3	41	2.1	29	2.1	2.1
Ph_4PBr	0.77	3.3_4	44	1.6	31	1.6	1.6

phonium bromides, D_o, are obtained by graphical extrapolation. These results are given in Table 2.

The D_o value is considered to be the distribution ratio for the undissociated and monomer species of the phosphonium bromide in the organic phase. The possible species in the organic phase are the dissociated ions, hydrated and non-hydrated monomer, and the aggregated species. The activity coefficients of RBr in aqueous phase are expected to be constant because of constant ionic strength in the aqueous phase. Hence, the increase in D with increase in $\bar{c}_{RBr}$ is attributed to the decrease in the activity coefficient of RBr in the chloroform phase, probably due to the aggregation of RBr[17-19]. The aggregation effect on D can be subtracted by extrapolation of D to zero concentration of RBr, the dissociation effect on D being considered insignificant. This can be judged from the behavior of D in the low concentration range of RBr. A tendency of increase in D toward zero concentration, which should be seen if the dissociation is significant, was not observed. An estimation for the degree of dissociation of RBr in chloroform phase saturated with water also supports the view. If we apply Bjerrum's equation,[20] the dissociation constant is estimated to be *ca.* 2×10^{-7} for phosphonium bromides. In the estimation the distance of closest approach is taken as 6.5 Å[21] and the dielectric constant of chloroform solution saturated with water, 5.[22] The dissociation constant thus obtained gives the degree of dissociation of the order of 0.01 at $\bar{c}_{RBr}$ of 0.001 mol dm^{-3}, which is lower than the lowest concentration examined. For dichloromethane as organic phase, the degree of dissociation is estimated as 0.14 even at 0.01 mol dm^{-3}. In fact, an increase in D for Ph_4PBr was found[25] at lower concentrations in dichloromethane.

It is reasonable concluded that the D_o values given in Table 2 are the overall distribution ratios for monomer species of hydrated and non-hydrated RBr in chloroform phase at zero concentration of RBr.

Discussion

Hydration Constant. The distribution equilibria in the present systems can be expressed as

$$H_2O \rightleftharpoons \overline{H_2O} \qquad (a)$$

$$R^+ + Br^- \rightleftharpoons \overline{RBr} \qquad (b)$$

$$\overline{RBr} + \overline{H_2O} \rightleftharpoons \overline{RBr\cdot H_2O}, \qquad (c)$$

where R^+ stands for the phosphonium ion, the bar indicating the species in chloroform phase. The aggregation process is neglected, the fact that the average hydration number is less than unity for all RBr examined being taken into account.

The hydration constant in chloroform phase, K_h, corresponding to the equilibrium (c), is given by

$$K_h = \frac{\alpha}{1-\alpha}\frac{1}{\bar{a}_w}\frac{\bar{y}_h}{\bar{y}_{RBr}}, \qquad (7)$$

where $\bar{a}_w$ is the water activity in chloroform phase, $\bar{y}_i$ the activity coefficient of species i in chloroform phase, referred to the concentration scale of mol dm^{-3}, and subscript h denotes the hydrated phosphonium bromide. With pure water chosen as a standard state for water in chloroform phase, $\bar{a}_w$ is equal to a_w. Since the water activity is close to unity, $\bar{a}_w$ is taken as unity. At infinite dilution of $\overline{RBr}$, the last factor in Eq. 7 becomes unity, and we obtain the hydration constant simply by replacing α with the numerical values given in Table 1. The hydration constants in chloroform phase at 25 °C are given in Table 2.

The K_h value increases gradually from Bu_4PBr to Bu_2Ph_2PBr and rapidly to $BuPh_3PBr$ and to Ph_4PBr. This suggests that the hydrated water molecule is stabilized through interactions with phenyl-rich cations ($n\geq3$) to a greater extent than butyl-rich cations ($n\leq1$).

Free Energy of Transfer of RBr from Water to Chloroform. In order to examine the effects of the substituent of phosphonium bromides upon distribution equilibria, it is essential to split the distribution constant, K_D, (equilibrium (b)), from the overall distribution ratios, D_o. Since the distribution ratio for the non-hydrated species of RBr in chloroform phase is given by $(1-\alpha)D$, we have

$$K_D = \frac{\bar{a}_{RBr}}{a_R a_{Br}} = \frac{(1-\alpha)D}{c_{Br}}\frac{\bar{y}_{RBr}}{\gamma^2_{RBr(NaBr)}}, \qquad (8)$$

where $\gamma_{RBr(NaBr)}$ is the mean activity coefficient of RBr in the aqueous phase in molality in the presence of NaBr, the small difference between the two concentration scales in aqueous solution being ignored. At zero concentration of RBr in the organic phase, we have

$$K_D = \frac{(1-\alpha)D_o}{c_{Br}}\frac{1}{\gamma^2_{(0)RBr}}, \qquad (9)$$

where $\gamma_{(0)RBr}$ is the activity coefficient of RBr at zero concentration in the presence of NaBr at the ionic strength of 0.08 and/or 0.125, in aqueous solution. In order to obtain the values for $\gamma_{(0)RBr}$, we need parameters, either the interaction parameters for mixed electrolyte solutions[26] or Harned's coefficients,[27] α_{ij}. So far they do not seem to have been reported. For the present purpose we can use the equation[27,28]

$$\log\gamma_{(0)MX} = \log\gamma_{(0)NX} = \frac{1}{2}\log\gamma_{MX(0)}\cdot\gamma_{NX(0)}, \qquad (10)$$

where $\gamma_{(0)MX}$ is the activity coefficient of MX at zero concentration in the presence of electrolyte, MX, at a given ionic strength, $\gamma_{MX(0)}$ and $\gamma_{NX(0)}$ being the activity coefficients of MX and NX in the pure solutions of MX and NX at the same ionic strength, respectively. The equation is found to be useful for some binary mixtures, including tetraalkyl ammonium bromides, at least for dilute solutions ($I\leq0.1$): For mixed aqueous solutions of HBr (1) and Bu_4NBr (2),[29] α_{12} are 0.3304 and 0.268 at ionic strengths of 0.1 and 0.25, respectively, which give the values 0.746 and 0.668 for $\gamma_{(0)HBr}$. Equation 10 gives the values 0.747 and 0.656, respectively. For α_{21} at ionic strength of 0.1, the reported value is −0.2057. This leads to the value 0.727 for $\gamma_{(0)Bu_4NBr}$, which is less by only 3% than the value estimated by means of Eq. 10. In the mixed solutions of KBr and $(C_3H_7)_4NBr$,[30] $\gamma_{(0)Pr_4NBr}$ values are determined to be 0.748 and 0.594 at ionic strengths of 0.1 and 0.5,

respectively, Eq. 10 giving 0.736 and 0.561, respectively.

By assuming Eq. 10, we can rewrite Eq. 9 as:

$$K_D = \frac{(1-\alpha)D_o}{a_{\pm(NaBr)}} \frac{1}{\gamma_{RBr(0)}}. \quad (11)$$

Since no activity coefficients for RBr in each of the pure solutions are known, some estimations must be made. Use of the activity coefficient of Bu_4NBr might be a good approximation for Bu_4PBr. The γ_{Bu_4NBr}[30] in aqueous solution at 25 °C fits the Debye-Hückel limiting law up to moderate concentration; *e.g.*, the deviations from the law amount to only 0.6% at 0.1 and 5% even at 0.4 mol dm^{-3}, though the consistence is regarded as accidental.[23] Thus, we obtain the value of 1.3×10^2 for K_D, which is common to both systems with different ionic strengths. For other phosphonium bromides, the limiting law was also applied to obtain $\gamma_{RBr(0)}$. The K_D values thus obtained are given in Table 2. The agreement between two values for K_D at different ionic strengths is good in spite of a considerable difference between D_o values. This supports the validity of the assumption.

From K_D, we obtain the free energy of transfer for RBr (non-hydrated in chloroform) from water to chloroform at 25°, $\Delta G_{C\leftarrow W}$, by means of

$$\Delta G_{C\leftarrow W} = -RT \ln K_D,$$

where a hypothetical solution of 1 mol dm^{-3} in each phase is taken as the standard state for RBr.

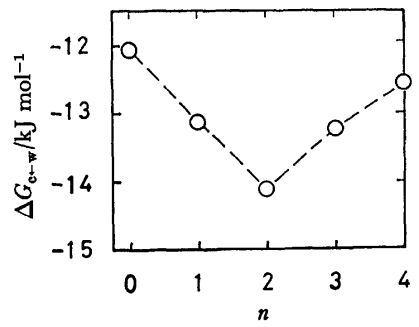

Fig. 5. The free energy of transfer for $Bu_{4-n}Ph_nPBr$ from water to chloroform as a function of n, at 25 °C. The standard state is taken as a hypothetical solution of 1 mol dm^{-3} of the salt.

$\Delta G_{C\leftarrow W}$ is shown as a function of n in Fig. 5. No additivity of group contributions to $\Delta G_{C\leftarrow W}$ is found; $\Delta G_{C\leftarrow W}$ is the lowest for Bu_2Ph_2PBr. This might be related to hydration processes in the aqueous phase, since there is no reason to expect that, of the phosphonium bromides, Bu_2Ph_2PBr interacts most effectively with the solvent chloroform. The state of cosphere water of phenyl groups differs from that of butyl groups. Different types of cospheres coexist in each cation with n=1—3. Thus, we find the interpretation for the variation of $\Delta G_{C\leftarrow W}$ with n in terms of the statement by Friedman and Krishnan:[2] adjacent cospheres interfere with each other so that the overall solvation is less energetic than one might guess from the properties of separate cospheres.

State of Hydration Water. Comparing δ'_h with the hydration number (Table 1), we find: (1) As found in a series of Ph_4PX's, δ'_h increases (low-field shift) in the order X^-, Br^-, NO_3^-, Cl^-, in accordance with that of the average hydration number; (2) with respect to a series of phosphonium bromides, the low-field shift remains nearly constant or gradually increases from Bu_4PBr to Bu_2Ph_2PBr with gradual increase in hydration number, and decreases to $BuPh_3PBr$ and to Ph_4PBr in spite of rapid increase in the hydration number (Fig. 6).

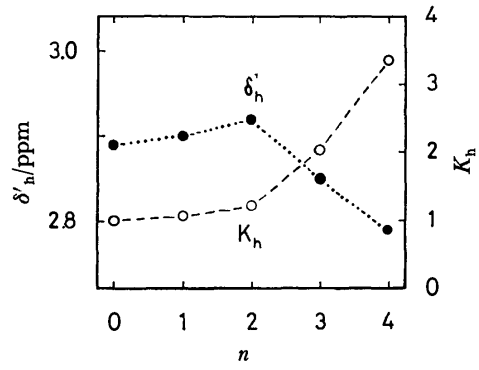

Fig. 6. ^1H chemical shift of water solvated to $Bu_{4-n}Ph_nPBr$ in chloroform phase and their hydration constants, as function of n, at 25 °C.

We infer from (1) that the hydrated water is hydrogen-bonded with anions of the phosphonium salts. Since the δ'_h values are the average values from two protons of hydrated water molecule, the chemical shift for the proton which participates in hydrogen bond, δ°_h, is roughly estimated from δ'_h by the relation

$$\delta^\circ_h = 2\delta'_h - \delta^\circ_f,$$

where assumptions are made that the chemical shift for the other proton is equal to that of non-hydrated water, the correction factor, $\bar{c}_o\beta/\alpha$, being relatively small as expected from Fig. 2. The values for δ°_h are, for example, 4.0, 4.4, and 4.7 ppm (against TMS), for Ph_4PBr, Ph_4PNO_3, and Ph_4PCl, respectively.

Let us examine the salt effect upon the chemical shift of free water proton: (a) polarization of free water due to the salts as electric dipoles, and (b) magnetic anisotropy due to phenyl groups and polarization of free water due to charges located on the phenyl groups. Effect (a) leads to the net low-field shift of free water proton (Fig. 2), the effect being expected to nearly the same degree for all onium bromides examined since their molal volumes are nearly the same[13] while effect (b) due to phenyl rings leads to net high-field shift. With the present onium salts, however, the phenyl groups may differ from benzene or chlorobenzene as regards their interactions with water because of geometric effects and charge delocalization effects. The π-electron donation from phenyl groups to phosphorus d-orbitals of quaternary phosphonium salts was shown by Gim and McFarlane.[8] The charge delocalization for Ph_4P^+ ion was estimated to be 0.18 electron unit per phenyl group.[9] When a water molecule is situated in the vicinity of the peripheries of phenyl rings, it will undergo deshielding effects due to the local magnetic

field of phenyl rings as well as possible polarization induced by delocalized charges. In contrast, high-field shift should be observed when the water molecule is located so close to the central atom that the proton undergoes the diamagnetic effect due to phenyl rings. In this case, however, the water molecule is not regarded as "free," but "hydrated." Onium salts lead to deshielding free water protons.

We can conclude from (2) that the hydrated water molecule interacts not only with anions but with cations, especially with phenyl-rich cations ($n \geq 3$), as evidenced by relatively large hydration constants for these salts. Starting with Bu_4PBr, we find the most favorable site for water molecule at $BuPh_3PBr$, since it is free from steric hindrance by butyl groups. For butyl-rich salts, no sites of this kind are available and thus their hydration constants are expected to be nearly the same.

The hydration constant for Ph_4AsBr seems to be somewhat larger than that for Ph_4PBr, in accordance with the less low-field shift for the former. This is consistent with the results obtained by Orenberg *et al.*[10]

Photoelectrochemical Behavior of Chlorophyll a-Lipid Films on a Platinum Electrode in an Aqueous Electrolyte

Tsutomu MIYASAKA,* Akira FUJISHIMA, and Kenichi HONDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received March 19, 1980)

The photoelectrochemical behavior of chlorophyll a-lipid mixed monolayers coated on a platinum electrode by the Langmuir-Blodgett technique was investigated under potentiostatic conditions in an aqueous electrolyte in the absence of redox agents. Under illumination, cathodic photocurrents were observed at electrodes coated with a sufficient number of monolayers. The quantum efficiency of the photocurrent was estimated to be about 10^{-4}, much lower than that obtainable for dye-sensitized photocurrent on semiconductor electrode. The cathodic photocurrent increased with lowering in the pH of electrolyte. The possibility of the photoreduction of water by excited triplet chlorophyll a is discussed on the basis of observed pH dependence and correlation of the redox potentials involved.

During the last decade an increasing number of studies have appeared on the photoelectrical and photoelectrochemical behavior of chlorophyll (Chl) in the form of solid layers coated on metal electrodes.[1-13] The photoconductive nature of solid Chl films in various forms, such as amorphous layers,[1,3,5] microcrystals,[2,4,5] and monolayer assemblies,[6,7] in contact with metal substrates has been established by the use of metal/Chl/metal sandwich-type photovoltaic cells. However, the organic semiconductivity inherent to solid-state Chl, postulated for the microcrystalline films[2,14] in order to explain the photoelectrical rectifying effects at metal/Chl contacts, is the subject of controversy;[4,15] in particular, it seems unlikely for the monolayer assemblies.[6,16,17] In photoelectrochemical cells employing metal electrodes (mostly platinum) coated with various forms of Chl films,[8-13] cathodic photocurrents have usually been obtained, presumably reflecting the *p*-type semiconduction formed within a bulk Chl layer. Water splitting reactions with use of Chl-coated platinum photocathodes have been demonstrated by several groups.[10,13] Such behavior is in contrast to the case of Chl-coated *n*-type semiconductor electrodes which produce anodic sensitized photocurrents.[18,19]

According to the principles of dye sensitization processes, the photocurrent of dye molecules adsorbed on a metal electrode should be incomparably less efficient than that obtained at a semiconductor electrode, owing mainly to the rapid energy quenching of dye excited states by free electrons in the metal, as reported by Memming[20] and Gerischer and Williug.[21] Ample efficiency for dye-sensitized photocurrent on a metal electrode could thus be expected in cases where the dye layer is thick enough to develop the bulk effects such as *p*-type photoconductivity. Typical of this case are solid films of metal phthalocyanines[22] and porphyrins[23] which are regarded as *p*-type organic semiconductors.

Reports have been given on the anodic sensitized photocurrents obtained for various monolayer assemblies (Langmuir-Blodgett films) of Chl coated on an SnO_2 semiconductor electrode,[19,24-26] where quantum efficiency of the photocurrent was investigated as a function of the surface concentration of Chl[19,24] and thickness of the monolayers.[25] For such a Chl-sensitized semiconductor photoanode, it was confirmed that the single monolayer film of Chl that is amply diluted in the surface concentration gives the highest quantum efficiency (≤ 0.25) for photocurrent generation.[26]

By means of the Langmuir-Blodgett technique which allows a precise and uniform control of the film thickness, we have investigated the photocurrent behavior at the thin monolayer assemblies of a Chl-lipid mixture on a platinum electrode. The behavior observed in this system, such as photocurrent-potential characteristics, pH dependence of photocurrent, and effect of the film thickness was found to be in contrast to the corresponding observations in a Chl multilayer/semiconductor system.[25]

Experimental

Pure Chl a was obtained from spinach leaves in the usual manner.[19] L-α-Dipalmitoyllectithin (DPL from Sigma Chemical.) was employed as a two-dimensional diluent for a Chl a monolayer,[24] in order to keep Chl a from possible photodegradation[27] as well as to suppress the energy dissipation within layers due to the concentration quenching characteristic of Chl a molecules.[28] A monomolecular layer consisting of Chl a and DPL at molar ratio 1/1 was prepared, using benzene as a spreading solvent, on an aqueous phosphate buffer (pH$\approx$ 8) in a Langmuir trough. The monolayers were then deposited on the surface of a platinum electrode substrate (0.05 mm thick, 2.5×2.5 cm^2), which had been treated with several organic solvents and hot sulfuric acid to make the surface hydrophilic, by serial dipping of the substrate across the supernatant monolayer under a surface pressure of 20 dyn cm^{-1} (1 dyn$=10^{-5}$ N); each monolayer coated on the substrate was vacuum-dried prior to the subsequent deposition. The deposition ratio for the Chl a–DPL mixed monolayer with respect to the platinum surface area was 0.7—1.0, indicating that the film was packed less densely on the electrode than on the water.[29]

Sodium sulfate (reagent grade) dissolved in doubly distilled water, 0.1 M (1 M$=1$ mol dm^{-3}), was used as a neutral electrolyte except when H_2SO_4 and/or NaOH was added for pH variation. The electrolyte solution was flushed with nitrogen which had been deoxygenated by passing over an activated copper column. The electrochemical cell employed was of one compartment including three electrodes; the potential of the Chl a–DPL film-coated platinum electrode was regulated with a Hokuto Denko Model HA-101 potentiostat, using a saturated calomel electrode (SCE) and a platinum wire as a reference electrode and a counterelectrode, respectively. Photo- and dark currents were measured on a Keithley Model 610 B

picoammeter. The light source was a 500-W Xe arc lamp in combination with a grating monochromator. The observed photocurrents were corrected for incident photon flux, corresponding to *ca.* 1.2×10^{16} photons s^{-1}. For details of the experimental setup as well as the monolayer deposition technique, refer to the previous paper.[19]

Results and Discussion

Photocurrent Characteristics. When a single Chl a-DPL monolayer on the platinum electrode was illuminated, almost no significant photocurrent was observed. This can be ascribed to the rapid energy-quenching of excited Chl a by free electrons in the metal[20,21] as well as to a reversible and simultaneous exchange of electrons *via* the metal/Chl a interface (no rectifying property). The former phenomenon, mainly responsible for the minimal photocurrent, has been elucidated by Kuhn[30] on the basis of fluorimetric studies.

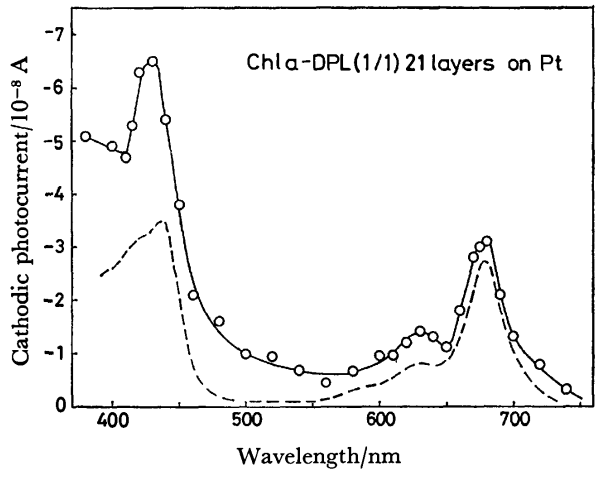

Fig. 1. Photocurrent action spectrum for Chl a-DPL (1/1) film consisting of 21 monolayers on a platinum electrode. Electrolyte, 0.1 M Na_2SO_4 (pH *ca.* 7); electrode potential, 0 V *vs.* SCE. The broken line shows the absorption spectrum of Chl a multilayer at solid-electrolyte interface in arbitrary units.[25] Photocurrent (solid line) is for the total area illuminated on the electrode (*ca.* 5 cm^2). Photocurrents plotted in figures hereinafter show an experimental error of *ca.* $\pm0.3\times10^{-8}$ A.

Electrodes coated with more than several monolayers were found to develop significant cathodic photocurrents upon illumination. Figure 1 shows the photocurrent action spectrum obtained for a film consisting of 21 monolayers with an absorption spectrum of a pure Chl a multilayer[25] for comparison. Apparently the cathodic photoresponse follows the absorption of Chl a, showing peaks at around 680 nm and 430 nm in the red and blue bands, respectively. The observed action spectrum suggests that the monomeric form of Chl a is the main species participating in the present photoelectrochemical reaction. No significant changes due to the formation and photochemical involvement of the hydrated Chl species absorbing in the far-red region (≈740 nm)[2,4,5,12,13] was detected, at least not in the action spectrum.

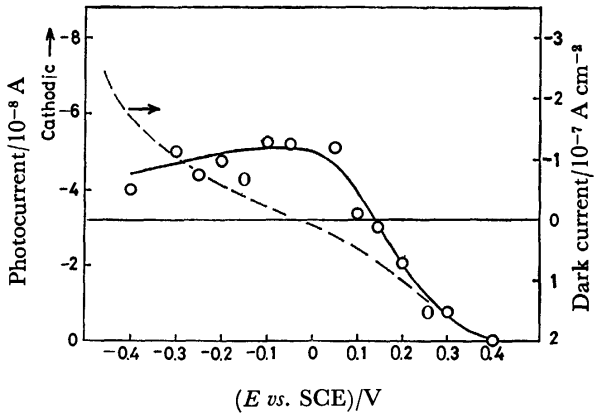

Fig. 2. Photocurrent-potential characteristics.
—○—: Photocurrent, ----: dark current. Illumination at 675 nm. Film and electrolyte composition are the same as in Fig. 1.

Figure 2 shows the dependence of the photocurrent on electrode potential. Cathodic photocurrent, *i.e.*, electron injection from the Pt/Chl a electrode to the solution, occurred at potentials more negative (cathodic) than +0.4 V *vs.* SCE, increasing with cathodic polarization until it became saturated at around 0 V.

Generation of cathodic photocurrent can be interpreted schematically in terms of the electron donation from excited Chl a molecules at the film-electrolyte interface to some reducible species (A) in the electrolyte and the subsequent reduction of the produced Chl a cation radical by free electrons of the electrode, namely,

$$\text{Chl a} \xrightarrow{h\nu} \text{Chl a}^* \quad (1)$$

$$\text{Chl a}^* + \text{A} \longrightarrow \text{Chl a}^+ + \text{A}^- \quad (2)$$

$$\text{Chl a}^+ + e^-_{Pt} \longrightarrow \text{Chl a}. \quad (3)$$

Such a mechanism is substantially the same as that proposed for an electron transfer process involved in dye sensitization on a *p*-type semiconductor photocathode.[31] The above reaction, however, hardly proceeds if the dye layer on a metal is not as thick as several monolayers, because of the quenching phenomenon as well as the absence of rectifying properties. This differs from the case of semiconductor electrode surface where only monolayer-thick adsorption of dye is sufficient to develop a considerable efficiency of photocurrent. In the semiconductor electrode, electron flow is rectified *via* the space charge layer in which energy transferred from the dye, if any, can be utilized for charge separation which leads to photocurrent generation. If, however, the dye layer on a metal is of sufficient thickness, the photooxidation of Chl a with an acceptor in solution (Eq. 2) can take place at the film/electrolyte interface where the quenching of excited dye by the metal can be suppressed by the spatial separation of its interface from the metal surface. The photooxidized Chl a may subsequently be reduced by electrons which migrate from the metal surface by hopping through the dye layer. Another reaction mechanism, applicable to the *p*-type semiconductor/dye interface, which involves the direct reduction of excited-state Chl a by electrode at the metal/film interface (Chl $a^*+e^-_{Pt}\rightarrow$

Chl a^{+}) is unlikely since reoxidation of Chl a^{+} into Chl a would occur simultaneously at the metal surface.

The proposed mechanism is compatible with the fact that the onset potential for the cathodic photocurrent, 0.4 V *vs.* SCE, was observed at a somewhat more negative potential than the oxidation potential of the ground state Chl a, *ca.* 0.54 V *vs.* SCE,[32] since the reaction process of reducing Chl a cation radical (Eq. 3) is expected to be promoted at potentials $<$*ca.* 0.54 V on an electrochemical basis. According to the mechanism, the observed onset potential further implies that the oxidation potential of Chl a, which has so far been estimated in nonaqueous media on account of the insolubility of Chl, would be situated at $\geq$0.4 V *vs.* SCE in the monolayer assembly in contact with an aqueous electrolyte.

In the present system, semiconduction in the solid Chl film is not important to explain the observed photoeffect because the monolayer assemblies of Chl are generally not regarded as good semiconductor materials,[16,17] unlike the amorphous or microcrystalline films which display significant photoconductivity.[1,2,5] It should be noted that the Chl a monolayers studied here were doped with lipid molecules which diminish the Chl–Chl electronic interaction needed for the developing of photoconduction.

A blank test was carried out by irradiating a platinum electrode free of Chl a with 680 nm and 430 nm light. No photocurrent was detected at electrode potentials below +0.4 V *vs.* SCE. A slight anodic photocurrent was detectable under 430 nm irradiation at *ca.* 0.4 V, but this intrinsic photoresponse of platinum was within experimental error and is negligible.

Effect of Film Thickness. The magnitudes of the cathodic photocurrents for various numbers of layers on the platinum were compared at an applied elecrode potential of 0 V *vs.* SCE where the photocurrent tends to be saturated (Fig. 2). The results are summarized in Fig. 3.

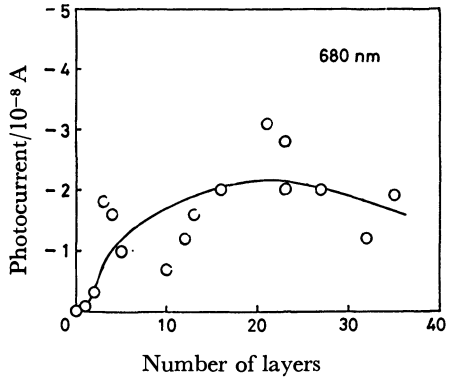

Fig. 3. Relation between cathodic photocurrent and the number of layers deposited on the platinum electrode. Illumination at 680 nm. Electrolyte, 0.1 M Na_2SO_4; electrode potential, 0 V *vs.* SCE.

No significant photocurrent was observed with a single monolayer film. Photocurrent, however, increased with an increase in the number of layers (*i.e.*, total film thickness), reaching a maximum at 20—30 layers. The increase may result from the spatial separation of the film/solution interface participating in the photooxidation reaction of Chl a with an acceptor in the electrolyte (Eq. 2) from the metal/film interface involved in the dark electron transfer (Eq. 3). Such a separation of the two interfaces by stacking a sufficient number of monolayers would thus suppress the energy dissipation of dye excited at the film/electrolyte interface due to energy transfer as well as back electron transfer[33] toward the metal. The observed saturation of photocurrent above 20 layers may be due to the increased electrical resistance within the film.

The quantum yields of steady state cathodic photocurrents obtained for 20—30 layers, estimated taking into account the surface reflectance of platinum (*ca.* 0.7) with respect to incident light, are of the order 10^{-4} electron/photon. This is incomparably lower than the value, 10^{-1} electron/photon, reported for dye-sensitized cathodic photocurrents at a *p*-type semiconductor.[31] Such a low efficiency is apparently due to the minimal rectifying properties of the metal electrode. Using platinum electrodes coated with microcrystalline Chl a aggregates, Fong and co-workers have reported relatively efficient cathodic photocurrents[12] and claimed evidence for water splitting reaction.[13] However, it is presumed that the electrodes used in their system, prepared by drastic treatments of the surface Chl a layers with repeated platinizations,[13] may involve a certain photocatalytic effect ascribed to some Chl a-Pt composite and the observed phenomena cannot be attributed simply to the light reaction of Chl aggregate itself.

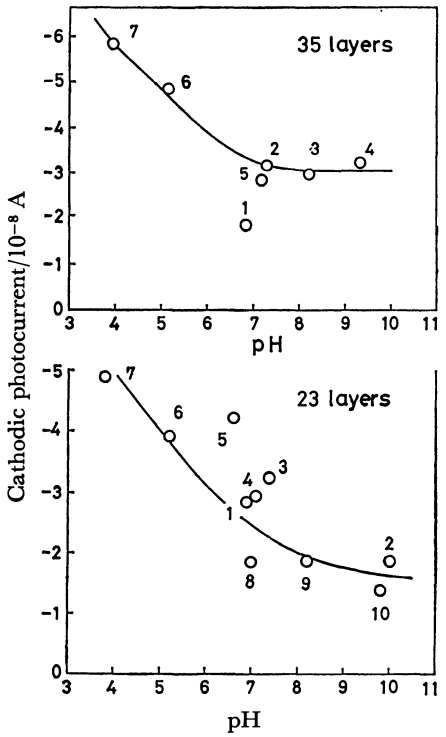

Fig. 4. Dependence of cathodic photocurrent on electrolyte pH. 35 layers and 23 layers on the platinum were examined under the same experimental conditions as in Fig. 3. The numbers on the plots stand for the experimental sequence.

Effect of pH on Photocurrent. The pH dependence of the photocurrent was investigated in order to clarify the nature of acceptor species involved in the photooxidation reaction of Chl a. Figure 4 shows the results obtained for films of 23 and 35 monolayers under a constant electrode potential of 0 V *vs.* SCE. In both cases, cathodic photocurrents tend to increase with lowering in pH. The increase occurs at pH's $<$*ca.* 7. Since the redox potential of Chl a can be regarded as almost independent of pH, the behavior clearly indicates that some protonic oxidant in the solution acts as an electron acceptor for excited Chl a. After a series of pH variation, an attempt was made to check the chemical degradation of Chl a by dissolving the illuminated samples in benzene. No significant change assigned to decomposed Chl a species, such as pheophytin, could be detected in the absorption spectrum, indicating that the chemical changes in Chl a during the course of pH variation is almost negligible.

In order to discuss the photooxidation reaction of Chl a with an acceptor, involvement of two donor states of Chl a, excited singlet and excited triplet states, should first be taken into account. It is known that the photoionization of Chl a by reaction with a redox agent in solution takes place exclusively *via* the excited triplet state, a long-lived species with a lifetime of *ca.* 2 ms.[34] A variety of oxidants[35] has thus far been found to react with the triplet state of Chl a producing Chl a radical cations. Using photovoltaic cells, Janzen and Bolton[6] found a large contribution of triplet state Chl a to the reduction of acceptor species immobilized in monolayer assemblies. Consequently, it is reasonable to assume that in the present system the photooxidation of Chl a (Eq. 2) takes place *via* the triplet state, from the viewpoint that an amply long lifetime of the excited state is needed to achieve the reaction with a dilute oxidant diffusing from the bulk of solution.

If we assume that the electrolyte used contains no impurities that can act as electron acceptors, water (proton) is the only possible oxidant involved because it can be reduced on an energetic basis by both the singlet and triplet excited states of Chl a which have oxidation potentials of -1.31 V and -0.79 V *vs.* SCE,[32] respectively. Here, the oxidation potential of the triplet state Chl a, the predominant species involved in the photooxidation process, is situated somewhat negative of the reduction potential of water at pH 7, namely -0.66 V *vs.* SCE. This suggests that the triplet Chl a cannot reduce water very efficiently in neutral solutions because of a rather small free energy change (overpotential). Since the lowering of pH brings about a positive shift in water redox potential which facilitates the reaction of triplet Chl a with a proton, the observed increase in photocurrent at pH's below 7 might result from the reduction of water by the excited triplet Chl a.

In contrast with the result shown in Fig. 4, the reverse behavior in pH dependence has been obtained with a Chl a multilayer-coated SnO_2 *photoanode*[25] using a similar electrolyte to that of the present system. Anodic sensitized photocurrent of Chl a observed was found to increase at pH's higher than 7. This was rationalized by the recognition that the oxidation potential of ground state Chl a, 0.54 V *vs.* SCE, is in the vicinity of the water oxidation potential at pH 7, 0.57 V *vs.* SCE, and the reduction by water of the Chl a cation radical produced by electron injection into SnO_2 is promoted by increasing of pH (*i.e.*, a negative shift in water oxidation potential).

The combination of both features of Chl a *photoanode* and *photocathode* in pH dependence brings us to the view that the oxidation and reduction of water by *in vitro* photoexcited Chl a, or at least by monomeric Chl a, would be difficult in *neutral* aqueous solutions owing to the absence of any overpotential (*i.e.*, free energy change) sufficient for an electron transfer reaction. Watanabe and Honda[36] have recently found that Chl a cation radical produced by electrolysis, which corresponds to the photooxidized form of Chl a produced at the photoanode, has an extremely low rate constant for the reaction with water in an organic solution, suggesting that the oxidation of water by excited Chl a is inefficient. Consequently, photosplitting of water by *in vitro* Chl a is thought to be feasible under either acidic or alkaline conditions which can promote, respectively, the photoreduction and photooxidation of water. This is in line with the demonstrations of hydrogen[10,13] and oxygen[37] evolutions at illuminated Chl electrodes with use of acidic and alkaline electrolyte solutions, respectively.

The authors wish to thank Dr. K. Itoh for his helpful discussion. This work was supported by a Grant-in-Aid from the Ministry of Education, Science and Culture.

The Crystal Structures of Hexamethyleneiminium *p*-Chlorobenzoate and Dimorphs of Hexamethyleneiminium *p*-Bromobenzoate

Setsuo KASHINO,* Norimitsu SASAHARA, Shin-ichi KATAOKA, and Masao HAISA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received June 12, 1980)

The crystal structures of hexamethyleneiminium *p*-chlorobenzoate (**1**), and the monoclinic [**2**(**m**)] and orthorhombic [**2**(**o**)] forms of hexamethyleneiminium *p*-bromobenzoate have been determined from visually estimated Cu $K\alpha$ data. The crystal data are: $P2_1/c$, $a=10.10(2)$, $b=16.78(1)$, $c=9.01(2)$ Å, $\beta=118.4(2)°$, $Z=4$ for **1**; C2/c, $a=25.47(2)$, $b=7.01(1)$, $c=16.29(1)$ Å, $\beta=109.1(1)°$, $Z=8$ for **2**(**m**); and Pbca, $a=11.55(1)$, $b=27.40(1)$, $c=8.57(1)$ Å, $Z=8$ for **2**(**o**). The structures of **1**, **2**(**m**), and **2**(**o**) were refined to R values of 0.072, 0.100, and 0.083 for 1628, 1009, and 1013 non-zero reflections, respectively. In the crystals of **1**, the type of hydrogen bond and the molecular arrangement in (010) plane are the same as those in piperazinediylium terephthalate. In **2**(**m**), two pairs of the base and acid ions related by a twofold axis are linked together by N–H···O hydrogen bonds. The crystal structure of **2**(**o**) is very similar to that of piperidinium and pyrrolidinium *p*-substituted benzoates in Pbca, but there is a difference in the combination mode of the base and acid ions participating in the hydrogen bonds. In all the crystals, the hydrogen bond extending along the long axis of the acid ion is shorter than that nearly perpendicular to the axis. Hexamethyleneimine rings in **1**, **2**(**m**), and **2**(**o**) take a similar twist-chair conformation.

It has been found for crystals of piperidinium and pyrrolidinium *p*-substituted benzoates that the N–H···O hydrogen bonds linking together the base and acid ions are usually formed around a 2_1 axis.[1-3] The crystal structures of the title compounds have been examined in order to ascertain whether the type of hydrogen bonds is maintained or not by the enlargement of the ring size of the base, to see what types of hydrogen bonds other than the 2_1 type are possible in the crystals, if any, and to determine the conformation of hexamethyleneimine ring in the crystals.

Experimental

Equimolar amounts of the base and the acid were dissolved in dry benzene. The crystals of hexamethyleneiminium *p*-chlorobenzoate (**1**) and of monoclinic form of hexamethyleneiminium *p*-bromobenzoate [**2**(**m**)] were grown from the solutions by slow evaporation. The crystals of orthorhombic form of hexamethyleneiminium *p*-bromobenzoate [**2**(**o**)] were grown from the filtrate of **2**(**m**) by slow evaporation. Crystal data and experimental details are given in Table 1. The systematic absences for **2**(**m**) showed the possible space group to be C2/c or Cc, but the latter was ruled out by the structure analysis.

The specimens were sealed in glass capillaries, since the crystals of the compounds decompose gradually. The intensity data were collected on equi-inclination Weissenberg photographs using Cu $K\alpha$ radiation. Intensities were estimated visually and corrected for Lorentz and polarization factors and spot shape.

Structure Determination and Refinement

The structure of **1** was solved by the symbolic addition procedure and the structures of **2(m)** and **2(o)** by the Patterson method. Refinement was made by block-diagonal least-squares calculations. For **1** all the H atoms were located from a difference Fourier synthesis. Further refinement was carried out including the parameters of the H atoms. The weighting scheme used was $w=1.0$ for $0<|F_o|\leq F_{max}$, and $w=(F_{max}/|F_o|)^2$ for $|F_o|>F_{max}$, where $F_{max}=6.5$.

For **2(m)** and **2(o)**, the coordinates of nine and thirteen H atoms were determined from difference Fourier syntheses at the stages of $R=0.124$ and 0.110, respectively. The positional parameters of the remaining H atoms were calculated by assuming the usual geometry, and were included in the subsequent refinement. The same weighting scheme was used with $F_{max}=16.0$ for **2(m)** and 14.0 for **2(o)**. The final R values for the non-zero reflections were 0.072 for **1**, 0.100 for **2(m)**, and 0.083 for **2(o)**. The final atomic parameters are given in Table 2.[4]

The atomic scattering factors were taken from International Tables for X-Ray Crystallography.[5] Computations were carried out at the Okayama University Computer Center. The programs used were SIGM, TANG, HBLS-V, and DAPH.[6]

Results and Discussion

The projections of the crystal structures and the numbering of the atoms are shown in Fig. 1. Geometry of the hydrogen bonds is summarized in Table 3. Bond lengths and angles are given in Table 4.

Crystal Structures. In the crystals of **1**, the base and acid ions are linked together by two kinds of N–H···O hydrogen bonds to form a ribbon along a c glide plane. The type of hydrogen bond is the same as that found in piperazinediylium terephthalate (**3**).[7] The ribbons are stacked along a in alternate succession of the base and acid ions to form a sheet parallel to (010). The molecular arrangement in the sheet is also the same as that in **3**. The doubling of b occurs in **1** because of the loss of molecular symmetry $\bar{1}$ in the base and acid ions.

In the crystals of **2(m)**, two pairs of the base and acid ions related by a twofold axis are linked together by two kinds of N–H···O hydrogen bonds. The hydrogen-bonded units are stacked along b in alternate succession of the base and acid ions to form a ribbon. The ribbons related by $\bar{1}$ are held together by van der Waals interactions and dipole-dipole interactions between the acid ions to form a sheet parallel to (100). The sheets are stacked along a by weak interactions.

In **2(o)** all atoms of the acid ion and a center of the base ion occupy positions similar to those of piperidinium *p*-substituted benzoates[1,2] and of pyrrolidinium *p*-substituted benzoates[3] in Pbca, but the position of N

differs by about $c/4$. This difference causes a change in the combination mode of the base and acid ions participating in the hydrogen bonds. In **2**(**o**) base ion (i) donates the hydrogen bonds to acid ions (i) and (ii), while in the others it is base ion (ii) that doantes the hydrogen bonds to the corresponding acid ions, where the symmetry code follows that given in Fig. 1(c) for all the crystals.

For the crystals of **1**, **2**(**m**), and **2**(**o**), all the intermolecular contacts correspond to those expected for the usual van der Waals interactions. The shortest contacts are found between C(7^{i}) and H($11B^{i}$): 2.42(7) Å for **1**, 2.44(13) Å for **2**(**m**) and 2.59(16) Å for **2**(**o**).

Geometry of the Hydrogen Bonds. Irrespective of the type of hydrogen bond, the bond N(11^{i})···O(9^{i}) extending nearly parallel to the long axis of the acid ion is shorter than the other one N(11^{i})···O(8^{ii}) lying nearly perpendicular to the long axis. A notable difference between the two hydrogen bonds is that the former is associated with the nearly tetrahedral C–O···N angle, while in the latter the angle takes a significantly larger value, especially for the glide type.

Molecular Structures. *(a) Benzoate Ions*: The benzene rings and carboxylate groups are planar within experimental errors (Table 5). The C(1)–C(7)–O(9) angles remain constant in these crystals, the O(9) participating in shorter hydrogen bond. The corresponding angles in the related compounds also take a restricted range of values, 116.1—117.4°.[1-3,7] On the other hand, in **2**(**m**) the C(1)–C(7)–O(8) angle is smaller and the O(8)–C(7)–O(9) angle larger than the corresponding angles in **1** and **2**(**o**). A similar opening of the O–C–O angle has been observed in trifluoroacetic acid.[8] Shortening of the C(7)–O(9) bond in **2**(**m**) can be explained in terms of the *s*-character of the C(7) atom,[9] the C(7)–O(8) bond length in **2**(**m**) being unexpectedly large.

TABLE 6. THE TORSION ANGLES (ϕ/°) IN THE HEXAMETHYLENEIMINE RINGS

		1	**2**(**m**)	**2**(**o**)
χ_0	C(17)-N(11)-C(12)-C(13)	41.3	37.9	29.0
χ_1	N(11)-C(12)-C(13)-C(14)	36.4	33.2	46.3
χ_2	C(12)-C(13)-C(14)-C(15)	−81.8	−79.5	−83.4
χ_3	C(13)-C(14)-C(15)-C(16)	68.6	71.3	68.3
χ_4	C(14)-C(15)-C(16)-C(17)	−54.0	−58.3	−60.4
χ_5	C(15)-C(16)-C(17)-N(11)	70.8	72.7	79.3
χ_6	C(16)-C(17)-N(11)-C(12)	−86.7	−81.8	−84.4

(b) Hexamethyleneiminium Ions: Let $A(i)$ be the non-hydrogen atoms in the rings, where i is an integer from 11 to 17 and $A(i+7)=A(i)$ in the present numbering system. In each crystal of **1**, **2**(**m**) and **2**(**o**), the planarity through the four atoms $A(i)$, $A(i+1)$, $A(i+4)$, and $A(i+5)$ is the best when $i=11$ (Table 5). In each ring the C(14) and C(17) deviate from the plane in opposite directions. The torsion angles around each bond in the rings show the twist-chair conformation[10] (Table 6). The hexamethyleneimine rings in **1**, **2**(**m**), and **2**(**o**) take similar conformations irrespective of the crystallographic environment of the rings. For cycloheptane the conformation has been estimated to be more stable than the chair conformation by 5.9 kJ mol^{-1}.[10]

(Received June 14, 1980)

Two-configuration SCF wave functions constructed with multiconfiguration SCF localized-orbitals are obtained for several molecules, cations, and anions. The weights of the valence-bond resonance-structures are obtained from the wave functions for these molecules and molecular ions. A new formula of the ionic character of a chemical bond is proposed using these weights. For these neutral molecules, the values calculated from this formula are consistent with Pauling's scale of the ionic character. The present formula is shown to be applicable even for molecular ions.

The ionic character is an important concept in understanding chemical bonds. Several scales of the ionic character in relation to the electronegativity difference were proposed by Pauling,[1] by Hannay and Smyth,[2] by Nethercot,[3] by Hinze, Whitehead, and Jaffe,[4] and by others. They are not so satisfactory. Coulson[5] defined a scale of the ionic character from the weight of the ionic structure in the valence-bond wave function. However, few calculations have been performed along this line, so that the validity of this scale has not been confirmed extensively.

In the present paper, we propose a new scale for the ionic character using the weights obtained from the two-configuration SCF wave function constructed with multiconfiguration SCF localized molecular orbitals (MCSCF-LMOs).[6,7] Properties of this wave function (referred to as Ψ[2c] from now on) and its relation to the ionic character are described in the second section. In the third section, we apply the new scale to simple molecules and molecular ions: LiF, LiH, HF, H_2O, NH_3, CH_4, H_2, OH^-, NH_2^-, CH_3^-, H_3O^+, and NH_4^+. The values calculated are compared with the observed partial charges[8] and other scales. The present scale is shown to be in an excellent agreement with Pauling's scale as improved by Nethercot[3] for these neutral molecules.

Theory

The Ψ[2c] is fully described in a previous paper.[7] It can be briefly sketched as follows:

A Ψ[2c] wave function to discuss the nature of a local bond, say A–B, in a polyatomic molecule can be expressed as

$$\Psi[2c] = a_1\|(\text{other MCSCF-LMOs})\sigma_{AB}\bar{\sigma}_{AB}\| + a_2\|(\text{other MCSCF-LMOs})\sigma^*_{AB}\bar{\sigma}^*_{AB}\|, \quad (1)$$

where σ_{AB} is the bonding orbital, σ^*_{AB} is the corresponding antibonding orbital, a_1 and a_2 are the configuration mixing coefficients. All orbitals are the MCSCF-LMOs and can be expanded in terms of atomic orbitals (AOs) χ_t. All LCAO coefficients and the configuration mixing coefficients are optimized variationally.

The bonding orbital σ_{AB} and the antiboding orbital σ^*_{AB} can be expressed as

$$\sigma_{AB} = \sum_p^{\text{on A}} \chi_p c_p + \sum_q^{\text{on B}} \chi_q c_q + \sum_r \chi_r c_r,$$
$$\sigma^*_{AB} = \sum_p^{\text{on A}} \chi_p d_p + \sum_q^{\text{on B}} \chi_q d_q + \sum_r \chi_r d_r, \quad (2)$$

where the subscript p denotes the numbering of AO's on atom A, q denotes that of AO's on atom B, and r denotes that of AO's on other atoms. Since σ_{AB} and σ^*_{AB} (also the other orbitals) are MCSCF-LMOs, all of c_r and d_r (which are the LCAO coefficients of AO's on the other atoms) can usually be neglected. Neglecting the last term in Eq. 2 and then substituting Eq. 2 into Eq. 1, we have the following equation, which clarifies the physical significance of the Ψ[2c]:

$$\Psi[2c] \simeq \Psi(A^-B^+) + \Psi(A^+B^-) + \Psi(A{:}B), \quad (3)$$

where

$$\Psi(A^-B^+) = \sum_p^{\text{on A}} \sum_{p'}^{\text{on A}} b_{pp'}\|(\text{other MCSCF-LMOs})\chi_p\bar{\chi}_{p'}\|, \quad (4)$$

$$\Psi(A^+B^-) = \sum_q^{\text{on B}} \sum_{q'}^{\text{on B}} b_{qq'}\|(\text{other MCSCF-LMOs})\chi_q\bar{\chi}_{q'}\|, \quad (5)$$

$$\Psi(A{:}B) = \sum_p^{\text{on A}} \sum_q^{\text{on B}} b_{pq}\|(\text{other MCSCF-LMOs})(\chi_p\bar{\chi}_q - \chi_p\bar{\chi}_q)/\sqrt{2}\|, \quad (6)$$

$$b_{pp'} = a_1c_pc_{p'} + a_2d_pd_{p'}, \quad b_{qq'} = a_1c_qc_{q'} + a_2d_qd_{q'},$$
$$b_{pq} = \sqrt{2}(a_1c_pc_q + a_2d_pd_q).$$

The $\Psi(A^-B^+)$ is an ionic structure in which two bonding-electrons belong to atom A (see Eq. 4). In the covalent structure $\Psi(A:B)$, those electrons are shared by the two atoms.

Let us define the following three weights, which include interference terms:

$$W(A^-B^+) = \|\Psi(A^-B^+)\|^2 + \langle\Psi(A^-B^+)|\Psi(A^+B^-) + \Psi(A{:}B)\rangle, \quad (7)$$

$$W(A^+B^-) = \|\Psi(A^+B^-)\|^2 + \langle\Psi(A^+B^-)|\Psi(A^-B^+) + \Psi(A{:}B)\rangle, \quad (8)$$

$$W(A{:}B) = \|\Psi(A{:}B)\|^2 + \langle\Psi(A{:}B)|\Psi(A^-B^+) + \Psi(A^+B^-)\rangle. \quad (9)$$

Using these weights of the structures, we can define a new scale of the ionic character for the local bond A–B as

$$\lambda_{AB} = [W(A^-B^+) - W(A^+B^-)] \times 100\%. \quad (10)$$

The more electronegative one of these two atoms should

be referred to as A in Eq. 10. Thus λ_{AB} happens to be negative when atom A happens to be more positive than atom B, as seen in Table 5 for the CH_3^- anion.

Results and Discussion

Ab initio calculations of the ionic character λ_{AB} were performed in the observed geometries with the 6-31G basis set[9] and with the STO-3G basis set[10] for neutral molecules: LiF, LiH, HF, H_2O, NH_3, CH_4, and H_2, and for molecular ions: H_3O^+, NH_4^+, OH^-, NH_2^-, and CH_3^-. The dipole moment (μ) was also computed directly for each of these neutral molecules with the same basis set (*i.e.*, not obtained from λ_{AB}).

Geometry optimization is omitted. The optimization will not greatly affect the ionic character, since the change of the bond length will be less than 0.01 Å in the 6-31G basis set.[11] Table 1 shows the geometries used in the present calculations.

TABLE 1. THE GEOMETRIES OF MOLECULES AND IONS

Molecule	Bond length / Å	Bond angle / °	Ref.

CH_4	11	0.0	0.0	...
H_2	0	0.0	0.0	...

a) P-type basis functions on lithium are excluded. b) P-type basis functions on lithium are excluded and a p_z-type basis function (α=0.25) on hydrogen is added. c) See footnote (a) of Table 1. d) B. Starck, Landolt-Börnstein Table, New Series, II/4, Springer (1967).

Table 2 shows the comparison of the λ_{AB} with the observed partial charge and the comparison of the calculated dipole moment with that observed for neutral molecules. The relative error of the dipole moment calculated to that observed is 50% at most. For a better agreement, polarization functions should be added to the basis set. The difference of the λ_{AB} from the observed partial charge is 10% at most (except for LiH). The λ_{AB} would be less sensitive than the dipole moment with respect to the absence of the polarization functions. In the case of the STO-3G basis set, the values of the λ_{AB} are too small in all molecules (*i.e.*, only 2% for LiF, 31% for LiH, 12% for HF, 11% for H_2O, and 10% for NH_3). Good λ_{AB} seems to require the 6-31G level basis-set at least.

The basis-set dependence of the λ_{HLi} for LiH was investigated by using various basis-sets. These results are in Table 3. In the STO-3G basis-set, the values of both the calculated dipole moment and the λ_{HLi} are extremely small. In the original 6-31G basis-set in which p-type basis functions on lithium (abbreviated to p(Li) from now on) are included, the calculated value of the dipole moment is in excellent agreement with the observed value, but the value of λ_{HLi} is in rather poor agreement with the observed partial charge.

TABLE 3. THE BASIS-SET DEPENDENCE OF THE VALUE OF THE IONIC CHARACTER FOR LiH MOLECULE

Basis set		E / Hartree	μ / Debye	λ_{HLi} / %

Fig. 1. The weights of resonance structures for a local bond in neutral molecules.

The function p(Li) extends into the bonding region, so it can improve the description of the region. The resulting description near the center of the electronic charge becomes reasonable (leads to a good dipole moment). However, the bonding electrons are accumulated in the p(Li) too much, so that the sharing ratio of the bonding electrons between Li and H is biased. In the 6-31G basis-set, the value of λ_{HLi} is remarkably improved by excluding the p(Li), as seen in Table 3 at basis-set (VIII). Further, the λ_{HLi} is improved by adding a p_z-type GTO on hydrogen to either the 6-31G set (without p(Li)) or the CGTO better values of λ_{HLi}, a larger basis set may be used and/or other configuration(s) may be taken into account.

Generally speaking, the λ_{AB} would be the sharing ratio of the bonding electrons between atoms A and B, so that λ_{AB} is sensitive to the balance of basis functions in the basis set used. Therefore, the p(Li) should be excluded from the 6-31G set for the calculations of λ_{XLi} as was done in the calculations for LiF and LiH.

Figure 1 shows the resonance-structures for a local-bond and their weights calculated for neutral molecules. The structures denoted by (A) and (B) are the ionic structures ($A:^- B^+$) and ($A^+ :B^-$), respectively. The covalent structure (A· ·B) is denoted by (C).**

The Ψ[2c] reduces to the Hartree-Fock wave function in the limit where a_2 goes to zero (see Eq. 1). The MCSCF-LMO reduce to the LMO in the limiting case. Therefore, the weights of resonance structures for the Hartree-Fock wave function can be calculated with the use of Eqs. 4—9 by seting a_2 to zero and using LMOs instead of MCSCF-LMOs. The results are as follows: The weights of the structures (A), (B), and (C) are 96, 0, and 4%, respectively, for LiF. For LiH, they are 66, 3, and 30%. For HF, they are 56, 6, and 38%. For H_2O, they are 47, 12, and 47%. For NH_3, they are 44, 15, and 52%. For CH_4, they are 36, 22, and 56%. They are 25, 25, and 50%, for H_2. In all molecules, the weight of the ionic structure calculated from the Hartree-Fock wave function is always larger than that calculated from the Ψ[2c] (see Fig. 1 for the values). The present weights calculated from the Ψ[2c] are reasonable, since the MO method usually overestimates the weights of the ionic structures.

Comparison with Other Scales. Several empirical relations between the ionic character and the electronegativity difference $|X_A - X_B|$, were proposed in the early days, for example, by Pauling[1] and by Hannay and Smyth;[2]

$$q_P = [1-\exp(-|X_A-X_B|^2/4)] \times 100\%, \quad (11)$$

$$q_{HS} = 16|X_A-X_B| + 3.5|X_A-X_B|^2 \ (\%), \quad (12)$$

where q_P is the ionic character determined by Pauling and q_{HS} is that determined by Hannay and Smyth. Nethercot[3] recently proposed an improved relation:

$$q_N = [1-\exp(-|X_A-X_B|^{3/2}/X_{GM}^{3/2})] \times 100\%, \quad (13)$$

where X_{GM} is the geometric mean of X_A and X_B. Table 4 shows the values of these scales in comparison with the present λ_{AB} for several molecules.

The present scale λ_{AB} is in an excellent agreement with the Nethercot scale (the improved Pauling scale), as seen in Table 4.

Table 4. The comparison of the present scale of the ionic character λ_{AB} with other scales: q_P by Pauling, q_{HS} by Hannay and Smyth, q_N by Nethercot. The observed partial charge is again listed for convenience

Molecule	q_P/%	q_{HS}/%	q_N/%	λ_{AB}/%	$[\mu/er_e]_{obsd}$/%
LiF	89	78	84	94	83.675
LiH	26	22	48	49	76.762
HF	59	43	42	40	41.47
H_2O	39	29	31	32	34.8
NH_3	18	17	19	24	28.00
CH_4	4	7	7	11	...
H_2	0	0	0	0	...

For Ionic Species. We further calculate λ_{AB} for several cation and anion molecules. It is difficult to obtain the "observed ionic character" of any bond in any ionic species. In addition, it will be difficult to extend any scale which makes use of the electronegativity difference to make it applicable to the ionic species. On the other hand, the λ_{AB} can be evaluated in the ionic species without any difficulty.

Table 5. The value of the ionic character λ_{AB} for anion and cation calculated with the 6-31G basis-set. The values for neutral molecules are again listed for convenience

Ion	λ_{OH}/%	Ion	λ_{NH}/%	Ion	λ_{CH}/%
OH^-	9	NH_2^-	0	CH_3^-	−12
H_2O	32	NH_3	24	CH_4	11
H_3O^+	50	NH_4^+	42		

Table 5 shows the values of λ_{AB} calculated with the 6-31G basis set for OH^-, NH_2^-, CH_3^-, H_3O^+, and NH_4^+ (geometries are shown in Table 1). In all cases, the λ_{XH} (X=C, N, O) shows an increase of about 20% from the neutral molecule to its cation (proton adduct), and also a decrease of about 20% to its anion (product from the elimination of a proton). Figure 2 shows the resonance structures and their weights for molecular

** The sum of values of these weights is not always unity, because all of the c_r and d_r values in Eq. 2 are not always zero. In other words, the MCSCF-LMO are not completely localized.

	$[O-H]^-$	$[H-NH]^-$	$[H-CH_2]^-$	$[H-OH_2]^+$	$[H-N_3]^+$
(A)	$H^+: O^{2-}$ 19%	$H^+: NH^{2-}$ 14%	$H^+: CH_2^{2-}$ 9%	$H^+: OH_2$ 52%	$H^+: NH_3$ 45%
(B)	$H:^- O$ 10%	$H:^- NH$ 14%	$H:^- CH_2$ 20%	$H:^- OH_2^{2+}$ 2%	$H:^- NH_3^{2+}$ 3%
(C)	$H\cdot\ \cdot O^-$ 70%	$H\cdot\ \cdot NH^-$ 73%	$H\cdot\ \cdot CH_2^-$ 76%	$H\cdot\ \cdot OH_2^+$ 43%	$H\cdot\ \cdot NH_3^+$ 53%

Fig. 2. The weights of resonance structures for a local bond in molecular ions.

ions. In Fig. 2, the structure denoted by (A) is the resonance structure in which two bonding-electrons belong to the more electronegative atom. The (B) is the resonance structure in which those electrons belong to the less electronegative atom. In structure (C), the bonding-electrons are shared between both atoms.

The weights of the resonance structures can also be evaluated from the Hartree-Fock wave function in the same manner as described in this section. The results are as follows: The weights of the structures (A), (B), and (C) are 32, 19, and 49%, respectively, for OH^-. For NH_2^-, they are 27, 28, and 54%. For CH_3^-, they are 9, 29, and 33%. For H_3O^+, they are 63, 5, and 35%. They are 57, 8, and 42% for NH_4^+. In all ions, the values of the weights of the ionic structures calculated from the Hartree-Fock wave function are always larger than those from the Ψ[2c] (see Fig. 2 for the values). In the case of molecular ions, the present weights calculated from the Ψ[2c] are reasonable (as well as for the case of neutral molecules).

Conclusion

The scale of the ionic character λ_{AB} presented here is reasonable not only for neutral molecules but also for molecular ions. One may apply this scale to systems with hydrogen bonding, organometalic compounds, complex ions, metal complexes, and so on. One may use an effective core-potential[13] in order to reduce the computational time. Even for this case, no modifications of the theory are needed.

To obtain good values of λ_{AB} requires that the 6-31G level basis-set ("double-zeta" level) be used and that some care be taken in the choice of the basis functions used in this basis set.

The authors wish to thank Prof. Dr. M. Kasha for his kind and valuable discussions. A part of this work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan. Computations were carried out at the Computer Center of the University of Tokyo or at the Computer Center of the Institute for Molecular Science.

A New Interpretation of the Fast Relaxation in a Micellar Solution

Tohru INOUE,* Ryoichi TASHIRO, and Ryosuke SHIMOZAWA
Department of Chemistry, Faculty of Science, Fukuoka University, Fukuoka 814-01
(Received June 16, 1980)

Some contradictions are pointed out in the kinetic parameters of the fast relaxation in a micellar solution deduced from the previously proposed kinetic models. A modification of the previous models is proposed. The proposed model eliminates the contradictions and leads to a consistent interpretation of the experimental results.

In many surfactant solutions there exist two well-separated relaxation processes associated with micelle-monomer equilibria. The fast process has been attributed to the perturbation of the exchange equilibrium of the monomer between micellar and bulk phases. Thus far, two different kinetic models for this process have been widely accepted for the analysis of the fast relaxation data; one of them has been proposed by Wyn-Jones *et al.*,[1] and the other, by Aniansson and Wall.[2] However, as will be shown later, it seems that neither of the two models successfully lead to a consistent kinetic parameter from the experimental data. This paper will show that a consistent interpretation becomes possible by combining the two basic concepts incorporated in the previous models.

The Treatment of Wyn-Jones *et al.*

Wyn-Jones *et al.*[1b] have treated the monomer exchange just as the adsorption-desorption phenomena of a monomer from the bulk phase to the micelles. They assumed that the rate of the entering of the monomer into the micelle is proportional to the product of the monomer concentration in the bulk phase and the area of the micellar surface uncovered by the surfactant molecules, and that the rate of the escape of the monomer from the micelle is proportional to the area of the micellar surface covered by the surfactant molecules. On these assumptions, the rate of the disappearance of the monomer from the bulk phase is given by:

$$-\frac{dA_1}{dt} = k_1 A_1(1-\alpha)S - k_{-1}\alpha S, \quad (1)$$

where A_1 represents the monomer concentration in the bulk phase; k_1 and k_{-1}, the rate constants of the entering and escaping processes of the monomer; S, the sum of the surface area of micelles present in the solution, and α, the fraction of the surface area covered by monomers. Letting a_0 be the molar area of the micellized monomer at the micellar surface, S is given by the following expression:

$$S = \sum_i iA_i\frac{a_0}{\alpha} = \frac{a_0}{\alpha}(C_0 - A_1), \quad (2)$$

where A_i is the concentration of the micelle with the aggregation number i, and C_0, the total surfactant concentration. From Eqs. 1 and 2, the following expression is derived for the relaxation time:

$$\tau_1^{-1} = k_1 a_0\frac{1-\alpha}{\alpha}C_0 - k_{-1}a_0 = k_a C_0 - k_d, \quad (3)$$

where k_a and k_d are the apparent rate constants for the entering and escaping processes of the monomer. Furthermore, from the equilibrium condition, $k_d/k_a = \bar{A}_1 \simeq$ CMC, Eq. 3 is rearranged to:

$$\tau_1^{-1} = k_d\frac{C_0 - \mathrm{CMC}}{\mathrm{CMC}}. \quad (4)$$

Equation 4 well explains the experimental finding that τ_1^{-1} increases linearly with C_0. However, the experimental findings for various surfactant systems indicate that τ_1^{-1} has a positive intercept when the abscissa is taken as $(C_0 - \mathrm{CMC})$.[3-9] Thus, the Wyn-Jones model can only partly explain the experimental results.

The Treatment of Aniansson and Wall

Aniansson and Wall[2] have explicitly taken account of the distribution of the aggregation number, s, for micelles. They assumed that the association rate of the monomer with s-mer is proportional to the product of the concentrations of the monomer and s-mer, and that the dissociation rate of the monomer from s-mer is proportional to the concentration of s-mer. Thus, the rate of flow into the aggregation number, s, is expressed by:

$$\frac{dA_s}{dt} = k_s^+ A_1 A_{s-1} - k_s^- A_s - (k_{s+1}^+ A_1 A_s - k_{s+1}^- A_{s+1}), \quad (5)$$

where A_1 and A_s represent the concentrations of the monomer and s-mer; k_s^+, the rate constant of the formation of s-mer from the monomer and $(s-1)$-mer, and k_s^-, the rate constant of the degradation of s-mer into $(s-1)$-mer. Introducing the relative deviation from the equilibrium concentration, $\xi_s = (A_s - \bar{A}_s)/\bar{A}_s$, and assuming that the distribution curve of the aggregation number is continuous, Eq. 5 is transformed to Eq. 6, which is an analogue of the one-dimensional diffusion equation:

$$\bar{A}_s\frac{\partial\xi(s,t)}{\partial t} = \frac{\partial}{\partial s}k_s^-\bar{A}_s\left[\frac{\partial\xi(s,t)}{\partial s} - \xi_1\right]. \quad (6)$$

Solving Eq. 6 under appropriate boundary conditions and assumptions, the following expression for the relaxation time is finally obtained:

$$\tau_1^{-1} = \frac{k^-}{\sigma^2} + \frac{k^-}{n}\frac{C_0 - \bar{A}_1}{\bar{A}_1}. \quad (7)$$

Furthermore, $k^+\bar{A}_1\bar{A}_{s-1} = k^-\bar{A}_s$, the equilibrium condition, leads to:

$$k^+ \simeq k^-/\bar{A}_1 \simeq k^-/\mathrm{CMC}. \quad (8)$$

In Eqs. 7 and 8, k^- and k^+ are the dissociation and association rate constants, which are assumed to be independent of s for proper micelles, σ, the parameter

characterizing the width of the distribution curve of a micellar size, and n, the average aggregation number.

According to Eq. 7, τ_1^{-1} increases linearly with C_0 and has a definite value at the CMC, which corresponds to k^-/σ^2. This agrees with experimental findings on the behavior of τ_1^{-1} with C_0. In Table 1 the values of the kinetic parameters evaluated from Eqs. 7 and 8 are summarized for several surfactant systems. All the k^- and k^+ values are those reported by Hoffmann *et al.*[4,5,8] The E_A^+'s are the apparent activation energies for the association process, estimated from the temperature dependence of k^+. A precise examination of the kinetic parameters in Table 1 will be given in the subsequent descriptions, (i), (ii), and (iii).

TABLE 1. VALUES OF THE KINETIC PARAMETERS EVALUATED FROM ANIANSSON AND WALL THEORY

DP=dodecylpyridinium, TP=tetradecylpyridinium, HP =hexadecylpyridinium, DS=dodecylsulfate, TS=tetradecyl sulfate, HS=hexadecyl sulfate.
The k^- and k^+ are those reported by Hoffmann *et al.* a) Ref. 4. b) Ref. 5. c) Ref. 8.

(i) According to Debye,[10] the rate constant to be expected for encounter-controlled ionic reaction is given by:

$$k = \frac{4\pi N_A z_A z_B e^2}{1000\varepsilon kT} \frac{D_A+D_B}{\exp(z_A z_B e^2/\varepsilon rkT)-1}, \quad (9)$$

where D and z are the diffusion coefficient and the electrovalency of the reacting species respectively, r is the center-to-center distance at which two reactants enter into the reaction, ε is the dielectric constant of the medium, and the other symbols have their usual meanings.

Applying Eq. 9 to the present association reaction between a single surfactant ion and a micelle in an aqueous solution, the rate constant is roughly estimated to be 3×10^9—1×10^8 mol^{-1} dm^3 s^{-1} at 25 °C using the appropriate numerical values; the diffusion coefficient of the monomer$\approx1\times10^{-5}$ cm^2 s^{-1}; the diffusion coefficient of the micelle is negligibly small compared with that of the monomer; the micelle radius is 15—20 Å; the micelle charge is $\pm$10—20;[11] the radius of the spherical monomer is 5 Å; hence, $r\approx$20—25 Å and $z_A z_B\approx+$10—20. Thus, the k^+ values in Table 1 imply that the association of the monomer with the micelle is controlled by the diffusion of the monomer to the micelle.

(ii) The apparent activation energy expected for a diffusion-controlled ionic reaction is estimated from Eq. 10:

$$E_A = -RT^2\frac{d\ln\eta}{dT} + RT\left\{LT+\frac{z_A z_B e^2}{\varepsilon rkT}(1-LT) \times[1-\exp(-z_A z_B e^2/\varepsilon rkT)]^{-1}\right\}. \quad (10)$$

Equation 10 is derived from Eq. 9, taking into account the fact that the diffusion coefficient is proportional to kT/η, where η is the viscosity of the medium, and that $\varepsilon=\varepsilon_0\exp(-LT)$, where L is a constant specific to the medium. In the case of an aqueous solution at 25 °C, $-RT^2d\ln\eta/dT\simeq17$ kJ mol^{-1} and $LT\simeq1.4$.[12] By substituting these numerical values into Eq. 10, one obtains E_A values of 13—17 kJ mol^{-1} for the diffusion-controlled association of the monomer with the micelle. The experimentally obtained activation energies listed in Table 1 are obviously too large to be attributed to a diffusion-controlled process.

(iii) It is expected from the conductance data that the diffusion coefficient of a surfactant ion increases by a factor of approximately 1.1 per methylene unit decrease in the chain.[13] On the other hand, as is shown in Table 1, the k^+ value for the homologous surfactant series is increased by a factor of about three to four per methylene unit decrease. Although the larger ionic strength due to the larger CMC of the shorter chain surfactant may cause a certain enhancement of the association rate, since the two reactants have the same sign of the charge, the variation of k^+ in Table 1 with alkyl chain length seems to be much larger than that expected for a diffusion-controlled association reaction.

The facts described in (ii) and (iii) are not in accordance with the order of the magnitude of k^+ estimated by means of the Aniansson and Wall theory. In order to obtain self-consistent rate constants and activation energies, an alternative approach will be proposed in the next section.

Alternative Treatment

Aniansson and Wall have considered that the dissociation rate is proportional to the micelle concentration, and that the association rate is proportional to the product of the monomer concentration and the micelle concentration. However, as assumed by Wyn-Jones *et al.*,[1a] it may be reasonable to regard the dissociation rate of the monomer as proportional to the concentration of the surfactant ion which can dissociate from the micelle, *i.e.*, the product of the concentration of the micelle and the aggregation number. Also, the association rate may be regarded as proportional to the product of the concentration of the monomer and the concentration of the site in the micellar phase into which the surfactant ion can enter. The concentration of the vacant site on the micellar surface may be expressed by a manner analogous to the treatment of Wyn-Jones *et al.* Let a_0 be the area occupied by a monomer on the micellar surface; α, the fraction of the surface area occupied by monomers, and m, the aggrega-

tion number. Then, the vacant area on the surface of a micelle is expressed by $m(1-\alpha)/\alpha \cdot a_0$. We assume here that the number of vacant sites per micelle is given by dividing the vacant area by a_0, *i.e.*, $m(1-\alpha)/\alpha$. Then, the concentration of the vacant site is expressed by $m(1-\alpha)/\alpha \cdot A_m$ for the micelle with the aggregation number m. Thus, the following relations are obtained:

$$\text{association rate} = k_{a,m+1}A_1 m\frac{1-\alpha}{\alpha}A_m = mk'_{a,m+1}A_1A_m \quad (11)$$

$$\text{dissociation rate} = mk_{d,m}A_m, \quad (12)$$

where $k_{a,m+1}$ and $k_{d,m}$ are the elementary rate constants for the monomer to enter into, and to escape from, the micelle with the aggregation number m, and where $k'_{a,m+1}=(1-\alpha)/\alpha \cdot k_{a,m+1}$. Taking account of the probable dependence of $k'_{a,m+1}$ and $k_{d,m}$ on m, and the size distribution of the micelle, the rate expression for the monomer-concentration change in the bulk phase induced by the exchange process is given by:

$$\frac{dA_1}{dt} = \sum_{m'}^{m''}[mk_{d,m}A_m-(m-1)k'_{a,m}A_1A_{m-1}], \quad (13)$$

where the aggregates with the aggregation numbers $m' \leq m \leq m''$ are regarded as micelles and where the concentrations of the oligomers are neglected. Then, according to the usual procedure of relaxation kinetics, one obtains:

$$\frac{d\Delta A_1}{dt} = \sum_{m'}^{m''}mk_{d,m}\left(\Delta A_m-\frac{\bar{A}_m}{\bar{A}_{m-1}}\Delta A_{m-1}-\frac{\bar{A}_m}{\bar{A}_1}\Delta A_1\right), \quad (14)$$

where $\Delta A_1=A_1-\bar{A}_1$, *etc.*; the bar indicates the concentration at the equilibrium for the fast relaxation process, *i.e.*, pseudo-equilibrium. If $k_{d,m}$ is assumed to be independent of m in the region of $m' \leq m \leq m''$ and is replaced by k_d, Eq. 14 leads to:

$$\frac{d\Delta A_1}{dt} = k_d\sum_{m'}^{m''}m\left(\Delta A_m-\frac{\bar{A}_m}{\bar{A}_{m-1}}\Delta A_{m-1}\right) - \frac{k_d}{\bar{A}_1}\sum_{m'}^{m''}m\bar{A}_m\Delta A_1. \quad (15)$$

If we choose the m'—m'' range properly, the first term on the right-hand side of Eq. 15 is transformed to:

$$k_d\sum_{m'}^{m''}m\left(\Delta A_m-\frac{\bar{A}_m}{\bar{A}_{m-1}}\Delta A_{m-1}\right) \simeq k_d\sum_{m'}^{m''}m\Delta A_m\left(1-\frac{\bar{A}_{m+1}}{\bar{A}_m}\right),$$

Assuming the distribution of the aggregates to be Gaussian, *i.e.*,

$$\bar{A}_m = \bar{A}_{\tilde{m}}e^{-(m-\tilde{m})^2/2\sigma^2},$$

where $\tilde{m}$ represents the average aggregation number at the pseudo-equilibrium, and σ^2, the variance of the distribution curve, we obtain:

$$\frac{\bar{A}_{m+1}}{\bar{A}_m} = e^{-1/2\sigma^2}e^{-(m-\tilde{m})/\sigma^2} \simeq 1-\frac{m-\tilde{m}}{\sigma^2}. \quad (16)$$

Equation 16 is obtained by expanding the exponential terms and neglecting the higher terms, since $\sigma \approx 10$, and $|m-\tilde{m}|$ is usually about 20 at most. Thus,

$$\sum_{m'}^{m''}m\left(1-\frac{\bar{A}_{m+1}}{\bar{A}_m}\right)\Delta A_m \simeq \frac{1}{\sigma^2}\sum_{m'}^{m''}m\left(m-\tilde{m}\right)\Delta A_m = \frac{1}{\sigma^2}\sum_{m'}^{m''}\left[\left(m-\tilde{m}\right)^2-\tilde{m}^2+m\tilde{m}\right]\Delta A_m. \quad (17)$$

In Eq. 17, $(m-\tilde{m})^2$ can be neglected compared with $m\tilde{m}$, and the $\tilde{m}^2$ term can be dropped out since $\sum_{m'}^{m''}\Delta A_m=0$ under the assumption that the distribution curve undergoes a parallel shift during the fast relaxation process. Then, under conditions of mass balance, $\Delta A_1+\sum_{m'}^{m''}m\Delta A_m \simeq 0$, the following relation is obtained from Eq. 17:

$$\text{First term of Eq. 15} = -\frac{\tilde{m}k_d}{\sigma^2}\Delta A_1. \quad (18)$$

Furthermore, the total concentration of the surfactant is expressed by:

$$C_0 \simeq \bar{A}_1+\sum_{m'}^{m''}m\bar{A}_m$$

since the concentrations of the oligomers are much smaller than those of the monomer and the micelle. Therefore,

$$\text{Second term of Eq. 15} = -k_d\frac{C_0-\bar{A}_1}{\bar{A}_1}\Delta A_1. \quad (19)$$

From Eqs. 15, 18, and 19, one obtains:

$$\frac{d\Delta A_1}{dt} = -\left(\frac{\tilde{m}k_d}{\sigma^2}+k_d\frac{C_0-\bar{A}_1}{\bar{A}_1}\right)\Delta A_1. \quad (20)$$

Thus, the reciprocal of the fast relaxation time is expressed by:

$$\tau_1^{-1} = \frac{\tilde{m}k_d}{\sigma^2}+k_d\frac{C_0-\bar{A}_1}{\bar{A}_1}, \quad (21)$$

which becomes equivalent to the expression of Aniansson and Wall (Eq. 7) when k_d in Eq. 21 is read as k^-/n. According to Eq. 21, the dissociation rate constant of the monomer from the micelle, k_d, is obtained from the slope of the τ_1^{-1} *vs.* C_0 plot. Here, $\bar{A}_1$ is the monomer concentration at the pseudo-equilibrium, but it may be practically assumed to be the CMC since the relaxation measurements are carried out under the condition of a small perturbation.

The equilibrium condition gives:

$$mk_d\bar{A}_m = (m-1)k'_a\bar{A}_1\bar{A}_{m-1}.$$

Since $\bar{A}_m \simeq \bar{A}_{m-1}$ for a broad distribution ($\sigma \approx 10$) and $m \simeq m-1$ for a usual, proper micelle, one obtains:

$$k'_a \simeq k_d/\bar{A}_1 \text{ and } k_a = \frac{\alpha}{1-\alpha}k'_a. \quad (22)$$

In the above expressions, k'_a and k_a are assumed to be independent of the aggregation number in the region of $m' \leq m \leq m''$. This assumption necessarily implies that α, the fraction of the occupied surface, is virtually invariant with m. Thus, from Eq. 22, k_a, the elementary association rate constant, can be determined if α is known. The precise value of α is not available at the present time, but an approximate estimation of it is possible. According to Tanford's calculation[14] based on geometrial considerations, S/m is 80—70 Å^2 in the range of $50 \leq m \leq 80$ for a globular micelle formed from the surfactant molecule with 12 carbon atoms. There-

TABLE 2. VALUES OF k_d AND k_a EVALUATED FROM Eqs. 21 AND 22

$CoDS_2$	25	2.4×10^4	4.2×10^6

a) From the data in Ref. 6. b) From the data in Refs. 5 and 9.

fore, taking the value of 2—3 Å as a radius of the head group, α can be estimated to be 0.2—0.4.

Table 2 lists the k_d and k_a values evaluated from Eqs. 21 and 22 for several surfactant systems. For the evaluation of k_a, we adopted $\alpha=0.3$. Although the k_a values have some uncertainty associated with α, they may be reliable at least to the order of magnitude. When α is varied from 0.2 to 0.4, k_a increases by a factor of 2.7.

As is shown in Table 2, the alternative treatment proposed in this work gives k_a values of the order of 10^6—10^7 $mol^{-1}\,dm^3\,s^{-1}$, smaller by about 10^2 than the k^+ values deduced from the Aniansson-Wall model. This difference in rate constants results from the m and α factors in Eq. 11 ($m\approx10^2$ and $\alpha\approx0.2$—0.4). These values of k_a suggest the non-diffusion-controlled association reaction of a monomer with a micelle and are reasonably consistent with the facts described in (ii) and (iii) of the preceding section.

It is considered that the association proceeds *via* the activated state, which exists in the course of the incorporation of a monomer present at the micellar surface into the interior. This activated state probably consists of the hydrocarbon tail of a monomer being partly inserted into the micellar hydrocarbon core, just to the depth where further incorporation tends to be favored by the hydrophobic interaction. For the attainment of this state, a vacant space must be formed in the hydrocarbon core where the terminal group of a hydrocarbon tail can enter. Furthermore, it is necessary for the water molecules attached to the hydrocarbon tail of the entering monomer to be released. Thus, it is likely that the energies required for such processes contribute mainly to the activation energy for the association reaction.

A Magnetic Resonance Study of the Fe_2O_3/Al_2O_3 Catalyst in a CO-N_2O Reaction

Miki Niwa,* Kunihiko Yagi, and Yuichi Murakami

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464

(Received July 18, 1980)

A magnetic resonance study was performed in order to determine the phase of iron oxide supported on Al_2O_3 and to measure *in situ* the surface conditions during the reaction. The irreversible transition of α-Fe_2O_3 into Fe_3O_4 by the reduction of the supported catalyst and the reversible transition between Fe_3O_4 and γ-Fe_2O_3 were confirmed at 280 °C. The spectrum appearing at $g=2.03$ and having the line width of about 1000 gauss clearly showed ferrimagnetic behavior; it could be attributed to the ferrimagnetic resonance (FMR) of Fe_3O_4 and/or γ-Fe_2O_3. Kinetic study suggested that the CO–N_2O reaction took place in the oxidation-reduction mechanism. The concentration of γ-Fe_2O_3 was calculated from not only the kinetic equation, but also the *in situ* measurement of the FMR signal; these values were consistent. The γ-Fe_2O_3/Al_2O_3 had nearly the same activity as the α-Fe_2O_3/Al_2O_3, whereas the unsupported γ-Fe_2O_3 had a lower activity than the α-Fe_2O_3. Such a difference in catalytic activity was discussed in comparison with other oxidation reactions.

It is well known that iron and iron oxides are differentiated into ferromagnetic and paramagnetic inorganic compounds according to their chemical composition.[1] Fe metal, Fe_3O_4 (magnetite), and γ-Fe_2O_3 (maghemite) are ferromagnetic or ferrimagnetic, and they have large magnetic moments. A Magneto-chemical investigation of catalysts has been already carried out by Selwood.[2] However, it seems that such magnetic measurements should be replaced by magnetic-resonance studies because the latter have a higher sensitivity and greater availability. Nevertheless, only a few reports about magnetic resonance studies of catalysis or adsorption have been published. For example, Loy and Noddings have investigated the hydrogen chemisorbed on a nickel catalyst.[3] The ferro-magnetic resonance (FMR) of nickel is very simple, because nickel metal should be only ferromagnetic. On the other hand, iron compounds are fairly complex, because three different phases can be observed by the FMR, as has been described above. However, the magnetic resonance of iron oxides provides a unique phenomenon, and it is particularly suitable for the measurement of solids containing small quantities of these species.

The purpose of the present study is to demonstrate the usefulness of the FMR study of the CO–N_2O reaction on Fe_2O_3 supported by the Al_2O_3 catalyst. The FMR measurements as well as the kinetic study will be used to show the reaction mechanism and the transition of the solid phases during the CO–N_2O reaction. Furthermore, the difference in catalytic activity between α- and γ-Fe_2O_3 in this reaction will be discussed.

Experimental

Catalyst and Reagent. The Al_2O_3 (Sumitomo KHD) was calcined at 450 °C for 3 h and then dipped into a solution of $Fe(NO_3)_3 \cdot 9H_2O$. After drying at 110 °C, this was calcined at 450 °C for 2 h in the stream of an O_2–N_2 (1 : 4) mixture. The final Fe_2O_3 content in the supported Fe_2O_3/Al_2O_3 catalyst was in the range between 0.15 and 13.0 wt%. Unsupported iron oxide was prepared from precipitates of $Fe(OH)_3$ obtained by the neutralization of a $Fe(NO_3)_3 \cdot 9H_2O$ solution with ammonia water. The calcination was carried out at 500 °C for 5 h in the air.

The N_2O (99.8%) and CO (99.9%) were supplied from the Takachiho Chemical Co., Ltd., and were used without further purification.

Apparatus and Procedure. An *in situ* cell, made with a Pyrex glass outer tube (3 mm i.d.) and inner tube (1 mm o.d.) was placed in an ESR cavity and heated with temperature-variant equipment. A reactant gas cosisting of N_2O, CO, Ar, and He was allowed to flow into the reactor, and the products were directly analyzed by means of a gas chromatograph connected with the reactor cell. A Porapak Q column (2.8 m) for CO_2 and N_2O and Molecular Sieve 13X column (3.5 m) for Ar, N_2, and CO were used at room temperature for the separation. The ESR was measured by means of a JEOL X-band spectrometer (JEX-ME-1X).

A conventional pulse technique was performed with helium carrier gas deoxidized through a Ti-sponge bed at 700 °C.

The amount of CO adsorbed was measured gravimetrically with a quartz spring balance.

Results and Discussion

Measurement of Phases of Supported Fe_2O_3 by Magnetic Resonance and Stoichiometry. The Fe_2O_3 supported on Al_2O_3 catalysts with different loadings have been measured in the ESR cavity at room temperature up to 280 °C. Figure 1 shows the ESR spectra of the fresh Fe_2O_3/Al_2O_3 catalyst, with 6.7% by weight Fe_2O_3 loading, as an example. As is shown clearly, this spectrum can be fitted to the simulated one assuming three differenet species with Lorentz line shapes. The computation was performed with a FACOM 230-75 at Nagoya University Computation Center. Obviously, the signal showed a greater intensity at room temperature than at 280 °C, as is usually observed in the ESR measurement of paramagnetic species.

The spectrum observed here is approximately identical with the spectrum of the iron impurity in ammonium-exchanged NaY-zeolite previously reported by Derouane *et al.*[4] According to their identification, there are three distinct paramagnetic species, *i.e.*, Fe^{3+} species in the alumino-silicate framework at $g=4.3$, an exchangeable Fe^{3+} ion at $g=2.1$, and another precipitated Fe^{3+} compound with a strong spin-exchange interaction at $g=2.3$. Consequently, the observed spectrum in Fig. 1 may be composed of these identified species. The

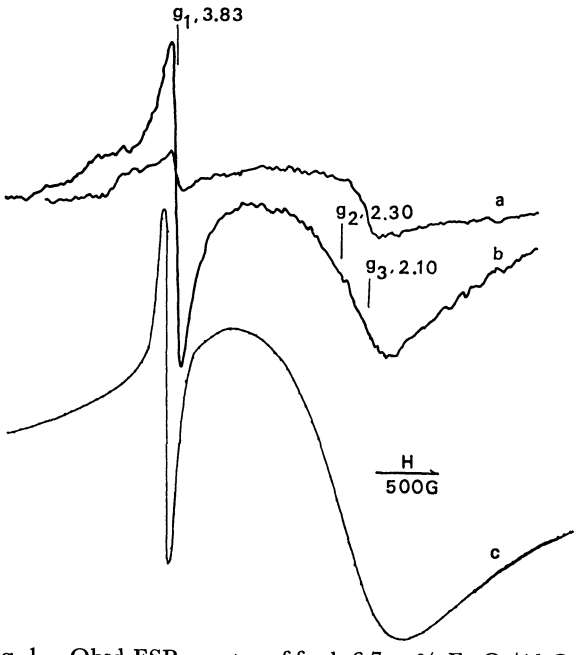

Fig. 1. Obsd ESR spectra of fresh 6.7 wt% Fe_2O_3/Al_2O_3 catalyst at 280 °C (a) and room temp (b) and simulated spectrum (c), which was obtained by the assumption of g_1, g_2, and g_3 signals whose parameters were 70, 1500, and 700 G (1 G = 10^{-4} T) as line width and 0.005, 0.933, and 0.062 as normalized coefficient of linear combination, respectively.

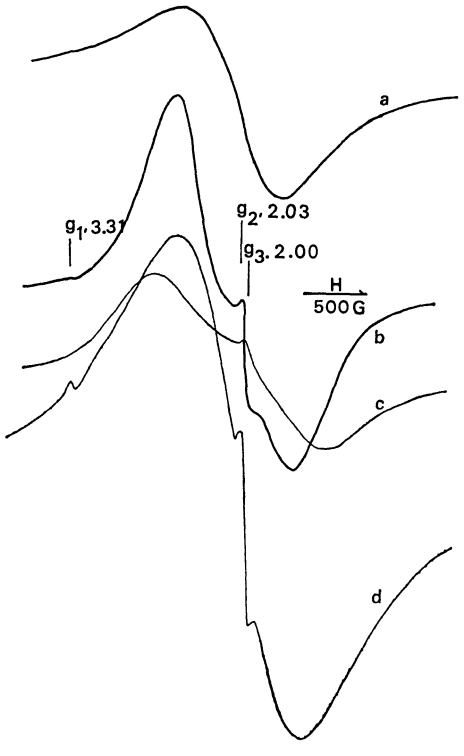

Fig. 2. Obsed ESR spectra of treated 6.7 wt% Fe_2O_3/Al_2O_3 catalyst in the reduced state at 280 °C (a) and in the oxidized state at 280 °C (b) and room temp (c). Simulated spectrum (d) was obtained by the assumption of g_1, g_2, and g_3 signals whose parameters were 50, 960, and 50 G (1 G = 10^{-4} T) as line width and 0.0002, 0.999, and 0.001 as normalized coefficient of linear combination, respectively.

substituted Fe^{3+} species may be shifted lower from g= 4.3 to g=3.8 because of the difference in the support.

The sample of Fe_2O_3 was then reduced by the current of CO at 280 °C; after confirming the steady state of ESR signal, it was reoxidized by N_2O at 280 °C. Such a treatment of the catalyst drastically changed the ESR spectrum, the intensity being magnified by about 100 times (Fig. 2). The spectrum of the oxidized sample in Fig. 2-b contained three different species, while that of the reduced sample lost the sharp signal at g=2.00. The oxidized one showed a broader signal at room temperature than at 280 °C.

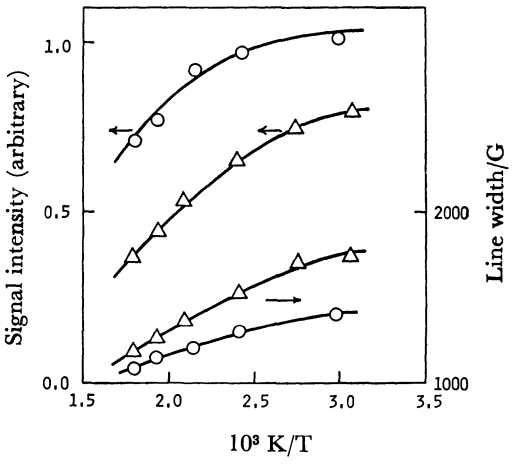

Fig. 3. Dependence of the signal intensity and the line width on the measurement temp using oxidized (○) and reduced (△) samples of the treated catalyst.

The spectra of such reduced and oxidized samples of the treated 6.7-wt% Fe_2O_3/Al_2O_3 were examined in more detail at different temperatures. After the sample had been reduced or oxidized with a CO–N_2 or N_2O–N_2 mixture at 280 °C respectively, it was sealed and subjected to measurement. In Fig. 3, the intensity and line-width of the g_2 signal are plotted against the reciprocal absolute temperature. Remarkably, the line width increased with a decrease in the temperature. Such a dependence does not indicate the paramagnetic property, but the ferro- (or ferri-) magnetic property of the samples. The small deviation from the linearity between the signal intensity and the reciprocal absolute temperature may also show the ferro- (or ferri-) magnetic property.

A pulse technique was then used to determine the phases of the treated Fe_2O_3/Al_2O_3. The injection of CO into the bed of reoxidized 6.7-wt% Fe_2O_3/Al_2O_3 formed CO_2 at 280 °C. Successive injections of CO reduced the catalyst by the depletion of the catalyst oxygen. The total amount of the CO_2 formed on 150 mg of the catalyst was 29.6 μmol. This was nearly in agreement with the expected value, 21 μmol, in which the iron oxide was assumed to be reduced to the magnetite; *i.e.*,

$$3Fe_2O_3 + CO \longrightarrow 2Fe_3O_4 + CO_2.$$

Consequently, the phase of the reduced catalyst may be identified as Fe_3O_4.

As has previously been indicated,[5] the unsupported

α-Fe_2O_3 was reduced by carbon monoxide to Fe_3O_4 at a low temperature such as 280 °C. However, the magnetite was not reversibly reoxidized to γ-Fe_2O_3 unless it was oxidized above 400 °C.[6] In other words, the reduction-reoxidation of the Fe_2O_3 can be described as;

$$\alpha\text{-}Fe_2O_3 \xrightarrow[\text{red}]{} Fe_3O_4 \underset{\text{red}}{\overset{\text{oxi}}{\rightleftharpoons}} \gamma\text{-}Fe_2O_3 .$$

The magnification of the signal by the reduction-reoxidation and its temperature dependence are, therefore, correlated with the change in the magnetic property, *i.e.*, from the paramagnetic Fe^{3+} ion to ferrimagnetic Fe_3O_4 and γ-Fe_2O_3. The sharpening of the line-width at a high temperature, as is the case of a treated catalyst, has already been indicated by Singer in the measurement of the magnetite.[7] Furthermore, it was found by the pulse method that the reoxidized catalyst could be only reduced to the level of the Fe_3O_4. Therefore, the signal at $g=2.03$ (g_2) of the treated catalyst is attributed to the ferrimagnetic-resonance (FMR) spectra of γ-Fe_2O_3 and Fe_3O_4 in the oxidized and reduced samples respectively. The g-values of γ-Fe_2O_3 and Fe_3O_4 were not distinguished from that of the pure oxide; they have been reported to be 1.96[8] and 2.13[9] respectively.

X-Ray diffraction, Mössbauer spectroscopy, or XPS has been used to distinguish the phases of iron oxide.[5,10] Infrared spectroscopy has also been recommended to identify them[11] However, these analytical methods can not be used for the supported catalysts, for the iron oxide content is too low to be detected. In fact, the X-ray diffraction of the Fe_2O_3/Al_2O_3 catalyst revealed only aluminum oxide as the support. Furthermore, it was found that the ir spectroscopy could not be used because of the intense absorption of the Al–O band. The ESR or the magnetic resonance is the most suitable for this case, for iron oxides should exhibit different resonances with high intensities depending on their magnetic properties.

On other samples of the Fe_2O_3/Al_2O_3 catalyst with a different loading of iron oxide, nearly the same spectrum as that shown in Fig. 1 was observed in the fresh condition. Although the intensities of the substituted Fe^{3+} ion at $g=3.8$ increased with the loading up to about 9 wt%, the principal signal at $g=2.3$ showed nearly the same intensity regardless of the iron-oxide content, while it turned into the FMR signal upon reduction-reoxidation treatment. The sharp signal of the treated catalyst at $g=2.00$ (g_3) which was observed in the oxidized condition became outstanding in the catalyst with a low iron content. Because this signal has a broader line-width at room temperature than at 280 °C, it might be attributed to ferromagnetic Fe metal, which may be considered to disappear upon the formation of $Fe(CO)_x$ in the reduction by CO.

In Situ *Measurement of the Reversible Transition between γ-Fe_2O_3 and Fe_3O_4.* By the use of an *in situ* cell, the FMR spectrum was measured *in situ* during the reduction and reoxidation of the catalyst at 280 °C. A Fe_2O_3/Al_2O_3 catalyst supported by 6.7-wt% Fe_2O_3 which had been treated by CO and N_2O was measured. The intensity of the signal at $g=2.03$ due to γ-Fe_2O_3

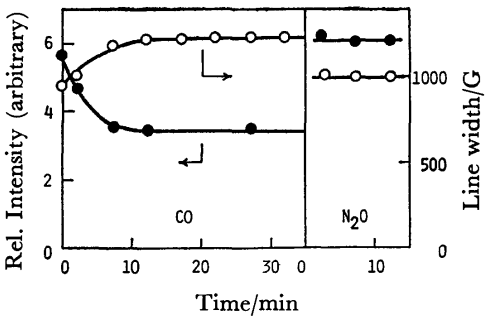

Fig. 4. Variation of signal parameters with the course of reduction by CO or oxidation by N_2O over the ferrimanetic Fe_2O_3/Al_2O_3 catalyst.

gradually decreased in flowing carbon monoxide (Fig. 4) and attained a steady state 15 min later. Simultaneously, the line-width also increased. As has been described above, the reduced state of the catalyst was attributed to Fe_3O_4. The reduced catalyst was then reoxidized by the flowing of N_2O. As is shown in Fig. 4, the signal intensity was increased rapidly by the reoxidation, and the resultant spectrum was in good agreement with the initial one. Consequently, it can be said that the transition between γ-Fe_2O_3 and Fe_3O_4 proceeds reversibly and that the rate of reoxidation is obviously faster than that of reduction. Furthermore, the intensity of Fe_3O_4 is evaluated to be 0.60 times that of γ-Fe_2O_3. The relative ratio of these signal intensities will be used in the next section of this paper to calculate the relative concentration of γ-F_2O_3. The relative intensity was measured over as wide a range of the spectrum as possible in order to minimize the error which would be contained in the evaluations of the intensity of the broad spectrum. *In situ* measurement afforded the advantage of the precise determination of the relative intensity, because the sample was measured under exactly the same conditions except for the oxidation state of the catalyst.

Kinetics and in Situ *Measurement of the CO–N_2O Reaction.* The reduction of dinitrogen monoxide by carbon

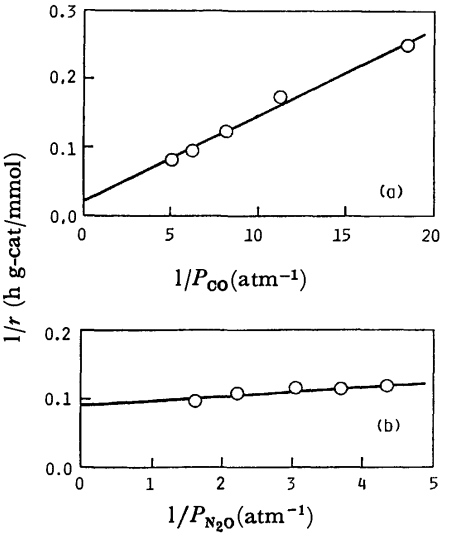

Fig. 5. Kinetics of the CO–N_2O reaction on the treated catalyst at 270 °C; Partial pressures of CO (a) or N_2O (b) were varied with other conditions kept const.

monoxide on the ferrimagnetic 6.7 wt% Fe_2O_3/Al_2O_3 catalyst was then investigated kinetically using the *in situ* cell. Simultaneously, the FMR spectrum was measured in order to monitor the condition of the catalyst.

Although the CO–N_2O reaction should form equimolar amounts of CO_2 and N_2, the CO_2 exceeded slightly the N_2 in this experiment. This was caused by the impurity of the oxygen in the cylinder of N_2O (0.16 vol%). Consequently, the rate of CO–N_2O reaction is here described by the rate of N_2 formation. Figure 5 shows the kinetics of the N_2O–CO reaction at 270 °C, in which the partial pressures of CO or N_2O are shown to vary in Fig. 5-a and Fig. 5-b respectively. The reciprocal plots between the rate of formation and the partial pressure both gave straight lines.

By taking into consideration the reversible transition between γ-Fe_2O_3 and Fe_3O_4, this reaction was assumed to proceed according to the following oxidation-reduction mechanism;

$$CO + \gamma\text{-}Fe_2O_3 \xrightarrow[k_1]{} CO_2 + Fe_3O_4 \quad (1)$$

$$N_2O + Fe_3O_4 \xrightarrow[k_2]{} N_2 + \gamma\text{-}Fe_2O_3. \quad (2)$$

In the stationary state, we abtain;

$$\frac{1}{r_{N_2}} = \frac{1}{k_1 P_{CO}} + \frac{1}{k_2 P_{N_2O}}, \quad (3)$$

where r_{N_2} denotes the rate of N_2 formation and where P_{CO} and P_{N_2O} show the partial pressures of CO and N_2O respectively. Furthermore, the concentration of γ-Fe_2O_3 during the reaction can be described as

$$\left[\gamma\text{-}Fe_2O_3\right] = \frac{1}{1 + \frac{k_1 P_{CO}}{k_2 P_{N_2O}}}. \quad (4)$$

Based on Eq. 3, the values of k_1 and k_2 can be calculated from the slope and intercept in Fig. 5. The k_1 and k_2 calculated from Fig. 5-a were 76 and 270 (mmol/h g-cat atm) respectively. Likewise, 84 and 170 (mmol/h g-cat atm) were obtained from Fig. 5-b as the values of k_1 and k_2. Because these values of the rate constant were approximately consistent, the mechanism described above seems reasonable.

The simultaneous observation of the FMR signal showed that the reaction proceeded in a state close to the γ-Fe_2O_3, for the signal intensity decreased only a little, even when there was more CO than N_2O in the gas phase. This is in agreement with the rapid reoxidation by N_2O described above and is supported by the greater value of k_2 (reoxidation step) than k_1 (reduction step).

The relative concentration of γ-Fe_2O_3 can be estimated from the kinetic equation (4) as well as from the observed FMR signal intensity (see the previous section); the concentrations of γ-Fe_2O_3 we have obtained are compared in Fig. 6. These are consistent, though a little deviation from linearity was observed in a reduced condition.

The precise determination of the concentration of γ-Fe_2O_3 from FMR is rather difficult in this case, for the signal does not vary much. Such an *in situ* measurement of the catalyst should, however, have a potential

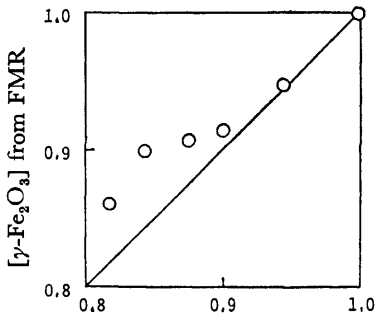

Fig. 6. Plot for the comaprison between calcd concns of γ-Fe_2O_3 based on the kinetics and the FMR signal.

ability to show direct evidence for help in solving a given problem. In this paper, the reaction mechanism shown above for the CO–N_2O reaction is supported by the *in situ* measurement of the FMR spectra.

Reactivity of α- and γ-Fe_2O_3. Misono *et al.* have already shown that γ-Fe_2O_3 has a higher activity for the oxidative dehydrogenation of 1-butene than does α-F_2O_3.[5] They suspected, because of its structural characteristics, that the high reactivity of γ-Fe_2O_3 probably originates from the rapid uptake and removal of oxygen. The reactivities of α- and γ-Fe_2O_3 were measured also in the CO–N_2O reaction. Figure 7 shows

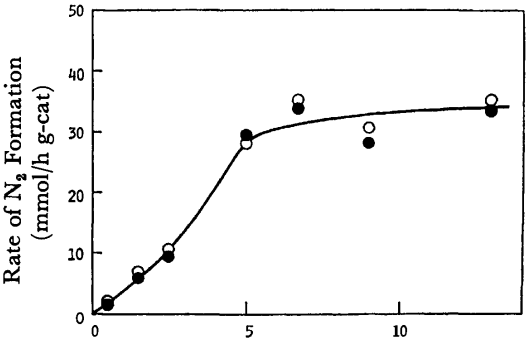

Fig. 7. Activity of α- (●) and γ- (○) Fe_2O_3/Al_2O_3 catalysts having different loadings in the CO–N_2O reaction at 280 °C in the *in situ* cell. Partial pressures of N_2O and CO were 0.23 and 0.22 atm, respectively, and 0.14 atm of Ar was contained as the internal standard for the chromatography.

the activity of α- and γ-Fe_2O_3/Al_2O_3 catalysts of various loadings in the CO–N_2O reaction. The reaction was performed in the *in situ* cell, and the phase of the catalyst was confirmed by ESR. The catalytic activity increased linearly with iron-oxide content up to about 5 wt%, while it kept nearly constant in higher concentrations. As is clearly shown, no difference was observed between the activities of α- and γ-Fe_2O_3/Al_2O_3.

In order to confirm this fact, various reactions, *i.e.*, the CO–N_2O reaction, the oxidative dehydrogenation of 1-butene, and the oxidation of hydrogen, were carried out on both supported and unsupported iron oxides by

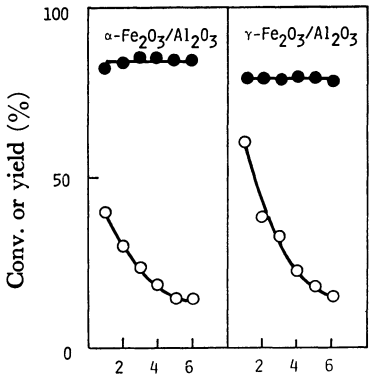

Fig. 8. Comparison of catalytic activities between α- and γ-Fe_2O_3/Al_2O_3 supported by 6.7 wt % Fe_2O_3; 0.2 ml of $CO-N_2O$ (1 : 1) (●) or 0.1 ml of 1-butene (○) was injected successively into the catalyst bed at 280 °C, and conversion into CO_2 and butadiene were plotted *vs.* number of pulse.

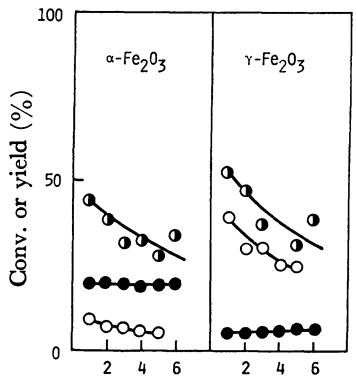

Fig. 9. Comparison of catalytic activities between α- and γ-Fe_2O_3 in the pulse reaction of $CO-N_2O$ (●), 1-butene (○) or H_2 (◑); Oxidation of hydrogen was done at 313 °C, and other were referred to in Fig. 8.

the pulse technique. Figure 8 shows the activities of α- and γ-Fe_2O_3/Al_2O_3 for the $CO-N_2O$ reaction and the oxidative dehydrogenation of 1-butene. Furthermore, Figure 9 shows the activity of unsupported oxide in these oxidation reactions. Both α- and γ-Fe_2O_3/Al_2O_3 had similar activities in the $CO-N_2O$ reaction (Fig. 8). In the case of pure iron oxide, on the other hand, α-Fe_2O_3 had a higher activity than γ-Fe_2O_3 in the $CO-N_2O$ reaction (Fig. 9). The high activity of γ-Fe_2O_3 in the oxidative dehydrogenation of 1-butene which was reported by Misono *et al.*[5] was reproducible also in this study. However, the difference between them was very small in the supported catalyst.

Not only the $CO-N_2O$ reaction, but also the oxidative dehydrogenation of 1-butene, is considered to take place in the oxidation-reduction mechanism, as has been mentioned above and described previously by Misono *et al.*[5] Furthermore, the specific surface areas of α- and γ-Fe_2O_3 were exactly the same, 18 m^2/g. Nevertheless, the catalytic activity of α- and γ-Fe_2O_3 was reversed in these reactions. Therefore, different characteristics controling these activities should be considered.

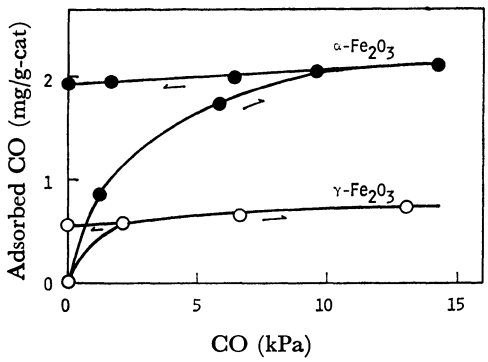

Fig. 10. Adsorption isotherms of CO on α- (●) and γ- (○) Fe_2O_3 at room temp, following the arrow in the figure.

The amount of CO adsorbed on iron oxides may be one of the reasons, because the saturated adsorbed amounts of CO on α- and γ-Fe_2O_3 at room temperature were 1.93 and 0.55 (mg/g-cat), and such a difference was analogous to the activity profile of the $CO-N_2O$ reaction. As is shown in Fig. 10, the adsorption of CO was irreversible at this temperature, and probably it was stabilized as a carbonyl complex with an exposed iron ion. In other words, the metal ions responsible for the adsorption of carbon monoxide are exposed on the surface of α-Fe_2O_3 more than on that of γ-Fe_2O_3 and seem to contribute to the high activity of the $CO-N_2O$ reaction.

As is shown in Fig. 9, γ-Fe_2O_3 had a higher activity than α-Fe_2O_3 also in the hydrogen oxidation, which can be regarded as the simplest oxidation reaction, and therefore as the reaction which is the most sensitive to the activity of surface oxygen. This adds support to the consideration by Misono *et al.* about the high activity of oxygen of γ-Fe_2O_3. On the other hand, the $CO-N_2O$ reaction may be influenced by the activation of carbon monoxide by the surface iron ion.

The Effect of Crystallite Size of Nickel on the Enantioselectivity of Modified Nickel Catalysts

Yuriko NITTA, Fumimaro SEKINE, Toshinobu IMANAKA, and Shiichiro TERANISHI*

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received August 6, 1980)

Enantioselective hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate with various unsupported nickel catalysts modified by (2*R*,3*R*)-tartaric acid was studied under mild conditions in order to elucidate the dependence of the selectivity upon the surface states of the catalysts. The catalyst with the larger crystallite size has the higher enantioselectivity, presumably because of the higher probability to obtain large ensembles of regularly-arranged nickel atoms in the catalyst surface for the modifier to adsorb strongly and regularly. The nickel boride catalyst has very low enantioselectivity, mainly due to its amorphous structure. The detrimental effect of additives (B, P, and Al in Ni–B, Ni–P, and R–Ni catalysts) was explained as the effect of their lowering the crystallinity of the catalysts.

There have been many studies on the effects of the structure of modifiers, modifying conditions, and reaction conditions on the enantioselectivities of modified nickel catalysts, mainly for the hydrogenation of methyl acetoacetate (MAA) to methyl 3-hydroxybutyrate (MHB).[1-3] On the other hand, it is well known that the enantioselectivity of modified catalysts is affected strongly by the preparation methods or the conditions of pretreatments of the metal catalysts.[4-6] However, only a few studies have established a correlation of enantioselectivity to the structure or the surface state of the modified catalysts.

We have been studying the activities and selectivities of various nickel catalysts, such as nickel boride (Ni–B), nickel phosphide (Ni–P), Raney nickel (R-Ni), Urushibara nickel(U-Ni), and the other nickel blacks, for the hydrogenation of olefins, aldehydes, and ketones by comparing with the surface states of the catalysts.[7] In the present study, we examined the enantioselective hydrogenation over various nickel catalysts in order to establish the correlation between the selectivity and the surface structure of nickel catalysts. The enantioselective hydrogenation with heterogeneous catalysts has usually been investigated by using nickel catalysts and the reaction seems very sensitive to the structure of the catalysts. (2*R*,3*R*)-Tartaric acid (TA) and MAA were selected as a modifier and a reactant in this study because most previous experiments have used them.

The Ni–B catalyst, which is known to have similar activities and selectivities to the R-Ni catalyst in many hydrogenation reactions, has a very low enantioselectivity compared to that of the R-Ni catalyst. The reason for this low enantioselectivity will be discussed later.

Experimental

Catalyst Preparation. *Nickel Boride(Ni–B)*: $Ni(CH_3COO)_2 \cdot 4H_2O$ (4.24 g) in 50 ml of distilled water was reduced with 20 ml of $NaBH_4$ (1.94 g) aqueous solution at 30 °C with vigorous stirring (P-1 method according to Brown[8]). This catalyst is called Ni–B-1 here. After 10 min, the precipitated catalyst was washed 3 times with portions of 50 ml of distilled water before modification. The catalyst was separated by centrifugation after each wash. In order to vary the surface concentration of boron in the resulting catalyst,[7f] $NiCl_2 \cdot 6H_2O$ was used instead of nickel acetate. The Ni–B-2 catalyst was prepared in 95% ethanol instead of water (P-2 method).

Nickel Phosphide(Ni–P): Nickel hydroxide, obtained by the addition of NaOH aqueous solution into 30 ml of $NiCl_2 \cdot 6H_2O$ (4.1 g) aqueous solution, was reduced with NaH_2PO_2 (5.5 g) in water at about 72 °C according to a method described by Sada.[9] This catalyst is abbreviated as Ni–P-1. For the preparation of Ni–P-2 catalyst, the reduction of nickel hydroxide was carried out in 50% ethyl alcohol instead of water.[7f] The precipitated catalyst was washed in the same way as the Ni–B catalyst was.

Raney Nickel (R-Ni): Ni–Al (42 : 58) alloy (1.43 g) was added during 10 min in small portions to 60 ml of 20% NaOH aqueous solution, usually at 70 °C, and this mixture was kept at the temperature for 20 min with gentle stirring. The leached catalyst was washed 5 times with portions of 100 ml of distilled water by decantation. The alloy was also leached at different temperatures in order to make the catalysts with different surface states.[7g]

Nickel Blacks (D–Ni and H–Ni): D–Ni catalysts were prepared by decomposing $Ni(HCOO)_2 \cdot 2H_2O$ (9.5 g) at 300 °C for 1.5—6 h (usually 3 h) followed by hydrogen flushings. NiO (3.8 g) was reduced under a hydrogen stream of 8 l/h at 350 °C for 1.5 h to prepare H–Ni catalyst. After cooled to room temperature in the hydrogen atmosphere, the nickel black was washed twice with distilled water before modification.

Modification. The modification of a catalyst was carried out at 83 °C by soaking a freshly prepared catalyst in a 1.6% aqueous solution of TA(pH=5.1) for 1.5 h with occasional shaking according to the method described by Izumi *et al.*[1,10] Several kinds of amino acids were also used as modifiers to check the enantioselectivity of modified nickel boride catalyst. After the modification, the catalyst was rinsed once with water, twice with methanol, and then once with ethyl acetate (10 ml portion of each).

Hydrogenation. 10 ml of MAA was added to the described amount of catalyst in 10 ml of ethyl acetate and hydrogenated at 60 °C in a 50 ml glass autoclave (TEM-U-50, Taiatsu Glass Industry Co., LTD.) equipped with a 200 ml gas tube and with a magnetic stirring system. The starting pressure of hydrogen was 10 kg/cm² and the pressure dropped to about 3 kg/cm² at 100% conversion. Almost all conversions were 100%. Ethyl acetate, used as a solvent, was dried and distilled before use. All the reactants were obtained from commercial sources and used without further purification.

Analysis. The reaction product was filtered off and distilled under reduced pressure. The conversion and the purity of the distilled product was measured with GLC (Shimadzu model 4APT) with a 2 m column of 20% PEG

20M on Celite 545.

The optical rotation (α_D) of the distilled product was determined with a Union PM-101 automatic digital polarimeter at room temperature (about 25 °C) in a 0.1 dm cell. The optical yield (OY) of (−)-MHB was calculated from the observed α_D value by the equation $OY=(\alpha_D/22.95)\times 100$.[11]

The X-ray diffraction pattern of the catalyst filtered after the reaction was measured with a Shimadzu VD-1 diffractometer after wetting the catalyst with ethylene glycol to avoid the oxidation of nickel metal. The mean crystallite size of nickel (D_c) was calculated from the half width of the peak from the (111) plane of nickel metal.

BET surface areas of the catalysts were measured separately by N_2 adsorption at 77 K after washing with acetone and after evacuation by a diffusion pump for 4 h at ambient temperature.

The surface compositions of some catalysts used were estimated from the analysis of X-ray photoelectron spectra (XPS) with a Hitachi 507 photoelectron spectrometer. The detailed procedures were reported elsewhere.[7f]

The amount of TA adsorbed on the modified catalyst was determined colorimetrically with Hitachi 200-20 spectrophotometer by the method reported by Christian[12] and by Harada *et al.*[13]

Results and Discussion

For the enantioselective hydrogenation of MAA with Ni–B-1 catalyst modified by TA, preliminary experiments showed that the effects of modification conditions (pH, temperature, and modifying time) and of hydrogenation conditions (temperature, H_2 pressure) on the optical yields of MHB were similar to those for the hydrogenation with modified R-Ni catalyst reported previously.[1] However, as shown in Table 1, the enantioselectivity of the modified Ni–B catalyst was very low compared to that of modified R-Ni catalyst for all the substrates and modifiers examined. The enantioselectivity of Ni–P catalyst was also very low. The negative effect of water added to the reaction mixture on the optical yield of (−)-MHB was previously reported for the enantioselective hydrogenation of MAA with modified R-Ni.[14] Therefore, the effect of the water which was contained in larger quantities within the Ni–B than within the R-Ni catalyst was examined by drying the Ni–B catalyst after modification or by adding a small amount of molecular sieve to the reaction mixture to remove the water. The result showed that the water contained within the Ni–B catalyst was not the cause of the low enantioselectivity of the catalyst. No racemization of the product on the Ni–B catalyst under the reaction conditions was observed.

Using a modified R-Ni catalyst, Harada *et al.*[5] suggested that aluminum derivatives on the catalyst surface decrease the enantioselectivity of the catalyst and that the exclusion of aluminum or related metal compounds from the catalyst surface is an essential factor for obtaining a highly enantioselective catalyst.

Table 1. Product optical purities for some hydrogenations with modified nickel catalysts

Catalyst	Modifying variables			Hydrogenation variables		Conversion	Optical activity	
	Modifier	pH	Temp/°C	Substrate[a]	Time/h	%	$[\alpha]_D^{25}$	OY/%[b]

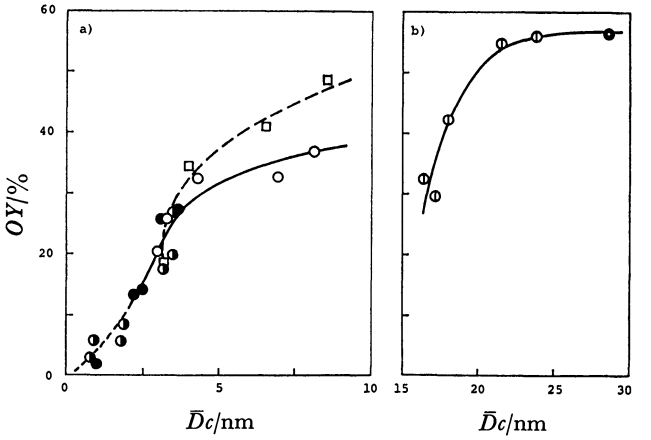

Fig. 2. Dependence of optical yields on mean crystallite sizes of nickel in various catalysts.
○: R-Ni, ◑: Ni-B, ●: Ni-P, ⓓ: D-Ni, ◎: H-Ni, —: R-Ni by Gross and Rys.[4]

Therefore, the relations between the enantioselectivity of R-Ni, Ni–B, and Ni–P catalysts and the surface contents of Al, B and P in each catalyst were investigated here. Since catalytic activities and selectivities should be compared with the states on the surface (not in the bulk) of the catalysts, we measured the surface contents of additives in various nickel catalysts by XPS.

It can be seen from Fig. 1 that the enantioselectivity of the Ni–B or Ni–P catalyst increases with decrease of the surface content of B or P in each catalyst similarly to the case of the R-Ni catalyst. The enantioselectivities of the catalysts refluxed in 20% NaOH aqueous solution for 2—6 h in order to remove the additives approach the selectivity of H–Ni catalyst, which has essentially no additives on the catalyst surface. However, the extents of the decrease in the selectivity of the Ni–B and Ni–P catalysts with the increase of additives are so large compared with that of the R-Ni catalysts that the low enantioselectivities of those catalysts are not directly attributable to the amount of additives.

On the other hand, the Ni–B and Ni–P catalysts have been reported to have amorphous structures considerably different from the structure of the R-Ni catalyst and to have similar selectivities in hydrogenation reactions.[7d,7h]

Fish and Ollis suggested, from their results on an electrochemical technique for measuring the surface coverage of TA on nickel, that a reactant molecule adsorbed on an optically selective site requires more metal surface area than one adsorbed at an optically nonselective site.[15] Alternatively this suggestion may be stated as follows: the optically selective site must consist of an ensemble of regularly-arranged nickel atoms for reactant molecules and modifiers to adsorb strongly and regularly. Accordingly, amorphous surfaces of catalysts, such as the Ni–B catalyst, are supposed to exhibit a low enantioselectivity because of the low probability of finding such ensembles. A higher optical yield is expected for a catalyst with a larger crystallite size, by assuming that the surface structure reflects directly the bulk structure of the catalyst.

With these considerations in mind, the dependence of the enantioselectivities of various nickel catalysts modified by TA upon the crystallite sizes of nickel metal in them has been investigated.

As can be seen from Fig. 2, the enantioselectivities of the catalysts are clearly related to the mean crystallite sizes of nickel in the catalysts, although the crystallite sizes in the Ni–B and Ni–P catalysts are too small to calculate exactly by the XRD method. In addition, the removal of Al, B, or P from the R–Ni, Ni–B, or Ni–P catalyst by refluxing the catalyst in 20% NaOH aqueous solution led to the larger crystallite size of nickel and correspondingly to the higher enantioselectivity of the catalyst. Also noteworthy is that the plots for the three kinds of catalysts of different preparative methods (*i.e.*, Ni–B, Ni–P, and R–Ni) in Fig. 2a) are almost all on the same line, while the plots in Fig. 1 are on different lines for the three kinds of catalysts. Moreover, the data of *OY* of (−)-MHB reported by Gross and Rys[4] for a similar enantioselective hydrogenation over various R-Ni catalysts, under slightly different experimental conditions from ours, were found to be in good correlation to the crystallite sizes of nickel in the catalysts, as shown in Fig. 2a). The relatively low enantioselectivities of the D–Ni catalysts with the crystallite sizes under 20 nm in Fig. 2b) are probably due to the impurities from decomposed nickel(II) formate still remaining on the nickel surface after the short decomposition time of 1.5—3 h. A similar dependence of enantioselectivity on the crystallite size of nickel was observed for the hydrogenation of diacetone alcohol (4-hydroxy-4-methyl-2-pentanone), as can be seen from Table 1 (Nos. 16—20).

These findings are in accordance with the report by Klabunovskii for the enantioselective hydrogenation of ethyl acetoacetate (EAA) on Ru/SiO_2 catalysts with the particle sizes of Ru smaller than 4.5 nm,[6c] although the enantioselectivity should be compared, not with the particle size, but with the crystallite size, because of the reason discussed above.

These results suggest that the size of ensembles of

regularly-arranged nickel atoms on the catalyst surface is a more important factor for a catalyst to be enantioselective than the surface content of additives is. The detrimental effect of additives (B, P, and Al) shown in Fig. 1 can be attributed to the effect of their lowering the crystallinity of the catalysts. The difference between the influence of Al and that of B or P is explained by the fact that the aluminum in R-Ni segregates in the catalyst as Al_2O_3[7g] and that it does not lower the crystallinity of the catalyst so much as B or P in the Ni–B or Ni–P catalyst.

Table 2. The amounts of adsorbed (2*R*,3*R*)-tartaric acid on various nickel catalysts

Catalyst	Sa[a]	Amount of adsorbed acid[b]		OY[c]
	m^2 g-Ni^{-1}	10^{-2} mmol × g-Ni^{-1}	10^{-3} mmol × m^{-2}	%
Ni–B-1	21.8	10.7	4.91	3.0
Ni–B-1[d]	21.8	4.65	2.13	0.7
Ni–B-2	38.2	7.03	1.84	5.6
Ni–B-2[e]	62.7	3.16	0.50	26.7
R-Ni	100.4	5.71	0.57	25.7
D-Ni	10.5	1.06	1.01	42.2
H-Ni	3.4	0.35	1.03	56.2

a) BET surface area. b) Modifying conditions: pH=5.1, 83 °C, 1.5 h. c) The optical yield of (−)-MHB. d) The catalyst was washed 6 times with water after modification instead of 2 times. e) The catalyst was refluxed for 6 h in 20% NaOH aq solution before modification.

In Table 2, the amounts of adsorbed TA on various nickel catalysts measured after modification are shown, together with the surface areas and the enantioselectivities of the catalysts. The amount of adsorbed TA on unit surface area of nickel in the Ni–B catalyst is rather more than the amount on the R-Ni or the other catalysts. When the Ni–B-1 catalyst was washed much more than usual after modification, it lost more than half of the adsorbed acid and there was a drastic decrease of the enantioselectivity of the catalyst. The remaining amount of the adsorbed acid was, however, still much more than that on the R-Ni catalyst. These facts suggest that the adsorption strength of the acid on Ni metal in the surface of the Ni–B catalyst is rather weak and that the adsorbed acid remaining after the heavy washing may be bound to the boron in the catalyst by esterification, contributing nothing to the enantioselectivity of the catalyst. On the other hand, the Ni–B-2 catalyst freed of the boron by refluxing in alkaline solution before modification had a much higher enantioselectivity than the untreated catalyst, in spite of the much smaller amount of the adsorbed acid on the treated catalyst. As for the catalysts in Table 2 other than the Ni–B, the increase of the adsorbed modifier results in the increase of the enantioselectivity.

These facts show that the total amount of the adsorbed modifier is not a direct factor affecting the enantioselectivity of modified catalysts, but the amount of the modifier adsorbed strongly and regularly on the surface of a large crystallite is important for the enantioselectivity. Thus, the poor enantioselectivities of modified Ni–B and Ni–P catalysts can be explained mainly by the exceedingly low crystallinity of these catalysts.

A binary boride catalyst, Co–Ni–B (Co : Ni=6 : 4), had only a negligible degree of enantioselectivity (OY=0.8%). This is also attributable to the more amorphous structure of the binary boride catalyst than that of Ni–B catalyst, as reported before.[16] The much lower enantioselectivity of Raney-Cu–Ru catalyst (Ru= 0.01—0.5%) than those of Raney-Cu and Raney-Ru catalysts reported by Klabunovskii[17] may also be explained in terms of the crystallite size of the catalyst.

From the discussion above, it can be concluded that the catalyst with the larger crystallite size has the higher enantioselectivity, presumably because of the higher probability to find ensembles of regularly-arranged nickel atoms (*i.e.*, optically selective sites) on the catalyst surface.

Recently, Klabunovskii[18] proposed a model of the active sites for enantioselective hydrogenation located not on the plane but on the edge in the catalyst surface. In order to make clear the more detailed structure of optically selective sites in the catalyst surface, further studies will be required.

As for the reaction rate, the catalyst of the higher enantioselectivity has the lower hydrogenation activity, as can be deduced from the data in Table 1. This is easily understandable from the fact that the catalyst with the larger crystallite size generally has the smaller specific surface area. In order to obtain a highly enantioselective catalyst with a high hydrogenation activity, it seems a good idea to use supported nickel catalysts. Moreover, the supported catalysts are very useful in order to elucidate the relation between the surface states and the enantioselectivities of the catalysts, since it is possible to vary the surface states or the size distribution of metal particles of the supported catalysts by employing various preparation methods. With these expectations in mind, further studies on the effect of preparation methods upon the enantioselectivity of supported nickel catalysts are now in progress.

The authors wish to thank Professors Yoshiharu Izumi and Akira Tai, Osaka University, for their helpful suggestions, and Dr. Yasuaki Okamoto of our laboratory for his valuable advice.

Studies on Chemiluminescent Compounds. I. Syntheses of Acyl-substituted Anthracene Derivatives and Their Chemiluminescence

Toshiyuki HIRAMATSU,* Toshiaki HARADA, and Teizo YAMAJI

Products Development Institute, Teijin Limited, 2-1 Hinode-cho, Iwakuni, Yamaguchi 740

(Received August 14, 1980)

New anthracene derivatives with a –COCH– group, such as 1,5-dipropionylanthracene, 1,8-dipropionylanthracene, 1,5-di-isobutyrylanthracene, 1,8-diisobutyrylanthracene, 1,5-bis[3-(methoxycarbonyl)propionyl]-anthracene, 1,8-bis[3-(methoxycarbonyl)propionyl]anthracene, 1,5-bis(cyclohexylcarbonyl)anthracene, 3,7-diisopropyl-1,5-diisobutyrylanthracene, and 5-dimethylamino-4-isobutyryl-1-methoxyanthracene (**10**) have been synthesized. Their direct chemiluminescences were studied by air oxidation in alkaline solutions. The properties of the chemiluminescence have been found to be influenced by not only the class of the C–H bond adjacent to the carbonyl group but also by the electronic properties of the aromatic ring system, the solvent, and the additive. **10** exhibited the longest chemiluminescence. This chemiluminescent phenomenon might be explained by a chemically initiated electron exchange luminescence (CIEEL) mechanism.

Since luminescence is an emission from an electronic excited state, the necessary excited molecule must be produced in any chemiluminescent reaction. Recent investigations suggest that effective excited molecules (singlet state) are produced in decomposition reactions of cyclic peroxides such as 1,2-dioxetanes, and 1,2-dioxetanones.[1] These intermediate peroxides are thought to exist also in bioluminescence. Most of the bioluminescence processes are remarkably efficient and show direct luminescence from the air oxidation of luciferins. The quantum yield for an enzymatic process as in a firefly is approximately 0.88 einstein mol^{-1}.[2]

Kamiya and Sugimoto studied indirect chemiluminescence: the transfer of energy from activated carbonyl intermediates in the oxidation of compounds having –COCH– groups to 9,10-dibromoanthracene or 9,10-diphenylanthracene. They observed strong luminescence when the C–H bond adjacent to the carbonyl group is tertiary C–H. They also reported that 4-hydroxy or 4-methoxy-substituted aromatic ketones gave effective singlet excited states. They did not, however, mention the effect of the catalyst and the additives on the chemiluminescence of the compounds mentioned above.[3] They recently reported the direct chemiluminescence of 9,10-diisobutyrylanthracene in the alkaline air oxidation, but they did not mention the effects of substitution in the anthracene ring, of basicity of the catalyst, and of the additives.[3]

In the practical use of chemiluminescence, the radiation of light of 500—520 nm is preferred because of strong human sensitivity to light in this region. Direct chemiluminescence in the benzene system fails to produce visible radiation of such a long wave length. But the use of anthracene compounds makes it possible to radiate the light of 500 nm and to make a practical light source for human beings. The lack of the investigation of details in the mechanism of chemiluminescence of anthracene type ketones motivated our present work.

We report in this paper the effects of substitution in anthracene ring, of basicity of catalyst, and of the additives, with the hope of the development of light for practical use.

To investigate the direct chemiluminescence mechanism, anthracene compounds **1**—**10** were synthesized and examined in various alkali catalyst oxidations with additives such as crown ether. We will discuss the chemiluminescence mechanism based on the observed chemiluminescence spectra. We suggest that an excited singlet state carbonyl may be generated by the air oxidation of these anthracenes. The mechanism is explained in terms of chemically initiated electron exchange luminescence (CIEEL).[4]

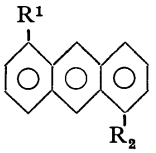
Results and Discussion

In order to investigate the substituent effects on the direct chemiluminescence from the air oxidation of anthracene derivatives, we newly synthesized several compounds listed in Tables 1, 2, and 3 using the usual Friedel-Crafts acylation.[5]

Reaction of Acyl Chloride with Anthracenes. The reaction of anthracene derivatives with several acyl chlorides and anhydrous aluminum chloride in anhydrous carbon disulfide afforded the corresponding compounds **1**—**10**. In most cases, carbonyl groups are introduced at the 1-position or at both 1 and 5-positions of anthracene.[6] However, in the reaction of anthracene with isobutyryl chloride, alkylation reaction also occurred in part to afford 3,7-diisopropyl-1,5-diisobutyrylanthracene (**9**). The reaction of isopropyl chloride with 1,5-diisobutyrylanthracene (**3**) in the presence of excess anhydrous aluminum chloride gave the same alkylated diketone **9**. A similar alkylation in the Friedel-Crafts acylation reaction has been reported by Rothstein and Saville.[7] They suggested that alkylation took place *via* the decarbonylated acyl chloride-aluminum chloride addition complex ($R^+ \cdot AlCl_4^-$) when less reactive aromatic compounds were used. Compound **9** might be produced in the same manner. Anthracene and more reactive anthracene derivatives such as 1-dimethylamino-5-methoxyanthracene were easily acylated. The acylation of 1,5-diisobutyrylanthracene did not proceed. The reaction gave only a dialkyl diacyl derivative. This might be due to the deactivation by two carbonyl groups.

Chemiluminescence in the Air Oxidation of Anthracenes. The direct chemiluminescence was observed upon adding potassium *t*-butoxide (^{t}BuOK) in *t*-butyl alcohol or potassium hydroxide (KOH) in water to these ketones in various aerated solvents, such as

TABLE 1. THE CHEMILUMINESCENCE WITH 1,5-DISUBSTITUTED ANTHRACENES BY AIR OXIDATION[a)]



R_1, R_2		Base	Life time / min	Light emission	Colors of resulting solns
$COCH_3$	(1)	^{t}BuOK or KOH	≈0	none	dark purple (in DMSO)

dimethyl sulfoxide (DMSO), *N,N*-dimethylformamide (DMF), benzene, or phthalic esters. The chemiluminescent responses were changed by the experimental conditions—*i.e.* by the solvent, by the concentrations of ketones and catalysts, more essentially by the electronic properties of the aromatic ring systems, and by the chemical structures of the ketones. The properties of chemiluminescence examined in DMSO or dibutyl phthalate (DBP) solution, using ^{t}BuOK or KOH as a base, are listed in Tables 1, 2, and 3 for 1,5-disubstituted, 1,8-disubstituted, and multi-substituted anthracenes, respectively, together with the colors of the resulting solutions. The results in the tables show that the efficiency of the emission is influenced both by the class of the C–H bond adjacent to the carbonyl group and by the electronic properties of the aromatic ring systems. The former was discussed by Kamiya *et al.*, who showed that a compound possessing a C–H bond adjacent to carbonyl group gave the most intensive chemiluminescence.[3] Our results showed the similar behavior of the chemiluminescent reaction. From Table 3, it can be seen that electron-donating groups such as dimethylamino or methoxy groups strongly increase quantum yield and lengthen chemiluminescence time. Thus, 5-dimethylamino-4-isobutyryl-1-methoxyanthracene (**10**) exhibits the most intensive and longest chemiluminescence among all of these ketones.

We also examined the fluorescence and chemiluminescence spectra of ketones **3**, **9**, and **10**, which are shown in Figs. 1, 2, and 3. In Figs. 1 and 2, the chemiluminescent spectra of the ketones **3** and **9** are red-shifted compared to those of the two air-oxidated products. Contrary to this, in Fig. 3, the chemiluminescent spectrum of ketone **10** shows a pattern closely similar to the fluorescent spectrum of the methyl ester of its air-oxidated product. The final products of the air oxidation of these ketones were the corresponding acids.

In order to obtain the best conditions for the chemi-

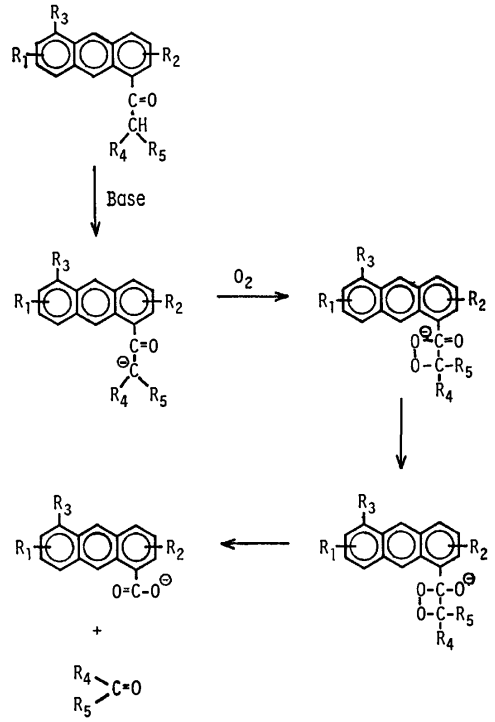
TABLE 4. THE EFFECTS OF BASE AND ADDITIVE (DICYCLOHEXANO-18-CROWN-6(C.E.)) ON THE EFFICIENCY OF EMISSION OF COMPOUND **10**

Condition	1[e]	2[e]	3[e]	4[f]
Base and additive	^{t}BuOK / ^{t}BuOH	^{t}BuORb / ^{t}BuOH	^{t}BuOCs / ^{t}BuOH	^{t}BuOK+ C.E.
i_{max}[a]	1.00	0.61	0.88	46.0
t_{max}[b]	10 min	20 min	11 min	0.5 min
$t_{1/4}$[c]	81 min	110 min	75 min	1.0 min
Quantum yield[d]	2.5%	2.0%	2.0%	4.6%

a) The relative intensity of the emission peaks; the intensity of the emission peak under conditions 1 was defined as 1.00. b) The time needed for the intensity of the emission to reach a maximum. c) The time for the intensity to decay to one-fourth of the maximum value. d) These were measured in benzene solution at 25 °C. e) To a stirred solution of compound **10** (0.002 mmol) in benzene (1 ml) was added a solution of ^{t}BuOM (0.35 mmol) in ^{t}BuOH (1 ml). f) To a stirred mixture of compound **10** (0.002 mmol), benzene (1.9 ml), and powdered ^{t}BuOK (40 mg) was added dicyclohexano-18-crown-6 (0.2 mmol).

luminescent reaction, we investigated the effects of solvent, of base, and of additives, using ketone **10**, which has the longest chemiluminescence. Nonpolar solvents such as benzene, toluene and xylene extended the life-time of the emission. The effects of the base and the additive are summarized in Table 4. When benzene was used as a solvent, the addition of dicyclohexano-18-crown-6 as an additive was the most effective: the quantum yield of chemiluminescence reached 0.046 einstein mol^{-1}. This value is approximately three-times as high as those produced using the Seliger-Lee luminol standard.[8] These results suggest that intermediate dioxetane species which will be generated by the oxygenation of the anion of ketones are formed as described in the following mechanism:



Conclusion

The efficiency of chemiluminescence increases when an electron-donating group is attached to the aromatic ring (**10**) and the chemiluminescent spectrum of ketone **10** shows a pattern closely similar to the fluorescent spectrum of its air-oxidated product. These findings suggest that this chemiluminescence may be generated *via* CIEEL mechanism. By contrast, the emission from ketones **3** and **9** may be generated from the intermediate intramolecular exciplex, because the chemiluminescent spectra are red-shifted compared to those of the air-oxidated products.

Werner *et al.* reported that, for anthracenes in general, the energy of the first excited singlet state (S_1) is observed to decrease as solvent polarity increases.[9] We think that the low efficiency of chemiluminescence in polar solvents is due to the efficient intersystem crossing from S_1 to T_1. Dicyclohexano-18-crown-6 may play an important role in dissolving the catalyst in a nonpolar solvent.

In summary, we have synthesized several anthracene derivatives which showed chemiluminescence by air-oxidation, using a base as a catalyst. 5-Dimethylamino-4-isobutyryl-1-methoxyanthracene (**10**) exhibits the most intensive chemiluminescence. This may be generated *via* CIEEL mechanism.

Experimental

Melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. ^{1}H NMR spectra were run on a JEOL-MH-100 NMR spectrometer using $CDCl_3$ as a solvent and tetramethylsilane as an internal standard. ^{13}C NMR spectra were taken on a JEOL-FT-NMR spectrometer FX200 apparatus, using $CDCl_3$ as solvent and tetramethylsilane as an internal reference. Infrared spectra were recorded on Shimadzu IR-400 spectrometer as Nujol mulls. Mass spectra were determined on a JEOL-JMS-D-100. Chemiluminescence spectra were measured using a Shimadzu spectrofluorophotometer RF-520 and are uncorrected. Column chromatography was carried out using Wako silica gel C-200 with cyclohexane–benzene mixture from 1 : 0.1—1 : 3 or benzene as an eluent. The solvents for the column chromatography were obtained from Tokyo Kasei Co., Ltd. and were used without purification.

General Procedure for Friedel-Crafts Acylation of Anthracenes with Acyl Chlorides. A solution of anhydrous aluminum chloride (0.06 mol) and the acyl chloride (0.06 mol) in 30 ml of anhydrous carbon disulfide was added to a stirred solution of anthracene (3.6 g, 0.02 mol) in 35 ml anhydrous carbon disulfide at 20—25 °C and the mixture was stirred for 2—5 h at room temperature or at reflux. The reaction mixture was poured to a 200 ml beaker nearly filled with a mixture of crushed ice and concentrated hydrochloric acid. The organic layer was extracted with benzene, washed with 5% aqueous sodium hydrogencarbonate solution, and evaporated to dryness. Isolation and purification of each product were performed with column chromatography on silica gel.

Analyses and properties of the products are described below. Specific examples of the acylation are given in detail below.

1,5-Dipropionylanthracene (2): Yield 28%; mp 169—171.5 °C; IR 1675 cm^{-1}; NMR ($CDCl_3$): δ=1.32 (6H, t, J=9.0 Hz), 3.12 (4H, q, J=9.0 Hz), 7.45 (2H, dd, J=7.0 and 8.0

Hz), 7.96 (2H, d, J=7.0 Hz), 8.20 (2H, d, J=8.0 Hz), and 9.40 (2H, s). MS *m/e*: 290. Found: C, 82.70; H, 6.23%. Calcd for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%.

1,8-Dipropionylanthracene (6): Yield 13%; mp 169—171.5 °C; IR 1675 cm^{-1}; NMR ($CDCl_3$): δ=1.30 (6H, t, J=7.5 Hz), 3.08 (4H, q, J=7.5 Hz), 7.40 (2H, dd, J=7.0 and 7.5 Hz), 7.75 (2H, d, J=7.0 Hz), 8.04 (2H, d, J=7.5 Hz), 8.36 (1H, s), and 9.77 (1H, s). MS *m/e*: 290. Found: C, 82.91; H, 6.24%. Calcd for $C_{20}H_{18}O_2$: C, 82.73, H, 6.25%.

1,5-Bis(cyclohexylcarbonyl)anthracene (4): Yield 37%; mp 208—210 °C; IR 1690 cm^{-1}; NMR ($CDCl_3$): δ=1.20—2.10 (20H, m), 3.10—3.50 (2H, m), 7.46 (2H, dd, J=7.0 and 8.5 Hz), 7.86 (2H, d, J=7.0 Hz), 8.16 (2H, d, J=8.5 Hz), and 9.06 (2H, s). MS *m/e*: 398. Found: C, 84.26; H, 7.62%. Calcd for $C_{28}H_{30}O_2$: C, 84.38; H, 7.59%.

1,5-Bis[3-(methoxycarbonyl)propionyl]anthracene (5): Yield 23%; IR 1735 cm^{-1}; NMR ($CDCl_3$): δ=2.88 (4H, t, J=6.0 Hz), 3.48 (4H, t, J=6.0 Hz), 3.76 (6H, s), 7.52 (2H, dd, J=7.0 and 8.5 Hz), 8.12 (2H, d, J=7.0 Hz), 8.26 (2H, d, J=8.5 Hz), and 9.45 (2H, s). MS *m/e*: Found: C, 71.20; H, 5.32%. Calcd for $C_{24}H_{22}O_6$: C, 70.92; H, 5.46%.

1,8-Bis[3-(methoxycarbonyl)propionyl]anthracene (8): Yield 11%; mp 172.5—175 °C; IR 1730—1745 cm^{-1}; NMR ($CDCl_3$): δ=2.92 (4H, t, J=7.0 Hz), 3.45 (4H, t, J=7.0 Hz), 3.76 (6H, s), 7.45 (2H, dd, J=7.0 and 8.0 Hz), 8.02 (2H, d, J=7.0 Hz), 8.18 (2H, d, J=8.0 Hz), 8.50 (1H, s), and 9.92 (1H, s). MS *m/e*: 406. Found: C, 70.98; H, 5.42%. Calcd for $C_{24}H_{22}O_6$: C, 70.92; H, 5.46%.

Reaction of Anthracene with Isobutyryl Chloride. A solution of aluminum chloride (8.0 g) and isobutyryl chloride (6.4 g) in 30 ml of anhydrous carbon disulfide was added to a stirred solution of anthracene (3.6 g) in 35 ml anhydrous carbon disulfide at 20 °C and the mixture was stirred for 5 h at reflux. The reaction mixture was poured into a 200 ml beaker nearly filled with a mixture of ice and concentrated hydrochloric acid. The organic substances were extracted with benzene and washed with 5% aqueous sodium hydrogencarbonate. Then the solvent was evaporated to dryness. The obtained residue was subjected to column chromatography with benzene as an eluent. The crude crystalline products were separated and recrystallized from ethanol to afford three pure products:

1,5-Diisobutyrylanthracene (3): Yield 2.16 g (34%). Mp 124.5—126 °C; IR 1675 cm^{-1}; NMR ($CDCl_3$): δ=1.28 (12H, d, J=8.0 Hz), 3.69 (2H, sept, J=8.0 Hz), 7.44 (2H, dd, J=7.0 and 8.0 Hz), 7.83 (2H, d, J=7.0 Hz), 8.14 (2H, d, J=8.0 Hz), and 9.08 (2H, s). ^{13}C-NMR ($CDCl_3$): δ=18.9, 39.0, 124.1, 126.0, 127.5, 128.3, 133.0, 133.5, 135.5, and 208.2 Hz. MS *m/e*: 318. Found: C, 83.10; H, 6.88%. Calcd for $C_{22}H_{22}O_2$: C, 82.98; H, 6.96%.

1,8-Diisobutyrylanthracene (7): Yield 0.75 g (12%). Mp 102.5—104.5 °C; IR 1675 cm^{-1}; NMR ($CDCl_3$): δ=1.28 (12H, d, J=8.0 Hz), 3.54 (2H, sept. J=8.0 Hz), 7.43 (2H, dd, J=7.0 and 8.0 Hz), 7.67 (2H, d, J=7.0 Hz), 8.04 (2H, d, J=8.0 Hz), 8.40 (1H, s), and 9.18 (1H, s). MS *m/e*: 318. Found: C, 82.73; H, 6.99%. Calcd for $C_{22}H_{22}O_2$: C, 82.98; H, 6.96%.

3,7-Diisopropyl-1,5-diisobutyrylanthracene (9): Yield 0.12 g (1.5%). Mp 192—195 °C; IR 1680 cm^{-1}; NMR ($CDCl_3$): δ=1.27 (12H, d, J=8.0 Hz), 1.40 (12H, d, J=8.0 Hz), 3.08 (2H, sept, J=8.0 Hz), 3.56 (2H, sept, J=8.0 Hz), 7.65 (2H, s), 7.90 (2H, s), and 8.91 (2H, s). ^{13}C-NMR ($CDCl_3$): δ= 19.0, 23.5 34.1, 39.1, 125.0, 127.5, 128.1 128.2, 132.9, 135.7, 143.8, and 208.5 Hz. MS *m/e*: 402. Found: C, 83.38; H, 8.44%. Calcd for $C_{28}H_{34}O_2$: C, 83.54; H, 8.51%.

Reaction of 1,5-Diisobutyrylanthracene with Isobutyryl Chloride. To a stirred mixture of 1,5-diisobutyrylanthracene (4.8 g) and aluminum chloride (16 g) in anhydrous carbon disulfide (20 ml) was added a solution of isobutyryl chloride (8.0 g) in anhydrous carbon disulfide (5 ml) at 20 °C. The mixture was stirred overnight and treated as described above. Separation by column chromatography and recrystallization from ethanol–hexane afforded 3,7-diisopropyl-1,5-diisobutyrylanthracene (**9**): Yield 1.05 g (17.4%).

Reaction of 1-Isobutyrylanthracene with Isobutyryl Chloride. To a stirred mixture of 1-isobutyrylanthracene (2.5 g) and aluminum chloride (10.7 g) in anhydrous carbon disulfide (20 ml) was added a solution of isobutyryl chloride (8.5 g) in anhydrous carbon disulfide (5 ml) at 25 °C. The mixture was stirred overnight at 25 °C and treated as described above. Separation using column chromatography and recrystallization from ethanol–hexane afforded 1,5-diisobutyrylanthracene (**3**) (0.36 g, 11%), and 3,7-diisopropyl-1,5-diisobutyrylanthracene (**9**) (0.4 g, 10%).

Reaction of 1,5-Diisobutyrylanthracene with Isopropyl Chloride. To a stirred mixture of 1,5-diisobutyrylanthracene (1.6 g) and aluminum chloride (6.7 g) in anhydrous carbon disulfide (20 ml) was added a solution of isopropyl chloride (4.0 g) in anhydrous carbon disulfide (10 ml) at 25 °C. The mixture was stirred at 25 °C for 6 h, then for 2 d at reflux, and treated as described above. The starting 1.5-diisobutyrylanthracene was recovered (1.1 g) and 3.7-diisopropyl-1,5-diisobutyrylanthracene (**9**) (0.4 g, 19.4%) was separated out.

Reaction of 1-Dimethylamino-5-methoxyanthracene with Isobutyryl Chloride. A solution of anhydrous aluminum chloride (0.06 mol) and isobutyryl chloride (0.06 mol) in 30 ml of anhydrous carbon disulfide was added to a stirred mixture of 1-dimethylamino-5-methoxyanthracene (5.0 g, 0.02 mol) in 30 ml anhydrous carbon disulfide at 0—5 °C. The mixture was stirred at the same temperature for 3 h. The reaction mixture was treated as described above. Isolation and purification gave a greenish crystalline material identified as 5-dimethylamino-4-isobutyryl-1-methoxyanthracene; Yield 2.0 g (31.2%). Mp 134.5—139 °C; IR 1675 cm^{-1}; NMR ($CDCl_3$): δ=1.30 (6H, d, J=6.0 Hz), 3.00 (6H, s), 3.66 (1H, sept, J=6.0 Hz), 4.12 (3H, s), 6.66 (1H, d, J=8.5 Hz), 6.98 (1H, d, J=8.0 Hz), 7.38 (1H, dd, J=8.0 and 9.0 Hz), 7.66 (1H, d, J=9.0 Hz), 7.86 (1H, d, J=8.5 Hz), 8.80 (1H, s), and 9.58 (1H, s). MS *m/e*: 321. Found: C, 78.27; H, 7.10; N, 4.56%. Calcd for $C_{21}H_{23}O_2N$: C, 78.47; H, 7.21; N, 4.36%.

The Measurement of Chemiluminescence. Commercially available KOH (from Kanto Chemical Co., Inc.), and ^{t}BuOK (from Merck for synthesis) were used without further purification. Other alkali metal *t*-butoxides were prepared by dissolving an alkali metal in *t*-butyl alcohol. Luminol was recrystallized from dilute hydrochloric acid prior to use. All solvents used were purified by distillation. The luminescent reaction was initiated by adding a base to an aerated solution of ketone, with stirring, in a quartz cell (10×10×45 mm) which was situated in a thermostatically-controlled cell holder. The chemiluminescent intensity was measured on a Shimazu spectrofluorophotometer RF-520 with no exciting source. The total light emission was determined graphically from the *I-t* curves. A standard solution of luminol in anhydrous DMSO having an optical density at 359.5 nm (the absorption peak) of 0.010 (1.26×10^{-6} mol l^{-1}) was prepared, and the *I-t* curve of the chemiluminescence initiated by adding 0.2 ml of a ^{t}BuOK solution to 2 ml of the standard solution was measured on the same apparatus at 313 K. Using the value of 1.28×10^{-2} einstein mol^{-1} proposed by Lee *et al.* for the chemiluminescence exhibited from the luminol solution, the quantum yields for direct chemiluminescence from ketones were determined from the ratio of the total light emitted from the luminol solutionto the total measured light emission from the ketone

solutions.

Methyl Ester of the Air-oxidated Product of Compound **3**, **9**, *and* **10**. To a stirred solution of compound **3**, **9**, or **10** in benzene was added a solution of excess amount of potassium *t*-butoxide in *t*-butyl alcohol at 20 °C. Then chemiluminescence was observed. Water was added to the resulting mixture and stirred vigorously. The aqueous layer was separated, neutralized with acetic acid and extracted with chloroform. To this organic solution was added a solution of diazomethane in ethyl ether. After stirring for 1 h, the solvent was evaporated to dryness. The obtained residue was subjetced to column chromatography with benzene as an eluent. The methyl ester of compound **3**, **9**, or **10** was obtained.

1,5-Bis(methoxycarbonyl)anthracene: Mp 123—125 °C; IR 1710 cm^{-1}; NMR ($CDCl_3$): $\delta=4.06$ (6H, s), 7.54 (2H, t, $J=8.0$ Hz), 8.30 (4H, d, $J=8.0$ Hz), and 9.65 (2H, s). Found: C, 73.63; H, 4.53%. Calcd for $C_{18}H_{14}O_4$: C, 73.46; H, 4.80%.

3,7-Diisopropyl-1,5-bis(methoxycarbonyl)anthracene: Mp 149—151 °C; IR 1705 cm^{-1}; NMR ($CDCl_3$): $\delta=1.38$ (12H, d, $J=8.0$ Hz), 3.10 (2H, sept, $J=8.0$ Hz), 4.02 (6H, s), 8.00 (2H, s), 8.12 (2H, s), and 9.40 (2H, s). Found: C, 75.80; H, 7.02%. Calcd for $C_{24}H_{26}O_4$: C, 76.16; H, 6.93%.

5-Dimethylamino-1-methoxy-4-(methoxycarbonyl)anthracene: Mp 130—131 °C; IR 1700 cm^{-1}; NMR ($CDCl_3$): $\delta=3.00$ (6H, s), 3.96 (3H, s), 4.00 (3H, s), 6.58 (1H, d, $J=8.0$ Hz), 6.92 (1H, d, $J=8.0$ Hz), 7.32 (1H, t, $J=8.0$ Hz), 7.58 (1H, d, $J=8.0$ Hz), 8.14 (1H, d, $J=8.0$ Hz), 8.74 (1H, s), and 9.92 (1H, s). Found: C, 74.00; H, 6.02; N, 4.62%. Calcd for $C_{19}H_{19}O_3N$: C, 73.76; H, 6.19; N, 4.53%.

Observation of Mutual Diffusion Coefficients and Cooperative Motions in Binary Solutions of *t*-Butyl Alcohol-Water and 2-Butoxyethanol-Water

Nobuyuki Ito,† Koichi Saito,† Tadashi Kato, and Tsunetake Fujiyama*

Institute for Molecular Science, Myodaiji, Okazaki 444

†*Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158*

(Received August 18, 1980)

Rayleigh scattering spectra were observed for the binary solutions of t-butyl alcohol(TBA)–water and 2-butoxyethanol (BE)–water. The observed line-widths were reduced to mutual diffusion coefficients. The observed concentration dependencies of the mutual diffusion coefficients were well explained by postulating the existence of "moving units"— a group of molecules which move together for a time much longer than the velocity auto-correlation time. The structure of the moving units which are formed in the TBA–water solution was $(H_2O)_{20}$TBA for $X_{TBA} \lesssim 0.05$, and $4(H_2O)_{20}$TBA for $X_{TBA} \gtrsim 0.05$, where X_{TBA} is the mole fraction of TBA. For the BE–water solution, the structure was found to be $(H_2O)_{50}$BE for $X_{BE} \lesssim 0.02$ and $3(H_2O)_{50}$BE for $X_{BE} \gtrsim 0.02$. These results were compared with the results which had been obtained from the concentration dependencies of the mean-square concentration fluctuation values.

Local fluctuations of concentration afford information which is useful for understanding the mixing of liquids from a molecular viewpoint. Since the mean-square amplitude of concentration fluctuation is related to the spatial correlation between positions of different molecules, it affords information about the local structure formation in solution. In our previous reports, we have discussed the local structures in various solutions on the basis of the quantitative analysis of the mean-square concentration fluctuation obtained from the Rayleigh scattering intensities.[1-9] The local structures were expressed in terms of the mean association number in the ordinary sense.

In order to discuss the state of mixing from a dynamical standpoint, however, the life-time of local structures should be taken into account along with the mean association number. Here, we define the "life-time" as the time during which the relative positions of molecules in a local structure change very little. Instead of observing the life-time directly, we introduced the concept of a "moving unit"—a group of molecules which move together for a time much longer than the velocity auto-correlation time—in our preceding report[10] as a useful concept for describing dynamical aspects of local structures. The mutual diffusion coefficient was theoretically expressed in terms of the self diffusion coefficients and the number of moving units. The theoretical results were applied to the study of the mutual diffusion coefficients for methanol–carbon tetrachloride and ethanol–carbon tetrachloride systems obtained from the intensity distribution measurements of Rayleigh lines. It was shown that the mean number of alcohol molecules which constitutes a moving unit was much smaller than the mean association number of alcohol, especially in the high concentration range of alcohol. This indicated that the hydrogen-bonded polymer of alcohol molecules cannot move without changing shape within the velocity auto-correlation time.

The present report concerns itself with the extension of this line of approach to the aqueous solutions of *t*-butyl alcohol (TBA hereafter) and 2-butoxyethanol (BE hereafter). Our expectation is that the life-times of the local structures formed in these solution are much longer than those in the ordinary binary solutions like methanol–carbon tetrachloride and ethanol–carbon tetrachloride.[10]

Recently, Iwasaki *et al.* have observed the light scattering spectra for the binary solution of *t*-butyl alcohol and water.[7,8] They have concluded that clathrate hydrate-like structures of the type $g[(H_2O)_{21}TBA]$ ($g=1$—5) exist in the solution, from the analysis of the observed concentration dependence of the mean-square concentration fluctuation. By considering the results of X-ray diffraction analyses for the structure of solid clathrate hydrate, it has been suggested that a TBA molecule is surrounded by water molecules which form a polyhedron. This result indicates that the life-time of these local structures in the TBA–water solution might be much longer than those observed in the carbon tetrachloride solutions of alcohols.[10] This expectation is confirmed by the measurement and analysis of the concentration dependence of the mutual diffusion coefficient, which is obtained from the line-width of Rayleigh line. The binary solution of water–BE is also included in the present study.

Experimental

The light scattering spectrometer (heterodyne detection) used in the present study was designed and constructed in our laboratory.[11] The light source is an argon ion laser (Spectra-Physics model 165-09) which produced 0.1—1 W power at 488 nm. The scattering angle, θ, was defined by two pinholes approximately 50 cm apart and 0.5 mm in diameter. The laser beam is focused into a rectangular scattering cell. Scattered light and local oscillator beam (scattered from the cell walls) are collected onto the surface of a photomultiplier tube (HTV R-374). The photocurrent is amplified and then fed to a spectrum analyzer (Takeda-Riken TR 4120S). This analyzer is designed for use in the spectral region 50 Hz—30 MHz. The out-put of the analyzer is averaged by a signal averager (Kawasaki Electronica M50E-TMC 600). The averaged spectrum is squared prior to recording, so that the final output signal is proportional to the power spectrum of the scattered light. Details of the spectrometer have been reported elsewhere along with the reliability of the observed

data.[11]

Light scattering spectra were recorded at the temperature of 25±1 °C in the scattering angle range of $5°<\theta<21°$.

All the chemicals were commercial products (Tokyo Kasei's Extra Pure). 2-Butoxyethanol was purified by distillation and *t*-butyl alcohol was used without further purification. Water was triply distilled. The binary mixtures of TBA and water were made dust free by the use of a Nuclepore filter with a pore size of 0.1 μm.

Results and Discussion

Mutual Diffusion Coefficients and Velocity Correlation between Different Molecules. The procedure for obtaining the mutual diffusion coefficient from the Rayleigh scattering spectra is the same as that described in the preceding report.[10] Figures 1 and 2 show the concentration dependences of the mutual diffusion coefficients for the binary solutions of TBA–water and BE–water, respectively.

The mutual diffusion coefficient for the binary solution whose components are molecules A and B is expressed in terms of velocity correlation functions as

$$D = QL \tag{1}$$

with

$$L = X_B D_A + X_A D_B + X_B(n_A - 1)\, V_{aa'} + X_A (n_B - 1)\, V_{bb'} - 2X_A X_B (n_A + n_B)\, V_{ab} \tag{2}$$

$$Q = \frac{X_A X_B}{N\langle(\Delta X)^2\rangle} \tag{3}$$

$$V_{ij} = \frac{1}{3}\int_0^\infty \langle \mathbf{v}_i(t)\cdot\mathbf{v}_j(0)\rangle dt \tag{4}$$

(i, j, = a, a', b or b').

The notations in these equations are the same as those used in the preceding report.[10]

In the case where velocity correlation between different molecules can be neglected, L is reduced to

$$L^\circ = X_B D_A + X_A D_B. \tag{5}$$

Equation 2 can be rewritten in terms of L° as

$$L \simeq L^\circ + X_A X_B (n_A + n_B)\,(V_{aa'} + V_{bb'} - 2V_{ab}), \tag{6}$$

where we have taken $n_A - 1 \simeq n_A$ and $n_B - 1 \simeq n_B$ because $n_A, n_B \gg 1$. Equation 6 indicates that L is larger than L° when the velocity correlation between same species is stronger than that between different species, that is, $V_{aa'}+V_{bb'} > 2V_{ab}$. In the case where $V_{aa'}+V_{bb'} < 2V_{ab}$, on the other hand, L takes a smaller value than L°.

Figures 3 and 4 show the concentration dependences of L calculated from the observed values of D and $N\langle(\Delta X)^2\rangle$ for the binary solutions of TBA–water and BE–water. The observed values of $N\langle(\Delta X)^2\rangle$ for the BE–water system are shown in Fig. 12. The observed values for the TBA–water system were already reported.[7,8] It is seen from Figs. 3 and 4, that L takes a minimum value at $X \approx 0.05$ for the TBA–water system and $X \approx 0.02$ for the BE–water system, where X is the mole fraction of TBA or BE.

The broken line of Fig. 3 shows the concentration dependence of L° calculated from Eq. 5 where experimental values of the self diffusion coefficients found in the literature[12,13] was used (see Fig. 5). It is seen from

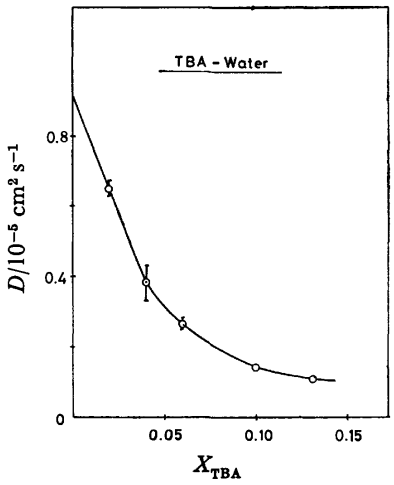

Fig. 1. Observed mutual diffusion coefficients for TBA–water system at 25 °C.

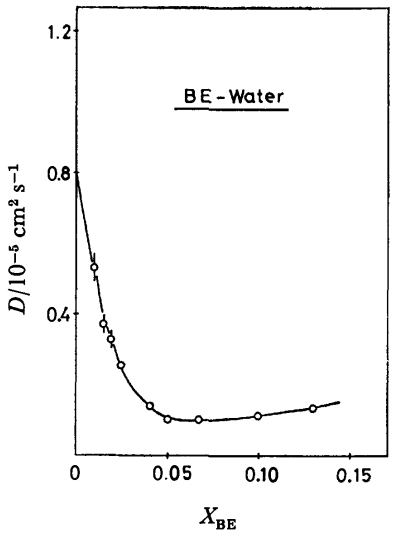

Fig. 2. Observed mutual diffusion coefficients for BE–water system.

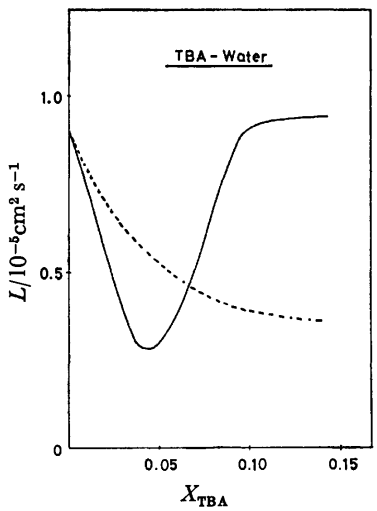

Fig. 3. Observed values of L (see Eqs. 1—3) for TBA–water system. The dashed line shows L° (see Eq. 5).

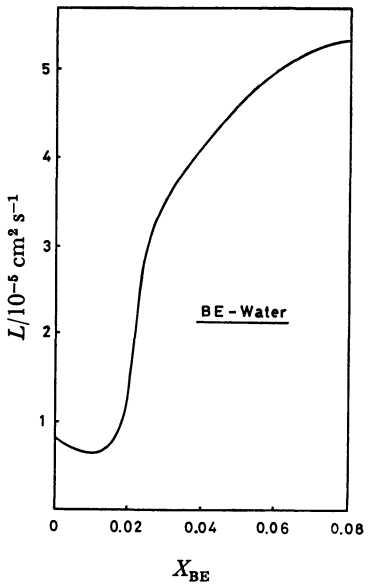

Fig. 4. Observed values of L (see Eqs. 1—3) for BE–water system.

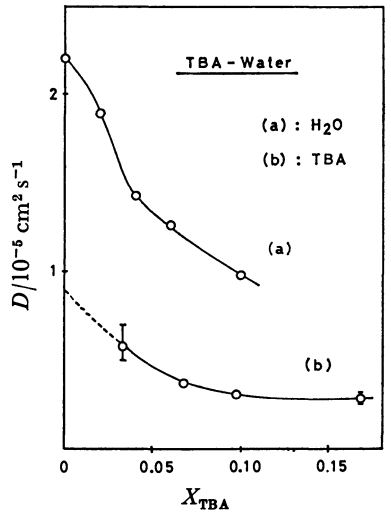

Fig. 5. Observed self diffusion coefficients for TBA–water system.

the figure that L is smaller than L° for $0<X<0.065$ and is larger than L° for $0.065<X$. These results suggest that $(V_{aa'}+V_{bb'}-2V_{ab})$ in Eq. 6 is not equal to zero for the present system.

Moving Unit in TBA–Water System. In the previous report,[10] we have introduced the concept of a moving unit in order to obtain information about the cooperative translational motion of molecules in solution. We will try to explain the observed concentration dependence of L by using this concept.

The analysis[7] of the Rayleigh intensities for the TBA–water system has shown the existence of clathrate hydrate-like structures of the type $(H_2O)_{21}TBA$ for $0<X<1/22$ and of the type $5[(H_2O)_{21}TBA]$ for $1/22<X$. Therefore, we consider first a moving unit of the A_lB-type where A and B represent water and TBA molecules, respectively. Then, L is expressed as

$$L = \frac{X_B}{n_A}\left[r^2 n_{A_r} D_{A_r} + l^2 n_{A_lB} D_{A_lB}\right] + \frac{X_A}{n_B}\left[n_{B_1} D_{B_1} + n_{A_lB} D_{A_lB}\right] - 2l\frac{n_{A_lB}}{n_A+n_B} D_{A_lB}, \quad (7)$$

where $n_\alpha(\alpha=A_lB$ *etc.*$)$ is the number of moving units of α-type and D_α the self diffusion coefficient of a moving unit α. In Eq. 7, a moving unit of the A_l-type has also been assumed to exist. Since the relations

$$n_A = rn_{A_r} + ln_{A_lB}$$
$$n_B = n_{B_1} + n_{A_lB} \quad (8)$$

hold, Eq. 7 is reduced to

$$L = X_B r D_{A_r} + X_A D_{B_1} + X_{A_lB}\left[\frac{X_B}{X_A} l\left(lD_{A_lB} - rD_{A_r}\right) + \frac{X_A}{X_B}\left(D_{A_lB} - D_{B_1}\right) - 2lD_{A_lB}\right] \quad (9)$$

$$X_{A_lB} = \frac{n_{A_lB}}{n_A + n_B}. \quad (10)$$

(a) L for a Model System Composed of A_l, A_lB, and B_1. In order to determine the l-dependence of L, we consider the special case where $r=l$ and $D_{A_lB}=D_{A_l}=D_{B_1}\equiv D^s$. We further assume that for $0\leq X_B\leq 1/(l+1)$ there exist only those moving units of the types A_l and A_lB and for $1/(l+1)\leq X_B$ only those of the types A_lB and B_1. This corresponds to the conditions $X_{A_lB}=X_B$ for $0\leq X_B\leq 1/(l+1)$, and $X_{A_lB}=X_A/l$ for $1/(l+1)\leq X_B$. Figure 6 shows the concentration dependences of L for $D^s=1$ and for various values. It is seen from the figure that there exists a specific concentration, X_l, at which L is zero. X_l is equal to $1/(l+1)$, which is the number ratio of B molecules to all the molecules in the moving unit A_lB. By comparing Fig. 6 with Fig. 3, we can see that the theoretical curve for $l=20$ in Fig. 6 explains the observed concentration dependence of L in the sense that L takes a minimum value at $X_B\sim 0.05$. However, the observed value of L does not go to zero at any concentration. This suggests the existence of other types of moving units than A_lB even at $X_B=$

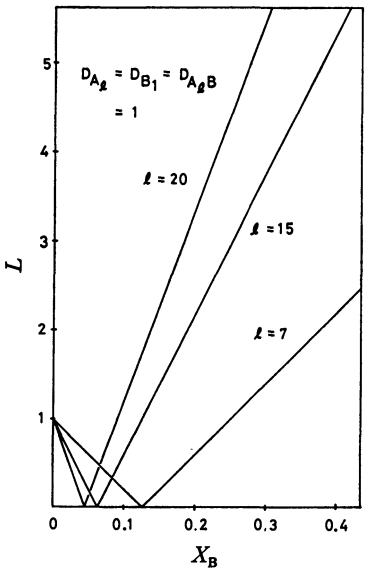

Fig. 6. Theoretical values of L calculated from Eq. 9 for $D_{A_lB}=D_{A_r}=D_{B_1}=1$ $(r=l)$ and for various l values.

$1/(l+1)$. Therefore, we consider the coexistence of the types A_l, A_lB, and B_1. In order to determine the concentration dependence of X_{A_lB}, we further assume the relation

$$\frac{n_{A_lB}}{N'} = K\frac{n_{A_l}}{N'}\frac{n_{B_1}}{N'}$$

$$N' = n_{A_l} + n_{A_lB} + n_{B_1}. \tag{11}$$

This corresponds to assuming the association equilibrium

$$A_l + B_1 \overset{K}{\rightleftharpoons} A_lB, \tag{12}$$

where K is an equilibrium constant. Then, X_{A_lB} can be expressed in terms of K as

$$X_{A_lB} = \frac{1}{2l}\left[\left(X_A + lX_B\right) - \left\{\left(X_A + lX_B\right)^2 - 4l\frac{K}{K+1}X_AX_B\right\}^{1/2}\right]. \tag{13}$$

Figure 7 shows the concentration dependences of L calculated from Eqs. 10 and 13 for $l=r=20$ and for various K values. It is seen from the figure that L takes a minimum value at $X_B \approx 0.05$.

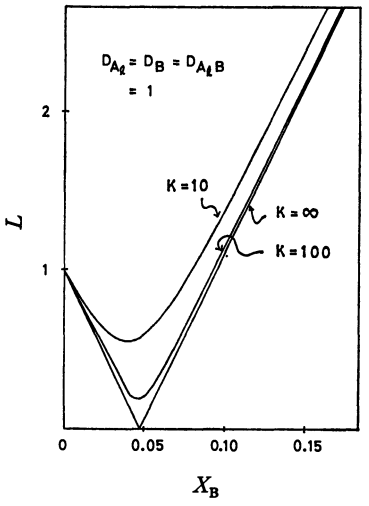

Fig. 7. Theoretical values of L calculated from Eqs. 10 and 13 for $l=r=20$ and for various K values.

(b) L for a Model System Composed of A_r, A_lB, and B_1. In the above analysis, we have assumed that the self diffusion coefficients of the moving units (D_{A_r}, D_{A_lB}, and D_{B_1}) are equal and independent on concentration. This assumption, however, is not quite reasonable, for the following reasons. The self diffusion coefficients, D_{A_r}, D_{A_lB}, and D_{B_1}, can be related to the self diffusion coefficients, D_A and D_B, which correspond to the species A and B by the equations

$$D_A = \frac{rn_{A_r}}{n_A}D_{A_r} + \frac{ln_{A_lB}}{n_A}D_{A_lB}$$

$$D_B = \frac{n_{A_lB}}{n_B}D_{A_lB} + \frac{n_{B_1}}{n_B}D_{B_1}. \tag{14}$$

Therefore, the above assumption is equivalent to assuming $D_A=D_B$ at any concentrations. Actually, the observed D_A and D_B values are different and depend on concentration (see Fig. 5).

In order to take into account the observed concentration dependences of D_A and D_B properly, we rewrite Eq. 11 by using Eq. 14 as

$$L = rX_BD_A + X_AD_B - lX_{A_lB}D_{A_lB} \times \left[2 - \frac{X_B}{X_A}\left(l - r\right)\right]. \tag{15}$$

As Eq. 15 has four unknown parameters, l, r, X_{A_lB}, and D_{A_lB}, on the right hand side, it is difficult to determine these parameters from the observed data uniquely. Fortunately, however, we can restrict the probable magnitudes of these parameter values as follows.

As the sizes and weights of A_r and B_1 are both smaller than those of A_lB, the lower limit of the D_{A_lB} value may be defined as: $D_{A_lB} \leq D_{A_r}$ and $D_{A_lB} \leq D_{B_1}$. We can also define the upper limits of D_{A_lB} and D_{B_1}, so that the probable magnitudes of these parameters are restricted by the relations

$$D_{A_lB} \leq D_{A_r} \leq aD_{A_lB}$$
$$D_{A_lB} \leq D_{B_1} \leq bD_{A_lB}. \tag{16}$$

The constants a and b of Eq. 16 are arbitraly. However, it is improbable that D_{B_1} is larger than $10D_{A_lB}$ because the self diffusion coefficient of a moving unit is inversely proportional to its weight, approximately,[14] and because the weight of A_lB is about six times as large as that of B_1. So, we set $b=10$. Similarly, we may set $a=40/r$ because the weight of B_1 is about $4/r$ times as large as that of A_r. D_{A_r} and D_{B_1} can be expressed in terms of D_A, D_B, and D_{A_lB} as

$$D_{A_r} = \frac{D_AX_A - lX_{A_lB}D_{A_lB}}{X_A - lX_{A_lB}} \tag{17a}$$

$$D_{B_1} = \frac{D_BX_B - X_{A_lB}D_{A_lB}}{X_B - X_{A_lB}}. \tag{17b}$$

Combination of Eqs. 16 and 17 gives the relations

$$D_A \geq D_{A_lB} \geq \frac{X_AD_A}{a\left(X_A - lX_{A_lB}\right) + lX_{A_lB}} \tag{18a}$$

$$D_B \geq D_{A_lB} \geq \frac{X_BD_B}{b\left(X_B - X_{A_lB}\right) + X_{A_lB}}. \tag{18a}$$

Therefore, we can define the smallest value, L_{min}, and the largest value, L_{max}, of L as

$$L_{min} = M - X_{A_lB}D_AH \tag{19}$$

$$L^a_{max} = M - \frac{X_AD_AX_{A_lB}}{a\left(X_A - lX_{A_lB}\right) + lX_{A_lB}}H \tag{20a}$$

$$L^b_{max} = M - \frac{X_BD_BX_{A_lB}}{b\left(X_B - X_{A_lB}\right) + X_{A_lB}}H \tag{20b}$$

$$M = X_BrD_A + X_AD_B$$
$$H = l[2 - X_B(l-r)/X_A] \quad (a=40/r,\ b=10)$$

if $H>0$. The values of L^a_{max} and L^b_{max} are determined from Eqs. 18a and 18b, respectively. The values of L_{min} are determined from Eq. 18 and the relation that $D_A>D_B$ (see Fig. 5). For $H<0$, L_{min} in Eq. 19 becomes a maximum value and L_{max} in Eq. 20 becomes a minimum value. Figures 8—10 show the domain of L calculated from Eqs. 19 and 20 for some values of r and K, where the concentration dependence of X_{A_lB} is assumed to be determined by Eq. 13. It is seen from these figures that the observed L values satisfy the inequality represented by Eqs. 19 and 20 for $r=4$ in the

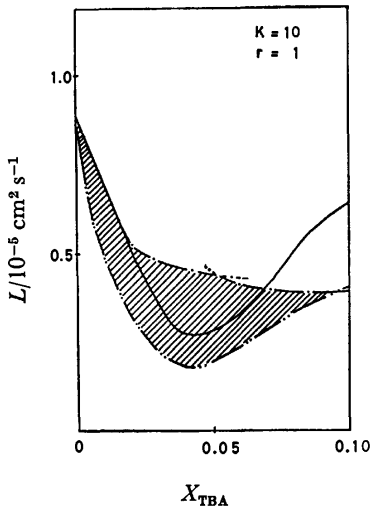

Fig. 8. Domain of L calculated from Eqs. 19 and for $l=20$, $r=1$, and $K=10$ (shaded area).

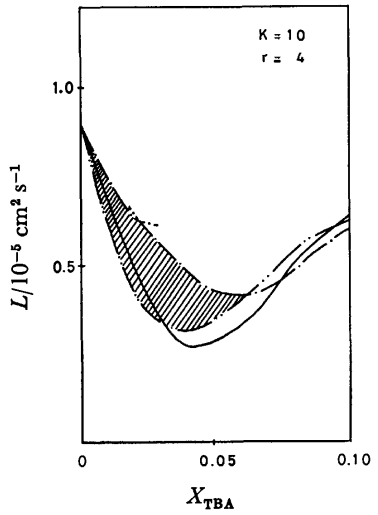

Fig. 9. Domain of L calculated from Eqs. 19 and 20 for $l=20$, $r=4$, and $K=10$ (shaded area).

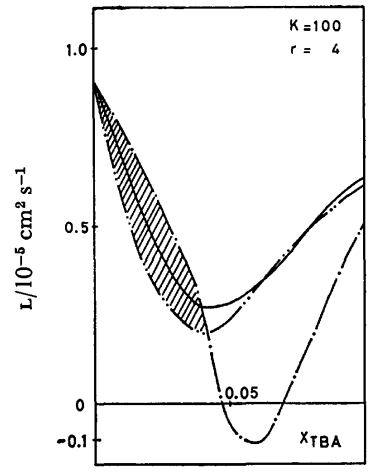

Fig. 10. Domain of L calculated from Eqs. 19 and 20 for $l=20$, $r=4$, and $K=100$ (shaded area).

low concentration range of TBA ($X<0.03$). In the high concentration range, however, the domain calculated for any r or K value does not cover the observed L values. This implies that the present model is not applicable in the high concentration range.

(c) L for a Model System Composed of A_r, gA_lB, and B_1. In the Rayleigh intensity analysis, the existence of the local structure of the type $5[(H_2O)_{l'}TBA]$ has been proposed for $1/(l'+1)<X_B(l'\approx 21)$. So we assume the coexistence of the moving units of the types gA_lB ($g=2, 3, ..$), A_r, and B_1 for $X_B>1(l+1)$. Then, L is expressed as

$$L = M + X_{A_lB}D_{gA_lB}H'$$

$$H' \equiv l\left[2g - \frac{X_B}{X_A}\left(gl - r\right)\right] - \left[\frac{X_A}{X_B}\left(g - 1\right)\right]$$

$$X_{A_lB} = gX_{gA_lB}. \tag{21}$$

In this case the relations corresponding to Eq. 16 are

$$D_{gA_lB} \leq D_{A_r} \leq \frac{ag}{r} D_{gA_lB} \tag{22a}$$

$$D_{gA_lB} \leq D_{B_1} \leq bgD_{gA_lB}. \tag{22b}$$

Therefore,

$$L_{min} = M - D_A X_{A_lB} H' \tag{23}$$

$$L^a_{max} = M - \frac{X_A D_A X_{A_lB}}{ag(X_A - lX_{A_lB}) + lX_{A_lB}} H' \tag{24a}$$

$$L^b_{max} = M - \frac{X_B D_B X_{A_lB}}{bg(X_B - X_{A_lB}) + X_{A_lB}} H' \tag{24b}$$

for $H'>0$. The domain of L calculated from Eqs. 23 and 24 for $r=1$, $K=10$, and $g=4$ is shown in Fig. 11, where the domain of L for $X_B<1/(l+1)$ is calculated from Eqs. 19 and 20. It can be seen from the figure that the calculated domain covers the observed values of $X>0.02$.

We could not find any other r and g values which give a domain of L which covers the observed values for $X<0.1$. However, for $X<0.075$, for example, the domain calculated for $r=1$ and $g=3$ also covers the observed L values. Similarly, for $X<0.07$, we can find

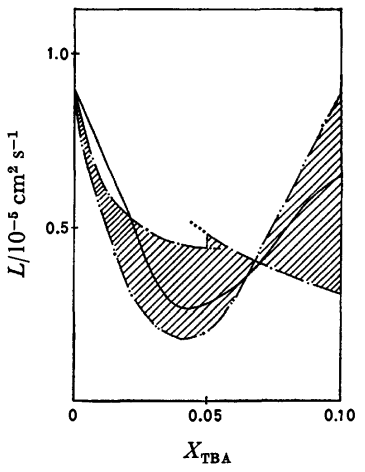

Fig. 11. Domain of L calculated from Eqs. 23 and 24 for $l=20$, $r=1$, $K=10$, and $g=4$ ($X\geq 0.02$) and that calculated from Eqs. 19 and 20 for $l=20$, $r=1$, and $K=10$ ($X\leq 0.02$).

that three sets of values: $(r, g)=(1, 4)$, $(1, 3)$, and $(2, 2)$, can produce domains which can cover the observed L. These results may suggest an increase of g and decrease of r with the increasing concentration of TBA.

From the above analysis, the following types of moving units can be expected in the TBA–water solution:

A_r ($r = 4$—10), $A_{20}B$, and B_1 for $0 < X_B \lesssim 0.05$

A_1, $4A_{20}B$, and B_1, for $0.05 \lesssim X_B$.

An approximate l value can be determined from the concentration at which L takes a minimum value.

Moving Unit in BE–Water System. We have analyzed the observed mean-square concentration fluctuation for the BE–water system by the same way as was used for the TBA–water system.[7] Our conclusion is that there are local structures of the type $(H_2O)_{55}BE$ for $0<X_{BE}<1/56$ and of the type $3(H_2O)_{55}$ BE for $1/56>X_{BE}$.

For the BE–water system, the self diffusion coefficients have not been reported. However, the observed concentration dependence of L in Fig. 4 suggests the existence of moving units similar to those in the TBA–water system, that is, the $(H_2O)_lBE$ type. From the concentration at which L takes a minimum value, the l value is obtained to be about 50.

Concluding Discussion. We have shown that moving units of the types $g[(H_2O)_{20}TBA]$ and $g'[(H_2O)_{50}BE]$ exist in the binary solution of TBA–water and BE–water, respectively. The analysis of the concentration dependences of the mutual diffusion coefficients gave these results. In the study of the mean-square concentration fluctuations for these systems, on the other hand, the existence of local structures of the types $g''[(H_2O)_{20}TBA]$ and $g'''[(H_2O)_{55}BE]$ has been suggested. With the help of the results of X-ray diffraction analyses for the structure of solid clathrate hydrate,[15] the following picture can be drawn for the mixing state of TBA–water mixtures. In the concentration range of $0<X_{TBA}<1/22$, a TBA molecule forms a polyhedron surrounded by water molecules and the polyhedra are dispersed in water. In the concentration range of $1/22<X_{TBA}<0.1$, the aggregates of five polyhedra are dispersed in TBA. Because the ratio of water molecules to a TBA molecule in a moving unit is nearly equal to that in the above polyhedron, it can be concluded that the life-time of the clathrate hydrate-like structure is much longer than the order of the velocity auto-correlation time (10^{-13}—10^{-12} s). This is in contrast with the results obtained for the binary solutions of methanol–carbon tetrachloride and ethanol–carbon tetrachloride. In these systems, a group of hydrogen-bonded alcohols cannot be a moving unit, especially in the high concentration range of alcohol ($X_{alcohol} \gg 0.1$). This result has been explained as follows. Consider the velocity correlation between two alcohols which form a linear hydrogen-bonded polymer. If these two molecules are adjacent to each other, the velocity correlation between them is expected to be strong. If these two molecules are not adjacent to each other, on the other hand, the velocity correlation between them becomes relatively weak. Therefore it is expected that

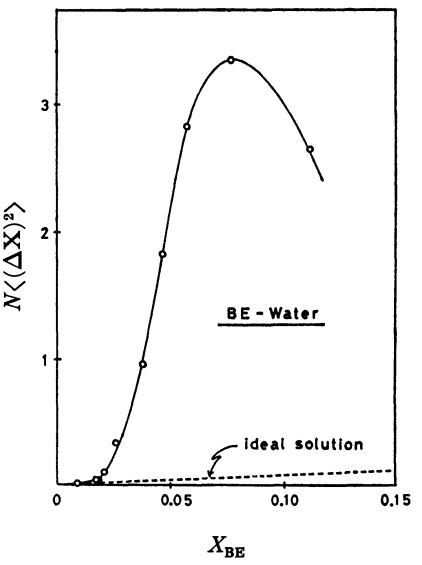

Fig. 12. Observed mean-square concentration fluctuation for BE–water system.

the number of alcohols which form a moving unit cannot exceed a certain number, no matter how large the association number of hydrogen-bonded polymer is. In other words, the long hydrogen-bonded polymer cannot be a moving unit.

The present results are not inconsistent with this viewpoint. In the TBA–water solution, the distances between the TBA molecule and each water molecule which form a polyhedron are almost the same. Therefore, the velocity correlation between the TBA molecule and each water molecule is expected to be strong. For the BE–water system, no picture for the mixing state has been drawn. We suggest the picture is similar to that in the TBA–water systems, because the present study has shown that the local structure predicted by the Rayleigh intensity analysis can be a moving unit itself.

(Received August 23, 1980)

The structure of the triclinic form of octaethylporphinium (monocation) triiodide was determined by X-ray analysis. The structure of the previously determined orthorhombic form was refined using diffractometer data. The final R values for the triclinic and the orthorhombic forms were 0.060 and 0.069, respectively. The present analysis has established the inherent structure of porphyrin monocations; three pyrrole rings are coplanar and the plane of the fourth ring is tilted from the mean plane of the other three. The magnitude of the tilt angle is 12.5° for the triclinic form and 16.1° for the orthorhombic form.

Porphyrins exist in solution as the free base, monocationic and/or dicationic species, each of which shows the characteristic absorption spectrum.[1] As the equilibrium between the free base and the monocation is sensitive to pH and other factors,[2] the cationic species could be present in a biological environment.[3] The resemblance of spectrum between the monocation and the reaction intermediate of metal incorporation[4] suggests that in the final stage of oxidation from porphyrinogen to porphyrin, which occurs in the mitochondoria or in cytoplasm,[5] the monocationic species plays a role in controlling the formation of metalloporphyrins.

For comprehensive studies in porphyrin stereochemistry, it is important to reveal the structure of porphyrin monocation, since structural studies have been done for the free base and dicationic species.[6,7] As a first example, we have previously reported the structure of the orthorhombic form of octaethylporphinium (monocation) triiodide crystal,[8] in which one pyrrole ring is inclined by 14° with respect to the plane of the remaining porphyrin nucleus. This is quite different from the typical structures of the other species; the free base is planar within ±0.05 Å,[6] whilst the dication is deformed considerably, assuming $\bar{4}$ symmetry.[7] Although the inner hydrogen atoms are expected to determine the stereochemistry of monocation, their positions were not directly obtained owing to the low accuracy of intensity data. We have tried to refine the structure using new diffractometer data. On the other hand, we obtained the triclinic crystals of octaethylporphinium(monocation) triiodide [$(H_3OEP)^+I_3^-$], in which benzene molecules are solvated. The structure of this crystal has been determined in order to examine the packing effect of the crystal upon the structural feature of the monocation. A comparison of the two structures in detail will give the inherent structure of porphyrin monocation.

Experimental and Structure Determination

Triclinic Crystal. Triclinic crystals of $(H_3OEP)^+I_3^-$, reddish brown plates, were obtained from a dichloromethane–benzene solution of octaethylporphinium(dication) tetraiodide, A crystal 0.16×0.16×0.32 mm³ was used for data collection on a Rigaku automated, four-circle diffractometer with graphite monochromated Mo $K\alpha$ (λ=0.71069 Å) radiation. Density measured by the flotation method suggested the benzene hemi-solvate. The unit-cell dimensions were determined by least-squares calculations with 47 high-angle reflexions. Intensities of the independent reflexions within the range $2\theta \leqq 55°$ were measured by use of the $\omega/2\theta$ scan mode with a scanning rate of 2° (2θ) min^{-1}. Stationary background counts were accumulated for 30 s before and after each scan. Periodic checks of the intensity values of five standard reflexions showed no significant X-ray damage or crystal decay. Corrections for absorption or extinction were not applied. A total of 9099 independent reflexions were obtained, of which 3096 were zero; the observed threshold value, F_{11m}, was 5.56. The space group $P\bar{1}$ was deduced by the intensity statistics.

The structure was solved by the heavy-atom method. The structural parameters were refined by block-diagonal least-squares techniques; the quantity minimized was $\sum w\Delta^2$, where $\Delta=|F_o|-|F_c|$. All the hydrogen atoms were found by the difference synthesis. The zero-reflexions, for which $|F_c|>F_{11m}$, were included in the least-squares calculation by assuming $F_o=F_{11m}$. The following weights were applied; $w=\exp(-(As^2+Bt^2+Cst+Ds+Et+F))$ where $s=|F_o|\times 10^2$ and $t=\sin\theta/\lambda$ for $|F_o|\geqq F_{11m}$. and $w=1/\langle\Delta^2\rangle$ for $|F_o|<F_{11m}$. The coefficients, A–F, were evaluated by least-squares calculation at each cycle of structure refinement so that $\langle w\Delta^2\rangle=1$ in (s, t) space; their values in the final stage of refinement were, −0.8951, 14.35, −0.2166, 7.782, −6.059, and 1.845, respectively. The final R value was 0.06 for 6829 reflexions ($|F_o|>3/\sqrt{w(s,t)}$). Atomic scattering factors were taken from "International Tables for X-Ray Crystallography" Vol.

Orthorhombic Crystal. Orthorhombic crystals, reddish brown hexagonal plates, were obtained from methylenechloride–benzene solution. A crystal with dimensions of $0.15\times0.10\times0.02$ mm^3 was used for data collection on the automated, four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation. The unit-cell dimensions were determined by least-squares calculations with 34 high-angle reflexions. Diffraction intensities of all the independent reflexions within the range $2\theta\leqq40°$ were measured by use of the ω scan mode at a scanning rate of 1° min^{-1}. Stationary background counts were accumulated for 50 s before and after each scan. Periodic checks of the intensity of three standard reflexions showed no significant X-ray damage or crystal decay. Corrections for absorption and extinction were not applied. A total of 1784 independent reflexions were obtained, of which 731 were zero. The structural parameters, determined by photographic data,[8] were used as the initial values. They were refined by the full-matrix least-squares methods. All the hydrogen atoms were located by the difference synthesis. The final R value was 0.069 for 1345 reflexions ($|F_o|>3/\sqrt{w(s,t)}$). The atomic parameters of most of the hydrogen atoms were fixed during the refinement. Details of refinement including anomalous dispersion effect of iodine were the same as those for the triclinic crystal. $F_{\rm lim}$ was 9.00 and the weighting coefficients A—F were 0.4916, 22.01, −0.03600, −1.585, −6.020, and 6.661, respectively. Crystal data are summarized in Table 1, and the final coordinates of both crystals are

given in Tables 2 and 3.††

†† The tables of thermal parameters, hydrogen coordinates, and observed and calculated structure factors are kept as Document No. 8125 at the Chemical Society of Japan.

Results and Discussion

Cation. Figure 1 shows the atom numbering system used for both crystals. The monocation in the orthorhombic crystal has a crystallographic mirror plane perpendicular to the mean molecular plane through N(1) and N(3). Similar approximate local mirror symmetry is also observed in the triclinic monocation. The symmetry-related atoms are indicated with asterisk. The bond lengths and angles are listed in Tables 4 and 5 for triclinic and orthorhombic forms, respectively.

In the both crystals the imino hydrogen atoms are localized on rings B, B*, and C just as we postulated from the geometrical considerations in the previous paper on the orthorhombic form.[8] In the triclinic form, the C_α–N–C_α bond angle in the ring A, pyrrolenine ring, is 103.7°, while those of the ring B, B*, and C are 111.2, 110.9, and 109.3°, respectively. The corresponding values in the orthorhombic form are 107, 110, 110, and 109°, respectively. These values are consistent with those of pyrrole rings with and without attached hydrogen atoms.[11]

The stereoscopic drawings of the cations are shown in Fig. 2. Both cations take essentially the same architecture except the orientation of the peripheral ethyl groups. In the triclinic form the two ethyl groups attached to the ring C are oriented opposite to the other six ethyl groups with respect to the plane of the porphyrin nucleus, while all ethyl groups stick out on the same side in the orthorhombic form.

The common feature of the cations in the two different crystalline field is of particular interest. As shown in Table 6, three of the four pyrrole rings, each of which are planar within the experimental errors, are approximately coplanar. The fourth ring C is tilted from the plane consisting of the three rings by 16.1(6) and 12.5(8)° for orthorhombic and triclinic forms, respectively. The difference between the two values may be due to the packing effects. Similar deformation mode is seen in octaethylporphinium tri-μ-chloro-hexacarbonyl-dirhenate[12] and in 21-ethoxycarbonylmethyl-2,3,7,-8,12,13,17,18-octaethylporphyrin.[13] In the former case the corresponding tilt angle is smaller (8.6°) probably due to the hydrogen bonding between the pyrrole nitrogen atoms and the water molecule of solvation. In the latter case the angle is much larger apparently due to the bulky alkyl substituents.

The tilt of the fourth pyrrole ring is believed to be due

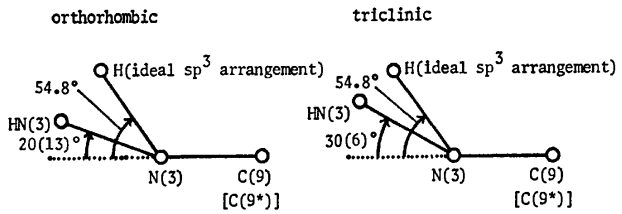

Fig. 3. Deviations of HN(3) atoms from the plane defined by N(3), C(9), and C(9*) atoms. The degree of deviations is expressed by the angle between N(3)→H vector and the plane. Estimated standard deviations are in parentheses.

mainly to the steric hindrance of the imino hydrogen atoms. As shown in Tables 4 and 5, H···H distances are 2.06 to 2.63 Å which indicate the relieved nonbonded H···H repulsion, if we take 1.9—2.0 Å as the minimum H···H nonbonded contact.[14] While HN(2)···HN(2*) distance are longer than 2.5 Å, HN(2)···HN(3) and HN(2*)···HN(3) distances are shorter than 2.3 Å. These distances suggest that the steric hindrance is effectively relieved by the tilt of the ring C. In addition, it is noted that the imino hydrogen atom of the ring C deviates from the plane of C_α–N–C_α. Figure 3 illustrates the angles between the N–H vector and the C_α–N–C_α planes for orthorhombic and triclinic cations, together with the N–H vector for the ideal sp^3 hybridization. Although these differences are not statistically significant enough, it may be concluded that the nitrogen atoms of the ring C have some sp^3 character. Such sp^3 character of N(3) is favourable for relieving the steric hindrance.

The values of corresponding bond lengths and angles in both cations are quite similar. In addition to this, the crystallographic and local mirror symmetries justify averaging equivalent bond lengths and angles to give the typical molecular dimensions as shown in Fig. 4.

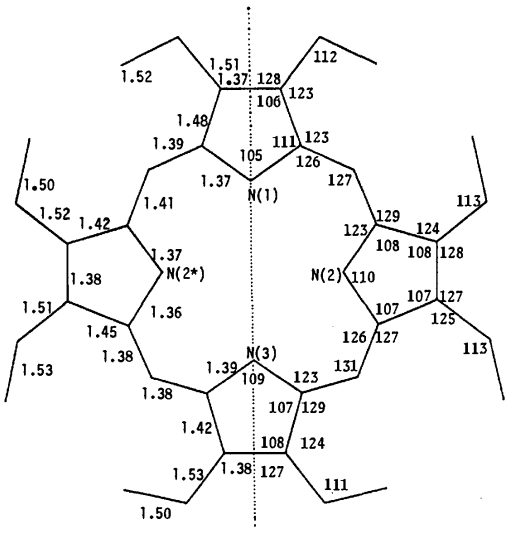

Fig. 4. Bond lengths and angles obtained by averaging equivalent halves of the two independent molecules. The dotted line reveals the crystallographic or local mirror plane.

The C_α–N distances are slightly longer in the ring C than in the other rings. The C_α–C_m–C_α angles, especially C(7)–C(8)–C(9), are larger than those normally found.[11] These features are similar to those of octaethylporphinium tri-μ-chloro-hexacarbonyldirhenate.[14] Other bond lengths and angles fall within the range tabulated by Hoard.[11]

The observed structures are the essential feature of monocationic species of porphyrins. Absorption spectra of many porphyrin monocations exhibit a similar pattern,[3,15] which reflects the common conjugate system determined by the present steric structure.

Anion and Molecular Packing. In the orthorhombic crystal, the central iodine atom of the triiodide anion is on the two-fold axis; therefore it has a symmetrical structure with the I–I distance of 2.910(3) Å and the I–I–I angle of 180°. In the triclinic crystal, on the other hand, the anion is free from any crystallographic restriction; the I(1)–I(2) distance of 2.889 Å is significantly shorter than the I(2)–I(3) of 2.945 Å, and I(1)–I(2)–I(3) angle is 176.77(5)°. The asymmetry may be due to the asymmetric environment around the anion in the crystal.[16] The gravity centre of benzene molecule in the triclinic crystal is placed on the centre of symmetry at (1/2, 1/2, 1/2).

The stereoscopic drawings of the crystal structures of both polymorphs are shown in Fig. 5. The common packing feature is "face-to-face" stacking of the porphyrin nuclei. There is no NH···N hydrogen bond between the faces. The similar packing mode is found in the crystal of other octaethylporphyrin derivatives.[12,13] This "face-to-face" stacking well explains the orientation of the terminal ethyl groups. The exceptional direction of the two ethyl groups attached to the C ring is seen in the triclinic crystal.

No unusual van der Waals contact is seen between the anion and the peripheral part of the cations. There is no charge transfer interaction between the benzene molecule and the anion in the triclinic crystal.

Figures 2 and 5 were drawn by TSD : XTAL, which is a computer-graphics interactive modeling programme for the NOVA3 computer.[17]

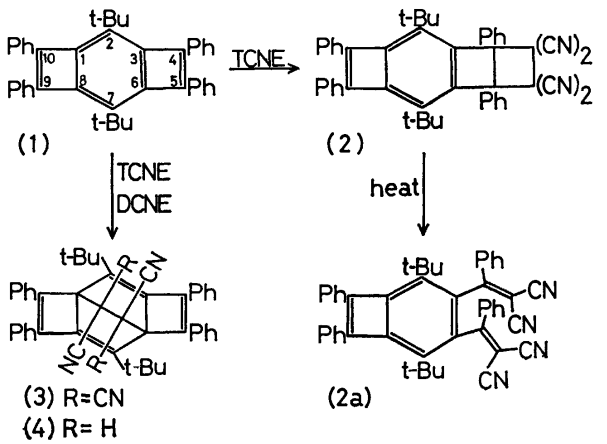
(Received September 16, 1980)

trans-1,2-Dicyanoethylene (DCNE) reacts with substituted benzo[1,2 : 4,5]dicyclobutene (**1**) to give only one adduct (**4**), the title compound, whereas tetracyanoethylene (TCNE) gives two isomers. Crystals of **4** are triclinic; space group P$\bar{1}$, a=13.505(2), b=14.118(2), c=10.722(1) Å, α=98.87(1), β=102.36(1), γ=111.71(1)° and Z=2. The structure was solved by the direct method and was refined by the block-diagonal least-squares method to the final R factor of 0.055 for 5479 observed reflections. The absence of two cyano groups in **4** makes less steric hindrance than **3**. Introducing the empirical parameters, non-bonded interaction energy was calculated for the approaching model of **1** and DCNE. The result well explains the addition of DCNE to the C(1)–C(6) position of **1**.

We have investigated a series of Diels-Alder adducts formed by the reaction of substituted benzo[1,2 : 4,5]-dicyclobutene (**1**)[1] and some dienophiles. In the first two papers, we reported the crystal structures of molecules **2** and **2a**[2,3] which are the first stable compounds with an *anti*-aromatic 8π electron benzo[1,2 : 4,5]-cyclobutene skeleton, and observed some degree of electron localization in agreement with a result of molecular orbital calculation. In the third paper,[4] we presented the crystal structure of **3**, a by-product of the addition reaction of **1** and tetracyanoethylene (TCNE). The analysis revealed the stereochemical differences between the main (**2**) and by-product (**3**) of this reaction. We calculated the electronic and steric interactions between approaching **1** and TCNE, and obtained an explanation for the bifurcate reactivity.

trans-1,2-Dicyanoethylene (DCNE) gives, on the contrary, only one product **4**.[5] The present study on the X-ray analysis of **4** is, therefore, not only an assertation of the proposed molecular structure, but also the stereochemical approach to a complicated organic reaction mechanism.



Experimental and Structure Determination

Colorless needles were recrystallized from acetone–methanol solution. Oscillation and Weissenberg photographs indicated triclinic symmetry. A crystal with dimensions 0.35×0.40×0.40 mm was mounted on a Rigaku automated four-circle diffratometer with graphite monochromated Mo $K\alpha$ radiation (λ=0.71069 Å). The crystal data are listed in Table 1. A total of 6317 independent reflections ($2\theta \leqq 50°$) was obtained in which 5479 had net intensities greater than the background. The intensities were corrected for Lorentz and polarization effects. The statistical distribution of the normalized structure factors, $|E|$'s, shows that the space group is P$\bar{1}$.

Table 1. Crystal data

2,7-Di-*t*-butyl-11,12-dicyano-4,5,9,10-tetraphenyltetracyclo-[4.4.2.$0^{1,8}$.$0^{3,6}$]dodeca-2,4,7,9-tetraene
$C_{46}H_{40}N_2$

Space group: P$\bar{1}$
a=13.505(2) Å
b=14.118(2) Å
c=10.722(2) Å
α=98.87(1)°
β=102.36(1)°
γ=111.71(1)°
U=1793 Å^3
D_m=1.148 g cm^{-3}
D_x=1.150 g cm^{-3}
Z=2

The structure was solved by the direct method.[6] All the 48 non-hydrogen atoms were found on the first E map calculated with 475 $|E|$'s greater than 1.6. The atomic parameters were refined by the block-diagonal least-squares method. Although hydrogen atoms were found by the difference Fourier synthesis, they were fixed at geometrically calculated positions, which were recalculated at the last stage of the refinement. Their isotropic thermal parameters were also fixed. Three reflections had $|F_o|$'s abnormally lower than $|F_c|$'s. As they seem to suffer from the secondary extinction, the final refinement was carried out without these reflections. The weighting scheme used was

$$w = 0.3 \quad \text{for } |F| = 0.0$$
$$w = 1/(1 + 0.44(4 - |F|)) \quad \text{for } 0 < |F| \leqq 4$$
$$w = 1 \quad \text{for } 4 < |F| \leqq 15$$
$$w = 1/(1 + 0.44(|F| - 15)) \quad \text{for } |F| > 15.$$

The final R factor was 0.55 for the observed reflections, and

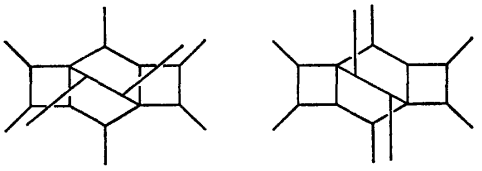
adducts of **1** and DCNE, **4** and **4a**, would be possible, the present analysis revealed that the former is the correct one. This stereoselectivity of the addition reaction will be discussed later.



4 4a

The present structure is quite similar to that of **3** except that the latter has two more cyano groups on the central bridge. Therefore, the framework of **4** without terminal substituents also consists of three planar parts, which include C(1)–C(6) interatomic vector in common. Least-squares planes and deviations of the atoms from the planes are given in Table 5. Dihedral angles between these planes are shown in Table 6. The planes I and II make an angle of 125.7°. The plane III, formed by the addition of DCNE, bisects this dihedral angle. These were also the case in **3**; the corresponding value is 125.0°. But the detailed observation of the planarity and dihedral angle indicates some characteristic differences between **3** and **4**. A slight folding of the four-membered ring observed in **3** is reduced in **4**. Mean deviation from these planes is 0.014 Å in **3** and 0.007 Å in **4**. On the contrary, coplanarity between I and this four-membered ring is poorer in **4**; the dihedral angle between them is 4.6° in **4**, whereas it is 2.0° in **3**. The direction of this bending is upward to the cyano group just above the four-membered ring. However, the largest difference between these molecules is the deviation of *t*-butyl groups. The trend observed in **3** in which the *t*-butyl groups are bent away from the plane I opposite to the cyano group just above is greatly reduced in **4**. The mean deviation of C(13) of the *t*-butyl group from the plane I is up to 0.13 Å in **3**, and it is 0.048 Å in **4**.

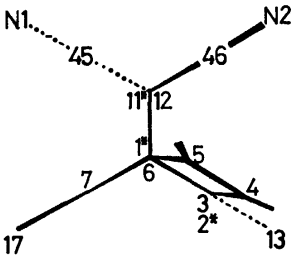


Fig. 4. Schematic drawing of the molecule projected along the C(1)–C(6) direction.

These differences may be consistently explained as follows. Figure 4 is a schematic drawing of the molecule projected along the C(1)–C(6) direction. Absence of the two cyano groups on the central bridge in the case of **4** reduces the repulsion with *t*-butyl groups and the latter can be nearly on the plane I. At the same time, the torsion angle along the C(11)–C(12) bond will be changed to be favourable against the other steric effect. The torsion angle C(1)–C(11)–C(12)–C(6) in **4** [121.2(1)°] is greater than that of **3** by 2.5°. Then the four-membered ring, C(3)–C(4)–C(5)–C(6), below this cyano group may slightly go upward so as to avoid the repulsion between the *t*-butyl group which is attached to the other plane II.

The lack of the two cyano groups also reduces the steric hindrance in the central bridge bond. The mean bond length C(1)–C(11) in **4** is 1.571 Å, which is 0.016 Å shorter than that of **3**. Moreover, the difference of the C(11)–C(12) distances between **3** and **4** is 0.042 Å. This shortening is partly due to the elimination of an electron withdrawing cyano group, but more important is the reduction of the repulsion between the cyano groups in the eclipse conformation.

Discussion

In a previous paper,[4] we have shown a new approach to a reaction mechanism of complicated molecules. Its interaction energy was divided into two parts, a stabilization energy in the intermediate state[8] of the approaching molecules, and a steric effect of the bulky substituents estimated from the empirical non-bonded interaction parameters.[9] The former was calculated in the reaction intermediate of unsubstituted benzo[1,2 : 4,5]dicyclobutene and TCNE or ethylene. The preference of the cross addition of TCNE is expected from this result. However, it is overcome by the repulsion between the bulky substituents. These results are in good agreement with the observed reaction of **1** and TCNE. It is, therefore, quite important to carry out the same kind of calculation for the reaction of **1** and DCNE which is

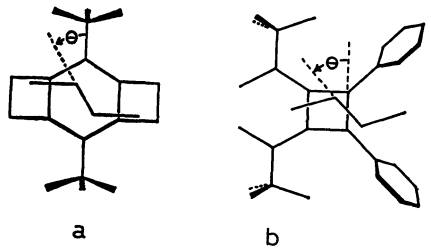

Fig. 5. Relative orientation θ in the (a) cross, and (b) linear approaching mode.

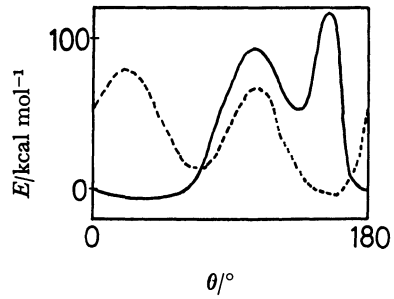

Fig. 6. Variations of the non-bonded interaction energy with the relative orientation θ at a constant distance (3.4 Å).

expected to be less repulsive than TCNE. The procedure is almost the same as that in the previous report. Since the electronic interaction energy was calculated without bulky substituents, the result is also applicable to that of DCNE. Relative orientation θ in the reaction intermediate is defined in Fig. 5. Non-bonded interaction energy in the case where the interplane distance is 3.4 Å is shown in Fig. 6. The solid curve refers to the cross addition (Fig. 5a). Its minimum is -6.6 kcal mol^{-1}†† at about 50° of θ. The dashed curve indicates the energy value of the linear addition (Fig. 5b). It has a minimum energy -5.0 kcal mol^{-1} when θ is $-10°$. In order to reduce the total number of parameters, terminal substituents are fixed as those in Fig. 5, which may be regarded as least repulsive conformations. Both of the minimum energy and the shape of the potential groove indicate that the cross approaching mode is less hindered than that of the linear approach. Taking the electronic interaction energy into account, we conclude that the cross addition is much preferable to the linear addition, and it is consistent with the reaction of **1** and DCNE.

The present calculation also explains why **4**, not a possible isomer **4a**, was actually formed. They correspond to the adducts with the θ value of 60° and 120° respectively. There is a local minimum at 120° in Fig. 6, but the energy value is high because of the repulsion between *t*-butyl groups and cyano groups.

The authors are grateful to Professor Fumio Toda of Ehime University for supplying the sample and also for his valuable suggestions.

†† 1 kcal mol^{-1}=4.184 kJ mol^{-1}.

(Received September 1, 1980)

The phase equilibrium in $C_8H_{17}(OCH_2CH_2)_3OH$/water/decane system was studied at 13.6, 15.8, 21.5, 26.0, and 30.0 °C. An upper critical solution point for the surfactant and oil phases, and a lower critical solution point for the surfactant and water phases were found. Strong critical opalescence was observed in the vicinity of the critical points. In a temperature range between two critical points, a three-phase region appeared due to the superposition of three miscibility gaps, *i.e.*, 1) surfactant+water; 2) surfactant+oil, and 3) oil+water phases. The correlations between the phase equilibria and the ultralow interfacial tensions were straightforward. An ionic surfactant/cosurfactant/brine/oil system gave similar phase equilibria as the nonionic surfactant system, but the effect of temperature was the reverse.

In ordinary binary-liquid systems, mutual solubility of two phases increases with the increase of temperature and the compositions of the two phase coincide at the critical temperature, at which the interfacial tension between them becomes zero.[1-3] In a critical region, due to the large concentration fluctuation large clusters of molecules develop since the dimensions of the clusters are of the order of the wave length of light. Such systems scatter light strongly and the phenomenon is called critical opalescence.[4]

In surfactant solutions, the micelles present may be interpreted as large concentration fluctuations in a wider range of temperature than that in ordinary binary mixtures. According to the traditional interpretation[5-6] micelles grow with increasing temperature in nonionic surfactant aqueous solutions and their aggregation number becomes infinite in the vicinity of the solubility curve (cloud point curve), above which a surfactant and a water phases coexist. The recent NMR investigations by Tiddy and collaborators[7] have given results at variance with this interpretation. Their evaluation rather pointed to the presence of aggregates of flocculated micelles instead of larger ones.

In nonionic surfactant/water/oil systems, the surfactant mainly dissolves in water at lower temperature, whereas it dissolves in oil at higher temperature. At the transition temperature range of the surfactant from water-soluble to oil-soluble, there is a three-phase region consisted of a water phase, an oil phase and a surfactant phase which solubilizes a large amount of water and oil.[8-10] In this region, following phenomena are observed; 1) the amount of the solubilization of oil or water in a surfactant phase is attained to maximum, and the surfactant phase scatters a considerable amount of light, 2) ultralow interfacial tensions between the surfactant and oil (water) phases are obtained.[11] It is considered that these resemble critical phenomena in ordinary liquid systems. But the correlation between these phenomena and phase equilibria has not been clarified.

In this paper, solution behavior of $C_8H_{17}(OCH_2CH_2)_3OH$ in water and oil has been studied and compared with phase equilibria in ordinary binary or ternary mixtures. The solution behavior of ionic surfactant has also been evaluated for comparison.

Experimental

Materials. Pure $C_8H_{17}(OCH_2CH_2)_3OH$ was synthesized by POLA Research Laboratory and pure $C_{12}H_{25}(OCH_2CH_2)_5OH$ was synthesized by Nikko Chemicals; the high purity was confirmed by gas chromatographic analysis. *p*-$C_8H_{17}C_6H_4SO_3Na$ was kindly supplied by Kao Soap Company. Extra pure grade decane, hexadecane, 2,2,4-trimethylpentane were obtained from Tokyo Kasei Kogyo Company, and used without further purification.

Procedures. The procedures for the determinations of the phase diagrams were described in previous papers.[9-12]

Results and Discussion

$C_8H_{17}(OCH_2CH_2)_3OH$/Water/Decane System. Complicated phase equilibria are observed in long-chain surfactant/water/oil system, since liquid crystalline phases exist in a wide range of composition.[8-13] Therefore, the use of a short-chain surfactant is of advantage in order to understand the basic solution behavior of nonionic surfactant in oil and water. The short hydrocarbon chain is not sufficient to stabilize a liquid crystalline phase, hence the phase equilibria involving only liquid phases are more easily achieved.

With this fact in mind phase diagrams for $C_8H_{17}(OCH_2CH_2)_3OH$/water/decane system were determined at 13.6, 15.8, 21.5, 26.0, and 30.0 °C and are shown in Figs. 1(a)—(e).

There are two two-phase regions in Fig. 1(a). One contains a surfactant phase (D) and an aqueous phase (W) located in the vicinity of water apex. Compositions of coexisting D phase and W phase coincide at the plait point K (isothermal critical point) on the miscibility curve. Kc means the upper limit of K as described later. The other two-phase region is comprised of a surfactant (or water) phase and an oil phase (O). Compositions of both phases coincide at the plait point L on the miscibility curve, but the boundary between the surfactant phase and the water phase cannot be distinguished since there is no plait point between these phases.

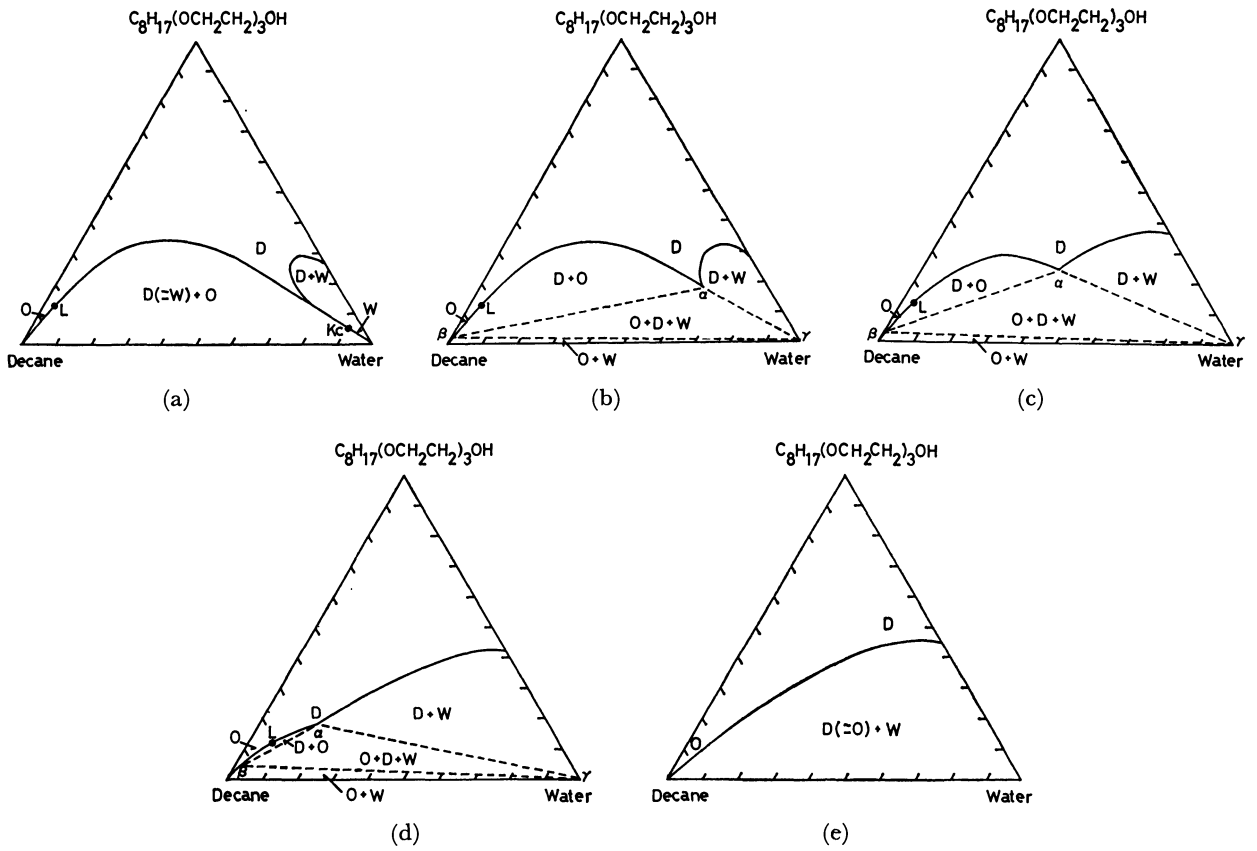

Fig. 1. Phase diagrams for $C_8H_{17}(OCH_2CH_2)_3OH$/water/decane system at various temperatures. (a) 13.6 °C, (b) 15.8 °C, (c) 21.5 °C, (d) 26.0 °C, (e) 30.0 °C. O, an oil phase; W, a water phase; D, a surfactant phase; α, β and γ, invariant points; K and L, plait points. Kc and Lc are upper limits of K and L (*cf.* Fig. 3).

The water phase continuously changes to the surfactant phase with increasing the content of a surfactant/decane solution of the ratio 1.2. Therefore, this latter two-phase region contains two miscibility gaps, *i.e.*, D+O and W+O so that the notation, D(≃W) is used. Below this temperature the two-phase D(≃W)+O region becomes wider, whereas D+W region becomes narrower and the plait point K approaches to water apex and the plait point L approaches the oil-surfactant axis (*cf.* Fig. 3).

Point Kc is still in contact with the miscibility curve between D(≃W) and O at 13.6 °C as shown in Fig. 1(a). Slightly above this temperature, the single-phase region splits into two realms, *i.e.*, the surfactant phase and the water phase at point Kc, and a three-phase region is formed consisted of a water, and oil and a surfactant phases. In other words, the equilibrium of three liquid phases causes the superposition of three miscibility gaps, *i.e.*, O+W, D+W, and D+O. The three coexisting liquids are the point, α, β, and γ as shown in Fig. 1(b).

This kind of phenomenon is also known in ordinary ternary systems, such as water/ether/succinonitrile systems.[14,15] The single water-phase region abruptly falls to the water apex in a very narrow range of temperature. The plait point Kc is the lower critical point between the surfactant and the water phases in the presence of oil. W or D phase in the vicinity of the plait point Kc scatters light and looks blue. The system is called a microemulsion.[10]

Point α shifts to the oil apex and the three-phase and D+W phase regions become wider with increasing temperature as shown in Fig. 1(c). Point α in Fig. 1(c) is the minimum concentration of $C_8H_{17}(OCH_2CH_2)_3OH$ to make equal amount of oil and water a single phase. Three points, α, β, and L approach each other with increasing temperature as shown in Fig. 1(d) and coalesce at 26.6 °C which is the upper critical point, (Lc) between the surfactant and the oil phases in the presence of water. Three-phase and D+O regions disappear and only the two-phase D(≃O)+W phase region is observed above this temperature as shown in Fig. 1(e).

Since the plait point does not exist on the miscibility curve in Fig. 1(e), the boundary between an oil phase and a surfactant phase cannot be distinguished. In other words, this two-phase region contains two miscibility gaps, *i.e.*, D+W and O+W so that the notation D(≃O) is used.

It is clear that the mutual dissolution between the surfactant phase and the water phase is increased with decreasing temperature, whereas that between the surfactant phase and the oil phase is increased with increasing temperature as shown in Figs. 1(a)—(e).

The correlations between phase equilibria and ultralow interfacial tensions are also made clear from Figs. 1(a)—(e). It is known that the interfacial tension

becomes zero at a critical point in ordinary liquid system.[3,16] The interfacial tension between the surfactant phase and the water phase approaches zero at the plait point K, because the compositions of both phases become equal. On the other hand, the interfacial tension between a surfactant phase and an oil phase approaches zero at the plait point L. Since no plait points exists above 26.6 °C as shown in Fig. 1(e), the interfacial tension does not become zero at any points in two-phase region. In three-phase region, the interfacial tension between a surfactant and a water phase becomes zero on the line at which the two lines, α-β and β-γ coalesce each other at 13.6 °C. On the other hand, the interfacial tension between a surfactant phase and an oil phase becomes zero on the line at which the two lines, α-γ and β-γ coalesce each other at 26.6 °C.

These results are in excellent accordance with those by Friberg and coworkers,[17,18] whose more complex equilibria were due to the influence of longer hydrocarbon chains. These favor the formation of lamellar phases.[19]

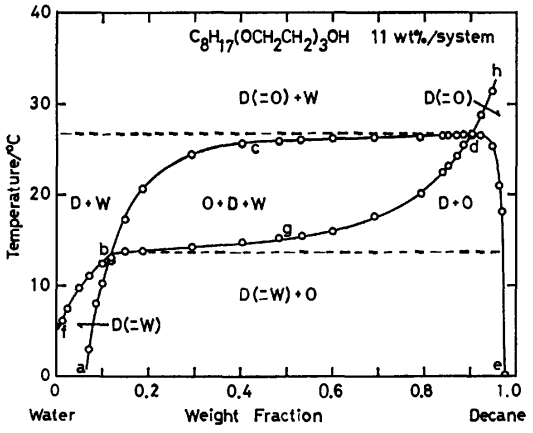

Fig. 2. Phase diagrams for water–decane containing 11 wt% of $C_8H_{17}(OCH_2CH_2)_3OH$/system as a function of temperature.

The effect of temperature on the phase equilibria of water-decane containing 11 wt% of $C_8H_{17}(OCH_2CH_2)_3$-OH was also studied and is shown in Fig. 2. This kind of phase diagrams have been extensively investigated by Shinoda and coworkers.[8-10] D($\simeq$O) and D($\simeq$W) are single-phase regions. (*cf.* Fig. 1). Above the curve a-b-c-d-e which is the miscibility curve of an oil and a surfactant phases, O and D phases cannot coexist in equilibrium. On the other hand, the surfactant phase and the water phase cannot coexist in equilibrium below the miscibility curve f-b-g-d-h. Hence the surfactant phase may coexist with the oil and the water phases only in the closed region, b-c-d-g. The curve a-b-c-d-e is smoothly continuous but the curve f-b-g-d-h has a break at point b in Fig. 2. From Fig. 2, it is clear that the solubilization of oil or water attains maximum in the vicinity of critical point (Kc or Lc).

Figure 3 is the polythermal projection of Figs. 1(a)—(e). Broken line means the locus of invariant point α and in the region of lower side of this line, a single liquid phasc does not appear at any temperatures.

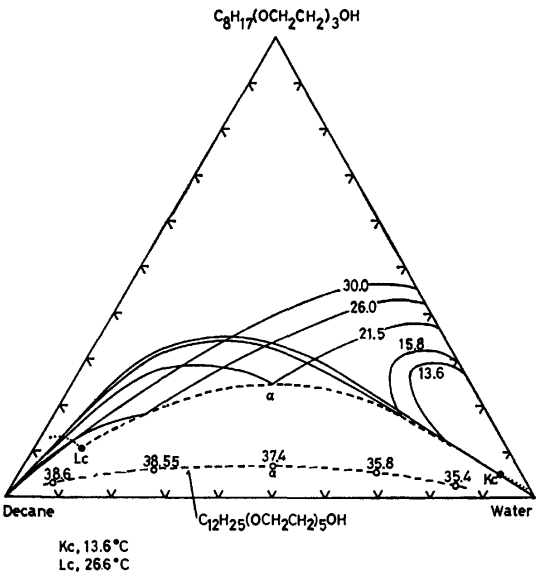

Fig. 3. Polythermal projection of Figs. 1(a)—(e). Dotted lines are the loci of plait points. —○— is a locus of α in $C_{12}H_{25}(OCH_2CH_2)_5OH$/water/decane system. Numerical numbers indicate the temperature (°C). Kc, $C_8H_{17}(OCH_2CH_2)_3OH$ 5 wt%, water 91 wt%, decane 4 wt%; Lc, $C_8H_{17}(OCH_2CH_2)_3OH$ 11 wt%, water 9 wt%, decane 80 wt%.

Dotted lines represent the loci of the plait points K and L. Since the locus of α is far from water–oil axis in $C_8H_{17}(OCH_2CH_2)_3OH$/water/decane system, the solubilizations of oil and water in surfactant phase are relatively small. The locus of α in $C_{12}H_{25}(OCH_2CH_2)_5$-OH/water/decane system (open circles) is also shown in Fig. 3. α is very close to oil–water axis so that the solubilization is very large. But, the composition of α is rapidly changed with increasing temperature.

The critical phenomenon at the composition of point Kc in Fig. 1(a) is captured in the sequence of the photographs shown in Figs. 4(a)—(d). Well above the critical temperature, both an upper surfactant phase and a lower water phase are clear and there is no appreciable scattered light. With decreasing temperature, the solubilization of water in a surfactant phase is increasing and D phase (upper) begins to scatter light as shown in Fig. 4(a). Just above the critical temperature, the dissolution of D phase in W phase will strongly increase and both show pronounced phases light-scattered as shown in Fig. 4(b). At the critical temperature (13.6 °C), the boundary between two phases suddenly disappears and the scattered light attains a maximum as shown in Fig. 4(c). Below this temperature, the light-scattering weakens and excess oil is separated from D($\simeq$W) phase as shown in Fig. 4(d). (See the meniscus). It is essential to point out that the scattered light observed in microemulsion systems[9] is a critical opalescence. Except these critical points, it is known that two critical phenomena exist on the oil-surfactant axis and the water-surfactant axis in nonionic surfactant system.[20-23]

Phase diagram of equal amount of oil and water containing $C_8H_{17}(OCH_2CH_2)_3OH$ as a function of temperature is shown in Fig. 5. The curve a-b-c-d is

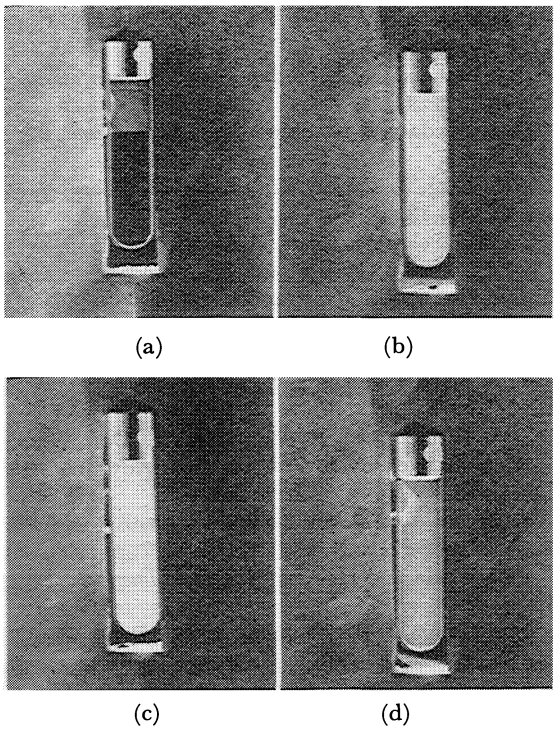

Fig. 4. The critical phenomenon captured in the sequence of the photographs at the composition of the lower critical point (Kc) in Fig. 1(a). (a) 14.0 °C, (b) 13.7 °C, (c) 13.6 °C, (d) 12.0 °C.

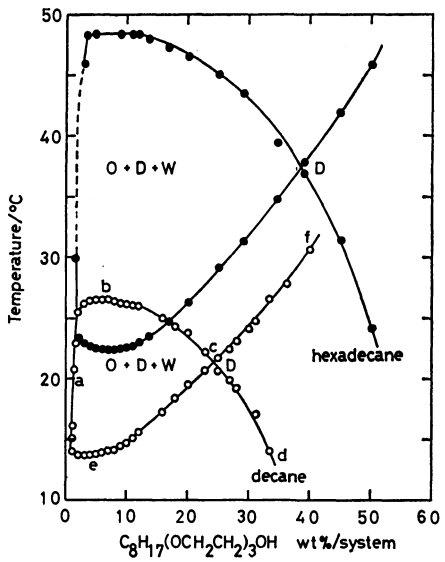

Fig. 5. The effect of the concentrations of $C_8H_{17}(OCH_2CH_2)_3OH$ on the equi-weight mixture of water and decane (or hexadecane) as a function of temperature.

the coexisting curve of the surfactant phase and the oil phase in the presence of water, whereas the curve a-e-c-f is that of the surfactant and the water phases in the presence of oil. If a molecular volume of oil is large (hexadecane), two coexisting curves shift to higher temperature as shown in Fig. 5. This fact means that a surfactant becomes more soluble in the water phase. Upper coexisting curve shifts more to higher temperature than the lower one does and the three-phase region becomes wider. Hence the minimum content of surfactant to make equal amount of oil and water a single phase is increased. This is in agreement with earlier solubilization studies.[17]

Ionic Surfactant/Cosurfactant/Brine/Oil System. Ordinary ionic surfactant dissolves in water and solubilizes a small amount of oil and the solubilization is little affected by temperature change.[19] Even hydrophile-lipophile balanced ionic surfactant, Aerosol OT (sodium 1,2-bis(2-ethylhexyloxycarbonyl)ethanesulfonate) dissolves mainly in water in dilute system, in which aqueous micellar solution phase coexists with an excess oil.[23-24] If brine is used instead of water, a three-phase region consisting of an oil, a water and a surfactant phases has been shown appearing in certain temperature ranges in Aerosol OT system as well as nonionic surfactant systems.[24-26] On the other hand, it is known that the solution behavior of Aerosol OT in water is similar to that of the appropriate mixture of ordinary ionic surfactant and cosurfactant such as long-chain alcohol.[27] Hence, it is expected that same solution behavior as that in Aerosol OT or nonionic surfactant systems appears in ordinary ionic surfactant systems if proper amounts of brine and cosurfactant are used. Phase diagram of p-$C_8H_{17}C_6H_4SO_3Na$, brine, 2,2,4-trimethylpentane and 1-hexanol as a function of temperature is shown in Fig. 6. Brine/2,2,4-trimethyl-

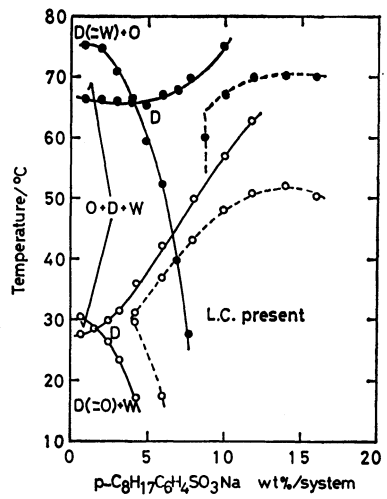

Fig. 6. The effect of the concentration of p-$C_8H_{17}C_6H_4$-SO_3Na on the equi-weight mixtures of brine (○, 1 wt% NaCl; ●, 3 wt% NaCl) and 2,2,4-trimethylpentane containing 30 wt% of 1-hexanol as a function of temperature.

pentane (containing 30 wt% of 1-hexanol) ratio is unity (W/W). Concentrations of salt in water are 1 wt% (open circles) and 3 wt% (filled circles) respectively. Below the temperature indicated by broken lines, liquid crystalline phase is separated. Below the curve which is concave downward, an excess water and a surfactant phase are separated, whereas an excess oil and a surfactant phase are separated above the curve which is concave upward. Therefore, three-phase consisted of a water, an oil and a surfactant phases appears in overlapping realm which is indicated by

O+D+W. From this result, it is clear that ionic surfactant becomes more hydrophilic with increasing temperature. Overlapping realm, *i.e.*, three-phase region shifts to lower temperature with decreasing salt content as shown in Fig. 6 and finally, it may disappear and a surfactant phase and an excess oil phase remain at room temperature in the absence of salt.

The authors thank Prof. Kōzō Shinoda for his stimulating discussion. Senior author thanks Sakko-kai Foundation for its financial support.

Hydrodimerization of Methyl Acrylate Catalyzed by Halogenotris(triphenylphosphine)cobalt

Hiroyoshi KANAI* and Keiji ISHII

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received September 4, 1980)

Methyl acrylate was hydrodimerized in a methanolic solution by $CoX(PPh_3)_3$ (X=halogen) into dimethyl adipate. The *in situ* prepared cobalt complexes from cobalt halides, triphenylphosphine, and zinc gave higher yields of the hydrodimer in the presence of alkali halides. A mechanism is proposed which involves the protonation of Co(I)–methyl acrylate π-complex to give (2-methoxycarbonylethyl)cobalt complex, followed by a further addition of methyl acrylate.

Olefins substituted with electron-withdrawing groups are dimerized to head-to-head or head-to-tail dimers by bases,[1,2] electrolytic coupling,[3] and transition metal complexes.[4,5] The head-to-head hydrodimerization has been extensively studied because head-to-head dimers are of considerable interest as starting materials for the preparation of monomers.[3,5] We have previously reported that acrylic esters were hydrodimerized by cobalt(I)–triphenylphosphine complexes and that the addition of alkali halides and zinc increased the yield.[5j] We wish to report our subsequent work on the development of good catalysts for and the mechanism of the hydrodimerization of methyl acrylate.

Experimental

All reagents were used directly as obtained commercially unless otherwise noted. Tetrahydrofuran (THF) and alcohols were refluxed over sodium and sodium alkoxides, respectively, distilled, and stored under an atmosphere of nitrogen. Methyl acrylate was distilled and stored under N_2 in a refrigerator. ^1H NMR spectra were obtained on a JEOL PM-60 spectrometer. A Shimadzu 6A gas chromatograph with a FID detector was used for most GLC analyses [PEG 20M (25% on celite 545), 4 m×3 mm i.d. column, 175°]

Cobalt Complexes. Cobalt (I) complexes were prepared by modifying the procedure used by Aresta *et al.*[6] slightly. A solution of cobalt iodide (0.30 g, 1 mmol) and triphenylphosphine (0.93 g, 3.5 mmol) in THF (15 ml) and ethanol (1 ml) was treated with zinc dust (0.36 g, 5.5 mmol) under stirring at room temperature for 1 h. The resulting green suspension was filtered and the filtrate was concentrated almost to dryness. Ethanol (25 ml) was added and the precipitate was washed with three portions of ethanol (6 ml) and dried. The yield was 0.69 g (60%). Anal. Found: C, 66.79; H, 4.66%. Calcd for $C_{54}H_{45}ICoP_3$: C, 66.68; H, 4.66%. Bromo- and chlorotris(triphenylphosphine)cobalt were obtained similarly. The yields were 42 and 22%, respectively. Their elementary analyses were in fair agreement with the calculated values.

Reactions. The complex (*ca.* 0.2 mmol) was placed in a 100-ml flask which was flushed with nitrogen. Tetrahydrofuran (8 ml), methanol (2 ml), and methyl acrylate (1.5 ml, 16.4 mmol) were added by syringes. The reaction mixture was stirred for 16—20 h at room temperature.

Reactions with in Situ *Prepared Complexes.* In a 100-ml flask were placed cobalt halide (1 mmol), triphenylphosphine (3 mmol), and zinc (8 mmol). Tetrahydrofuran (8 ml) and methanol (2 ml) were added and the solution was stirred for half an hour. To the resulting yellow-green solution was added methyl acrylate (16.4 mmol) and the reaction mixture was stirred for an adequate interval. The determination of yields was carried out by gas chromatography using an internal standard.

Results and Discussion

Stoichiometric Reactions. When methyl acrylate (MA) was treated with $CoX(PPh_3)_3$ (X=halogen) in THF–methanol, the yellow-green solution turned brown and finally blue. The former color change suggests an interaction between the Co(I) complex and MA. The products were identified as dimethyl adipate and methyl 2-methoxypropionate. The yield of dimethyl adipate is dependent upon halides and decreases in the order I>Br>Cl, as shown in Table 1. The higher

Table 1. Hydrodimerization of methyl acrylate catalyzed by $CoX(PPh_3)_3$[a]

X	mmol	MA mmol	Yield of dimethyl adipate Co base mol/g atom

Br	0.20	16.4	0.26(0.18)[b]
I	0.23	2.2	0.18
I	0.22	16.4	0.31(0.30)[b]

a) KX 5 mmol, THF 8 ml, CH_3OH 2 ml, r.t., 16—20 h.
b) In the absence of KX.

concentration of MA causes the increase of Co(I)–MA complex, resulting in the higher yield of the hydrodimer.

$$2\,CH_2{=}CHCO_2CH_3 + 2\,CH_3OH + CoX(PPh_3)_3 \longrightarrow H_3CO_2C(CH_2)_4CO_2CH_3 + XCo(OCH_3)_2(PPh_3)_n \quad (1)^{7)}$$

$$CH_2{=}CHCO_2CH_3 + CH_3OH \xrightarrow{XCo(OCH_3)_2(PPh_3)_n} H_3COCH_2CH_2CO_2CH_3. \quad (2)$$

The hydrodimerization was little affected by the addition of potassium halides. A Michael reaction (Eq. 2) is responsible for the catalysis of the cobalt methoxide formed.

Use of in Situ *Prepared Cobalt(I) Complexes in the Presence of Alkali Halides and Zinc.* Cobalt(I) complexes were prepared by the reaction of cobalt halides, triphenylphosphine (PPh_3), and zinc in THF–methanol at room temperature. If methoxyl group in $XCo(OCH_3)_2(PPh_3)_n$ is replaced by halogens, Co(I) complexes are expected to be regenerated in the presence of zinc. Catalytic hydrodimerization of MA was, in fact, carried out successfully by cobalt complexes in the

$$CoX_2 + 3\,PPh_3 + \frac{1}{2}Zn \longrightarrow CoX(PPh_3)_3 + \frac{1}{2}ZnX_2 \quad (3)$$

presence of alkali halides and zinc, as shown in Table 2. The addition of zinc affords dimethyl adipate in more than 100% yields, based on cobalt complexes, even in the absence of alkali halides. The reaction of $XCo(OCH_3)_2(PPh_3)_n$ and ZnX_2 in the presence of zinc might regenerate a Co(I) complex. The trend in the reactivity of $CoX(PPh_3)_3$ in the presence of zinc is the same as that in the isolated complexes. Alkali iodides and lithium chloride are effective and potassium iodide is the most effective among the alkali halides investigated. Although lithium salts are more soluble,[8] none of them exert any positive effect toward the hydrodimerization. It is not clear why potassium iodide is the most effective even though it is less soluble. Counter ions also play an important role in the hydrodimerization.[9]

TABLE 2. EFFECTS OF THE ADDITION OF ALKALI HALIDES ON THE HYDRODIMERIZATION OF METHYL ACRYLATE BY $CoX(PPh_3)_3$ IN THE PRESENCE OF ZINC[a]

a) $CoX(PPh_3)_3$ was prepared *in situ* from CoX_2 (1 mmol), PPh_3 (3 mmol), and Zn (10 mmol) in THF (10 ml) and CH_3OH (2 ml). MA (16.4 mmol), 20 °C, 2 h. b) The number in parentheses is the yield based on MA consumed. c) Yield based on cobalt complex. d) r.t., 20—24 h. e) Methyl 2-methoxypropionate 20%. f) Methyl propionate 12%. g) r.t., 2 d. h) r.t., 4 d. i) Methyl 2-methoxypropionate 5.4%. j) Methyl 2-methoxypropionate 50%. k) Methyl 2-methoxypropionate 2.7%. l) Methyl propionate 16%.

The yield of the hydrodimer is dependent upon the amount of alkali halides. The excess of alkali halides lowers both yield and selectivity. The appropriate amount of alkali halides nearly corresponds to that of the dimethyl adipate to be produced. A considerable amount of methyl 2-methoxypropionate and propionate were formed in the presence of lithium and ammonium salts, respectively.

TABLE 3. EFFECTS OF TEMPERATURE AND ADDITIVES ON THE HYDRODIMERIZATION OF METHYL ACRYLATE[a]

	5.0	—	2	68	1.61 (29)
	5.0	2	2	55	4.09 (91)
	5.0	2	6	83	5.87 (86)
40	5.0	2	6	46	2.81 (75)

a) Catalysts prepared *in situ* from CoI_2 (1 mmol), PPh_3 (3 mmol), and Zn (10 mmol) in THF (8 ml). MA 16.4 mmol. b) Yields are the same as those in Table 2.

The effects of methanol and temperature were examined as shown in Table 3. Even in the absence of methanol, hydrodimerization occurred, but the addition of methanol appreciably increased the yield of the hydrodimer. Low temperatures are preferable because catalytic species are so thermally unstable as to be easily decomposed.[6]

TABLE 4. SOLVENT EFFECTS ON THE HYDRODIMERIZATION OF METHYL ACRYLATE BY $CoX(PPh_3)_3$[a]

X	Solvent ml	Yield of dimethyl adipate Co base mol/g atom
Cl	THF 8, MeOH 2	1.51
	DMF 8, MeOH 2	2.89

	MeOH 10	2.23
I	THF 8, MeOH 2	5.26
	THF 10	0.56
	CH_3CN 8, MeOH 2	0.67
	CH_3CN 10	1.20
	MeOH 10	0.45

a) $CoX(PPh_3)_3$ prepared *in situ* from CoX_2 (1 mmol), PPh_3 (3 mmol), and Zn (8—10 mmol) in solvents. MA 16.4 mmol, r.t., 20—90 h.

Tetrahydrofuran and *N,N*-dimethylformamide were found to be the most suitable solvents among several investigated in the catalysis of $CoI(PPh_3)_3$ and $CoCl(PPh_3)_3$, respectively (Table 4). Polar solvents are preferable. The reduction to the Co(I) complexes occurred in all solvents listed in Table 4, but it was accelerated by the addition of methanol. The effects of methanol on the hydrodimerization of MA in THF–methanol are shown in Fig. 1. The appropriate mole ratio of methanol to MA is 4—5. The Michael reaction took place in preference to the hydrodimerization in a large excess of methanol : methyl 2-methoxypropionate was obtained in a 52% yield in methanol as the sole solvent. Ethanol functions similarly to methanol in the hydrodimerization, but ester exchange occurs in it.

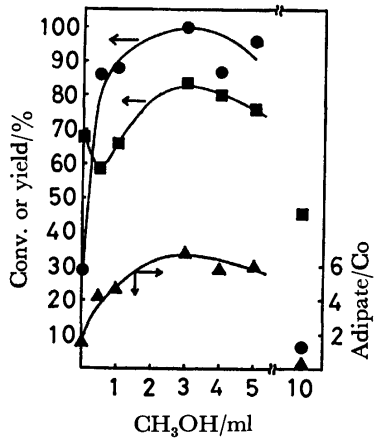

Fig. 1. Effects of the amount of methanol on the hydrodimerization of methyl acrylate by *in situ* prepared $CoI(PPh_3)_3$ in THF (8 ml)–methanol. (Methanol (10 ml) without THF.)
■: Conversion, ●: yield based on MA consumed, ▲: yield based on the cobalt complex.

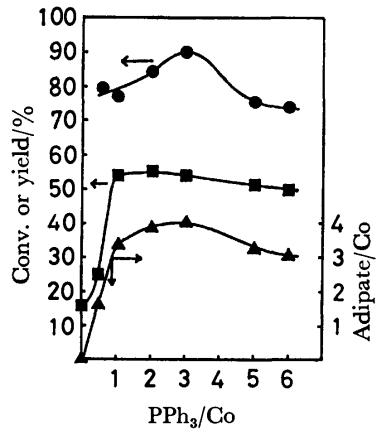

Fig. 2. Effects of the ratio of triphenylphosphine to cobalt on the hydrodimerization of methyl acrylate by *in situ* prepared $CoI(PPh_3)_3$. Symbols are the same as those in Fig. 1.

The effects of the ratio of PPh_3 to a cobalt complex are shown in Fig. 2. The optimum ratio is 3, which is in accord with the ratio of the isolated complexes. The excess of PPh_3 did not affect the conversion of MA, but lowered the yield of the hydrodimer. The coordination of MA is blocked by excess PPh_3 which, however, does not inhibit the Michael reaction.

Mechanism. The hydrodimer obtained in deuterated compounds was analyzed by ^1H NMR as shown in Table 5. Most of the hydrogen added originates from the hydroxyl hydrogen in methanol. The rest seems to be from solvents and MA itself, because we have not detected ortho-hydrogen of PPh_3 in the hydrodimer. No hydrogen attached to β-carbon of MA exchanged with that of solvents such as THF and benzene, but a part of the hydrogen exchanged with that of acetonitrile. Acetonitrile is sometimes split to H and CH_2CN radicals by oxidative addition to low-valent transition metal complexes.[10] Since $CoX(PPh_3)_3$, one of the low-valent d^8 complexes, is susceptible to oxidative addition,[11] deuterium incorporation into the hydrodimer may occur *via* deuterium atom abstraction of acetonitrile-d_3 by the Co(I) complex and the transfer of the deuterium.

Table 5. Analysis of hydrogen of dimethyl adipate produced by the reaction of MA with *in situ* prepared $CoX(PPh_3)_3$ in deuterated compounds

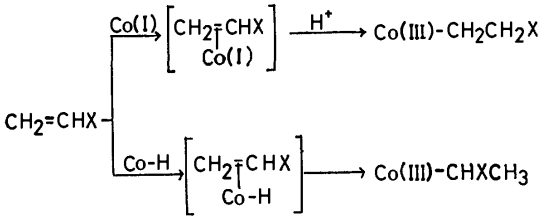
a) P=PPh_3. b) Based on the assumption that the number of hydrogens of the methoxy group is 3.00. c) Before the end of the reaction, D_2O was added.

Hydrodimerization of acrylonitrile by iron carbonyls and ruthenium complexes has been extensively investigated by Misono *et al.*,[5a-e] McClure *et al.*,[5f] and Billig and coworkers.[5g] They explained the reaction involving insertion of acrylonitrile into an M–H or M–cyanoethyl or an M–vinyl bond (M=Fe, Ru), some of which were isolated and characterized. The products are not only a hydrodimer but also propionitrile, 2-methylglutaronitrile, and *cis*- and *trans*-2-hexenedinitrile. The products from the reaction of MA with Co(I) complexes are a head-to-head hydrodimer, Michael adduct, and methyl propionate. We could not observe 2-methylglutarate and *cis*- and *trans*-2-hexenedioate at all. The products of the latter reaction are very similar to those derived from the electrolytic coupling.[3] The difference in products suggests that the hydrodimerization of MA by $CoX(PPh_3)_3$ proceeds by a mechanism different from that of the hydrodimerization of acrylonitrile by iron carbonyls and ruthenium complexes. Another characteristic feature is that the hydrogen incorporated into the hydrodimer in the Co(I) complex systems originates mainly from alcohols, but that in the ruthenium complex systems comes from atmospheric hydrogen.

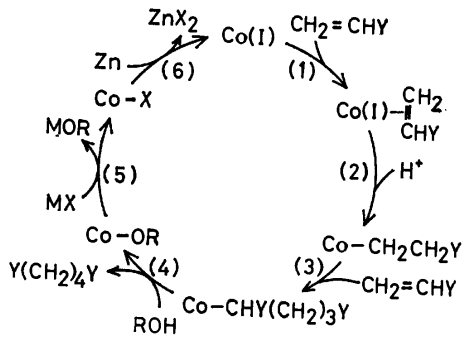
The addition of MA to $CoX(PPh_3)_3$ in methanolic solution produces a red-brown color from a yellow-green one. A similar color change was observed between cobaloxime(I) and ethyl acrylate or acrylonitrile.[12] Spectroscopic study showed an interchange between the cobaloxime–ethyl acrylate π-complex and (2-ethoxycarbonylethyl)cobaloxime.[12b] However, a hydride $HCo(dmg)_2P(n\text{-}C_4H_9)_3$ (dmg=dimethylglyoximato) reacted with acrylonitrile or acrylates to yield the α-substituted ethylcobaloxime derivatives,[13] in contrast with β-substituted isomers from the protonation of the cobaloxime(I)–olefin π-complex (Scheme 1). The latter has been exemplified by the work on the rhodium–olefin complexes.[14]

We postulate a mechanism for the hydrodimerization of methyl acrylate by Co(I) complexes (Scheme 2). Red-brown species are responsible for the formation



Co=cobaloxime, X=CN, CO_2R.

Scheme 1.



Co=$CoX(PPh_3)_n$, X=halogen,

Scheme 2.

of Co(I)–MA π-complex. A β-substituted ethylcobalt complex is formed from the protonation of the Co(I)–MA π-complex with alcohol. Further addition of MA to the ethylcobalt complex gives 1,4-bis(methoxycarbonyl)butylcobalt complex, which is protonated to yield dimethyl adipate. No reverse reaction in (2) occurs because hydrogen exchange between MA and alcohol has not been observed. The susceptibility of protonation of the 1,4-bis(methoxycarbonyl)butylcobalt complex, in comparison with that of the β-substituted ethylcobalt complex, is correlated with the stability of the cobalt-carbon: alkylmetal complexes bearing primary carbons are more stable than those bearing secondary carbons.[15] The Co(I) complex can be regenerated by the reduction of the cobalt halide complex which is formed by replacing the alkoxyl group with alkali halides. Cobalt alkoxide or alkali metal alkoxide released in (5) causes the Michael reaction to occur.

(Received October 17, 1980)

The transport number of the ions, $t^{\pm}$, of $(C_2H_5)_4NClO_4$, $NaClO_4$, NaCl, KCl, and HCl in *N,N*-dimethylformamide(DMF)–water solvents were determined by the agar–salt bridge method. In order to compare this method, t^+(HCl)'s in DMF–water media were measured by both the Hittorf method and the concentration cell method. Good agreement among these methods leads to the conclusion that t^+(KCl) and t^-(KCl) are nearly equal in the whole range of DMF–water media. The results suggest that potentials obtained in nonaqueous polarography with the bridged SCE by correcting the bridge potential with a slow flowing type aqueous SCE are always referred to the ordinary aqueous SCE.

It is desirable that all potentials be referred to a common aqueous scale, such as the ordinary calomel electrode, regardless of the fact that the medium is aqueous or nonaqueous. A few attempts to do this in nonaqueous polarography have been made.[1–4] On prolonged immersion of an aqueous saturated potassium chloride salt bridge in a nonaqueous medium, a plug of solid KCl formed on the tip of the bridge and caused a significant increase in the resistance of the cell[2,3] and an increase in the liquid junction potential.[4] This resulted in a drift of the potential with time.

The use of the reference redox couple such as rubidium ion-rubidium amalgam,[5] ferricinum ion-ferrocene,[6] tris-(phenanthroline)iron(II, III) complex,[7] $[Fe(bpy)_3]^+$–$[Fe(bpy)_3]^\circ$,[8] and the form R^--R^+ type[9] have an advantage for the purpose of comparing redox potentials of a given couple in different solvents. Those, however, are relative and contain some assumption concerning the solvation of couple ions or neutral particles.

Suitable reference electrodes in individual solvent systems are convenient,[10–13] but it is desirable, if possible, to use a common reference for emf measurements made in a variety of solvent systems.

In this connection, Fujinaga *et al.* have proposed a bridged SCE as an external reference electrode,[14] and polarographic behaviours of some compounds in the solvents of *N,N*-dimethylformamide (DMF)–water binary system have been studied with exact comparison of potentials referred to the bridged SCE.[15–18] One of the authors has investigated in detail the characteristics of the bridged SCE and emphasized its great utility,[19] showing that the potential drift during a period of polarographic scanning is less than 3 mV and that the potentials could be referred to the ordinary aqueous SCE with a precision of a few millivolts when the potentials were corrected for the bridged potential measured with a slow flowing-type aqueous SCE just after the scan was completed.

This conclusion is based on the coincidence of both the final bridge potential E_∞ and the calculated liquid junction potential $E_j(C_1, C_2)$ as tabulated in Table 1. The E_j were calculated by using the equation

$$E_j(C_1, C_2) = \frac{RT}{F}(t^- - t^+) \ln (C_2/C_1). \quad (1)$$

The differences in transport number $(t^- - t^+)$ were obtained from the slope of the bridge potential E *vs.* log (C_2/C_1) plots at each DMF concentration. If the transport number thus obtained is right, all the voltammetric measurements with the bridged SCE are always referred to the common aqueous SCE, when a correction for the bridge potential is applied.

Table 1. Bridge potential and recalculated liquid junction potential[19]

$v_1=v_2$[a]	C_1	C_2[b]	E_0	E_∞[c]	$(t^- - t^+)$[d]	$E_j(C_1,C_2)$[e]

a) The isometric volume % of DMF in the test soln(1) and in the tip of the bridge(2). b) Molarity of tetraethylammonium perchlorate (TEAP) in the test soln(1) and in the tip of the bridge(2). c) The bridge potential (mV) at the same day(0) and 30 d after the preparation of the bridge. d) Transport number of TEAP obtained from the slope of the E *vs.* log (C_2/C_1). e) Recalculated liquid junction potential at 25 °C by the help of Eq. 1.

In the present communication, the subject of the transport number was investigated in order to clarify the above point. The experimental methods available for measuring transport numbers fall into four categories: the Hittorf method, the concentration cell method, the moving boundary method, and the agar–salt bridge method.[20] The last of these is like that in the previous paper.[19] The purpose of this paper is, indeed, to compare the transport number obtained by the last method with those obtained by the first two methods.

Experimental

Preparation of the Test Solution in DMF–Water Media. Although it is a simple matter to prepare the solutions of a substance at various concentrations in different compositions of mixed solvent, it is difficult in practice to represent exactly and simultaneously both the solute and solvent composition. The present paper has solved this problem by introducing an isometric volume concentration, by which can be expressed a molarity, C, for the solute and a volume percent of either solvent composition. The conversion of the isometric volume percent to a weight percent or a mole fraction is easy.

Suppose a mixed solvent is prepared by adding V_A and V_B cm³ of pure solvents A and B whose densities d_A and d_B,

respectively. Then the total volume V_0 whose density d is

$$V_A d_A + V_B d_B = V_0 d. \quad (2)$$

When weight percent w_i and mole fraction X_i of solvent i are introduced into Eq. 2, we have

$$\frac{V_A}{V_0} = \frac{d}{d_A}\frac{w_A}{100} = \frac{d}{d_A}\frac{X_A M_A}{X_A M_A + X_B M_B}. \quad (3)$$

Equation 3 contains two unknown variables w_i and d, or X_i and d. Since the relation between w_i and d is measured experimentally, the isometric volume percent $v_i = 100\, V_i/V_0$ is easily converted to a weight percent w_i or mole fraction X_i. The conversion table for DMF–water binary system is shown in Table 2.

a) Density (g/cm³) of the mixed solvent from Ref. 21. b) Isometric volume % of water (A) and DMF (B). c) Values obtained by interpolating between w_B=95 and 100%. d) Ref. 26.

Electrolyte solutions were prepared, for example, by pipetting adequate amounts of aqueous stock solution of electrolyte and V_B cm³ of pure DMF, and then diluting with water in a V_0 cm³ volumetric flask. After reaching room temperature or thermostat temperature, the decrement is adjusted by adding water. Since the conductance of hydrochloric acid solutions in DMF–water media varies with time after its preparation, the potential measurement for the HCl solutions was carried out one day after preparation. In this paper, DMF volume percent means thus $v_B = 100\, V_B/V_0$, unless otherwise stated. This method is convenient to prepare a series of sample solutions with changing solute concentration and/or in varying solvent composition, contineously.

All electrolytes used were of extra-pure reagent grade. The solvents were purified as described previously.[14] Even 100% DMF contains water about 0.03% (*cf.* Table 2) in this experiment.

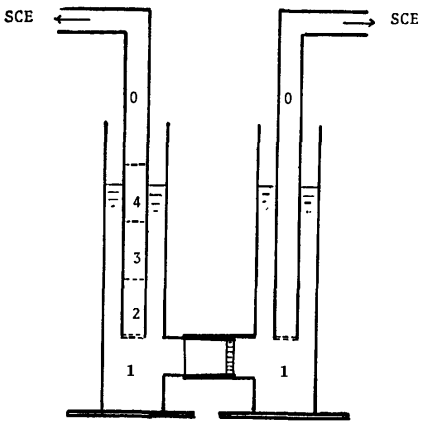

Fig. 1. Bridge potential measurement.
Phase 0, aq satd. KCl soln; 1, test soln (C_1, v_1); 2, DMF agar-salt bridge (C_2, v_2); 3, aq 0.5 M $NaClO_4$ agar bridge; 4, aq 1 M NaCl agar bridge.

Measurement of Transport Number. The Agar-Salt Bridge Method: Figure 1 shows the experimental set-up for measuring the bridge potential E. The agar-salt bridge, dipping into the left compartment of the H-type cell in the figure, was prepared according to the previous paper,[19] and the compositions in phase 2 are shown in Table 3. When not in use, the end of the phase 2 side of the bridge was stored in the renewed preserving solution, having C_2=0.1 mol/dm³ of the electrolyte and v_2 volume percent of DMF. A reference bridge, in the right-hand comaprtment, was an aqueous solution saturated with potassium chloride, which was allowed to flow very slowly into the test solution of phase 1, so as not to plug the tip of the bridge.

TABLE 3. COMPOSITION OF THE PHASE 2

Electrolyte	C / mol dm^{-3}	DMF vol%, v
TEAP[a]	0.1	0, 40, 70, 100
$NaClO_4$	0.1	0, 40, 70, 100
NaCl	0.1	0, 40, 70, 100
KCl	0.1	0, 40, 70, 100
HCl	0.1	0, 40, 70, 85

a) Tetraethylammonium perchlorate.

In Fig. 1, the cell is filled with a test solution (phase 1) which consists of C_1 mol/dm³ of an electrolyte and v_1 % of DMF. The potential difference E between two SCE's was measured within one minute after both bridges have been dipped at the same time (or the agar bridge later than the reference) into the test solution. The E's were measured every time in renewed test solution under the condition of various electrolyte concentrations C_1 but C_2=0.1 and at various DMF contents, but v_1 was always equal to v_2. In each DMF solvent, the E's thus obtained were plotted against log (C_2/C_1); the slope gives the difference of transport number of anion and cation by the equation

$$t^- - t^+ = \frac{F}{RT}\frac{dE}{d\ln(C_2/C_1)}. \quad (4)$$

The Hittorf Method: For simplicity in the determination, only hydrochloric acid was chosen as an electrolye in this method.

Two 1×1 cm^2 platinum plates were used as electrodes. The copper coulometer consisted of 150 g of copper sulfate, 50 cm^3 of 3 M sulfuric acid, 50 cm^3 of ethanol and 1 dm^3 of pure water. Electrolyses were performed at room temperature, and the electrolysis time was fixed between 90—150 min.

Volumetric determination of HCl concentration in both compartments, cathode and middle, was carried out by titration with aqueous sodium hydroxide solutions with phenolphthalein as an indicator, using a microburette. Since the color change at end-point was not clear in the solution containing more than 70% DMF, the solution were diluted with water appropriately. The decrement of HCl in the cathode compartment, Δn_c, is calculated by

$$\Delta n_c = (V_m - V_c)\frac{1}{b}N\frac{V}{1000}, \quad (5)$$

where V_m and V_c are the titer of N normality NaOH solution for b cm^3 of the respective middle and cathode compartments, V is the total amount in the cathode compartment. Hence the transport number of H^+ in HCl solution is

$$t^+(\mathrm{HCl}) = 1 - \Delta n_c \cdot \frac{F}{Q}, \quad (6)$$

where Q is the amount of electricity passed through the coulometer and F the Faraday constant.

The Concentration Cell Method: The potential E of Cell-1 without liquid junction

$$\mathrm{Ag|AgCl|HCl}(C_1)\mathrm{|H_2(Pt)|HCl}(C_2)\mathrm{|AgCl|Ag} \quad \text{Cell-1}$$

and the potential E_t of Cell-2 with liquid junction

$$\mathrm{Ag|AgCl|HCl}(C_1) \vdots \mathrm{HCl}(C_2)\mathrm{|AgCl|Ag} \quad \text{Cell-2}$$

are expressed by the equations

$$E = \frac{2RT}{F}\ln\frac{a_\pm(C_1)}{a_\pm(C_2)} \quad (7)$$

$$E_t = t^+\frac{2RT}{F}\ln\frac{a_\pm(C_1)}{a_\pm(C_2)}. \quad (8)$$

In each solution having a definite DMF content, the logarithmic terms in Eq. 7 and 8 are equal, hence the combination of the two equations gives a transport number

$$t^+(\mathrm{HCl}) = E_t/E. \quad (9)$$

Since the hydrogen electrodes and the silver-silver chloride electrodes have asymmetry potentials ΔE_h and ΔE_t, respectively, the equation 9 must be replaced in practice by

$$t^+(\mathrm{HCl}) = \frac{E_{t,\mathrm{exp}} - \Delta E_t}{E_{\mathrm{exp}} - (E_h - \Delta E_t)}. \quad (10)$$

Potential measurements were made with a Shimadzu Precision Potentiometer K-2 Type. The hydrogen electrodes, 1×1 cm^2 platinum plates, and Ag–AgCl electrodes, the electrolytic type and the thermal-electrolytic type, were prepared and stored according to the accepted methods.[22-24] The latter were kept in water saturated with AgCl for 3 d (for use in water) and 7 d (for use in DMF–water media) after preparation, in order to stabilize the asymmetry potential ΔE_t.

For the E_{exp} and $E_{t,\mathrm{exp}}$ measurements, the cell consists of four compartments (A, B, C, and D) connecting to a four-way stopcock. Two test solutions C_1 and C_2, whose DMF contents were the same, were placed in the compartments A, C and B, D, respectively. To A and B an appropriate amount of AgCl powder was added and stirred to saturate, and then the Ag–AgCl electrodes were inserted. The hydrogen electrodes were put into C and D compartments. The four compartments were bubbled with hydrogen gas (purified through pyrogallol solution) for 30—60 min. After the bubbling, the compartments A-C and B-D were connected by turning the four-way stopcock and the potential difference E_{exp} between A and B was measured (Cell-1). When two hydrogen electrodes were exchanged for a salt bridge or when the two compartments A and B were connected by the stopcock, the potential corresponds to $E_{t,\mathrm{exp}}$ (Cell-2).

The asymmetry potentials ΔE_h and ΔE_t were measured before each E_{exp} measurement, using, an H-type cell in which the concentrations of electrolyte in both compartments were fixed at C_2 and the other concentrations were the same as in the measurement of E_{exp}. The ΔE_t potentials have large values just after the Ag–AgCl electrodes have been transferred to DMF–water media from the aqueous preserving solution, but they decrease with time and stabilize after about half an hour in water and 1 h in DMF, respectively. The addition of solid AgCl is necessary because the silver chloride of the electrode is dissolved in DMF.[25]

Results

The Agar–Salt Bridge Method. The bridge potentials E were measured at room temperature by changing the electrolyte concentration C_1 of the test solution under the condition of $v_1 = v_2$. The results of plotting the E *va.* log (C_2/C_1) for several electrolytes at DMF contents of 0, 40, 70% and DMF-rich solutions are

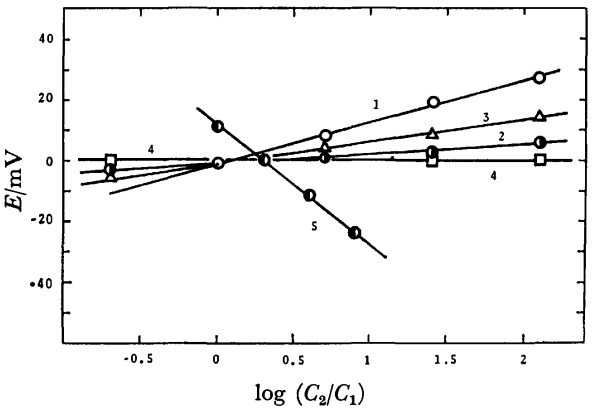

Fig. 2. Plots of E *vs.* log (C_2/C_1) at $C_2 = 0.1$ in water. Electrolyte: curve 1, TEAP; 2, $NaClO_4$; 3, NaCl; 4, KCl; 5, HCl.

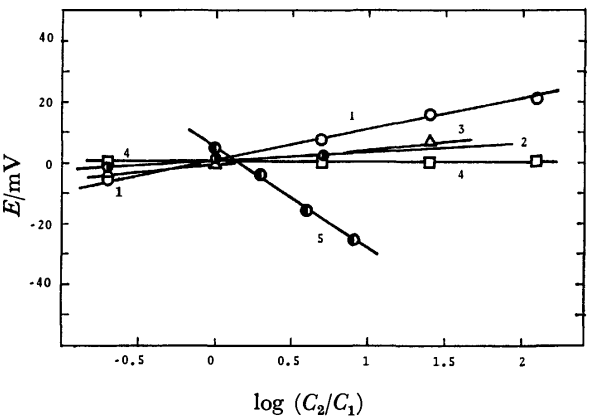

Fig. 3. Plots of E *vs.* log (C_2/C_1) at $C_2 = 0.1$ in 40% DMF. Electrolyte: curve 1, TEAP; 2, $NaClO_4$; 3, NaCl; 4, KCl; 5, HCl.

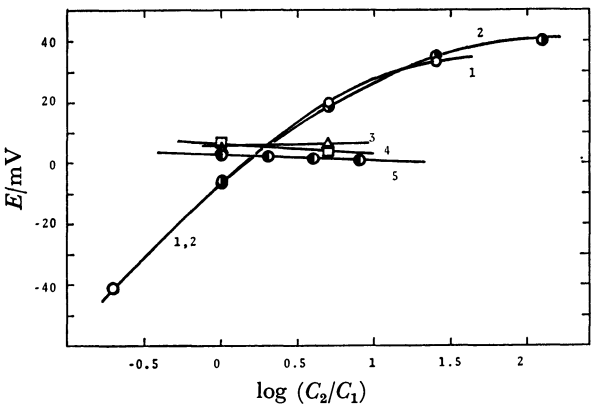

Fig. 5. Plots of E *vs.* log (C_2/C_1) at $C_2=0.1$ in DMF–water.
Electrolyte: curve 1, TEAP in DMF; 2, $NaClO_4$ in DMF; 3, NaCl in DMF; 4, KCl in DMF; 5, HCl in 85% DMF.

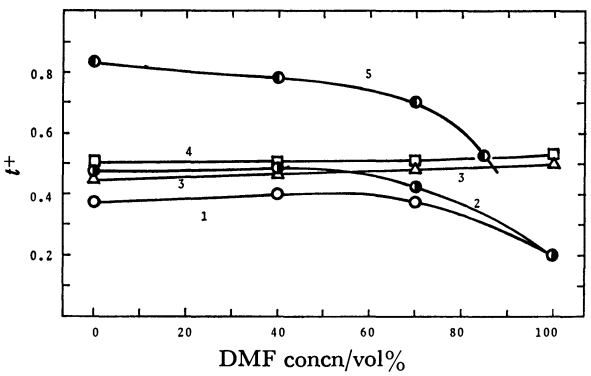

Fig. 6. Transport number of cations t^+ by the Agar–salt bridge method in DMF–water media at room temperature.
Electrolyte; curve 1, TEAP; 2, $NaClO_4$; 3, NaCl; 4, KCl; 5, HCl.

shown in Figs. 2, 3, 4, and 5, respectively. From these figures, one sees that good linear relations are found, except for tetraethylammonium perchlorate (TEAP) in solutions DMF content above 70% (curve 1 in Figs. 4

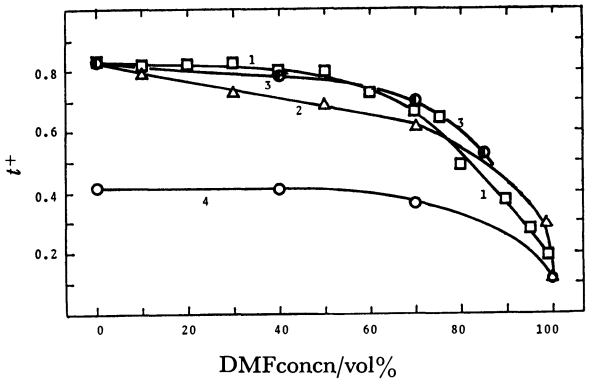

Fig. 7. Comparison of different methods of transport number in DMF–water media.
Curve 1, Hittofrt method t^+(HCl) at $C=0.1$, 2 Concn cell method t^+(HCl) at $C=0.01$—0.0005; 3, Agar–salt bridge method t^+(HCl) at $C=0.1$—0.02 from Fig. 6; 4, Agar–salt bridge method t^+(TEAP) at $C=0.5$—0.1.[19]

and 5) and for $NaClO_4$ in DMF (curve 2 in Fig. 5). By taking the slope between 0 and 0.7 in the abscissa and introducing this slope into Eq. 4, the transport number was calculated. In this way, the transport numbers of cation t^+ in each electrolyte were plotted against DMF content as shown in Fig. 6.

The Hittorf Method. Measurements were carried out at room temperature at a concentration of hydrochloric acid about 0.1 mol/dm^3 and in the range of DMF content $v=0$—99%. The amounts of electricity (Q) passed through the cell for a definite time were decreased with increase of DMF content from 50 coulombs in water to about 4 coulombs in 99% DMF media. The values of t^+(HCl) varied from 0.825 in water to 0.188 in 99% DMF media. A plot of the t^+(HCl) against DMF content is shown as curve 1 in Fig. 7.

The Concentration Cell Method. In order to compare with the Hittorf method, hydrochloric acid in DMF–water media was studied by this concentration cell method. All the cell electromotive forces E_{exp} and $E_{t,exp}$ were measured at the condition of $C_1=2C_2$, and the asymmetry potentials ΔE_h and ΔE_t were measured at the lower concentration of C_2. The data tabulated in Table 4 were obtained with a Ag–AgCl electrode made by the electrolytic method. The plot of these average values t^+(HCl) against the DMF content is shown as curve 2 of Fig. 7.

The t^+ in 99.9 wt% of DMF, about 0.11, is quite uncertain, due possibly to a failure of the hydrogen electrodes. From the limiting ionic conductances $\lambda_0(Cl^-)=55.1$[26] and $\Lambda_0(HCl)=(79.3+70+75.5)/3\fallingdotseq 74.9$,[27] the calculated transport number of the proton in hydrochloric acid in most carefully purified DMF is 0.26, a value obtained by dividing the difference $\Lambda(HCl)-\lambda_0(Cl^-)$ by the $\Lambda_0(HCl)$.

Discussion

Curves 1, 2, and 3 in Fig. 7 are transport numbers of the proton of HCl in DMF–water media, obtained by the three methods. Because of the dissimilarity in

a) Weight percent.

the concentration and in the temperature, a precise comparison among them is difficult. Nevertheless, one may conclude that the method of the agar–salt bridge (curve 3 in Fig. 7) is consistent with the other two methods (curves 1 and 2) of measuring the transport number. Consequently, the transport numbers shown in Fig. 6 for different electrolytes and the t^+(TEAP) in curve 4 of Fig. 7 (taken from the reference 19) are also correct.

It may be noted that curve 4 of Fig. 6 shows that the transport numbers t^+(KCl) and t^-(KCl) are nearly equal in the whole range of DMF–water binary solutions. Thus the liquid junction potential E_j is expected to be zero in terms of Eq. 1 for KCl solutions.

From the above discussion, it can be concluded that potentials obtained in nonaqueous polarography with a slow flowing-type aqueous SCE can be referred to the ordinary aqueous SCE exactly within a few millivolts.

The authors express their cordial gratitude to Professor Taitiro Fujinaga at Kyoto University for his continuing encouragement. Thanks are also given to Hideo Hattori, Hiroshi Yamamoto and Keiko Sasakawa for their assistance in parts of the experimental work.

Deactivation of Excited 2-Naphthylamine Due to Hydrogen Bonding Interaction with Pyridines. Fluorescence and Picosecond Laser Photolysis Studies

Noriaki IKEDA, Tadashi OKADA, and Noboru MATAGA*

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received October 24, 1980)

The mechanism of the strong fluorescence quenching observed when two conjugated π-electron systems are directly connected by hydrogen bonding has been studied by means of transient absorption spectral measurements with ps as well as ns laser photolysis method and fluorescence measurement. The bimolecular rate constants of quenching of 2-naphthylamine fluorescence by pyridine and 4-cyanopyridine have been determined in various solvents. The bimolecular reaction rate of fluorescence quenching by pyridine is smaller than the diffusion controlled one in many cases and depends considerably upon the dipole moment and the ability of formation of hydrogen bonding chain of solvent. However, the quenching by 4-cyanopyridine is diffusion controlled in every solvent examined here. By means of ps laser photolysis method, the state formed by charge transfer from excited 2-naphthylamine to hydrogen bonded pyridine in the quenching process has been observed for the first time. The possibility of the hydrogen atom transfer due to the mechanism of charge transfer followed by proton transfer in hexane solution is also discussed.

Many investigations have been carried out on the inter- and intramolecular hydrogen bonding interactions from various viewpoints.[1]

Regarding the effect of hydrogen bonding interaction upon fluorescence yield, it has been observed frequently that, when two conjugate π-electronic systems are directly combined by hydrogen bonding interaction, fluorescence of proton donor or acceptor is strongly or thoroughly quenched.[1-7] Moreover, it has been confirmed in the cases of some systems that the hydrogen bonding interaction induces strong deactivation of S_1 state but does not lead to the enhanced intersystem crossing.[5,7] Especially detailed luminescence kinetic studies have been made for carbazole–pyridine systems[4,7,8] and the lifetime of the singlet excited state of carbazole–pyridine complex was estimated to be 28 ps.[8]

It was suggested that CT (charge transfer) interaction between proton donor and acceptor π-electron systems *via* hydrogen bond was responsible for the quenching.[2-4,6-8] Namely, the CT state in this case was assumed very weakly fluorescent or nonfluorescent.[8] Hydrogen atom transfer from proton donor to acceptor was also suggested as a possible mechanism of quenching.[9]

From the investigation of naphthol–pyridine system by means of absorption-emission flash technique, it has been concluded that the fluorescence quenching in this system is partly due to hydrogen atom transfer.[10] On the other hand, it has been proposed that the primary process in the hydrogen bonding system in the triplet state is the electron transfer followed by proton transfer between the proton donor and acceptor.[11] However, direct proof of the electron transfer mechanism has not yet been given.

In relation to this problem, we have made ps laser photolysis studies upon naphthylamine–pyridine systems in addition to detailed investigations of solvent effects upon fluorescence quenching due to hydrogen bonding interaction.[12]

Experimental

Materials. 2-Naphthylamine (GR grade, Tokyo Kasei) was recrystallized twice from ligroine, and sublimated in a vacuum. *N,N*-Dimethyl-2-naphthylamine (GR grade, Tokyo Kasei) was recrystallized three times from ethanol–water mixture and sublimated in a vacuum. Pyridine (spectro grade, Kishida) was refluxed over calcium hydride and distilled. 4-Cyanopyridine (GR grade, Nakarai) was recrystallized twice from ether–ligroine mixture and sublimated in a vacuum. Laboratory deionized water was distilled and redistilled by nonboiling type distillation apparatus. *N*-Methylformamide (GR grade, Tokyo Kasei) and the other solvents (spectro grade) were used as received. The solvents for solutions examined by laser photolysis were refluxed over appropriate desiccant and distilled before use. All sample solutions were deaerated by freeze-pump-thaw cycles.

Apparatus and Measurements. Absorption and fluorescence spectra were measured using respectively a JASCO UVIDEC-1 type spectrophotometer and an Aminco-Bowman spectrophotofluorometer. Fluorescence lifetimes were determined by using a pulsed nitrogen laser with 1 kW peak power as an exciting light source, combined with a monochromator, 1P28 photomultiplier, a sampling oscilloscope and a XY recorder. The time resolution of this system was about 2.5 ns. Nanosecond laser photolysis apparatus was the same as described elsewhere.[13]

Picosecond laser photolysis measurements were made as follows. Single picosecond pulse of the second harmonic from a mode-locked ruby laser was used for excitation. Pulse width was *ca.* 30 ps. Picosecond continuum for monitoring the transient absorption spectra was generated by focussing the single fundamental pulse into heated polyphosphoric acid solution, BK-7 glass or fused quartz plate. The generated picosecond continuum was split into two beams one of which was passed through the excited sample solution. Both beams were detected by multichannel detectors of photodiode arrays (abbreviated as MCPD) through polychromators, respectively. Both MCPD's were connected with a microcomputer system for data processing and transient absorption spectra at various delay times were stored in disk and displayed on a recorder or oscilloscope.

The transient absorption spectrum can be obtained by measuring intensities of monitoring light pulse in the presence

($I(\lambda)$) as well as in the absence ($I^0(\lambda)$) of exciting pulse, and by evaluating the absorbance $A(\lambda)$ at the wavelength λ according to the following equation. λ covers wavelength range of 200 nm in one measurement.

$$A(\lambda) = \log\{I_1(\lambda)/I_2(\lambda)\} - \log\{I_1^0(\lambda)/I_2^0(\lambda)\},$$

where the subscripts 1 and 2 mean the light intensities detected by MCPD1 and MCPD2, respectively, and MCPD2 receives the monitoring light passed through the sample solution. More details of the picosecond apparatus will be described elsewhere.[14]

Results and Discussion

(A) Hydrogen Bonding Equilibrium in the Ground State. The change of absorption spectra of 2-naphthylamine (NA) caused by hydrogen bonding interaction with pyridine (P) is not so large and the equilibrium constant K_g of the hydrogen bond formation in the ground state is rather small. For example, K_g of NA–P in hexane is 0.6 M^{-1} (1 M=1 mol dm^{-3}) at 20 °C, while it was reported that K_g=0.2 M^{-1} in benzene at 13 °C[3] and K_g=12 M^{-1} in cyclohexane at 15 °C.[4] In the case of NA–4-cyanopyridine (CNP) system in hexane solution, the absorption spectra of NA were little affected by the addition of CNP in the range of concentration (up to 4×10^{-2} M) used in the measurements. We have confirmed that the ability of CNP to make hydrogen bond with NA is considerably smaller than that of pyridine. Moreover, the hydrogen bonding interaction between NA and pyridine or NA and CNP in polar solvents becomes much weaker than in nonpolar solvents probably owing to solvation of NA as well as pyridines. Therefore, hydrogen bonding interaction in the ground state of these systems in polar solvents can be neglected.

(B) Fluorescence Quenching Reaction and Its Solvent Dependence. As is well-known, the hydrogen bonding ability of aromatic hydroxy and amine compounds is considerably larger in the lowest excited singlet state than in the ground state, which results the red shift of electronic spectra due to the hydrogen bonding interaction. Actually, in the case of naphthylamines and carbazole, the change of the fluorescence spectra caused by the hydrogen bonding interaction with proton acceptors in nonpolar solvents was confirmed to arise at much smaller concentrations of acceptor than those of absorption spectra.[3,4,8]

The progressive changes of fluorescence spectra of NA caused by adding pyridine in hexane solution are indicated in Fig. 1. In relation to the hydrogen bonding quenching of fluorescence, we have examined the *N,N*-dimethyl-2-naphthylamine (DMNA)–P system, and have confirmed that the fluorescence of DMNA is not quenched by pyridine in hexane. This result shows evidently that the hydrogen bonding interaction is essential for the quenching of NA–P system. In pure pyridine solution of NA, a very weak fluorescence band which is a little red-shifted compared with that of NA in hexane was observed. Analogous results were obtained also in the case of carbazole–pyridine system.[8] The very weak fluorescence band seems to be ascribed to the hydrogen bonded complex. In the case of the strong quenching by CNP, no red-shifted fluorescence band was observed. Moreover, CNP quenches not only the fluorescence of NA but also the fluorescence of DMNA in hexane, which indicates that the quenching by CNP is due to the molecular interaction other than hydrogen bonding, probably the direct charge transfer interaction.

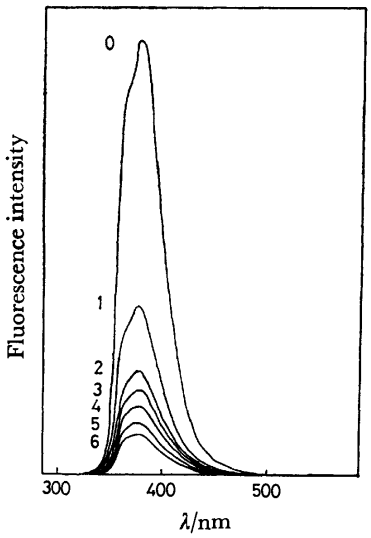

Fig. 1. Quenching of NA fluorescence caused by added P in hexane solution.
[NA]=3.6×10^{-4} M, [P]/M: 0. 0, 1. 0.004, 2. 0.008, 3. 0.012, 4. 0.016, 5. 0.020, 6. 0.030.

In general, for the fluorescence behaviors of hydrogen bonding as well as the other molecular complex forming systems, the following mechanism may be assumed.

$$\begin{array}{ccc} DH^* + A & \underset{k_{-q}}{\overset{k_q}{\rightleftharpoons}} & (DH\cdot A)^* \\ I_{abs}\cdot\delta \Big\downarrow (k_f+k_i) & & I_{abs}\cdot\delta' \Big\downarrow (k_f'+k_i') \\ DH + A & \underset{K_g}{\rightleftharpoons} & (DH\cdot A) \end{array} \qquad (1)$$

In the above scheme, I_{abs} is the total light quanta absorbed by the solution. δ and δ' are the fractions absorbed by free DH and complex, respectively. k_q and k_{-q} are rate constants of complex formation and decomposition reactions, respectively. k_f and k_i are rate constants of radiative and radiationless transitions of the excited free DH, respectively, and k_f' and k_i' are those of the excited complex.

When the equilibrium constant K_g of the complex formation in the ground state is very small and, moreover, $k_i' \gg k_f'$, $k_{-q'}$, simple Stern-Volmer equation may be valid approximately to reproduce the observed fluorescence yield.

$$I_f^0/I_f = 1 + k_q\tau_0[A], \qquad (2)$$

where $\tau_0=1/(k_f+k_i)$. Equation 2 holds approximately for NA–P and NA–CNP systems in various solvents, from which the quenching rate constants have been obtained.

As typical examples, the Stern-Volmer plots for NA–P and NA–CNP systems in hexane as well as aqueous solutions are shown in Fig. 2. Values of the quenching rate constant in various solvents are indicated in

Table 1. Solvent dependence of the fluorescence quenching rate constants (~25°C)

●: NA–P in hexane, ▲: NA–P in water, ○: NA–CNP in hexane, △: NA–CNP in water.

Table 1 together with those of solvent dielectric constant and dipole moment as well as τ_0 values of NA measured in various solvents. Moreover, k_q values are compared with the values of the diffusion controlled rate constant estimated by, $k_d=8RT/3000\,\eta$.

As can be seen from Table 1, the quenching by CNP is almost diffusion controlled in every solvent used here. Although the quenching by pyridine is also approximately diffusion controlled in nonpolar solvents, it shows remarkable solvent dependence in polar solvents. The dipole moment of the solvent molecule seems to be an appropriate parameter representing the solvent effect upon the interaction between pyridine and excited NA, except in the case of protic solvents. This result indicates that the solvation by polar solvent molecules hinders more or less the hydrogen bonding interaction. The quenching efficiency (k_q^P/k_d) changes about one order of magnitude around the value of the solvent dipole moment equal to that of pyridine (2.37 D).

The ability of solvent to form hydrogen bonding chains seems to affect also the quenching efficiency. For example, the quenching efficiency (k_q^P/k_d) in methanol (0.3) is much larger than that in acetone (0.03) which has dipole moment very close to that of methanol. Similar result can be seen in the case of NMF as compared to DMF solvents. Thus, the quenching efficiency in protic solvent is larger than in aprotic solvent which has dipole moment close to that of the protic solvent. This result suggests that the hydrogen bonding chains in solvents assist in some way the quenching of NA–P system.

In relation to this effect of hydrogen bonding solvent upon the NA–P hydrogen bonding quenching of fluorescence, we have confirmed that the fluorescence of DMNA is not quenched by P not only in nonpolar solvent but also in polar aprotic solvent, but even in the case of DMNA–P system, fluorescence is quenched remarkably in aqueous ($k_q=3.2\times10^9$ M^{-1} s^{-1}) and ethanol solutions, to almost the same extent as in the case of NA–P system. Thus, the important role of hydrogen bonding interaction among solvent molecules which assists the interaction between solute fluorescer and quencher leading to the fluorescence quenching has been confirmed, although its mechanism is not very clear at the present stage of investigation.

Contrary to the case of the quenching by pyridine, fluorescence of DMNA is quenched strongly by CNP not only in polar protic solvent ($k_q=7.4\times10^9$ M^{-1} s^{-1} in water), but also in polar aprotic solvent ($k_q=1.8\times10^{10}$ M^{-1} s^{-1} in acetonitrile) just as in the nonpolar solvent ($k_q=3.2\times10^{10}$ M^{-1} s^{-1} in hexane). These values of the bimolecular rate constant are rather similar to those of NA–CNP system in various solvents which are approximately diffusion controlled. As it is discussed already, this result shows that the quenching is due to the direct complex formation in the excited state rather than hydrogen bonding interaction.

(*C*) *Measurements of Transient Absorption Spectra by Means of Picosecond and Nanosecond Laser Spectroscopy.* If the charge transfer interaction between the hydrogen bonded pair in the excited state is responsible for the fluorescence quenching in the case of NA–P system, one may expect to observe the transient CT state by means of laser spectroscopy.

Results of ps laser photolysis measurements upon NA and NA–P systems in hexane solution are shown in Fig. 3. In Fig. 3, the spectra of NA cation radical[15] produced by γ-irradiation in *s*-butyl chloride solution at 77 K are indicated for the purpose of comparison. The spectra of NA in hexane at the delay time of 200

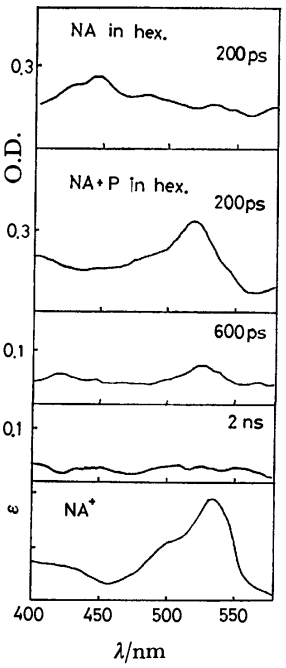

Fig. 3. Transient absorption spectra of NA and NA–P systems in hexane solution obtained by ps laser photolysis method.
[NA]$=3.45\times10^{-4}$ M, [P]$=0.37$ M.

ps may be due to the $S_n\leftarrow S_1$ transition. With addition of sufficient P, completely different spectra appeared. The spectra at 200 ps are similar to the spectra of NA cation radical. The delay time of 200 ps is necessary in order to convert completely the excited NA into the hydrogen bonded complexes at [P]$=0.37$ M. We have examined also the ps transient spectra of NA in pure pyridine solvent and observed again the band similar to that of NA cation radical.

The observed transient spectra are most probably due to the state formed by CT from excited NA to hydrogen bonded pyridine, ($D^{+\delta}$–H$\cdots A^{-\delta}$). Thus, we have directly demonstrated for the first time that the CT state is responsible for the deactivation of excited singlet hydrogen bonded species. The absorbance of the CT state decays during a few hundreds ps and at 2 ns we cannot recognize any characteristic band due to the CT state. We have examined also the very weak fluorescence of the hydrogen bonded complex by means of ps streak camera and obtained the decay time of a few hundred ps.[17]

The possibility of intermolecular electron transfer in the excited state may be examined by evaluating the standard free energy change ΔG° for the process, $D^*\cdots A\rightarrow D^+\cdots A^-$, in the encounter complex according to Eq. 3.

$$\Delta G^\circ = E(D/D^+) - E(A^-/A) - (e^2/\varepsilon R) - \Delta E + \Delta G_s$$

$$\Delta G_s = (e^2/2)\left(\frac{1}{R^+}+\frac{1}{R^-}\right)\left(\frac{1}{\varepsilon}-\frac{1}{37.5}\right), \qquad (3)$$

where $E(D/D^+)$ and $E(A^-/A)$ are respectively the oxidation potential (*vs.* SCE) of electron donor and the reduction potential of the electron acceptor in acetonitrile. R is the center to center distance between D^+ and A^- assumed to be 7 Å. ΔE is the electronic excitation energy of D and ΔG_s is the correction term for solvation energy of cation and anion with radius R^+ and R^-, respectively, in a solvent with dielectric constant ε. Values of $E(D/D^+)$ and $E(A^-/A)$ were taken from literatures[9,16,18] and ΔG° values were estimated for the present systems as shown in Table 2.

Table 2. ΔG° for NA–P and NA–CNP systems

	ΔG°/kcal mol^{-1}			
	Hexane	Acetonitrile	Water	Pyridine
NA–P	14.4	−8.1	−11.4	−4.4
NA–CNP	−13.3	−35.7	−39.0	—

For example, ΔG° value of NA–P system in hexane is estimated to be 14.4 kcal/mol, which means that the electron transfer in the encounter complex is not possible. Even if we take a little smaller encounter distance $R=5$ Å, ΔG° is estimated to be 4.4 kcal/mol, which means that the reaction is much slower than the diffusion-controlled one. Since the fluorescence quenching reaction was observed to be diffusion-controlled in the case of NA–P system and the quenching is caused by hydrogen bonding interaction as it is discussed in (*B*), the above result shows that the hydrogen bonding interaction assists the π-electronic CT state formation. It is expected that the hydrogen bonding decreases the ionization potential of NA and increases the electron affinity of pyridine.

Contrary to the case of NA–P system, the fluorescence quenching by CNP is almost diffusion-controlled not only in nonpolar solvents but also in polar solvents in both cases of NA and DMNA, which indicates the direct CT interaction without hydrogen bonding as it is discussed already in (*B*). Actually, we have observed by means of ps laser photolysis an absorption band which is very similar to that of DMNA cation in the case of DMNA–CNP system in benzene. This absorption band may be ascribed most probably to non-fluorescent heteroexcimer formed by excited DMNA and CNP. In the case of NA–CNP system in hexane as well as in benzene, however, the characteristic absorption band due to the CT state was not observed in the ps transient spectra. Very rapid deactivation process associated with the CT interaction seems to be predominant in this case.

We have examined the transient absorption spectra of NA–P system in hexane also by means of ns laser photolysis method. The results of measurements are indicated in Fig. 4. The spectra of NA in hexane at the delay time of 100 ns seems to be due to $T_n\leftarrow T_1$ transition. Similar absorption spectra were observed at the delay time of 100 ns also in the case of NA–P system in hexane. However, it might be possible to assign the band around 450 nm of the NA–P system to the absorption spectra of 2-naphthylaminyl radical which are similar to the $T_n\leftarrow T_1$ spectra of NA.[19,20]

If the observed spectra of NA–P system are due to the 2-naphthylaminyl radical, it may be produced by the mechanism of CT followed by proton transfer competing

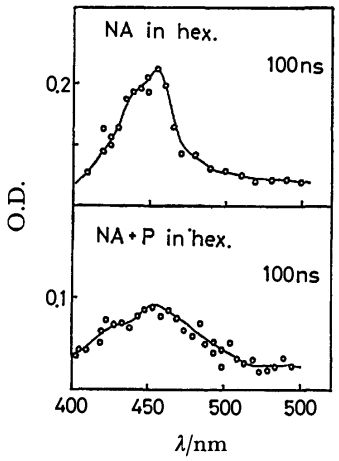

Fig. 4. Transient absorption spectra of NA and NA–P systems in hexane solution obtained by ns laser photolysis method at 100 ns. Concentrations of NA and P are respectively the same as in Fig. 3.

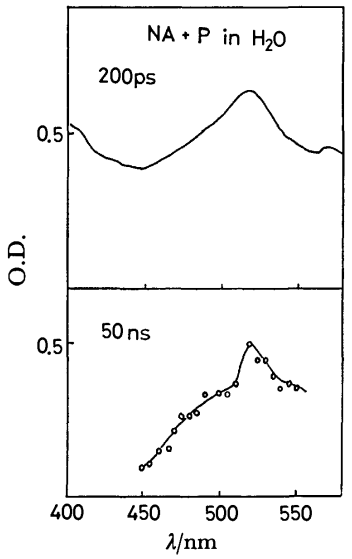

Fig. 5. Transient absorption spectra of NA–P system in water obtained by ps and ns laser photolysis method. [NA]=3×10^{-4} M, [P]=0.25 M.

with the deactivation to the ground state. This interpretation seems to be supported by the fact that the intersystem crossing rate constant is little influenced by hydrogen bonding interaction.[5,7,21] Namely, the $S_1 \rightsquigarrow T_1$ intersystem crossing seems to be negligible owing to the other overwhelming non-radiative processes from S_1 state of the NA–P hydrogen bonded complex. Thus, the formation of 2-naphthylaminyl radical from the CT state seems to be probable. Nevertheless the rise of its absorption band was not recognized clearly by means of ps laser photolysis at the delay time of 2 ns. This result may be due to the smaller extinction coefficient of 2-naphthylaminyl radical than that of NA cation and the lower power of exciting ps pulse compared with ns pulse.

We have examined also the transient spectra of NA–P and NA–CNP systems in polar solvents such as acetonitrile and water by means of ps as well as ns laser photolysis, and have observed clearly the spectra due to NA cation in both 100 ps and 10 ns —100 ns time regions. This result shows clearly that dissociated ion radicals are produced in these polar solvents. However, contrary to the case of nonpolar solvent, cation radicals can be produced not only by electron transfer from excited NA to pyridines followed by ionic dissociation but also by laser induced electron ejection to polar solvent. Therefore, more quantitative studies are necessary for the elucidation of the details of reaction mechanism. In Fig. 5, transient absorption spectra in water observed by means of ps and ns laser photolysis methods are indicated in the case of NA–P system.

Peculiar Nature of the Quenching by Pyridine. There is a definite relation between the bimolecular quenching rate constant k_q and the free energy change $\Delta G°$ of Eq. 3 in acetonitrile solution for some typical electron donor acceptor systems including heteroexcimers.[9] According to this relation between k_q and $\Delta G°$, the $\Delta G°$ value estimated for NA–P system in acetonitrile (−8.1 kcal/mol, Table 2) corresponds to almost diffusion-controlled value of k_q ($\approx 10^{10}$ M^{-1} s^{-1}), contrary to the observed value of 10^8 M^{-1} s^{-1}. Moreover, since the ionization potential of DMNA may be smaller than that of NA, the $\Delta G°$ value of DMNA–P system in acetonitrile seems to be more negative predicting diffusion-controlled k_q value. Actually, however, fluorescence of DNMA is not affected by added pyridine in acetonitrile solution. These results clearly show that the ordinary k_q-$\Delta G°$ relation of electron transfer quenching does not hold for the NA–P and DMNA–P systems. Thus, even if the reaction is sufficiently exothermic, the electron transfer reaction does not occur in the case of DMNA–P system in acetonitrile and the hydrogen bonding interaction is necessary in the case of NA–P system in acetonitrile. Although the reason for this result is not very clear at the present stage of investigation, one should note this specific nature of photochemical electron transfer.

The hydrogen bonding interactions between chromophores as well as between chromophores and environmental water seem to play important roles in biological systems. The present results may be of some importance also from such a point of view. More detailed fluorescence quenching and ionic photodissociation studies upon various hydrogen bonding systems are now going on in this laboratory.

The authors wish to express their thanks to Dr. T. Shida of Kyoto University for informing us of his unpublished result of the absorption spectra of NA cation radical. Thanks are also due to Mr. K. Kida for his help in the ps laser photolysis measurements. N. M. and T. O. acknowledge the support by Toray Science Foundation and Mitsubishi Foundation, and N. M. also acknowledges the support by Grant-in-Aid for special project research on photobiology from the Japanese Ministry of Education, Science and Culture.

Molecular Dynamics Study on Transport Properties of Fluids

Kazuo TOKIWANO† and Kiyoshi ARAKAWA*

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

†*Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received November 13, 1980)

A molecular dynamics "experiment" has been performed for a system of 216 molecules interacting through a modified Lennard-Jones-type potential. The velocity autocorrelation functions and associated self-diffusion coefficients were computed for varying degrees of the steepness of the repulsive part in the pair potential. The dependence of these quantities upon the hardness of the core, and then the applicability of a perturbation approach to the transport theory, was elucidated. The computed self-diffusion coefficients were compared with the prediction of the Rice-Allnatt theory.

With the advent of computer experiment techniques, it has become possible to acquire useful information on dynamical processes in liquids by simulation. The velocity autocorrelation function $\Psi(t)$ is of particular interest, here, because it is the most important quantity for the description of the dynamics of liquids. Molecular dynamics experiments have been performed for the Lennard-Jones potential fluids by Rahman[1] and by Levesque-Verlet,[2] and, also for a rigid sphere fluid, those have been done by Alder-Wainwright and others.[3,4] The results have brought us some valuable information on $\Psi(t)$. Recent progress in the transport theory of liquids has been strongly promoted by these studies.[1-7]

The most important problem in the transport theory of liquids is to present a theoretical model amenable to the analytical treatment for various correlated motions of molecules in a liquid. In explaining the equilibrium properties of liquids, the perturbation approach has proved to be successful for the last decade.[8,9] The theory rests on the idea that the short range structure of liquids is governed primarily by a steep repulsive part of the intermolecular potential. Then, the attractive potential is regarded as a perturbation on a rigid sphere potential. Concerning transport properties, however, no successful perturbation theory has been proposed yet, and for the advancement of the theory, it is required to elucidate further the effect of the intermolecular potential upon the transport properties of fluids. Considerable efforts through computer experiments have been devoted to the presentation of a reference fluid, which is useful in predicting the transport properties of liquids. The predominant role of the repulsive interaction by hard cores in the dynamics of dense fluids has been confirmed through the molecular dynamics results.[6,10,11] Levesque *et al.*[2] stated that the transport coefficient for the Lennard-Jones fluids was practically explained in terms of a corresponding hard sphere model. On the other hand, concerning the effect of softness of the core, it seems that a soft core potential gives rise to remarked oscillations in $\Psi(t)$ while the diffusion coefficient is rather insensitive to the steepness of the repulsive core.[12] Then, for the elucidation of these properties of liquids, further examinations are required.

The purpose of the present work is to study the effect of the repulsive core on the transport properties of liquids with varying degrees of the steepness of the repulsive part of the potential. For that purpose, we consider a fluid system composed of molecules interacting through a modified Lennard-Jones-type potential: a parameter which shows the hardness of the repulsive core is introduced there. Velocity autocorrelation functions and associated self-diffusion coefficients for the systems are calculated by means of molecular dynamics experiments. The dependence of those quantities upon the hardness of the core and the applicability of a perturbation approach to the transport theory are investigated. Detailes of the results will be given in the following sections.

Molecular Dynamics Method

Description of the System. We consider a system composed of molecules interacting through a pair potential of the form

$$u(r_{ij}) = 4h\varepsilon\left[\left(\frac{\sigma}{r_{ij}}\right)^{12} - \left(\frac{\sigma}{r_{ij}}\right)^{6}\right] + (h-1)\varepsilon \quad r_{ij} \leq r_0$$
$$= 4\varepsilon\left[\left(\frac{\sigma}{r_{ij}}\right)^{12} - \left(\frac{\sigma}{r_{ij}}\right)^{6}\right] \quad r_{ij} > r_0, \quad (1)$$

where r_{ij} is the separation between molecules i and j, ε an energy parameter, and $r_0 = 2^{1/6}\sigma$. This potential function has a minimum of $-\varepsilon$ at r_0 and crosses the abscissa at the distance σ_0, and

$$\sigma_0 = [2(h - \sqrt{h})/(h-1)]^{1/6}\sigma \quad h \neq 1$$
$$= \sigma \quad h = 1. \quad (2)$$

h is a parameter which shows the hardness of the repulsive core. When $h=1$, $u(r_{ij})$ becomes a Lennard-Jonse 12-6 potential with parameters ε and σ. Figure 1 displays the potential curves for different values of h for the same ε and σ (Fig. 1-(a)) and those for the same ε and σ_0 (Fig. 1-(b)). For large values of h the potential may be regarded as a nearly rigid sphere potential with an attractive part.

Reduced quantities have been used throughout. There is some arbitrariness in choosing the reduction units for the present potential system. We have taken the reduced density ρ^* and the reduced temperature T^* as

$$\rho^* = N\sigma_0^3/V \text{ and } T^* = kT/\varepsilon, \quad (3)$$

respectively, where k is the Boltzmann constant.

The magnitude of ρ^* of the systems considered were taken to be not larger than 0.95. When exceeded this reduced density, the system actually lost its fluidity for the lowest temperature chosen, showing an adrupt

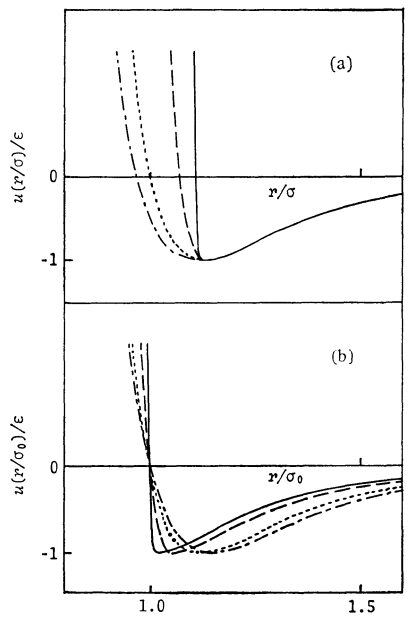

Fig. 1. Intermolecular potentials for varying degrees of the steepness of the repulsive potential.
(a): For constant ε and σ, (b): for constant ε and σ_0.
——: $h=200$, – – –: $h=10$, ·····: $h=1$, –·–·–: $h=0.5$.

drop in the diffusion coefficient. With respect to temperature, we have taken the range of T^* of 0.6—4.0, because we consider the liquids composed of molecules interacting with comparatively strong forces, such as H_2O, C_6H_6, CCl_4, CH_3OH *etc.*[13]

Computational Technique. Molecular dynamics calculations have been performed for the system of 216 molecules confined to a cubic box with volume V, interacting through the potential Eq. 1. Following the usual procedure in molecular dynamics studies, the periodic boundary conditions were employed and interactions beyond a cutoff distance r_c were ignored. The cutoff was placed at $r_c=2.5\,\sigma_0$. The technique due to Verlet[15] was used to integrate the $3N$ coupled Newton equations of motion,

$$m\frac{\mathrm{d}^2\boldsymbol{r}_i}{\mathrm{d}t^2} = -\nabla_i \sum_{i\neq j}^{N} u(r_{ij}). \tag{4}$$

The basic time increment for the numerical integration has been taken to be 0.012 (in $(m\sigma_0^2/\varepsilon)^{1/2}$), taking the conservation of total energy of the system into account. The number of time steps required to investigate a given thermodynamic state was about 12000 time steps; 2000 time steps were sufficient, usually, to reach equilibrium, and a period of 10000 time steps was utilized to form the statistical average. The results were stable and reproducible.

Radial Distribution Function. The radial distribution function gives the average local density of molecules at distance r from the central molecule, and is indicative of the local structure in a liquid.

Figure 2 displays the computed radial distribution functions, $g(r^*)$, *vs.* $r^*=r/\sigma_0$ at $\rho^*=0.80$ for varying h, including the result of Alder and Hecht on rigid spheres.[16] It is seen that the curve for $h=200$ agrees closely with that for the rigid spheres. As the softness

——: $h=200$, – – –: $h=10$, ·····: $h=1$, ○: rigid spheres for $V/V_0=1.7$ given by Alder and Hecht.[16] Refer to Fig. 1-(b) for the potentials.

of the repulsive core increases, the first peak of the distribution function is less sharp.[12,17] The $g(r^*)$ for $h=1$ can be compared with the distribution function of liquid Ar.[18] These results show the effectiveness of the present potential function.

Velocity Autocorrelation Function

The normalized velocity autocorrelation function at time t has been calculated as

$$\Psi(t) = \frac{\langle \boldsymbol{v}(0)\cdot\boldsymbol{v}(t)\rangle}{\langle \boldsymbol{v}^2\rangle} = \frac{\langle \frac{1}{N}\sum_i^N \boldsymbol{v}_i(t_0)\cdot\boldsymbol{v}_i(t_0+t)\rangle_{t_0}}{\langle \frac{1}{N}\sum_i^N \boldsymbol{v}_i(t_0)\cdot\boldsymbol{v}_i(t_0)\rangle_{t_0}}, \tag{6}$$

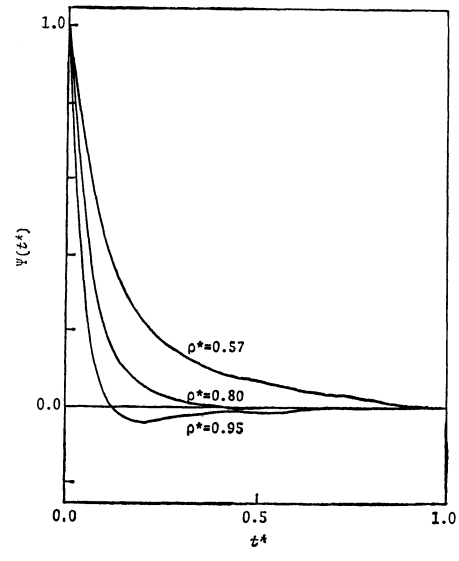

Fig. 3. Velocity autocorrelation functions for $h=200$ at $T^*\simeq 1.0$.

where $v_i(t)$ is the linear velocity of a molecule i at t, and the angular brackets $< >_{t_0}$ imply a mean value over time origins.

For a short time behavior of $\Psi(t)$, we have made a comparison of molecular dynamics computations with the values given by the Brownian and Gaussian approximations (see Appendix I).

Figure 3 shows the normalized velocity autocorrelation functions, $\Psi(t^*)$, computed by means of Eq. 6 for various values of ρ^* for $h=200$ and $T^*=1$, where t^* is the reduced time given by $t^*=t/(m\sigma_0^2/\varepsilon)^{1/2}$. The statistical error on the normalized velocity autocorrelation function is due mainly to the replacement of an equilibrium ensemble average by a time average over a finite time interval. In the present case, the error is estimated to be $\pm 0.015|\Psi(t)-1|$ by means of Zwanzig and Ailawadi's formula.[19]

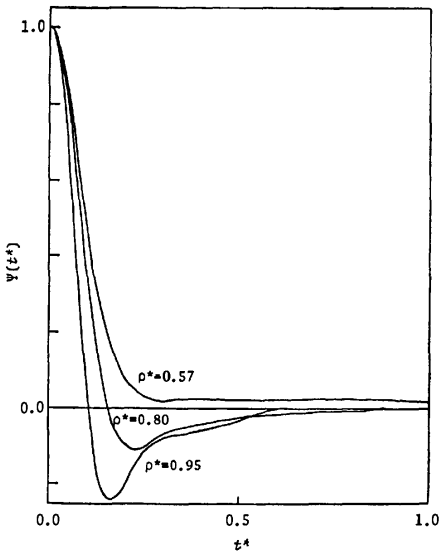

Fig. 4. Velocity autocorrelation functions for $h=1$ at $T^*\simeq 0.6$.

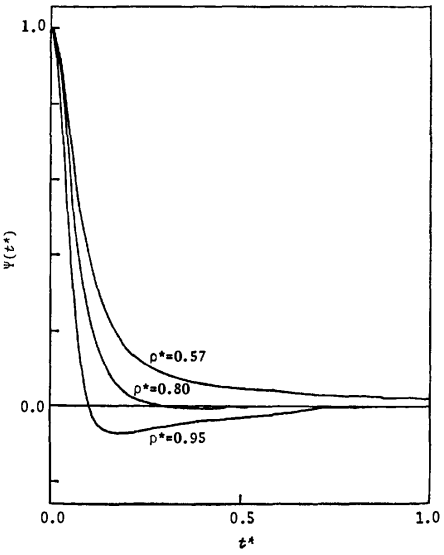

Fig. 5. Velocity autocorrelation functions for $h=10$ at $T^*\simeq 0.6$.

At low density $\Psi(t^*)$ decays steadily. When the density is higher, $\Psi(t^*)$ has a pronounced minimum attributed to the "back-scattering" of the diffusing molecule due to its collisions with surrounding molecules,[1,10] followed by a negative plateau. The level of the negative region rises up with decreasing density, becoming eventually positive at a low density. The qualitative behavior of $\Psi(t^*)$ is consistent not only with Alder and Wainwright's[4] computer results on rigid spheres but also with Levesque and Verlet's[2] results on the Lennard-Jones fluid.

We now examine the effect of the steepness of the repulsive core potential on the velocity autocorrelation function. Figures 4—9 present $\Psi(t^*)$ computed at the same reduced temperature ($T^*=0.6$) and different densities, for $h=0.1$, 0.5, 1, 10, and 200. The results

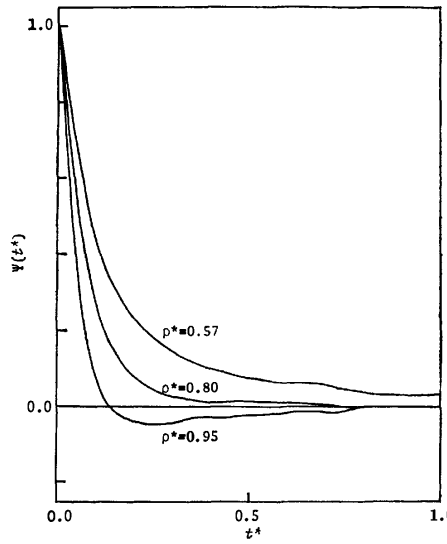

Fig. 6. Velocity autocorrelation functions for $h=200$ at $T^*\simeq 0.6$.

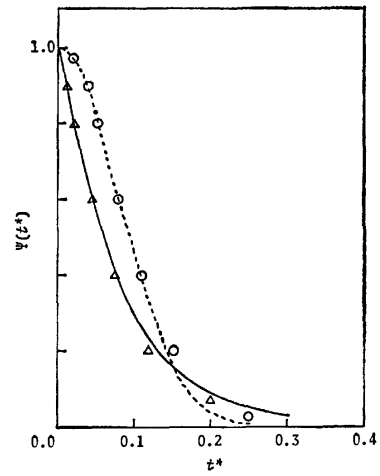

Fig. 7. Comparison of the velocity autocorrelation functions computed by molecular dynamics at $\rho^*=0.80$ and $T^*\simeq 0.6$ with those predicted by Brownian and Gaussian approximations.
△: $h=200$ by MD, ——: $h=200$ by Brownian approx. (Eq. AI-1), ○: $h=1$ by MD, ·····: $h=1$ by Gaussian approx. (Eq. AI-4). Refer to Fig. 1-(b) for the potentials.

are summarized as in the following (1)—(4).

(1) At short times, $\Psi(t^*)$ for large values of h has an appearence of the exponential or nearly exponential decay (Fig. 6). When h becomes smaller, the initial behavior of $\Psi(t^*)$ shows an extended Gaussian appearence (Fig. 4). The extent of the Gaussian decay at a soft core system can be understood intuitively as the effect of the duration of a collision. This is more clearly seen in Fig. 7. The figure displays the $\Psi(t^*)$ computed for the soft core ($h=1$), together with the curve predicted by the Gaussian approximation (Eq. AI-4), and also that for the hard core ($h=200$) with the curve obtained from the Brownian approximation (Eq. AI-1). The agreement between the computed and predicted values is very good.[20] It is confirmed that the initial decay of $\Psi(t^*)$ for $h=200$ is still Gaussian at extremely short times. The initial purely-Gaussian decay is attributed to a quasi-Brownian motion of the pair of molecules in the relatively weak, but rapidly fluctuating, field of all the neighboring molecules, in which the momentum transfer is understood to be small.[21]

(2) At intermediate times, $\Psi(t^*)$ at high density has a negative region with a long plateau. As seen in Figs. 4—6, the soft core potential has an effect enhancing the negative correlations. $\Psi(t^*)$ for large h shows the overdamped behavior and no oscillatory features. The oscillatory aspect of the self motion associated with the soft core is very weak in the Lennard-Jones case (Fig. 4). However, as Fig. 8 shows, $\Psi(t^*)$ of $h=0.1$ apparently shows the oscillatory behavior similar to that found in molecular dynamics experiments on liquid metals[12] and also has no longer an appreciably long plateau. The long plateau is not a consequence of an attractive potential tail but an essential feature for rigid sphere systems; it is generally believed to arise from repeated collisions between the two molecules due to the cage effect of its neighbors.[22]

(3) As seen in Fig. 9, when h increases at the same

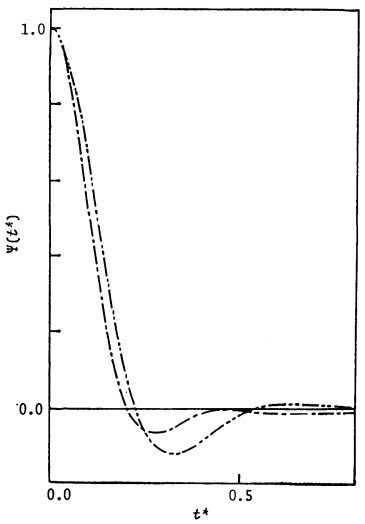

Fig. 8. Velocity autocorrelation functions for $h<1$ at $\rho^*=0.70$ and $T^*\simeq 0.6$.
——: $h=0.5$, – – –: $h=0.1$. Refer to Fig. 1-(b) for the potentials.

reduced density, the behavior of $\Psi(t^*)$ approaches that of $\Psi(t^*)$ for rigid spheres. The area under $\Psi(t^*)$ increases at small times with increasing softness of the core, but at intermediate times we observe an opposite trend on $\Psi(t^*)$ throughout three cases (a) ($\rho^*=0.57$), (b) ($\rho^*=0.85$), and (c) ($\rho^*=0.95$). In this respect, the three groups of curves given in Figs. 9(a), (b), and (c) may be said to have a similar trend of change with the increase of h over all the range of t^*. The decrease of $\Psi(t^*)$ at intermediate times is largely compensated for by its increase at small times. This is the reason why the self-diffusion coefficient, which is given by the integral of $\Psi(t)$, is rather insensitive to the shape of intermolecular potentials (Table 1). Figure 10 shows $\Psi(t^*)$ for varying h at $T^*=1.0$. The trend of change

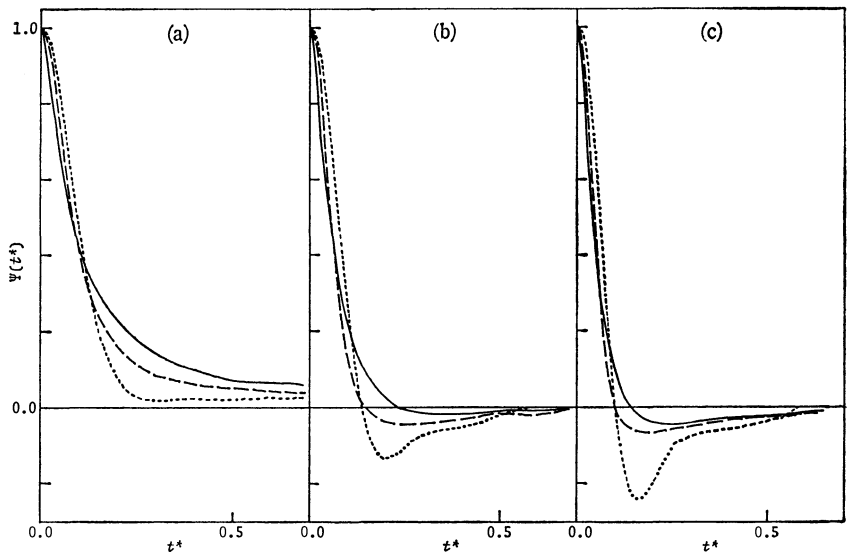

Fig. 9. Velocity autocorrelation functions for potential functions presented in Fig. 1-(b) at $T^*\simeq 0.6$.

——: $h=200$, - - - -: $h=10$, ·····: $h=1$.

with the increasing h is found to be essentially similar to that at $T^*=0.6$, though its magnitude is small.

The fundamental behavior of velocity autocorrelation functions for continuous potential fluids may be explained by the extreme one of rigid spheres with an appropreate diameter at the same volume. The existence of such an extreme offer the basis of a perturbation approach in the transport theory. In Fig. 9 we have used simply σ_0 as a diameter of rigid spheres as a reference. A useful way to determine the rigid core diameter will be the one due to Dymond and Alder.[10]

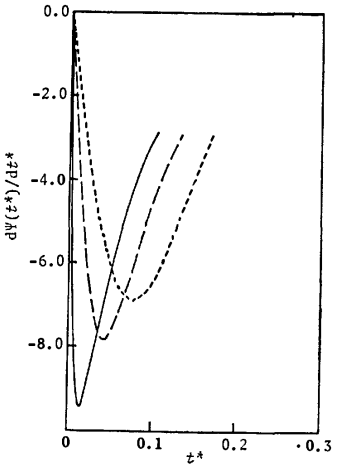

Fig. 11. First derivatives of the velocity autocorrelation functions at $\rho^*=0.57$ and $T^*\simeq 0.6$.
——: $h=200$, - - -: $h=10$, ·····: $h=1$. Refer to Fig. 1-(b) for the potentials.

(4) We present the first derivative $d\Psi(t^*)/dt^*$ in the region of initially fast decay for varying h in Fig. 11. The first minimum point of $d\Psi(t^*)/dt^*$ *vs.* t^* curves, or the first inflexion point of $\Psi(t^*)$ *vs.* t^* curves, gives the time at which the force autocorrelation function first passes through zero. As Fig. 11 shows, that is strongly dependent on the steepness of the core potential, going to zero as a rigid core limit as h becomes large.[23] The decay time of $\Psi(t^*)$ appears to be relatively insensitive to the steepness of the repulsive core potential in spite of the strong dependence of the force autocorrelation. This implies that the motion of a molecule in the systems considered is far from harmonic oscillations.

Here, we would mention the following point. The extreme of $h=\infty$ in the present potential may be closer to a square-well potential for the presence of an attractive part rather than to rigid spheres (see Fig. 1). The velocity autocorrelation functions for square-well potential fluids have been calculated by Michels and Trappeniers.[24] Unfortuately, their molecular dynamics calculations were made at too low densities to confirm the velocity autocorrelation at liquid densities. Einwohner and Alder[25] computed the free-path distributions and collision rates in square-well potential fluids as well as those in rigid sphere fluids, and made the comparison between the two cases. They found that at liquid density the majority of collisions were hard core collisions and the free-path distribution was nearly indifferent to the presence of an attractive potential. For the extreme of $h=\infty$ in the present potential, the velocity autocorrelation function is supposed to be approximately equal to the one for rigid spheres, except for low densities.

Self-diffusion Coefficient

Procedure of Calculations. The self-diffusion coefficient D is calculated either from the velocity autocorrelation function,

$$D=\frac{kT}{m}\int_0^\infty \Psi(t)\mathrm{d}t, \tag{7}$$

or from the long time limit of the mean-square displacement of a selected molecule i,

$$D=\lim_{t\to 0}\left[\frac{1}{6t}<[r_i(0)-r_i(t)]^2>\right]. \tag{8}$$

The evaluation of integral in Eq. 7 was carried out over the range of t, 0—2000 time steps. In the application of Eq. 8, we used the slope of the linear part of the curve for the mean-square displacement at 2000 time steps. The error of both results are considered to be of the order of 10%, and then, both results may be safely said to agree to each other within the range of errors. The diffusion coefficient for liquid Ar (at 94 °K and 1.374 g cm^{-3}) was calculated to be 2.44×10^{-5} cm^2 s^{-1} in agreement with Rahman's result.[1]

The self-diffusion coefficients, D_{MD}, calculated from the velocity autocorrelation function are listed in Table 1, where we have used as the reduced quantity

$$D^*=D/(\sigma_0^2\varepsilon/m)^{1/2}. \tag{9}$$

We can not make a direct comparison of the values for $h=1$ with the results of Levesque and Verlet[2] on the Lennard-Jones fluid. It is possible to compare those by the use of $(\sigma^2\varepsilon/m)^{1/2}(kT/\varepsilon)^{5/12}$ as a unit of D and $\rho'=(\rho\sigma^3/\sqrt{2})(\varepsilon/kT)^{1/4}$ as the reduced density.[26] Both results are confirmed to be quite similar each other

Table 1. Self-diffusion coefficients

ρ^*	h	T^*	D_{MD}^*
0.42	1	0.61	0.084
0.51	10	0.61	0.094
0.57	1	0.60	0.072
0.57	10	0.61	0.085
0.57	200	0.60	0.101
0.57	200	0.99	0.143
0.57	200	4.01	0.430
0.59	1	0.61	0.067

0.72	10	0.61	0.067
0.80	1	0.61	0.029
0.80	10	0.59	0.041
0.80	50	0.60	0.042
0.80	100	0.60	0.049
0.80	200	0.59	0.050
0.80	200	0.99	0.061
0.80	200	3.94	0.148
0.86	10	0.60	0.022
0.95	1	0.61	0.006
0.95	10	0.60	0.011
0.95	200	0.59	0.016
0.95	200	1.02	0.022
0.95	200	3.97	0.064

except for those at the low density ($\rho'<0.55$), showing that the scaling variables for the inverse 12-th power potential may be useful for the Lennard-Jones fluids.

Density Dependence of Self-Diffusion Coefficient. Figure 12 illustrates the density dependence of the self-diffusion coefficients at $T^*=0.6$ for a variety of the steepness of core potentials. The curves are found to shift along an arrow in the figure, when the hardness of the repulsive core increases.

We now attempt here an interpretation of this result by means of a rigid sphere model. The self-diffusion coefficient for rigid sphere gas of packing fraction

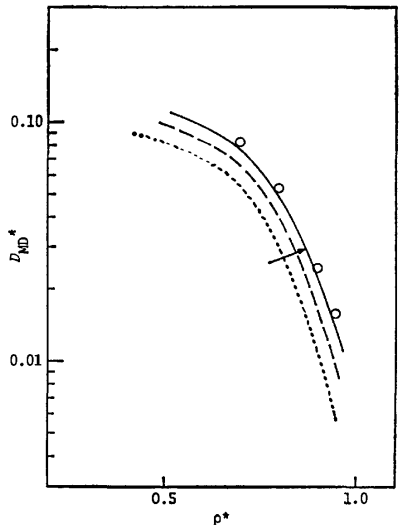

Fig. 12. Density dependence of self-diffusion coefficients at $T^*\simeq 0.6$.
——: $h=200$, — — : $h=10$, ·····: $h=1$, ○: D_∞^* calculated by means of Eq. 11.

$\xi(=(\pi/6)\rho d^3)$, where d is the diameter of spherical molecules, is given by the Enskog theory as

$$D_E=\frac{3}{8}\frac{1}{\rho d^2}\left(\frac{kT}{\pi m}\right)^{1/2}\Big/\left[\frac{3}{2\pi\rho d^3}(\chi(\xi)-1)\right], \qquad (10)$$

in which $\chi(\xi)$ $(=pV/NkT)$ is the compressibility factor of a rigid sphere system. We consider the extreme of $h=\infty$ in the present potential *i.e.* the nearly rigid sphere potential with an attractive potential well. Let us assume that the self-diffusion coefficient for the system is given by the Enskog's value corrected by the Alder-Wainwright factor as the ratio $(D_{MD}^H/D_E)_A$,[3,4] where D_{MD}^H is the molecular dynamics values of diffusion coefficients for rigid spheres. It is written as[2]

$$D_\infty^*=\frac{(\sqrt{\pi}/4)\sqrt{T^*}}{\chi(\xi)-1}\left(\frac{D_{MD}^H}{D_E}\right)_A, \qquad (11)$$

where D_∞^* is expressed as the reduced coefficient given by Eq. 9. $\chi(\xi)$ is given by the formula $\chi(\xi)=(1+\xi+\xi^2)/(1-\xi)^3$. D_∞^* calculated at $T^*=0.6$ are plotted against ρ^* in Fig. 12. We can see that the D_{MD}^* *vs.* ρ^* curve for $h=200$ nearly agrees with the D_∞^* *vs.* ρ^* one. That is, when the hardness of the core increases, the D_{MD}^* *vs.* ρ^* curve at a given temperature, shifting along the arrow in Fig. 12, approaches the extreme curve of rigid spheres at the same temperature. This confirms that the rigid sphere model expressed as Eq. 11 gives a good description of self-diffusion coefficients for realistic continuous potential systems. An appropriate evaluation of the equivalent rigid sphere diameter for the Lennard-Jones fluid was given by Verlet,[18] who took for it the value to fit the equilibrium structure factor to the Wertheim-Thiele solution of the PY equation for rigid spheres. Using the core diameter thus determined, Levesque *et al.*[2] calculated diffusion coefficients for Lennard-Jones fluids, which were found to be about 10% larger than those by molecular dynamics computations. According to Verlet,[18] at low temperatures, the equivalent diameter is larger than the original core size σ in the Lennard-Jones potential. The direction of the arrow in Fig. 12 is consistent with the result of Verlet.

In addition to the interpretation described above, it can also be said from Fig. 12 that the duration of collisions between molecules, associated with the finite steepness of the repulsive potential, brings an important perturbation on the dynamical behavior of molecules mainly determined by the rigid sphere potential.

Comparison with the Rice-Allnatt Theory. The basic assumption underlying the transport theory of Rice and Allnatt[21] is that the motion of a molecule in a fluid consists of a strongly repulsive binary encounter followed by a quasi-Brownian motion of the molecules in the fluctuating field of neighboring molecules. The successive repulsive encounters are assumed to occur independently. This assumption is in direct opposition to the van der Waals picture of transport processes discussed by Dymond and Alder and others,[10] in which the dynamical event consists of correlated collisions of rigid spheres. The real situation lies between these two extremes, probably.

We attempt here to test the Rice-Allnatt theory through the examination of self-diffusion coefficients

calculated for various degrees of the steepness of the repulsive potential.[27] In the theory,

$$V(r) = V^{H}(r) + V^{S}(r)$$
$$\begin{cases} V^{H}(r) = \infty, \quad V^{S}(r) = 0 & r \leq a \\ V^{H}(r) = 0 & r > a, \end{cases} \tag{12}$$

where V^S is the soft potential. The forces on the molecules in a liquid are working on two time scales: one corresponds to the large momentum and energy transfers which occur during rigid sphere collisions, and the other to the frequent small momentum transfers which occur during the quasi-Brownian motion of a molecule in the soft force field. Then, the friction coefficient is expressed as $\zeta=\zeta^H+\zeta^S$, and the self-diffusion coefficient is

$$D_{RA} = \frac{kT}{\zeta^H+\zeta^S}, \tag{13}$$

where the friction coefficients become

$$\zeta^H = \frac{8}{3}(\pi m k T)^{1/2}\rho a^2 g(a), \tag{14}$$

and

$$\zeta^S = -\frac{16\pi^4}{3}\rho\left(\frac{\pi m}{kT}\right)^{1/2}\int_0^\infty dq\, q^3 V_q^S G_q. \tag{15}$$

The Fourier transforms V_q^s and G_q are given by

$$V_q^S = \frac{1}{8\pi^3}\int d\boldsymbol{r}\, e^{-i\boldsymbol{q}\cdot\boldsymbol{r}} V^S(r), \tag{16}$$

and

$$G_q = \frac{1}{8\pi^3}\int d\boldsymbol{r}\, e^{-i\boldsymbol{q}\cdot\boldsymbol{r}}(g(r) - 1), \tag{17}$$

respectively. The rigid core contribution, Eq. 14, is the Enskog expression. The evaluation of ζ^S, Eq. 15, is identical with the friction coefficient given by Helfand by applying the linear trajectory approximation.[29] For the application of the Rice-Allnatt theory to the present system, there is obviously some arbitrariness in choosing the core diameter a in Eq. 12. In this work, the distance where the potential crosses abscissa has been taken as the diameter. Equation 1 is rewritten as follows,

$$V^H(x) = \infty, \quad V^S(x) = 0 \qquad x \leq x_0$$
$$V^H(x) = 0, \quad V^S(x) = u(\sigma x) \quad x > x_0, \tag{18}$$

where $x=r/\sigma$ and $x_0=\sigma_0/\sigma$.

It is difficult to calculate ζ^S using Eq. 15 because of the presence of the factor q^3 and the oscillating behavior due to G_q in the integrand. However, for the present potential (Eq. 18) we can invert Eq. 15 according to the procedure used by Helfand. The details of the inversion are described in Appendix II. If we use the dimensionless coefficient $\zeta_r^S=\zeta^S/\zeta^*$ where $\zeta^*=(8/3)\rho x_0^2(\pi m k T)^{1/2}$, ζ_r^S is given by

$$\zeta_r^S = \left(\frac{\varepsilon}{kT}\right)\int_{x_*}^\infty dx f(x)\,(g(\sigma x) - 1) - \left(\frac{\varepsilon}{kT}\right)\int_0^{x_*} dx f(x), \tag{19}$$

and

$$f(x) = (1-h)\left[\frac{11}{2^{11/6}}f_{12}\left(\frac{x}{2^{1/6}}\right) - \frac{5}{2^{5/6}}f_6\left(\frac{x}{2^{1/6}}\right)\right] + h\left[\frac{11}{x_0^{11}}f_{12}\left(\frac{x}{x_0}\right) - \frac{5}{x_0^5}f_6\left(\frac{x}{x_0}\right)\right], \tag{20}$$

where

$$f_n(x) = 2\sum_{j=1}^{n/2}\frac{x^{2j-1}}{2j-1} - x^{1-n}\ln\left|\frac{x+1}{x-1}\right|. \tag{21}$$

Table 2. Friction and self-diffusion coefficients given by the Rice-Allnatt theory at $T^*\simeq 0.6$

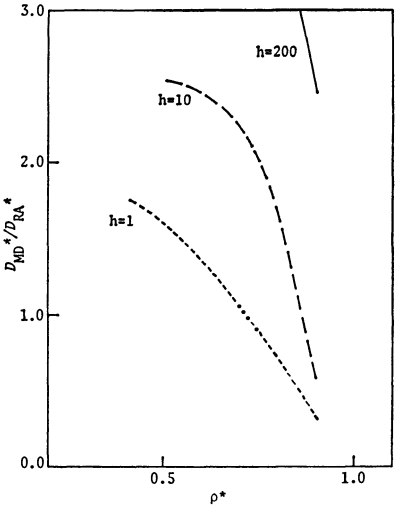

Fig. 13. Ratio of the values of self-diffusion coefficients at $T^*\simeq 0.6$ calculated by molecular dynamics to those predicted by the Rice-Allnatt thery.

$\zeta_r^H(=\zeta^H/\zeta^*)$, ζ_r^S, and D_{RA}^* are calculated by means of Eqs. 14, 19, and 13, respectively, using the radial distribution functions calculated by the molecular dynamics runs for the potential Eq. 1.[30] The results are given in Table 2, together with the molecular dynamics computations, $\zeta_{MD,r}^*(=(kT/D_{MD})/\zeta^*)$.

Figure 13 shows the D_{MD}^*/D_{RA}^* *vs.* ρ^* curves, for $h=1$, 10, and 200. As seen in Table 2 and Fig. 13, a good agreement between the predicted and computed values is obtained only for the Lennard-Jones potential ($h=1$) at a moderate density and also for the more rigid potential ($h=10$) at a high density. Too small values of D_{RA}^* for large h are evidently attributed to the overestimation of ζ_r^S about the contributions of the repulsive part, including the improperly strong repulsive contribution. The prediction of the Rice-Allnatt theory using the linear trajectory procedure is found to depend too sensitively upon how to separate the intermolecular potential. We have taken the diameter of rigid core to be equal to σ_0.

It is found from Fig. 13 that the ratio D_{MD}^*/D_{RA}^* for $h=1$ is smaller than 1 at high densities, and at low

densities we have an opposite result. This density dependence of the ratio D_{MD}^*/D_{RA}^* is supposed to be partly associated with that of the Alder-Wainwright ratio $(D_{MD}^H/D_E)_A$ for rigid spheres.

Concluding Remarks

By means of molecular dynamics calculations, we have examined the transport properties of a fluid composed of molecules interacting through the potential expressed in terms of three parameters: the depth of potential well ε, core size σ_0, and hardness parameter h. The results are summarized as follows.

(a) The essential feature of the behavior of velocity autocorrelation functions for continuous potential fluids can be explained by the extreme of rigid spheres with an appropriate diameter at the same volume. This implies that the rigid-sphere fluid can serve as a reference system suitable for the representation of dynamical properties of liquids.

(b) The detailed behavior of velocity autocorrelation functions is sensibly dependent upon the steepness of the repulsive core potential. The oscillatory behavior superimposed on the extreme behavior of rigid spheres becomes more pronounced as the softness of the core increases. Then, the decrease of the area under $\Psi(t)$ at intermediate times is largely compensated for by its increase at small times. This is the reason why the self-diffusion coefficient is rather insensitive to the shape of intermolecular potentials.

(c) The density dependence curve of self-diffusion coefficients in a continuous potential fluid shifts and approaches to that of rigid spheres at the same temperature with the increasing hardness of the core.

These results appear to offer a sound basis for the equivalent hard sphere model as well as for the applicability of the perturbation approach to the transport theory. The idea of separating the intermolecular potential into a rigid core part and a soft one, treating the latter as a perturbation, is considered to be essentially applicable to the transport theory of liquids. This is the basic physical assumption underlying the generalized van der Waals theory[10,31] and the dynamical model of liquids due to Rice and Allnatt. The results calculated by the use of the Rice-Allnatt model are also found to be strongly dependent of the arbitrariness in splitting the potential into two parts. At high densities and low temperatures, the correlated successive rigid core collisions of a pair of molecules is considered to have more important effects on the self-diffusion coefficients.

Appendix I

A Langevin type of velocity autocorrelation function arising from a Markovian velocity evolution is expressed as

$$\Psi(t) = \exp\left(-\frac{kT}{mD}t\right), \tag{AI-1}$$

where D is a self-diffusion coefficient. Equation AI-1 is expected to give a good description to $\Psi(t)$ for a hard core potential (large h) at a moderate density. It is evident that $\Psi(t)$ for a soft core potential (small h) is far from the simple exponential behavior. If the interaction potential is a smooth function where there is no rigid core, then $\Psi(t)$ can be assumed to be analytical in the neighborhood of $t=0$ and expanded in a Taylor series

$$\Psi(t) = 1 - \frac{\omega_e^2}{2!}t^2 + O(t^4), \tag{AI-2}$$

where the square of the Einstein frequency, ω_e^2, is given in terms of the average of the Laplacian of the total potential energy U:

$$\omega_e^2 = \frac{\langle \dot{v}^2 \rangle}{\langle v^2 \rangle} = \frac{1}{3m}\langle \nabla^2 U \rangle. \tag{AI-3}$$

Then, the Gaussian decay of $\Psi(t)$ is given by

$$\Psi(t) \simeq \exp\left[-\frac{\langle \nabla^2 U \rangle}{6m}t^2\right]. \tag{AI-4}$$

Since the potential function, Eq. 1, is continuous, the slope of $\Psi(t)$ at $t=0$ is zero and the decay at a small time should be Gaussian even for large values of h. For a completely rigid core, however, collisions are instantaneous and this results in a cusp of $\Psi(t)$ at $t=0$.

Appendix II

The inversion of the transforms in Eq. 15 can be made according to the same procedure as used by Helfand.[29] Equation 16 is integrated by parts to give

$$V_q^S = \frac{1}{2\pi^2}\int_0^\infty dq \frac{\cos(qr)}{q^2}\frac{d}{dr}[rV^S(r)]. \tag{AII-1}$$

Substitution of Eq. AII-1 into Eq. 15 gives

$$\zeta_r^S = -\frac{1}{4\sigma^2}\frac{1}{kT}\int_0^\infty dq\int_0^\infty dr\int_0^\infty dr'r'[\sin q(r'+r) + \sin q(r'-r)] \times [g(r') - 1]\frac{d}{dr}[rV^S(r)], \tag{AII-2}$$

Using the relation $\int_0^\infty \sin(qr)dq = p/r$, where p stands for the principal part, and introducting the change of variables $y = r/r'$ and $x = r'/\sigma$, we obtain from the integration over q of Eq. AII-2

$$\zeta_r^S = -\frac{1}{4}\frac{1}{kT}\int_0^\infty dx\int_{x_0/x}^\infty dy\left(\frac{p}{1+y}+\frac{p}{1-y}\right)x\frac{d}{dy}[yV^S(\sigma xy)][g(\sigma x) - 1]. \tag{AII-3}$$

For the potential function given by Eq. 18, Eq. AII-3 can be integrated over y explicitly to lead

$$\zeta_r^S = \left(\frac{\varepsilon}{kT}\right)\int_0^\infty dx f(x)[g(\sigma x) - 1], \tag{AII-4}$$

where $f(x)$ is given by Eq. 20. When $h=1$ and hence $x_0=1$, Eq. AII-4 is reduced to the expression of Helfand. Since $g(\sigma x)$ vanishes in the region $0<x<x_0$, Eq. AII-4 is rewritten as Eq. 19.

We acknowledge generous grants of computing time from Hokkaido University Computing Center.

Effects of Salts on the Solubility of Elemental Mercury in Water

Isao SANEMASA,* Kenji HARAGUCHI, and Hideo NAGAI

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860

(Received September 22, 1979)

The effects of 11 salts, NaCl, $NaNO_3$, Na_2SO_4, NaBr, NaSCN, NaF, $NaClO_4$, KCl, $BaCl_2$, $(CH_3)_4NBr$, and $(C_2H_5)_4NBr$, on the solubility of elemental mercury in water have been studied at 25 °C. Salting coefficients were determined and compared with those predicted by both the McDevit-Long equation and the scaled particle theory (SPT). The McDevit-Long equation gave reasonably good predictions except for NaBr, $NaClO_4$, and NaSCN. SPT is also applicable to prediction of the salt effect when the energy parameter of mercury determined from the Henry law constant of aqueous solubility of mercury vapor is employed. Attempts to predict the effects of tetraalkylammonium salts by SPT failed.

Attention is being paid to the influence of salts on the activity coefficients of nonelectrolytes in aqueous solutions from both experimental and theoretical interest and many reports have appeared.[1] However, few are concerned with elemental mercury as a nonelectrolyte except for the report by Glew and Hames, who restricted their study to conditions of 6.10 molal sodium chloride solution.[2]

It has been pointed out that there is an essential difference between the solution properties for inert gases and nonpolar molecules in water and in organic solvents. A similar anomaly of elemental mercury in water solvent was suggested by Spencer and Voigt.[3] They attributed this to the tendency of water molecules to form a structure around mercury atoms. The study of salt effects on the solubility of elemental mercury will help clarify the role of water.

The solubility of a nonelectrolyte in aqueous electrolyte solutions has been found to depend on the concentration and type of the salt present in the solution. In a sufficiently dilute nonelectrolyte solution, the activity coefficient of nonelectrolyte, f, in the salt solution of molar concentration, C, is given by

$$\log f = \log(S^\circ/S) = k_s C, \quad (1)$$

where S and S° denote the solubility of nonelectrolyte in salt and salt-free solutions, respectively, k_S being the salting coefficient.

In the present work, 11 salts showing no chemical reaction with elemental mercury were used. We have compared the values of observed k_S with those predicted from theoretical equations such as the McDevit-Long equation[4] and the scaled particle theory (SPT),[5] which have been accepted to give reasonably good predictions for inert gases and nonpolar nonelectrolyte.

Experimental

Electrolytes of analytical reagent grade were used except for a tetraethylammonium bromide of reagent grade. The salts were dissolved without further purification in redistilled water after drying at suitable temperatures. The concentrations of chloride, bromide, and thiocyanate salts were checked by the argentometric method. Purification of metallic mercury, the procedure of attaining saturated solubility of mercury vapor and measurements were the same as those described,[6] the solubility apparatus being essentially the same as that previously used except for a slight modification to include two identical 300 cm^3 solubility flasks instead of one flask. Mercury vapor was passed through a three-way stop-cock to each flask, and then combined with another three-way stop-cock attached to the outlet of each flask. One of the flasks was filled with pure water and the other with electrolyte solution. Saturated mercury solutions in both pure water and electrolyte solution can be obtained at the same time. It was confirmed by filling each flask with the same solution that concentrations of the saturated mercury solutions in the two flasks were identical with each other. A time of 30 min was found to be sufficient to attain the solubility equilibrium. The relative solubility of mercury in pure water and in the salt solution, S°/S, was measured directly by reading atomic-absorption peak-heights recorded on a chart for a set of samples withdrawn from the two solubility flasks. The value of S° was taken to be 63.9×10^{-6} g dm^{-3}.[6] Preliminary experiments for some electrolyte solutions revealed that the values of S thus estimated are in reasonably good agreement with those measured by addition of standard mercury (II) solutions. Determination of the S°/S ratios was repeated at least three times for each electrolyte concentration at 25 °C. No data were obtained for iodide; use of I^- ion gave abnormal results probably due to some chemical reaction with elemental mercury.

Results and Discussion

Experimental Salting Coefficients. The solubility ratios, S°/S, of elemental mercury obtained at each electrolyte concentration and salting coefficients, k_S, for 11 salts determined by the least-squares method according to Eq. 1 are given in Table 1, together with correlation coefficients for log (S°/S) *vs.* C plots and intercepts of these plots at $C=0$. We see that the salt effects are well represented by Eq. 1 over the concentration range examined. The value of k_S for 6.10 mol dm^{-3} NaCl, 0.0413 at 25 °C, determined by Glew and Hames[2] and expressed as reciprocal molality, is much lower than the present result. The apparent discrepancy can be attributed to the fact that a negative deviation from Eq. 1 occurs at such a high electrolyte concentration.

Salting Coefficients Calculated by the McDevit-Long Equation. Several theories have been given to explain the salt effects on the solubility of nonelectrolyte such as hydration, electrostatic, van der Waals force, internal pressure and scaled particle. The last two theories give a good prediction of the trend of the observed k_S value. Based on the internal pressure concept, McDevit and Long derived the equation[4]

$$k_s = \bar{V}_l^\circ(V_s - \bar{V}_S^\circ)/2.3\,\beta_o RT, \quad (2)$$

where $\bar{V}_l^\circ$ is the molar volume of the liquid nonelec-

a) S° and S denote pure water and salt solution, respectively. b) Correlation coefficient. c) Defined by $k_S^*=k_S+(0.036-\phi_0\times10^{-3})/2.30$, where ϕ_0 is the apparent molal volume of the salt. d) Calculated by the McDevit-Long equation. e) Calculated by the scaled particle theory.

trolyte, V_S the molar volume of pure (liquid) electrolyte, $\bar{V}_S^\circ$ the partial molar volume of the salt at infinite dilution, and β_0 the compressibility of pure water. The factor ($V_S-\bar{V}_S^\circ$) in Eq. 2 indicates electrostriction of the solvent caused by the salt, which is related to modification of the water structure by the salt added. The values of k_S calculated by using Eq. 2 are given in Table 1. The molar volume of liquid mercury 14.8 cm^3 was obtained by dividing atomic weight by density at 25 °C. The value of β_0 was taken to be 45.6×10^{-6} bar^{-1}.[4] All the V_S data were taken from the work of Lundén,[7] and the values for $\bar{V}_S^\circ$, the sum of partial

molar volumes of individual cation and anion, from that of Millero.[8]

The calculated k_s values are in reasonably good agreement with the observed values except for NaBr, NaSCN, and $NaClO_4$. In the McDevit-Long equation, the parameter concerned with nonelectrolyte is only its molar volume, hence the characteristic properties of nonelectrolyte such as nonelectrolyte-solvent and nonelectrolyte-electrolyte interactions are not taken into consideration. This probably causes the discrepancies observed for these three salts. The observed k_s values indicate that the increased interactions of mercury atoms with Br^- or SCN^- ions play an important role for NaBr or NaSCN salt and that the decreased interactions of mercury atoms with surrounding water molecules should be considered for $NaClO_4$ salt.

Salting Coefficients Calculated by the Scaled Particle Theory. In the SPT, which has been successfully applied to predict the solubility of nonelectrolyte in various solvents,[5] two steps are involved: (1) the creation of a cavity in the solvent of a suitable size to accommodate a nonelectrolyte molecule, and (2) the introduction of a nonelectrolyte into the cavity, the nonelectrolyte molecule interacting with the solvent and electrolyte species through repulsive, dispersion, and inductive forces. The SPT allows computations of the free energies involved in (1) and (2). The theory would reflect the characteristic properties of nonelectrolyte in its solubility in electrolyte solution more adequately than the McDevit-Long equation.

On the basis of SPT considerations given by Shoor and Guggins,[9] Masterton and Lee[10] have presented useful equations which enable one to estimate the salting coefficient k_S^*, defined by

$$k_S^* = \lim_{C\to 0} \frac{1}{C} \log \frac{X_0}{X}, \tag{3}$$

where X_0 and X denote the mole fraction solubility of nonelectrolyte in pure water and an electrolyte solution of molarity of C, respectively. The salting coefficient can be written as follows:

$$k_S^* = k_\alpha + k_\beta + k_\gamma, \tag{4}$$

where k_α and k_β are related to steps (1) and (2), respectively, and k_γ refers to the number densities of species present in the solvent. The expressions k_α, k_β, and k_γ are given by Eqs. 32, 19, and 11, respectively, in Ref. 10. These equations are expressed as functions of hard sphere diameter, σ, the energy parameter, ε/κ, polarizability, α, and apparent molal volume of salt at infinite dilution, ϕ_0. Subscripts 1, 2, 3, and 4 refer, respectively, to nonelectrolyte, water, cation, and anion. The hard sphere diameter is taken as twice that of the crystal ionic radius. Values of σ are given in Table 2, references being specified in the footnote. For water molecules, the following parameters are employed: $\sigma_2=0.275$ nm, $\varepsilon_2/\kappa=85.3$ K, and the dipole moment$=6.14\times10^{-30}$ C m. When values corresponding to ϕ_0, (σ_1, σ_3, σ_4), (α_1, α_3, α_4), and ε_1/κ are known, the value of k_S for a given nonelectrolyte-salt pair can be calculated. The value of ϕ_0 is taken as the sum of the partial molal volume, $\bar{V}_{ion}$, of cation and anion, that is $\phi_0=\bar{V}_3+\bar{V}_4$. Since the expression for k_S^* defined by Eq. 3 differs from the conventional k_S appearing in Eq. 1, the observed k_S is converted into k_S^* by means of the relation[11]

$$k_S^* = k_S + (0.036 - \phi_0 \times 10^{-3})/2.30. \tag{5}$$

In calculating k_S^* by the SPT, it is important to choose adequate parameters, since the calculated k_S^* value varies to a great extent with them. First, let us discuss the parameters for elemental mercury as a nonelectrolyte. The value 5.05×10^{-24} cm^3/molecule can be taken for α_1,[12] but it is difficult to select proper σ_1 and ε_1/κ values. We adopt here the value of 0.290 nm for the hard sphere diameter of mercury atom.[13] Calculations were first made using $\varepsilon_1/\kappa=851$ K but the results (Table 1) are unsatisfactory. An attempt was made to estimate the ε_1/κ value according to the derivation made by Pierotti,[14] who gave a relation between Henry's law constant, k_H, and the free energy changes in steps (1) and (2). Using $\sigma_1=0.290$ nm and $K_H=422$ atm at 25 °C,[6] we estimated the value ε_1/κ of elemental mercury to be 283 K, which is much smaller than the value obtained from viscosity data. The parameters used in the present calculation by the SPT are given in Table 2. The values of both observed and calculated k_S^* are given in Table 1.

If we employ the energy parameter derived from Henry's constant, the SPT is applicable, at least to an extent that the McDevit-Long equation can predict, to the salt effect on the elemental mercury solubility in water. Similarly to the McDevit-Long equation, the SPT approach gives poor agreement for NaBr and NaSCN salts. No reasonable interpretation can been given. The results of the SPT calculations for salt effects are sensitive to the ionic diameter of the electrolyte. It is difficult to estimate ionic diameters of polyatomic ions, since no accurate crystal ionic radii are

TABLE 2. PARAMETERS USED FOR CALCULATI NG SALTING COEFFICIENTS BY SCALED PARTICLE THEORY

Elemental Mercury: $\sigma=0.290$ nm,[a] $\alpha=5.05\times10^{-24}$ cm (molecule)$^{-1}$,[b] $\varepsilon/\kappa=851$[a], or 283 K[c]

known. In the present calculations, ionic radii adopted for polyatomic ions except for tetraalkylammonium ions are those estimated using Hepler's semiempirical equation.[15] It is not clear whether the equation can be properly extended to these ions. Masterton *et al.* tried to estimate the best ionic radii for SPT calculation which give the best fit to the observed salting coefficients.[11] In contrast with the McDevit-Long equation, the SPT gives great discrepancies between observed and calculated k_S^* for $(CH_3)_4NBr$ and $(C_2H_5)_4NBr$ salts. This can not be overcome even if diameters for tetraalkylammonium cations proposed by Masterton *et al.* are used. The failure of the SPT for tetraalkylammonium salts certainly does not lie solely with uncertainty of their ionic diameters, but should be ascribed to their abnormal physico-chemical properties for which the SPT does not account. The anomalous behavior exhibited by tetraalkylammonium ions has been revealed by many experimental observations and theoretical considerations.[16,17]

The authors wish to thank Dr. Toshio Deguchi, Kumamoto University, for valuable discussions. The present work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Organopalladium(II) Complexes Derived from Chloro[4-[2-(diphenylphosphino)ethylamino]-3-penten-2-onato-*O,N,P*]palladium(II)

Katsuma Hiraki,* Toyohiko Masumoto, Yoshio Fuchita,* and Yasushi Zegi

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852

(Received July 17, 1980)

A new tertiary phosphine containing α,β-unsaturated β-amino ketone, 4-[2-(diphenylphosphino)ethylamino]-3-penten-2-one (Hdpeap), reacts with sodium tetrachloropalladate(II) in the absence or presence of sodium ethoxide to give $[PdCl_2(Hdpeap)_2]$ or [PdCl(dpeap)] [dpeap ≡ 4-[2-(diphenylphosphino)ethylamino]-3-penten-2-onato-*O,N,P*], respectively. The latter complex reacts with terminal acetylenes in the presence of catalytic amounts of copper(I) iodide to produce alkynyl complexes, [Pd(C≡CR)(dpeap)]. Carbanions derived from active methylene compounds, and sodium dimethyldithiocarbamate also react with [PdCl(dpeap)] to afford [Pd(CHYY')(dpeap)] and $[Pd(S_2CNMe_2)_2]$, respectively.

Many investigations have been reported about the quadridentate Schiff bases derived from β-diketones and primary diamines[1] and about their transition metal complexes.[2] However, there have been only few papers on tridentate Schiff bases, derived from acetylacetone and primary monoamines containing a hetero atom on their β-position, except the diamines.[3-5] Uhlig and Gottschling[4] reported that 4-(2-picolylamino)-3-penten-2-one (Hpip), produced from acetylacetone and 2-picolylamine, forms univalent ONN-type tridentate chelates to nickel(II) and copper(II) ions. The previous paper from our laboratory dealt with the preparation of chloro[4-(2-picolylamino)-3-penten-2-onato-*O,N,N*]-palladium(II) and with the reactions of this complex with carbanions derived from active methylene compounds.[5]

In this paper, we present the preparation of a new, tertiary phosphine-containing tridentate α,β-unsaturated β-amino ketone, 4-[2-(diphenylphosphino)ethylamino]-3-penten-2-one (Hdpeap), and its reactions towards tetrachloropalladate(II) in the absence and presence of sodium ethoxide, resulting in the formation of $[PdCl_2(Hdpeap)_2]$ and [PdCl(dpeap)] [dpeap ≡ 4-[(2-diphenylphosphino)ethylamino]-3-penten-2-onato-*O,N,P*], respectively. In addition, the reactions of the latter complex with terminal acetylenes, carbanions, and sodium dimethyldithiocarbamate [Na(dmdc)] are reported.

Experimental

Materials and General Procedures. 2-(Diphenylphosphino)-ethylamine,[6] methyl propiolate,[7] and thallium(I) acetylacetonate [Tl(acac)][8] were prepared according to the published procedures. Solvents were dried by standard methods and distilled. The other reagents were commercial samples and were used without further purification.

Melting points were measured in capillary tubes on a Yanagimoto MP-S3 microstage apparatus and are uncorrected. IR and ^{1}H-NMR spectra were recorded according to the previous paper.[5] All preparative operations were performed in an atmosphere of dry nitrogen.

Preparation of Hdpeap. A benzene solution of 2-(diphenylphosphino)ethylamine (26 mmol) and acetylacetone (52 mmol) was heated under reflux for 3.5 h. After the reaction mixture had been evaporated to dryness, the residue was recrystallized from hexane to give crystalline solids, 4-[2-(diphenylphosphino)ethylamino]-3-penten-2-one (Hdpeap) **1**.

Reaction of Hdpeap with Sodium Tetrachloropalladate(II). An ethanol solution (100 ml) containing Hdpeap (3.93 mmol) and $Na_2[PdCl_4]$ (1.96 mmol) was stirred at room temperature for 15 h. After the solvent had been evaporated, the residue was extracted with 30 ml of benzene. The benzene-extract was evaporated *in vacuo*, and the resulting solids were recrystallized from THF and hexane to afford crystalline solids $[PdCl_2(Hdpeap)_2]$ **2**. Hdpeap (2.15 mmol) was added to an ethanol solution (40 ml) of sodium ethoxide (2.15 mmol). The resulting solution was added dropwise to an ethanol solution of $Na_2[PdCl_4]$ (2.36 mmol) for 2 h, and the reaction mixture was stirred at room temperature for 6 h. After filtration, the filtrate was concentrated to give a precipitate, which was collected by filtration and washed with diethyl ether to yield [PdCl(dpeap)] **3**.

Halogen Metathesis of 3. An acetone suspension (30 ml) containing **3** (0.66 mmol) and $LiBr \cdot H_2O$ (2.86 mmol) was heated under reflux for 10 h. The reaction mixture was evaporated to dryness, and the residue was extracted with benzene. The extract was diluted with diethyl ether to give a precipitate of [PdBr(dpeap)] **4**.

Reactions of 3 with Terminal Acetylenes. A diethyl ether solution (8 ml) of methyl propiolate (6.4 mmol) was added to a diethylamine solution (50 ml) containing **3** (1.28 mmol) and copper(I) iodide (3.8×10^{-2} mmol). The reaction mixture was heated under reflux for 31 h. After the volatile matters had been evaporated, the residue was washed with water and recrystallized from benzene and diethyl ether to give [Pd(C≡CCO$_2$Me)(dpeap)] **5**. Complex **3** reacted with phenylacetylene (at room temperature for 6.5 h) or 1-hexyne (under reflux for 13 h) in a diethylamine–diethyl ether mixture in the presence of a catalytic amount of copper(I) iodide followed by the similar recrystallization to yield [Pd(C≡C–Ph)(depeap)] **6** or [Pd(C≡C–*n*-C$_4$H$_9$)(dpeap)] **7**, respectively.

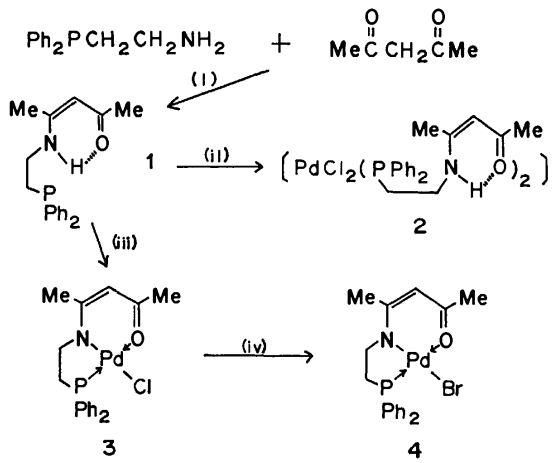
Reaction of 3 with Tl(acac). Thallium (I) acetylacetonate (0.51 mmol) was added to a dichloromethane solution (10 ml) of **3** (0.44 mmol). The resulting suspension was stirred at room temperature for 16.5 h. After filtration, the filtrate was concentrated and diluted with hexane to give a precipitate of [Pd{CH(COMe)$_2$}(dpeap)] **8**.

Reactions of 3 with Carbanions Formed from Active Methylene Compounds. A THF suspension containing **3** (0.44 mmol), malononitrile (0.55 mmol) and sodium methoxide (0.55 mmol) was stirred at room temperature for 24 h. After filtration, the resulting filtrate was evaporated *in vacuo*. The residue was recrystallized from dichloromethane–diethyl ether to afford [Pd{CH(CN)$_2$}(dpeap)] **9**. Complex **3** was analogously treated with carbanion formed from methyl cyanoacetate, followed by recrystallization from dichloromethane and hexane to yield [Pd{CH(CN)CO$_2$Me}(dpeap)] **10**.

Reaction of 3 with Sodium Dimethyldithiocarbamate-water (1/2). A dichloromethane suspension (30 ml) containing **3** (0.79 mmol) and sodium dimethyldithiocarbamate-water(1/2) (0.84 mmol) was stirred at room temperature for 27 h. The resulting solids were collected and washed with water and then diethyl ether to give yellow powders, $[Pd(S_2CNMe_2)_2]$ [in 54% yield, based on **3**, and in 100%, based on $Na(S_2CNMe_2)\cdot 2H_2O$]. Mp>300 °C (lit,[9] >300 °C).

Results and Discussion

Preparation of Hdpeap and its Palladium(II) Complexes. 2-(Diphenylphosphino)ethylamine and acetylacetone reacted easily in refluxing benzene to give a new tridentate Schiff base ligand, Hdpeap **1**. This ligand was treated with $Na_2[PdCl_4]$ in ethanol in the absence of alkali metal alkoxide, resulting in the formation of the adduct, $[PdCl_2(Hdpeap)_2]$, **2**. The Schiff base **1** reacted with equimolar amounts of sodium ethoxide and $Na_2[PdCl_4]$ in ethanol to afford [PdCl(dpeap)], **3**. Complex **3** reacted with $LiBr\cdot H_2O$, terminal acetylenes, Tl(acac), and carbanion formed from active methylene compounds, such as malononitrile and methyl cyanoacetate, giving new complexes **4**, **5**—**7**, **8**, and **9**—**10**, respectively. The yields, elemental analyses, and some physical properties of compounds **1**—**10** are summarized in Table 1. Complexes **2**—**7** are stable in the air and soluble in chloroform and dichloromethane.



Scheme 1. Formation and reactions of Hdpeap, **1**.
i) Reflux in benzene; ii) $Na_2[PdCl_4]$; iii) $Na_2[PdCl_4]$+ NaOEt; iv) $LiBr\cdot H_2O$.

The Schiff base **1** and its adduct **2** showed a ν(NH) frequency at 3160 and 3400 cm^{-1}, respectively. Furthermore, they exhibited three bands near 1510, 1560, and 1590 cm^{-1}, characteristic of the 4-amino-3-penten-2-one moiety. The ^{1}H-NMR spectra of **1** and **2** showed a broad signal near δ 10.8, assignable to NH proton, in addition to three singlets near δ 1.77 (3H, Me), 1.93 (3H, Me), and 4.91 (1H, CH) and two multiplets near δ 2.3—2.7 (2H, CH_2P) and 3.43 (2H, CH_2N) (Table 3). These data confirm unambiguously that **2** retains the uncoordinated 4-amino-3-penten-2-one moiety. This was in contrast with the case of 4-(2-picolylamino)-3-penten-2-one, which had acted also as a proton acceptor.[5]

The IR spectra of **3**—**10** showed two bands near 1575 and 1505 cm^{-1}, attributable to the coordinated 4-amino-3-penten-2-onato-*N,O* group. The ^{1}H-NMR spectra of **3**—**10** exhibited three singlets near δ 2.0 (3H, Me), 2.1 (3H, Me), and 5.0 (1H, CH), and two double triplets in the ranges δ 2.2—2.7 [2H, CH_2P, ^2J(PH)=*ca.* 10 Hz, ^3J(HH)=*ca.* 6 Hz] and 3.0—3.7 [2H, CH_2N, ^3J(PH)=23—30 Hz]. These facts indicate that **3**—**10** have the tridentate dpeap group.

The Ethynyl Type Complexes 5—7. Complex **3** reacted smoothly with phenylacetylene at room temperature in the diethylamine–diethyl ether mixture in the presence of 1 mol percent of copper(I) iodide.[10] Complex **3** reacted fairly slowly with methyl propiolate in the same conditions, because about 30% of **3** remained unchanged after stirring at room temperature for 3.5 d. However, **3** did not react with 1-hexyne at room temperature even in the presence of CuI. It was found from the above results that the order of the reactivity of terminal acetylenes towards **3** was; phenylacetylene>methyl propiolate$\gg$1-hexyne. Taking the pK_a values of the terminal acetylenes [$Bu^nC{\equiv}CH$ (26.2[11])>$PhC{\equiv}CH$ (23.7,[11] 21[12])>$MeO_2CC{\equiv}CH$] into consideration, it seems likely that the ethynylation of **3** is influenced by two factors: one is the susceptibility of the acetylenes to deprotonation, resulting in the formation of the intermediates, ethynyl–copper complexes[10] and the other is the reactivity of the intermediates toward **3**.

Table 1. Yields and elemental analyses

Compound		Yield %	Color	Mp[a] °C	Found (Calcd) (%) C	H	N

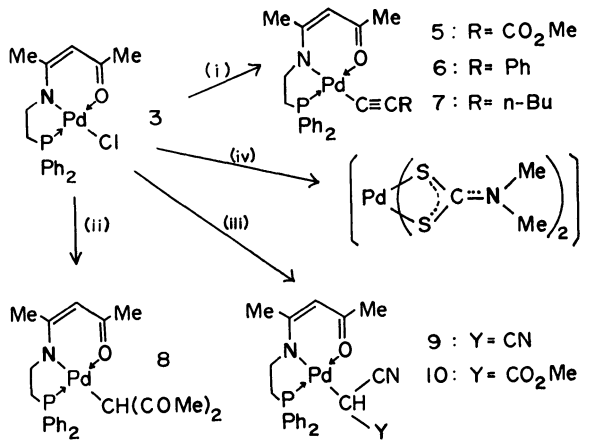
10	—	1715	2220[ν(C≡N)]

a) In cm^{-1}, in KBr disk. b) Assignment is given parentheses.

Complexes **5**—**7** showed a strong ν(C≡C) band near 2100 cm^{-1}, lower (*ca.* 35, 55, and 5 cm^{-1}, respectively) than those of the corresponding free acetylenes. Attempts to isolate **8**, **10**, and [Pd{$CHNO_2(CO_2Me)$}(dpeap)] by reactions of **7** with acetylacetone, methyl cyanoacetate, and methyl nitroacetate, respectively, were fruitless, **7** being recovered quantitatively after refluxing in THF for 5 h. The inertness of **7** toward the active methylene compounds is in contrast with phenylethynyl-[13] and 1-hexynyl[1,1,1-tris(diphenylphosphinomethyl)ethane]-copper(I).[14] However, the phenylethynyl complex **6** easily reacted with dimethyl acetylenedicarboxylate in dioxane at room temperature to afford an insertion product. It seems likely that this insertion reaction is comparable with that between halogeno(phenylethynyl)-bis(trialkylphosphine)palladium(II) and dimethyl acetylenedicarboxylate in dioxane at 85 °C.[15] Details of the former insertion reaction will be reported later.

The Disubstituted Alkyl Type Complexes ***8***—***10***.

The ^{1}H-NMR spectra of complexes **8**—**10** exhibited a doublet in the range δ 2.8—3.9 [1H, ^3J(PH)=2—5 Hz], characteristic of a palladium-bonded methine proton. The IR spectrum of **8** showed a strong ν(C=O) band at 1660 cm^{-1}, implying two free and equivalent acetyl groups. Complexes **9** and **10** showed a medium ν(C≡N) band near 2220 cm^{-1}, attributable to an uncoordinate cyano group. These data indicate unambiguously that the disubstituted alkyl groups were σ-bonded to palladium in an analogous fashion to those in [Pd(pip)-(CHYY')] type complexes.[5] Complexes **8**—**10** are stable in the solid state and in dichloromethane and chloroform and unreactive towards water or ethanol. The stability of **8**—**10** is possibly associated both with the electron delocalization effect to a π^* orbital of the conjugate 4-amino-3-penten-2-onato-*N*,*O* moiety and vacant d orbitals of the phosphorus atom in the dpeap ligand and with the electron-withdrawing effect of the substituents attached to the methine group, similar to the case of [Pd(pip)(CHYY')].[5]



Scheme 2. Reactions of [PdCl(dpeap)], **3**.
i) HC≡CR+CuI (3 mol %) in $NHEt_2$; ii) Tl(acac); iii) $CH_2(CN)Y$+NaOMe; iv) $Na(S_2CNMe_2)\cdot 2H_2O$.

An attempt to isolate a dinuclear complex by the reaction between **8** and bis(acetylacetonato)palladium-(II) was unsuccessful, **8** being recovered quantitatively after heating under reflux in 1,2-dichloroethane for 6.5 h. The methine proton of the diacetylmethyl moiety in **8** is strongly bonded to the methine carbon, and does not give rise to tautomerism leading to 4-hydroxy-3-palladio-3-penten-2-one moiety, in contrast to the case of (2,2'-bipyridine)chloro(2,4-dioxopentyl)palladium(II).[15]

In contrast to the rapid reaction of **3** with Tl(acac), **3** reacted slowly with a carbanion formed from acetyl-

a) In $CDCl_3$. b) Appearing as a singlet. c) ^3J(H,H)=*ca.* 6 Hz. d) A multiplet near δ 1.1(4H) for 4''- and 5''-CH_2 protons was observed.

acetone and sodium methoxide, and gave a nearly 1 : 1 mixture of **3** and **8** after treatment with the carbanion in THF at room temperature for 24 h. However, **3** did not react with methyl nitroacetate in the presence of an equimolar amount of sodium methoxide. The reactivities of the carbanions toward **3** were ordered as follows.

$$^{-}CH(CN)CO_2Me \approx {}^{-}CH(CN)_2 >$$
$$^{-}CH(COCH_3)_2 \gg {}^{-}CH(NO_2)CO_2Me$$

This order is consistent with that of the nucleophilicity of the carbanions.[13,17]

*Reaction of **3** with Dimethyldithiocarbamate.* Complex **3** reacted with $Na(S_2CNMe_2)\cdot 2H_2O$ in dichloromethane, giving yellow powders. The IR spectrum of the powders lacked the bands characteristic of the dpeap ligand, and newly showed two bands at 1545 and 970 cm^{-1}, assignable to $\nu(C{=}N)$ and $\nu(S{=}C)$ frequencies, respectively. Accordingly, the powders were assigned to bis(dimethyldithiocarbamato)-palladium(II).[9] It is noteworthy that the tridentate dpeap ligand in **3** is substituted virtually quantitatively by bidentate dimethyldithiocarbamato ligands, which are soft themselves and are expected to be coordinated strongly to soft palladium(II) ion.

The authors thank Mrs. Hisako Mazume and Miss Yumi Kojima of Nagasaki University for their technical assistance.

The Crystal Structure and Luminescence Properties of Europium(II) Haloborates

Ken-ichi MACHIDA, Gin-ya ADACHI,* Yoshikazu MORIWAKI, and Jiro SHIOKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received May 10, 1980)

The crystal structures of $Eu_2B_5O_9X$ (X=Cl and Br) were determined by the method of X-ray diffraction analysis and refined by the least-square method to give $R=0.054$ for 1967 observed reflections of $Eu_2B_5O_9Cl$ and $R=0.047$ for 1979 observed reflections of $Eu_2B_5O_9Br$. These haloborates are isostructural and belong to the orthorhombic (pseudotetragonal) system, with the *Pnn*2 space group and with four formula units in a cell of those dimensions: $a=11.364(3)$, $b=11.301(3)$, and $c=6.504(2)$ Å for $Eu_2B_5O_9Cl$, and $a=11.503(3)$, $b=11.382(3)$, and $c=6.484(2)$ Å for $Eu_2B_5O_9Br$. The structure consists of a three-dimensional $(B_5O_9)_\infty$ network, the B_5O_{12} groups of three BO_4 tetrahedra and two BO_3 triangles being linked together with one another. The Eu and X atoms are located alternately in tunnels of the $(B_5O_9)_\infty$ network extending along the c axis. Each Eu atom is surrounded by two X atoms and seven O atoms, and is isolated from the neighboring Eu atoms attributable to borate units and X atoms. This arrangement of anions around Eu atoms relates to the fact that the Eu^{2+}-activated phosphors of alkaline earth analogs give emissions with a high quantum efficiency.

Phosphors of Eu^{2+}-activated alkaline earth compounds give emissions based on the $4f^7-4f^65d$ transition or the $4f^7-4f^7$ transition of the Eu^{2+} ion.[1] Recently we have reported that the quantum efficiencies of compounds in the $EuO-B_2O_3$ system and their Eu^{2+}-activated strontium analogs depend greatly on the structural frameworks of borate units.[2] In the ternary system $EuO-EuX_2-B_2O_3$ (X=Cl and Br), $Eu_2B_5O_9$-type compounds have been obtained in attempts to prepare their boracite-type compounds,[3] they are paramagnetic and give blue emissions based on the $4f^7-4f^65d$ transition of the Eu^{2+} ion.[4] The compounds obtained by the dilution of the Eu^{2+} ions in the $Eu_2B_5O_9X$ matrix with alkaline-earth cations have been found to be efficient photoluminescent materials.[5] In this paper, we wish to report on the crystal structure of $Eu_2B_5O_9X$ and discuss their luminescence properties on the basis of X-ray structural analysis.

Experimental

Sample Preparation. Single crystals of $Eu_2B_5O_9X$ were prepared as follows: mixtures of EuB_2O_4 and B_2O_3 containing a large excess of EuX_2 as a flux were heated on molybdenum boats above the congruent melting points of haloborates (about 1100 °C) for 1—2 h in He gas; the molten samples were then allowed to cool at a rate of 3—5 °C/h. When the unreactive EuX_2 was then removed from the samples with washing with water, light-yellow crystals were obtained. Their crystal habits were prismatic for $Eu_2B_5O_9Cl$ and needle-like for $Eu_2B_5O_9Br$.

The Eu^{2+}-activated strontium haloborates, $Sr_2B_5O_9Cl$: Eu^{2+} and $Sr_2B_5O_9Br$: Eu^{2+}, were obtained by the following standard ceramic technique: appropriate amounts of SrX_2, H_3BO_3, and $SrCO_3$: Eu^{3+}, coprecipitated from a dilute HCl solution of $Sr(NO_3)_2$ and Eu_2O_3 (99.99%) by the slow addition of a $(NH_4)_2CO_3$ solution, were fully mixed, pelletized, and heated at 950 °C for 2 h in a stream of a reducing atmosphere, H_2.

Optical Measurements. The ultraviolet luminescence spectra were measured according to a technique described elsewhere.[2]

X-Ray Data Collection. Preliminary Weissenberg photographs and the Patterson syntheses showed that $Eu_2B_5O_9X$ belongs to the orthorhombic (pseudotetragonal) system, with a noncentrosymmetric space group *Pnn*2 and with $Z=4$.† The accurate cell parameters of $Eu_2B_5O_9Cl$ and $Eu_2B_5O_9Br$ were determined by least-square treatments of the X-ray powder diffraction patterns (Cu $K\alpha_1$), calibrated with high purity silicon. The crystal data are summarized in Table 1.

Table 1. Crystal data

	$Eu_2B_5O_9Cl$	$Eu_2B_5O_9Br$
F.W.	537.43	581.88
Orthorhombic		
Pnn2 ($0kl$, $k+l=2n+1$; $h0l$, $h+l=2n+1$)		
a/Å	11.364(3)	11.503(3)
b/Å	11.301(3)	11.382(3)
c/Å	6.504(2)	6.484(2)
V/Å^3	835.2(5)	848.9(4)
D_m/g cm^{-3}	4.30	4.53
D_x/g cm^{-3}	4.28	4.55
Z	4	4
$F(000)$	960	1032
Crystal size/mm^3	$0.14\times0.08\times0.17$	$0.10\times0.10\times0.20$
μ(Mo $K\alpha$)/mm^{-1}	15.283	19.264

The intensity data were measured on a Rigaku Denki automated four-circle diffractometer with Mo $K\alpha$ radiation ($\lambda=0.71069$ Å) monochromated with graphite. The ω-2θ scan technique was employed with a scanning rate of 4°/min. All the independent reflections were collected up to $2\theta=70°$. Three standard reflections were monitored every 50 or 60 reflections; no apparent decay in intensity was detected. The reflections with $F_o>3\sigma(F_o)$ were considered as observed: 1967 and 1979 observed reflections were obtained for $Eu_2B_5O_9Cl$ and $Eu_2B_5O_9Br$ respectively. The Lorentz and polarization corrections were applied, but the absorption correction was not.

Structure Determination and Refinements. The structures of europium (II) haloborates were solved by the conventional heavy-atom method and were refined by the method of block-diagonal least-squares (*HBLS*-V program[6]), the minimized function being $\sum w(|F_o|-|F_c|)^2$. From the three-dimensional Patterson syntheses, the coordinates of Eu and X atoms were determined: Eu(1) and Eu(2) atoms can be located on the general positions (4*c* site), while X(1) and X(2) atoms occupy

† The symmetry of $Eu_2B_5O_9Cl$ has been erroneously reported as tetragonal in a previous paper.[4]

the special positions (2*a* and 2*b* sites). The remaining O and B atoms were located on the successive Fourier maps. The isotropic refinements gave a conventional R value of 0.06 for both compounds; further refinements with anisotropic thermal factors for heavy atoms reduced the R and R_w values to 0.054 and 0.068 for 1967 reflections of $Eu_2B_5O_9Cl$ and 0.047 and 0.053 for 1979 reflections of $Eu_2B_5O_9Br$, where $R_w=[\sum w(|F_o|-|F_c|)^2/\sum w(F_o)^2]^{1/2}$. The weighting schemes of $w=(F_{max}/F_o)^2$ for $F_o>F_{max}$ and $w=1.0$ for $F_o\leqq F_{max}$ ($Eu_2B_5O_9Cl$, $F_{max}=20.0$; $Eu_2B_5O_9Br$, $F_{max}=40.0$), were employed. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[7] The final positional and thermal parameters are listed in Tables 2 and 3.††

Results and Discussion

Since the final parameters of $Eu_2B_5O_9Cl$ are almost equal to those of $Eu_2B_5O_9Br$, the two europium(II) haloborates were considered to be isostructural with each other.

The interatomic distances and angles of $Eu_2B_5O_9Cl$ are given in Table 4. There are two types of B atoms: in the first type [B(1), B(2), and B(3)], each B atom is tetrahedrally coordinated with four oxygens with B–O distances from 1.44 to 1.49 Å, while the second type [B(4) and B(5)] are triangularly coordinated borons with B–O distances from 1.30 to 1.41 Å. The O–B–O angles are about 110° for the tetrahedra and about 120° for the triangles. Three BO_4 tetrahedra and two BO_3 triangles form a B_5O_{12} group with sharing O atoms, and these groups are linked together with one another to form a three-dimensional $(B_5O_9)_\infty$ network. The projection of the $Eu_2B_5O_9Cl$ structure viewed along the c axis is shown in Fig. 1. The Eu and Cl atoms are alternately located in tunnels of the $(B_5O_9)_\infty$ network, and each Eu atom is almost entirely isolated from neighboring Eu atoms because of the $(B_5O_9)_\infty$ network for the a and b directions and Cl atoms for the c direction.

Each Eu atom has four nearest Eu neighbors with the mean interatomic distance of 4.387 Å and four next-nearest Eu neighbors with the mean interatomic

†† The F_o-F_c Table is kept as Document No. 8111 at the Chemical Society of Japan.

distance of 5.823 Å for the Eu(1) atom or 5.772 Å for the Eu(2) atom. These interatomic distances are long compared with those of other europium(II) compounds with magnetic transitions,[8] and are insufficient for the magnetic interactions between neighboring Eu^{2+} ions.[9] For example, the Eu–Eu distances in EuO (T_C=69 K) are 3.63 and 5.14 Å for the nearest and next-nearest Eu neighbors respectively. Therefore, $Eu_2B_5O_9X$ is paramagnetic even at low temperature.

The anion environments around Eu(1) and Eu(2) atoms in $Eu_2B_5O_9Cl$ are shown in Fig. 2. Both Eu(1) and Eu(2) atoms are surrounded with two Cl atoms and seven O atoms to form $Eu(1)O_7Cl_2$ and $Eu(2)O_7Cl_2$ polyhedra with Eu–Cl distances from 2.985 to 3.052 Å and Eu–O distances from 2.465 to 3.000 Å.

Peters *et al.*[5] and Fouassier *et al.*[3] have obtained $M^{II}_2B_5O_9X$ phases in their attempts to prepare boracite ($M^{II}_3B_7O_{13}X$)-type compounds .(M=Ca, Sr, Ba, Eu, and Pb). That is to say, these metal ions do not give boracite-type compounds. Each M^{2+} ion in boracites, which are formed in a ternary system, MO–MX_2–B_2O_3 (M=Mg, Cr, Mn, Fe, Co, Ni, Cu, Zn, and Cd), is surrounded by two X^- ions and four O^{2-} ions.[10] The fact that $M_2B_5O_9X$-type compounds are formed for M=Ca, Sr, Ba, Eu, and Pb may be due to their large ionic radii, since these ions hardly seem to occupy the sixfold sites of boracites.

The haloborates, $Eu_2B_5O_9Cl$ and $Eu_2B_5O_9Br$, give

emissions at about 430 and 435 nm, and their Eu^{2+}-activated alkaline earth analogs are efficient phosphors. Since the ionic radius of the Sr^{2+} ion among alkaline earth cations is almost equal to that of the Eu^{2+} ion, strontium compounds are expected to be entirely isostructural with europium(II) analogs. Consequently, in order to discuss the relationship between the luminescence and structure of haloborates, we summarize the luminescence and structural properties for some Eu^{2+}-activated strontium compounds in Table 5.

The emission peak positions and shapes of Eu^{2+}-activated phosphors depend on the coordination numbers and symmetries of anions around Eu^{2+} ions, because the level of the $4f^65d$ excited state is affected by the crystal field. The haloborates, $Sr_2B_5O_9Cl : Eu^{2+}$ and $Sr_2B_5O_9Br : Eu^{2+}$, give emissions with a half-width of about 30 nm at 425—430 nm, while the emissions of $SrB_2O_4 : Eu^{2+}$ and $SrB_4O_7 : Eu^{2+}$ peak at about 367 nm. This must be because the symmetry of the EuO_7X_2 polyhedra (Fig. 2) is low compared with those[2a] of the EuO_8 and EuO_9 polyhedra in $SrB_2O_4 : Eu^{2+}$ and $SrB_4O_7 : Eu^{2+}$ because of the large X^- ions, although the Eu–O distances in these compounds are similar to one another (*e.g.*, 2.519 to 2.783 Å for EuB_2O_4[11] and 2.531 to 2.841 Å for EuB_4O_7[12]).

The quantum efficiencies of a series of Eu^{2+}-activated strontium borates greatly depend on the constructions of their borate units.[2] One of the quenching effects on Eu^{2+}-activated phosphors is a non-radiative process which proceeds by repeating the energy transfer *via* dipole-dipole interactions of Eu^{2+} ions.[13] Consequently, if the electrostatic shield effects of anions around the Eu^{2+} ions within them differ from one another, the values of their quantum efficiencies should vary with the degree of the shield effect. The Eu^{2+} ions in $SrB_2O_4 : Eu^{2+}$ are closely packed along $(BO_2)_\infty$ chains and are expected to interact easily with the neighboring Eu^{2+} ions on the (010) and (020) planes. The borate, $SrB_4O_7 : Eu^{2+}$, in which the Eu^{2+} ions are completely surrounded with the BO_4 tetrahedra of $(B_4O_7)_\infty$ network, gives a higher quantum efficiency than $SrB_2O_4 : Eu^{2+}$.

The quantum efficiency of $Sr_2B_5O_9X : Eu^{2+}$ is also very high compared with that of $SrB_2O_4 : Eu^{2+}$. The Eu^{2+} ions in $Sr_2B_5O_9X : Eu^{2+}$ are isolated from neighboring Eu^{2+} ions by the $(B_5O_9)_\infty$ network and X^- ions as well as those in $SrB_4O_7 : Eu^{2+}$; hence, the above-mentioned quenching effect can be expected to be small. Therefore, the high quantum efficiency of $Sr_2B_5O_9X : Eu^{2+}$ must be attributable to the arrangement of the borate units of the $(B_5O_9)_\infty$ network and X^- ions.

The authors wish to thank Dr. Noritake Yasuoka (Institute for Protein Research) and Professor Nobutami Kasai and Dr. Kunio Miki (Department of Applied Chemistry) for their helpful suggestions in connection with this study. The computations were carried out on an ACOS series 77 NEAC System 700 computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

The Crystal Structure and Magnetic Property of Europium(II) Orthoborate

Ken-ichi MACHIDA, Gin-ya ADACHI,* Hajime HATA, and Jiro SHIOKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received August 4, 1980)

The europium(II) orthoborate $Eu_3(BO_3)_2$ is trigonal, space group $R\bar{3}c$, with $a=9.069(1)$, $c=12.542(2)$ Å and $Z=6$. The structure has been refined to $R=0.082$ for 259 observed reflections with isotropic thermal parameters. The borate contains isolated and planar triangle BO_3^{3-} ions, the anions and Eu atoms being hexagonally packed along c. Each Eu atom is surrounded by 8 oxygens with Eu–O distances varying from 2.36 to 2.95 Å. The interatomic distances between Eu atoms are 3.509—4.200 Å for 8 nearest Eu neighbors and 4.831—5.450 Å for 6 second-nearest Eu neighbors. The 6 nearest Eu neighbors with the interatomic distances of 3.509 and 3.778 Å and the 4 second-nearest Eu neighbors with the Eu–O–Eu angle of 166.0° are effective for the magnetic exchange and superexchange interactions between Eu^{2+} ions, giving rise to ferromagnetism at low temperature.

Some europium(II) compounds have unique magnetic properties caused by the exchange and superexchange interactions between neighboring Eu^{2+} ions.[1] These interactions in oxides are closely related to the distances and angles *via* O^{2-} ions between the magnetic ions,[2] the arrangement of neighboring Eu^{2+} and O^{2-} ions around given Eu^{2+} ions being significant for interpreting their magnetic properties. For highly symmetrical compounds, *e.g.* EuO (rock salt type), $EuTiO_3$ (perovskite type) and Eu_2TiO_4 (K_2NiF_4 type), their magnetism has been discussed on the basis of their crystal structure.[3]

In a binary system $EuO-B_2O_3$, we have obtained a ferromagnetic compound, $Eu_3(BO_3)_2$, with $T_C=7.5$ K. This borate has been found to be isostructural with $Ca_3(BO_3)_2$,[4] which crystallizes in the trigonal system.[5] No three-dimensional structure analysis has been performed. The structures of other bivalent-cation orthoborates, $Zn_3(BO_3)_2$[6] and $Ni_3(BO_3)_2$,[7] have been determined. They consist of isolated triangle anions of BO_3 groups. Since the IR spectrum of $Eu_3(BO_3)_2$ is similar to that of zinc(II) and nickel(II) analogs,[8] $Eu_3(BO_3)_2$ is expected to contain BO_3^{3-} ions.

In this paper, we report the crystal structure of $Eu_3(BO_3)_2$ and discuss its magnetic property.

Experimental

Crystal Growth. The alkaline earth orthoborates [*e.g.* $Ca_3(BO_3)_2$ and $Sr_3(BO_3)_2$] have congruent melting points at 1400—1500 °C. However, $Eu_3(BO_3)_2$ has no melting point, decomposing into unknown compounds above 1400 °C. This might be due to the thermodynamic lability of Eu^{2+} ion.[9] The single crystals were prepared with use of a suitable flux: polycrystalline $Eu_3(BO_3)_2$ powder was mixed with a large excess of KCl, and the pelletized mixture was heated on a molybdenum boat at 1050 °C for 2 h in H_2 stream. The molten sample was allowed to cool to 750 °C at a rate of 3 °C/h, fine black hexagonal prisms being obtained by removing the flux with water.

Magnetic Susceptibility Measurements. The magnetic susceptibility of the powder sample was measured with a Shimadzu magnetic balance MB-11 (80—300 K) and a Faraday magnetic balance (2—80 K) constructed by Muneyuki Date and Ki-ichi Okuda (Department of Physics, Osaka University).

X-Ray Data Collection. Preliminary Weissenberg photographs showed that the crystals obtained belong to the trigonal system and that its space group is R3c or $R\bar{3}c$ from the systematic absence (*hkl*, $-h+k+l=3n+1$ and $3n+2$; *h0l*, $l=2n+1$). The cell parameters (Table 1) were determined by a least-squares treatment of the X-ray powder pattern (Cu $K\alpha$) calibrated with high purity silicon as an internal standard. The intensity data were measured on a Rigaku Denki automated four-circle diffractometer with Mo $K\alpha$ radiation monochromated with graphite. The ω-2θ scan method was employed at a scanning rate of 4°/min, the dimension of the crystal used being 0.08 mm (side to side of hexagonal cross section) × 0.04 mm (thickness). All possible reflections with the indices of hkl and *hkl* were collected up to $2\theta=70°$. Three standard reflections were monitored every 60 reflections, no apparent decay in intensity being detected. The intensity values for equivalent reflections were averaged and 259 nonzero reflections were used for analysis. The Lorentz and polarization corrections were applied, but not the absorption correction.

Table 1. CRYSTAL DATA

$F.W.=573.50$	$\lambda=0.71069$ Å

$c=12.542(2)$	$Z=6$
$V=893.3(3)$Å^3	$F(000)=1482$

Structure Determination and Refinement. The structure was solved by the conventional heavy atom method and refined by the full-matrix least-square method (*FMLS* program[10]) based on the observed reflections, the minimized function being $\sum w(|F_o|-|F_c|)^2$ where $w=1$ for all $|F_o|$. From a three-dimensional Patterson synthesis, the centrosymmetric space group $R\bar{3}c$ was chosen and the coordinate of Eu atom determined to be at a special position (18e site). The remaining atoms (O and B) were located on the successive Fourier maps: O at the general position (36d site) and B at the 12c site on three-fold axis. Isotropic refinement for all atomic paramaters was carried out to give $R=0.082$ for 259 observed reflections. The atomic scattering factors for Eu, O, and B atoms were those given in International Tables for X-Ray Crystallography.[11] The final positional and thermal param-

eters are given in Table 2.†

Results and Discussion

The crystal structure of $Eu_3(BO_3)_2$ is shown in Fig. 1, and the bond lengths and angles are given in Table 3. The borate contains isolated and planar triangles of BO_3 groups with a B–O distance of 1.36 Å like other orthoborates,[6,7] the crystal consisting of Eu atoms and BO_3 groups hexagonally packed along c. The triangle planes of BO_3 groups are perpendicular to the c axis. Each Eu atom is surrounded by 8 oxygens to form an EuO_8 polyhedron with Eu–O distances varying from 2.36 to 2.95 Å (Fig. 2). An Eu atom has 8 nearest and 6 second-nearest neighboring Eu atoms with the mean interatomic distances 3.816 and 5.244 Å, respectively.

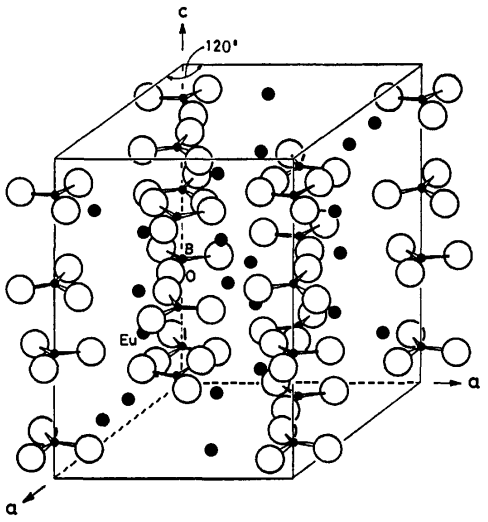

Fig. 1. Crystal structure of $Eu_3(BO_3)_2$.

† The F_o-F_c Table is kept as Document No. 8115 at the Chemical Society of Japan.

The temperature dependence of magnetization and susceptibility of $Eu_3(BO_3)_2$ are shown in Fig. 3. The borate is a ferromagnetic with a Curie point (T_C) of *ca.* 7.5 K and a paramagnetic Curie temperature (θ_C) of *ca.* 8 K. The magnetization per Eu^{2+} ion below the Curie point is saturated to *ca.* 7 μB.

Kasuya[2] suggested that the magnetism of europium-(II) compounds is attributable to the magnetic exchange and superexchange interactions taking place *via* the overlap of 4f and 5d orbitals between neighboring Eu^{2+} ions. The magnetism of highly symmetrical compounds, EuO (T_C=69 K),[1d] $EuTiO_3$ (T_N=5.3 K)[1f] and Eu_2TiO_4 (T_C=9 K),[3] has been interpreted in terms of the magnitude of the magnetic interactions between the nearest and second-nearest neighboring Eu^{2+} ions. The direct Eu^{2+}–Eu^{2+} interactions between the nearest Eu neighbors are responsible for the ferromagnetic interaction, the 90° Eu^{2+}–O^{2-}–Eu^{2+} superexchanging pairs undergoing the antiferromagnetic interaction *via*

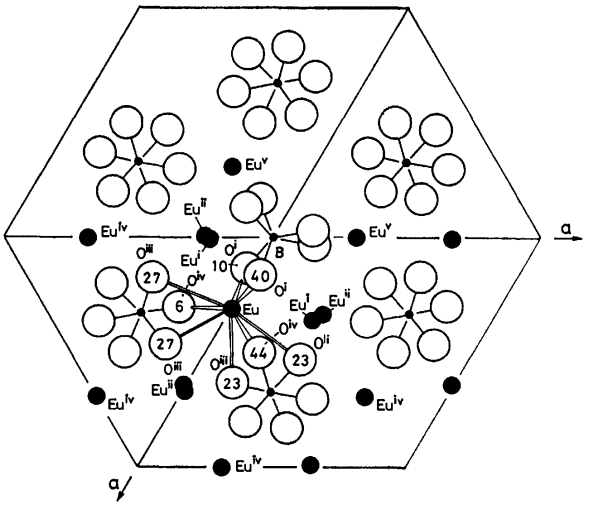

Fig. 2. A projection between z=0 and 0.5 of the $Eu_3(BO_3)_2$ structure viewed along the c axis. Numerical values give the fractional Z coordinates of O atoms.

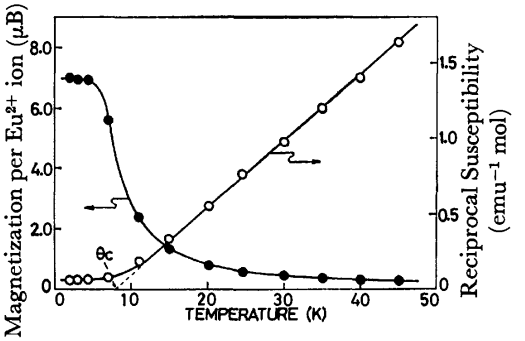

Fig. 3. Temperature dependences of magnetization and reciprocal susceptibility of $Eu_3(BO_3)_2$.

the O^{2-} ions at an angle of 90°. The 180° Eu^{2+}–O^{2-}–Eu^{2+} superexchange interactions between the second-nearest Eu neighbors contribute to the overall magnetism, ferromagnetically or antiferromagnetically, as the case may be. The difference among the magnetic properties of europium(II) compounds results from the difference in magnitude for the above-mentioned interactions.

From the Heisenberg model and molecular field approximation, McGuire *et al.*[1b,1d,1f] expressed the θ_C value as follows:

$$\theta_C = \frac{2}{3k} S\,(S+1)\,(Z_1J_1 + Z_2J_2), \qquad (1)$$

where J_1 and J_2 denote the effective exchange integrals between the nearest and second-nearest neighboring Eu^{2+} ions, respectively, and Z_1 and Z_2 the numbers of the nearest and second-nearest Eu neighbors, respectively. For the oxides, EuO, $EuTiO_3$, and Eu_2TiO_4, the direct Eu^{2+}–Eu^{2+} exchange and indirect 90° Eu^{2+}–O^{2-}–Eu^{2+} superexchange interactions are responsible for J_1, positively and negatively, respectively. The 180° Eu^{2+}–O^{2-}–Eu^{2+} superexchange interactions contribute to the value of J_2. The magnitude of direct exchange interactions is strongly influenced by the Eu–Eu distance, but that of superexchange interactions is not.

Each Eu^{2+} ion in $Eu_3(BO_3)_2$ has 8 nearest and 6 second-nearest neighboring Eu^{2+} ions. The nearest Eu neighbors with the interatomic distances of 3.509 and 3.778 Å contribute as the exchanging and superexchanging pairs, but not the nearest Eu neighbors with 4.200 Å, the distance of 4.200 Å appearing to be too great to interact with the neighboring Eu^{2+} ions as judged by the cases of other europium(II) compounds. For example, the mean distance between the nearest Eu neighbors in EuB_4O_7 (paramagnetic) is 4.338 Å and insufficient for the magnetic interactions.[12] In the nearest Eu neighbors, therefore, we can point out two kinds of effective exchanging pairs (Fig. 4). Type 1: the Eu–Eu^{i} pair with two 82.7° Eu^{2+}–O^{2-}–Eu^{2+}; Type 2: the Eu–Eu^{ii} pair with three 80.1—99.8° Eu^{2+}–O^{2-}–Eu^{2+}.

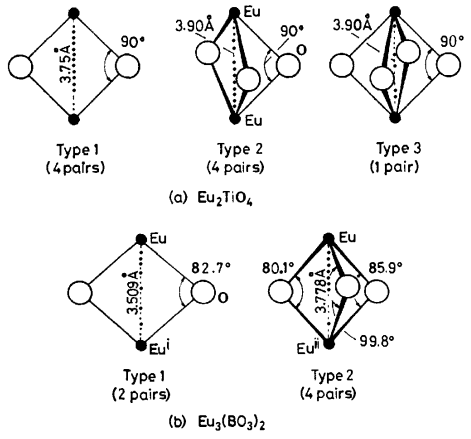

Fig. 4. Anions environments around exchanging pairs between nearest neighboring Eu^{2+} ions in Eu_2TiO_4 and $Eu_3(BO_3)_2$.

For the second-nearest Eu neighbors, four Eu–Eu^{iv} pairs *via* an O^{2-} ion at 166.0° correspond to the 180° Eu^{2+}–O^{2-}–Eu^{2+} superexchanging pairs in EuO, $EuTiO_3$ and Eu_2TiO_4, although the Eu–O–Eu angle somewhat deviates from the value of 180°. The remaining two Eu–Eu^{v} pairs can not be regarded as the superexchanging pairs because no oxygen occupies the position between them.

Greedan and McCarthy[3] estimated the values of exchange integrals J_1/k and J_2/k of Eu_2TiO_4 to confirm agreement with the experimental value (θ_C=10 K) using Eq. 1: J_1/k=0.07 and J_2/k=0.04 K (Table 4). An Eu^{2+} ion in Eu_2TiO_4 is surrounded by 9 nearest and 8 second-nearest neighboring Eu^{2+} ions with the interatomic distances of 3.75 to 3.90 Å and 5.51 Å, respectively. The Eu–Eu distances and Eu–O–Eu angles in Eu_2TiO_4 are closely similar to those of $Eu_3(BO_3)_2$.

In Eu_2TiO_4, there are three kinds of exchanging pairs between the nearest Eu neighbors, Types 1 and 2 correspond to those of $Eu_3(BO_3)_2$, the Eu–Eu distances in the borate being smaller than those in the titanate (Fig. 4). The exchanging pair (Type 3), not existing in $Eu_3(BO_3)_2$, is the pair with four 90° Eu^{2+}–O^{2-}–Eu^{2+} and contributing antiferromagnetically to the overall magnetism in a simillar manner to that of the exchanging pairs in $EuTiO_3$.[1f,3] Thus, $Eu_3(BO_3)_2$ is expected to give the greater values of J_1/k than Eu_2TiO_4. The superexchanging pairs between the second-nearest Eu neighbors in Eu_2TiO_4 and $Eu_3(BO_3)_2$ should give similar values of J_2/k from the similarity of the Eu–Eu distances and Eu–O–Eu angles. From the observed θ_C value of 8 K, we can estimate the values of J_1/k and J_2/k to be 0.10 and 0.04 K, substituting S=7/2,

TABLE 4. MAGNETIC EXCHANGE AND SUPEREXCHANGE INTERACTIONS IN Eu_2TiO_4 AND $Eu_3(BO_3)_2$

	Eu_2TiO_4[a]	$Eu_3(BO_3)_2$
T_c/K	9	7.5
θ_c/K[b]	10	8
Nearest neighbors	5 Eu^+ at 3.90 Å 4 Eu^+ at 3.75	2 Eu^+ at 3.509 Å 4 Eu^+ at 3.778
Second-nearest neighbors	8 Eu^+ at 5.51	4 Eu^+ at 5.450

a) Ref. 8. b) θ_c = paramagnetic Curie temperature.

$Z_1=6$ and $Z_2=4$ into Eq. 1. It is concluded that the 166.0° Eu^{2+}–O^{2-}–Eu^{2+} superexchanging pairs contribute ferromagnetically and the ferromagnetism of $Eu_3(BO_3)_2$ is attributable to the direct Eu^{2+}–Eu^{2+} and the 166.0° Eu^{2+}–O^{2-}–Eu^{2+} ferromagnetic interactions.

The authors wish to thank Mr. Ken-ichi Sakaguchi for the measurements on the four-circle X-ray diffractometer, and Dr. Noritake Yasuoka (Institute for Protein Research) and Prof. Nobutami Kasai and Dr. Kunio Miki (Department of Applied Chemistry) for their valuable suggestions. The computations were carried out on an ACOS series 77 NEAC System 700 computer at Crystallographic Center, Institute for Protein Research, Osaka University.

Optical Resolution and Circular Dichroism Spectra of Mixed-diamine Palladium(II) Complexes with Configurational Chirality

Kazuhiko NAKAYAMA,* Takashi KOMORITA, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 18, 1980)

Six square-planar complexes, [PdL(*meso*-stien)]$(ClO_4)_2$ (*meso*-stien=*meso*-1,2-diphenyl-1,2-ethanediamine; L=*N*,*N*-diethylethylenediamine, *N*,*N*-dimethylethylenediamine, 2-methyl-1,2-propanediamine, N^2,N^2-dimethyl-2-methyl-1,2-propanediamine, *N*,*N*-dimethyl-1,3-propanediamine, and (2*S*)-N^1,N^1-diethyl-1,2-propanediamine), were prepared and optically resolved (or separated in the case of the last named ligand) using diacetyl-*d*-tartaric anhydride as the resolving agent. Their electronic absorption and CD spectra were measured. A definite additivity has been confirmed between the configurational CD caused by the chiral configuration and the vicinal CD due to the asymmetric carbon atom in the (2*S*)-N^1,N^1-diethyl-1,2-propanediamine complex. Absolute configurations of this and the other five complexes have been assigned by examining molecular models and the CD spectra.

Circular dichroism (CD) of a metal complex in the d-d transition region generally arises from two kinds of main chirality, *i.e.*, the configurational one of the whole complex, and the vicinal one due to the asymmetric atoms of the ligands, the latter including the so-called conformational chirality of the chelate rings, if any. Although many kinds of Pt(II) and Pd(II) complex show d-d CD spectra owing to the vicinal effect,[1] only a limited number of square-planar complexes have been found to have the configurational chirality. The well-known complexes [M(2-methyl-1,2-propanediamine) (*meso*-stien)]$^{2+}$ (M=Pt[2] and Pd[3]) are unique examples of a successful optical resolution of the configurationally chiral complexes with square-planar coordination geometry. These complexes have a particular kind of configurational chirality, which arises from a combination of two types of bidentate ligands, an h-type which has a symmetry plane coplanar to the coordination square but none perpendicular to it in the conformationally averaged state, and a v-type which has the latter kind of symmetry plane but not the former kind (Fig. 1).

This paper reports the preparation, optical resolution, CD spectra, and absolute-configuration assignment of a series of such complexes, [Pd(h-type diamine) (*meso*-stien)]$^{2+}$. The ligands are given in Table 1. The complex [Pd(N^1,N^1-Et_2-(*S*)-pn) (*meso*-stien)]$^{2+}$ containing both kinds of chirality due to the asymmetric carbon atom and to the configuration was also examined in order to establish a criterion for the assignment of absolute configuration.

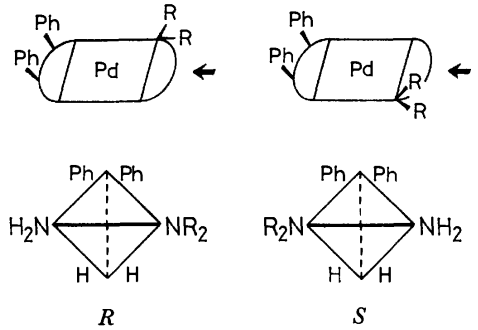

Fig. 1. Absolute configuration of the complex; the lower drawing shows the complex which is viewed along the arrow and regarded as a tetrahedron.

Table 1. Abbreviations and classification of the ligands

Abbreviation	Rational formula	Classification
N,*N*-Et_2en	$(C_2H_5)_2NCH_2CH_2NH_2$	h-type
N^1,N^1-Et_2-(*S*)-pn	$(C_2H_5)_2NCH_2CH(CH_3)NH_2$	——
N,*N*-Me_2en	$(CH_3)_2NCH_2CH_2NH_2$	h-type
C,*C*-Me_2en[a]	$H_2NC(CH_3)_2CH_2NH_2$	h-type
N,*N*,*C*,*C*-Me_4en[b]	$(CH_3)_2NC(CH_3)_2CH_2NH_2$	h-type
N,*N*-Me_2tn	$(CH_3)_2NCH_2CH_2CH_2NH_2$	h-type
meso-stien	$H_2NCH(Ph)CH(Ph)NH_2$	v-type
en	$H_2NCH_2CH_2NH_2$	——

a) 2-Methyl-1,2-propanediamine; the abbreviation is based on the name for a substituted ethylenediamine, specifying the atom to which the substituents attach. b) N^2,N^2-Dimethyl-2-methyl-1,2-propanediamine; abbreviation as in a).

Experimental

Ligands. *(1)* N,N,C,C-*Me_4en*: 2-Dimethylamino-2-methylpropanenitrile[4] (bp 54.3 °C/3.13 kPa; 56.6 g) in 130 cm^3 of anhydrous ether was added dropwise with stirring (at *ca.* −5 °C) to 25 g of lithium tetrahydridoaluminate suspended in 950 cm^3 of anhydrous ether. After the mixture had been stirred in an ice-bath for five hours, 28 cm^3 of water and 24 cm^3 of a 20% aqueous solution of potassium hydroxide were successively added with vigorous stirring. The ether layer was decanted from the slurry, from which the residue was extracted three times with 150 cm^3 portions of boiling ether. The combined mother liquor and extracts were treated with dry hydrogen chloride gas in an ice-bath. The white precipitate was mixed with a large excess of potassium hydroxide and a small amount of water, and the oil separated was extracted several times with boiling ether. The combined ether extracts were dried over potassium hydroxide pellets and then with sodium wire, and fractionally distilled. The fraction boiling at 61—62 °C/5.20 kPa was collected. Yield: 38.3 g.

(2) C,C-*Me_2en*: 2-Amino-2-methylpropanenitrile was obtained according to the method reported;[5] bp 61.5—62.0 °C/

3.60 kPa. The subsequent procedure was the same as described in *(1)*. bp 41.5 °C/2.87 kPa.

(3) Other Ligands: The following ligands were prepared by the methods reported: N^1,N^1-Et_2-(*S*)-pn[6] (bp 145—152 °C/100 kPa) and *meso*-stien[2,7] (Found: C, 79.25; H, 7.57; N, 13.19%).

Resolving Agent. Diacetyl-*d*-tartaric anhydride was obtained by the method of Chattaway and Parkes[8] (Found: C, 43.85; H, 3.88%).

[$PdCl_2L$]-type Complexes. (1) L=N,N-*Et_2en and* N^1,N^1-*Et_2-(S)-pn*: These complexes were prepared by a method similar to that of Suzuki and Nishida.[6] Found: C, 24.36; H, 5.52; N, 9.55%. Calcd for [$PdCl_2$(*N,N*-Et_2en)]=$C_6H_{16}N_2Cl_2Pd$: C, 24.55; H, 5.49; N, 9.54%. Found: C, 27.30; H, 5.92; N, 9.11%. Calcd for [$PdCl_2$(N^1,N^1-Et_2-(*S*)-pn)]=$C_7H_{18}N_2Cl_2Pd$: C, 27.34; H, 5.90; N, 9.11%.

(2) L=N,N-*Me_2en*, C,C-*Me_2en*, N,N,C,C-*Me_4en, and* N,N-*Me_2tn*: These complexes were obtained by a method similar to that for [$PdCl_2$(en)][9] as light orange to yellow crystals. Found: C, 18.01; H, 4.58; N, 10.56%. Calcd for [$PdCl_2$(*N,N*-Me_2en)]=$C_4H_{12}N_2Cl_2Pd$: C, 18.10; H, 4.56; N, 10.55%. Found: C, 18.09; H, 4.56; N, 10.65%. Calcd for [$PdCl_2$(*C,C*-Me_2en)]=$C_4H_{12}N_2Cl_2Pd$: C, 18.10; H, 4.56; N, 10.55%. Found: C, 23.06; H, 5.81; N, 8.97%. Calcd for [$PdCl_2$(*N,N,C,C*-Me_4en)]·H_2O=$C_6H_{18}N_2Cl_2OPd$: C, 23.13; H, 5.82; N, 8.99%. Found: C, 21.54; H, 5.07; N, 9.96%. Calcd for [$PdCl_2$(*N,N*-Me_2tn)]=$C_5H_{14}N_2Cl_2Pd$: C, 21.49; H, 5.05; N, 10.02%.

(3) L=meso-*stien*: When a methanol solution of *meso*-stien was mixed with an aqueous solution of K_2[$PdCl_4$] at *ca.* 60 °C (molar ratio 2 : 1), an ivory-colored insoluble precipitate was obtained. After two hours of heating and stirring, hydrochloric acid (equimolar with the *meso*-stien) was added to the mixture. The precipitate which had turned pale yellow was collected and washed with boiling water several times in order to remove *meso*-stien·2HCl (only slightly soluble). Found: C, 43.09; H, 4.15; N, 7.18%. Calcd for [$PdCl_2$(*meso*-stien)]=$C_{14}H_{16}N_2Cl_2Pd$: C, 43.16; H, 4.14; N, 7.19%.

[Pd(N)$_4$]-type Complexes. (1) [*Pd(*N,N-*Et_2en)(*meso-*stien)*]*(ClO_4)$_2$*: A hot methanol-solution (3 cm^3) containing 0.76 g of *meso*-stien was added (at *ca.* 55 °C) to an aqueous solution (30 cm^3) of [$PdCl_2$(*N,N*-Et_2en)] (1.05 g). The almost colorless solution was filtered and treated with an aqueous solution of sodium perchlorate (1.2 g), at *ca.* 50 °C with stirring. The desired complex precipitated during the course of addition of perchlorate drop by drop. The mixture was allowed to stand at room temperature and then in a refrigerator overnight. Very pale yellow crystals were collected, washed with water, and dried *in vacuo*. Yield: 2.0 g. This product is sparingly soluble in water, being more soluble in methanol. Found: C, 37.82; H, 5.12; N, 8.92%. Calcd for $C_{20}H_{32}N_4Cl_2O_8Pd$: C, 37.90; H, 5.09; N, 8.84%.

(2) [*Pd(*N^1,N^1-*Et_2-(S)-pn)(*meso-*stien)*]*(ClO_4)$_2$*: This was prepared by the same method as described in *(1)*. The crude product was purified by conversion into the corresponding chloride with an anion-exchange resin (Dowex 1×8, 200—400 mesh, Cl^- form) and then by reconversion into the perchlorate crystals. The yield was good. The product, labeled **2′**, is a mixture of *R*(*S*) and *S*(*S*) isomer, neither a pseudo racemate nor an equilibrium mixture. Found: C, 38.96; H, 5.35; N, 8.71%. Calcd for $C_{21}H_{34}N_4Cl_2O_8Pd$: C, 38.93; H, 5.29; N, 8.65%.

(3) [*Pd(*N,N-*Me_2en)(*meso-*stien)*]*(ClO_4)$_2$·H_2O*: To a suspension of [$PdCl_2$(*N,N*-Me_2en)] (1.00 g) in 35 cm^3 of water was added (at *ca.* 60 °C) 0.80 g of *meso*-stien dissolved in hot methanol (4 cm^3). When the mixture was stirred for a few minutes, the starting material was dissolved, the solution turning almost colorless. An aqueous solution of sodium perchlorate (1.2 g) was added to the filtered solution, at *ca.* 55 °C with stirring. The resulting cloudy solution was allowed to stand at room temperature for three hours, a powder product (very pale yellow; 0.82 g) being collected. The residual glassy solid adhering to the bottom of the beaker was dissolved again in the mother liquor at 70—75 °C, and the solution was allowed to stand at room temperature and then in a refrigerator overnight; an additional amount of the product was obtained (0.36 g). After removal of the potassium chloride by methanol extraction, further crops (0.52 and 0.31 g) were obtained from the mother liquor. Total yield: 2.01 g. The complex is more soluble in water and in methanol than the corresponding *N,N*-Et_2en complex. Found: C, 34.76; H, 4.83; N, 8.89%. Calcd for $C_{18}H_{30}N_4Cl_2O_9Pd$: C, 34.66; H, 4.85; N, 8.98%.

(4) [*Pd(*C,C-*Me_2en)(*meso-*stien)*]*(ClO_4)$_2$*: This was prepared by a method similar to that described in *(3)*, but is more difficult to crystallize. The yield was 1.63 g for 1.00 g of the starting material [$PdCl_2$(*C,C*-Me_2en)]. The solubility (in water and in methanol) is comparable to that of the corresponding *N,N*-Me_2en complex. Found: C, 35.67; H, 4.72; N, 9.22%. Calcd for $C_{18}H_{28}N_4Cl_2O_8Pd$: C, 35.69; H, 4.66; N, 9.25%.

(5) [*Pd(*N,N,C,C-*Me_4en)(*meso-*stien)*]*(ClO_4)$_2$*: This was obtained in the same way as described in *(3)*, and is more difficult to crystallize than the corresponding *C,C*-Me_2en complex. It tended to disproportionate to [Pd(*N,N,C,C*-Me_4en)$_2$]$^{2+}$ and [Pd(*meso*-stien)$_2$]$^{2+}$ during the course of preparation. The yield was 1.63 g for 1.30 g of the starting material [$PdCl_2$(*N,N,C,C*-Me_4en)]. Found: C, 38.09; H, 5.11; N, 8.77%. Calcd for $C_{20}H_{32}N_4Cl_2O_8Pd$: C, 37.90; H, 5.09; N, 8.84%.

(6) [*Pd(*N,N-*Me_2tn)(*meso-*stien)*]*(ClO_4)$_2$·0.5H_2O*: A methanol solution (3 cm^3) containing 0.26 g of *N,N*-Me_2tn was added to 0.985 g of [$PdCl_2$(*meso*-stien)] suspended in a water (23 cm^3)–methanol (7 cm^3) mixture. After the reaction mixture had been stirred at *ca.* 50 °C for 1.5 h, undissolved material was filtered off. The filtrate was treated with an aqueous solution of sodium perchlorate (0.80 g), and evaporated under reduced pressure to give a sirup. The sodium chloride was removed by extracting the complex with methanol, *ca.* 25 cm^3 of water being added to the extract (*ca.* 15 cm^3). The warmed mixture was allowed to stand at room temperature. The desired product was obtained as pale yellow needles (1.00 g). Total yield was 1.18 g, including another crop from the mother liquor. Found: C, 36.17; H, 4.99; N, 8.83%. Calcd for $C_{19}H_{31}N_4Cl_2O_{8.5}Pd$: C, 36.29; H, 4.97; N, 8.91%.

The anhydrous salt, [Pd(*N,N*-Me_2tn)(*meso*-stien)](ClO_4)$_2$ (pale yellow blocks), was also obtained by using [$PdCl_2$(*N,N*-Me_2tn)] as a starting material, the yield being low. Found: C, 36.91; H, 4.89; N, 8.96%. Calcd for $C_{19}H_{30}N_4Cl_2O_8Pd$: C, 36.82; H, 4.88; N, 9.04%.

(7) [*Pd(*N^1,N^1-*Et_2-(S)-pn)(en)*]Cl_2·H_2O (**7**): An aqueous solution containing 0.12 g of ethylenediamine was added at *ca.* 65 °C to 0.61 g of [$PdCl_2$(N^1,N^1-Et_2-(*S*)-pn)] suspended in 16 cm^3 of water. The reaction was fast. The almost colorless solution was filtered and evaporated under reduced pressure. The resulting sirup was dissolved in a small amount of ethanol and mixed with 15 cm^3 of acetone. The mixture was cooled in a refrigerator overnight to give very pale yellow needles. Yield: 0.60 g. The compound can be recrystallized from 95% ethanol by adding acetone, when necessary. Found: C, 28.02; H, 7.25; N, 14.63%. Calcd for $C_9H_{28}N_4Cl_2OPd$: C, 28.03; H, 7.32; N, 14.53%.

Optical Resolution and Separation. The diacetyl-*d*-tartrate

salts of all the configurationally chiral complexes were obtained as a sirup as follows.

General Procedure: A suspension of racemic perchlorate salt[10] (1.80 mmol) in 50 cm³ of water was stirred with an anion-exchange resin (Dowex 1×8, 200—400 mesh, Cl^- form) for one hour. After removal of the resin the reaction mixture was treated with silver carbonate (2.0 mmol) at room temperature for two hours in the dark. The silver chloride was filtered off and diacetyl-*d*-tartaric anhydride (1.75 mmol) was dissolved in the filtrate. The solution was evaporated under reduced pressure to give a sirup.

The subsequent procedure for individual complexes is as follows.

(1) $(+)^{CD}_{220}$-[*Pd*(N,N-*Et*$_2$*en*)(meso-*stien*)]$(ClO_4)_2$ (**1**): The sirup obtained by the general procedure was dissolved in methanol (6 cm³) and mixed with 20 cm³ of acetone. Almost white powder was deposited on scratching the wall of the beaker. It was collected and recrystallized twice from 90% methanol by adding acetone. An additional amount of the product was obtained from the mother liquor and repeatedly recrystallized. A high yield (91% based on the half of the racemate) was attained in total because of the moderately fast shift of the equilibrium ($R \rightleftharpoons S$) in the mother liquor. Found: C, 48.84; H, 6.18; N, 8.13%. Calcd for $(+)^{CD}_{220}$-[Pd(*N*,*N*-Et_2en)(*meso*-stien)](diac-*d*-tart)·H_2O[11] = $C_{28}H_{42}N_4O_9Pd$: C, 49.09; H, 6.18; N, 8.18%. The less-soluble diastereomer (0.18 g) was dissolved in 7 cm³ of water and treated with an aqueous solution (2 cm³) of sodium perchlorate (0.09 g). Very pale yellow crystals were collected after several hours, washed with water, and dried *in vacuo*. Yield: 0.135 g. Found: C, 37.93; H, 5.10; N, 8.84%. Calcd for $C_{20}H_{32}N_4Cl_2O_8Pd$: C, 37.90; H, 5.09; N, 8.84%.

(2) $(+)^{CD}_{220}$-[*Pd*(N^1,N^1-*Et*$_2$-(S)-*pn*)(meso-*stien*)]$(ClO_4)_2$ (**2**): The sirup obtained by the general procedure was crystallized from a 90% ethanol–acetone (2 : 1) mixture, giving a crude less-soluble diastereomer (diac-*d*-tart salt), which was recrystallized three times from 90% ethanol by adding acetone. Found: C, 48.38; H, 6.29; N, 7.79%. Calcd for $(+)^{CD}_{220}$-[Pd(*N*^{1},*N*^{1}-Et_2-(*S*)-pn)(*meso*-stien)](diac-*d*-tart)·$2H_2O$ = $C_{29}H_{46}N_4O_{10}Pd$: C, 48.57; H, 6.47; N, 7.81%. The resolving agent was removed by the same method as described in *(1)*. Found: C, 38.92; H, 5.29; N, 8.65%. Calcd for $C_{21}H_{34}N_4Cl_2O_8Pd$: C, 38.93; H, 5.29; N, 8.65%.

(3) $(+)^{CD}_{220}$-[*Pd*(N,N-*Me*$_2$*en*)(meso-*stien*)]$(ClO_4)_2 \cdot 0.5H_2O$ (**3**): A crude less-soluble diastereomer (diac-*d*-tart salt) was obtained from the corresponding sirup in the same manner as described in *(2)* and recrystallized twice from the same solvent as in *(1)*. Found: C, 47.66; H, 5.68; N, 8.48%. Calcd for $(+)^{CD}_{220}$-[Pd(*N*,*N*-Me_2en)(*meso*-stien)](diac-*d*-tart)·H_2O = $C_{26}H_{38}N_4O_9Pd$: C, 47.53; H, 5.83; N, 8.53%. The compound free from the resolving agent was obtained by the same method as in *(1)* but from a more concentrated solution. Found: C, 35.06; H, 4.63; N, 9.13%. Calcd for $C_{18}H_{29}N_4Cl_2O_{8.5}Pd$: C, 35.17; H, 4.75; N, 9.11%.

(4) $(-)^{CD}_{220}$-[*Pd*(C,C-*Me*$_2$*en*)(meso-*stien*)]$(ClO_4)_2 \cdot H_2O$ (**4**): A less-soluble diastereomer (diac-*d*-tart salt) was obtained by the method of Lidstone and Mills[3] with a slight modification. At first almost racemic[12] diacetyl-*d*-tartrate salt was obtained from the corresponding sirup in 95% ethanol by scratching the wall of the beaker, and recrystallized several times from the minimum quantity of water by adding ethanol, giving the corresponding optically pure salt. Found: C, 45.79; H, 6.23; N, 7.91%. Calcd for $(-)^{CD}_{220}$-[Pd(*C*,*C*-Me_2en)(*meso*-stien)](diac-*d*-tart)·$3H_2O$ = $C_{26}H_{42}N_4O_{11}Pd$: C, 45.06; H, 6.11; N, 8.08%. The resolving agent was removed by the same method as in *(3)*. Found: C, 34.67; H, 4.82; N, 9.02%. Calcd for $C_{18}H_{30}N_4Cl_2O_9Pd$: C, 34.66; H, 4.85; N, 8.98%.

(5) $(+)^{CD}_{220}$-[*Pd*(N,N,C,C-*Me*$_4$*en*)(meso-*stien*)]$(ClO_4)_2 \cdot H_2O$ (**5**): The sirup obtained by the general procedure was crystallized from a water–ethanol–acetone (1 : 3 : 14) mixture, giving a less-soluble diastereomer (diac-*d*-tart salt). Recrystallization was carried out four times from water by adding an ethanol–acetone (1 : 2) mixture. Found: C, 47.68; H, 6.48; N, 7.58%. Calcd for $(+)^{CD}_{220}$-[Pd(*N*,*N*,*C*,*C*-Me_4en)(*meso*-stien)](diac-*d*-tart)·$3H_2O$ = $C_{28}H_{46}N_4O_{11}Pd$: C, 46.64; H, 6.43; N, 7.77%. The product free from the resolving agent was obtained by the same method as in *(3)* but in water–methanol. Found: C, 37.06; H, 5.14; N, 8.59%. Calcd for $C_{20}H_{34}N_4Cl_2O_9Pd$: C, 36.85; H, 5.26; N, 8.60%.

(6) $(-)^{CD}_{220}$-[*Pd*(N,N-*Me*$_2$*tn*)(meso-*stien*)]Cl_2 *Solution* (**6**): A crude less-soluble diastereomer (diac-*d*-tart salt) was obtained from the corresponding sirup in a 90% ethanol–acetone (4 : 5) mixture, and recrystallized four times from the same solvent as described in *(5)*. Found: C, 49.47; H, 5.86; N, 8.56%. Calcd for $(-)^{CD}_{220}$-[Pd(*N*,*N*-Me_2tn)(*meso*-stien)](diac-*d*-tart) = $C_{27}H_{38}N_4O_8Pd$: C, 49.66; H, 5.87; N, 8.58%. No corresponding optically active perchlorate salt was obtained by a method similar to that for **1**, **3**, or **5**; the diastereomer was converted into the corresponding optically active chloride with a column containing an anion-exchange resin (Dowex 1×8, 200—400 mesh, Cl^- form). The CD spectrum of this complex was measured with the eluate, the concentration being calculated from the molar absorption coefficient of the corresponding racemic perchlorate.

Measurements. Electronic absorption spectra were recorded with a Hitachi 330 spectrophotometer and CD spectra with a JASCO MOE-1 spectropolarimeter. All the measurements were made in aqueous solutions at room temperature, except the electronic absorption spectrum of *meso*-stien measured in methanol and a water–methanol (9 : 1) mixture. A 10-cm cell was employed for the CD measurements in the long wavelength region. No spectral change was observed during the course of measurements.

Results and Discussion

Absolute Configuration. The enantiomeric configurations are denoted by *R* and *S* (Fig. 1) from analogy with the axial chirality[13] of organic compounds. The absorption spectrum of **2** is almost identical with that of **1** (Table 2 and Fig. 2). Both these optically pure complexes were derived from the less-soluble diastereomers. The CD spectra of both **1** and **2** contain a configurational contribution; in addition that of **2** contains the vicinal contribution due to the asymmetric carbon atom. Assuming the additivity of the configurational and vicinal contributions, a calculated vicinal CD curve can be obtained by subtracting the CD of **1** from that of **2**. The same configurational chirality of **1** and **2** was also assumed in the calculation, and justified by comparing the calculated vicinal CD with the CD spectrum of **7** containing the same asymmetric carbon atom as in **2** (Fig. 3); these two curves are of a similar pattern to each other, differing slightly in intensity.

The spectrum of **2′**[14] recorded immediately after dissolution can be reproduced by adding 0.25 part of the CD of **1** to the calculated vicinal CD of **2** (Fig. 4); this demonstrates the additivity of the configurational and vicinal CD. The CD spectrum of **2′** (*ca.* 10^{-3} mol dm^{-3}, in water) became constant in about five days at *ca.* 17 °C, indicating that the solution attained

equilibrium. However, the CD spectrum could not be accurately measured in the region of wavelengths shorter than 250 nm because of the low intensity. This can be expained by the cancellation between the vicinal and the increasing configurational CD contribution. The CD additivity, therefore, was examined with the solution of **2′** immediately after dissolution over the range 500—200 nm. The configuration of the predominant isomer both in solid **2′** and in the equilibrium mixture is found to be the same as the absolute configuration of **1** from a comparison of the configurational CD. The abundance of the diastereomers in **2′** was estimated on the basis of CD additivity as follows: *R*(*S*), 62.5 and *S*(*S*), 37.5%[15] immediately after dissolution; *R*(*S*), 67.5 and *S*(*S*), 32.5% at equilibrium. The abundance at equilibrium was evaluated from $\Delta\varepsilon_{ext}$ at about 35000 cm^{-1}.

The absolute configuration predominating in aqueous solutions can be assigned by considering the steric

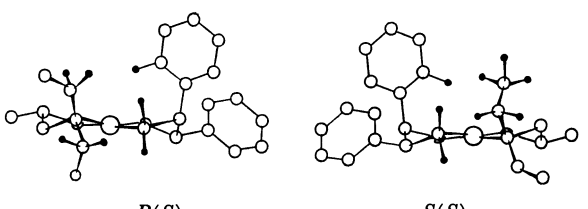

Fig. 5. A pair of diastereomers of [Pd(N^1,N^1-Et_2-(*S*)-pn)-(*meso*-stien)]$^{2+}$. Hydrogen atoms which are less concerned with the steric repulsions are omitted; one of two possible conformations of *meso*-stien is shown.

repulsions between the phenyl groups on *meso*-stien and one of the ethyl groups on N^1,N^1-Et_2-(*S*)-pn (Fig. 5). The ligand N^1,N^1-Et_2-(*S*)-pn is likely to be in almost pure δ-form, because of the repulsion between the *C*(*S*)-methyl and one of the two *N*-ethyl groups. As a result, the orientations of the two *N*-ethyl groups might be restricted. The steric interactions between the *N*-ethyl and the two phenyl groups should differ between the *R*(*S*) and the *S*(*S*) isomer. Thus, the repulsive interaction in *R* configuration is concluded to be smaller than that in *S*, and the predominant configuration in solid **2'** and in the equilibrium mixture can be assigned to *R*; consequently complex **1** has *R* configuration.

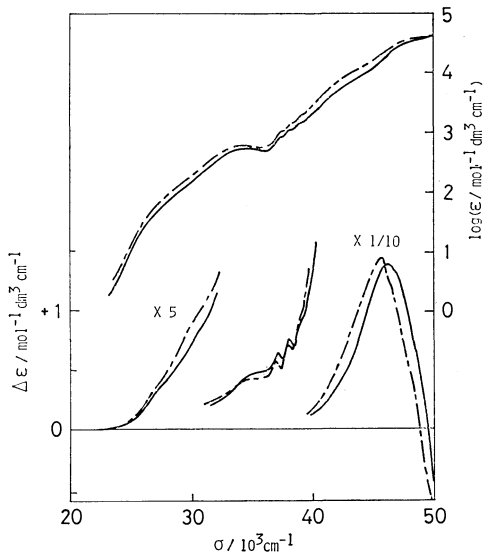

Fig. 6. Absorption and CD spectra of $(+)^{CD}_{220}$-[Pd(*N*,*N*-Me_2en)(*meso*-stien)]$^{2+}$, **3** (——) and $(+)^{CD}_{220}$-[Pd(*N*,*N*,*C*,*C*-Me_4en)(*meso*-stien)]$^{2+}$, **5** (—·—).

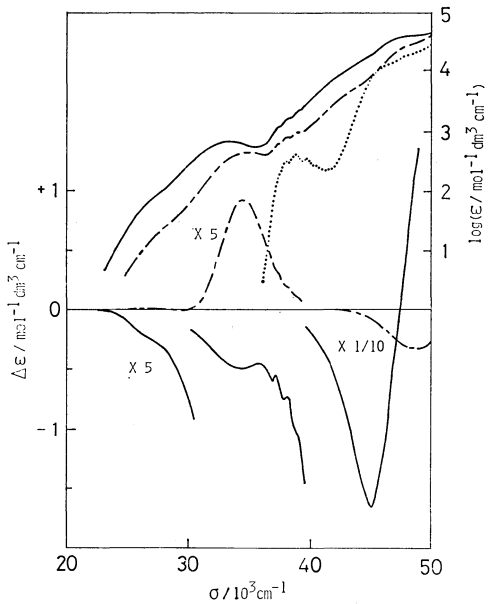

Fig. 7. Absorption and CD spectra of $(-)^{CD}_{220}$-[Pd(*C*,*C*-Me_2en)(*meso*-stien)]$^{2+}$, **4** (— — —) and $(-)^{CD}_{220}$-[Pd(*N*,*N*-Me_2tn)(*meso*-stien)]$^{2+}$, **6** (——); absorption spectrum of *meso*-stien in methanol (……).

The absolute configuration of **3** is easily assigned to *R* by comparing its CD curve with that of **1**; both CD patterns are very similar to each other throughout the range 500—200 nm, though the CD intensity is somewhat different (Figs. 2 and 6). However, the absolute configuration of **4** cannot be easily determined. The sign of the major CD band in the region of spin-allowed d-d transitions is the same as that for **1** or **3**, whereas the sign of the band at *ca.* 49000 cm^{-1} is opposite (Figs. 2, 6, and 7). In order to solve this problem complex **5** was prepared. The ligand *N*,*N*,*C*,*C*-Me_4en has four methyl substituents: two on a nitrogen, the other two on the carbon adjacent to the nitrogen atom (Table 1). From the fact complex **4** displays remarkably weak CD in comparison with **3**, the CD pattern of **5** is expected to be similar to that of **3**. Figure 6 shows the *R* configuration of **5**, indicating the validity of the expectation. The small deviation (from the CD curve of **3**) associated with the introduction of the *C*-methyl groups is considered to have a pattern similar to that of the CD spectrum of *R*-[Pd(*C*,*C*-Me_2en)(*meso*-stien)]$^{2+}$. Upon comparing the CD curves of **3** and **5**, the difference between their ligand-field-strengths should be taken into account. Quantitative estimation of the difference is not only difficult but also unnecessary. It is approximated by the energy difference in the d-d absorption maxima. In practice, the CD curve of **3** (27000—37000 cm^{-1}) is displaced to the side of lower energies by the difference (240 cm^{-1}) and then compared with the intact CD curve of **5** (Fig. 8). The positive (*ca.* 30000 cm^{-1}) and the negative (*ca.* 35000 cm^{-1}) deviation of the CD curve of **5** from that of **3** are visualized; the sign pattern is opposite that of the CD spectrum of **4** in the region. It is concluded that complex **4** has *S* configuration.

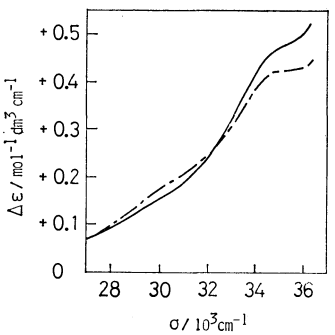

Fig. 8. CD curve of **3**, shifted by 240 cm^{-1} to the side of lower energies (——) and intact CD curve of **5** (—·—).

Complex **6** was similarly derived from the corresponding less-soluble diastereomer using the same resolving agent as used for **1**—**5**. The entire CD pattern, however, is enantiomeric to those of **1**, **3**, and **5**. No marked change is found in the CD pattern with increase in chelate-ring size (Figs. 6 and 7); we conclude that complex **6** has *S* configuration. The absolute configuration of the above six complexes are given in Table 3. The results can be summarized as follows: Positive sign of the first CD band in the region of wave numbers larger than 40000 cm^{-1} indicates *R* configuration.

CD and Absorption Spectra. Absorption and CD data of the complexes are given in Tables 2 and 3, respectively, those concerning π-π^* intraligand transitions in Table 4. The complexes generally exhibit four configurational-CD bands (27000, 30000, 35000, and beyond 45000 cm^{-1}) within the range 20000—50000 cm^{-1}. The CD pattern of the complexes with *N*-alkyl substituents, however, is different from that for the *C*-alkyl analog. In the former complexes all of the four bands have the same sign (*i.e.*, plus for *R* isomer), whereas in the latter the sign pattern is −, +, −, and + (from the side of smaller wave numbers) for *R* isomer. For all of these complexes, the first band is assigned to a spin-forbidden d-d transition and the second and third to spin-allowed d-d transitions. The last band should be assigned to either d-p transition or nitrogen-σ-to-metal-d charge-transfer transition.

In the present series of complexes, h-type ligands were varied with the v-type ligand unchanged; the relative intensity of configurational CD varied in the following order: N,N-Et$_2$en > N,N-Me$_2$tn > N,N-Me$_2$en > C,C-Me$_2$en. This result indicates three factors determining the intensity, the size of alkyl substituent, the location of alkyl substituent and the size of chelate ring: (1) The CD intensity increases with increasing bulkiness of substituents. (2) Alkyl groups on the nitrogen atom cause CD intensity higher than those on the carbon atom. (3) The increase in chelate-ring size from five to six is accompanied by an increase in the CD intensity. The finding (1) can be explained in terms

a) sh: shoulder. b) log (ε_{max}/mol^{-1} dm^3 cm^{-1}).

of the symmetry of complex cations. Although the present complexes have a square-planar coordination geometry around the central metal ion, the distribution of the peripheral substituents can be regarded as a tetrahedron: $Pd(\overline{Ph_2})(\overline{H_2})(\overline{NR_2})(\overline{NH_2})$ (Fig. 1). Thus the configurational-CD intensity increases with the bulkiness of R. Care should be taken for simultaneous operations of the factors producing mutually opposite CD signs. For example, complex **5** has a larger degree of the pseudo-tetrahedral chirality than **3**, but it exhibits a smaller CD intensity than the latter in *ca.* 34000—38500 cm^{-1}. This can be attributed to the *C*-methyl and *N*-methyl groups contributing to opposite CD signs in the region.

The CD intensity in the region of π-π^* intraligand transitions seems to depend upon another factor. The CD intensity of *C*-alkyl-substituted complex **4** considerably differs from those of the *N*-alkyl analogs **1**, **3**, and **6**. The former complex shows only very weak CD bands (shoulders) in the 36000—40000 cm^{-1} region, whereas the latter complexes show rather strong bands (Figs. 2, 6, and 7; Table 4). These bands have been assigned to α-bands[16] relating to the π-π^* transitions. The *N*-alkyl-substituted complexes give additional CD bands assigned to *p*-bands[16] in the 45000—49000 cm^{-1} region as very weak shoulders. In these complexes, the two phenyl groups are expected to interact with the *N*-alkyl group in a different way. It seems that the disposition of the two phenyl groups acquires a chirality, giving a strong CD in the region of the π-π^* intraligand transitions. For the *C*-methyl-substituted complex, however, no such a chirality around the two phenyl groups is expected since the *C*-methyl groups are remote from both phenyl groups; therefore complex **4** should exhibit only weak π-π^* CD as actually observed.

The vicinal CD due to the asymmetric carbon atom comprises four bands, as well as the configurational CD, in the range 20000—50000 cm^{-1}, but the band assignments in the two cases slightly differ. The weak CD bands at *ca.* 24500 and 28200 cm^{-1} and the strong band at 34800 cm^{-1} of complex **7** can be assigned to the spin-forbidden and -allowed d-d transitions, respectively, by comparing their positions with those of the corresponding absorption bands. Another CD band at 49000 cm^{-1}, which corresponds to the absorption peak at 49900 cm^{-1}, should be assigned to either d-p transition or nitrogen-σ-to-metal-d charge-transfer transition. The intensity of this CD band is significantly smaller than that of the corresponding bands in the configurational CD. This is fortunate in the assignment of absolute configuration for the complexes with asymmetric carbon atoms, such as **2**.

The absorption spectra apparently consist of three bands except those due to the π-π^* intraligand transitions. A shoulder at 28000—29000 cm^{-1} and a peak at 33500—35000 cm^{-1} can be assigned to the spin-forbidden and -allowed d-d transitions, respectively (Table 2). A bulge at *ca.* 45000 cm^{-1} is considered to be an apparent shoulder produced by the overlap of the *p*-bands with the band which has the same origin as the 49900 cm^{-1} band of **7**. In the absorption spectra of the present series of complexes the α-bands shift only slightly to lower energies and the *p*-bands by about 2000 cm^{-1} to higher energies than the absorption bands of *meso*-stien in a methanol solution[17] (Fig. 7). The bands in a water–methanol (9 : 1) mixture appear at almost the same places as in methanol. It is thus concluded that the shifts are caused by coordination and not by a solvent effect.

Binuclear Metal Complexes. XXXVII.[1] Crystal and Molecular Structure of a Binuclear Manganese(III) Complex Bridged by Two Alkoxo Oxygens and Two Bidentate Acetate Ions

Masahiro MIKURIYA, Naoyuki TORIHARA, Hisashi OKAWA, and Sigeo KIDA*

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received September 16, 1980)

The crystal structure of binuclear manganese(III) complex, Mn(spa)(ac) (H_2spa=3-salicylideneamino-1-propanol, ac=acetate), was determined by the single-crystal X-ray diffraction method. The crystals are triclinic, space group $P\bar{1}$, $a=8.804(3)$, $b=9.376(3)$, $c=8.671(3)$ Å, $\alpha=111.24(3)$, $\beta=101.34(3)$, $\gamma=65.00(3)°$, and $Z=1$. The structure was solved by the heavy atom method and refined by the block-diagonal least-squares method to an R factor of 0.034. The crystal structure consists of discrete binuclear clusters, where the two manganese atoms are bridged by two alkoxo oxygens of the spa ligands and two bidentate acetate ions. The structural detail is in conformity with the magnetic and spectral properties previously reported.

The chemistry of binuclear manganese(III) and manganese(IV) complexes is of importance in connection with the metalloenzymes in biological systems.[2,3] However, X-ray structural investigations on binuclear manganese complexes are very limited.[4-6]

In the previous paper of this series, we reported the synthesis and magnetic property of binuclear manganese(III) complexes with 3-salicylideneamino-1-propanol and its homologues, MnL(ac) and MnLX·H_2O (L=Schiff base dianion; ac=acetate ion; X=Cl, Br, N_3).[7] The temperature dependence of their magnetic susceptibilities (80—300 K) could be well interpreted in terms of the Van Vleck equation for the high-spin d^4-d^4 system based on the Heisenberg model, $\mathcal{H}=-2JS_1\cdot S_2$ ($J=-13.5$——20.4 cm^{-1}). Thus, it was thought that they possess a discrete binuclear structure in which an antiferromagnetic spin-exchange interaction is operating between a pair of manganese(III) ions. Based on the infrared and electronic spectral data, it was proposed that the binuclear complexes, MnL(ac) and MnLX·H_2O, are both bridged by an alcoholic oxygen. The antisymmetric and symmetric C–O stretching frequencies of the acetate group in the MnL(ac) led us to the conclusion that the acetate groups also bridge the two manganese(III) ions (Fig. 1). The binuclear structure consisting of two monatomic and two triatomic bridges as supposed for MnL(ac) is quite rare. Although such a mode of bridging has been observed for α-di-μ-hydroxo-bis[2-(2-dimethylaminoethyl)pyridine]dicopper(II) perchlorate,[8] to our knowledge it has not yet been documented in carboxylate chemistry. In order to confirm the bridging mode we have determined the crystal structure of Mn(spa)(ac) (H_2spa=3-salicylideneamino-1-propanol) by the single-crystal X-ray diffraction method.

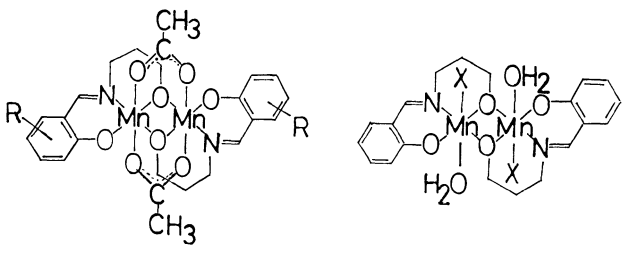

Fig. 1. Structures of MnL(ac) and MnLX·H_2O.

Experimental

Greenish black crystals of Mn(spa)(ac) were prepared by the method previously reported.[7] A crystal with dimensions of $0.23\times0.25\times0.50$ mm was used for the X-ray analysis. Preliminary Weissenberg photographs revealed no systematic absences and showed the triclinic symmetry. The cell parameters and intensities were measured on a Rigaku AFC-5 automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation ($\lambda=0.71069$ Å).

Crystal data: $C_{24}H_{28}N_2O_8Mn_2$, F.W.=582.37, triclinic, $P\bar{1}$, $a=8.804$ (3), $b=9.376$ (3), $c=8.671$ (3) Å, $\alpha=111.24$ (3), $\beta=101.34$ (3), $\gamma=65.00$ (3)°, $D_m=1.59$ (by floatation in n-C_6H_{14}–CCl_4), $D_c=1.60$ gcm^{-3}, $Z=1$, μ(Mo $K\alpha$)=10.5 cm^{-1}.

Intensity data were collected by the 2θ-ω scan technique with a scan rate of 8 °min^{-1}. For weak reflections the peak scan was repeated up to four times depending on their intensities. The intensities of three standard reflections monitored every 100 reflections showed a good stability. A total of 2784 reflections with $2\theta<55°$ were collected. The intensity data were corrected for the Lorentz and the polarization effects, but not for absorption. 2614 Independent reflections with $|F_o|>3\sigma(|F_o|)$ were considered as "observed" and were used for the structure analysis.

Structure Determination and Refinement

The structure was solved by the heavy atom method. Of the two possible space groups, the centrosymmetric space group $P\bar{1}$ was assumed. Successful solution and refinement support this choice. The position of the manganese atom was obtained from a three-dimensional Patterson synthesis. Successive Fourier synthesis revealed all the nonhydrogen atoms. Refinement was carried out by the block-diagonal least-squares method. Anisotropic thermal parameters being introduced, the least-squares refinement yielded discrepancy factors $R_1=\sum||F_o|-|F_c||/\sum|F_o|=0.047$ and $R_2=[\sum\omega(|F_o|-|F_c|)^2/\sum\omega|F_o|^2]^{1/2}=0.075$. All the hydrogen atoms were located from the subsequent difference Fourier map. Further refinement with anisotropic thermal parameters for nonhydrogen atoms and isotropic temperature factors for hydrogen atoms gave final values of 0.034 and 0.052 for R_1 and R_2, respectively. In the least-squares refinement the function minimized was $\sum w(|F_o|-k|F_c|)^2$, where $w=(2.0+|F_o|+$

$0.016|F_o|^2)^{-1}$.[9] The final shifts in the atomic parameters of the nonhydrogen atoms were less than 0.13σ. The final difference Fourier synthesis showed no peaks higher than 0.77 e/Å^3.

The atomic scattering factors for Mn, O, N, C_{val}, and H and the anomalous dispersion corrections, $\Delta f'$ and $\Delta f''$ for Mn, were taken from the International Tables for X-Ray Crystallography.[10] All the calculations were carried out on the FACOM M-200 computer in the Computer Center of Kyushu University by the use of a local version[11] of the UNICS-II[12] and the ORTEP[13] programs.

The final positional and thermal parameters with their estimated standard deviations are given in Tables 1 and 2.***

*** Lists of structure factors and anisotropic thermal parameters have been deposited with the Chemical Society of Japan as a Document No. 8123.

Results and Discussion

The molecular structure is shown in Fig. 2. The bond distances and angles with their estimated standard deviations are listed in Table 3. Some least-squares planes with the deviations of atoms from the planes are given in Table 4.

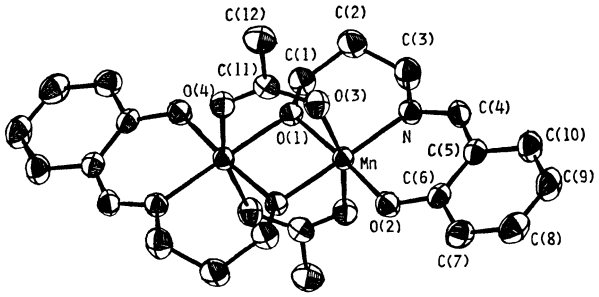

Fig. 2. Molecular Structure of Mn(spa)(ac) with thermal ellipsoids (50% probability level).

The crystal structure consists of discrete binuclear clusters, the closest intercluster contact being O(4)–C(9) (3.279(3) Å). Therefore, the binuclear clusters must be considered to be magnetically isolated. This is in harmony with the result of our magnetic investigation of MnL(ac).[7] The manganese atoms are bridged by the alcoholic oxygens. For the binuclear complexes with 3-salicylideneamino-1-propanol, alcoholic oxygen-bridged and phenolic oxygen-bridged binuclear structures are known.[14–27] As stated above, the infrared spectra of MnL(ac) and $MnLX\cdot H_2O$ suggest the alcoholic oxygen-bridged binuclear structures,[7] and this has been confirmed by the present X-ray structure analysis.

The coordination geometry around the manganese atom is an elongated octahedron. The approximate square plane involving the manganese atom at its center is formed by two alcoholic oxygen, imino nitrogen and phenolic oxygen atoms of the spa ligands (Table 4). The Mn–O(1) (1.899(2) Å), Mn–O(1)^i (1.951(2) Å), Mn–O(2) (1.849(2) Å) and Mn–N (2.006(2) Å) distances are normal for the in-plane bonds of manganese(III) complex.[4,6,28] The bond angles around the manganese atom vary from 82 to 97°. The axial Mn–O distances (2.208(2), 2.251(2) Å) are considerably longer than the in-plane Mn–O distances. Thus the coordination geometry around the manganese atom evidently deviates from a regular octahedron and this tetragonal elongation is attributable to the Jahn-Teller effect. Therefore, the ground ^5E_g and the excited $^5T_{2g}$ states for octahedral manganese(III) should split into sublevels. In fact, the diffuse reflectance spectrum of Mn(spa)(ac) shows d-d bands at 13000, 16400, 21200, and 22200 cm^{-1}.[7]

The four-membered Mn_2O_2 ring is exactly planar owing to the presence of an inversion center. The carbon atom, C(1), attatched to the bridging oxygen, O(1), deviates significantly from the plane of the four-membered Mn_2O_2 ring (Table 4). Each bond length in the spa ligand has a normal value.[29] The spa moiety

a) The equation of the plane is expressed as $LX+MY+NZ=D$, where X, Y, and Z are in Å units referred to the crystallographic axes.
b) Deviations (l/Å) of atoms from the planes are listed in square brackets. Superscript (i) refers to the equivalent position $(-x, -y, -z)$.

forms two six-membered chelate rings with the manganese atom. The Mn–O(1)–C(1)–C(2)–C(3)–N chelate ring has a chair conformation, and Mn and C(2) are located 0.426 Å below and 0.680 Å above the plane defined by O(1), C(1), C(3) and N, respectively. On the other hand, the Mn–N–C(4)–C(5)–C(6)–O(2) chelate ring is nearly planar, the maximum deviation from the least-squares plane being 0.113 Å.

As was predicted,[7] the acetate groups are involved in the bridges in a syn-syn configuration. The acetate group is positioned above or below the Schiff base dimeric unit. The only example of two-acetate bridging in a similar fashion is found in di-μ-acetato-bis(diphenyltin), $Sn(Ph)_2(ac)$.[30] However, this complex is different from Mn(spa)(ac) in having a direct Sn–Sn bond and no monatomic bridging. Thus, the present complex, Mn(spa)(ac), including two monatomic and two triatomic bridges is unique in this regard. The manganese-carboxyl oxygen bonds deviate in several degrees from the axis perpendicular to the equatorial plane (Fig. 2), the O(3)–Mn–$O(4)^i$ bond angle being 164.00(5)°. This is due to the fact that the acetate bite (the O(3)–O(4) distance, 2.250(2) Å) is much less than the manganese-manganese distance (2.869(1) Å). The C(11)–O(3) and C(11)–O(4) distances are equal within experimental error. The $\begin{matrix}O\\O\end{matrix}\!>\!C-C$ plane retains its planarity (Table 4). Such planarity was also observed for dimeric copper(II) carboxylates.[31–36]

The authors wish to express sincere thanks to Professors Ikuhiko Ueda and Shigeaki Kawano of Kyushu University for their helpful advices and discussions. They are also grateful to Dr. Yuzo Nishida of Kyushu University for the help in data collection.

Study of the Mixed Ligand Complexes of Heavy Rare Earth Elements by Electromigration

Emiko Ohyoshi

Yatsushiro College of Technology, 2627, Hirayamashinmachi, Yatsushiro 866

(Received May 6, 1980)

The formation of the mixed ligand complexes of heavy rare earth elements with α-hydroxyisobutyric acid (AHIB or HA) and nitrilotriacetic acid (NTA or H_3L) was studied by electromigration. The equations expressing the zone mobility as a function of the concentrations of the two ligands were derived with or without the mixed ligand complexes, MLA^-. The experimental results showed that the MLA^- complexes were formed. The formation constants for the Tb(III), Dy(III), Ho(III), Er(III), Tm(III), Yb(III), and Lu(III) complexes were determined. The results obtained by using the two series of solutions, with varying $[L^{3-}]$ at a constant $[A^-]$ and with varying $[A^-]$ at a constant $[L^{3-}]$, were in good agreement. The stability trend was in an ordinary decreasing sequence of: Lu>Yb>Tm>Er>Ho>Dy>Tb.

The separation factor, the difference in the zone mobilities of two adjacent rare earth elements, is enhanced by the consecutive formation of complexes, ML_n.[1] This enhancement becomes more appreciable the closer the first and the second formation constants are to each other. This means that when various species, such as M, ML, and ML_2, are coexisting, more effective separation can be expected. If some mixed ligand complexes, such as MLA, were to be formed with another ligand A other than the binary complexes, ML_n, separation would be more improved. Therefore, it seems that a system containing two different ligands is more favorable for separating heavy rare earth elements than the conventional system. In this case, however, it is assumed that the formation constants of the mixed ligand complexes increase with increasing atomic number as observed in the case of the binary complexes, ML_n. To justify this assumption, it is necessary to obtain the data on the formation of the mixed ligand complexes of the heavy rare earth elements.

This work includes the results of a study on the mixed ligand complexes of the heavy rare earth elements with AHIB and NTA by paper electromigration.

Experimental

All chemicals used were of G.R. grade. The rare earth nitrate solutions of 2.0×10^{-2} mol dm^{-3} were prepared by dissolving the respective oxides in nitric acid. Mixed sample solutions of Tb(III), Dy(III), Er(III), and Yb(III), and of Tb(III), Ho(III), Tm(III) and Lu(III) at the same concentration of 1.5×10^{-4} mol dm^{-3} (pH≈1) were prepared. The other solutions were prepared as follows. Either AHIB(HA) or NTA (H_3L) was dissolved in chloroacetate buffer solution of pH 2.0 to give a concentration from 0.1 to 1.0 mol dm^{-3} or 10^{-3} to 10^{-2} mol dm^{-3}, respectively. By using the acid dissociation constants of AHIB[2] ($pK_{HA}=3.79$) and NTA[3] ($pK_{H_3L}=1.75$, $pK_{H_2L^-}=2.47$ and $pK_{HL^{2-}}=9.71$), the ligand ion concentrations are calculated to be $1.33-13.3\times10^{-3}$ mol dm^{-3} (A^-) and $2.33—23.3\times10^{-12}$ mol dm^{-3} (L^{3-}). The zone mobilities calculated by using these values of $[A^-]$ and $[L^{3-}]$ were found to agree well with the observed ones. In these concentration ranges, successive formation of the AHIB complexes proceeds, while that of the NTA complexes does not. The final ionic strength was adjusted to 0.1 with sodium chloride. In NaCl solution of 0.1 mol dm^{-3}, no appreciable complex formation of rare earth elements with chloride was observed.

Paper electromigration was carried out as described previously.[4]

Results and Discussion

The Effect of Two Ligands on the Zone Mobility of the Heavy Rare Earth Elements. At first, the experiment was carried out by using AHIB and NTA separately; the results are shown in Figs. 1a(AHIB) and 1b(NTA). In the ligand concentration ranges used here, the predominant complex species formed with NTA is ML, that is, the range of $[L^{3-}]$ is too low to form the ML_2 complex. On the other hand, various forms of complexes (MA^{2+}, MA_2^+, MA_3, and MA_4^-) are formed with increasing concentration of AHIB. In both cases, the zone mobility of each rare earth becomes close to each other with increasing ligand concentrations, but

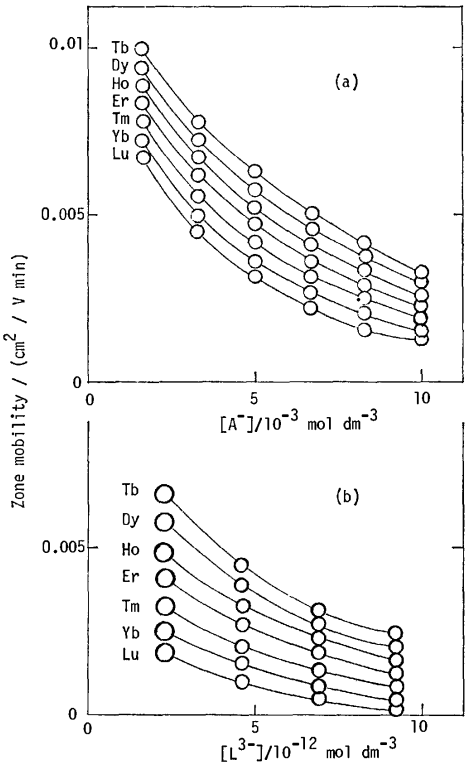

Fig. 1. Plots of the zone mobility *vs.* $[A^-]$(1a) or $[L^{3-}]$-(1b).

the range of AHIB concentration suitable for separation is broader than that of NTA. By lowering the concentration of NTA, the difference in the zone mobility becomes larger than that in the case of AHIB, but the zone width also becomes larger. This would be due to the large difference in the mobility between M^{3+} and ML. It may thus be concluded that AHIB generally gives better separation than NTA.

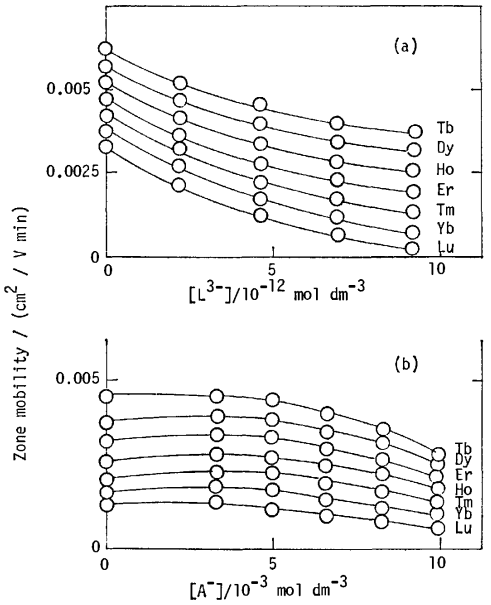

Fig. 2. (a): Plots of the zone mobility *vs.* $[L^{3-}]$ at $[A^-]=5.0\times10^{-3}$ mol dm^{-3}. (b): Plots of the zone mobility *vs.* $[A^-]$ at $[L^{3-}]=4.7\times10^{-12}$ mol dm^{-3}.

To examine the effect of mixed complexing agents on the zone mobility, experiments were done using mixtures of AHIB and NTA as electrolyte solutions. The results are shown in Fig. 2; $[L^{3-}]$ was varied at a constant $[A^-]$(2a) and $[A^-]$ was varied at a constant $[L^{3-}]$(2b). The zone location is found to be much more affected by increasing $[L^{3-}]$ than by increasing $[A^-]$. The formation of the neutral complexes with NTA considerably alters the zone mobility. In general, the zone is located between the limits found in cases where AHIB or NTA is separately used at the same concentration. With increasing concentration of AHIB, however, the zone mobility becomes lower than those in either case where the respective agent is separately used (Fig. 2b). This suggests that some mixed ligand complexes of the rare earth elements with NTA and AHIB, possibly as anionic species, might be formed, and that the zone mobility of each element is lowered.

Estimation of the Formation Constants of the Mixed Ligand Complexes. If there are no mixed ligand complexes in solutions containing M, H_3L, and HA, the species in equilibrium would be M, ML, MA, MA_2, MA_3, and MA_4 under the present experimental conditions (the charges are omitted for simplicity). When the equilibria among these species are rapidly attained under the electric field, the zone mobility u_{AL} can be related to the mobility and the amount of each species.[1,4,5]

$$u_{AL}([M]+[ML]+[MA]+[MA_2]+[MA_3]+[MA_4]) = u_M[M] + u_{ML}[ML] + u_{MA}[MA] + u_{MA_2}[MA_2] + u_{MA_3}[MA_3] + u_{MA_4}[MA_4], \quad (1)$$

where u means the mobility of the respective species. Using the overall formation constants of the above complexes, β's, Eq. 1 can be brought into the form:

$$u_{AL}(1+\beta_{ML}[L]+\beta_{MA}[A]+\beta_{MA_2}[A]^2+\beta_{MA_3}[A]^3+\beta_{MA_4}[A]^4) = u_M + u_{ML}\beta_{ML}[L] + u_{MA}\beta_{MA}[A] + u_{MA_2}\beta_{MA_2}[A]^2 + u_{MA_3}\beta_{MA_3}[A]^3 + u_{MA_4}\beta_{MA_4}[A]^4, \quad (2)$$

where $\beta_{ML}=[ML]/([M][L])$ and $\beta_{MA_n}=[MA_n]/([M][A]^n)$.

When H_3L or HA is separately used at the same concentrations as the above case, the appropriate following equation is applicable:

$$u_L(1+\beta_{ML}[L]) = u_M + u_{ML}\beta_{ML}[L] \quad (3)$$

$$u_A(1+\beta_{MA}[A]+\beta_{MA_2}[A]^2+\beta_{MA_3}[A]^3+\beta_{MA_4}[A]^4) = u_M + u_{MA}\beta_{MA}[A] + u_{MA_2}\beta_{MA_2}[A]^2 + u_{MA_3}\beta_{MA_3}[A]^3 + u_{MA_4}\beta_{MA_4}[A]^4, \quad (4)$$

where u_L or u_A is the zone mobility given by using H_3L or HA separately. Combining Eq. 2 with Eqs. 3 and 4, we obtain

$$(u_{AL}-u_L)(1+\beta_{ML}[L]) + (u_{AL}-u_A)(\beta_{MA}[A]+\beta_{MA_2}[A]^2 + \beta_{MA_3}[A]^3+\beta_{MA_4}[A]^4) + u_M - u_A = 0. \quad (5)$$

The left hand side of Eq. 5 can be calculated using the values of u_{AL}, u_L, u_A, and u_M obtained experimentally, as well as the overall formation constants of the respective complexes reported in the literature. The experimental results showed that Eq. 5 does not become zero, except for the case of Tb(III) at low values of [L] and [A]. Negative values which decrease with increasing [L] and [A] are obtained for all the elements. This indicates that the values of u_{AL} observed are smaller than those predicted by Eq. 5, which was derived by assuming that no mixed ligand complexes were formed. Hence, some mixed ligand complexes with negative charges other than the above complexes should be present in the mixed ligand solutions.

Assuming the mixed ligand complex to be MLA^-, Eq. 2 can be modified to the form:

$$u_{AL}(1+\beta_{ML}[L]+\beta_{MA}[A]+\beta_{MA_2}[A]^2+\beta_{MA_3}[A]^3+\beta_{MA_4}[A]^4 + \beta_{MLA}[L][A]) = u_M + u_{ML}\beta_{ML}[L] + u_{MA}\beta_{MA}[A] + u_{MA_2}\beta_{MA_2}[A]^2 + u_{MA_3}\beta_{MA_3}[A]^3 + u_{MA_4}\beta_{MA_4}[A]^4 + u_{MLA}\beta_{MLA}[L][A], \quad (6)$$

where u_{MLA} is the mobility of MLA and $\beta_{MLA}=[MLA]/([M][L][A])$. Combining Eq. 6 with Eqs. 3 and 4, we obtain

$$(u_{AL}-u_L)(u_{MLA}-u_{AL})^{-1}(1+\beta_{ML}[L])+(u_{AL}-u_A)(u_{MLA}-u_{AL})^{-1} \times (\beta_{MA}[A]+\beta_{MA_2}[A]^2+\beta_{MA_3}[A]^3+\beta_{MA_4}[A]^4) + (u_M-u_A)(u_{MLA}-u_{AL})^{-1} = \beta_{MLA}[L][A]. \quad (7)$$

If u_{MLA} is known, the left hand side of Eq. 7 can be obtained as a function of the product of [L] and [A]. If a linear relation is obtained between the left hand side of Eq. 7 and the product of [L] and [A], the formation constant of MLA^- can be determined from the slope of the line.

Various values have been reported for the formation constants of the rare earth complexes with NTA and AHIB. We tried to find the most suitable values by comparing the zone mobilities u_L and u_A calculated from Eqs. 3 and 4 with the observed ones. To estimate the mobilities of various complexes required for calculation, $u_{MA}^{2+}=0.007$ cm²/V min[4] and $u_{ML_2}^{-}=0.012\pm0.001$ cm²/V min measured at $I=0.1$ were used. When we consider that the value for u_{MA}^{2+} was measured with the presence of MA_2^+, the mobility is roughly proportional to the charge of the species. Hence, the following values might be given for the mobility of each species: $u_{ML}=0$, $u_{MA}^{2+}=0.008$, $u_{MA_2}^{+}=0.004$, $u_{MA_2}=0$, $u_{MA_4}=-0.004$, and $u_{MLA}^{-}=-0.004$ cm²/V min. The calculation of u_L and u_A was made by using the reported values for the formation constants of the rare earth complexes with NTA[6] and AHIB[7] determined at an ionic strength of 0.1. For all the elements the values calculated for u_L well agreed with those observed, whereas there were appreciable differences between the calculated and observed values of u_A. The values of u_A calculated by using another data for β_{MA_n} at higher ionic strength of 0.2[8] well agreed with the observed ones.

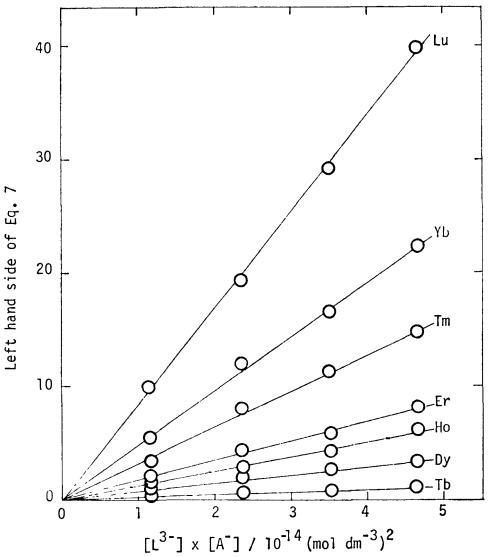

Fig. 3. Plots of the left hand side of Eq. 7 *vs.* $[L^{3-}]\times[A^-]$ at $[A^-]=5.0\times10^{-3}$ mol dm^{-3}.

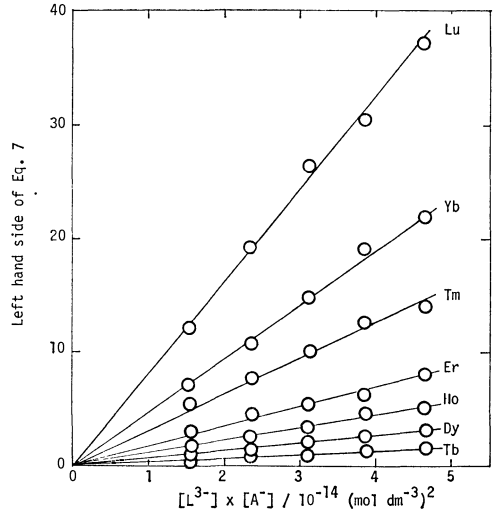

Fig. 4. Plots of the left hand side of Eq. 7 *vs.* $[L^{3-}]\times[A^-]$ at $[L^3]=4.7\times10^{-12}$ mol dm^{-3}.

Using the values of β_{ML},[6] β_{MA_n},[8] and u_{MLA} estimated above, the calculation of the left hand side of Eq. 7 was made. The results as a function of the product of [L] and [A] are shown in Figs. 3 and 4, where [A] or [L] is respectively kept constant. For all the elements, the plots in either Fig. 3 or 4 exhibit linear relations, indicating that the MLA^- complex is present in a mixture of NTA and AHIB solutions at the ligand concentrations studied. The values of β_{MLA}- for these rare earths were obtained from the slopes of the lines in both Figs. 3 and 4, as listed in Table 1. The two values obtained from Figs. 3 and 4 for each element are in good agreement. The stability trend was in an ordinary sequence, as expected. To obtain further information on the stability of the MLA^- complexes, the values of K^{ML}_{MLA} and K^{MA}_{MLA}, the equilibrium constants of Eqs. 8 and 9 and those of $\Delta\log K$ and $\log X$ defined by Sigel[9] (Eqs. 10 and 11) were calculated:

$$ML + A = MLA \quad k^{ML}_{MLA} = \beta_{MLA}/\beta_{ML}\ ^{6)} \tag{8}$$

$$MA + L = MAL \quad k^{MA}_{MAL} = \beta_{MLA}/\beta_{MA}\ ^{8)} \tag{9}$$

$$\Delta\log k = \log k^{ML}_{MLA} - \log\beta_{MA}\ ^{8)} = \log k^{MA}_{MAL} - \log\beta_{ML}\ ^{6)} \tag{10}$$

$$\log X = 2\log\beta_{MLA} - (\log\beta_{ML_2}\ ^{6)} + \log\beta_{MA_2}\ ^{8)}). \tag{11}$$

These results are also given in Table 1. For all the elements, $\Delta\log K$ values are nearly the same but $\log X$

Table 1. Formation constants of the mixed ligand complexes (MLA^-) of heavy rare earths at $I=0.1$(NaCl) and at 25 °C

Element	$\log\beta_{MLA}$- A[a]	B[b]	$\log K^{ML}_{MLA}$	$\log K^{MA}_{MAL}$	$\Delta\log K$	$\log X$
Tb(III)	13.4	13.5	1.86	10.53	−1.06	0.69

Table 2. Differences in logarithms of formation constants of the binary and the ternary complexes between adjacent rare earths

Element M_1–M_2	log $K(M_1)$ − log $K(M_2)$					
	$K=K_{MA}^{M}$ [8]	$K=K_{ML}^{M}$ [6]	$K=K_{MA_2}^{MA}$ [8]	$K=K_{ML_2}^{ML}$ [6]	$K=K_{MAL}^{MA}$	$K=K_{MAL}^{ML}$
Dy–Tb	0.02	0.15	0.19	0.03	0.33	0.20
Ho–Dy	0.04	0.16	0.05	−0.06	0.21	0.09
Er–Ho	0.03	0.13	0.13	−0.09	0.12	0.02
Tm–Er	0.09	0.19	0	−0.03	0.21	0.11
Yb–Tm	0.03	0.18	0.01	0.06	0.17	0.02
Lu–Yb	0.05	0.09	0.17	0.13	0.15	0.11

increases roughly with atomic number, indicating that the heavier the element is, the more the formation of the MLA^- complex is promoted.

Table 2 shows the differences in logarithms of the formation constants of the binary[6,8] and the ternary (Table 1) complexes between adjacent rare earth elements. There are considerable differences in both $\log K_{MAL}^{MA}$ and $\log K_{MLA}^{ML}$ between adjacent elements, suggesting that successive formation of the MLA complexes gives larger differences in the zone mobilities of adjacent elements. On the other hand, formation of the ML_2 complexes reduces the effect on the separation of the metals from dysprosium to thulium, since $K_{ML_2}^{ML}$ for these metals decrease with atomic number. Separation of the heavy rare earth elements would be improved by the formation of the MLA complexes other than the binary complexes ML and MA_n.

(Received June 14, 1980)

The crystal structures of wine-red $[Cu(1,3\text{-chxn})_2]Br_2$ (**1**), $[Cu(1,3\text{-chxn})_2](NO_3)_2$ (**2**), and blue-violet $[CuCl(1,3\text{-chxn})_2]ClO_4$ (**3**) (1,3-chxn=*cis*-1,3-cyclohexanediamine) have been determined from the diffractometer data measured by the use of Mo $K\alpha$ radiation. The structures were solved by the Patterson-Fourier method and refined by the least-squares method to $R=0.042$ (**1**), 0.033 (**2**), and 0.057 (**3**) for 1309, 1210, and 776 nonzero reflections respectively. The Cu atoms in **1** and **2** have a square-planar coordination by 4 N atoms, while the complex ion in **3** has a 5-coordinate square-pyramidal geometry, with the Cl atom at the apical position. The 6-membered chelate rings in **1**, **2**, and **3** are of the chair, flattened-chair, and envelope conformations respectively. The complex ions in **1** and **2** have virtually a C_{2h} symmetry, the two-fold axis of which lies on the CuN_4 plane. The virtual symmetry for $[CuCl(1,3\text{-chxn})_2]^+$ is C_{2v}, the approximate two-fold axis being coincident with the Cu–Cl bond. The cyclohexane rings (chair conformation) in **2** and **3** are roughly perpendicular to the coordination plane, but that in **1** leans toward the central Cu(II) atom. The formation of such coordinatively unsaturated Cu(II) complexes as **1**—**3** is attributable to the steric hindrance of the bulky cyclohexane ring to the axial coordination site.

Although *cis*-1,3-cyclohexanediamine (1,3-chxn) is capable of chelating to a metal ion, as has been demonstrated by X-ray structure analyses of Pd(II) and Pt(II) chelates,[1,2] it has received much less attention in coordination chemistry than the *trans*-1,2-isomer, which is chiral and stereoselective for complex formation. Recently, however, the bis 1,3-chxn chelates of several metal ions have been prepared and characterized by means of the spectral method.[3] Of these chelates, $Cu(1,3\text{-chxn})_2X_2$-type compounds show various colors depending on the course of the preparation; *e.g.*, the recrystallization of the violet bromide from methanol yields wine-red crystals, whose color is unusual for the CuN_4X_2 chromophore, while the color of the bromide is unchanged by recrystallization from ethanol. The crystal structures of wine-red $Cu(1,3\text{-chxn})_2Br_2$ (**1**), $Cu(1,3\text{-chxn})_2(NO_3)_2$ (**2**), and blue-violet $Cu(1,3\text{-chxn})_2ClClO_4$ (**3**) have been investigated in order to reveal the stereochemical features of the 1,3-chxn as a ligand.

Experimental

The preparations of **1**, **2**, and **3** were described elsewhere.[3] The unit-cell dimensions of **1**, **2**, and **3** were determined from the least-squares analyses of 18, 16, and 12 θ values of the high-angle reflections measured on an automated diffractometer. Table 1 lists the crystal data and experimental details. The intensities were measured on the diffractometer using graphite-monochromated Mo $K\alpha$ radiation, and corrected for the Lp factor, but not for absorption. For each of the three compounds, the intensities of three standard reflections were monitored every 4 h, but they showed no ap-

preciable decay.

The crystal structures were solved by the Patterson-Fourier method. The positional and thermal parameters were refined by the block-diagonal-matrix least-squares method. The minimized functions were $\sum w(F_o-|F_c|)^2$, where $w=1/\sigma^2(F_o)$. The systematic extinctions for **2** were indicative of three possible space groups: C2/m, C2, and Cm. Refinements for nonhydrogen atoms on the assumptions of the former two gave no further improvements over $R=0.098$ and 0.118, but R was reduced to 0.051 by the refinement based on the Cm space group. The systematic extinctions for **3**, $h+l=2n+1$ for $h0l$ and $k=2n+1$ for $0kl$, indicated two possible space groups, Pbnm and $Pbn2_1$; the former was confirmed by the successful refinement of the structure.

For **1**—**3**, peaks due to all H atoms were found from the difference syntheses after anisotropic refinement for nonhydrogen atoms. The positions of these H atoms were almost entirely in agreement with those calculated on the assumption that the C–H and N–H distances are 1.00 Å. The H atoms were included in the least-squares calculations, but their parameters were not refined. The isotropic temperature factors assigned to the H atoms were as follows:

	1	**2**	**3**
B_H/Å^2	4.5	$B_P+1.0$	$B_P+1.0$,

where B_p is the isotropic temperature factor of the nonhydrogen atom to which the H atom is bonded (the temperature factor obtained at the final cycle of isotropic refinement was used as the B_p).

The atomic scattering factors, with corrections for dispersion effects for Cu^0, Br^-, Cl^-, and Cl, were taken from Ref. 4. The atomic coordinates are listed in Table 2. The corodinates of the H atoms, the anisotropic thermal parameters, and the F_o-F_c tables for the three compounds are preserved by the Chemical Society of Japan (Document No. 8120). All the computations were performed by a FACOM 230-60 computer at Osaka City University using programs in the UNICS.[5]

a) Equivalent isotropic temperature factor (W.C. Hamilton, *Acta Crystallogr.*, **12**, 609 (1959)).

Results and Discussion

Figure 1 shows a part of the crystal structure for each of the three compounds. The interatomic distances and bond angles are given in Table 3. In **1** the Br and its symmetry-related ions lying above and below the coordination plane participate in hydrogen bonding with the axial H atoms of NH_2 groups, but not in coordination with the Cu atom ($Cu\cdots Br^-=4.015(1)$ Å). The NO_3^- ions around the complex ion in **2** are distant from the Cu atom and take part in the hydrogen bonds with NH_2 groups. The complex ions in **1** and **2** thus have the 4-coordinate square-planar coordination. The Cl^- ion in **3** is bonded to the Cu atom, thus completing a 5-coordinate square-pyramidal configuration. Although the IR spectrum of **3** at the 1000—1200 cm^{-1} region is indicative of the participation of the ClO_4^- ion in the coordination sphere,[3] the structure analysis

a) The subscript ax indicates the axial H atom with respect to the cyclohexane ring. b) Roman-numeral superscripts refer to the following equivalent positions: I $x, y, 1+z$; II $-1/2+x, 1/2-y, z$; III $1/2+x, 1/2-y, z$; IV $-x, -y, 1-z$. c) The atom disposition in each [N,C,C′,N′] plane is completely planar in **2** and **3**; it is also planar in **1** within the limits of experimental error.

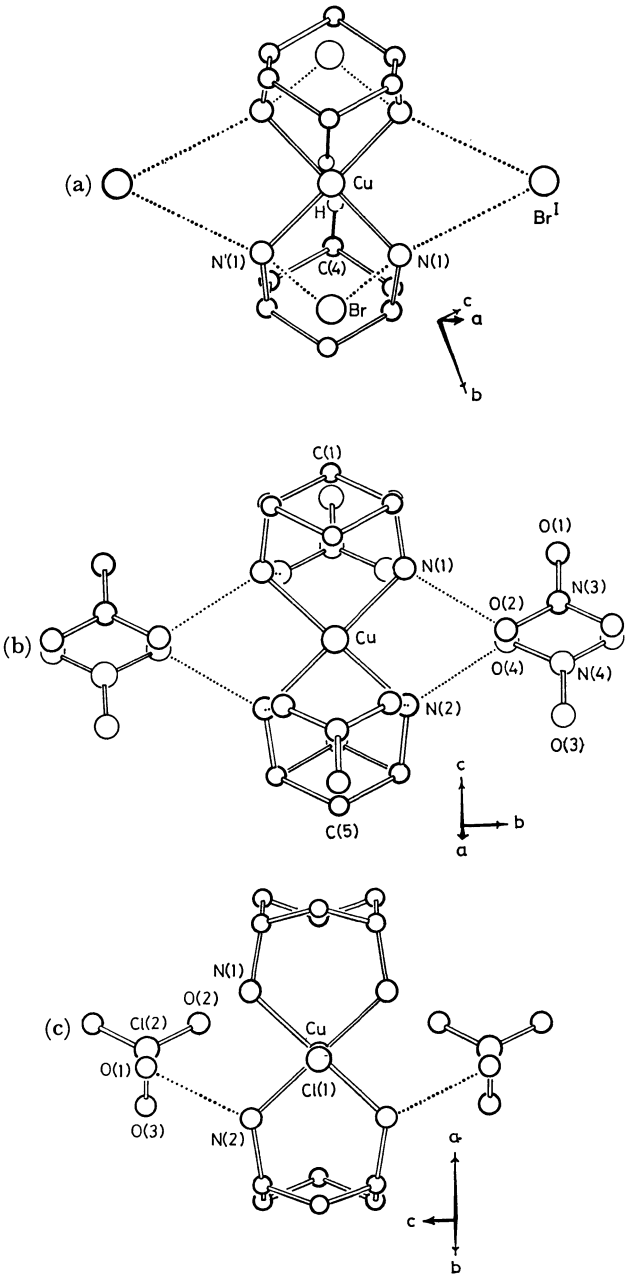

Fig. 1. Environments of the complex cations: (a) $[Cu(1,3\text{-chxn})_2]Br_2$, (b) $[Cu(1,3\text{-chxn})_2](NO_3)_2$, and (c) $[CuCl(1,3\text{-chxn})_2]ClO_4$. Each figure is the projection of a part of the crystal structure on the coordination plane defined by the 4 N atoms. The dotted lines indicate hydrogen bonds.

disclosed that one of the O atom [O(1)] of the ClO_4^- is linked to the H atom of the $N(2)H_2$ group. The ClO_4^- ion has no higher symmetry than the crystallographically imposed C_s symmetry, as was indicated by the examination of O–Cl–O bond angles,[6] and this low symmetry is responsible for the splitting of the IR band in that region.

The complex ions in **1** and **2** have strict C_i and C_s symmetries respectively, but both also have a virtual C_{2h} symmetry in which the two-fold axis bisects the N(1)–Cu–N(2) bond angle (for **1** N(2) stands for the

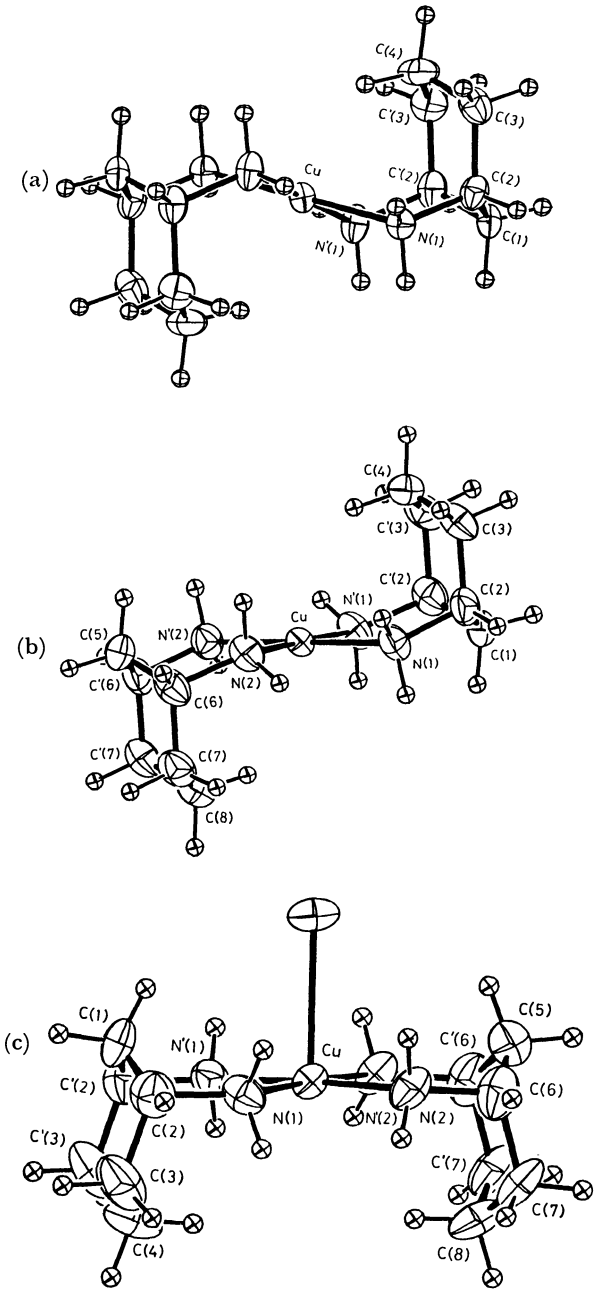

Fig. 2. Perspective views of (a) $[Cu(1,3\text{-chxn})_2]^{2+}$ in **1**, (b) $[Cu(1,3\text{-chxn})_2]^{2+}$ in **2**, and (c) $[CuCl(1,3\text{-chxn})_2]^{+}$ in **3**. Thermal ellipsoids are drawn at 50% probability level. Hydrogen atom is shown by a sphere with arbitrary radius.

equivalent of N'(1) at the $-x$, $-y$, $-z$ position). Above and below the coordination plane the most proximate atoms to the Cu are the axial H atom of $C(4)H_2$ and its symmetry-related (C_{2h}) atom [Fig. 2(a) and (b)], the Cu···H distances in **1** and **2** being 2.28 and 2.61 Å. The Cu···H vector in **1** intersects the CuN_4 plane at 79.1°, while those in 2 intersect it at 64.6° and 64.9°. The Cu–N bond lengths in **2** are slightly shorter than those in **1** and are comparable to the Cu–N (primary amine) length in the red form of bis(*N*,*N*-diethylethylenediamine)copper(II) perchlorate, in which the Cu atom has a square-planar coordination.[7] In general, however, the Cu–N distance in the planar complex is not appreciably different from those in 6-coordinate tetragonal and 5-coordinate square-pyramidal complexes.[7,8]

A perspective view of $[CuCl(1,3\text{-chxn})_2]^{+}$ is shown in Fig. 2(c). In addition to the crystallographically imposed mirror plane on which Cu, Cl(1), C(1), C(4), C(5), and C(8) lie, there is an approximate two-fold axis normal to the coordination plane; therefore, the virtual symmetry is regarded as C_{2v}. The Cu atom is displaced by 0.045 Å toward the apical atom, but this deviation is very small in comparison with that (0.33 Å) in chloro(2,7,12-trimethyl-3,7,11,17-tetraazabicyclo-[11.3.1]heptadeca-1(17),2,11,13,15-pentane)copper(II) nitrate dihydrate,[9] which involves the $CuClN_4$ coordination framework. Concomitantly, the Cu–Cl bond in **3** is much longer than that (2.50 Å) in the complex cited for comparison.[9] The $C(1)H_2$ and $C(5)H_2$ groups are in close contact with the Cl(1) atom and prevent the Cl atom from approaching Cu further. The visible spectrum of **3** in methanol ($\tilde{\nu}_{max}=18000\ cm^{-1}$) is somewhat different from that in the solid state ($\tilde{\nu}_{max}=18400\ cm^{-1}$), suggesting some change in the coordination sphere.

The 6-membered chelate rings in **1** and **2** are of the chair conformation, but those in **3** take the envelope conformation. The N–Cu–N′ coordination angles are greater than 90° in **2** and **3** and are comparable to that in $[Pd(1,3\text{-chxn})_2]Cl_2$.[1] The coordination angle in **1** is significantly smaller than those in **2** and **3**; it has a value of less than 90°. The [Cu,N,N′]–[N,C,C′,N′] interplanar angle in **1** is smallest (Table 3), but is comparable to that in $[Cu(tn)_2](NO_2)_2$ (132.5°)[10] (tn=1,3-propanediamine). In the chair ring, the increase in the interplanar angle gives rise to an enlargement of the coordination angle,[11] and the envelope ring has the largest angle (Table 3). The interplanar angle in the planar complex is thought to be susceptible to its surroundings. The different interplanar angles in **1** and **2** may result from the difference between the crystal packings.

As may be seen from Fig. 2, the 1,3-chxn ligand has the diaxial conformation, in which two C–NH_2 bonds are axial with respect to the cyclohexane ring. A CH_2 group at the 5-position ($C(4)H_2$ in **1**; $C(4)H_2$ and $C(8)H_2$ in **2** and **3**) is located close to the axial coordination site. A chelation of the diaxial 1,3-chxn thus situates the bulky cyclohexane moiety in the proximity of the metal ion, preventing the axial site from ligand access. This is in contrast to the case of the *trans*-1,2-isomer, whose cyclohexane ring is distant from the metal ion and has little influence on the adjacent coordination site.[12] The 1,3-chxn ligand, therefore, tends to give a coordinatively unsaturated complex and prefers a metal ion with tetragonal stereochemistry rather than one with an octahedral one. The steric hindrance of the cyclohexane moiety is responsible for the formation of the 4-coordinate planar Cu(II) complex unusual for the coordination geometry of $Cu(diamine)_2X_2$.

The reaction of $CuCl_2$ with twice as many mols of the 1,3-chxn in methanol yielded a violet compound,

$Cu(1,3\text{-chxn})_2Cl_2$; the violet bromide was also obtained by a similar reaction of $CuBr_2$ with the ligand in ethanol. The reflectance spectra of these compounds were indicative of a 6-coordinate tetragonal geometry.[3] The possible disposition of the 1,3-chxn ligands in this geometry is of the C_{2h} type (*vide supra*), since the C_{2v} disposition is unable to have a coordination number greater than 5 because of the steric interference of the cyclohexane rings. In the "6-coordinate C_{2h}" complex, however, the halide ligands are thought to be displaced greatly from the usual axial coordination sites to avoid the CH_2 groups at the 5-position of the 1,3-chxn. The distortion from tetragonal coordination geometry may be diminished if the cyclohexane ring assumes the boat conformation at the expense of the conformational energy. Unfortunately, no single crystals of the violet compounds have yet been obtained.

(Received September 11, 1980)

trans-Dichlorobis(benzonitrile)platinum(II) reacted with twice the molar amount of thallium(I) acetylacetonate and benzoylacetonate in dichloromethane at room temperature to afford mainly *N*-acetyl β-ketoamine chelates, *trans*-[Pt{N(COMe)=C(Ph)CH=COMe(and Ph)}$_2$] (**1a** and **3a**). This *N,O*-chelate structure of **1a** was determined by X-ray analysis. Reactions of *cis*-[$PtCl_2(PhCN)_2$] gave *C*-acetyl and *C*-benzoyl β-ketoamine chelates, *cis*-[Pt{NH=C(Ph)C(COMe(and Ph))=COMe}$_2$], together with other minor products. Formation of these β-ketoamine chelates is explained by the nucleophilic reactions of the β-diketonate carbanions at the coordinated cyanide carbon atom, followed by migration of the acetyl group or the methine proton of the nucleophiles onto the imino nitrogen atom formed during these reactions. In the presence of free β-diketones, migration of the acyl group was generally suppressed; this led to high yields of *C*-acyl complexes especially in reactions of *cis*-[$PtCl_2$-$(PhCN)_2$]. In each case, the reaction proceeded with retention of the geometrical configuration around the central metal atom. The structures of other products, including a compound obtained by acid hydrolysis of **1a**, were explored and discussed, based on IR and ^{1}H NMR data.

It is well known that nitriles in the coordination sphere of metal ions are very susceptible to nucleophilic attack and readily react with water, alcohols, and amines to yield the corresponding amides, imidic esters, and amidines, respectively.[1] Stephenson[2] examined the X-ray structure of the reaction product between [$PtCl_2(MeCN)_2$] and aqueous ammonia. The product originally formulated as [$Pt(NH_3)_4(MeCN)_2$]$Cl_2\cdot H_2O$ was shown to be an amidine complex of the stoichiometry [$Pt(NH_3)_2${$NHC(NH_2)Me$}$_2$]$^{2+}$ in which the imine nitrogens are bound to the platinum. Recently, Braunstein *et al.*[3] demonstrated that cyanide carbons in the benzonitrile analogue [$PtCl_2(PhCN)_2$] undergo the nucleophilic attack of carbanions Ph_2PCHY (Y= CO_2Et and CN) in tetrahydrofuran at 0 °C to afford *trans*-[Pt{P(Ph)$_2$C(Y)=C(Ph)NH}$_2$]. Similar reactions of metal complexes with β-diketonate ions have not been examined, although the nucleophiles are known to add to the coordinated unsaturated hydrocarbon[4-6] and imine[7] ligands. We have briefly reported[8] the reaction of [$PtCl_2(PhCN)_2$] with an acetylacetonate ion in dichloromethane at room temperature to give an *N*-acetyl β-ketoamine chelate, *trans*-[Pt{N(COMe)=C(Ph)CH=COMe}$_2$] (**1a**). It is noteworthy that the nucleophilic reaction occurred for [$PtCl_2(PhCN)_2$], which has been widely used as a starting material for the preparation of organoplatinum(II) complexes.[9] In our previous study,[10] the complex [$PtCl_2(PhCN)_2$] prepared by Kharasch's procedure[11] was found to exist as a mixture of *cis* and *trans* isomers, and both isomers were successfully isolated by column chromatography on silica gel. Details of reactions of *trans*- and *cis*-[$PtCl_2(PhCN)_2$] with thallium(I) acetylacetonate, Tl(acac), and benzoylacetonate, Tl(bzac), in dichloromethane at room temperature are presented here, together with the full account of the X-ray structure of **1a** as an example of products in these reactions.

† In this paper, the term "β-ketoamine" means an α,β-unsaturated β-amino ketone.

Experimental

Materials. The *trans*- and *cis*-[$PtCl_2(PhCN)_2$] complexes were prepared as described in the previous paper.[10] Thallium (I) salts of acetylacetone and benzoylacetone were synthesized according to the literature.[12] Dichloromethane over Molecular Sieve Type 3A was decanted, further dried over calcium hydride, and then distilled. For column chromatographic separation of reaction products, silica gel 60 F_{254} (Merck, 70-230 mesh) or aluminium oxide 60 (Merck, active, basic) was used as a packing. A technique of preparative layer chromatography (PLC) was applied in order to collect samples in the preparative scale, using the chromatoplate of silica gel 60PF_{254} containing $CaSO_4$ (Merck) or aluminium oxide 60PF_{254} (Merck, Type E). For the preparation of a PLC plate, one (25 g) of these adsorbents was suspended in deionized water (60 cm^3) and the mixture was applied on a glass plate (20×20 cm) and activated before use at 130—140 °C for 4 h.

Reaction of trans-[$PtCl_2(PhCN)_2$] *with Thallium (I) Acetylacetonate.* When Tl (acac) (376 mg, 1.24 mmol) was added to a yellow solution of *trans*-[$PtCl_2(PhCN)_2$] (293 mg, 0.62 mmol) in dichloromethane (20 cm^3) and the mixture was stirred for 1 h at room temperature, a white precipitate of thallium (I) chloride was formed and the solution turned brown-yellow. The mixture was passed through a short column (5×2 cm d) of silica gel, leaving thallium (I) chloride and a brown residue at the top of the column. The yellow eluent was concentrated and put on the PLC plate of silica gel. Development with benzene split the original band into two. The first band component with a large R_f value was extracted with benzene and the solvent was evaporated to dryness, leaving the yellow compound **1a** (26 mg, 7% yield). A dichloromethane-extract of the second band was concentrated and developed, once again, on the PLC plate in diethyl ether, resulting in two bands. Yellow compound **1b** (16 mg, 5% yield based on the platinum atom used) precipitated on addition of hexane to a diethyl ether-extract of the smaller R_f component. A trace amount of substance was obtained from

the larger R_f component; this was not characterized.

Reaction of cis-[$PtCl_2(PhCN)_2$] *with Thallium (I) Acetylacetonate.* Tl (acac) (413 mg, 1.36 mmol) was suspended in a dichloromethane solution (20 cm³) of *cis*-[$PtCl_2(PhCN)_2$] (320 mg, 0.68 mmol), and the mixture was stirred for 5 h at room temperature. After the volume of the solution was reduced by vacuum evaporation, the concentrate was mounted on the PLC plate of aluminium oxide without removal of thallium (I) chloride. Two bands appeared upon development with a benzene–acetone (20 : 1 by volume) mixture. The components with small and large R_f values were extracted separately with dichloromethane and the extracts were concentrated to obtain a yellow powder of **2a** (72 mg, 18% yield) and red crystals of **2b** (34 mg, 8% yield) on addition of diethyl ether, respectively. Reprecipitation of **2a** from acetone by adding diethyl ether gave yellow needles.

Reaction of trans-[$PtCl_2(PhCN)_2$] *with Thallium (I) Benzoylacetonate.* A mixture of *trans*-[$PtCl_2(PhCN)_2$](297 mg, 0.63 mmol) and Tl(bzac) (461 mg, 1.26 mmol) in dichloromethane (25 cm³) was stirred for 5 h at room temperature. After filtration of the precipitated thallium (I) chloride, the filtrate was concentrated to a small volume and placed on a PLC plate of silica gel. Development with benzene–hexane (3 : 2 by volume) resulted in three bands; each component was extracted with dichloromethane and isolated on addition of diethyl ether to the concentrated extract. Orange (**3a**) and yellow (**3a′**) powders were isolated from bands with middle and small R_f values, respectively, and another orange powder (**3b**) from that with a large R_f. The yields of **3a**, **3a′**, and **3b** were 48 mg (11%), 28 mg (6%), and 27 mg (6%), respectively.

Reaction of cis-[$PtCl_2(PhCN)_2$] *with Thallium (I) Benzoylacetonate.* *cis*-[$PtCl_2(PhCN)_2$] (282 mg, 0.60 mmol) was allowed to react with Tl(bzac) (439 mg, 1.20 mmol) in the same way as described above. After filtration of thallium (I) chloride, the concentrated orange-yellow solution was placed on the top of the column (40×2 cm d) of silica gel and developed with dichloromethane. The first fraction contained benzoylacetone (5 mg, 3% yield based on the Tl(I) salt used). After evaporation of the last and middle fractions to dryness, the resulting powders were recrystallized from acetone–petroleum ether and diethyl ether to give yellow needles of **4a** (19 mg, 4% yield) and red crystals of **4b** (14 mg, 3% yield), respectively.

Reactions of trans- *and* cis-[$PtCl_2(PhCN)_2$] *with Thallium (I) Acetylacetonate and Benzoylacetonate in the Presence of the Corresponding Free β-Diketones in Large Excess.* For example, in the case of reactions with Tl(acac), a mixed solvent of dichloromethane–acetylacetone (1 : 1 by volume) was used. Molar ratios of Tl(acac) and free acetylacetone to [$PtCl_2(PhCN)_2$] were 2 : 1 and *ca.* 350 : 1, respectively. After reactions for 5 h, adequate treatments were performed to isolate products. In the case of reaction with *trans*-[$PtCl_2(PhCN)_2$], yellow powders of **5a** and **5b** were obtained in 3 and 8% yields, respectively, while in the case of *cis*-[$PtCl_2(PhCN)_2$], compound **2a** was isolated in a 75% yield.

In the reactions with Tl(bzac), 2.5 g (*ca.* 15 mmol) of solid benzoylacetone was added to [$PtCl_2(PhCN)_2$] in dichloromethane prior to the reaction. Molar ratios of Tl(bzac) and free benzoylacetone to [$PtCl_2(PhCN)_2$] were 2 : 1 and *ca.* 24 : 1, respectively. Isolation of the reaction products without any contamination with benzoylacetone was somewhat difficult. After reactions for 7 h, compounds **3a** and **3a′** and yellow powder **6** were isolated from the reaction mixture with *trans*-[$PtCl_2(PhCN)_2$] in 15, 4, and 5% yields, respectively, while compound **4a** was obtained from the reaction mixture with *cis*-[$PtCl_2(PhCN)_2$] in a 57% yield.

Reaction of cis-[$PtCl_2(PhCN)_2$] *with Thallium (I) Acetylacetonate in the Presence of Excess* o-*Nitrophenol.* To examine the effect of protonic acids on the yield of **2a**, *o*-nitrophenol was used as a proton donor instead of acetylacetone. Ten times the molar amount of *o*-nitrophenol was added to *cis*-[$PtCl_2(PhCN)_2$] in dichloromethane and the mixture was allowed to react with twice the molar amount of Tl(acac) for 4 d, giving **2a** only in a 14% yield.

Acid Hydrolysis of ***1a*** *with Perchloric Acid.* Compound **1a** (88 mg, 0.15 mmol) was dissolved in a dichloromethane–acetone (1 : 1 by volume) mixture (160 cm³) and 60% $HClO_4$ (6 cm³) was added to the solution. After being stirred for 2.5 h, the solution was concentrated to 30 cm³ at room temperature under reduced pressure and allowed to stand overnight to deposit **7**. After addition of methanol to the mother liquor, the mixture was concentrated to a small volume and allowed to stand overnight again, depositing another crop of **7**. The total yield of golden crystals **7** was 58 mg, 76%. Attempts to detect acetic acid, which was thought to be produced in this reaction, were unsuccessful.

An Attempt to Synthesize Complex ***1a*** *by the Reaction of Bis(acetylacetonato)platinum(II) with Benzonitrile.* Although a mixture of bis(acetylacetonato)platinum (II) (92 mg, 0.23 mmol) and benzonitrile (2 cm³) in dichloromethane (7 cm³) was stirred at room temperature for **3d**, no reaction occurred and 40% of the starting platinum (II) complex was recovered. Even in benzonitrile at 100 °C for 5 h, 26% of the starting material was recovered with some decomposed black residue.

An Attempt to Synthesize 4-Acetylamino-4-phenyl-3-buten-2-one (the Ligand in ***1a****) by a Schiff Base Condensation.* Benzoylacetone (3.55 g, 22.0 mmol) was allowed to react with acetamide (1.30 g, 22.0 mmol) in refluxing ethanol (2.5 cm³) for 5 h, but no condensation occurred. Seventy-six per cent of the benzoylacetone used was recovered.

Crystal Data for ***1a****.* Crystals of **1a** suitable for X-ray crystallography were obtained by slow evaporation of a dichloromethane solution. They are monoclinic with $a=8.426(2)$, $b=9.347(3)$, $c=15.293(9)$ Å, $\beta=111.62(4)°$, $U=1119.8(9)$ Å³, $Z=2$, $D_c=1.77$, $D_m=1.76$ g·cm⁻³, μ(Mo $K\alpha$)=66.2 cm⁻¹, and space group $P2_1/c$. The Laue symmetries, space group, and approximate unit-cell dimensions were determined from oscillation and Weissenberg photographs taken with Cu $K\alpha$ radiation. The unit-cell dimensions were refined by the least-squares analysis of 30θ values measured on a Philips PW 1100 four circle diffractometer with Mo $K\alpha$ radiation.

X-Ray Data Collection. The intensity data with $2\theta \leq 55°$ were collected by the ω-scan mode with graphite-monochromated Mo $K\alpha$ radiation. The specimen size was 0.23× on a Philips PW 1100 four circle diffractometer with Mo $K\alpha$ 0.13×0.11 mm. A scan speed of 1°/min and a scan range of $(1.3+0.2\tan\theta)°$ were chosen. The background was counted for 20 s on each side of the scan range. Three standard reflections ($\bar{3}02$, 060, 002), measured every 4 h, showed no appreciable decay throughout the data collection. A total of 1433 independent reflections with $I>3\sigma(I)$ were classified as observed. The Lorenz-polarization corrections were applied and relative structure factors were derived.[13]

Structure Determination and Refinement. The structure of **1a** was solved by the heavy-atom technique. The positional and thermal parameters were initially refined isotropically by the block-diagonal least-squares method. Further refinement with an anisotropic temperature factor for the Pt atom gave an R value of 5.1%. At this stage, the absorption correction was applied.[14] The maximum and minimum transmission coefficients were 2.48 and 1.82, respectively. The convergence was attained with $R=3.9\%$. The function

a) Equivalent isotropic thermal parameter.

minimized was $\sum w(F_o-|F_c|)^2$, with $w=(54.0/F_o)^2$ for $F_o>54.0$, $w=1.0$ for $54.0\geq F_o\geq 17.3$, $w=0.6$ for $F_o>17.3$. The scattering factors for the neutral Pt, O, N, and C atoms were taken from Ref. 15. No attempt was made to locate hydrogen atoms. In the final cycle of the refinement all parameter shifts were less than 0.2σ. A final difference map showed no significant features. The atomic coordinates are presented in Table 1, along with their temperature factors. The observed and calculated structure factors are preserved by the Chemical Society of Japan (Document No. 8118). All the calculations were performed on a FACOM 230-60 computer at Osaka City University by the use of a local version of the UNICS.[16]

Measurements. IR spectra (4000—200 cm^{-1}) were measured in Nujol mull with a JASCO DS 701G spectrophotometer. ^{1}H NMR spectra were recorded at 100 M Hz on a JEOL JNM-MH 100 spectrometer. Molecular weights were determined with a vapor pressure osmometer manufactured by Knauer, West Berlin, West Germany.

Results and Discussion

In recent studies, we have found that $[PdCl_2(PhCN)_2]$ reacts with acetylacetone in acetone at room temperature to produce di-μ-chloro-bis(η^3-1-acetyl-2-hydroxyallyl)dipalladium(II), liberating benzonitrile molecules.[17] On the contrary, no reaction occurred between $[PtCl_2(PhCN)_2]$ and acetylacetone even in refluxing acetone, but the complex reacted with the acetylacetonate anion in dichloromethane at room temperature, giving rise to a nucleophilic attack on the cyanide carbons. A similar reaction occurred with the benzoylacetonate anion. Analytical data for all products isolated in this study are listed in Table 2, where compounds **1** and **2** represent products obtained by reactions of Tl(acac) with *trans*- and *cis*-$[PtCl_2(PhCN)_2]$, respectively, and **3** and **4** represent the corresponding reaction products of Tl(bzac). In each of these reactions, two or three compounds were isolated by PLC. Figure 1 depicts the structures proposed on the basis of spectroscopic data. Although compounds **3b** and **4b** were not obtained in amounts sufficient for measurements, the molecular weight data of all other compounds indicate

that these are mononuclear in each solvent used.

X-Ray Structure of Compound ***1a***. Two yellow compounds, **1a** and **1b**, were isolated from the reaction mixture of *trans*-$[PtCl_2(PhCN)_2]$ with Tl(acac) in dichloromethane at room temperature. Although compound **1a** was analyzed to have the composition of $Pt(acac)_2(PhCN)_2$, its X-ray structure analysis disclosed that the compound is the bis(*N*-acetyl β-ketoamine)-chelate of platinum(II), $[Pt\{N(COMe)=C(Ph)CH=CO\text{-}Me\}_2]$, as shown in Fig. 2. The Pt atom has a *trans* planar coordination by 2N and 2O atoms. The molecule has a crystallographically imposed center of symmetry. The six-membered chelate ring, phenyl group, and *N*-acetyl moiety are planar within ±0.03, ±0.01, and ±0.02 Å, respectively. The *N*-acetyl plane is perpendicular to the chelate ring plane (interplanar angle =89.7°). The C(6) and O(2) are in contact with the O′(1) atom, the C(6)···O′(1) and O(2)···O′(1) distances being 3.12(2) and 2.96(1) Å, respectively. Such a disposition of the acetyl group relative to the chelate ring imposes some restriction on the rotational orientation of the phenyl group about C(4)–C(7) axis: the short contact between the O(2) and the C(8) atoms makes the phenyl ring slant (59.2°) against the chelate ring plane. Much smaller angles (16° and 41°) between the phenyl and chelate rings are found in *cis*-bis(benzoylacetonato)palladium(II),[18] but in this case the disposition of the phenyl group relative to the chelate ring results from the intermolecular interaction. Bond

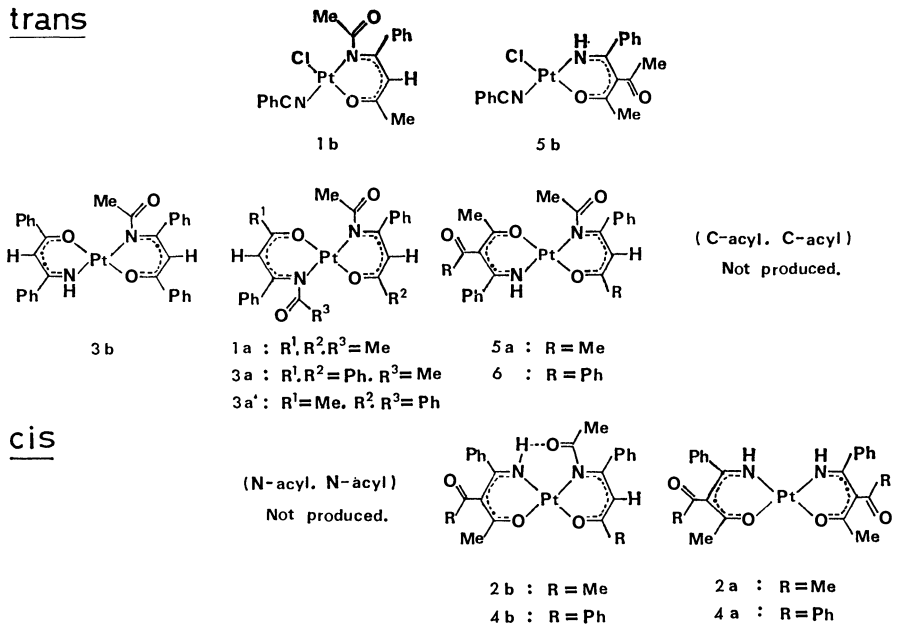

Fig. 1. Schematic drawings of the structure of reaction products between $[PtCl_2(PhCN)_2]$ and Thallium(I) β-diketonates. Numbering indicates products from the following reactions; **1**, *trans*-$[PtCl_2(PhCN)_2]$+Tl(acac); **2**, *cis*-$[PtCl_2(PhCN)_2]$+Tl(acac); **3**, *trans*-$[PtCl_2(PhCN)_2]$+Tl(bzac); **4**, *cis*-$[PtCl_2(PhCN)_2]$+Tl(bzac). **5** and **6** denote reaction products between *trans*-$[PtCl_2(PhCN)_2]$ and Tl(acac) or Tl(bzac), respectively, in the presence of the corresponding free β-diketones in large excess.

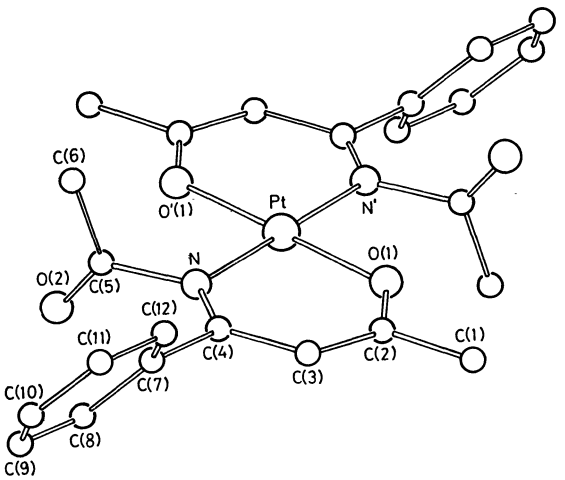

Fig. 2. A perspective view of **1a** with the atom numbering scheme.

distances and angles are summarized in Table 3.

Characterization of the Isolated Compounds by IR and ^1H NMR. Two compounds (**1a** and **1b**) were obtained by the reaction of *trans*-$[PtCl_2(PhCN)_2]$ with Tl(acac); the IR spectrum of **1a** showed no absorption due to the cyano group at around 2200 cm^{-1}, but instead a strong band at 1748 cm^{-1} and three medium to strong bands at 1580—1500 cm^{-1}, as shown in Table 4. Based on the molecular structure of **1a** given in the previous section, we can unequivocally assign the former band to the C=O stretching vibration of the *N*-acetyl group, although the frequency is a little higher than that of the amide I band of gaseous *N*-methylacetamide.[19] On the other hand, the latter three bands may be ascribed to the skeletal vibrations (ν(C=O), ν(C=N), and ν(C=C)) of the β-ketoamine chelate[20] and phenyl rings, but cannot be identified separately.

The ^1H NMR spectrum of **1a** in $CDCl_3$ showed one methine signal at 5.10 ppm and two methyl signals at 2.00 and 1.81 ppm, together with phenyl resonances as shown in Table 5. Of these, the methine signal and one of the methyl signals at 1.81 ppm are accompanied by ^{195}Pt satellites, the coupling constants, $^4J_{Pt-H}$ being 4 and 5 Hz, respectively; these two signals are assigned to the ring-proton and the methyl group attached to the β-ketoamine chelate ring, respectively. Similar couplings of methine and methyl protons to ^{195}Pt are observed to be 11 and 5 Hz, respectively, in the case of bis(acetylacetonato)platinum(II).[21] The other methyl signal at 2.00 ppm, with no coupling to ^{195}Pt was attributed to the *N*-acetyl protons. Compound **1b**, whose composition was $PtCl(acac)(PhCN)_2$, was easily identified to be the 1 : 1 reaction product, since it showed the same IR and ^1H NMR spectral patterns as those for **1a**, except the presence of ν(C≡N) and ν(Pt–Cl) bands in the IR spectrum.

If a similar nucleophilic reaction occurs between *cis*-$[PtCl_2(PhCN)_2]$ and Tl(acac), at least one of the products should show the same spectral patterns in IR and ^1H NMR as those of **1a**. Contrary to our expectation, both of the two products (**2a** and **2b**) isolated exhibited different IR and ^1H NMR patterns. Compound **2a** showed a single ν(C=O) band at 1675 cm^{-1}, much lower than 1748 cm^{-1} for **1a**, with an additional band of ν(NH) at 3270 cm^{-1}, indicating the absence of *N*-acetyl substituents. We can suppose the structure of **2a** to be that shown in Fig. 1 by ascribing

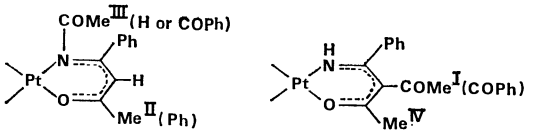
Table 5. ^{1}H NMR data[a]: Chemical shifts (δ) in ppm from internal TMS and coupling constants (J) in Hz.



No.	CH_3[b]				CH	NH
	I	II	III	IV		
1a		1.81s $^4J_{Pt-H}=5$	2.00s		5.10s $^4J_{Pt-H}=4$	
1b		1.95s $^4J_{Pt-H}=2$	2.00s		5.16s $^4J_{Pt-H}=2$	
2a	1.60s			2.07s		c)
2b	1.64s	1.71s	2.10s	2.17s	5.42s	8.80br
3a			2.03s		5.84s	
3a′		1.86s	2.04s		5.19, 5.45s	
3b			2.06s		6.05d, 5.74s $^4J_{H-H}=3$	c)
4a				2.02s		7.89br
5a	1.63s	1.83s	1.92s	1.96s	5.01s	7.76br
5b	1.65s			2.02s		c)
6			1.92s	2.12s	5.88s	c)
7		1.88s			5.34d $^4J_{H-H}=4$	7.86br

a) In $CDCl_3$, except for **1b**, **3a**, **5b**, and **6**, whose spectra were recorded in CD_2Cl_2. Phenyl resonances are omitted for brevity. b) As shown above, I, II, III, and IV represent the following methyl resonances: I, *C*-acetyl; II, methyl on the *C*-unsubstituted chelate ring; III, *N*-acetyl; IV, methyl on the *C*-acetylated or -benzoylated chelate ring. c) Not detectable or overlapped with phenylsignals.

the band at 1675 cm^{-1} to vibration of the uncoordinated *C*-acetyl carbonyl. The uncoodinated acetyl carbonyls in the central-carbon-bonded acetylacetonate complex, $Na_2[PtCl_2(acac)_2]\cdot 2H_2O$,[22] absorb at 1652 and 1626 cm^{-1}, and those in the cobalt(III) tris-chelate of 3-acetyl-acetylacetone[23] at 1680 cm^{-1}.

In conformity with the proposed structure, no ring-methine signal appeared in the ^{1}H NMR spectrum of **2a**, although no signal assignable to the NH proton was detected, probably due to the H–D exchange with $CDCl_3$ used as the solvent.[24] Difficulty arose in finding any coupling to ^{195}Pt of the methyl signals at 2.07 and 1.66 ppm; this made it impossible to determine which signal is due to the methyl groups on the chelate rings. Collman *et al.*[23] examined ^{1}H NMR spectra of cobalt(III) tris-chelates of acetylacetone and 3-acetyl-acetylacetone in benzene and assigned peaks at 1.90 and 2.02 ppm to their corresponding ring-methyls. Such a downfield shift of the ring-methyl signal on acetylation at the central carbon atom of the chelate rings was also recognized in the case of rhodium(III) acetylacetonate in chloroform, and seems to be reasonable because of the electron-attracting nature of the acetyl substituent. If this relative resonance position of these two signals is valid in the case of the present β-ketoamine chelates, the methyl signal at 2.07 ppm, lower than 1.81 ppm found for **1a**, can be assigned to the methyl groups on the *C*-acetylated chelate rings of **2a**, while the signals at 1.66 ppm can be assigned to the uncoordinated *C*-acetyl groups.

These four methyl signals, including two for **1a**, resonate at their characteristic fields and can be classified into four types: I, II, III, and IV, as described in Table 5. This classification can facilitate structural assignments for other products. Thus compound **2b**, which exhibits four methyl signals at all these fields and a methine signal at 5.42 ppm in the intensity ratios of 3 : 3 : 3 : 3 : 1, was supposed to have the mixed-ligand chelate structure which comprises both chelate rings of *N*-acetyl and *C*-acetyl β-ketoamines, as shown in Fig. 1. The somewhat lower frequency in *N*-acetyl carbonyl stretching for **2b** may be caused by its hydrogen-bonded structure, indicating *cis* configuration around the platinum atom.

Compounds **4a** and **4b**, produced by the reaction between *cis*-$[PtCl_2(PhCN)_2]$ and Tl(bzac), exactly correspound to **2a** and **2b** in their structures, although the uncoordinated *C*-acyl groups are benzoyl instead of the acetyl groups in the former compounds. Unfortunately, the amount of **4b** obtained was not enough to allow recording of the ^{1}H NMR spectrum. However, the similarities in color and IR data of **4b** and **2b** support the structures depicted in Fig. 1.

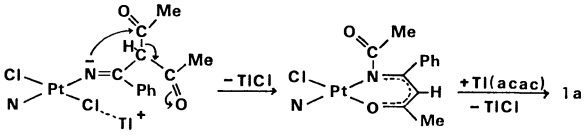
Three compounds were produced by the reaction between *trans*-$[PtCl_2(PhCN)_2]$ and Tl(bzac). **3a** exhibits a single ν(C=O) band at 1748 cm^{-1} in its IR spectrum and one methine and one methyl signal at 5.84 and 2.03 ppm, respectively, in the intensity ratio of 1 : 3 in its ^{1}H NMR spectrum. These features are quite similar to those for **1a** except for the loss of a ring-methyl resonance, and hence a *trans*-bis-(*N*-acetyl β-ketoamine)chelate structure like **1a** was assigned for **3a**. On the contrary, **3a′** shows two ν(C=O) bands at 1750 and 1698 cm^{-1}, and two methine and two methyl

signals at 5.45 and 5.19 ppm and at 2.04 and 1.86 ppm, respectively, in the intensity ratios of 1 : 1 : 3 : 3. Especially, the presence of two methine signals and a ring-methyl signal suggests that the structure of **3a'** has different chelate rings of *N*-acetyl and *N*-benzoyl β-ketoamines (see Fig. 1).

The presence of *N*-acetyl carbonyl and NH bands in the IR spectrum of **3b** allowed us to presume that this compound was the *trans* counterpart of **4b**. No band appeared, however, in the region of *C*-benzoyl carbonyl stretching. A similar disparity also arose in the ^{1}H NMR spectrum of **3b**. No ring-methyl signal of type II is present, but a methyl signal of type III was observed along with two methine signals, in the intensity ratios of 3 : 1 : 1, indicating the presence of the *N*-acetyl group and the two central ring-methines of a different magnetic environment. Thus the structure shown in Fig. 1 was assigned for **3b**; this structure is in good agreement with its analytical data. Of the two methine signals resonating at 6.05 and 5.74 ppm, the downfield signal appeared as a doublet with $J=3$ Hz and was ascribed to the methine proton on the *N*-unsubstituted chelate ring based on the W-rule.[25]

Nucleophilic Reactions of β-Diketonate Carbanions at Coordinated Cyanide Carbons in trans- *and* cis-[$PtCl_2(PhCN)_2$]. Based on the confirmed structures of products, we suggest the following reaction course: 1) the initial step of these reactions involves the nucleophilic attack by a β-diketonate carbanion on the coordinated cyanide carbon atom; 2) the acetyl group or the central methine proton of the nuclephile migrates to the coordinated nitrogen atom in order to stabilize the imino anion formed in the initial step; 3) the carbonyl group in the residue coordinates to the metal to form the *N,O*-chelate ring, in cooperation with metal-assisted abstraction of the chloride ion. Thus the reaction path to produce **1a** can be formulated as below.

trans-[$PtCl_2(PhCN)_2$]+Tl(acac) ⟶



(1)

As was ascertained by X-ray analysis, *trans* configuration around the metal atom in the starting complex is kept in the reaction product **1a**. Although IR and ^{1}H NMR spectra were not helpful in deciding geometrical configurations for other reaction products, it was possible to confirm that neither of the products (**1** and **3**) from *trans*-[$PtCl_2(PhCN)_2$] is the same as either of those (**2** and **4**) from *cis*-[$PtCl_2(PhCN)_2$]. Moreover, the *cis*(*N,N*)-configuration was the most probable for the two products (**2b** and **4b**) from *cis*-[$PtCl_2(PhCN)_2$], on the basis of the IR data showing the presence of the hydrogen bond. Formation of the hydrogen bond will induce the *N*-acetyl group and the *N*-acetyl chelate ring to be coplanar. The red color of **2b** and **4b** might be brought about by the increased delocalization of π-electrons through these two planes. All these facts suport the above-mentioned reaction scheme, which proceeds with retention of the original configuration without breaking of the metal-nitrogen bond. No reaction to produce **1a** occurred between bis(acetylacetonato)platinum(II) and free benzonitrile even at 100 °C, although hexafluoro-2-butyne underwent 1,4-addition across palladium(II)–acetylacetonato rings on treating C_4F_6 with bis(acetylacetonato)-palladium(II).[26]

When *trans*-[$PtCl_2(PhCN)_2$] was reacted with β-diketonate anions, all products (**1** and **3**) were the *N*-acyl β-ketoamine chelates. In the case of reaction with a benzoylacetonate anion, only the former two complexes (**3a** and **3a'**) of all the possible (*N*-acetyl, *N*-acetyl)-, (*N*-acetyl, *N*-benzoyl)-, and (*N*-benzoyl, *N*-benzoyl)-complexes were isolated in 11 and 6% yields, respectively, indicating greater electrophilicity of the acetyl carbonyl carbon atom. On the contrary, the main products from *cis*-[$PtCl_2(PhCN)_2$] were (*C*-acyl, *C*-acyl)-(**2a** and **4a**) or (*C*-acyl, *N*-acyl)-(**2b** and **4b**)-complexes, and no (*N*-acyl, *N*-acyl)-complexes were obtained. These results may be due to steric hindrance at the *cis*-*N,N* positions to prevent an (*N*-acyl, *N*-acyl)-complex. Among these isolated compounds, **1a**, **2a**, and **2b** are isomers, and **3a**, **4a**, and **4b**, which are products from a benzoylacetonate anion, also are the corresponding isomers. These isomers which comprise the different combinations of *N*-acyl and *C*-acyl chelate rings are classified to summation isomerism.

The series of *N*-acetyl β-ketoamine chelates produced by the nucleophilic attack of β-diketonate carbanions on the cyanide carbons in *trans*- and *cis*-[$PtCl_2(PhCN)_2$] are a kind of Schiff base complexes having the acid amide moiety in the ligand. However, such an *N*-acetyl Schiff base has never been prepared by condensation of benzoylacetone and acetamide since the amide protons are generally protected against reactions by the acetyl group. This fact and the acid-lability of the *N*-acetyl bond (see later), together with the difficulty in separation of analogous complexes by PLC, cause the lowering in yields of the reaction products.

Table 6. Reaction products in the presence of excess free β-diketones or *o*-nitrophenol[a]

	Tl-(RCOCHCOMe)	Products (Yields/%)
trans-[$PtCl_2(PhCN)_2$]	R=Me	**5a** (3),**5b**(8)
	Ph	**3a** (15),**3a'**(4),**6**(5)
cis-[$PtCl_2(PhCN)_2$]	R=Me	**2a** (75)
	Me*	**2a** (14)
	Ph	**4a** (57)

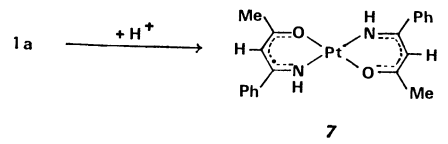
a) The asterisk mark denotes the reaction in the presence of excess *o*-nitrophenol.

Reactions of trans- *and* cis-[$PtCl_2(PhCN)_2$] *with Thallium(I) β-Diketonate in the Presence of the Corresponding Excess Free β-Diketone or* o-*Nitrophenol.* With the exceptions of **5a**, **5b**, and **6**, each of the other compounds produced in these reactions is also found in the reaction products in the absence of free β-diketones. These products are summarized in Table 6 with their yields. **5a** and **5b** are compounds in which one *N*-acetyl chelate ring in **1a** and **1b** was formally replaced by a *C*-acetyl

chelate ring, respectively, and hence **5a** corresponds to the *trans* isomer of **2b**. Similarly, **6** and **4b** make another isomeric pair of *trans* and *cis*. From Table 6, we can see that the *C*-acyl compounds are main products in these cases; their amounts are increased especially in the reactions with *cis*-$[PtCl_2(PhCN)_2]$. The following process can produce such high yields of *C*-acyl products: protons from free β-diketone are used to stabilize imino nitrogens produced during the reaction; hence, migration of *C*-acyl groups onto the nitrogen atoms are suppressed; and then CH protons are accepted by the β-diketonate anions present in solution.

To examine the effect of other proton donors, *o*-nitrophenol instead of free β-diketone was used in the reaction of *cis*-$[PtCl_2(PhCN)_2]$ with Tl(acac), as an example. However, no increase in yield of *C*-acetyl product **2a** was found (see Table 6). The reason why the reagent has no effect has not yet been elucidated, but the rather strong acidity ($pK_a=7.2$) of *o*-nitrophenol compared with that of acetylacetone ($pK_a=9.0$) might be the reason for its inefficancy as catalyst.

Acid Hydrolysis of trans-N-*Acetyl Compound* **1a**. In the previous section, we showed that the presence of free β-diketone suppresses migration of the *C*-acyl group onto the imino nitrogen atom, affording *C*-acyl compounds, namely, *N*-unsubstituted β-ketoamine chelates in high yields. Next we examined the acid stability of the *N*-acetyl bonds in **1a**. This bond is readily hydrolyzed by aqueous perchloric acid to yield golden crystals of **7**. The compound did not show any



7 (2)

IR band in the carbonyl region higher than 1600 cm^{-1}, indicating the absence of uncoordinated acetyl carbonyl. The ^1H NMR spectrum exhibited only one methine and one ring-methyl signal at 5.34 and 1.88 ppm, respectively, together with one broad NH signal at 7.86 ppm in the intensity ratios of 1 : 3 : 1; this shows that the *N*-acetyl bonds in **1a** are hydrolyzed to the N-H. In fact, coupling ($^4J_{H-H}=4.0$ Hz) based on the W-rule[25] is again observed between the ring methine and the NH protons. Such an acid lability of the *N*-acetyl bonds might also play a part in the original reactions of $[PtCl_2(PhCN)_2]$ with β-diketonate anions. The compound **3b**, which is one of the reaction products between *trans*-$[PtCl_2(PhCN)_2]$ and Tl(bzac), might have been produced by the effect of a little amount of acid present accidentally in solution.

We are grateful to Mr. Junichi Gohda for the elemental analysis, and also to the Ministry of Education, Science and Culture for partial support by a Grant-in-Aid (Grant number 243014).

(Received September 29, 1980)

A number of palladium(II) and platinum(II) bis-chelates have been prepared which contain one kind of symmetric or unsymmetric β-diketonate anions, or involve two different β-diketonate anions. Existence of the *cis* and *trans* isomers in solution of the binary chelates of unsymmetric β-diketones was confirmed by ^{1}H and ^{13}C NMR spectroscopy. Geometrical isomerization of the palladium(II) complexes to attain equilibrium in solution is fast, while the platinum(II) complexes are quite inert. The mixed-ligand chelates are stable in solution, showing no sign of disproportionation. The isomeric pairs of bis(1-phenyl-1,3-butanedionato)palladium(II), bis(2,4-hexanedionato)palladium(II), and bis(1,1,1-trifluoro-2,4-pentanedionato)platinum(II) were isolated, and molecular structure of the *cis* isomer of the first complex was determined by X-ray analysis.

2,4-Pentanedione and other β-dicarbonyl compounds (β-dikH) react with a wide variety of metal ions to form the (O,O') chelates[1] of the $[M(\beta\text{-dik})_n]$ type which are soluble in organic solvents, and are used frequently as analytical reagents. These complexes are useful not only for comparative studies of various metal ions, but also as starting materials for preparation of organometallic compounds and as catalysts for organic syntheses. Thus a huge number of papers have appeared concerning the complexes containing β-dicarbonyl compounds as a ligand.[2]

Although optical and geometrical isomerization of the octahedral $[M(\beta\text{-dik})_3]$ and related complexes have been studied extensively,[3] investigations on geometrical isomerism of the square-planar $[M(\beta\text{-dik})_2]$ complexes containing unsymmetrical β-dicarbonyl compounds are rather few. Recently two of the present authors have prepared bis(1-ethoxy-1,3-butanedionato)palladium(II) and showed that it exists as an equilibrium mixture of *cis* and *trans* isomers in chloroform.[4] This paper is concerned with preparation and spectroscopic studies of a number of palladium(II) and platinum(II) complexes of symmetric and unsymmetric β-dicarbonyl compounds including several mixed-ligand bis-chelates. A preliminary report on isolation of *cis*- and *trans*-bis(1-phenyl-1,3-butanedionato)palladium(II) and X-ray structure of the *cis* isomer was published in a short communication,[5] and the full account will be included in this paper.

Experimental

Preparation of Complexes. The palladium(II) and platinum(II) chelates of β-dicarbonyl compounds were prepared by one of the following four methods. (A) To an aqueous solution of sodium tetrachloropalladate(II), $Na_2[PdCl_4]$, was added more than twice moles of a ligand together with an appropriate amount of base. (B) Mercury(II) perchlorate and/or silver(I) perchlorate was added to $Na_2[PdCl_4]$ or potassium tetrachloroplatinate(II), $K_2[PtCl_4]$, in aqueous solution to prepare $[M(H_2O)_4]^{2+}$ ions *in situ*, which were allowed in turn to react with a sodium or potassium salt of the β-dicarbonyl compounds.[6] (C) To a methanol solution of sodium hexachlorodipalladate(II), $Na_2[Pd_2Cl_6]$, was added more than twice equivalents of a free ligand followed by an appropriate amount of sodium carbonate.[7] (D) The reaction between [PdCl(hfac)py] and Tl(β-dik) was convenient for preparation of the mixed-ligand palladium(II) chelates containing 1,1,1,5,5,5-hexafluoro-2,4-pentanedione (hfacH) and another β-diketone.

β-Dicarbonyl compounds were purchased and used without further purification except *t*-butyl acetoacetate which was prepared according to literature.[8] Aqueous solution of $Na_2[PdCl_4]$ was prepared by dissolving palladium(II) chloride and a two and half times molar amount of sodium chloride in a small amount of hot water and adjusting the complex concentration to 0.5 mol dm^{-3}. Methanol solution of $Na_2[Pd_2Cl_6]$ was prepared by dissolving palladium(II) chloride and an equimolar amount of sodium chloride in a small amount of hot methanol and then diluting the resultant solution to [Pd]=0.3 mol dm^{-3}.

*Bis(2,4-pentanedionato)palladium(II), [Pd(acac)$_2$] (**1a**):* An aqueous solution (4 cm^3) of sodium hydroxide (5 mol dm^{-3}) was added with stirring to a mixture of acacH (2.5 cm^3) and a solution (10 cm^3) of $Na_2[PdCl_4]$ (0.5 mol dm^{-3}) to form a yellow precipitate, which was filtered and washed three times each with small portions of water, methanol, and diethyl ether, successively. A yellow powder formed was dissolved in dichloromethane and filtered to avoid a small amount of insoluble material. The solvent was allowed to evaporate spontaneously at room temperature to leave large orange-red crystals (1.37 g) in a 90% yield. The yield is better than that (76%) reported in literature[9] using palladium(II) chloride as a starting material.

cis- *and* trans-*Bis(2,4-hexanedionato)palladium(II), cis- and* trans-*[Pd(hxd)$_2$] (**1f**):* The complex was prepared in a similar way as for **1a**. Recrystallization from hot toluene gave orange plates, while a mixture of orange plates and yellow needles was obtained from hot methanol. The yellow needles can conveniently be obtained by prompt evaporation of a dichloromethane solution under reduced pressure. They are geometrical isomers giving identical analyses and slightly different IR and NMR spectra. Orange plates were assigned to *cis* and yellow needles *trans*.

*Bis(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)palladium(II),[Pd(hfac)$_2$] (**1d**):* Yellow mercury(II) oxide (6.49 g, 30 mmol) was dissolved in a solution (60 cm^3) of perchloric acid (1 mol dm^{-3}). The solution of mercury(II) perchlorate thus prepared was added with stirring to a solution (20 cm^3) of $Na_2[PdCl_4]$ (0.5 mol dm^{-3}) kept at 0 °C. A greenish yellow precipitate appeared at once but stirring was continued for further several minutes. To the mixture was added dropwise a solution of Na(hfac) which had been prepared by dissolving hfacH (8 cm^3, 50 mmol) in a solution (20 cm^3) of sodium hydroxide (2 mol dm^{-3}). A precipitate was filtered, washed

several times with water, and dried *in vacuo*. The red-brown powder was treated with hexane and insoluble material was filtered off. The solvent was distilled away under reduced pressure to leave yellow fine needles (4.71 g) in a 91% yield. Recrystallization from hot hexane gave large red needles, while orange plates of trihydrate were obtained from methanol. When silver(I) nitrate was used instead of mercury(II) perchlorate, the yield was as low as 50%. Compound **1d** must be kept at cold place, since it gradually decomposes at room temperature.

Chloro(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)(pyridine)palladium(II), [PdCl(hfac)py]: A solution of **1d** (564 mg, 1.08 mmol) in dichloromethane (2 cm^3) was added to a solution of pyridinium chloride (130 mg, hygroscopic *ca.* 1 mmol) in methanol (5 cm^3) and the mixture was allowed to stand one day at room temperature to deposit red plates (318 mg). Hexane was added to the filtrate and the mixture was cooled to precipitate another crop (53 mg) of the product. The same procedure was repeated once more and the total yield of the product reached 92% (426 mg).

cis- *and* trans-*Bis(1-phenyl-1,3-butanedionato)palladium(II)*, cis- *and* trans-*[Pd(bzac)$_2$] (**1g**)*: The literature method[10] was improved to attain better yields. A solution (10 cm^3) of potassium hydroxide (1.5 mol dm^{-3}) was added to a solution of bzacH (2.6 g, 16 mmol) in methanol (20 cm^3). A solution (10 cm^3) of $Na_2[PdCl_4]$ (0.5 mol dm^{-3}) was added dropwise through a pipette to the above solution with stirring. A yellow precipitate was filtered, washed three times each with water, methanol, and diethyl ether, and dried *in vacuo*. Compound **1g** was obtained as a mixture of *cis* and *trans* isomers in a 90% yield (1.93 g). When the isomeric mixture was dissolved in dichloromethane and the solvent was evaporated spontaneously at room temperature, only the *trans* isomer was obtained quantitatively as orange-yellow needles. On the other hand, when ethyl acetate (20 cm^3) and petroleum ether boiling below 60 °C (several cm^3) were added to a solution of the *cis-trans* mixture (226 mg) in dichloromethane (25 cm^3) and the solution was kept in a shallow vessel to allow vaporization of solvents at room temperature, both of orange-red hexagonal plates of the *cis* isomer and orange-yellow needles of the *trans* isomer were left to be separated manually. Separation of the isomeric mixture by means of thin layer chromatography was tried over silica gel with dichloromethane as a developing solvent. The R_f values were 0.80 and 0.84 for *cis* and *trans*, respectively. Separation of isomers through a column was not successful because of rather fast isomerization reactions.

*Bis(1,1,1-trifluoro-2,4-pentandionato)palladium(II), [Pd(tfac)$_2$] (**1h**)*: To a methanol solution (20 cm^3) of $Na_2[Pd_2Cl_6]$ (0.15 mol dm^{-3}) was added tfacH (1.4 g, 9 mmol) with stirring. On addition of a fine powder of sodium carbonate in limited amounts to the solution, an increasing amount of a yellow precipitate appeared and *ca.* 20 cm^3 of methanol was added to make stirring easy. Addition of the base was stopped when no more precipitate was produced. The precipitate was filtered, washed three times each with water, methanol, and diethyl ether, successively and dried *in vacuo*. Recrystallization from dichloromethane–hexane gave orange-yellow needles (2.0 g) in an 81% yield.

*Bis(1,3-diphenyl-1,3-propanedionato)palladium(II), [Pd(dbm)$_2$] (**1b**), bis(2,2,6,6-tetramethyl-3,5-heptanedionato)palladium(II), [Pd(dpm)$_2$] (**1c**), bis-(3-phenyl-2,4-pentanedionato)palladium(II), [Pd(Ph-acac)$_2$] (**1e**), bis(1,1,1-trifluoro-5,5-dimethyl-2,4-hexanedionato)palladium(II), [Pd(pta)$_2$] (**1l**), and bis(1,1,1-trifluoro-4-(2-thienyl)-2,4-butanedionato)palladium(II), [Pd(tta)$_2$] (**1m**)*: These complexes were prepared by method C in a similar manner as for **1h**. Recrystallization of **1b**, **1c**, **1e**, and **1l** was performed from dichloromethane–hexane, benzene–hexane, dichloromethane, and diethyl ether, respectively. Compound **1m** is sparingly soluble in common solvents and was not recrystallized.

*Bis(1-t-butoxy-1,3-butanedionato)palladium(II), [Pd(buac)$_2$] (**1j**)*: *t*-Butyl acetoacetate (buacH, 1.5 cm^3, 10 mmol) was dissolved in a solution (10 cm^3) of potassium hydroxide (1 mol dm^{-3}). The solution was added drop by drop with stirring to a solution (10 cm^3) of $Na_2[PdCl_4]$ (0.5 mol dm^{-3}) to deposit a brown precipitate, which was filtered and dried *in vacuo*. The precipitate was dissolved in petroleum ether (bp$<$50 °C, 50 cm^3) and insoluble substance was filtered off. Then the solvent was allowed to evaporate spontaneously at room temperature to deposit light brown plates on the wall of vessel. The yield was 14% (295 mg). *Bis(1-ethoxy-1,3-butanedionato)palladium(II),*[4] *[Pd(etac)$_2$] (**1i**)* and *bis(1-phenyl-3-ethoxy-1,3-propanedionato)palladium(II), [Pd(etbz)$_2$] (**1k**)* were also prepared in a similar manner as above.

*2,4-Pentanedionato(1,1,1-trifluoro-2,4-pentanedionato)palladium(II), [Pd(acac)(tfac)] (**1n**)*: A methanol solution (20 cm^3) containing K(acac)·H_2O (0.97 g, hygroscopic, *ca.* 6 mmol) and K(tfac)·H_2O (1.35 g, 6.4 mmol) was added with stirring to a methanol solution (20 cm^3) of $Na_2[Pd_2Cl_6]$ (0.15 mol dm^{-3}) to deposit a yellow precipitate. After stirring of the mixture for 2 h, the precipitate was filtered, washed with water and methanol, successively, and dried *in vacuo* to give a yellow powder (1.85 g). Chromatographic separation of the crude product through a silica-gel column (70×3d cm) using a mixture of dichloromethane, benzene, and petroleum ether (4 : 1 : 1 by volume) as the developing solvent resulted in three fractions. The middle fraction gave yellow fine needles of **1n** (736 mg) in a 34% yield. The first and third eluents afforded [Pd(tfac)$_2$] (**1h**) and [Pd(acac)$_2$] (**1a**) in each 20% yields, respectively. The same preparative method was applied to various couples of acac, bzac, tfac, and hfac salts, but no mixed-ligand chelate was obtained successfully except the above acac-tfac case.

Alternatively, complex **1n** was also prepared by the partial substitution reaction of [Pd(tfac)$_2$]. To a solution of [Pd(tfac)$_2$] (500 mg, 1.21 mmol) in acetone (20 cm^3) was added with stirring a solution of K(acac)·H_2O (160 mg, *ca.* 1 mmol) in methanol (1 cm^3), when color of the solution changed from yellow to yellow-brown. After stirring of the mixture for 5 min, the solvent was evaporated under reduced pressure to leave a yellow powder, which was extracted with dichloromethane and the extract was subjected to the chromatographic separation as above. Complex **1n** was obtained in a 17% yield (72 mg). The residue which was insoluble in dichloromethane consisted mainly of K(tfac)·H_2O (210 mg, 1.0 mmol).

*1,1,1,5,5,5-Hexafluoro-2,4-pentanedionato(2,4-pentanedionato)palladium(II), [Pd(acac)(hfac)] (**1o**)*: A suspension of Tl(acac) (88 mg, 0.29 mmol) in dichloromethane (3 cm^3) was added with stirring to a solution of [PdCl(hfac)py] (152 mg, 0.36 mmol) in dichloromethane (1 cm^3) kept at −10 °C. After stirring of the mixture for 30 min, a white precipitate of thallium chloride was filtered off. Hexane was added to the filtrate and the solution was kept at −20 to −30 °C for 1 h. An additional precipitate of thallium chloride was separated by filtration and the solvent was distilled away under reduced pressure. The residue was dissolved in dichloromethane, hexane was added to the solution, and the mixture was cooled to deposit pale yellow crystals of $[Pd(py)_4](hfac)_2$ accompanied by a powder of thallium chloride. After separation of the precipitate, the solution was poured onto a column of silica gel. Development with dichloromethane gave rise to three zones and the first fraction gave lemon-yellow fine needles of

1o (28 mg) in a 18% yield on the basis of the starting complex. Substances recovered from the second and third fractions were not enough in amount to be identified.

1, 1, 1,5, 5, 5-Hexafluoro-2, 4-pentanedionato (1-phenyl-1, 3-butanedionato)palladium(II), [Pd(bzac)(hfac)] (1p): The same preparative method was used and the first fraction from the column chromatography gave **1p** in a 18% yield. The second fraction contained [Pd(bzac)$_2$] (**1g**) in a 7% yield. The substance in the third fraction was not identified.

Bis(2,4-pentanedionato)platinum(II), [Pt(acac)$_2$] (2a), bis-(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)platinum(II), [Pt-(hfac)$_2$] (2d), and cis- *and* trans-*bis(1,1,1-trifluoro-2,4-pentanedionato)platinum(II),* cis- *and* trans-*[Pt(tfac)$_2$] (2h)*: These complexes were prepared by the revised method B reported very recently.[6]

2,4-Pentanedionato(1, 1, 1-trifluoro-2, 4-pentanedionato) platinum-(II), [Pt(acac)(tfac)] (2n): Both of acacH (5 g, 50 mmol) and tfacH (7.7 g, 50 mmol) were dissolved in a solution (30 cm^3) of sodium hydroxide (5 mol dm^{-3}). To this solution was added with stirring a solution (500 cm^3) of [Pt(H$_2$O)$_4$](ClO$_4$)$_2$[6] (0.025 mol dm^{-3}) followed by a solution (73 cm^3) of sodium hydroxide (5 mol dm^{-3}) drop by drop from pipettes, respectively. A yellow-brown precipitate deposited gradually, which was filtered after being stirred for 15 h, washed three times with water, and dried *in vacuo*. The resultant yellow-brown powder was dissolved in dichloromethane, separated from insoluble material by filtration, and subjected to chromatographic separation through a column of silica gel (70× 3d cm) using dichloromethane as the eluent. The first fraction contained [Pt(tfac)$_2$] (**2h**) (656 mg, 10% yield) and the second gave **2n** (1.69 g), which was recrystallized from benzene–hexane to give yellow needles in a 29% yield (1.59 g).

1,1,1,5,5,5-Hexafluoro-2, 4-pentanedionato (2, 4-pentanedionato)-plantinum(II), [Pt(acac)(hfac)] (2o): In a similar manner as above, an equimolar mixture of Na(acac) and Na(hfac) was allowed to react with [Pt(H$_2$O)$_4$](ClO$_4$)$_2$ in aqueous solution and the crude product was subjected to chromatographic separation through a silica-gel column. Development with dichloromethane gave rise to four zones. The first fraction contained [Pt(hfac)$_2$] (547 mg, 7% yield) and the second gave purple fine needles of **2o** in a 15% yield (945 mg). The fourth fraction gave [Pt(acac)$_2$] (1067 mg, 22% yield) and the third a little amount of lemon-yellow substance which was not identified. An analogous preparative trial using a mixture of tfacH and hfacH was not successful in obtaining [Pt(tfac)-(hfac)].

Measurements. Infrared spectra were recorded in Nujol on Hitachi 295 and JASCO DS-701G spectrophotometers. JEOL JNM C60HL, MH-100, and FX-60Q instruments were used to obtain NMR spectra. Mass spectra were taken on a JEOL JMS-D300 mass-spectrometer. A vapor-pressure osmometer manufactured by Knauer in West Berlin, West Germany, was also used for molecular-weight determination.

X-Ray Analysis. X-Ray analysis of *cis*-[Pd(bzac)$_2$] (**1g**-*cis*) was performed. Laue symmetry and approximate cell dimensions were determined from Weissenberg photographs taken with Cu $K\alpha$ radiation. The cell dimensions were refined by the least-squares analysis of θ values of 16 reflections measured on an automated four-circle diffractometer with Mo $K\alpha$ radiation. Crystal data: Monoclinic, a=11.024(3), b=19.629(4), c=9.472(2) Å, β=119.78(2)°, space group P2$_1$/c, D_m=1.60, D_c=1.60 g cm^{-3}, Z=4, μ(Mo $K\alpha$)=10.5 cm^{-1}.

Intensity data were collected by the ω-2θ scan method by the diffractometer with graphite-monochromated Mo $K\alpha$ radiation, using a crystal specimen with size of 0.22×0.30×0.08 mm^3. The scan speed and scan width in ω were 0.017 s^{-1} and (0.7+0.2 tan θ)°, respectively. The background was counted for 20 s at each side of the scan range. A total of 1927 unique reflections having intensity $I_t-2\sqrt{I_t}>I_b$ was collected in the $2\theta\leq55°$ range (I_t, intensity at the peak of reflection; I_b, mean background intensity obtained from preliminary background measurement of 5 s at each side of the scan range). The intensities of three standard reflections monitored every 4 h showed no appreciable variation. Intensities were corrected for Lp factor but not for absorption. Of 1927 reflections 1814 with $F_o^2>3\sigma(F_o^2)$ were used for the structure analysis.

The crystal structure was solved by the heavy atom method, and the positional and thermal parameters were refined by the least-squares. The minimized function was $\sum w(F_o-|F_c|)^2$. The weighting scheme, w=0.82 for $F_o<35.7$, w=1.0 for $35.7\leq F_o\leq71.4$, and $w=(71.4/F_o)^2$ for $F_o>71.4$, were found to be optimal. All H atoms could be located on the difference Fourier map calculated after anisotropic refinement for nonhydrogen atoms. These H atoms were included in the least-squares refinement with isotropic temperature factor $B_H=B_p+1.0$ Å^2, the positional parameter being fixed (B_p, the isotropic temperature factor of nonhydrogen atom to which the H atom is bonded). The convergence was attained with R=0.033 and $R'(=[\sum w(F_o-|F_c|)^2/\sum wF_o^2]^{1/2})$=0.042.

a) Equivalent isotropic temperature factor.

Atomic scattering factors were taken from Ref. 11. Real part of the anomalous dispersion corrections were applied for Pd[0]. Atomic coordinates are given in Table 1. The anisotropic thermal parameters, H atom coordinates, and F_o-F_c tables are preserved by the Chemical Society of Japan (Document No. 8127). All computations were performed on a FACOM 230-60 computer at the Osaka City University using programs in the UNICS.[12]

Results and Discussion

Syntheses. A number of palladium(II) (**1**) and platinum(II) (**2**) bis-chelates of β-dicarbonyl compounds were prepared including the binary chelates of both the symmetric (**1a—1e**, **2a**, and **2d**) and unsymmetric (**1f—1m** and **2h**) β-dicarbonyl anions as well as the mixed-ligand chelates (**1n—1p**, **2n**, and **2o**). The appearance, preparative method, yield, decomposition temperature, and elemental analyses of the new compounds are listed in Table 2 together with some molecular-weight data.

Of the four preparative methods summarized at the outset, method A represented by Eq. 1 is suitable for

$$[MCl_4]^{2-} + 2(\beta\text{-dik})^- \longrightarrow [M(\beta\text{-dik})_2] + 4Cl^- \quad (1)$$

more basic anions such as those of acacH, bzacH, and the β-keto esters. Very low yields of the β-keto-ester chelates may be related to weaker basicity of the oxygen atoms than that of the central carbon atom in the ligand anions as exemplified by the low [enol]/[keto] values of the β-keto ester molecules.[13] The fact that both of the chelating ligands in [Pd(etac)$_2$] (**1i**) are readily transformed to the central-carbon-bonded state on reactions with nitrogen bases,[4] whereas only one of the acac anions in [Pd(acac)$_2$] (**1a**) is converted in similar reactions[14] also shows the difference in the preference of bonding modes between acac and β-keto ester anions.

In the platinum(II) case, method A affords [Pt(acac)$_2$] (**2a**) in a much lower yield (35%) than that for [Pd(acac)$_2$] together with the central-carbon-bonded by-products such as K[PtCl(acac)(acac-C^3)] and K[PtCl$_2$(acac-C^3)$_2$].[15] Furthermore the platinum(II) chelates of less basic tfac and hfac anions have not been obtained. The Pt–Cl bonds might be more stable than the Pt–(β-dik) chelate, resisting the ligand substitution. On this supposition, the chloride anions in $[MCl_4]^{2-}$ were displaced by virtue of mercury(II)[16] and/or silver(I) ions prior to reactions with the β-dik ligands.[6] Thus

a) X=H except compound **1e** for which X=C_6H_5. b) See text. c) Trihydrate, orange crystals. Found: C, 20.99; H, 1.11%. Calcd: C, 20.90; H, 1.40%. d) Sublimation temperature. e) Parent peaks in mass spectra containing the ^{106}Pd or ^{195}Pt atom were used. f) The ligand is 3-phenyl-2,4-pentanedionate. g) Determined by the vapor pressure osmometry in chloroform at 42 °C.

the chelate formation reactions in method B are expressed by Eq. 2. [Pd(tfac)$_2$] (**1h**) was prepared in

$$[M(H_2O)_4]^{2+} + 2(\beta\text{-dik})^- \longrightarrow [M(\beta\text{-dik})_2] + 4H_2O. \quad (2)$$

a high yield by the reaction between $Na_2[Pd_2Cl_6]$ and tfacH in cooperation with sodium carbonate. Method C[7] is convenient and successfully applied to preparation of the [Pd(β-dik)$_2$] complexes other than **1d**.

$$[Pd_2Cl_6]^{2-} + 4(\beta\text{-dik})^- \xrightarrow[\text{in MeOH}]{} 2[Pd(\beta\text{-dik})_2] + 6Cl^- \quad (3)$$

By employing an equimolar mixture of two kinds of β-dicarbonyl compounds, [Pd(acac)(tfac)] (**1n**), [Pt(acac)(tfac)] (**2n**), and [Pt(acac)(hfac)] (**2o**) were obtained according to methods C, B, and B, respectively. In each of these cases binary bis-chelates were accompanied and separated by column chromatography. On the other hand, [Pd(acac)(hfac)] (**1o**) and [Pd(bzac)(hfac)] (**1p**) could not be prepared by this way, but were obtained by the metal-assisted ligand substitution reactions of [PdCl(hfac)(py)] with Tl(β-dik) (method D). Unfortunately the yield was low in either case and the desired reaction 4 seems to be accompanied by subsidiary reactions 5 and 6. The by-product [Pd-

$$[PdCl(hfac)(py)] + Tl(\beta\text{-dik}) \longrightarrow [Pd(hfac)(\beta\text{-dik})] + py + TlCl \quad (4)$$

$$[Pd(hfac)(\beta\text{-dik})] + Tl(\beta\text{-dik}) \longrightarrow [Pd(\beta\text{-dik})_2] + Tl(hfac) \quad (5)$$

$$[PdCl(hfac)(py)] + Tl(hfac) + 3py \longrightarrow [Pd(py)_4](hfac)_2 + TlCl \quad (6)$$

(py)$_4$](hfac)$_2$ was identified by comparison with the authentic sample prepared by the reaction between [Pd(hfac)$_2$] and pyridine.[17]

Geometrical isomerism is possible in the case of [M(β-dik)$_2$] complexes containing unsymmetrical β-dicarbonyl compounds as a ligand. The structures of *cis*-[VO(bzac)$_2$],[18] *cis*-[Zn(bzac)$_2$]·EtOH,[19] *trans*-[Cu(bzac)$_2$],[20] *trans*-[Pd(bzac)$_2$],[10] and *trans*-[Cu(etac)$_2$][21] were confirmed by X-ray analysis, but their geometrical isomers have not been reported and identification of isomers in solution has not been performed either, except for [Pd(etac)$_2$].[4] Recrystallization of [Pd(bzac)$_2$] (**1g**) from dichloromethane gave only orange-yellow needles of the *trans* isomer which had been reported.[10]

a) Atoms marked with an asterisk were included in the calculation of the mean plane.

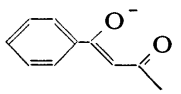
Interplanar angles (ϕ/°)	
(1)—(2)	170.1
(1)—(3)	177.0
(2)—(4)	17.0
(3)—(5)	41.1

On the other hand, orange-red hexagonal plates of the *cis* isomer accompanied by *trans* appeared from a mixture of dichloromethane, ethyl acetate, and petroleum ether. Detail of the X-ray structure of *cis*-[Pd(bzac)$_2$] is reported below. The isomeric pairs of [Pt(tfac)$_2$][6] and [Pd(hxd)$_2$] were also isolated and characterized. Isomers of the other [Pd(β-dik)$_2$] complexes of unsymmetric ligands were not isolated but were identified in solution by ^{1}H NMR spectroscopy as will be described in later sections.

X-Ray Structure of cis-[*Pd(bzac)*$_2$]. Figures 1 and 2 show the crystal structure and a view of the molecule normal to the coordination plane defined by four oxygen atoms. Bond lengths and angles are given in Table 3. Table 4 lists deviations of atoms from least-squares plane. The Pd atom has a usual square-planar coordination by four oxygen atoms. Both O–C–C–C–O planes in the six-membered chelate rings are slightly bent upward from the coordination plane, the interplanar angles being given in Table 4. The C(13) atom of the adjacent molecule ($-x$, $-y$, $-z$), the mean molecular plane of which is parallel to that of the molecule (x, y, z) under consideration, is located just above the Pd atom. The Pd···C(13) distance is 3.301(7) Å, and Pd···C(13) vector intersects the coordination plane at 80.8°.

The phenyl group is rotated about C–C bond joining the group to the chelate ring, being slant against the O–C–C–C–O plane. The torsion angle is 17.0° in the ligand A and 41.1° in B.[22] In the other metal chelates of the bzac the torsion angles are in the 4—23° range (6.5° and 19.0° in *cis*-[VO(bzac)$_2$],[18] 14.3° in *trans*-[Cu(bzac)$_2$],[20] 23° in *trans*-[Pd(bzac)$_2$],[10] 3.8° and 7.5° in *cis*-[Zn(bzac)$_2$]·EtOH.[19]). The ligand conformation for A is therefore thought to be preferred over that for B with larger torsion angle. The unfavorable conformation of B presumably results from crystal packing.

The approximate coplanarity of the phenyl and chelate rings in the preferred conformation suggests a conjugation of π systems between two rings. On the basis of the X-ray structures of the *trans* isomers of Cu and Pd complexes, Hon *et al.*[10] claimed that there is an effective inter-ring conjugation and that the chelate ring has a significant contribution from the following resonance structure. In the case of the *cis* isomer of Pd



complex, however, the bond lengths in the O–C–C–C–O segment of A show no localization of π electrons. The C(4)–C(5) bond length, which may reflect the extent of the conjugation, is not different from the length for single C(sp^2)–C(sp^2) bond. Furthermore the structural parameters in A agree well with chemically equivalent ones in B of which larger torsion angle indicates smaller inter-ring conjugation; the extent of conjugation is not detectable from structural parameters. Bond lengths and angles in the chelate rings of *cis*-[Pd(bzac)$_2$] are rather in agreement with the corresponding ones in Pd(acac)$_2$(TTF)[23] (TTF=tetrathiafulvalene).

Thermal Stability and IR Spectra. Most of the chelates in Table 2 are thermally stable and the following features in volatility are noted which are similar to those observed for the β-dicarbonyl chelates of other metals.[2] (i) When the methyl groups in acac are replaced by the ethyl, *t*-butyl, and trifluoromethyl groups, volatility of the complex increases in this sequence. (ii) Substitution with phenyl and thienyl groups makes the complex less volatile. (iii) Sublimation temperature of a mixed-ligand chelate is intermediary of those for the two binary chelates. As is indicated in Table 2, molecular-weight data of volatile complexes were determined by mass spectrometry.

Infrared bands in the 1650—1500 and 830—770 cm^{-1} regions which are assigned to the ν(C=O)+ν(C=C) and chelate-ring π(CH) vibrations, respectively,[24] are listed in Table 5 together with some other characteristic vibrations. Substitution of the methyl group in the acac chelate with the electron-attracting trifluoromethyl group increases the ν(C=O)+ν(C=C) frequencies. IR spectra in the higher frequency region are not so sensitive to the geometry of complexes, but those in the region lower than 700 cm^{-1} show ap-

a) Mikami, *et al.* recorded the corresponding bands at 1569, 1549, 1524, 786, and 779 cm^{-1} [M. Mikami, I. Nakagawa, and T. Shimanouchi, *Spectrochim. Acta, Part A*, **23**, 1037 (1967)]. b) The spectrum was shown in Ref. 7. c) Nakamoto, *et al.* recorded only the ν(Pd–O) band at 478 cm^{-1} for [Pd(bzac)$_2$] [K. Nakamoto, P. J. McCarthy, and A. E. Martell, *Nature*, **183**, 459 (1959)]. As is seen in Fig. 3, this band may be assigned to the *trans* isomer. d) Exact frequencies were not given in Ref. 4. e) The corresponding literature data probably in KBr are 1565s, 1555s, 1527s, and 774s cm^{-1} [J. Lewis, R. F. Long, and C. Oldham, *J. Chem. Soc.*, **1965**, 6740]. f) Ref. 6.

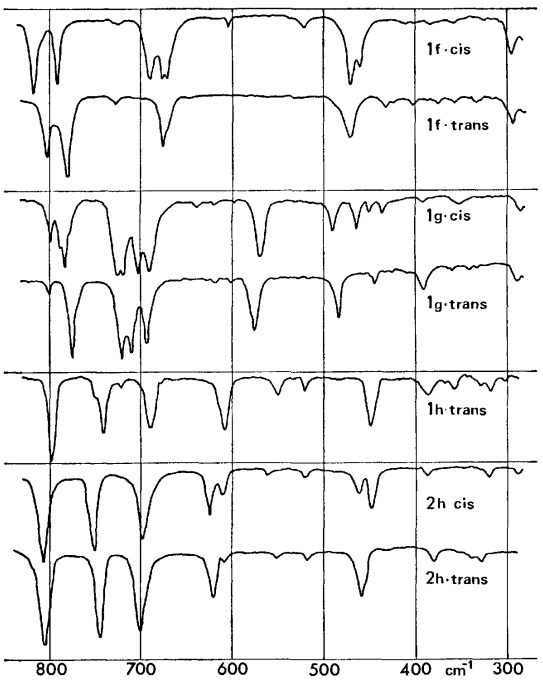

Fig. 3. IR spectra in Nujol in the lower-frequency region of [Pd(hxd)$_2$] (**1f**), [Pd(bzac)$_2$] (**1g**), [Pd(tfac)$_2$] (**1h**), and [Pt(tfac)$_2$] (**2h**).

preciable difference between the *cis* and *trans* isomers. Figure 3 compares the spectra of three isomeric pairs. In accordance with the lower symmetry, *cis* isomers of [Pd(hxd)$_2$] (**1f**), [Pd(bzac)$_2$] (**1g**) and [Pt(tfac)$_2$] (**2h**) exhibit more composite spectra than *trans* isomers. The spectrum of [Pd(tfac)$_2$] (**1h**) in this region shows a close resemblance to that of *trans*-**2h** and may be considered to be *trans*, although the *cis* isomer has not yet been isolated. As is seen in Fig. 3, orange plates of [Pd(hxd)$_2$] (**1f**) show more composite IR spectra than yellow needles and are tentatively assigned to the *cis* isomer.

IR spectrum of a mixed-ligand chelate [M(β-dik)(β-dik′)] looks like a superposition of spectra of the binary chelates [M(β-dik)$_2$] and [M(β-dik′)$_2$] and is complicated especially in the π(CH) and lower-frequency regions.

NMR Spectra. Tables 6—10 list the ^{1}H, ^{13}C, and ^{19}F NMR data. Substitution of the CH_3 group with CF_3 deshields the methine proton but increases shielding of the methine carbon. Inductive effect of the CF_3 group might shift the shared electrons of the C–H bond to the carbon side. It is noticed that C_6D_6 shows a remarkable effect on the ^{1}H NMR spectra, most signals showing substantial upfield shifts as compared with those taken in other solvents. Strange to say, the methyl protons of [M(acac)$_2$] (**1a** and **2a**)

a) X=H except **1e** for which X=C_6H_5. When two values of chemical shift are given for a signal from a mixture of geometric isomers, the former one refers to *cis* and the latter to *trans*. Chemical shifts are given in ppm from internal Me_4Si and *J* values in Hz. m, multiplet; q, quartet; t, triplet; others, singlet. b) The literature values are CH: 5.65 and $C(CH_3)_3$: 1.13 ppm.[7] c) Identification of isomers is not possible. d) The isomer ratio was determined based on the ^{13}C NMR spectra. e) Only one isomer seems to exist, but is not identified. f) The literature values are CH_3: 2.08[5] and CH: 5.53[11] [J. Lewis, R. F. Long, and C. Oldham, *J. Chem. Soc.*, **1965**, 6740]. g) Redetermined[6] on an FX-60Q instrument.

resonate at higher field in $CDCl_3$ but at lower field in C_6D_6 than those of [M(tfac)$_2$] (**1h** and **2h**), respectively. Similar reversion of the methyl-signal positions in the two solvents was also observed for similar Zr(IV), Hf(IV), Ce(IV), and Th(IV) complexes, and even for free ligands, acacH and tfacH.[25] The upfield shift in benzene may be attributed to the diamagnetic anisotropy of the solvent molecule interacting with the chelates and ligands, but reasonable rationalization of much more remarkable effect exerted on the tfac chelates than on the acac chelates is not possible at present.

NMR spectra are useful for distinguishing between geometrical isomers of bis-chelates of unsymmetrical ligands. The platinum(II) chelates are very inert and both isomers of [Pt(tfac)$_2$] (**2h**) showed no sign of isomerization in C_6D_6 for more than one month. The corresponding palladium(II) complex [Pd(tfac)$_2$] (**1h**) showed a single methyl signal at 1.32 ppm immediately after dissolution in C_6D_6, but a new signal at 1.36 ppm grew gradually with time at the expense of the 1.32 ppm signal to attain equilibrium within one day at the area ratio of 3 : 1. By reference to the spectra of **2h**

a) Chemical shifts in ppm from internal Me_4Si and the J(Pt–C) in brackets and J(F–C) in parentheses in Hz.

Table 10. $^{19}F\{^1H\}$ NMR data[a]

No.	Solvent	δ [J(Pt-F)]
1d[b]	CH_2Cl_2	−73.8
1h[c]	$CDCl_3$	−69.5(*cis*), −69.6(*trans*)[d]
2d[b]	CH_2Cl_2	−73.8[17]
2h-*cis*[c]	$CDCl_3$	−69.8[18]
2h-*trans*[c]	$CDCl_3$	−69.9[18]

a) Chemical shifts in ppm downfield from $CFCl_3$ and the J (Pt–F) values in brackets in Hz. b) The chemical shifts were measured to be 4.68 and 4.74 ppm from external CF_3COOH for **1d** and **2d**, respectively, and converted to the $CFCl_3$ reference by means of the equation, $\delta_{CFCl_3}=\delta_{CF_3COOH}-78.5$ppm. c) The chemical shifts were measured from external C_6F_6[6] and converted to values referring to $CFCl_3$ by virtue of $\delta_{CFCl_3}=\delta_{C_6F_6}-162.9$ ppm. d) The more intense signal was assigned to *trans*.

in C_6D_6, the more intense upfield signal of **1h** was assigned to the *trans* isomer (Table 6) in accordance with the information from IR spectrum that crystalline **1h** is *trans* (Fig. 3). The ^{19}F NMR data for **1h** as compared with those for **2h** are consistent with this assignment, the more intense *trans* signal appearing in slightly higher field than the *cis* signal (Table 10).

The chemical shifts of methine protons in *cis*- and *trans*-[Pd(bzac)$_2$] (**1g**) are slightly different from each other in $CDCl_3$. Isomerization reaction between them was followed by virtue of these signals and found to attain equilibrium at [*cis*]/[*trans*]=2/1 within one day. Both isomers of **1g** also show different ^{13}C chemical shifts except for some of the benzoyl carbons (Table 8). The ^{13}C NMR spectrum of orange plates of [Pd(hxd)$_2$] (**1f**) in $CDCl_3$, which were assumed to be *cis* based on the IR spectra, changed with time to attain equilibrium after *ca.* 6 h at the isomer ratio of 1 : 1. The ^1H NMR spectra of [Pd(etac)$_2$] (**1i**) showed signal splitting for the acetyl methyl and $C\underline{H}_2$–CH_3 protons in $CDCl_3$ but only for the CH_2–$C\underline{H}_3$ protons in C_6D_6. The more abundant species in $CDCl_3$ was tentatively assigned to *trans* by reference to the previous studies on the d^8-metal chelates of *O*-ethyl 3-thioxobutanethioate.[26] Isomerization of **1i** in $CDCl_3$ is rapid, attaining equilibrium within 10 min at −40 °C.[4] The ^1H NMR spectrum of [Pd(etbz)$_2$] (**1k**) also shows coexistence of *cis* and *trans* isomers in $CDCl_3$.

Assignment of the ^1H and ^{13}C NMR signals for the mixed-ligand chelates to each β-diketonate ligand (Tables 7 and 9) was made by reference to the data for the respective binary bis-chelates. Methyl protons of the acac ligand in [M(acac)(tfac)] (**1n** and **2n**) exhibit two signals in C_6D_6 due to the unsymmetric nature of tfac. Unambiguous assignment of these signals to the two unequivalent methyl groups is difficult, since the *trans* influence of the trifluoroacetyl part relative to the other acetyl part of the tfac ligand is not certain on the basis of the present ^1H NMR data. Thus in C_6D_6, the methyl protons in [Pt(acac)(hfac)] (**2o**) resonate at 0.08 ppm upfield compared with those in [Pt(acac)$_2$] (**2a**), whereas the methyl protons in *cis*-[Pt(tfac)$_2$] (**2h**) resonate at 0.07 ppm downfield compared with those in the *trans* isomer, and the methyl signals for *cis*-[Pd(tfac)$_2$] (**1h**) are observed at 0.04 ppm lower field than those for *trans*.

The mixed-ligand palladium(II) and platinum(II) chelates are rather stable in solution, showing no appreciable change in their ^1H NMR spectra even after one month. On the other hand, refluxing of dichloromethane or methanol solution of two kinds of bis-chelates did not give rise to the mixed-ligand chelates, whereas the ligand exchange reactions have been reported for many β-diketonate chelates of Cu(II), Al(III), In(III), Ce(IV), Ti(IV), Zr(IV), Hf(IV), V(IV), Fe(III), Co(III), and Ni(II).[2] Thus the geometrical isomerization of bis(unsymmetric β-diketonato)palladium(II) complexes seems to proceed *via* a reaction pathway other than the intermolecular mechanism.

We wish to thank Mr. Junichi Gohda for elemental analyses and Mr. Tetsu Hinomoto of JEOL, Ltd for measurements of the ^{19}F NMR spectra. Assistance in preparation of complexes by Mr. Hiroyuki Sazaki, Mr. Fumiharu Egawa, Mr. Masato Oka, and Miss Hiroko Asai is also acknowledged. This work was partly supported by Grant-in-Aid for Scientific Research (Grant No. 243014) from the Ministry of Education, Science and Culture.

The Role Played by Water in Spin State Variations among Nickel(II) Halide Complexes Containing (7*R*, 14*S*)-5,5,7,12,12,14-Hexamethyl-1,4,8,11-tetraazacyclotetradecane

(Received October 21, 1980)

A complex dihydrate formed with nickel(II) bromide and the title macrocyclic ligand (*meso*-Me_6[14]aneN_4) crystallizes in triclinic space group $P\bar{1}$ and in orthorhombic space group Pcab. The crystal and molecular structures of the two crystal modifications have been determined by single crystal X-ray diffraction. In each compound, the nickel(II) is surrounded by a square-planar array of nitrogen atoms, giving low-spin complexes. In both compounds, water of crystallization and bromide ions are located above the hydrogen atoms of N–H groups and form hydrogen-bonded chelate rings of the type Ni–N–H···Br^-···H–O···H–N. The N–H groups adjacent to the single methyl carbon and the geminal dimethyl carbon interact with bromide ion and water, respectively, in the $P\bar{1}$ form, whereas *vice versa* in the Pcab form. Water molecules in the present crystals and those in the previously reported crystal structure of [Ni(*meso*-Me_6[14]aneN_4)]$Cl_2\cdot 2H_2O$ are involved in the same type of specific hydrogen-bonds. Because of the specific hydrogen-bonding effects, the presence of water prevents coordination of not only water itself but also halide ions, yielding thereby low-spin four coordinate complexes.

Nickel(II) halide (Cl^- and Br^-) and the title macrocyclic ligand form orange low-spin complexes, [Ni(*meso*-Me_6[14]aneN_4)]$X_2\cdot 2H_2O$, and violet high-spin complexes, [NiX_2(*meso*-Me_6[14]aneN_4)].[1,2] The macrocyclic ligand *meso*-Me_6[14]aneN_4 is constrained by steric requirements to coordinate in a single plane. From their electronic spectra and magnetic properties[1] and the X-ray analyses on [Ni(*meso*-Me_6[14]aneN_4)]$Cl_2\cdot 2H_2O$ and [$NiCl_2$(*meso*-Me_6[14]aneN_4)],[3] it has been shown that the orange dihydrates are square-planar four coordinate complexes having a singlet ground state, whereas the violet anhydrides are *trans*-dihalogeno six coordinate complexes having a triplet ground state. The solid, orange diamagnetic dihydrates are converted upon heating to violet paramagnetic anhydrides.[4] Conversely, the solid, violet, paramagnetic anhydrous complexes readily revert to [Ni(*meso*-Me_6[14]aneN_4)]$X_2\cdot 2H_2O$ when moisture is available.[1] Of particular interest is the fact that the low-spin four coordinate complexes are dihydrates, whereas the six coordinate high-spin complexes are anhydrides. Although water has considerably high coordinating ability as compared with halide ion, the water molecules in the dihydrates are not involved in coordination.

Spin states of the complexes are affected also in the solution states by the presence or the absence of water. The anhydrous, violet high-spin complex dissolves in water to give an orange solution, which indicates that the complex turns to the low-spin four coordinate complex.[1] When the anhydrous high-spin complex is dissolved in freshly purified stabilizer-free chloroform, almost all the complexes remain high-spin six coordinate, but the solution contains a small amount of the four coordinate singlet form, giving an equilibrium mixture of the low- and high-spin species. The amount of the singlet species depends on the water content in the chloroform solution and increases with an increase in the amount of water in solution.[5]

Busch has pointed out the importance of the role played by water in the spin state variations and proposed a model for the interaction between water and the complex ions.[1,2]

The present study is a part of series of investigations on the spin state variations, *viz.*, coordination number isomerism among the nickel(II) complexes of the title and related macrocyclic ligands.[3–7] The main feature of interest in the present study is the elucidation of the role of water in spin-state variations. For this purpose, the crystal structures of two crystal modifications of [Ni(*meso*-Me_6[14]aneN_4)]$Br_2\cdot 2H_2O$ were determined by X-ray analyses. The dispositions of the water molecules in the vicinities of the nickel(II) ions in the present crystals and those in the previously reported crystal structures of [Ni(*meso*-Me_6[14]aneN_4)]$Cl_2\cdot 2H_2O$[3] and [NiF_2(*meso*-Me_6[14]aneN_4)]$\cdot 5H_2O$[7] were examined.

Experimental

Materials. The bromide dihydrate of the complex ion, [Ni(*meso*-Me_6[14]aneN_4)]$Br_2\cdot 2H_2O$, was prepared from the corresponding perchlorate salt [Ni(*meso*-Me_6[14]aneN_4)]$(ClO_4)_2$[8] by ion exchange (Dowex 1X8). Slow evaporation of the eluate from the column yielded mixture of orange needle ($P\bar{1}$) and large reddish orange plate (Pcab) crystals of [Ni(*meso*-Me_6[14]aneN_4)]$Br_2\cdot 2H_2O$. The orange and reddish orange forms can be separated mechanically under a microscope or more easily in carbon tetrachloride, using the difference in the crystal densities. The density of neat carbon tetrachloride ($D=1.59$ g cm^{-3}), in which the compounds are not soluble, is between densities of the crystals of the reddish orange ($D=1.57$ g cm^{-3}) and the orange ($D=1.62$ g cm^{-3}) form. The crystals of the compounds consists of 61% of the orange and 39% of the reddish orange form. Found for the orange ($P\bar{1}$) form; C, 35.56; H, 7.41; N, 10.24; Br, 30.09%. Found for the reddish orange (Pcab) form; C, 35.40; H, 7.44; N, 10.11; Br, 30.09%. Calcd for $NiC_{16}H_{40}N_4Br_2O_2$: C, 35.65; H, 7.48; N, 10.40; Br, 29.64%.

X-Ray Analyses. Preliminary X-ray work showed that the crystals of the orange complex belong to the triclinic space group $P\bar{1}$, whereas those of the reddish orange complex belong to the orthorhombic space group Pcab. Intensities of reflections were measured on a Rigaku automated four circle diffractometer AFC-5 with graphite monochromatized Mo $K\alpha$

† Present address: Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464.

radiation (λ=0.71073 Å), the θ-2θ scan technique being employed.

For the orange P$\bar{1}$ form, a specimen with dimensions of 0.40×0.44×0.36 mm was used for the intensity measurements. A total of 5126 reflections was measured up to 2θ=70°. Of these, 3681 reflections with $|F_o|>3\sigma(|F_o|)$ were used in the calculations. Crystal data are: Triclinic, P$\bar{1}$, Z=1, a=8.650(1), b=9.417(1), c=7.813(1) Å, α=94.47(1), β=100.07(1), γ=115.39(1)°, U=557.1(1) Å^3, D_x=1.62, D_m=1.61g cm^{-3}, μ(Mo $K\alpha$)=46.84 cm^{-1}.

For the reddish orange Pcab form, a specimen shaped approximately into a sphere with a diameter of 0.42 mm was used for the intensity measurements. A total of 4935 intensities was measured up to 2θ=70°. Of these, 1938 reflections with $|F_o|>3\sigma(|F_o|)$ were used in the calculations. Crystal data are: Orthorhombic, Pcab, Z=4, a=14.146(2), b=15.739(2), c=10.338(2) Å, U=2301.7(5) Å^3, D_x=1.57, D_m=1.56 g cm^{-3}, μ(Mo $K\alpha$)=45.40 cm^{-1}.

The intensity data used in the structure refinements were corrected for Lorentz and polarization factors and for absorptions. In the absorption corrections, the specimen of the Pcab form was assumed to be a sphere, whereas, for the P$\bar{1}$ form, the numerical Gaussian integration method[9] was used. Both the structures were solved by the heavy atom method and refined by a block-diagonal least-squares method. The weighting scheme, $w=[\sigma_{count}^2+(0.015|F_o|)^2]^{-1}$, was employed. All hydrogen atoms were located by the difference Fourier syntheses, and included in the final refinements with the isotropic temperature factors. The scattering factors for non-hydrogen atoms were taken from International Tables for X-Ray Crystallography.[10] For hydrogen atom, the values given by Stewart *et al.* were used.[11] The final R indices were R=0.046 and R_w=0.051 for the P$\bar{1}$ form, and R=0.056 and R_w=0.046 for the Pcab form, respectively. Atomic parameters for each crystal are given in Table 1.[12]

The calculations were carried out on the HITAC M-180 computer at the Computer Center of the Institute for Molecular Science with Universal Crystallographic Computation Program System UNICS III.[13]

The equivalent isotropic thermal parameter is calculated using the expression $B_{eq}=4/3\ (\sum_i\sum_j a_i a_j \beta_{ij})$, where the a_i's are the unit-cell edges in direct space.

Results and Discussion

Description of the Molecular and Crystal Structures of [Ni(meso-Me$_6$[14]aneN$_4$)]Br$_2$·2H$_2$O. In both the P$\bar{1}$ and Pcab forms, the nickel(II) ions are required to lie on a center of symmetry. Table 2 lists bond lengths and angles within the complex ion in the two crystal modifications. As shown in Table 2, the structures of the complex ion, [Ni(*meso*-Me$_6$[14]aneN$_4$)]$^{2+}$, in the P$\bar{1}$

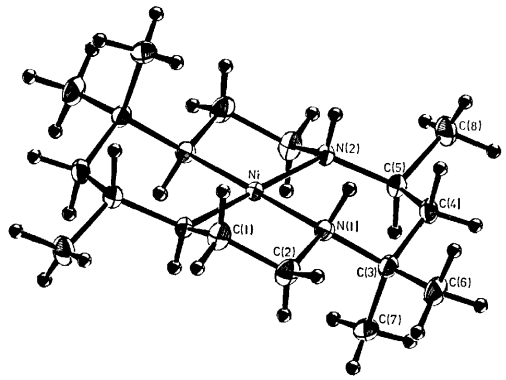

Fig. 1. A perspective drawing of [Ni(*meso*-Me_6[14]-$aneN_4$)]$^{2+}$ in the crystal structure of the P$\bar{1}$ form.

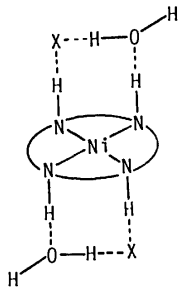
and Pcab forms are not significantly different. Figure 1 shows a perspective drawing of [Ni(*meso*-Me_6[14]-$aneN_4$)]$^{2+}$ in the P$\bar{1}$ form, which is essentially the same as those in the Pcab form and in [Ni(*meso*-Me_6[14]-$aneN_4$)]$Cl_2 \cdot 2H_2O$.[3] The nickel(II) is surrounded by four secondary nitrogen atoms of the macrocyclic ligand in a single plane, yielding a square-planar, diamagnetic nickel(II) complex. The average Ni–N bond distances are 1.954(7) Å for the P$\bar{1}$ form and 1.953(4) Å for the Pcab form, which are in the normal range for a low-spin nickel(II) complex with four planar nitrogen donors.[3,14,15] The macrocyclic skeleton adopts the most stable conformation: the six-membered chelate rings take the chair form with the C(5)–CH_3 bonds in equatorial positions; the five-membered rings are in the gauche conformation.

Three significant deviations from tetrahedral angles are noted. These are the large angles of Ni–N(1)–C(3), Ni–N(2)–C(5), and C(3)–C(4)–C(5) (see Table 2). These distortions are in common with six-membered chelate rings of metal complexes which have the title ligand in planar coordination.[3,7,16]

Figures 2(a) and 2(b) show dispositions of bromide ions and water of crystallization around the complex ions, as viewed along the normal to the coordination plane, in the P$\bar{1}$ and Pcab forms, respectively. The structures around the nickel(II) ions in the two different crystal modifications are very similar to each other as depicted in Fig. 2 in the following sense: (i) the bromide ions are located above the hydrogen atoms of N–H groups and the oxygen atoms of water lie also above the hydrogen atoms of the other crystallographically independent N–H groups; (ii) bromide ions and water molecules are involved in the hydrogen-bonds of the type shown in **1**, forming hydrogen-bonded chelate rings. The hydrogen-bond distances are normal (see Figs. 4(c) and 4(d)). Although the N–H···Y (Y=Br^- or H_2O) interactions in the two structures are very similar to each other in their features and lengths, the nitrogen atoms involved in such interactions are chemically different, N(1) and N(2) being hydrogen-bonded to the oxygen atom and bromide ion, respectively, in the



1

P$\bar{1}$ form, whereas *vice versa* in the Pcab form. A very similar situations has been found for the N–H···O interactions around the two crystallographically independent nickel(II) complexes in the crystals of [NiF_2(*meso*-Me_6[14]$aneN_4$)]$\cdot 5H_2O$ (see Figs. 4(e) and 4(f)).[7] The positions of bromide ions in [Ni(*meso*-Me_6[14]$aneN_4$)]$Br_2 \cdot 2H_2O$ are nearer to the axial coordination sites than that of the chloride ion in

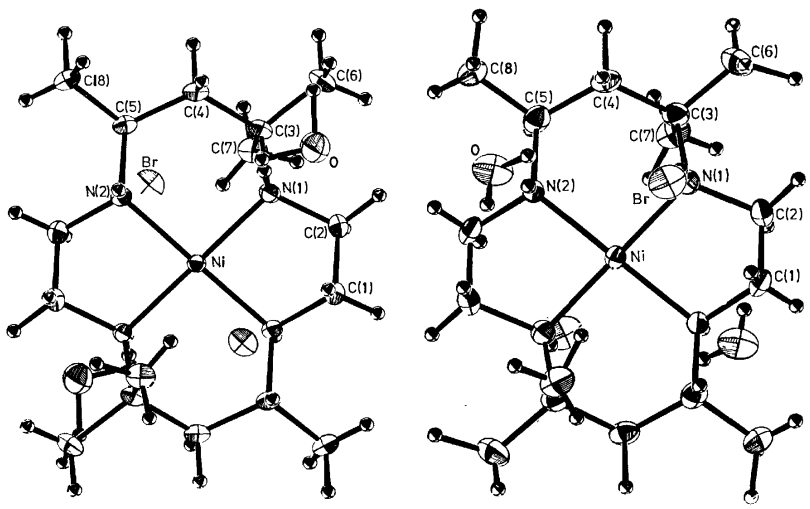


Fig. 2. Dispositions of bromide ions and water molecules around the nickel(II) ion in the crystal structures of the P$\bar{1}$ (a) and Pcab forms (b), as viewed along the normal to each of the coordination planes.

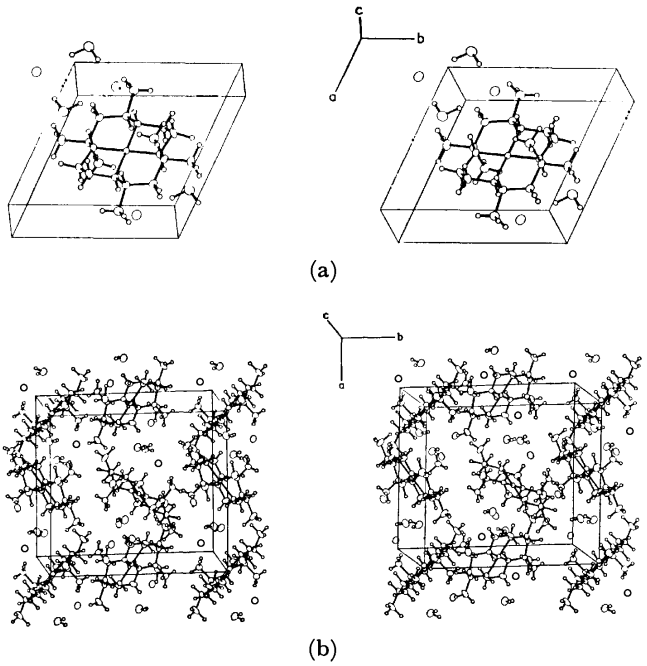

Fig. 3. Crystal structures of the $P\bar{1}$ (a) and Pcab forms (b).

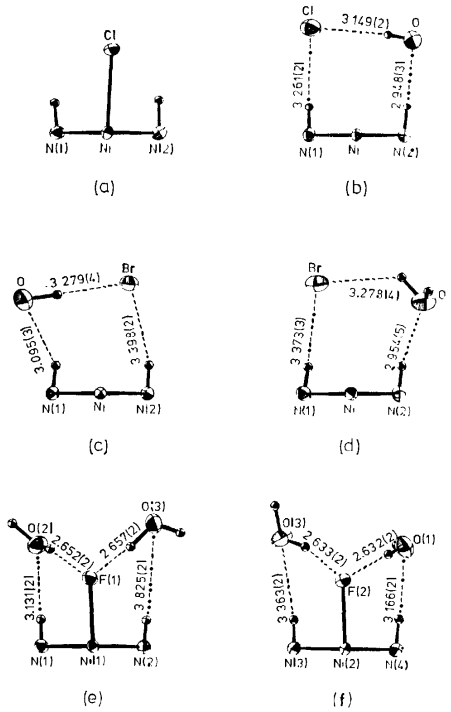

Fig. 4. Dispositions of halide ions and water of crystallization in the vicinities of the nickel(II) ions in $[NiCl_2(meso\text{-}Me_6[14]aneN_4)]\cdot 2CHCl_3$ (a),[3] $[Ni(meso\text{-}Me_6[14]aneN_4)]Cl_2\cdot 2H_2O$ (b),[3] $[Ni(meso\text{-}Me_6[14]aneN_4)]Br_2\cdot 2H_2O$ in the $P\bar{1}$ (c) and Pcab (d) form, and $[NiF_2(meso\text{-}Me_6[14]aneN_4)]\cdot 5H_2O$ ((e) and (f)).[7] In each compound, the nickel(II) ion sits on a crystallographic inversion center. In the fluoride system, there are two crystallographically independent complexes.[7] Hydrogen-bond distances corresponding to the lengths between donor and accepter atoms are given in Å.

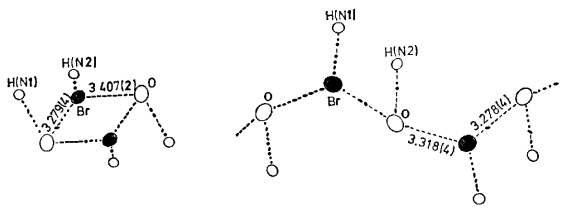
$[Ni(meso\text{-}Me_6[14]aneN_4)]Cl_2\cdot 2H_2O$ (see Fig. 4). This may be related to the fact that $[NiBr_2(meso\text{-}Me_6[14]aneN_4)]$ reverts more easily to the bromide dihydrate than $[NiCl_2(meso\text{-}Me_6[14]aneN_4)]$ to the chloride dihydrate, when moisture is available.[1,5]

Stereoscopic views of the crystal structures for the $P\bar{1}$ and Pcab forms are presented in Figs. 3(a) and 3(b), respectively. Bromide ions and water molecules are further hydrogen-bonded with adjacent water molecules and bromide ions, respectively. Through these interactions the adjacent complex ions are held together, but the features of the interactions differ in the $P\bar{1}$ and Pcab forms. In the $P\bar{1}$ form, the interaction appears to be of the type shown in **2**, whereas that in the Pcab form, an infinite zigzag chain parallel to the c-axis as shown in **3**. The hydrogen-bond parameters are given in **2**, **3**, and Figs. 4(c) and 4(d). All other intermolecular contacts appear to be normal both in the two structures.



2 **3**

Specific Hydrogen-bonding Effects. The occurence of the spin-state variation is invariably associated with the presence or the absence of water. One exception is the fluoride system in the solid state, *trans*-$[NiF_2(meso\text{-}Me_6[14]aneN_4)]\cdot 5H_2O$, where fluoride ions occupy the axial coordination sites yielding a high-spin six coordinate complex in the hydrate.[7] Although water has high coordinating ability as compared with halogen ions for a nickel(II) ion in general, no evidence has been reported for coordination of water to a nickel(II) ion in the present systems.

Figure 4 shows the dispositions of water and halide ion in the vicinity of the nickel(II) ion found in the present study together with those in the crystal structures of $[Ni(meso\text{-}Me_6[14]aneN_4)]Cl_2\cdot 2H_2O$,[3] $[NiCl_2(meso\text{-}Me_6[14]aneN_4)]\cdot 2CHCl_3$,[3] and $[NiF_2(meso\text{-}Me_6[14]aneN_4)]\cdot 5H_2O$,[7] as viewed along each coordination plane. Note that all the nickel(II) ions in these complexes lie on centers of symmetry. Therefore, for simplicity, only the crystallographically independent two nitrogen atoms and a nickel(II) ion are depicted for each complex. In the fluoride system, there are two crystallographically independent complexes, which are shown in Figs. 4(e) and 4(f). Of particular interest in Fig. 4 is the fact that the dispositions of water and a halide ion and the features of the hydrogen-bond framework in the vicinity of the nickel(II) ion are very similar to each other in each hydrate. In all the hydrates except for the pentahydrate of the fluoro complex, water molecules and halide ions are located above the hydrogen atoms of N–H groups. As can be seen in Figs. 4(b), 4(c), and 4(d), hydrogen-bonded chelate rings of the type **1** are invariably formed.

Busch proposed that the halogen ions in the dihydrates occupy the axial coordination sites but are

displaced from the nickel(II) ion so that the ligand field of the halide ions cannot exert on the nickel(II) ions.[1] It was found in the present and previous studies that neither water molecules nor the halide ions are located near the axial coordination sites in the dihydrates. The specific hydrogen-bond effects such as the hydrogen-bonded chelate rings are undoubtedly responsible for failure of coordination of the water molecule. The occurence of such specific interactions would be much more favorable over the hypothetical occupation by the water molecules at the coordination sites. Because of the specific hydrogen-bonding effects, the presence of water not only prevents coordination of water itself but also prevents halide ions from coordinating, giving low-spin four coordinate complexes. Under water free circumstances such as in dry chloroform solutions or in solid states of the anhydride, halide ions can coordinate to nickel(II) to produce high-spin six coordinate complexes. These specific hydrogen-bonding effects also produce large enthalpy values for dehydrations of the hydrates of the present complexes.[4,7]

In the case of the fluoride system, axial coordination sites are occupied by fluoride ions even in the hydrate. Water molecules are located above the hydrogen atoms of all the N–H groups. Hydrogen-bonded chelate rings different from the type **1** can be seen in Figs. 4(e) and 4(f), which contain O–H···F–Ni bond. The reason for the change in geometry is most likely due to the ionic size of the fluoride ion. The fluoride ion is too small to form hydrogen-bonded chelate ring of the type **1**. In addition, a fluoride ion has high coordinating ability as compared with other halide ions for a nickel(II) ion.[1]

As described earlier, the spin state variations in solutions are also associated with the presence or the absence of water. In aqueous solutions or solutions of organic solvents containing water, hydrations take place around N–H groups. Structural feature of the hydration would be similar to the disposition of water molecules in solid state shown in Fig. 4. Water molecules involved in the hydration would play a role similar to water of crystallization in the solid dihydrates to give low-spin complexes.

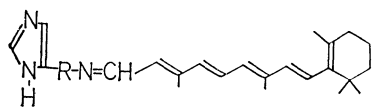
Models for Visual Pigments. The Effect of the Imidazolyl Group on the Absorption Maxima of the Retinal Schiff Base

Masato NANASAWA* and Hiroyoshi KAMOGAWA
Faculty of Engineering, Yamanashi University, Takeda, Kofu 400

(Received April 3, 1980)

The title effect has been investigated with the imidazolyl group either externally added or intramolecularly combined. *N*-Retinylidenebutylamine was protonated with imidazole derivatives under neutral conditions and was absorbed at longer wavelengths compared with carboxylic acids. The absorption peak with the imidazolyl group intramolecularly combined was highly affected by the structure, protonated N^{α}-retinylidene-L-histidine octadecylamide having an absorption maximum at 494 nm caused by the inductive effect and the polar imidazolyl group.

The absorption maxima of visual pigments bound to opsin by a Schiff-base linkage are observed at 500 nm, although the protonated products of synthetic analogues absorb at approximately 450 nm. As regards this bathochromic shift, a large number of interesting observations and theories have been reported: the polarizability of the micro environment,[1] the electrostatic effect of polar or charged groups in the vicinity of the chromophore,[2] and the twist or distortion of the π-conjugated system.[3] However, there are still many unsolved problems. Recently two synthetic models were reported which absorb at longer wavelengths by means of protonation with trifluoroacetic acid[4] or in an aqueous hydrochloric acid solution.[5] Since native photochromic processes proceed under mild conditions, we examined the effects of amino acids as protonating agents.[6] In this paper we intend to deal especially with the imidazolyl group of the histidine residue. The imidazolyl group is known to be responsible for a buffering capacity;[7] hence, it may be able to protonate the Schiff-base linkage in a physiological pH range and to mediate a charge relay system between protonated Schiff-base nitrogens and counter anions. On the basis of these assumptions, we have examined the protonation of *N*-retinylidenebutylamine(Bu–SB) with the salt of N^{α}-benzyloxycarbonyl-L-histidine butylamide (**1**) plus *N*-benzyloxycarbonyl-L-alanine (Z–α-Ala), N^{α}-octadecanoyl-L-histidine (**2**), and 4,5-imidazoledicarboxylic acid monohexadecyl ester (**3**). As Schiff-base models with the imidazolyl group, the following were synthesized, and the absorption maxima of the protonated products were determined:



R = $-CH_2-$: **4**–SB. $-CH_2CH_2-$: **5**–SB.
$-CH_2\underset{|}{C}H-CONH-C_{18}H_{37}$: **6**–SB.
$-CH_2CH_2NHCOCH_2CH_2-$: **7**–SB.
$-CH_2CH_2-NHCO(CH_2)_5-$: **8**–SB.

Experimental

all-trans-Retinal was prepared by the oxidation of vitamin-A with MnO_2 and was recrystallized from petroleum ether;[8] mp 59—60 °C, λ_{max} 367.5, nm, E_1 % 1536 in petroleum ether. Isomerization to the *cis*-isomer was conducted by the irradiation of *all-trans*-retinal (1% in petroleum ether) containing iodine (1% to retinal), using a 150 W xenon lamp with a UV filter fitted as the light source;[9] λ_{max} 364.5 nm, $E_{1\%}$ 1259 in petroleum ether.

Preparation of N^{α}*-Benzyloxycarbonyl-L-histidinamide*: A mixture of N^{α},N^{im}-bis(benzyloxycarbonyl)-L-histidine(Z–His–Z 6.85 g, 15.5 mmol, the benzyloxycarbonyl group was abbreviated as Z) and dicyclohexylcarbodiimide(DCC 3.5 g, 17 mmol) in CH_2Cl_2 (50 ml) was stirred in an ice bath for 45 min, filtered, and washed with CH_2Cl_2. To the filtrate, alkylamine (31 mmol) in $CHCl_3$ (50 ml) was added, the mixture being stirred in an ice bath, allowed to stand overnight, and then refluxed for 30 min. While hot, the reaction mixture was filtered and washed with $CHCl_3$. The filtrate was dried over Na_2SO_4, concentrated to about 30 ml, and then cooled at −20 °C. The product thus precipitated was recrystallized from acetone or ethanol. **1**: yield, 62% mp; 143—145 °C. IR (KBr): 3300 (NH), 3150 (imidazole–NH), 1690 (carbamate C=O), 1650 cm^{-1} (amide C=O). ^{1}H-NMR ($CDCl_3$): 0.9—1.5 (m, 7H, $CH_3CH_2CH_2-$), 3.0 (m, 4H NH–C$\underline{H}_2$– and imi–CH_2–), 4.3 (q, 1H, α-CH), 5.2 (s, 2H, phenyl–C$\underline{H}_2$–), 6.9, 7.8 (s, 2H, imidazole ring), 7.3 ppm (8H, phenyl, NH). Found: C, 62.68; H, 7.32; N, 16.01%. Calcd for $C_{18}H_{23}N_4O_3$: C, 62.97; H, 6.31; N, 16.33%. MS (*m/e*): 343 (M^+, 11%). N^{α}-Benzyloxycarbonyl-L-histidine octadecylamide: yield, 36%; mp 151—154 °C.

N^{α}-Octadecanoyl-L-histidine (**2**) was prepared with octadecanoyl chloride; yield, 45%; mp 165—180 °C.[10] The 4,5-imidazoledicarboxylic acid monohexadecyl ester (**3**) was obtained by condensation with 4,5-bis(chloroformyl)imidazole[11] and hexadecyl alcohol; yield, 71%; mp 167—170 °C. In the IR of the salt containing **1** and Z–α-Ala (mp 125—126 °C), the absorption at 1710 cm^{-1} (COOH) no longer exists, and the salt peak is observed at 2000—2750 cm^{-1}. ^{1}H-NMR and elemental analyses made it posisble to identify the structure. 4-(Aminomethyl)imidazole (**4**) was obtained starting with D-fructose *via* 4-(hydroxymethyl)imidazole, oxidation with HNO_3 to aldehyde, conversion to oxime, and reduction with H_2 (5% Pd on charcoal) in methanol saturated with HCl.[12]

L-Histidine Octadecylamide (6): To N^{α}-Z–histidine octadecylamide (2.35 g, 4.4 mmol) in anhydrous acetic acid (5.0 ml), a 30% solution of hydrogen bromide in acetic acid (5.7 ml) was added with vigorous stirring at room temperature. The reaction mixture was stirred for 1 h and then poured into anhydrous ether (100 ml). **6**·HBr was filtered, thoroughly washed with ether, and then dissolved in ethanol (10 ml). The solution was basified with saturated aqueous Na_2CO_3. The product was extracted with ethanol and recrystallized from ethanol–ether, **6**: yield, 42%; mp 110—115 °C. Found: C, 70.79; H, 11.53; N, 13.73%. Calcd for $C_{24}H_{40}N_4O$: C,

70.93; H, 11.33; N, 13.79%.

Preparation of N-*(ω-Aminoalkanoyl)histamine (7, 8)*: A mixture of Z-β-Ala (3.94 g, 17.7 mmol) and DCC (4 g, 19.5 mmol) in a 1 : 2 mixture of dimethylformamide–acetonitrile (20 ml) was stirred in an ice bath for 45 min; the reaction mixture was then filtered and washed with dimethylformamide–acetonitrile (30 ml). To the filtrate, histamine dihydrochloride (3 g, 16.1 mmol) and NaOH (0.7 g) in H_2O (15 ml) were added in one portion; the mixture was vigorously stirred for 5 h, and then filtered. The filtrate was concentrated to about 40 ml and poured into cold 10^{-1} M hydrochloric acid (250 ml, 1 M= 1 mol dm^{-3}). The insoluble by-product (DCC urea, Z-β-Ala–DCC) was filtered off. The filtrate was basified with saturated aqueous Na_2CO_3 and cooled in a refrigerator overnight. The product thus precipitated was filtered, washed with H_2O, and then recrystallized from ethanol–ethyl acetate. *N*-(*N*-Benzyloxycarbonyl-β-alanyl)histamine: yield, 62%; mp 137—139 °C. *N*-[ω-(Benzyloxyamino)hexanoyl]-histamine: yield, 82%; mp 111—114 °C. Deblocking of the ω-amino group were conducted in a manner similar to that used for **6**. **7**: yield, 52%; mp 67—68 °C, Found: C, 52.89; H, 8.38; N, 29.94%. Calcd for $C_8H_{14}N_4O$: C, 52.75; H, 7.69: N, 30.77%. **8**: yield, 67%; mp 44—46 °C. Found: C, 59.04; H, 9.50; N, 24.32%. Calcd for $C_{11}H_{20}N_4O$: C, 58.93; H, 8.93; N, 25.00%.

The Schiff base was prepared by mixing solution of retinal (10^{-2} M) and imidazole derivatives (10^{-2} M) in absolute ethanol containing 3A molecular sive 1/16 in. pellets at room temperature for 8 h in the dark. In the case of **4** and **6**, the reaction time was prolonged to 24 h. The absorption spectra were recorded on a Hitachi 200-10 spectrophotometer, using quartz cells 1 mm and 10 mm in path length. The pH of the protonating solution (90% aqueous ethanol) was measured on a Horiba M-7E pH meter. The calibration curve for the protonated *N*-retinylidenebutylamine (Bu–SBH$^+$) satisfied the Lambert Law over the concentration range from 1.4×10^{-5} to 2.2×10^{-4} M.

Results and Discussion

Effect of Imidazole Derivatives on the Protonation of N-*Retinylidenebutylamine (Bu–SB).* Figure 1 shows the degree of protonation plotted against the pH values of the solution, in which the pH values were controlled by the addition of Z-α-Ala (10^{-2} M) to **1** (2.5×10^{-3} M) in 90% aqueous ethanol. The basic nitrogen of imidazole ring (N^3, pK_a 14.5) is, of course, neutralized with Z-α-Ala in a polar solvent, and some association may take place between **1** and Z-α-Ala. However, the absorption peak at 440 nm appeared even under neutral conditions, which indicates that undissociated imine hydrogen

(N^1–H of imidazole ring) protonated the Schiff-base linkage.

In a nonpolar solvent such as chloroform, in which carboxylic acids with no steric hindrance at the α-position (Z-β-Ala, hexanoic acid) remain almost in undissociated or dimeric state, the extent of protonation increased upon the addition of **1** (5×10^{-3} M) to the

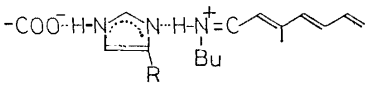
mixture of Bu–SB (5×10^{-4} M) and Z–β-Ala (2.5×10^{-3} M). It is possible that the proton transfer from undissociated or dimeric carboxylic acid to **1** took place and that the resulting positive charge at the imidazole ring promoted the formation of Bu–SBH$^+$.

The protonation with **1** did not appear in ethanol or even in its aqueous solution (N^1–H, pK_a 7.2), whereas in chloroform a small absorption appeared at about 470 nm. The hydrogen bond at N^3 with a solvent presumably aided proton release at the N^1 of the imidazole ring. With **2** and **3** existing as an ion pair in chloroform, the absorption peaks were slightly shifted to longer wavelengths (**2**, 455 nm, **3**, 458 nm) than that with Z–α-Ala (450 nm). The red shift might be explained by Scheme 1, in which electrostatic energy[13] between the counter anion and the positive charge on the nitrogen of the Schiff-base linkage is decreased by the charge-relay system.

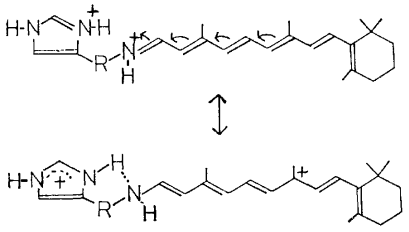


Scheme 1.

Absorption Maxima of the Protonated Schiff Base of Imidazole Derivatives. The 11-*cis*-retinal of rhodopsin is bound to an ε-amino group of a lysnine, and the bathochromic shift is caused by the placement of amino-acid residues near the protonated chromophore.[2] Schiff bases (**4**–SB—**8**–SB) with different distances between the Schiff-base linkage and the imidazole ring were synthesized in order to investigate the effect of the neighboring group on the absorption spectra. An attempt to synthesize a Schiff-base model with the least distance, such as a 4-aminoimidazole derivative, was unsuccessful because of the weak basicity of the amino group attached to the imidazole ring. It required 24 h to reach the constant absorption maxima of **4**–SB and **6**–SB after mixing, and their absorption peaks were slightly shifted to longer wavelengths compared with others; this shift was caused by the presence of an electron-withdrawing group at the α-position.[14] With one or two equivalents of Z–α-Ala, a protonated Schiff base did not indicate any absorption peaks, but only shoulders. With the intention of obtaining more obvious results, the protonation was conducted by the addition of an ethanolic solution containing one or two equivalents of hydrochloric acid to a Schiff base (2.5×10^{-2} M). Mono- and diprotonated Schiff bases were represented by SBH$^+$ and SBH^{2+} respectively; the pH values were 6.4 and 4.5 respectively in aqueous ethanol. The absorption maximum of the protonated *N*-retinylidene-L-alanine butylamide shifted to the red by approximately 106 nm, the magnitude of the shift against Bu–SBH$^+$ being large compared with that of the unprotonated product (SB: 371—366=5 nm, SBH$^+$: 477—460=17 nm). It seems reasonable to say that the carbonyl group at the α-position enhanced the electron-withdrawing character of the Schiff-base nitrogen.

The absorbance obtained by the addition of equimolar acid components was very small in the case of a Schiff base prepared with alkanediamines with short chains (ethylene, trimethylene) compared with that of imidazole derivatives. This denotes that the proton transfer from a Schiff-base linkage to primary amine might proceed, while in the latter case the transfer from the amphoteric imidazole ring is predominant. The red shifts caused by the neutral imidazolyl group (**4**–SBH$^+$, **5**–SBH$^+$) were approximately 7 nm compared with the absorption maximum of Bu–SBH$^+$, the magnitude of which was almost similar to that of Bu–SB with **2** and **3** externally added.

When the amount of acid was increased, the red shift was highly affected by the structure: shorter distances between two protonated sites might increase the repulsion between two cations (Scheme 2), thus bringing about an extrusion of the positive charge on the Schiff-base nitrogen to the ionane ring. The interaction of separated ions as observed in the absorption maxima was calculated over 8 Å on the basis of a molecular orbital theory.[15] The results of this calculation agree with those of our experiment, in which the maximum length affecting the red shift was six methylene chains (hexamethylenediamine–SBH$_2^{2+}$, 463 nm). The shifts caused by the protonated imidazole rings were larger than those of the corresponding model compounds, ethylenediamine–SBH$_2^{2+}$ (470 nm) and trimethylenediamine–SBH$_2^{2+}$ (468 nm).



Scheme 2.

The magnitude of shift against the absorption maximum of Bu–SBH$^+$ was 19 nm in terms of the influence of the protonated imidazole ring and 12 nm in terms of the inductive effect of the α-carbonyl group, the large shift of **6**–SBH^{2+} being explicable by adding the two values.

When a *cis*-isomerized retinal was bound to the imidazole derivatives, some interaction could be postulated between rings (β-ionane–imidazole). However, the absorption maxima of the protonated products were almost consistent with those of the *all-trans*-retinal. In actual visual pigments, the twist or distortion of the retinal moiety and a complicating structure of opsin might cause the red shift up to 580 nm. It is experimentally impossible to make a highly selective and restrictive model until the complete structure is known. We have, therefore, synthesized simple models simulating visual pigments, in which the absorption spectra shifted toward longer wavelengths close to that of rhodopsin.

(Received April 14, 1980)

The crystal structure of N-(thioacetyl)tryptamine, a radioprotective agent, has been determined by the X-ray method. The crystal is monoclinic, space, group $P2_1/c$ with the unit cell dimensions: $a=23.761(5)$, $b=5.553(1)$, $c=8.889(2)$ Å, and $\beta=94.04(4)°$. The structure was solved by the direct method and succesive Fourier syntheses, and refined by the block-diagonal least-squares method to give a final R-value of 0.072. In the crystal, the molecules are held together with van der Waals contacts between the nonpolar groups of adjacent molecules, and an intermolecular hydrogen bond between the sulfur and nitrogen atoms of the side chain (N–H···S=3.322 Å). The folded conformation observed in this compound could be related to the protection of DNA against irradiation.

Indolylalkylamines containing sulfur atoms could be expected to be rādioprotective agents in living cells, because other indolylalkylamines such as serotonin and tryptamine are well known to act as radioprotective agents,[1-4] and the sulfur compounds such as cysteine, cysteamine and 2-(2-aminoethyl) thiouronium salts are also used as radioprotective agents.[5-9] Shinoda *et al.*[10] examined the relationship between the chemical structures of these indolylalkylamines and their effects in protecting radiation damage, using mice irradiated with X-rays, and confirmed that *N*-(thioacetyl)tryptamine (TATP) was a potent radioprotective agent.

During a series of structural studies of the radioprotective indolylalkylamines,[11] we have determined the crystal structure of TATP; this will be reported in this paper.

Experimental

Preliminary oscillation and Weissenberg photographs showed the space group to be $P2_1/c$. The density was measured by the floatation method in a benzene–carbon tetrachloride mixture. The unit cell dimensions were refined on a Rigaku Denki automatic four-circle diffractometer with graphite-monochromated Cu $K\alpha$ radiation. The crystal data are shown in Table 1.

The intensity data were collected, using a single crystal with dimensions $0.5\times0.3\times0.2$ mm, on the diffractometer by $\omega/2\theta$ scanning technique within $\sin\theta/\lambda$ less than 0.595 Å^{-1}. Scan speed was 4°/min, background being measured for 5 s.

Table 1. Crystal data

D_m/g cm^{-3}	1.233(1)
D_x/g cm^{-3}	1.240
F (0 0 0)	464

Intensities of 2009 independent reflections were corrected for Lorentz and polarization factors, but not for absorption. The intensities of four standard reflections, measured every 100 reflections, showed no deterioration during the course of the data collection.

All numerical calculations were carried out on an ACOS-700 computer of the Computation Center of Osaka University using UNICS program.[12] Atomic scattering factors in "International Tables for X-Ray Crystallography"[13] were used.

Determination and Refinement

The structure was solved by the direct method (program MULTAN[14]). An E-map computed using the 160 reflections with $|E|\geqq1.20$ (absolute figure of merit=1.14) revealed the positions of sulfur atom and non-hydrogen atoms of the indole ring. The coordinates of all the remaining non-hydrogen atoms were obtained by successive Fourier syntheses. The structure was refined by a block-diagonal least-squares method. From a difference map at the stage of R-value=0.12, the positions of all fourteen hydrogen atoms were

determined (peak height: 0.25—0.40 e·Å^{-3}); these positions were included in subsequent refinements with isotropic temperature factors.

In the later stage of refinement, the following weighting scheme was used: $w=0.71$ for $F_o=0.0$, $w=1.0$ for $0<F_o\leqq 15.0$ and $w=1.0/[1.0+0.095(F_o-15.0)]$ for $F_o>15.0$. In the last stage of refinement, none of the positional parameters shifted more than one-fourth of the estimated standard deviations. The final R-value excluding $F_o=0$ is 0.072. The residuals in the difference map were within the range of ± 0.2 e·Å^{-3}. The observed and calculated structure factors are listed in Table 2.[15] The final positional and thermal parameters for non-hydrogen atoms are given in Tables 3 and 4,[15] respectively. The coordinates for hydrogen atoms are given in Table 5.

Results and Discussion

Molecular Structure. The bond lengths and angles are given in Fig. 1, together with the atomic numbering used in this work. Their standard deviations are 0.004 to 0.009 Å for lengths and 0.3 to 0.5° for angles. The bond lengths of N–H or C–H are from 0.87 to 1.13 Å. The equations of the least-squares planes for the indole ring and the thioacetyl group and the deviations of atoms from these planes are listed in Table 6.

Table 6.

Equations of the best planes expressed by $m_1X+m_2Y+m_3Z=d$ in an orthogonal space

Plane	m_1	m_2	m_3	d
Indole ring	0.1669	−0.5961	0.7854	6.0448
Thioacetyl group	0.6013	−0.6039	−0.5233	2.0865

Deviations (Å) from the best planes:

Indole ring		Thioacetyl group	
N(1)*	0.025	N(12)*	0.019
C(2)*	0.011	C(13)*	−0.021

C(8)*	0.022		
C(9)*	−0.021		
C(10)	−0.120		
H(1)	0.088		
H(2)	0.006		
H(4)	0.022		
H(5)	−0.018		
H(6)	0.014		
H(7)	0.042		

Atoms with asterisks define the plane.

The bond lengths and angles of the indole ring agree well with those found in the related indole derivatives within their standard deviations,[16] but the bond lengths of the side chain are significantly different: the C(10)–C(11) and C(11)–N(12) bonds are shorter than 1.511 and 1.463 Å of the average bond lengths found in the substituted tryptamine derivatives.[16] The shortening of the N(12)–C(13) bond indicates clearly the contribution of a resonance form:–N(12)=C(13)–S(13).

The indole ring is planar within a maximum deviation of 0.025 Å at the N(1) atom, whereas the C(10) atom deviates significantly from the plane, probably due to the effect of the crystal packing. The thioacetyl group is also planar and its plane makes a dihedral angle of 87.2° to the indole ring.

The conformation of TATP projected onto the indole ring plane is shown in Fig. 2. The bond sequence of C(3)–C(10)–C(11)–N(12) is the extended form, due

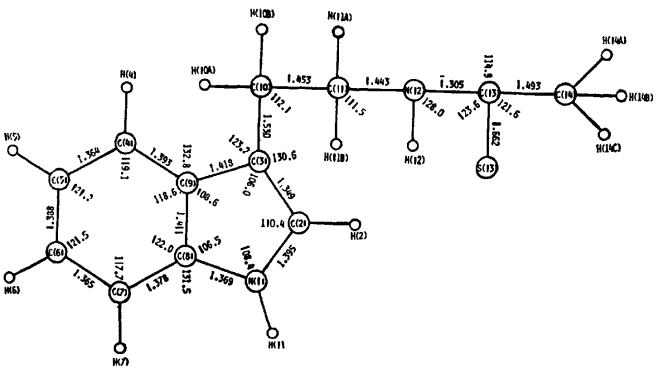

Fig. 1. The bond lengths and angles for non-hydrogen atoms.

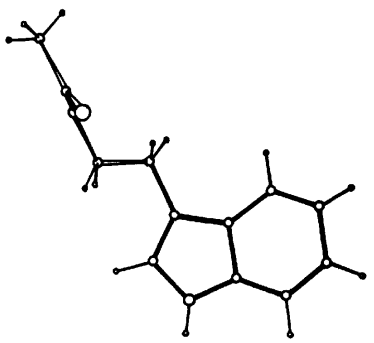

Fig. 2. The conformation of TATP molecule projected onto the indole ring.

to the attachment of the thioacetyl group to the N(12) atom; the torsion angles of C(2)–C(3)–C(10)–C(11) and C(3)–C(10)–C(11)–N(12) are 12.6° and 176.0°, respectively. A similar conformation is also found in the *N*-monosubstituted tryptamine such as melatonin.[17,18] On the other hand, the bond sequence of C(11)–N(12)–C(13)–S(13) takes the folded form: the torsion angles of C(10)–C(11)–N(12)–C(13) and C(11)–N(12)–C(13)–S(13) are −104.4° and 4.9°, respectively.

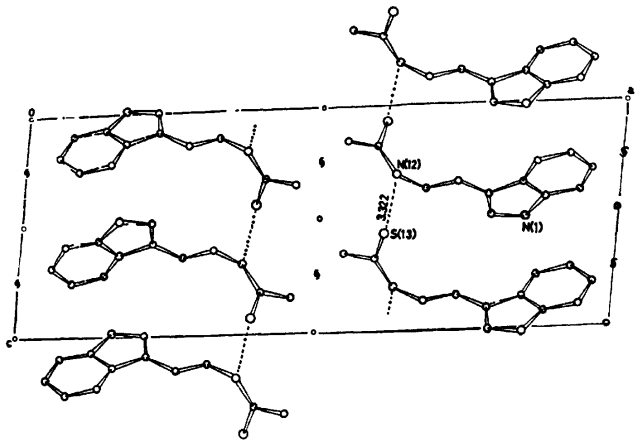

Fig. 3. Crystal packing of TATP viewed along the b-axis. The dotted lines represent possible hydrogen bonds.

Crystal Structure. Figure 3 shows the crystal structure viewed down the b-axis, where the hydrogen bonds are represented by the dotted lines. The indole rings related by c-glide form a zig-zag sheet which is stabilized by the van der Waals contacts with the neighboring sheets related by b-translation and inversion. The N(1) atom does not take part in any hydrogen bond. The 2-(thioacetylamino)ethyl side chains arranged parallel to the c-axis are linked by the hydrogen bonds between the N(12) and S(13) atoms (N(12)···S(13), 3.322 Å, H(12)···S(13), 2.42 Å, ∠N(12)–H(12)···S(13), 159.8°).

No stacking between the indole rings and no contacts shorter than 3.5 Å were observed.

The TATP molecule could exert its radioprotective effect in a manner similar to the mechanism proposed for indolylalkylamines:[19] the formation of the charge-transfer complex between nucleic acid bases and indole ring may protect the formation of peroxide radicals of the bases by irradiation. The role of the sulfur atom is thought to be the stabilization of the charge-transfer complex by the hydrogen bond between S(13) atom and the hydroxyl group of phosphate backbone of DNA, from the CPK model fitting based on the B-type DNA. Since the sulfur atom is said to act as a radical scavenger,[20] it may further protect the cleavage of the phosphodiester linkage of DNA.

(Received April 28, 1980)

The steric and electronic structures of the most potent uncoupler of oxidative phosphorylation known, SF 6847, and its derivatives were studied. ^{1}H and ^{13}C NMR measurements showed that the malononitrile moiety is not planar with the benzene ring and that its intramolecular motional freedom is reduced on acid dissociation of the phenolic proton. The activation energies of the tumbling motion of the malononitrile moiety in the anionic forms of SF 6847 and its derivatives were also determined from their ^{1}H NMR measured at various temperatures. The CNDO/2 and *ab initio* MO calculations of the model compounds of SF 6847 showed that the planar form is quite unstable and that the malononitrile moiety is twisted considerably relative to the benzene ring. The effect of the dynamic structure on the acidity of SF 6847 was discussed based on the above results.

It is widely known that phenols exhibit a wide variety of biological activities, such as fungicidal, bacteriocidal and acaricidal effects, probably due to uncoupling of the phosphorylation reaction from the oxidoreduction reaction in microorganisms and organelles.[1-4] Among phenols, 3,5-di-*t*-butyl-4-hydroxybenzylidenemalononitrile (SF 6847) was found to show the most potent uncoupling activity in mitochondria.[4] This compound is characterized by being hydrophobic and having a strong electron-withdrawing group (malononitrile group) and an acid dissociable proton (phenolic hydroxyl group). These features are common to other potent uncouplers of oxidative phosphorylation, such as carbonyl cyanide-*p*-trifluoromethoxyphenylhydrazone (FCCP), 4,5,6,7-tetrachloro-2-trifluoromethoxybenzimidazole (TTFB) and 5-chloro-3-*t*-butyl-2′-chloro-4′-nitrosalicylanilide (S-13).[5-7] However, the structural requirements of uncouplers required for their activities are not yet fully clarified, although considerable attention has been paid to this problem.[8-12]

The neutral molecular form of SF 6847 has an absorption band at about 365 nm and the anionic form has one at about 456 nm.[13,14] On binding of SF 6847 to mitochondria and liposomes with various phospholipid compositions, its absorption spectrum changes greatly.[13,14] Changes in spectral properties are also observed when this compound is dissolved in organic solvents or when it forms a dimer.[13-17] These results suggest that the structural properties of SF 6847 change greatly in different circumstances. This paper deals with the dynamic structure of SF 6847 and its derivatives examined by NMR spectroscopic and molecular orbital (MO) studies.

Experimental

All the 3,5-dialkylbenzylidenemalononitriles were prepared by the procedure of Horiuchi *et al.*[18] and purified by chromatography and repeated recrystallization.

Fourier-transformed ^{1}H and ^{13}C NMR spectra were obtained at 90 MHz and 22.5 MHz, respectively, with a JEOL FX-90Q NMR spectrometer.

Molecular orbital (MO) calculations were performed according to the CNDO/2 method.[19] Since the energy of the dissociated forms (anions) of SF 6847 derivatives did not converge in the usual CNDO/2 program, we adopted a modified program using the density matrix method proposed by McWeeny.[20] *Ab initio* (STO 3G) MO calculations were also carried out using the GAUSSIAN 70 program.[21] The standard bond angles and bond lengths were used in the calculation referring to the crystal geometry of SF 6847 determined by X-ray diffractometry.[22]

Results and Discussion

^{1}H and ^{13}C NMR. Figure 1A shows the 90 MHz ^{1}H NMR spectrum of the neutral (undissociated) form of SF 6847 in $CDCl_3$ at room temperature. From the signal intensity in the figure, all the signals are easily assigned; δ 1.46 (*t*-butyl), 6.04 (-OH), 7.65 (benzylidene), and 7.80 (aromatic). The chemical shift

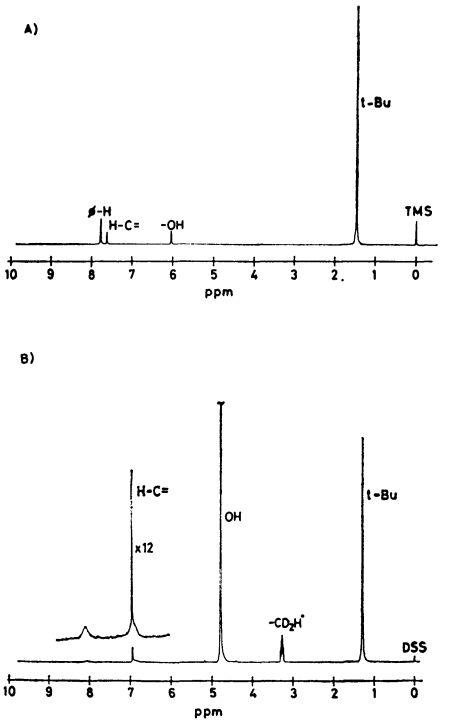

Fig. 1. 90 MHz ^{1}H NMR spectrum of SF 6847 in $CDCl_3$ (A) and in methanol-d_4 containing 0.1 mol dm^{-3} sodium hydroxide (B).

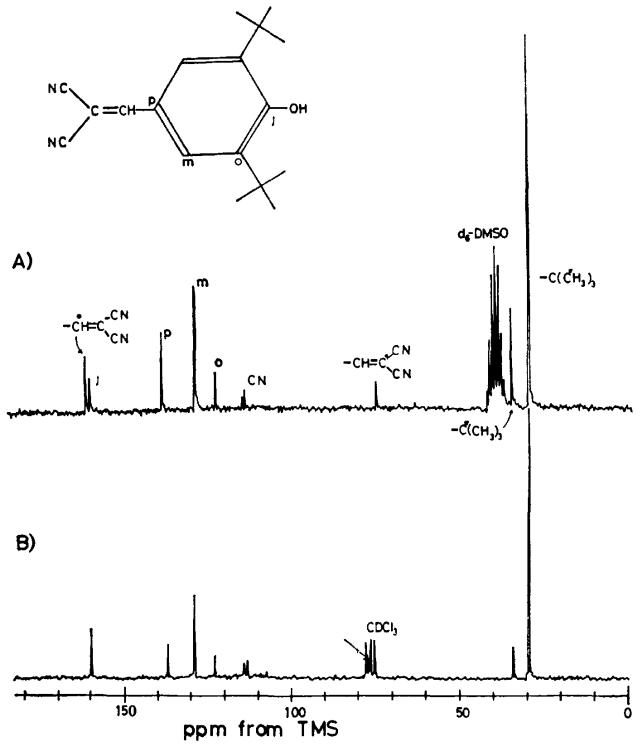

Fig. 2. 22.5 MHz ^{13}C NMR spectrum of SF 6847 in dimethyl-d_6 sulfoxide (A) and in $CDCl_3$ (B).

of the two aromatic protons (meta to the hydroxyl group) is the same in Fig. 1A, and this still exhibited a single resonance when the temperature was lowered to −90 °C in $CDCl_3$ (spectrum not shown). Figure 2 shows the ^{13}C NMR of the neutral form of SF 6847 in $CDCl_3$ (A) and in DMSO-d_6 (dimethyl-d_6 sulfoxide) (B). The carbon signals were assigned as shown in Fig. 2, with reference to the splitting pattern in the proton-coupled spectra (spectrum not shown). It is noted in the figure that the 2- and 3-carbons are equivalent to the 6- and 5-carbons, respectively. The ^1H and ^{13}C NMR spectra indicate that the malononitrile moiety of the neutral form of SF 6847 does not remain fixed in the same plane as the benzene ring.

On the other hand, the ^1H NMR spectrum of the anionic form of SF 6847 in alkaline methanol solution in Fig. 1B shows broad signals of the aromatic protons at 6.9 and 8.1 ppm from DSS. Figure 3 shows the temperature dependence of the ^1H NMR spectrum of the aromatic protons of SF 6847 in the anionic form. As can be seen, the two separate proton signals become narrower when the temperature is decreased to 0 °C from room temperature (23 °C), while they become broad (at 28 °C) and then coalescence into a single resonance (at 58 °C) when the temperature is raised from 23 °C. These results suggest that the malononitrile moiety of the anionic form is less mobile than that in the neutral form. Figure 3 also shows that the signal of the benzylidene proton shifts to a higher field when the temperature is raised. This is attributable to the change of the inter- or intramolecular anisotropic shielding effect of the benzene ring in SF 6847 molecules.

From the temperature dependence of the signal

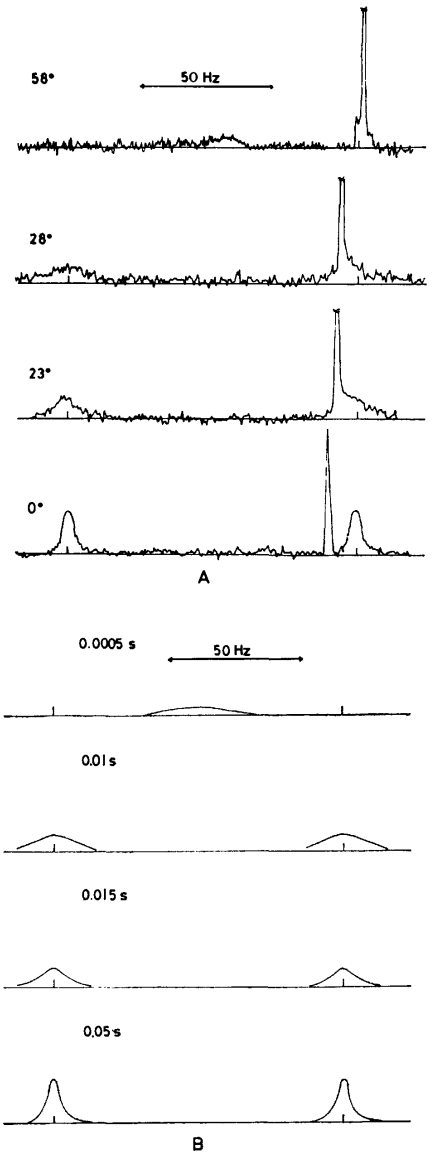

Fig. 3. (A) Temperature dependent ^1H NMR spectra of the benzylic protons of SF 6847 in methanol-d_4 containing 0.1 mol dm^{-3} sodium hydroxide. (B) Calculated spectra for the mean lifetime (τ) indicated. The sharp signal in (A) is due to the benzylic proton.

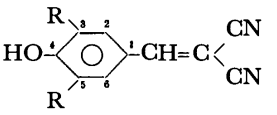
pattern of the aromatic protons, it is possible to calculate the activation energies of the rotational or tumbling motion around the C–C bond between the benzene ring and the malononitrile moiety. Table 1 gives the calculated activation energies based on a simple line-shaped analysis[23] for SF 6847 and its dialkyl derivatives (**1**—**5**), together with the differences of the chemical shifts between the two aromatic protons at low temperatures and the coalescence temperatures. Table 1



R = H	**1**
Methyl	**2**
Ethyl	**3**
Isopropyl	**4**
t-Butyl	**5**

indicates that the motional barrier tends to increase with increase in the bulkiness of the 3,5-dialkyl groups, and that the activation energy (E_a) of the di-*t*-butyl

Table 1. Activation energies (E_a) in the anionic forms of SF 6847 (**5**) and its derivatives

Compound	R	$\Delta\nu$[a] / Hz	T_c[b] / K	E_a / K J mol^{-1}	ΔE_a[c] / K J mol^{-1}
1	H	90	213	42±2	—
2	Methyl	90	233	46±2	4
3	Ethyl	93	251	50±2	4
4	Isopropyl	97	261	54±2	4

derivative **5** (SF 6847) is higher than those of derivatives substituted with smaller alkyl groups (**1**—**4**). It is of interest to note that the energy difference of E_a between **4** and **5** is apparently greater than that between **1** and **2**, or **2** and **3**, or **3** and **4**, indicating that the "steric" effect of the *t*-butyl group is significant.

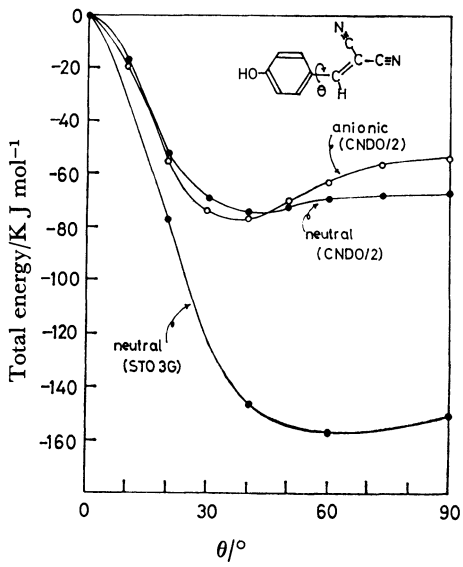

Fig. 4. Changes of the total energy with the angle θ between the benzene ring and the malononitrile moiety in the anionic and neutral forms of **1** calculated using CNDO/2 and *ab initio* (STO 3G) MO calculations. The total energy of the planar form (θ=0°) is standardized to zero.

MO Calculation. In order to gain further insight into the dynamic structure of the SF 6847 molecule, MO calculations were performed for **1**. The changes of the total energy with the angle θ between the benzene ring and the malononitrile moiety in the anionic and neutral forms of compound **1** are shown in Fig. 4. The CNDO/2 calculation shows that the "planar form" (θ=0°) is quite unstable and the minimum energy is found at about θ=40° for both molecular forms. As shown in Fig. 4, essentially the same results were obtained in the *ab initio* calculations, *i.e.*, the planar form is the most unstable conformation. However, the position at the minimum energy determined by the *ab initio* calculation is slightly shifted giving a greater angle θ than that in the CNDO/2 MO calculation. These MO results show clearly that the energy barrier at θ=90° is very small in the neutral form of **1** and a little greater in the anionic form. Similar angular dependence of the total energy based on the MO calculation has also been observed with compound **2**.[17] In view of these results, all the compounds in the series of 3,5-dialkyl derivatives of SF 6847 (compounds **3**, **4**, and **5**) can be regarded as having a similar profile of energy change with θ.

Dynamic Structure. From the above results obtained by NMR and MO calculations, the following conclusions can be drawn concerning the dynamic structure of SF 6847 (**5**) and its derivatives (**1**—**4**.)

(1) The planar conformation (θ=0°) is quite unstable.

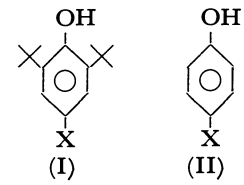
(2) In the most stable conformation of these molecules the benzene ring and the malononitrile moiety are twisted.

(3) The energy barrier at θ=90° is rather small, and thus the malononitrile group can tumble beyond the barrier at θ=90°.

(4) The activation energy of the intramolecular tumbling motion of the malononitrile moiety is greater in the anionic form than in the neutral form.

Here it should be stressed that the degree of conjugation between the benzene ring and the malononitrile moiety in SF 6847 and its derivatives is quite small in solutions. A recent X-ray diffraction study on SF 6847 (**5**)[22] showed that **5** is almost planar in a single crystal. This may be due to the stressed packing of **5** in the crystal, because of the rather strong intermolecular interaction between the benzene ring and the malononitrile moieties of SF 6847 molecules.[22] Difference in the conformation between in crystalline and in solution was also reported for the case of biphenyl.[24]

On Acidity of SF 6847. Next with regard to the acidity of SF 6847 and its derivatives, it is well known[25,26] that introduction of *t*-butyl groups into a molecule near an acidic or basic site causes a large change in acidity or basicity of the molecule. The acid ionization constants (pK_a) of series of 4-substituted 2,6-di-*t*-butylphenols (I) and their unhindered analogues (II) in water and methanol have been reported by some workers.[25,26] It was reported that the hindered



phenol (I) is a weaker acid than its unhindered analogue (II).[27,28] However, in the case of X=–CH=C(CN)$_2$, the acidity of the hindered phenol (R=*t*-butyl, SF 6847) is stronger than that of the unhindered one (R=H, the compound **1**), *i.e.*, the pK_a for SF 6847 is 6.83 and for its unhindered derivatives is 7.25.[27,28] This is explained as follows. As discussed above, in the dissociated (anionic) form the activation energy of the rotational motion around the C–C bond between the benzene ring and the malononitrile moiety of the hindered phenol, SF 6847, is higher than that of the corresponding

unhindered phenol (*cf.* Table 1). Thus, the non-planarity of the π conjugated system, *i.e.*, the angle between the benzene ring and the malononitrile moiety, is possibly reduced in the hindered form, accompanied with the increase in the activation energy at $\theta=90°$. This implies that the conjugation between the benzene ring and the malononitrile moiety is greater when di-*t*-butyl groups are introduced onto the 3,5-carbons of the benzene ring. Consequently the electron-withdrawing power of the malononitrile moiety is stronger in SF 6847 than in the unhindered analogue. Thus, the *t*-butyl groups electronically enhance the acidity of SF 6847, and this overcomes the steric effect of the bulky *t*-butyl groups which weaken the acidity. Therefore, SF 6847 is more acidic than the unhindered derivative.

It is sometimes pointed out that for exhibiting uncoupling activity, the anionic form of an uncoupler should be present in the hydrophobic biological membrane, and thus that a bulky hydrophobic group adjacent to the acid dissociable proton and the electron-withdrawing group is essential for a potent uncoupler.[7,12,29,30] The unique effect of the hydrophobic *t*-butyl group on the acid dissociation of SF 6847 will explain why SF 6847 is such a very potent uncoupler of oxidative phosphorylation.

One of the authors (K. Y.) wishes to express his thanks to Professor Michiya Itoh, Faculty of Pharmaceutical Science, Kanazawa University, for data on the molecular structure of SF 6847 determined by X-ray diffractometry. The authors are indebted to Messrs. Tadahiro Dohi, Hiroshi Fujiwara, and Yoshiaki Tsuda, Otsuka Pharmaceutical Factory Inc., for facilitating use of an NMR spectrometer. They are also grateful to Professor Akira Imamura, Siga University of Medical Science, for making his program available, and to Professor Kichisuke Nishimoto, Faculty of Science, Osaka City University, for helpful discussion. They would also like to thank members of the Computer Center of the Institute for Molecular Science for assistance. The present work was partially supported by Grants-in-Aid for Scientific Research No. 421324 and No. 311901 from the Ministry of Education, Science and Culture of Japan.

Photoadducts of 2-Pyridones with Chloroethylenes and Their Derivatives

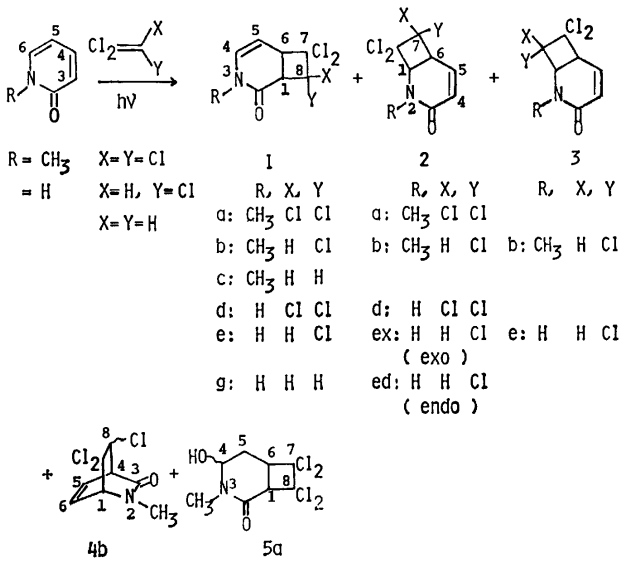
Kenichi SOMEKAWA,* Ryusuke IMAI, Ryuichi FURUKIDO, and Sanetada KUMAMOTO
Department of Applied Chemistry, Faculty of Engineering, Kagoshima University, Korimoto, Kagoshima 890
(Received May 6, 1980)

Sensitized photoirradiations of 2-pyridones with tetrachloroethylene or trichloroethylene gave chlorinated 3-azabicyclo[4.2.0]oct-4-en-2-ones (**1**) and 2-azabicyclo[4.2.0]oct-4-en-3-ones (**2** and **3**), 7,7,8-trichloro-2-methyl-2-azabicyclo[2.2.2]oct-5-en-3-one (**4**), and other products. The reaction with 1,1-dichloroethylene, though, gave only 7,7-dichloro-3-azabicyclo[4.2.0]oct-4-en-2-one. **1**, **2**, **3**, and **4** were reduced by zinc to give 7,8-dichloromethyl-3-azabicyclo[4.2.0]octa-4,7-dien-2-one, 2-azabicyclo[4.2.0]octa-4,7-dien-3-ones (**7**) and 6-chloro-2-methyl-2-azabicyclo[2.2.2]octa-5,7-dien-3-one respectively. Then, **7** thermally gave valence isomers, 7-azabicyclo[4.2.0]-octa-2,4-dien-8-ones, which were β-lactams.

Photocycloadditions between α,β : γ,δ-unsaturated cyclic compounds and unsaturated substances are very interesting because of the possibility of valence isomerizations,[1] and 1 : 2-cycloadditions,[2] followed by ring expansions.[3] 2-Pyridone is a typical heterocyclic α,β : γ,δ-unsaturated carbonyl compound and has a few novel features with regard to its photoreactions.[4] The objectives of the present research are to synthesize the photocycloadducts between 2-pyridones and chloroethylenes, reduce the adducts, and obtain the valence isomers.

Results and Discussion

Photochemical Cycloadditions. All of the preparative reactions described herein were conducted in benzene or methanol with irradiation by means of a 400 W high-pressure mercury lamp through a Pyrex filter. The photoadditions with trichloroethylene or 1,1-dichloroethylene demanded a sensitizer, as aid that with tetrachloroethylene. The progress of the reactions was traced by means of GC. After concentration, the residues were passed through silica-gel columns to give products given in Scheme 1. The data of the elemental analyses and mass spectra indicated that the products of the **1**, **2**, **3**, and **4b** types were the expected 1 : 1 cycloadducts of 2-pyridones with chloroethylenes, while **5a** was the 1 : 1 adduct between **1a** and water.



Scheme 1. Photoreactions and products.

The ^{1}H-NMR data of the products are shown in Table 1. The products, **1a—g**, have two absorption bands in the range of 1690—1650 cm^{-1} ($\nu_{C=O}$, $\nu_{C=C}$) and peaks of δ *ca.* 6.1 (4-H) and 5.0 ppm (5-H). On the basis of those data, the structures of 3-azabicyclo[4.2.0]-oct-4-en-2-ones (3,4-adducts), being consisting of [2+2]-cycloadducts at the C-3 and C-4 positions of 2-pyridones,[5] were determined. The orientational mode of the cycloaddition in Scheme 1 was confirmed from the ^{1}H-NMR coupling multiplicities of the angular methine protons.

The IR data of *ca.* 1680 ($\nu_{C=O}$) and 1630 cm^{-1} ($\nu_{C=C}$) and the ^{1}H-NMR data of δ *ca.* 6.0 (4-H) and 6.5 ppm (5-H) of **2a**, **2b**, **2d**, **2ex**, **2ed**, **3b**, and **3e** are characteristic of the rings of 2-azabicyclo[4.2.0]oct-4-en-3-ones (5,6-adducts).[5] The orientational features of the additions are apparent from the coupling patterns of the ^{1}H-NMR data, as is shown in Table 1. As the stereoisomers, **2ex** and **2ed**, suffered no change upon treatment with basic alumina, which was used to infer the steric structures with regard to bicyclo-alicyclic compounds,[4] the bridgeheads of these adducts were presumed to be *cis*-forms. The chemical shift (δ) of 7-H of **2ex** was smaller than that of **2ed**. This difference is caused by the magnetic-shielding effect of the double bond between C-4 and C-5 on **2ex**.[4] Accordingly, the configurations of **2ex** and **2ed** are, respectively, *exo* and *endo*, making the 7-Cl an target.

The ^{1}H-NMR data of δ 6.6 of two olefinic protons (5-H and 6-H) on **4b** is characteristic of the ring of 2-azabicyclo[2.2.2]oct-5-en-3-one, which is a [4+2]-cycloadduct.[6] **5a** had an IR peak of 3400 cm^{-1}, a ^{1}H-NMR peak of δ 3.27 ppm (which disappeared with hot D_2O), which was assigned to an OH group, and no ^{1}H-NMR peak of olefinic protons. By means of these facts and the characteristic peak of *m/e* 291 (=M$^+$), the structural feature was confirmed. The position of the OH group was determined by means of the ^{1}H-NMR coupling patterns ($J_{4,5}$=4 Hz).

The following properties of the present photoreactions consequently thus became apparent. The photoreaction with 1,1-dichloroethylene gave one regiospecific 3,4-adduct. That with trichloroethylene gave 3,4-adducts, 5,6-adducts, and a [4+2]adduct which was a new type of product,[4] the main products were 5,6-adducts, the regioselectivity of which was varied by the solvents. That with tetrachloroethylene gave 3,4-adducts and 5,6-adducts (main product); it also afforded a hydrate

Nothing	0.03	0	0	0	

a) The solution is, for example, a mixture of pyridone (2.3 mmol), tetrachloroethylene (23 mmol), xanthone (0.61 mmol), and benzene–acetonitrile (10 : 1) (20 ml). b) Ref. 4.

of the 3,4-adduct upon prolonged irradiation. All these photocycloadditions were promoted by sensitizers, Michler's ketone, thioxanthen-9-one, benzophenone, and xanthone, all of those triplet energies are over 62 kcal/mol. This phenomenon was similar to the triplet reactions of 2-pyridones with methyl acrylate.[4)]

The photoreactivity of *N*-methyl-2-pyridone with chloroethylenes in the presence of xanthone decreased in the following order, as is shown in Table 2: 1,1-dichloroethylene > trichloroethylene > tetrachloroethylene $\gg$ *trans*-dichloroethylene, *cis*-dichloroethylene. The reactions with both dichloroethylenes gave no product. The reaction with the more polar chloroethylene is more reactive. Those phenomena are contarry to those of 5,6-dihydro-2-pyridone, which was more reactive with 1,2-dichloroethylene and which had, photochemically, a likeness to α,β-unsaturated enones.[7)] Enones add effectively to electron-donating ethylenes, and the excited species are $n\pi^*$ triplets. The triplet species of the present cycloadditions are inferred to be the same as those of sensitized cycloadditions between 2-pyridones and electron-withdrawing ethylenes,[4)] because the reactivity was not diminished by protic solvents and both the triplet energies were the same. The direct photoexcitation of 2-pyridone hardly gave the triplet species.[4)] From the several findings and inferrences cited above, it is considered that the excited species of 2-pyridones are $\pi\pi^*$ triplets and that the 3,4-positions are more polar than the 5,6-positions.

In order to determine the true nature of the excited state responsible for the present cycloaddition reaction, further, detailed mechanistic investigations should be done.

Synthetic Applications. *Reductions of Photoadducts*:

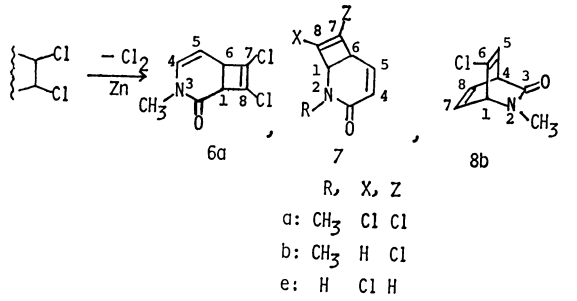
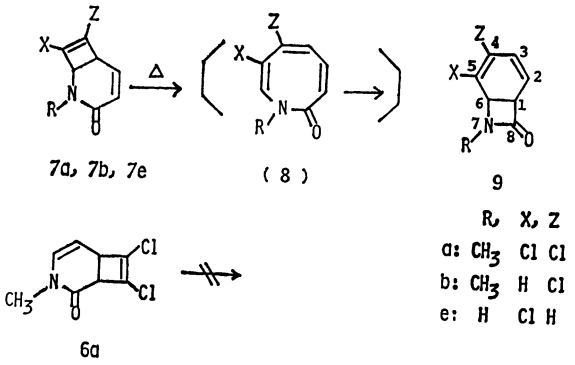


Scheme 2. Reductions of photoadducts.



Scheme 3. Valence isomerizations of azabicyclo[4.2.0]-octadienones.

Mixtures of the photoadducts and zinc dust in the solvent were warmed at the refluxing temperature. After checking the disappearance of the reactants by TLC and the concentration of the filtrate, treatment by the use of column chromatography afforded the compounds shown in Scheme 2. That is, **1a**, **2a**, **3b**, **2ex**, and **4b** gave 7,8-dichloro-3-methyl-3-azabicyclo-[4.2.0]octa-4,7-dien-2-one (**6a**), chlorinated 2-azabicyclo[4.2.0]octa-4,7-dien-3-ones (**7a**, **7b**, and **7e**), and 6-chloro-2-methyl-2-azabicyclo[2.2.2]octa-5,7-dien-3-one (**8b**) respectively. The structures were confirmed by their elemental analyses and the spectral data. The increased IR peaks of 1635—1580 cm^{-1} and the ^{1}H-NMR data in Table 3 were exactly same as had been expected. The reactions are the normal eliminations of a chlorine molecule by zinc dust. The reactivities were as follows: **2a**, **3b**, **2ex**>**4b**>**1a**. That of the chlorinated 2-azabicyclo[4.2.0]oct-4-en-3-one ring is large. **7e** in refluxed benzene suffered valence isomerization.

Valence Isomerization of Azabicyclo[4.2.0]octa-4,7-dienes: The heating of the solution of **7a** and **7b** in the solvent at 120 °C, and that of **7e** at 90 °C, resulted in the complete disappearance of the materials and afforded 7-azabicyclo[4.2.0]octa-2,4-dien-8-ones (**9a**, **9b**, and **9e** respectively) in high yields; all were compounds of the β-lactam type. The structures in Scheme 3 were based on the IR peaks of 1745—1759 cm^{-1} ($\nu_{C=O}$ of β-lactam[8]) and 1635—1648 cm^{-1} ($\nu_{C=C}$) and on the ^{1}H-NMR data of the lower part of Table 3.

The intermediates of the reactions for **9** from **7** may be 2(1*H*)-azocinones (**8**), which are unstable.[9] The heating of **9a** and **9b** at 180 °C and that of **9e** at 120 °C gave the respective chlorobenzenes. These phenomena bore a close parallel to those shown by the MS data.

These results were distinctly different from the behavior of **6a**, which was stable in heating reactions up to 190 °C (Scheme 3).

Experimental

All the melting points were measured on a Yanagimoto Mel-temp apparatus and are uncorrected. The IR, ^{1}H-NMR, and mass spectra were recorded on JASCO A-3, JEOL JNM-MH-100 (100 MHz), and JEOL JMS-01SG spectrometers respectively. The ^{1}H-NMR spectra were recorded with TMS as an internal standard and $CDCl_3$ as the solvent, unless otherwise indicated. The reported values are on the cm^{-1} scale in IR and on the δ (ppm) scale in ^{1}H-NMR. All the photoaddition and synthetic application reactions were monitored by the use of GC, which was performed at 170—200 °C (column temp) on a Yanagimoto G80 instrument using a column of Silicone SE-30 (10%)/Chromosorb W(AW).

Photoreactions of N-Methyl-2-pyridone. (a) With Tetrachloroethylene: A solution of pyridone (45 mmol) and chloroethylene (225 mmol) in 200 ml of methanol was irradiated with a Rikō immersion-type 400 W high-pressure mercury

lamp through a Pyrex jacket for 31 h. The solvent was then removed by the use of a rotary evaporator, and the residue was chromatographed on a silica-gel (Wakogel C-200, 200 g) column with benzene, diethyl ether, and acetone (in this order) as the eluents. The materials obtained from the first and second fractions were recrystallized from benzene to give **1a** (mp 110—112 °C, 4%) and **2a** (mp 134—135 °C, 4%) respectively. The recrystallization of the third fraction from acetonitrile gave **5a** (mp 186—188 °C, 1%). The photoirradiation of the benzene solution of the same reactants, containing thioxanthen-9-one (1.5 mmol) as a sensitizer, gave **1a** and **2a** in 7 and 16% yields respectively. **1a**: IR (KBr) 1663—1650 (sh); MS 109 (M−C_2Cl_4, 100%). Found: C, 35.03; H, 2.61; N, 5.09%. Calcd for $C_8H_7NOCl_4$: C, 34.95; H, 2.57; N, 5.09%. **2a**: IR (KBr) 1675, 1630; MS 238 (M−Cl, 100%). Found: C, 35.05; H, 2.52; N, 5.08%. **5a**: IR (KBr) 1665; MS 291 (M^+, 5%). Found: C, 32.95; H, 3.24; N, 4.88%. Calcd for $C_8H_9NO_2Cl_4$: C, 32.80; H, 3.10; N, 4.78%.

(b) With Trichloroethylene: A solution of pyridone (57 mmol), chloroethylene (570 mmol), and benzophenone (10 mmol) in 200 ml of benzene was irradiated for 30 h and then worked up much as in the procedure described in (*a*). **1b** (mp 97—100 °C (benzene), 1%), **3b** (mp 126—128 °C (benzene), 7%), and **4b** (oil, 2%) were thus obtained. The **4b** was further purified by repeated column chromatography (diethyl ether). The photoirradiation of the methanol solution of the same reactants containing thioxanthen-9-one instead of benzophenone gave **1b** (2%), **2b** (mp 128—130 °C (benzene), 4%), and **4b** (0.5%). The non-sensitized irradiation in methanol gave no cycloadduct. **1b**: IR (KBr) 1658—1645 (sh); MS 239 (M^+, 10%). Found: C, 40.15; H, 3.31; N, 5.83%. Calcd for $C_8H_8NOCl_3$: C, 39.95; H, 3.35; N, 5.82%. **2b**: IR (KBr) 1690, 1633; MS 239 (M^+, 1%). Found: C, 39.91; H, 3.25; N, 5.72%. **3b**: IR (KBr) 1683, 1623; MS 239 (M^+, 2%). Found: C, 39.98; H, 3.33; N, 5.82%. **4b**: IR (neat) 1690, 1622; MS 239 (M^+, 1%). Found: C, 39.93; H, 3.34; N, 5.91%.

(c) With 1,1-Dichloroethylene: A solution of pyridone (28 mmol), chloroethylene (280 mmol), and xanthone (7 mmol) in 200 ml of benzene was irradiated for 6 h and then worked up much as in the procedure described in (*a*). Benzene–diethyl ether (2 : 1) was used as the eluent of the column chromatography. **1c** (oil, 28%) was thus obtained. IR (neat) 1662; MS 205 (M^+, 1%). Found: C, 46.95; H, 4.33; N, 6.85%. Calcd for $C_8H_9NOCl_2$: C, 46.63; H, 4.40; N, 6.80%.

Photoreactions of 2-Pyridone. (a) With Tetrachloroethylene: A solution of pyridone (40 mmol), chloroethylene (400 mmol), and benzophenone (13 mmol) in 200 ml of methanol was irradiated for 15 h and then worked up much as in the procedure of column chromatography described above (*a*). As the eluents, benzene and diethyl ether were used; **1d** (mp 172—175 °C, 9%) and **2d** (mp 212—218 °C, 16%) respectively were thus obtained. **1d**: IR (KBr) 1692, 1663; MS 259 (M^+, 1%). Found: C, 32.30; H, 1.98; N, 5.36%. Calcd for $C_7H_5NOCl_4$: C, 32.21; H, 1.93; N, 5.37%. **2d**: IR (KBr) 1683, 1623; MS 224 (M−Cl, 5%). Found: C, 32.18; H, 1.90; N, 5.25%.

(b) With Trichloroethylene: A solution of pyridone (57 mmol), chloroethylene (570 mmol), benzophenone (10 mmol), and methanol (200 ml) was irradiated for 23 h, the work-up described in (*a*) (eluents: benzene, diethyl ether, and acetone) then gave **1e** (mp 84—86 °C, 5%), **2ex** (mp 172—175 °C, 9%), **2ed** (mp 192—195 °C, 2%), and **3e** (mp 155—158 °C, 7%). **2ex** (0.5 mmol) and **2ed** (0.05 mmol) were passed through a basic alumina (Merck) column (ϕ8 mm × 30 mm), using chloroform as the eluent, and the solutions were concentrated. The ^{1}H-NMR analysis showed that there was no change during this treatment, confirming the *cis* four-six ring fusions. **1e**: IR (KBr) 1670—1650; MS 155 (M−2Cl, 3%). Found: C, 37.08; H, 2.69; N, 6.27%. Calcd for $C_7H_6NOCl_3$: C, 37.12; H, 2.67; N, 6.18%. **2ex**: IR (KBr) 1690, 1623: MS 190 (M−Cl, 10%). Found: C, 37.13; H, 2.69; N, 6.05%. **2ed**: IR (KBr) 1688, 1618. Found: C, 37.15; H, 2.67; N, 5.96%. **3e**: IR (KBr) 1679, 1621; MS 190 (M−Cl, 10%). Found: C, 37.40; H, 2.70; N, 6.02%.

(c) With 1,1-Dichloroethylene: After the irradiation of a solution of pyridone (32 mmol), chloroethylene (320 mmol), and benzophenone (6 mmol) in 200 ml of benzene for 32 h, the same work-up as above gave **1g** (mp 139—141 °C, 10%). IR (KBr) 1683, 1657. Found: C, 44.23; H, 3.70; N, 6.94%. Calcd for $C_7H_7NOCl_2$: C, 43.78; H, 3.67; 7.29%.

Reactivities of Photoreactions: After solutions of *N*-methyl-2-pyridone (2.3 mmol), chloroethylene (23 mmol), a predetermined amount of sensitizers[4] (or none), and benzene–acetonitrile (10 : 1) (20 ml) in Pyrex reaction tubes (ϕ20) had been irradiated by the use of a Rikō Rotary 400 W high-pressure mercury lamp, the relative product ratio was determined by removing aliquots with a syringe and examining them by means of GC.

Reductions of Photoadducts by Zinc. (a) The Reaction of 1a: A mixture of **1a** (370 mg) and zinc dust (550 mg) in 20 ml of benzene was refluxed for 60 h. After the concentration of the filtrate, the precipitate was recrystallized from benzene to give **6a** (mp 91—93 °C, 67%). IR (KBr) 1670, 1635; MS 203 (M^+, 50%). Found: C, 46.83; H, 3.47; N, 6.73%. Calcd for $C_8H_7NOCl_2$: C, 47.09; H, 3.46; N, 6.86%.

(b) The Reactions of 2a, 3b and 2ex: A mixture of **2a** (770 mg) and zinc dust (700 mg) in 35 ml of benzene was refluxed for 4 h. After the concentration of the filtrate, the residue was chromatographed on a silica-gel column (benzene, diethyl ether) to give **7a** (mp 83—87 °C, 75%). IR (KBr) 1740, 1670, 1615; MS 203 (M^+, 30%). Found: C, 46.72; H, 3.64; N, 6.76%. Calcd for $C_8H_7NOCl_2$: C, 47.09; H, 3.46; N, 6.86%.

The refluxing of a mixture of **3b** (300 mg) and zinc (1.2 g) in 20 ml of benzene for 7 h, and of **2ex** (720 mg) and zinc (1.0 g) in 50 ml of methanol for 20 h, followed by treatment by the use of column chromatography similar to that described above, gave **7b** (oil, 80%) and **7e** (mp 124—128 °C, 45%) respectively. **7b**: IR (neat) 1663, 1610—1580. Found: C, 57.05; H, 4.78; N, 8.20%. Calcd for C_8H_8NOCl: C, 56.83; H, 4.74; N, 8.29%. **7e**: IR (KBr) 1674, 1613, 1582; MS 155 (M^+, 3%). Found: C, 54.06; H, 3.94; N, 9.04%. Calcd for C_7H_6NOCl: C, 54.04; H, 3.89; N, 9.00%.

(c) The Reaction of 4b: A mixture of **4b** (140 mg) and zinc (400 mg) in 10 ml of benzene was refluxed for 17 h. Subsequent treatment similar to that given (*b*) afforded **8b** (oil, 58%). IR (neat) 1681, 1623, 1580. Found: C, 56.80; H, 4.79; N, 8.36%. Calcd for C_8H_8NOCl: C, 56.83; H, 4.74; N, 8.29%.

Valence Isomerizations of 7a, 7b, and 7e. (a) The Reactions of 7a and 7b: The heating of **7a** (1.0 mmol) or **7b** (1.0 mmol) in 10 ml of 1,2,4-trichlorobenzene at 120 °C for 5 h resulted in the complete disappearance of the starting materials. The residues were chromatographed on a silica-gel column, with benzene and diethyl ether as eluents, to give **9a** (oil, 70%) and **9b** (oil, 73%) respectively. The reactions, monitored by the use of TLC and ^{1}H-NMR, were almost quantitative. The **9a** and **9b** were decomposed by heating them at 180 °C in glass tubes to give dichlorobenzene and chlorobenzene respectively. **9a**: IR (neat) 1759, 1635; MS 203 (M^+, 2%). Found: C, 47.17; H, 3.50; N, 6.89%. Calcd for $C_8H_7NOCl_2$:

C, 47.09; H, 3.46; N, 6.86%. **9b**: IR (neat) 1750, 1640. Found: C, 56.90; H, 4.85; N, 8.27%. Calcd for C_8H_8NOCl: C, 56.83; H, 4.74; N, 8.29%.

(b) The Reaction of ***7e***: A solution of **7e** (1.0 mmol) in benzene (15 ml) was refluxed for 10 h. The residue was chromatographed in a manner similar to the above to give **9e** (mp 86—90 °C, 45%). The half-life time of **7e** was 50 min at 90 °C, and the generated **9e** was decomposed by heating at 120 °C to give chlorobenzene. IR (KBr) 1745, 1648; MS 155 (M^+, 5%), 112 (M−NHCO, 100%). Found: C, 53.87; H, 3.93; N, 8.87%. Calcd for C_7H_6NOCl: C, 54.04; H, 3.89; N, 9.00%.

The heating reaction of **6a** (1.0 mmol) in 1,2,4-trichlorobenzene (10 ml) was attempted up to 190 °C, and the progress was monitored by similar methods. However, no reaction occurred.

Preparation of Several 1,5,5,11,11-Pentamethyltricyclo-[6.2.1.0^{2,6}]undecane Derivatives

Yoshinobu INOUYE,* Chikara FUKAYA, and Hiroshi KAKISAWA

Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305

(Received June 12, 1980)

1,6-Diketone, available in eight steps from homocamphorquinone, was converted into 1,5,5,11,11-pentamethyltricyclo[6.2.1.0^{2,6}]undecan-7-one by treatment with potassium *t*-butoxide and then lithium dimethylcuprate, while α,α-dimethyl-γ-valerolactone, prepared in five steps from homocamphor, was converted into 1,5,5,11,11-pentamethyltricyclo[6.2.1.0^{2,6}]undec-2-en-4-one by treatment with diphosphorus pentoxide–methanesulfonic acid.

Taxinine (**1**), the major component isolated from the Japanese *Taxus cuspidata*,[1] has a unique carbon skeleton, named "taxane," containing an 8-membered ring as a part of the bicyclo[5.3.1]undecane system. Several attempts[2-4] to synthesize this compound have been reported, but none have succeeded.

In the course of our synthetic approach to this skeleton,[4] we were faced with the necessity to prepare a compound **2** having a 5-alkyl-1,5,11,11-tetramethyltricyclo[6.2.1.0^{2,6}]undecane system. This compound was thought to be derivable from a homocamphor framework by creating a 5-membered ring on it. The readily available ketone **3**, prepared by Büchi *et al.*[5] during their investigation of the synthesis of pachouli alcohol, was at first attractive, but our preliminary attempts at the conversion of **3** into **2** were unsuccessful, especially in the introduction of two alkyl groups at the C-5 position of the tricyclo[6.2.1.0^{2,6}]undecane system.

The present paper will describe the syntheses of two 1,5,5,11,11-pentamethyltricyclo[6.2.1.0^{2,6}]undecane derivatives (**26** and **39**) as possible model compounds for **2**. The synthetic efforts were mainly concentrated on the creation of a 5-membered ring with a geminate dimethyl group on the homocamphor framework.

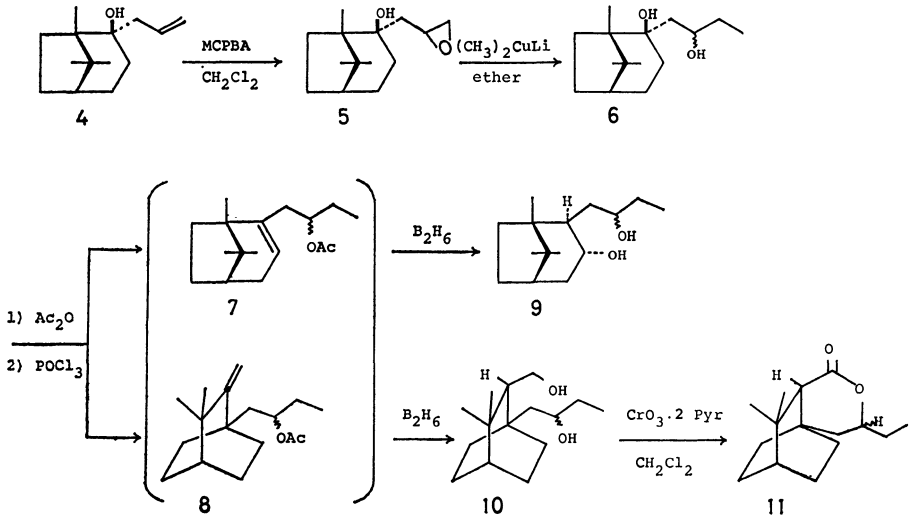
2 R_1=CH_3, R_2=Alkyl

3 R_1=R_2=O

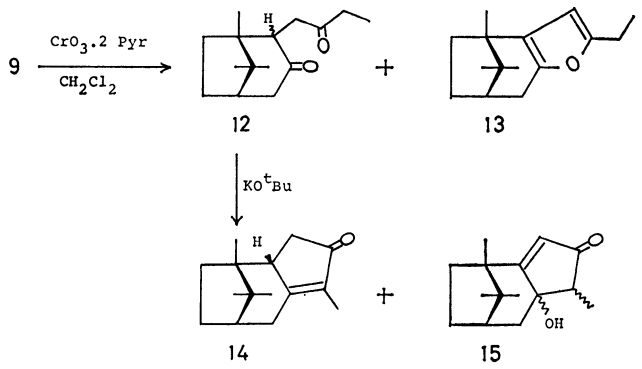
Construction of a 5-Membered Ring Prior to the Introduction of a Methyl Group. One of the methods most widely used to create the cyclopentane ring is an intramolecular aldol condensation of 1,4-diketones. An initial effort was directed at preparing a cyclopentenone, 1,5,11,11-tetramethyltricyclo[6.2.1.0^{2,6}]undec-5-en-4-one (**14**), from the 1,4-diketone **12**. The preparation of **12** from the easily avairable unsaturated alcohol **4**[5] is shown in Schemes 1 and 2.

The alcohol **4** was oxidized to the epoxy alcohol **5** by treatment with *m*-chloroperbenzoic acid. The direct dehydration of this epoxy alcohol **5** with phosphoryl chloride or thionyl chloride in pyridine gave no fruitful results; however, the introduction of a chlorine atom was recognized from the analysis of the mass spectrum. This is thought to arise from the participation of the epoxy group.[7] The trouble was overcome by opening the epoxy ring prior to the dehydration. Thus, when **5** was treated with lithium dimethylcuprate in ether, the diol **6** was obtained in 89% yield as a result of the selective opening of the epoxy ring into a secondary alcohol.[8] After the secondary hydroxyl group had been protected by acetylation, the tertiary one was dehydrated with phosphoryl chloride in pyridine to give a mixture of an unsaturated acetate **7** and a



Scheme 1.

rearranged acetate **8**. The mixture, without the separation of its components, was converted into two diols, **9** and **10** (49 and 14% yields respectively from **6**), by hydroboration with diborane.[9] The structure of the rearranged diol **10** was determined by NMR spectroscopy. In the NMR spectrum of the diacetate of **10**, only two tertiary methyl signals are observed, at 0.99 and 1.04 ppm, while one -CH-OAc group and one $-CH_2-OAc$ group are recognized at 4.8 and 4.1 ppm respectively. The structure was finally confirmed by the oxidation of **10** with chromium trioxide to afford a δ-lactone **11** [$\nu(CCl_4)$: 1740 cm^{-1}; δ ($CDCl_3$): 4.0 (m, 1H) and 1.95 (s, 1H)]. The configurations at the newly formed asymmetric centers of the major diol are assigned as in **9** by considering the less-hindered-side attack of diborane.[10]



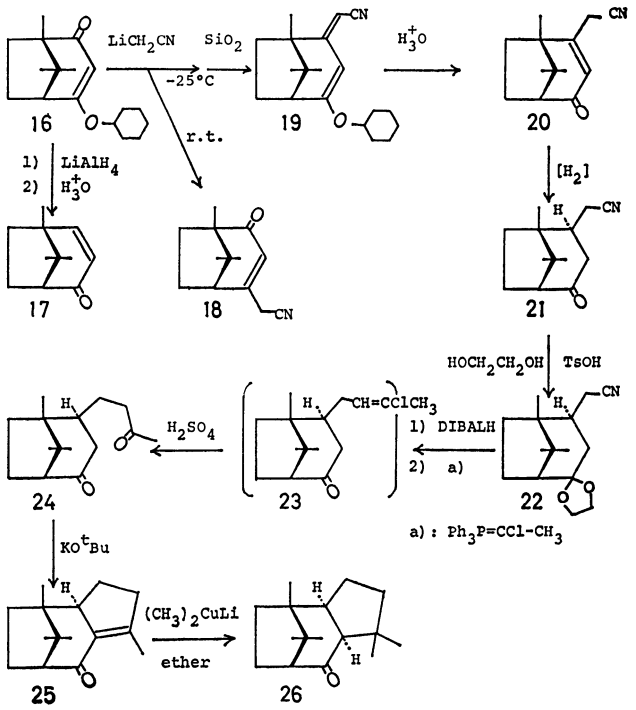
Scheme 2.

The oxidation of the major diol **9** gave the desired 1,4-diketone **12** in 72% yield, accompanied by a small amount (17%) of a furan derivative **13**. When **12** was treated with potassium *t*-butoxide in *t*-butyl alcohol at room temperature (30 min), 1,5,11,11-tetramethyl-[6.2.1.$0^{2,6}$]undec-5-en-4-one (**14**) and 6-hydroxy-1,5,11,-11-tetramethyltricyclo[6.2.1.$0^{2,6}$]undec-2-en-4-one (**15**) were obtained in 79 and 9% yields respectively. The methyl group attached to the double bond of the major product **14** was recognized at 1.59 ppm in the NMR spectrum. The structure of the minor product **15** was deduced from the presence of one secondary methyl doublet (1.08 ppm, J=7 Hz) and one proton singlet on the double bond (5.77 ppm), which has no allylic proton coupled to it (*cf.* **39**). The stereochemistry of C-2 in **14** was assigned as is shown by the conformational analysis of the molecule. The mechanism for the formation of **15** during the cyclization of the diketone **12** was not clarified.

Several attempts to introduce an alkyl group into the C-5 position of **14** were unsuccessful: the treatment of **14** with allyl bromide–sodium hydride gave a 3-allyl derivatives, while a protected **14**, the 3,3-butylthiomethylene derivative, did not react with allyl bromide–sodium hydride in benzene or diglyme.

Another approach to the title compound is summarized in Scheme 3. Here, a 1,6-diketone **24** was chosen as the precursor because no epimerization at C-2 was anticipated during the alkaline cyclization.

The treatment of homocamphorquinone with cyclohexanol led to the regiospecific production of an enol



Scheme 3.

ether **16** in 73% yield, ν(KBr): 1650 and 1600s cm^{-1}. None of the other isomers was detected in the reaction product. The structure of **16** was confirmed by reduction with lithium aluminum hydride, followed by hydrolysis with hydrochloric acid, to convert it into the known unsaturated enone **17**.[11] The lithioacetonitrile, prepared[12] from acetonitrile and butyllithium, was treated with the enol ether **16** at −78 °C, after which the mixture was brought to room temperature to give a cyanomethyl enone **18** in 95% yield. The structure of **18** was determined by comparison of its spectra with those of an isomer **20** (see below). The formation of **18** resulted from the 1,4-addition of the reagent to an α,β-unsaturated ketone. When the reaction was controlled at lower temperatures (−25——30 °C), the reaction proceeded by means of the 1,2-addition of the reagent; the initial product was dehydrated during the isolation procedure (silica gel chromatography) to give **19** exclusively. The NMR spectrum of **19** shows the presence of a cyclohexyloxy group (multiplet at 4.2 ppm) and two vinylic protons (singlets at 4.53 and 5.53 ppm). A similar temperature-dependence of the 1,2- *vs.* 1,4-addition of a reagent to an α,β-unsaturated ketone system has recently been reported.[13]

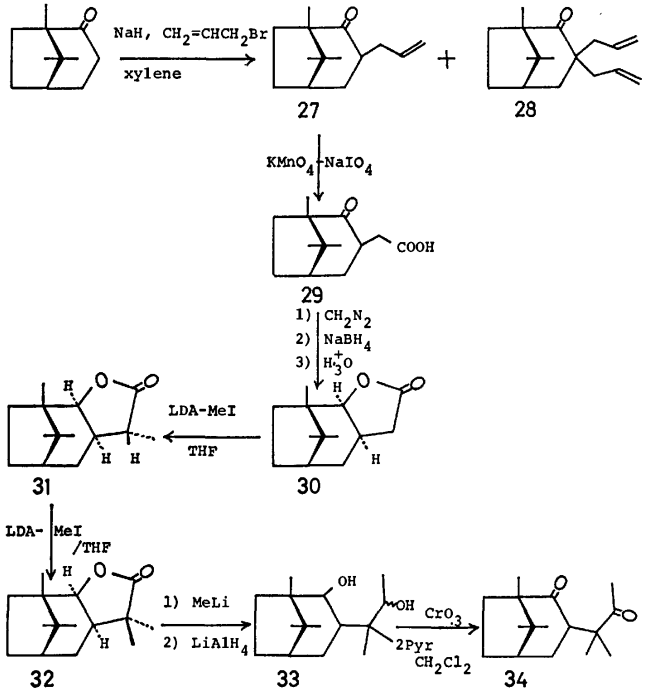
The acid hydrolysis of **19** afforded the desired cyanomethyl enone **20**. The double bond in **20** was readily hydrogenated over a palladized charcoal catalyst. The configuration of the side chain in the dihydro-compound **21** was postulated from the known reactions;[10] the hydrogen approaches **20** from the α-side of the molecule.

After protecting the carbonyl group with ethylene glycol, the acetalized nitrile **22** (mp 83—84 °C) was reduced with diisobutyl aluminum hydride,[14] after which the intermediate imine was hydrolyzed in aqueous ammonium chloride, giving an aldehyde

[$\nu(CCl_4)$: 2700 and 1720 cm^{-1}; and $\delta(CDCl_3)$: 9.7 ppm (t, 1H)] in 90% yield. The treatment of the crude aldehyde with (1-chloroethylidene)triphenylphosphorane, a new reagent prepared according to the procedure of Seyferth *et al.*,[15] and the subsequent hydrolysis of the acetal group afforded a mixture of chlorovinyl ketones, **23** (a mixture of *E*- and *Z*-isomers), in 70% yield. **23** was then hydrolyzed with concentrated sulfuric acid to afford a crystalline 1,6-diketone **24**; mp 59—60 °C; ν(KBr): 1705 and 1690 cm^{-1}.

The cyclization of **24** was effected by the use of potassium *t*-butoxide to give 1,5,11,11-tetramethyltricyclo-[6.2.1.0^{2,6}]undec-5-en-7-one (**25**); $\nu(CCl_4)$: 1675 and 1615 cm^{-1}: $\delta(CCl_4)$: 0.85, 0.90, 0.96 (each s, 3H), and 2.12 (br. s, 3H). The enone **25** was unstable, and even when it was left in an icebox under nitrogen, some unidentifiable crystalline substances resulted. **25** was, therfore, promptly converted into a stable compound, **26**; the freshly purified **25** was treated with lithium dimethylcuprate to afford the expected 1,5,5,11,11-pentamethyltricyclo[6.2.1.0^{2,6}]undecan-7-one (**26**) in 91% yield by the conjugate addition of methyl to an α,β-unsaturated ketone.[16]

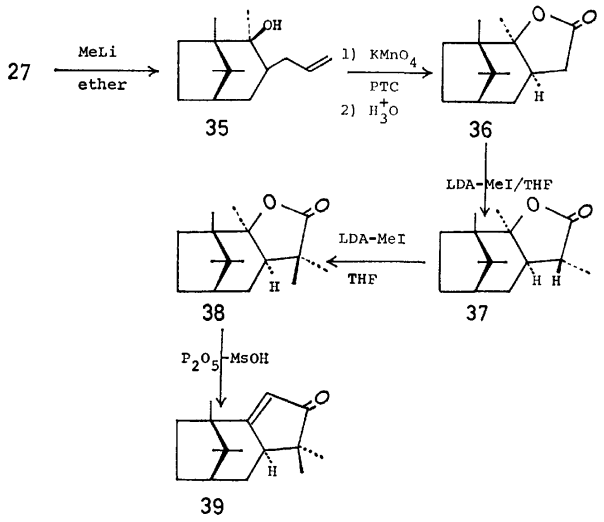
Introduction of a Geminate Dimethyl Group Prior to the Formation of a 5-Membered Carbocyclic Ring. Another approach to the title compound was to introduce a geminate dimethyl group before the construction of a 5-membered carbocyclic ring. γ-Lactones, such as **30** and **36**, were chosen as the starting materials.



Scheme 4.

The allyl group was introduced into the C-2 position of homocamphor according to Fried's procedure.[17] The resulting **27**, separated from the dially derivative **28** by fractional distillation, was subjected to Lemiux's oxidation, thus giving a keto acid **29**. The methyl ester of **29** was then reduced with sodium borohydride in methanol, followed by acid treatment, to afford a γ-lactone **30** in 90% yield from **27**. The stereochemistry of **30** was deduced from the facts that the coupling constant, J=5 Hz, between the protons on the ring junctures of the lactone ring requires a *cis* relationship of these two protons, and that the hydride in the sodium borohydride reduction of **29** attacks from the rear side of the molecule.[10] The methylation of **30** with one equivalent of lithium diisopropylamide (LDA)[18] and methyl iodide afforded α-methyl-γ-lactone **31** in a quantitative yield. Because of the concave shape of **30**, reagents were expected to attack exclusively from the convex side of the molecule. The further treatment of **31** with excess LDA–methyl iodide gave dimethyl-γ-lactone **32**. The conversion of **32** into a diketone **34** was achieved by successive treatment with methyllithium in ether, lithium aluminum hydride in ether, and chromium trioxide–pyridine complex in dichloromethane.

Several attempts at the cyclization of **34** to cyclopentenone under alkaline (*t*-BuOK/*t*-BuOH, NaH/benzene, or NaOH/EtOH) or acid conditions ($Et_3N\cdot C_6H_5COOH$/xylene or TsOH/benzene) were unsuccessful. This failure is thought to have arisen from a severe steric repulsion in the transition state as a result of changing the hybridization of the C-2 carbon from sp^2 to sp^3. These difficulties were finally overcome by using the γ-valerolactone derivative described in Scheme 5 and by cyclizing under acid conditions, where the carbon bearing the oxygen atom changes hybridization from sp^3 to sp^2.



Scheme 5.

Allylhomocamphor (**27**) was treated with methyllithium to give an alcohol **35**. The stereochemistry of **35** was deduced from the rear-side attack of the reagent. **35** was oxidized with potassium permanganate in the presence of alkyldimethylbenzylammonium chloride[19] to afford a γ-valerolactone derivative **36**. The methylation with LDA–methyl iodide proceeded much as in the case of **30**; the dimethyl derivative **38** was thus obtained in a quantitative yield.

The transformation of γ-valerolactone into cyclopentenone had been reported by only Fisini and Manjean; 7a-methylperhydro-2-benzofuranone was con-

verted into hexahydroindenone by treatment with polyphosphoric acid, but in only 25% yield, accompanied by the same amount of a rearranged product.[20] As will be shown in the Experimental section, we used diphosphorus pentoxide–methanesulfonic acid, a more effective reagent[21] than polyphosphoric acid; the yield of hexahydroindenone could thus be raised to 59%.

The treatment of **38** with diphosphorus pentoxide–methanesulfonic acid at 70 °C for 2 h afforded the expected 1,5,5,11,11-pentamethyltricyclo[6.2.1.$0^{2,6}$]-undec-2-en-4-one (**39**) in 50% yield; $\nu(CCl_4)$: 1700 and 1605 cm^{-1}. Besides five methyl singlets, at 0.78, 0.91, 0.98, 1.03, and 1.12 ppm, one vinylic proton is recognized at 5.51 ppm; it couples to an allylic proton with a coupling constant of 2 Hz.

In conclusion, 1,5,5,11,11-pentamethyltricyclo-[6.2.1.$0^{2,6}$]undecane derivatives have been successfully prepared through two different routes (**16**→**24**→**26** and **36**→**38**→**39**). Further investigations of the conversion of an appropriate intermediate (*e.g.*, 5α-allyl instead of 5α-methyl in **38**) to a taxane framework *via* **2** are in progress.

Experimental

All the melting points are uncorrected. The NMR spectra were obtained with Hitachi H-60 and JEOL MH-100 spectrophotometers, using TMS as the internal standard; the chemical shifts are given in δ values. The IR spectra were taken on a Hitachi 215 grating spectrophotometer. *dl*-Camphor was used in all cases.

Epoxidation of the Unsaturated Alcohol **4**. To a cooled mixture of **4** (4.4 g, prepared according to Büchi's procedure[5]) in 40 ml of dichloromethane there was added a solution of *m*-chloroperbenzoic acid (4.3 g) in 80 ml of dichloromethane. After having been stirred overnight at room temperature, the mixture was extracted with ether. The extract was washed with aqueous sodium hydroxide (10%), water, and brine, and was dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent afforded a crystalline epoxide, **5** (4.5 g, 94%), which was recrystallized from pentane; mp 61—62 °C; $\nu(CHCl_3)$: 3500, 2950, 1260, and 1240 cm^{-1}; $\delta(CDCl_3)$: 0.87 (s, 3H), 0.90 (s, 3H), 1.22 (s, 3H), 2.45 (dd, 1H, J=4.5 and 2 Hz), 2.80 (t, 1H, J=4.5 Hz), and 3.17 (m, 1H). Found: C, 75.02; H, 10.63%. Calcd for $C_{14}H_{24}O_2$: C, 74.95; H, 10.78%.

Reaction of **5** *with Lithium Dimethylcuprate.*[22] To a suspension of 6.46 g (34 mmol) of copper(I) iodide in 40 ml of anhydrous ether at 0 °C, there was added 88 ml (68 mmol) of a methyllithium–ether solution over a 15-min period. After 10 more min of stirring, a solution of 1.99 g (9 mmol) of **5** in 30 ml of ether was added over a 10-min peroid, and the mixture was stirred at 0—5 °C for 20 h.[8] The whole was treated with aqueous ammonium chloride (30 ml), and the products were extracted with ether. The extract was washed with water and brine, and then dried over anhydrous sodium sulfate. The solvent was evaporated to give a crystalline diol, **6**, (1.93 g 89%), which was subsequently recrystallized from ethyl acetate to afford a pure **6**; mp 104 °C; ν(KBr): 3430, 3360, 2950, 1390, 1380, 1370, 1080, 1060, and 1030 cm^{-1}; $\delta(CDCl_3)$: 0.85 (s, 3H), 0.95 (s, 3H), 0.95 (t, 3H, J=7 Hz), 1.22 (s, 3H), 2.7 (br. s, 2H), and 3.9 (m, 1H). Found: C, 74.82; H, 12.00% Calcd for $C_{15}H_{28}O_2$: C, 74.95; H, 11.74%.

A Mixture of Two Unsaturated Acetates, **7** *and* **8**. A solution of 3.15 g of **6** in 15 ml of pyridine and 15 ml of acetic anhydride was allowed to react for 17 h at room temperature. A subsequent, usual work-up gave 3.68 g of a monoacetat $\nu(CCl_4)$: 3580, 3500, 2950, 1740, 1390, 1370, 1250, 1230, 1110, 1080, 1020, and 960 cm^{-1}; $\delta(CDCl_3)$: 0.85 (s, 3H), 0.89 (t, 3H, J=7 Hz), 0.93 (s, 3H), 1.20 (s, 3H), 2.07 (s, 3H), 4.8 (m, 1H), and 5.1 (m, 1H). The monoacetate (3.68 g) was placed in a sturdy flask with 80 ml of pyridine, 16 ml of phosphoryl chloride was then added, the flask was stoppered tightly, and the contents were heated on an oil bath at 95 °C for 6 h. After colling, the dark mixture was cautiously poured onto 500 g of ice and stirred briefly. The mixture was extracted with pentane, and the extract was washed with water, dried, and evaporated to yield an oil (3.05 g). By chromatography on silica gel (50 g), 2.75 g of a mixture of unsaturated acetates (**7** and **8**) were obtained; $\nu(CCl_4)$: 2950, 1730, 1630w, 1380, 1370, 1245, 1020, and 960 cm^{-1}. The oil showed two peaks on VPC (5% OV-1, glass column 3φ× 1.7 m, 170 °C), but was used directly in the subsequent reaction without any separation of the components.

Hydroboration of the Mixture of **7** *and* **8**. A solution of 2.87 g of the mixture (**7** and **8**) in 50 ml of THF was treated with diborane as usual[9] to give an oil (2.94 g). The oil was chromatographed on silica gel (three times with 20 g each). From hexane–ethyl acetate (100 : 10) eluates, 385 mg (14%) of **9** were obtained. From hexane–ethyl acetate (50 : 50), 1.28 g of **10** resulted.

9, mp 113.5—116 °C (from hexane); ν(KBr): 3200br, 1045, 1005, 980, 970, and 955 cm^{-1}; δ(100 MHz, $CDCl_3$): 0.89 (t, 3H, J=7 Hz), 0.90 (s, 3H), 1.04 (s, 3H), 3.60—3.8 (m, 5H; the addition of D_2O changes the area to 3H). Found: C, 74.80; H, 11.95%. Calcd for $C_{15}H_{28}O_2$: C, 74.94; H, 11.74%.

Diacetate of **9**, bath temp 136—139 °C/0.25 mmHg (Kugelrohr dist); $\nu(CCl_4)$: 1735 and 1240 cm^{-1}; δ(100 MHz, CCl_4): 0.84 (t, 3H, J=7 Hz), 0.99 (s, 3H), 1.04 (s, 3H), 1.90 (s, 3H), 1.96 (s, 3H), 4.1 (m, 2H), and 4.8 (m, 1H). Found: C, 70.22; H, 9.93%. Calcd for $C_{19}H_{32}O_4$: C, 70.33; H, 9.94%.

10, mp 131—133.5 °C (from hexane); ν(KBr): 3300br, 1035, and 960 cm^{-1}; δ(100 MHz, $CDCl_3$): 0.81 (s, 3H), 0.86 (s, 3H), 0.88 (s, 3H), 0.94 (t, 3H, J=7 Hz), 2.9 (br. s, 2H, -OH×2), 3.8 (m, 1H), 3.86 (br. d, 1H, J=6 Hz). Found: C, 74.93; H, 12.07%. Calcd for $C_{15}H_{28}O_2$: C, 74.94; H, 11.74%.

Diacetate of **10**, bath temp 127—130 °C/0.25 mmHg (Kugelrohr dist); $\nu(CCl_4)$: 1730 and 1250 cm^{-1}; δ(100 MHz, CCl_4): 0.83 (s, 3H), 0.88 (t, 3H, J=7 Hz), 0.91 (s, 6H), 1.91 (s, 3H), 1.97 (s, 3H), 4.7 (m, 1H), and 4.82 (br. d, 1H, J= 6 Hz). Found: C, 70.23; H, 9.99%. Calcd for $C_{19}H_{32}O_4$: C, 70.33; H, 9.94%.

Oxidation of **9**. To a solution of 300 mg of chromium trioxide and 0.49 ml of pyridine in 8 ml of dichloromethane[23] there was added a solution of 60 mg of **9** in 5 ml of dichloromethane in one portion. After stirring for 3 h at room temtemperature, the solution was decanted and the residue was washed with 10 ml of ether. The combined organic solutions were washed successively with 5% aqueous sodium hydroxide (3×5 ml), 5% hydrochloric acid (5 ml), 5% aqueous sodium hydrogencarbonate (5 ml), and saline, and were dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent afforded an oil, which was then chromatographed on silica gel (5 g). From hexane–ethyl acetate (100 : 2), 29 mg (49%) of a crystalline **11** were obtained. Recrystallization from hexane gave a pure **11**; mp 77—78 °C; $\nu(CCl_4)$: 1740, 1200, and 1195 cm^{-1}; δ(100 MHz, $CDCl_3$): 0.96 (t, 3H, J=7 Hz), 1.10 (s, 3H), 1.37 (s, 3H), 1.95 (s, 1H), and 4.0 (m, 1H). Found: C, 76.28; H, 10.35%. Calcd for $C_{15}H_{24}O_2$:

C, 76.22; H, 10.24%.

1,5,11,11-Tetramethyltricyclo[6.2.1.0^{2,6}]undec-5-en-one (14). By the same procedure as in the case of **10**, **9** (240 mg) was oxidized with 1.2 g of chromium trioxide. The crude oil was chromatographed on silica gel (5 g) to give 38 mg (17%) of a furan derivative **13** from the hexane eluates. Pure **13**, mp 65—66 °C (from pentane, at −70 °C); ν(KBr): 1620, 1560, 930, and 800 cm^{-1}; δ(CCl_4): 0.82 (s, 3H), 0.94 (s, 3H), 1.08 (s, 3H), 1.18 (t, 3H, J=7 Hz), 2.53 (q, 2H, J=7 Hz), and 5.62 (s, 1H); Found: C, 82.43; H, 10.27%. Calcd for $C_{15}H_{22}O$: C, 82.51; H, 10.15%. Further elution with hexane–ethyl acetate (10 : 1) gave 171 mg (72%) of **12**, ν(CCl_4): 1710 and 1690 cm^{-1}; two peaks on VPC.

A solution of the diketone **12** (171 mg), without any separation of the components, in 5 ml of *t*-butyl alcohol was added to a stirred solution of potassium *t*-butoxide (prepared from 53 mg of potassium) in 5 ml of *t*-butyl alcohol, after which the mixture was stirred at room temperature for 30 min. Water was added, and the products were extracted with ether. The ether layer was washed with water and dried over anhydrous sodium sulfate. By flash chromatography (hexane–ethyl acetate=5 : 1), 124 mg (79%) of a cyclopentenone **14** were obtained. Bath temp: 99—101 °C/0.2 mmHg (Kugelrohr dist); mp 44—46 °C from pentane, at −70 °C); ν(CCl_4): 1700 and 1645 cm^{-1}; δ (CCl_4): 0.87 (s, 3H), 0.94 (s, 3H), 1.12 (s, 3H), and 1.59 (br. s, 3H). Found: C, 82.40; H, 10.18%. Calcd for $C_{15}H_{22}O$: C, 82.51; H, 10.15%.

When the residue was eluted with hexane–ethyl acetate (3 : 1), 16 mg (9%) of 6-hydroxy-1,5,11,11-tetramethyltricyclo[6.2.1.0^{2,6}]undec-2-en-4-one (**15**) were obtained in a crystalline form; mp 141—142 °C (from pentane); ν(CCl_4): 3500, 1700, and 1600 cm^{-1}; δ($CDCl_3$): 0.74 (s, 3H), 1.00 (s, 3H), 1.08 (d, 3H, J=7 Hz), 1.13 (s, 3H), and 5.77 (s, 1H). Found: C, 77.16; H, 9.66%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

*Preparation of the Enol Ether **16**.* In a flask fitted with a water separator there was placed a solution of 1.03 g of homocamphorquinone, 50 mg of *p*-toluenesulfonic acid, and 0.6 ml of cyclohexanol in 90 ml of toluene. The mixture was then heated to boiling, the azeotrope composed of toluene and water being removed continuously. Several hours later, the water separator was filled with a molecular sieve of the 4A type and heating was continued for 2 more days. The solution was washed with 10% aqueous sodium hydroxide (10 ml×2), water (10 ml×3), and brine. After having been dried over anhydrous sodium sulfate, the solvent was evaporated to give an oil, which crystallized when chilled in pentane (1.1 g, 73%). Recrystallization from pentane gave a pure **16**; mp 74—76 °C; ν(CCl_4): 1650, 1600, and 1210 cm^{-1}; δ($CDCl_3$): 0.94 (s, 6H), 1.07 (s, 3H), 4.1 (br. m, 1H), and 5.14 (br. s, 1H). Found: C, 77.95; H, 9.98%. Calcd for $C_{17}H_{26}O_2$: C 77.82; H, 9.99%.

*Conversion of **16** to the Known Enone **17**.* A solution of 100 mg of **16** in 10 ml of dry THF was refluxed for 1 h with $LiAlH_4$. After the excess reagents had then been decomposed by the careful addition of water, a 5-ml portion of 10% sulfuric acid was added and the mixture was stirred at room temperature for 30 min. The products were taken up in ether, and the ether extract was evaporated to give an oil, which was subsequently chromatographed on alumina (10 g). From the benzene eluates, 47 mg (75%) of the enone **17** were obtained. The NMR spectrum of **17** [δ($CDCl_3$): 0.92 (s, 6H), 1.14 (s, 3H) 5.88 (dd, 1H, J=10 and 1.5 Hz), 6.73 (d, 1H, J=10 Hz) was in accord with the previously reported value.[11]

*Treatment of **16** with Lithioacetonitrile. A) At −25—−30 °C:* A solution of 5.25 g (18.4 mmol) of **16** in 25 ml of THF was added, drop by drop, over a 5-min period to 4 eq of $LiCH_2CN$ (prepared from 56 ml of a 1.6 M buthyllithium–hexane solution and 4.2 ml of acetonitrile in 30 ml of THF at −78 °C)[12] at −78 °C, after which the mixture was stirred at that temperature for 1.5 h. The temperature was then raised to −25 °C and stirring was continued for 3 h at −25 ——30 °C. A saturated ammonium chloride solution (30 ml) was added, drop by drop, while the temperature was kept below −25 °C by the occasional cooling of the flask. Water (30 ml) was added, and an organic layer was separated. The aqueous layer was extracted with ether, and the combined extracts were washed with a small portion of water and saline, and dried over anhydrous sodium sulfate. The evaporation of the solvent gave an oil, which was then chromatographed on silica gel (150 g). Elutions with 50% benzene–hexane and then with benzene gave 3.64 g (64%) of **19**.

19, mp 76—77 °C (from pentane); ν(CCl_4): 2210, 1610, and 1215 cm^{-1}; δ(CCl_4): 0.85 (s, 3H), 0.95 (s, 3H), 1.05 (s, 3H), 4.2 (m, 1H), 4.53 (s, 1H), and 5.53 (br. s, 1H). Found: C, 80.08; H, 9.62; N, 5.18%. Calcd for $C_{19}H_{27}NO$: C, 79.95; H, 9.53; N, 4.90%.

B) At Room Temperature: A mixture of 130 mg of **16** and 10 eq of $LiCH_2CN$ was stirred at −78 °C for 1.5 h, at −25 ——30 °C for 3 h, and finally at room temperature for 1 h. By a subsequent work-up as in A), 95 mg (95%) of **18** were obtained.

18, mp 67—70 °C (from ether); ν($CHCl_3$): 2220 and 1670 cm^{-1}; δ($CDCl_3$): 0.90 (s, 3H), 0.99 (s, 3H), 1.07 (s, 3H), 3.31 (d, 2H, J=2 Hz), and 6.00 (br. s, 1H). Found: C, 76.93; H, 8.49; N, 6.89%. Calcd for $C_{13}H_{17}NO$: C, 76.80; H, 8.42; N, 6.89%.

*Cyanomethyl Enone **20**.* A solution of 5.13 g of **19** in 110 ml of methanol and 30 ml of water containing 2 ml of concd sulfuric acid was stirred at room temperature for 20 h. After the addition of solid sodium hydrogencarbonate (6.3 g), the solution was neutralized with aqueous sodium hydrogencarbonate and diluted with 80 ml of water. The **20** thus precipitated (2.18 g) was collected, and the filtrate was extracted with ethyl acetate. Evaporating the solvent afforded solids, from which a further 0.96 g of **20** was obtained by recrystallization from benzene–hexane. The total yield was 3.14 g (86%).

20, mp 117—118 °C (from ether); ν(KBr); 2250, 1660, and 1610 cm^{-1}; δ($CDCl_3$): 0.95 (s, 3H), 0.99 (s, 3H), 1.18 (s, 3H), 3.3 (d, 2H, J=2 Hz), and 6.17 (q, 1H, J=2 Hz). Found: C, 76.80; H, 8.44; N, 6.73%. Calcd for $C_{13}H_{17}NO$: C, 76.80; H, 8.42; N, 6.89%.

*Hydrogenation of **20**.* A mixture of 2.17 g of **20** and 1 g of 10% Pd-C in 120 ml of ethanol was shaken under a hydrogen atmosphere. The hydrogen uptake ceased after 305 ml of hydrogen had been absorbed (27 h). The catalyst was removed by filtration, and the filtrate was evaporated to give an oil, which was then purified through alumina (40 g). From the benzene eluates, 2.03 g (92%) of **21** were obtained.

21, mp 114—115 °C (from ether): ν(KBr): 2230 and 1700 cm^{-1}; δ($CDCl_3$): 0.95 (s, 6H) and 1.10 (s, 3H). Found: C, 75.80; H, 9.27; N, 6.64%. Calcd for $C_{13}H_{19}NO$: C, 76.05; H, 9.33; N, 6.82%.

*Acetalization of **21**.* A solution of 3.45 g of **21**, 100 mg of *p*-toluenesulfonic acid, and 5 ml of ethylene glycol in 120 ml of benzene was heated under reflux *via* a water separator. After 40 ml of an azeotropic distilate had been removed, a molecular sieve (4A) was placed in the water separator and heating was continued for further 20 h. The mixture was then cooled and diluted with water. The organic phase thus separated was washed with aqueous sodium hydrogen-

carbonate, water, and brine. The subsequent evaporation of the solvent gave a crude acetal (4.09 g), which was chromatographed on alumina (90 g). Elution with hexane–benzene (1 : 1) gave 3.38 g (81%) of a solid acetal, **22**; mp 83—84 °C (from pentane); ν(KBr): 2240 cm^{-1}; δ($CDCl_3$): 0.83 (s, 3H), 0.98 (s, 3H), 1.10 (s, 3H), and 4.85 (m, 4H). Found: C, 72.25; H, 9.22; N, 5.42%. Calcd for $C_{15}H_{23}NO_2$: C, 72.25; H, 9.30; N, 5.62%.

(1-Chloroethyl)triphenylphosphonium Bromide. According to Seyferth's procedure,[15] 30 g (0.115 mol) of triphenylphosphine and 12.9 g (0.13 mol) of 1,1-dichloroethane in 200 ml of anhydrous ether were treated at −30——40 °C by the drop-by-drop addition of a butyllithium–hexane solution (0.10 mol) under vigorous stirring. When the cooling bath was then removed and hydrogen bromide was bubbled into the flask, the orange colour was immediately lost and white solids were formed. The solids were collected on a glass filter, washed with benzene and petroleum ether, and dried *in vacuo* at 70 °C overnight. The dried product weighed 44 g.

The purification was done as follows: a 40-ml portion of water was added to 2.0 g of the crude product, and the undissolved materials were removed by filtration. The filtrate was evaporated to give solids (1.0 g), which were then recrystallized from water (6 ml) to afford 0.5 g of pure (1-chloroethyl)-triphenylphosphonium bromide. An analytical sample was obtained by repeated recrystallizations from water and by heating at 100 °C over P_2O_5 *in vacuo* for 24 h; mp 203—205 °C. Found: C, 59.40; H, 4.56%. Calcd for $C_{20}H_{19}PClBr$: C, 59.21; H, 4.72%.

The reagent should be dried at 80 °C *in vacuo* just before use.

Conversion of 22 into the Diketone 24. To a solution of 1.00 g of **22** in 4 ml of toluene, 3.5 ml (1.5 eq) of a DIBAL-H solution was added, drop by drop, at −78 °C, after which the mixture was stirred at that temperature for 1 h. Methanol (0.3 ml) was then added, the cold bath was removed, and 5 ml of a saturated ammonium chloride solution was added. The whole was stirred at room temperature for 1 h. The ether extract was evaporated to give an oil, from which an oily, acetalized aldehyde [900 mg, 90%; ν(CCl_4): 2700, 1720, and 1090 cm^{-1}] was isolated by chromatography on silica gel (20 g) with benzene–ethyl acetate (19 : 1). The aldehyde was used directly in the next reaction without any further purification.

To a suspension of 1.34 g (3.3 mmol) of (1-chloroethyl)-triphenylphosphonium bromide in 5 ml of THF, 2.2 ml (3.2 mmol) of a butyllithium–hexane solution was added, drop by drop, at −78 °C, after which the dark red mixture was stirred for 30 min at that temperature. A solution of 410 mg (1.6 mmol) of the acetalized aldehyde in 2 ml of THF was added, and the whole was stirred at −78 °C for 30 min, at room temperature for 30 min, and finally under reflux for 2 h. After cooling, 4 ml of 6 M hydrochloric acid was added, and the mixture was stirred for 30 min. The products were taken up in ether, and the ether extract was evaporated to give an oil which contained some triphenylphosphine oxide. The residue was heated with 10 ml of hexane, and the hexane solution was chromatographed on silica gel (20 g). The benzene eluates afforded a mixture of vinyl chloride **23** (295 mg, 71%; two peaks on VPC). The components are separable by repeated chromatography (see below).

A mixture of vinyl chloride, **23**(295 mg), was stirred overnight with 5 ml of concd sulfuric acid. The red solution was then poured onto ice, and the products were taken up in ether. The ether extract was evaporated to give an oil, which was subsequently purified by flash chromatography (hexane–ethyl acetate=5 : 3) to afford a crystalline diketone **24** (208 mg, 76%); mp 59—60.5 °C (from pentane); ν(KBr): 1705br and 1690 cm^{-1}; δ ($CDCl_3$): 0.90 (s, 3H), 0.92 (s, 3H), 1.08 (s, 3H), and 2.12 (s, 3H). Found: C, 76.28; H, 10.27%. Calcd for $C_{15}H_{24}O_2$: C, 76.22; H, 10.23%.

Separation of Z and E Isomers of 23. **23** was chromatographed repeatedly on silica gel; two vinyl chlorides were thus isolated in a pure state.

(**A**): liquid, δ($CDCl_3$): 0.91 (s, 6H), 1.06 (s, 3H), 2.03 (br.s, 3H), and 5.38 (br. t, 1H, J=7 Hz).

The acetal, prepared with ethylene glycol and *p*-toluenesulfonic acid in benzene, of (**A**): mp 51—52 °C (from pentane, at −78 °C). Found: C, 68.63; H, 9.16%. Calcd for $C_{17}H_{27}ClO_2$: C, 68.32; H, 9.10%.

(**B**): liquid; δ($CDCl_3$): 0.90 (s, 3H), 0.95 (s, 3H), 1.07 (s, 3H), 2.08 (br. s, 3H), and 5.33 (br. t, 1H, J=7 Hz).

The acetal of (**B**): mp 66—67 °C (from pentane, at −78 °C). Found: C, 68.23; H, 9.14%. Calcd for $C_{17}H_{27}ClO_2$: C, 68.32; H, 9.10%.

1,5,11,11-Tetramethyltricyclo[6.2.1.0^{2,6}]undec-5-en-7-one (25). To a stirred portion of potassium *t*-butoxide (1 mmol) in 5 ml of *t*-butyl alcohol, 133 mg (0.5 mmol) of **24** in 2 ml of *t*-butyl alcohol was added, after which the mixture was stirred at room temperature for 30 min. The whole was then poured into ether, and the solution was well washed with water. After drying over anhydrous sodium sulfate and after the solvent had been evaporated, a crude oil (120 mg) was chromatographed on silica gel (5 g). From hexane–ethyl acetate (100 : 1), 107 mg (88%) of an enone **25** was obtained; ν(CCl_4); 1675 and 1615 cm^{-1}; δ(CCl_4): 0.85 (s, 3H), 0.90 (s, 3H), 0.96 (s, 3H), and 2.12 (br. s, 3H).

25 can be purified by flash chromatography (hexane–ethyl acetate=10 : 1), but it is apt to change to an unidentified crystalline material even when standing overnight under nitrogen and in an ice-box. Therefore, freshly purified **25** was used immediately in the subsequent reaction.

1,5,5,11,11-Pentamethyltricyclo[6.2.1.0^{2,6}]undecan-7-one(26). To a stirred suspension of 190 mg (1 mmol) of copper (I) iodide in 5 ml of dry ether, 5 ml of a methyllithium–ether solution (2 mmol) was added, drop by drop, at 0 °C. A solution of 107 mg (0.5 mmol) of **25** in 5 ml of ether was then added to this almost colorless solution . The resulting yellow suspension was stirred for 30 min at 0 °C. After then being allowed to warm to room temperature (5 min), the whole was poured into 50 ml of a saturated ammonium chloride solution. The solids were removed by filtration, and the products were extracted with ether. Evaporating the solvent gave an oil, which was chromatographed on silica gel (5 g) to afford 103 mg (91%) of **26**; bath temp 79—83 °C/0.1 mmHg (Kugelrohr dist); ν(CCl_4): 1710 and 1695 cm^{-1}; δ(CCl_4): 0.87 (s, 3H), 0.93 (s, 3H), 1.01 (s, 3H), 1.08 (s, 3H), and 1.20 (s, 3H). Found: C, 81.45; H, 11.24%. Calcd for $C_{16}H_{26}O$: C, 81.99; H, 11.18%.

2-Allylhomocamphor (27). Homocamphor[24] (6.66 g) was dissolved in 70 ml of xylene, and then 40 ml of the xylene was distilled off.[17] To the solution, a 4-g portion of 50% sodium hydride (washed two times with xylene) was added, after which the mixture was refluxed for 2 h. After it had then cooled to room temperature, a 8-ml portion of allyl bromide was added and the whole was heated to 130 °C, whereupon massy precipitates resulted. Heating was continued at that temperature for 20 h. After the solution had then cooled to room temperature, water was added and the organic layer was separated. The aqueous layer was extracted with ether, and the combined organic extracts were washed with water and saline. The subsequent evaporation of the solvent gave an oil, which distilled fractionally at 3

mmHg to give 2-allylhomocamphor (**27**) (bp 75—90 °C; 5 g) and 2,2-diallylhomocamphor (**28**) (bp>110 °C).

27, bp 110—113 °C/8 mmHg; $\nu(CCl_4)$: 3070, 1700, 1635, 990, and 910 cm^{-1}; $\delta(CCl_4)$: 0.71 (s, 3H), 0.91 (s, 6H), and 4.7—6.2 (m, 3H); *m/e*: 206 (M^+), 191, 163, 95. Found: C, 81.38; H, 10.62%. Calcd for $C_{14}H_{22}O$: C, 81.49; H, 10.74%.

28, bp 113—116 °C/3 mmHg; $\nu(CCl_4)$: 3070, 1695sh, 1685, 1630, 985, and 910 cm^{-1}; $\delta(CCl_4)$: 0.78 (s, 3H), 0.93 (s, 6H), and 4.7—6.2 (m, 6H). *m/e*: 246 (M^+), 231, 95.

2-(Carboxymethyl)homocamphor (29). 2-Allylhomocamphor (**27**, 4.1 g) in 500 ml of *t*-butyl alcohol was mixed with a solution of 24 g of $NaIO_4$ and 100 mg of $KMnO_4$ in 1 liter of water. To the mixture there was then added 40 ml of 5% aqueous potassium carbonate, and the whole was stirred at room temperature for 2 d.[25] The products were taken up in ether, and the acidic materials were extracted with a 5% aqueous sodium hydroxide solution to give a crystalline **29** (4.4 g, 100%).

29, mp 94—94.5 °C (from pentane); ν(KBr): 3300—2400 and 1695br cm^{-1}. Found: C, 69.39; H, 8.85%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%.

γ-Lactone 30. **29** (1.0 g) was converted into its methyl ester by treating it with ethereal diazomethane. After evaporating off the ether, a residual oil (1.07 g) was dissolved in 20 ml of methanol and was treated with 400 mg of $NaBH_4$ at 0 °C. After 2 h, a further 200 mg of $NaBH_4$ was added and stirring was continued for another 2 h. Concd hydrochloric acid (2 ml) was then added, drop by drop, and the whole was stirred for 10 min. After it had then been concentrated to a small volume, the products were extracted with ether. The extract was evaporated to give a crystalline oil (918 mg), from which 772 mg (89%) of γ-lactone **30** was collected.

30, mp 85—86 °C (from pentane); ν(KBr): 1755sh, 1735, and 1410 cm^{-1}; $\delta(CDCl_3)$: 0.89 (s, 3H), 1.00 (s, 3H), 1.10 (s, 3H), and 4.08 (d, 1H, J=5.5 Hz). Found: C, 74.95; H, 9.57%. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%.

α-Methyl-γ-lactone 31. To a mixture of 5 ml of dry THF and 3.4 ml of a butyllithium–hexane solution (5.6 mmol) there was added 0.8 ml (5.7 mmol) of diisopropylamine (freshly distilled over NaH) at 0 °C, after which the mixture was stirred at that temperature for 45 min.[18] The whole was then cooled to −78 °C, and 1.03 g (5 mmol) of **30** in 10 ml of THF was added, drop by drop, during a 15-min period. Some excess methyl iodide (1 ml) was added all at once, and the mixture was stirred for 15 min. A saturated ammonium chloride solution (5 ml) was added to the mixture, and the products were taken up in ether. The ether extract was evaporated to give a crystalline residue (1.12 g). Recrystallization from pentane gave α-methyl-γ-lactone **31** (1.07 g, 97%); mp 116—117 °C (sublimable); ν(KBr): 1750 cm^{-1}; $\delta(CDCl_3)$: 0.87 (s, 3H), 0.99 (s, 3H), 1.10 (s, 3H), 1.27 (d, 3H, J=7.5 Hz), and 4.17 (d, 1H, J=5.5 Hz). Found: C, 75.43; H, 9.92%. Calcd for $C_{14}H_{22}O_2$: C, 75.67; H, 9.97%.

Dimethyl-γ-lactone 32. To lithium diisopropylamide (5.6 mmol) prepared as above, 972 mg (4.4 mmol) of **31** in 10 ml of THF was added, drop by drop, at −78 °C; the mixture was then stirred at that tempreature for 15 min. After 0.5 ml of HMPA had then been added, the whole was warmed to room temperature and 1 ml of methyl iodide was added. After 30 min stirring, 5 ml of a saturated ammonium chloride solution was added and the products were extracted with ether. The ether was evaporated to give a crystalline oil (1.01 g). Crystallization from pentane gave 909 mg (88%) of the dimethyl-γ-lactone, **32**, mp 106—107 °C; ν(KBr): 1755 cm^{-1}; $\delta(CDCl_3)$: 0.88 (s, 3H), 0.98 (s, 3H), 1.10 (s, 3H), 1.16 (s, 3H), 1.27 (s, 3H), and 4.13 (d, 1H, J=5.5 Hz). Found: C, 75.94; H, 10.17%. Calcd for $C_{15}H_{24}O_2$: C, 76.22; H, 10.23%.

Diol 33. To a solution of 845 mg of **32** in 20 ml of dry ether, an excess methyllithium–ether solution was added at 0 °C; the mixture was then stirred unitl **32** disappeared (VPC analysis). A large excess (1 g) of $LiAlH_4$ was added to the mixture, and the whole was refluxed for 1.5 h. After cooling to room temperature, the excess $LiAlH_4$ was carefully decomposed by the addition of ethyl acetate, and then an aqueous ammonium chloride solution. The ether extract, when evaporated, gave crystals (905 mg, 100%). The crystals showed two spots on TLC, and two recrystallizations from pentane afforded one isomer; mp 94—95 °C; ν(KBr): 3300br, 1110, and 1075 cm^{-1}; $\delta(CDCl_3)$: 0.82 (s, 3H), 0.89 (s, 3H), 0.98 (s, 6H), 1.14 (s, 3H), 1.17 (d, 3H, J=7 Hz), 3.60 (br. d. 1H J=4 Hz), and 3.82 (q, 1H, J=7 Hz). Found: C, 75.53; H, 11.91%. Calcd for $C_{16}H_{30}O_2$: C, 75.53; H, 11.88%.

Diketone 34. To a stirred solution of 2.4 g (24 mmol) of chromiun trioxide and 3.9 g (48 mmol) of pyridine in 60 ml of dichloromethane, 490 mg (1.9 mmol) of **33** in 10 ml of dichloromethane were added all at once, after which the mixture was stirred at room temperature for 15 min. The black materials were removed by filtration, and the filtrate was evaporated to give a brown residue. The residue was heated under reflux with 50 ml of pentane, and the undissolved material was removed by filtration. The filtrate was then evaporated to give colorless crystals (415 mg). Recrystallization from pentane afforded 280 mg of a diketone **34**. The mother liquor was chromatographed on silica gel (5 g, hexane–benzene=1 : 1) to give a further 78 mg of **34**.

34, mp 114—115 °C; ν(KBr): 1690sh and 1685 cm^{-1}: $\delta(CDCl_3)$: 0.73 (s, 3H), 0.88 (s, 3H), 0.92 (s, 3H), 1.15 (s, 3H), and 2.18 (s, 3H). Found: C, 76.59; H, 10.40%. Calcd for $C_{16}H_{26}O_2$: C, 76.75; H, 10.46%.

γ-Valerolactone 36. To a cooled solution (0 °C) of 3.82 g of **27** in 60 ml of dry ether, 20 ml of a 5% methyllithium–ether solution was added, drop by drop, after which the whole was stirred at room temperature for 1 h. An aqueous ammonium chloride solution was then added, and the products were taken up in ether. Evaporating the solvent gave a crude **35** (3.95 g); $\delta(CCl_4)$: methyl signals at 0.82, 0.92, 1.12, and 1.15.

To a stirred solution of 3.16 g of $KMnO_4$ in 12 ml of water and 6 ml of benzene containing 75 mg of $R(CH_3)_2C_6H_5CH_2N^+Cl^-$, 1.06 g of the above alcohol **35** was added, drop by drop, during a 10-min period. The temperature of the mixture was kept at 35—40 °C during addition. The mixture was then stirred at that temperature for 1 h,[19] and the precipitates were removed by filtration. The products were divided into a neutral part (0.81 g) and an acid part; the former was chromatographed on silica gel (10 g) to give a pure lactone **36** (0.48 g, 45%) in a crystalline form.

36, mp 95—97 °C (from pentane, in a sealed tube); ν(KBr): 1750 and 930 cm^{-1}; $\delta(CCl_4)$: 0.92 (s, 3H), 1.02 (s, 3H), 1.08 (s, 3H), 1.34 (s, 3H), 2.0 (d, 1H, J=17 Hz), 2.8 (dd, 1H, J=17 and 7 Hz). Found: C, 75.45; H, 9.70%. Calcd for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%.

α-Methyl-γ-valerolactone 37. To a stirred lithium diisopropylamide (0.65 mmol) in THF, 135 mg (0.61 mmol) of **36** in 15 ml of THF were added, drop by drop. After 15 min, 0.2 ml of methyl iodide was added all at once and stirring was continued for a further 15 min. A saturated ammonium chloride solution was added, and the products were taken up in ether to give crystalline **37** (143 mg, 100%).

37, mp 72—74 °C (from pentane, sublimable); ν(KBr): 1750 cm^{-1}; $\delta(CCl_4)$: 0.92 (s, 3H), 0.98 (s, 3H), 1.08 (s, 3H),

1.42 (d, 3H, J=7 Hz), 1.43 (s, 3H), and 2.32 (br. q, 1H, J= 7 Hz). Found: C, 76.18; H, 10.25%. Calcd for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%.

Dimethyl-γ-valerolactone 38. α-Methyl-γ-valerolactone **37** was converted into the dimethyl derivative, **38**, in a quantitative yield when treated with excess lithium diisopropylamide and methyl iodide in the presence of HMPA.

38, mp 99—100 °C (from pentane); ν(KBr): 1740 cm^{-1}; δ(CCl_4): 0.88 (s, 3H), 0.90 (s, 3H), 1.08 (s, 3H), 1.23 (s, 3H), 1.46 (s, 3H), and 1.56 (s, 3H). Found: C, 76.71; H, 10.51%. Calcd for $C_{16}H_{26}O_2$: C, 76.75; H, 10.47%.

P_2O_5–Methanesulfonic Acid Treatment of 7a-Methylperhydro-2-benzofuranone (vi). General procedure: The lactone (vi) was heated at a given temperature with 10 parts (weight) of a P_2O_5–methanesulfonic acid (1 : 10) solution.[21] The dark red solution was then poured into ice water, and the products were taken up in ether. The ether extract was washed with water and saline, and dried over anhydrous sodium sulfate. In every case, only two products (vii) and (viii) were recognized on VPC. The products were separated by column chromatography on silica gel. The results are shown on Table 1.

1,5,5,11,11-Pentamethyltricyclo[6.2.1.0^{2,6}]undec-2-en-4-one (39) To a stirred solution of 10 g of P_2O_5–methanesulfonic acid, there was added 395 mg of **38**, after which the mixture was heated at 70 °C for 2 h. After cooling, the red solution was poured into water (50 ml) and extracted with chloroform. The chloroform layer was washed with water, aqueous sodium hydrogencarbonate, and saline and dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent gave an oil (380 mg), which was then chromatographed on silica gel (20 g). The elution with chloroform afforded 195 mg (50%) of a cyclopentenone **39** as an oil.

39, bath temp 83—86.5 °C/0.05 mmHg (Kugelrohr dist); mp 38—40 °C (from pentane, −78 °C); ν(CCl_4): 1700 and 1605 cm^{-1}; δ(CCl_4; the Δ values show the pseudocontact shift upon the addition of 0.05 eq of Eu-FOD): 0.78 (s, 3H, Δ 0.17), 0.91 (s, 3H, Δ 0.52), 0.98 (s, 3H, Δ 0.07), 1.03 (s, 3H, Δ0.51), 1.12 (s, 3H, Δ0.11), 2.58 (ddd, 1H, J=2, 9, and 11.5 Hz, Δ 0.38), and 5.51 (d, 1H, J=2 Hz, Δ 0.97). Found: C, 82.68; H, 10.49%. Calcd for $C_{16}H_{24}O$: C, 82.70; H, 10.41%.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 164147 from the Ministry of Education, Science and Culture.

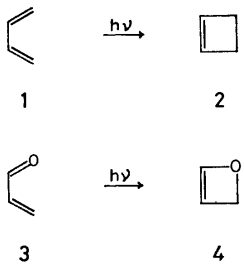
Reaction Paths of the Photochemical Electrocyclic Reaction of Acrylaldehyde. A Possible Path *via* a Zwitterion

Osamu KIKUCHI,* Hiroshi KUBOTA, and Keizo SUZUKI
Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305
(Received June 16, 1980)

The photochemical electrocyclic reaction paths of *s-cis*-acrylaldehyde to oxetene were examined on the basis of the potential surfaces obtained by the MINDO/3 CI calculation, and compared with those of the corresponding conjugated hydrocarbon system. The strong S_0-S_2 interaction, which appears in the disrotatory mode of the cyclization of butadiene, was not observed in the acrylaldehyde–oxetene system. There appears to be a step-by-step path, in which the $\pi\rightarrow\pi^*$ induced rotation of the methylene group is followed by the ring-closing step. The zwitterion in which the positive charge is localized on the terminal carbon atom is involved in this step. Since the σ lone-pair electrons of the oxygen atom play a key role in the ring-closing step, this path is characteristic of the hetero-atom conjugated system and cannot be deduced by analogy or by a simple extension of the concepts established for the photoreactions of all-hydrocarbon conjugated systems. The possible decay paths from acrylaldehyde in the excited states were also discussed.

Orbital symmetry arguments[1] and calculated reaction paths[2] have well elucidated the thermal and photochemical electrocyclic reactions of the all-hydrocarbon conjugated system, **1**→**2**. Little attention, however, has been paid to the electrocyclic processes of the hetero-atom conjugated system, in which one of the terminal methylene groups is replaced by a hetero atom. The formal photochemical electrocyclic reaction of *s-cis*-acrylaldehyde **3**→**4**, for example, has been considered to proceed by means of a mechanism similar to that of *s-cis*-butadiene, **1**→**2**, if the $\pi\rightarrow\pi^*$



1 2

3 4

excited state is involved.[3] However, there are two essential differences between the **1**→**2** and **3**→**4** reactions. The first is the mode of rotation of the methylene groups. In the conjugated hydrocarbon system, the disrotatory and conrotatory modes give very different shapes of the potential cuves, while there is no distinction between these two modes in the **3**→**4** reaction, since only one methylene group is involved in the acrylaldehyde–oxetene system. It is thus impossible to consider the photochemical reaction mechanism of the **3**→**4** reaction by simple analogy with the disrotatory cyclization of the **1**→**2** reaction.

The second difference is the existence of the lone-pair electrons of the terminal hetero atom. Since the lone-pair electrons are distributed on the σ framework where the new σ bond is being formed, the lone-pair electrons should participate in the electrocyclic reaction mechanism of the hetero-atom conjugated system, even if the photochemical reaction proceeds from the $\pi\rightarrow\pi^*$ excited state. Because of these essential differences, the electron behavior during the **3**→**4** reaction cannot be understood sufficiently well by analogy with the **1**→**2** reaction; therefore, it is worthwhile to investigate the reaction processes of the **3**→**4** reaction and to compare the reaction mechanism with that of the all-hydrocarbon system, **1**→**2**.

The experimental evidence applicable to the **3**→**4** reaction has been reported by Friedrich and Schuster.[4] The irradiation of 3,4-dimethyl-3-penten-2-one in a hexane solution through a Pyrex filter gave no observable reaction, while the irradiation with Vicor-filtered UV light gave cyclic compound, the oxetene. They also investigated the thermal ring-opening reaction of the methyl-substituted oxetene and compared it with that of the cyclobutene derivatives.[4b]

In the present study, the potential curves for the ground and several excited states of the **3**→**4** reaction were obtained by means of the semi-empirical MINDO/3[5] CI calculations. On the basis of these potential surfaces, the possible photochemical paths of the **3**→**4** reaction are discussed. Attention is mostly paid to the clarification of the differences between the reaction mechanisms of the **1**→**2** and **3**→**4** reactions, and also to the comparison between the theoretical and experimental results.

Method of Calculation

The structures of Compounds **1**—**4** were optimized by the SCF (without CI) calculation; Fletcher's variable metric method[6] was employed. They are shown in Fig. 1. The potential surfaces for the **1**→**2** and **3**→**4** reactions are the functions of many geometrical variables. In the present study, the potential surfaces were calculated with respect to two independent parameters. One of these is the rotation algle, θ, of the methylene group(s). All the other geometrical variables were allowed to vary simultaneously from their inital to final values. This variation is expressed by the second parameter, d, which varies from 0.0(initial) to 1.0(final). In the CI calculation, 47 and 43 configuration functions were selected from the singly- and doubly-excited configurations for the singlet and triplet states respectively. MINDO/3 underestimates the strain energy of small cyclic compounds, while it overestimates the heats of formation of acrylaldehyde and butadiene.[5] The

excitation energies as calculated by MINDO/3 CI were compared with the experimental values (Table 1). Although the MINDO/3 and MINDO/3 CI calculations do not give sufficiently good results for the energetics of the present systems, we feel that the present objectives can be achieved satisfactorily on the basis of the MINDO/3 calculations.

Results and Discussion

Linear Variation of Geometrical Variables. First let us consider the concerted path in which the θ and d parameters are changed simultaneously. Figure 2 shows the potential curves of several electronic states for the disrotatory mode of the butadiene–cyclobutene system. Their shapes are very similar to those obtained previously by semi-empirical[2b] and *ab initio*[2c] methods. Notice two important features which appear in Fig. 2. The first is a true crossing at C_1 which takes place at the beginning of the cyclization and which involves the $\pi\rightarrow\pi^*$ singly-excited B_2 state and its doubly-excited counterpart. The second is an avoiding crossing at C_2 involving the ground state and the $\pi\rightarrow\pi^*$ doubly-excited state. The cyclobutene formation from the $\pi\rightarrow\pi^*$ state of butadiene can be understood in terms of these two crossings; the $\pi\rightarrow\pi^*$ state of butadiene populates the W_b well through the C_1 crossing, and this well is a leakage channel[8] from the excited state to the ground state.

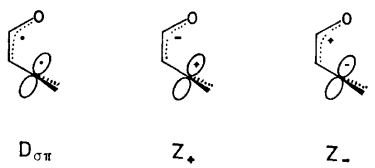
Figure 3 shows the corresponding potential curves for the *s-cis*-acrylaldehyde–oxetene system. In this system, there is no distinction between the disrotatory and conrotatory modes of the methylene rotation,[9] and both the thermal and photochemical processes can be considered on the basis of these potential curves. The thermal ring-opening reaction of the substituted

oxetene has been studied by Friedrich and Schuster.[4b] The activation enthalpy of 1,2,3,3-tetramethyloxetene was found to be 100—105 kJ mol^{-1} (solvent dependent),[4b] while that of 1,2,3,4-tetramethylcyclobutene is 152 kJ mol^{-1}.[4b] The calculated values 213 kJ mol^{-1} for the oxetene and 242 kJ mol^{-1} for cyclobutene,[10] are somewhat larger than the observed values for the substituted compounds. This discrepancy comes partially from a deficiency in the MINDO/3 approximation, which overestimates the heats of formation of butadiene and acrylaldehyde, while underestimating the strain energy of the cyclic compounds. However, the faster thermal ring opening of the oxetene in comparison with that of cyclobutene is reflected in the calculated values.

The S_1 and T_1 states of acrylaldehyde are the singlet and triplet $n\rightarrow\pi^*$ states which are missing in butadiene. The S_2 and T_2 states are the $\pi\rightarrow\pi^*$ states which correspond to the B_2 singlet and triplet states of butadiene respectively. The most important feature observed in the potential curves of the acrylaldehyde–oxetene system is the absence of the crossings related to the doubly-excited configuration; they appear at C_1 and C_2 in the case of the butadiene–cyclobutene system. This is due to the non-symmetric property of acrylaldehyde with respect to the vertical plane; no crossing occurs between the π_2 and π_3 orbitals. Two new types of crossings are observed in the acrylaldehyde–oxetene system. They are the C_4 crossing between the $n\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ states, and the C_5 crossing between S_0 and S_1 states at the later part of cyclization. The concerted cyclization path of *s-cis*-acrylaldehyde may be elucidated as follows: the reaction proceeds from the $\pi\rightarrow\pi^*$ excited state of acrylaldehyde, this state reaches the W_a well through the C_4 crossing, and the non-adiabatic transition from W_a to the ground state gives the oxetene. As will be described later, the W_a well is not a clear well on the two-dimensional S_1 surface, and the transition from the W_a well to the ground state is expected to be much more inefficient than that from the W_b well to the ground state in the butadiene–cyclobutene system.

The $n\rightarrow\pi^*$ excited acrylaldehyde cannot reach the W_a well because of the high activation energy, and no appreciable formation of the oxetene is expected from the $n\rightarrow\pi^*$ state of acrylaldehyde. This agrees well with the experimental evidences.[4b]

Step-by-step Path via *a Zwitterion.* The rotation of methylene occurs easily in the $\pi\rightarrow\pi^*$ excited state of acrylaldehyde to give the twisted acrylaldehyde. The lower electronic states of the twisted acrylaldehyde involve the diradical,[11] $D_{\sigma\pi}$, and two zwitterions, Z_+ and Z_-.[12] The energies of several states of the twisted



acrylaldehyde are shown in Fig. 4. The Z_+ zwitterion, in which the positive charge is located at the terminal

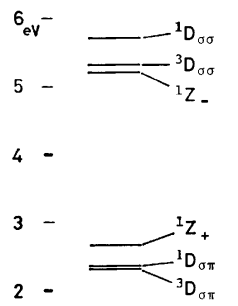


Fig. 4. Energy levels for several lower states of the twisted acrylaldehyde.

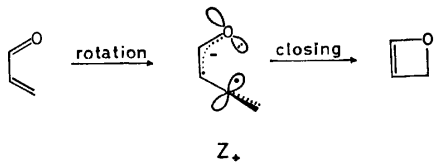
carbon atom, can undergo ring closing very easily, since a strong attraction is expected between the positive charge and the lone-pair electrons of the oxygen atom. The step-by-step path in which the



rotation of the methylene group is followed by the ring-closing is expected to exist. The state correlation diagram for this path is shown in Fig. 5.[13] As may be seen from Fig. 5, the excited Z_+ state correlates with the ground state of the oxetene. It can thus be expected that, if the Z_+ state of the twisted acrylaldehyde is formed from the $\pi\rightarrow\pi^*$ excited state of acrylaldehyde, the oxetene formation proceeds without any activation

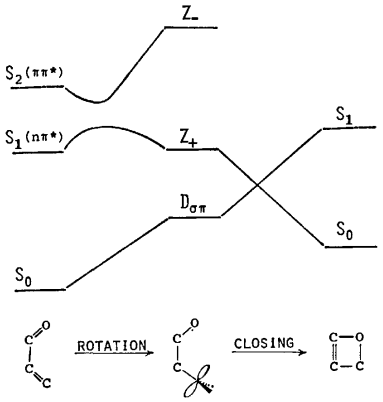


Fig. 5. State correlation diagram for the acrylaldehyde–twisted acrylaldehyde–oxetene system.

energy or with only a small activation energy. The potential curves along the suggested path are shown in Fig. 6. The molecule has a distinctive zwitterionic character between A and C on the Z_+ potential curve.[15] Figure 6 indicates that the internal conversion from the Z_+ state to the $D_{\sigma\pi}$ state occurs efficiently at the twisted acrylaldehyde; this results in the reproduction of the ground state of acrylaldehyde, and no formation of oxetene is expected. However, if the Z_+ zwitterion is formed from the $\pi\rightarrow\pi^*$ excited state[16] and has a high

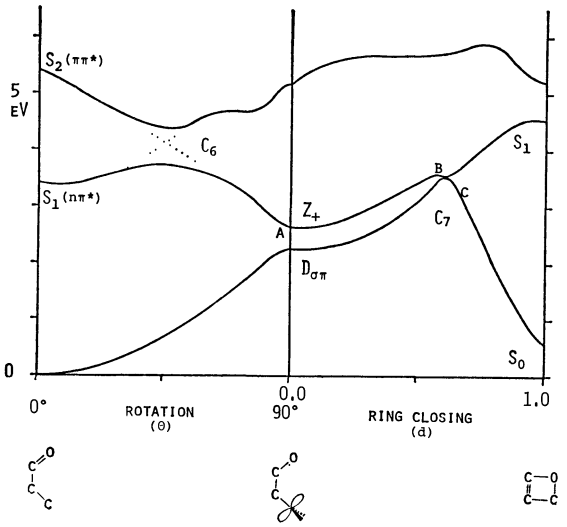

Fig. 6. Potential curves for the step-wise path of the acrylaldehyde–oxetene system. Only three lower singlet states are shown. θ is the rotation angle of the terminal methylene and d represents the simultaneous change in all the geometrical variables other than θ.

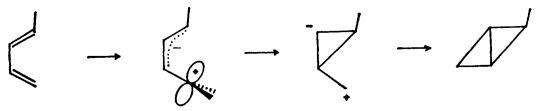
vibration energy, it can cyclize to form the oxetene *via* the C_7 crossing.

An important role of the zwitterion has been pointed out by Dauben *et al.*[14,17] and by Salem[18] in the photochemical cyclization of non-symmetric polyenes. In



5 6

the **5→6** reaction, the primary step is the photoinduced rotation of the terminal methylene, which gives the zwitterion. This step is followed by the 1,3 ring closing of the anionic allyl group by another rotation about the C–C bonds. The reaction scheme of the zwitterion in the present **3→4** reaction is clearly different from that proposed for the **5→6** process. In the **3→4** reaction, the ring closing occurs between the positive carbon atom and the lone-pair electrons of the terminal hetero atom, without another rotation. This path can occur only if the terminal atom has the lone-pair electrons and is characteristic of the hetero-atom conjugated system.

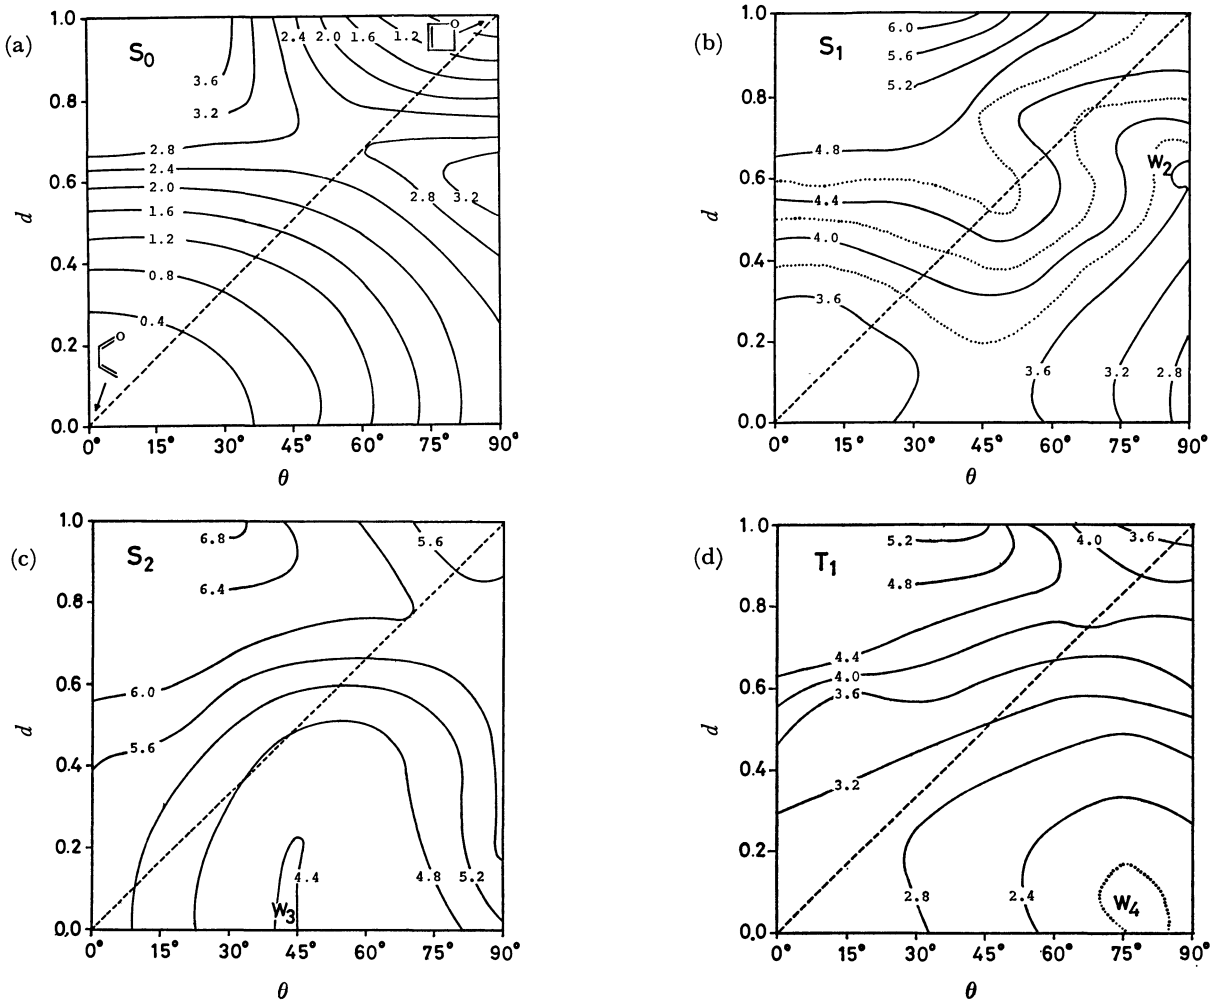


Fig. 7. Two-dimensional potential surfaces of (a) S_0, (b) S_1, (c) S_2, and (d) T_1 states of the acrylaldehyde–oxetene system. The energies (eV) are relative values with respect to that of the ground state of *s-cis*-acrylaldehyde.

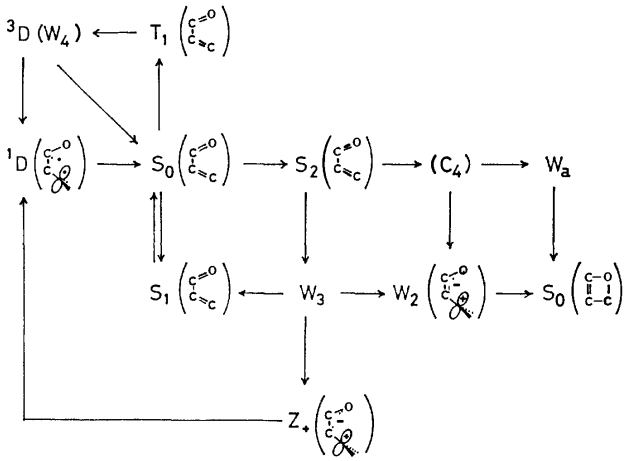
Two-dimensional Potential Surfaces. The potential surfaces of several electronic states of the acrylaldehyde–oxetene system were obtained as the function of two geometrical parameters, θ and d. They are shown in Fig. 7. Although two-dimensional surfaces are still only a distant approximation of the real multi-dimensional hypersurfaces, they give much more information than one-dimensional ones; they are useful as confirmation of and complement to the results obtained from the one-dimensional potential curves. The $n\rightarrow\pi^*$ singlet state of acrylaldehyde is located at the energy minimum on the S_1 surface and is stable even when the molecular structure is deformed (Fig. 7-b). An important characteristic of this S_1 surface is the absence of the W_a well which appears in one-dimensional curves (Fig. 3). Instead, the W_a well in Fig. 3 is a part of the shallow well, W_2, the minimum point of which is located at the C_7 crossing point in Fig. 6. The transition from the W_2 region to the ground state occurs very easily to form the oxetene.

From Fig. 7-c, it may be seen that acrylaldehyde in its $\pi\rightarrow\pi^*$ excited state can move around most ($0.0<\theta<0.6$, and $0°<d<90°$) of the S_2 surface. The transition from the W_3 well to the S_1 state produces the normal acrylaldehyde or the twisted acrylaldehyde. However, Fig. 7-b indicates that the S_1 species formed from the W_3 well is capable of access to the W_2 well. In this case, the oxetene is formed *via* the Z_+ zwitterion. The smallest energy separation between the S_1 and S_2 surfaces is observed at the central region of the two-dimensional maps; this region corresponds to the C_4 crossing region in Fig. 3. The strong coupling between S_1 and S_2 is suggested by the calculated CI coefficients, and an appreciable transition from S_2 to S_1 is expected in this region. As may be seen from Figs. 7-b and 7-c, the Z_+ zwitterion (corresponding to the W_2 well) is formed from the S_1 species generated from S_2 through the C_4 crossing. From the analysis of the two-dimensional surfaces, it is confirmed that there is a path through the Z_+ zwitterion in the **3→4** photochemical process.

Figure 7-d shows the potential surface of the T_1 triplet state. The acrylaldehyde side of this surface corresponds to the $\pi\rightarrow\pi^*$ triplet state of acrylaldehyde. The rotation of methylene occurs easily in this state and gives the twisted acrylaldehyde, the triplet diradical, $^3D_{\sigma\pi}$. The crossing of this surface with the lowest S_0 state occurs near the W_4 well, and the reproduction of the ground state of acrylaldehyde proceeds from the triplet T_1 state through this singlet-triplet crossing. This path corresponds to the photochemical *cis-trans* isomerization of acrylaldehyde. The intersystem crossing rate between the $^3D_{\sigma\pi}$ and $^1D_{\sigma\pi}$ states is not expected to be particularly fast, but the intersystem crossing is still an efficient process, since the triplet is at a minimum.[14]

Conclusion

The possible decay paths for the photochemically excited *s-cis*-acrylaldehyde have been considered on the basis of the potential surfaces obtained by MINDO/3 CI calculations. Two possible paths have been predicted for the photochemical electrocyclic reaction of *s-cis*-



acrylaldehyde into oxetene. The concerted type of cyclization proceeds from the $\pi\rightarrow\pi^*$ state: acrylaldehyde $\rightarrow S_2\rightarrow C_4\rightarrow W_a\rightarrow$oxetene. The step-by-step path, in which the Z_+ zwitterion is involved, also proceeds from the $\pi\rightarrow\pi^*$ state: acrylaldehyde$\rightarrow S_2\rightarrow(C_4$ or $W_3)\rightarrow W_2\rightarrow$ oxetene. Since no quantitative examinations were performed for the transition probability between the electronic states, the efficiency of the above two possible paths to form the oxetene can not be determined from the present study. The W_a well appearing in the concerted path is actually a part of the W_2 well which corresponds to the Z_+ zwitterion. Therefore, the Z_+ zwitterion also plays an important role in the concerted-type pathway. The path *via* the Z_+ zwitterion proposed in this study is a new type of mechanism for the formal photochemical electrocyclic reactions. Since the lone-pair electrons play a key role in the ring-closing step, this path can not be deduced by analogy or a simple extension of the concepts established for the all-hydrocarbon conjugated systems.

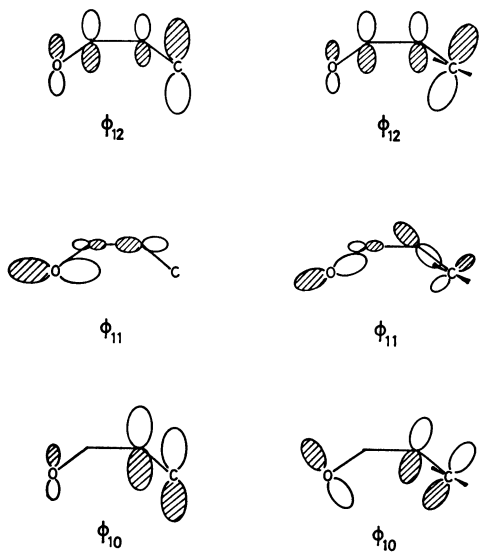
9) Since only one methylene group is involved in acrylaldehyde, there is no distinction between the conrotatory and disrotatory modes, which can be defined by means of the relative motion of the two terminal methylene groups. However, it may be interesting to illustrate the change in the orbital shape on the oxygen atom, which is induced by the rotation of the terminal methylene. The two highest occupied MO's, ϕ_{10} and ϕ_{11}, and the lowest unoccupied MO, ϕ_{12}, are shown here for acrylaldehyde, and also for the structure in which the terminal methylene group is twisted by 30°. When the terminal methylene group is rotated, the lone-pair orbital (ϕ_{11}) and the occupied π orbital (ϕ_{10}) of acryladehyde mix well to give the ϕ_{10} and ϕ_{11} MO's of the twisted structure, while the OCC part of the LUMO is unchanged. From these MO shapes, we may say that the orbital fragments on the oxygen atom in the occupied ϕ_{10} and ϕ_{11} MO's rotate in a disrotatory-like manner with respect to the methylene group. However, it should be noted again that we cannot define the methylene rotation in acrylaldehyde as the disrotatory rotation: only one kind of rotation exists in acrylaldehyde,.



Planar 30° Twisted

Dehydrooligopeptides. II. The Synthesis of Dehydrodehydrodipeptides by Direct Coupling and Base-catalyzed β-Elimination[1]

Chung-gi SHIN,* Yasuchika YONEZAWA, Masatoshi TAKAHASHI, and Juji YOSHIMURA†

Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221

†*Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227*

(Received June 19, 1980)

The direct coupling between N-protected α-dehydroamino acid (**1**) and N-free α-dehydroamino acid ester (**2**) by the acid-chloride method was carried out to give several dehydrodehydrodipeptides (**7**). Furthermore, the two kinds of dehydrodipeptides with a hydroxyl group, obtained by the coupling of **1** with a serine or threonine ester, and that of N-protected serine or threonine with **2**, followed by mesylation and subsequent base-catalyzed β-elimination gave a number of **7** substances in good yields. The configurational structures of **7** obtained by both direct condensation and elimination were found to have (*Z*,*Z*)-geometry.

Much attention has been focused on the correlation between the structure and the bioactivity of dehydrooligopeptides containing one or more α-dehydroamino acid (DHA or ⊿AA)[2] residues.[3-7] Recently, antibiotic berninamycin A, a cyclodehydrodecapeptide with two dehydrodehydrodipeptide (⊿DHP) sequences and seven DHA moieties, has been isolated from a culture of *Streptomyces bernensis*, and the primary structure confirmed, by Liesch and Rinehart.[8] However, concerning the synthesis of ⊿DHP, few reports have been published on its preparation by means of the base-catalyzed β-elimination or by the direct coupling between two different DHA's, these being the indirect and restricted preparative methods from unsaturated azlactone.[9,10]

In a previous communication,[11] we briefly reported on the synthesis of the N-protected ⊿DHP ester by the coupling of benzyloxycarbonyl (Cbz)–DHA (**1**) with the N-free DHA ester (**2**) by the acid-chloride method. Here, we wish to report on a method of synthesis featuring the base-catalyzed β-elimination to dehydrodipeptide with a leaving group; we wish also to describe the direct method in detail.

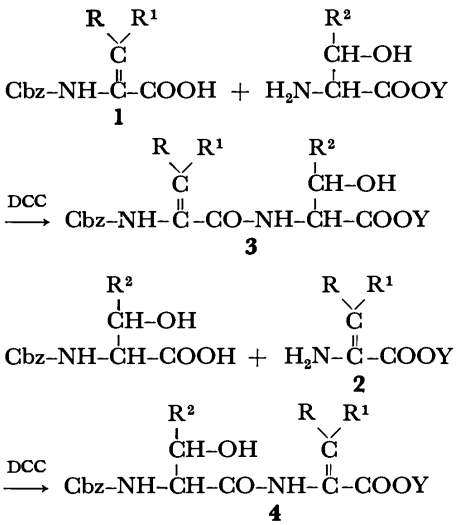
Results and Discussion

Coupling of (Z)-DHA with β-Hydroxy α-Amino Acid. In order to prepare a dehydrodipeptide containing a Ser or Thr residue at the C- or N-terminus according to the method previously reported by us,[1,12] first, the coupling of **1** with α-amino acid ester was performed. The (*Z*)-**1** compound, as a carboxyl component, readily reacted with a racemic Ser or Thr ester by the usual peptide synthetic method [mixed anhydride (MA), dicyclohexylcarbodiimide (DCC), acid chloride, and azide method] to give Cbz–(*Z*)-α-dehydroaminoacyl–Ser and –Thr esters (**3**) respectively, as a colorless syrup or crystals, in *ca.* 70% yields. Therefore, although the yield was not significantly different, the preparation of **3** by the DCC method was found to be superior to that by the other methods. In Table 1, the yield of **3** by the DCC method is listed.

On the other hand, N-protected Ser or Thr was also coupled with (*Z*)-**2** as an amine component by the similar DCC method to give Cbz–Ser– and –Thr–(*Z*)-α-dehydroamino acid esters (**4**) respectively as colorless crystals in *ca.* a 34% yield. However, because of the weak basicity of the amino group in the amine component, the yield was lower than that of **3**, and the coupling of the α-dehydrophenylalanine ester with Cbz–Ser or –Thr was found to proceed to only a very small degree.

In the IR spectral data, the characteristic differences between **3** and **4** could not be recognized. The absorption bands of the hydroxyl and NH (3475—3175 cm^{-1}), ester carbonyl (1760—1720 cm^{-1}), secondary amide (1665—1625 cm^{-1}), and carbon-carbon double bond (1670—1620 cm^{-1}) functions are consistent with the assignment of the dehydrodipeptide structure.

The chemical shifts and the coupling constants of **3** and **4** were assigned as is shown in Tables 1 and 2. In the NMR spectrum of **3**, the signals at δ 4.56—4.76 as double doublets or double triplets, at δ 7.07—7.53 as doublets, and at δ 2.84—3.80 as broad singlets are attributable to methine, NH, and hydroxyl protons of the α-AA residue, respectively and the signals at δ 5.34—6.08, 6.37—7.10, and 6.76—7.52 regions as singlets, to vinyl, olefinic, and NH protons of the ⊿AA



DHA and DHA residues = ⊿Ala, ⊿But, ⊿norVal, ⊿Val, ⊿norLeu, ⊿Leu, and ⊿Phe; R^2 = H and CH_3; Y = CH_3 and C_2H_5.

Scheme 1.

residue respectively. On the other hand, in the case of **4**, the corresponding signals appeared at δ 4.30—4.35 (methine) as multiplets, at δ 6.01—6.19 (NH) as doublets, and at δ 3.40—3.88 (hydroxyl) as broad singlets of the α-AA residue, and at δ 6.55—6.81 and at δ 7.96—8.15 (vinyl and olefinic protons) regions as broad singlets of the ⊿AA residue. As a result, it was found that the IR and NMR spectral patterns of **3** were remarkably similar to those of **4**.

According to the method confirmed previously,[1] the configurations of **3** and **4** could be readily determined to have (*Z*)-geometry.

The yields, physical constants, and NMR spectral data of **3** and **4** are summarized in Tables 1 and 2.

Preparation of Dehydro-dehydrodipeptides. In order to carry out the following base-catalyzed β-elimination easily, the mesylation of the hydroxyl group in **3** and **4** was performed. We followed a procedure reported

a) Yield by the DCC method. b) Colorless fibrous from CCl_4. c) α-Proton of α-AA residue.

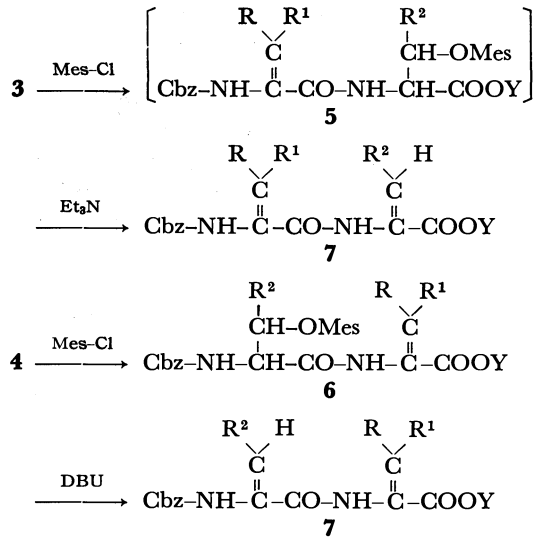
previously,[13] treating a solution of **3** and methanesulfonyl (mesyl) chloride in CH_2Cl_2 with excess triethylamine but, unexpectedly, ⊿DHP (**7**) as a colorless syrup or crystals was obtained directly in *ca.* a 74% yield, without any yield of the corresponding mesyloxy intermediates (**5**).

On the other hand, a similar treatment of **4** with mesyl chloride gave the corresponding stable mesyloxy derivative (**6**) as colorless crystals in *ca.* an 80% yield. The subsequent elimination reaction of the **6** isolated purely was attempted in the presence of triethylamine, but the reaction did not proceed at all. In consequence, the treatment of a solution of **6** in THF in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), a stronger base than triethylamine, was carried out successfully, and the desired **7** was obtained in *ca.* a 65% yield.

In the spectrum of **6**, the disappearance of the hydroxyl absorption and in the 3260—3300 cm^{-1} region and the appearance of characteristic strong sulfonyl function bands in the 1345—1360 and 1160—1190 cm^{-1} regions indicate unambiguously the formation of the mesyloxy derivative. Moreover, the IR spectrum of **7** showed bands in the 3280—3400 and 3200—3300 cm^{-1} regions due to the NH group, bands in the 1680—1728 and 1500—1540, and 1620—1650 and 1490—1500 cm^{-1} regions due to two secondary amide functions, and a weak band in the 1620—1670 cm^{-1} region due to the carbon-carbon double bond.

On the other hand, from the NMR spectral data of **7** listed in Tables 4 and 5, it was found that the signals in the δ 4.46—7.74 and 7.61—8.61 regions as broad singlets due to two NH protons, and the characteristic signals at δ 5.26—6.76 and at δ 6.30—7.24 due to vinyl and olefinic protons of the ⊿AA-⊿AA moeties respectively, are consistent with the assignment of the dehydrodehydrodipeptide structure. In consequence, it can be said that the appearance of two olefinic proton signals indicates unambiguously the formation of **7**.

As a result, it was found that the IR and NMR spectral patterns of **7** derived from **3** *via* **5** were in fairly good agreement with those of **7** from **4** *via* **6**.



DHA residues = ⊿Ala, ⊿But, ⊿norVal, ⊿Val, ⊿norLeu, ⊿Leu, and ⊿Phe; Y = CH_3 and C_2H_5

Scheme 2.

The yields, physical constants, and NMR spectral data of **6** and **7** are summarized in Tables 3, 4, and 5.

The geometric structure of **7** could be readily determined to have (*Z*,*Z*)-geometry, since the chemical shifts and the spectral patterns of the individual ⊿AA residue in **7** were quite similar to the starting, (*Z*)-configurational **1** and **2**.[13,14] The above determination was further confirmed independently by the following direct coupling between two different (*Z*)-DHA's.[11]

The equimolar coupling of (*Z*)-**1** as a carboxyl component with (*Z*)-**2** as an amine component by the usual acid-chloride method gave the desired ⊿DHP (**7**) in *ca.* a 50% yield; its structure was completely in agreement with that of **7** derived from **3** and **4** respectively. Therefore, it was further ascertained that the (*Z*)-geometry of the DHA and DHA residues was maintained during the peptide-formation reaction and the base-catalyzed β-elimination reaction.

Scheme 3.

The yields, physical constants, and NMR spectral data of **7** obtained by the direct coupling are summarized in Table 6.

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 Spectrometer. The NMR spectra were measured with a JNM-PS-100 Spectrometer (Japan Electron Laboratory Co., Ltd.), using tetramethylsilane as the internal standard.

Starting Materials. The starting (*Z*)-**1** and (*Z*)-**2** were prepared by the methods reported previously.[1,11,12]

Preparation of ***3***. Into a solution of (*Z*)-**1** (10 mmol) and the Ser or Thr ester (10 mmol) in DMF (10 ml), we stirred DCC (11 mmol) under cooling. After stirring at room temperature for 12 h, the dicyclohexylurea deposited was filtered off and washed well with ethyl acetate. The filtrate was poured into water (70 ml), and the aqueous solution was extracted twice with ethyl acetate (60 ml). The combined extracts were successively washed with 2% aqueous HCl, water, saturated aqueous $NaHCO_3$, and water, and finally dried over anhydrous Na_2CO_3. The subsequent evaporation of the ethyl acetate under reduced pressure gave crude crystals or a syrup, subsequently purified on a silica gel column using benzene–ethyl acetate (4 : 1 v/v) to give **3**. See Table 1.

Preparation of ***4***. Into a solution of (*Z*)-**2** (10 mmol) and Cbz–Ser or –Thr (10 mmol) in CH_2Cl_2 (10 ml), we vigorously stirred DCC (11 mmol), portion by portion, below 0 °C. After stirring at room temperature for 20 h, the reaction solution was worked-up exactly according to the above treatment procedure to give **4**. See Table 2.

Preparation of ***6***. Into a solution of **4** (4 mmol) and mesyl chloride (5 mmol) in CH_2Cl_2 (20 ml) we stirred triethylamine (12 mmol), drop by drop, at 0 °C for 1 h, and then the stirring was continued at room temperature for 2 more h. The reaction solution was then poured into CH_2Cl_2 (50 ml), and the resulting solution was washed once with chilled 1 M HCl (50 ml) and twice with water and finally dried over anhydrous $MgSO_4$. The subsequent evaporation of the solvent gave a crude syrupy residue, which was crystallized with CCl_4 to give **6** as colorless needles. See Table 3.

Preparation of ***7***. *From Ser Derivatives (**3**)*: Into a solution of **3** (4 mmol) and mesyl chloride (5 mmol) in CH_2Cl_2 (20 ml) we stirred triethylamine (12 mmol), drop by drop, at 0—2 °C for 0.5 h, and then the stirring was continued at room temperature for 1.5 more h. Dichloromethane (40 ml) was further added to the reaction solution, and the resulting solution was washed with chilled 1 M HCl till the washing solution reached pH 4 and twice with water, and finally dried over $MgSO_4$. The subsequent evaporation of the CH_2Cl_2 gave **7** as a colorless syrup or crystals. See Table 4.

*From Thr Derivatives (**3**)*: Similarly, the treatment of **3** (4 mmol) with mesyl chloride (5 mmol) in the presence of triethylamine (20 mmol) was worked-up for 1 h; it was then stirred at room temperature for 12 h to give a crude syrupy substance, which was purified on a silica gel column using a mixture of benzene–ethyl acetate (3 : 1 v/v) as the eluent to give **7** as a colorless syrup or crystals. See Table 4.

From ***6***: Into a solution of **6** (4 mmol) in THF (20 ml) we stirred DBU (4.5 mmol) under cooling. After stirring at the same temperature for 2 h, the evaporation of THF gave a crude reaction product; this product was dissolved in ethyl acetate (20 ml) and chilled 1 M HCl (40 ml), and then the residual solution was well shaked. The organic layer thus separated was washed with water and dried over anhydrous Na_2SO_4. After the removal of the ethyl acetate under reduced pressure, the residual syrup thus obtained was chromatographed on a silica-gel column, using a mixture of benzene–ethyl acetate (4 : 1 v/v) as the eluent, to give **7** from the second fraction. See Table 5.

From ***1*** *and* ***2***: Into a solution of **1** (10 mmol) in dry THF (20 ml) we successively stirred PCl_5 (11 mmol), portion by portion, at 0 °C and then, after 20 min, a chilled solution of **2** (10 mmol) in dry pyridine (15 ml), drop by drop, all below 5 °C. The reaction mixture was continuously stirred at room temperature for 3 more h, and then the resulting solution was poured into ice water (100 ml). The resulting aqueous solution was extracted three times with ethyl acetate (180 ml). The extracts were washed once with 3 M HCl (50 ml) and three times with water (100 ml), and then dried over anhydrous Na_2SO_4. After the evaporation of the ethyl acetate under reduced pressure, the residual syrup thus obtained was purified on a silica-gel column, using a mixture of benzene–ethyl acetate (8 : 1 v/v) as the eluent, to give **7** as a pure colorless syrup or crystals. See Table 6.

α,β-Unsaturated Carboxylic Acid Derivatives. XIX. The Convenient Synthesis of α-Alkoxy-, α-Hydroxy-α-amino Acid, and Its Cyclic Dipeptide from α-Dehydroamino Acid[1]

Chung-gi SHIN,* Yoshiaki SATO, Hisao OHMATSU, and Juji YOSHIMURA†

Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221

†*Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227*

(Received July 22, 1980)

The facile conversion of α-dehydroamino acid into α-alkoxy-α-amino acid and its cyclic dipeptide is described. The reaction of *t*-butyl 2-acetylamino-2-alkenoate or 1-benzyl-3-ethylidene-2,5-piperazinedione with alcohol, water, or acetic acid in the presence of NBS or NCS, followed by reduction with 10% Pd-C, gives *t*-butyl 2-alkoxy-, 2-hydroxy-, and 2-acetoxy-2-(acetylamino)alkanoates, and 3-alkoxy-3-ethyl-2,5-piperazinedione respectively. All the new compounds were characterized by spectroscopic analysis.

Recently, increasing interest has been directed to the synthesis of ergot alkaloids and cyclic peptide antibiotics containing an α-alkoxy- or α-hydroxy-α-amino acid moiety as an very important constituent or precursor.[2-5]

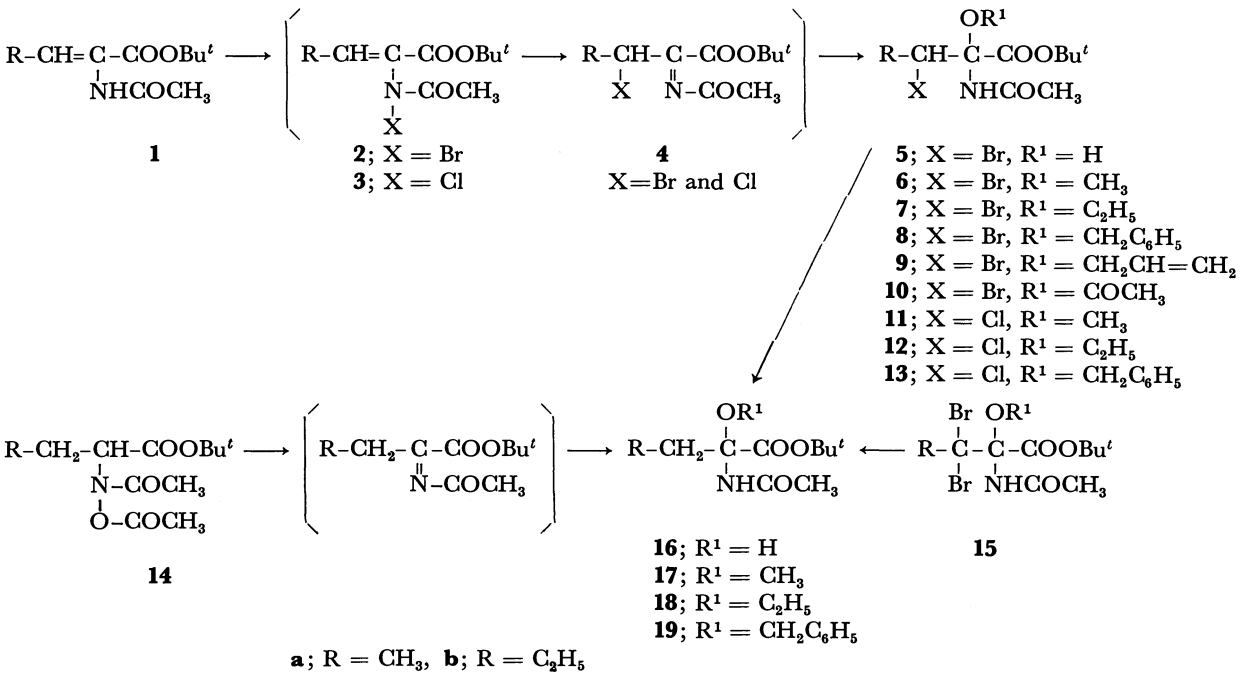
So far, several syntheses of α-alkoxy- and α-hydroxy-α-amino acids from α-amino acid[6-9] and from α-aminoacrylic acid,[10-13] as well as the semi-synthesis of 6-alkoxypenicillins and 7-alkoxycephalosporins,[14] have been reported. However, it seems that no facile and general synthetic method for α-alkoxy- and α-hydroxy-α-amino acids and their cyclic dipeptides has yet been achieved.

Previously, we reported briefly on the addition of alcohol to α,β-unsaturated α-amino acid (α-dehydroamino acid; DHA) in the presence of *N*-bromosuccinimide (NBS).[15] In order to apply and extend the addition reaction in a more versatile manner, various reactions of *t*-butyl 2-acetylamino-2-alkenoate (**1**) or 1-benzyl-3-ethylidene-2,5-piperazinedione (2,5-piperazinedione=PDO) (**21**) with several alcohols, acetic acid, or water in the presence of NBS or *N*-chlorosuccinimide (NCS) have here been studied thoroughly. As a result, the synthetic route for α-alkoxy- and α-hydroxy-α-amino acids and their cyclic dipeptides was established.

More recently, after the completion of our work,[16,17] Ottenheijm *et al.* reported a similar addition of methanol to acylimine intermediates.[18,19]

Results and Discussion

α-Alkoxy-α-amino Acid. A one-pot reaction of DHA (**1**: **a**; R=CH_3, **b**; R=C_2H_5) with an appropriate alcohol in the presence of NBS or NCS at room temperature gave directly the desired *t*-butyl 2-alkoxy-3-halo-2-(acetylamino)alkanoate (**6**—**13**) in an excellent yield. On the other hand, a similar reaction of *t*-butyl 2-acetylamino-2-butenoate (**1a**) with water in DMF barely proceeded to give *t*-butyl 2-hydroxy-3-bromo-2-(acetylamino)butanoate (**5a**) in a poor yield, whereas



Scheme 1.

the reaction of **1** with glacial acetic acid was worked-up similarly to give *t*-butyl 2-acetoxy-3-bromo-2-(acetylamino)alkanoate (**10**) in *ca.* a 51% yield.

Subsequently, an attempt at the catalytic reduction of bromine at the 3-position of the **5**—**8** thus obtained with 10% Pd-C and equimolar triethylamine in methanol was successful; the expected *t*-butyl 2-alkoxy-2-(acetylamino)alkanoate (**16**—**19**) was thus obtained as colorless crystals in a fairly good yield. A similar reduction was further applied to *t*-butyl 3,3-dibromo-2-alkoxy-2-(acetylamino)alkanoate (**15**), prepared and reported previously,[15] using 10% Pd-C and two molar triethylamine to give **16**—**19** in an almost quantitative yield.

Moreover, it was found that *t*-butyl 2-benzyloxy-2-(acetylamino)alkanoate (**19**) was hydrogenolyzed with 10% Pd-C in the absence of triethylamine to give **16** in *ca.* a 60% yield.

On the other hand, in order to prepare independently and to confirm the structure of **16**—**19**, *t*-butyl 2-(*N*,*O*-diacetyl-hydroxyamino)alkanoate (**14**)[20] was subjected to the elimination of acetic acid and the subsequent addition of alcohol to the acylimine thus formed as an intermediate. When a solution in an appropriate alcohol was treated with sodium alkoxide, the expected elimination-addition reaction was carried out to give α-alkoxy derivative, which was found to be completely identical with **17** and **18**. This method, however, was found to be ineffective for the preparation of an α-hydroxy- or α-benzyloxy-α-amino acid moiety, *e.g.*, *t*-butyl 2-hydroxy- and 2-benzyloxy-2-(acetylamino)-alkanoate (**16** and **19**), which were thought to be very

important segments in many of the natural products mentioned above.

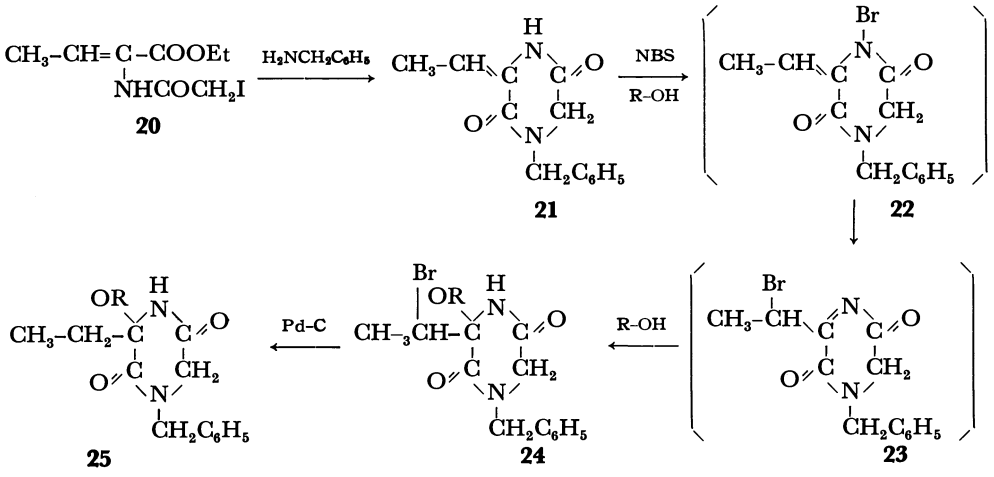
In consequence, a convenient synthetic method for α-alkoxy-α-amino acid in a 75% overall yield was established by only two steps from DHA (**1**).

As is shown in Scheme 1, a formation mechanism of **5**—**13** was deduced in which, at first, the substitution of halogen to the nitrogen atom of **1** yielded *t*-butyl 2-(*N*-haloacetylamino)-2-alkenoate (**2** and **3**), followed by the 1,3-shift of the halogen to form *t*-butyl 3-halo-2-(acetylimino)alkanoate (**4**) as an unstable intermediate, to which immediately the present protic solvent was added. This deduction has already been supported by the fact that, to the *t*-butyl 3,3-dibromo-2-(acetylimino)-alkanoate isolated stably, we added alcohols to give **15**.[15]

In the IR spectral data of **5**—**13** and **16**—**19**, the characteristic absorption bands of the NH, ester carbonyl, and secondary amide functions appeared in the 3260—3390, 1730—1760, and 1660—1700 cm^{-1} regions respectively. Moreover, from the NMR spectral data, the disappearance of the characteristic olefinic proton signals in the δ 6.59—7.13 region of **1** and the appearance of the C-3 proton signals of **5**—**13** and **16**—**19** in the δ 4.12—5.56 and δ 1.66—2.78 regions respectively, resonating in a considerably higher magnetic field, are consistent with the formation of the α-substituted-α-amino acid structure.

The yields, physical constants, and NMR spectral data of **5**—**13** and **16**—**19** are summarized in Tables 1, 2, and 3.

3-Alkoxy-2,5-piperazinedione. In order to apply extensively and generalize the protic reagent-addition utilizing the halogen migration, 3-alkylidene-PDO was for instance, employed. Exactly, according to the synthetic method for α-alkoxy-α-amino acid, the starting 1-benzyl-3-ethylidene-PDO (**21**), which has been prepared by the cyclization of ethyl 2-iodoacetylamino-2-butenoate (**20**)[21] with benzylamine in a good yield, was treated with an appropriate alcohol in the



26; R = H **a**; R = CH_3, **b**; R = C_2H_5, **c**; R = $CH_2C_6H_5$

Scheme 2.

a) Colorless prisms from ethyl acetate–diethyl ether. b) Colorless needles from benzene–hexane. c) Colorless prisms from benzene–hexane. d) Colorless needles from benzene. e) Recorded in KBr. f) Measured in $CDCl_3$.

presence of NBS to give 1-benzyl-3-(1-bromoethyl)-3-alkoxy-PDO (**24**) as colorless crystals in *ca.* an 80% yield. The subsequent catalytic reduction of **24** with Pd–C and triethylamine was also carried out to give the desired 1-benzyl-3-alkoxy-3-ethyl-PDO (**25**) in a 90% yield.

Furthermore, the catalytic hydrogenolysis of **25** with 10% Pd–C was performed smoothly to give 1-benzyl-3-ethyl-3-hydroxy-PDO (**26**) in *ca.* a 90% yield.

From the above results, the yield of the each step from **21** to **26** was found to be excellent; the overall yield reached to *ca.* 50%.

As was illustrated in Scheme 2, the formation mechanism of **24** was also supposed that the initial substitution of bromine to the 4-position of **21** (**22**), followed by the immediate migration to the 2-position of exocyclic carbon, gave acylimine (**23**); finally, the addition reaction of alcohol to **23** occurred to give **24**.

Judging from the IR and NMR spectral data of **21** and **24**—**26**, the appearance of the carbon-carbon double bond at 1635 cm^{-1} and the olefinic proton signal at δ 6.29 in **21**, and the appearance of exocyclic 1-methine proton signals resonating at comparatively higher magnetic fields (at δ 4.72—4.78 in **24** and in the δ 1.96—2.08 region in **25** and **26**), indicate unambiguously the formation of 3-alkoxy- and 3-hydroxy-PDO structures.

All the new compounds thus obtained gave satisfactory results in their elemental analyses as well as in the spectroscopy.

The yields, physical constants, and NMR spectral data of **21**, **24**, **25**, and **26** are summarized in Table 4.

It is noteworthy that the addition reaction of protic reagent *via* the substitution and the subsequent migration in one pot is also applicable to linear and cyclic acylenamines, as is shown below (Fig. 1).

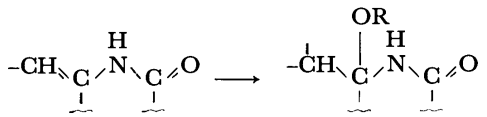

Fig. 1.

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 Spectrometer. The NMR spectra were measured with a JNM-PS-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.), using tetramethylsilane as the internal standard.

Preparation of ***5a***. Into a solution of **1a** (10.0 mmol) in water–DMF (15 ml, 1 : 9 v/v) we stirred NBS (11.0 mmol), portion by portion, at room temperature for 3 h. The reaction solution was poured into saturated aqueous NaCl (30 ml), and then the crystals deposited were collected by filtration. The recrystallization of the crystals from methanol–water gave colorless needles identified as *t*-butyl 3-bromo-2-hydroxy-2-(acetylamino)butanoate (**5a**).

Preparation of ***6***. Similarly, **1** and methanol (20 ml), in the presence of NBS, were worked-up for 2 h. The reaction solution was concentrated under reduced pressure to give a residue, which was subsequently dissolved in diethyl ether (30 ml). The resulting solution was washed twice with water and then dried over anhydrous Na_2SO_4. The evaporation of the ether gave colorless crystals or a syrup identified as *t*-butyl 3-bromo-2-methoxy-2-(acetylamino)alkanoate (**6**).

Preparation of ***7***. Similarly, a solution of **1** and NBS in ethanol (20 ml) was worked-up to give colorless crystals or a syrup identified as *t*-butyl 3-bromo-2-ethoxy-2-(acetylamino)-alkanoate (**7**).

Preparation of ***8***. A solution of **1a** in benzyl alcohol (6 ml) in the presence of NBS was similarly worked-up for 40 min to yield colorless crystals, which were then collected and washed with 50% ethanol. The crystals were identified as *t*-butyl 2-benzyloxy-3-bromo-2-(acetylamino)butanoate (**8a**).

Similarly, a solution of **1b** and NBS in benzyl alcohol was worked-up. The reaction solution was poured into water (250 ml), and then the aqueous solution was extracted three times with petroleum ether (180 ml). The combined extracts were washed three times with water, dried over anhydrous

Na_2SO_4, and then concentrated under reduced pressure to give colorless crystals identified as *t*-butyl 2-benzyloxy-3-bromo-2-(acetylamino)pentanoate (**8b**).

Preparation of ***9***. A solution of **1** in allyl alcohol (6 ml) in the presence of NBS was similarly worked-up for 10 h; to the reaction mixture we then added cyclohexane (60 ml). The resulting solution was washed twice with water and dried over anhydrous Na_2SO_4. The evaporation of the cyclohexane under reduced pressure gave colorless crystals or a syrup identified as *t*-butyl 2-allyloxy-3-bromo-2-(acetylamino)-alkanoate (**9**).

Preparation of ***10***. Into a solution of **1** (10.0 mmol) in acetic acid (5 ml) we stirred NBS (11.0 mmol), portion by portion, at room temperature for 3 h. To the reaction solution thus obtained we added hexane (100 ml). After the resulting solution had been washed twice with water, the crystals which separated out were collected by filtration. The filtrate was further washed twice with water and then dried over anhydrous $MgSO_4$. The removal of the hexane gave more of the crystals obtained above. The combined crystals were recrystallized from hexane to give colorless needles identified as *t*-butyl 3-bromo-2-acetoxy-2-(acetylamino)alkanoate (**10**).

Preparation of ***11***. A solution of **1a** in methanol (40 ml) in the presence of NCS (11.0 mmol) was similarly worked-up for 5 h to give colorless crystals identified as *t*-butyl 3-chloro-2-methoxy-2-(acetylamino)butanoate (**11a**).

In a similar manner, the reaction of **1b** with methanol and NCS for 24 h gave a syrupy residue, which was then purified on a silica gel column, using a mixture of benzene–ethyl acetate (15 : 1 v/v) as the eluent. The fraction thus obtained was concentrated under reduced pressure to give a colorless syrup identified as *t*-butyl 3-chloro-2-methoxy-2-(acetylamino)pentanoate (**11b**).

Preparation of ***12***. Similarly, a solution of **1** in ethanol (20 ml) in the presence of NCS was worked-up for 20 h to give a residual syrup. The crude syrup was purified on a silica gel column, using a mixture of benzene–ethyl acetate (15 : 1 v/v) as the eluent, to give a colorless amorphous substance or a syrup identified as *t*-butyl 3-chloro-2-ethoxy-2-(acetylamino)alkanoate (**12**).

Preparation of ***13***. Similarly, a solution of **1a** and NCS in benzyl alcohol (30 ml) was worked-up for 3 h to give colorless crystals identified as *t*-butyl 3-chloro-2-benzyloxy-2-(acetylamino)butanoate (**13a**).

In a similar manner, the treatment of **1b** with benzyl alcohol (10 ml) in the presence of NCS for 24 h gave a reaction solution which was then poured into water (400 ml). The resulting aqueous solution was extracted three times with petroleum ether (150 ml). The combined extracts were washed three times with water and then dried over anhydrous Na_2SO_4. The removal of the ether under reduced pressure gave colorless crystals identified as *t*-butyl 3-chloro-2-benzyloxy-2-(acetylamino)pentanoate (**13b**).

Preparation of ***16—19***. *a) From* ***5—8***: A solution of **5—8** (5.0 mmol) and triethylamine (5.5 mmol) in methanol (70 ml) was reduced in the presence of 10% Pd-C (500 mg). After 15 min, the catalyst was filtered off, and the reaction solution was concentrated under reduced pressure to give a residue, which was subsequently dissolved in chloroform (50 ml). The resulting solution was washed three times with water and then dried over anhydrous $MgSO_4$. The evaporation of the chloroform gave colorless crystals identified as *t*-butyl 2-alkoxy- and 2-hydroxy-2-(acetylamino)alkanoate (**16—19**).

b) From ***15***: A similar treatment of **15** (5.0 mmol) with triethylamine (10.5 mmol) in the presence of 10% Pd-C (500 mg) was worked-up to give the expected **16—19.**

c) From ***14***: Into a solution of **14** (10.0 mmol) in an appropriate alcohol (10 ml) we stirred sodium alkoxide (12.0 mmol) in alcohol (5 ml), drop by drop, below 10 °C. After the solution had been stirred for 2 h, the reaction solution was concentrated under reduced pressure to give a residue which was subsequently dissolved in chloroform (30 ml). The resulting solution was washed twice with water and then dried over anhydrous $MgSO_4$. The removal of the chloroform gave **17** and **18**.

Preparation of ***16*** *from* ***19***. A solution of **8** (3.8 mmol) in methanol (30 ml) was hydrogenolyzed in the presence of 10% Pd-C (100 mg) at room temperature for 1 h. After the removal of the catalyst, the resultant solution was concentrated to give a residual pale yellow syrup. The crude syrup was purified on a silica-gel column, using a mixture of benzene–ethyl acetate (5 : 2 v/v) as the eluent. The fraction was concentrated under reduced pressure to give colorless crystals, in agreement with the **16** prepared above.

Preparation of ***21***. Into a solution of **20** (6.73 mmol) in ethanol (20 ml) we stirred benzylamine (16.84 mmol), drop by drop, at room temperature. After the mixture had been stirred for 3 h, the reaction solution was concentrated under reduced pressure to give a residue, which was subsequently dissolved in 1 M HCl (50 ml). The aqueous solution was extracted three times with benzene (60 ml). The combined extracts were washed twice with saturated aqueous NaCl and then dried over anhydrous Na_2SO_4. The removal of the benzene under reduced pressure gave colorless crystals identified as 1-benzyl-3-ethylidene-PDO (**21**).

Preparation of ***24***. Into a solution of **21** (2.17 mmol) in an appropriate alcohol (5 ml) we stirred NBS (2.17 mmol), portion by portion, at room temperature. After the mixture had been stirred for 10 min, the reaction solution was concentrated under reduced pressure to give a residue, which was then dissolved in chloroform (20 ml). The resulting solution was washed twice with water and then dried over anhydrous Na_2SO_4. The removal of the chloroform gave colorless crystals identified as 1-benzyl-3-alkoxy-3-(1-bromoethyl)-PDO (**24**).

Preparation of ***25***. A solution of **24** (1.69 mmol) and triethylamine (2.03 mmol) in methanol (30 ml) was reduced in the presence of 10% Pd-C (170 mg) at room temperature for 1 h. After the removal of the catalyst, the reaction solution was concentrated under reduced pressure to give a residue, which was then dissolved in dichloromethane (20 ml). The resulting solution was washed twice with water and then dried over anhydrous Na_2SO_4. The evaporation of the dichlorome thane gave colorless crystals identified as 1-benzyl-3-alkoxy-3-ethyl-PDO (**25**).

Preparation of ***26***. A solution of 1-benzyl-3-benzyloxy-3-ethyl-PDO (**25c**; 2.07 mmol) in methanol (40 ml) was hydrogenolyzed in the presence of 10% Pd-C (500 mg) at room temperature for 24 h. After the removal of the catalyst, the resultant solution was concentrated under reduced pressure to give colorless crystals identified as 1-benzyl-3-ethyl-3-hydroxy-PDO (**26**).

The Preparation of Optically Active β-Keto Sulfoxides by Means of an Enantiomer-differentiating Reaction of α-Lithio Aryl Methyl Sulfoxides with Chiral Carboxylates[1)]

Norio KUNIEDA,* Akira SUZUKI, and Masayoshi KINOSHITA

(Received June 26, 1980)

The reaction of α-lithio aryl methyl sulfoxides with a limited amount of chiral carboxylates (R^2–CO–O–R*) was found to be an enantiomer-differentiating reaction, affording the corresponding optically active β-keto sulfoxides (**3**), together with optically active aryl methyl sulfoxides which have the opposite configuration. The optical purity and the predominant configuration of **3** obtained were assigned by means of a combination of polarimetric analysis and NMR. The degree of enantioselectivity of this reaction was affected by the nature of the ester moiety R^2, indicating an increase in optical yields, from 1.3%, where R^2 was ethyl (**3b**), to 70.3%, where R^2 was *t*-butyl (**3f**). The stereochemical course of the reaction has been discussed by considering a six-membered cyclic transition state. Furthermore, the repeated recrystallizations of several β-keto sulfoxides thus obtained, such as (−)-**3e**, (−)-**3f**, (−)-**3g**, and (−)-**3p**, were found to give the corresponding highly optically pure β-keto sulfoxides.

β-Keto sulfoxides are useful as key synthetic intermediates.[2)] Previously, we have found that optically active β-keto sulfoxides can serve as good chiral precursors in the asymmetric synthesis of optically active alcohols.[3c)] The optically active β-keto sulfoxides hitherto reported have generally been prepared by either the reaction of carboxylic esters with α-sulfinyl carbanions, which are derived from optically active sulfoxides,[1,3c)] or by the oxidation of optically active β-hydroxy sulfoxides, which are prepared from optically active sulfoxides and aldehydes,[3e,4b)] exclusive of microbiological methods.[4)] However, these procedures involve the rather hard task of synthesizing optically active sulfoxides as the starting materials.[5)]

During the course of our research concerned with the asymmetric induction by the chiral sulfinyl group,[3)] we recently reported that 2 equivalents of a racemic α-sulfinyl carbanion reacted with a (−)-menthyl (*S*)-arenesulfinate to yield a diastereomeric mixture of (*R*,*S*)- and (*R*,*R*)-β-disulfoxides in a ratio of about 6 : 4.[3b)] In view of this finding, we considered that the reaction of a racemic α-sulfinyl carbanion with a limited amount of a chiral carboxylate might provide a kinetic resolution of the α-sulfinyl carbanion, together with the production of optically active β-keto sulfoxide. As expected, we have now found that the reaction of 2 equivalents of racemic α-lithio aryl methyl sulfoxides (**1**)[8)] with chiral carboxylates(**2**) affords the corresponding optically active β-keto sulfoxides(**3**), together with the optically active aryl methyl sulfoxides (Scheme 1). We wish herein to report on the application of this method to the synthesis of some optically active β-keto sulfoxides and the determination of their optical purities and absolute configurations.

Scheme 1.

Results and Discussion

To cite a typical reaction, (*R*)-(−)-menthyl benzoate (**2h**), $[\alpha]_D^{20}$ −90.5°(C_2H_5OH), was treated with 2 equivalents of α-lithiomethyl *p*-tolyl sulfoxide(**1a**), derived from racemic methyl *p*-tolyl sulfoxide and lithium diethylamide(Et_2NLi), in tetrahydrofuran (THF) at −78 °C in an atmosphere of nitrogen. After 2 h reaction, the work-up, followed by a preparative

a) In THF at −78 °C. b) $(i\text{-}C_3H_7)_2NLi$. c) Yields are based on the starting carboxylic esters (**2**). d) Average values of 2—7 experiments (in acetone, at 18—30 °C). e) Calculated on the basis of the specific rotations for the corresponding authentic β-keto sulfoxides (see Table 2). f) Determined in methanol. g) This value was calculated using the reported specific rotation of (*R*)-(+)-α-(*p*-tolylsulfinyl)acetate, $[\alpha]_D^{29}$ +197° (CH_3OH) (Ref. 4b). h) Evaluated by NMR using Eu(TFC)$_3$. i) Overnight at room temperature. j) Calculated using the reported specific rotation of (*R*)-(+)-α-(phenylsulfinyl)acetate, $[\alpha]_D$ +156° (Ref. 4a). k) Assigned on the basis of the absolute configuration of methyl phenyl sulfoxide which was produced concomitantly by the reaction.

TLC(diethyl ether), afforded dextrorotatory α-(*p*-tolylsulfinyl)acetophenone (**3h**) (93% yield, $[\alpha]_D^{20}$ +35.0° (*c* 0.622, acetone), 13.2% optical purity, (*R*)-rich) and (*S*)-(−)-methyl *p*-tolyl sulfoxide (92% yield, $[\alpha]_D^{20}$ −19.5° (*c* 0.995, acetone), 13.4% optical purity). By a similar procedure, a series of reactions were conducted using thirteen (*R*)-(−)-menthyl carboxylates (**2a—m**), two (*R*)-(−)-bornyl carboxylates (**2n—o**), and three (*R*)-(−)- and (*S*)-(+)-1-methylheptyl carboxylates (**2p—r**). The results are summarized in Table 1. The resultant β-keto sulfoxides (**3a—q**), which possess a variety of R^2 groups, were characterized by means of NMR, IR, mass-spectrum, and elemental analyses.

In order to get a clue as to the optical purity as well as the absolute configuration of the β-keto sulfoxides obtained, we synthesized, as authentic samples, twelve dextrorotatory alkyl and aryl α-(*p*-tolylsulfinyl)methyl ketones (**3b—m**) by the reactions of α-lithiomethyl *p*-tolyl sulfoxide, which has been derived from optically pure (*R*)-(+)-methyl *p*-tolyl sulfoxide, with the corresponding ethyl carboxylates. The specific rotations of the authentic β-keto sulfoxides are compiled in Table 2. Since the formation of carbanions from optically active aryl methyl sulfoxides has been known to take place without any loss of stereochemical integrity,[3b,10,13] and since the reaction of the carbanions with carboxylates is sure to proceed through the complete retention of the configuration at sulfur, the dextrorotatory, β-keto sulfoxides synthesized by the above method should be in an optically pure form with a (*R*)-configuration. This assignment may also be confirmed by the following reaction. That is, the treatment of (*R*)-(+)-α-(*p*-

TABLE 2. SPECIFIC ROTATIONS OF THE AUTHENTIC β-KETO SULFOXIDES (*p*-$CH_3C_6H_4$-SO-CH_2-CO-R^2)

	25		+19.5°±0.8°(2)	7.3	0.36		

a) Average values of 2—7 experiments. The number of experiments is shown in parentheses. b) o.p.=Optical purities which were determined by comparison with the specific rotations for the authentic β-keto sulfoxides listed in Table 2.

tolylsulfinyl)acetophenone (**3h**), $[\alpha]_D^{25}$ +265.5° (acetone), with methylmagnesium iodide in THF yielded (*S*)-(−)-methyl *p*-tolyl sulfoxide, $[\alpha]_D^{25}$ −145°(acetone) (99.3% optical purity) *via* a normal S_N2-type process, with a complete inversion of the configuration at sulfur.[14] In addition, the optical purities, in the cases of the authentic **3b**, **3e**, and **3f**, were confirmed with the aid of NMR using the chiral-shift reagent tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]europium(III) [Eu(TFC)$_3$] (see Experimental). By a similar procedure, optically pure (*S*)-(−)-**3f** and (*S*)-(−)-**3h** were also prepared using α-lithiomethyl *p*-tolyl sulfoxide derived from optically pure (*S*)-(−)-methyl *p*-tolyl sulfoxide.

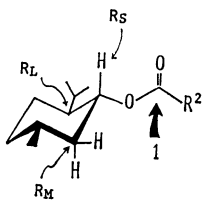
Accordingly, the optical purities and the predominant configurations of the β-keto sulfoxides listed in Table 1 were assigned mainly by comparison with the specific rotations for the corresponding authentic substances. In the cases of **3a**, **3f**, **3n**, and **3p**, their optical purities were further confirmed by NMR using Eu(TFC)$_3$.

The degree of enantioselectivity of the reaction was dependent on the reaction temperature (see Table 3). In the reactions of **1a** with **2f** and **2h**, the decrease in temperature favored the formation of the predominant enantiomers, (*S*)-(−)-**3f** and (*R*)-(+)-**3h** respectively, and the plot of $1/T$ *vs.* $\ln(R)/(S)$ (for **3h**) or $\ln(S)/(R)$ (for **3f**) gave a linear relationship with a positive slope. For both the reactions either the $\Delta\Delta H^*$ value or the $\Delta\Delta S^*$ value exhibited a negative sign.

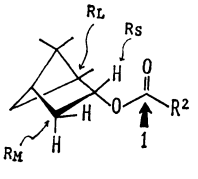
Table 1 reveals that the degree of enantioselectivity varies drastically from 1.3% to 70.3% depending on the nature of the ester moiety, R^2. Generally, the extent of the enantioselectivity is higher when the inducing chiral moiety is menthyl rather than bornyl and 1-methylheptyl, and the chiral carboxylates which have a bulky R^2 group (R^2=phenyl, naphthyl, 3,5-di-*t*-butylphenyl, cyclohexyl, or *t*-butyl) give a relatively high degree of enantioselectivity. The best result has been obtained from the reaction of (*R*)-(−)-menthyl pivalate (**2f**) with **1a**, affording (*S*)-(−)-**3f** of a 70.3% optical purity.

The reactions of two kinds of (*R*)-(−)-bornyl carboxylates, **2n** (R^2=*t*-butyl) and **2o** (R^2=phenyl), with **1a** both gave (*S*)-rich β-keto sulfoxides, (−)-**3f** and (−)-**3h**. From the reactions of both (*S*)-(+)-1-methylheptyl pivalate(**2p**) and (*S*)-(+)-1-methylheptyl benzoate (**2q**) with **1a**, the (*R*)-rich β-keto sulfoxides, (+)-**3f** and (+)-**3h**, were produced preferentially. However, a reversal in the configuration with the variation in the ester moiety, R^2, is observed in the series of reactions of (*R*)-(−)-menthyl carboxylates with **1a**. That is, the carboxylates (−)-**2a**(R^2=methyl), (−)-**2b**(R^2=ethyl), and (−)-**2h**—**m** (R^2=aryl) preferentially react with (*R*)-**1a** to yield an excess of (*R*)-β-keto sulfoxides, while the carboxylates (−)-**2c** (R^2=propyl), (−)-**2d** (R^2=nonyl), (−)-**2e** (R^2=isopropyl), (−)-**2f** (R^2=*t*-butyl), and (−)-**2g**(R^2=cyclohexyl) preferentially react with (*S*)-**1a** to afford the (*S*)-β-keto sulfoxides in excess.

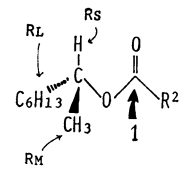
The oxygen atom of sulfoxides is known to have a donor ability towards electron acceptors.[15] Furthermore, in connection with the stereochemistry of the electrophilic substitution reactions of α-lithiosulfoxides, Marquet *et al.*[16] and Biellmann *et al.*[17] have proposed that an electrophilic assistance (a chelation) by the lithium cation on the α-lithiosulfoxides towards the electrophiles plays an important role. By considering this evidence together with a B_{AC} 2-type of mechanism for the reactions of carbanions with carboxylic esters,[18] it appears that the stereochemical course of this reaction can be explained by a six-membered cyclic transition state, as in the case of the reaction of (*R*)-(+)-α-(*p*-tolylsulfinyl)acetophenone with alkyl Grignard reagents reported previously.[19] Therefore, the stereochemical feature of the reaction can be illustrated in terms of the



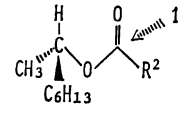
(*R*)-(−)-**2a**—**m**



(*R*)-(−)-**2n**, **o**



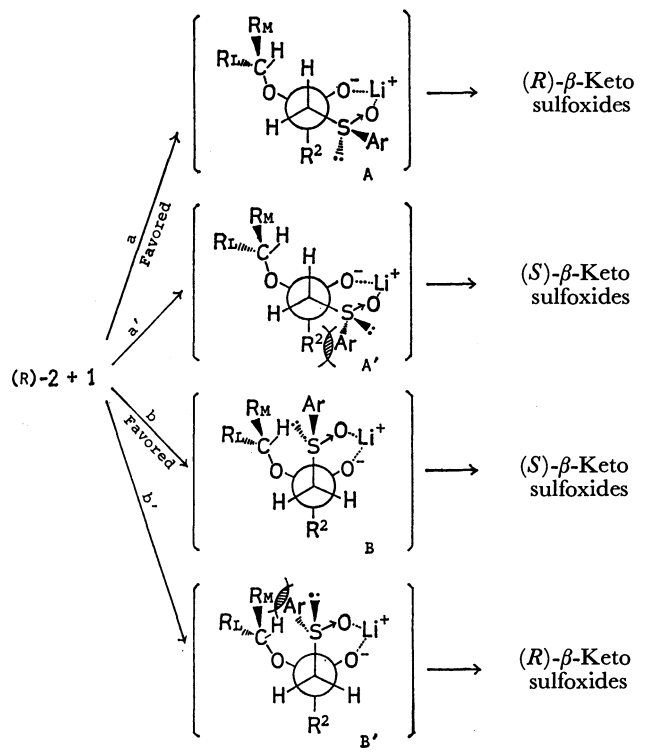
(*R*)-(−)-**2r**



(*S*)-(+)-**2p**, **q**

(The symbols R_S, R_M, and R_L indicate small, medium, and large groups respectively.)

Scheme 2.



Scheme 3.

following schemes (Schemes 2 and 3). At first, by analogy with the empirical model predictions derived from Prelog's rule[20] and Cram's rule,[21] it can be recognized that the preferential attack of the α-lithiosulfoxides (**1**) towards the carbonyl carbon takes place from the less hindered diastereotopic face of the chiral carboxylates(**2**),[22] as indicated by the arrows (see Scheme 2). Next, the following four reaction paths, (a), (a'), (b), and (b'), involving the respective six-membered cyclic transitions, A, A', B, and B', are conceivable for the substitution reaction of (*R*)-**2** and **1** (see Scheme 3). However, the steric requirements in the transition states seem to indicate that Path (a) or (b) is the most likely possibility, while Paths (a') and (b') are unfavorable, since the significantly greater interactions of the arenesulfinyl group *vs.* the R^2 group or the substituents of the chiral alcohol moiety should contribute to the crowding of the transition states A' and B'. The (*R*)-β-keto sulfoxides will then be produced *via* the transition state A (Path a), while the reactions which proceed *via* the transition state B (Path b) will give the (*S*)-β-keto sulfoxides, and the direction and the degree of enantioselectivities of the reactions should depend upon the magnitudes of the mutual interactions among the arenesulfinyl group, the R^2 group, and the substituents of the chiral alcohol moiety (especially, the R_M group acts as an effective bulk to influence the steric course of the reaction) in the A and B transition states. In the cases of the reactions of **1** with (*R*)(—)-bornyl carboxylates (**2n** and **2o**) and (*R*)-(—)-1-methylheptyl benzoate (**2r**), Path b will predominate, since the sterical interaction between the arenesulfinyl group and the R_M group is considered to be smaller than that between the arenesulfinyl group and the bulky R^2 group. The reactions of the (*R*)-(—)-menthyl carboxylates, **2e**, **2f**, and **2g**, which have rather bulkier R^2 groups, will preferentially take place *via* the transition state B to yield the (*S*)-rich β-keto sulfoxides as well. On the other hand, in the cases of the reactions of the (*R*)-(—)-menthyl carboxylates, **2a** and **2b**, which have smaller R^2 groups, Path a will predominate, since the interaction between the arenesulfinyl group and the R_M group should be larger than that between the arenesulfinyl group and the R^2 group in this case. Actually, most of the experimental results in Table 1 agree fairly well with these predictions. The reversal in configuration from (*R*) to (*S*) in going from **3b** to **3c** may be attributed to the fact that the differences in magnitudes of the interactions of the arenesulfinyl group *vs.* the R^2 group and of the arenesulfinyl group *vs.* the R_M group are reversed with the change in the R^2 group from ethyl to propyl. On the other hand, contrary to our expections, the experimental results from the reactions of (*R*)-(—)-menthyl carboxylates (**2h**—**m**), which have aryl groups, indicate that the reactions proceed *via* the A transition state rather than B. We have now considered that, compared with the aryl groups, the R_M moiety of the menthyl group involving a C-2 equatorial hydrogen and a C-1 methyl group would act more effectively as a steric bulk towards the arenesulfinyl group in this case.

Further investigations, including kinetic experiments, are now under way in an effort to obtain detailed knowledge of the stereochemistry of the reaction.

Finally, we have now found that some of the β-keto sulfoxides thus obtained, **3e**, **3f**, **3g**, **3h**, **3n**, and **3p**, increase their optical purities upon repeated recrystallizations. As is shown in Table 4, especially, the repeated recrystallizations of the partially optically pure **3e**, **3f**, **3g**, and **3p** from a mixture of diethyl ether and hexane

Table 4. Results of the repeated recrystallizations of some β-keto sulfoxides obtained[a]

β-Keto sulfoxides	Specific rotation in acetone at 25 °C	
	Starting (%o.p.)[b]	After recrystallization(%o.p.)[b]
(−)-**3e**	−12.8° (*c* 0.530) (5.0)	−256° (*c* 0.190) (99.2)
(−)-**3f**	−180° (*c* 0.500) (68.4)	−262° (*c* 0.200) (99.6)
(−)-**3g**	−51.0° (*c* 0.680) (21.3)	−240° (*c* 0.331) (100)
(+)-**3h**	+32.3° (*c* 0.690)(12.2)	+55.0° (*c* 0.218) (20.7)
(−)-**3p**	−163°(*c* 0.460)	−266° (*c* 0.294)[c]

a) The recrystallization was repeated three times by the use of a mixture of diethyl ether and hexane. b) o.p.=Optical purities which were determined by comparison with the specific rotations for the authentic β-keto sulfoxides listed in Table 2. c) A single enantiomer was detected by NMR using $Eu(TFC)_3$.

supplied the corresponding β-keto sulfoxides with optical purities higher than 99%. While, the β-keto sulfoxides, **3a**, **3b**, **3c**, and **3j**, decreased in their optical purities to nearly zero upon repeated recrystallizations from diethyl ether or a mixture of diethyl ether and hexane. In these cases, the crystals obtained from the mother liquid exhibited a larger specific rotation than that of the starting β-keto sulfoxides.

In summary, we suppose at present that the present reaction, in combination with the recrystallization procedure, should be satisfactorily applicable to the synthesis of optically active β-keto sulfoxides, provided that the appropriate chiral carboxylates are used.

Experimental

General. The optical rotations were measured with a JASCO DIP-4 type polarimeter. The IR spectra were obtained with a JASCO IR-G type spectrometer. All the melting points are uncorrected. The NMR spectra were determined with a Hitachi-Perkin-Elmer R-20 or JEOL PS-100 spectrometer; the chemical shifts are reported in δ units, using tetramethylsilane as the internal reference. The CD spectra were determined for ethanol and cyclohexane solutions with a JASCO ORD/CD-5 spectrophotometer. The mass spectra were taken on a JEOL JMS 06 spectrometer.

Starting Materials. *(R)-(+)-Methyl* p-*Tolyl Sulfoxide* was prepared from (−)-menthyl (*S*)-(−)-*p*-toluenesulfinate, mp 107—107.5 °C, $[\alpha]_D^{25}$ −200°(*c* 0.520, acetone), and methylmagnesium iodide according to the method developed by Andersen;[6a] mp 74.5 °C, $[\alpha]_D^{20}$ +146°(*c* 0.460, acetone) [lit,[6b] mp 73—74.5 °C, $[\alpha]_D$ +145.5°(acetone)]. *(S)-(−)-Methyl* p-*Tolyl Sulfoxide* was prepared by the hydrolysis of the ethoxysulfonium salt of (*R*)-(+)-methyl *p*-tolyl sulfoxide according to the method of Johnson and McCants;[26] mp 74.5 °C, $[\alpha]_D^{20}$ −146° (*c* 0.325, acetone). *Racemic Methyl* p-*Tolyl Sulfoxide* and *Methyl Phenyl Sulfoxide* were prepared by the periodate oxidation of the corresponding sulfides.[27] C_6H_5-SO-CH_3; bp 98—99 °C/1 Torr (1 Torr=133.322 Pa)(lit,[28] bp 84 °C/0.25 Torr). *p*-$CH_3C_6H_4$-SO-CH_3; mp 43 °C (lit,[29] 42—43 °C). (−)-*Menthol* (Hoei Chemicals, $[\alpha]_D^{20}$ −50° (C_2H_5OH)) and (−)-*Borneol* (Aldrich, $[\alpha]_D^{20}$ −35.3° (C_2H_5OH)) used here are of a commercial grade. *(R)-(−)-* and *(S)-(+)-1-Methylhepty Alcohol* were prepared by the resolution of racemic 2-octyl alcohol.[30] (*R*)-(−)-1-Methylheptyl alcohol; $[\alpha]_D^{20}$ −10.1° (*c* 2.00, C_2H_5OH)(lit,[30] $[\alpha]_D^{17}$ −9.9° (neat)). (*S*)-(+)-*1*-Methylheptyl alcohol; $[\alpha]_D^{20}$ +10.0° (*c* 2.00, C_2H_5OH)(lit,[30] $[\alpha]_D^{17}$ +9.9° (neat)). *Optically Active Carboxylates* were prepared by treating optically active alcohols with the corresponding carboxylic acid chlorides in diethyl ether in the presence of pyridine. *(R)-(−)-Menthyl Corboxylates*: (−)-$C_{10}H_{19}$-O-CO-R^2; [R^2, mp or bp, Specific rotation (*c*, solvent)], CH_3(**2a**); 108.5—109.5 °C/15 Torr (lit, [31] 117.5—118 °C/25 Torr), $[\alpha]_D^{19}$ −85.0° (1.32, C_2H_5OH) (lit,[34] $[\alpha]_D$ −85.23° (C_2H_5OH)), C_2H_5 (**2b**); 136 °C/29 Torr (lit,[32] 118 °C/15 Torr), $[\alpha]_D^{20}$ −81.0° (1.45, C_2H_5OH)(lit,[32] $[\alpha]_D$ −76.66° (C_2H_5OH)), *n*-C_3H_7 (**2c**); 152 °C/30 Torr (lit,[33] 126 °C/12.5 Torr), $[\alpha]_D^{20}$ −76.0° (1.56, C_2H_5OH)(lit,[32] $[\alpha]_D$ −72.91° (C_2H_5OH)), $[\alpha]_D^{20}$ −72.4° (1.00, benzene) (lit,[33] $[\alpha]_D^{20}$ −70.56° (benzene)), C_9H_{19} (**2d**); 145 °C/2 Torr, $[\alpha]_D^{22}$ −55.8° (2.00, C_2H_5OH), *i*-C_3H_7 (**2e**); 121 °C/13 Torr (lit,[33] 116—117 °C /12 Torr), $[\alpha]_D^{20}$ −76.8° (1.20, C_2H_5OH), $[\alpha]_D^{22}$ −72.0° (1.00, benzene) (lit,[33] $[\alpha]_D^{20}$ −72.05 °(benzene)), *t*-C_4H_9 (**2f**); 124.5 °C/13.5 Torr, $[\alpha]_D^{20}$ −76.4° (1.85, C_2H_5OH), C_6H_{11} (**2g**); 48.3 °C (lit,[32] 48 °C), $[\alpha]_D^{17}$ −65.5° (0.531, C_2H_5OH) (lit,[32] $[\alpha]_D$ −59.11° (C_2H_5OH)), C_6H_5 (**2h**); 54.5 °C (lit,[32] 55 °C), $[\alpha]_D^{20}$ −90.5°(1.53, C_2H_5OH) (lit,[32] $[\alpha]_D^{20}$ −83.53° (C_2H_5OH)), *p*-$CH_3C_6H_4$ (**2i**); 140—141 °C/2 Torr (lit,[35] 196—198 °C/11 Torr), $[\alpha]_D^{22}$ −85.3° (1.26, C_2H_5OH) (lit,[35] $[\alpha]_D^{20}$ −89.9° (neat)), *o*-$CH_3C_6H_4$ (**2j**); 145 °C/3 Torr (lit,[35] 213—215 °C/25 Torr), $[\alpha]_D^{20}$ −81.0° (1.54, C_2H_5OH) (lit,[35] $[\alpha]_D^{20}$ −84.35° (neat)), 3,5-(*t*-C_4H_9)$_2C_6H_3$ (**2k**); 167—169 °C/2 Torr, $[\alpha]_D^{20}$ −67.5° (0.550, C_2H_5OH), α-$C_{10}H_7$ (**2l**); 185 °C/2 Torr (lit,[32] 231—232 °C/11 Torr), $[\alpha]_D^{20}$ −84.5° (1.59, C_2H_5OH) (lit,[32] $[\alpha]_D$ −79.08° (C_2H_5OH)), Mesityl (**2m**); 156—157 °C/2 Torr, $[\alpha]_D^{20}$ −65.0° (0.735, C_2H_5OH). *(R)-(−)-Bornyl Carboxylates*: (−)-$C_{10}H_{17}$-O-CO-R^2; [R^2, bp, Specific rotation], *t*-C_4H_9(**2n**); 74.0 °C/1 Torr, $[\alpha]_D^{15}$ −39.5° (1.68, C_2H_5OH), C_6H_5 (**2o**); 129—130 °C/1 Torr, $[\alpha]_D^{15}$ −42.7° (1.69, C_2H_5OH). *(S)-(+)-1-Methylheptyl Carboxylates*: (+)-C_8H_{17}-O-CO-R^2; [R^2, bp, Specific rotation (*c*, solvent)]; *t*-C_4H_9(**2p**); 61.0 °C /1 Torr, $[\alpha]_D^{20}$ +11.3° (2.00, C_2H_5OH), C_6H_5(**2q**); 109 °C/1 Torr (lit,[36] 171 °C/20 Torr), $[\alpha]_D^{20}$ +40.0° (3.04, C_2H_5OH) (lit,[36] $[\alpha]_D^{20}$ +33.27° (neat)). *(R)-(−)-1-Methylheptyl Benzoate*; 109 °C/1 Torr, $[\alpha]_D^{20}$ −40.1° (*c* 2.18, C_2H_5OH).

Reaction of α-Lithiosulfoxides (1) with Optically Active Carboxylates (2). A typical procedure is as follows. A 50-ml, two-necked, round-bottomed flask containing a magnetic stirring bar was equipped with a rubber septum and a nitrogen-inlet tube. After flusing with dry nitrogen, 15 cm³ of tetrahydrofuran (THF) (freshly distilled over $LiAlH_4$), 3.2 cm³ of a 100 mg/cm³ solution of butyllithium in hexane, and 370 mg of diethylamine were successively injected into the flask through the septum *via* a syringe at 0 °C. The flask was then cooled to −78 °C with a dry ice–acetone bath, a solution of 5 mmol of an aryl methyl sulfoxide in 2.5 cm³ of dry THF was added, and the solution was stirred vigorously for 30 min. A solution of an optically active carboxylate (**2**) (2.5 mmol) in 2.5 cm³ of dry THF was injected *via* a syringe, drop by drop, into the solution. After being stirred for an adequate time at −78 °C (the progress of the reaction was checked from time to time by TLC), water (10 cm³) was added; the mixture was then acidified (*ca.* pH 3) with 10% hydrochloric acid and extracted with chloroform(3×30 cm³). The combined extracts were then washed with brine, dried (Na_2SO_4), and evaporated under a vacuum. The residue was chromatographed on silica gel using a preparative thin-layer chromatoplate. Elution with diethyl ether yielded optically active aryl methyl sulfoxide and the corresponding β-keto sulfoxide(**3**). These products, which exhibited satisfactory NMR and IR spectra, were subjected to optical rotation measurements. The optical purities and the predominant configurations of the β-keto sulfoxides listed in Table 1 were assigned mainly by direct comparison with the specific rotations for the corresponding authentic β-keto sulfoxides.

The NMR spectral non-equivalence was observed for the enantiomers of several β-keto sulfoxides in the presence of

Table 5. Chemical-shift differences induced by $Eu(TFC)_3$ for some alkyl-substituted β-keto sulfoxides

β-Keto sulfoxides	Alkyl groups	$\Delta\Delta\delta$/Hz[a]
3a	$C\underline{H}_3$	3.5
3b	$CH_2C\underline{H}_3$	3.8
3e	$CH(C\underline{H}_3)_2$	2.7
3f	$C(C\underline{H}_3)_3$	1.8(5.0)[b]
3n	$C\underline{H}_3$	4.0
3p	$C(C\underline{H}_3)_3$	(3.0)[b]

a) $\Delta\Delta\delta=|\Delta\delta_R-\Delta\delta_S|$Hz. β-Keto sulfoxides =0.1mol/dm³ solution in CCl_4, $Eu(TFC)_3$=0.7 equiv. b) $Eu(TFC)_3$=1.0 equiv.

$Eu(TFC)_3$.[37] The chemical-shift differences for the resonances of alkyl substituents of β-keto sulfoxides are summarized in Table 5. The optical purities for **3a**, **3f**, **3n**, and **3p** were also evaluated from the NMR spectra by the integration of the respective signals (see Table 1).

By careful, repeated recrystallizations of the resulting **3e**, **3f**, **3g**, and **3p**, the corresponding highly optically pure β-keto sulfoxides were obtained. That is, when a 440 mg of (−)-**3f** ($[\alpha]_D^{25}$ −180° (*c* 0.500, acetone)) was recrystallized three times from a mixture of diethyl ether and hexane (1 : 3 volume ratio), highly optically pure (−)-**3f** (230 mg, $[\alpha]_D^{25}$ −262° (*c* 0.200, acetone), 99.6% optical purity) was obtained. Its physical properties were found to be identical with those of the authentic (*S*)-(−)-**3f**. Three recrystallizations of (−)-**3e** (1.06 g, $[\alpha]_D^{25}$ −12.8° (*c* 0.530, acetone)) and (−)-**3g** (800 mg, $[\alpha]_D^{25}$ −51.0° (*c* 0.680, acetone)) from a mixture of diethyl ether and hexane afforded (−)-**3e** (36 mg, $[\alpha]_D^{25}$ −256° (*c* 0.170, acetone), 99.2% optical purity) and optically pure (−)-**3g** (110 mg, $[\alpha]_D^{25}$ −240° (*c* 0.311, acetone)) respectively. Similarly, from the partially optically pure (−)-**3p** (380 mg, $[\alpha]^{25}$ −163° (*c* 0.460, acetone)), (−)-**3p** (146 mg, $[\alpha]_D^{25}$ −266° (*c* 0.294, acetone)) was obtained. Although the specific rotation for the optically pure (−)-**3p** has never been determined, one enantiomer of **3p** is detected by NMR using $Eu(TFC)_3$. The β-keto sulfoxide **3h** also increased its optical purity upon repeated recrystallizations from a mixture of diethyl ether and hexane. Three recrystallizations of (+)-**3h** (900 mg, $[\alpha]_D^{25}$ +32.3° (*c* 0.690, acetone)), which has been prepared by the reaction of **1a** with (−)-**2h**, afforded a 20.7% optically pure (+)-**3h** (320 mg, $[\alpha]_D^{25}$ +55.0° (*c* 0.218, acetone)). However, in the case of **3h**, we have not found a solvent for recrystallization effective enough to give a highly optically pure **3h**.

Preparation of Authentic Optically Active β-Keto Sulfoxides (p-$CH_3C_6H_4$–SO–CH_2–CO–R^2). The same experimental setup as has been described above was used. (*R*)-(+)-Methyl *p*-tolyl sulfoxide (1.54 g, 10 mmol) was treated with a solution of Et_2NLi (prepared from 6.4 cm^3 of a 100 mg/cm^3 solution of butyllithium in hexane and 740 mg of diethylamine) in 20 cm^3 of dry THF at 0 °C under nitrogen. After 30 min, a solution of an ethyl carboxylate (5 mmol) in 2.5 cm^3 of dry THF was added, and the mixture was stirred for 1—5 h. To the solution was then added water (10 cm^3); the mixture was acidified (*ca.* pH 3) with 10% hydrochloric acid and extracted with chloroform (3×30 cm^3). The combined extracts were washed with brine, dried (Na_2SO_4), and evaporated under a vacuum. The residue was chromatographed using a preparative thin-layer chromatoplate on silica gel; subsequent elution with diethyl ether gave the corresponding dextrorotatory β-keto sulfoxide. The recrystallization of the product from diethyl ether or ethyl acetate afforded the analytically pure β-keto sulfoxide. The β-keto sulfoxides obtained by the above procedure exhibited the following preperties.

(*R*)-(+)-**3b**; mp 68—68.5 °C. $[\alpha]_D^{23}$ +265° (*c* 0.194, acetone). NMR ($CDCl_3$): δ 1.01 (t, 3H, *J*=7 Hz, $-CH_2C\underline{H}_3$) 2.41 (s, 3H, $-CH_3$), 2.50 (q, *J*=7 Hz, 2H, $-C\underline{H}_2CH_3$), 3.76, 3.82 (dd, 2H, *J*=14 Hz, $-CH_2-$), 7.36, 7.53 (dd, 4H, aromatic). *Preparation of (S)-(−)-α-(p-Tolylsulfinyl)acetophenone (**3h**).* Using a procedure similar to that described for (*R*)-(+)-**3h**, the treatment of α-lithiomethyl *p*-tolyl sulfoxide derived from (*S*)-(−)-methyl *p*-tolyl sulfoxide (771 mg, 5 mmol) and LDA (5 mmol)) with 375 mg (2.5 mmol) of ethyl benzoate in 20 cm^3 of dry THF at 0 °C afforded levorotatory α-(*p*-tolylsulfinyl)acetophenone (**3h**) (565 mg, 87.5% yield) after the usual work-up and chromatography on silica gel, with elution with diethyl ether. Subsequent recrystallization from diethyl ether gave analytically pure (S)-(−)-**3h**; mp 89 °C. $[\alpha]_D^{20}$ −265° (c 0.500, acetone). NMR ($CDCl_3$): δ 2.40 (s, 3H, $-CH_3$), 4.26, 4.51 (dd, *J*=14 Hz, 2H, $-CH_2-$), 7.18—7.95 (m, 9H, aromatic).

*Reaction of (R)-(+)-**3h** with Methylmagnesium Iodide.* An ethereal solution of methylmagnesium iodide (7 mmol; 1 mmol/cm^3 solution) was added, drop by drop, to a solution of 517 mg (2 mmol) of (*R*)-(+)-**3h**, $[\alpha]_D^{25}$ +265.5° (*c* 0.264, acetone), in 50 cm^3 of dry THF; the mixture was then stirred for 3 h at −5—0 °C under nitrogen, followed by the careful addition of 10 cm^3 of a saturated solution of ammonium chloride. After the separation of the ethereal layer, the aqueous layer was extracted with chloroform (3×30 cm^3). The combined organic layers were dried(Na_2SO_4) and evaporated under a vacuum. The subsequent preparative TLC of the residue on silica gel, eluting with diethyl ether, afforded (*S*)-(−)-methyl *p*-tolyl sulfoxide (62 mg, 20% yield, $[\alpha]_D^{25}$ −145° (*c* 0.300, acetone), together with the recovery of 370 mg of (*R*)-(+)-**3h**.

Reactions of Perfluoro-2-methyl-2-pentene with Carboxylic Acids, Alcohols, and Some Cyclic Amides. A New Fluorinating Reagent

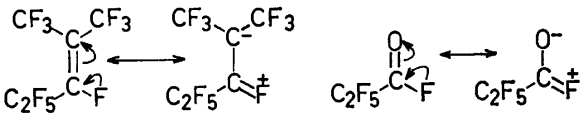
Shozo YANAGIDA,* Yukihiro NOJI, and Mitsuo OKAHARA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received July 1, 1980)

Perfluoro-2-methyl-2-pentene (PMP) reacts with carboxylic acids, alcohols, and 2-pyridone, giving Michael-type addition products, 1,1,1,3,4,4,5,5,5-nonafluoro-2-trifluoromethyl-3-acyloxypentane, 1,1,1,3,4,4,5,5,5-nonafluoro-2-trifluoromethyl-3-alkoxypentane, 1,1,1,3,4,4,5,5,5-nonafluoro-2-trifluoromethyl-3(2-pyridyloxy)pentane, respectively, in good yields. In the presence of bases, carboxylic acids give acid fluorides, 1,1,1,4,4,5,5,5-octafluoro-2-trifluoromethyl-3-pentanone, and 1,1,1,4,4,5,5,5-octafluoro-2-trifluoromethyl-3-acyloxy-2-pentene (**4**), the yields changing with base, solvent, phase-transfer catalyst, and their combination. In the presence of triethylamine, fluorination occurs exclusively, producing acid fluorides in good yields. Alcohols and 2-pyridone are converted into alkyl fluorides and 2-fluoropyridine, respectively, with use of triethylamine as a base with an aprotic solvent. The reactions of PMP with 4-pyridone and 6-chloro-2-ethyl-5-methyl-4(3*H*)-pyrimidone were also examined. The fluorination reactions were rationalized by preferential replacement of the vinylic fluorine of PMP and a good leaving function of the perfluoro enol group of the intermediates such as **4**.

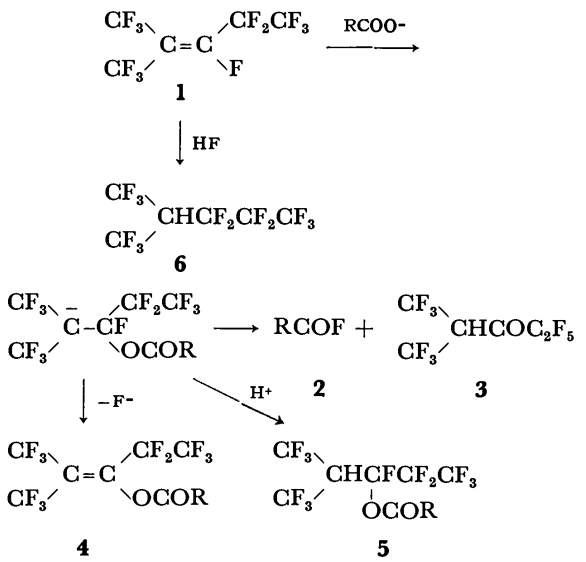
Since the discovery of oligomerization of tetrafluoroethylene and hexafuluoropropylene, studies on their oligomers have drawn much attentions.[1-5] Among the oligomers, perfuluoro-2-methyl-2-pentene (PMP) (**1**), a dimer of hexafluoropropene, is very susceptible to attack by nucleophiles. This high reactivity is attributable to the mesomeric assistance of the vinylic fluorine, the presence of two electrone-withdrawing trifluoromethyl groups which stabilize intermediate carbanion leading to polarization similar to that in the acid fluoride as shown below:[6]



PMP can be regarded as a homolog of perfluoropropionyl fluoride. On the other hand, perfluoro carboxylic acid esters are labile since perfluorocarboxylates are good leaving groups. Thus, the reaction products of PMP with hydroxyl compounds through replacement of the vinylic fluorine are also labile and undergo further reactions under appropriate reaction conditions. We have investigated the reactions of PMP with some carboxylic acids, alcohols, and cyclic amides and found that PMP acts as a fluorinating agent to replace the hydroxyl group with fluorine.

Results and Discussion

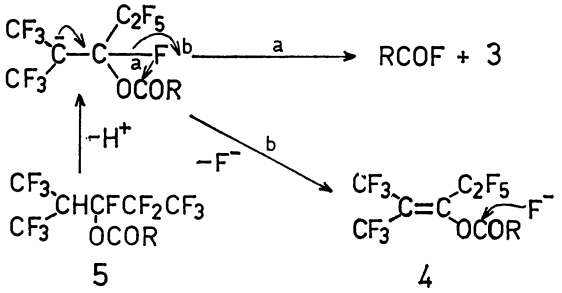
Reactions with Carboxylic Acids. Carboxylate anions react readily with PMP (**1**) either in a dipolar aprotic solvent (DMSO, DMF, acetone, or acetonitrile) or under nonaqueous phase-transfer catalysis conditions, giving acid fluorides (**2**) in good yields along with 1,1,1,4,4,5,5,5-octafluoro-2-trifluoromethyl-3-pentanone (**3**), 1,1,1,4,4,5,5,5-octafluoro-2-trifluoromethyl-3-acyloxy-2-pentene (**4**), 1,1,1,3,4,4,5,5,5-nonafluoro-2-trifluoromethyl-3-acyloxypentane (**5**), and the HF addition product (**6**) (Scheme 1).[5] Further investigation has revealed that the reaction products are strongly dependent on the choice of base, solvent, phase-transfer catalysts and their combination.



Scheme 1.

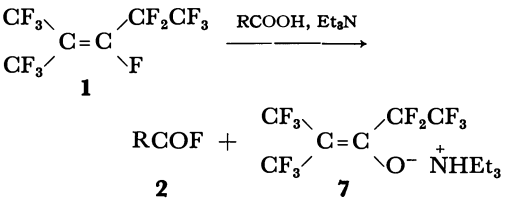
The results obtained by use of inorganic bases are summarized in Table 1. While the reaction of benzoic acid in acetone in the absence of base gave the Michael type addition product (**5**) (R=Ph) in moderate yield (run 1), K_2CO_3–acetone (run 2), K_2CO_3–acetonitrile–18-crown-6 (run 3), and K_2CO_3–benzene–octaglyme (run 6) reaction systems gave good yields of benzoyl fluoride. In the K_2CO_3–CH_2Cl_2–18-crown-6 (run 5) and K_2CO_3–CH_2Cl_2–quaternary ammonium salts (runs 9 and 10) reaction systems, the esters **4** and **5** (R=Ph) were formed concomitantly with benzoyl fluoride. The cases are typical for all reactions using Na_2CO_3 as a base. In spite of the strong interaction of Na^+ with 12-crown-4,[7] no significant difference was observed in the catalysis as compared with that of 18-crown-6 (runs 12 and 13). Use of $CaCO_3$ or CaO led to the exclusive formation of the saturated ester **5**, the reaction of calcium benzoate giving the unsaturated ester **4** selectively. The preferential formation of either the ester **4** or **5** in the presence of Na_2CO_3 or $CaCO_3$ is apparently due to the absence of an active fluoride anion in solution because of the low solubility of NaF and CaF_2.

The fluorination reactions were rationalized by assuming that the reaction goes through the esters **4** and **5**.[5] In fact, the reaction of the enol ester **4** (R=$PhCH_2$) with KF gave the benzoyl fluoride. The reaction, however, was slower than that of the saturated ester **5** (R=$PhCH_2$) with K_2CO_3, suggesting that intramolecular fluoride transfer is also possible (Path a, Scheme 2). The reaction mechanism is similar to that proposed in the fluorination reactions by 2-fluoropyridinium salts[8] and by picryl fluoride.[9]



Scheme 2.

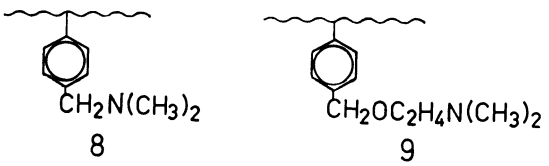
When triethylamine was used instead of inorganic bases, the reaction occurred within 1 h, giving acid fluorides with triethylammonium perfluoro-2-methyl-1-ethyl-1-propenolate (**7**) almost quantitatively. (Scheme 3 and Table 2).



Scheme 3.

Enolate **7** was stable to distillation and characterized by mass, IR, ^{19}F NMR, and ^1H NMR spectra. Martini and Schumann[10] reported its formation by the reaction of PMP with water.

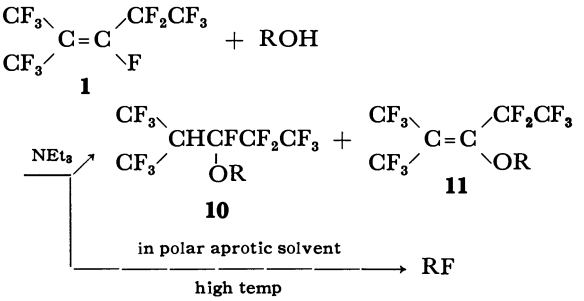
Employment of insoluble polystyrene-bound tertiary amines **8** (Amberlite IRA 68) and **9** gave acid fluorides in good yields (Table 2, runs 8—13). Even a catalytic



amount of the tertiary amine (run 13) gave acid fluorides in reasonable yield. The fluorination reactions using PMP and the insoluble resins (Table 1, run 10) are very simple, acid fluorides being readily obtained solely by filtration of the resins and the evaporation of solvent.

The reaction in the presence of triethylamine were extended to formic acid and perfluorooctanoic acid but were unsuccessful.

Reactions with Alcohols. Alcohols such as methanol, ethanol, and phenol react with PMP in the presence of triethylamine, yielding the following Michael-type addition products, 1,1,1,3,4,4,5,5,5-nonafluoro-2-trifluoromethyl-3-alkoxypentane (**10**) and their HF elimination products, 1,1,1,4,4,5,5,5-octafluoro-2-trifluoromethyl-3-alkoxy-2-pentene (**11**) (Scheme 4).[2c]



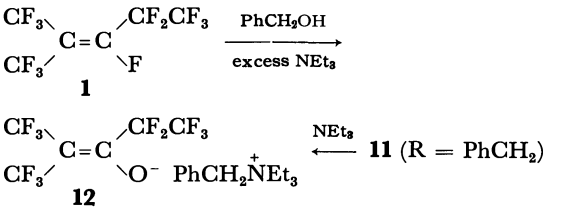
Scheme 4.

It has been found that PMP fluorinates alcohols in the presence of an equimolar amount of triethylamine in an aprotic polar solvent at high reaction temperatures, giving alkyl fluorides in fair to good yields (Scheme 4).

When a mixture of 1-dodecanol, PMP, and triethylamine in a 1 : 1 : 1 mole ratio was made to react in acetonitrile at 80 °C for 8 h, 1-fluorododecane was formed in 28% yield with the enol ether **11** (R=n-$C_{12}H_{25}$). The yield was almost unchanged even when the mole ratio was varied to 1 : 1 : 2, 1 : 2 : 1, and 1 : 2 : 2. Reaction of the mixture in 1 : 1 : 1 mole ratio was examined in various solvents (Table 3). Dipolar aprotic solvents such as DMF and sulfolane, when coupled with higher reaction temperatures, were favorable for the fluorination of alcohols. 2-Octanol was also fluorinated in one-step in moderate yield (runs 15 and 16).

The course of fluorination reaction can be monitored by ^{19}F NMR spectroscopy. In the reaction with 1-octanol, the perfluoro ethers **10** and **11** (R=n-C_8H_{17}) were formed initially in 26 and 56% yields, respectively, the prolonged reaction in sulfolane at 120 °C giving 1-fluorooctane in 74% yield. When the isolated ether **11** (R=n-$C_{12}H_{25}$) was reacted with triethylamine and PMP, 1-fluorododecane was formed in 45—58% yields. This indicates that the fluorination proceeds *via* the attack of fluoride ion on the perfluoro enol ethers **11**.

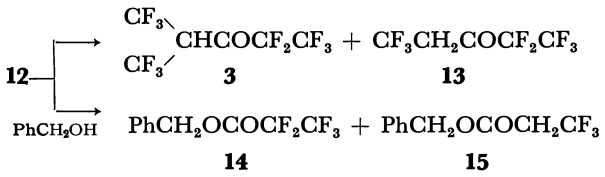
In the reactions with benzyl alcohol (runs 17 and 18), benzyl fluoride was formed in poor yields. Use of potassium carbonate as a base with 18-crown-6 in dichloromethane led to preferential formation of the perfluoroenol ether **11** (R=$PhCH_2$) (84% yield). Use of excess triethylamine gave rise to the formation of a viscous oily product without givin benzyl fluoride



Scheme 5.

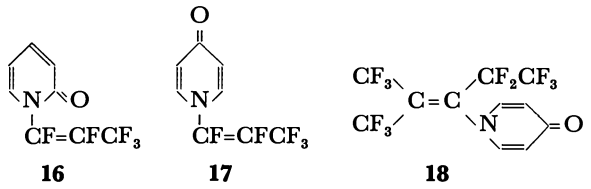
and the enol ether **11**. The oily product was identical with the product readily obtained by mixing the enol ether **11** (R=$PhCH_2$) with triethylamine, and identified as benzyltriethylammonium perfluoro-2-methyl-1-ethyl-1-propenolate (**12**) (Scheme 5).

^{19}F NMR analysis of the reaction of the enolate **12** with trifluoroacetic acid showed that the ketones **3** and **13** are formed in a 2 : 1 ratio (Scheme 6). The acid degradation of the triethylammonium enolate **7** also gave the two products.[7] Enolate **12** reacts slowly with benzyl alcohol, giving the two esters **14** and **15** (Scheme 6). These facts well explain the low yield of benzyl fluoride.

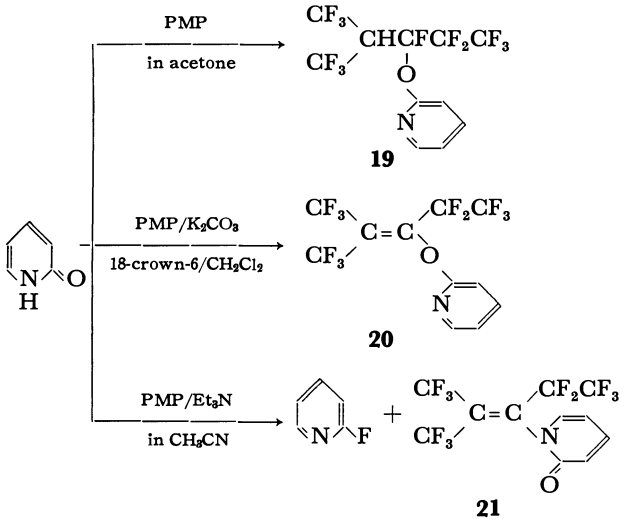


Scheme 6.

Reactions with Some Cyclic Amides. It was claimed in a Japanese patent[11] that 2-pyridone and 4-pyridone react with hexafluoropropene in the presence of potassium carbonate, giving the *N*-substituted products **16** and **17**, respectively. When 4-pyridone was made to

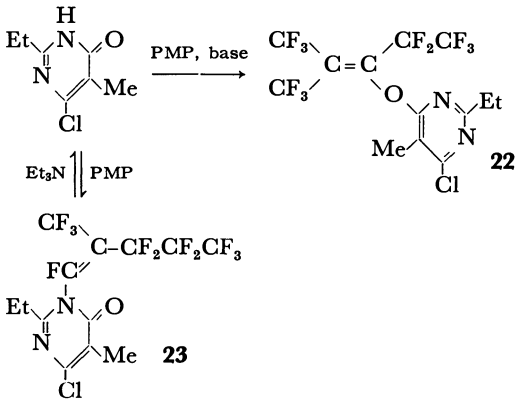


react with excess PMP in the absence of base in acetone at room temperature for 48 h, the *N*-substituted product **18** was formed quantitatively with the HF addition product **6**. However, a similar treatment of 2-pyridone in acetone gave *O*-substituted product, 1,1,1,3,4,4,5,5,5-nonafluoro-2-trifluoromethyl-3-(2-pyridyloxy)pentane (**19**) (Michael-type addition product) in 84% yield. Another *O*-substituted product **20** was formed in 64% yield in dichloromethane in the presence of potassium carbonate and 18-crown-6. When triethylamine was employed as a base and the reaction was conducted in acetonitrile under reflux for 24 h, 2-fluoropyridine was formed in 73% yield with the *N*-substituted product **21** (25% yield) (Scheme 7). Use of DMF as a solvent also gave rise to the formation of 2-fluoropyridine (69% yield) after reaction at 120 °C for 2 h.



Scheme 7.

GLPC analysis of the course of the fluorination revealed that the *O*-substituted pyridine **20** and the *N*-substituted 2-pyridone **21** are initially formed, 2-fluoropyridine being gradually produced at the expence of **20**. Treatment of **20** with PMP and triethylamine in acetonitrile at 80 °C for 12 h gave 2-fluoropyridine in 90% yield (^{19}F NMR). No reaction took place in the absence of PMP. The reaction of **19** with triethylamine gave 2-fluoropyridine in 75% yield (^{19}F NMR). These facts clearly indicate that the fluorination occurs through the *O*-substituted pyridines **19** and **20**, and that active fluoride ion can also be formed by the degradation of PMP by triethylamine.



Scheme 8.

Fluorination by PMP in the presence of bases was extended to two pyrimidinones and cyanuric acid. 6-Hydroxy-2-methyl-4(3*H*)-pyrimidinone and cyanuric acid were recovered unchanged by the reaction in dichloromethane at room temperature for 48 h. By a similar treatment of 6-chloro-2-ethyl-5-methyl-4(3*H*)-pyrimidinone with excess PMP in the presence of base, the *O*-substituted product **22** was obtained in good yield (Scheme 8). No fluorination was observed even in the presence of triethylamine in dry sulfolane.

Close examination of the early stage of the reaction shows that the *N*-substituted products having larger retention volume are also formed as a mixture of at least three isomers, two of which were confirmed to be the unexpected *cis* and *trans* isomers **23** (Scheme 8). The attack of nucleophiles on the trifluoromethyl of PMP, *i.e.* the replacement of the allylic fluorine of PMP followed by rearrangement, was also observed in the cyclization reaction of PMP with *N,N*-dimethylhydrazine.[12] When a mixture of the *O*-substituted and *N*-substituted products was treated with triethylamine at room temperature, the *N*-substituted products gradually decomposed into the starting pyrimidinone, the *O*-substituted product **22** remaining unchanged.

Conclusion. The fluorination reactions of PMP

consist of two reactions, (a) replacement of the vinylic fluorine by carboxylates, alkoxides, or enolates leading to the perfluoropropenol esters or ethers, and (b) perfluoro enol oxygen-carbon fission followed by displacement by fluoride ion. The preferential fission of the enol oxygen-carbon was also observed in the isopropenyl derivatives.[13] Triethylammonium fluoride formed during the course of reactions in the presence of triethylamine might be the source of active fluoride ion causing an effective enol oxygen-carbon fission. The present fluorination reactions can be conducted in conventional glass vessels, the by-products being easily separable low-boiling substances and salts. Stable, storable, and low toxic PMP can be easily prepared from hexafluoropropene and is very easy to handle.[14] PMP appears to be advantageous as a small-scale fluorinating reagent as compared with *N,N*-diethyl-2-chloro-1,1,2-trifluoroethylamine,[15] SF_4–amine reagents,[16] HF–amine reagents,[17] and selenium tetrafluoride.[18] From the fact that most perfluoro enol derivatives with boiling points lower than expected are stable against distillation, PMP like trimethylsilyl chloride is promising as a protecting reagent of hydroxyl groups.

TABLE 1. REACTIONS OF BENZOIC ACID WITH PERFLUORO-2-METHYL-2-PENTENE (PMP) IN THE PRESENCE OF INORGANIC BASES WITH AND WITHOUT PHASE-TRANSFER CATALYSIS[a]

a) See Experimental. b) ^1H NMR yield using triphenylmethane as internal references. c) Isolated yield.

Experimental

^1H NMR and ^{19}F NMR spectra were recorded with a JEOL LMN-PS-100 spectrometer, ^{19}F NMR spectra being obtained in the presence of 1,1,2-trichlorotrifluoroethane as an internal standard and peak center positions being given in ppm upfield from trichlorofluoromethane. Mass spectra were determined with a Hitachi RMU-6E mass spectrometer, GC–Mass spectra with a Hitachi RMU-6MG spectrometer at 20 eV connected with a Hitachi M-5201 apparatus using 3 m $\times$3 mm column of 5% Silicone OV-1 on Uniport KS, and IR spectra with a JEOL IR-E spectrophotometer. GLPC analysis and preparative scale GLPC were carried out on a Yanagimoto G-8 model instrument equipped with a thermal conductivity detector. The columns were Silicone SE-30 on a Diasolid L (60—80 mesh) (1.5 m$\times$4 mm) and Silicone OV-1 on a Uniport KS (60—80 mesh) (3 m$\times$4 mm).

Materials. Perfluoro-2-methyl-2-pentene (PMP) (supplied from Neos Co. Kobe) was used after distillation. All inorganic bases were used after being ground to powder and dried in a vacuum oven at 100 °C for 24 h. 6-Chloro-2-ethyl-5-methyl-4(3*H*)-pyrimidinone was prepared from propionitrile, phosgene and hydrogen chloride.[16] Amberlite IRA-900 (ammonium chloride type) and IRA-68 (tertiary amine type) (resin **8**) were used after washing and drying. Other commercial chemicals were used after purification.

Preparation of the 2-(Dimethylamino)ethoxy Resin **9**. 2-(Dimethylamino)ethanol (5.5 g, 61.8 mmol) and 40 ml of toluene were placed in a 100 ml three-necked flask equipped with a magnetic stirrer, reflux condenser, thermometer, and an inlet tube for nitrogen gas. Into this was added sodium hydride (2.0 g, *ca.* 42 mmol) under nitrogen. After the solution had been stirred at room temperature until the evolution of hydrogen gas ceased, 3.0 g of chloromethylated poly (styrene) (6.48 mmol) (2% DVB) (100—200 mesh) (Nakarai Chemical Co.) was added. The flask was then placed in an oil bath maintained at 85 °C and the mixture was stirred for 48 h under nitrogen. The resulting resin (**9**) was collected by filtration, washed successively with 350 ml of 4 : 1 THF : H_2O and 500 ml of THF, and washed continuously with THF using a Soxhlet apparatus for 48 h and then dried *in vacuo* at 100 °C. The resin (3.13 g) was obtained. Found: C, 86.09; H, 8.00; N, 2.35; Cl, 0.29%. Calcd for: C, 85.79; H, 8.33; N, 2.61; Cl, 0.29%. Calulation is based on chloromethyl unit mole of the starting resin, the degree of cross-linking by 2% DVB, and the unreacted chlorine content of the resin. Dimethylamino unit: 1.87 mmol/g-resin (dry).

Reactions. The technique used in each reaction was almost the same. Hydroxyl compounds (10 mmol), base (equivalent), and solvent (10 ml) were placed in a 30 ml-flask equipped with a magnetic stirrer and a reflux condenser. When necessary, phase transfer catalysts (4—56 mol%) were added. Stirring was started and the slurry was cooled down to 0 °C with an ice-water bath. PMP (10 mmol or more) was added dropwise and the reaction mixture was then warmed to room temperature or higher. After an appropriate reaction time the solid products and/or solid catalysts were filtered off and the filtrate was concentrated, distilled and analyzed by GLPC, ^1H NMR, and ^{19}F NMR spectroscopy. In case of the reaction mixture containing high-boiling solvent and/or ammonium salts, the products were extracted continuously with pentane using a liquid-liquid extraction apparatus. Most products were known compounds, giving ^1H NMR, ^{19}F NMR, IR, and mass spectra in line with their structures. The following are representative examples (Tables 1, 2, and 3.)

Reaction of Benzoic Acid with PMP in the Presence of K_2CO_3 and Octaglyme (Table 1 and run 7). Benzoic acid (1.22 g, 10 mmol), PMP (3 g, 10 mmol), K_2CO_3 (0.7 g, 5 mmol) and octaglyme (1 g) were made to react in CH_2Cl_2 (10 ml) under reflux for 8 h. After removal of solvent, the concentrate was distilled under reduced pressure, giving two fractions (Fr-1 2.49 g, Fr-2 0.16 g). GLPC analysis showed that each fraction consists of the benzoyl fluoride (**2**, R=Ph) and the ester **4** (R=Ph). Thus the fractions were quantitatively analyzed by GLPC (Silicone SE-30, toluene as an internal reference. *cf.* Table 1). In another reaction under similar conditions, a very small amount of the ester **5** (R=Ph) with a larger retention volume than that of **4** (R=Ph), was also observed with a trace of an unidentified product having the

largest retention volume.

Reaction of Benzoic Acid with PMP in the Presence of $CaCO_3$ (run 14). Benzoic acid (1.22 g) was treated with $CaCO_3$ (0.5 g) and PMP (3 g) in acetone (10 ml) under reflux for 12 h. The reaction mixture was concentrated and distilled under reduced pressure, giving a distillate (3.2 g). GLPC analysis indicated that it consists of the ester **5** (R=Ph), a small amount of the ester **4** (R=Ph), and traces of benzoyl fluoride and an unidentified product.

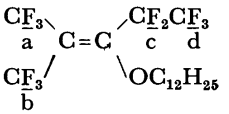
Reaction of Benzoic Acid with PMP in the Presence of Triethylamine (Table 2 and run 1). Benzoic acid (1.22 g) was treated with triethylamine (1.0 g) and PMP (3 g) in acetone (30 ml) at room temparature for 3 h. After removal of solvent, the concentrate was distilled under reduced pressure, yielding benzoyl fluoride (1.2 g, 86%) and triethylammonium perfluoro-2-methyl-1-ethyl-1-propenolate (**7**) (1.2 g, 30%). The latter product gave IR, ^{19}F NMR, and mass spectra in line with those of the product obtained by the reaction of PMP with triethylamine and water in acetonitrile. (bp 40—55 °C/0.1—0.2 Torr, lit,[8] 44.5 °C/0.2 Torr). (1 Torr=133.322 Pa).

Reaction of Octanoic Acid with PMP in the Presence of the Amberlite-IRA-68 (resin 8) (Table 2 and run 10). Octanoic acid (1.44 g, 10 mmol), PMP (3.0 g, 10 mmol), and Amberlite IRA-68 (1 g, 5.6 mmol of the amino unit) was made to react in 10 ml of acetone at room temperature for 48 h. The reaction mixture was filtered, concentrated, and distilled under reduced pressure, giving octanoic acid fluoride (1.31 g, 81%).

Reaction of Octanoic Acid with PMP in the Presence of the Resin 9 (Table 2 and run 13). Octanoic acid (0.144 g), PMP (0.3 g), and the resin **9** (0.05 g, 0.1 mmol) were allowed to react in benzene (1 ml) at room temparature for 48 h. The reaction mixture was filtered, concentrated, and analyzed by GLPC and ^1H NMR. GLPC analysis showed the disappearance of the starting octanoic acid and the absence of the ester **4** ($R=C_8H_{17}$). On the basis of ^1H NMR analysis, 90% yield of octanoic acid and 10% yield of the ester **5** ($R=C_8H_{17}$) were confirmed.

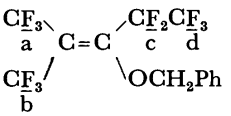
Reaction of 1-Dodecanol with PMP in the Presence of Triethylamine (Table 3 and run 2). A mixture of 1-dodecanol (1.86 g, 10 mmol), triethylamine (1.0 g, 10 mmol), and PMP (3.0 g, 10 mmol) was treated in acetonitrile (10 ml) under reflux for 8 h. After removal of the solvent, the product was extracted with pentane using a liquid-liquid extraction apparatus (8 h). The extract was concentrated to *ca.* 20% solution and analyzed by ^1H NMR spectroscopy. 40% yield of dodecyl fluoride was confirmed. By vacuum distillation, a mixture (2.03 g) of dodecyl fluoride and 1,1,1,4,4,5,5,5-octafluoro-2-trifluoromethyl-3-dodecyl-2-pentene (**11**) was obtained. The latter product (*ca.* 29% yield), confirmed on the basis of ^1H NMR and GLPC analysis, was isolated by preparative GLPC: IR (neat) 2940 (CH_2), 1640 (C=C), 1100—1400 (C–F) cm^{-1}; MS (70 eV), *m/e* (rel intensity, fragmentation), 466 (<1, M^+), 423 (<1, $M^+-C_3H_7$), 409 (<1, $M^+-C_4H_9$), 395 (<1, $M^+-C_5H_{11}$), 381 (<1, $M^+-C_6H_{13}$), 281 (<1, C_6F_{11}), 259 (<1, C_6F_9O), 181 (<1, C_4F_7), 179 (<1, C_4F_6HO), 169 (<1, $C_{12}H_{25}$), 168 (<1, $C_{12}H_{24}$), 159 (2, C_4F_5O), 140 (1, $C_{10}H_{20}$), 128 (4, C_9H_{20}), 119 (1, C_2F_5), 113 (9, C_8H_{17}), 112 (1, C_8H_{16}), 111 (2, C_8H_{15}), 99 (14, C_7H_{15}), 98 (3, C_7H_{14}), 97 (6, C_7H_{13}), 86 (4, C_6H_{14}), 85 (31, C_6H_{13}), 84 (4, C_6H_{12}), 83 (9, C_6H_{11}), 82 (2, C_6H_{10}), 72 (3, C_5H_{12}), 71 (79, C_5H_{11}), 70 (8, C_5H_{10}), 69 (15, CF_3), 68 (3), 67 (3), 58 (5), 57 (100), 56 (9), 55 (27), 54 (3), 53 (2), 44 (3), 43 (78), 42 (10), 41 (35), 39 (15): ^{19}F NMR ($CDCl_3$) $\delta_a=56.9$, $\delta_b=60.0$, $\delta_c=114.5$, $\delta_d=81.2$, $J_{a-b}=9.8$, $J_{a-c}=20.2$, $J_{a-d}=3.3$ Hz.

Fluorination of 1-Dodecanol with PMP (Table 3 and run 12). 1-Dodecanol (1.86 g, 10 mmol) was treated with triethylamine (1.0 g, 10 mmol) and PMP (3.0 g, 10 mmol) in 5 ml of sulfolane at room temperature until the reaction mixture became homogeneous. The mixture was further reacted at 130 °C for 2 h. After removal of the low-boiling products, the residue was extracted with pentane using a liquid-liquid extraction apparatus (6 h). The extarct was distilled to give 1.26 g of pure dodecyl fluoride (67% yield).



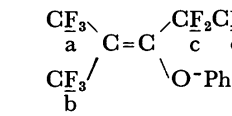
11 (P = $C_{12}H_{25}$)

Reaction of Benzyl Alcohol with PMP in the presence of K_2CO_3 and 18-Crown-6. To a slurry of benzyl alcohol (0.54 g, 5 mmol), K_2CO_3 (0.35 g, 2.5 mmol), and CH_2Cl_2 (10 ml) were added PMP (1.5 g, 5 mmol) and 18-crown-6 (0.13 g, 0.5 mmol). The mixture was refluxed for 4 h. The solid products were filtered and the filtrate was concentrated and distilled under reduced pressure, giving 1,1,1,4,4,5,5,5-octafluoro-2-trifluoromethyl-3-benzyloxy-2-pentene (**11**) (1.63 g, 84% yield): bp 56 °C/4 Torr; IR (neat) 1640 ($(CF_3)_2C$=C), 1100—1400 (C–F); MS (70 eV), *m/e* (relintensity, fragmentation), 388 (<1, M^+), 181 (2, C_4F_7), 179 (2, C_4F_5HO), 159 (2, C_4F_5O), 119 (2, C_2F_5), 107 (5, $PhCH_2O$), 91 (100, $PhCH_2$); ^{19}F NMR ($CDCl_3$) $\delta_a=56.6$, $\delta_b=59.6$, $\delta_c=114.3$, $\delta_d=81.3$, $J_{a-b}=9.5$, $J_{a-c}=20$, $J_{a-d}=3.3$, $J_{b-d}\simeq 1$, $J_{c-d}\simeq <1$ Hz.



11 (R = $PhCH_2$)

Isolation of Benzyltriethylammonium Perfluoro-2-methyl-1-ethyl-1-propenolate (12). Benzyl alcohol (1.08 g, 10 mmol) was treated with PMP (3.0 g, 10 mmol) and triethylamine (1.01 g, 10 mmol) in dichloromethane (10 ml) at room temperature for 24 h. The reaction mixture was concentrated and distilled under reduced pressure. The distillate (0.723 g) consists of the enol ether **11** (R=$PhCH_2$) and the ammonium enolate **7** as a minor component. The residue is identical with benzyltriethylammonium perfluoro-2-methyl-1-ethyl-1-propenolate (**12**), which was obtained quantitatively by the 1 : 1 reaction of the enol ether **11** and triethylamine in CH_2Cl_2: IR (neat) 1600 ($(CF_3)_2C$=C), 1100—1400 (C–F) cm^{-1}; MS (70 eV, DI), *m/e* (rel intensity, fragmentation), 163 (13, $PhCH_2NEt_2$), 148 (48, $PhCH_2NEtCH_2$), 91 (100, $PhCH_2$); ^1H NMR ($CDCl_3$) δ=1.4 (9H, t), 3.2 (6H, q), 4.4 (2H, s), 7.7 (5H, s); ^{19}F NMR ($CDCl_3$) $\delta_a=49.8$, $\delta_b=55.3$, $\delta_c=117.3$, $\delta_d=81.6$, $J_{a-b}=10.7$, $J_{a-c}=19.6$, $J_{a-d}=1.4$, $J_{b-c}=2.0$, $J_{b-d}<1$, $J_{c-d}<1$, Hz.



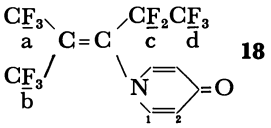
12

The chemical shift at 166.9 ppm observed can be assigned to the fluoride ion of triethylammonium fluoride formed during the course of reaction.

Reaction of the Benzyltriethylammonium Enolate 12 with Benzyl Alcohol. The ammonium enolate **12** (0.389 g, 0.08 mmol) was reacted with benzyl alcohol (0.11 g, 0.1 mmol) in 1 ml of CH_2Cl_2 at room temperature for 3 d. GC mass analysis showed that benzyl perfluoropropionate (**14**) and benzyl 3,3,3-trifluoropionate (**15**) are formed with a small amount of benzyl fluoride. Products **14** and **15** were isolated by preparative GLPC and analyzed. Benzyl perfluoropropionate (**14**): IR (neat) 1780 (C=O), 1215, 1155 (C–F), 1025 (C–O ester) cm^{-1}; MS (70 eV), *m/e* (rel intensity, fragmentation), 254 (57, M^+), 204 (1, $M^+-C_2F_5$), 119 (10, C_2F_5), 107

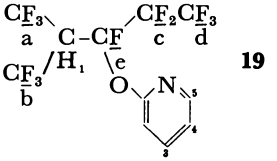
(11, $PhCH_2O$), 91 (100, $PhCH_2$), 90 (93, PhCH); ^1H NMR ($CDCl_3$) $\delta=5.32$ (2H, s), 7.34 (5H, s); ^{19}F NMR ($CDCl_3$) $\delta=84$ (3F, t), 122.6 (2F, q), $J=1.8$ Hz. Benzyl 3.3.3-trifluoropropionate (**15**): IR (neat) 1755 (C=O) cm^{-1}; MS (70 eV) *m/e* (rel intensity, fragmentation), 218 (42, M^+), 198 (4, M^+-HF), 111 (6, CF_3CH_2CO), 108 (100, $PhCH_2OH$ or $C_3F_2H_2O_2$), 107 (20, $PhCH_2O$), 91 (70, $PhCH_2$ or C_3F_2OH), 90 (84, PhCH, or C_3F_2O); ^1H NMR ($CDCl_3$) $\delta=3.16$ (2H, q, $J_{H-F}=10$ Hz), 5.16 (2H, s), 7.34 (5H, s); ^{19}F NMR ($CDCl_3$) $\delta=64.3$ (t, $J_{F-H}=10$).

Reaction of 4-Pyridone with PMP. 4-Pyridone having one mole of water of crystalization (0.452 g, 4 mmol) was treated with PMP (3 g, 10 mmol) in acetone (10 ml) at room temperature for 6 h. GLPC analysis indicated the formation of a single product. After the reaction mixture was evaporated to dryness, the solid product was purified by sublimation under reduced pressure (1 Torr, 120—140 °C), giving 1-(perfluoro-2-methyl-1-ethyl-1-propenyl)-4-pyridone (**18**) (0.82 g, 55% yield): mp 90—93 °C; IR (KBr disk) 1660 (shoulder) ($(CF_3)_2$-C=C), 1635 (C=O) cm^{-1}; MS (70 eV), *m/e* (rel intensity, fragmentation), 375 (10, M^+), 356 (1, M^+-F), 347 (7, M^+-CO), 337 (5, M^+-F_2), 328 (2, M^+-CFO), 318 (1, M^+-3F), 309 (3, M^+-CF_2O), 124 (100, C_6H_3FNO), 105 (48, C_6H_3NO), 96 (59, C_5H_3FN), 77 (37, C_5H_3N), 69 (13, CF_3), 51 (22, C_4H_3), 50 (19, CF_2), 44 (100, CH_2NO); ^1H NMR (acetone-d_6) $\delta_1=7.87$ (d), $\delta_2=6.26$ (d), $J_{12}=ca.$ 9 Hz; ^{19}F NMR (acetone-d_6) $\delta_a=58.1$, $\delta_b=60.5$, $\delta_c=112.7$, $\delta_d=80.5$, $J_{a-b}=10.8$, $J_{a-d}=9.7$, $J_{b-d}<1$, $J_{b-c}<1$, $J_{c-d}=2.0$ Hz. The same reaction (4-pyridone, 22.6 mg (0.2 mmol) and PMP, 300 mg (1 mmol) in acetone-d_6 (1 ml))was monitored by ^1H NMR and GLPC analysis. Quantitative formation of **6** and **18** was confirmed, suggesting that PMP acts as a scavenger of HF.



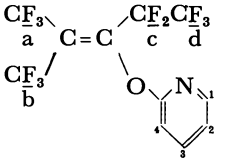
18

Reaction of 2-Pyridone with PMP in the absence of Base. 2-Pyridone (0.95 g, 10 mmol) was treated with PMP (6 g, 20 mmol) in acetone (15 ml) at room temparature for 3 h. After removal of the solvent, the unreacted 2-pyridone was filtered and the residue distilled unde reduced pressure, giving 1,1,1,3,4,4,5,5,5-nonafluoro-2-trifluoromethyl-3(2-pyridyloxy)-pentane (**19**) (3.31 g, 84% yield): bp 66—66.5 °C/5 Torr; IR (neat) 1600 (ring), 1170—1300 (C–F) cm^{-1}; MS (70 eV), *m/e* (rel intensity, fragmentation), 395 (1, M^+), 376 (1, M^+-F), 356 (1, M^+-HF_2), 306 (8, M^+-CHF_4), 300 (3, C_6F_{12}), 281 (27, C_6F_{11}), 231 (35, C_5F_9), 212 (5, C_5H_8), 193 (4, C_5F_7), 181 (100, C_4F_7), 162 (2, C_4F_6), 159 (3, C_4F_5O), 143 (9, C_4F_5), 97 (16, C_5H_4FN), 95 (47, C_5H_5NO), 78 (90, C_5H_4N), 69 (90, CF_3), 51 (13, CF_2H); ^1H NMR ($CDCl_3$) $\delta_1=6.20$ (heptulet), $\delta_2=6.90$ (d), $\delta_3=7.76$ (mc), $\delta_4=7.17$ (mc), $\delta_5=8.21$ (dd), $J_{1a}=J_{1b}=8.6$, $J_{1-e}=8.6$, $J_{23}=ca.$ 8, $J_{34}=ca.$ 8, $J_{45}=ca.$ 5; ^{19}F NMR ($CDCl_3$) $\delta_a,\delta_b=60.1$ (mc), $\delta_c=122.1$ (m), $\delta_d=79.5$ (d), $\delta_e=115.3$ (m), $J_{a-c}=J_{b-c}=ca.$ 26, $J_{d-e}=12$ Hz.



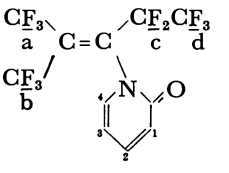
19

Reaction of 2-Pyridone with PMP in the presence of K_2CO_3 and 18-Crown-6. 2-Pyridone (0.476 g, 5 mmol) was treated with PMP (3.0 g, 10 mmol) in CH_2Cl_2 (10 ml) in the presence of K_2CO_3 (0.7 g, 5 mmol) and 18-crown-6 (0.15 g, 0.56 mmol) at room temparature for 24 h. The reaction mixture was worked up as described above, giving 1,1,1,4,4,5,5,5-octafluoro-2-trifluoromethyl-3(2-pyridyloxy)-2-pentene (**20**) (1.21 g, 64% yield): bp 57 °C/10 Torr; IR (neat) 1665 ($(CF_3)_2$-C–C), 1600, 1580 (ring), 1100—1300 (C–F) cm^{-1}. MS (70 eV), *m/e* (rel intensity, fragmentation), 375 (<1, M^+), 356 (8, M^+-F), 337 (<1, M^+-F_2), 318 (1, M^+-F_3), 306 (68, M^+-CF_3), 287 (1, M^+-CF_4), 268 (7, M^+-CF_5), 237 (16, $M^+-C_2F_6$), 218 (2, $M^+-C_2F_7$), 206 (1, $M^+-C_3F_7$), 181 (<1, C_4F_7); 159 (1, C_4F_5O), 119 (1, C_2F_5), 97 (4, C_5H_4FN), 78 (100, C_5H_4N), 69 (10, CF_3), 51 (26, C_4H_3); ^1H NMR ($CDCl_3$) $\delta_1=8.14$ (mc), $\delta_2=7.14$ (mc), $\delta_3=7.74$ (mc), $\delta_4=6.96$ (d), $J_{12}=ca.$ 4.5, $J_{23}=ca.$ 7, $J_{34}=ca.$ 9 Hz; ^{19}F NMR ($CDCl_3$) $\delta_a=57.7$, $\delta_b=61.1$, $\delta_c=113.4$, $\delta=81.4$, $J_{a-b}=9.9$, $J_{a-c}=20.1$, $J_{a-d}=6.2$, $J_{b-c}=1.9$, $J_{c-d}=1.5$ Hz.



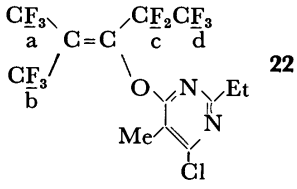
20

Reaction of 2-Pyridone with PMP in the Presence of Triethylamine. 2-Pyridone (0.95 g, 10 mmol), triethylamine (1.0 g, 10 mmol) and PMP (3.0 g, 10 mmol) were treated in 15 ml of acetonitrile under reflux for 24 h. Quantitative analysis by ^{19}F NMR using trifluoromethylbenzene as an internal standard revealed the formation of 2-fluoropyridine (73%) and 1-(perfluoro-2-methyl-1-ethyl-1-propenyl)-2-pyridone (**21**) (25%). The reaction mixture was concentrated under reduced pressure, each product being isolated by preparative GLPC (Silicone SE-30) and analyzed. 2-Fluoropyridine was identified by IR comparison. 1-(perfluoro-2-methyl-1-ethyl-1-propenyl)-2-pyridone (**21**): mp 61—65 °C; IR (KBr disk) 1695 ($(CF_3)_2C=C$), 1610 (ring), 1100—1300 (C–F); MS (70 eV), *m/e* (rel intensity, fragmentation), 375 (2, M^+), 356 (4, M^+-F), 318 (19, M^+-F_3), 306 (33, M^+-CF_3), 268 (100, M^+-CF_3), 243 (8, $M^+-C_3F_5H$), 237 (6, $M^+-C_2F_6$), 78 (86, C_5H_4N), 69 (25, CF_3), 51 (22, C_4H_3); ^1H NMR ($CDCl_3$) $\delta_1=6.54$ (d), $\delta_2=7.38$ (m), $\delta_3=6.24$ (t), $\delta_4=7.0$ (d), $J_{12}=ca.$ 10, $J_{23}=ca.$ 7, $J_{34}=ca.$ 7, $J_{24}=ca.$ 2 Hz; ^{19}F NMR ($CDCl_3$) $\delta_a=58.5$, $\delta_b=61.4$, $\delta_c=110.7$, $\delta_d=80.2$, $J_{a-b}=10.9$, $J_{a-c}=20.7$, $J_{a-d}=9.8$ Hz.



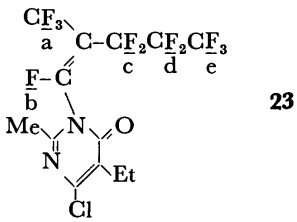
21

Reaction of 6-Chloro-2-ethyl-5-methyl-4(3H)-pyrimidinone with PMP in the presence of Triethylamine. The pyrimidinone (0.518 g, 3 mmol), triethylamine (1.0 g, 10 mmol) and PMP (3.0 g, 10 mmol) were reacted in CH_2Cl_2 (10 ml) at room temparature for 48 h. The reaction mixture was subjected to the usual work-up. Pure 6-chloro-2-ethyl-5-methyl-4-(perfluoro-1-ethyl-2-methyl-1-propenoxy)pyrimidine (**22**) was obtained by vacuum distillation (1.27 g, 94% yield): bp 59 °C/1 Torr; IR (neat) 1675 ($(CF_3)_2C=C$), 1610, 1535 (ring) cm^{-1}; MS (70 eV), *m/e* (rel intensity, fragmentation), 452 (19, M^+), 433 (7, M^+-F), 383 (100, M^+-CF_3), 345 (31, M^+-CF_5), 334 (17, $M^+-C_2H_3F_3Cl$), 171 (6, $M^+-C_6F_{11}$), 155 (40, $M^+-C_6F_{11}O$), 69 (17, CF_3); ^1H NMR ($CDCl_3$) $\delta=1.25$ (3H, t), 2.28 (3H, s), 2.84 (2H, q), $J=8$ Hz; ^{19}F NMR ($CDCl_3$) $\delta_a=57.9$, $\delta_b=61.3$, $\delta_c=113.5$, $\delta_d=81.7$, $J_{a-b}=10$, $J_{a-c}=20.5$, $J_{a-d}=6.2$, $J_{b-d}=-1$, $J_{b-c}=1.3$, $J_{c-d}=1.5$ Hz.



22

Reaction of 6-Chloro-2-ethyl-5-methyl-(3H)-pyrimidinone with PMP in the presence of K_2CO_3 and 18-crown-6. The pyrimidinone (0.518 g, 3 mmol) was reacted with PMP (3.0 g, 10 mmol) in CH_2Cl_2 (10 ml) in the presence of K_2CO_3 (0.7 g, 5 mmol) and 18-crown-6 (0.08 g, 0.3 mmol) at room temparature for 8 h. The reaction mixture was worked up in the usual manner, 0.86 g of the oil products being obtained by vaccum distillation. GLPC analysis (Silicone OV-1, 120 °C, 60 ml (H_2)/min) showed the formation of one major product (retention volume 64 ml) with three minor components (retention volume: peak a, 90 ml, peak b, 110 ml, peak c, 130 ml, peak area ratio a : b : c = 1 : 4 : 6). Each component was isolated by preparative GLPC. The major product was identified as **22** and the components b and c as isomers of 6-chloro-5-ethyl-2-methyl-3-(perfluoro-2-methyl-1-pentenyl)-4(3H)-pyrimidinone (**23**). component b: IR (neat) 1710 (RfC=CF and C=O), 1605 and 1530 (ring) cm^{-1}. MS (70 eV), *m/e* (rel intensity, fragmentation), 452 (13, M^+), 433 (<1, M^+-F), 383 (1, M^+-CF_3), 333 (1, C_2F_5), 283 (17, $M^+-C_3F_7$), 181 (<1, C_4F_7), 171 (1, $M^+-C_6F_{11}$), 155 (100, $M^+-C_6F_{11}O$), 69 (6, CF_3); ^1H NMR ($CDCl_3$) $\delta=1.30$ (3H, t), 2.86 (2H, q), 2.27 (3H, s), $J=8$ Hz; ^{19}F NMR ($CDCl_3$) $\delta_a=57.5$, $\delta_b=51.9$, $\delta_c=109.2$, $\delta_d=126.5$, $\delta_e=81.3$, $J_{a-b}=25.4$, $J_{a-c}=12.2$, $J_{a-d}=6.6$, $J_{b-c}=10.3$, $J_{c-e}=10.3$ Hz. Component c: IR (neat) 1710 (RfC=CF), 1610, 1535 (ring)



23

cm^{-1}; MS (70 eV), *m/e* (rel intensity, fragmentation), 452 283 (16, $M^+-C_3F_7$), 181 (<1, C_4H_7), 155 (100, $M^+-C_6F_{11}O$), 69 (5, CF_3); ^1H NMR ($CDCl_3$) $\delta=1.28$ (3H, t), 2.30 (3H,s), 2.85 (2H, q), $J=8$ Hz; ^{19}F NMR ($CDCl_3$) $\delta_a=58.0$, $\delta_b=53.3$, $\delta_c=109.5$, $\delta_d=127.4$, $\delta_e=81.2$. The spectrum was less amenable to analysis due to the combined effects of many unresolved couplings; component a was only analyzed by GC-mass spectrum: MS (20 eV) *m/e* (rel intensity, fragmentation), 452 (100, M^+), 433 (8, M^+-F), 383 (23, M^+-CF_3), 333 (17, $M^+-C_2F_5$), 281 (22, C_6F_{11}), 171 (46, $M^+-C_6F_{11}$), 155 (18, $M^+-C_6F_{11}O$), 69 (4, CF_3).

The authors wish to express their thanks to Prof. Daniel Swern, Temple University, for his encouragement and helpful suggestion. They are also grateful to the Neos Co. Ltd. for the supply of the fluorocompounds. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Sulfonation of 4*H*-Cyclopenta[*def*]phenanthrene and Its Carbonyl Derivative

Masaaki Yoshida,* Makoto Kobayashi, Masahiro Minabe, and Kazuo Suzuki

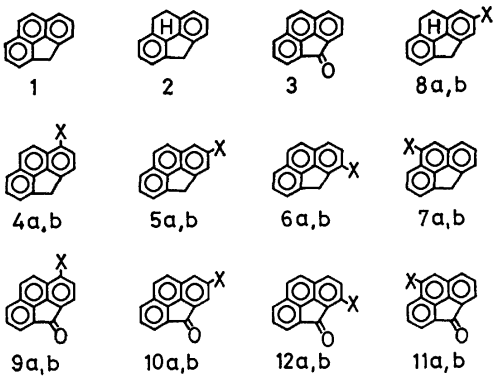
Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321

(Received July 10, 1980)

The sulfonation of 4*H*-cyclopenta[*def*]phenanthrene gave 1-sulfonic acid accompanied by formation of 2-, 3-, and 8-analogues. The reaction of 8,9-dihydro derivative with sulfuric acid in acetic anhydride yielded exclusively the 2-acid. Also, 4*H*-cyclopenta[*def*]phenanthren-4-one afforded the 8-acid as the main product, and 1- and 2-isomers as minor products. The formation of the keto 2-sulfonic acid would be controlled thermodynamically and that of the 8-isomer is controlled kinetically.

The hydrocarbon 4*H*-cyclopenta[*def*]phenanthrene (**1**) is a characteristic arene. It was the subject of some interesting studies at its active methylene[1,2] and at its C_8–C_9 bond.[3] The reactivity in electrophilic substitution of **1** differs somewhat from those of phenanthrene and of fluorene during nitration,[4] bromination,[5] and acetylation.[6] Sulfonation of phenanthrene[7] and anthracene[8] has been investigated in detail and the distribution for the reaction products has been described.

The present work deals with sulfonation of **1**, 8,9-dihydro-4*H*-cyclopenta[*def*]phenanthrene (**2**), and 4*H*-cyclopenta[*def*]phenanthren-4-one (**3**) in order to clarify the property of the skeleton of **1** toward electrophile.



Scheme 1. (Descriptions **a** shows X=SO_3H and **b** is X=SO_3Et.)

Results and Discussion

The sulfonation of **1** afforded 4*H*-cyclopenta[*def*]-phenanthrene-1- (**4a**), -2- (**5a**), -3- (**6a**), and -8-sulfonic acids (**7a**), as is shown in Table 1 (Scheme 1). The assignment of these compounds was established by comparison of their ^1H NMR spectra with those of their nitro[4] and acetyl analogues.[6] The proportion of each isomer was determined by comparison of liquid phase chromatograms (HLPC) of the ester mixture derived from the reaction products with those of pure esters, **4b**, **5b**, **6b**, and **7b**. The error of the yield was within ± 3 (%) as the average of several experiments and the error of proportion was smaller than ± 1 (%) of the standard.

The predominant formation of **4a** would be explained by asserting that the electron density of the 1-position is higher than those of the other positions; this accords with the other electrophilic substitutions.[4–6]

The proportion of **4a** decreases and that of **6a** increases with elevation of the reaction temperature. In sulfonation of phenanthrene, 1-isomer is obtained moderately at low temperature.[7] These results suggest that the formation of **4a** is controlled kinetically and that of **6a** is controlled thermodynamically. Acid **6a** could be stabilized partially due to the hydrogen bond between the active methylene and the sulfonyl group at the 3-position as in the case of 9*H*-fluorene-1-carboxylic acid.[9]

The sulfonation of **2** gave 8,9-dihydro-4*H*-cyclopenta-[*def*]phenanthrene-2-sulfonic acid (**8a**) exclusively, as occurred with fluorene. Other electrophilic attacks to **2** behave in the same way. This tendency can also be seen in the reaction of 1,2,3,3a-tetrahydro-4*H*-cyclopenta[*def*]phenanthrene with electrophiles. This reaction takes place mainly at the 8-position, which corresponds to the 5-position of acenaphthene.[10]

The electron density at the 1- and 3-positions of ketone **3** would be reduced due to the carbonyl group. The reactivity at the 2- and 8-positions may be important. Sulfonation of **3** was examined using 30% oleum–

* The yield is smaller than 1% as the average. a) A trace amount of **12a** was found.

80% sulfuric acid at 0—160 °C for time periods between 20 min and 24 h. The formation of 4-oxo-4*H*-cyclopenta[*def*]phenanthrene-1- (**9a**), -2- (**10a**) and -8-sulfonic acids (**11a**) was confirmed by comparison of their HLPC with those of pure compounds. Table 2 shows typical runs of sulfonation of **3**. The experimental error of the yield is smaller than ±3 (%) and that of the proportion is within ±2 (%).

The major formation of **11a**, accompanied by **10a**, would be expected because of the influence of the 4-carbonyl group. The proportion of **11a** decreases with extension of the reaction time (runs 2—4), with elevation of reaction temperature (runs 2, 5—7), and with the combination of dilution of the acid and elevation of the temperature (runs 1, 6, 8, and 9). On the contrary, the proportion of **10a** increases.

The reaction of **3** using 20% oleum at 0 °C afforded **11a** (72%) and disulfonic acids (5%). Treatment of **11a** in sulfuric acid at 140 °C yielded **10a**. This finding would suggest that the formation of **11a** is kinetically controlled, that the production of **10a** is governed thermodynamically, and that **10a** forms by isomerization of **11a** under these conditions.

Notice that the positions thermodynamically controlled, that is, the 3-position of **1** and 2-position of **3**, correspond to the positions controlled thermodynamically in naphthalene[11] and phenanthrene.[12]

The π-π^* transition at *ca.* 255 nm on UV spectrum of **5a** shows a larger red shift than those of the other derivatives. This would suggest that the resonance is enlarged by replacement at the 2-position of **1**.[5,6]

The stretching vibrations on IR spectra of **6a** and **6b** show broad and complex peaks due to symmetrical and unsymmetrical S–O bonds. The NMR spectra of the 4-methylene protons of **6a** and **6b** shift to lower fields than those of the other isomers. These findings may be interpreted as due to a combination of an electronic effect and the steric factor between the SO_2 group and methylene group.

The carbonyl absorption of 4-oxo-4*H*-cyclopenta[*def*]-phenanthrene-3-sulfonic acid (**12a**) shifts in frequency about 10 cm^{-1} beyond the shifts those of the others; the UV shows a blue shift at *ca.* 370 nm, beyond that of the parent **3**. These shifts can be explained by the fact that the resonance between the 3-sulfonic acid and the 4-carbonyl group is disturbed both sterically and electronically.

Experimental

All the melting points are uncorrected. The IR spectra were measured on a JASCO IR-G spectrophotometer as KBr disks and the ^1H NMR were determined with a JEOL JNM-C60-HL spectrometer (60 MHz) in D_2O using TSP as internal reference for the sulfonic acids or in $CDCl_3$ using TMS for the esters. The UV spectra were obtained with a JASCO ORD/UV-5 apparatus in H_2O with a scanning speed of 0.76 s/nm. Mass spectra were recorded on a Hitachi RMU-6E apparatus by means of a direct inlet system.

The HLPC data were obtained on an FLC-150 instrument (JASCO) equipped with a UV detector using a reversed phase partition type SS-10-ODS column (JASCO, 25 cm). The elemental analyses of the sulfonic acids show that these crystals have waters of crystallization in the range of 1 to 3 mol, according to the degree of drying.

Sulfonation of 4H-Cyclopenta[def]*phenanthrene (1).* *(a) Quantitative Treatment*: To a solution of **1** (190 mg, 1 mmol) in Ac_2O (9 ml) there was added a mixture of H_2SO_4 (95%, 0.1 ml) and Ac_2O (1 ml); the resulting mixture was stirred for 10 min. After dilution with cold water (100 ml), the precipitate was filtered to give unreacted **1**. The aqueous layer was treated with NaCl and the deposited materials were filtered and ion-exchanged over a cation exchange resin (Amberlite IR-120). The eluate was evaporated off and the residue was extracted with benzene (50 ml). Hexane (150 ml) was added to the solution and the precipitate was filtered. The precipitate was dissolved in water and a part of the solution was titrated with aqueous NaOH (2 mmol/l) to estimate the total yield of the sulfonic acids.

An equimolar amount of NaCl was added to the rest of the solution, which was evaporated, and the residue was treated with $POCl_3$ (2 ml) at 100 °C for 10 min. The reaction mixture was diluted with water and the precipitate was esterified with EtOH (50 ml) in the presence of pyridine (0.5 ml) at 5 °C for 3 h. The ester mixture was applied to HPLC to determine the ratio of isomers. The mobile phase used was (*a*) 2,2,4-trimethylpentane–EtOAc (89/11 volume ratio) or (*b*) hexane–dioxane (92/8). The retention time and the

sensitivity were as follows: **1** (internal standard, 6.1 min for *a*, 6.2 min for *b*, 1.00), **4b** (*a*, 13.5 min, 0.69), **5b** (*a*, 12.5 min, 1.00), **6b** (*b*, 11.1 min, 0.60), and **7b** (*b*, 11.8 min, 0.70).

The reaction mixture of **1** (190 mg, 1 mmol) in dioxane (9 ml) with $ClSO_3H$ (0.2 ml, 3 mmol) in dioxane (1 ml) was treated in a manner similar to that described above.

(b) Separation of ***4a***: A solution of **1** (1.90 g, 10 mmol) in dioxane (50 ml) was refluxed with $ClSO_3H$ (1 ml, 15 mmol) for 10 min and the resulting mixture was poured into cold water (200 ml) containing NaCl (60 g). The precipitate was treated with $POCl_3$ to afford 2.208 g (77%) of the sulfonyl chlorides; these were estirified to give 2.065 g (69%) of the ethyl esters. The ester mixture was recrystallized from benzene–cyclohexane (1/1 volume ratio) to yield 1.082 g (47% based on **1**) of ethyl 4*H*-cyclopenta[*def*]phenanthrene-1-sulfonate (**4b**), mp 159.5—160.5 °C; IR, 1350 and 1165 cm^{-1}; NMR δ 1.23 (3H, t, J=7.2 Hz), 4.11 (2H, q), 4.41 (2H, s), 7.68—7.93 (4H, m), 8.04 (1H, d, J=9.0 Hz, H_8), 8.32 (1H, d, J=7.8 Hz, H_2), and 8.44 (1H, d, J=9.0 Hz, H_9); MS, *m/e*, 298 (M^+), 269, 244, and 189. Found: C, 68.51; H, 4.81%. Calcd for $C_{17}H_{14}O_3S$: C, 68.43; H, 4.73%.

The mother liquor was evaporated to dryness and the residue was dissolved in CCl_4 (100 ml) and chromatographed on a silica gel: the lower band on the column gave 15 mg (1%) of ethyl 4*H*-cyclopenta[*def*]phenanthrene-2-sulfonate (**5b**), mp 167—168 °C; IR, 1349 and 1171 cm^{-1}; NMR δ 1.30 (3H, t, J=7.2 Hz), 4.16 (2H, q), 4.39 (2H, s), 7.64—7.91 (5H, m), 8.13 (1H, s, H_3), and 8.45 (1H, s, H_1); MS, *m/e*, 298 (M^+), 269, and 189. Found: C, 68.57; H, 4.93%. Calcd for $C_{17}H_{14}O_3S$: C, 68.43; H, 4.73%.

The upper band afforded 152 mg (7%) of ethyl 4*H*-cyclopenta[*def*]phenanthrene-3-sulfonate (**6b**), mp 98.5—99.5 °C; IR, 1354 and 1178 cm^{-1}; NMR δ 1.30 (3H, t, J=7.2 Hz), 4.17 (2H, q), 4.67 (2H, s), and 7.67—8.14 (7H, m); MS, *m/e*, 298 (M^+), 269, 253, 244, 205, and 189. Found: C, 68.37; H, 4.86%. Calcd for $C_{17}H_{14}O_3S$: C, 68.43; H, 4.73%.

Sulfonation of 8,9-Dihydro-4H-cyclopenta[def]*phenanthrene (2).* A solution of H_2SO_4 (100%, 0.2 ml) and Ac_2O (1 ml) was added to **2** (576 mg, 3 mmol) in Ac_2O (14 ml). The resulting mixture was stirred for 10 min at room temperature. By a treatment similar to that given above, 506 mg (56% based on **2**) of ethyl 8,9-dihydro-4*H*-cyclopenta[*def*]phenanthrene-2-sulfonate (**8b**) was isolated, mp 144—145 °C; IR, 1357 and 1168 cm^{-1}; NMR δ 1.46 (3H, t, J=7.2 Hz), 3.40 (4H, s), 4.13 (2H, s), 4.30 (2H, q), 7.07—7.40 (3H, m), 7.64 (1H, s, H_1), and 7.78 (1H, s, H_3); MS, *m/e*, 300 (M^+), 271, 245, 207, and 191. Found: C, 67.80; H, 5.29%. Calcd for $C_{17}H_{16}O_3S$: C, 67.97; H, 5.37%.

Sulfonation of 4H-Cyclopenta[def]*phenanthren-4-one (3).*

(a) Quantitative Treatment: A mixture of **3** (204 mg, 1 mmol) and H_2SO_4 (1 ml) was shaken for a prescribed time at a suitable temperature. After dilution with water, the precipitate was filtered to give unreacted **3**. The aqueous layer was treated with NaCl and the deposited materials were ion-exchanged. The eluate was evaporated off and the residue was extracted with EtOAc (50 ml). Hexane (150 ml) was added to the EtOAc solution. The precipitate formed was dissolved in water (200 ml) and submitted to titration and HLPC to estimate the yield of acids and the ratio of isomers, respectively. The mobile phase used in HLPC comprised dioxane (35%) and aqueous Bu_4NBr (5 mmol/l, 65%). The retention time and sensitivity were as follows: **9a** (13.0 min, 45.5), **10a** (14.8 min, 47.1), **11a** (11.5 min, 35.3), **12a** (9.8 min, 36.1), disulfonic acids (*ca.* 5 min, 38.5), and *p*-toluenesulfonic acid (as reference sample, 5.3 min, 1.0).

(b) Separation of ***11b***. A mixture of **3** (2.04 g, 10 mmol) and H_2SO_4 (85%, 10 ml) was stirred for 50 min at 140 °C. After treatment with aqueous NaCl, the sodium salt was refluxed gently with $POCl_3$ (40 ml) for 15 min, giving 2.58 g (85%) of the sulfonyl chloride.

The resulting chloride (3.0 g, 10 mmol) was esterified with dry EtOH (1000 ml) in the presence of pyridine (40 ml) at 5 °C for 7 h and the reaction mixture was poured into cold water. The precipitate was chromatographed on a silica-gel column. The lower band afforded 2.24 g (74% based on sulfonyl chloride) of ethyl 4-oxo-4*H*-cyclopenta[*def*]-phenanthrene-8-sulfonate (**11b**), mp 218—219 °C; IR, 1710 (C=O), 1352, and 1167 cm^{-1}; NMR δ 1.29 (3H, t, J=7.2 Hz), 4.17 (2H, q), 7.51—8.09 (5H, m), 8.42 (1H, d, J=7.8 Hz, H_7), and 8.55 (1H, s, H_9); MS, *m/e*, 312 (M^+), 283, 257, 220, 219, 204, and 203. Found: C, 65.27; H, 3.67%. Calcd for $C_{17}H_{12}O_4S$: C, 65.37; H, 3.87%.

The upper band on the column gave 637 mg (22%) of ethyl 4-oxo-4*H*-cyclopenta[*def*]phenanthrene-2-sulfonate (**10b**) mp 208—209 °C; IR, 1710 (C=O), 1360 and 1173 cm^{-1}; NMR δ 1.33 (3H, t, J=7.2 Hz), 4.21 (2H, q), 7.64—8.03 (5H, m), 8.17 (1H, s, H_3), and 8.53 (1H, s, H_1); MS, *m/e*, 312 (M^+), 283, 257, 220, 219, 204, and 203. Found: C, 65.29; H, 3.93%. Calcd for $C_{17}H_{12}O_4S$: C, 65.37; H, 3.87%.

Isomerization of ***11a***. Acid **11a** (323 mg, 1 mmol) in H_2SO_4 (85%, 1 ml) was heated at 140 °C for 30 min. Upon similar treatment to that described above, 5% of **10a** and 92% of **11a** were detected by HLPC.

Oxidation of Sulfonic Acid Mixture. Hydrocarbon **1** (1.90 g, 10 mmol) was sulfonated with 20% oleum (2 ml) in dioxane (50 ml) under refluxing for 2 h, followed by salting-out, chlorination, and esterification. The yield was 787 mg (26% based on **1**) of the ethyl esters. In addition, 845 mg (44%) of **1** was recovered.

The ester mixture in aqueous EtOH (90%, 110 ml) was heated for 6 h and the solution was evaporated off. The residue was refluxed with MnO_2 (1 g) in water (50 ml) for 30 min. After filtration, the filtrate was added to a solution of $BaCl_2$ (20 g) in water (100 ml) to form the barium salt, which was treated with $POCl_3$, followed by esterification with EtOH. The keto ester was chromatographed on a silica-gel column with benzene. The first eluate afforded 151 mg (5.1% based on **1**) of ethyl 4-oxo-4*H*-cyclopenta[*def*]phenanthrene-1-sulfonate (**9b**), mp 185—186 °C; IR, 1712 (C=O), 1362, and 1172 cm^{-1}; NMR δ 1.30 (3H, t, J=7.2 Hz), 4.16 (2H, q), 7.50—8.04 (5H, m), 8.21 (1H, d, J=7.2 Hz, H_2), and 8.40 (1H, d, J=9.0 Hz, H_9); MS, *m/e*, 312 (M^+), 283, 257, 220, 219, 204, and 203. Found: C, 65.44; H, 3.83%. Calcd for $C_{17}H_{12}O_4S$: C, 65.37; H, 3.87%.

The second eluate gave 8 mg (0.3%) of **10b**, mp 208—209 °C.

The third eluate yielded 43 mg (1.4%) of ethyl 4-oxo-4*H*-cyclopenta[*def*]phenanthrene-3-sulfonate (**12b**), mp 182.5—183.0 °C; IR, 1722 (C=O), 1360, and 1182 cm^{-1}; NMR δ 1.40 (3H, t, J=7.2 Hz), 4.46 (2H, q), and 7.48—8.04 (7H, m); MS, *m/e*, 312 (M^+), 283, 220, 204, and 203. Found: C, 65.43; H, 3.66%. Calcd for $C_{17}H_{12}O_4S$: C, 65.37; H, 3.87%.

Reduction of ***11b***. Ester **11b** (312 mg, 1 mmol) in EtOH (100 ml) was refluxed with $N_2H_4 \cdot H_2O$ (90%, 0.5 ml) for 12 h to give the corresponding hydrazone. The hydrazone was warmed in ethylene glycol (40 ml) containing KOH (2 g) at 170 °C for 3 min and the mixture was poured into water. The precipitate was treated with $POCl_3$ and the chloride was converted into ethyl 4*H*-cyclopenta[*def*]phenanthrene-8-sulfonate (**7b**), yield 164 mg (55%), mp 137—138 °C; IR, 1351 and 1171 cm^{-1}; NMR δ 1.25 (3H, t, J=7.2 Hz), 4.12 (2H, q), 4.37 (2H, s), 7.64—8.00 (5H, m), 8.19—8.44 (1H, m, H_7), and 8.64 (1H, s, H_9); MS, *m/e*, 298 (M^+), 269, 243, and

189. Found: C, 68.70; H, 4.67%. Calcd for $C_{17}H_{14}O_3S$: C, 68.43; H, 4.73%.

By a similar procedure, **10b** (312 mg, 1 mmol) was reduced to **5b** (196 mg, 66%), and **9a** (312 mg, 1 mmol) afforded **4a** (154 mg, 52%).

Hydrolyses of the Esters into the Corresponding Sulfonic Acids. Ester **4b** (298 mg, 1 mmol) was refluxed in EtOH (100 ml) containing water (10 ml) for 6 h to give acid **4a**, yield 287 mg (94%), mp 191—194 °C (dec); IR, 1222, 1165, 1082, and 1034 cm^{-1}; UV_{max} 225 nm (log ε 4.47), 249 (4.62), 293 (3.86), 305 (3.85), 331 (2.95), and 347 (2.87); NMR δ 3.52 (2H, s), 7.01—7.51 (4H, m), 7.71 (1H, d, J=9.0 Hz, H_8), 8.09 (1H, d, J=7.2 Hz, H_2), and 8.28 (1H, d, J=9.0 Hz, H_9); MS, *m/e*, 270 (M^+), 205, and 189.

Acid **5a** was obtained from **5b**, by a method similar to that described above, in a 76% yield, mp 180—183 °C (dec); IR, 1205, 1178, 1095, and 1040 cm^{-1}; UV, 216 (4.52), 256 (4.79), 299 (3.88), 331 (2.54), and 350 (2.40); NMR δ 3.50 (2H, s), 7.03—7.36 (5H, m), 7.90 (1H, s, H_3), and 8.14 (1H, s, H_1); MS, *m/e*, 270 (M^+) and 189.

Acid **6a** was derived from **6b**, yield 95%, mp 175—179 °C (dec); IR, 1257—1128 (broad), 1081, and 1036 cm^{-1}; UV, 225 (4.66), 250 (4.55), 292 (3.96), 304 (3.95), 332 (2.77), and 348 (2.65); NMR δ 4.24 (2H, s), 7.08—7.51 (5H, m), 7.64 (1H, d, J=7.8 Hz, H_1), and 8.02 (1H, d, J=7.8 Hz, H_2); MS, *m/e*, 270 (M^+), 222, 205, and 189.

Acid **7a** was prepared from **7b**, yield 78%, mp 179—183 °C (dec); IR, 1198, 1080, and 1030 cm^{-1}; UV, 226 (4.73), 254 (4.58), 294 (3.78), 304 (3.75), 333 (2.85), and 351 (2.81); NMR δ 3.53 (2H, s), 7.05—7.84 (5H, m), 8.24 (1H, s, H_9), and 8.29 (1H, d, J=7.8 Hz, H_7); MS, *m/e*, 270 (M^+), 205, and 189.

Acid **8a** was obtained from **8b**, yield 86%, mp 179.5—181.0 °C (dec); IR, 1205, 1180, 1097, and 1035 cm^{-1}; UV, 211 (4.58) and 282 (4.16); NMR δ 2.83 (4H, s), 3.46 (2H, s), 6.96—7.23 (3H, m), 8.03 (1H, s, H_1), and 8.21 (1H, s, H_3); MS, *m/e*, 272 (M^+) and 191.

Acid **9a** was derived from **9b**, yield 98%, mp 254—256 °C (dec); IR, 1708 (C=O), 1256, 1224, 1172, 1084, and 1034 cm^{-1}; UV, 235 (5.29), 300 (3.79), and 381 (2.58); NMR δ 6.11—6.93 (5H, m), 7.37 (1H, d, J=9.0 Hz, H_9), and 7.47 (1H, d, J=7.2 Hz, H_2); MS, *m/e*, 284 (M^+), 204, and 203.

Acid **10a** was prepared from **10b**, yield 93%, mp 225—227 °C (dec); IR, 1708 (C=O), 1195, 1188, 1094, and 1049 cm^{-1}; UV, 239 (5.22) and 386 (2.59); NMR δ 6.09—6.81 (6H, m) and 7.23 (1H, s, H_1); MS, *m/e*, 284 (M^+), 204, and 203.

The acid **10a** was also obtained by the acidic hydrolysis of the corresponding sulfonyl chloride in a 79% yield.

Acid **12a** was derived from **12b**, yield 95%, mp 249—255 °C (dec); IR, 1716 (C=O), 1222, 1204, 1094, and 1034 cm^{-1}; UV, 238 (4.96), 275 (4.03), 320 (3.76), and 370 (2.37); NMR δ 6.60—6.89 (5H, m), 7.23 (1H, d, J=8.4 Hz, H_1), and 7.48 (1H, d, J=8.4 Hz, H_2); MS, *m/e*, 284 (M^+), 204, and 203.

Acid **11a** was prepared from **11b**, yield 99%, mp 245—251 °C (dec); IR, 1706 (C=O), 1231, 1202, 1061, and 1021 cm^{-1}; UV, 236 (5.27), 279 (3.94), and 366 (2,38); NMR δ 5.98—7.20 (5H, m), 7.29 (1H, s, H_9), and 7.68 (1H, d, J=7.8 Hz, H_7); MS, *m/e*, 284 (M^+), 204, and 203.

Enzymatic Oxidation of Alkyl Sulfides by Cytochrome P-450 and Hydroxyl Radical

Yoshihito WATANABE, Tatsuo NUMATA, Takashi IYANAGI,** and Shigeru OAE*

Department of Chemistry, University of Tsukuba, Sakuramura, Ibaraki 305

***Division of Biochemistry, School of Medicine, University of Tsukuba, Ibaraki 305*

(Received July 11, 1980)

The oxidation of alkyl sulfides, sulfoxides, and sulfones was examined with either rabbit liver microsomes or a reconstituted system containing purified cytochrome P-450, *S*-dealkylation being found to take place more readily with alkyl sulfides bearing a higher acidic α-hydrogen. Similar results were obtained in the oxidation of alkyl sulfides by hydroxyl radical. Both *S*-dealkylation and *S*-oxygenation products are presumed to be formed *via* the cation radical intermediate.

N- and *O*-Dealkylation with hepatic microsomes and the reconstituted system with purified cytochrome P-450 has been studied with many substrates.[1] However, *S*-dealkylation with hepatic microsomes was observed only with a few anticancer agents such as 6-(methylthio)-purine and its analogues by Mazel *et al.*[2-4] who focused their attention on the effect of inhibitors and the dependency of inducers on *S*-dealkylase activity. They observed the formation of formaldehyde but not that of other products. 6-(Methylthio)purine was reported to be metabolized *in vivo* in man giving 6-mercaptopurine as a urinary metabolite.[5] However, the product analysis was incomplete, and the general nature of *S*-dealkylation has remained unexplored. We found a markedly large structural dependency of alkyl sulfide in the *S*-dealkylation with a few biomimetic oxygenase systems.[6,7]

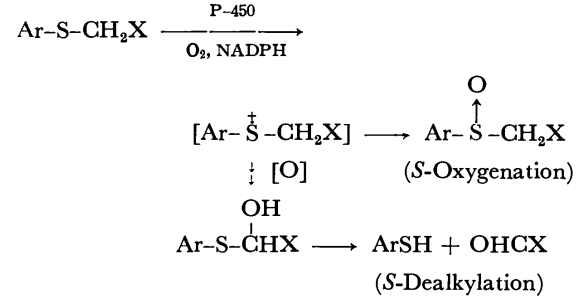
The enzymatic hydroxylation of hydrocarbons by cytochrome P-450 which has recently been examined,[8,9] is suggested to proceed *via* homolytic process involving hydrogen abstruction by iron-bound "oxenoid" species such as $(P\text{-}450\cdot FeO)^{3+}$ analogous to Compound I of peroxidase.[10,11] On the other hand, the oxygenation of sulfur atom of cyclic and acyclic sulfides by cytochrome P-450 seems to result by the electrophilic attack of active oxygen bound to the active site of the heme iron,[12] as suggested by Ullrich and Duppel.[13] We have observed that neither singlet oxygen ($^1O_2$) nor hydrogen peroxide is the active oxygenating species in view of the lack of inhibition with both DABCO (1,4-diazabicyclo[2.2.2]octane, inhibitor for singlet oxygen), and catalase in the reaction with the reconstituted system.[12]

Chemical oxygenation using model systems has been studied,[14-17] the best-studied being Fenton's reagent (hydroxyl radical) which catalyzes the hydroxylation of a variety of substrates.[17]

Gilbert *et al.*[18] and others[19,20] examined the reaction of alkyl sulfides with hydroxyl radical generated by treating hydrogen peroxide with transition metal ions of low oxidation state such as Fe(II) and Ti(III) by means of UV and ESR spectroscopic studies, and found that the cation radical intermediate (III) is formed as the key intermediate in the reaction of sulfides with hydroxyl radical.

We have extended our study on the oxygenation of various sulfides, sulfoxides, and sulfones with phenobarbital-induced rabbit liver microsomes and also with a reconstituted system of purified cytochrome P-450 in order to understand the whole mechanistic feature of the enzymatic oxygenation of organosulfur compounds. We found that both *S*-dealkylation and *S*-oxygenation take place simultaneously, the acidity of α-hydrogen of alkyl sulfides playing an important role in determining the mode of the enzymatic oxygenation (Scheme 1).

We also carried out the oxidation of sulfides by hydroxyl radical and found that a similar mode of oxidation to that in the enzymatic oxygenation takes place.



Scheme 1.

Experimental

Reagents. The following commercial compounds were used. $NADP^+$, D-glucose 6-phosphate (G6P), and D-glucose 6-phosphate dehydrogenase (G6P-DH) (Oriental Yeast); 16% Titanium trichloride solution (Kanto Chemicals); 30% Hydrogen peroxide, diphenyl disulfide, thioanisole, and thiophenol (Wako Chemicals).

Organic Synthesis. All the sulfides except thioanisole, diphenyl disulfide, and 4-(*p*-chlorophenyl)thiane were prepared by treating thiophenol with alkyl halides in the presence of sodium hydroxide in good yields,[21] and isolated by SiO_2 column chromatography (Merck Kieselgel 60, benzene as eluent). ^1H NMR (δ-value in $CDCl_3$, ppm) $PhSCH_2COPh$[22]; 4.05 (2H, s), 7.2—7.6 (8H, m), 7.8—8.0 (2H, m): $PhSCH_2\text{-}C_6H_4\text{-}NO_2\text{-}p$[23]; 4.01 (2H, s), 7.06 (5H, brs), 7.23 (2H, d, J=8.0), 7.93 (2H, d, J=8.0): $PhSCH_2CN$[24]; 3.44 (2H, s), 7.3—7.5 (5H, m): $PhSCH_2Ph$;[25] 4.11 (2H, s), 7.25 (10H, brs).

Deuterated sulfide, $PhSCD_2COPh$, was synthesized by the following method. Twenty equivalent of deuterium oxide (Merck, min 99.75%) was placed into a pyridine solution containing 2 mmol of phenacyl phenyl sulfide (5 ml) under argon atmosphere. The mixture was stirred at room temperature for 2 d, acidified (pH≈3) by adding 4 M HCl at 0 °C, and then extracted three times with chloroform (60 ml). The chloroform layer was washed with 1 M HCl (20 ml) to

remove a small amount of residual pyridine and dried over anhydrous magnesium sulfate. Chloroform was evaporated under reduced pressure and the deuterium content of phenacyl phenyl sulfide was determined from the ^1H NMR spectrum (95%-D_2). 4-(*p*-Chlorophenyl)thiane was prepared by the procedure described by Johnson.[26] ^1H NMR ($CDCl_3$) 2.1 (4H, m), 2.4 (1H, m), 2.8 (4H, m), 7.10 (2H, d, J=8.25), 7.25 (2H, d, J=8.25). All the sulfoxides used for the reactions and authentic samples were synthesized by the oxidation of corresponding sulfides with hydrogen peroxide in acetic acid.[27] ^1H NMR ($CDCl_3$), $PhS(O)CH_2COPh$;[28] 4.23 (1H, d' J=14.3), 4.25 (1H, d, J=14.3), 8—7.4 (10H, m): $PhS(O)CH_2$-C_6H_4-NO_2-*p*;[23] 4.0 (1H, d, J=12.8), 4.16 (1H, d, J=12.8), 7.1 (2H, d, J=9.0), 7.4 (5H, brs), 8.05 (2H, d, J=9.0): $PhS(O)CH_2CN$;[24] 3.70 (1H, d, J=15), 3.88 (1H, d, J=15), 7.6 (5H, m): $PhS(O)CH_2Ph$;[29] 4.0 (2H, brs), 7.4—6.9 (10H, m): $PhS(O)CH_3$;[30] 2.68 (2H, brs), 7.3—7.8 (5H, m), *trans*- and *cis*-4-(*p*-Chlorophenyl)thiane 1-oxide were separated by recrystallization (AcOEt) prior to Al_2O_3 column chromatography[31] (Wako, Alumina activated 200 mesh, AcOEt: $CHCl_3$=4 : 1 as eluent): *trans* sulfoxide; 2.0 (4H, m), 2.7 (1H, m), 2.7 (2H, dt, J=3.0, 12.0), 3.36 (2H, dt, J=2.4, 12.0), 7.0 (2H, d, J=7.5), 7.22 (2H, d, J=7.5): *cis* sulfoxide; 1.8 (2H, m), 2.6 (5H, m), 3.1 (2H, m), 7.11 (2H, d, J=7.5), 7.23 (2H, d, J=7.5). Sulfones were prepared by the treatment of corresponding sulfoxides with hydrogen peroxide in acetic acid.[23] ^1H NMR ($CDCl_3$) $PhS(O_2)CH_2$-C_6H_4-NO_2-*p*;[23] 4.4 (2H, s), 7.3 (2H, d, J=9.0), 7.6 (5H, m), 8.13 (2H, d, J=9.0): $PhS(O_2)CH_3$;[34] 3.05 (3H, s), 7.5—7.7 (3H, m), 7.8—8.1 (2H, m).

All the substrates were distilled or recrystallized prior to use. ^1H NMR spectra described above were recorded on a Parkin Elmer Hitachi R 20 (60 MHz).

Preparation of Microsomes, Purified Cytochrome P-450, and NADPH-Cytochrome P-450 Reductase. The hepatic microsomes (cytochrome P-450, 2.54 nmol/mg protein) were obtained from male rabbit (2—3 kg) pretreated with sodium phenobarbital (50 mg/kg of body weight, each day for 5 d) according to the procedure reported,[12] the purified cytochrome P-450 being obtained by the method of Imai and Sato.[35] NADPH-cytochrome P-450 reductase was purified by the method of Iyanagi *et al.*[36]

Enzyme Assay. The standard reaction mixture for assaying the *S*-dealkylation and *S*-oxygenation activities was made to contain 150—300 μmol of the substrates, the hepatic microsomes (130 mg protein), the NADPH generating system [30 μmol of $NADP^+$, 300 μmol of G6P (2 Na salt), and 36 units of G6P-DH], and phosphate buffer (pH 7.4, 0.1 M) in a final volume of 20 ml. The reaction mixture, except for G6P-DH, was incubated for 10 min at 36 °C to dissolve the substrates, prior to the addition of G6P-DH to the mixture. After the reaction mixture had been incubated at 36 °C for 2 h in the air, the reaction was stopped by adding 10 ml of acetone and 0.5 M of trichloroacetic acid (to pH 3) to the mixture which was cooled at 0 °C for 10 min in order to precipitate protein. After centrifugation (3000 rpm) of the mixture for 15 min, the supernatant layer was separated, neutralized by adding aqueous KOH solution, and then extracted 4 times with chloroform (200 ml). The chloroform layer was dried over anhydrous magnesium sulfate and concentrated under reduced pressure. The residue was diluted with acetone and analyzed by gas chromatography (GLC: Hitachi 163 Gas Chromatograph, 1 m glass column, 10% SE-30) and thin layer chromatography (TLC: Merck, Kieselgel 60-GF_{254}, and Aluminiumoxid GF-254, 60/E). The oxidation products were isolated by preparative TLC (chloroform was used as eluent), and identified by comparison with authentic samples. Formaldehyde was determined by the Nash reagent.[37]

Oxidation of Sulfides with Reconstituted System Containing Purified Cytochrome P-450. After a mixture of 35 nmol of cytochrome P-450, 38 nmol of the reductase and 0.3 ml of 1% detergent (Emalgen 913, KAO-ATRAS Chemicals) had been kept standing at room temperature for 5 min, 134 nmol of catalase, 22 ml of phosphate buffer (pH 7.4, 0.1 M), 250 μmol of G6P, 5 μmol of $NADP^+$, and 36 units of G6P-DH were added to the mixture. The substrate (480 μmol) was then suspended into the reaction mixture and the whole solution was incubated at room temperature for 1 h in the air. After the usual work-up, the products obtained were analyzed by GLC.

Measurement of the Difference Spectra Caused by the Addition of Substrates to the Purified Cytochrome P-450. Cytochrome P-450 (3.6 μM in 0.1 M of phosphate buffer containing 20% glycerol) was placed in 10 mm cuvettes for spectrometric recording. The substrate was dissolved in methanol (0.5—30 μl), into which was added the sample solution. The same volume of methanol was placed in the reference cuvette.

Analytic Procedure. The amount of protein in the microsomes was determined by the method of Lowry *et al.*[38] using bovin serum albumine. The concentration of cytochrome P-450 was determined by the carbon monoxide-difference spectrum of dithionite treated liver microsomes. The absorbance between 450 and 490 nm ($\Delta A_{450-490}$) was used for calculation of cytochrome P-450 content (ε, 91 mM^{-1} cm^{-1}).[39,40] The concentration of purified cytochrome P-450 was determined by measuring the absorption of the oxidized form ($\Delta A_{418-500}$), which has a molar extinction coefficient of 107 mM^{-1} cm^{-1}.[35] (UV: JASCO UVIDEC-1)

Oxidation of Sulfides by Iron(II) Perchlorate–Hydrogen Peroxide System. A mixture of sulfide (0.2 mmol) and iron(II) perchlorate (250 mg, 1 mmol) in methanol–7% perchloric acid aqueous solution (10 ml–5 ml) was stirred at room temperature under argon atomsphere for 5 min. 7% Perchloric acid (5 ml) containing 0.2 ml of hydrogen peroxide (30% solution in water) was then added dropwise slowly to the ethanolic solution and the reaction mixture was stirred for 10 min. The reaction mixture was extracted three times with chloroform (100 ml). The products were determined by GLC and SiO_2-TLC (eluent; $CHCl_3$).

Oxidation of Sulfides by Titanium Trichloride–Hydrogen Peroxide System. A mixture of sulfide (0.25 mmol) and methanol (10 ml) was stirred at room temperature under argon atmosphere for 5 min. Titanium trichloride solution (16% solution, 0.5 ml) was added in one portion to the mixture which was stirred for 1 min prior to the addition of hydrogen peroxide (30%, 0.2 ml) dissolved in 5 ml of H_2O, and the reaction mixture was stirred further for 5 min. The reaction was stopped by adding 30 ml of water and the mixture was subjected to the usual work-up.

Preparation of ^{18}O-Labeled Hepatic Microsomes. The hepatic microsome obtained above was diluted with $H_2{}^{18}O$ which contains 1.5% excess ^{18}O while phosphate buffer was prepared with $H_2{}^{18}O$-containing 1.5% excess ^{18}O (The British Oxygen Company Limited).

Oxidation of Sulfides by ^{18}O-Labeled Titanium Trichloride–Hydrogen Peroxide System. Five ml of ^{18}O-labeled (1.5 atom % excess) water was used instead of ordinary water.

^{18}O-Analyses. All the ^{18}O-labeled substrates were placed in a breakable glass tube together with well-dried $HgCl_2$ and $Hg(CN)_2$. The tube was evacuated by diffusion pump for 15 min, and sealed. The sealed tube was heated at 500 °C for 12 h. The gas (CO_2) produced was distilled repeatedly 3 times and transferred into a sampler of the mass spectrometer (Hitachi RMU 6MG). The ^{18}O-content of carbon dioxide

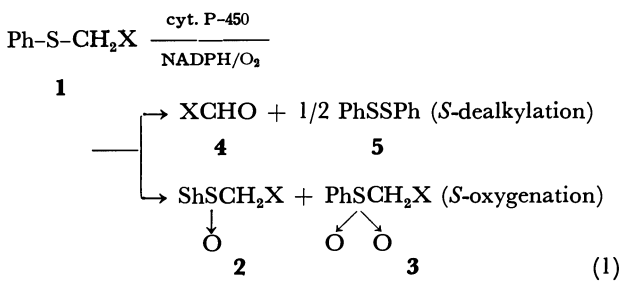
was calculated from the height of flat peaks of *m/e* 44 and 46.

Measurement of Cyclic Voltammogram. Cyclic voltammograms of substrates were obtained in 0.1 M n-Bu_4NClO_4/CH_3CN solution. (scan rate: 300, 150, and 50 mV/s) (Hokuto Denko Ltd., Potentiostat Galvanostat HA-301).

Results

When the β-keto sulfide (**1e**) was incubated with the hepatic microsomes, *S*-dealkylation and *S*-oxygenation took place simultaneously, giving aldehyde (**4e**) and diphenyl disulfide (**5**) as the *S*-dealkylated products and the corresponding sulfoxide (**2e**) as the *S*-oxygenated product (Table 1). Similarly, *p*-nitrobenzyl phenyl sulfide (**1d**) gave *p*-nitrobenzaldehyde (**4d**) together with a comparable amount of **5**, accompanied by sulfoxide (**2d**) and sulfone (**3d**) as the *S*-oxygenated products. This is in contrast to the chemical oxidation of the sulfides (**1d**, **1e**) with hydrogen peroxide or *m*-chloroperbenzoic acid which gave only sulfoxides (**2d**, **2e**). Compounds **2d** and **3d**, microsomal oxidation products, were separated by Al_2O_3-PTLC (eluent; $CHCl_3$: AcOEt=1 : 1) and identified by comparison of mass spectra and GLC with those of authentic samples.

In the oxidation of thioanisole (**1a**) and benzyl



(1)

X: **a** = H, **b** = Ph, **c** = CN, **d** = C_6H_4-NO_2-*p*, **e** = COPh

phenyl sulfide (**1b**), *S*-oxygenation was found to take place predominantly giving the corresponding sulfoxides (**2a** and **2b**), respectively.

Thus, in the microsomal oxidation of alkyl sulfides, the mode of the reaction appears to depend markedly on the structure of the alkyl group; *viz.*, the ratio between the *S*-dealkylation and the *S*-oxygenation was found to increase with the increase of the acidity of α-hydrogen of the alkyl sulfide. (Tables 1 and 8). This trend is analogous to that in the biomimetic oxidation of the same sulfides with both Co^{II}(bzacen)–O_2 system and Udenfriend's system.[6,7]

Table 2. Relative S-dealkylation and S-oxygenation activity of rabbit liver microsomes

Additions		Products[a] PhSCH$_2$COPh (O)	Products[a] PhSSPh
Complete system	Ms. + O_2 + NADPH generating system	100	100
Complete system	minus NADPH generating system	0	0
Complete system	minus Ms. plus boiled Ms	0	0
Complete system	plus 50% CO	80	71

a) Products were compared in final yields determined by GLC described in Experimental part.

The requirements for cofactors in the reaction of the β-keto sulfide (**1e**) are given in Table 2. NADPH was required in the enzymatic reaction while boiled microsomes completely lost activities for both *S*-dealkylation and *S*-oxygenation. Carbon monoxide also inhibited enzymatic activity for both *S*-dealkylation and *S*-oxygenation of **1e**, respectively. This indicates that both *S*-dealkylation and *S*-oxygenation reactions are typical oxidation reactions promoted by cytochrome P-450.

Cyanomethyl phenyl sulfide (**1c**) and *p*-nitrobenzyl phenyl sulfide (**1d**) were metabolized with a reconstituted system, containing purified cytochrome P-450, NADPH-cytochrome P-450 reductase, 1% detergent and a NADPH generating system, and retaining similar activities for both *S*-dealkylation and *S*-oxygenation.

The sulfide (**1d**), however, was insoluble in a reconstituted system so that the net activity was low, and yet the oxidation of **1d** with the reconstituted cytochrome P-450 system was found to proceed in the two types of oxidation as denoted by cytochrome P-450.

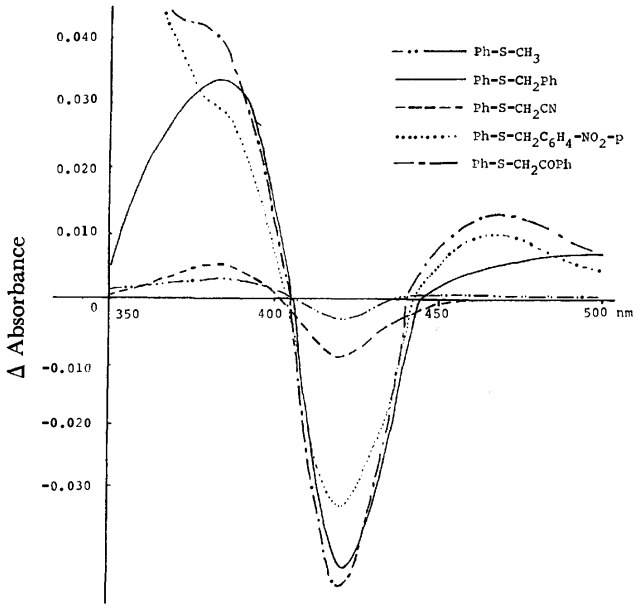


Fig. 1. Cytochrome P-450 from phenobarbital-treated rabbit were diluted to 3.6 μmol in 0.1 M phosphate buffer. After establishment of a base line of equal light absorbance, methanolic solution of sulfide (0.2 mM) was added to the sample cuvvett.

When methanolic solutions (0.5—30 μl) of these sulfides (**1a—e**) were added to the buffer solution of purified cytochrome P-450 (2 ml), and the difference spectra with iron(III) heme were found to be typical type I,[41,42] having a maximum at 385—390 nm and a minimum at 420 nm (Fig. 1), suggesting that the mode of the whole interaction between the sulfides and the hemoprotein is similar during the course of enzymatic oxidation.

The microsomal oxidation of sulfoxides (**2a**, **d**) and sulfones (**3a**, **d**) was performed for further assay of both *S*-oxygenation and *S*-dealkylation (Table 3). However, neither sulfoxides nor sulfones, both of which possess higher acidic α-hydrogen than the corresponding sulfides (see Table 8), underwent facile *S*-dealkylation, *e.g.*, *p*-nitrobenzyl phenyl sulfoxide (**2d**) gave both *S*-dealkylated product (**4d**) and *S*-oxygenated product (**3d**). However, the reaction was slow and the product ratio between the former and the latter is *ca.* 1/3 while in the oxygenation of the corresponding sulfide (**1d**) the ratio is *ca.* 4/3 (Table 3).

Table 3. Microsomal oxidation of sulfides, sulfoxides, and sulfones

In the reaction of the sulfoxide to sulfone with microsomal cytochrome P-450, diphenyl disulfide (**5**) was not obtained as *S*-dealkylated product, despite the formation of the aldehyde, ruling out the possibility of the normal Pummerer rearrangement involving sulfoxide as the reaction intermediate for the *S*-dealkylation of sulfide.

$$\mathrm{Ph\text{-}S\text{-}CH_2X} \xrightarrow[\mathrm{NADPH/O_2}]{\text{cyt. Thioanisole (**1a**) and benzyl phenyl sulfide (**1b**) were found to react with hydroxyl radical generated by the reaction of iron(II) or titanium(III)–hydrogen peroxide system, giving only *S*-oxygenated products (**2a** and **2b**) in contrast to the oxidation of (**1c—e**), which gave both *S*-oxygenated products (**2c—e**) and *S*-dealkylated product (**4**) (Tables 4 and 5). The ratio of **5**/**2** increased from **1c** to **1e**. This is in line with the results given in both the microsomal and the purified cytochrome P-450 oxidations of alkyl sulfides (Table 1). The ratio between *S*-dealkylation and *S*-oxygenation

a) 250 μmol of sulfides was suspended in all cases. b) Determined by GLC and SiO_2 TLC.

was found to vary in different media (Table 4, systems A, B, and C), while the tendency for *S*-dealkylation remained unchanged. The difference between the microsomal and the reconstituted systems can be explained on the basis of varying conditions of media used.

When the 95% deuterated sulfide (**1e**-d_2, $PhSCD_2COPh$) was incubated with hepatic microsomes in the complete system at 36 °C, both *S*-dealkylation and S-oxygenation proceeded concurrently. In this reaction only a small kinetic isotope effect ($k_H/k_D \fallingdotseq 1.2$) was observed while the ratio **5**/**2** remained nearly the same with both **1e** and **1e**-d_2. The k_H/k_D values were computed approximately by [**5**/**2**]/[**5**-d_2/**2**-d_2] for both microsomal and Fenton's oxidation. In the reaction with Fenton's system (system A), k_H/k_D was 1.3, being analogous to that in the oxidation (Table 6). The deuterium label of the recovered sulfide (**1e**-d_2) remained in both cases (measured by ^1H NMR).

When the oxidation of sulfide (**1c**) by both the microsomal and Fenton's oxidation systems was carried out in ^{18}O-labeled phosphate buffer solution, only 1.3 and 4.7% of oxygen were found to be incorporated into the sulfoxide (**2c**) from heavy water, $H_2{}^{18}O$ used (Table 7).

Discussion

A multienzyme system containing cytochrome P-450 located in liver microsomes, and a reconstituted system of the purified cytochrome P-450 and its reductase from liver microsomes of phenobarbital-treated rabbit and NADPH were found to catalyze readily both *S*-dealkylation and *S*-oxygenation of common sulfides and only sluggishly those of sulfoxides and sulfones.

The relatively higher acidity of the α-hydrogen is required for *S*-dealkylation, though other factors are also necessary, since sulfoxides (**2**) and sulfones (**3**) having more acidic α-hydrogen are less reactive than the sulfides for *S*-dealkylation (Tables 1 and 8).

Free radicals are stabilized substantially when the central carbon is substituted by a divalent sulfur atom but less stabilized by an adjacent α-sulfinyl or α-sulfonyl group.[43] This is in line with the trend of the Q-values of substituted vinyl compounds. Vinyl sulfoxide possesses the smallest Q-value in copolymerization as suggested by the stability of α-substituted free radicals ($RS\dot{C}HR' > RS(O_2)\dot{C}HR' \geq RS(O)\dot{C}HR'$ in Table 8). Cyano, *p*-nitrophenyl, and carbonyl groups have larger Q-values than benzyl, and methyl groups.[44] Such a free radical-stabilizing effect of sulfenyl group may be partially responsible for the facile *S*-dealkylation of sulfides.

Several substrates, which are deuterated prior to hydroxylation at aliphatic sites have been tested with hepatic microsomes. Groves *et al.*[8] suggested that hydroxylation by highly purified liver microsomal cytochrome P-450 involves the direct hydrogen abstraction by iron-bound "oxenoid" species $(P\text{-}450\cdot FeO)^{3+}$, which is analogous to Compound I of peroxidase,[11] to generate the carbon radical intermediates on the basis of their observed kinetic isotope effects ($k_H/k_D = 11.5 \pm 1$)[8] and $k_H/k_D = 11 \pm 1$ for benzylic hydroxylation of 1,3-diphenylpropane (and 1,1-dideuterio derivative) by Hjelmeland *et al.*[9]

Sulfides are good substrates for the oxygenation with cytochrome P-450 enzyme system to give sulfoxides.[12,45] Since the "oxenoid" intermediate should be highly electron deficient, *S*-oxygenation is expected to be initiated by an electron transfer from divalent sulfur atom to "oxenoid" species, generating sulfenium cation radical. The oxygenation of alkyl sulfides with a highly purified cytochrome P-450 gave kinetic evidence for one-electron transfer mechanism.[46]

$$Ar\text{–}S\text{–}CH_3 \xrightarrow[\text{rate determining step}]{\text{cyt. P-450 } (FeO)^{3+}} Ar\overset{+}{S}\text{–}CH_3 + (FeO)^{2+} \longrightarrow Ar\text{–}S(\overset{\overset{O}{\uparrow}}{})\text{–}CH_3 + Fe(III) \quad (3)$$

In the oxidative dealkylation of tertiary amine by enzymes, a similar cation radical intermediate seems to be involved.[47] The oxygenation of aminopyrine by horseradish peroxidase has been suggested to involve the cation radical intermediate on the basis of ESR spectroscopic studies.[48]

Richardson, "Mechanism and Theory in Organic Chemistry," Harper and Row Publishers, New York (1976). d) W. Tagaki, "Organic Chemistry of Sulfur," ed by S. Oae, Plenum Press, New York (1977), p.231.

$$\begin{aligned} &R_2N\text{-}CH_2R \xrightarrow{-e^-} R_2\overset{+}{N}\text{-}CH_2R \xrightarrow{-H^+} \\ &\qquad\qquad \downarrow (\text{or } -H\cdot) \\ &R_2N\text{-}\dot{C}HR \xrightarrow{-e^-} R_2\overset{+}{N}{=}CHR \xrightarrow{H_2O} \\ &[R_2N\text{-}\underset{\displaystyle OH}{\underset{|}{C}}HR] \longrightarrow R_2NH + RCHO \end{aligned} \qquad (4)$$

α-Hydroxyl sulfides (III) are formed as the intermediates *via* initial electron-transfer, subsequent proton removal, and final hydroxylation in the *S*-dealkylation (Eq. 5), and the formation of the α-sulfenyl radical (II) by direct hydrogen abstraction by electron deficient $(FeO)^{3+}$ is unlikely, since the ease of the *S*-dealkylation was found to be correlated not with the order of radical-stabilizing effect of α-substituent but with the acidity of α-hydrogen of the alkyl sulfides used.[49,50]

$$R\text{-}S\text{-}CH_2R' \xrightarrow[NADPH/O_2]{\text{cyt. P-450}} \underset{\text{(III)}}{R\text{-}S\text{-}\underset{\displaystyle OH}{\underset{|}{C}}HR'} \xrightarrow{H_2O} RSH + R'CHO \qquad (5)$$

The kinetic isotope effect observed for the *S*-dealkylation of phenacyl phenyl sulfide (**1e**) was rather small ($k_H/k_D=1.2$), differing from the results obtained by Groves *et al.*[8] and Hjelmeland *et al.*[9] A similar trend was observed in the reaction of sulfides with hydroxyl radical (Table 6).

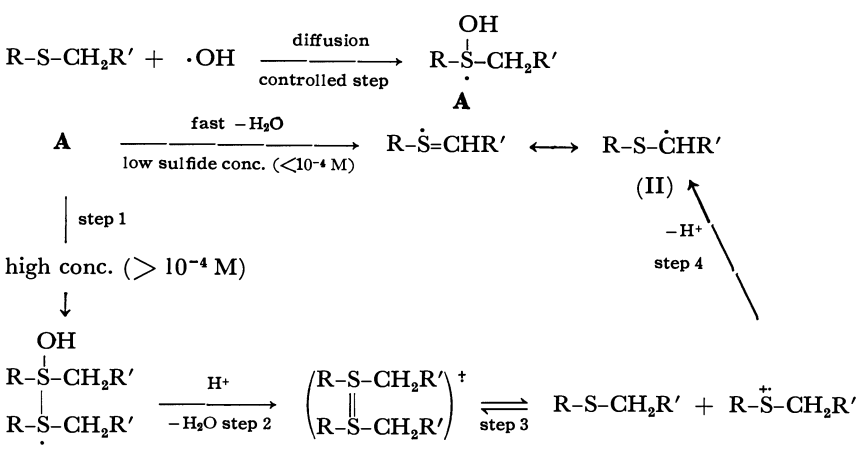
Hydroxyl radical is an electrophilic species, reacting readily with electron rich sulfenyl sulfur, and giving the corresponding sulfenium cation radicals.

$$R\text{-}S\text{-}R' + \cdot OH \longrightarrow R\text{-}\overset{+}{S}\text{-}R + OH^- \qquad (6)$$

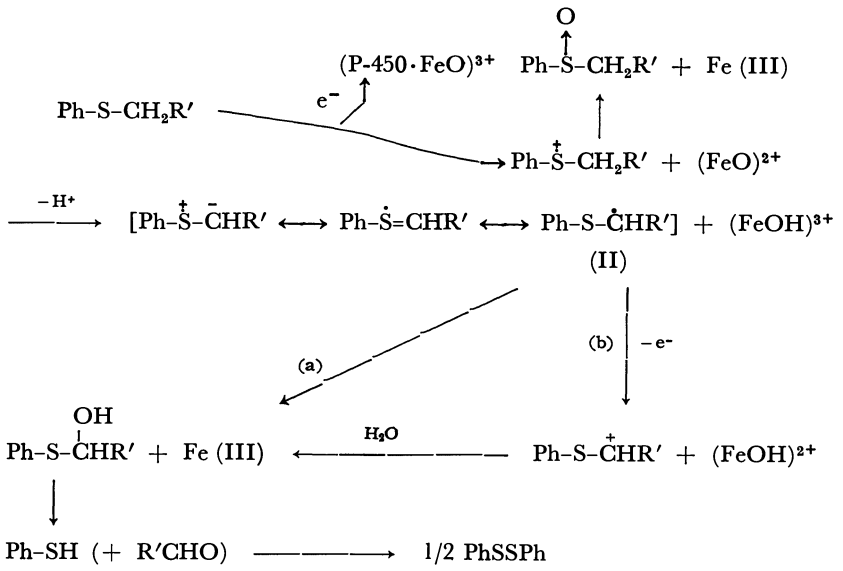
The reaction of sulfides with hydroxyl radical has been studied extensively by Gilbert *et al.*[18] and others[19,20] by means of UV and ESR and is illustrated in the following scheme (Scheme 2).

In this Scheme, step 4 should definitely be accelerated by either an electron-withdrawing substituents R′ or a group which stabilizes the intermediate radical (II), or by both. The Scheme is in line with our results with Fenton's oxidation system. In many ways, the reaction of step 4 can be considered as a 1,2 elimination of Elcb type,[51] and somewhat similar to the Pummerer rearrangement which shows a secondary kinetic isotope effect.[52] In the oxidation of tertiary amines, the deprotonation (Eq. 4) from nitrogen cation radical intermediate gives a kinetic isotope effect ($k_H/k_D=2.2$).[53]

Observation on the *S*-dealkylation can be interpreted, if we assume that the sulfenium cation radical initially formed is the common intermediate for both *S*-dealkylation and *S*-oxygenation through one electron transfer from divalent sulfur atom to the highly electron deficient "oxenoid." Electron-withdrawing substituent R′ would

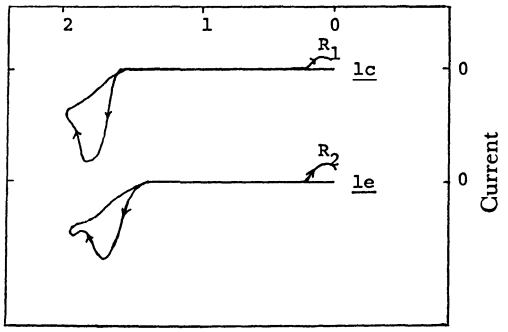


Scheme 2.



Scheme 3.

facilitate the α-proton removal to form the α-sulfenyl radical (II) which upon subsequent hydroxylation would undergo facile hydrolysis to afford the aldehyde and thiophenol which is readily oxidized further to diphenyl disulfide (Scheme 3). The cyclic voltammograms of sulfides (Fig. 2) show the ready α-proton removal from the sulfenium cation radicals as suggested by Sato and Kamada.[56] However, we cannot rule out the possibility of path (b) in Scheme 3.



Potential (V *vs.* SCE)

$$PhSCH_2R' \xrightarrow{-e^-} PhSCH_2R'^{+\cdot} \xrightarrow{-H^+} PhS\dot{C}HR'$$

Fig. 2. Cyclic voltammograms for sulfides in CH_3CN *vs.* SCE. Cathodic peaks (R_1 and R_2) suggest the abstraction of a proton.[56]

One way to demonstrate the generation of the sulfenium cation radical as the reaction intermediate by chemical procedure is to examine whether or not the oxygen of the sulfoxide formed by both microsomal and Fenton's oxidation originates not only from the "oxenoid" bound to iron of heme protein but also from water. The reaction of the sulfenium cation radicals of sulfides with water has been examined somewhat in detail and shown by Evans and Blount[54] and Murata and Shine[55] to give the corresponding sulfoxides stoichiometrically.[7] However, in the reaction of thioanisole (**1a**) with Ti(III)–H_2O_2 system, the amount of ^{18}O incorporated into the sulfoxide (**2a**) was only

$$2\,R_2S^{+\cdot} + H_2O \longrightarrow R_2S{\rightarrow}O + R_2S + 2\,H^+ \quad (7)$$

4.7% of $H_2{}^{18}O$ used. This indicates that the cation radical reacts with hydroxyl radical preferentially even though the cation radical is surrounded by water of the medium.

The incorporation of ^{18}O into the sulfoxide through the microsomal oxygenation was only 1.3% of $H_2{}^{18}O$ used. In the oxygenation of sulfides with cytochrome P-450, the substrate seems to be tightly coordinated to the active site; the amount of water around the reaction site of the enzyme is too small to compete with "oxenoid" bound to the enzymatic active site so that the ^{18}O incorporation would be smaller than that with Fenton's system. The slight incorporation of ^{18}O into the sulfoxide from $H_2{}^{18}O$ water used in the microsomal oxygenation suggests that the transient intermediate, presumably the sulfenium cation radical, is still tightly held in the cavity of the enzyme which lacks enough water and eventually reacts oxygen bound to the enzyme. The ^{18}O experiment gave no information whether the key active sulfur intermediate is the sulfenium cation radical or dication. However, involvement of the dication species is quite unlikely in view of our earlier work, in which *p*-substituted thioanisole derivatives were oxygenated by a reconstituted system of purified cytochrome P-450, V_{max}'s of oxygenation being correlated nicely with Hammett σ^+-values rather than σ-values ($\rho^+ = -0.16$), and also with one electron oxidation potential of sulfides.[46]

In this study, we found a large structural dependency of alkyl sulfide in the *S*-dealkylation with both microsomal and hydroxyl radical oxidation systems. The over-all reaction may be explained by the generation of cation radical species as the common intermediate for both *S*-dealkylation and *S*-oxygenation as suggested in the enzymatic *N*-dealkylation.

The Application of Field-ionization and Field-desorption Mass Spectrometry to the Analysis of Coal-derived Oil

Tadashi Yoshida,* Yosuke Maekawa, Tetsuo Higuchi,** Eiji Kubota,** Yasuhiro Itagaki,** and Susumu Yokoyama***

Government Industrial Development Laboratory, Hokkaido, Sapporo 061-01
***JEOL, Ltd., 1418 Nakagami, Akishima, Tokyo 196*
****Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received July 28, 1980)

Field-ionization (FI) and field-desorption (FD) mass-spectroscopic techniques have been applied to the analysis of ring-type fractions of coal-derived oil, obtained by liquid chromatography. These techniques produce only the molecular ion and its isotopic signals, free from fragment ions, of a molecule, consequently the exact molecular-weight-distribution profiles of chromatographic fractions. The peak intensities are reproducible within a variation coefficient ($\sigma/\bar{x}$) of about 5—8% on repeated runs. The number-average molecular weights ($\overline{Mn}$) of the ring-type fractions, as calculated from the peak intensities, are close to those obtained by means of a vapor-pressure osmometer (VPO). These techniques, on the whole, give reliable mass spectra of coal-derived oil, although the isotope-ion ratios are overestimated compared to the theoretical natural abundances. The group-type analysis of the ring-type fractions has been made on the basis of their mass spectra, and the skeletal structures corresponding to each mass z series have been proposed.

In recent yeras, the shortage in energy resources has become a serious problem all over the world. Therefore, coal has been recognized again as one of the most valuable energy resources, and the development of an economical coal liquefaction process has been attempted.

Coal-derived oil is a multicomponent mixture of aromatic and hydroaromatic hydrocarbons. To date, however, there has been very little information on the mass distribution of the individual components, and coal-derived oil has generally been characterized as having an average molecular weight. Since a large portion of the coal-derived oil consists of low-volatile fractions, such as heavy oil and asphaltene, the use of a gas chromatograph-mass spectrometer (GC-MS) equipped with an electron-impact (EI) ion source has been severely limited.

On the other hand, the FI and FD techniques[1,2] produce only molecular ions and their isotopic peaks of the components in a mixture. The FD technique especially does not require the vaporization process of the sample for ionization, in contrast to the EI and FI techniques; consequently, it permits the analysis of thermally labile or nonvolatile substances. The usefulness of these techniques has already been proved in the analysis of biochemical substances[3] and aromatic hydrocarbons.[4] They can also be expected to be useful for the compositional analysis and determination of the molecular-weight distribution of coal-derived oil.

The purposes of the present work are to perform a quantitative mass analysis of coal-derived oil and to determine the types of hydrocarbons and their distribution in the coal-derived oil based on group-type analysis. The determination of the sensitivity coefficients of the hydrocarbons is beyond the scope of this work.

Experimental

The coal sample used in the present work was obtained from Akabira, Hokkaido. The sample was hydrogenated over Adkins catalyst at 400 °C for 60 min under an initial hydrogen pressure of 100 kg/cm^2. The hydrogenated product was extracted with hexane in a Soxhlet extractor. The extracted coal-derived oil was separated into five fractions on the liquid chromatograph by means of a modification of the Bureau of Mines-API 60 method:[5] saturates(Fr-P), monocyclic aromatics(Fr-M), bicyclic aromatics(Fr-D), tri- and tetracyclic aromatics(Fr-T), and polycyclic aromatics and polar compounds(Fr-PP). The Fr-PP fraction was further subdivided into eight fractions by gel-permeation chromatography(GPC). The volatile fractions were subjected to FI analysis by the direct-inlet method; they were charged into a glass tube with active alumina powder. On the other hand, the nonvolatile fraction(Fr-PP-8) was subjected to FD analysis by loading about 1 μg of a sample on the emitter with a microsyringe. The emitter was prepared by Beckey's method.[6] The FI and FD mass spectra were measured by means of a JMS-D300 double-focusing mass spectrometer equipped with an EI/FI/FD-combination ion source(JEOL Ltd). Ions were detected through an electrical detector connected to a data-analysis system, JMA-2000. The emitter current was kept at 5 mA for the FI analysis in order to prevent any condensation of the sample on the emitter and was elevated at a rate of 4 mA/min for the FD analysis. The scan speed for the mass range of m/z 100—550 was 5 s/cycle. Scanning was repeated 300—400 times in the FI and 40—50 times in the FD. The chamber temperature was maintained at 200 °C for the FI and at 60 °C for the FD. Throughout this work, homologs are assumed to have identical sensitivity coefficients.[7]

The average molecular weight was determined by the VPO (Knauer) method. Chloroform was used as the solvent.

Results and Discussion

Aspects of FI and FD Mass Spectra of Coal-derived Oil. Since any ring-type fraction of coal-derived oil is a multicomponent mixture, a sample must be introduced into an ion source without changing the composition of the mixture. However, the boiling points of these fractions cover a wide temperature range; therefore, a special technique is needed to effect simultaneous evaporation.

Figure 1 compares the total ion-current profiles (TICP) with the mass spectra of the Fr-P fraction as obtained by means of the FI and FD techniques. The TICP in FI with a direct-inlet probe suggests that the

sample in a glass tube was not vaporized until the probe was heated enough. No residue was found in the tube after measurement. In contrast, the TICP in FD indicates that the majority of the sample molecules had vaporized *in vacuo* before the mass measurements started. The resulting FD mass spectrum reveals the absence of volatile components in the low-mass range. Thus, the FI technique with the direct-inlet probe was found to be suitable for the measurements of the volatile fractions,[8] which comprise about 30 wt% of coal-derived oil (hexane extract), while the FD technique was found to be suitable for the measurements of nonvolatile fractions and polar substances containing phenolic OH and nitrogen atoms.

Few quantitative studies of the FI and FD mass spectra of multicomponent mixtures have been reported.[9-12] The components of coal-derived oil have larger and more complex chemical structures than the model compounds, and the preparation of a multicomponent "model mixture" for coal-derived oil is practically impossible. Therefore, we abandoned our attempts to estimate the sensitivity coefficients of the components and to perform quantitative FI and FD mass analysis using the "model mixture." For this reason, the ring-type fractions of coal-derived oil, which have their own structural characteristics, were used as samples in the present work. Since the compositions of the ring-type fractions used are unknown, the reproducibility of the peak intensities, the isotope-ion ratios, and the number-average molecular weights, as calculated from the intensities of the peaks, were studied.

The reproducibility of the peak intensities in the FI and FD mass spectra of the Fr-P and T fractions is shown in Table 1. The reproducibility is expressed by the variation coefficient ($\sigma/\bar{x}$), defined by the following equation:

$$\sigma/\bar{x}(\%) = \frac{100}{\bar{x}}\sqrt{\frac{\Sigma(x-x_i)^2}{N-1}},$$

where $\bar{x}$ is the arithmetic mean value calculated from N

measured values of x_i. The variation coefficients of the peaks with high ion intensities are approximately 8% for FI and approximately 5% for FD. In both spectra, the variation coefficients increased with the decrease in the peak intensity. On the whole, the reproducibility of the FD mass spectra is better than that of the FI mass spectra. Both mass spectra generally tended to improve the reproducibility of the peak intensity with an increase in the amount of ions detected.

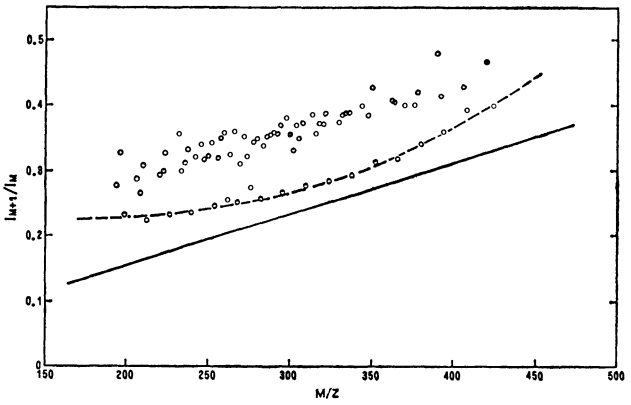

Fig. 2. Comparison of observed and calculated isotope ion ratios.

The reliability of the peak intensity was investigated by comparing the observed and calculated isotope-ion ratios. The isotope ratios in the FI mass spectrum of the Fr-P fraction are compared with the natural abundance (straight line) in Fig. 2. The observed isotope ratios are close to natural abundance when the peak intensities are high (broken line), but they tended to increase with the decrease in the peak intensity. The isotope ratios of peaks with small ion intensities are overestimated. These tendencies were observed in the FI and FD mass spectra of every ring-type fraction. Further studies are needed to elucidate the phenomenon. As a whole, the intensities of the peaks in the FI and FD mass spectra were well reproduced, although the isotope ratios deviated slightly from their natural abundances.

The FI and FD techniques give the molecular-weight-distribution profiles of mixtures. The reliability of the profiles was tested in terms of the number-average molecular weight, as calculated from the intensities of the mass peaks. The number-average molecular weight obtained from the mass spectrum is defined by the following equation:

$$Mn = \frac{\Sigma M_i I_i}{\Sigma I_i},$$

where M_i is the mass of the i th peak and where I_i is the intensity of the i th peak. The number-average molecular weights calculated from the FI and FD mass spectra of the Fr-P and T fractions are shown in Table 2. The molecular weight, like the peak intensity, is reproduced better in the FD mass spectra than in the FI mass spectra.

Furthermore, the calculated number-average molecular weights were compared with those measured by the VPO method in order to check whether or not the spectral patterns of mixtures corresponded to their real molecular-weight distributions. The number-average molecular weights of the ring-type fractions (Fr-P, -M, -D, -T, and -PP-8) were calculated from the FI and FD mass spectra in Figure 3 and are summarized in Table 3. The volatile fractions (Fr-P, -M, -D, and -T) were measured by FI, and the nonvolatile fraction (Fr-PP-8), by FD. In all the mass spectra of the ring-type fractions, ions were scarcely detected in the mass range below m/z 150, where the appearance of fragment ions was anticipated. Table 3 shows that the calculated molecular weights of all fractions but Fr-PP-8 are slightly greater than the VPO values. The overestimation is probably caused by an increase in the sensitivity coefficient with the number of carbon atoms in the molecule.[7] The great overestimation of the Fr-PP-8 fraction must be caused by the increase in the sensitivity coefficient and by the vaporization of the volatile components in this fraction. Table 3 suggests that most of the peaks in the mass spectra can be assigned to molecular and isotopic ions alone. Thus, the FI and FD mass spectra are suitable for the compositional analysis and for the determination of the molecular-weight distribution of coal-derived oil.

In conclusion, we advise that the FI technique is applied to the analyses of volatile fractions, and the FD technique, to the analyses of nonvolatile fractions, of coal-derived oil. These techniques provide more precise and useful data than those obtained by conventional analytical methods, such as GPC and VPO, and may be one of the most powerful tools for elucidating the components of coal-derived oil, although several problems must be solved before we can obtain fully quantitative FI and FD mass spectra.

Group-type Analysis of Ring-type Fraction. As discussed in the preceding section, ring-type fractions

Table 2. Number-average molecular weights as calculated from FI and FD mass spectra of Fr-P and T

Sample :	Fr-P FI	Fr-T FD

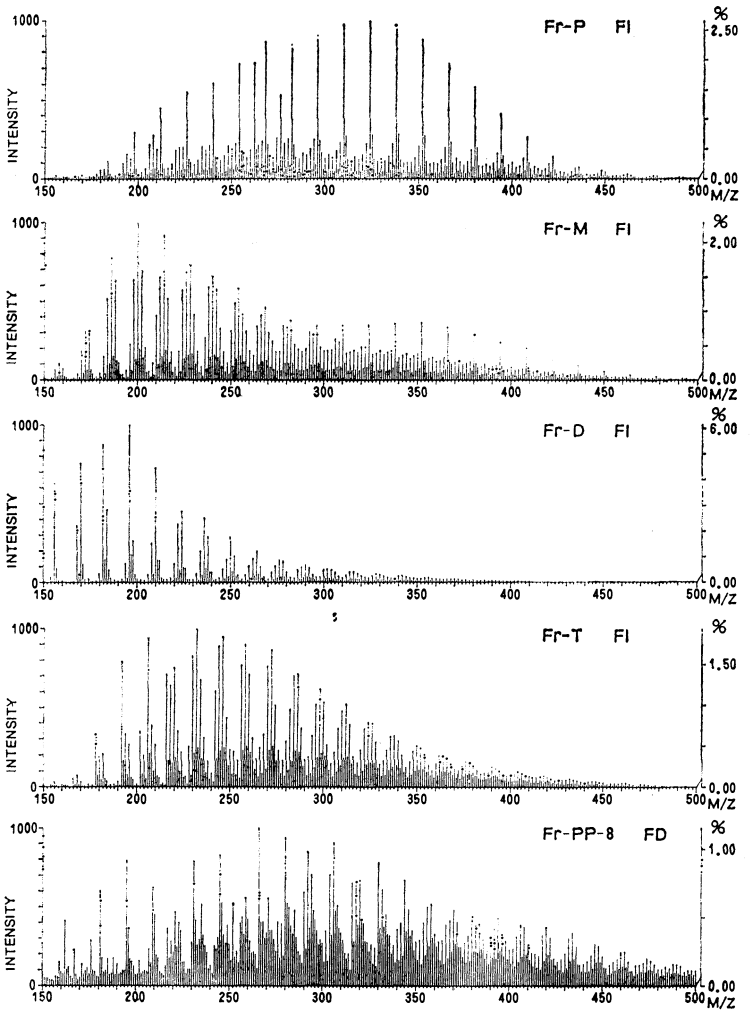

Fig. 3. FI and FD mass spectra of ring-type fractions.

of coal-derived oil can be analyzed semiquantitatively by the combined use of FI and FD techniques. The resulting spectra show their molecular-weight distribution profiles and number-average molecular weights. The group-type analysis based on the molecular weights of components should give information on their chemical structures. That is, the molecular weight of hydrocarbon is expressed by the following equation: $M=12C_n+H_{2n+z}$, and the components in coal-derived oil can be assigned to several group types by the use of the value of z.

In the present work, the ring-type fractions of coal-derived oil separated beforehand by liquid chromatography were used as samples in order to get more detailed structural information. As is shown in Fig. 3, the molecular-weight distributions of all the ring-type fractions but Fr-PP-8 cover the mass range between m/z 150 and 450, with the dominant components of the Fr-M, -D, and -T fractions being distributed in the low-mass range of m/z 200—250. In the Fr-PP-8 fraction, the high-mass ions of nonvolatile components were detected; this proves that the FD technique is suitable for the measurement of nonvolatile components.

The FI mass spectrum of the Fr-P fraction was characterized by the regular occurrence of molecular ions and isotopic ions at m/z 14 intervals. These ions were assigned to $z=2$, that is, paraffins. Other ions with a small ion intensity can be assigned to $z=0$, -2, -4, -6, -8, and -10, that is, cycloparaffins and olefins. Thus, the Fr-P fraction is a mixture of various types of paraffins (C_{13-33}), plus small amounts of cycloparaffins and olefins. The mass spectra of the Fr-M, -D, -T, and -PP-8 fractions were more complicated than Fr-P. The Fr-M fraction consists predominantly of alkyl-substituted monocyclic aromatics, such as 1,2,3,4,4a,9,9a,10-octahydroanthracene ($z=-10$) and 1,2,3,4,5,9,10,11,12,15-decahydropyrene ($z=-12$), and is contaminated by small amounts of the components in the Fr-P fraction. Judging from the values of z, most of the peaks beyond m/z 280 must be paraffins and cycloparaffins. The FI mass spectrum of the Fr-D fraction is comparatively simple, and the dominant components are alkyl-substituted biphenyl ($z=-14$) and alkyl-substituted bicyclic aromatics such as 1,2,3,4-tetrahydrophenanthrene ($z=-14$). The components of the Fr-T fraction have more complicated skeletal structures than Fr-M and -D. The ^{1}H-NMR spectrum of the Fr-T fraction indicates that the average skeletal structure of Fr-T is not a cata type such as anthracene, but a phenanthrene type.[13] Since the Fr-PP-8 fraction

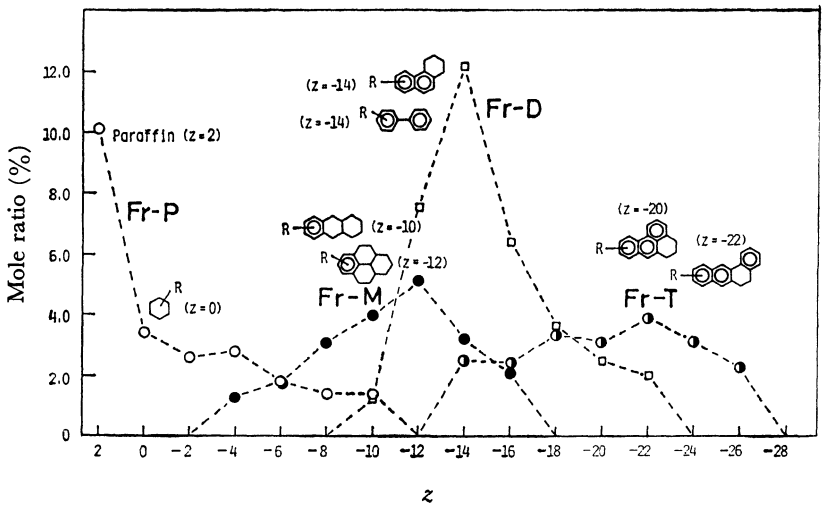

Fig. 4. Distribution of mass z series and an example of probable chemical structures for each z value.

contains the hetero atoms (oxygen and nitrogen), the assignments of the peaks must be made by using a high-resolution mass spectrometer. The distribution of the mass z series and an example of a probable chemical structure for each z value are illustrated in Fig. 4.

The FI and FD mass analysis of coal-derived oil made it possible not only to determine the molecular-weight-distribution profile, but also to speculate on the skeletal structures of components by means of group-type analysis.

Photolysis of Organic Azides. VI.[1] 1,4-Diacetoxy-2,3-diazidonaphthalene. Formation of Isoquinoline Structure from α,α'-Dicyano-o-xylylene

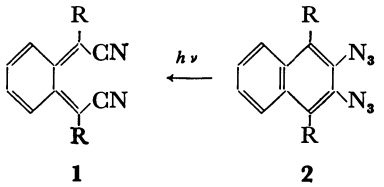
Akira YABE

National Chemical Laboratory for Industry, Yatabe-Higashi 1-1, Tsukuba, Ibaraki 305

(Received July 29, 1980)

Transient absorbing in the 400—450 nm range was observed in the photolysis of 1,4-diacetoxy-2,3-diazidonaphthalene in rigid matrices at 77 K. The transient was assigned as α,α'-diacetoxy-α,α'-dicyano-*o*-xylylene by comparison with the low-temperature photolysis of the other precursors, 1,2-diacetoxy-1,2-dicyano-1,2-dihydrobenzocyclobutenes. The three *o*-xylylene stereoisomers showed differences in the longest-wavelength absorption maxima. Continued irradiation of the *o*-xylylenes converted them to 2-acetoxy-2-methyl[1,3]dioxolo[4,5-*c*]-isoquinoline-5-carbonitrile as the result of the reaction of a cyano group with the *o*-xylylene system and the migration of an acetoxyl group. The rate of formation of the isoquinoline in rigid matrices depends on the viscosity of glassy solvents and the configuration of the intermediate *o*-xylylenes. The room-temperature photolysis of the diazide gave 2,3-diacetamido-1,4-naphthoquinone as the main product and compounds *via* the *o*-xylylene as minor products. A mechanism involving two competitive reactions is discussed.

There has been considerable interest in the structures and properties of *o*-xylylene (*o*-quinodimethane: 5,6-dimethylene-1,3-cyclohexadiene) and its various derivatives.[2-4] In a previous paper we reported the formation of α,α'-dicyano-*o*-xylylenes (**1**) by the photolysis of 2,3-diazidonaphthalenes (**2**).[5] Among the three derivatives,

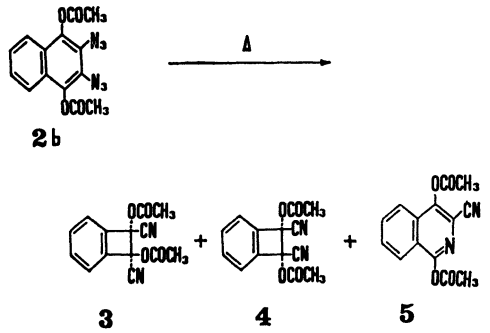


1 **2**

a: R = H
b: R = $OCOCH_3$
c: R = OCH_3

2b gave efficiently an unknown photoproduct *via* **1b** by prolonged irradiation at low temperature in rigid medium, while continued irradiation of the others, **1a** or **1c**, resulted in almost no reaction. We now report a new photochemical reaction of the *o*-xylylene system at low temperature in rigid medium.

In addition, the room-temperature photolysis of **2b** was investigated in connection with the low-temperature photolysis. Pearce *et al.*[6] found the formation of *cis*- and *trans*-1,2-diacetoxy-1,2-dicyano-1,2-dihydrobenzocyclobutenes (**3** and **4**, respectively) and 1,4-diacetoxy-3-isoquinoline (**5**) by the thermal decomposition of **2b**.



2b

3 (23%) **4** (<3%) **5** (39%)

On the other hand, the room-temperature photolysis of **2b** was quite complicated and considerably different from the thermolysis or the low-temperature photolysis. A new reaction involving the migration of acyl groups to nitreno groups has been found in addition to the formation of **3** *via* **1b**, while **5** has not been produced. The mechanism of the room-temperature *vs.* low-temperature photolysis will be discussed, and a characterization of the photoproducts will be given.

Results and Discussion

Low-temperature Photolysis. A rigid glassy solution of **2b** in EPA (diethyl ether/isopentane/ethanol, 5 : 5 : 2) was irradiated at 77 K with a 500-W super high-pressure mercury lamp through a 300 nm cutoff filter. Figure 1 shows the photochemical process followed by absorption spectroscopy. The absorbance in the range of 424—450 nm increased in the early stage of irradiation. At this stage, warming of the glassy solution to room temperature resulted in disappearance of the absorption. This transient absorbing in the 400—450 nm range was tentatively identified as the α,α'-dicyano-*o*-xylylene (**1b**) in the previous paper,[5] by analogy to the low-temperature photolysis of the parent 2,3-diazidonaphthalene. Continued irradiation resulted in the disappearance of the absorption in the 400—450 nm range and in the appearance of a new absorption in the 355—380 nm range. In the cases of the other diazidonaphthalenes, **2a** and **2c**, the conversion from the *o*-xylylenes, **1a** and **1c**, proceeded even after prolonged irradiation. The secondary photoproduct having absorption bands at 355—380 nm was stable at room temperature. By a separate irradiation of **2b** on a preparative scale, a product with two fewer nitrogen molecules than the starting material was isolated in an almost quantitative yield. Although the product was presumed to be an isoquinoline derivative, on the basis of the IR, ^{1}H-NMR, and ^{13}C-NMR spectra, its final identification was difficult because its UV absorption spectrum (longest-wavelength: λ_{max} 376, 368, 358, 355 sh nm) was considerably different from that (λ_{max} 304 nm) of the isoquinoline (**5**) given by the thermal treatment. Therefore, an X-ray crystal structure analysis was made of a single-crystal grown from dichloromethane–ethanol. The structure was established as 2-acetoxy-

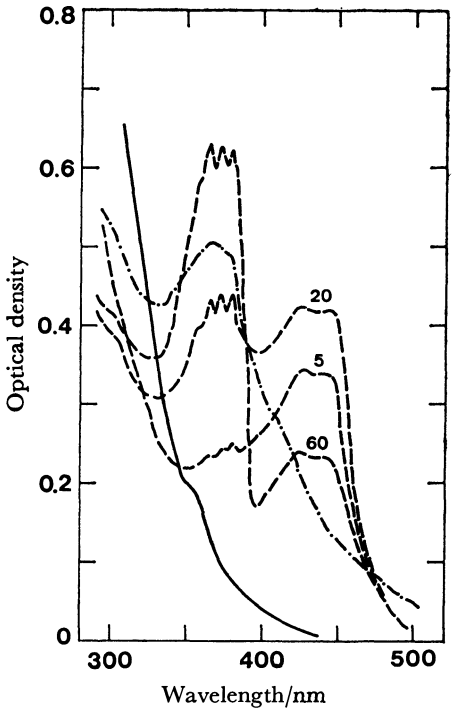


Fig. 1. Absorption spectra of **2b** in EPA at 77 K before (——) and after (----) irradiation. Numbers refer to irradiation times in min. Absorption spectrum (—·—) of **2b** recorded at room temperature after irradiation for 60 min.

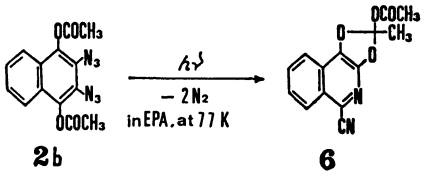
2-methyl[1,3]dioxolo[4,5-*c*]isoquinoline-5-carbonitrile (**6**).[7] The formation of such an isoquinoline derivative by the photolysis in a rigid matrix was quite unexpected.



2b **6**

In addition, it is interesting that the electronic absorption spectra of isoquinoline derivatives depend highly on the position of the cyano group and on the presence of the dioxolane ring fused with the isoquinoline nucleus.

Irradiation of **2b** at 77 K was carried out in various media. The reaction proceeded as in the case of EPA. Figure 2 shows the relation between the irradiation time and the yield of the secondary photoproduct **6**, which was measured by monitoring the peak height of the 362 nm UV absorption due to **6** during stepwise photolysis. From a consideration of the viscosity of media as given in Table 1, it was found that the rate of formation decreased with the increase of the viscosity in a series of mixed solvents of isopentane and 3-methylpentane. In the case of EPA, the highly efficient formation, compared with other nonpolar media, may be attributed to solvent polarity.

Low-temperature photolyses of *trans*- and *cis*-1,2-diacetoxy-1,2-dicyano-1,2-dihydrobenzocyclobutenes (**3** and **4**, respectively) were carried out in order to confirm the intermediate and to study the mechanism of low-temperature photolysis of **2b**. Figures 3 and 4 show

the photochemical processes of **3** and **4**, respectively, in EPA at 77 K. As in the case of **2b**, the longer-wavelength transient absorptions appear in the range of 400—450 nm in the early stage of irradiation, and a new absorption in the range of 355—380 nm begins to appear with the increase of irradiation time. Moreover, the prolonged irradiation with longer-wavelength light (>300 nm) results in the increase of that absorption, together with the decrease of the 400—450 nm absorption. The absorption peaks in the 355—380 nm range are completely consistent with those of **6**. However, the peaks of the transients generated from **3** and **4** are shifted to slightly shorter wavelengths than those of the intermediate generated from **2b**. This spectral shift could be explained in terms of the different configurations of the *o*-xylylenes. The intermediate generated

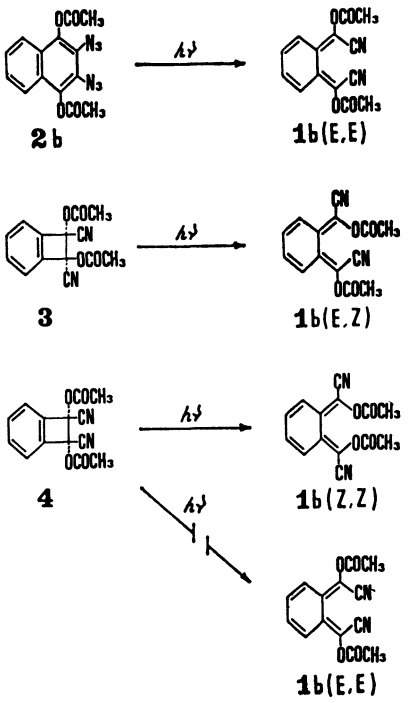
from **2b** must be the *E,E*-form stereoisomer (**1b**(*E,E*)) of α,α′-diacetoxy-α,α′-dicyano-*o*-xylylenes, as described in the previous paper[5] by analogy to the case of 1,2-diazidobenzene. The intermediates generated from **3** and **4** are presumed the *E,Z*-form **1b**(*E,Z*), and the



Z,Z-form **1b**(*Z,Z*) or *E,E*-form **1b**(*E,E*), respectively, from a consideration of the orbital symmetry rule. In the case of **4**, the intermediate structure must be **1b**(*Z,Z*)', because the absorption peaks generated from **4** are not identical with those generated from **2b**. The spectral shifts of these stereoisomers are consistent with those of the *o*-xylylene derivatives. The absorbing peaks of the *o*-xylylene stereoisomers are summarized in Table 2.

The secondary photoproduct from **3** or **4** is identified as **6** on the basis of the spectral properties of the crystals isolated from a separate irradiation on a preparative scale. The results of this photochemical reaction show that final product **6** is formed by a similar mechanism from the different stereoisomers of **1b**. A plausible mechanism which accounts for the formation of the isoquinoline (**6**) is depicted in Scheme 1.

Although the formation of **6** *via* **1b** from **2b** proceeds efficiently with the irradiation of a high-pressure mercury lamp, the rate of formation of **6** from **3** or **4** is very slow during irradiation of a low-pressure mercury lamp. In particular, the formation of **6** in the case of **4** occurs in a lower yield, compared with the case of **3**, after 10 min irradiation, as shown in Figs. 3 and 4. When the concentration of the intermediate **1b** was increased appropriately after 10 min irradiation, prolonged irradiation was carried out with a high-pressure mercury lamp (>300 nm). However, the rate of formation of **6** from **4** was much lower than that of **6** from **3** or, particularly, from **2b**. In the isoquinoline

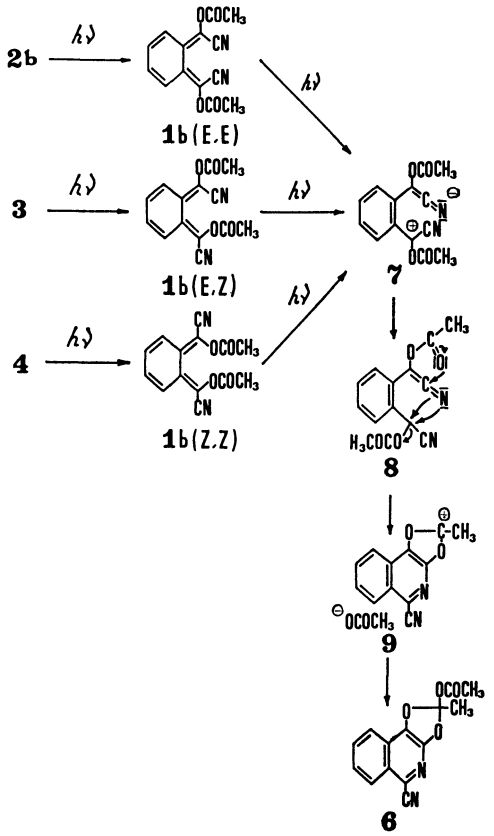
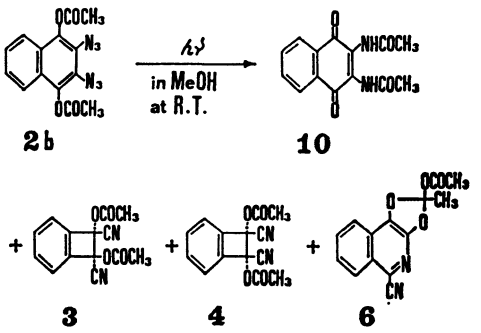


Scheme 1.

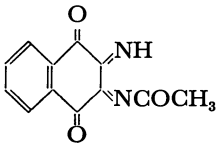
formation, the *o*-xylylene derivatives **1b**(*E*,*E*) and **1b**(*E*,*Z*) would have more favorable configurations than **1b**(*Z*,*Z*). The rigid medium at low temperature would control large rotational motions in each stereoisomer. The rigidity effects of glassy solvents have also been observed in the photolysis of **2b**, as shown in Fig. 2 and Table 1. The π-electrons of the *o*-xylylene system are delocalized by the substitution of the two cyano groups, and consequently the aromatization is liable to occur. The deactivation of the *o*-xylylene system by the cyano groups is consistent with the fact that the attempt to trap **1b** with dienophiles, such as *N*-phenylmaleimide or maleic anhydride, has failed. The formation of the isoquinoline structure is accomplished *via* the dipolar intermediate **7**, as shown in Scheme 1. The formation of the dioxolane ring is accompanied by the formation of the C–N bond, and the cleavage of the acetoxyl group follows. Finally, the migration of the acetate anion to the positive carbon atom of the dioxolane ring proceeds in the cage of rigid medium.

Although various photochemical and thermal reactions of *o*-xylylenes have been reported, it is interesting that the cyano groups conjugated with *o*-xylylene system participate in the reaction of *o*-xylylene structure. Moreover, it should be noted that the reactions involving a large rotational motion and a migration of the large acetoxyl group proceed readily in the rigid matrices at low temperature.[8]

Room-temperature Photolysis. A methanol solution of **2b** (0.52 mol m^{-3}) was irradiated at room temperature with a 400-W high-pressure mercury lamp through Pyrex. The photoproducts showed very complicated spots on a thin layer chromatogram of silica gel. As a major product, 2,3-diacetamido-1,4-naphthoquinone (**10**) was isolated in a 46% yield, together with the dihydrobenzocyclobutene **3** (25%) and the compound **6** (8%). Interestingly, the yield of the dihydrobenzocyclobutene **4** was only less than 1%, and 1,4-diacetoxy-3-cyanoisoquinoline (**5**), the main product in the case of the thermal decomposition of **2b**, was not detected.



Irradiation of **2b** in hexane gave a new compound instead of **10** as a main product, together with **6** as a minor product. Its structure was identified as 2,3-dihydro-2-imino-3-acetylimino-1,4-naphthoquinone (**11**) based on the spectral properties.



11

The product distributions were sensitive to the solvent used. The results for the room-temperature photolysis of **2b** in various solvents are summarized in Table 3. An unknown photoproduct having UV absorption bands at 362 and 285—325 nm was observed in the case of hexane, and was the main product in the case of benzene. This was not characterized, although it is

TABLE 3. ROOM-TEMPERATURE PHOTOLYSIS OF 1,4-DIACETOXY-2,3-DIAZIDONAPHTHALENE (**2b**)

Solvent	Concn/mol m^{-3}	Irrad time/min	Yield/%				
			3	**4**	**6**	**10**	**11**

presumed to be 1,2,3,4-naphthalenetetrone derivative (IR absorption bands at 1798, 1725, and 1690 cm^{-1}). It is certain that the products **3**, **4**, and **6** were given *via* the *o*-xylyelene **1b**, and **10** and **11** were formed by a different mechanism. Furthermore, in these room-temperature photolyses, the dihydrobenzocyclobutene, the product *via* the *o*-xylylene **1b**(*E*,*E*), was exclusively the *trans*-isomer (**3**). A consideration of the orbital symmetry rule shows that the cyclization of the *o*-xylylene is not a photoinduced but a thermal reaction.

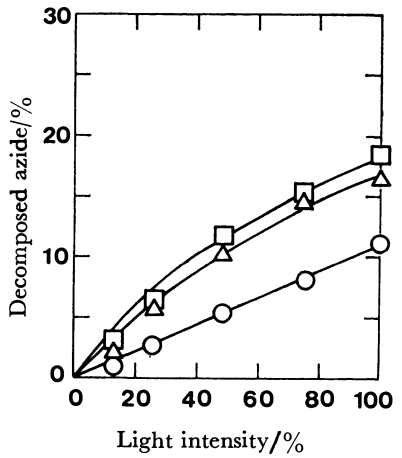

Fig. 5. Relation between the decomposed azide **2b** and light intensity. Photolyses (○) in EPA at 77 K, (△) in methanol at room temp, and (□) in hexane at room temp.

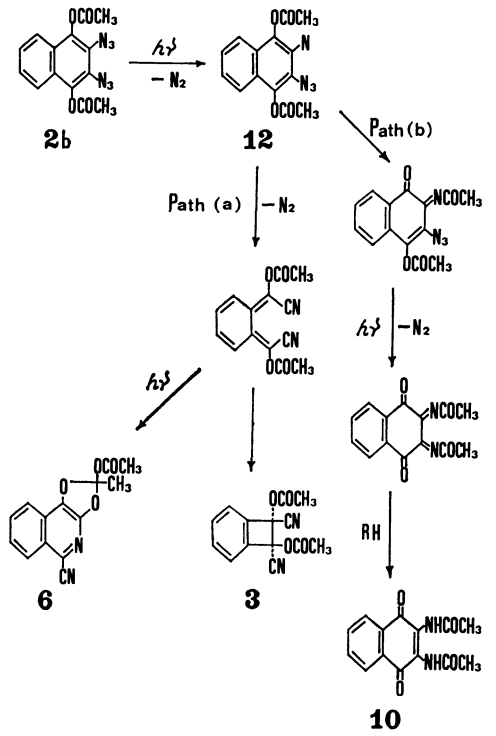
The dependence of the rate of decomposition of **2b** on the light intensity was examined. The amounts (%) of the decomposed azide were calculated on the basis of the measurement of the decrease in absorbance after 10 s irradiation. The results involving the low-temperature photolysis are shown in Fig. 5. In the previous paper,[5] it was found that the formation of **1a** or **1c** from **2a** or **2c**, respectively, was a monophotonic process. Similarly, the decomposition of **2b** in a rigid matrix at 77 K would lead quantitatively to the *o*-xylylene **1b**. Therefore, the relationship between the rate and the light intensity shows good linearity, suggesting a monophotonic reaction. On the other hand, the relationship deviates from linearity and displays downward curvature in the cases of the photolyses in methanol and in hexane. This indicates the participation of a biphotonic process. Therefore, the formation of **10** and **11** would be interpreted by the mechanism involving the stepwise decomposition of the two azido groups. Thus, there are two competitive reactions (Paths (a) and (b)) after the first azido group was decomposed. The process of the room-temperature photolysis is depicted in Scheme 2.



Scheme 2.

In Path (b), the attack of the nitreno groups upon the neighboring acetoxyl groups has been observed in the thermal decomposition of 1,4-diacetoxy-2-azidobenzenes.[6] The migration of acyl groups proceeded in a high yield (45—89%) for the reported compounds, although **5** was given as a main product and **10** was not given completely in the thermal decomposition of **2b**. In the room-temperature photolysis of **2b**, the migration of the acyl groups (Path (b)) has become the main process, taking the place of the formation of the *o*-xylylene (Path (a)) or **5**. Along Path (a), the cyclization to the dihydrobenzocyclobutene has become the main process, as a typical reaction of *o*-xylylene system.

The room-temperature photolysis of **2b** in the presence of some additives was carried out in order to study the factors governing the two competitive processes and the spin state of the nitrene **12**. The results are summarized in Table 4. The presence of dichloromethane (known to enhance singlet processes[9]) or iodomethane (heavy atom effect) gave nearly the same

product distribution as in the case of the direct irradiation (Runs 1 and 2). However, the addition of pyrene (a triplet quencher and singlet promoter[10]) in methanol raised the yield of **10** to 58%, while the yields of **3** and **6** were decreased (Run 3). The addition of benzophenone or acetophenone (triplet sensitizers[10]) seemed to show no remarkable effects (Runs 4 and 5). Based on the results of Run 3, one could predict that Paths (a) and (b) were divided into triplet-derived and singlet-derived processes, respectively. That is to say, the spin state of the nitrene (**12**) which attacks the neighboring acetoxyl group is singlet, whereas the nitrene (**12**) which attacks the remaining azido group is in the triplet state. The direct observations of actual precursors and quenching rates are lacking, so this conclusion cannot be confirmed yet.

Table 4. Room-temperature photolysis of **2b** in the presence of additives

5	Benzene/Benzophenone (9.2 mol m^{-3})	6	15	<1

a) Concentration of **2b**: 0.52 mol m^{-3}. Irradiation time: 120 min.

Some differences in the low-temperature *vs.* room-temperature photolysis have been found in the processes of the attack by a nitreno group upon an acetoxyl group and the cyclization of the *o*-xylylene to the benzocyclobutene. The suppression of these processes in the low-temperature photolysis could be ascribed to a rigidity-controlled and activation-energy-controlled field.

Experimental

Measurements. The melting point is uncorrected. The IR and UV/VIS spectra were recorded on Hitachi Model 260-30 and Shimadzu Model UV-300 spectrophotometers respectively. The ^1H NMR and ^{13}C-NMR spectra were recorded on Varian Model XL-100-12 (100 MHz) and JEOL Model FX-100 (25 MHz) spectrometers respectively using TMS as an internal standard. The mass spectra were recorded on a Hitachi Model RMU-6M spectrometer. The microanalysis was performed at the Institute of Physical and Chemical Research.

Materials. 1,4-Diacetoxy-2,3-diazidonaphthalene (**2b**), and *cis*- and *trans*-1,2-diacetoxy-1,2-dicyano-1,2-dihydrobenzocyclobutenes were prepared according to the literature.[6]

Irradiations of 2b in Rigid Media at 77 K. Irradiation on preparative scale was carried out in a doughnut-shaped Pyrex vessel (volume: about 160 ml; thickness: 7 mm) which was immersed in liquid nitrogen with a 400-W high-pressure mercury lamp (Riko UVL-400HA) protected with a transparent quartz Dewar vessel. A solution of **2b** in 160 ml of EPA (0.37 mol m^{-3}) was irradiated for 10 min. Upon warming to room temperature, the solution was condensed on a rotary evaporator. Preparative-TLC (Merck Silica-gel 60 F_{254}) analysis of the concentrate gave the starting material (about 40%) and yellow crystals (55%). The crystals were recrystallized from dichloromethane–ethanol. Mp 146 °C (dec). IR (KBr): 2230, 1778, 1598, 1448, 1440, 1388 cm^{-1}. UV (Hexane): 376 (ε 3800), 368 (4500), 358 (4500), 355 sh (4100), 308 (6200), 296 (4600), 233 (19000) nm. ^1H-NMR ($CDCl_3$) δ: 2.09 (s, 3H, CH_3), 2.18 (s, 3H, $COCH_3$), 7.5—7.9 (m, 3H, aromatic), 8.20 (s, 1H, aromatic) ppm. ^{13}C-NMR ($CDCl_3$) δ: 21.6 (q), 24.7 (q), 116.0 (s), 119.9 (d), 121.4 (s), 122.0 (s), 125.5 (d), 125.9 (s), 128.2 (d), 129.3 (s), 130.9 (d), 136.0 (s), 150.8 (s), 167.0 (s) ppm. MS: *m/e* 270 (M^+), 218, 214, 212, 211, 186. Found: C, 62.33; H, 3.75; N, 10.45%. Calcd for $C_{14}H_{10}N_2O_4$: C, 62.22; H, 3.73; N, 10.37%. The structure of the crystals was determined as *2-acetoxy-2-methyl[1,3]-dioxolo[4,5-c]isoquinoline-5-carbonitrile* based on the spectral properties as described above and finally on the results of X-ray crystallography.

Irradiation for spectroscopy was carried out with a cell (path length: 10 mm) which had been immersed in liquid nitrogen in a quartz Dewar vessel equipped with optical windows on opposite sides. The light source was an Ushio USH-500D 500-W super high-pressure mercury lamp which transimitted through a 300 nm cutoff filter.

Irradiation of 3 or 4 in EPA at 77 K. Irradiation on a preparative scale was performed in the doughnut-shaped quartz vessel which was immersed in liquid nitrogen with a 160-W low-pressure mercury lamp (Riko UVL-160LA) protected with a transparent quartz Dewar vessel. A solution of **3** in 160 ml of EPA (0.44 mol m^{-3}) was irradiated for 2 h. The starting material and yellow crystals were isolated by a similar procedure to that for **2b**. The crystals were identical with those formed by the photolysis of **2b**.

Irradiation of **3** or **4** for spectroscopy was carried out in a manner like that described above for **2b**. The light source was a 15-W low-pressure mercury lamp (Toshiba GL-15).

Irradiation of 2b in Fluid Media at Room Temperature. Irradiation was performed under bubbling of nitrogen in a conventional immersion well-type reactor (volume: about 1200 ml) equipped with a 400-W high-pressure mercury lamp (Riko UVL-400HA) through Pyrex. The separation of the photoproducts was performed by the preparative TLC, and the yield determination was carried out by UV analysis (Tables 3 and 4).

The main photoproduct from the photolysis in methanol was precipitated in condensed solution (46% yield). The crystals were recrystallized from acetone–methanol, yielding yellow needles, mp 249 °C (dec). This product was identified as 2,3-diacetamido-1,4-naphthoquinone (**10**) by comparing the absorption spectrum with that of an authentic sample[11] and by the following spectral data. IR (KBr): 3310 (NH), 1668, and 1650 (quinone CO, acetamido CO) cm^{-1}. ^1H-NMR ($CDCl_3$) δ: 2.3 (s, 6H, CH_3), 7.6—7.9 (m, 2H, aromatic), 8.0—8.2 (m, 2H, aromatic), 8.5 (s, broad, NH) ppm. ^{13}C-NMR ($CDCl_3$) δ: 23.8 (q), 126.9 (d), 128.1 (s), 130.8 (s), 134.3 (d), 167.4 (q) ppm.

The main product from the photolysis in hexane was precipitated in condensed solution (48% yield). The crystals were recrystallized from acetone–dichloromethane. Yellow crystals, mp 180 °C (dec). It was identified as 2,3-dihydro-2-imino-3-acetylimino-1,4-naphthoquinone (**11**) on the basis of the following spectral data. IR (KBr): 1674 and 1640 (quinone CO, acetimino CO) cm^{-1}. MS: *m/e* 228 (M^+), 186 (M—ketene), 132. ^1H-NMR (DMSO-d_6) δ: 2.45 (s, 3H, CH_3), 7.8—7.9 (m, 2H, aromatic), 8.4—8.6 (m, 2H, aromatic), 12.8 (broad, 1H, NH) ppm. ^{13}C-NMR (DMSO-d_6) δ: 13.1 (q), 120.4 (s), 129.8 (s), 129.9 (s), 132.6 (s), 133.0 (s), 133.4 (s), 136.0 (s), 151.2 (s), 155.0 (s), 162.9 (s), 176.0 (s) ppm.

Preparative TLC (Merck Silica-gel 60 F_{254}) of the filtrates from the condensed solutions gave the photoproducts shown in Table 3.

The author wishes to thank to Professor Michio Kobayashi (Tokyo Metropolitan University) for helpful discussions, Professor Tamaichi Ashida (Nagoya University) and Mr. Yukishige Kitano (Toray Research Center) for X-ray crystal structure analyses, and Dr. Ikuo Sakai (Toray Research Center) for NMR spectral analyses.

The Mechanism of the Reactions of Alkoxy- and Aryloxytrimethylsilanes with Sulfinyl Chlorides. A Doubt about 4-Center Mechanism for the Bimolecular IVb–VIb Bond Cleavages[1)]

Seizi KOZUKA* and Tetsuji HIGASHINO

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received August 2, 1980)

Kinetic studies have been conducted for the reactions of ethoxytrimethylsilane with benzenesulfinyl chloride and aryloxytrimethylsilane with methanesulfinyl chloride. Both the reactions were found to obey second order rate equation. A clear negative ρ value was observed for the reaction of aryloxytrimethylsilane. The solvent effects suggested that both the two reactions were quite similar in their mechanisms. Nucleophilic addition of silyl-oxygen atom to sulfinyl group has been suggested for these two reactions.

Recently, Harpp *et al.* conducted kinetic studies for the reaction of alkoxytrimethylsilanes with benzenesulfinyl chloride.[2)] They observed that the reaction was rather insensitive to the solvent polarity and sensitive to the steric effect of the alkoxyl group. A *four-centered nonionic transition state* (I) has been suggested for the reaction.

$$\mathrm{RO\text{-}SiMe_3 + PhS(O)Cl \longrightarrow \left[\begin{array}{l} O \\ \| \\ Ph\text{-}S\cdots Cl \\ \vdots \quad \vdots \\ RO\cdots SiMe_3 \end{array}\right] \longrightarrow PhS(O)OR + ClSiMe_3} \quad (1)$$

R = Me, Et.

I

The mechanism has widely been accepted to explain the course of the reaction involving the IVb element at the reaction center,[3)] however, only few were supported by kinetic and/or stereochemical evidences.[4,5)] Restricting to bimolecular IVb–VIb bond cleavage reactions as expressed by the following general formula (Eq. 2),[6)]

$$\equiv\mathrm{IVb\text{-}VIb\text{-}} + \mathrm{E\text{-}Nu} \longrightarrow \equiv\mathrm{IVb\text{-}Nu} + \mathrm{E\text{-}VIb\text{-}} \quad (2)$$

IVb = Si, Ge, Sn *etc.* VIb = O, S, Se *etc.*

E-Nu = H_2O, ROH, RCO_2H, RX, RCOX, RS(O)X *etc.*

the reaction of alkoxysilane reported by Harpp *et al.* is the only one reaction involving the mechanism supported by kinetic evidence.[2)]

We have reexamined the reaction of alkoxysilane with sulfinyl chloride in order to obtain additional kinetic aspects of the bimolecular *nonionic four-centered reaction*, or to take a new look at the mechanism and found that the reaction involved *ionic* nucleophilic attack of the silyl-oxygen atom.

Results and Discussion

Examination of the substituent effect of the *nonionic four-centered reaction* would be of interest or important to clarify the reaction mechanism. Thus, we tried to prepare substituted-benzenesulfinyl chlorides to examine the substituent effect of the reaction shown in Eq. 1. The substituted-sulfinyl chlorides can be prepared either from the corresponding disulfides[7a)] or from sodium sulfinates,[7b)] however, it was found to be difficult to prepare them in pure forms enough for kinetic experiments. Alternatively, the reaction of aryloxytrimethylsilane with methanesulfinyl chloride was chosen for our study. The reaction was found to give methanesulfinate and chlorotrimethylsilane in nearly quantitative yields.

$$p\text{-X-}C_6H_4OSiMe_3 + MeS(O)Cl \longrightarrow p\text{-X-}C_6H_4OS(O)Me + Me_3SiCl \quad (3)$$

The rate of the reaction was measured by monitoring ^{1}H NMR trimethyl signals of the starting aryloxysilane and the formed chlorosilane at time. A good second order kinetic plot was obtained with satisfactory reproducibility. The results are given in Table 1.

Table 1. Rate of the reaction of $Me_3SiOC_6H_4X$-*p* (0.19 mol/dm^3) with MeS(O)Cl (0.23 mol/dm^3) in PhCN

X	Temp/°C[a)]	k/dm^{3}mol^{-1} s^{-1}	Remarks

Cl	—	6.60×10^{-4}	($\gamma=0.984$)
Br	—	6.30×10^{-4}	
NO_2	—	7.04×10^{-5}	

a) JEOL PS-100, VT Probe was used for measurement of activation parameters. Temperatures were calibrated. Substituent effect was measured on Hitachi R-20, at magnet temperature (36 °C); not calibrated.

The activation parameters appeared as normal magnitude for the reactions of this type shown in Eq. 2; not particular from the reactions involving either 5-coordination of the IVb element[8)] or nucleophilic attack of the VIb atom.[9)] More clear evidence in support of an *ionic mechanism* for the reaction is the substituent effect. A clearly negative ρ value was observed for the reaction in almost the same magnitude with those of the analogous reactions of (arylthio)trimethylstannanes with haloalkane (-1.40)[9a)] and with benzoyl chloride (-1.6)[9b)] in which nucleophilic attacks of the stannyl-sulfur atoms have been suggested for the reactions based on kinetic

and stereochemical results. The value is also pretty close to that of sulfonium salt formation which undoubtedly involves nucleophilic attack (-1.2).[10] In addition to these similarities, the magnitude of the entropy of activation is in accordance with that of the sulfonium salt formation (-138 J K^{-1} mol^{-1}).[10] These results would suggest a rate-determining nucleophilic attack of the silyl-oxygen atom giving oxonium intermediate for the reaction of aryloxytrimethylsilane with sulfinyl chloride (Eq. 3). Thus, the mechanism shown below would be the most plausible for the reaction.

$$Me_3SiOAr + MeS(O)Cl \xrightarrow{slow} \left[\begin{array}{c} Cl \\ | \\ Me_3SiO^+\text{–}SMe \\ | \quad | \\ Ar \quad O^- \end{array}\right] \quad \text{II}$$

$$\xrightarrow{fast} Me_3SiCl + ArOS(O)Me \qquad (4)$$

The detailed mechanism leading to the product from the onium intermediate (II) is not clear but *ionic four-centered transition state* (III) for the step is unlikely based on the similarities of the ρ and entropy values as discussed above.

$$\left[\begin{array}{c} Me_3Si\ldots Cl \\ \vdots \quad \vdots \\ ArO^+\text{–}S\text{–}Me \\ | \\ O^- \end{array}\right] \quad \text{III}$$

The remaining question is whether the nucleophilic addition mechanism is applicable to the reaction of Harpp *et al.* shown in Eq. 1.[2] Different mechanisms for the two reactions (Eqs. 1 and 3) are unlikely since the nucleophilic mechanism has been suggested even for the reaction of less nucleophilic aryloxy-oxygen atom. The more nucleophilic alkoxy-oxygen would attack the sulfinyl group in the same manner. Solvent effects on both the reactions were examined in order to prove the similarity of their mechanisms. The rates of the reactions were measured in various solvents including carbon tetrachloride and dichloromethane which have been employed by Harpp *et al.* The effect presently observed [$k(CH_2Cl_2)/k(CCl_4)=3.8$] is in accordance with that of them (5) as shown in Table 2.[11]

Both the rates of the reactions were clearly accelerated in polar solvents. The observed solvent effect for the reaction of aryloxysilane [Eq. 3, X=MeO; $k(Ph_6CN/k(CCl_4)=70$] is pretty close to that observed for the reaction of arylthiostannane with halo-alkane [$k(PhCN)/k(C_6H_6)=ca.$ 100] in which nucleophilic attack was suggested as the mechanism.[9a] The effect, however, appeared substantially smaller for the reaction of ethoxysilane (Eq. 1, R=Et). The difference in the magnitudes of the solvent effects is not clear; may perhaps due to difference in charge delocalization in the intermediates or in solvations, but both the rates in various solvents exhibit clearly linear correlation as shown in Fig. 1. The linear correlation ($\gamma=0.998$) would reveal that these two reactions proceed in a similar manner *i.e.*, the nucleophilic addition mechanism. The *nonionic four-center mechanism* suggested by Harpp *et al.*[2] has thus been ruled out also for the reaction of alkoxysilane (Eq. 1).

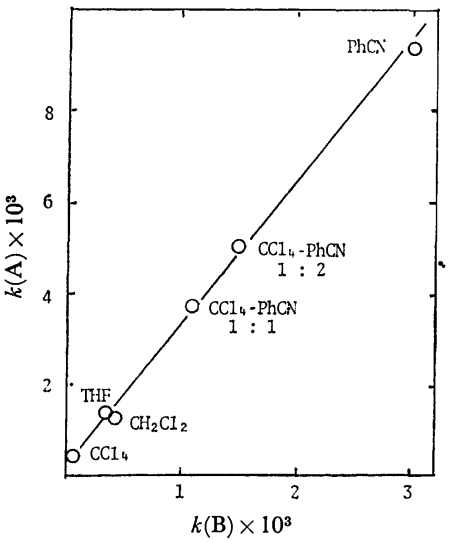

Fig. 1. Plot of the rates of the reaction A (Eq. 3, X=OMe) *vs.* reaction B (Eq. 1, R=Et) in various solvents.

The evidences cited by them in support of their mechanism were the solvent effect and the steric effect.[2] They examined five different solvents but all nonpolar ones. They compared their result with that of cheleotropic denitrogenation reaction of a caged diazo compound[12] in support of their *nonionic mechanism.* The auther claimed that the solvent effect of the reaction of alkoxysilane [$k(CH_2Cl_2)/k(C_6D_{12})=9$] was pretty close

Table 2. Rates of the reactions; $Me_3SiOC_6H_4OMe$-*p* (0.19 mol/dm^3)+MeS(O)Cl (0.23 mol/dm^3) [A] and Me_3SiOEt (0.16 mol/dm^3)+PhS(O)Cl(0.20 mol/dm^3) [B] in various solvents at 36 °C[a]

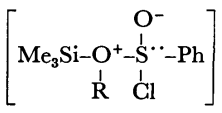
a) Hitachi R-20 NMR magnet temperature; not calibrated. b) Reaction A and B are correspond to the reactions shown in Eqs. 3 and 1 in the text, respectively. c) Data from Ref. 2; initial concentrations were not recorded. d) Second order rate in dm^3 mol^{-1} s^{-1}. e) v/v Mixture.

to that of the cheleotropic reaction which was studied over a wide variety of solvents and a small solvent effect ($\simeq$15-fold) was noted.[2] The effects, however, appeared opposite. The rates of the cheleotropic reaction appeared no correlation to the solvent polarity; rather accelerated in nonpolar solvent (2-Me-heptane) and depressed in polar solvent (96% EtOH).[12] On the other hand, the rates of the reaction of alkoxysilane were apparently accelerated in a polar solvent (CH_2Cl_2).[2] In the present study, it was shown to be accelerated more in more polar solvent.

The steric effect of the alkoxy moiety [k(EtO)/k(MeO)=10] indicates that the reaction is sensitive to the steric hindrance as they claimed.[2] The sensitivity to the steric hindrance, however, is also acceptable to the steric crowd in the onium intermediate (IV), bearing bulky trimethylsilyl group and trigonal bipyramid sulfur functionality.



R = Me, Et,

IV

The *nonionic four-centered mechanism* has been ruled out for the reactions of (arylalkoxy)silanes with sulfinyl chlorides. None of the bimolecular reactions of this type shown in Eq. 2, has been known to proceed *via* either *ionic* or *nonionic four-center transition state* which has been supported by any evidence.

Experimental

Materials. Trimethylphenoxysilane was prepared from hexamethyldisilazane (5.0 g) and phenol (4.7 g) in the presence of imidazole,[2] bp 41 °C/2 mmHg (1 mmHg=133.332 Pa), 88% yield. Other aryloxytrimethylsilanes were prepared similarly. Methanesulfinyl chloride was prepared by chlorination of dimethyl disulfide in acetic anhydride,[7a] bp 38—41 °C/14 mmHg, 84% yield. Benzenesulfinyl chloride was prepared from sodium benzenesulfinate and thionyl chloride,[7b] 77 °C/1 mmHg, 95% yield.

Product Analysis. An equimolar mixture of methanesulfinyl chloride and trimethylphenoxysilane (10 mmol) in dichloromethane (4 ml) was heated at 45 °C for 20 h in a sealed tube. The solvent and volatile product were distilled off. Only chlorotrimethylsilane was detected in the distillate. ^{1}H NMR spectrum of the residue was consisted of the signals due to the remaining trimethylphenoxysilane and phenyl methanesulfinate with trace amounts of impurities which probably derived from thermal decomposition of the sulfinate ester. Signals were identified by comparing with those of the authentic phenyl methanesulfinate prepared from methanesulfinyl chloride and phenol in the presence of pyridine.[13] Attempts to isolate the sulfinate from the remaining trimethylphenoxysilane were failed due to its thermal instability. Accordingly, the conversion was obtained by integration of the NMR signals of the reaction mixture, 70%. Other aryloxytrimethylsilanes gave similar results. Substituent, reaction conditions, and conversion were: p-OMe, 45 °C 5 h, 80%; p-NO_2, 45 °C 24 h, 50%.

Kinetics. The procedure is essentially the same as that employed for the acyloxyl exchange reaction of acetoxysilane.[8a] Trimethylphenoxysilane (21 mm^3, 0.121 mmol) and methanesulfinyl chloride (10 mm^3, 0.143 mmol) were dissolved in the solvent (600 mm^3) and the reaction was monitored by following ^{1}H NMR trimethyl signals of the starting trimethylphenoxysilane (δ 0.27 ppm) and the product, chlorotrimethylsilane (δ 0.40 ppm) with time.

11) The rates of the reaction in CCl_4 and CH_2Cl_2 reported by Harpp *et al.* could not be reporduced, *e.g.*, 5×10^{-5} and 2.7×10^{-4} in CCl_4 and CH_2Cl_2, respectively,[2] although the k_{rel} appeared quite similar. These deviations in the k values may be due to the difference in the initial concentrations of the substrates and also in temperatures which were not calibrated.

(Received August 4, 1980)

When treated with concentrated nitric acid in dichloromethane at room temperature, the title compounds undergo an exclusive attack on the methyl group at the most crowded site, giving 6-acyl-2,3,4,5-tetramethylbenzyl nitrates, and 2,6-diacyl-3,4,5-trimethylbenzyl nitrates and/or (2,6-diacyl-3,4,5-trimethylphenyl)nitromethanes respectively, as the major products. While the predominant mode of the side-chain substitution reactions is nitrooxylation for acylpentamethylbenzenes and 1,3-dipivaloyl-2,4,5,6-tetramethylbenzene, it shifts to nitration for 1,3-bis(trihalogenoacetyl)-2,4,5,6-tetramethylbenzenes. Nitrodeacylation is seen to some extent for pivaloylbenzenes, but not for trihalogenoacetylbenzenes. The exclusive attack on the methyl group at the most hindered position can be explained by a sequence involving the attachment of a nitronium ion at the site *meta* to the acyl group, followed by a proton release from the resulting arenium ion to form a nitromethylenecyclohexadiene intermediate, which is then transformed into the benzylic compounds *via* a benzyl cation/nitrite anion pair.

When treated with nitric acid at a low temperature, polyalkylated aromatic compounds often suffer the side-chain substitution to give benzylic compounds in addition to the normal nuclear substitution products. The side-chain reaction is characterized by a peculiar orientation and high regiospecificity in the products, which stand in marked contrast to the ordinary side-chain substitution occurring through a homolytic mechanism. The puzzling features of this reaction have been a subject of numerous recent studies,[2] but its mechanism still remains a matter of controversy and speculation. Recently, we have made a systematic investigation of the nitration of hexamethylbenzene and presented the first quantitative data of the product distribution; these data favor the S_Nl' mechanism, in which the side-chain substitution products are formed from the methylenecyclohexadiene intermediate through the intervention of an ion-pair.[3] To obtain further information about the character of the reaction, especially the steric effect of the substituent group on the course of the side-chain substitution, a series of acylpentamethylbenzenes and 1,3-diacyl-2,4,5,6-tetramethylbenzenes bearing bulky acyl groups, such as pivaloyl, trichloroacetyl, and tribromoacetyl groups, have been prepared, and their reactions with concentrated nitric acid have been investigated.

Experimental

All the melting points were determined on a hot-stage apparatus and are uncorrected. The infrared spectra were run as Nujol mulls on a Hitachi 215 spectrophotometer, and only prominent peaks were recorded. The ^{1}H-NMR spectra were measured in chloroform-*d* with a Varian T-60 apparatus and a JEOL MH-100 apparatus, using TMS as the internal standard, unless otherwise stated. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer, with an ionizing current of 70 eV.

Materials. *1,3-Dipivaloyl-2,4,5,6-tetramethylbenzene (7b)* was prepared from 1,3-dipropanoylbenzene (**6**) by repeated treatment with potassium *t*-butoxide and methyl iodide.[4]

Pentamethylpivalophenone (3b). Into a mixture of pivaloyl chloride (3.4 g, 28.2 mmol), aluminium chloride (6.5 g, 48.7 mmol), and carbon disulfide (20 ml), pentamethylbenzene (**1**; 5.0 g, 33.7 mmol) in carbon disulfide (15 ml) was stirred under ice-salt-bath cooling during the course of 0.3 h. After the addition, the brown viscous mixture was stirred for a further 0.7 h at room temperature and then decomposed with dilute hydrochloric acid. The organic layer was separated, the carbon disulfide was removed, and the residual solid product was collected by filtration and subjected to chromatography over silica gel, using hexane as a solvent. The unchanged hydrocarbon and then the ketone **3b** were eluted, and the latter was recrystallized from ethanol. White needles, mp 129—130 °C. Yield, 2.8 g (42% based on the pivaloyl chloride used).

1,3-Bis(tribromoacetyl)-2,4,5,6-tetramethylbenzene (7d).[5] Bromine (8.0 g, 50 mmol) was stirred into a solution of sodium hydroxide (8.0 g, 200 mmol) in water (70 ml). The temperature was kept below 10 °C during the addition. To the resulting solution, 1,3-diacetyl-2,4,5,6-tetramethylbenzene (**5**; 1.1 g, 5 mmol) dissolved in benzene (15 ml) was added; the mixture was then heated with vigorous stirring at 60 °C, while the progress of the reaction was monitored by means of ^{1}H-NMR. After 40 h, a further amount of aqueous sodium hypobromite (50 mmol) was added; heating was then continued for an additional 20 h. The organic layer was then separated, washed thoroughly with aqueous sodium hydrogensulfite and then water, and dried over magnesium sulfate. The solvent was removed, and the residue was recrystallized from benzene to give **7d** as colorless prisms; mp 195—197 °C. Yield, 2.28 g (65%).

1,3-Bis(trichloroacetyl)-2,4,5,6-tetramethylbenzene (7c) was similarly prepared by treating **5** with a large excess of aqueous sodium hypochlorite at 60 °C. It was recrystallized from benzene to give white needles; mp 138—139 °C. Yield, 37%.

Procedures for Nitration of Acylpentamethylbenzenes and 1,3-Diacyl-2,4,5,6-tetramethylbenzenes. Some typical examples are shown below for the nitration of α,α,α-trichloropentamethylacetophenone (**3c**) and 1,3-bis(trichloroacetyl)-2,4,5,6-tetramethylbenzene (**7c**).

i): Nitric acid (d=1.5; 0.63 g, 10 mmol) in dichloromethane (2 ml) was added to a vigorously stirred suspension of **3c** (0.50 g, 1.7 mmol) in dichloromethane (4 ml). The

mixture was stirred at room temperature for 1.5 h and then diluted with water. The organic layer was separated, and the aqueous layer was extracted with dichloromethane. The combined organic solutions were washed thoroughly with water, dried over magnesium sulfate, and evaporated to leave a solid residue, which was recrystallized several times from hexane to give **4c** as white crystals; mp 106—109 °C. Yield 0.27 g (45%).

ii): A suspension of 1,3-bis(trichloroacetyl)-2,4,5,6-tetramethylbenzene (**7c**; 1.0 g, 2.35 mmol) in dichloromethane (5 ml) was cooled to −10—0 °C, after which fuming nitric acid (d=1.5; 1.48 g, 23.5 mmol) was stirred in over a period of 5 min. The resulting brown mixture was stirred at room temperature for 3 h and then diluted with water. The organic layer was separated and worked up as usual to give a light brown, pasty solid, which was then passed through a short silica-gel column to obtaine the unchanged substrate (0.67 g) and a product mixture (0.151 g). The latter was then chromatographed on a thin-layer silica-gel plate, using hexane as the eluant. Two main bands were scraped off from the glass plate and extracted with ether; *1,3-bis(trichloroacetyl)-2-nitrooxymethyl-4,5,6-trimethylbenzene* (**9c**; 22 mg, 6%) was obtained from the fast moving band, and *1,3-bis(trichloroacetyl)-2-nitromethyl-5,4,6-trimethylbenzene* (**8c**; 39 mg, 11%), from the slow moving band.

In an alternative way, the product mixture was dissolved in a minimum amount of pentane, after which the solution was kept in a refrigerator for several days. Compounds **8c** and **9c** crystallized out as prisms and needles, respectively and were partially separated by hand-picking.

Results and Discussion

Acylbenzenes undergo nitration mainly at the position *meta* to the acyl group, as would be expected from the deactivating effect of the acyl group. Some examples of an acyl group being replaced by a nitro group are also well known.[6] However, the literature so far contains no report on the nitration of fully methylated acylbenzenes and diacylbenzenes.

Pentamethylacetophenone (**2**) reacted slowly with concentrated nitric acid in dichloromethane at −5—0 °C to give a four-component mixture, from which the major product was isolated and identified as 6-nitrooxymethyl-2,3,4,5-tetramethylacetophenone (**4a**). On similar treatment, 1,3-diacetyl-2,4,5,6-tetramethylbenzene (**5**) gave a complex mixture of products, one component of which was isolated by TLC and identified as 5-nitro-2,3,4,6-tetramethylacetophenone (**14**). The general pattern of the reaction was similar to those found in the nitrations of pentamethylbenzoic acid[7] and pentamethylbenzamide.[8] The nitrating agent seems to attack the acetyl group partially, making the products more complicated and difficult to separate.

Based on the results obtained from these preliminary experiments, we turned to the nitration of the title hindered mono- and diketones in order to see if the replacement of the acetyl group by a bulky acyl group, such as the pivaloyl and trihalogenoacetyl groups, may produce any effect on the course of the reaction or the product distribution. Pentamethylpivalophenone (**3b**) was obtained by the Friedel-Crafts acylation of pentamethylbenzene (**1**) with pivaloyl chloride. 1,3-Dipivaloyl-2,4,5,6-tetramethylbenzene (**7b**) could not be obtained by the similar acylation of 1,2,3,5-tetramethylbenzene; after several unsuccessful attempts, it was, however, prepared by the exhaustive methylation of 1,3-dipropanoyl-2,4,5,6-tetramethylbenzene (**6**) with potassium *t*-butoxide and methyl iodide. α,α,α-Trihalogenopentamethylacetophenones (**3c** and **3d**) and 1,3-bis(trihalogenoacetyl)-2,4,5,6-tetramethylbenzenes (**7c** and **7d**) were obtained following the routes outlined in Schemes 1 and 2. The halogenation with sodium hypohalite of the **2** and **5** ketones proceeded quite slowly, and the repeated treatment of partially halogenated ketones with a fresh batch of aqueous sodium hypohalite was necessary to obtain **7c** and **7d** in acceptable yields. All of these mono- and diketones are well-crystallized solids and are poorly soluble in ordinary non-polar solvents.

The treatment of acylpentamethylbenzenes **3b**—**3d** with an excess of nitric acid (d=1.5) in dichloromethane at room temperature, followed by the chromatography of the product over silica gel, gave the corresponding 6-nitrooxymethyl-2,3,4,5-tetramethylacylbenzenes **4b**—**4d** in 40—60% yields. The characteristic appearance of benzylic protons as a pair of doublets at δ 5.0—5.3 and 5.4—5.5 ppm indicated the presence of a nitrooxymethyl group adjacent to the bulky acyl group. Thus, irrespective of any difference in bulkiness or electron-withdrawing ability, the propensity of the acyl group to direct an entering group on the adjacent alkyl side-chain

* Determined in carbon tetrachloride.

was maintained through the whole series of four acylpentamethylbenzenes **3a**—**3d**. Nitrodeacylation was observed to some extent with pivalophenone, **7b**, but not at all with α,α,α-trihalogenoacetophenones, **7c** and **7d**. By similar treatment, 1,3-dipivaloyl-2,4,5,6-tetramethylbenzene (**7b**) gave 2,6-dipivaloyl-3,4,5-trimethylbenzyl nitrate (**9b**) as a side product (10—20%), in addition to the expected nitrodeacylation product, 5-nitro-2,3,4,6-tetramethylpivalophenone (**10**). Only the methyl group, flanked on both sides by bulky pivaloyl groups, suffered side-chain nitrooxylation. Those results, together with those obtained from the nitration of acylpentamethylbenzenes, **3b**—**3d**, present a striking contrast to the ordinary aromatic substitutions, which are quite sensitive to the bulkiness of the substituent groups.

The action of nitric acid upon the diacyl compounds, **7c**—**7d**, afforded a mixture of (2,6-diacyl-3,4,5-trimethylphenyl)nitromethanes, **8c**—**8d**, and 2,6-diacyl-3,4,5-trimethylbenzyl nitrates, **9c**—**9d**; the yields, as estimated from the ^{1}H-NMR peak integration, were 40—45 % and 20—25%, respectively, based on the unrecovered starting materials. With these halogeno-ketones, no nitrodeacylation was observed. The methyl group between two bulky acyl groups was exclusively attacked again. In these cases, however, the major mode of the side-chain reaction changed from nitrooxylation to nitration. Such a marked change produced by a slight modification of the substituent groups was unexpected, and we can find no parallel previously in the reported literature.

At room temperature the benzylic protons of the

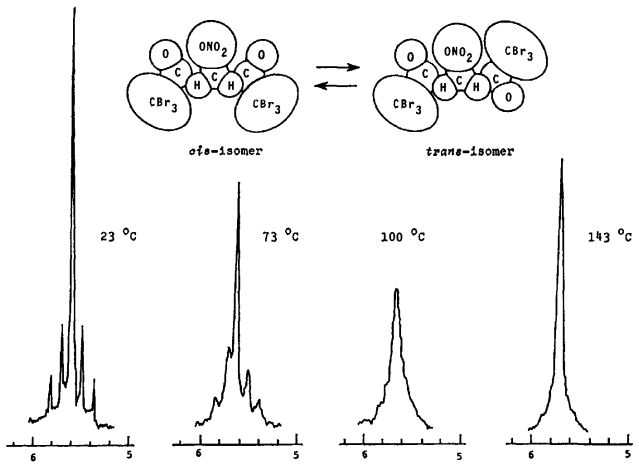

Fig. 1. Selected variable temperature ^{1}H-NMR signals (100 MHz) for benzylic protons of *cis*/*trans* isomers of 2,6-bis(tribromoacetyl)-3,4,5-trimethylbenzyl nitrate (**9d**) in *o*-dichlorobenzene.

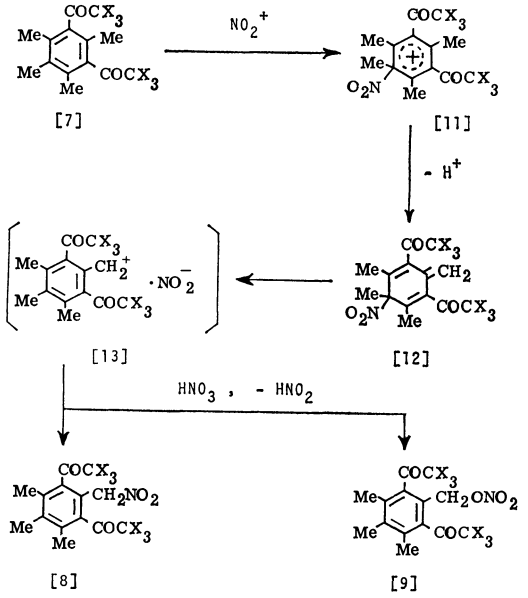
nitrates, **9b**—**9d** and nitromethanes, **8c**—**8d**, appear as a peak cluster consisting of one double doublet signal and one singlet signal in the ^{1}H-NMR spectrum (Table 1). In the high-temperature spectrum, however, this peak cluster converges into a new single peak which occurs at the average position of the corresponding peaks in the low-temperature spectrum, indicating that these nitrates and nitromethanes exist in a pair of stable conformations resulting from the *cis*/*trans* isomerism due to restricted rotation about carbonyl groups. A variable-



Scheme 3.

temperature ^{1}H-NMR spectrum of the **9d** nitrate is shown in Fig. 1. Clearly, at room temperature and below **9d** exists in the form of *cis/trans* isomers, the ratio of which is estimated to be 2.6 from the peak-area integration. The details of this interesting isomerism will be described elsewhere.

An examination of the CPK molecular models of the **7b—7d** ketones indicates the difficulty of a direct attack by a solvated electrophile on a methyl group flanked on both sides by bulky acyl groups. Thus, the nitration and nitrooxylation occurring exclusively on the methyl group at the most crowded site can be explained by the indirect sequence depicted in Scheme 3: an *ipso* attack of a nitronium ion on the most reactive ring site of **7** to form the arenium ion (**11**) is followed by a proton release from the activated methyl group *para* to the site of attack to give the triene (**12**), which is then transformed into the benzylic compounds, **8** and **9** *via* the assumed ion-pair (**13**).[3]

The authors wish to thank Dr. Tetsuo Ohtsuki of Kyoto University for measuring the variable-temperature ^{1}H-NMR spectra of hindered ketones described herein.

Synthesis and Reactions of Perylenecarboxylic Acid Derivatives. VIII. Synthesis of *N*-Alkyl-3,4:9,10-Perylenetetracarboxylic Monoanhydride Monoimide

Yukinori NAGAO* and Takahisa MISONO

Department of Industrial Chemistry, Faculty of Science and Technology, Science University of Tokyo, Yamazaki, Noda 278

(Received August 6, 1980)

The condensations of 3,4 : 9,10-perylenetetracarboxylic dianhydride with alkylamines (isobutyl-, pentyl-, hexyl-, and octylamines) were spectroscopically determined. Under all of the reaction conditions employed, *N*-alkyl-3,4 : 9,10-perylenetetracarboxylic monoanhydride monoimide (**2a—d**) (alkyl=a; isobutyl, b; pentyl, c; hexyl, d; octyl) were obtained. As the reaction proceeded, the yield of **2a—d** increased at an initial stage but decreased gradually after reaching a maximum. This maximum yield of **2a—d** was: **2a**; 85—88%, **2b**; 85—89%, **2c**; 78—84%, **2d**; 79—85%. The kinetics of the reaction were also examined.

In general, 3,4 : 9,10-perylenebis(dicarboximide) derivatives are synthesized by the condensation of 3,4 : 9,10-perylenetetracarboxylic dianhydride (**1**) with amines,[1-4] and have excellent resistance to light, heat, and solvents. Some of them are used as dyes or pigments. In previous papers[5,6] we described the preparation of unsymmetrical 3,4 : 9,10-perylenebis(dicarboximide)s having different substituents on N and N′ atoms by the reaction of 3,4 : 9,10-perylenetetracarboxylic monoanhydride monoimide (**2**), which was prepared by the condensation of **1** with an alkylamine, with arylamines. In the condensation of **1** with alkylamines, higher alkylamines appeared to be favorable for the formation of **2**. This suggests a possibility of selective formation of **2** in the condensation of **1** with amines by using higher or branched alkylamines. In this paper, we report the formation of **2** from isobutyl-, pentyl-, hexyl-, and octylamines and the kinetical study of the reaction by spectroscopic techniques.

Experimental

Materials. **1** was supplied by BASF. Isobutyl-, pentyl-, hexyl-, and octylamines were obtained commercially.

Preparation of N-Alkyl-3,4 : 9,10-perylenetetracarboxylic Monoanhydride Monoimide (2a—d) and N,N′-Dialkyl-3,4 : 9,10-perylenebis(dicarboximide) (3a—d). ***2a—d***: Into a solution of an amine in an appropriate solvent was added **1** with stirring at a definite temperature. The mixture was stirred vigorously for an appropriate reaction time. The reaction conditions for each reaction are given in Table 1. The reaction mixture was acidified with 10% hydrochloric acid, and the precipitate formed was filtered, washed with water to remove amine, dissolved in 1% hot potassium hydroxide, and filtered to remove insoluble precipitates of **3a—d**. The soluble material which remained in the precipitate was again dissolved in 1% hot potassium hydroxide. The combined filtrate was heated again to dissolved the precipitate which had formed in cooling, and filtered to remove the small amount of the floating precipitate of **3a—d** which had passed through the filter. To the filtrate was added potassium chloride until 10% concentration, and the precipitated potassium salt of **2a—d** was filtered. The solid was dissolved in water and acidified with 10% hydrochloric acid, and the precipitate formed was filtered, washed with water, and dried to yield **2a—d**.

3a—d: **3a—d** was prepared by the treatment of **1** with a corresponding amine solution at 200 °C for 10 h in an autoclave. Unreacted **1** and **2a—d** were dissolved in hot 1% potassium hydroxide solution and removed from the precipitate of **3a—d**.

IR, visible spectra, mass spectra, and analysis data are given in Table 2. Samples for elementary analysis were obtained by a sublimation at 300—350 °C/3—5 mmHg.

Condensation of 1 with Amines. To a flask containing **1** 0.50 g (1.27×10^{-3} mol) and 30 ml solvent (isobutyl- and pentylamines; water, hexyl- and octylamines; water : 1-propanol=2 : 1 and 1 : 1), and maintained at the optimum temperature in a thermostat was added an amine solution 20 ml (optimum amine was dissolved in the same solvent) maintained at the same temperature with stirring. The reaction mixture showed a complicated suspension and not a homogeneous solution. This was stirred vigorously to maintain a homogeneous solution. Samples were collected at regular intervals and acidified with 10% hydrochloric acid. The precipitate was centrifuged, dried, and dissolved in 95% sulfuric acid, and the absorbances were measured. The composition of the reaction mixture were calculated from the absorbances. The optimum wavelengths (510 nm and λ_{max} of **2a—d** and **3a—d**) for the determination were decided from the standard 95% sulfuric acid solution of **1**, **2a—d**, and **3a—d**.

Measurements and Calculations. Paper Chromatography: Samples were dissolved in 1% potassium hydroxide or DMSO, placed on the paper, and developed by a mixture of equal volumes of 1-butanol, pyridine, 28% ammonia, and water.

The composition and rate ratio (K) were calculated using an IBM 370 computer. Mass spectra were recorded on a Hitachi RMU-7M mass spectrometer. Visible spectra were recorded on a Hitachi 124 spectrometer for solutions in concd sulfuric acid, and IR spectra on a Nippon Bunko IR-E spectrometer.

Results and Discussion

Preparation of 2a—d and 3a—d. Table 1 gives the reaction conditions, and the yields of **2a—d** and the by-product **3a—d**. The analytical and spectral data for **2a—d** and **3a—d** are given in Table 2. λ_{max}

in visible spectra of 95% concd sulfuric acid solution is 580—581 nm for **2a—d** and 598—599 nm for **3a—d**. *N*-Alkyl substituents in **2a—d** or **3a—d** caused no significant difference in the λ_{max}. IR spectra indicate that $\nu_{C=O}$ of anhydride and imide both exist in **2a—d**, and only $\nu_{C=O}$ of imide exists in **3a—d**. Mass spectra showed the corresponding molecular ion peak.

*Condensation of **1** with Amine.* In the reactions at 40—80 °C, the reaction mixture, after the amine was removed, has been proved to give no other products than the **2a—d** and **3a—d** by paper chromatography. The molar ratios, $C_A/(C_A+C_M+C_I)$, $C_M/(C_A+C_M+C_I)$,

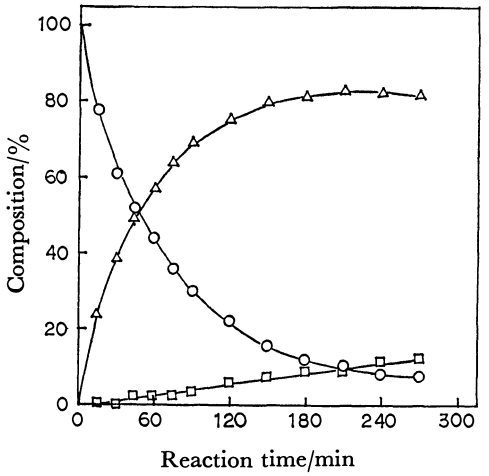

Fig. 1. Reaction of 3,4: 9,10-perylenetetracarboxylic dianhydride (**1**) with isobutylamine.
1; 1.27×10^{-3} mol/50 ml H_2O, temp; 60 °C, mole ratio (amine/**1**); 10. ○; 3,4: 9,10-Peryleneteracarboxylic dianhydride (**1**), △; *N*-Isobutyl-3,4: 9,10-perylenetetracarboxylic monoanhydride monoimide (**2a**), □; *N,N'*-Diisobutyl-3,4: 9,10-perylenebis(dicarboximide) (**3a**).

$C_I/(C_A+C_M+C_I)$, were determined by spectrometry, where C_A, C_M, and C_I are the concentrations of **1**, **2a—d**, and **3a—d**, respectively. Figure 1 shows a typical time-conversion curve showing that the reaction proceeded in successive manner. The maximum yields of **2a—d** on the time-conversion cuves, at the best temperature, are given in Table 3 for the reactions at 40—80 °C. Lower temperatures were favorable for selective preparation of **2c** and **2d**.

Plots of $\ln(C_A/C_{Ao})$, where C_{Ao} is the initial concentration of **1**, *vs.* time were linear, and the rate constants k_1 for the reaction of **1** to **2a—d**, were calculated from the slopes. Then the rate ratios $K(=k_2/k_1)$, where k_2 is the rate constant of **2a—d** to **3a—d** were calculated from Eq. 1.[5] Most of the K values in each reaction were constant. These results indicated that the reaction followed a pseudo first order process of **1**→**2a—d**→**3a—d**.

$$C_M/C_{AO} = \{1/(1-K)\}\{(C_A/C_{AO})^K - (C_A/C_{AO})\} \quad (1)$$

Figure 2 shows the variation of the maximum yield of **2a—d** and K with the number of carbon atoms in amine. As the number of carbon atoms in amine increases, the maximum yields of **2** increase in the reaction of **1** with methyl-, ethyl-, propyl-, and butylamines.[5] Though there is an increasing of the maximum yields of **2a—b** in isobutyl- and pentylamines, it is followed by an approximately constant in hexyl- and octylamines. It also indicate the pseudo first order reaction that the small K value increase the maximum yields of **2a—d**.

Figure 3 shows the variation of k_1 with the number of carbon atoms. This result shows that k_1 decreases with an increasing of the number of carbon atoms in all amines except octylamine. The reactions with methyl-, ethyl-, propyl-, and butylamines gave a similar results.[5] Lower k_1 in isobutylamine shows that the steric hindrance of alkyl group affects this reaction. The mixture

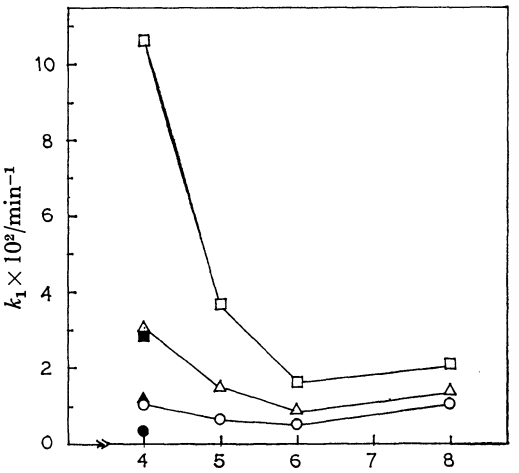

Fig. 3. Variation of k_1 with the number of carbon atoms in amine.
1; 1.27×10^{-3} mol/50 ml solvent, temp; 60 °C. Mole ratio (amine/**1**): 4: ○; butyl-, pentyl-, hexyl-, octylamines, ●; isobutylamine. 10: △; butyl-, pentyl-, hexyl-, octylamines, ▲; isobutylamine. 24: □; butyl-, dentyl-, hexyl-, octylamines, ■; isobutylamine.

of water and propanol was used for the solvent in the reaction with hexyl- and octylamines because of their poor solubility in water. Then the solvent effects have to be considered in these amines: the increasing k_1 in octylamine is explained as the effect of the solvent.

Catalysis of Metal(II) Acetate-2,2'-Bipyridine Complexes in the Aldol Condensations

Kazuo IRIE and Ken-ichi WATANABE*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received September 30, 1980)

The rate of the condensation of benzaldehyde with excess acetophenone catalyzed by Co(II) acetate-2,2'-bipyridine complex was obtained by GLC analysis. The rate increased in proportion as the amount of the complex catalyst. 2,2'-Bipyridine ligand in the Co(II) complex enhanced the catalytic activity remarkably, though the ligand itself had no activity. When the molar ratio of Co(II): bpy was 1 : 1 or 1 : 2, the highest activity was observed. The activation energy of the complex (1 : 1) catalyzed reaction was calculated as 13.7 kcal/mol. The catalysis of the complex behaved like a base catalyst. Briefly, the relation of the complex catalyzed aldol condensations with the enzymatic reaction of Class II aldolase is also described.

The aldol condensation reactions are generally catalyzed by strong acids or bases. In preceding paper, we have reported that many kinds of the condensation are catalyzed by metal(II) complexes under neutral conditions and afford only cross condensation products, α,β-unsaturated ketones, in satisfactory yields.[1,2] The potent catalysts are complexes of 2,2'-bipyridine(bpy) and the first-row transition metal acetates, particularly Co(II), Ni(II), Cu(II), and Zn(II), and DMF is an excellent solvent.

In this paper, we describe the kinetics of the condensation of the benzaldehyde with acetophenone in DMF containing $Co(OAc)_2$–bpy complex and features of M(II)acetate–bpy complex. As this study might be connection with the catalysis of Class II aldolase governing the aldol condensation in microorganism, some considerations are also described briefly.

Results and Discussion

Catalytic Behavior of the Metal(II) Complexes. In order to examine the catalytic behavior of the metal complexes in the reaction, the condensations of benzaldehyde with acetophenone(excess) in the presence of $Co(OAc)_2$–bpy complex were carried out. In the case of this reaction system, dehydration of the addition product occurred immediately to give 1,3-diphenyl-2-propen-1-one(chalcone) without any by-product. The yields of chalcone were determined by GLC analysis.

$$PhCH(=O) + CH_3C(=O)Ph \xrightarrow[DMF]{Co(OAc)_2\text{-bpy}} PhCH{=}CHC(=O)Ph \quad \text{(Chalocone)}$$

The correlation of the yield(%) with reaction time was observed as a curve line shown in left hand of Fig. 1 which is a typical example. The ln plot of $(a-x)$ (a: initial concentration of the aldehyde, x: concentration of the chalcone produced) *versus* reaction time was shown as a straight line (right hand in Fig. 1). This meant the first order reaction for the concentration of the aldehyde used. The observed rate constant (k'_{obsd}) was calculated from the slope. Thus similar reaction profile was observed in other examples as mentioned below, and therefore, these rate constants were compared to elucidate the catalytic activity.

Firstly, the dependence of k'_{obsd} on the concentration of the complex was examined. The reaction and the catalyst used were similar to that mentioned above, and the concentrations of the catalyst employed were 8 mmol/l, 4 mmol/l, and 2 mmol/l to that of the aldehyde 200 mmol/l. The $k'_{obsd}\times 10^5$ (s^{-1}) were 12.3, 2.66, and 0.65, respectively, and the reaction rate was dependent apparently on the concentration of the complex catalyst. Thus, it has been shown that Co(II)–bpy complex has worked as true catalyst in this reaction.

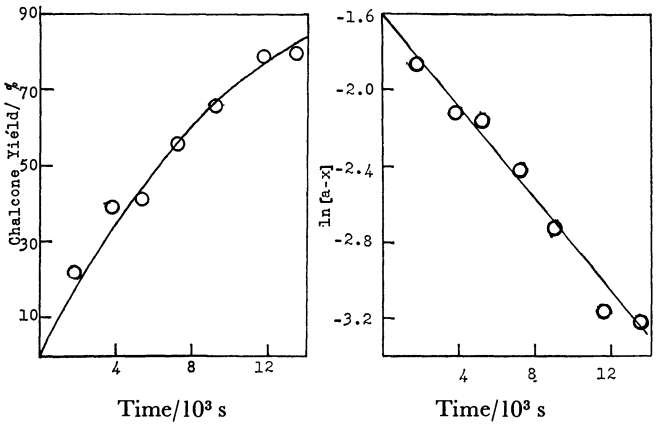

Fig. 1. Reaction profile of the aldol condensation catalyzed by $Co(OAc)_2$–bpy(1: 1)complex in DMF at 82 °C. [catalyst]=0.008 mol/dm³, [benzaldehyde]=0.2 mol/dm³, [acetophenone]=4 mol/dm³.
a: Initial concentration of the aldehyde, x: concentration of the chalcone produced.

Next, the effect of the molar ratio of bpy to the Co(II) on the catalytic activity was examined in the similar reaction as was shown in Table 1. According to the table, it was observed that the activities increased with

Table. 1 Effect of the molar ratio of bpy to Co (II) on the rate constants of the aldol condensation[a)]

$cat=\frac{(bpy)_n}{Co(II)}$	$k'_{obsd}\times 10^5/s^{-1}$
$n=0$	1.26
$n=0.5$	4.83
$n=1$	12.3
$n=2$	10.9
$n=3$	2.65

a) The reaction of benzaldehyde with acetophenone[b)] was carried out in DMF at 82 °C. b) [cat]=0.008 mol/dm³, [aldehyde]=0.2 mol/dm³, [ketone]=4 mol/dm³.

an increase in the amount of bpy to a certain extent. When the molar ratio was $n=1$ or $n=2$, the highest activity was observed. However, when the molar ratio increased to $n=3$, the activity decreased remarkably. The suppressed reaction can be explained in terms of that the molar ratio of $n=3$ is enough amount to occupy the residual vacant coordination sites in Co(II) and that bpy as bidentate ligand can coordinate to Co(II) more easily than the substrates as monodentate ligand. Therefore, the assumption may be made that the reaction proceeds *via* a mixed ligand complex between the substrates and Co(II)–bpy$_n$ complexes.

Furthermore, the effect of the reaction temperature on the reaction was examined in the similar reaction mentioned above. As the result, the $k'_{obsd}\times 10^5$ (s^{-1}) were 1.27 at 62 °C, 2.53 at 72 °C and 12.3 at 82 °C, respectively. Thus, the correlation of the log k'_{obsd} and three different reaction temperatures was shown as a straight line in Fig. 2 and the activation energy was calculated as 13.7 kcal/mol.

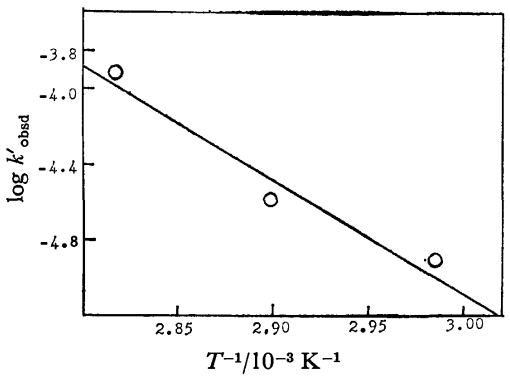

Fig. 2. Arrhenius plot for the aldol condensation of benzaldehyde with acetophenone catalyzed by Co(OAc)$_2$–bpy(1: 1) complex.
[cat.]=0.008 mol/dm^3, [aldehyde]=0.2 mol/dm^3, [ketone]=4 mol/dm^3 in DMF.

Effects of Kind of the Ligand. The complex catalyzed aldol condensations are largely affected by the kind of ligand in the complex, and such ligand as bpy or 1,10-phenanthroline is fairly effective to give the reaction products in high yield.[2] Therefore, the effects of ligands on the catalytic activity of the Co(II) complexes were examined in detail at 82 °C in the similar reaction system mentioned above. The k'_{obsd} of the reactions catalyzed by Co(II)–L(bpy, en, 4-dm-bpy, and 6-dm-bpy) complexes and by Co(OAc)$_2$ itself are shown in Table 2.

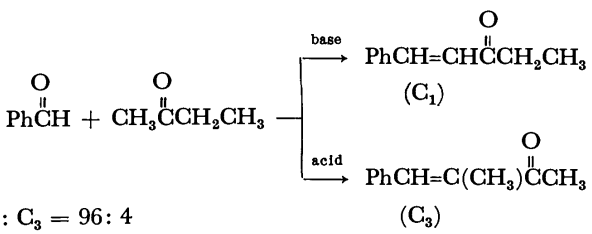
TABLE 2. LIGAND EFFECT ON THE RATE CONSTANTS OF THE ALDOL CONDENSATION

Cat[b,c]	$k'_{obsd}\times 10^5/s^{-1}$
Co(II)	1.26
Co(II)–bpy	12.3
Co(II)–en	1.41
Co(II)–4-dm-bpy	1.49
Co(II)–6-dm-bpy	0.33
Mn(II)–bpy	0.85

a) The reaction of benzaldehyde[b] with acetophenone[b] was carried out in DMF at 82 °C. b) [cat]=0.008 mol/dm^3, [aldehyde]=0.2 mol/dm^3, [ketone]=4 mol/dm^3. c) The molar ratio of the ligand molecule to anhydrous Co(II)acetate is 1.

It is observed that the catalytic activity of Co(II)–bpy complex in the reaction increases remarkably in comparison with the k'_{obsd} of Co(OAc)$_2$, while bpy itself has no catalytic activity at all. The activity of Co(II)–ethylenediamine(en) complex is almost similar to that of Co(OAc)$_2$. The effect of 4,4′-dimethyl-2,2′-bipyridine ligand(4-dm-bpy) containing methyl groups as electrodonative substituent is surprisingly low. Furthermore, 6,6′-dimethyl-2,2′-bipyridine ligand(6-dm-bpy) deactivates the catalytic activity of the complex extremely probably owing to steric hindrance of the ligand molecule to the reaction. With regard to the enhanced effect of 2,2′-bipyridine on the metal complex catalysts, seveal studies on other organic catalytic reactions were already reported.[3] According to their accounts, the net plus charge of M(II) will increase by π-back donation of M(II) to 2,2′-bipyridine in the complex, then the resulting enhanced coordination force of substrates to M(II) naturally accelerate the reactions. The ligand effects on the aldol condensations are also explainable by the similar π-back donation between M(II) and bpy. Table 2 also shows low catalytic activity of Mn(II)–bpy complex in comparison with that of Co(II)-bpy complex. It is assumed that this result is due to the different stabilities of general complexes in Irving-Williams series.[4]

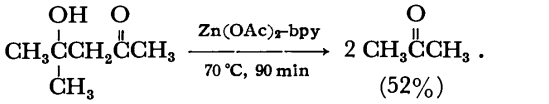
The Feature of the Catalysis. In order to show a feature of the complex catalysts, two different reactions catalyzed by the complex catalyst were investigated. One example is the condensation of benzaldehyde with 2-butanone. It was known that the base-catalyzed reaction gave, preferentially, the condensation product at C_1 of the ketone, while the acid-catalyzed reaction occurred preferentially at C_3.[5] In our reaction system



C_1: C_3 = 96: 4

with Co(OAc)$_2$–bpy complex, the regioselective condensation product at C_1-position was obtained in high yield as well as that with base catalysts.

Another reaction, the decomposition of 4-hydroxy-4-methyl-2-pentanone, which has been also known to take place only by the use of base catalysts,[6] was examined in the presence of Zn(OAc)$_2$–bpy (1 : 1) complex in the NMR tube. It was observed that the reaction proceeded smoothly as follows:



These findings show that the complex catalysts behave as a base catalyst. Both reactions do not commonly

proceed in the presence of bpy itself. Accordingly, it is assumed that the basic function in the complex catalyst is not by bpy ligand but by the counter ion, AcO^-, of the metal salts. It is widely recognized that the metal ion is considered as an acid and the counter ion is considered as a base.

Consideration of the Reaction Process. It has been known that enolization of ketone is the first stage in the aldol condensation catalyzed by acid or base.[5] In our reaction system with M(II)–bpy complexes, H-D exchange reaction of acetophenone with deuterium oxide in the presence of $Zn(OAc)_2$–bpy catalyst was carried out in order to ascertain the formation of enolate

$$PhCCH_3 \xrightarrow[70\,^\circ C,\ 18\,h]{Zn(II)\text{-}bpy} PhC{=}CH_2 \xrightarrow{D_2O} PhCCH_nD_{3-n} \quad (57\%)$$

anion. The reaction was remarkably catalyzed and the ratio of H-D exchange was 57% determined by NMR. When bpy itself was used, however, the reaction did not proceed.

At the second stage, it has been known that the reaction of aldehyde with the enolated ketone affords β-hydroxy ketone (aldol type product). However, the compound is easily dehydrated to give α,β-unsaturated ketone. In order to ascertain the formation of the aldol type product, the condensation of benzaldehyde with acetone in the place of acetophenone was carried out in the presence of Co(II)–bpy complex (1 : 1) at 80 °C in DMF for 3 h. The reaction gave yellow oil that was analyzed by ^{1}H-NMR and GC-MS spectra, and two kinds of product, 4-hydroxy-4-phenyl-2-butanone(**1**) and benzylideneacetone(**2**) were determined as follows:

$$PhCH + CH_3CCH_3 \xrightarrow[DMF,\ 80\,^\circ C,\ 3\,h]{Co(II)\text{-}bpy} PhCHCH_2CCH_3 + PhCH{=}CHCCH_3$$

1 **2**

25%	11%
NMR: 2.10 (CH_3)	: 2.28 (CH_3)
MS: 164 (M^+)	: 146 (M^+)

When the similar reactions were carried out for longer time, it was observed that the yields of **1** decreased with the increasing yields of **2**. Consequently, it was assumed that the reaction afforded the product **1** in the first instance which was succesively dehydrated to give the product **2** as well as acid or base catalyzed reaction.

Consideration of Coordination. A coordination of aldehyde to the metal ion was examined by absorption spectroscopy. A solution of nickel(II) acetate in DMF showed an absorption maximum at 430 nm as shown in Fig. 3. When bpy was added to this solution, an absorption maximum appeared at 630 nm, which was attributed to the d-d band of Ni(II)–bpy chelation. When benzaldehyde was added to this solution of Ni(II)–bpy complex, the absorption maximum at 630 nm shifted to 622 nm. The fact might suggest that the carbonyl oxygen atom of aldehyde entered the first coordination sphere of Ni(II). While, no similar shift was observed by addition of acetophenone to the Ni(II)–bpy system.

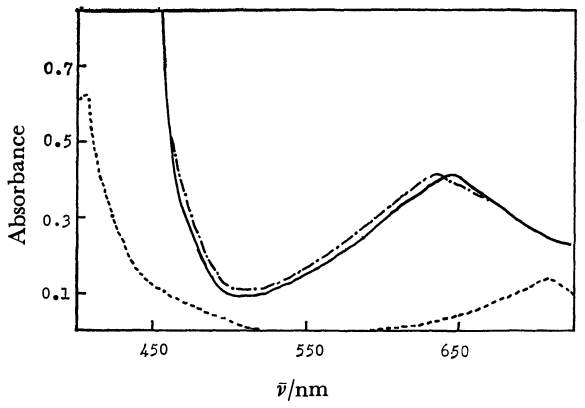


Fig. 3. Electronic absorption spectra of nickel (II) acetate–bpy–benzaldehyde and nickel (II) acetate–bpy–acetophenone complexes in DMF. $[Ni(OAc)_2]=0.060$ mol/dm^3, $[bpy]=0.060$ mol/dm^3, $[aldehyde]=0.075$ mol/dm^3, $[ketone]=0.075$ mol/dm^3.
·····: $Ni(OAc)_2$ (λ_{max} 430 nm), ——: $Ni(OAc)_2$–bpy (λ_{max} 630 nm) and $Ni(OAc)_2$–bpy acetophenone (λ_{max} 630 nm), —·—: $Ni(OAc)_2$–bpy–benzaldehyde (λ_{max} 622 nm).

Since acetophenone was enolized by M(II)–bpy complex, the interaction between acetophenone and M(II) seemed to be extremely weak. In other words, the ketone may be located in far distance from the metal ion. Considering in connection with the results described above, the aldol condensation reaction may proceed *via* a coordination of aldehydes to the M(II).

It has been known that aldol condensation in biological system are catalyzed by aldolase enzymes, Class I and II.[7] Class II aldolase is a metalloenzyme containing Zn(II) in the active site. In the reaction of Class II aldolase, however, catalysis of the enzyme has not been elucidated enough although some models of the reaction mechanism were presented by biochemists.[8–12] Therefore, our reaction system with Zn(II)–bpy complex may present a new example for understanding of the Zn(II) catalysis in Class II aldolase from a side of organic catalytic reactions.

Some information withdrawn from our study on the catalysis of M(II)–bpy complex are summerized as follows:

(1) 2,2'-Bipyridine ligand in the Co(II) complex enhanced the catalytic activity remarkably, though the ligand itself had no activity.

(2) M(II)–bpy complex showed a feature of basic catalyst. Such effect of (1) may be important in the metalloenzyme if there is interaction between the metal ion and imidazole ring of a histidine residue, since imidazole as well as bpy can form π-bonding by coordinating to the M(II). Ingram reported that Class II aldolase showed a basic catalysis.[8] Further, it was suggested that the basic group may be an appropriately located β-COO^- of aspartic acid or γ-COO^- of glutamic acid.[8] However, from a viewpoint of our metal(II)–bpy complex catalysis(2), another suggestion that basic group is the counter ion of the metal ion being located at active center of the metalloenzyme may be permitted. Further, a detail investigation of a model reaction of Class II aldolase is now in progress.

Experimental

Kinetics of Aldol Condensation. In order to study the rate of the aldol condensation of benzaldehyde with acetophenone, a sample of catalyst (for example; $Co(OAc)_2$ (0.0142 g, 0.08 mmol) and 2,2′-bipyridine (0.0125 g, 0.08 mmol)) was weighed into a volumeric flask (10 ml) and DMF (3 ml) was added to the flask to dissolve the catalyst. The solution was stirred at room temperature for 21 h. Benzaldehyde (0.212 g, 2 mmol) and acetophenone (4.8 g, 40 mmol) were poured in this flask and DMF was added to the mark. The solution was poured in each ampoule (1 ml×8). The sealed ampoules were heated at 82 °C and were withdrawn from time to time and then were quenched in a freezer. *p*-MeO–$C_6H_4COCH_2C_6H_5$ as an internal standard was added to the solution in opened ampoules which were analyzed by GLC (column temp at 220 °C, 1 m, Carbowax 20 M). The solution showed only one product (chalcone) other than unreacted benzaldehyde and acetophenone. The amount of chalcone was determined by comparing the relative peak area of chalcone *vs.* the internal standard with those of the calibration chart.

Regioselectivity in the Reaction of Benzaldehyde with 2-Butanone. A DMF (5 ml) solution of benzaldehyde (1.875 mmol), 2-butanone (5 ml), $Co(OAc)_2$ (0.300 mmol), and 2,2′-bipyridine (0.300 mmol) was stirred at a reflux temperature for 6 h. After the completion of the reaction, the solvent was removed *in vacuo* and the residue was extracted with ether–water system. The organic layer was dried over anhydrous sodium sulfate and was evaporated to give a mixture of 1-phenyl-1-penten-3-one (a) and 3-methyl-4-phenyl-3-buten-2-one (b) in 95% yield. The ratio (a) : (b) was 96 : 4 which was determined by NMR spectra.

Decomposition Reaction of 4-Hydroxy-4-methyl-2-pentanone (DAA). DAA (2 mmol) was added to a solution of anhydrous zinc acetate (0.1 mmol) and 2,2′-bipyridine (0.1 mmol) in DMSO-d_6 (0.09 ml) in NMR tube. The tube was sealed off and heated at 70 °C for 90 min. For the calculation of the amount of unreacted DAA determined by NMR, 1,1,2,2-tetrachloroethane as an internal standard was added to the reaction mixture and DAA was decomposed in 52%.

H-D Exchange of Acetophenone. A solution of acetophenone (1.0 mmol), $Zn(OAc)_2$ (0.1 mmol), D_2O (2.75 mmol), and CD_3CN (0.4 ml) in sealed NMR tube was heated at 70 °C for 18 h. The integration ratio of methyl proton *versus* aromatic proton was determined by NMR and the H-D exchanged ratio of methyl group of acetophenone was calculated in 54%.

Restricted Rotation Involving the Tetrahedral Carbon. XXXVIII. Barriers to Rotation and Population Distributions of 9-(8-Methyl-1-naphthyl)fluorene and Its 1-Methyl Derivative[1)]

Teruo Mori and Michinori Ōki*

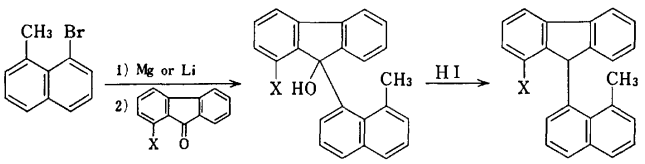
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 31, 1980)

The title compounds were prepared to see the effect of an 8-methyl group on the populations and the barriers to rotation of rotamers. As expected, the substituent destablized the *syn* conformation to a considerable extent, although the extent appeared to be a little less than that of a 2-*t*-butylphenyl group. Atropisomers of 1-methyl-9-(8-methyl-1-naphthyl)fluorene were isolated. The barriers to rotation were discussed with reference to related compounds.

In one of the previous papers, we have demonstrated that the conformational equilibrium of 9-(2-*t*-butylphenyl)fluorene is lop-sided: since the ground state of the *ap* conformation is so energy-rich that it rotates slowly at room temperature, although it can be made, to form the corresponding *sp* isomer, of which isomerization to the *ap* is practically nonexistent at room temperature.[2)] This finding aroused our interest in investigating the effect of an 8-methyl-1-naphthyl group in the 9-position of fluorene on the barriers to rotation and population equilibriums, because the bulkiness of a *t*-butyl group is often compared with that of an 8-methyl-1-naphthyl substituent: the compound may give stable atropisomers. It is also interesting to see how atropisomers become stable when we introduce a methyl group into 1-position of the fluorene ring, since such an operation is known to raise the barriers to rotation to a considerable extent.[3,4)]

Syntheses of the compounds were carried out in the following way. Fluorenones were added to a Grignard or a lithium compound derived from 1-bromo-8-methylnaphthalene (**1**) and the resultant 9-aryl-9-fluorenols (**2** and **3**) were reduced with hydriodic acid at room temperature to afford 9-(8-methyl-1-naphthyl)fluorenes (**4** and **5**).



1 2 : X=H 3 : X=CH3 4 : X=H 5 : X=CH3

The syntheses afforded an isomer exclusively: **2** gave *syn*-**4** whereas **3** gave *anti*-**5**. Thus *syn*-**4** had to be converted to *anti*-**4** to examine the barrier to rotation. It was accomplished by taking advantage of the fact that protonation after lithiation of the 9-position proceeds from the less hindered side.[2,5)]

This paper reports the findings on the equilibriums of rotamers of 9-(8-methyl-1-naphthyl)fluorene and its 1-methyl derivative in addition to the syntheses and compares the barriers and populations of rotamers, which are affected by the substituents, with related compounds.

Experimental

syn-9-(8-Methyl-1-naphthyl)fluorene (syn-**4**). A solution of 279 mg (1.26 mmol) of 1-bromo-8-methylnaphthalene (**1**)[6)] in 30 mL of tetrahydrofuran was refluxed with 33 mg (1.4 mmol) of magnesium until most of the magnesium disappeared (*ca.* 3 h). Fluorenone (346 mg or 1.92 mmol) was added to the solution in the form of powder and the whole was refluxed for 2 h. The resultant mixture was treated in a usual manner and the desired product (**2**) was obtained in 28% yield. ^{1}H NMR ($CDCl_3$, δ): 1.40 (3H, s), 2.17 (1H, s), 7.0—7.8 (13H, m), 8.67 (1H, q). This compound must exist as an *anti* form from the ^{1}H NMR data.

A solution of 100 mg of **2** in 20 mL of acetic acid was mixed with 3 mL of 57% hydriodic acid and stirred for 6 h at room temperature. The solution was poured into water, treated with aqueous sodium dithionite and then with aqueous sodium hydrogencarbonate, and extracted with ether. The product was chromatographed on silica gel to afford *syn*-**4**, oil, in 90% yield. The purity was checked by a ^{1}H NMR spectrum and a high resolution mass spectrum. MS: found (M^+) 306.1399; calcd for $C_{24}H_{18}$, 306.1409. ^{1}H NMR ($CDCl_3$, δ): 3.17 (3H, s), 6.40 (1H, s), 6.62 (1/2H, d), 6.73 (1/2H, d), 7.0—7.8 (13H, m).

anti-9-(8-Methyl-1-naphthyl)fluorene (anti-**4**). A solution of 20 mg of *syn*-**4** in 0.4 mL of tetrahydrofuran was mixed with 0.5 mmol of butyllithium in hexane at room temperature. The mixture was heated at 60 °C for 3 h and was quenched with trifluoroacetic acid. The mixture was quickly treated in a usual manner and the product was purified by TLC on a silica gel plate at 0 °C. The operation afforded a mixture of *syn*-**4** and *anti*-**4** (*ca.* 3 : 7), which was directly used for the measurements of rates of isomerization. The following ^{1}H NMR data ($CDCl_3$, δ) were obtained by subtracting the signals due to *syn*-**4**: 1.32 (3H, s), 5.40 (1H, s).

anti-1-Methyl-9-(8-methyl-1-naphthyl)fluorene (anti-**5**). A mixture of 1.2 g (5.4 mmol) of **1** and 95 mg (14 mmol) of lithium in 20 mL of ether was refluxed until a reddish brown solution was obtained (*ca.* 2 h). To the solution was added 1.12 g (5.8 mmol) of 1-methyl-9-fluorenone[7)] in 20 mL of benzene over a period of 20 min. The solution was refluxed for 3 h and treated in a usual manner. The product was purified by silica-gel chromatography to afford 51% oil (**3**), which existed as *anti* conformation only as judged from its ^{1}H NMR spectrum ($CDCl_3$, δ): 1.44 (3H, s), 1.54 (3H, s), 2.30 (1H, s), 6.7—7.9 (12H, m), 8.76 (1H, q).

A solution of **3** in acetic acid was treated with hydriodic acid as described above to afford *anti*-**5**, mp 126—128 °C, in 93% yield. Found: C, 93.99; H, 6.10%. Calcd for $C_{25}H_{20}$: C, 93.71; H, 6.29%. ^{1}H NMR ($CDCl_3$, δ): 1.32 (3H, s), 1.71

(3H, s), 5.36 (1H, s), 6.7—8.0 (13H, s). ^{13}C NMR ($CDCl_3$, ppm from TMS): 19.3, 21.5, 59.8, 118.0, 120.2, 123.8, 126.8, 127.0, 127.7, 129.0, 129.4, 129.6, 130.4, 133.1, 134.4, 134.9, 135.0, 135.6, 135.9, 139.8, 146.3, 148.9.

syn-*1-Methyl-9-(8-methyl-1-naphthyl)fluorene* (syn-**5**). An equilibrium mixture of *syn* and *anti* forms of **5** was obtained by the kinetic study described below. The solution was evaporated and the residue was crystallized from dichloromethane-hexane. Mp 123—125 °C. Found: C, 93.66; H, 6.04%. Calcd for $C_{25}H_{20}$: C, 93.71; H, 6.29%. ^1H NMR ($CDCl_3$, δ): 1.90 (3H, s), 3.23 (3H, s), 6.47 (1H, s), 6.8—8.0 (13H, m). ^{13}C NMR ($CDCl_3$, ppm from TMS): 19.4, 27.2, 50.7, 118.0, 120.0, 124.8, 125.3, 126.2, 126.8, 127.1, 127.4, 128.5, 128.9, 130.8, 132.1, 133.3, 134.6, 135.7, 137.3, 140.2, 141.3, 147.6, 149.8.

Spectral Measurements. ^1H NMR spectra were measured on a Hitachi R-20B spectrometer and ^{13}C NMR with a JEOL FX-60 spectrometer. ^{13}C NMR spectra of *syn*- and *anti*-**5** were obtained at −20 °C to avoid isomerization of the latter during the measurement. A high resolution mass spectrum was obtained with a JEOL JMS-D-300 spectrometer.

Measurements of Rates of Rotation. Kinetic measurements were carried out with solutions of chloroform-*d*. Measurements which were necessary for both determination of the rates of rotation and equilibrium constants were carried out using ^1H NMR spectra where appropriate. In the cases where one isomer was so predominant that the errors involved in the measurements by the NMR spectra were large, a Waters HPLC instrument which was equipped with a UV detecter was used for the analysis. The correspondence of the peak areas in HPLC to the real populations was checked by comparing those with the populations obtained by the NMR spectra, where the latter was applicable. The correspondence was found to be satisfactory without considering the difference in absorption strengths per molecule of the isomers. The kinetic data were treated as a reversible unimolecular reaction to afford satisfactory results. The errors in rate constants are given for 95% confidence intervals in the least squares method, adopting t-distribution.

Results and Discussion

The first problem we wish to discuss is the nomenclature of the conformers concerned. If the fluorene ring is unsubstituted or symmetrically substituted, there is no problem in designating the rotational isomers by the present IUPAC rule E.[8] Namely we do have *ap* and *sp* isomers of 9-(8-methyl-1-naphthyl)fluorene (**4**) and they involve no ambiguities. The same is true for 9-(1-naphthyl)fluorene (**6**) and 9-(2-methyl-1-naphthyl)-fluorene (**8**). However, as soon as a methyl group is introduced into the 1-position of fluorene, we come across a difficulty. One may designate the conformation of 1-methyl-9-(8-methyl-1-naphthyl)fluorene (**5**), which corresponds to the *ap* conformation of **4**, as $\pm sc$. However, there is another conformation which is $\pm sc$ in this case: if we consider a conformation in which the 8-methyl-1-naphthyl group eclipses the bond connecting C_9 and an aromatic carbon of which ring bears no substituent, the conformation is also $\pm sc$ if the prefered side, in the sequence rule,[9] of the naphthyl moiety is close to the 1-methyl group. This type of ambiguity arises always when a conformation involves at least one chiral center. We must specify the configuration of the chiral center, in addition to the conformation, to avoid ambiguities. Thus the conformation becomes $[-sc(R)]+[+sc(S)]$.[10] In practice, however, comparing the *ap* form of **4** and $[-sc(R)]+[+sc(S)]$ form of **5** may be too complicated in writing and may cause confusion. Therefore, in designation of conformations concerned, we prefer to commonly use "*syn*" for the conformation in which a prefered group in the sequence rule is synclinal to the C_9–H bond (C_9–OH in the case of **2** and **3**). This nomenclature is conventional but is more convenient in the present case.

(Only one enantiomer is shown when X is CH_3.)

9-(8-Methyl-1-naphthyl)-9-fluorenols. The assignment of the conformation is straightforward, because the methyl group substituting the naphthyl moiety is expected to give a signal at a high magnetic field in the ^1H NMR spectrum if it is *anti* and that, in the *syn*, it must give a signal at a lower field. It is interesting to note that the *anti* isomer overwhelms in **2** and **3** in contrast to the fact that, in 9-(2-*t*-butylphenyl)-9-fluorenol, the *syn* isomer is overwhelming.[2] The distribution of conformers in **2** and **3** is similar with the cases of other 9-(2-alkylphenyl)-9-fluorenols. Probably the repulsive interaction between the *t*-butylphenyl group and the fluorene ring is much more severe than that between the 8-methylnaphthyl group and the fluorene. This is reflected in the equilibrium constants of the hydrocarbons also (*vide infra*).

It is well documented that substitution of the 9-hydrogen in 9-arylfluorenes by other groups decreases the barrier to rotation.[11] Thus it is not possible to isolate rotational isomers of 9-(2-methyl-1-naphthyl)-9-fluorenol (**10**), although rotamers of its parent hydrocarbon (**8**) were isolated.[2,12] However, Ford *et al.* reported that the introduction of a methyl group into the 1-position of the fluorene ring of **10** caused the increase in the rotational barrier (in **11**) and suggested that the barrier would be over 26 kcal/mol (1 kcal= 4.18 kJ):[3] the value is high enough for isolation of rotamers at room temperature. Indeed, Kajigaeshi *et al.* were able to isolate one of the rotamers of a benzo-annelated derivative of **10**, the barrier ($\Delta G^{\ddagger}_{323}$) being 24.6 kcal/mol.[13]

We found a similar situation for **3**, though to a lesser degree of enhancement of the barrier. The ^1H NMR spectra of the compound suggested the presence of a negligible amount of the *syn* isomer and overwhelming population of the *anti* isomer at room temperature.

Table 1. Kinetic and thermodynamic data for the rotation about the C_9–C_{Ar} bond of 9-(1-naphthyl)fluorenes and 9-(2-*t*-butylphenyl)fluorene

Comopund	Substituent		Rate Constant for Rotation (*anti*→*syn*)[a] ($\times 10^5$ s^{-1})	$\Delta G^{\ddagger}$[a] kcal mol^{-1}	Equilium Constant[a] (*syn*/*anti*)	Reference
	Fluorene	Naphthalene				
12	—	—	39(272)	20.1(307)[b]	>100(273)	2
4	H	8-CH_3	5.6±4.2(307) 170±20(327)	23.9(307)	25[c]	This work
5	1-CH_3	8-CH_3	0.80±0.03(307) 11.5±0.7(327)	25.2(307)	33[c]	This work
6	H	H		17.4(307)[b] 17.7(307)[b]	2[d] 2(303)	18 12
7	1-CH_3	H		21.4(433)	2[e]	4
8	H	2-CH_3		29.2(393)	1(373)	12
9	1-CH_3	2-CH_3		33.3(429)	1(429)	3

a) Numericals in parentheses are temperatures in Kelvin. b) Calculated from available data. c) These values were independent of temperatures examined. d) At room temperature and below. e) At room temperature.

However, on raising the temperature, we found that the signal due to the methyl group broadened considerably at about 120 °C to suggest that coalescence of two signals took place. The barriers to rotation in **3** is not certain, because we could not detect the signal due to the *syn* isomer, but is of the order of 20 kcal/mol.

Populations of 9-(8-Methyl-1-naphthyl)fluorene Rotamers. Assignment of the conformations was carried out both from the ^1H NMR features as described above and from the mode of protonation. It is interesting to note that the unstable *anti* form of **5** was prepared preferentially, whereas the stable *syn*-**4** was the sole product in the preparation of **4**. This must be caused because **5** gave the kinetially controlled product owing to its high barrier to rotation whereas **4** gave the thermodynamically controlled product due to its low barrier to rotation. Although the mechanisms of the reaction are not well understood, the reaction conceivably proceeds *via* an iodide followed by a reaction with complex iodide anions.[14] In both cases, a bulky iodide ion is involved in the reaction and the approach from the less hindered side is favored to produce *anti*-**5**.

Equilibrium constants between the rotamers of **4** and **5** are summarized in Table 1 together with those of related compounds. From the molecular models, the 8-methyl group is expected to give severe steric interaction with the fluorene ring when the molecule has the *anti* conformation. This effect is apparent if one compares the equilibrium constants of **4** and **5** with those of the compounds which do not possess a methyl in the 8-position but do or do not carry a methyl in a position other than 8 of the naphthyl group. The ground states of **4** and **5** are raised to a considerable extent.

If one compares the equilibrium constants of **4** and **5** with that of 9-(2-*t*-butylphenyl)fluorene (**12**), however, one notices an interesting point. That is, although the steric effect of the *t*-butyl group given to the *o*-position of a phenyl group is often compared with that of the 8-methyl group given to the 1-position of naphthalene and the latter is often referred to be larger than the former because of rigidity, the data in Table 1 suggest that the ground state of the *anti* conformations of **4** and **5** are, relatively speaking, more stable than that of *anti*-**12**.

This is also reflected to the ^{13}C–^1H coupling constants of the NMR spectra: the coupling constants are 115.4 Hz[2] and 120.2 Hz for the *anti* forms of **12** and **5**, respectively. The coupling constants in the *syn* conformations of 9-(2-alkylphenyl)fluorenes are reported to be 128±1 Hz[2] and the *syn* form of **5** is no exception. The ^{13}C–^1H coupling constant is known to reflect the *s*-character of the carbon orbital:[15] the smaller coupling constant is due to higher *p*-character of the bonding orbital concerned. The geometry of the 9-carbon of the fluorene ring is more flattened than others in the *anti* conformation due to the steric compression between the fluorene ring and the *t*-butyl or 8-methyl group. The ^{13}C chemical shift data support the idea that the C_9 configuration has moved toward the trigonal in the *anti*-conformation of **5**: the chemical shift of the C_9 in *anti*-**5** is 9.1 ppm down field relative to that in *syn*-**5**. Therefore the anomaly in the *anti* conformations must be attributed to the steric strain rather than the electronic effect.

The smaller J_{C-H} of the *t*-butyl compound (**12**) than **5** may be taken as a reflection of the fact that the *anti* conformation of **12** has more severe steric interaction than *anti*-**5**. The reason for these phenomena is not apparent at present but may be connected to the fact that the 8-methyl-1-naphthyl group is thinner than the 2-*t*-butylphenyl group.

The effect of the 1-methyl group in the fluorene ring on the equilibrium constants seems to be very small. The difference between **4** and **5** may not be taken significant. This is in agreement with others[4,16] which generally show no difference in the equilibrium constants between a parent compound and a 1,4-dimethyl derivative. There is but one case, 9-(2-methylphenyl)-fluorene and its 1,4-dimethyl derivative, which shows a significant dependence of the equilibrium constant

on the 1-methyl group.[2,17]

Rotational Barriers. Kinetic data of internal rotation (*anti*→*syn*) of **4** and **5** are shown in Table 1 with those of related compounds. It is interesting to note that the introduction of a methyl group into the 8-position of the 1-naphthyl group raised the barrier to a considerable extent relative to the parent hydrocarbon (**6**). Since the ground state of *anti*-**4** is of high energy relative to *anti*-**6**, the high barrier for *anti*-**4** must be attributed to the steric repulsion involving the C–H group in the 1-position of the fluorene and the 8-methyl group in the transition state for rotation.

The effect of the 8-methyl group on the transition state seems to be larger than that of the 2-methyl in the naphthyl moiety, from the molecular model considerations. It seems to be reflected to the relatively high barriers to rotation of *anti*-**4** with respect to that of 9-(2-methyl-1-naphthyl)fluorene (**8**), when the very unstable ground state of *anti*-**4** is considered. Introduction of a methyl group into the 1-position of the fluorene ring caused the increase in barriers of *ca.* 3 kcal/mol and *ca.* 4 kcal/mol for the pairs of **6** : **7** and **8** : **9**, respectively, whereas the increase for the pair of **4** : **5** is 1.3 kcal/mol. The relative unimportance of the 1-methyl in *anti*-**5** in determining the barrier height may be attributed to two factors. The first is the rise of the ground state of *anti*-**5**: this will make the difference in energies between the *anti* and the transition state smaller. The second is the geometry of the transition state. The molecular model indicates that **5** can assume a transition state for rotation in which the 8-methyl group of the naphthyl avoids the 1-methyl of the fluorene. Then the transition state for rotation of **5** is very similar with that of **4**, unlike the case of a pair of **8** and **9**. The situation is rather close to that of **6** and **7** pair. Combination of these factors can give the smallest difference in barriers to rotation in the pair of **4** and **5**, if the difference is compared with others in Table 1.

Emission Spectra of Aromatic Hydrocarbons by Controlled Electron Impact

Teiichiro OGAWA,* Naoki YAMAMI, Masaharu TSUJI, and Yukio NISHIMURA
Department of Molecular Science and Technology, Kyushu University, Hakozaki, Fukuoka 812
(Received July 25, 1980)

The emission spectra of benzene, toluene, ethylbenzene, xylenes, trimethylbenzenes, cymene, and naphthalene were investigated under controlled electron-impact excitation. These aromatic hydrocarbons showed a characteristic band in the 250—400 nm region and several bands of such excited fragment species as H and CH. The characteristic bands are similar to those of fluorescence spectra obtained by optical excitation and, thus, were assigned to fluorescence emissions of the parent molecules. The intensity of the fluorescence emission of benzene decreased at higher electron energies, and fragment emissions became dominant above 100 eV. However, its vibrational structure did not change for electron energies of 5—60 eV. This indicates that cascade processes from high-lying states are negligible for benzene. The fluorescence emission of naphthalene shifted to a shorter wavelength for low electron energies. Together with a theoretical estimation based on the Born approximation, cascade effects from higher excited states (S_2 and S_3) are found to be the major source of the fluorescence emission of naphthalene.

The emission spectrum excited by the controlled electron beam provides valuable information for a detailed analysis of the mechanism of the excitation and fragmentation of molecules at very low pressures where the effect of collisions is greatly reduced.[1] A large molecule does not usually show photoemissions from its own excited state, but, instead, shows various fragment emissions, since non-radiative processes become more dominant for a large molecule. The aromatic molecules, however, give intense photoemissions of the parent molecules in the ultraviolet region. The emission spectra of benzene,[2-4] toluene,[2,4,5] xylenes,[2,5] and naphthalene[6,7] have been measured, and the similarity of their spectra with the fluorescence spectra has been pointed out.[2-7] The spectra and the lifetime of benzene emission by electron impact have also been studied.[8,9]

The fluorescence emission of aromatic molecules can be observed either by direct excitation into the fluorescing state or through the cascade process from the initially prepared states to the lower fluorescing state. These excitation processes have been studied with the Bethe theory.[10-12] The excitation cross section to a particular excited state is proportional to the molecular oscillator strength from the ground state to that excited state; on the other hand, the probability of photoemission from a specified state is expressed by the quantum yield of fluorescence.[3,4,6] The cascade effects from the S_n state to the S_1 state may be studied by photoexcitation; however, the electron-impact method can be applied to molecules at very low pressures, since a more intense beam is available and the cross section is large.

In the present paper, the emission spectra of nine aromatic hydrocarbons are described as an extension of previous investigations.[2,6] The electron energy dependence of the spectra was studied for two basic molecules. The excitation processes of these aromatic hydrocarbons are also discussed.

Experimental

A schematic diagram of the apparatus is shown in Fig. 1. The collision chamber was made of stainless steel, with its inside covered with soot to suppress secondary electrons and any stray light. Thermal electrons from a tungsten filament were accelerated, collimated, and introduced into the collision region through a hole (4 mm in diameter). The sample molecule was jetted into the collision region through a needle valve and a multichannel nozzle (0.5 mm × 40). The collision chamber was continuously evacuated with two oil-diffusion pumps; the base pressure was of the order of 10^{-7} Torr, while the operating pressure was of the order of 10^{-4} Torr (uncorrected ion gauge reading). The photoemission produced in the collision region was observed through a quartz window at a angle of 90° with respect to the electron beam.

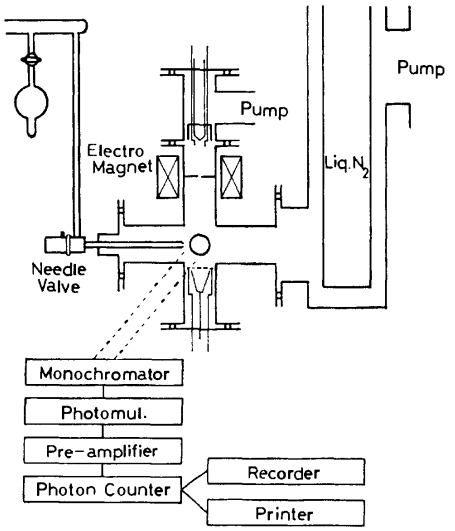

Fig. 1. Schematic diagram of the apparatus.

The emission spectra were observed with a JASCO CT-50 monochromator equipped with a 1200 grooves/mm grating blazed at 300 nm. The photons were measured with an HTV R212UH photomultiplier and a Burr-Brown 3421K OP amplifier or with an HTV R585 photomultiplier and an NF PC-545A photon counter. The wavelength dependence of the instrumental response was not corrected.

All the spectra were measured in a region where the intensity was proportional to both the gas pressure and the electron-beam current. In the case of the $6_1^0 1_2^0$ band of benzene, the intensity was linear in the region below 600 μA and 7.0×10^{-4} Torr. The effect of secondary electrons was estimated from the ratio of the emission intensity of the first negative band of N_2^+ (391.4 nm) to that of the second positive band of N_2 (337.1 nm);[13] the result is shown in Fig. 2.

All the compounds used were of a research grade; they were

deaerated before use by repeated freeze-pump-thaw cycles.

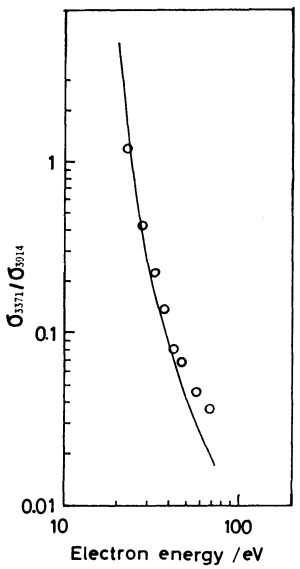

Fig. 2. Ratio of the emission intensity of N_2 (3371 Å) to that of N_2^+ (3914 Å). ○: This work.
The solid line is the estimated one.[13] The result indicates the effect of secondary electrons can be ignored below *ca.* 50 eV. The electron-beam current was 1 μA and the gas pressure was 1×10^{-4} Torr.

Results

The emission spectra of benzene, toluene, ethylbenzene, *o*- and *p*-xylenes, mesitylene, 1,2,3-trimethylbenzene, *p*-cymene, and naphthalene by controlled electron impact were measured; they are shown in Fig. 3. The energy of the incident electrons was 40 eV, and the spectral resolution was about 1 nm. All the aromatic hydrocarbons thus far studied have shown a characteristic band in the 250—400 nm region.[1] The fluorescence spectra taken in the gas phase and in the dilute solution were found to correspond well to the observed emission spectra. Thus, the characteristic bands observed in the present study were assigned to the fluorescence transition from the lowest excited singlet state (S_1) to the ground state (S_0); in the case of benzene, this is the symmetry forbidden $^1B_{2u}$—$^1A_{1g}$ transition.[2-4] Since Vroom and de Heer reported that the excitation cross sections of the Balmer line from various hydrocarbons differ little,[14] the relative intensity of the fluorescence emission can be estimated approximately from Fig. 3.

The spectrum of benzene has a striking dependence on the electron energy, as is shown in Fig. 4. The photoemission of the parent molecule becomes weaker at higher electron energies and almost disappears above

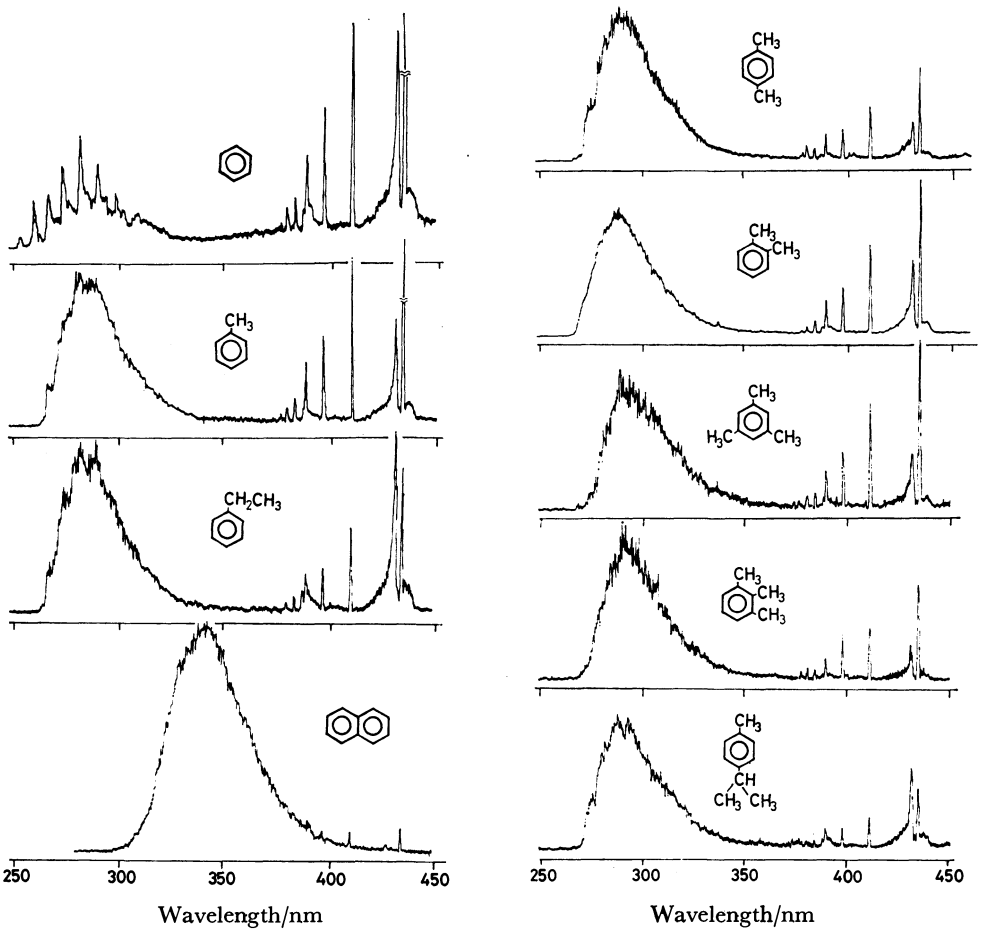

Fig. 3. Emission spectra of aromatic hydrocarbons by controlled electron impact.

100 eV, as was shown by Smyth *et al.*[4] The spectrum of naphthalene, however, did not show such a dependence, and the band of its parent molecule could be observed even at 300 eV.

The shape and structure of this fluorescence emission were observed at various electron energies, as is shown in Fig. 5 for benzene and in Fig. 6 for naphthalene. The vibrational structure of the benzene emission did not change in the optical resolution of 1 nm at 5—60 eV; however, the peak of the band of naphthalene shifted to a shorter wavelength for lower electron energies.

The Balmer series of hydrogen and the $B^2\Sigma^- - X^2\Pi$ transition and the $A^2\Delta - X^2\Pi$ transition of CH were also observed in the 370—440 nm region, as is indicated in Fig. 4. In addition, the $C^2\Sigma^+ - X^2\Pi$ transition of CH (about 315 nm) and the bands of CH^+ (423 nm and 350—370 nm) were identified in the spectrum of benzene taken at a higher sensitivity. The Schüler's T spectrum of $C_4H_2^+$ and the C_2 Swan bands were also observed in the 430—570 nm region.[15]

In all the cases measured, the intensity of the fluorescence emissions was directly proportional to the electron-beam current and to the gas pressure. This indicates that the excited states of these aromatic hydrocarbons were all produced in a one-electron primary collision process.

Discussion

Spectrum of the Fluorescence Emission. The emission spectrum excited by controlled electron impact resembles the discharge spectrum and the equilibrated fluorescence;[16,17] all of these have a prominent vibrational

TABLE 1. ESTIMATION OF CONTRIBUTIONS OF THE S_1, S_2, AND S_3 EXCITATION PROCESSES TO THE OBSERVED FLUORESCENCE EMISSION

structure and a broad background continuum. The present spectrum of benzene, however, clearly indicates the $6^0_1 1^2_0$ and $6^0_1 1^1_0$ transitions at 255 and 260 nm, which are not appreciable in the equilibrated fluorescence. The resonance fluorescence spectrum of benzene reveals a group of sharp lines,[17,18] whereas the present spectrum is broader and has a more vibrational structure. These facts indicate that the electron energy is large enough to excite many vibronic levels of the S_1 state simultaneously because of the non-resonant character of the electron excitation; however, the pressure is so low that the excited molecules undergo no collisional deactivation, and the vibrational population is not distributed in a 300 K Boltzman distribution. The electron impact spectrum is, thus, similar to the one excited by the irradiation of white light, whose maximum photon energy is that of the electrons.

The equilibrated fluorescence of toluene,[19] and the resonance fluorescence of toluene and xylenes[17] have previously been reported. The comparison of the present spectra with them leads to a conclusion similar to that in the case of benzene; the emission spectrum by controlled electron impact has some vibrational structure, including one above the 0-0 transition, and a broad background continuum. In the case of naphthalene, the vibrational structure becomes very diffuse, and the broad background continuum consists of the major part of the spectrum.

The fluorescence emissions of the other hydrocarbons may be compared with those of the fluorescence spectra taken in solution.[20] For all of the aromatic hydrocarbons studied, the emission spectra by controlled electron impact are more similar to the equilibrated fluorescence spectra in the gas phase or to the fluorescence spectra in solutions than to the resonance fluorescence in a low pressure gas.

Estimation of Excitation Processes. For most molecules, the bulk of the oscillator strength of the valence shell electrons lies at very great values of the excitation energy.[11] Thus, the most important primary processes of the electron-molecule collisions are high-lying electronic excitations of the valence electrons. If the intramolecular radiationless relaxation is very fast, the primarily-excited high-lying states can fall to the lowest excited singlet (S_1) state and contribute to the observed photoemission.

When the energy of the incident electrons for the excitation substantially exceeds the threshold energy of the molecule, the Born approximation is applicable;[10,12] the cross section of the excitation into the ith level (σ_i) is expressed by the optical oscillator strength (f_i) and the transition energy (E_i). The probability of photoemission from this level is proportional to the fluorescence quantum yield (ϕ_i). Thus, the contribution of the photoemission process involving the ith level on the total photoemission (Γ_i) is given as follows:[6]

$$\Gamma_i = b'\sigma_i\phi_i = b\phi_i f_i/E_i, \quad (1)$$

where b is a proportionality constant. Thus, Eq. 1 allows an estimation of the excitation and cascade processes with the available spectroscopic parameters. In actuality, the transition to a particular excited state is not very discrete, and both ϕ_i and f_i are dependent on the excitation energy; however, average values can be used for an order of magnitude estimation.

The very high-lying states seem not to be important for the observed fluorescence emission, since the spectra do not change above 7 eV (Figs. 5 and 6). Accordingly, the estimation of the cascade processes has been confined to the lower three excited states (S_1, S_2, and S_3). The dipole oscillator strength can be obtained from the electron energy loss spectrum.[21,22] The electron energy loss spectrum is closely related with the photoabsorption; the optical values[23] were used for benzene because of the lack of an explicit value of f in the electron energy loss spectrum. The quantum yields were taken from the vapor fluorescence of benzene[24-26] and naphthalene.[27-30] The results are shown in Table 1. The preliminary result[6] was revised by using more recent spectroscopic parameters.

Excitation Processes of Benzene and Naphthalene. The calculation (Table 1) shows that the direct excitation into the S_1 state is the most important process for benzene, while the contribution of the cascade process from the S_2 and S_3 states into the S_1 state is more predominant for naphthalene.

The observed spectrum of benzene has a characteristic vibrational structure, which does not change upon 5—60 eV excitation. This finding leads to the conclusion that the fluorescing S_1 state, whose excitation energy is about 5 eV, does not originate from a cascading process from the higher excited states. The smaller contribution of the higher excited states is due to the faster photochemical process of benzene and/or the direct internal conversion to the ground state, when benzene is excited into the S_2 or S_3 states.[24,25]

The vibrational structure of the fluorescence emission of naphthalene is less pronounced. The intramolecular internal conversion from the higher excited states causes a high vibrational excitation of the emissive S_1

state and makes the appearance of the spectrum more diffuse. The onset of the emission of naphthalene was found at 4.45 eV, which is the spectroscopic energy of the S_2 state.[7] Since a radiationless relaxation of the higher excited states results in the formation of the vibrationally highly-excited S_1 state, the Franck-Condon transition energy from such a highly-excited S_1 state is smaller than that of the directly excited S_1 states. The peak shift (Fig. 6) can be ascribed to the decrease in the contribution of cascading for the low energy excitation. The optical measurement also indicated that the fluorescence shifts to the red and becomes increasingly diffuse as the excitation energy increases.[31] Thus, the calculated and the observed findings are consistent.

The fact that the intensity of the fluorescence emission of benzene decreases rapidly as the increase of the electron energy and becomes negligibly small at a higher electron energy (Fig. 4) indicates that the major process of the excitation is neither a typical optically-allowed nor a typical symmetry-forbidden transition, since a Fano plot of an optically-allowed or a symmetry-forbidden transition has a positive or a zero slope. This finding indicates that another excitation process plays a more important role than those calculated. Smyth *et al.*[5] suggested the contribution of the resonance. Klump and Lassettre[32] indicated the importance of an electric octupole transition. Whereas, Doering,[33] and Wilden and Comer[34] showed the formation of the $^3E_{1u}$ state in this energy region; Matsuzawa[35] calculated that the excitation cross section to the $^3E_{1u}$ state is as large as that to the $^1B_{2u}$ state at a low incident energy and at a large angle. Such processes may be important in the excitation of the fluorescing S_1 ($^1B_{2u}$) state of benzene.

The spectroscopic data for other hydrocarbons in the vapor phase are so scanty that it is difficult to carry out similar estimations for them. However, the spectroscopic parameters obtained for the dilute solution often agree approximately with those in the gas phase, and the oscillator strength and the quantum yield in the dilute solution can be carried over to the rough estimation of the excitation processes. Those of some substituted aromatic molecules have been discussed in this approximation.[36,37]

The authors with to thank Professor Nobuhiko Ishibashi for his encouragment and Morihide Higo for his discussion.

The Electronic Absorption Spectra of Fatty Acid Mono-, Bi-, and Multilayers with Bivalent Metal Ions

Yukio NAGAHIRA,*,† Kazunori MATSUKI, and Hideo FUKUTOME
Department of Physics, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received August 28, 1980)

The electronic absorption spectra of fatty acid multilayers with bivalent metal ions were studied in the vacuum ultraviolet (VUV) to ultraviolet (UV) energy region below 8 eV; they are due to transitions in the carboxylic acid and metal carboxylate moieties. Infrared (IR) absorptions due to the C–O stretching vibration in the carboxylate moiety are also studied. Stearic acid multilayers without metal ions are shown to form hydrogen-bonded dimers. The spectra of multilayers with metal ions show a marked dependence on the subphase pH which is different for different kinds of adsorbed metal ions. Their VUV spectra are conspicuously dependent on the kind of metal ions adsorbed. All the multilayers with alkaline earth metals, metals of the 2B group, transition metals, Cu, and Pb have at least two bands in the VUV region, 7.3—6.3 eV. The polarization spectra of the Ba stearate multilayer suggest that the two transitions may be the intramolecular π-π^* and n-π^* transitions in the carboxylate anion moiety. The multilayers with Cu and Pb have another band in the UV region. The spectra of the UV bands of the Pb and Cu stearate mono-, bi-, and multilayers were studied. In the Pb stearate layers, the positions of the UV bands in the bi- and multilayers are the same, but those in the monolayers are at considerably shorter wavelengths. The positions of the UV band in the Cu stearate mono-, bi-, and multilayers are successively red shifted. The polarization spectra of the UV bands of the mono- and bilayers showed that they are charge-transfer bands between the Pb or Cu ion and the coordinated carboxylate moiety.

In an accompanying paper[1] (hereafter we will refer to it as I), we have shown that the vacuum ultraviolet (VUV) absorption spectra of fatty acid multilayers in the energy region below 10 eV consist of two parts, a strong absorption in the region above 8 eV (Region 1) and a weaker absorption in the region below 8 eV (Region 2). From the chain length and pH dependences of the spectra, we have assigned the absorption in Region 1 to the σ-σ^* transitions in the alkane chain moiety, and that in Region 2 to the transitions in the carboxylic acid and metal carboxylate moieties.

In this paper, we wish to present the results of our detailed studies of the absorption spectra of fatty acid multilayers and monolayers in Region 2. Fatty acid multilayers prepared on the water subphase containing metal ions adsorb the metal ions to a varying extent, depending on the pH of the subphase.[2,3] The pH profile of the metal ion adsorption is characteristic of the kind of metal ion. The physical properties of fatty acid monolayers such as the π-A profiles and the surface potential are dependent of the kind and amount of adsorbed metal ions. However, little direct information has been obtained about the interaction of metal ions with carboxylic acid moieties in fatty acid mono- and multilayers. The absorption spectra in Region 2 of fatty acid multilayers, that are due to the electronic transitions in the carboxylic acid and metal carboxylate moieties, provide direct information about the interaction of metal ions with fatty acid monolayers. In this paper, we will study the pH and metal ion dependencies and polarization of the spectra in Region 2. We will study also the infrared (IR) absorptions due to the carboxylic acid and carboxylate moieties.

Experimental

Materials. The fatty acids and other materials used in the present study were the same as those described in I. The spectrograde acetic acid and dichlorodimethylsilane were purchased from Nakarai Chemicals, Ltd. Optically flat quartz plates were obtained from the Takahashi Giken Co.

Methods. Fatty acid multilayers with metal ions and pure stearic acid multilayers were deposited on CaF_2 plates, as has been described in I. Monolayers of Cu stearate and Pb stearate were deposited on quartz plates with hydrophilic surfaces, as has been described by Matsuki *et al.*[4] Bilayers of Cu stearate and Pb stearate were deposited on quartz plates whose surfaces had been made hydrophobic by rinsing with a dichlorodimethylsilane solution.[5] All the multilayers and monolayers were prepared at 19 ± 0.5 °C.

The measurements of VUV absorption spectra were performed as has been described in I. The IR spectra were measured on Shimadzu-IRG and JASCO-IRA-2 spectrometers; the latter apparatus was five times more sensitive than the former. The measurements of the ultraviolet (UV) spectra of the monolayers and bilayers of Cu stearate and Pb stearate were performed on a high-sensitivity spectrometer using the single-beam and sample in-sample out technique described by Matsuki *et al.*[4] The apparatus was equipped with a CaF_2 Glan-Thompson prism for measurements of the polarized spectra.

The UV spectra of $PbCl_2$, $Pb(CH_3COO)_2$, and $Cu(CH_3COO)_2$ in water and acetic acid were measured with a Shimadzu-UV-180 spectrometer. To minimize the absorption of the solvent, acetic acid, the spectra were measured for solutions of high concentrations in the order of 10^{-2} M with the use of a thin cell, with the path length of 12 microns and the cell was made of two quartz plates and a polyethylene film spacer.

All the measurements of the VUV spectra in Region 2 (below 8 eV) and of the IR specrta in the region from 1000 cm^{-1} to 4000 cm^{-1} were performed for multilayers prepared by 15 dippings of the substrate.

The efficiency of the deposition of multilayers may change from sample to sample depending on the subphase pH, the kinds of metal ions, and the substrate.[6–10] In order to avoid uncertainty in the deposition ratio, we measured both the VUV and IR spectra for each multilayer sample. We nomalized the deposition ratio using the 2910 cm^{-1} IR band, which is attributable to the antisymmetric stretching vibration

† Present address: Osaka University of Economics and Law, Yao, Osaka 581.

of the CH_2 groups in the alkane chain moiety.[2,11-13] The 2910 cm^{-1} IR band of the Ba heneicosanoate multilayer was used as the standard for the normalization of the deposition ratio. The Ba heneicosanoate multilayer prepared at a neutral pH forms Y layers with a nearly perpendicular molecular arrangement.[1,13] Its deposition on a CaF_2 plate coated with Fe stearate was confirmed by the linearity of the VUV[14] and IR spectra to the dipping number. The number, L, of fatty acid layers deposited on a plate by 15 dippings was calculated by means of:

$$L = 60 \times \frac{20}{n} \times \mathrm{OD}(2910\ \mathrm{cm}^{-1})/\mathrm{OD}(2910\ \mathrm{cm}^{-1}\ \mathrm{Ba\ heneicosanoate}),$$

where n is the carbon number in the alkane chain, we assumed the deposition of 4 layers of Ba heneicosanoate on the substrate per dipping into the subphase.

For pure stearic acid and Zn stearate multilayers with molecular arrangements tilted against the normal of the layer plane, the intensity of the 2910 cm^{-1} band was corrected for the tilting of molecular axes by the method of Akutsu *et al.*[15]

All the VUV and UV spectra of multilayers except for Fig. 1 are normalized to the per-layer value. The molar extinction coefficient, ε, is obtained from the per-layer absorption, A, by means of:

$$\varepsilon = A \cdot a \cdot N = 12 \times 10^5 \times A,$$

where N is the Avogadro's number and a is the area (in cm^2) occupied by a fatty acid molecule, which is estimated to be about 20×10^{-16} cm^2 from the limiting area in the π-A profile of fatty acid monolayers.[16,17]

Results and Discussion

VUV Spectrum of Pure Stearic Acid Multilayer. The deposition of the pure stearic acid monolayer, which was spread on the subphase without any metal ions at acid pH (3.1), onto the CaF_2 plate was most uncertain, as was mentioned in I. The number of deposited layers appropriate for the measurements of the VUV spectra in Region 1 was limited to only a few layers because of the strong absorption of Region 1, so the intensity of the 2910 cm^{-1} IR band was too weak to use for the nomalization of the deposition ratio. However, in the measurements of the spectra in Region 2 much thicker multilayers could be used because of the weaker absorptions in that region, so the 2910 cm^{-1} IR band could be effectively used in the normalization of the deposition ratio. The pure stearic acid multilayer prepared at the acid pH was reported to have a molecular arrangement with chain axes tilted against the normal of the layer plane by about 30°.[12] The VUV spectrum in Region 1 also gave a tilting angle of about 30°, as has been discussed in I. Therefore, in the normalization of the deposition ratio, the intensity of the 2910 cm^{-1} band was corrected for the tilting by assuming the tilting angle of 30°. The Region 2 VUV spectrum of the pure stearic acid multilayer is shown in Fig. 1, as well as the spectra of the acetic acid dimer and the monomer in the gas state obtained by Barnes and Simpson.[18] The spectrum of the pure stearic acid multilayer has a band at 7.7 eV which resembles, in position and strength, the lowest energy band of the acetic acid dimer, but which has no absorption in the region near 7.2 eV where the absorption of the acetic acid monomer exists. This

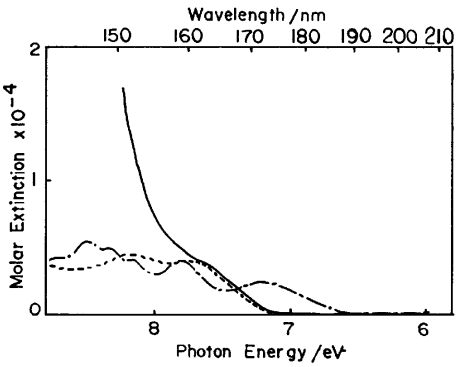

Fig. 1. Spectrum of pure stearic acid multilayer in molar extinction scale (——). The multilayer was prepared on the subphase without metal ions at pH 3.1. The spectra of acetic acid monomer (-·-) and dimer (----) obtained by Barnes and Simpson[18] were also shown.

shows that the carboxylic acid moieties in the pure stearic acid multilayer are not in the monomeric states but form hydrogen-bonded dimers. The existence of hydrogen bonding in pure fatty acid multilayers was also suggested by Koyama *et al.* from the broadness of the 1700 cm^{-1} IR band.[19]

pH *Dependencies of the VUV and IR Spectra of Fatty Acid Multilayers with Bivalint Metal Ions.* Fatty acid multilayers prepared on the subphase with metal ions adsorb the metal ions to a varying extent, depending on the pH of the subphase.[2,3] Corresponding to the pH dependencies of the metal ion adsorptions, the VUV spectra in Region 2 of the multilayers show marked dependencies on the subphase pH. In Figs. 2a and 3a we show the pH dependencies of the Region 2 spectra of the arachidic acid multilayers with Sr^{2+} and Cd^{2+} ions respectively.

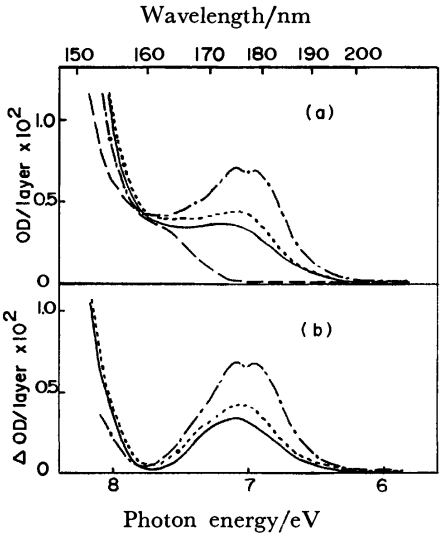

Fig. 2. (a): The pH dependence of the spectra of arachidic acid multilayers with Sr^{2+} ions prepared on the subphases with 10^{-4} M $SrCl_2$ at pH 6.6 (——), at pH 9.3 (----) and pH 10.7 (— - —). The spectrum of pure stearic acid multilayer prepared at pH 3.1 (——) is also shown. (b): The difference spectra presentation of the spectra in (a) with the reference of the pure stearic acid multilayer spectrum. The notation is the same as (a).

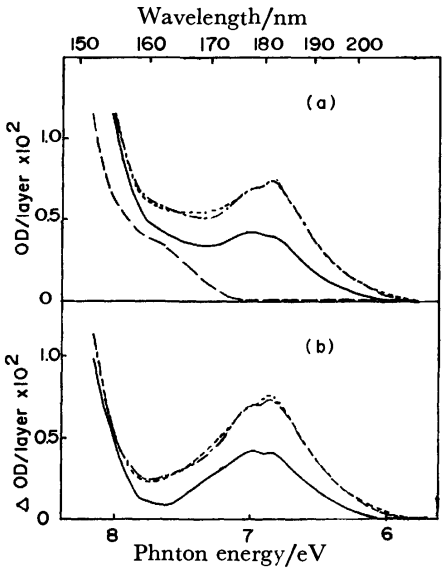

Fig. 3. (a): The pH dependence of the spectra of arachidic acid multilayers with Cd^{2+} ions prepared on the subphases with 10^{-4} M $CdCl_2$ at pH 6.15 (——), at pH 6.9 (----) and at pH 8.15 (— — —). The spectrum of pure stearic acid multilayer prepared at pH 3.1 is also shown (——). (b): The difference spectra presentation of the spectra in (a) with the reference of the pure stearic acid multilayer spectrum. The notation is the same as (a).

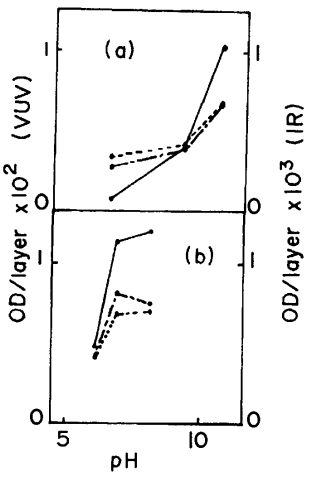

Fig. 4. (a): The pH dependences of the intensities of the VUV bands at 7.10 eV (——) and 6.95 eV (—·—) and of the IR band at 1515 cm^{-1} (——) of arachidic acid multilayers with Sr^{2+}. (b): Those of the VUV bands at 7.00 eV (— — —) and 6.85 eV (—·—) and of the IR band at 1546 cm^{-1} (——) of arachidic acid multilayer with Cd^{2+}.

At pH 3.1 little adsorption of these ions took place, and the spectra in Region 2 were almost the same as that of pure stearic acid multilayer. As the subphase pH was increased up to the pH region where the adsorption of the metal ions took place, however, new bands appeared in the energy region around 7 eV, where little absorption existed at pH 3.1, and their intensities increased with an increase in the pH. To establish the shapes of the new bands more clearly, in Figs. 2b and 3b we show the difference spectra with reference to the pH 3.1 spectra. The new bands depend on the kinds on metal ions adsorbed. At least two peaks can be discriminated for the multilayers with both Sr^{2+} and Cd^{2+} ions, at 7.10 and 6.95 eV for Sr^{2+} and at 7.00 and 6.85 eV for Cd^{2+}.

We show in Fig. 4 the pH dependencies of the absorption strengths at the positions of the two peaks. We note that the shapes of the spectra had a dependence on the pH. The relative strength of the lower energy peak to the higher energy one increased with the increase in the pH. This suggests that the metal ion dependent absorption around 7 eV contains contributions from at least two different molecular species.

To elucidate the nature of the molecular species responsible for the absorption, we inspected the pH dependencies of the IR spectra of the same multilayer samples in the wavenumber region from 1350 to 1850 cm^{-1} (Figs. 5 and 6). In this wavenumber region, there were two bands with marked pH dependencies, the broad band at 1700 cm^{-1} and the band at 1515 cm^{-1} (Sr^{2+}) or 1546 cm^{-1} (Cd^{2+}). The intensity of the 1700 cm^{-1} band was maximal at an acid pH and decreased with the increase in the pH. Its position was independent of the kinds of metal ions adsorbed. The 1700 cm^{-1} band can be assigned to the C=O stretching vibration in the unionized carboxylic acid moiety, because its position is identical with that of the C=O stretching band in the stearic acid crystal.[11] The metal ion dependent band at 1515 cm^{-1} (Sr^{2+}) or 1546 cm^{-1} (Cd^{2+}), on the other hand, was absent at an acid pH, but emerged in the pH region where the adsorption of the metal

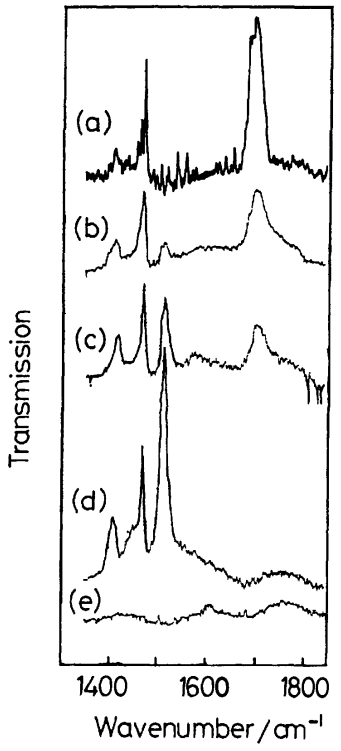

Fig. 5. IR spectra in the region 1850—1350 cm^{-1} of arachidic acid multilayers with Sr^{2+} ions prepared at pH 6.6 (b), at pH 9.3 (c), and at pH 10.7 (d). The spectrum of the pure stearic acid multilayer is also shown (a). (e) is the base line of the spectra.

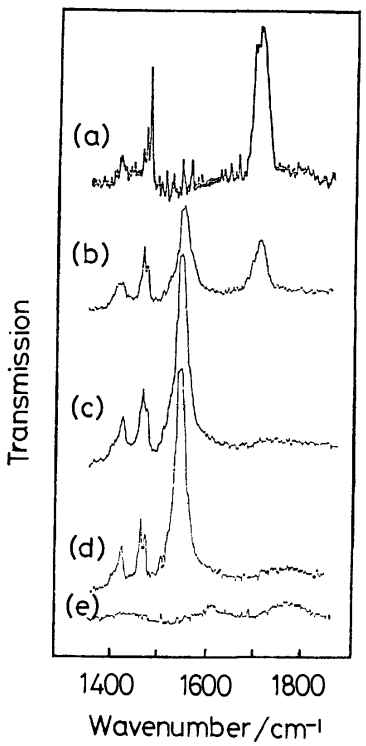

Fig. 6. IR spectra in the region 1850—1350 cm^{-1} of arachidic acid multilayers with Cd^{2+} ions prepared at pH 6.15 (b), pH 6.9 (c), and pH 8.15 (d). The spectrum of the pure stearic acid multilayer is also shown (a). (e) is the base line of the spectra.

ions begun to occur, and its intensity increased with the increase in the pH. The band can be assigned to the COO^- antisymmetric stretching vibration in the metal carboxylates moiety, because its position is very close to the position, 1514 cm^{-1} or 1548 cm^{-1}, of the vibration mode in Sr or Cd stearate crystal respectively.[11] The intensity of the band, therefore, is considered to be proportional to the amount of the metal ions adsorbed to the multilayer.

We show in Fig. 4 the pH dependencies of the 1515 cm^{-1} and 1546 cm^{-1} IR bands. One may see in Fig. 4 that there is a difference in the pH dependencies of the VUV and IR absorptions. The strength of the VUV absorption relative to that of the IR absorption was larger in the lower pH region, where the adsorption of the metal ions was incomplete, than in the high pH region, where the adsorption of the metal ions had been completed. This indicates that a molecular species which is present in the pH region with a partial adsorption of the metal ions contributes to the VUV absorption, but not to the IR band. This molecular species is considered to be unionized fatty acid molecules unhydrogen-bonded in their carboxylic acid moieties. As is shown in Fig. 1, the carboxylic acid moieties in pure fatty acid multilayers form hydrogen-bonded dimers. As the pH of the subphase is increased, a fraction of the fatty acid molecules is ionized and adsorbs metal ions. Therefore, the hydrogen bonds in a fraction of the remaining unionized molecules may be broken by the disturbance of the regular structure of the multilayer by the partial adsorption of metal ions. The unionized fatty acid monomers thus produced will have an absorption near 7.2 eV, as judged from the absorption spectrum of the acetic acid monomer shown in Fig. 1, and will contribure to the VUV absorption, but not to the IR band due to the metal salts of fatty acids. This mechanism can explain also the pH dependent change in the shape of the VUV absorption. The two peaks in the VUV spectra which were most clearly seen in the high pH region are

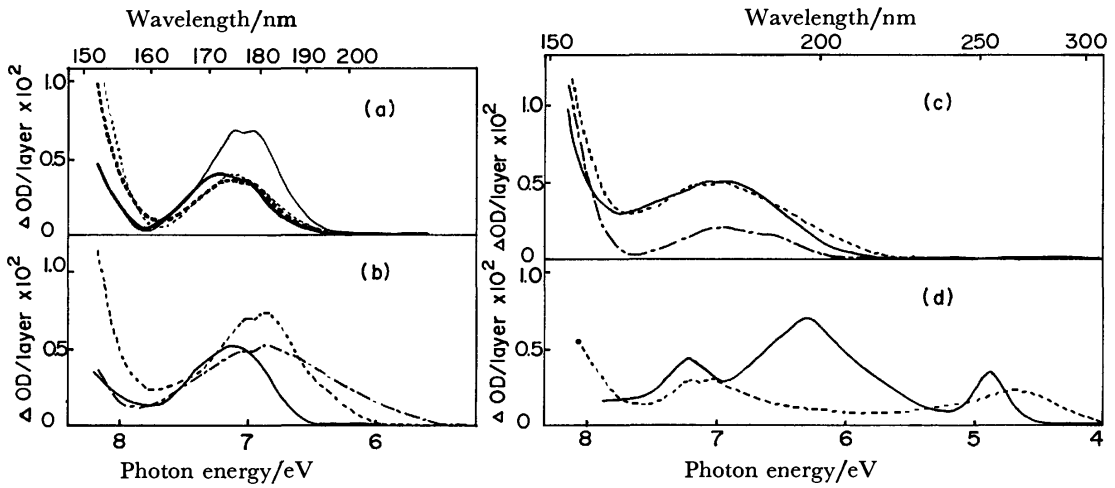

Fig. 7. The VUV difference spectra of fatty acid multilayers with alkaline earth metals (a), with 2B group metals (b), with transition metals (c), and with Cu and Pb (d). The reference is the spectrum of pure stearic acid multilayer prepared at pH 3.1. The metal ions and the pH's of the subphases are (a) Mg^{2+}, pH 10.1 (——), Ca^{2+}, pH 7.6 (- - -), Sr^{2+}, pH 10.7 (——), and Ba^{2+} at pH 9.6 (— — —), (b) Zn^{2+}, pH 7.3 (——), Cd^{2+}, pH 8.15 (— — —), and Hg^{2+}, pH 5.4 (—·—), (c) Mn^{2+}, pH 8.4 (——), Co^{2+}, pH 8.4 (— — —), and Ni^{2+}, pH 5.8 (—·—) and (d) Pb^{2+}, pH 5.7 (——) and Cu^{2+}, pH 5.4 (— — —). All the subphases contained 10^{-4} M metal chloride except for the Pb case with 6×10^{-7} M $PbCl_2$. The fatty acids used are indicated in Table 1. In the case of the multilayer with Zn^{2+} ions, the layer number was calculated assuming the tilted arrangement of molecules with the angle 26°[1,11] against the normal of the layer plane.

TABLE 1. POSITIONS OF THE ELECTRONIC ABSORPTION BANDS AND THE COO^- ANTISYMMETRIC STRETCHING VIBRATIONS OF FATTY ACID MULTILAYERS WITH BIVALENT METAL IONS

	Metal ions	Carbon[a] number	Metal[b] adsorption %	Electronic bands eV			The COO^- band cm^{-1}	Crystals[c] The COO^- band/cm^{-1}	Crystals[c] State of hydration
Alkaline earth metals	Mg	17	100	7.22	7.00		1560(b)	1564(b)	$3H_2O$
	Ca	17	50	7.15	6.95		1540, 1575	1540, 1581	H_2O

(b): broad band, (s): sharp band, (sh): shoulder. a) The carbon number of the alkane chain of fatty acids used as the multilayer samples. b) Calculated from the intensity of the 1700 cm^{-1} IR band. c) The IR and hydration data for metal stearate crystals obtained by R. Matsuura.[11]

considered to be due to the metal carboxylate moieties. The absorption due to the unionized monomer carboxylic acid moieties is superimposed on them in the low pH region, so that a pH dependent change in the spectral shape is produced. The swelling near 7.2 eV present only in the low pH VUV spectra may be due to the absorption of the unionized monomer species.

Metal Ion Dependence of Region 2 Spectra of Fatty Acid Multilayers. The Region 2 spectra of fatty acid multilayers with bivalent metal ions have a conspicuous dependence on the kinds of metal ions adsorbed. We show in Fig. 7 the difference spectra of the multilayers with metal ions of an alkaline earth group (Fig. 7a), the 2B group (Fig. 7b), a transition metal group (Fig. 7c), and Cu^{2+} and Pb^{2+} (Fig. 7d). The reference was the spectrum of the pure stearic acid multilayer prepared at pH 3.1. The depositions of the multilayers were performed at the pH's where the adsorptions of the metal ions were almost complete, except in a few cases in which the efficiency of deposition was not so good in such a pH region. The spectra, therefore, represent the absorptions of the metal carboxylate moieties. In Table 1 we list the positions of the absorption peaks which could be clearly discriminated.

We measured also the IR spectra of the same samples. In Table 1 we list the positions of the IR bands which were assigned to the COO^- antisymmetric stretching vibration in the metal carboxylate moieties. We show also the data of the positions of the vibration mode in the metal stearate crystals.[11] Several multilayers have two bands for the vibration mode that may be ascribed to different hydration states. It has previously been reported that, in crystals, the band width of the vibration mode was broadened by hydration to metal carboxylate moieties.[11] We show also the qualitative data about the band width and the data of hydration in crystals. We may see in Table 1 that there are good correspondences between multilayers and crystals in the band positions and the states of hydration, as judged by the band splitting and the band width. We also show in Table 1 the extent of metal ion adsorption in the multilayers, as estimated by the intensity of the 1700 cm^{-1} IR band.

We may see in Fig. 7 and Table 1 that all the multilayers have a band in the 7.0—7.3 eV energy region. This band may have a common origin in all the multilayers. A possible origin is the intramolecular π-π^* transition in the carboxylate anion moiety. The spectrum of the carboxylate anion has not been obtained. Barnes and Simpson suggested, from their observation of its absorption edge, that the π-π^* transition of the carboxylate anion may lie near 7.2 eV.[18] The position of the π-π^* transition may be shifted a little depending on the kind of bound metal ion.

All the multilayers also have another band in the 6.3—7.1 eV energy region. The assignment of this second band is not clear. In the Ba stearate multilayer it has a polarization perpendicular to the first band, as we shall show in the next section. Hence, it may be due to an intramolecular transition in the carboxylate anion moiety, possibly the n-π^* transition. The intensity of the n-π^* transition may be enhanced by the distortion of the n electron orbital caused by the interaction with bound metal ions. In the case of the multilayer with Pb^{2+}, the intensity of the second band is too strong to be assigned to the n-π^* transition, though, its position is shifted to a much lower energy compared to the other multilayers. The nature of the second band in the multilayer with Pb^{2+} may, therefore, be different from those of the other multilayers. To obtain a certain assignment of the transitions, further studies seem to be necessary.

The absorptions of the multilayers with Cu^{2+} and Pb^{2+} extend up to the UV region and have their bands at

4.70 and 4.86 eV respectively. The UV band is due to the charge-transfer transition between the carboxylate anion moiety and the bound metal ion, as we shall show later by means of the polarization spectra in the UV region.

The absorption edges of the multilayers with transition metals and 2B group metals, except for Zn, extend to a much lower energy region (up to about 5.5 eV) than do the multilayers with alkaline earth metals. The low energy tails of the absorptions of those multilayers may, therefore, contain weak transitions with the charge-transfer character.

Polarization Spectra of the Ba Stearate Multilayer. We show in Fig. 8 the polarization spectra of the Ba stearate multilayer measured with a 45° angle incidence of plane polarized lights. The absorption of the light polarized perpendicularly to the plane of incidence (S-polarization) was stronger than that of the light polarized parallel to the plane of incidence (P-polarization) throughout the energy region. The Ba stearate multilayer has been reported to have a layer structure with molecular axes arranged perpendicularly to the layer plane.[13,20-25] Assuming the perpendicular molecular arrangement and using Akutsu *et al.*'s method, we calculated the angle, θ, of the transition moment against the molecular axis. In the calculation, we used as the refractive index, n, of the multilayer both the value, $n=1.70$, of quartz near 7.0 eV[26] and the value, $n=1.50$, of the multilayer in the visible region,[20] as we have done in I. The theoretical value of the dichroic ratio, $R=A_S/A_P$, where A_S and A_P are the absorbances for S and P polarized lights respectively, became maximal for $\theta=90°$. The theoretical maximal value of R is 1.21 for $n=1.70$ and 1.29 for $n=1.50$. In all the energies, the observed dichroic ratio was close to the theoretical maximal value; for instance, $R=1.29$ at 7.1 eV. Therefore, we can conclude that $\theta=90°$ within the limits of experimental error.

This result shows that the transitions near 7 eV in the Ba stearate multilayer are intramolecular transitions in the carboxylate anion moiety. The π-π^* transition in the carboxylate anion has its direction along the line connecting the two oxygen atoms, and the n-π^* transition is perpendicular to the carboxylate plane, so that they are polarized perpendicularly to the molecular axis. The charge-transfer transition between the carboxylate anion moiety and the bound metal ion, on the other hand, is expected to have its direction of the transition moment not perpendicular to the molecular axis, because bound metal ions are arranged outside

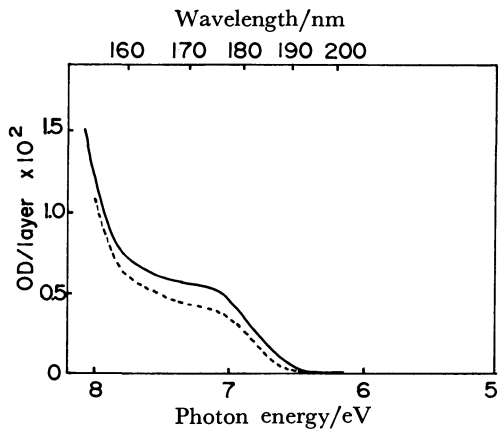

Fig. 8. Polarized absorption spectra of stearic acid multilayers with Ba^{2+} ions prepared on the subphase with 3×10^{-5} M $BaCl_2$ at pH 7.2 with 45° angle incidence of the light plane polarized perpendicularly (——), or parallely (– – –) to the plane of incidence.

Cu	Multilayer	263	2.1×10^{-3}	5000
	Bilayer	260	1.9×10^{-3}	4600
	Monolayer	254	1.8×10^{-3}	4300
	$Cu(CH_3COO)_2$ in CH_3COOH	245	—	3600
	$Cu(CH_3COO)_2$ in H_2O	235	—	6600

a) The molar extinctions of the L B layers were calculated as has been described in the Materials and Methods section.

the layer plane of the carboxylate anion moieties. The above conclusion is considered to be valid for the multilayers with alkaline earth metals. However, for the multilayers with metal ions of other kinds, further studies to check the validity of the assignment are necessary because their electronic structures are so different from those of alkaline earth metals that their interactions with the carboxylate anion moiety may be different from the interaction of the alkaline earth metals.

UV Spectra of Pb Stearate and Cu Stearate Mono- and Bilayers. As is shown in Fig. 7d, the Pb and Cu stearate multilayers have an absorption band in the UV region. The UV absorptions of the mono- and bilayers as well as those of the multilayers can be measured by using the high-sensitivity spectrometer for thin layers with the sample-in, sample-out technique developed in Kuhn's laboratory.[27] We show in Figs. 9a and 10a the UV spectra of the Pb and Cu stearate mono-, bi-, and multilayers. We also show, in Figs. 9b and 10b, the UV spectra of Pb acetate, $PbCl_2$ and Cu acetate in acetic acid and water solutions. The positions and molar extinctions of the UV bands are listed in Table 2.

The positions of the UV band in the bi- and multilayers with Pb ions were the same, though the breadth of the band was a little different, perhaps because of the larger light scattering in the bilayer. The coincidence of the peak position suggests that the structure and arrangement of the chromophores in the bilayer were unchanged by the formation of multilayer. The intensity of the absorption was larger in multilayer than in bilayer. This hyperchromicity of the multilayer may be due to the interlayer excitonic interaction of chromophores, as we shall discuss later. The peak position in the monolayer, on the other hand, was at a considerably shorter wavelength than those of the bi- and multilayers, and the intensity was stronger than that of the bilayer. This shows that the structure of coordination in the Pb carboxylate moieties is different between the mono- and bilayers. The peak position and the band width were almost the same in the monolayer and Pb acetate in an acetic acid solution. Therefore, the coordination of Pb ions in the monolayer is considered to be similar to that in an acetic acid solution.

The peak position of the UV band in the Cu stearate multilayer was red shifted a little against that of the bilayer, and the absorption intensity was a little stronger in the multilayer, showing that the structure and arrangement of chromophores in the bilayer are affected by the formation of the multilayer. The UV band in the bilayer was red shifted against that of the monolayer. This indicates that there is a difference between the mono- and bilayers in the coordination of Cu ions with the surrounding carboxylate anion moieties. The position of the UV band of the monolayer was closest to the UV band of Cu acetate in the acetic acid solution, though it was at a little longer wavelength position. Therefore, the coordination of Cu ions in the monolayer is considered to be similar to, but not identical with, the coordination in the acetic acid solution.

In order to determine the directions of the transition moments of the UV bands in Pb and Cu stearate mono- and bilayers, we measured their polarization spectra with the 45° oblique angle incidence of plane polarized lights, as is shown in Figs. 11 and 12. The absorption for the S-polarized light was stronger than that for the P-polarized lights, in all the cases. From the dichroic

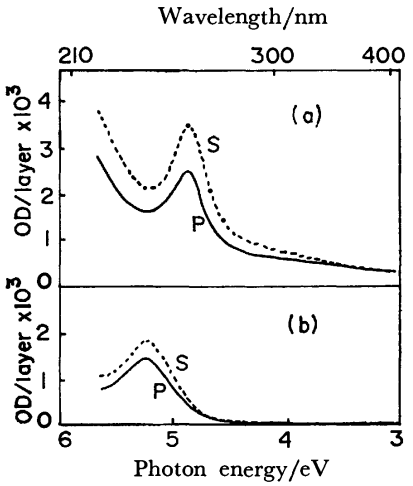

Fig. 11. UV polarization spectra of stearic acid bilayer (a) and monolayer (b) with Cu^{2+} prepared on the subphases containing 6×10^{-7} M $PbCl_2$ at pH 5.4 and 5.7, respectively. The angle of incidence was 45° with the lights plane polarized perpendicularly (---) and parallely (——) to the plane of incidence.

Table 3. The direction of the transition moment of the UV bands of Pb and Cu stearate mono- and bilayers

Ion	Layer number	R_{app} [a]	R [b]	n [c]	θ [d]
Pb	Monolayer	1.28 (at 237 nm)	1.07	1.515	59°
	Bilayer	1.41 (at 255 nm)	1.18	1.505	69°
Cu	Monolayer	1.37 (at 254 nm)	1.15	1.506	65°
	Bilayer	1.30 (at 260 nm)	1.09	1.503	61°

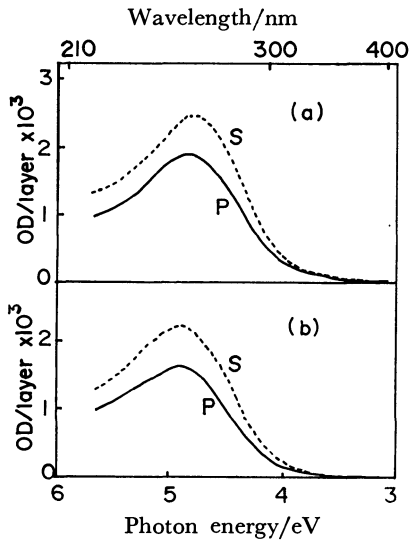

Fig. 12. UV polarization spectra of stearic acid bilayer (a) and monolayer (b) with Cu^{2+} prepared on the subphase containing 5×10^{-4} M $CuCl_2$ at pH 5.1. The angle of incidence was 45° with the lights plane polarized perpendicularly (---) and parallely (——) to the plane of incidence.

ratios at the peak positions, we calculated the angle, θ, of the transition moment against the molecular axis (Table 3). In the calculation, the molecular axes were assumed to be arranged perpendicularly to the layer plane; we used as the refractive index of the mono- and bilayers the values of quartz[26] at the peak positions, since we had no data about the refractive index at the peak positions and since quartz had a refractive index with a value close to those of the fatty acid multilayers at the Na D line, as was mentioned in I. We also made a correction for the interference effect[27] according to Matsuki *et al.*,[4] because, in the present systems, chromopores are arranged in a restricted layer.

The directions of the transition moments are tilted against the normal of the layer plane, as may be seen in Table 3. From the X-ray data of the Pb stearate multilayer,[28] we can estimate as about 40° the angle of the direction connecting the Pb ion and the oxygen atom in a lead(II) carboxylate complex against the normal of the layer plane. This angle is smaller than the angles of the transition moment obtained by us. However, the X-ray value is not so reliable because of the technical difficulty in the X-ray analysis of multilayers.

The tilting of the transition moments against the normal of the layer plane shows that the transitions are of a charge-transfer character. The same assignment was made for the UV bands of $PbCl_2$ and $CuCl_2$ in an aqueous solution.[29]

The θ angle in the Pb stearate bilayer is larger by about 10° than that in the Pb stearate monolayer. This shows that the lead(II) carboxylate complexes in the bilayer are distorted compared to the complexes in the monolayer in a manner to arrange the Pb ions closer to the layer plane of the carboxylate anions. The large red shift of the peak position in the bilayer may be due to this distortion, that may accompany an increase in the coordination number.[29]

The θ angles in Cu stearate mono- and bilayers are nearly the same. The small red shift in the peak position of the bilayer suggests that there may be a small distortion in the copper(II) carboxylate complexes, accompanied by the formation of a bilayer. Our data about the θ angle are consistent with the smallness of the red shift, but, unfortunately, are not of so high a precision as to enable us to detect conclusively such a small change in θ as only a few degrees.

It was shown that hyperchromicity is produced by the excitonic interaction of chromophores when they are packed in a head to tail arrangement of their transition moments.[30,31] The hyperchromicity of Pb and Cu stearate multilayers against the bilayers may be due to the interlayer excitonic interaction of the Pb and Cu carboxylate complexes. The tilting of the transition moments against the layer plane may produce a head to tail like packing of them. The interlayer distance is too long to produce a strong excitonic interaction between individual chromophores. However, in multilayers, chromophores form infinitely wide, two-dimensional layers, so that the integrated excitonic interaction between layers may become strong in spite of the weak interaction between individual chromophores. To elucidate the origin of the hyperchromocity, it is necessary to develop theory for excitonic interaction and its optical consequences in multilayers.

The authors would like to express their thanks to Professor Katsunosuke Machida for allowing us to use the JASCO-IRA-2 spectrometer in his laboratory and to Professor Rizo Kato for allowing us to use the VUV polarizer in his laboratory.

The Vacuum Ultraviolet Absorption Spectra of Fatty Acid Multilayers

Yukio NAGAHIRA,*,† Kazunori MATSUKI, and Hideo FUKUTOME
Department of Physics, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received August 28, 1980)

The electronic absorption spectra of fatty acid multilayers were measured in the vacuum ultraviolet region with an energy below 10 eV. From the chain length dependence of the spectra, the strong absorption (above 8 eV) was assigned to the σ-σ^* transitions in the alkane chain moiety, and the weaker one (below 8 eV), to the transitions in the carboxylic acid and metal carboxylate moieties. The polarized spectra of the Ba stearate multilayer showed that the band near 8.8 eV was polarized perpendicularly to the alkane chain. The spectra of the stearic acid multilayer without metal ions and the multilayer of the Zn stearate showed that their alkane chains were titled against the normal of the layer plane.

Fatty acid multilayers prepared by the Langmuir-Blodgett technique[1] are excellent objects for the measurement of the electronic absorption spectra of long alkane chains. In multilayers, the alkane chain and carboxylic acid moieties of fatty acids are arranged in regular two-dimensional layers, and the number of the layer can be controlled at any desired value. This property of multilayers makes it possible to measure the spectra of long alkane chains, which are difficult to measure in crystalline samples. The electronic absorption spectra of alkane chains and carboxylic acids lie in the vacuum ultraviolet (VUV) region. However, by depositing multilayers on a LiF or CaF_2 plate, spectra up to 10 eV can be measured. In a previous paper[2] we reported preliminary results for the VUV spectra of fatty acid multilayers. The VUV spectra of fatty acid multilayers provide information about the structures of multilayers and their interaction with metal ions, as well as basic information about the electronic structures of alkane chains. In this and an accompanying paper, we present the results of a systematic study of the VUV spectra of fatty acid multilayers. In this paper we deal mainly with the contribution of the alkane chain moiety in the VUV spectra. Studies of the chain length dependence and the polarization of the spectra are the main subjects of this paper. The application of the VUV spectra to the study of the molecular arrangement in multilayers is also made. Studies of the spectra of metal carboxylate moieties will be presented in an accompaying paper.[20]

Experimental

The crystalline stearic acid ($C_{17}H_{35}COOH$) was purchased from the Merck Co. The arachidic acid ($C_{19}H_{39}COOH$), heneicosanoic acid ($C_{20}H_{41}COOH$), and behenic acid ($C_{21}H_{43}COOH$) were purchased from Nakarai Chemicals, Ltd. The melting points of theses fatty acids were 70.0 °C, 76.0 °C, 74.0 °C, and 79.0 °C respectively, they agreed with the reported values[3] within an error of 1 °C. Guaranteed-reagent grade metal chlorides and spectrograde benzene were purchased from Nakarai Chemicals, Ltd. These chemicals were used without further purification. Twice-distilled water was used in all the experiments. A single crystal of CaF_2 was purchased from the Hursh Co., Ltd.

The fatty acid multilayers were prepared according to the Langmuir-Blodgett method[1] at 19±0.5 °C in a thermostated room. The pH of the water subphase was adjusted by the use of $KHCO_3$, HCl, or KOH. The fatty acids were spread on the water surface as a 0.1% (w/v) benzene solution, and caster oil was used as the piston oil (pressure, 16.5 dyn/cm). Plates of CaF_2 cleaved from a CaF_2 single crystal by a clean razor were used as the depositing plates. The CaF_2 plates were transparent up to 10 eV; their absorption was confirmed to be unchanged by dipping into water.

The deposition of fatty acid multilayers with bivalent metal ions was performed using CaF_2 plates coated with one layer of Fe stearate by the Langmuir method[4] and on the water subphase containing 10^{-4} M metal chloride at a neutral pH. Under these conditions with $BaCl_2$ and $CdCl_2$ multilayers were deposited as Y layers.[1,4-6] The deposition of multilayers was confirmed by the observation of the meniscus of the subphase near the dipping plate and by the linearity of the VUV absorption strength of the deposited multilayers to the number of times the plates were dipped into the subphase.[2]

The stearic acid monolayer on the subphase without metal ions at an acid pH could not be deposited on the CaF_2 plate coated with one layer of Fe stearate. To make the deposition possible, 4 layers of stearic acid with Ba ions were pre-deposited on the plate from the subphase with 10^{-4} M $BaCl_2$ at a neutral pH. After this treatment of the plate, the deposition of stearic acid multilayers at an acid pH became possible, but not so surely as the deposition at a neutral pH. From the observation of the meniscus when the plate was dipped only a few times, the stearic acid multilayer prepared at an acid pH without metal ions appeared to be of X-type layers.

The VUV absorption spectra were measured with a Shimadzu-SGV-50 VUV spectrometer (Seya-Namioka type with 50 cm focus concave grating blazed at 1500 Å and with 1200 rulings/mm. Light source, Tousey-type hydrogen discharge arc.). The apparatus was equipped with a beam splitter made of grazing incidence mirrors, and both the reference and sample signals were recorded. We used as the reference a CaF_2 plate coated with one layer of Fe stearate, so that the reflection at the surface of the sample plate was almost completely compensated for. A spectrum was measured after a plate with a multilayer had stood *in vacuo* for about three hours. An LiF polarizer with the Brewster angle reflection was used to obtain plane polarized VUV light. The polarizer was inserted between the light source and the entrance slit of the monochrometer.

Plates deposited with 8 layers of fatty acid (with 2 dippings of the plates for Y-type layers or 4 dippings for X-type layers) were used in all the spectral measurements to make the optical density in an appropriate range. The background spectra due to the pre-coating of the plates were substrated from the apparent spectra. All the spectra shown in this paper are those normalized to the per-layer value except for that of the pure stearic acid multilayer prepared at an acid pH, in which

† Present address: Osaka University of Economics and Law, Yao, Osaka 581.

the deposition at each dipping is not sure (see text).

Results and Discussion

We show in Fig. 1 the VUV absorption spectra of the stearic acid, arachidic acid, and behenic acid multilayers prepared on the water subphase containing Ba ions at a neutral pH. The spectra can be divided into two regions; the region of high absorption above 8 eV (Region 1), and the region of weaker absorption below 8 eV (Region 2). The spectra in Region 2 all have the same strength and shape, which do not depend on the carbon number, n, of the alkane chain moiety. The spectra in Region 1, on the other hand, have a broad maximum near 8.8 eV, and their strengths increase with the carbon number, n, though their shapes are homologous. We show in Fig. 2 the n dependence of the absorption in Region 1 (at 9 eV). The multilayers were prepared on the subphase containing Ba, Sr, Mg, Mn, or Cd ions at a neutral pH. In all the cases, the shapes of the spectra in Region 1 were homologous. We show in Fig. 2 that the absorption in Region 1 is proportional to n except for the stearic acid ($n=17$) multilayers with Mn, Sr, or Ba. The absorptions of these stearic acid multilayers, which showed deviations from the proportionality to n, were found to decrease slowly with the time, keeping their spectral shapes homologous in the whole wavelength region when they were kept *in vacuo*. This shows that stearic acids in the multilayers sublime slowly *in vacuo*, leading to the formation of a skeletal film.[4] The sublimation of stearic acids from the multilayers can explain the deviation from the proportionality to n.

From these results, we can assign the absorption in the Region 1 mainly to the σ-σ^* transitions in the alkane chain moiety, and that in Region 2, to the transitions in the carboxylic acid and metal carboxylate moieties. The absorption edge of polyethylene was reported to lie at 7.5 eV. The edge of the strong absorption of Region 1 is at the same position as the absorption edge of polyethylene, supporting our assignment.

In order to ascertain the polarization of the σ-σ^* transitions of the alkane chain moiety in Region 1, we measured the polarization spectra of a stearic acid multilayer with Ba ions prepared at a neutral pH (Fig. 3). The polarization spectra of normal incidence had no anisotropy, showing that the multilayer was uniaxial. The polarization spectra of 45° angle incidence showed a stronger absorption for the light with an electric field vector perpendicular to the plane of incidence (S-polarization) than the light with an electric field vector parallel to it (P-polarization) in both the regions, 1 and 2. We show in Table 1 the photon energy dependence of the dichroic ratio, A_S/A_P,

in Region 1, where A_S and A_P are the absorption strengths for the S and P polarized lights respectively. In the present system, the apparant dichroic ratio, A_S/A_P, represents the true dichroic ratio because the chromophores, *i.e.*, the alkane chains, are distributed nearly uniformly in the multilayer, and so no correction for the interference effect,[7] such as is necessary for multilayers with chromophores distributed only in a restricted layer, is necessary.

Stearic acid multilayers with Ba ions prepared at a neutral pH have been reported to have a layer structure with the molecular axes arranged near perpendicularly to the layer plane.[1,4,6,8-11] Assuming a perpendicular arrangement of alkane chains, and using the method of Akutsu *et al.*,[12] we calculated, from the observed dichroic ratio, the angle, θ, between the chain axis and the transition moment of the σ-σ^* transition near the absorption maximum of Region 1. (Akutsu *et al.*'s method assumes that the alkane chains in a monolayer have a uniform uniaxial distribution in their directions, with a tilting angle, γ, against the normal of the layer plane and that the transition moments with an angle, θ, against the chain axis, also have a uniform distribution around chain axis). The results are shown in Table 1. In the calculation of the angle, the value of the refractive index, n, in the VUV region is necessary. However, no data are available for it, and so we used $n=1.70$, that is, the value of quartz near 8 eV.[13] Since quartz has a refractive index with a value in the visible region similar to that of the fatty acid multilayer ($n=1.46$ for quartz and $n=1.49$—1.51, depending on the mixing ratio of stearic acid and metal stearate, for the fatty acid multilayer at the visible wavelength of 5890 nm[4,13]), and has an absorption edge near 7.5 eV, that is, close to that of the Region 1 absorption of fatty acid multilayers, the refractive index of fatty acid multilayers in the VUV region is considered to have a value similar to that of quartz. For the sake of comparison, we also show in Table 1 the results of the calculation using the value of $n=1.50$ in the visible region.

One may see in Table 1 that the dichroic ratio is nearly constant and that the angle between the transition moment and the chain axis calculated with $n=1.70$ is nearly perpendicular in the energy region from 8.6 eV to 8.8 eV. The angle calculated with $n=1.50$ is somewhat smaller. It is certain that the refractive index is larger in the VUV region than in the visible region and that the true value of the angle is larger than the one calculated with $n=1.50$.

Thus, the present measurement of the polarized spectra leads to the conclusion that the σ-σ^* transitions forming the absorption maximum in Region 1 are polarized perpendicularly to the molecular axis. The dichroic ratio begins to decrease in the higher energy region over 9 eV and becomes unity at 9.94 eV. This suggests that weak σ-σ^* transitions polarized in a parallel direction are present in this energy region or that the low energy tail of a strong σ-σ^* transition polarized in a parallel direction which may be present in the high energy region over 10 eV extends up to this energy region.

Based on the intramolecular exciton theory, Partridge estimated that the lowest parallel and perpendicular σ-σ^* transitions in polyethylene lie at 8.16 eV and 10.08 eV respectively.[14] Therefore, his estimates contradict our data. Based on the interband transition theory, McCubbin calculated that the lowest three transitions in polyethylene lie at 12.6, 13.6, and 16.9 eV and that all of them have perpendicular polarization.[15] The calculated peak positions are too high, but the direction of the transition moments is consistent with our data.

The polarization of the σ-σ^* transitions in Region 1 can be used for the study of the molecular arrangement in fatty acid multilayers. We show in Fig. 4 the normal incidence spectrum of the stearic acid multilayer prepared on the subphase with Zn ions at a neutral pH. The spectrum in Region 1 is apparently different from that of the stearic acid multilayer with Ba ions, with a weaker absorption strength in the energy region near 8.8 eV. We show in Table 2 the ratio of the absorption of the multilayer with Zn to that of the multilayer with Ba in the energy region near the absorption maximum. The ratio is nearly constant, though there is a weak decrease with the photon energy. The difference in the spectral shape can be ascribed to the fact that the multilayer with Zn ions has a tilting of the alkane chain axes against the normal of the layer plane. Assuming that the alkane chain axes in the multilayer with Ba ions are arranged perpendicularly to the layer plane, and that the σ-σ^* transitions near the absorption maximum are perpendicularly polarized against the chain axis, we calculated from the ratio the angle, γ, of the tilting of the chain axes in the multilayer with Zn ions using the method of Akutsu *et al.*[12] The results are shown in Table 2. The calculation gives angles of tilting in the range from 20° to 28°. The X-ray data about Ba stearate and Zn stearate crystals[16] showed that the inter-layer distances in these crystals were 47.5 Å and 42.6 Å respectively. The inter-layer distance of the Ba stearate crystal is consistent with the perpendicular packing of molecules against the layer plane. On the other hand, the inter-layer distence of the Zn stearate crystal shows that the axes of molecules are tilted against the normal of the layer plane. Assuming the perpendicular arrangement of molecules in the Ba stearate crystal, the angle, γ, of the tilting in the Zn

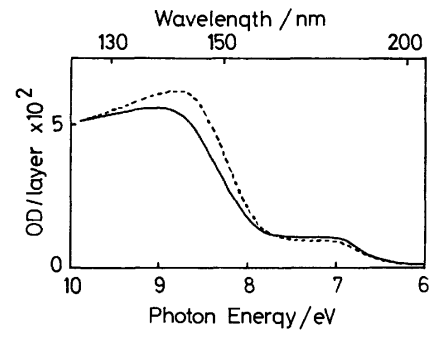

Fig. 4. Per-layer absorption spectrum of the stearic acid multilayer prepared on the subphase with 10^{-4} M $ZnCl_2$ at pH 6.5 (——). The per-layer spectrum of the stearic acid multilayer prepared on the subphase with 10^{-4} M $BaCl_2$ at pH 6.9 is also shown (– – –).

TABLE 2. THE TILTING ANGLE OF THE MOLECULAR AXIS AGAINST THE NORMAL OF THE LAYER PLANE IN THE Zn STEARATE MULTILAYER

Photon energy/eV	t[a)]	γ[b)]
8.4	0.90	19°
8.5	0.87	21°
8.6	0.85	23°
8.7	0.82	25°
8.8	0.80	27°
8.9	0.78	28°

a) t is the ratio of the per-layer absorptions of the Zn stearate multilayer to the Ba stearate multilayer. b) γ is the tilting angle of the molecular axis calculated from t.

stearate crystal is estimated from the $\cos\gamma=42.6/47.5$ relation to be $\gamma=26°$. The tilting angle estimated from our spectral data is in agreement with this X-ray value. We note also that the spectrum of the multilayer with Zn ions has the same intensity as that of the multilayer with Ba ions at the photon energy of 9.94 eV, just the energy where the S and P polarized spectra at the 45° incidence of the multilayer with Ba ions have the same strength (Fig. 3). This fact is also consistent with our interpretation that the change in the spectral shape of the multilayer with Zn ions is due to a change of polarization caused by a tilting of the molecular axis.

The spectrum in Region 1 of a pure stearic acid multilayer prepared on the subphase without metal ions at an acid pH is also different from that of the multilayer with Ba ions, as is shown in Fig. 5. In the case of the pure stearic acid multilayer, the deposition of monolayers on the plate is not so sure as in the case of the multilayers with bivalent metal ions. Furthermore, observation of the meniscus showed that the deposition occurred in such a manner as to give X-type layers for the first several dippings of the plate, but they became Y-type layers after several dippings. Therefore, it is difficult to determine the number of deposited layers in a pure stearic acid multilayer. The multilayers of our samples, prepared with only four dippings, are too thin to apply the interference and infrared techniques in measuring their thicknesses. Therefore, we normalized the spectrum of the pure stearic acid multilayer by the following indirect method.

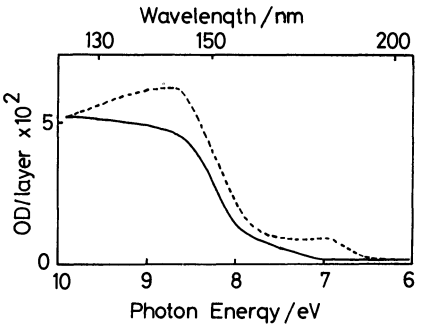

Fig. 5. Absorption spectrum of the stearic acid multilayer prepared on the subphase without metal ions at pH 3.0 (——). For the normalization of the spectrum, see text. The per layer spectrum of the stearic acid multilayer prepared on the subphase with 10^{-4} M $BaCl_2$ at pH 6.9 is also shown (----).

As may be seen in Figs. 3 and 4, the absorption of the alkane chain of stearic acid has the same strength at 9.94 eV irrespective of the polarization of incident light or the tilting of the chain axis. Hence, the photon energy of 9.94 eV is considered to be the isosbestic point for stearic acid multilayers with different directions of the σ-σ^* transition moments. Therefore, we normalized the spectrum of the pure stearic acid multilayer so as to have the same absorption strength at 9.94 eV as the multilayer with Ba ions.

We show in Table 3 the ratio of the absorption strength of the pure stearic acid multilayer thus normalized to the absorption strength of the stearic acid multilayer with Ba ions in the energy region near the absorption maximum. The ratio is fairly constant in this energy region. We calculated from the ratio the tilting angle of alkane chain axis in the pure stearic acid multilayer (Table 3). The calculation showed that alkane chain axes in the pure stearic acid multilayer are tilted by about 30° against the normal of the layer plane. This tilting is in good agreement with the reported value, ≈30°, measured with the infrared spectra.[17]

TABLE 3. THE TILTING ANGLE OF THE MOLECULAR AXIS AGAINST THE NORMAL OF THE LAYER PLANE IN THE PURE STEARIC ACID MULTILAYER

Photon energy/eV	t[a)]	γ[b)]
8.4	0.74	31°
8.5	0.76	30°
8.6	0.73	32°
8.7	0.75	30°
8.8	0.76	30°
8.9	0.78	28°

a) t is the ratio of the per-layer absorptions of the pure stearic acid multilayer to the Ba stearate multilayer. b) γ is the same as Table 2.

The spectrum in Region 2 of the stearic acid multilayer lacks the absorption near 7 eV which is present in the spectrum of the multilayer with Ba ions. The absence of the band near 7 eV cannot be explained by the tilting of the molecules, rather, it is attributable to the difference in the state of the carboxylic acid moiety. The former multilayer consists only of unionized stearic acids, but the latter is a mixture of Ba stearate and unionized stearic acid.[18,19] As we shall show in the accompanying paper, the band near 7 eV can be ascribed to the Ba carboxylate and unhydrogen-bonded carboxylic acid moieties, but the carboxylic acid moieties in the pure stearic acid multilayer are hydrogen-bonded. We stress that the marked pH dependence (and the metal ion dependence discussed in the accompanying paper) of the absorption in Region 2 support the assignment of it to the transitions in the carboxylic acid and metal carboxylate moieties.

Kinetic Isotope Effect of Chemically Activated Vinyl Radicals

Ken-ichi KOWARI, Ko-ichi SUGAWARA, Shin SATO,* and Shigeru NAGASE†

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

†Chemistry Division, Faculty of Education, Yokohama National University, Hodogaya-ku, Yokohama 240

(Received September 1, 1980)

The apparent decay rates of hydrogen and deuterium atoms in the reactions with acetylene-d_0 and -d_2 in helium in the pressure range from 100 to 800 Torr (1 Torr=133.3 Pa) have been measured by the pulse radiolysis-Lyman-α absorption method at 300±2 K. The helium pressure dependence of the rate constants was well interpreted in terms of the RRKM theory including a tunneling effect, using the geometry and force constants of the activated complex and vinyl radical estimated by the *ab initio* calculation. (S. Nagase and C. W. Kern, *J. Am. Chem. Soc.*, **101**, 2544 (1979).)

The reaction of hydrogen atoms with acetylene has been investigated during the last half century.[1-10] The primary reaction mechanism established may be expressed as follows:

$$H + C_2H_2 \leftrightarrows C_2H_3^* \xrightarrow{+M} C_2H_3$$

Here $C_2H_3^*$ denotes an energized vinyl radical which can re-form reactants or be deactivated to a stable vinyl radical by a collision with a third body.

Recently Keil *et al.* reported two kinds of experiments:[11] one used a mass spectrometer in a flow system for the measurement of the rate constants of the reactions $H+C_2H_2$, $H+C_2D_2$, $D+C_2H_2$, and $D+C_2D_2$ in the pressure range from 1 to 7 Torr, and the other used a time-resolved Lyman-α photometric method for the measurement of the decay rate of H atoms in the reaction with C_2H_2 in flowing helium in the pressure range from 1 to 742 Torr. In order to explain the pressure dependence of these rate constants, they applied the RRKM theory, in which various parameters such as the geometry and vibrational frequencies of an activated complex were estimated by a somewhat arbitrary method.

In a previous investigation,[12] we measured the rate constants of the reactions $H+C_2H_2$, $H+C_2D_2$, $D+C_2H_2$, and $D+C_2D_2$, by means of the pulse radiolysis-Lyman-α absorption method. In that measurement, the hydrogen pressure was varied from 300 to 1200 Torr and no pressure dependence of the rate constants was observed. In the present study, we used helium as the third body and found the pressure dependence similar to that observed by Keil *et al.*

The recent development of the *ab initio* calculation has been considerable and the potential energy surfaces calculated for some simple reactions are believed to be not far from the real ones. Nagase and Kern have calculated the potential energy surface for the $H+C_2H_2$ reaction and predicted the geometry and force constants of the activated complex and of the vinyl radical.[13] We tried to use these calculated results to explain the kinetic isotope effects observed in the present experiments in terms of the RRKM theory. In the present calculation, however, there is an important assumption, which should in fairness be stated at the outset. The energy barrier for the reaction of $H+C_2H_2$ calculated by Nagase and Kern was 6.2 kcal/mol (1 kcal=4.184 kJ). This value seemed to be too large and was not used in the following calculation.

Experimental

The apparatus and procedures used in this study are the same as those described in a previous paper,[14] so we mention here only the major features.

Figure 1 shows the apparatus schematically. A mixture of 5 Torr H_2 or D_2 and a small amount of C_2H_2 or C_2D_2 (50—130 mTorr) diluted with He (100—800 Torr) was irradiated with an electron pulse (pulse width, 3 ns; upper limit of energy, 600 keV) generated by a Febetron 706 (Hewlett Packard Co.). The time dependence of the concentration of H or D atoms was measured by the absorption of Lyman-α (121.57 nm for H and 121.53 nm for D). The transmitted light was directly detected with a head-on type photomultiplier (Hamamatsu TV Co., R976), which was monitored with an oscilloscope (Tektronix 465). As has been discussed in previous papers,[14,15] the optical density used for the measurement is proportional to the atom concentration in this technique.

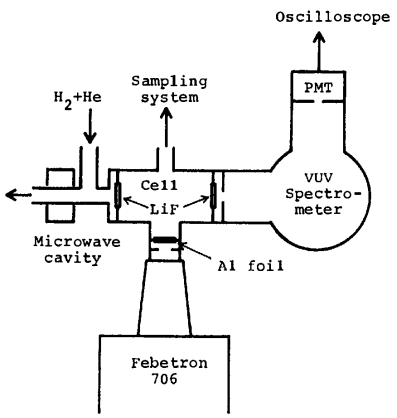

Fig. 1. Schematic diagram of the apparatus.

The high-purity dried He (Nihon Helium Co.) was passed through a trap filled with molecular sieve 4A at 77 K before use. Research grade H_2, D_2, and C_2H_2 (Takachiho Shoji Co.) were used without further purification. C_2D_2 was synthesized by the reaction of D_2O (above 99.99%, Merck Co.) with CaC_2 (Tokyo Kasei Co.), which was heated at about 500 °C for 70 h in vacuum prior to use. The C_2D_2 thus obtained was shaken with sulfuric acid for 1 h. The mass and infrared spectra showed that the purity of C_2D_2 was better than 99%.

Results

In the absence of acetylene, practically no change of the atom concentration could be observed in the time

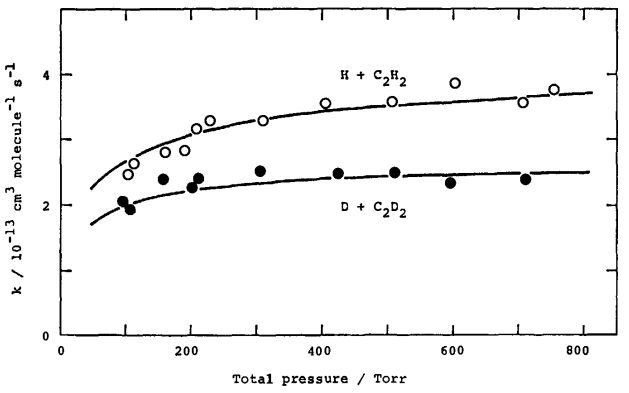

Fig. 2. The apparent decay rates of H atoms in the H+C_2H_2 reaction (○), and of D atoms in the D+C_2D_2 reaction (●) as functions of the total pressure. Solid curves were theoretically calculated.

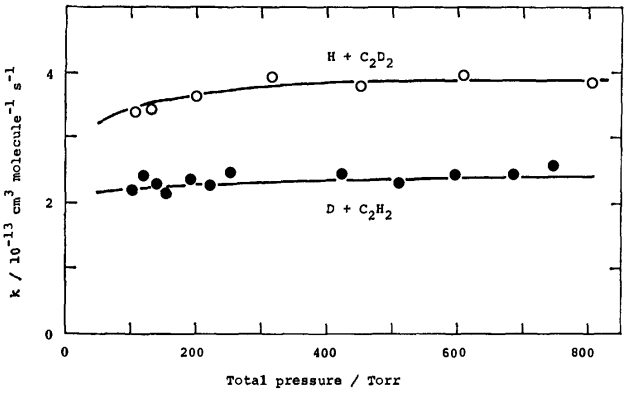

Fig. 3. The apparent decay rates of H atoms in the H+C_2D_2 reaction (○), and of D atoms in the D+C_2H_2 reaction (●) as functions of the total pressure. Solid curves were theoretically calculated.

range of 10 ms, while in the presence of 50 mTorr acetylene, the atoms decayed completely within 10 ms. From this first-order decay curve and the concentration of acetylene used, the rate constant of the reaction could be estimated.

Figures 2 and 3 show the rate constants obtained for the reactions of H+C_2H_2, D+C_2D_2, D+C_2H_2, and H+C_2D_2 as functions of total pressure. Below 100 Torr of helium, the atom concentration was too small for the measurement of the time dependence. It should be noted that the rate constant of the H+C_2H_2 reaction is strongly dependent upon helium pressure, while that for the D+C_2H_2 reaction is almost independent of helium pressure.

Theoretical Calculation

The treatment of the RRKM theory has been fully discussed in a book by Robinson and Holbrook.[16] The present experiments correspond to one of the chemical activations discussed in that book.

Let us consider the following reaction:

$$R + R' \leftrightarrows A^\dagger \leftrightarrows A^* \xrightarrow{+M} A.$$

Here, R and R′ denote reactants, $A^\dagger$ an activated complex, A* an energized product, and A a stabilized product. In the nomenclature used by Robinson and Holbrook, the bimolecular rate constant of the reaction between R and R′ may be expressed as follows:

$$k = k_\infty \int_0^\infty \frac{\omega f(E)}{\omega + k_a(E)} dE. \quad (1)$$

Here ω is the collision frequency between A* and the third body, $k_a(E)$ the rate constant of the decomposition of A*, $f(E)$ the non-equilibrium distribution of energy of A*, and k_∞ the bimolecular rate constant in the limit of high pressure.

In order to calculate these parameters, we have to use many approximations, which appear in the RRKM theory. Since many different degrees of approximation are introduced in the book of Robinson and Holbrook, the minimum number of equations used in the present calculation will be given below without any detailed interpretations.

$$\omega = \beta_c z p \quad (2)$$

$$z = \sigma_d^2 (8\pi N_A/\mu kT)^{1/2} \quad (3)$$

Here β_c is the collisional efficiency, z the collision frequency at 1 Torr of the third body, p the pressure, σ_d the collision radius, μ the reduced mass of A* and the third body, T the temperature, N_A Avogadro's number, and k the Boltzmann constant.

$$k_a(E) = L^\dagger (Q^\dagger/Q)[1/hN(E)] \times \left[\sum_{E_{vr}^\dagger=0}^{E} \kappa(E - E_{vr}^\dagger) P(E_{vr}^\dagger)\right] \quad (4)$$

$L^\dagger$ is the reaction path degeneracy and $Q^\dagger$ and Q the partition functions for the over-all rotations of $A^\dagger$ and A. The term $\kappa(E-E_{vr}^\dagger)$ is the transmission coefficient, which was not discussed in the book of Robinson and Holbrook; however, recent theoretical calculations on the hydrogen atom-molecule reaction revealed that the tunneling effect cannot be ignored even at room temperature, if a hydrogen atom is transferred in the reaction.[17] There are several ways to estimate the tunneling effect. One of the simplest ways is to use the transmission coefficient for the inverted parabolic potential barrier in one dimension.

$$\kappa(E) = (1 + \exp[2\pi(E - V_0)/h\nu])^{-1} \quad (5)$$

Here V_0 is the barrier height and $h\nu$ is the magnitude of the immaginary vibrational quanta. This expression has already been discussed by Kato and Morokuma in the unimolecular decomposition of CH_2CH_2F radicals.[18] $P(E_{vr}^\dagger)$ denotes the number of vibrational-rotational quantum states of $A^\dagger$ with vibrational-rotational non-fixed energy equal to $E_{vr}^\dagger$, h the Planck's constant, and $N(E)$ the density of quantum states of A* with energy between E and $E+dE$. Since in the H+C_2H_2 reaction, no active rotation is involved in $A^\dagger$, the term $P(E_{vr}^\dagger)$ becomes simply $P(E_v^\dagger)$, a value which has been counted directly. The $N(E)$ has been calculated by using the Whitten-Rabinovitch approximation:

$$N(E) = \frac{Q_r}{(kT)^{r/2}} \frac{(E + aE_z)^{s+r/2-1}}{\Gamma\left(s + \frac{r}{2}\right) \Pi h\nu_i} \left[1 - \beta\left(\frac{dw}{dE'}\right)\right]. \quad (6)$$

Here, Q_r is the partition function for the active rotations

in A*, r and s the number of active rotations and vibrations, E_z the sum of zero-point energies, ν_i the frequency of the i-th mode, and $E'=E/E_z$. According to Whitten and Rabinovitch, a, β, and w can be expressed as follows:

$$a = 1 - \beta w(E') \tag{7}$$

$$\left.\begin{aligned}(0.1<E'<1.0)\ \mathrm{d}w/\mathrm{d}E' &= -(5.00+1.365\,E'^{-0.75})w^2\\ (1.0<E'<8.0)\ \mathrm{d}w/\mathrm{d}E' &= -(0.60478E'^{-0.75})w\end{aligned}\right\} \tag{8}$$

$$\beta = \frac{s-1}{s}\,\frac{s+\frac{r}{2}}{s}\,\frac{\langle\nu^2\rangle}{\langle\nu\rangle^2}. \tag{9}$$

Here $\langle\nu\rangle$ and $\langle\nu^2\rangle$ are the mean frequency and mean-square frequency of A. In the present calculation, all vibrations and the rotation around the C–C bond in vinyl radical were taken as active. If the rotation was taken as inactive, we had to assume an extraordinarily large collision radius.

The distribution function $f(E)$ can be derived by using the principle of detailed balance:

$$f(E) = k_a(E)K(E)/\int_0^\infty k_a(E)K(E)\mathrm{d}E\,. \tag{10}$$

Here $K(E)$ is the Boltzmann distribution function of A.

$$K(E) = N(E)\exp(-E/kT)/\int_0^\infty N(E)\exp(-E/kT)\mathrm{d}E \tag{11}$$

To perform the RRKM calculation, we need the moments of inertia and the vibrational frequencies of the activated complex and the vinyl radical, the barrier height, and the minimum energy of the energized product, E_{min}, together with the molecular diameters of He (0.257 nm) and the vinyl radical (0.423 nm); the latter was assumed to be the average of acetylene and ethylene.[19] The *ad initio* calculation of Nagase and Kern using the 4-31G basis set provides the necessary data. Figure 4 shows the geometry of the activated complex and the vinyl radical. Table 1 summarizes the moments of inertia and the fundamental vibrational frequencies calculated by the GF-matrix method using the force constants reported. Here it should be noted that the activated complexes C_2H_2–D* and C_2HD–H* are different. Similarly two vinyl radicals, $\overset{D}{H}\!>\!C\!=\!C\!<^{H}$ and $\overset{D}{H}\!>\!C\!=\!C\!<^{H}$, should be taken as different radicals at the temperature of absolute zero, but, in the present calculation, these two radicals were assumed to be the same, since these two radicals are known to be in equilibrium even at 93 K.[20] In fact, the partition functions for these two radicals are the same in value within the limits of the calculation.

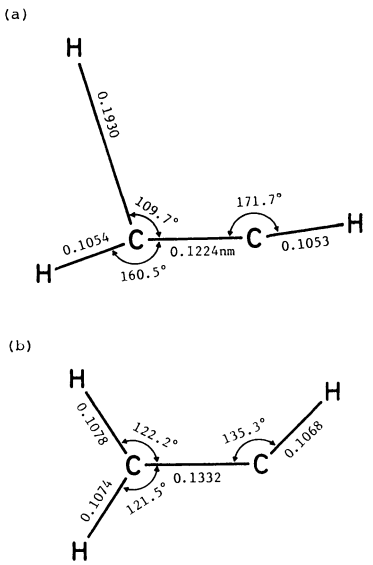

Fig. 4. The geometry of activated complex in the reaction of $H+C_2H_2$ (a) and of vinyl radical (b).

There is some uncertainty in the value of E_{min} because the heat of formation of vinyl radicals and the activation energy for the $H+C_2H_2$ reaction have not been established. We tentatively adopted 40 kcal/mol for the E_{min} of C_2H_3*. Since the $N(E)$ value is not strongly dependent on E_{min} around 40 kcal/mol, the adoption of this value does not restrict the conclusions of the following discussion. In the present calculation, the barrier height V_0 was also assumed to be equal to E_{min}. Table 1 contains the values of E_{min} for other isotopic vinyl radicals, which were calculated by taking into account the zero-point energies of each vinyl radical.

In order to calculate the absolute values of k, we need the values of k_∞ for each reaction. Table 2 summarizes the k_∞ values used in the present calculation. Since we have not measured the temperature dependence of the rate constants, we will not discuss the k_∞ values theoretically.

Reactions of $H+C_2H_2$ and $D+C_2D_2$. The calculation of Eq. 1 is now straight-forward for the $H+C_2H_2$ reaction. An adjustable parameter is the collisional frequency β_c in Eq. 3. The upper solid curve shown in Fig. 2 was drawn by assuming $\beta_c=0.078$. The scattering of the experimental results allowed us to estimate this value only within the error limit of $\pm15\%$. A similar calculation can be carried out for the $D+C_2D_2$ reaction. The lower solid curve in Fig. 2 was drawn by using the same collisional efficiency.

Reactions of $H+C_2D_2$ and $D+C_2H_2$. In these reactions, we have to consider two processes for the decomposition of energized vinyl radicals:

$$\begin{aligned}H + C_2D_2 &\rightarrow C_2D_2H^*\\ C_2D_2H^* &\rightarrow H + C_2D_2 \qquad k_{aH}(E)\\ &\rightarrow D + C_2DH \qquad k_{aD}(E)\\ &\overset{\omega}{\rightarrow} C_2D_2H.\end{aligned}$$

Consequently, the pressure dependence of the decay rate of H atoms should be expressed as follows:

$$k = k_\infty\int_0^\infty \frac{[\omega + k_{aD}(E)]f(E)}{\omega + k_{aH}(E) + k_{aD}(E)}\,\mathrm{d}E\,. \tag{12}$$

A similar equation can easily be constructed for the case of $D+C_2H_2$. The solid curves shown in Fig. 3 were calculated by using these equations. The same collisional efficiency was used. Although the scatter of the experimental data precludes any detailed comparison between experiment and theory, the trend of the pressure dependence could be reproduced by the calculation.

TABLE 2. k_∞ USED FOR CALCULATION

Reaction	$k_\infty/10^{-13}$ cm^3 $molecule^{-1}$ s^{-1}
$H+C_2H_2$	4.0
$D+C_2D_2$	2.6
$D+C_2H_2$	2.5
$H+C_2D_2$	4.0

Discussion

As has been discussed in a previous paper,[12] the rate constant of the $H+C_2H_2$ reaction we obtained in the limit of high pressure is more than twice that reported by Payne and Stief (1.56×10^{-13} cm^3 $molecule^{-1}$ s^{-1}).[10] The result of Keil *et al.* is consistent with theirs. We therefore reconsidered this discrepancy. One possible reason is the participation of the reaction of

vinyl radicals in the decay of hydrogen atoms in our reaction system.

$$H + C_2H_2 \rightarrow C_2H_3 \quad (a)$$
$$C_2H_3 + H \rightarrow C_2H_2 + H_2 \quad (b)$$
$$2\,C_2H_3 \rightarrow C_2H_2 + C_2H_4 \quad (c)$$

The apparent decay rate of hydrogen atoms may be expressed as follows:

$$k_{app} = k_a\left(1 + \frac{k_b[C_2H_3]}{k_a[C_2H_2]}\right) = k_a\gamma. \quad (12)$$

The correction factor γ ranges from 1 to 2. The time dependence of $[C_2H_3]$ can be calculated by the Runge-Kutta integration procedure if the ratios of k_b/k_a and k_c/k_a and the initial concentration of H and C_2H_2 are known. Such calculations have already been made in a previous paper, in which the reaction between hydrogen atoms and ethylene has been discussed.[15] In the present experiments, we may approximate that $k_a \approx 4\times10^{-13}$, $k_b \approx 6\times10^{-11}$, and $k_c \approx 10^{-11}$ in units of cm^3 $molecule^{-1}$ s^{-1}, and the initial concentration of hydrogen atoms is in the order of 10^{12} cm^{-3} and $[C_2H_2]$, larger than 2×10^{15} cm^{-3}. The substitution of these data gives a γ factor of less than 1.1, *i.e.*, no correction seems to be necessary. However, the electron pulse-irradiation might produce an inhomogeneous distribution of atoms in the reaction cell, which cannot easily be estimated. If this occurred, the value of the γ factor would become close to 2. Consequently, it may be safe at present to retain the final conclusion until new evidence can be obtained. The measurement of the activation energy is now being undetraken.

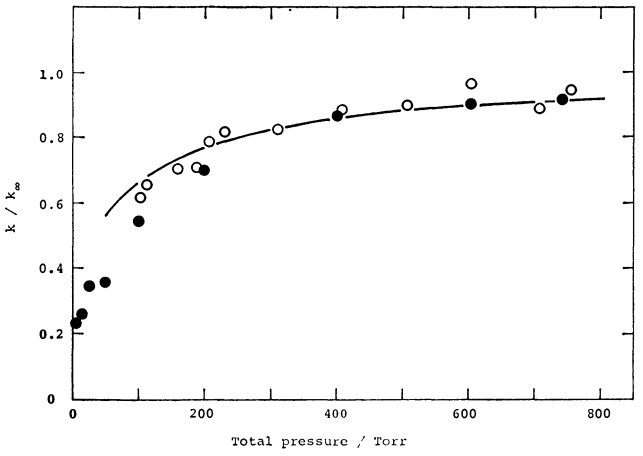

Fig. 5. Comparison of experiments obtained by Keil *et al.* (●) and by the present work (○) with theoretical curve. The value of k_∞ for the data of Keil *et al.* was assumed to be 1.7×10^{-13} cm^3 $molecule^{-1}$ s^{-1}.

Comparison with the Data of Keil et al. In Fig. 5, we plotted the pressure dependence of the k/k_∞ ratios for the $H+C_2H_2$ reaction obtained by Keil *et al.* and by us. Both experiments are in fair agreement with theoretical curve. According to Keil *et al.*, their RRKM calculation well explained this pressure dependence.[11] This fact probably means that the differences between the parameters of the moments of inertia and of the vibrational frequencies for the activated complex and vinyl radicals are not large enough to cause any difference in the pressure dependence of the rate constant. Since there is an adjustable parameter, β_c, in the theory, we cannot make a definite comparison. Incidentally, Keil *et al.* took the value of 0.25 for β_c.

Tunneling Effect. In the above treatment, we introduced a tunneling effect into the RRKM calculation. The calculation without a tunneling effect has also been carried out, and similar agreement between experiment and theory could be obtained, although the adjustable parameter, β_c, increased to 0.21. As far as the consistency between experiment and theoretical calculation is concerned, no substantial difference could be found between including and excluding the tunneling effect. Probably this effect will become a crucial problem when k_∞ is discussed theoretically.

Chlorination of Polyacrylonitrile and Analysis of Its Products

Masao Okamoto,* Ryōji Yamada, and Osamu Ishizuka

Department of Fiber and Polymer Engineering, Faculty of Engineering, Yamagata University, Jonan, Yonezawa 992

(Received July 8, 1980)

Chlorination of polyacrylonitrile (PAN) was carried out by passing dried chlorine gas through a tetrahydrothiophene 1,1-dioxide (sulfolane) solution of PAN or a powdery mixture of PAN with sodium chloride. The chlorinated products were examined by comparison with acrylonitrile–α-chloroacrylonitrile (CAN) copolymers corresponding to α-chlorinated PANs. In solution the reaction proceeded easily below 100 °C, but due to side reactions analysis of the products was difficult. In the powdery mixture hardly any reaction took place below 100 °C, but in the range 120—140 °C, the reaction proceeded smoothly and its rate became *ca.* 2.7 times in proportion as its temperature was raised by 10 °C. The chlorinated products were investigated by means of infrared and thermal analyses. The chlorinated moiety consists mainly of α,β-dichlorinated units, which seem to result from the addition of chlorine to the double bonds produced by dehydrochlorination after β-chlorination. These chlorinated products were dehydrochlorinated at lower temperature than acrylonitrile–CAN copolymers, but in many respects they resemble each other in the behavior of thermal degradation.

Grassie and McGuchan[1] carried out bulk copolymerization of acrylonitrile with α-chloroacrylonitrile (CAN) and recognized from the favorable thermoanalytical behavior of the copolymers obtained that the copolymers can be used for carbon fiber processing. They correspond to the partially α-chlorinated polyacrylonitrile (PAN). Chlorination of PAN remains to be investigated. However, if it proceeds preferentially on the α-carbon of the PAN molecule, its products should assume the same thermal behavior as copolymers.

Chlorination of PAN was studied in three different states: (1) dispersed powder in carbon tetrachloride, (2) solute in tetrahydrothiophene 1,1-dioxide (sulfolane), and (3) dispersed powder in sodium chloride powder. The reaction did not proceed in the first state but the chlorinated products could be obtained in the second and third states. In this work, these products were examined in comparison with acrylonitrile–CAN copolymers.

Experimental

Preparation of PAN. Two hundred and ninety grams of freshly distilled acrylonitrile was dissolved in 400 cm³ of *N,N*-dimethylformamide (DMF). This solution and 0.8 g of α,α′-azobisisobutyronitrile (AIBN) dissolved in 40 cm³ of DMF were put into a three-necked flask which had been evacuated with an oil pump and flushed with nitrogen several times. Stirring was started. The temperature inside the flask was maintained at 47 °C; it rose to 52 °C immediately after addition of AIBN. After 11.5 h, the reaction mixture was diluted with 400 cm³ of DMF containing 0.01 g of hydroquinone, and then poured into 20 dm³ of distilled water. The precipitate was filtered, washed with methanol and distilled water at 70 °C, and dried in a vacuum at 50 °C to constant weight. The yield was 92.7 g. The intrinsic viscosity, $[\eta]$, in DMF at 35 °C was 2.54.

Preparation of Acrylonitrile–CAN Copolymers. The method was reported in a previous work.[2]

Chlorination of PAN in A Solution State. Sulfolane (bp 122 °C at 4 mmHg (1 mmHg≈133.3 Pa)) was used as a solvent. Chlorination was carried out by passing dried chlorine gas at *ca.* 25 cm³/min through a polymer solution consisting of 0.2 g of PAN and 40 cm³ (at 100 °C) of sulfolane. The solution was bubbled with nitrogen for 15 min prior to the admission of chlorine gas. A magnetic stirrer was used and the solution was illuminated with a 100-W National Electric street lamp. After the lapse of reaction time (Table 1), the reaction system was purged with nitrogen and the solution was poured into 1 dm³ of methanol. The precipitate was filtered, washed with methanol for 18 h using a Soxhlet extractor, and dried at 30 °C in a vacuum oven to constant weight.

Chlorination of PAN in a Solid State. One gram of PAN powder was dispersed in 50 g of sodium chloride powder. The mixture was thoroughly dried and then charged in a U tube

Table 1. Chlorination of PAN in a solution state

Reaction temperature / °C	Reaction time / h	Chlorine content of product / wt%

Table 2. Chlorination of PAN in a solid state

Reaction temperature / °C	Reaction time / h	Chlorine content of product / wt%
100	20	4.49
120	4	4.03
120	7	7.32
120	10	9.85
130	2	2.70
130	3	4.35
130	5	10.81
130	10	20.82
140	2	5.73
140	3	10.84
140	5	22.45
140	8	34.84
140	10	42.11
140	20	49.54

The process of chlorination was similar to that for solution state. The reaction temperature and time are given in Table 2. After the reaction, the mixture was washed with distilled water until no chloride ion could be detected. The product obtained was dried in a vacuum at 30 °C to constant weight.

Chlorine Analysis and Measurement of Infrared Absorption Spectra. The methods were reported in a previous work.[3]

Thermomechanical Analysis (TMA). The measurement was carried out under tension at a heating rate of 10 °C/min with a Shimadzu TMA-20 Thermomechanical Analyzer. The sample was cut from the casting film (15—40 μm thick), the measurement being carried out with 5 g load.

Differential Thermal Analysis (DTA). A Rigaku CAT. No. 8001 Thermoflex was used. Fifty milligrams of sample was employed in each experiment and heated at a 5 °C/min rate under nitrogen.

Results and Discussion

Infrared Absorption Spectra of Acrylonitrile–CAN Copolymers. Acrylonitrile–CAN copolymers,[2] corresponding to α-chlorinated PANs, were studied before examining the chlorination of PAN. The infrared spectrum of a copolymer, shown in Fig. 1, is similar to the combination of spectra of PAN[2] and poly(α-chloroacrylonitrile)[3] (PCAN). In the copolymers, the bands at 2240 and 500 cm^{-1} were chosen as the characteristic bands of acrylonitrile and CAN[4] units, respectively. The absorbances and whether the molar extinction coefficients were affected by copolymerization were determined. Each absorbance was normalized by the equation

$$A = \frac{a}{w} \times \left(1 + \frac{34.445\,x}{3545.3 - 34.445\,x}\right), \qquad (1)$$

where A is the normalized absorbance, a the observed absorbance for w mg of sample, and x the chlorine content of sample.

The relationship between the number of chlorine atoms in 100 monomer units (N_{Cl}) and the absorbances at 2240 and 500 cm^{-1} (A_{2240} and A_{500}) is shown in Figs. 2 and 3 by solid lines. N_{Cl} was calculated by the equation

$$N_{Cl} = \frac{53.064\,x}{3545.3 - 34.445\,x} \times 100. \qquad (2)$$

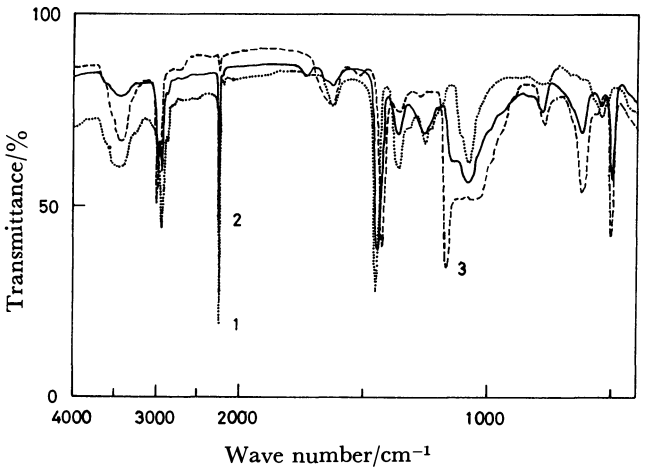

Fig. 1. Infrared absorption spectra of (1) PAN, (2) acrylonitrile–CAN copolymer (chlorine content: 20.25 wt%), and (3) PCAN.

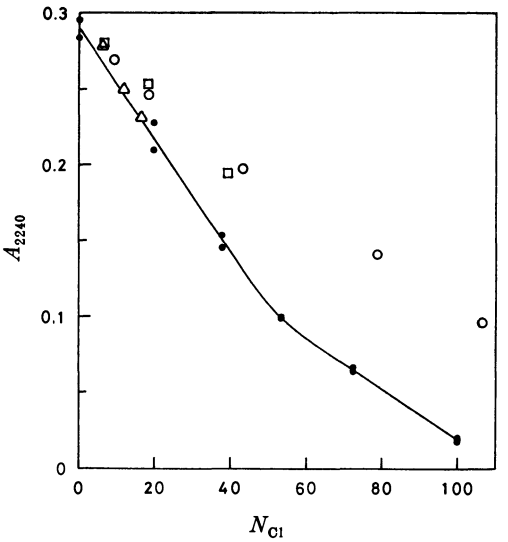

Fig. 2. Relationship between the number of chlorine atoms in 100 monomer units and the absorbance at 2240 cm^{-1}. ●: Acrylonitrile–CAN copolymers. △, □, and ○: Products chlorinated at 120, 130, and 140 °C, respectively, in a solid state.

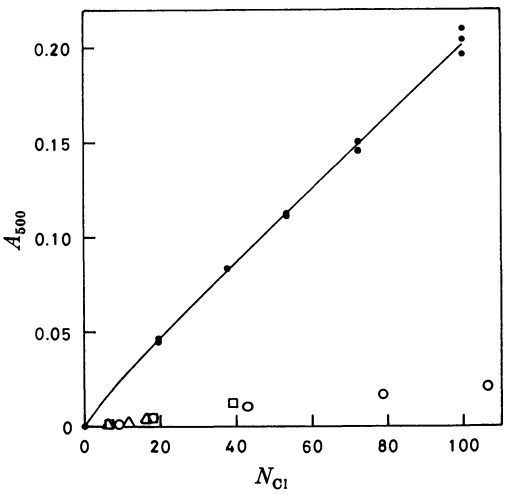

Fig. 3. Relationship between the number of chlorine atoms in 100 monomer units and the absorbance at 500 cm^{-1}. The symbols used here are the same as those in Fig. 2.

We see that the result for the band at 2240 cm^{-1} deviates considerably from the combination of absorbances of homopolymers, while at 500 cm^{-1} they are nearly equal. The chemical environment of acrylonitrile units in copolymer changes with position in the chain. In such cases, band broadening may occur. However, none was observed, indicating that the molar extinction coefficient of the 2240 cm^{-1} band in the copolymer is smaller than that in PAN, and that great care should be taken when using the absorbance of the band at 2240 cm^{-1} for determining the mole fraction of acrylonitrile units in a chlorinated PAN.

If only α-chlorination takes place during the course of chlorination of PAN, methylene groups do not change in number. However, with change in their chemical

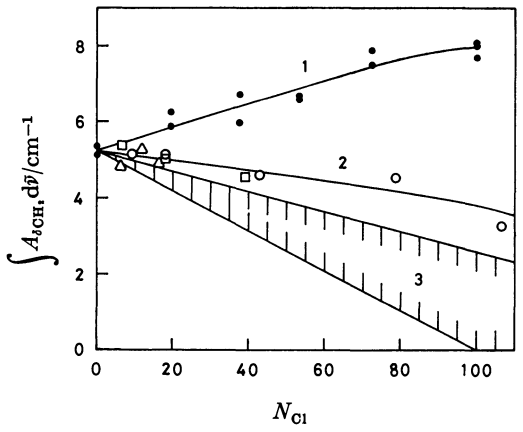

Fig. 4. Relationship between the number of chlorine atoms in 100 monomer units and the areal intensity of methylene scissoring vibration band. The symbols used here are the same as those in Fig. 2. Curves 1 and 2 express the changes which follow α-chlorination and the chlorination in a solid state, respectively. Area 3 is the expected one for β-chlorination (including β,β-dichlorination).

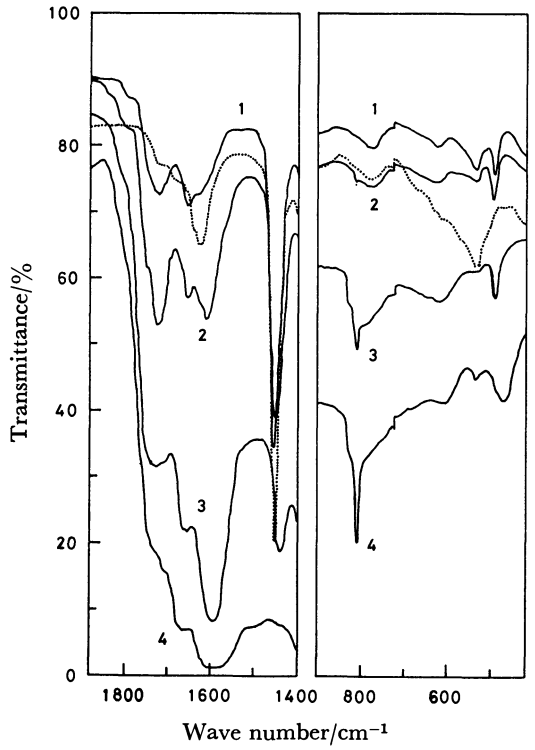

Fig. 5. Infrared absorption spectra of products chlorinated in sulfolane.
1, 2, 3, and 4: Products chlorinated at 55, 80, 110, and 135 °C, respectively, for 10 h. ·····: PAN heated at 150 °C for 10 h in sulfolane under nitrogen flow.

environment both methylene stretching and bending vibrations are affected (Fig. 1). The methylene scissoring vibration band appears at 1455 cm^{-1} in PAN and 1430 cm^{-1} in PCAN. In the copolymers, the integrated intensity of this band, $\int A_{\delta CH_2} d\bar{\nu}$, was calculated in the range 1540—1400 cm^{-1} (Fig. 4). Here, $A_{\delta CH_2}$ is the absorbance of methylene scissoring vibration band at a wave number ($\bar{\nu}$). We see from Curve 1 that the integrated intensity increases with the progress of α-chlorination, being nearly equal to the combination of the intensities in PAN and PCAN.

Chlorination of PAN in a Solution State and Analysis of Its Products. The chlorine content and infrared spectra of chlorinated products are shown in Table 1 and Fig. 5, respectively. In the case of chlorination above 100 °C, there is a ceiling in the chlorine content (Table 1). Although the 500 cm^{-1} band appears, its intensity is weak in comparison with that in the copolymer which has a corresponding chlorine content (see Fig. 1). In addition, strong absorptions are observed in the range 1800—1500 cm^{-1}. The absorptions in the neighborhood of 1700 cm^{-1} show that cyano groups have been transformed into carboxyl or carbamoyl groups. Since the formation of these groups was hardly observed without the admission of chlorine gas (Fig. 5), some side reaction should proceed simultaneously with chlorination.[5] The absorption at *ca.* 1600 cm^{-1} shows the progress of polymerization of cyano groups. A conspicuous absorption appears at *ca.* 810 cm^{-1} which seems to correspond to the characteristic band appearing in the heat-treatment of PAN in the air.[7] Chlorination is accompanied by several side reactions, making the analysis of chlorinated products difficult. The side reactions seem to cause the above-mentioned ceiling in the chlorine content.

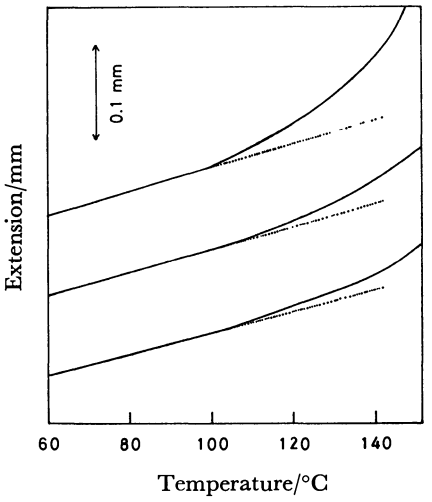

Fig. 6. TMA curves for PAN.

Chlorination of PAN in a Solid State and Analysis of Its Products. Change of Chlorine Content Following Chlorination: The chlorine content of chlorinated products is given in Table 2. It was found that the reaction scarcely proceeds at 100 °C. The reaction in a solid state should be accompanied by diffusion of chlorine into PAN granules. The rate of diffusion in a rubbery material is expected to be considerably higher than in a glassy one. Figure 6 shows TMA curves for original PAN. The rates of extension are equal below 100 °C but start to change at 100—110 °C, the glass transition temperature being *ca.* 100 °C. The reaction proceeded smoothly at 120, 130, and 140 °C. In the reaction at 140 °C, one chlorine atom per monomer unit was incorporated

after *ca.* 10 h, chlorination proceeding further.

The degree of chlorination is proportional to the weight gain resulting from chlorination, since no side reaction which brings about the change in sample weight was observed during the course of chlorination. The weight gain is expressed by the following equation:

$$\text{Weight gain} = \frac{34.445x}{3545.3-34.445x} \times 100(\%), \qquad (3)$$

where x is the chlorine content of chlorinated PAN. The relationship between chlorination time and weight gain is shown in Fig. 7. The rate of chlorination above 120 °C becomes *ca.* 2.7 times in proportion as the reaction temperature was raised by 10 °C.

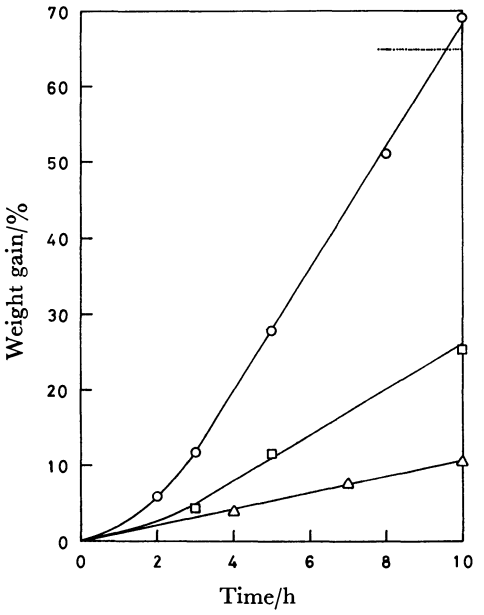

Fig. 7. Weight gain due to chlorination in a solid state. Chlorination temperatures are 120 (△), 130 (□), and 140 °C (○). A dotted line indicates the level of weight gain due to substitution of one hydrogen atom per monomer unit with one chlorine atom.

Infrared Analysis of Chlorinated Products: Infrared spectra of chlorinated products are shown in Fig. 8. No absorption related with side reactions was observed except in the neighborhood of 1600 cm^{-1}. New absorptions appearing in the neighborhood of 800 cm^{-1} and increasing with the progress of chlorination can be assigned to C–Cl stretching vibrations. A slight polymerization of the cyano groups proceeds simultaneously with chlorination but sample weight is changed by only chlorination. Thus each infrared absorption band can be quantitatively treated by means of the weight gain which follows chlorination.

A_{2240}, A_{500}, and $\int A_{\delta CH_2}d\bar{\nu}$ were calculated using Eq. 1. The results shown in Figs. 2, 3, and 4, respectively, indicate that a preferential α-chlorination hardly occurs. Here, β-chlorination should be considered. In this case, $\int A_{\delta CH_2}d\bar{\nu}$ is an effective measure. When only β-chlorination (including β,β-dichlorination) proceeds, the value should be in Area 3. However, Curve 2

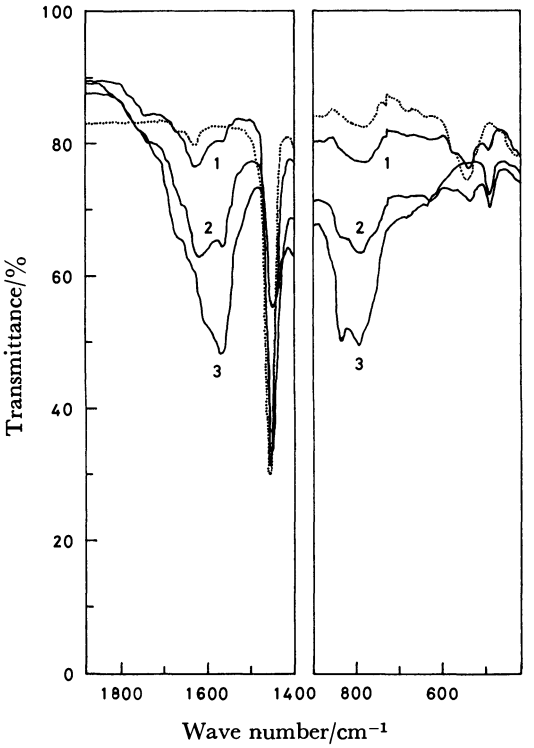

Fig. 8. Infrared absorption spectra of products chlorinated in a solid state.
1, 2, and 3: Products chlorinated at 120, 130, and 140 °C, respectively, for 10 h. ·····: PAN heated at 130 °C for 10 h in sodium chloride powder under nitrogen flow.

expresses the change of this value which follows chlorination at 120, 130, and 140 °C. It is in agreement with the change in PAN which undergoes nearly equal chlorination on both CH_2 and CH groups. If the chlorination on CH groups proceeds independently of that on CH_2 groups, absorbance of the 500 cm^{-1} band should become much higher than that in Fig. 3. It seems that the chlorinated moiety consists mainly of α,β-dichlorinated units. Figure 2 is not contradictory, since the rate of decrease in the absorbance is about half of that in α-chlorination. Such a substitution of two chlorine atoms per monomer unit would still leave many monomer units even if 100 chlorine atoms per 100 monomer units were incorporated, making further chlorination possible.

Thermal Analysis of Chlorinated Products: Figure 9 shows the DTA curves for products chlorinated at 130 and 140 °C for 10 h. The differential temperature, ΔT, is very small, exothermic reaction taking place at a temperature lower than that of the reactions in PCAN, acrylonitrile–CAN copolymers,[1] and PAN. When these two chlorinated products were heated at a rate of 5 °C/min under nitrogen in the DTA apparatus, their chlorine contents changed (Table 3). Since the number of chlorine atoms in 100 monomer units changes with dehydrochlorination following heating, its value, N'_{Cl}, was calculated by the following equation:

$$N'_{Cl} = \frac{\left(53.064-2.016\times\frac{N_{Cl}}{100}\right)x'}{3545.3-36.461x'} \times 100, \qquad (4)$$

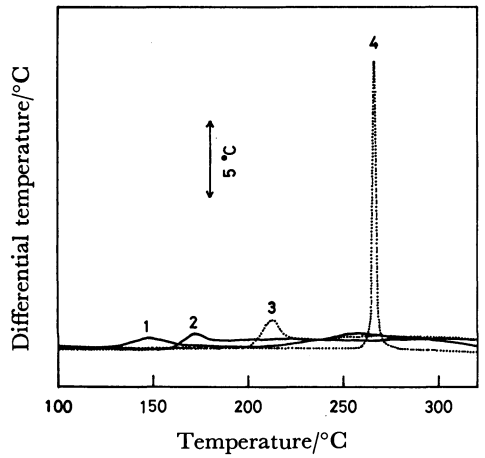

Fig. 9. Comparison in DTA curves between products chlorinated in a solid state (1 and 2) and PCAN (3) or PAN (4). 1 and 2: Products chlorinated at 130 and 140 °C, respectively, for 10 h.

where x' is the chlorine content of heated sample. The values obtained are shown in Fig. 10. From a comparison of Figs. 9 and 10, it was found that thermal dehydrochlorination starts at about the initiation temperature of exothermic reaction. The mode resembles that in PCAN and acrylonitrile–CAN copolymers.[1,4,8)] This indicates that, even in chlorinated PANs, the initiation of polymerization of cyano groups takes place as a side effect of the thermal dehydrochlorination.[1)] On the other hand, dehydrochlorination in chlorinated PANs occurs at a temperature lower than that in acrylonitrile–CAN copolymers[1)] and PCAN. This indicates that β-substituted chlorine atoms are easily dehydrochlorinated at lower temperature than α-chlorine atoms. It seems that α,β-dichlorinated units

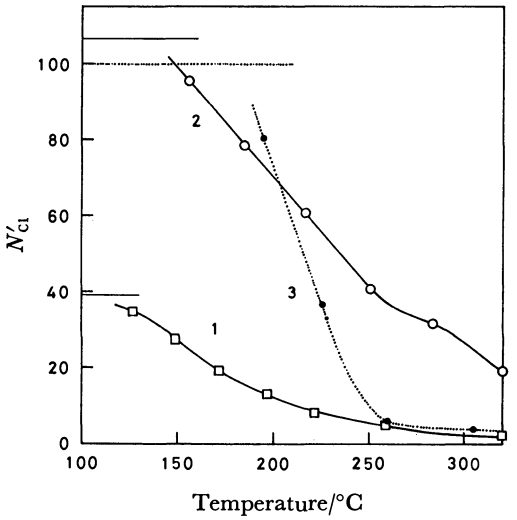

Fig. 10. Changes of the number of chlorine atoms in 100 monomer units during heating process.
1 and 2: Products chlorinated at 130 and 140 °C, respectively, for 10 h in a solid state, 3: PCAN.

result from the addition of chlorine to the double bonds produced by dehydrochlorination after β-chlorination. The dehydrochlorination shown in Fig. 10 is nearly completed in both PCAN and slightly chlorinated PAN, but not in highly chlorinated PAN before the sample temperature reaches 300 °C. This can be interpreted by considering the α,β-dichlorinated unit as a chlorinated moiety. A chlorinated moiety is usually easily dehydrochlorinated. The reaction can be expressed by

$$-CH_2-\underset{Cl}{C}(C\equiv N)-\underset{Cl}{CH}-CH(C\equiv N)- \longrightarrow$$
$$-CH=C(C\equiv N)-CH=C(C\equiv N)- + 2\,HCl.$$

When dehydrochlorination took place, three new infrared absorption bands appeared, corresponding to the characteristic bands of dehydrochlorinated PCAN.[3)] However, complete dehydrochlorination is difficult in highly chlorinated PAN, since there should be chlorine atoms not subjected to intramolecular dehydrochlorination. An example is the case of chlorine atom 1 or 2 in

$$-CH_2-\underset{Cl}{C}(C\equiv N)-\underset{Cl}{\underset{1}{CH}}-CH(C\equiv N)-\underset{Cl}{\underset{2}{CH}}-\underset{Cl}{C}(C\equiv N)-.$$

In order to examine the change of thermal behavior which follows chlorination, DTA curves were constructed for the products chlorinated at 130 °C (Fig. 11). In the case of the sample of low chlorine content, ΔT is still fairly high, the exothermic peak temperature

Table 4. Chlorination of PCAN in a solid state

Reaction temperature °C	Reaction time h	Chlorine content of product wt%
No chlorination		39.37[a)]
120	5	38.99
130	10	40.45
150	4	38.73

1, 2, 3, and 4: Products chlorinated for 2, 3, 5, and 10 h, respectively.

becoming higher than in PAN. Highly chlorinated samples exhibit broad complex exotherms at lower temperatures. Such DTA behavior is similar to that in acrylonitrile–CAN copolymers.[1] Although chlorinated PAN differs from acrylonitrile–CAN copolymer in chemical structure, they resemble each other as regards the mode of thermal degradation.

Possibility of The Chlorination or Hydrochlorination of Cyano Groups: There is a possibility that cyano groups in PAN undergo chlorination or hydrochlorination during the course of chlorination of PAN in a solid state. It is difficult to confirm whether cyano groups are chlorinated in the case of PAN; the groups in PCAN[9] are not chlorinated under similar conditions (Table 4). There might be a similarity in the case of PAN. If hydrochlorination takes place, a band would appear at *ca.* 1690 cm^{-1},[6] but no such band was observed (Fig. **9**).

Structure of the Galacturonate and Glucuronate Complexes with Copper(II) in Aqueous Solution. A Calorimetric Study

Roberto ARUGA

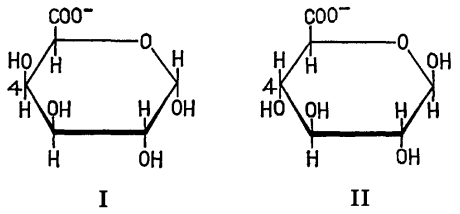
Institute of Analytical Chemistry, University of Turin, via *P. Giuria 5, 10125 Turin, Italy*

(Received October 13, 1979)

Heat and entropy of reaction of copper(II) with galacturonate and glucuronate anions have been determined by calorimetry. The measurements were performed in an aqueous medium at 25 °C and ionic strength $I=1$ M ($NaNO_3$). The results indicate a bidentate action of the two ligands towards copper. The carboxylate group as well as the oxygen atom of the ring, the latter by means of an outer-sphere electrostatic bond, seem to interact with the cation.

Acid polysaccharides are of importance among the polyelectrolytes of biological interest.[1] Complex formation of these polysaccharides with metal ions gives rise to particular structures and biological functions. Our knowledge of the structures and bonding sites is fragmentary. Data are insufficient for the reactions of not only polysaccharides but also the corresponding acid monosaccharides such as uronic acids. Of the few studies on the metal associations of uronic acids in solution, those of Anthonsen *et al.*[2-4] and Makridou *et al.*[5] may be cited. As regards the bond nature for galacturonate with some metals, the results of the above works do not agree. The NMR data suggest a tridentate behavior towards metal ions of large dimensions, the potentiometric results indicating a monodentate action with only the $-COO^-$ group bound to the metal. The latter conclusion, particularly for copper, appears curious. Thermodynamic studies on the association between this metal and some hydroxy and alkoxy carboxylic acids showed that some groups such as ethereal oxygen or alcoholic –OH group, in particular positions, can form bonds with copper.[6,7]

Taking into consideration the disagreement of these conclusions and the absence of calorimetric studies on metal-uronic acid reactions, it was thought of interest to extend the calorimetric investigations to the reaction of copper(II) with galacturonate and glucuronate (Fig. 1). The results obtained refer to the aqueous medium at 25 °C and $I=1$ M.



I II

Fig. 1. Galacturonate ion (I) and glucuronate ion (II).

Experimental

Materials. Copper(II) nitrate (C. Erba RPE) was used. The concentration of metal was determined by complexometric titration with EDTA (0.1 M solution, C. Erba RPE). Solutions of the ligands were prepared by D(+)-galacturonic acid monohydrate Fluka puriss and D-glucuronic acid Fluka purum. The purity of the acids was checked by potentiometric titration. Inert electrolyte: sodium nitrate (C. Erba RPE).

Equipment. Calorimetric measurements were carried out at 25.00 °C with an LKB 8700-2 Precision Calorimetry System and an LKB 8726-1 100-ml titration vessel equipped with a standard resistor (50Ω) and a thermistor (2000Ω). The accuracy of the instrument was checked by measuring the molar enthalpy of the reaction between tris(hydroxymethyl)methylamine and HCl in aqueous solution. The calorimeter was also equipped with a Radiometer ABU 12b autoburet for the addition of titrant. The calorimetric experiments were carried out in a room whose temperature was kept constant within ±0.3 °C. For the pH measurements a Metrohm Compensator E 388 potentiometer was used at 25 °C.

Procedure. For each ligand several sets of measurements of the reaction and dilution heats were carried out, each set being performed in the following way. 2.5±0.002 ml of 4×10^{-1} M copper nitrate solution was added in succession to 88.00 ml of the uronic acid solution contained in the calorimetric cell, the heat being measured for each addition. The pH of the copper solution was made 3.6± 0.1 in order to avoid the metal hydrolysis. The ligands were partly transformed into sodium salt by adding NaOH to pH=4.55±0.02. The ionic strength of all the solutions was brought to 1 M with sodium nitrate. The corresponding heat of dilution was measured by adding the same amounts of copper nitrate solution to 88.00 ml of 1 M $NaNO_3$, without ligand, at pH=4.55. The following results were obtained. (a) Formation of only the ML^+ complex species; in fact, the presence of only the ML^+ species was shown up to a C_L/C_M ratio of 2.[5] (b) Absence of polynuclear species.[5] (c) A negligible neutralization heat between H^+ and OH^-. The pH value in the cell, after each addition of titrant, was measured potentiometrically by means of titration performed in the same manner as the calorimetric one.

Treatment of the Experimental Data. Owing to the pH difference between metal and ligand solutions, a slight protonation process of the latter took place. The protonation heat was calculated by means of the acid ionization enthalpy of both glycolic acid (0.15 kcal mol^{-1})[8] and acetic acid (0.09 kcal mol^{-1}).[9] It was found to be lower than 0.7% of the measured heat, with no influence on the $\Delta H°$ values, and was thus neglected. Data for one series of the measurements: initial concentration of ligand (C_l) and initial pH (pH_l) in the cell, cumulative volume of titrant added (ΣV_T), pH in the cell (pH_f) and concentration of the species (C_{ML^+}, C_{L^-}, C_{HL}) after each addition of titrant, and cumulative heat corrected for the dilution (ΣQ_c) are given as an example in Table 1.

The molar enthalpy of association was determined from the heat (ΣQ_c) experimentally obtained and the complex species concentrations, the latter being obtained from the stability constants.[5] The calculation of $\Delta H°$ was carried out by two methods:[7,10] (a) the numerical method of minimization of the error square sum, and (b) the graphical

method derived from the equations of Leden and Fronaeus for the overall formation constants. The results agree. The entropy was obtained by means of: $\Delta S° = 10^3(\Delta H° - \Delta G°)/T$.

Results and Discussion

The molar thermodynamic quantities for the reactions of copper(II) with galacturonate and glucuronate are given in Table 2. For the sake of comparison, the values obtained for a series of monocarboxylic ligands[6,7] (under the same conditions of T and I) are also given.

The values in Table 2 for the uronate anions show that only the entropy factor is favorable for the association but not $\Delta H°$. The positive values of these parameters can be caused by two factors: (a) partial solvent destruction accompanying the charge association, and (b) the displacement of at least one water molecule by carboxylate from the metal hydration sphere.[11] Nevertheless, the crystal fields produced by oxygen coordinating ligands are quite similar to those of the water molecules.[11] As regards the entropy variation, the displacement of one water molecule is counterbalanced by the metal-ligand association. Consequently it seems that both $\Delta H°$ and $\Delta S°$ are mainly influenced by factor (a).

One of the following arrangements might take place as regards the metal-ion interaction: (a) monodentate behavior of the uronate ions, with carboxylate group as the only bonding site, the structure being proposed on the grounds of the formation constants values;[5] (b) bidentate behavior, with $-COO^-$ and $-OH$ on C-4 as bonding sites; (c) bidentate action as in (b), but with $-COO^-$ and the ethereal oxygen of the ring taking part in the binding; (d) a tridentate action, by means of $-COO^-$, $-OH$ on C-4 and the oxygen of the ring, the structure being suggested for the association of galacturonate with Ca(II) and Eu(III) ions.[2]

Considering the fact that the log K values for uronate ions are greater than those for acetate (in spite of the latter's greater basicity towards proton), assumption (a) appears to be questionable. For the sake of illustration the values of (log K)/pK_a are given for each ligand (Table 2). The (log K)/pK_a ratio allows a comparison, for each ligand, between the stability of its association with copper and with proton. If a ligand acts as a monodentate towards copper (*i.e.*, the bond only through carboxylate is formed), the other groups in the ligand molecule have the same solvent ordering ability both in the case of copper and of proton. If a ligand acts as a bidentate towards the metal, another hydrophilic group besides carboxylate is neutralized by the metal charges. Consequently, the solvent ordering ability of this group is different before and after the reaction. In this case its external contribution to $\Delta G°$ of association with copper differs from that with proton. In the same way, the ratio (log K)/pK_a should differ as compared with the former case. Therefore the value of this ratio should be determined by a mono- or bidentate behavior of the ligand towards copper (last column, Table 2). For acetate the value is 0.30, while the other ligands (for which a bidentate action was demonstrated) give values in the range 0.50—0.62. The values of (log K)/pK_a for uronate ions (0.57 and 0.50) tend to discard the hypothesis of a monodentate action of galacturonate and glucuronate towards copper.

As regards hypothesis (b), it must be considered that in uronic acids the respective positions of $-OH$ on C-4 and $-COO^-$ are the same as in 3-hydroxypropionic acid. The monodentate action of this

ligand towards Cu(II) and other bivalent cations, and the consequent non-participation of –OH in the β-position in the binding of metal were demonstrated.[12,13] Considering also that –OH group, if taking part in complex formation, leads to exothermic values of $\Delta H°$ (the values for glycolate, Table 2), the suggestion in (b) may be unlikely.

The structure in (d) does not seem very reliable, both for the preceding considerations on –OH in β-position and for the following reasons. In a tridentate structure there is a strong difference in stability between the galacturonate complex (more stable) and that of glucuronate. This might be due to the different positions, in the molecule of the two ligands, of the hydroxyl group on C-4, which is axial and equatorial, respectively.[5] On the contrary, similar values of log K, $\Delta H°$, and $\Delta S°$ (Table 2) lead to the conclusion that both uronate ligands have the same behavior. Moreover, in the case of galacturonate, it was found[2] that a structure with three bonding sites fits the cations of particular dimensions, as Eu(III) and Ca(II) (crystalline radii: 0.95 and 0.99 Å, respectively), while Cu(II) is markedly smaller (0.72 Å, Ref. 14).

The structure given in (c) seems to be probable, considering the fact that the respective positions of ethereal oxygen and carboxylate group are the same as in methoxy- and ethoxyacetate, and that the participation of ethereal oxygen in the chelation of Cu(II) was confirmed for these two ligands.[6,7] In this case the metal-ethereal oxygen bond appeared to be of electrostatic character, and limited to the outer sphere of the cation. Similar values of log K, $\Delta H°$, and $\Delta S°$ between the two uronic and the two alkoxyacetic ligands (in particular, the values for galacturonate are between those for the two alkoxyacetates), support the last hypothesis.

Taft's Plot for the Co-pyrolysis of 2-Chloroethyl Compound and Methanol on Activated Alumina

Kiyonori SHINODA
Toyama Technical College, Hongo, Toyama 930-11
(Received August 12, 1980)

Synopsis. For the co-pyrolysis of 2-chloroethyl compounds with methanol on activated alumina, the ρ^* value was +0.49, indicating a nucleophilic reaction mechanism.

For the pyrolysis of chloroethanes on activated alumina, ρ^* values were negative, indicating an electrophilic reaction mechanism.[1] On the other hand, positive ρ^* values were observed for the elimination of hydrogen chloride from chloroethanes with sodium hydroxide in ethanol, as well as in the co-pyrolysis with methanol on activated alumina.[1,2]

The effect of the molecular structure on the consumption rate of the substrate was studied by carrying out the co-pyrolysis of 2-chloroethyl compounds and methanol on activated alumina.

Results and Discussion

It has been reported that the co-pyrolysis of organic chlorides and methanol on activated alumina proceeded according to good first-order kinetics.[3] Even if two organic chlorides were competitively co-pyrolyzed with methanol on activated alumina, it seemed reasonable to assume that the consumption rates were first-order in each substrate.

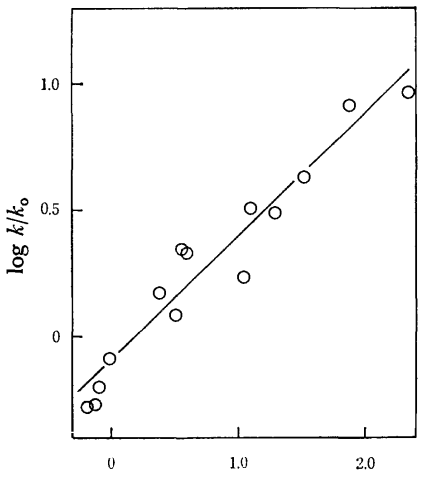

Fig. 1. Taft's plot for co-pyrolyses of 2-chloroethyl compounds and methanol on activated alumina at 250 °C.

In order to investigate the effect of the polar nature of the substituent upon the reactivity in the co-pyrolysis of organic chlorides with methanol on activated alumina, Taft's plot was applied to this heterogeneous catalysis:

$$\log k/k_0 = \rho^*\sigma^*, \quad (1)$$

where k/k_0 is the relative rate constant with respect to the standard reaction (1,1,2,2-tetrachloroethane in this case) and where σ^* represents the polar substituent parameter, which is a measure of the inductive effect.[4] A linear free-energy relationship was found to exist between the reactivity and Taft's σ^*, as is shown in Fig. 1. A value of ρ^* was calculated by the method of least squares to be +0.49.

Experimental

Materials. The 4-chlorobutyronitrile was prepared by the reaction of 1-bromo-3-chloropropane and potassium cyanide described in the literature.[5] The 1-chloro-3-methoxypropane was prepared from 1-bromo-3-chloropropane by modifying the method of Henne and Haeckl.[6] All of the other reagents used in this work were purchased from the Tokyo Kasei Kogyo Co. except for methanol and ethanol, which were obtained from Nakarai Chemicals. All the chemicals were used without further purification. The activated alumina used as catalyst (KHD-24) was supplied by the Sumitomo Chemical Co.: the particle diameter was in the range from 2 to 4 mm.

General Procedure for Co-pyrolysis. The flow-type reaction system of a previous work[7] was used. The organic chlorides were mixed with methanol in the volume ratio of 1.0 : 1.0 : 5.0. In all runs, two organic chlorides were competitively pyrolyzed at 250 °C to check the balance of such volatile products as propylene and to keep the effect of the time factor and the concentration of methanol constant.

Synthesis and Electrical Resistivity of TCNQ Radical Anion Salts with 4,5-Disubstituted *N,N*-Dimethyl-1,3-dithiolan-2-iminium Cations

Futoshi KATO and Toshio TANAKA*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received October 31, 1980)

Synopsis. The title salts with the formula $[S\text{-}CHR^1\text{-}CHR^2\text{-}S\text{-}C{=}\overset{+}{N}Me_2](TCNQ)_n^{\cdot}$ (R^1,R^2=Me, H; Et, H; Ph, H; Me, Me; and Me, Br; n=1 and 2) were prepared. Electrical resistivities, electronic spectra, and magnetic susceptibilities of these salts in the solid state are reported.

Recently, one of the authors reported the preparation of a series of 7,7,8,8-tetracyanoquinodimethane (TCNQ) radical anion salts with *N,N*-dialkyl-1,3-dithiolan-2-iminium cations, $[S(CH_2)_2SC{=}\overset{+}{N}R_2](TCNQ)_n^{\cdot}$ (R= Me, Et, *n*-Pr, *n*-Bu, *n*-C_6H_{13}, and *n*-C_8H_{17}; n=1 and 2, but not all combinations),[1,2] whose electrical resistivities increase with the bulkiness of substituents on the iminium nitrogen atom for each series of n=1 and 2, respectively.[2] The present work was undertaken to examine the effect of substituents on the dithiolane ring on the resistivity of $TCNQ^{\cdot}$ radical anion salts. This note reports the preparation and the electrical resistivities of some simple and complex salts of $TCNQ^{\cdot}$ radical anion with 4,5-disubstituted *N,N*-dimethyl-1,3-dithiolan-2-iminium cations, $[S\text{-}CHR^1\text{-}CHR^2\text{-}S\text{-}C{=}\overset{+}{N}Me_2](TCNQ)_n^{\cdot}$ (R^1,R^2=Me,H; Et,H; Ph,H; Me,Me; and Me,Br; n=1 and 2). Electronic spectra and magnetic susceptibilities of these salts are described in terms of the modes of stacking of TCNQ in the solid state. For the sake of abbreviation, the following numbers are used for compounds appeared in this note.

Compound	Number	R^1	R^2	X
	**1a**	Me	H	Br
	1b	Et	H	Br
	1c	Ph	H	Br
	1d	Me	Me	PF_6
	1e	Me	Br	Br

Compound	Number	R^1	R^2	*n*
	**2a**	Me	H	1
	2b	Et	H	1
	2c	Ph	H	1
	2d	Me	Me	1
	2e	Me	Br	1
	3a	Me	H	2
	3b	Et	H	2
	3c	Ph	H	2
	3d	Me	Me	2
	3e	Me	Br	2

Experimental

Materials. Compounds **1a**—**c** were prepared by the reactions of sodium dimethyldithiocarbamate, $Na(S_2CNMe_2)$, with 1,2-dibromopropane, 1,2-dibromobutane, and 1-phenyl-1,2-dibromoethane, respectively, in refluxing acetone by the procedure described elsewhere.[3] The reaction of $Na(S_2CNMe_2)$ with 2,3-dibromobutane in refluxing acetone yielded an oily product, which was dissolved in ethanol, followed by the addition of an equimolar ethanol solution of $NaPF_6$ to give white microcrystals of **1d**. Recrystallization was carried out from dichloromethane–petroleum ether (1 : 1). Compound **1e** was obtained according to the literature method.[4]

Preparation of Simple Salts ***2a—e.*** To a filtered solution of $Li^+TCNQ^{\cdot}$ (0.74 g, 3.5 mmol) in boiling ethanol (40 cm^3) was added a hot ethanol (20 cm^3) solution of **1a** (0.85 g, 3.5 mmol). The mixture was allowed to stand in a refrigerator overnight. The resulting precipitate was collected by filtration and recrystallized from ethanol to afford purple plates of **2a** in 85% yield. Similarly, purple needles or plates of **2b—e** were prepared in 60—80% yields by the equimolar reactions of $Li^+TCNQ^{\cdot}$ with **1b—e**, respectively, in ethanol.

Preparation of Complex Salts ***3a—e.*** To a hot acetonitrile (30 cm^3) solution of **2a** (0.52 g, 1.4 mmol) was added a solution of neutral TCNQ (0.29 g, 1.4 mmol) in boiling acetonitrile (30 cm^3). The mixture was allowed to stand in a refrigerator overnight, giving black microcrystals of **3a**, which was recrystallized from acetonitrile, 68% yield. Dark violet or black crystals of **3b—e** were obtained similarly in 45—76% yields by the reaction of neutral TCNQ with the appropriate simple salts in acetonitrile.

TABLE 1. MELTING POINT AND ANALYTICAL DATA OF THE $TCNQ^{\cdot}$ SALTS

Salt	Mp(dec) °C	%C Found (Calcd)	%H Found (Calcd)	%N Found (Calcd)
2a	174—177	59.06 (58.99)	4.20 (4.40)	19.36 (19.11)
2b	139—141	59.75 (59.98)	4.57 (4.77)	18.18 (18.41)
2c	166—168	64.51 (64.46)	4.13 (4.23)	16.45 (16.34)
2d	166—168	59.78 (59.98)	4.60 (4.77)	18.43 (18.41)

to air. Plots of log ρ (ρ: electrical resistivities as compacted sample) *vs.* the reciprocal temperature ($1/T$) for each salt show a good linear relation in the 20—90 °C range, indicating that all the salts are typical semiconductors in the temperature range measured. The ρ values of simple salts **2a**—**e** and complex salts **3a**—**e** at 25 °C (Table 2) are the same order of magnitude as or larger by one or two orders of magnitude than those of the iminium salts without substituents on the 1,3-dithiolane ring, $[\overline{S(CH_2)_2SC}{=}\overset{+}{N}Me_2](TCNQ)_n^{\cdot}$ (8.7×10^5 Ω cm for $n=1$ and 3.8 Ω cm for $n=2$),[1] respectively. In view of these results, there may be a trend that the introduction of substituents on the 1,3-dithilane ring results in occasional increases of the resistivity of the $TCNQ^{\cdot}$ radical anion salts depending on the nature of substituents, although no detail of the trend is evident in this study.

The electronic absorption spectra of simple salt **2a** and complex salt **3a** in the solid state (Fig. 1) resemble well those of the iminium salts without substituents on the 1,3-dithiolane ring, as one may expect. The spectral patterns similar to **2a** and **3a** were obtained for simple salts **2b**—**e** and complex salts **3b**—**e**, respectively, except that the lowest frequency bands of **2b** and **2c**, assignable to charge-transfer (CT) transitions between the $TCNQ^{\cdot}$ radical anions,[5] are shifted to higher frequencies than that of **2a** (Table 2). In addition, all the complex salts exhibited a broad absorption band in the 4000—2500 cm^{-1} range, which is due to the CT transition between the $TCNQ^{\cdot}$ radical anion and neutral TCNQ.[5] These results can be subjected to the same discussion as that given previously,[1] which leads us to the conclusion that simple salts **2a**—**e** involve the $(TCNQ)_2^{2-}$ dimer, whereas complex salts **3a**—**e** contain monomeric $TCNQ^{\cdot}$ radical anions in their columnar structure in the solid state. This is consistent with the facts that simple and complex salts show diamagnetic and paramagnetic properties, respectively, at room temperature (Table 2).

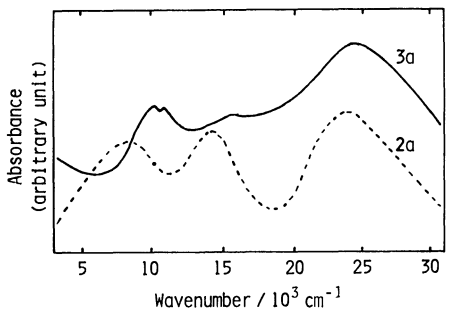

Fig. 1. Absorption spectra of **2a** and **3a** in Nujol mulls.

Adsorption of Pyranine onto Cationic Liposomal Membranes as Evidenced by Fluorescence Polarization†

Tadashi NOMURA, Hiroki KONDO, and Junzo SUNAMOTO*

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received October 21, 1980)

Synopsis. A trianionic fluorescent probe, pyranine, was found to bind to positively charged liposomes as evidenced by a linear increase in the fluorescence polarization with the liposome concentration. Addition of perchlorate ion reduced the polarization of fluorescence, suggesting that perchlorate and pyranine compete for the same binding site on the surface of cationic liposomal membranes.

A knowledge of properties of membrane surface is essential to understand various phenomena occurring on membranes, because in biological systems most of events begins with the adsorption of a substance onto and permeation into membranes.[1] The surface of liposomal membranes as well as natural biomembranes has been characterized by a variety of techniques such as NMR[2] or neutron diffraction.[3] A focus has been on the negatively charged membranes to which cations bind through electrostatic interaction with a different degree of specificity.[4-6] In this work we would like to describe the interaction of positively charged liposomes with an anionic fluorescent probe, pyranine (trisodium 8-hydroxy-1,3,6-pyrenetrisulfonate), by means of fluorescence polarization. An advantage of utilizing this particular probe lies in the fact that it emits strong fluorescence at 510 nm and that it can bind to a charged membrane surface through the electrostatic interaction.[7,8] When the probe adsorbs onto the membrane surface the molecular motion of the probe will be depressed, possibly giving rise to a significant increase in the polarization of fluorescence.

Experimental

Pyranine was obtained from Eastman Kodak Co. and its purity was assessed before use by TLC on silica gel in butanol–water (6 : 1 by volume). Its concentration was determined on the basis of molar extinction coefficient of 1.02×10^4 M^{-1} cm^{-1} (1 M = 1 mol dm^{-3}) at 405 nm. Single-compartment liposomes of egg lecithin were prepared as described previously.[9,10] In the preparation of positively charged liposomes, hexadecylamine (20 mol% to lecithin) was added.[9] The pH of the liposome suspension was adjusted to 5 with either 0.6 mM CH_3CO_2H–1.4 mM CH_3CO_2Na or 5.4 mM $HClO_4$–9.6 mM $NaClO_4$. Fluorescence spectra were taken on a Hitachi 650-10 spectrofluorometer with 1 nm bandpaths for both excitation and emission sides. Fluorescence polarization was determined on a Union FS-501 fluorescence depolarization instrument which was connected to a Sord Microcomputer M 200 Mark II. Pyranine was excited at 405 nm and its fluorescence polarization was determined at 510 nm[11] The vertical and horizontal components of the emission were funneled through a Y-46 cut-off filter (50% transmittance at 460 nm). Fluorescence polarization is defined by Eq. 1:[9]

$$p = \frac{I_{VV} - C_f \cdot I_{VH}}{I_{VV} + C_f \cdot I_{VH}} \quad (1) \qquad C_f = I_{HV}/I_{HH},$$

where C_f is the grating correction factor[11] and I stands for the collected intensity of fluorescence at parallel and perpendicular positions of the polarizer. Subscripts V and cH refer to vertical and horizontal beams, respectively. For example, I_{VH} means the intensity of horizontal component of fluorescence when excited by the vertically polarized beam. All measurements were made at 25.0 °C under aerobic conditions.

Results and Discussion

The polarization of pyranine fluorescence was determined in the presence of neutral or positively charged liposomes in an aqueous buffered solution (pH 5) containing acetate or perchlorate ions (Fig. 1).

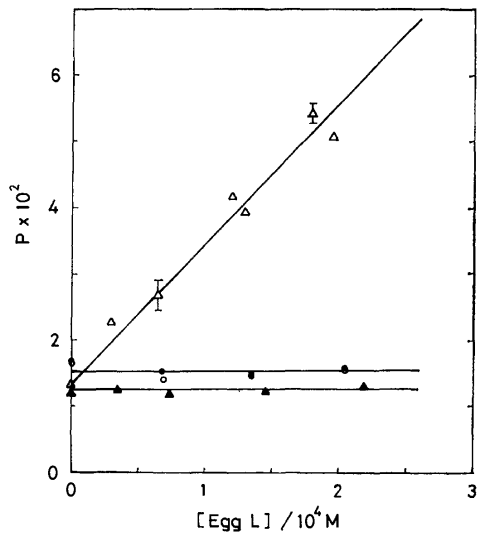

Fig. 1. Fluorescence polarization of pyranine as a function of egg lecithin concentration at pH 5 and 25.0 °C. Experiments were carried out using neutral liposomes in an aqueous acetate (▲) or perchlorate (●) solution and positively charged liposomes in an aqueous acetate (△) or perchlorate (○) solution. The concentration of pyranine was 2×10^{-6} M in all the runs.

For neutral liposomes the polarization did not vary over the liposome concentration range studied. This trend was common to the two salts adopted. These results indicate that no significant interaction takes place between pyranine and neutral liposomes. In the case of cationic liposomes in an acetate buffer, on the other hand, the polarization of pyranine fluorescence increased linearly with increasing liposome concentration. However, this was not the case for the perchlorate solution, suggesting that perchlorate ion interferes with the adsorption of pyranine onto the liposome surface. This was confirmed by the following experiment. When sodium perchlorate was further added to a cationic liposome suspension containing pyranine and acetate ion, the polarization decreased with an increase in the

† Liposomal Membranes, Part X from this laboratory.

Table 1. Effect of perchlorate anion on the fluorescence polarization of pyranine in the egg lecithin single-walled and positively charged liposome suspension at 25.0 °C and pH 5[a)]

$[NaClO_4]$/M	$p \times 10^2$
0	5.0(1.1)[b)]
2.0×10^{-3}	2.9
6.1×10^{-3}	1.9(1.2)

a) A liposome suspension contains 0.10 M NaCl, 1.4 mM CH_3CO_2Na, and 0.6 mM CH_3CO_2H. [Pyranine] $=2.0 \times 10^{-6}$ M; [Egg L] $=2.4 \times 10^{-4}$ M. b) Numbers in parentheses are p-values of pyranine in the absence of liposomes.

perchlorate concentration (Table 1).

From the result that the polarization of pyranine increases in the presence of cationic liposome, it is now evident that pyranine binds to the surface of positively charged liposomes through the electrostatic interaction and consequently the molecular motion of the probe is considerably hindered. It is of special interest that perchlorate ion competes for the same binding site whereas acetate ion does not. This difference seems to arise from the difference in the mode of hydration to these anions. It is presumed that the hydration to perchlorate is weaker than that to acetate, because the charge delocalization is more extensive for the former.[12)] This means that the weakly hydrated perchlorate ion may more easily form an ion pair with (more strongly binds to) the positive site of liposomal membranes. Certainly, the binding of these anions to positively charged liposomes follows a closely similar order to that for their interaction with anion exchange resins[13)] or acetyltetraglycine ethyl ester;[14)] perchlorate> sulfonate>acetate. The high lyophilicity as well as trianionic character of pyranine may make the probe to show the affinity for the cationic membrane surface.

It should be mentioned that the emission maxima and intensity of fluorescence from pyranine were not much affected upon the binding to liposomes. Thus the relative ratio of fluorescence intensity in the presence and absence of liposomes, I/I_0, changed by less than 10% over the egg lecithin concentration range $\approx$400 μM. The relative intensity was also independent of the probe concentration at least in a range of 1—5 μM. These results imply that quenching of pyranine fluorescence upon the binding to liposomes is negligible under the present experimental conditions. This is in contrast to the previous findings in which the concentration quenching of fluorescence was observed through the ionic probe aggregation on the surface of charged membranes.[15,16)] This also supports the contention that hexadecylamine molecules are dispersed evenly in the phospholipid bilayers and that no significant phase separation occurs even by the adsorption of the polyanionic probe.

We are grateful to Dr. Kaoru Tsujii, Tochigi Research Laboratories, Kao Soap Co. Ltd., for his helpful comments. This work was supported by a Grant-in-Aid for Scientific Research No. 447068, from the Ministry of Education Science and Culture.

The Effect of Polar Solvent on the $^1J_{CH}$ Spin-Spin Coupling Constants in Halomethanes and Haloethylenes

Shosuke WATANABE*,† and Isao ANDO

Department of Polymer Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 31, 1980)

Synopsis. The solvent effect on the ^{13}C–^1H nuclear spin-spin coupling constants ($^1J_{CH}$) of halomethanes and haloethylenes is calculated by means of the finite perturbation theory based on the CNDO/2 approximations incorporating the 'solvaton' theory. The results of the calculation explained the tendency of the observed solvent effect data in the literature.

Nuclear spin-spin coupling constants are known to be solvent-dependent,[1] and Johnston and Barfield[2–4] have handled the observed solvent effect on spin-spin coupling constants by means of the so-called reaction field model,[2] the cluster model[3] and the rotating-point dipole model.[4] So far as $^1J_{CH}$ is concerned, that is, they have numerically estimated the solvent effect on the $^1J_{CH}$ values of fluoromethanes only.

Most recently,[5,6] we have quantitatively calculated the solvent effect of the one-bond ^{13}C–^1H coupling constant($^1J_{CH}$) by applying the finite perturbation theory (FPT)[7] with the INDO and CNDO/2 MO methods incorporating Klopman's solvaton theory.[8] This approach successfully offers a quantitative description of the solvent effects on the $^1J_{CH}$ values of some small organic compounds (*e.g.*, methane derivatives,[5] acrylonitrile,[5] $CHCl_2CHCl_2$,[6] and $CHCl_2CH_2Cl$[6]).

In the present work we applied the FPT method which we have developed ourselves[5,6] to estimate the substitution effects on the solvent effect of $^1J_{CH}$ coupling constants in such rigid molecules as halomethanes (fluoro- and chloro-) and haloethylenes (fluoro- and chloro-). The results of the calculation are compared with the tendency of the observed solvent effects in the literature.

Results and Discussion

In all the calculations of this work, $S_C^2(0)S_H^2(0) = 2.2240$ a.u. was used as the value of the integral product.

Table 1 shows the results of the calculation of fluoromethanes using the experimental values reported by Cox and Smith[9] and of that on chloromethanes using the experimental values obtained by Watts and Goldstein.[10]

It is evident from the results in Table 1 that the calculated results agree qualitatively well with such observed results as that the solvent-induced change in the $^1J_{CH}$ value increases as the number of substituted fluorine or chlorine atoms increases, or that the $^1J_{CH}$ value increases as the dielectric constant (ε) of the solvent increases.

It is also evident from Table 1 that the respective $^1J_{CH}$ values increase in the order of mono-, di- and trihalogen-substituted compounds, and also that, when the number of substituting halogen atoms is equal in the molecules under consideration, the fluorine deriva-

tives exhibit a larger $^1J_{CH}$ value than the chlorine derivatives. This may be due to the greater electronegativity of the fluorine atom. This tendency agrees with the observed result.

The calculated results of the solvent effect on the $^1J_{CH}$ calculation of dichloroethylenes and trichloroethylene are tabulated in Table 2 in comparison with the corresponding experimental values reported by Watts *et al.*[11] It is now clear that the $^1J_{CH}$ value of 1,1-dichloroethylene is smaller than those of the 1,2-dichloroethylenes and that those of its *trans*- and *cis*-forms are nearly equal to each other. It is found that the trisubstituted ethylene has a larger $^1J_{CH}$ value than the disubstituted one and that, in both cases, its values depend highly on ε.

Table 3 shows the calculated results of the solvent effect on the $^1J_{CH}$ for 1,2-dichlorofluoroethylenes, together with the corresponding experimental data reported by Bell and Danyluk.[12] The (*E*) form exhibits a larger $^1J_{CH}$ value than the (*Z*) form, and both values depend on ε. The calculated results agree well with the experimental findings.

The authors wish to thank Professor Riichirô Chûjô of our department for his helpful suggestions and discussions.

^{1}H NMR Study of Dissociation and Re-association of Apoferritin and Ferritin

Noboru IMAI,* Yoji ARATA, and Shizuo FUJIWARA
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received November 4, 1980)

Synopsis. The processes of dissociation and re-association of apoferritin and the protein part of ferritin were investigated by ^{1}H NMR. It was suggested that the re-association of ferritin occurs more easily than that of apoferritin.

Ferritin is an iron storage protein consisting of 24 subunits around the iron core which is the polymerized iron (the composition is $(FeOOH)_8(FeOOPO_3H_2)$) and contains 0—4000 iron atoms.[1] Apoferritin, the protein part of ferritin (M.W. 445000), can be dissociated to subunits by sodium dodecyl sulfate,[2] 7 M (1 M=1 mol dm^{-3}) guanidinium chloride[3] and 67% (v/v) acetic acid.[4] It has been shown that the dissociation of apoferritin is reversible; However a significant degree of hysteresis is known to exist in the re-association process.[5] In a previous paper,[6] we have applied the technique of nuclear magnetic resonance (NMR) to the study of ferritin to discuss the state and role of the phosphate group on the surface of the iron core. In the present experiment, it will be shown that the processes of dissociation and re-association of the protein assembly in ferritin and apoferritin can be followed by ^{1}H NMR. The NMR signal from the protein part can be observed only after the protein part dissociates into subunits (M.W. 18500). Of special advantage of NMR over other methods is the fact that, in the case of ferritin, the iron core influences only little the NMR signal of the protein. The process of dissolution of the iron core to iron(III) ion will also be discussed using the linewidth of the peak of solvent water. On the basis of these results, we will discuss a possible role of the iron core in the processes of dissociation and re-association of ferritin.

Horse spleen ferritin (Nutritional Biochemicals Corporation, twice recrystallized, Cd free) was dialyzed against dilute EDTA solution. All reagents used are of reagent grade. The concentration of iron was determined by using atomic absorption[6] and that of protein by Lowry method.[7] ^{1}H NMR spectra were recorded using a JEOL PS-100 spectrometer operating at 100 MHz.

The pH of sample solution was changed in either of the following two ways: For the study of dissolution of the iron core to iron(III) ion, a small amount of ferritin solution (0.35 M, as iron) was added to a glycine–HCl buffer solution with pH pre-adjusted, and the linewidth of the NMR signal of water in the solution was measured. Before and after the above treatment, no precipitation occurred and very little change in pH was observed. 2) For the study of the dissociation of protein part for apoferritin and ferritin, the pH of sample solutions was changed by dialyzing for 24 h against a 10 mM glycine–HCl buffer. In the experiment of re-association, the solution, which had been dialyzed for 24 h against a 10 mM glycine–HCl buffer at pH 1.8, was further dialyzed for 24 h against the same buffer at higher pH.

Dissociation of the Protein Assembly in Ferritin and Apoferritin. The NMR signal of the protein part becomes observable when the pH of solutions of ferritin or apoferritin decreases below 3.5, suggesting that the protein part dissociates into subunits. The aliphatic region of the NMR spectrum of the protein part is shown in Fig. 1A. The signal indicated by an arrow is presumably due to the methyl groups of leucine, isoleucine, and valine. The height of the peak reaches maximum below pH 1.8; the extent of dissociation of the protein part was determined by measuring the height of these peaks. The dissociation curves for apoferritin and ferritin thus obtained are shown in Fig. 1B and Fig. 2, respectively; no significant difference was observed between ferritin and apoferritin.

The Process of Dissolution of the Iron Core to Iron(III) Ion. The red color of the ferritin solution fades when the pH decreases below 2.0, where the linewidth of H_2O signal greatly increases. This is most likely because the iron core dissolves and the amount of aqueous iron(III) ion increases at low pH, resulting in a large increase in the interaction of water molecule with the paramagnetic iron(III) ion. This suggests that the process of the dissolution of the iron core to iron(III) ion may

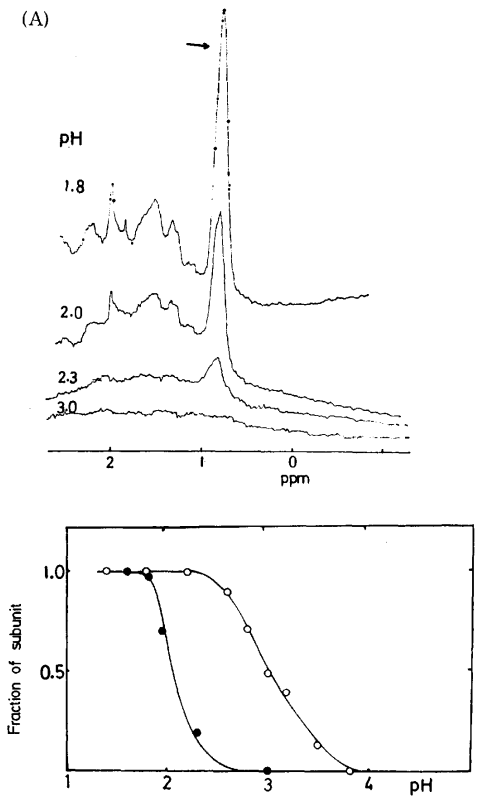

Fig. 1. (A) The aliphatic region of 100 MHz NMR spectra of apoferritin at low pH. The protein concentration was 12 mg/ml. (B) Dissociation and re-association of apoferritin at low pH.
●: Dissociation, ○: re-association.

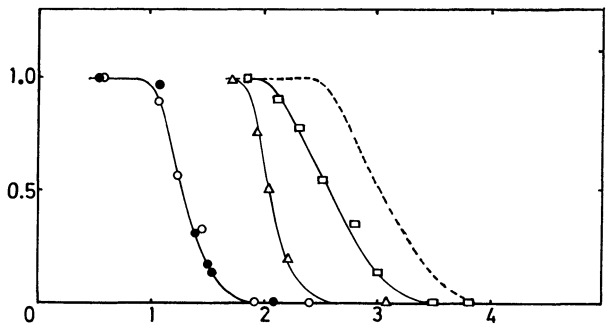

Fig. 2. Dissociation and re-association of ferritin at low pH.
○: Dissolution of iron core (NMR), ●: ($OD_{410\ nm}$), △: dissociation, □: re-association.

be followed quantitatively by observing the linewidth of the water signal. In the present experiment, the concentration of the ferritin solutions was 5 mM (as iron); at this concentration the solution is clear and there is no precipitation nor aggregation observed with the dissolution of the iron core. The results shown in Fig. 2 indicate that the iron core begins to dissolve at pH 1.8 and dissolves completely at pH 1.0. This process was also followed by the measurement of $OD_{410\ nm}$ and the result is in good agreement with that obtained by the NMR measurement. See Fig. 2. The results in Fig. 2 suggest that the protein part of ferritin begins to dissociate at pH 3.5 and dissociates completely at pH 1.8, but the iron core itself remains intact above pH 1.8. It is of interest that in a narrow range around pH 1.8 the protein part dissociates completely with the intact iron core.

Re-association of Subunits of Ferritin and Apoferritin. With an increase in pH of the solutions of ferritin or apoferritin where the protein part has been dissociated at low pH, the NMR signals of the protein part becomes undetectable, suggesting that the subunits re-associate. The fraction of re-association was determined from the peak height as in the case of dissociation. The re-association curve of apoferritin is shown in Fig. 1B. In this experiment, 0.01 M glycine–HCl buffer was used in dialysis at pH 1.8 to dissociate and at higher pH to re-associate the protein part. A similar experiment was carried out using ferritin. The re-association curve for ferritin is also included in Fig. 2. The broken line is the re-association curve of apoferritin. The curve of re-association for ferritin, which has already been dissociated at pH 1.8, deviates greatly from that for apoferritin. This suggests that re-association of the protein part occurs more easily in the case of ferritin than in the case of apoferritin.

Generalized Graph-theoretical Formula for London Diamagnetism

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 4, 1980)

Synopsis. The previous graph-theoretical formula for London diamagnetism was improved so as to include all kinds of cyclic conjugated systems. Bicyclo[6.2.0]decapentaene was then found to be diatropic but antiaromatic even though the central π bond was elongated.

Diamagnetic susceptibility due to ring currents is one of the key quantities in aromatic chemistry.[1] In 1937 London formulated it in quantum-mechanical terms,[2,3] so it has been called the London diamagnetism.[1] Recently I reformulated it[4,5] by means of Sachs' graph-theoretical theorem.[6] The obtained formula enabled us to estimate susceptibility contributions from individual π-electron rings in a conjugated system.[5] However, I later found that this formula was applicable only to conjugated hydrocarbons with no bond alternation. In this note, I would like to generalize the graph-theoretical formula for London diamagnetism so as to include not only conjugated hydrocarbons with appreciable bond alternation but also heterocycles.

Let us consider the conjugated system G placed perpendicularly in the external magnetic field H. The ith π-electron ring in G is denoted by r_i, which is identical with the ith ring component in Sachs' theorem.[6,7] The area of r_i is denoted by S_{r_i}. For simplicity, we define

$$\Theta_{r_i} = \frac{eS_{r_i}}{\hbar c}, \tag{1}$$

where e, $\hbar$, and c are the standard constants with these symbols. A characteristic polynomial for G is a function of H, so it is denoted by $P_G(X,H)$.[6,7] When there is no external field, the contribution of r_i to the coefficients of the characteristic polynomial is given by[7]

$$C(r_i, 0) = 2\prod_s^{r_i} k_s. \tag{2}$$

Here, k_s is a Hückel bond parameter for the sth π bond in G, and s runs over all π bonds in r_i. If the field H is applied to G, it should become[4,5]

$$C(r_i, H) = 2\cos(\Theta_{r_i}H)\prod_s^{r_i} k_s. \tag{3}$$

With this expression in mind and by analogy with Hosoya's way of expanding Hückel secular determinants,[8] $P_G(X,H)$ can be expanded as

$$P_G(X,H) = R_G(X) - 2\sum_i^G R_{G-r_i}(X)\cos(\Theta_{r_i}H)\prod_s^{r_i} k_s + 2^2\sum_{i<j}^G R_{G-r_i-r_j}(X)\cos(\Theta_{r_i}H)\cos(\Theta_{r_j}H)\prod_s^{r_i} k_s\prod_s^{r_j} k_s - \cdots. \tag{4}$$

Here, $R_G(X)$ is a reference polynomial defined for G, *i.e.*, a characteristic polynomial for the olefinic reference structure of G;[5,6,9] G-r_i is a subgraph of G, obtained by deleting r_i and all π bonds adjacent to it; G-r_i-r_j is a subgraph of G, obtained by deleting a pair of disjoint π-electron rings r_i and r_j and all π bonds adjacent to r_i and/or r_j; the first summation is practiced over all π-electron rings, and the second one over all possible pairs of disjoint π-electron rings.

Since the applied field H can be treated as a small perturbation,

$$\cos(\Theta_{r_i}H) \approx 1 - \frac{1}{2}\Theta_{r_i}^2H^2. \tag{5}$$

By applying this approximation to Eq. 4, the following expression can be derived:

$$\begin{aligned} P_G(X,H) &= R_G(X) - 2\sum_i^G R_{G-r_i}(X)\left(1-\frac{1}{2}\Theta_{r_i}^2H^2\right)\prod_s^{r_i} k_s \\ &\quad + 2^2\sum_{i<j}^G R_{G-r_i-r_j}(X)\left(1-\frac{1}{2}\Theta_{r_i}^2H^2\right)\left(1-\frac{1}{2}\Theta_{r_j}^2H^2\right) \\ &\quad \times \prod_s^{r_i} k_s\prod_s^{r_j} k_s - \cdots \\ &= P_G(X,0) + H^2\sum_i^G P_{G-r_i}(X,0)\Theta_{r_i}^2\prod_s^{r_i} k_s. \end{aligned} \tag{6}$$

In deriving the last expression, we used the relationship in this form:

$$P_G(X,0) = R_G(X) - 2\sum_i^G R_{G-r_i}(X)\prod_s^{r_i} k_s + 2^2\sum_{i<j}^G R_{G-r_i-r_j}(X)\prod_s^{r_i} k_s\prod_s^{r_j} k_s - \cdots. \tag{7}$$

This is nothing other than a generalized form of Hosoya's formula for obtaining $P_G(X,0)$.[8]

After a simple treatment of Eq. 6, analogous to that presented in Ref. 5, the diamagnetic susceptibility attributable to the mth orbital is given by

$$\chi_m = -2\beta\sum_i^G \frac{P_{G-r_i}(X_m^\circ, 0)}{P_G'(X_m^\circ, 0)}\Theta_{r_i}^2\prod_s^{r_i} k_s, \tag{8}$$

where X_m° is the mth largest root of the equation $P_G(X,0)=0$. Then, the overall susceptibility due to ring currents is

$$\chi = 2\sum_{m=1}^{m_0}\chi_m. \tag{9}$$

Here, m_0 indicates the highest occupied orbital. Unfortunately, Eq. 8 does not hold for degenerate orbitals. In this case, $P_G(X,0)$ is rewritten as

$$P_G(X,0) = U_G(X)(X-X_{m^*}^\circ)^2, \tag{10}$$

where m* indicates the degenerate orbitals. According to the mathematical treatment similar to that of Pullman and Pullman,[3] the diamagnetic susceptibility attributable to each of these orbitals becomes

$$\chi_{m^*} = \frac{U_G'(X_{m^*}^\circ)V_G(X_{m^*}^\circ) - U_G(X_{m^*}^\circ)V_G'(X_{m^*}^\circ)}{U_G(X_{m^*}^\circ)^2}, \tag{11}$$

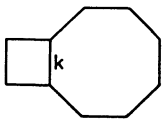
where

$$V_G(X) = \sum_i^G P_{G-r_i}(X,0)\Theta_{r_i}^2\prod_s^{r_i} k_s. \tag{12}$$

Now the graph-theoretical formulation of London diamagnetism has been completed. We can easily evaluate the susceptibility of any cyclic conjugated

system by means of these expressions, but without any knowledge of graph theory. They are really applicable to any kind of conjugated systems, including heterocycles.

As an example, it is instructive to calculate the susceptibility of the bicyclo[6.2.0]decapentaene conjugated system (I). Oda *et al.* showed that this compound



I

has relatively small alternation of the peripheral π bonds and a rather elongated central π bond.[10] Therefore, the susceptibility was calculated as a function of the bond parameter of the central π bond (k). The susceptibilities obtained according to Eq. 8 are 0.352 for $k=1.00$, 0.422 for $k=0.90$, 0.478 for $k=0.80$, 0.523 for $k=0.70$, 0.559 for $k=0.60$, and 0.587 for $k=0.50$, all in units of $\Theta_0^2\beta$. Here, Θ_0 is $e/\hbar c$, multiplied by the area of the benzene ring, and $\beta=|\beta|$. In this connection, the resonance energies due to aromatic stabilization[9] are -0.642 for $k=1.00$, -0.509 for $k=0.90$, -0.396 for $k=0.80$, -0.298 for $k=0.70$, -0.212 for $k=0.60$, and -0.137 for $k=0.50$, all in units of β. These results clearly indicate that the bicyclo[6.2.0]decapentaene conjugated system is diamagnetic but antiaromatic in nature. This conclusion is independent of the magnitude of the k value. Therefore, we might say that this compound is a diatropic antiaromatic compound. Diatropicity has been supported by experiment.[10] It is noteworthy that diatropicity and antiaromaticity coexist in such a bicyclic conjugated system.

The use of the facilities of the Hokkaido University Computing Center is gratefully acknowledged.

(Received June 5, 1980)

Synopsis. The crystal structure of the $Cu_2Br_2(PPh_3)_3 \cdot 1.5C_6H_6$ complex has been determined by three dimensional X-ray analysis. The crystals are monoclinic, and the space group is $P2_1/c$, with unit-cell parameters of $a=14.122$ (3), $b=19.573$ (4), $c=25.985$ (7) Å, $\beta=128.99$ (1)°, and $Z=4$. In the $Cu_2Br_2(PPh_3)_3$ molecule, one copper atom is three-coordinate, and the other, four-coordinate.

It has been known that copper(I) halides form a number of complexes with tertiary phosphine. A particularly interesting series is the 2 : 3 complexes, $Cu_2X_2(PPh_3)_3$, in which three- and four-coordinated copper atoms are both present and in which the stabilities of the two atoms are similar.[1-3] In this work, the bromide complex is investigated by means of the X-ray crystal analysis and the structure and bonding are discussed in connection with the NQR study.[4]

Experimental

Preparation. $Cu_2Br_2(PPh_3)_3 \cdot 1.5C_6H_6$, prepared as has been described in the literature,[5] was recrystallized from a mixed solvent of benzene and heptane (benzene : heptane = 3 : 1). Found: C, 62.94; H, 4.55%. Calcd for $C_{63}H_{54}Cu_2Br_2P_3$: C, 63.54; H, 4.57%.

X-Ray Data Collection. All the cell constants were determined by a least-squares treatment of the setting of 24 reflections measured on a Rigaku four-circle diffractometer, AFC-5, with Mo $K\alpha_1$ radiation ($\lambda_1=0.70926$ Å); $a=14.122$ (3), $b=19.573$ (3), $c=25.985$ (7) Å, $\beta=128.99$ (1)°. $Z=4$, and calculated density $\rho(\text{calcd})=1.42$ g cm^{-3}. The intensity data were collected by the ω-2θ scan technique to a maximum 2θ value of 42° at a scan rate of 16°/min (50 KV, 170 mA). The intensities of 4890 independent reflections were collected. Reflections for which the intensities were less than three times their standard deviations were regarded as "unobserved" and were not included in subsequent calculations. Thus, 4538 independent reflections were used for the structure determination. Their intensities were corrected for Lorentz and polarization factors, but no absorption corrections were made since the μ-values were low ($\mu=25.9$ cm^{-1}).

Structure Determination. The crystal structure was (solved by the heavy-atom technique, and the refinement was performed by a block-diagonal least-squares calculation. The quantity minimized was $w(|F_o|-k|F_c|)^2$. Cruickshank's weighting scheme was used, where $w=1/(a+|F_o|+b|F_o|^2)$, with $a=6.5$ and $b=0.019$. The atomic scattering factors from the International Tables for X-Ray Crystallography[6] were used. The effects of the anomalous dispersion of the P, Cu, and Br atoms for Mo $K\alpha$ radiation were included in the calculation. The final R value was 0.070. A list of observed and calculated structure factors is preserved by the Chemical Society of Japan (Document No. 8114). The final atomic coordinates are summarized in Table 1.

Results and Discussion

Crystals of $Cu_2Br_2(PPh_3)_3 \cdot 1.5C_6H_6$ are composed of discrete molecular units of $Cu_2Br_2(PPh_3)_3$ and benzene. The interatomic distances and bond angles, along with their estimated standard deviations, are listed in Table 2. The molecular structure obtained and the labelling of atoms are illustrated in Fig. 1. Two kinds of benzene molecules are present in this crystal. One benzene occupies interstitial sites in the structure centered at 1/2, 1/2, 0. In the other benzene, some degree of disorder is suggested by the large thermal parameters.

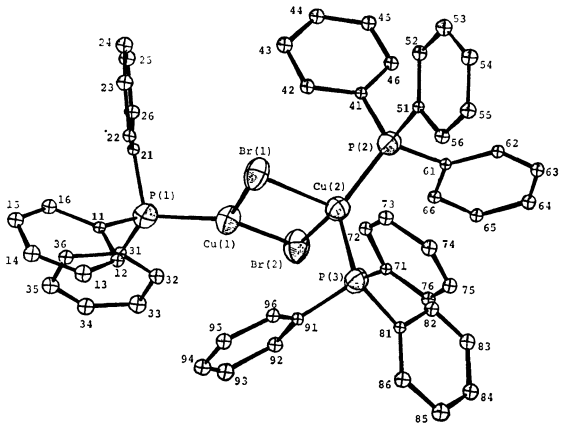

Fig. 1. View of the molecule $Cu_2Br_2(PPh_3)_3$ (drawn by use of ORTEP). The symbol, C, for each carbon atom has been omitted for clarity.

The structure of $Cu_2Br_2(PPh_3)_3$ consists of both three- and four-coordinated copper atoms. The geometry about Cu(I) is approximately trigonal planar, and the copper atom lies 0.183 Å above the plane including P(1), Br(1), and Br(2). The Cu(1)–P(1) distance, 2.190 Å, is nearly equal to the values observed cases where only one phosphine ligand is linked to the copper atom.[7,8] The environment of Cu(2) is distorted in a tetrahedral direction, and a marked departure from an idealized tetrahedral geometry is seen in the P(2)–Cu(2)–P(3) angle, which is 130.66°. The Cu(2)–P distances, 2.252 and 2.260 Å, are longer than the Cu(1)–P(1) distance in the three-coordinated copper atom.

The Cu–P distances involving the same kind of phosphines are dramatically influenced by the number of phosphine ligands bonded to the copper atom, whereas they are only slightly influenced by the coordination number of the copper atom.[7,8] In the ^{63}Cu NQR studies of $Cu_2X_2(PPh_3)_3$ (X=Cl, Br, and I),[4] the observed quadrupole coupling constant (e^2Qq/h) and the orientations of the efg principal axes of the three-coordinated copper atoms are mainly interpreted in terms of an sp^2-hybridization scheme. However, the observed frequencies are slightly higher than the maximum value expected for the sp^2 bonding. This discrepancy can be explained in terms of a bonding scheme involving 3d orbital mixing. This bonding scheme is applicable to the present compound, because the bromide complex is similar to the chloride and iodide complexes in the molecular structure as well as in ^{63}Cu NQR frequencies. In the case of the four-coordinated copper atom, the observed low frequency can be explained by sp^3 mixing only. However, from the distorted tetrahedral structure obtained in this compound, it seems likely that the Cu→P back-bonding exists and that it contributes to the Cu–P distance to some extent.

The Cu–Br distances in the four-coordinated copper atom are 0.203 Å (on the average) longer than those in the three-coordinated copper atom. In comparison with the case of the Cu–P distances, the copper-halogen distances increase with the copper coordination number. In the NQR studies of the $Cu_2X_2(PPh_3)_3$ series, it is observed that the e^2Qq/h values of the three-coordinated copper atoms decrease from X=Cl to I. This order is the reverse of the expectation for the sp^2 mixing scheme. This conflict can be explained by the existence of copper p_π-halogen p_π bonding; this π-bonding will reduce the e^2Qq/h value in this order; I>Br>Cl.[4] Therefore, the shortening of the copper-halogen distances in the three-coordinate copper atom is considered to be caused by the mixture of π-bonding.

The Correlation between the Relative Retention Behavior and the Number of Chlorine Substituents in the Phenol Ring

Sukeo ONODERA

Faculty of Pharmaceutical Sciences, Tokyo University of Science, 12 Ichigaya-funagawara, Shinjuku-ku, Tokyo 162

(Received July 11, 1980)

Synopsis. The gas-chromatographic behavior of chlorinated phenols, *m*-cresols, and 3,5-xylenols on polar and nonpolar columns connected to either FID or ECD has been studied. The relative retention times (t_R) for individual homologous series were determined as a function of the number of chlorine substituents in the molecule. It was found, for the homologous series of these chlorinated compounds, that a relationship between log t_R and the number of chlorine substituents is of only limited use in the identification of individual chlorinated phenols.

Gas-liquid chromatography (GLC) is a rapid, specific, and sensitive method for the separation and determination of a variety of such volatile compounds as organic contaminants in the environment. The identification of the chromatographic separated components is, though, a complex problem, one which requires the use of many standards or a combination of gas chromatography and mass spectrometry (GC–MS). Some attempts to identify the compounds being chromatographed on the basis of their relative retention times (t_R) have been made, and it has been found that the plots of log t_R for many substituted phenols,[1] paraffins,[2] and organometalic compounds[3] against the number of carbon atoms in the molecule give straight lines. The corresponding relationships for organochlorine compounds have not yet been established, however.

Chlorination is extensively practiced in waste-water treatment in order to disinfect the effluent prior to discharge, particularly where the water may subsequently be used for recreational purposes or as a source of potable water. One class of compounds recognized as a major source of pollutants in the environment is the phenols. Phenols are introduced into the environment in several ways; directly as industrial effluents and indirectly as transformation products from natural and synthetic chemicals. It has now became evident that the treatment with chlorine of water which has been polluted with phenols leads to the formation of a variety of chlorinated phenols and quinones.[4] The aim of the present work is to reveal the relationships between the relative retention behavior of chlorinated phenols, *m*-cresols, and 3,5-xylenols and the number of chlorine substituents in the phenol ring, using both polar and nonpolar stationary phases. We then intend to use this relationship to identify the unknown samples in the environment.

Experimental

The chlorinated derivatives of phenol, *m*-cresol, and 3,5-xylenol used for the present work were obtained from various commercial sources; they are summarized in Table 1. These compounds were checked by GLC and mass spectrometry and were then used without further purification .

A Model 20-KE gas chromatograph (Japan Electron Optic Laboratory) equipped with an electron-capture detector (ECD, ^{63}Ni 10 mCi) and a Shimadzu GC-6A gas chromatograph equipped with a flame ionization detector (FID) were used with nitrogen as the carrier gas. Two coiled glass tubes (2 m × 3 mm I. D), one packed with 10% Apiezon L/Chromosorb-W (AW-DMCS, 60—80 mesh) as the nonpolar stationary phase and the other packed with 5% DEGS + 1% H_3PO_4/Chromosorb-W (AW-DMCS, 60—80 mesh) as the polar one, were used for the present work.

TABLE 1. CHLORINATED PHENOLS, *m*-CRESOLS, AND 3,5-XYLENOLS EXAMINED IN THIS INVESTIGATION

Index number	Compound	Index number	Compound
1	Phenol	14	*m*-Cresol
2	2-Chlorophenol	15	4-Chloro-m-cresol
3	3-Chlorophenol	16	6-Chloro-m-cresol

7	2,5-Dichlorophenol	19	3,5-Xylenol
8	2,6-Dichlorophenol	20	2-Chloro-3,5-xylenol
9	3,4-Dichlorophenol	21	4-Chloro-3,5-xylenol
10	2,4,5-Trichlorophenol	22	2,4-Dichloro-3,5-xylenol
11	2,4,6-Trichlorophenol		
12	2,3,4,6-Tetrachlorophenol	23	2,4,6-Trichloro-3,5-xylenol
13	2,3,4,5,6-Pentachlorophenol		

Results and Discussion

In the present work, both polar and nonpolar stationary phases, connected to either FID and ECD, were tested for the direct chromatography of chlorinated derivatives of phenol, *m*-cresol, and 3,5-xylenol. The t_R values for these compounds are presented graphically in Figs. 1 and 2 as a plot of log t_R against the number of chlorine substituents in the molecule. Although GLC's of several chlorinated phenols have been reported by earlier workers,[5] the present results appear to be the first detailed GLC data for these compounds.

Since it is known that plots of log t_R for many organic compounds against their boiling points give approximately straight lines,[6] the t_R values of compounds with lower numbers of chlorine substituents and with low boiling points may be expected to be smaller that those of compounds with higher numbers and high boiling points when the compounds are chromatographed on a nonpolar column. Figures 1 and 2 show that plots of log t_R against the number of chlorine substituents in the molecule give approximately straight lines for each homologous series of these chlorinated phenols, *m*-cresols, and 3,5-xylenols, with few exceptions.

Figures 1 and 2 also show that the smallest t_R values are found for compounds with chlorine atoms, at least

one of which is substituted on the ortho-position in the phenol ring (Solid lines) in comparison with those of the meta- and/or para-chlorinated isomers (dashed lines). In addition, these compounds (Points 3, 4, 9, 15, and 21) are characterized by larger t_R values on the polar column than those of the corresponding compounds with higher numbers of chlorine substituents. These results can be explained in terms of the steric shielding of the hydroxyl groups in phenols by chlorine atoms substituted on the ortho-position in the phenol ring, which prevents the formation of a hydrogen bond between the polar stationary phase and the chlorinated compounds.

Unfortunately, poor separations of *m*-chlorophenol from the para-isomer and of 2,3- from 2,4- and 2,5-dichlorophenol on both polar and nonpolar columns were observed, for these compounds have similar polarities and boiling points. In addition, the peaks of some compounds (*e.g.*, 2,6-dichlorophenol and 2-chloro-3,5-xylenol) overlapped when a mixture of these compounds was chromatographed on both polar and nonpolar columns. However, dichlorinated compounds among a mixture of mono- and dichloro-derivatives with similar t_R values on the columns could be assigned on the basis of the differences in ECD responses, because well-defined ECD peaks are observed for the ng order of a sample injected in the column connected to ECD, though these were very small ECD peaks for monochlorinated compounds in spite of the μg order of sample injection.

The response data indicated that the sensitiveties of FID for the chlorinated phenols became smaller with an increase in the number of chlorine substituents in the molecule, while those of ECD became larger. Similar relative ECD responses have been reported previously[7] for other aromatic halogeno and nitro compounds. These results can be explained in terms of the reduction of the flame-ionization current with organochlorine compounds, or as an increase in the electron-capture reactions with these compounds, which were, chromatographed on the column and then introduced into the detector.[8]

The apparent differences in the FID and ECD sensitivities for the chlorinated derivatives of phenol, *m*-cresol, and 3,5-xylenol chromatographed on both polar and nonpolar columns may also arise as a result of peak broadening or narrowing associated with increases or decreases in t_R.

These results suggest that both the plots of log t_R against the number of chlorine substituents and the differences in ECD responses for the subject compounds can be used to investigate the chemical structure of chlorinated aromatic compounds formed during the chlorination of a variety of phenol compounds with aqueous hypochlorite.

Uptake of Zinc Ion by Hydrous Manganese (IV) Oxide

Eiichi NARITA* and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received August 1, 1980)

Synopsis. The uptake of zinc ion by hydrous manganese(IV) oxide in ammonium chloride solution containing zinc ion was investigated. The uptake of zinc ion was found to be proportional to the potassium content in the hydrous manganese(IV) oxide, the molar ratio of the sorbed Zn^{2+} to the released K^+ being *ca.* 1 : 2.

Adsorption studies of zinc ion on various kinds of anhydrous manganese(IV) oxides have been carried out in a 2 M† NH_4Cl solution containing zinc ion. An adsorption mechanism was postulated in order to explain the ion exchange reaction based on a surface chelation on the hydrated oxide.[1,2] Investigations have been carried out on the mode of metal adsorption by natural and synthetic manganese(IV) oxides as regards the characterization of oxides,[2,3] catalysis[4] and oceanology.[5] However, the effect of the chemical composition of manganese(IV) oxides on the mode of adsorption still remains unclarified.

Hydrous manganese(IV) oxide obtained by reduction and disproportionation of alkaline manganate(V), (VI), and (VII) solution usually contains a large amount of alkali and chemically bound water, exhibiting unusual properties differing a great deal from the anhydrous manganese(IV) oxides prepared by pyrolysis or oxidation of manganese(II) in acid solutions.[6]

In this study, the uptake of zinc ion by hydrous manganese(IV) oxide was investigated and the results were discussed in relation to the replacement of potassium ion present in the sorbent.

Experimental

The measurement of the uptake of zinc ion by hydrous manganese(IV) oxide was carried out in a way similar to that described by Kozawa.[1] The hydrous manganese(IV) oxide was dried by heating at 110 °C. 0.1 g of the sample was then added to 50 ml of zinc solution prepared by dissolving 0.01 M ZnO in 1.5 M NH_4Cl (pH 6.8). The hydrous manganese(IV) oxide suspended in an Erlenmeyer flask was stirred magnetically for 18 h at room temperature and then centrifuged. The supernatant layer was analyzed for zinc ion by titration. The uptake of zinc ion by the hydrous manganese(IV) oxide was calculated from the zinc ion concentrations in solution before and after the uptake was affected.

The preparation and characterization of the hydrous manganese(IV) oxide sample were the same as reported.[6]

Results and Discussion

The zinc ion uptake data and the chemical composition of hydrous manganese(IV) oxides are given in Table 1, together with those of manganese(IV) oxides of other types.

The uptake of zinc ion by typical amorphous and hydrous manganese(IV) oxides (Table 1, 1—4 and 7) was extremely high as compared to that of anhydrous manganese(IV) oxides (12—14). The hydrous manganese(IV) oxides prepared in a solution of high pH showed an approximately constant composition with the formula $K_2O \cdot 4MnO_2 \cdot 4H_2O$. Variation in chemical

a) The calculated chemical composition of the $K_2O \cdot 4MnO_2 \cdot 4H_2O$ formula is 18.3 K_2O, 67.7 MnO_2 and 14.0 H_2O(wt%), (1—8: amorphous, 9—11: tetramanganese dipotassium octaoxide[7]). b) The procedure is given in detail in a previous paper.[6] c) The reaction was performed by dilution of a (0.2M K_3MnO_4 + 10M KOH) solution with large amount of distilled water.

† 1 M = 1 mol dm^{-3}.

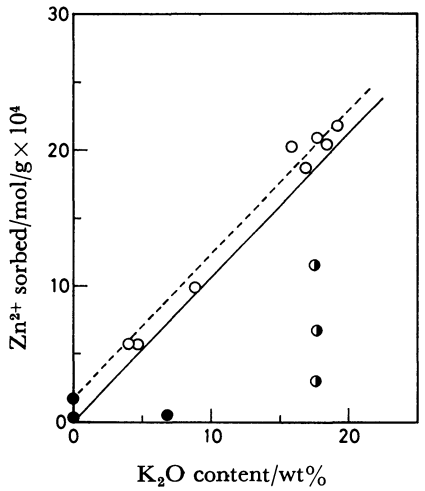

Fig. 1. Relationship between the uptake of Zn^{2+} and the K_2O content of MnO_2 substances.
○: Hydrous MnO_2 (Sample Nos. 1—10), ◑: Heated substances (Sample Nos. 9—11), ●: Crystalline MnO_2 (Sample Nos. 12—14). ——: (Zn^{2+} sorbed/K^+ content) m.r.=0.5.

composition remarkably influenced the zinc ion uptake. For example, the reduction in the K_2O content in the hydrous manganese(IV) oxides prepared by disproportionation (5 and 6) and by acid treatment (8) gave rise to the reduction of the uptake capacity of zinc ion. Potassium in the hydrous manganese(IV) oxide is responsible for the zinc ion uptake. It seems that potassium ions are replaced by zinc ions *via* ion-exchange mechanism. After the uptake reaction, the hydrous manganese(IV) oxide was found to be free from potassium. Figure 1 shows a linear relation between the zinc uptake and the K_2O content in the hydrous manganese(IV) oxide samples. The molar ratio, sorbed Zn^{2+}/released K^+, is slightly higher than 0.5. This can be attributed to the coexistence of H^+ with K^+ on the surface of the hydrated manganese(IV) oxide. γ-MnO_2 contains only H^+ and no K^+ (14).

At pH 6.8, under which most of the Zn^{2+} uptake reactions took place, ammonium ion dominates according to

$$\frac{a_{NH_3}}{a_{NH_4^+}} = 10^{(pH-9.27)}$$

Under these conditions, we see that $(ZnCl_4)^{2-}$ is the most stable zinc ion. It seems that the tetrachlorozincate ion acts on the hydrous manganese(IV) oxide as a bindetate as in the case of a previous study[1] in which H^+ instead of K^+ was the major concern.

On heating, the hydrous manganese(IV) oxide gradually crystallized into tetramanganese dipotassium octaoxide,[7] $K_2Mn_4O_8$ (9—11). This caused decrease in the uptake capacity of zinc ion. The same trend was found in the case of α-MnO_2 (12), showing a low uptake capacity due to its high crystallinity.

One of us (E. N) wishes to thank Prof. K. N. Han for his helpful discussions.

The Synthesis of Potassium Pentacyanohydroxochromate(III)

Yuzuru SAKABE* and Yoshio MATSUMOTO

Department of Chemistry, Faculty of Hygienic Science, Kitasato University, Asamizodai, Sagamihara, Kanagawa 228

(Received August 6, 1980)

Synopsis. The crystals of $K_3[Cr(CN)_5(OH)]\cdot H_2O$ have been obtained by making $[CrCl(NH_3)_5]Cl_2$ react with KCN, followed by purification on a Sephadex gel column.

On the cyano-hydroxo- and aqua-cyano- mixed-coordinated chromate(III) complexes, there have been only a few works reported.[1-4] All the experiments in those studies had been made on samples of the complexes formed in the aquation process of the $[Cr(CN)_6]^{3-}$ ion in an aqueous solution.

Accordingly, the works have more or less had difficulties in the isolation as well as in the identification of the complexes under consideration, which were yielded very scantly and had the property of continuing the sequential release of coordinating cyano ligands in an aqueous solution.

By the use of a new method quite different from the earlier processes, the present authors have obtained $K_3[Cr(CN)_5(OH)]\cdot H_2O$ in crystals. This product proved to be just the complex which had been presumed in one of the reports to have been formed in the reviewed aquation process;[3] this fact affords solid ground for the satisfactory settlement of an intriguing problem with regard to the spectrum-identification of the aqua-cyano-coordinated chromate(III) complexes.

The unit cell dimensions of the crystal were determined by means of X-ray diffraction.

Experimental

Potassium cyanide (25.5 g, 0.415 mol) and $[CrCl(NH_3)_5]Cl_2$ (15.0 g, 0.072 mol) were added to 170 cm³ of water, after which the mixture was boiled while being stirred. A considerable amount of undissolved $[CrCl(NH_3)_5]Cl_2$ which was at first observed disappered qiuckly at the beginning of the boiling, and the solution's color changed from deep-red to orange-yellow. The temperature of the oil-bath was maintained at about 140 °C, and the boiling was continued for 2—3 min after the disappearance of the solid $[CrCl(NH_3)_5]Cl_2$. Attention must be paid to the reaction time, since if the boiling is prolonged, most of the products are decomposed rapidly to form a black precipitate, and the desired complex is not obtained. The reaction mixture was cooled and evaporated to about one-half volume by means of a rotary evaporator. The concentrate, after the removal of a small amount of the black substance, was passed through a Sephadex G-15 gel column (5.5×49 cm). The fractionation of the products on the Sephadex column is illustrated in Fig. 1. The separated orange-yellow fraction which contained the desired complex was refined twice more by means of the same Sephadex column. The purified $K_3[Cr(CN)_5(OH)]$ solution was then evaporated to dryness in a rotary evaporator (the temperature being kept below 35 °C); 7.6 g of orange-yellow crystals as small needles were thus obtained. The crude crystals (2 g) were recrystallized by dissolving them in 2 cm³ of water and by slowly evaporating the solution thus formed in a KOH desiccator. About two days later, the deposited needle crystals were collected by filtration, washed with ethyl alcohol containing 20% water, and dried in a vaccum desiccator with sodium hydroxide: yield, 1.2 g. Analytical result, Found: Cr, 15.28; C, 17.72; H, 1.03; N, 21.05; K, 35.0; H_2O, 5.3%. Calcd for $K_3[Cr(CN)_5(OH)]\cdot H_2O$: Cr, 15.55; C, 17.96; H, 0.90; N, 20.94; K, 35.1; H_2O, 5.4%. The water of crystallization was determined by thermobalance analysis although the results varied to some extent corresponding to the conditions of drying applied to the crystals. The infrared spectrum is illustrated in Fig. 2.

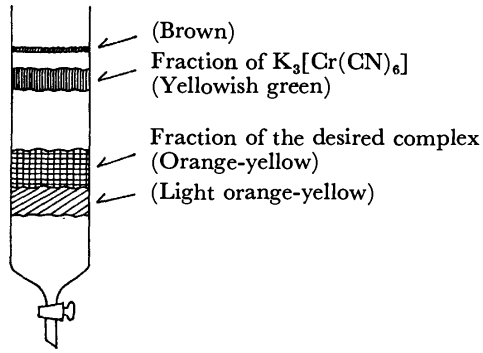

Fig. 1. Separation of the reaction products on Sephadex G-15 gel column.

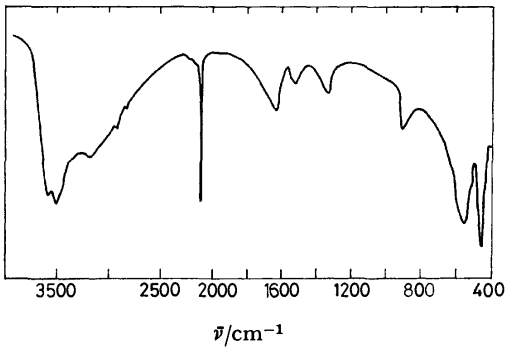

Fig. 2. Infrared spectrum of $K_3[Cr(CN)_5(OH)]\cdot H_2O$ in the 4000—400 cm^{-1} region.

Results and Discussion

The complex, $[CrCl(NH_3)_5]Cl_2$, was first made to react with KCN on the presumption that $K_3[CrCl(CN)_5]$ might be obtained, because an analogous cobaltate(III) complex, $K_3[CoCl(CN)_5]$, had been prepared[5] by making $[CoCl(NH_3)_5]Cl_2$ react with 5 mol of KCN. The complex isolated from the reaction products, however, was found to be not a chloro, but a hydroxo, complex, $K_3[Cr(CN)_5(OH)]$. In the past, the isolation of the pure substance of this complex was difficult, as has previously been explained, and the crystal could not be obtained. Accordingly, the properties of the complexes have been solely investigated on their aqueous solutions, the identification of the complexes being made mainly by means of the electronic spectra and the molar ratio, CN^-/Cr, of the solution.

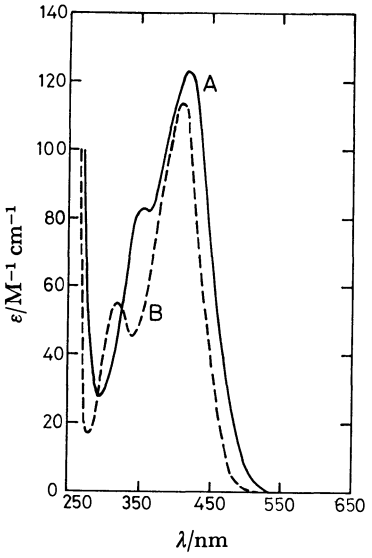

Fig. 3. Absorption spectra of $K_3[Cr(CN)_5(OH)]\cdot H_2O$ at pH 10.3 (——), and at pH 4.2 (– – –) in an aqueous solution.

Now, by virtue of the markedly increased yield by the new reaction process and the excellent ability of Sephadex gel to act as a molecular sieve, the complex has been obtained in crystals.

As a proof of the presence of a OH^- ligand in this complex, a 0.04 mol dm^{-3} (as $K_3[Cr(CN)_5(OH)]$) solution (pH=10.3) was titrated with 0.05 mol dm^{-3} amidosulfuric acid. A single break with a pK value of 8.8 was observed on the titration curve, indicating that the complex was a base with 1 g equivalent/mol. When the solution was made acidic, the complex varied to $K_2[Cr(CN)_5(H_2O)]$, and at pH 4.2 the electronic spectrum of the solution was observed to have been shifted in the direction of the shorter wave length from its initial position at pH 10.3, reinforcing our account of the OH^- ligand, as is illustrated in Fig. 3.

With respect to the spectrum of the cyano-aqua-mixedly coordinated complex of chromium(III), two arguments have been advanced by pioneers. The spectrum, which is identical to the B curve in Fig. 3, has been taken by Schaap *et al.*[1-2] as the spectrum of $[Cr(CN)_4(H_2O)_2]^-$, while the same spectrum was concluded to be that of $[Cr(CN)_5(H_2O)]^{2-}$ by Jeftić and Feldberg.[3] To the investigating made by the foregoing investigators, however elaborate, the result of our work can add adequate evidence which they wanted. The presented method would be of great value in preparing the authentic sample in crystals in quantity. On the three dimensional X-ray diffraction data collected by counter methods, the crystal was found to be monoclinic, with a unit cell of the dimensions: $a=4.45$, $b=8.29$, $c=20.23$ Å, $\beta=105.52°$, $Z=2$. Details of the crystal structure will be presented in another paper.

The authors are very grateful for the aid of Dr. Haruo Ogura, Professor of the Faculty of Pharmaceutical Sciences in Kitasato University, in performing the X-ray analysis of the crystal.

The Molecular Structure of Δ-*cis*-α-[(*S*)-*N*,*N*′-Bis(2-pyridylmethyl)-propylenediamine]dichlorochromium(III) Chloride

Yasuo HATA,† Yukihiro YAMAMOTO,* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

†*Institute for Protein Research, Osaka University, Yamadakami Suita, Osaka 565*

(Received September 5, 1980)

Synopsis. The molecular structure of Δ-*cis*-α-[$CrCl_2$-(*S*-picpn)]$^+$ (*S*-picpn=(*S*)-*N*,*N*′-bis(2-pyridylmethyl)propylenediamine) was determined by X-ray analysis, the absolute configuration being confirmed to coincide with that assigned from the circular dichroism spectrum.

Two diastereomers, $(+)_{600}^{CD}$ and $(-)_{600}^{CD}$ ones of *cis*-α-[$CrCl_2$(*S*-picpn)]$^+$ complex (*S*-picpn=(*S*)-*N*,*N*′-bis(2-pyridylmethyl)propylenediamine), were isolated and their absolute configurations assigned from the circular dichroism (CD) spectra.[1] The present note deals with the X-ray structure analysis of a chloride of the more stable isomer, $(+)_{600}^{CD}$ one, which has been assigned to a Δ configuration from its CD spectrum.

Experimental

Ruby-red needle-like single crystals suitable for X-ray analysis were prepared by slow evaporation of an aqueous solution of the complex $(+)_{600}^{CD}$-[$CrCl_2$(*S*-picpn)]Cl at room temperature. Systematic absence indicated the monoclinic space group $P2_1$. Unit cell dimensions obtained by least-squares refinement of the setting angles of 11 reflections measured on a diffractometer were a=8.46 (2), b=15.68 (1), c=7.20 (1) Å and β=103.6 (1) °. The observed density 1.48 g cm^{-3} (by flotation in benzene-carbon tetrachloride) coincides with the calculated value 1.48 g cm^{-3} for Z=2. A crystal of the dimension 0.36×0.15×0.11 mm was used for the intensity measurement. Intensities were measured on a Rigaku automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation (λ=0.71069 Å). The θ—2θ scan mode with a scan speed of 4 °min^{-1} in 2θ was employed. The scan range was calculated to be (1.0+0.35 tanθ)°. Intensities of 1704 independent reflections were collected in the range $1.0 \leq 2\theta \leq 50.0°$. Of these reflections 209 were measured as $|F_o|=0.0$. The intensities were corrected for Lorentz and polarization factors. No absorption correction was made [μ(Mo $K\alpha$)=1.072 mm^{-1}].

The structure was solved by the heavy atom method. The positions of chromium and two coordinated chlorine atoms were determined from a Patterson map. An electron density map based on the phases calculated from these atomic parameters revealed all the non-hydrogen atoms. The parameters were refined by the block-diagonal least-squares program HBLS-5,[2] with anisotropic thermal factors. The reliability factors $R=\sum||F_o|-|F_c||/\sum|F_o|$ and $Rw=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}$ were 0.077 and 0.088, respectively, for 1495 non-zero reflections. The final weighting scheme for minimization of $\sum w(|F_o|-|F_c|)^2$ was $w=[\sigma^2(F_o)+0.00022|F_o|+0.00357|F_o|^2]^{-1/2}$. The positions of the hydrogenes were not determined.

Results and Discussion

Final atomic parameters, bond distances and angles are given in Tables 1, 2, and 3, respectively. The F_o-F_c data and final thermal parameters are deposited as Document No. 8119 at the Office of the Chemical Society of Japan. The quadridentate ligand takes an α configuration, the two chloro ligands occupying *cis* positions. There is no significant difference between the distances of chromium to amine nitrogens and chromium to pyridine nitrogens. Angles N(1)–Cr–N(2) of the central chelate ring and Cl(1)–Cr–Cl(2) are 83.9° and 95.1°, respectively, the coordination geometry being slightly distorted from a regular octahedron.

A stereoscopic view of the complex cation drawn by PLUTO[4] is shown in Fig. 1. The absolute configuration of the complex was determined during the course of synthesis from the fact that the asymmetric carbon atom C(8) adopts the (*S*)-configuration,[1] without using the anomalous dispersion technique. The Δ configuration coincides with that assigned from the CD data.[1]

The least-squares planes and the dihedral angles between the planes are given in Table 4. The two

terminal chelate rings take distorted λ envelope conformations. The two pyridine rings are nearly planar within error and make an angle 75.9° with each other. The two planes P1 and P3 are nearly perpendicular to plane P2. The central chelate ring CrN(1)C(7)C(8)N(2) has a distorted δ conformation with an equatorial methyl carbon C(15), carbon C(8) being more deviated than C(7) from plane P2.

An Evaluation of Ion-exchange Membrane Electrodes

Hirokazu HARA, Satoshi OKAZAKI, and Taitiro FUJINAGA*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received September 8, 1980)

Synopsis. The potentiometric response behavior and selectivity characteristics of ion-exchange membrane electrodes have been investigated. Nernstian responses were obtained for inorganic anions such as perchlorate, nitrate, and chloride with each form of Selemion ASV membrane. Highly selective exclusions of the divalent sulfate and large organic sulfonate anions were observed with those membranes.

There have been many reports on the use of ion-exchange resins as heterogeneous resin membranes, which were made of ion-exchange resins embedded into high polymer or silicone rubber binders.[1-3] The electrodes of these types, however, have not shown good selectivity among individual ions and have been of little utility. Recently, a hydrophobic anion-exchange resin electrode having a wide selectivity range has been developed by Jyo *et al.*[4] On the other hand, a homogeneous ion-exchange membrane has never been successfully used as an ion-sensing material. Birch and Clarke have reported on a surfactant selective electrode with an Asahi anion-exchange membrane, which showed only a poor response to surfactant anions.[5]

In this paper, the authors examined commercially available ion-exchange membranes as ion-sensing materials and found that these membranes showed linear and quick responses for inorganic univalent anions, such as perchlorate, nitrate, and chloride over the concentration range from 10^{-1} M (1 M=1 mol dm^{-3}) to nearly 10^{-4} M. These membranes exhibited a highly selective exclusion of the divalent sulfate and large organic anions such as *p*-toluenesulfonate (TsO^-) and benzenesulfonate ($PhSO_3^-$), in contrast to liquid membrane electrodes. The differences of the selectivity characteristics among these membranes were discussed qualitatively on the basis of their membrane structures.

Experimental

Reagents. The ion-exchange membranes used were Selemion ASV, AMV, and DMV produced by the Asahi Glass Co. Ltd. AMV is an anion permselective membrane for the use of electrodialysis, having an ion-exchange site of $-N(CH_3)_3^+$. ASV is a univalent anion permselective membrane having not only a functional group similar to AMV but also a cation exchange site, which can effectively repel polyvalent anions.[6] DMV is an anion permselective membrane for use in diffusion dialysis, having functional groups of $-NH_3^+$ and $>NH_2^+$. Cations, except proton and nondissociative organic molecules cannot pass through a DMV membrane. The substrates of these membranes are made of polystyrene–butadiene copolymer.[6] The ClO_4^-, NO_3^-, and TsO^- forms of these membranes were made by soaking their original chloride forms in an aqueous solution of a sodium salt of the objective anion. The air-dried chloride form of ASV has been soaked in 1-decanol or nitrobenzene for 3 d in order to examine the effects of the impregnated solvents on membrane selectivity. Sodium hydroxide and *p*-toluene–sulfonic acid were used to control the pH of the sample solution.

Apparatus. A membrane electrode of the double junction type with an outer filling solution of 0.1 M sodium salt of each anion was used. The electrode potentials were measured by an Orion Digital Ionalyzer Model 601 connected to a Matsushita Penrecorder Model VP654A. All measurements were carried out by stirring at 25±0.5 °C.

Results and Discussion

The potentiometric response characteristics of ClO_4^-, NO_3^-, Cl^-, and TsO^- forms of ASV and DMV membranes with respect to the sensitivity, slope of the calibration curve, and response time are summarized in Table 1. Each value listed in the table is a mean value of four independent measurements. The ΔE_{1-4} denotes the potential difference between the solutions of 10^{-1} M and 10^{-4} M, which was used as an index of sensitivity. The slopes were estimated by a regression analysis in the concentration range of from 10^{-1} M to 10^{-3} M. The response time was defined as a period of time when the electrode was dipped until the membrane potential reached a steady value within ±0.5 mV, and was listed as a mean value obtained from 10^{-1} M to 10^{-4} M.

Table 1. Potentiometric response behavior of ion-exchange membrane electrodes

Membrane and form	ΔE_{1-4} / mV	Slope / mV/pa	Response time / min
ASV : ClO_4^-	174±3.5	59.8	0.87
DMV : ClO_4^-	160±5.2	58.6	1.4
ASV : NO_3^-	168±3.0	60.1	0.54
DMV : NO_3^-	159±2.0	59.9	0.82
ASV : Cl^-	162±2.4	60.2	0.78
DMV : Cl^-	154±3.7	59.1	0.89
ASV : TsO^-	148±6.1	55.9	4.2
DMV : TsO^-	168±4.6	61.0	0.73

Each form of ASV and DMV, except the TsO^- form of ASV, gave the Nernstian response over the concentration range of from 10^{-1} M to nearly 10^{-4} M, and considerably quick response at concentrations above 10^{-3} M. ASV was superior to DMV in sensisivity for the inorganic univalent anions, while DMV showed a better response to TsO^- than ASV did. The TsO^- form of ASV gave a poor response in both sensitivity and response time. This phenomenon was attributed not only to the repulsion between the surface cation exchange layer and an organic sulfonate anion but also to the steric hindrance between the ASV membrane and a large organic anion. The response characteristics of AMV were almost the same as those of DMV.

Table 2 summarizes the selectivity characteristics of these membranes. The selectivity coefficients, log $K_{i,j}^{pot}$ of the ClO_4^-, NO_3^-, Cl^-, and TsO^- forms of ASV and DMV were measured by the separate solution

TABLE 2. SELECTIVITY COEFFICIENTS, log K^{pot}_{i-j} OF ION-EXCHANGE MEMBRANE ELECTRODES

Membrane and form (Sensing anion, i)	Interfering anion, j					
	ClO_4^-	NO_3^-	Cl^-	$PhSO_3^-$	TsO^-	SO_4^{2-}
ASV : ClO_4^-	0	−0.72	−1.40	−2.11	−2.21	−3.00
DMV : ClO_4^-	0	−0.38	−0.60	−0.73	−0.80	−1.40

Concn of interfering anion; 10^{-2}M

method. The reproducibility of the value was within ±0.08.

The order of the magnitude of the selectivity coefficients among the univalent anions was $ClO_4^- > NO_3^- > Cl^- > PhSO_3^- > TsO^-$. This sequence of interference was different from the results reported with the liquid membrane electrodes of *o*-dichlorobenzene, *i.e.*, $ClO_4^- > TsO^- > PhSO_3^- > NO_3^- > Cl^-$.[7] It was found that organic anions, such as $PhSO_3^-$ or TsO^-, caused less interference with the ion-exchange membranes than with the liquid membranes. However, the sequence of the interference among the inorganic anions was similar to that of the liquid membrane. ASV suffered less from the interference of a divalent sulfate anion than DMV owing to its univalent permselectivity. The selectivity characteristics of these membranes were examined more extensively with their chloride forms, as shown in Fig. 1. The selectivity range was widest in ASV and decreased in the order of ASV≫AMV>DMV. From the results, the degree of quaternization of the ion-exchange site seems to exert a smaller effect on the selectivity range than the presence of the surface cation-exchange site. Almost all organic anions tested caused less interference with these membranes than the inorganic anions. This result may be attributed to the difficulty in diffusion of the large organic anions into these compact membranes owing to their strong interaction with the high polymer chains.

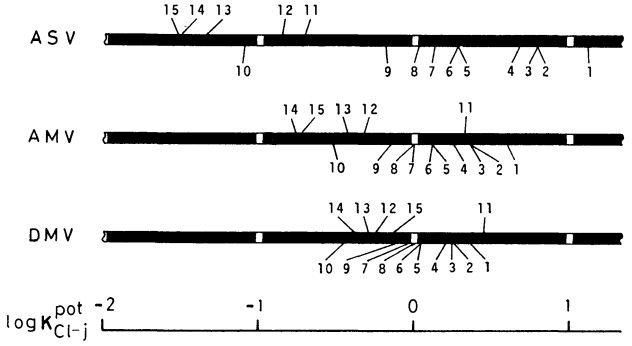

Fig. 1. Selectivity coefficient diagrams of Cl^- form ion-exchange membranes.
Interfering anion: (1) ClO_4^-, (2) BF_4^-, (3) SCN^-, (4) I^-, (5) NO_3^-, (6) Br^-, (7) ClO_3^-, (8) NO_2^-, (9) BrO_3^-, (10) SO_4^{2-}. (11) $C_8H_{17}OSO_3^-$ (octyl sulfate), (12) $PhSO_3^-$ (benzenesulfonate), (13) TsO^- (*p*-toluenesulfonate), (14) $C_8H_{17}SO_3^-$ (1-octanesulfonate), (15) 1-naphthalenesulfonate.

The effect of pH of the sample solution on the membrane potentials of the ClO_4^- forms of these membranes was examined. ASV sustained a constant potential over a wide pH range from 5.0 to 11.0, whereas DMV did so only in the range of from pH 6.0 to 9.0. This difference in the accessible pH range between ASV nad DMV is due to the degree of quaternization of their ion-exchange sites.

It has been reported by Jyo *et al.* that the selectivity range of the liquid membrane electrodes were influenced more by the membrane solvents than the ion-exchange sites.[8] The selectivity coefficients of the Cl^- form of ASV, however, were affected little by the impregnation of the membrane with 1-decanol. Nitrobenzene seemed to damage the high polymer chains of ASV.

In conclusion, though the ion-exchange membranes did not show a special advantage in sensitivity and in selectivity, in a conventional sense, over the liquid membranes, they did seem to have the following advantages: A high polymer membrane is very strong mechanically and has a very long life time. And in particular, a high polymer membrane has the possibility of making its selectivity highly specific for a certain ion by introducing a particular functional group into the high polymer chains, just as ASV showed a specific repulsion to divalent sulfate by its surface cation-exchange site, or to large organic sulfonate anions owing to their strong interaction with the high polymer chains.

Studies on the Chlorinated α-Santonins. III.[1] Revised Structure of α-Santonin Chlorohydrin

Hiroaki TAKAYANAGI, Haruo OGURA,* and T. BRIAN H. McMURRY††

School of Pharmaceutical Sciences, Kitasato University Shirokane, Minato-ku, Tokyo 108

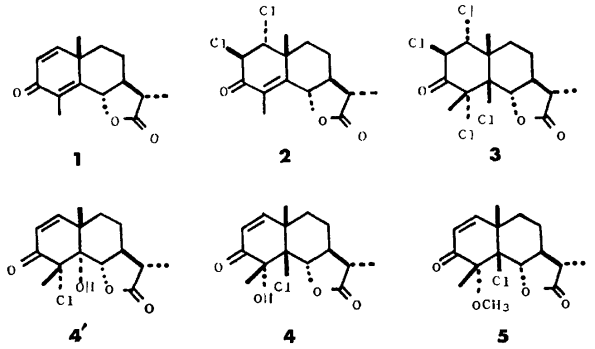
††*Chemistry Department, Trinity College, Dublin 2, Ireland*

(Received June 30, 1980)

Synopsis. The molecular structure of α-santonin chlorohydrin is revised to 5β-chloro-4α-hydroxysantonin from 4α-chloro-5α-hydroxysantonin (Hendrickson and Bogard) by X-ray analysis of the corresponding 5β-chloro-4α-methoxysantonin.

Hendrickson and Bogard[2] have re-examined the products derived from chlorination, epoxidation and subsequent changes of α-santonin (**1**), and assigned structures to the various products. We have revised their structure of dichloro-α-santonin to **2**, based on an X-ray analysis of the derived tetrachloro-α-santonin (**3**).[3]

In this paper we wish to report a further revision, that of santonin chlorohydrin from **4'** to **4**, on the basis of an X-ray analysis of the related 5β-chloro-4α-methoxysantonin (**5**), and the ready conversion (HI, 90°) of **5** to **4**.



1 **2** **3**

4' **4** **5**

Experimental

5β-Chloro-4α-methoxysantonin (5). Dry chlorine was passed into α-santonin (5.0 g) in methanol (20 ml) at 0° for 20 min. The methanol was evaporated, and the residue was crystallized from methanol to give **5** (2.84 g) as colorless plates, mp 216—219 °C. Except for the unchanged material, no other isomeric products were found by TLC and NMR spectral examination of the residue. IR ($CHCl_3$) 1782, and 1691 cm^{-1}; UV(EtOH) λ_{max} 231 nm (ε=6300); NMR($CDCl_3$) δ 6.30 (1H, d, $J_{1,2}$=11 Hz, 1-H), 5.89 (1H. d, $J_{2,1}$=11 Hz, 2-H), 4.41 (1H, d, $J_{6,7}$=12 Hz, 6-H), 3.10 (3H, s, OMe), 1.69 (3H, s, 4-Me), 1.48 (3H, s, 10-Me), and 1.23 (3H, d, J=7 Hz, 11-Me). Found: C, 61.28; H, 6.88; Cl, 11.54%; M^+, 312. Calcd for $C_{16}H_{21}ClO_4$: C, 61.44; H, 6.77; Cl, 11.33%; M, 312.

5β-Chloro-4α-hydroxysantonin (4) from 5. A suspension of **5** (1.0 g) in 57% hydriodic acid (20 ml) was kept heating at 80—90 °C for 10 h. After filtrating the precipitate, water was added to the filtrate to give a crystalline precipitate, which was dried and chromatographed over silica gel. Elution with chloroform gave **4** (0.2 g), which was recrystallized from methanol to give colorless plates, mp and mixed mp 235—237 °C (dec) with the products prepared by Wedekind and Tettweiler.[4] The IR and NMR spectra of the two samples were identical. No other isomeric products except the unchanged starting material were found by TLC and NMR spectral examination of the mother liquor.

Crystallographic Measurement. The crystal of **5** belongs to the orthorhombic space group $P2_12_12_1$, a=8.458 (7), b=27.100 (8), c=6.796 (3) Å, Dm=1.34 g cm^{-3}, Dc=1.334 g cm^{-3}, and Z=4. The three-dimensional intensity data were collected on a Rigaku automatic four-circle diffractometer with graphite monochromated Cu $K\alpha$ radiation . Reflections having an intensity exceeding the corresponding standard deviations by a factor of three were treated as observed. 981 reflections with $2\theta \leqq 139°$ were retained and corrected for Lorentz and polarization factors but not for absorption and extinction factors.

Determination and Refinement of the Structure. The structure was determined by the heavy atom method. From the three-dimensional Patterson map, the position of the chlorine atom was easily deduced. From the Fourier synthesis with the chlorine phases, all the 20 non-hydrogen atoms in the asymmetric unit were obtained. The oxygen atoms were identified by structural consideration. Refinement of atomic parameters was carried out by the block-diagonal least-squares method, the quantity minimized being $\sum\omega(|F_o|-|E_c|)^2$, with ω=1.0 for all the reflections used . All the hydrogen atoms except the 12 hydrogen atoms on the methyl groups were located on the difference map. The final R value was 0.081.

The final atomic parameters are given in Table 1. Anisotropic thermal parameters of non-hydrogen atoms and atomic parameters of hydrogen atoms and the complete Fo–Fc data are kept at the Chemical Society of Japan (Document No. 8131).

Results and Discussion

A perspective view of the molecule with numbering of the atoms is given in Fig. 1. The bond lengths and angles are given in Table 2. No abnormal lengths and angles were found in the structure.

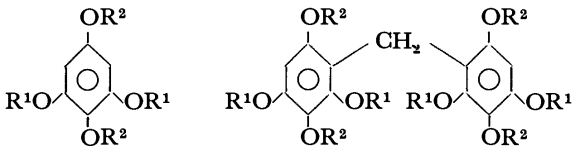
(Received May 19, 1980)

Synopsis. Three hexamethoxyxanthene isomers, 1,2,3,6,7,8-, 1,3,4,5,6,8-, and 1,2,3,5,6,8-hexamethoxyxanthene, were synthesized from the condensation products of 2,6-dimethoxyhydroquinone, 2,5-dimethoxyresorcinol, or 1,2,-3,5-benzenetetrol respectively with formaldehyde or ethyl formate.

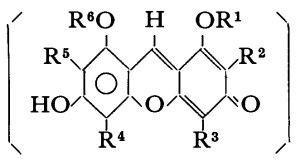
In connection with the synthetic studies of carthamin,[1] the synthesis of three isomers of hexamethoxyxanthene, 1,2,3,6,7,8-, 1,3,4,5,6,8-, and 1,2,3,5,-6,8-hexamethoxyxanthene (**4**, **9**, and **12**), was accomplished. Although many methods of preparing xanthenes have been known,[2] no detailed study has been reported on the synthesis of hexahydroxyxanthene derivatives.

1,2,3,6,7,8-Hexamethoxyxanthene (**4**) was obtained by the methylation of 1,3,6,8-tetramethoxy-2,7-xanthenediol (**3**), which had itself been prepared by the dehydration of 2,2′,4,4′-tetramethoxydiphenylmethane-3,3′,6,6′-tetrol (**2**), obtained by the condensation of 2,6-dimethoxyhydroquinone (**1**)[3] with formaldehyde. Two aromatic protons of this symmetrical hexamethoxyxanthene, **4**, appeared as a singlet at 6.33 ppm in its ^{1}H-NMR spectrum.

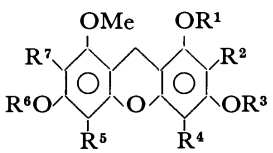
In a similar manner, we attempted the synthesis of 1,3,4,5,6,8-hexamethoxyxanthene (**9**) from 2,5-dimethoxyresorcinol (**5**),[4] however, the attempt at the dehydration of 3,3′,6,6′-tetramethoxydiphenylmethane-2,2′,4,4′-tetrol (**6**) was unsuccessful.



1 R^1 = Me, R^2 = H
2 R^1 = Me, R^2 = H
5 R^1 = H, R^2 = Me
6 R^1 = H, R^2 = Me
13 $R^1 = R^2$ = H



7 $R^1 = R^6$ = Me, $R^2 = R^5$ = H, $R^3 = R^4$ = OMe
10 $R^1 = R^3 = R^5$ = H, $R^2 = R^4$ = OMe, R^6 = Me
14 $R^1 = R^3 = R^5 = R^6$ = H, $R^2 = R^4$ = OH
15 $R^1 = R^3 = R^4 = R^6$ = H, $R^2 = R^5$ = OH



3 $R^1 = R^3 = R^6$ = Me, $R^2 = R^7$ = OH, $R^4 = R^5$ = H
4 $R^1 = R^3 = R^6$ = Me, $R^2 = R^7$ = OMe, $R^4 = R^5$ = H
8 R^1 = Me, $R^2 = R^3 = R^6 = R^7$ = H, $R^4 = R^5$ = OMe
9 $R^1 = R^3 = R^6$ = Me, $R^2 = R^7$ = H, $R^4 = R^5$ = OMe
11 $R^1 = R^3 = R^4 = R^6 = R^7$ = H, $R^2 = R^5$ = OMe
12 $R^1 = R^3 = R^6$ = Me, $R^2 = R^5$ = OMe, $R^4 = R^7$ = H

Compound **9** and, an unsymmetrical isomer, 1,2,3,5,-6,8-hexamethoxyxanthene (**12**), were obtained by the methylation of 1,4,5,8-tetramethoxy-3,6-xanthenediol (**8**) and 2,5,8-trimethoxy-1,3,6-xanthenetriol (**11**), respectively, obtained by the hydrogenation of the condensed-ring compound of 2,5-dimethoxyresorcinol (**5**) with ethyl formate. Two aromatic protons of **9** in the 2- and 7-positions appeared as a singlet at 6.21 ppm, while the 4- and 7-protons of **12** were observed at 6.18 and 6.48 ppm respectively in their ^{1}H-NMR spectra. Consequently, it is thought that the above crude condensed-ring compound was a mixture of 6-hydroxy-1,4,5,8-tetramethoxy- and 1,6-dihydroxy-2,5,8-trimethoxy-3*H*-xanthen-3-one (**7** and **10**).

Compound **12** was also obtained, along with **4**, by the methylation of the unstable hydrogenated products of the crude condensed-ring compound of 1,2,3,5-benzenetetrol (**13**)[5] with ethyl formate. The formation of 1,2,5,6,8- and 1,2,6,7,8-pentahydroxy-3*H*-xanthen-3-one (**14** and **15**) is also assumed in the above condensation.

From these results, significant information regarding the synthetic studies of hexamethoxyxanthene derivatives of carthamin[6] was obtained.

Experimental

All the melting points are uncorrected. The ^{1}H-NMR spectra were measured with a Hitachi R-22 spectrometer (90 MHz), using tetramethylsilane as the internal standard. The mass spectra were obtained on a Hitachi RMU-6M mass spectrometer.

2,2′,4,4′-Tetramethoxydiphenylmethane-3,3′,6,6′-tetrol (2). To a mixed solution of 2,6-dimethoxyhydroquinone (**1**) (3.7 g) and formalin (37%) (1.2 g) in ethanol (20 ml), we added one drop of concd hydrochloric acid. The reaction mixture was allowed to stand overnight, and the resulting colorless needles (**2**) were filtered and washed with water. Mp 180 °C (dec), 2.4 g (63%). Found: C, 57.67; H, 5.80%; M^+, 352. Calcd for $C_{17}H_{20}O_8$: C, 57.95; H, 5.72%; M, 352.

1,3,6,8-Tetramethoxy-2,7-xanthenediol (3). A mixed solution of **2** (240 mg) and phosphoryl chloride (100 mg) in dry toluene (140 ml) was refluxed for 2 h. The reaction mixture was then washed with water and dried over anhydrous sodium sulfate. The solvent was evaporated *in vacuo*, and the residue was chromatographed on silica gel. Elution with benzene–ethyl acetate (4 : 1) afforded **3** as light yellow needles; mp 204 °C (38 mg, 17%). Found: C, 60.81; H, 5.45%; M^+, 334. Calcd for $C_{17}H_{18}O_7$: C, 61.07; H, 5.43%; M. 334.

1,2,3,6,7,8-Hexamethoxyxanthene (4). A mixed solution of **3** (50 mg), dimethyl sulfate (47 mg), and anhydrous potassium carbonate (65 mg) in dry acetone (6.5 ml) was refluxed for 10 h. The reaction mixture was then worked up in the usual manner, and the crude product was chromatographed on a column of silica gel with benzene–ethyl acetate (10 : 1) to give **4** (10 mg, 18%) (mp 115—116 °C (from ether–petroleum ether)) as colorless needles. ^{1}H-NMR ($CDCl_3$) δ 3.76 (2H, s, $-CH_2-$), 3.82 (12H, s, $-OMe \times 4$), 3.93 (6H, s, $-OMe \times 2$), 6.33 (2H, s, $C_{4,5}-H$), Found: C, 62.87; H, 6.12%; M^+,

362. Calcd for $C_{19}H_{22}O_7$: C, 62.98; H, 6.07%; M, 362.

3,3',6,6'-Tetramethoxydiphenylmethane-2,2',4,4'-tetrol (6). This compound was prepared from 2,5-dimethoxyresorcinol (**5**) and formalin (37%) in a 72% yield by a manner similar to that used for **2**; mp 195 °C. Found: C, 57.89; H, 5.73%; M^+, 352. Calcd for $C_{17}H_{20}O_8$: C, 57.95; H, 5.73%; M, 352. The dehydration of this compound by a manner similar to that used for **2** was, however, unsuccessful.

1,4,5,8-Tetramethoxy-3,6-xanthenediol (8) and 2,5,8-Trimethoxy-1,3,6-xanthenetriol (11). Into a solution of 2,5-dimethoxyresorcinol (**5**) (1.0 g) in ethyl formate (8.0 ml), dry hydrogen chloride gas was stirred for 4 h under cooling with ice water. The reaction mixture was then allowed to stand for 2 d at 0 °C. The resulting deep purple-red ppt (850 mg) was filtered and washed with ether. The above condensation product was hydrogenated in ethanol (40 ml) with 5% palladium charcoal (980 mg) for 6 h. The reaction mixture was then filtered, and the solvent was removed *in vacuo*. The residue was chromatographed on a column of silica gel with benzene–ethyl acetate (2 : 1) to give **8** (85 mg, 10%) (mp 183 °C (from ether–petroleum ether)) from the first eluent. Found: C, 60.78; H, 5.41%; M^+, 334. Calcd for $C_{17}H_{18}O_7$: C, 61.07; H, 5.43%; M, 334. Compound **11** (400 mg, 49%) (mp 239°C (dec) (from toluene)) was obtained from the second eluent. Found: C, 59.72; H, 4.96%; M^+, 320. Calcd for $C_{16}H_{16}O_7$: C, 60.00; H, 5.03%; M, 320.

1,3,4,5,6,8-Hexamethoxyxanthene (9). A mixed solution of **8** (100 mg), dimethyl sulfate (0.12 ml), and anhydrous potassium carbonate (200 mg) in dry acetone (13 ml) was refluxed for 6 h. The reaction mixture was then worked up in the usual manner, and the crude product was chromatographed on a column of silica gel with benzene–ethyl acetate (10 : 1) to afford **9** (70 mg, 65%); mp 138—139 °C (from ether–petroleum ether). ^{1}H-NMR ($CDCl_3$) δ 3.65 (2H, s, $-CH_2-$), 3.82, 3.88, and 3.94 (each 6H, s, $-OMe\times6$), 6.21 (2H, s, $C_{2,7}-H$). Found: C, 62.60; H, 6.14%; M^+, 362. Calcd for $C_{19}H_{22}O_7$: C, 62.98; H, 6.07%; M, 362.

1,2,3,5,6,8-Hexamethoxyxanthene (12). This compound, **12**, was obtained by the methylation of **11** in a manner similar to that used for **9**; mp 120—121 °C (from ether–petroleum ether). ^{1}H-NMR ($CDCl_3$) δ 3.72 (2H, s, $-CH_2-$), 3.82 (9H, s, $-OMe\times3$), 3.85 and 3.87 (each 3H, s, $-OMe\times2$), 3.93 (3H, s, –OMe), 6.18 (1H, s, C_7-H), 6.48 (1H, s, C_4-H). Found: C, 62.94; H, 6.12%; M^+, 362. Calcd for $C_{19}H_{22}O_7$: C, 62.98; H, 6.07%; M, 362.

1,2,3,6,7,8- and 1,2,3,5,6,8-Hexamethoxyxanthene (4 and 12) from 1,2,3,5-Benzenetetrol (13). The condensation product (2.6 g) of 1,2,3,5-benzenetetrol (**13**) with ethyl formate, which was obtained in a manner similar to that used for **8**, was hydrogenated in ethanol (240 ml) with 5% palladium charcoal (20 g) for 6 h. The reaction mixture was then filtered, and the solvent was removed *in vacuo* to give an unstable reduction product (1.7 g), a mixture of **14** and **15**. A mixed solution of the above reduction product (100 mg), dimethyl sulfate (0.32 ml), and anhydrous potassium carbonate (460 mg) in dry acetone (15 ml) was refluxed for 6 h. The reaction mixture was then worked up in the usual manner, and the crude product was chromatographed on a column of silica gel with benzene–ethyl acetate (10 : 1). From the first eluent, **4** (59 mg, 44%) (mp 115—116 °C) was obtained. Similarly, **12** (6.0 mg, 4.6%) (mp 120—121 °C) was obtained from the second eluent.

The authors wish to express their thanks to Mr. Kazuaki Sato for the microanalyses.

Ammonolysis of *N*-Acylpyroglutamic Acid. Permanganate-oxidation of Peptides. II.

Keisuke TORIGOE, Yoshiaki MOTOKI, and Ichiro MURAMATSU*

Department of Chemistry, College of Science, Rikkyo University, Nishi-ikebukuro, Toshima-ku, Tokyo 171

(Received July 22, 1980)

Synopsis. The reaction of *N*-acylpyroglutamic acid with ammonia proceeds in two pathways. The one results in *N*-acylglutamine as a product, and the other in pyroglutamic acid and an amide formed from the *N*-acyl group. The ratio of the yields of the two reactions changes with the *N*-acyl group, being correlated with the acidity of the carboxylic acid from which the *N*-acyl group is derived, and also with the steric hindrance of the group.

In a previous paper,[1] it was reported that Z–Pro–OH[2] was oxidized to Z–pGlu–OH with $KMnO_4$ in the presence of strong acid. In further study, it has been found that Bz–Pro–OH is also oxidized to give Bz–pGlu–OH, and that the ammonolysis of Bz–pGlu–OH gives H–pGlu–OH as a main product. The latter result is in contrast to the well-known fact that Z–pGlu–OH is ammonolyzed to give Z–Gln–OH.[3] That is to say, two pathways seem possible in the ammonolysis of *N*-acyl–pGlu–OH.

In order to elucidate the factors determining the pathway, we synthesized several *N*-acyl–pGlu–OH's and their amides, and investigated the relationship between the *N*-acyl group and the reaction pathway.

Results and Discussion

The pathways in the ammonolysis of *N*-acyl–pGlu–OH are shown in Fig. 1. The reaction proceeds to produce *N*-acyl-Gln–OH with accompanying ring-opening in path I, and H–pGlu–OH and the amide in path II.

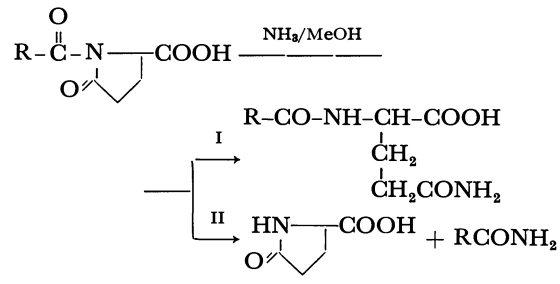

Fig. 1.

The results of ammonolysis are summarized in Table 1. Boc–pGlu–OH gave Boc–Gln–OH quantitatively, while pNBz–pGlu–OH gave H–pGlu–OH. The products vary with the acidity of the carboxylic acid from which the *N*-acyl group was derived. Namely, path II becomes predominant over I with increasing acidity of the carboxylic acid.

When the tosyl group was used as an *N*-protector, the product was Tos–Gln–OH only, although TosOH is a strong acid, showing deviation from the above correlation.

Ammonolysis of (A) Z–Ala–pGlu–NH_2 and (B) Z–Val–pGlu–NH_2 was carried out. In the case of (A), the peptide bond was cleaved almost quantitatively to give Z–Ala–NH_2 and H–pGlu–NH_2 (path II). In the case of (B), the reaction proceeded in two pathways, giving Z–Val–NH_2 and H–pGlu–NH_2 (path II), and Z–Val–Gln–NH_2 (path I) in the ratio 7 : 3.

Table 1. Ratio of the products in ammonolysis of *N*-acyl–pGlu–OH[a]

Acyl group	*N*-acyl–Gln–OH (Path I)	H–pGlu–OH (Path II)		pK_a[4]
Boc	1.00	0		
Z	0.83	0.17		
Ac	0.60	0.40	AcOH	4.67(5.84)[b]
Bz	0.15	0.85	BzOH	4.21(5.42)[b]
pNBz	0.04	0.96	pNBzOH	3.44(4.55)[b]
Tos	1.00	0	TosOH	1.70

a) Optically active (L-) in case of Boc, Z, and Tos; optically inactive in case of Ac, Bz, and pNBz. b) Measured in 50% MeOH at 27 °C.

The pK_a of Z–Ala–OH in 50% MeOH at 27 °C was determined to be 4.96, smaller than that of BzOH. Consequently the result of the ammonolysis of Z–Ala–pGlu–NH_2 is compatible with that of *N*-acyl–pGlu–OH. The pK_a of Z–Val–OH was 5.00 under the same conditions. It is conceivable that the ammonolysis of Z–Val–pGlu–NH_2 would give a similar result to that of Z–Ala–pGlu–NH_2. However, path I in the reaction of the valine peptide was not negligible. This shows that not only acidity but also steric hindrance of the *N*-acyl group affects the reaction pathway.

Z–Ala–pGlu–NH_2 and Z–Val–pGlu–NH_2 used in this study were obtained by the oxidation of Z–Ala–Pro–NH_2 and Z–Val–Pro–NH_2 by the method reported.[1]

Experimental

All melting points were uncorrected. NMR spectra were obtained on a Hitachi-Perkin Elmer R-20A Spectrometer, and IR spectra on a Hitachi Grating Infrared Spectrophotometer, Model 215. All *N*-acyl–pGlu–OH compounds were synthesized by the method reported.[3,5] All amino acids in peptide amides were of the L-series.

Ac–pGlu–OH·DCHA: Recrystallized from EtOH–EtOAc; yield[6] 32%; mp 174—175 °C; NMR (measured as free acid in $CDCl_3$) δ 2.54 (3H, s, CH_3–CO), 2.00—2.90 (4H, m, CH–CH_2–CH_2–CO), 4.73 (1H, m, >CH–COOH); IR (KBr) 1630, 1695, 1735 cm^{-1} (>C=O). Found: C, 64.83; H, 9.54; N, 8.11%. Calcd for $C_{19}H_{32}O_4N_2$: C, 64.74; H, 9.15; N, 7.95%.

Bz–pGlu–OH: Purified with a column of Sephadex LH-20 (solvent, benzene–EtOH–H_2O, 50 : 15 : 1), and recrystallized from EtOH–EtOAc; yield[6] 38%; mp 142—144 °C; NMR ($CDCl_3$–CD_3OD) δ 2.00—2.80 (4H, m, CH–CH_2–CH_2–CO), 4.88 (1H, m, >CH–COOH), 7.20—7.80 (5H, m, C_6H_5–CO); IR (KBr) 1655, 1710, 1730, 1770 cm^{-1} (>C=O). Found: C, 61.43; H, 4.63; N, 5.95%. Calcd for $C_{12}H_{11}O_4N$: C, 61.80;

H, 4.75; N, 6.01%.

pNBz–pGlu–OH: Recrystallized from EtOAc; yield[6] 41%; mp 180—181 °C; NMR ($CDCl_3$–CD_3OD) δ 1.80—2.80 (4H, m, CH–C$\underline{H}_2$–C$\underline{H}_2$–CO), 4.92 (1H, m, >C$\underline{H}$–COOH), 7.50—8.40 (4H, m, NO_2–$C_6\underline{H}_4$–CO); IR (KBr) 1695, 1705, 1750 cm^{-1} (>C=O). Found: C, 51.60; H, 3.34; N, 10.23%. Calcd for $C_{12}H_{10}O_6N_2$: C, 51.81; H, 3.62; N, 10.07%.

Z–Ala–pGlu–NH$_2$: Recrystallized from EtOAc–ether; yield[7] 38%; mp 156—158 °C; $[\alpha]_D^{26}$ −67.6° (*c* 1.0, EtOH); NMR ($CDCl_3$–CD_3OD) δ 1.37 (3H, d, >CH–C$\underline{H}_3$), 1.90—2.80 (4H, m, CH–C$\underline{H}_2$–C$\underline{H}_2$–CO), 4.56 (1H, m, >C$\underline{H}$–$CONH_2$), 5.06 (2H, s, C_6H_5–C$\underline{H}_2$O), 5.43 (1H, q, NH–C$\underline{H}$–CO), 7.31 (5H, s, $C_6\underline{H}_5$–CH_2); IR (KBr) 1670, 1690, 1745 cm^{-1} (>C=O). Found: C, 57.79; H, 6.05; N, 12.44%. Calcd for $C_{16}H_{19}O_5N_3$: C, 57.65; H, 5.75; N, 12.61%.

Z–Val–pGlu–NH$_2$: Purified with a column of silica gel (solvent, $CHCl_3$–EtOAc, 1 : 4), and recrystallized from EtOAc–hexane; yield[7] 17%; mp 145—147 °C; $[\alpha]_D^{26}$ −33.1° (*c* 1.2, MeOH); NMR ($CDCl_3$–CD_3OD) δ 0.80 (3H, d, CH–C$\underline{H}_3$), 1.05 (3H, d, CH–C$\underline{H}_3$), 1.90–2.80 (5H, m, CH–C$\underline{H}_2$–C$\underline{H}_2$–CO and CH_3–C$\underline{H}$–CH_3), 4.65 (1H, m, >C$\underline{H}$–$CONH_2$), 5.09 (2H, s, C_6H_5–C$\underline{H}_2$–O), 5.50 (1H, m, NH–C$\underline{H}$–CO), 7.34 (5H, s, $C_6\underline{H}_5$–CH_2); IR (KBr) 1670, 1685, 1745 cm^{-1} (>C=O). Found: C, 60.08; H, 6.46; N, 11.89%. Calcd for $C_{18}H_{23}O_5N_3$: C, 59.82; H, 6.42; N, 11.63%.

Method for Ammonolysis and Analysis of Products. To 1—3 mg of samples was added NH_3-saturated MeOH at 0 °C. The resulting solutions were allowed to stand at 0 °C overnight, and concentrated *in vacuo*. The products were identified with authentic samples[8] by TLC[9] on Kieselgel 60F-254 plate. The products were separated also by preparative TLC.[10] Silica gel layers at the position containing the products were raked up and treated with 6 M HCl for 10 h at 110 °C for hydrolysis. The ratios of amino acids in the hydrolyzates were determined by an amino acid analyzer (JEOL JLC-6AS).

We wish to thank Mr. Akira Ide for technical assistance and the staff of the Research Laboratory of Toyo Jozo Co. Ltd. for elemental analyses.

The Transition-metal Catalyzed Dehalogenation of Aromatic Halides by NaOH–Alcohols. A Facile Method of Destroying Aromatic Polyhalides

Tadashi OKAMOTO* and Shinzaburo OKA
Institute for Chemical Research, Kyoto University, Uji 611
(Received July 25, 1980)

Synopsis. Aromatic halides are dehalogenated by heating with NaOH in alcoholic solvents in the presence of transition metal salts, such as rhodium(III) chloride or palladium(II) acetate and triphenylphosphine. Bis(pentabromophenyl) ether was converted into diphenyl ether in 2-propanol when treated for 5 h at 355 K with a catalytic cycle of more than 80.

Lately transition metal catalysts have been found to be useful for the substitution of aromatic halides.[1] Dehalogenation is the simplest type of these reactions, and many reports on the catalysis of palladium, rhodium, or nickel complexes using borohydride, formate, alkoxide, or secondary alcohols as the hydrogen source have been published.[2] These methods in the literature usually require low-valent metal complexes or powerful reducing agents such as borohydride. There has been one report on a dehalogenation catalyzed by rhodium(III) chloride using Na_2CO_3 in ethanol, but the substrate is limited to such activated halides as α-keto halides or benzyl halide.[3] In this report we wish to present a facile and inexpensive method of dehalogenation. Aromatic halides were heated with sodium hydroxide in alcoholic solvents in the presence of transition metal salts and triphenylphosphine to give dehalogenated aromatic compounds in moderate to excellent yields. No previous preparation of a low-valent catalyst or alkoxide was necessary.

Results and Discussion

The results for various substrates are listed in Table 1. The reactivity of bromide is higher than that of chloride, and electron-releasing substituents on the aromatic ring retard the reaction, as in the case of the oxidative-addition reaction of aryl halides with low-valent transition-metal complexes.[4] Palladium acetate–$2P(C_6H_5)_3$ was a better catalyst than $RhCl_3$ hydrate–$2P(C_6H_5)_3$. $NiBr_2[P(C_6H_5)_3]_2$ or $CoCl_2$ hydrate–$2P(C_6H_5)_3$ was ineffective for the reaction. This trend of reactivity is in accordance with that of the reduction potential (E_o) of metal salts.[5] These observations suggest that a low-valent metal complex is generated *in situ* and reacts with aromatic halides to give oxidative-addition products, which are then reduced by the alkoxide ion (or alcohol) according to the scheme shown by Eqs. 1—3, where X represents an anion such as a halide or acetate ion:

$$M^{n+}X_n \xrightarrow{R'_2CHO^- \text{ (or } R'_2CHOH)} M^{(n-2)+}X_{n-2} \quad (1)$$

$$M^{(n-2)+}X_{n-2} + ArY \longrightarrow M^{n+}(Ar)X_{n-2}Y \quad (2)$$

$$M^{n+}(Ar)X_{n-2}Y + R'_2CHO^- \text{ (or } R'_2CHOH) \xrightarrow{-Y^- \text{ (or } HY)} M^{(n-2)+}X_{n-2} + R'_2CO + ArH \quad (3)$$

Table 1. Rhodium(III)-catalyzed dehalogenation of aromatic halides[a]

Substrate	Solvent	Yield of[b] arenes/%
Bromobenzene	MeOH	30
Bromobenzene	EtOH	78
4-Bromoanisole	EtOH	65[c]
4-Bromoanisole	*i*-PrOH	69
4-Bromoanisole	EtOH	27[d]
β-Bromostyrene	EtOH	65
3-Bromopyridine	EtOH	64
4-Bromoacetophenone	EtOH	15[e]
4-Bromoacetophenone	EtOH	25[f]
4-Bromobenzoicacid	EtOH	44[g]
4-Chlorobenzoic acid	EtOH	0[g]
1-Chloro-1-phenylethane	EtOH	h

a) Reactions were carried out at 335 K for 16 h with a substrate/catalyst of 50 and a NaOH/substrate of 1.5. Catalyst : $RhCl_3$–$2P(C_6H_5)_3$. b) Determined by gas chromatography based on the amount of substrate used. c) The reaction temperature was 351 K. d) Na_2CO_3 was used instead of NaOH; 73 h. e) Accompanied by 1-phenylethanol (7%). f) Accompanied by diphenylmethanol (*ca.* 25%). g) The NaOH/substrate was 2.5. h) The products were ethylbenzene and styrene, with the relative ratio being around 1. The yields were not determined.

There is a substantial difference in the reactivity of alcohols, MeOH<EtOH<*i*-PrOH. The slower reaction with Na_2CO_3 compared with NaOH suggests that NaOH is effective not only in neutralizing the hydrogen halide generated, but also in facilitating the reduction of metal complexes in some way.[6]

As may be seen from Table 1, the reaction is applicable to pyridine derivatives and also to vinyl halides. An aliphatic saturated halide such as 1-chloro-1-phenylethane was dehalogenated to give ethylbenzene, but it was accompanied by a substantial amount of styrene, the elimination product. The reduction of the carbonyl group is another side reaction; 4-bromobenzophenone gave almost equimolar amount of diphenylmethanol and the normal dehalogenation product of benzophenone.

Polyhalogenated aromatic compounds are dehalogenated by this system easily. The results are summarized in Table 2. Bis(pentabromophenyl) ether was converted to diphenyl ether (92% yield) by the catalysis of palladium acetate–$2P(C_6H_5)_3$ over a 5 h period at 355 K with a catalytic cycle of more than 80. Although polychlorinated biphenyl (Kanechlor) was dehalogenated more sluggishly than the bromide, the present reaction is suitable for the purpose of destroying

Table 2. Dehalogenation of polyhalogenated aromatic compounds[a)]

Substrate (mmol)	Catalyst	Time/h	Dehalogenation (%)[b)]
Bis(pentabromophenyl) ether (1.9)	$Pd(OAc)_2$–$2P(C_6H_5)_3$	5	100
	$Pd(OAc)_2$–2Pyridine	56	94
	$RhCl_3$–$2P(C_6H_5)_3$	21	74
	$RhCl_3$–2DPE[c)]	56	87
Kanechlor 600 (4.3)	$Pd(OAc)_2$–$2P(C_6H_5)_3$	45	50
	$RhCl_3$–$2P(C_6H_5)_3$	19	33

a) The reaction was carried out at 355 K with a 20% excess of NaOH and 0.20 mmol of the catalyst in 10 ml of 2-propanol. b) Determined by the elemetal analysis of the product (mixture). c) Ethylenebis(diphenylphosphine).

environment-contaminating aromatic polychlorides, because highly chlorinated compounds, which are known to be difficult to destroy, were dehalogenated preferentially, as is illustrated in Fig. 1 for the dehalogenation of 2,3,4,5,6-pentachloroanisole. The figure further suggests the step-by-step mechanism of the dehalogenation reaction. There is no indication of a benzyne intermediate with a simultaneous elimination of two halogen atoms.

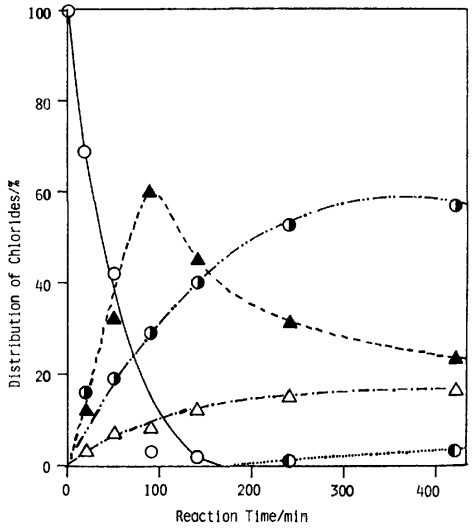

Fig. 1. Dehalogenation of 2,3,4,5,6-Pentachloroanisole. ○ Pentachloride, ▲ Tetrachloride, ◑ Trichloride, △ Dichloride, and ◐ Monochloride. $Pd(OAc)_2$, 0.27 mol; triphenylphosphine, 0.39 mmol; NaOH, 22.75 mol; substrate, 2.30 mmol in 10 ml of 2-propanol at 355 K. Product distribution was determined by gas chromatography.

Experimental

The palladium acetate was prepared by the method of Wilkinson.[7)] The other reagents were analytical-grade.

Dehalogenation of Aromatic Monohalides by $RhCl_3 \cdot 6H_2O$ and Triphenylphosphine. $RhCl_3 \cdot 6H_2O$ (20 mg), triphenylphosphine (40 mg), and NaOH (300 mg) were placed in a flask and deaerated. Into the flask we then added 5 mmoles of a substrate and 10 ml of a solvent, subsequently the mixture was stirred at 335 K for a specified period. The yields were determined by gas chromatography.

Dehalogenation of Bis(pentabromophenyl) Ether. Bis(pentabromophenyl) ether 1.78 g (1.9 mmol), NaOH 0.91 g (22.8 mmol), and the catalyst (0.2 mmol) were placed in a flask, and the mixture was flushed with nitrogen. Deaerated 2-propanol (10 ml) was then added to the flask, and the solution was refluxed for the specified period under stirring. The reaction mixture was then diluted with a 10-ml portion of H_2O and extracted by means of three 10-ml portions of hexane. The extract was concentrated and subsequently purified on a silica-gel column (hexane) from the base-promoted condensation products of acetone. The hexane effluent, which contained diphenyl ether and/or partly brominated diphenyl ethers, was concentrated and weighed. The average extent of dehalogenation was determined by the elemental analysis of the residue. The material balance of the reaction, as determined from the weight and the extent of dehalogenation of the residue, was generally good.[8)]

The dehalogenation of Kanechlor was carried out in a similar manner except for the amounts of the substrate and NaOH.

A Simple Method for the Esterification of Carboxylic Acids Using Chlorosilanes

Ren NAKAO,* Kunio OKA, and Tsugio FUKUMOTO
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka 593
(Received July 28, 1980)

Synopsis. Various carboxylic esters, including some with bulky substituents, are prepared in good yields from carboxylic acids and alcohols under mild conditions by the use of trimethylchlorosilane, dimethyldichlorosilane, methyltrichlorosilane, or tetrachlorosilane.

The esterification of carboxylic acids with alcohols is one of the most important reactions in organic synthesis, and quite a number of methods have been investigated. Among them, 2-halopyridinium salts,[1] (chloromethylene)dimethylammonium chloride,[2] 1-(sulfonyloxy)benzotriazoles[3] and graphite bisulfate[4] have been used successfully as coupling reagents for the reaction. In the course of the study of the reaction of acetoxytrimethylsilane with alcohols in the presence of hydrogen chloride,[5] we found that trimethylchlorosilane was a convenient reagent for the esterification of carboxylic acids with alcohols.

In this note, we wish to report some results of the esterification carried out by the use of chlorosilanes. The esterification was performed under the following standard conditions: $(CH_3)_3SiCl$ (1.7 mmol) was added to a mixture of RCOOH (3.3 mmol) and R'OH (5.0 mmol) in 2-methyltetrahydrofuran. After the reaction mixture had been allowed to stand for 15 min at room temperature, the products were analysed by GLPC. In a neat reaction, the starting homogeneous reaction mixture progressively separates into two layers as the reaction proceeds. Therefore, the solvent was chosen so as to be keep the reaction mixture homogeneous and to be favorable for GLPC analysis.

The results obtained with various carboxylic acids and alcohols by the use of trimethylchlorosilane are given in Table 1. In all cases, the production of hexamethyldisiloxane was confirmed. Although the esterification with secondary alcohols is slower than that with primary alcohols, the yields of all the esters, including sterically hinderd isobutyl pivalate, are very high. Therefore, trimethylchlorosilane can be said to be a very efficient and convenient reagent for the esterification of carboxylic acids with primary and secondary alcohols at room temperature. When, however, *t*-butyl alcohol and phenol were subjected to a reaction with acetic acid in the presence of trimethylchlorosilane, the reaction products were complicated and the yields of *t*-butyl acetate and phenyl acetate were only 9 and 19% respectively.

The rate of esterification decreases with the decrease in the amount of trimethylchlorosilane added. However, it must be emphasized that 1 mol of trimethylchlorosilane serves to produce more than 1 mol of the ester. This indicates that trimethylchlorosilane does not participate only as a hydrogen chloride source and/or a dehydrating agent in the reaction. When methoxytrimethylsilane, which is expected to be formed by the reaction of trimethylchlorosilane and methanol, was allowed to react with acetic acid in the presence of hydrogen chloride, methyl acetate was obtained in a 93% yield, along with the production of hexamethyldisiloxane. Therefore, the following scheme seems to be most probable for the esterification with trimethylchlorosilane:

$$(CH_3)_3SiCl + R'OH \longrightarrow (CH_3)_3SiOR' + HCl \quad (1)$$

$$RCOOH + (CH_3)_3SiOR' \xrightarrow{HCl} RCOOR' + (CH_3)_3SiOH \quad (2)$$

$$(CH_3)_3SiOH + R'OH \xrightarrow{H^+} (CH_3)_3SiOR' + H_2O \quad (3)$$

$$2(CH_3)_3SiOH \longrightarrow (CH_3)_3SiOSi(CH_3)_3 + H_2O \quad (4)$$

Table 1. Esterification of various carboxylic acids with alcohols using $(CH_3)_3SiCl$[a] $RCOOH + R'OH \xrightarrow{(CH_3)_3SiCl} RCOOR'$

R	R'	$\frac{[(CH_3)_3SiCl]}{[RCOOH]}$	Solvent	Reaction time	Yield of ester/%
CH_3	CH_3	0.13	2-Me-THF	30 min	72
CH_3	CH_3	0.13	2-Me-THF	110 min	87
CH_3	CH_3	0.5	2-Me-THF	15 min	97
C_2H_5	CH_3	0.5	2-Me-THF	15 min	95
$(CH_3)_2CH$	CH_3	0.5	THF	15 min	98
C_2H_5	CH_3	0.5	2-Me-THF	100 h	93
$(CH_3)_3C$	CH_3	0.5	THF	15 min	91
$(CH_3)_3C$	$(CH_3)_2CHCH_2$	0.5	2-Me-THF	15 min	90
CH_3	C_2H_5	0.5	2-Me-THF	15 min	92
CH_3	CH_2=$CHCH_2$	0.6	2-Me-THF	15 min	92
CH_3	$(CH_3)_2CH$	0.5	2-Me-THF	15 min	37
CH_3	$(CH_3)_2CH$	0.5	2-Me-THF	24 h	93
CH_3	$C_2H_5(CH_3)CH$	0.5	2-Me-THF	48 h	95
CH_3	*c*-C_6H_{11}	0.5	*n*-$C_{11}H_{24}$	48 h	81

a) Reactions were performed at room temperature.

In the initial stage of the reaction where alcohol remains in a large quantity, Eq. 3[6] may be faster than Eq. 4. However, in the final stage, Eq. 4 may become favorable. During the reaction, the alkoxytrimethylsilane produced in Eq. 3 participates repeatedly in the esterification of carboxylic acid *via* Eq. 2.

Other chlorosilanes can be used in this esterification as well as trimethylchlorosilane. By using dimethyldichlorosilane ($[(CH_3)_2SiCl_2]/[CH_3COOH]=0.25$), methyltrichlorosilane ($[CH_3SiCl_3]/[CH_3COOH]=0.17$) and tetrachlorosilane ($[SiCl_4]/[CH_3COOH]=0.13$) in the reaction of acetic acid and methanol, methyl acetate was obtained in 98, 97, and 96% yields respectively.

Experimental

The gas-chromatographic analyses were made by a Yanagimoto GCG-5DH apparatus on a 3-m column containing 30% dioctyl phthalate on Celite 545 or a 2.5-m column containing 25% silicon DC-200 on Celite 545, using helium as the carrier gas. The NMR spectrum was obtained on a JEOL JNM-100 apparatus, with tetramethylsilane as the internal standard.

All of the reagents and solvents were used after distillation. The products were identified and estimated by GLPC. Commercial materials were used as the standerds except for *s*-butyl pivalate. The *s*-butyl pivalate used as a standard was prepared by the reaction of pivalic acid and *s*-butyl alcohol using $(CH_3)_3SiCl$: bp 150 °C, NMR (CCl_4); δ 0.92 (d, 6, $CH(C\underline{H}_3)_2$), 1.15 (s, 9, $C(CH_3)_3$), 1.88 (m, 1, CH), 3.72 (d, 2, OCH_2).

Reaction of Acetic Acid with Methoxytrimethylsilane. CH_3COOH (1.2 mmol), $(CH_3)_3SiOCH_3$ (1.2 mmol), dry HCl (0.6 mmol), and 2-methyltetrahydrofuran (0.33 cm^3) were transferred from individual bulbs to a glass tube under a vacuum. The tube, after being sealed, was allowed to stand overnight at room temperature. The products were analysed by GLPC. Methoxytrimethylsilane was prepared from trimethylchlorosilane and methanol, using pyridine as the hydrogen chloride acceptor.

6) V. Bazant, V. Chvalovsky, and J. Rathousky, "Organosilicon Compounds," Academic Press, New York and London (1965), Vol. 1, p. 56; the reaction of silanols with an excess of methanol is of importance for determining the Si–OH bands. The equilibrium is rapidly established under acid catalysis and shifts toward the right by the removal of the water released. In our reaction, the equilibrium of Eq. 3 is shifted in the same direction by the removal of alkoxytrimethylsilane by means of Eq. 2.

Synthesis and Reactions of Perylenecarboxylic Acid Derivatives. VII. Hydrolysis of *N,N'*-Dialkyl-3,4 : 9,10-Perylenebis(dicarboximide) with Sulfuric Acid

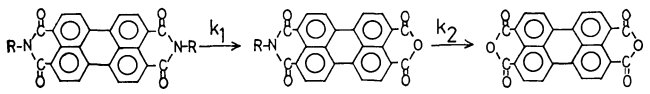
Yukinori NAGAO* and Takahisa MISONO

Department of Industrial Chemistry, Faculty of Science and Technology, Science University of Tokyo, Yamazaki, Noda 278

(Received August 6, 1980)

Synopsis. The hydrolysis of *N,N'*-dialkyl-3,4 : 9,10-perylenebis(dicarboximide) (alkyl=CH_3, CH_2CH_3, $CH_2CH_2CH_3$, and $CH_2CH_2CH_2CH_3$) with sulfuric acid at 180—200 °C gave *N*-alkyl-3,4 : 9,10-perylenetetracarboxylic monoanhydride monoimide (alkyl=CH_3, CH_2CH_3, $CH_2CH_2CH_3$, and $CH_2CH_2CH_2CH_3$). The kinetics of the reaction were determined spectroscopically.

Previous work has shown that 3,4 : 9,10-perylenetetracarboxylic monoanhydride monoimide (**2a**—**e**) can be prepared by the condensation of 3,4 : 9,10-perylenetetracarboxylic dianhydride (**3**) with alkylamine.[1] The condensation of **2a**—**e** with arylamine gave *N*-alkyl-*N'*-aryl-3,4 : 9,10-perylenebis(dicarboximide).[2] This work was undertaken to examine whether **2b**—**e** could be prepared from *N,N'*-dialkyl-3,4 : 9,10-perylenebis(dicarboximide) (**1b**—**e**). **2a** was prepared by the hydrolysis of 3,4 : 9,10-perylenebis(dicarboximide) (**1a**) with sulfuric acid.[3] The formation of **2b**—**e** in the hydrolysis of **1b**—**e** with sulfuric acid was then determined.



1a~e 2a~e 3

R = a; H, b; CH_3, c; CH_2CH_3, d; $CH_2CH_2CH_3$, e; $CH_2CH_2CH_2CH_3$

Experimental

Materials. **1b**—**e**, **2b**—**e**, and **3** were prepared by the procedures reported before.[1]

Hydrolysis. A flask containing 50.0 ml of 95%-sulfuric acid was set in a thermostated bath at the reaction temperature. To the flask was added 50 mg of finely powdered **1b**—**e** with stirring, and the reaction mixture was stirred to provide complete mixing. A small amount of the mixture was taken at an appropriate time interval. One half of the sample was used for measurement of absorbance after dilution with 95.0%-sulfuric acid and another half of the sample was poured into water to precipitate organic materials. These were separated by contrifugation, dried, dissolved in 1% potassium hydroxide, and analyzed by paper chromatography.

Measurements and Calculations. Absorbances were measured with a Hitachi 101 Spectrophotometer. The determination of the reaction mixture and paper chromatography were carried out as in the experiment reported before.[1] The calculations of composition or rate ratio $K(=k_2/k_1)$ were made by IBM 370 computer.

Results and Discussion

In the reactions at 180—200 °C, all the reaction mixtures have been proved to contain only three components, **1b**—**e**, **2b**—**e**, and **3** by paper chromatography. The compositions in the reaction mixture were determined by spectroscopy. The contents, $C_I/(C_I+C_M+C_A)$, $C_M/(C_I+C_M+C_A)$, and $C_A/(C_I+C_M+C_A)$ where C_I, C_M, and C_A are the concentrations of **1b**—**e**, **2b**—**e**, and **3**, respectively, were obtained from the standard absorbances of **1b**—**e**, **2b**—**e**, and **3**. Figure 1 shows a typical reaction curve. The pattern was similar in all reactions. As the reactions proceed, the yields of **2b**—**e** initially increased, but decreased after reaching a maximum. The maximum yields of **2b**—**e** were compared. Table 1 gives the maximum yields of **2b**—**e** in the reactions at 180, 190, and 200 °C. It is shown

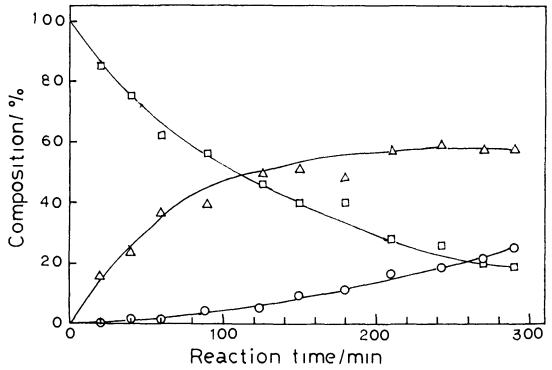


Fig. 1. Reaction of *N,N'*-dipropyl-3,4 : 9,10-perylenebis (dicarboximide) (**1d**) with H_2SO_4.
Reaction temp: 180 °C. □: *N,N'*-Dipropyl-3,4: 9,10-perylenebis(dicarboximide) (**1d**), △; *N*-Propyl-3,4: 9,10-perylenetracarboxylic monoahydride monoimide (**2d**), ○: 3,4: 9,10-Peryleneteracarboxylic dianhydride (**3**).

Table 1. The maximum yields of *N*-alkyl-3,4: 9,10-perylenetetracarboxylic monoanhydride monoimide (**2b**—**e**)

N,N'-Dialkyl-3,4 : 9,10-perylenebis-(dicarboximide)(**1b**—**e**) R		Temp °C	Time min	Maximum yield of **2b**—**e** %	
1b	CH_3	180	270	44	**2b**
		190	200	48	
		200	100	47	
1c	CH_2CH_3	180	220	55	**2c**
		190	140	49	
		200	40	45	
1d	$CH_2CH_2CH_3$	180	240	58	**2d**
		190	80	56	
		200	40	50	
1e	$CH_2CH_2CH_2CH_3$	180	180	53	**2e**
		190	150	47	
		200	40	40	

that all the values are in the range of 40—60%; the value is the smallest in **1b** and increases a little at lower temperature. The yields of **2b**—**e** isolated from the reaction mixture at 180 °C were **2b** : 31%, **2c** : 31%, **2d** : 31%, **2e** : 41%. Thus the yields of separable **2b**—**e** are lower than the spectroscopic yields in Table 1, because of the difficulty of their separation.

There was a scattering of the data points on a reaction curve as the concentration of **1b**—**e** increased over 100 mg/50 ml sulfuric acid; this became more serious at higher temperature, and was the largest in **1b** and the smallest in **1d**. In the reaction of **1a**,[3] no scattering was observed in ten times the concentration (500 mg/50 ml). This was attributed to the fact that the solubility of **1b**—**e**, which has an alkyl group, is smaller than that of **1a**. For these reasons, more sulfuric acid is necessary for the preparation of **2b**—**e** from **1b**—**e** than that from **1a**.

Plots of $\ln(C_I/C_{Io})$, where C_{Io} is the initial concentration of **1b**—**e**, *vs.* time are linear in the reaction of 50 mg **1b**—**e** at 180 °C. The rate constants k_1, for the reaction of **1b**—**e** to **2b**—**e**, were calculated from the slope. The rate ratios $K(k_2/k_1)$, where k_2 is the rate constant of **2b**—**e** to **3**, were calculated from Eq. 1.[1] Most of the values in each reaction were constant. These results indicated that the reaction followed a pseudo-first-order process. The rate constants k_1 and

$$C_M/C_{Io} = \{1/(1-K)\}\{(C_I/C_{Io})^K - (C_I/C_{Io})\} \quad (1)$$

rate ratio K are given in Table 2. All the rate constants are in the range of $0.45—0.95\times10^{-2}$ min^{-1}, and the rate ratio K are in the range of 0.35—0.50. A longer alkyl chain decreased the rate constants and ratios in the condensation of **3** with alkylamine,[1] but there was no such significant effect of alkyl groups in this reaction. All the k_1 values of **1b**—**e** were smaller than that of **1a** ($k_1=1.06\times10^{-2}$ min^{-1}).[3] Polar substituent constant σ^* are : H : +0.490, CH_3 : 0.000, C_2H_5 : −0.100, n-C_3H_7 : −0.115, n-C_4H_9 : −0.130.[4] The large k_1 value in **1a** is related to the polar effects of *N*-substituents.

(Received September 1, 1980)

Synopsis. The ^{13}C chemical shifts of 5-substituted polychlorobicyclo[2.2.1]heptene derivatives were determined. The chlorine, 5-*endo* and 5-*exo* substituent effects on the chemical shifts were discussed. The differences in the C_3 and C_7 chemical shifts are shown to be helpful for the identification of the *endo* and *exo* isomers. A possible operation of the interaction of pi electrons with a carbon-chlorine dipole is also discussed.

Because of their rigid molecular structures and fixed geometry, bicyclo[2.2.1]heptene derivatives have been extensively investigated by means of the ^1H and ^{13}C nuclear magnetic resonance methods.[1-3] The polar substituent effect on the ^1H and ^{13}C chemical shifts has been actively discussed as well as the molecular geometry effect on spin-coupling phenomena. Some chlorine nuclear quadrupole resonance (NQR) spectra of chlorobicyclo[2.2.1]heptenes were measured, and the ^{35}Cl NQR frequencies were discussed in terms of the charge density on the chlorine atoms.[4,5] However, the ^{13}C chemical shifts of chlorobicyclo[2.2.1]heptenes seem to have been reported only sporadically. In connection with our research project concerning high-pressure Diels-Alder reactions, we wish to report here some results of the systematic ^{13}C NMR examination of 5-substituted polychlorobicyclo[2.2.1]heptenes. The assignment of the C_5-*endo* and *exo* isomers by means of the ^{13}C NMR spectra is one of the purpose of the present investigation. Discussion will also be focused on the evidence of the interaction of the pi-electrons with a carbon-chlorine dipole.

Results and Discussion

The compounds employed in this work were synthesized by the usual Diels-Alder reactions and are listed in the Scheme. The proton chemical shifts of the compounds have been given elsewhere.[6] All the compounds gave nicely resolved ^{13}C NMR spectra. In most instances, the assignment of the signals to specific carbons was straightforward on the basis of the earlier results,[1-3] together with off-resonance decoupled spectra. In some cases, however, the assignment was made by using the substituent parameters of Lippmaa *et al.*[1]

Substituent Effect. The introduction of chlorine atoms onto C_1, C_4, and C_7 induced a pronounced paramagnetic effect on the substituted atoms and the neighbors. However, the chlorine atoms on C_2 and C_3 exerted a diamagnetic influence on the shifts of the substituted sp^2 carbon atoms.

For compounds **1** and **1'**, three carbons are in γ-positions with respect to the 5-substituent, and the orientation of the substituent affects the shieldings of the γ-carbon atoms (C_1, C_3, and C_7). The steric perturbation caused by the 5-substituent can be anticipated at C_3 by

Scheme 1.

the *endo* 5-substituent, and at C_7 by the *exo* one. Thus, for each *endo* isomer, the C_3 resonance appeared at a higher field than the C_3 of the corresponding *exo* isomer. This shielding effect of the *endo* 5-substituent decreased with the increase in the numbers of the chlorine substituents. On the contrary, the C_7 nuclei were indeed shielded by the *exo* 5-substituent, while the *endo* 5-substituent appeared to cause a slight deshielding of the C_7 atoms.[7] These effects increased in the presence of the chlorine substituents (except for **5'**). These differences, which are real but small, may provide an approach for the assignment of the *endo-exo* isomer pairs.

Pi Electron-Dipole Interaction. The observed high-field shifts of the C_2 and C_3 carbons of the polychloro derivatives can be explained in terms of the electromeric effect of the chlorine atoms.[8] Particularly, the pentachloro derivative with the *anti* chlorine atom on C_7(**3n**) exhibited both the C_2 and C_3 signals at lower fields than the corresponding 7-syn-Cl isomer (**4n**) did. In contrast, the C_7 of **3n** was observed at a higher field than that of **4n**. Because the usual inductive and electromeric effects of the chlorine atom are expected to be quite similar for **3n** and **4n**, and because the double-bond anisotropy can not explain the difference in the bridged methylene ^{13}C chemical shifts of these compounds, this observation implies the operation of some sort of charge delocalization from the double bond to the C_7 carbon atom of the *anti* isomer(**3n**). The high solvolytic reactivity of *anti*-7-norbornenyl chloride has been interpreted in terms of pi-participation. In this connection, Chihara[4] reported the ^{35}Cl NQR frequencies of *anti*-7-

Table 1. Carbon-13 chemical shifts of bicyclo[2.2.1] heptene derivatives (ppm from TMS)

and *syn*-7-norbornenyl chlorides. The results clearly showed that the s-character of the carbon orbital in the C–Cl bond of the latter was larger than that of the former. This conclusion agrees with the ^{13}C chemical shifts and $J_{^{13}C-H}$ values of the C_7 carbon atoms.[9,10] Since this pi-participation involves the transfer of the charge from the double bond to the polarized C_7–Cl bond, this participation may be inhibited by the chlorine substituents on C_2 and C_3, which make the double bond less nucleophilic. The difference in the ^{13}C chemical shift of C_7 between **3n** and **4n** is 2.9 ppm, whereas that between *anti*-7- and *syn*-7-norbornenyl chlorides is 5.4 ppm;[10] this indicates a weaker pi-participation for the 2,3-dichlorinated derivative, **3n**.

Experimental

All the ^{13}C NMR spectra were recorded on a JEOL PS-100 FT spectrometer. The chemical shifts were recorded in ppm from TMS. The compounds employed in this work were prepared from the corresponding dienes and methyl acrylate or acrylonitrile by the Diels-Alder reaction. The details were reported elsewhere.[6] Each isomeric adduct was obtained by preparative glc using a Yanagimoto GCG-3 or a Shimadzu GC-6A gas chromatograph.

Selectivity in the *N*- and/or *C*-Alkylation of Schiff Bases Catalyzed by Crown Ether

Sadatoshi AKABORI,* Michiko OHTOMI, Kazuhide SHIMADA, and Ayami TAKEMURA

Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274

(Received September 3, 1980)

Synopsis. The reaction of anions derived from Schiff bases (*N*-(α-methylbenzylidene)aniline and *N*-cyclohexylideneaniline) with ethyl iodide or diethyl sulfate in aprotic solvents, in the presence of 18-crown-6, is found to give a high ratio of $N/(N+C)$ or $C/(N+C)$ alkylation when conducted in benzene or in dioxane.

It is well known that the separation of ion-pairs and thus the anion activation can be obtained through the selective complexation of cations by organic ligands. This is dramatically shown by the enhancement in reaction rates by addition of crown ethers[1] and cryptands to homogeneous or heterogeneous reaction media. In previous papers,[2,3] we have shown that alkylation of sodium 2-naphtholate and sodium phenolate, in the presence of macrocyclic polyethers, is found to give high ratios of $O/(O+C)$ alkylation when conducted in aprotic solvents and in water. Heiszwolf *et al.*[4] found that ambident anions, derived from the reaction of a Schiff base with a strong base, could be alkylated with alkyl halide or dialkyl sulfate in aprotic solvents and that the nature of the solvent and of the alkylating agent played a decisive role in determining the reaction course of the ambident anion. Thus, in analogy with sodium phenolate or sodium 2-naphtholate,[2,3] it may be expected that in the presence of these macrocyclic polyethers the alkylation in solvents having low dielectric constants will result in predominant formation of the *N*- or *C*-alkylation product. Therefore, we have investigated the effect of 18-crown-6 on the yield and on the $N/(N+C)$ ratios of alkylation products in the reaction of anions (**2**), derived from Schiff bases, with ethyl iodide and diethyl sulfate under mild reaction conditions.

The following alkylations of ambident anions (**2a** and **2b**) derived from Schiff bases (**1a** and **1b**) with ethyl iodide or diethyl sulfate were run in aprotic solvents with or without added 18-crown-6 at appropriate temperatures. Table 1 summarizes the results of alkylation, where the effects of 18-crown-6 on the yields and on the $N/(N+C)$ ratios of the products can be seen. As the data in Table 1 show, the addition of 18-crown-6 to the reaction mixtures affects the $N/(N+C)$ ratios of the products to remarkable extents. In the absence of 18-crown-6, the reaction of Schiff base with ethyl iodide in benzene gave no alkylation products, whereas in the presence of 18-crown-6 the reaction occurs to give the *C*-alkyl derivative as the main product. These results may be interpreted on the basis that ionization of **1a** did not occur due to the low solubility of sodium hydride in benzene. Indeed, we could not observe any deep color change of the reaction mixture due to ambident anion formation when the reaction of **1a** with sodium hydride was carried out in benzene for several h at 80 °C. Furthermore, in the presence of 18-crown-6, the reactivity of the carbon site is enhanced relative to that of the nitrogen site of the ambident anion. These results can be explained as follows. Sodium hydride is solubilized in benzene to produce a "crowned" ion pair, in which Na^+ is linked coordinately to both the crown ether and the more electronegative nitrogen atom of the ambident anion. But the possibility of *C*-alkylation due to formation of a free naked anion cannot be ruled out. The *C*-alkylation is thought to take place as the main process.

In the reaction of the ambident anion (**2**) with diethyl sulfate in dioxane, the $N/(N+C)$ alkylation ratio is rather low; however, in the presence of 18-crown-6, the reaction under similar conditions gives a high yield of the *N*-alkylation, together with a low yield of the *C*-alkylation. These finding suggest that in the absence of 18-crown-6, the ambident anion (**2**), in analogy with sodium naphtholate[2] in dioxane and THF, exists as ion pairs and aggregates of a relatively high order; in the presence of 18-crown-6, however, the resulting ambident anion exists as an almost free anion due to solvation of the "crowned" sodium cation by dioxane because of the *N*-alkylation takes place. In support of this

Table 1. Alkylation of schiff bases[a]

Substrate	Alkylating agent	Solvent	18-Crown-6	Ionization time / h	Ionization temp / °C	Products, Yield/%[b] *C*-alkylation		*N*-alkylation		Total	$N/N+C$ ratio
1a	EtI	C_6H_6	presence	25	80	**3a**	58	**4a**	5	63	0.08

a) The alkylations of ambident anions with ethyl iodide or diethyl sulfate were carried out at 15 °C for 60 min. b) These results were obtained by GLC.

explanation, the reaction in Diglyme, in which the dissociation of sodio-derivative (**2**) takes place, fails to show any effect of the 18-crown-6 on the product ratio. It is quite remarkable that *C*-alkylation of Schiff bases proceeds smoothly to afford **3a** and **3b** in good yields. Furthermore, in the case of **1b**, the yield of *N*-alkylation products **4b** (84%) was higher than the yield reported from the described procedures,[4] whereas for **1a** yields were relatively low compared with those obtained by reported methods. Our method, however, requires milder conditions of the reaction than alkylation by means of Et_3OBF_4 in Ethyl Cellosolve and ethyl iodide in xylene.[4]

Experimental

The products were analyzed on a Hitachi-023 gas chromatography equipped with a flame-ionization detector. We used a 2 m×3 mm stainless steel column packed with 60—80 mesh Chromosorb-W NAW (washed with acid and treated with dimethyldichlorosilane) coated with 20% Apiezon-T (for the analysis of alkylation products of *N*-(α-methylbenzylidene)-aniline at *ca.* 222 °C) or a 1 m×3 mm stainless steel column packed with 60—80 mesh Chromosorb-W NAW (washed with acid and treated with dimethyldichlorosilane) coated with 20% Versamide (for the analysis of alkylation products of *N*-cyclohexylideneaniline at *ca.* 140 °C).

Materials. *N*-(α-methylbenzylidene)aniline,[5] *N*-cyclohexylideneaniline,[5] and authentic samples (*N*-(α-propylbenzylidene)aniline,[5] *N*-ethyl-*N*-(α-methylbenzylidene)-aniline,[6] *N*-(2-ethylcyclohexylidene)aniline[5] and *N*-(1-cyclohexenyl)-*N*-ethylaniline[6]) were prepared according to the procedures described in the literature. Sodium hydride and 18-crown-6 were of commercial origin and were used without further purification. Ethyl iodide and diethyl sulfate were purified by distillation, as were the solvents.

General Procedure. Typical procedures for the reaction of ethyl iodide or diethyl sulfate with *N*-(α-methylbenzylidene)-aniline and *N*-cyclohexylideneaniline follow.

Alkylation of N-*(α-Methylbenzylidene)aniline with Ethyl Iodide in Benzene.* Into a 50 ml round-bottomed flask equipped with a magnetic stirring bar, 60% sodium hydride in oil (7.5 mmol), *N*-(α-methylbenzylidene)aniline (6.2 mmol), 18-crown-6 (7.6 mmol), and 13 ml of benzene were introduced. The reaction mixture was stirred at 80 °C. There was evolution of hydrogen, which ceased after 25 h. The resulting turbid brown solution was cooled to 15 °C and ethyl iodide (13 mmol) was added with cooling. The color changed to light yellow at the end of the addition. The reaction mixture was stirred for a further 1.0 h and then filtered to remove inorganic salts and the filtrate was analyzed by GLC. GLC analysis revealed the presence of three components, which were identified as **4a** (5%), unreacted Schiff base **1a** (37%), and **3a** (58%); the relative retention times of these three components were 1.00 : 1.08 : 1.30.

Alkylation of N-*cyclohexylideneaniline with Ethyl Iodide in Benzene.* A solution of **1b** (9.2 mmol) and 18-crown-6 (9.1 mmol) in 20 ml of benzene was stirred with 60% sodium hydride in oil (13 mmol) at 80 °C for 16 h. There was evolution of hydrogen, which ceased after 16 h. The resulting turbid yellow-brown solution was then cooled to 15 °C and treated with diethyl sulfate (9.3 mmol). The color changed to light yellow at the end of the addition of diethyl sulfate. After the reaction mixture was stirred for 10 h, the inorganic salts were filtered off and the filtrate was analyzed by GLC. The analysis by GLC revealed the presence of **4b** (11%), **1b** (18%), and **3b** (67%); the relative retention times of these compounds were 1.00 : 0.28 : 1.20.

Azadi-π-methane Rearrangement Involving an Oxime Group

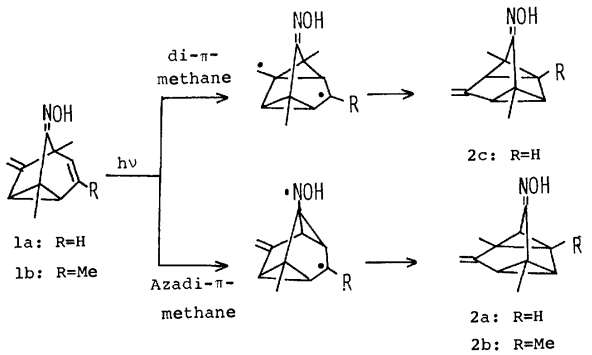
Makoto NITTA,* Ichiro KASAHARA, and Tomoshige KOBAYASHI

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received September 3, 1980)

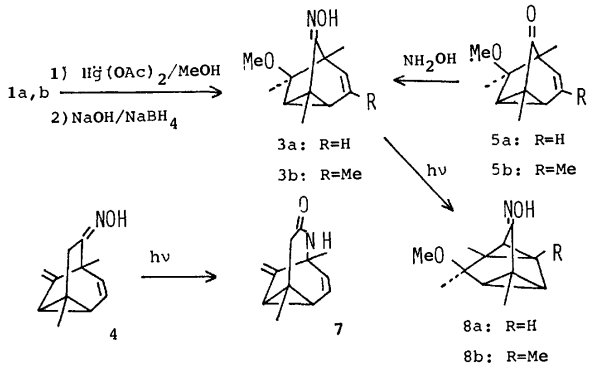
Synopsis. Photoreaction of *exo*-6-methoxy-1,5,6-trimethyl or *exo*-6-methoxy-1,3,5,6-tetramethyltricyclo[3.2.1.-$0^{2,7}$]oct-3-en-8-one oxime underwent azadi-π-methane rearrangement leading to endo-7-methoxy-2,6,7-trimethyl or endo-7-methoxy-1,2,6,7-tetramethyltetracyclo[3.3.0.0.$^{2,8}0^{4,6}$]octan-3-one oxime. However, the one-carbon ring enlarged 5,8-dimethyl-9-methylenetricyclo[3.3.1.$0^{2,8}$]nona-3-en-6-one oxime underwent photo-Beckmann rearrangement to afford 5-aza-2,6-dimethyl-10-methylenetricyclo[4.3.1.$0^{2,9}$]deca-7-en-4-one.

Oximes undergo photoreactions leading to nitriles[1] or oxaziridine which rearranges to amides and/or lactams (photo-Beckmann rearrangement).[2] In a previous paper, we reported the photochemical reaction of 1,5-dimethyl- and 1,3,5-trimethyl-6-methylenetricyclo[3.2.1.$0^{2,7}$]oct-3-en-8-one oximes (**1a** and **1b**). These compounds underwent two types of di-π-methane rearrangement to afford **2a**, **2b**, and **2c**. The former two photoproducts are considered to be derived from the azadi-π-methane rearrangement involving the oxime moiety.[3] To examine the complementary effect of the ring size and chromophore on the azadi-π-methane rearrangement, we investigated the photochemistry of *exo*-6-methoxy-1,5,6-trimethyl and *exo*-6-methoxy-1,3,5,-6-tetramethyltricyclo[3.2.1.$0^{2,7}$]oct-3-en-8-one oximes (**3a** and **3b**) and 5,8-dimethyl-9-methylenetricyclo-[3.3.1.$0^{2,8}$]nona-3-en-6-one oxime (**4**), which is an one-carbon ring enlarged oxime of **1a**.



Scheme 1.

The required oximes **3a**, **3b**, and **4** were synthesized from the known ketones by the standard method (see Experimental). Direct preparative irradiation of **3a** and **3b** in anhydrous acetonitrile with 254 nm lamps afforded **8a** and **8b** in 20% and 57% yields, respectively. The NMR spectrum of **8a** exhibited four protons of cyclopropane ring at δ 1.90 (d, J=6.0 Hz), 1.92 (d, J=6.0 Hz), 2.25 (d, J=6.0 Hz), 2.29 (d, J=6.0 Hz) and hydroxyl proton at δ 8.90 (broad s) in addition to the protons of three methyl groups and methoxyl group at δ 1.09, 1.17, 1.35, and 3.26. The NMR spectrum of **8b** exhibited three protons of cyclopropane ring at δ 1.44 (d, J=6.0 Hz), 1.82 (d, J=6.0 Hz), 2.04 (s) and hydroxyl proton at δ 8.20 (broad s), in addition to the protons of four methyl groups and methoxyl group at δ 1.06, 1.20, 1.29, 1.35, and 3.29. These chemical shifts, the coupling patterns of these photoproducts, and the comparison of these data with those of **2a**, **b**, **c**[3] and their related compounds[7] are in good agreement with the proposed structures. The formations of **8a**, **b** are ascribed to be an azadi-π-methane rearrangement involving the oxime group. Since the photorearrangement did not proceed in the presence of acetophenone or acetone as the sensitizer, the singlet excited state might be involved in the photorearrangement of **3a**, **b**.



Scheme 2.

On the other hand, the direct irradiation of **4** in anhydrous acetonitrile with 254 nm lamps afforded 5-aza-2,6-dimethyl-10-methylenetricyclo[4.3.1.$0^{2,9}$]deca-7-en-4-one (**7**) in 60% yield. The absorption due to a carbonyl group at 1695 cm^{-1} suggests the existence of an amide function. The NMR spectrum of **7** exhibited the existence of a divinylcyclopropane moiety (see Experimental) similar to **4**. Each signal and coupling constant could be assigned with the help of a decoupling technique. The relatively high chemical shift at δ 2.44 (2H, s) for hydrogens of methylene group is suggestive of α-methylene of carbonyl group;[2d,e] thus the structure of **7** was deduced. This photoproduct **7** might be derived from the intermediate of oxaziridine and subsequent photoinduced migration of an alkyl group.[2]

The oximes **3a**, **b** which have azadi-π-methane systems in similar skeletons to the oxime **1a**, **b** underwent azadi-π-methane rearrangement. An attempted photoreaction of bicyclo[2.2.1]hept-2-en-5-isopropylimine did not undergo azadi-π-methane rearrangement.[8] As is shown in the present study, the oxime **4** which has two di-π-methane systems in the one-carbon ring enlarged skeleton, underwent photo-Beckmann rearrangement. The present results provide a complementary support for the first example of azadi-π-methane rearrangement of **1a**, **b**[3] as well as suggesting that the azadi-π-methane rearrangement might be controlled by the effect of suitable chromophoric interaction and/or the rigidity of the molecular framework.

Experimental

Preparation of exo-*6-Methoxy-1,5,6-trimethyltricyclo[3.2.1.0^{2,7}]-oct-3-en-8-one Oxime (***3a***).* *Method A*: To the stirred solution of mercury (II) acetate (6.4 g, 20 mmol) in anhydrous methanol (40 cm^3) was added **1a** (3.5 g, 20 mmol). After 30 min, 20 cm^3 of 3 mol dm^{-3} aqueous sodium hydroxide, then 380 mg (10 mmol) of sodium borohydride in 20 cm^3 of 3 mol dm^{-3} aqueous sodium hydroxide were added to the reaction mixture. This reaction mixture was stirred an additional 15 min and extracted with ether. The dried (Na_2SO_4) organic portion was evaporated *in vacuo*, and the residue was separated by preparative TLC on alumina with chloroform as the eluent. The first band from the TLC plates gave a colorless crystalline solid of **3a**: mp 161—163 °C (from EtOH); IR ($CHCl_3$): 3580, 1680, 1115 cm^{-1}; NMR ($CDCl_3$): δ 1.00 (3H, s), 1.06 (3H, s), 1.8—2.0 (2H, m), 1.68 (3H, s), 3.32 (3H, s), 5.45 (1H, d×d, J=9.0, 3.5 Hz), 5.96 (1H, d×d, J=9.0, 5.0 Hz), 8.54 (1H, broad s); UV (EtOH): 240 nm (end absorption, ε 4000); MS *m/e* (rel intensity): 207 (38, M$^+$), 43 (100). Found: C, 69.43; H, 8.00; N, 6.74%. Calcd for $C_{12}H_{17}O_2N$: C, 69.54; H, 8.27; N, 6.76%.

Method B: The mixture of **5a**[4,5] (1.78 g, 9.3 mmol), hydroxylamine hydrochloride (1.3 g, 18.6 mmol), and 5 cm^3 of pyridine was heated for 4 h at 100 °C. The reaction mixture was then poured into 50 cm^3 of water, followed by ether extraction. The dried (Na_2SO_4) ethereal portion was filtered and evaporated *in vacuo* to give 1.35 g (70%) of **3a**.

Preparation of exo-*6-Methoxy-1,3,5,6-tetramethyltricyclo[3.2.1.-0^{2,7}]oct-3-en-8-one Oxime (***3b***).* *Method A*: Exactly the same procedure as *Method A* in the case of **3a** was applied to **1b**. The colorless crystalline solid of **3b** (47%) was obtained: mp 162—163 °C (from EtOH); IR (KBr): 3226, 1686, 1111 cm^{-1}; NMR ($CDCl_3$): δ 1.00 (3H, s), 1.03 (3H, s), 1.29 (1H, d, J=6.0 Hz), 1.68 (3H, s), 1.70 (overlapped with methyl signal, 1H), 1.80 (3H, s), 3.31 (3H, s), 5.13 (1H, m), 8.35 (1H, broad s); UV (EtOH): 230 nm (end absorption, ε, 3900); MS *m/e* (rel intensity): 221 (10, M$^+$), 188 (100). Found: C, 70.21; H, 8.51; N, 6.14%. Calcd for $C_{13}H_{19}O_2N$: C, 70.55; H, 8.65; N, 6.33%.

Method B: Exactly the same procedure as *Method B* in the case of **3a** was applied to **5b**,[5] and **3b** was obtained in 65% yield.

Irradiation of **3a**. A solution of **3a** (240 mg, 0.76 mmol) in a quartz vessel with 254 nm lamps (Rayonet Photoreactor, MGR-100) in a nitrogen atmosphere. After removal of the solvent, the residue was separated by preparative TLC on alumina with chloroform–ethyl acetate (5/2) as the eluent to give 11 mg of **3a** and colorless crystals of **8a** (146 mg, 20%): mp 119—120 °C (from EtOH); IR ($CHCl_3$): 1580, 1115 cm^{-1}; NMR ($CDCl_3$): δ 1.09 (3H, s), 1.17 (3H, s), 1.35 (3H, s), 1.90 (1H, d, J=6.0 Hz), 1.92 (1H, d, J=6.0 Hz), 2.25 (1H, d, J=6.0 Hz), 2.29 (1H, d, J=6.0 Hz), 3.26 (3H, s), 8.90 (1H, broad s); MS *m/e* (rel intensity): 207 (6, M$^+$), 160 (100). Found: C, 69.46; H, 8.63; N, 6.95%. Calcd for $C_{12}H_{17}O_2N$: C, 69.54; H, 8.27; N, 6.76%.

Irradiation of **3b**. A solution of **3b** (150 mg, 0.68 mmol) in anhydrous acetonitrile (50 cm^3) was irradiated for 3.6 h in a quartz vessel with 254 nm lamps in a nitrogen atmosphere. After removal of the solvent, the residue was separated by preparative TLC on silica gel with chloroform–ethyl acetate (5/2) as the eluent to give 85 mg (57%) of **8b**: mp 118—120 °C (from EtOH); IR ($CHCl_3$): 1580, 1115 cm^{-1}; NMR ($CDCl_3$): δ 1.06 (3H, s), 1.20 (3H, s), 1.29 (3H, s), 1.35 (3H, s), 1.44 (1H, d, J=6.0 Hz), 1.82 (1H, d, J=6.0 Hz), 2.04 (1H, s), 3.29 (1H, s), 8.20 (1H, broad s); MS *m/e* (rel intensity): 221 (3, M$^+$), 190 (100). Found: C, 70.94; H, 8.27; N, 6.36%. Calcd for $C_{13}H_{19}O_2N$: C, 70.55; H, 8.65; N, 6.33%.

Irradiation of **4**. A solution of **4**[6] (150 mg, 0.8 mmol) in anhydrous acetonitrile (50 cm^3) was irradiated for 3 h in a quartz vessel with 254 nm lamps in a nitrogen atmosphere. After removal of the solvent, the residue was separated by preparative TLC on silica gel with chloroform as the eluent. The first band from the TLC plates contained **7** (68 mg, 60% based on consumed **4**): mp 139—140 °C (from EtOH); IR ($CHCl_3$): 3290, 1695 cm^{-1}; NMR ($CDCl_3$): δ 1.06 (6H, s), 2.25 (1H, t, J=6.0 Hz), 2.41 (1H, d, J=6.0 Hz), 2.44 (2H, s), 4.77 (1H, s), 4.90 (1H, s), 5.88 (1H, d×d, J=8.0, 6.0 Hz), 6.26 (1H, broad d, J=8.0 Hz), 8.95 (1H, broad s); MS *m/e* (rel intensity): 189 (5, M$^+$), 131 (100). Found: C, 76.45; H, 7.92; N, 7.02%. Calcd for $C_{12}H_{15}ON$: C, 76.15; H, 7.99; N, 7.40%.

Sensitized Irradiation of **3a**. Three Pyrex vessels, which contained **3a** (30 mg, 0.14 mmol) in (a) acetonitrile (10 cm^3), (b) acetone (10 cm^3), and (c) acetonitrile contained acetophenone (35 mg, 0.29 mmol) were irradiated with 300 nm lamps (Rayonet photoreactor, MGR-100) for 10 h in a nitrogen atmosphere. The reactions were monitored by GC (5% SE-30 on Rhromosorb W, 130 °C), but no new peak was observed. After removal of the solvents, each of the residues was purified by preparative TLC on alumina with chloroform as the eluent to give the starting oxime **3a** in 80% (a), 80% (b), and 90% (c) yield.

We thank the Science and Engineering Research Laboratory of Waseda University for their financial support.

Studies on Heterocyclic Analogs of Azulene. VIII.[1] Reaction of 2-Alkoxycyclohepta[*b*]pyrroles with Dimethyl Acetylenedicarboxylate

Noritaka ABE* and Tarozaemon NISHIWAKI

Department of Chemistry, Faculty of Sciences, Yamaguchi University, Yamaguchi 753

(Received October 16, 1980)

Synopsis. 2-Alkoxycyclohepta[*b*]pyrroles reacted with dimethyl acetylenedicarboxylate to give tetramethyl 2-alkoxy-3*H*-2a-azacyclopenta[*ef*]heptalene-3,4,5,6-tetracarboxylates in benzene and dialkyl 2-(2-alkoxycyclohepta[*b*]pyrrol-1-yl)fumarate in alcoholic solvents.

We have previously reported that ethyl 2-chlorocyclohepta[*b*]pyrrole-3-carboxylate (**1a**) reacts with dimethyl acetylenedicarboxylate (DMAD) in benzene giving 1-ethyl 3,4,5,6-tetramethyl 2-chloro-3*H*-2a-azacyclopenta[*ef*]heptalene-1,3,4,5,6-pentacarboxylate (**2a**) *via* a 1,8-dipolar intermediate.[2,3] As nature of substituents and/or reaction conditions appear to play important roles for the cycloadditions of nitrogen-heterocycles with DMAD,[4] we studied the reactions of 2-alkoxycyclohepta[*b*]pyrroles with DMAD in both of benzene and alcoholic solvents.

Treatment of ethyl 2-ethoxycyclohepta[*b*]pyrrole-3-carboxylate (**1b**) with an excess of DMAD in benzene gave 59% yield of 1-ethyl 3,4,5,6-tetramethyl 2-ethoxy-3*H*-2a-azacyclopenta[*ef*]heptalene-1,3,4,5,6-pentacarboxylate (**2b**) along with 29% yield of cyclohepta[*b*]-pyrrol-2(1*H*)-one (**3a**).[5] The structure of **2b** was assigned from the similarity of its spectroscopic properties with those of **2a**.[3] When the reaction of **1b** with DMAD was carried out in boiling abs MeOH, dimethyl 2-(3-ethoxycarbonyl-2-oxo-1,2-dihydrocyclohepta[*b*]pyrrol-1-yl)fumarate (**3b**) was obtained in 94% yield, whose structure was assigned by means of its spectroscopic properties as well as elemental analyses. The ester groups are presumed to have a (*E*)-configuration from the chemical shift of a vinyl proton ($\delta=7.40$) [*e.g.* the vinyl proton of dimethyl 2-(2-oxo-1,2-dihydro-1-pyridyl)fumarate is seen at $\delta=7.05$].[6] Reaction of **3a** with DMAD yielded **3b**, and this supports the structure. Compound **3b** was also obtained in excellent yield from the reaction of **1a** with DMAD in abs MeOH.

Whilst the reaction of 2-methoxycyclohepta[*b*]pyrrole-3-carbonitrile (**1d**) with DMAD in benzene proceeded less efficiently to give only 25% yield of **2c**, with 84% of the starting **1d** being recovered, the reaction in abs EtOH is accompanied by transesterification to furnish diethyl 2-(3-cyano-2-oxo-1,2-dihydrocyclohepta[*b*]pyrrol-1-yl)fumarate (**3d**) despite the absence of acidic or basic materials. Reaction of **3c** with diethyl acetylenedicarboxylate (DEAD) to give **3d**, and this supports the structure.

When the acetylenic ester was absent, **1** did no change in an alcoholic solvent.

It is obvious that the reactions of 2-alkoxycyclohepta[*b*]pyrroles with DMAD give a cycloadduct in benzene, but they follow a different course in alcohols. It is conceivable that the yilde (**4**) reacts with an alcohol to produce an acetal (**5**), which must be hydrolyzed to cyclohepta[*b*]pyrrol-2(1*H*)-one (**3**) by a trace amount of water fortuitously present in the reaction mixture.

Experimental

Melting points were uncorrected. ^1H NMR spectra were taken with Hitachi R-24B spectrometer (60 MHz) for solutions in $CDCl_3$ with TMS as internal standard. UV spectra were measured for solutions in $CHCl_3$ and IR spectra for Nujol mulls. Kieselgel 60 was used for chromatography unless otherwise stated. Yields are based on consumed starting materials.

Synthesis of ***1b***. **1a** (1.00 g) was added to a sodium ethoxide solution prepared from Na (0.40 g) and abs EtOH (20 ml). The mixture was heated under reflux for 2 h, cooled, acidified with dil HCl, and extracted with chloroform. The extracts were washed with water, dried (Na_2SO_4), and evaporated. The residue was chromatographed on alumina with benzene–chloroform to give **1b** [0.914 g, 82%, yellow needles (from petroleum ether), mp 68—69 °C. UV_{max} 289 nm (log ε 4.67), 335 (3.82), 348 (3.71), 368 (3.61), 424 (3.27), 428 (3.26). IR 1675 cm^{-1} (C=O). ^1H NMR $\delta=1.45$ (3H, t, $J=7$ Hz, Me), 1.57 (3H, t, $J=7$ Hz, Me), 4.43 (2H, q, $J=7$ Hz, CH_2), 4.77 (2H, q, $J=7$ Hz, CH_2), 7.5—7.9 (3H, m, H-5,6,7), 8.15—8.4 (1H, m, H-8), 9.1—9.4 (1H, m, H-4). Found: C, 68.51; H, 6.20; N, 5.80%. Calcd for $C_{14}H_{15}NO_3$: C, 68.55; H, 6.16; N, 5.71%].

Synthesis of ***1d***. 2-Chlorocyclohepta[*b*]pyrrole-3-carbonitrile[7] (**1c**) (2.00 g) was added to a sodium methoxide solution prepared from Na (1.20 g) and abs MeOH (50 ml). The mixture was heated under reflux for 2 h and worked up as for **1b** to give **1d** [1.84 g, 94%, yellow needles (from MeOH), mp 186—187.5 °C. UV_{max} 285 nm (log ε 4.65), 334 (3.72), 347 (3.63), 369 (3.58), 423 (3.25), 430 (3.25). IR

2200 cm^{-1} (CN). ^1H NMR δ=4.32 (3H, s, OMe), 7.7—8.0 (3H, m, H-5,6,7), 8.2—8.5 (2H, m, H-4,8). Found: C, 71.68; H, 4.41; N, 15.25%. Calcd for $C_{11}H_8N_2O$: C, 71.73; H, 4.38; N, 15.21%].

Reaction of ***1b*** *with DMAD.* (*a*): A mixture of **1b** (1.00 g) and DMAD (4.06 g) in benzene (30 ml) was heated under reflux for 8 d. The solvent was evaporated and the residue was chromatographed with benzene–ethyl acetate (95 : 5) to give **1b** (0.305 g) followed by **2b** (0.873 g, 59%), which crystallized from cyclohexane as red prisms, mp 140—141 °C [UV_{max} 258 nm (log ε 4.37), 320^{sh} (3.89), 465 (4.01), IR 1740, 1730, 1710, and 1695 cm^{-1} (C=O), ^1H NMR δ= 1.37 (3H, t, J=7 Hz, Me), 1.41 (3H, t, J=7 Hz, Me), 3.72 (3H, s, OMe), 3.75 (3H, s, OMe), 3.83 (6H, s, OMe), 4.23 (2H, q, J=7 Hz, CH_2), 4.34 (2H, q, J=7 Hz, CH_2), 6.3—6.95 (3H, m, H-7,8,9), 6.48 (1H, s, H-3), 7.82 (1H, dd, J=10 and 3 Hz, H-10). Found: C, 49.51; H, 6.39; N, 3.18%. Calcd for $C_{26}H_{27}NO_{11}$: C, 49.43; H, 6.34; N, 3.26%]. Elution with ethyl acetate gave **3a** (0.147 g, 29%), yellow needles (from EtOH), mp 188.5—190 °C (lit,[5] mp 189—190 °C).

(*b*): A mixture of **1b** (1.00 g) and DMAD (4.06 g) in abs MeOH (50 ml) was heated under reflux for 4 d. The solvent was evaporated and the residue was chromatographed with benzene to give **1b** (0.13 g). Elution with chloroform gave **3b** (1.195 g, 94%), which crystallized from cyclohexane as yellow prisms, mp 119—121 °C [UV_{max} 277 nm (log ε 4.48), 432 (4.26), IR 1735, 1695, and 1670 cm^{-1} (C=O), ^1H NMR δ=1.42 (3H, t, J=7 Hz, Me), 3.63 (3H, s, OMe), 3.80 (3H, s, OMe), 4.43 (2H, q, J=7 Hz, CH_2), 6.8—7.75 (4H, m, H-5,6,7,8), 7.40 (1H, s, vinyl-H), 9.28 (1H, d, J=10 Hz, H-4). Found: C, 60.17; H, 4.78; N, 3.79%. Calcd for $C_{18}H_{17}NO_7$: C, 60.16; H, 4.77; N, 3.90%].

Reaction of ***3a*** *with DMAD.* A mixture of **3a** (1.00 g) and DMAD (2.00 g) in benzene (80 ml) was heated under reflux for 2 d. The solvent was evaporated and the residue was chromatographed with chloroform to give **3b** (1.030 g, 78%). Elution with ethyl acetate gave **3a** (0.205 g).

Reaction of ***1a*** *with DMAD.* A mixture of **1a** (1.00 g) and DMAD (4.22 g) in abs MeOH (40 ml) was heated under reflux for 6 h. The solvent was evaporated and the residue was chromatographed with chloroform to give **3b** (1.465 g, 98%).

Reaction of ***1d*** *with DMAD.* (*a*): A mixture of **1d** (1.00 g) and DMAD (4.00 g) in benzene (70 ml) was heated under reflux for 6 d. The solvent was evaporated and the residue was chromatographed with benzene–ethyl acetate (95 : 5) to give **1d** (0.837 g) followed by **2c** (0.101 g, 25%), which crystallized from cyclohexane as red needles, mp 101—103 °C [UV_{max} 285^{sh} nm (log ε 4.05), 459 (3.75), IR 2200 (CN) and 1740 and 1725 cm^{-1} (C=O), ^1H NMR δ=3.70 (3H, s, OMe), 3.73 (3H, s, OMe), 3.80 (6H, s, OMe), 4.30 (3H, s, OMe), 6.40 (1H, s, H-3), 6.7—7.1 (3H, m, H-7,8,9), 7.6—7.8 (1H, m, H-10). Found: C, 59.09; H, 4.39; N, 5.84%. Calcd for $C_{23}H_{20}N_2O_9$: C, 58.97; H, 4.30; N, 5.98%].

(*b*): A mixture of **1d** (0.500 g) and DMAD (2.00 g) in abs EtOH (70 ml) was heated under reflux for 2 d. The solvent was evapoated and the residue was chromatographed with benzene to give **1d** (0.140 g). Elution with benzene–chloroform (1 : 1) gave **3d** (0.367 g, 55%), which crystallized from ligroine–dichloromethane as yellow leaflets, mp 118—119 °C [UV_{max} 276 nm (log ε 4.37), 430 (4.10), IR 2210 (CN) and 1730 and 1690 cm^{-1} (C=O), ^1H NMR δ=1.13 (3H, t, J=7 Hz, Me), 1.29 (3H, t, J=7 Hz, Me), 4.12 (2H, q, J= 7 Hz, CH_2), 4.31 (2H, q, J=7 Hz, CH_2), 7.15—7.85 (4H, m, H-5,6,7,8), 7.40 (1H, s, vinyl-H), 7.93 (1H, d, J=10 Hz, H-4). Found: C, 63.76; H, 4.71; N, 8.46%. Calcd for $C_{18}H_{16}N_2O_5$: C, 63.52; H, 4.74; N, 8.23%]. Elution with MeOH gave **3c** (0.098 g, 29%), yellow needles (from ethyl acetate), mp 313 °C (lit.[7] mp 313 °C).

Reaction of ***3c*** *with DEAD.* A mixture of **3c** (0.100 g) and DEAD (0.35 g) in benzene (60 ml) was heated under reflux for 2 d and cooled. The product crystallized out of the solution was collected and recrystallized to give **3c** (0.087 g). The mother liquid was evaporated and the residue was chromatographed with chloroform to give **3d** (0.016 g, 80%). Elution with MeOH gave **3c** (0.003 g).

We thank Dr. Masafumi Yasunami, Tohoku University, for NMR spectral determination.

Reduction of Ketones and Aldehydes *via* Catalytic Hydrosilylation Using Triethoxysilane and Trimethoxysilane

Hideyuki MATSUMOTO, Yoshikazu HOSHINO, and Yoichiro NAGAI*

Department of Chemistry, Gunma University, Kiryu, Gunma 376

(Received October 30, 1980)

Synopsis. It was found that ketones and aldehydes can be effectively reduced *via* catalytic hydrosilylation using triethoxysilane and trimethoxysilane in the presence of $RhCl(PPh_3)_3$ or $RuCl_2(PPh_3)_3$, followed by ethanolysis or methanolysis.

Reduction of carbonyl compounds *via* hydrosilylation catalyzed by group VIII metal complexes has been extensively investigated.[1,2] In most of the previous work alkyl- and arylsilanes were employed (*e.g.*, Et_3SiH, Et_2SiH_2, $PhMe_2SiH$, and Ph_2SiH_2, *etc.*), and only few examples of the corresponding hydrosilylation by alkoxysilanes have been reported to date.[3] Recently, it has been reported that trialkoxysilanes such as $(EtO)_3SiH$ and $(MeO)_3SiH$ can be readily prepared in large quantities by the direct reaction of silicon with the corresponding alcohols.[4] With such situation in view, we felt it pertinent to explore the reduction of carbonyl compounds by these trialkoxysilanes in some detail. We report herein our finding that various ketones and aldehydes can be smoothly hydrosilylated by $(EtO)_3SiH$ and $(MeO)_3SiH$ in the presence of $[RhCl(PPh_3)_3]$ or $[RuCl_2(PPh_3)_3]$ as catalyst and that alcoholysis of the resultant adducts with the respective alcohol gave desired reduction products in good yields.

$$R^1COR^2 + (R^3O)_3SiH \xrightarrow[\text{Ru(II)}]{\text{Rh(I) or}} R^1CH(OSi(OR^3)_3)R^2 \xrightarrow{R^3OH} R^1CH(OH)R^2 + (R^3O)_4Si \quad (1)$$

Results for the reduction of ketones and aldehydes studied in the present work are summarized in Table 1. The addition of $(EtO)_3SiH$ and $(MeO)_3SiH$ to diethyl ketone, cyclopentanone, cyclohexanone, acetophenone, and benzaldehyde was conducted using the ruthenium complex $[RuCl_2(PPh_3)_3]$ as a catalyst. The reaction in the presence of 0.5 mol% of the catalyst at temperatures of 60—120 °C reached completion after 3—10 h to give the corresponding adducts in high yields. It has been reported that the ruthenium(II) complex catalyzes the reaction of Et_3SiH and $Ph(1\text{-}C_{10}H_7)SiH_2$ with ketones (*e.g.*, acetophenone) and aldehydes (*e.g.*, benzaldehyde), but that it is not as effective a catalyst as $[RhCl(PPh_3)_3]$.[5] We found that this particular ruthenium complex is much more selective than the rhodium(I) complex in the present addition reactions. For instance, the ruthenium(II)-catalyzed reaction of $(EtO)_3SiH$ with acetophenone produced the adduct in 85% yield whereas the rhodium(I)-catalysis was accompanied by the concurrent formation of a considerable amount of the silyl enol ether.

$$PhCOCH_3 + (EtO)_3SiH \xrightarrow{\text{Rh(I)}} \underset{(40\%)}{PhCH(OSi(OEt)_3)CH_3} + \underset{(27\%)}{PhC(OSi(OEt)_3)=CH_2} \quad (2)$$

The desilylation of the resulting silyl enol ethers was also studied. The method commonly employed for the desilylation involves acid- or base-catalyzed hydrolysis.[2] However, this method would be inconvenient in the present case, because such procedure would result in the formation of a complex mixture of siloxanes. This

TABLE 1. REDUCTION OF KETONES AND ALDEHYDES *via* THE HYDROSILYLATION BY TRIETHOXYSILANE (A) OR TRIMETHOXYSILANE (B) IN THE PRESENCE OF $[RhCl(PPh_3)_3]$ OR $[RuCl_2(PPh_3)_3]$[a)]

Carbonyl compound	Silane	Conditions[b]	Product	Yield/%

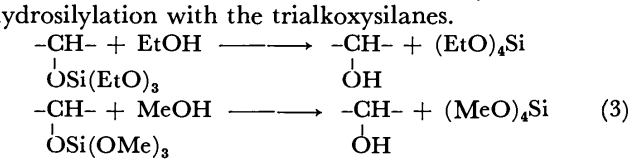
	B	Rh, 60 °C, 4 h		84(79)
	A	Rh, 70 °C, 3 h		93
	B	Rh, 70 °C, 5 h		88(75)
	B	Rh, 80 °C, 4 h		90

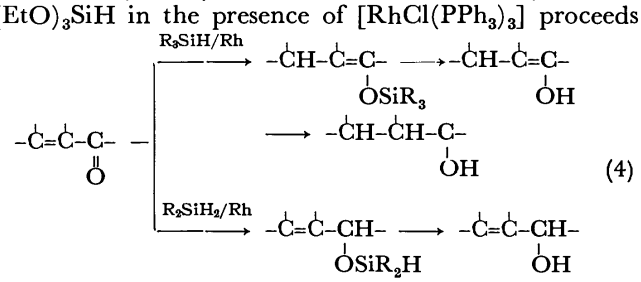
a) [Substrate]/[hydrosilane]/[catalyst] = 1/1.2/0.005. b) For hydrosilylation. c) Determined by GLC (based on the carbonyl compound charged); in parentheses are given isolated yields.

complication arises as a consequence of the high susceptibility of the ethoxyl and methoxyl groups on silicon to hydrolysis.[6] In fact, Kagan and coworkers obtained 1-Phenylethanol in at most 60% chemical yield (*via* GLC) from the reduction of acetophenone with $(EtO)_3SiH$ in the presence of a supported chiral rhodium complex after the treatment of the resulting silyl ether with an aqueous HCl–acetone solution.[3a] We found that the clean desilylation of the adducts of $(EtO)_3SiH$ or $(MeO)_3SiH$ can be achieved by ethanolysis or methanolysis in the presence of a catalytic amount of HCl or NaOH. The counter product, $(EtO)_4Si$ or $(MeO)_4Si$ can be readily removed by simple distillation in many cases. Thus, the corresponding alcohols were obtained in excellent yields *via* the hydrosilylation with the trialkoxysilanes.



(3)

An attempt was also made to reduce α,β-unsaturated terpene carbonyl compounds with the trialkoxysilanes. The regioselective reduction of α,β-unsaturated terpene ketones and aldehydes *via* hydrosilylation catalyzed by $[RhCl(PPh_3)_3]$ was reported by Ojima and coworkers who found that the reduction with monohydrosilanes (*e.g.*, Et_3SiH) gave only or mainly saturated ketones *via* 1,4-addition while dihydrosilanes (*e.g.*, Et_2SiH_2) afforded allylic alcohols *via* 1,2-addition.[7] More recently, it has been also reported by Lappert and Nile that the hydrosilylation of *trans*-crotonaldehyde with $(EtO)_3SiH$ in the presence of $[RhCl(PPh_3)_3]$ proceeds



(4)

through 1,4-addition while the same reaction in the presence of $[Ni(COD)_2]$ takes place *via* 1,2-addition.[3b] We found that the rhodium(I)catalyzed hydrosilylation of several conjugated terpene enones with $(EtO)_3SiH$ or $(MeO)_3SiH$ also proceeded smoothly in a manner of 1,4-addition as in the case of the rhodium-catalyzed reduction of crotonaldehyde. Thus, the reduction of α-ionone, β-ionone, citral, and pulegone gave exclusively α-dihydroionone, β-dihydroionone, citronellal, and menthone in over 80% yields, respectively.

Incidentally, the reduction of α,β-unsaturated terpene ketones with trialkoxysilanes seems to show somewhat higher regioselectivity compared to that with triorganohydrosilanes; it was reported that the reduction of pulegone with Et_3SiH or $PhMe_2SiH$ gave a mixture of menthone and the allylic alcohol in a ratio of 50 : 50 or 75 : 25, respectively.[7]

Experimental

$(EtO)_3SiH$ and $(MeO)_3SiH$ were supplied by Mitsubishi Kasei Industry Co., Ltd. Ketones and aldehydes were commercially available and used without further purification. Ethanol and methanol were purified by standard methods.[8] The complexes $[RhCl(PPh_3)_3]$[9] and $[RuCl_2(PPh_3)_3]$[10] were prepared according to literature directions.

The following reduction products were identified by comparison of their physical properties (GLC retention times, and IR and NMR spectra) with those of commercial authentic samples or literature;[11] 3-pentanol, cyclopentanol, cyclohexanol, 1-phenylethanol, benzyl alcohol, α-dihydroionone, β-dihydroionone,[11] citronellal, and menthone.

General Procedure for the Reduction of Ketones and Aldehydes. All runs were conducted in essentially the same manner; therefore, only the reduction of β-ionone by $(MeO)_3SiH$ is described in detail.

A mixture of 9.7 g (50 mmol) of β-ionone, 7.4 g (60 mmol) of $(MeO)_3SiH$, and 0.23 g (0.25 mmol) of $[RhCl(PPh_3)_3]$ was heated at 60 °C for 4 h under nitrogen with stirring. The reaction mixture was then poured into methanol (30 ml) containing a small amount of sodium hydroxide, and the resulting mixture was stirred at room temperature for 12 h. GLC analysis of the mixture disclosed the formation of β-dihydroionone in 84% yield. Evaporation of the alcohol and subsequent distillation gave 7.3 g (79% yield) of the product boiling at 93 °C/5 mmHg[12] (lit,[11] bp. 105 °C/10 mmHg).

We thank Mitsubishi Kasei Industry Co., Ltd., for gifts of trialkoxysilane.

Ketone Synthesis from Acid Chloride by Means of Organometallic Reagent Derived from R_3Al-$Cu(acac)_2$-PPh_3 System

Kazuhiko TAKAI, Koichiro OSHIMA,* and Hitosi NOZAKI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received November 18, 1980)

Synopsis. Reaction of acid chlorides or thiocarboxylic *S*-esters with the title reagent in tetrahydrofuran provides ketones in good to excellent yields. The coupling reactions with allylic halides to form alkene derivatives are also disclosed.

Synthetic reactions with organoaluminium reagent have received considerable attention recently.[1] The transformation[2] of R'COCl into R'COR fails, however, by means of plain R_3Al, as they react easily with the resultant ketones.[3] Now we wish to report that an organometallic reagent generated from trialkylaluminium, copper(II) bis(acetylacetonate), and triphenylphosphine in 2 : 1 : 2 molar ratio reacts cleanly with carboxylic acid derivatives to give the corresponding ketones, although the identity of the reactive species is not known yet.[4]

Addition of trialkylaluminium to a mixture of copper(II) bis(acetylacetonate) and triphenylphosphine in tetrahydrofuran produced a homogeneous solution. The absence of triphenylphosphine resulted in a suspension which did not react as expected. Treatment of an acid chloride with the resulting organometallic reagents gave the corresponding ketone in good yield. The results are summarized in Table 1. The reaction proceeded similarly with thiocarboxylic *S*-esters as shown in run 4, 5, 9, and 10. The simplicity and mildness of experimental conditions make the method as useful as other organometallic reagents.[2]

TABLE 1. KETONE SYNTHESIS FROM CARBOXYLIC ACID DERIVATIVES BY MEANS OF ORGANOMETALLIC REAGENT DERIVED FROM R_3Al-$Cu(acac)_2$-PPh_3 SYSTEM[a]

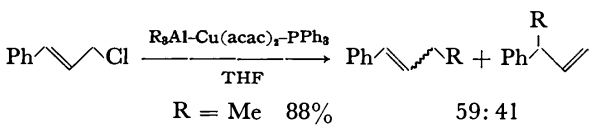
a) 2 mol of R_3Al, 1 mol of $Cu(acac)_2$, and 2 mol of PPh_3 were employed per mol of R'COX. b) Isolated yields.

The reagents readily reacted with cinnamyl chloride to provide the cross-coupling products as shown:[5]



R = Me	88%	59 : 41
R = Et	80%	24 : 76

Experimental

The IR spectra were determined on a Shimadzu IR-27-G spectrometer; the mass spectra, on a Hitachi RMU-6L machine. The NMR spectra were recorded on a Varian EM-390H spectrometer, using TMS as an internal standard. The analyses were performed at the Elemental Analyses Center of Kyoto University. Tetrahydrofuran (THF) was dried on benzophenone ketyl and distilled. All the experiments were carried out under an argon atmosphere. Purification of the product was performed by preparative thin layer chromatography (TLC) or column chromatography on silica gel (Merck Kiesel gel 60). *S*-Phenyl benzenecarbothioate and *S*-phenyl 10-dodecenethioate were prepared by the reaction of the acid chlorides with an excess of thiophenol in pyridine.

Preparation of Methyl Ketones by Means of Me_3Al-$Cu(acac)_2$-PPh_3 System: A dry flask was charged with copper(II) bis(acetylacetonate) (0.26 g, 1.0 mmol), triphenylphosphine (0.52 g, 2.0 mmol), and THF (10 ml). To the stirred blue suspension at −78 °C was added slowly a hexane solution of trimethylaluminium (1.0 M, 2.0 ml, 2.0 mmol). The mixture was allowed to warm to 0 °C and stirring was continued until the copper(II) salt was completely dissolved and a pale yellow homogeneous solution was obtained (10 min). A solution of acid chloride or thiocarboxylic *S*-ester (1.0 mmol) in THF (2 ml) was added. After stirring at 0 °C for an appropriate time described in Table 1, the resulting mixture was diluted with ether (10 ml) and the ethereal extracts were washed with 1 M hydrochloric acid (20 ml) and brine (2×20 ml), dried over anhydrous sodium sulfate, and concentrated. The crude product was purified by silica gel column chromatography (hexane–ether 20 : 1) and distillation under reduced pressure.

The same procedure was employed for the preparation of organometallic reagents from Et_3Al and $^iBu_3Al$. Dark green and dark brown homogeneous solutions were obtained, respectively.

Isobutyl Phenyl Ketone: Bp 85 °C (bath temp, 2 Torr, 1 Torr = 133.322 Pa); IR (neat) 2955, 1690, 1600, 1584, 1450, 1365, 1210, 1005, 750, 688 cm^{-1}; NMR (CCl_4) δ 1.02 (d, 6H, J= 7 Hz), 2.29 (qt, 1H, J=7 Hz), 2.76 (d, 2H, J=7 Hz), 7.30—8.05 (m, 5H); MS *m/e* (%) 162 (M^+, 13), 147 (6), 120 (28), 105 (100), 77 (54), 51 (24). Found: C, 79.07; H, 12.29%. Calcd for $C_{12}H_{22}O$: C, 79.06; H, 12.16%.

12-Tridecen-3-one: Bp 87 °C (bath temp. 2 Torr); IR (neat) 2925, 2850, 1715, 1642, 1460, 1108, 990, 904 cm^{-1}; NMR (CCl_4) δ 1.00 (t, 3H, J=7 Hz), 1.15—1.75 (m, 12H), 1.85—2.15 (m, 2H), 2.15—2.50 (m, 4H), 4.90 (d, 1H, J= 10 Hz), 4.94 (d, 1H, J=18 Hz), 5.50—6.00 (m, 1H); MS *m/e* (%) 196 (M^+, 1), 167 (6), 149 (11), 139 (8), 85 (26), 83 (26), 72 (76), 57 (100), 55 (73).

Found: C, 79.29; H, 12.58%. Calcd for $C_{13}H_{24}O$: C, 79.53; H, 12.32%.

2-Methyl-13-tetradecen-4-one: Bp 108 °C (bath temp, 2 Torr); IR (neat) 2940, 2860, 1712, 1642, 1468, 1365, 988, 905 cm^{-1}; NMR (CCl_4) δ 0.89 (d, 6H, J=7 Hz), 1.10—1.80 (m, 12H), 1.80—2.36 (m, 7H), 5.88 (d, 1H, J=10 Hz), 5.94 (d, 1H, J=18 Hz), 5.50—6.00 (m, 1H); MS *m/e* (%) 224 (M^+, 2), 209 (3), 167 (10), 149 (11), 113 (13), 100 (19), 85 (86), 69 (25), 67 (22), 58 (80), 57 (100).

Found: C, 80.11; H, 12.72%. Calcd for $C_{15}H_{28}O$: C, 80.29; H, 12.58%.

Methylation of Cinnamyl Chloride by Means of Me_3Al–$Cu(acac)_2$–PPh_3 System: A pale yellow organometallic reagent derived from trimethylaluminium (2.0 mmol), copper(II) bis-(acetylacetonate) (0.26 g, 1.0 mmol), and triphenylphosphine (0.52 g, 2.0 mmol) in THF (10 ml) was prepared as described above. A solution of cinnamyl chloride (0.15 g, 1.0 mmol) in THF (2 ml) was added slowly to the solution at 0 °C, and the resulting mixture was stirred at the same temperature for an additional 15 min. The mixture was diluted with ether (10 ml) and the ethereal extracts were washed with 1 M hydrochloric acid (20 ml) and brine (2×20 ml), dried over anhydrous sodium sulfate, and concentrated. The crude product was purified by preparative TLC with hexane as an eluent to give two isomeric methylated products (0.12 g, 88%) whose ratio was determined by GLPC (20% PEG 6000, 2 m, 100 °C). 1-Phenyl-1-butene (T_r=16.1 min, 59%) and 3-phenyl-1-butene (T_r=6.3 min, 41%) were identical with the authentic samples.[7]

The same procedure was employed for the coupling reaction of cinnamyl chloride and the organometallic reagent derived from triethylaluminium. GLPC (20% PEG 6000, 2 m, 100 °C) indicated two peaks, T_r=9.3 min (3-phenyl-1-pentene, 76%) and T_r=25.7 min (1-phenyl-1-pentene, 24%).

Conditional Monte Carlo Trajectory Calculation of Elementary Gas Reaction Rates

Ryuichi MINAMI† and Takashi OKADA*

Information Processing Research Center, Kwansei Gakuin University, Uegahara, Nishinomiya, Hyogo 662

(Received October 26, 1979)

A new Monte Carlo trajectory method is proposed to estimate the rate constants of elementary molecular reactions. In this study, we have introduced the conditional Monte Carlo technique and obtained the following advantages. First, the procedure of calculation has been simplified. That is, the trajectory data have been accumulated as only one data set, from which the rate constants at any temperature have been reduced easily. Secondly, the necessary number of trajectories has been decreased by employing appropriate conditional distribution functions. Lastly, the error estimation has become possible on a reasonable base. This method has been applied to the (H_2, H_2) direct exchange reaction as an example and the result is reported briefly.

Karplus, Porter, and Sharma have demonstrated the usefulness of the Monte Carlo trajectory method through the calculation of the rate constants of the (H, H_2) exchange reaction.[1] Since then, it has been frequently applied to the dynamics of various elementary molecular collisions.[2,3] In this procedure, the reaction cross sections are first estimated by the Monte Carlo trajectory calculation. Then, the rate constants are computed from the cross sections by the numerical integration method.

The cross sections are specified by the initial vibration-rotational quantum state and by the initial translational energy. Therefore, if we have to take account of many quantum states to estimate the rate constant, the necessary number of trajectory calculations becomes enormous. Some chemists have tried to get away from this trouble, but the results have been not so effective.[4,5]

The rate constant was originally defined as proportional to the expected value of the product of the relative velocity and the probability that a trajectory goes into the reaction channel. This aspect suggests that the calculation of cross sections can be bypassed and that the reaction rate may be computed directly from trajectory data. In this paper, the above idea is developed by introducing the conditional Monte Carlo method,[6] and the new technique is applied to the (H_2, H_2) direct exchange reaction[7] as an example.

Reaction Rate Calculation by the Conditional Monte Carlo Method

In this section, we discuss the development of the Monte Carlo trajectory method, using as an example the simplest exchange reaction **a**: A+BC→**b**: AB+C. Here, the collision system is identified by the vibration-rotational quantum state of the BC molecule, (v, j), and by the relative translational energy E_t. Other types of reactions can be treated in a similar way.

The overall thermal rate constant at temperature T is defined by

$$k_{a,b}(T) = N_A\left(\frac{8}{\pi\mu k_B{}^3T^3}\right)^{1/2} Q_{vib}{}^{-1}Q_{rot}{}^{-1}\sum_{v,j} g_j(2j+1) \times \exp\left(-\frac{E_v+E_j}{k_BT}\right)\int_0^\infty S_{a,b}(E_t, j, v) \times \exp\left(-\frac{E_t}{k_BT}\right)E_t dE_t, \quad (1)$$

where N_A is Avogadro's number, k_B is the Boltzmann constant, μ is the reduced mass of the A+BC system, Q_{vib} and Q_{rot} are the partition functions for the vibrational and the rotational motion, E_v and E_j are the vibrational and rotational energies of the BC molecule at the quantum states v and j, respectively, g_j is the statistical weight of the rotational state j, and $S_{a,b}(E_t, j, v)$ is the reaction cross section at the (E_t, j, v) state.[4] According to the quasiclassical trajectory theory, the cross section $S_{a,b}(E_t, j, v)$ is equal to the averaged probability that a trajectory with the (E_t, j, v) initial state goes into the reaction channel and is given by

$$S_{a,b}(E_t, j, v) = \frac{\pi\hbar^2}{\mu^2V_t{}^2}\sum_{l=0}^{\infty}(2l+1)\frac{1}{16\pi^3}\int_0^\pi d\theta\int_0^{2\pi}d\phi\int_0^{2\pi}d\phi \times\int_0^{2\pi}d\eta\sin\theta P_{a,b}(\theta, \phi, \psi, \eta, l, E_t, j, v), \quad (2)$$

where l is the orbital quantum number of the initial collision system, V_t is the initial collision velocity, (θ, ϕ) and ψ are the orientation angles for the BC axis and the instantaneous rotational angular momentum, respectively, η is the vibrational phase angle,[8] and $P_{a,b}(\cdots\cdots)$ is the probability that a trajectory goes into the reaction channel, **a**→**b**.

Substituting the above expression for $S_{a,b}(E_t, j, v)$ in Eq. 1 yields a relation between the rate constant and $P_{a,b}$ of each trajectory. If we wish to estimate directly a rate constant by using the Monte Carlo trajectory method,[9] the dynamical equations of trajectories are numerically solved according to the initial conditions generated from the natural distribution functions G's. Then the expression of $k_{a,b}(T)$ takes the following Monte Carlo integration form:[10]

$$k_{a,b}(T) = \pi N_A b_m{}^2\frac{1}{N}\sum_{i=1}^{N} V_t(i)\cdot P_{a,b}(i), \quad (3)$$

where b_m is the characteristic impact parameter that is large enough to include all reactive trajectories, i points out the i-th sample in an N-trajectories set, and the value of $P_{a,b}(i)$ becomes 1 for a case that i-th trajectory passes through the channel **a**→**b** and is 0 for the other cases. To estimate the rate constant

† Visiting fellow. Present address: Department of Chemistry, School of Science and Engineering, Waseda University, Okubo, Shinjuku-ku, Tokyo 160.

at a temperature, we need only perform the Monte Carlo integration of Eq. 3. However, if the most of $V_t(i)P_{a,b}(i)$'s are expected to be zero and only a few samples with non-zero value contribute to $k_{a,b}(T)$, this method also requires numerous sample trajectories.

The conditional Monte Carlo method has been proposed to estimate the expected value of a given function of a random variable by a comparatively small number of samplings.[6,11] The values of random variables are generated not according to the natural distribution functions but to the conditional distribution functions. The initial state (l, E_t, j, v) of a trajectroy is determined by the conditional Monte Carlo choice, while all initial phases (θ, ϕ, ψ and η) of the BC molecule are determined by the analog Monte Carlo choice.[11,12] In the introduction of the conditional Monte Carlo method, we first have to set up adequate forms of the conditional distribution functions F's. Next, the calculations of trajectories with the above initial conditions are performed numerically and the necessary results are stored in one data set. This data set is independent of temperature. Then the rate constant at any temperature can be estimated by the following equation, which has been transformed from Eq. 3 according to the conditional Monte Carlo integration: (See Appendix I.)

$$k_{a,b}(T) = \pi N_A b_m^2 \frac{1}{N} \sum_{i=1}^{N} V_t(i) P_{a,b}(i) J_i(T), \tag{4}$$

where $J_i(T)$ is the Jacobian determinant of the G's with respect to the F's. If there are strong correlations among the random variables, we have to evaluate fully the terms of $J_i(T)$. However, in cases of no correlation, as is usually assumed, $J_i(T)$ is simply estimated by

$$J_i(T) = \frac{G^{orb}_{l(i)} - G^{orb}_{l(i)-1}}{F^{orb}_{l(i)} - F^{orb}_{l(i)-1}} \cdot \frac{G^{vib}_{v(i)}(T) - G^{vib}_{v(i)-1}(T)}{F^{vib}_{v(i)} - F^{vib}_{v(i)-1}} \cdot \frac{G^{rot}_{J(i)}(T) - G^{rot}_{J(i)-1}(T)}{F^{rot}_{J(i)} - F^{rot}_{J(i)-1}} \cdot \frac{\partial G(E_t(i), T)/\partial E_t(i)}{\partial F(E_t(i))/\partial E_t(i)}, \tag{5}$$

where (G^{orb}_l, $G(E_t, T)$, $G^{rot}_J(T)$, $G^{vib}_v(T)$) and (F^{orb}_l, $F(E_t)$, F^{rot}_J, F^{vib}_v) are the natural and conditional distribution functions for (l, E_t, j, v), respectively. In this procedure, it is expected that the necessary number of trajectories is greatly decreased, since the rate constant estimation at any temperature requires no additional trajectory data, and since the forms of the conditional distribution functions may be taken so as to decrease the number of samples within the limitation of the required accuracy.

Reasonable error estimates of the calculated rate constants are readily possible in the conditional Monte Carlo method. If the variances of the sampled data set, $\sigma_{a,b}(T)^2$, are calculated, the relative errors of the calculated rate constant can be estimated in terms of the central limit theorem.[13] Then, the deviation at the α% confidence level is given by

$$|\pm\Delta k(T)| = \Phi^{-1}(\alpha/200)\sigma_{a,b}(T)N^{-1/2}, \tag{6}$$

where the function Φ^{-1} is the inverse function of the normal distribution function. Here, the sample variance $\sigma_{a,b}(T)^2$ is estimated by the following conditional Monte Carlo integration:

$$\sigma_{a,b}(T)^2 = (\pi N_A b_m^2)^2 \frac{1}{N-1} \left\{ \frac{1}{N} \sum_{i=1}^{N} [V_t(i)P_{a,b}(i)J_i(T)]^2 - \left[\frac{1}{N} \sum_{i=1}^{N} V_t(i)P_{a,b}(i)J_i(T) \right]^2 \right\}. \tag{7}$$

The conditional distribution functions should be formed so as to minimize the above variance.

Application to the (H_2, H_2) Exchange Reaction

We take up the (H_2, H_2) direct exchange reaction as a typical example among the AB+CD→AC+BD reactions. The determination of the conditional distribution functions F's for this reaction, the process of rate calculation, and the results will be briefly described below.

The Forms of F's. This exchange reaction happens with higher probability when the large energy present originates in vibrational and/or translational motions.[14] Now, if we adopt the thermal distribution functions at a representative temperature, there are few sample trajectories in the region where the reaction probability is comparatively high and the effect on the magnitude of rate constant is significant. On the other hand, the reaction probability is nearly zero where the density functions take large values and the samples are numerous. Therefore, we intend to adopt the conditional distribution functions so that the number of trajectories does not decrease in the high reactive conditions. The forms of F's for the various modes of motion are separately discussed as follows.

For Vibrational Quantum Number v: Since large vibrational energy is favourable for a trajectory to go into the reaction channel, it is desirable to provide many samples in the high energy levels. The simplest treatment would be to assign an equal weight factor to each vibrational level. Then we construct the conditional distribution function in the following simple form:

$$F^{vib}_v = (v+1)/(v_m+1) \qquad (0 \le v \le v_m \le v_{max}), \tag{8}$$

where v_m denotes the largest vibrational quantum number considered in the trajectory calculations and v_{max} means the dissociation limit of the hydrogen molecule, which has been assumed to be the Morse oscillator. We must choose the value of v_m carefully, because a too large v_m value gives many sample trajectories that are hardly expected in the thermal distribution, and because a too small v_m value neglects the samples necessary for the estimation of the rate constant.

For Rotational Quantum Number j: The rotational effect on this reaction is expected to be weak. Therefore, the conditional distribution function F^{rot}_J is assumed to be the thermal equilibrium distribution function G^{rot}_J at a representative temperature T_0.

$$F^{rot}_J = G^{rot}_J(T_0). \tag{9}$$

Here, $G^{rot}_J(T)$ is given by

$$G_j^{\mathrm{rot}}(T) = Q_{\mathrm{rot}}(T)^{-1} \sum_{j'=0}^{j} g_{j'}(2j'+1) \exp(-E_{j'}/k_{\mathrm{B}}T), \tag{10a}$$

$$Q_{\mathrm{rot}}(T) = \sum_{j'=0}^{\infty} g_{j'}(2j'+1) \exp(-E_{j'}/k_{\mathrm{B}}T), \tag{10b}$$

where the magnitude of statistical weight g_j is noted in Ref. 15. In the case of homonuclear diatomic molecule, the procedure to determine the j-value from the rotational distribution function F_j^{rot} is somewhat complex and is explained in Appendix II.

For Translational Energy E_t: For the same reason as for the vibrational motion, we have employed the following conditional distribution function:

$$F(E_t) = \begin{cases} E_t/E_{t,m} & : \ 0 \le E_t \le E_{t,m} \\ 1 & : \ E_{t,m} \le E_t \end{cases} \tag{11}$$

where $E_{t,m}$ is a sufficiently large value of E_t, similarly to v_m.

For Orbital Quantum Number l: The following form is assumed as in the vibrational case, because the smaller value of l is expected to give the higher reaction probability:

$$F_l^{\mathrm{orb}} = (l+1)/(l_m+1) \qquad (0 \le l \le l_m). \tag{12}$$

Here l_m denotes the maximum orbital quantum number for a given translational energy and is calculated by the following equation if the characteristic impact parameter b_m is fixed:

$$l_m = \left[\frac{\{1 + b_m(8\mu E_t)^{1/2}/\hbar\}^{1/2} - 1}{2} \right]_{\mathrm{int}}. \tag{13}$$

Here $[\ ]_{\mathrm{int}}$ means to omit the decimal part. Once l is chosen, the impact parameter b, which is necessary for trajectory calculation, is estimated by

$$b = \hbar\{l(l+1)/2\mu E_t\}^{1/2}. \tag{14}$$

We add the remark that a similar technique has already been applied for the orbital motion.[4,16]

Calculating Procedure. Two FORTRAN IV programs were written to estimate the rate constants. The first program initializes the trajectories according to the given conditional distribution functions, integrates the Hamilton equation numerically, and then writes out the results into a data file. The second program reads the trajectory data in the file, and then estimates the rate constant at an optional temperature by use of Eq. 4.

The parameter values of the conditional distribution functions are set to those shown in Table 1. T_0 shows a representative value in the range of 500 to 5000 K. The values of v_m, $E_{t,m}$, and b_m have been determined by analyzing the results of the 4000 trajectories test run which has employed sufficiently large values for them. The LEPS type potential

surface devised by Raff *et al.*[17] and the parameter values by Porter *et al.*[4] are used to specify the Hamilton equation of the system. Numerical integration has been performed by the Adams-Moulton fifth-order predictor, sixth-order corrector method, and the time increment is set to 2×10^{-16} s. More details of trajectory calculation can be found elsewhere.[2,8]

Results. The calculated rate constants at a temperature of 2000 K are plotted as a function of the number of sample trajectories in Fig. 1. The confidence intervals at the 90% level are also depicted by the error bars, the lengths of which tend to decrease with the increase of N.

Here, we will estimate the necessary number of trajectories to attain accuracy within an order of magnitude:

$$\frac{\Delta k(T)}{k(T)} \le 0.9 \ . \tag{15}$$

Since the relative error at the α% confidence level inherent in the N-samplings is evaluated by Eq. 6, the relative standard deviation $\sigma(T)/k(T)$ can be related to Eq. 15 as follows:

$$\sigma(T)/k(T) \le 0.9N^{1/2}/\Phi^{-1}(\alpha/200). \tag{16}$$

Therefore, we will seek the number N which satisfies the above relation. The procedure can be traced in Fig. 2, where the calculated $\sigma(T)/k(T)$'s at $T=$ 1000 K and 2000 K are plotted against $N^{1/2}$, and three straight lines are drawn to show the equality of Eq. 16 for $\alpha=90$, 95, and 99(%). If a calculated point of $\sigma(T)/k(T)$ lies below each line, the $k(T)$ value is regarded to have the desired accuracy at the corresponding degree of confidence. For instance, it can be seen from this figure that 4000 and 18000 trajectories are enough to reach the 90% level at $T=2000$ and 1000 K, respectively.

The Arrhenius plot of the calculated rate constants and their 90% confidence limits at 32000 trajectories are shown in Fig. 3. This plot tends to be slightly concave and an activation energy of *ca.* 67 kcal/mol has been evaluated by fitting the Arrhenius equation to this slope. We also note the tendency that the

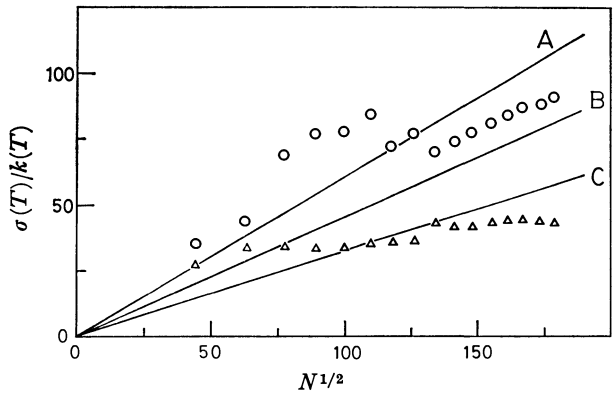

Fig. 2. Plot of $\sigma(T)/k(T)$ *vs.* $N^{1/2}$.
The marks ○ and △ represent the points of $\sigma(T)/k(T)$ at $T=1000$ and 2000 K, respectively. The straight lines A, B, and C mean the limits which satisfy the equality of Eq. 16 for $\alpha=90$, 95, and 99 (%), respectively.

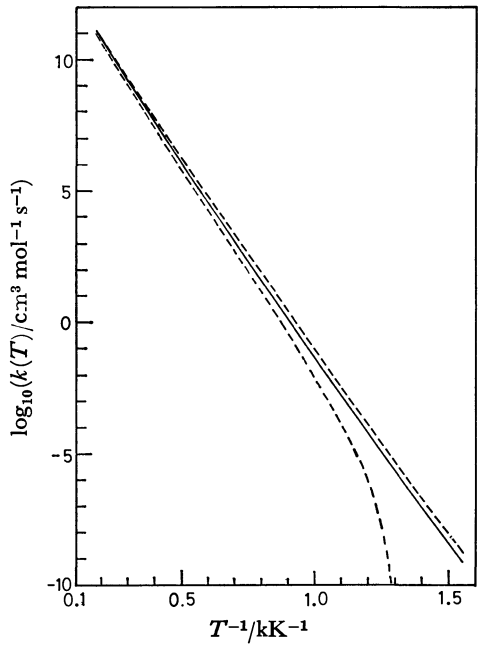

Fig. 3. Arrhenius plot for the (H_2, H_2) direct exchange reaction. The full line represents the Arrhenius plot calculated from 32000 trajectories. Two dotted lines show the 90% confidence limits.

accuracies attained at lower temperatures are poorer than those at higher ones. However, such results simply come from our choice of conditional distribution functions. Different tendencies are expected for other functional forms.

In this trial calculation, we have not determined the optimum functional forms of F's. Generally, a great number of test runs would be required to carry it out.[12] Therefore, we adopted appropriate forms of F's and performed a reasonable error estimation to determine the necessary number of trajectories.

Conclusion

We have presented a new technique for the numerical trajectory calculation of the rate constant for the elementary gas phase reaction. The conditional Monte Carlo method employed here has provided the following advantages. First, the dependence of the accuracy of the calculated rate constant on the number of sample trajectories has become clearer than that found in the conventional way. Next, the estimating procedure has become simpler. That is, the trajectory data are put into only one data set, from which the rate constant at any temperature can be calculated immediately. Lastly, even the smaller number of trajectories can give a fairly good estimation of rate constants, if the conditional distribution functions are formed well. Hence, the analysis of the collision process of complex molecules may be possible in the present method, while the necessary number of cross sections grows prohibitively with the increase of the intramolecular freedom of reactants in the conventional method.

One of the authors (M) is most grateful to Professor Keniti Higasi of Waseda University for his kind encouragement.

Appendix I. Conditional Monte Carlo Integration

The derivations of Eqs. 4 and 5 are inferred from analogy with the expected value of a function $P(x,n)$ of two random variables (x, n) which are generated according to natural distribution functions $G(x)$ and G_n, where x and n stand for continuous and integral values, respectively. The expected value of $P(x,n)$ is given by

$$\langle P(x,n)\rangle = \sum_{n=0}^{n(\max)} \int_0^1 P(x,n)\mathrm{d}G(x)(G_n - G_{n-1}), \tag{A1}$$

where the integral is a Rieman-Stieltjes type and G_{-1} and $G_{n(\max)}$ are defined by 0 and 1, respectively. If we want the values of random variables to be generated according to conditional distribution functions ($F(x)$, F_n), Eq. A1 should be reformulated as follows:

$$\langle P(x,n)\rangle = \sum_{n=0}^{n(\max)} \int_0^1 P(x,n)J(x,n)\mathrm{d}F(x)(F_n - F_{n-1}), \tag{A2}$$

where $J(x,n)$ is the Jacobian:

$$J(x,n) = \frac{\mathrm{d}G(x)}{\mathrm{d}F(x)} \cdot \frac{G_n - G_{n-1}}{F_n - F_{n-1}}. \tag{A3}$$

Employing the analog Monte Carlo method,[12] we can choose an N-samples set ($(x_i, n(i))$, $i=1,\ldots,N$) from the distribution according to the ($F(x)$, F_n)-functions and can simultaneously establish the corresponding set ($P(x_i,n(i))$ $J(x_i,n(i))$, $i=1,\ldots,N$). Then, Eq. A2 is approximated by

$$\langle P(x,n)\rangle = \frac{1}{N}\sum_{i=1}^{N} P(x_i,n(i))J(x_i,n(i)), \tag{A4}$$

where i-th sample values (x_i, $n(i)$) are derived from two uniform random numbers ξ_i and η_i using the following equations:

$$\begin{cases} x_i = F^{-1}(\xi_i) & (0 \le \xi_i < 1), \\ F_{n(i)-1} \le \eta_i < F_{n(i)} & (0 \le \eta_i < 1). \end{cases} \tag{A5}$$

Appendix II. Monte Carlo Choice of the Rotational State for Homonuclear Diatomic Molecule

The summation in Eq. 10 is first divided into two series with even and odd j-number, and these troublesome summations are carried out in the approximations of integral expression[8] as follows:

$$F_j^{\mathrm{rot}} = Q_{\mathrm{rot}}^{-1}\left\{g_{\mathrm{even}} \sum_{\mathrm{even}\ j'} (2j'+1)\exp\left(-\frac{\hbar^2 j'(j'+1)}{2Ik_{\mathrm{B}}T_{\mathrm{o}}}\right) + g_{\mathrm{odd}} \sum_{\mathrm{odd}\ j'} (2j'+1)\exp\left(-\frac{\hbar^2 j'(j'+1)}{2Ik_{\mathrm{B}}T_{\mathrm{o}}}\right)\right\}$$
$$= Q_{\mathrm{rot}}^{-1}\left\{g_{\mathrm{even}}\int_0 (8x+2)\exp\left(-\frac{\hbar^2 x(2x+1)}{Ik_{\mathrm{B}}T_{\mathrm{o}}}\right)\mathrm{d}x + g_{\mathrm{odd}}\int_0 (8x+6)\exp\left(-\frac{\hbar^2 (x+1)(2x+1)}{Ik_{\mathrm{B}}T_{\mathrm{o}}}\right)\mathrm{d}x\right\}, \quad \text{(A6)}$$

where I is the moment of inertia and the upper bounds of summations and integrals are limited by j-value. By calculating the above integrals between the interval $(0,\infty]$, Q_{rot} is expressed as

$$Q_{\mathrm{rot}} = Q_{\mathrm{rot}}(\mathrm{even}) + Q_{\mathrm{rot}}(\mathrm{odd}), \quad \text{(A7)}$$

$$Q_{\mathrm{rot}}(\mathrm{even}) = g_{\mathrm{even}}(2Ik_{\mathrm{B}}T_{\mathrm{o}}/\hbar^2), \quad \text{(A8a)}$$

$$Q_{\mathrm{rot}}(\mathrm{odd}) = g_{\mathrm{odd}}(2Ik_{\mathrm{B}}T_{\mathrm{o}}/\hbar^2)\exp\left(-\hbar^2/Ik_{\mathrm{B}}T_{\mathrm{o}}\right). \quad \text{(A8b)}$$

Then, F_j^{rot} is represented by the following formulae:

$$F_j^{\mathrm{rot}} = Q_{\mathrm{rot}}^{-1}\{Q_{\mathrm{rot}}(\mathrm{even})F_j^{\mathrm{rot}}(\mathrm{even}) + Q_{\mathrm{rot}}(\mathrm{odd})F_j^{\mathrm{rot}}(\mathrm{odd})\}, \quad \text{(A9)}$$

$$F_j^{\mathrm{rot}}(\mathrm{even}) = 1 - \exp\left(-\frac{\hbar^2 j(j+1)}{2Ik_{\mathrm{B}}T_{\mathrm{o}}}\right), \quad \text{(A10a)}$$

$$F_j^{\mathrm{rot}}(\mathrm{odd}) = 1 - \exp\left(-\frac{\hbar^2 (j-1)(j+2)}{2Ik_{\mathrm{B}}T_{\mathrm{o}}}\right), \quad \text{(A10b)}$$

where $F_j^{\mathrm{rot}}(\mathrm{even})$ and $F_j^{\mathrm{rot}}(\mathrm{odd})$ are considered to be distribution functions for even and odd rotational states alone, respectively.

In order to determine the quantum number j, we first distinguish whether it belongs to the even or the odd j-series by introducing a uniform random number η. Then, by use of another uniform random number ξ, the value of j in the respective series can be assigned as follows:
if $0 \leq \eta < Q_{\mathrm{rot}}(\mathrm{even})/Q_{\mathrm{rot}}$, even j-series:

$$j = \left[\frac{-1+(1-A)^{1/2}}{2}\right]_{\mathrm{even}}, \quad \text{(A11a)}$$

if $Q_{\mathrm{rot}}(\mathrm{even})/Q_{\mathrm{rot}} \leq \eta < 1$, odd j-series:

$$j = \left[\frac{-1+(9-A)^{1/2}}{2}\right]_{\mathrm{odd}}, \quad \text{(A11b)}$$

where A is given by

$$A = (8Ik_{\mathrm{B}}T_{\mathrm{o}}/\hbar^2)\ln\xi, \quad \text{(A12)}$$

and $[\ ]_{\mathrm{even}}$ and $[\ ]_{\mathrm{odd}}$ mean to adopt the maximum number in the even and the odd integer sequence below the given value, respectively.

The case of heteronuclear diatomic molecule has already been treated in Ref. 8.

Kinetic Studies on the Strictly Catalytic Acetylation of Mesitylene with Acetic Anhydride by HCl and Metal Chlorides in Acetic Acid

Tohr YAMANAKA* and Takashi IMAI

Central Research Laboratory of Takasago Perfumery Co., Ltd., Kamata, Ohta-ku, Tokyo 144

(Received June 13, 1980)

On the acetylation of mesitylene (**1**, 0.5—1 mol dm^{-3}) with acetic anhydride (Ac_2O, 0.5—1.5 mol dm^{-3}) at 30—90 °C in acetic acid as solvent, $SbCl_5$, $FeCl_3$, $SnCl_4$, or $ZnCl_2$ (each of 0.02—0.2 mol dm^{-3}) under the co-catalytic effect of HCl (0—0.75 mol dm^{-3}) showed a continuous catalytic activity. The product was exclusively 2′,4′,6′-trimethylacetophenone for conversions of **1** in the range of 0—90%. The reaction was first order with respect to **1** and Ac_2O. The rate constants were proportional to 1—1.4th power of the concentration of the metal chloride. The apparent activation energy was 18.8 kcal mol^{-1} for all the catalysts. The catalytically active species are thought to be the conjugate acids from the metal chloride and HCl. Relative catalytic activities of the metal chlorides varied in parallel with their relative Lewis acid-strengths.

With a few exceptions,[1a,2] the past Friedel-Crafts acylations of aromatic hydrocarbons with acid halides, acid anhydrides, or acids required[3-7] more than equimolar amounts of metal halides (MX_n) to the acyl component, because the resulting ketone combined with MX_n to form a complex.[7,8] Although a recent patent suggests an acylation by a *catalytic amount* of $FeCl_3$, namely by 0.05—0.1 mol of $FeCl_3$ for each mol of acetyl chloride (AcCl),[2] the efforts to reduce the amount of the catalyst were concentrated on dissociating the complexes by means of elevating the reaction temperature beyond the boiling point of the starting hydrocarbons, and the yield of ketones was not high.

Catalytic amounts of strong inorganic oxoacids are known to catalyze continuously the acetylation of thiophene,[1b] furan,[1b] and anisole[9] with acetic anhydride (Ac_2O). In the case of anisole,[9] the addition of acetic acid (AcOH) made the reaction mild and it prevented the formation of resinous products. These results should be compared with conventional acylations[3,4,10b] which required 2—3 times the molar quantity of metal halides such as $AlCl_3$ to acid anhydrides. Solutions of $SnCl_4$ or $ZnCl_2$ in AcOH, without undergoing solvolysis, form complex acids with the solvent, *e.g.*, $H_2ZnCl_2(OAc)_2$.[10a] In the system of $ZnCl_2$–HCl–AcOH, an acid stronger than $HClO_4$, H_2ZnCl_4 arises.[11] A Brönsted acid (HY) such as HCl, H_2O, and AcOH often functions as a co-catalyst in the systems of MX_n in an aprotic solvent, where a conjugate acid HMX_nY with a strong ability of proton donation was thought to be the catalytically active species.[12-15]

Prior to the present study there has been neither a kinetic study of Friedel-Crafts acylation with anhydrides, nor a catalytic study of the acylation of an aromatic hydrocarbon with anhydrides. Recently the authors found a new acetylation of cyclic sesquiterpenes with Ac_2O in the presence of a *catalytic amount* of ZnO or Fe_2O_3, and HCl in AcOH as solvent.[16] This paper deals with the kinetic study of the acetylations of mesitylene (**1**) with Ac_2O in the presence of *catalytic amounts* of various metal chlorides (MCl_n) and HCl in AcOH as solvent.

Experimental

Catalysts. $ZnCl_2$ of a guaranteed reagent grade, $SnCl_4$ and $FeCl_3$ of a purity greater than 99 wt%, and $SbCl_5$ of an electronics grade were used as the catalysts without further purification.

Materials. **1** of a purity greater than 98.5 wt% (by GLC), and Ac_2O, AcCl, and AcOH of a guaranteed reagent grade were used without further purification. (In one particular case, 6 mol dm^{-3} HCl was used instead of AcCl, water contained in which was predicted to react quantitatively with Ac_2O to form AcOH.)

Procedure. The acylation was carried out under an atmosphere of dry N_2 in a 30 ml three-necked flask equipped with a condenser which was connected to a bubble column sealed with concd H_2SO_4. N_2 was introduced through a side arm and discharged through the condenser. The desired amounts of AcCl or 6 mol dm^{-3} HCl, Ac_2O, and **1** were weighed into a 20 ml-measuring flask, and AcOH was added to the mixture to make the total amount 20 ml at room temperature. The desired amount of a catalyst (MCl_n) was weighed quickly into the reaction flask and the above AcOH solution was added to it. Immediately, the mixture was stirred vigorously by a magnetic stirrer in a water bath with a thermostat. At each reaction time, *ca.* 1.5 ml sample of the reaction mixture was taken out, diluted with 25 ml of 20 wt% NaCl aqueous solution to stop the reaction, and extracted with 10 ml of diethyl ether. The water layer was extracted again with 10 ml of diethyl ether. Both extracts were then combined, washed with NaCl-saturated water and, after concentration, used for the GLC analysis. Occasionally the N_2 flow was stopped. Each time, no bubbles were found in the bubble column. This showed that any losses of HCl or AcCl from the reactor were not substantial. AcCl or HCl (0—0.75 mol dm^{-3}), 0.5—1 mol dm^{-3} of **1**, 0.35—1.35 mol dm^{-3} of Ac_2O, and 0.02—0.2 mol dm^{-3} of a catalyst were used. The reaction temperature was between 30 and 90 °C. The reference volume of the reaction mixture used to express the concentration of components was taken at 25 °C.

GLC Analysis. Quantitative analysis was done by means of an internal standard method, using a Shimadzu GC-6A apparatus on a 1 m×2 mmϕ column packed with 5 wt% of FFAP on Chromosorb W,AW-DMCS of 80—100 mesh. The column temperature was elevated from 80 to 250 °C by 10 °C min^{-1}, N_2 was used as the carrier at 40 ml min^{-1}, and the injection temperature was 230 °C. Cyclododecane (extra pure reagent) was used as the standard. Compositions of products determined by the GLC analysis are shown in Table 1.

Table 1. Compositions of products[a)]

θ/h	Contents/wt%			
	1	2	Diacetyl-mesitylene	Others[b)]
0	98.5	0	0	1.5
2	26.3	70.5	trace	4.1
4	12.0	85.1	0.4	2.5
6	6.8	89.6	0.5	3.3
8	3.8	92.9	0.6	2.8

a) At 70 °C, $C_{1,0}=0.500$ mol dm^{-3}, $C_{Ac_2O,s}=1.20$ mol dm^{-3}, $C_{AcCl,s}=0.300$ mol dm^{-3}, and $C_{FeCl_3,s}=0.100$ mol dm^{-3}. b) Isomeric trimethylbenzenes, their monoacetylated prcducts, and an unknown product are included.

Identification of the Products. From the reaction mixture, **1**, 2′,4′,6′-trimethylacetophenone(**2**), and 2,4-diacetylmesitylene were identified by means of gas chromatography-mass spectroscopy(Hitachi M-80).

Results

Rate Equation. All the acetylation runs of **1** yielded 2′,4′,6′-trimethylacetophenone (**2**) exclusively. The initial rate of the acetylation was proportional to the initial concentration of **1** and also to the sum of the starting concentrations of AcCl and Ac_2O, in the reactions with 0.1 mol dm^{-3} of $FeCl_3$, 0.5—1 mol dm^{-3} of **1**, 0.35—1.35 mol dm^{-3} of Ac_2O, and 0.15 mol dm^{-3} of AcCl at 70 °C. When HCl and Ac_2O were adopted instead of using the equivalent amount of AcCl, the rate did not change. It was estimated that AcCl was rapidly solvolyzed by AcOH to form Ac_2O and HCl, and then participated in this reaction:

$$AcCl + AcOH \rightleftharpoons Ac_2O + HCl. \quad (1)$$

Therefore, the rate is proportional to the concentration of **1** and the effective concentration of Ac_2O *in the reaction system.* The rate of the acetylation was defined as $dC_2/d\theta$ and was expressed by the 2nd order rate equation(2):

$$dC_2/d\theta = k_2C_1C_{Ac_2O} = k_2(C_{1,0}-C_2)(C_{Ac_2O,s}+C_{AcCl,s}-C_2), \quad (2)$$

where θ, C, k_2, and 0 represent the time, the concentration of the species defined by the suffix, the second order rate constant, and $\theta=0$ respectively; the suffix s represents a starting concentration defined by: {the amount of the material or the catalyst used for the reaction}×{the volume of the reaction system}$^{-1}$. When $C_{1,0}\neq C_{Ac_2O,s}+C_{AcCl,s}$, integration of Eq. 2 gives

$$\log((C_{Ac_2O,s}+C_{AcCl,s}-C_2)/(C_{1,0}-C_2)) = k_2\theta(C_{Ac_2O,s}+C_{AcCl,s}-C_{1,0}) + \log((C_{Ac_2O,s}+C_{AcCl,s})/C_{1,0}). \quad (3)$$

The rate equation(2) fitted for reactions by each catalyst up to any conversion of **1** in the range of 0—90%, as illustrated by straight lines in Fig. 1. This is consistent with the above estimation that the equilibrium in Eq. 1 lies well to the right. This also indicates that the concentration of the catalytically active species does not change with the formation of **2**. Therefore, the present reaction medium avoids the deactivation of catalysts due to the complex formation[7)] between the Lewis acid and the product ketone(**2**).

Temperature Dependency of k_2. In Fig. 2, Arrhenius plots for k_2 by each catalyst are shown. The apparent activation energies are the same in all cases, *i.e.*, 18.8 kcal mol^{-1}. Therefore, relative activities of the catalysts must entirely be due to the pre-exponential factors of k_2. The constant activation energy suggests that each catalyst causes the same change of

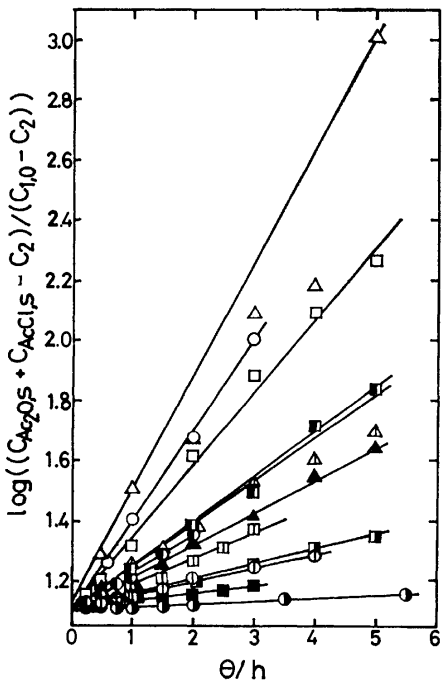

Fig. 1. Correlations between $\log((C_{Ac_2O,s}+C_{AcCl,s}-C_2)/(C_{1,0}-C_2))$, the left hand side of Eq. 3 and θ. $C_{1,0}=0.500$ mol dm^{-3}, $C_{Ac_2O,s}=1.350$ mol dm^{-3}, and $C_{AcCls,s}=0.150$—0.170 mol dm^{-3}. $FeCl_3$ 0.100 mol dm^{-3}, at 70 °C(○), 60 °C(◐), 50 °C(ⓓ), and 30 °C(◑); $SnCl_4$ 0.102 (□), 0.053 (▣), and 0.023 mol dm^{-3} (■) at 90 °C; $SnCl_4$ 0.201 (◧) and 0.101 mol dm^{-3} (◨) at 70 °C; $SbCl_5$ 0.108 (△) and 0.054 mol dm^{-3} (◬) at 70 °C; $SbCl_5$ 0.107 (▲) at 55 °C.

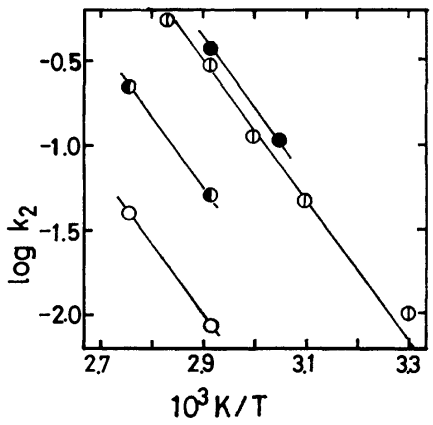

Fig. 2. Arrhenius plots of k_2 with 0.100 mol dm^{-3} of $SbCl_5$ (●), $FeCl_3$ (ⓓ), $SnCl_4$ (◐), and $ZnCl_2$ (○); $C_{AcCl,s}=0.150$ mol dm^{-3}.

the structure of species to form an activated complex in a rate determining step.

Dependency on the Catalyst Amount. In Fig. 3, the log k_2 values are plotted against the log $C_{MCl_n,s}$ of each catalyst. In the linear correlations of slope= 1—1.4, Fig. 3 shows that each k_2 is proportional to $C_{FeCl_3,s}^{1.0}$, $C_{SbCl_5,s}^{1.3}$, or $C_{SnCl_4,s}^{1.4}$. The slopes of $SnCl_4$ at 70 and 90 °C are the same. The specific activity of a catalyst, k_2', was estimated by the extrapolation of the straight line to the point where $C_{MCl_n,s}=1$ mol dm^{-3} in Fig. 3.

Effect of the Acid Strength of the Catalyst. In Fig. 4, log k_2' is plotted against the infrared spectroscopic shifts in carbonyl stretching frequencies ($\Delta\nu_{CO}$) between free xanthone and its complexes with metal halides.[17] These $\Delta\nu_{CO}$ values indicate the relative Lewis acid-strength of the catalysts. The correlation in Fig. 4 suggests that Lewis acid-strength is an important factor of the catalytic activity.

Effect of HCl-Concentration. Figure 5 indicates

the effect of C_{HCl} on the k_2 value of $FeCl_3$. The total HCl concentration was defined as the $\{C_{AcCl,s}+C_{HCl,s}\}$ value and was denoted by $C_{HCl,t}$. In Fig. 5, k_2 values vary with the $C_{HCl,t}$ value roughly along the same line. $FeCl_3$ still effected a catalytic activity when $C_{HCl,t}=0$. The k_2 value appears constant in the range of $C_{HCl,t}=0$—0.05 mol dm^{-3}, increases proportionally to the increase of $C_{HCl,t}$ in the range from 0.05 to 0.15 mol dm^{-3}, and attains approximately a maximum when $C_{HCl,t}\geq 0.15$ mol dm^{-3}.

Figure 5 shows that the catalytic activity of $FeCl_3$ when $C_{HCl,t}\approx 0.15$ mol dm^{-3} is 2.4 times as high as the one in the absence of HCl.

Discussion

Co-catalytic Action of HCl and AcOH on $FeCl_3$. In Friedel-Crafts acylations, the co-catalytic effects[12] of Brönsted acid(HY) on a metal halide have not been studied. Figure 5 suggests that the co-catalytic activity of AcOH is lower than that of HCl. The activity order seems parallel to the order of the reactivities of Brönsted acids HY in their hydrogen isotope exchange with aromatic solvents in the presence of $SnCl_4$ found by Satchell:[15] namely, HCl>H_2O>AcOH. He explained these observations by the co-catalytic effect of HY on $SnCl_4$.

Figure 5 shows that HCl prevails as the co-catalyst when $C_{HCl,t}\geq 0.15$ mol dm^{-3}, and that AcOH prevails when $C_{HCl,t}\leq 0.05$ mol dm^{-3}. Details of the k_2 value should be expressable by Eq. 4. When $C_{FeCl_3,s}=0.1$ mol dm^{-3},

$$k_2 = 0.126(1-C_{[FeCl_3\cdot HCl]}/C_{FeCl_3,s}) + 0.304\,C_{[FeCl_3\cdot HCl]}/C_{FeCl_3,s}, \quad (4)$$

where [$FeCl_3$·HCl] denotes the catalytically active species formed by $FeCl_3$ and HCl. The first term of the right hand side represents the co-catalytic effect of AcOH; the second term, that of HCl. If [$FeCl_3$·HCl] consists of $FeCl_3$ and HCl in the stoichiometric ratio of 1:1, and if it is formed quantitatively only when $C_{HCl,t}>0.05$, then $C_{[FeCl_3\cdot HCl]}$ equals the smaller value of $C_{FeCl_3,s}$ or $\{C_{HCl,t}-0.05\}$. Eq. 4 then agrees with the line in Fig. 5.

$HAlCl_4$ and $HAlBr_4$ are considered to be capable of being present in non-polar ternary systems of Lewis acid-catalyst/Brönsted acid-co-catalyst/solvent only when the solvent functions as a H^+-acceptor base.[12-14] If HCl and/or AcOH function(s) as co-catalyst(s) *via* the conjugate acid(s) $HFeCl_4$ and/or $HFeCl_3(OAc)$, they exist as ion pairs $AcOH_2^+FeCl_4^-$(**3**) and $AcOH_2^+$-$FeCl_3(OAc)^-$.[10a,11] This is because the present Ac_2O/AcOH–solvent system is polar and has a low dielectric constant, and the dissociation of the acid is suppressed.[18]

The equilibrium in Eq. 1 essentially lies to the left.[10b] When HCl is replaced by a strong acid such as perchloric or sulfonic acid, the equilibrium is shifted well to the right.[9,10a] Like $HAlCl_4$ and $HAlBr_4$, the conjugate acid $HFeCl_4$ formed by the interaction of Lewis and Brönsted acids presumably functions as an exceedingly strong acid and may be non-existent in the free state.[12,13] Then the observation in kinetics that the equilibrium in Eq. 1 lies well to the right can be interpreted in terms of the conjugate acid formation(5):

$$HCl + FeCl_3 + AcOH \overset{K_1}{\rightleftharpoons} AcOH_2^+FeCl_4^-. \quad (5)$$

Catalytic Action of the $FeCl_3$–HCl/AcOH System. In the results shown in Figs. 1—4, $C_{HCl,t}$ was 0.15—0.17, which was greater than $\{C_{FeCl_3,s}+0.05\}$ in every case. In those cases, k_2 of $FeCl_3$ is proportional to $C_{FeCl_3,s}$ but independent of $C_{HCl,t}$; $K_1 \gg 1$ is deduced from the analyses of Figs. 3 and 5.

According to Burton and Praill,[9] mixtures of perchloric and acetic acids which contain protons or solvated hydrogen ions, $AcOH_2^+$, are not O- or C-acetylating agents. Addition of Ac_2O to such mixtures leads to the formation of acetylium (Ac^+) and/or diacetoxyoxonium ion (Ac_2OH^+):

$$AcOH_2^+ + Ac_2O \rightleftharpoons Ac_2OH^+ + AcOH$$
$$\rightleftharpoons Ac^+ + 2AcOH.$$

These ions are both C-acetylating agents.[9] Because $C_{AcOH} \gg C_{Ac_2O}$ in the present medium, Ac_2OH^+ is estimated to prevail as the acetylating agent.[9,10] Therefore the acetylation in Scheme 1 is proposed; this proceeds *via* the formation of the diacetoxyoxonium ion pair(**4**):[9,10a]

$$\left.\begin{array}{ll} Ac_2O + \mathbf{3} \overset{K_2}{\rightleftharpoons} \underset{(\mathbf{4})}{Ac_2OH^+FeCl_4^-} + AcOH & (6) \\ \mathbf{1} + \mathbf{4} \longrightarrow \mathbf{2} + \mathbf{3} & (7) \end{array}\right\} \text{Scheme 1.}$$

This mechanism, with the pre-equilibrium(6) lying to the left, accounts formally for the observed kinetics of the first order dependence on Ac_2O, as in the O-acetylation of 2-naphthol.[10a] Provided that $K_2 \ll 1$ and that Step (7) is rate-determining in Scheme 1, the 2nd order rate expression (Eq. 2) is obtained. $FeCl_3$ functions strictly catalytically, because **3** is repeatedly regenerated. The suggestion by Burton *et al.*[9] that the formation of Ac_2OH^+ should be essential to the continuous activity of the acid catalysts seems to be kinetically proved in the present study. Because $FeCl_3$ does not exist in the free state, it does not form a complex[7] with the product ketone (**2**). The present results also kinetically support the suggestion by Hartough and Kosak for the acetylation of thiophene and furan that *catalytic amounts* of Lewis acid catalyst are sufficient in the absence of the complex formation.[1]

Catalytic Actions of $SbCl_5$, $SnCl_4$, and $ZnCl_2$. The same apparent activation energy and the observed first order dependency on Ac_2O suggest that the acetylations by $SbCl_5$, $SnCl_4$, and $ZnCl_2$ will also proceed *via* a diacetoxyoxonium ion pair like **4**. It seems reasonable to postulate that $SbCl_5$, $SnCl_4$, and $ZnCl_2$ function *via* steps similar to Scheme 1, as the active complex acid catalysts: $AcOH_2^+SbCl_6^-$ and $AcOH_2^+$-$SbCl_5(OAc)^-$, $AcOH_2^+HSnCl_6^-$ and $AcOH_2^+$-$HSnCl_5(OAc)^-$, or $AcOH_2^+HZnCl_4^-$ and $AcOH_2^+$-$HZnCl_3(OAc)^-$.[10a,11]

The observations in Fig. 3 suggest that the scheme of complex acid formation is somewhat different for each MCl_n. This should be responsible for variations in the degrees of the association and the solvation of the MCl_n's, variations in the stoichiometric compositions of the complex acids, and variations in the magnitudes of the equilibrium constants for the complex acid formations. Meanwhile, the observation of Fig. 4 suggests that Lewis acid-strength of MCl_n primarily effects the ability of proton donation to Ac_2O.

Providing that an attack of Ac_2OH^+ on the aromatic nucleus is the rate-determining step, and that the variation in the overall energy barriers of steps corresponding to Steps (6—7) by different MCl_n is negligibly small, the same apparent activation energy of each catalyst will be realized.

An MO Study of the Reaction Mechanism of Photoisomerization from Isoxazole *via* Azirine Intermediate to Oxazole

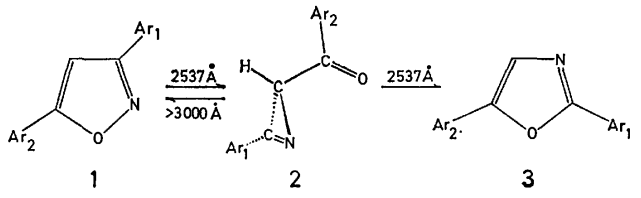
Hidetsugu TANAKA, Yoshihiro OSAMURA, Toshio MATSUSHITA, and Kichisuke NISHIMOTO*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 23, 1980)

The reaction mechanism of photoisomerization of isoxazoles and the wavelength dependent photochemistry of azirine intermediates which are the photoisomerization reaction intermediates are investigated theoretically by means of *ab initio* MO-CI calculation. The present calculation shows that the lowest excited singlet state, S_1, of azirine intermediate is an ($n\rightarrow\pi^*$) state localized at the carbonyl chromophore, while the S_2 state is assigned to be an ($n\rightarrow\pi^*$) state localized at the ketimine chromophore. Intersystem crossing from S_1 to T_1 states of azirine intermediate causes the N–C bond rupture of azirine ring and leads to isoxazole. On the other hand, azirine intermediate in the S_2 state proceeds to the C–C bond break of azirine ring and converts to oxazole *via* intersystem crossing to the T_1 state.

Some of five-membered heterocycles undergo the isomerization reactions in which two of ring atoms interchange their positions under the influence of UV-visible light. For instance, 2-substituted thiophenes were found to rearrange into 3-substituted thiophenes,[1] and 1,4-dimethylimidazoles into 1,2-dimethylimidazoles.[2] These reactions have been supposed to proceed *via* bridged-valence intermediates similar to those in the photochemical rearrangements of benzene derivatives.[3] Singh and his co-workers have studied the photochemical isomerization of diarylisoxazoles (**1**) to diaryloxazoles (**3**) and proposed an alternative



1 2 3

mechanism which proceeds *via* the three-membered intermediates.[4] This reaction is of compelling interest both experimentally and theoretically, since 2-aroyl-3-aryl-2*H*-azirines(**2**) have the reactivity strongly depending upon the wavelength of irradiation light.[4c]

In the present study, *ab initio* MO-CI calculations have been carried out for isoxazole (**1a**) (a: Ar_1=Ar_2=H, see Fig. 1), 2*H*-azirine-2-carbaldehyde (**2a**), and oxazole (**3a**) which are the parent molecules of **1**, **2**, and **3**, respectively.[5] On the basis of the calculated results, the reaction scheme and the wavelength dependency of the reactivity of **2** are discussed.

Calculations

Ab initio MO calculations of **1a**, **2a**, and **3a** are carried out with the STO-3G minimal basis set using the GAUSSIAN 70 program package.[6] The excited states of these species are calculated within the singly excited configuration interaction (SECI) procedure. In the SECI calculations, all the singly excited configurations are included except the inner-shell excitations.

The ground-state geometries of **1a**, **2a**, and **3a** are optimized using the STO-3G minimal basis set. Figure 2 shows the optimized geometries and those

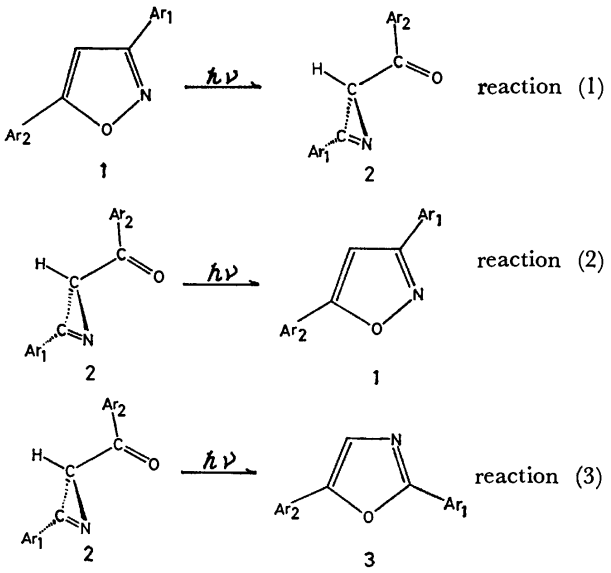


Fig. 1. Steps in the photoisomerization of isoxazole to oxazole.

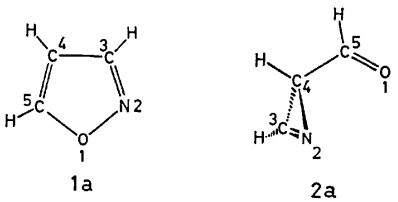
determined by means of double resonance modulated microwave spectroscopy[7] in parentheses. The agreement between the calculated and the observed geometry is satisfactory.

The numbering of atoms of **1a** and **2a** is as follows.



1a 2a

Results and Discussion

Excited States of 1a. The energy levels and their assignments of the ground (S_0) and some low-lying excited states of **1a**, **2a**, and **3a** at the optimized ground-state geometries are shown in Fig. 3.

Before discussing the mechanism of the reactions

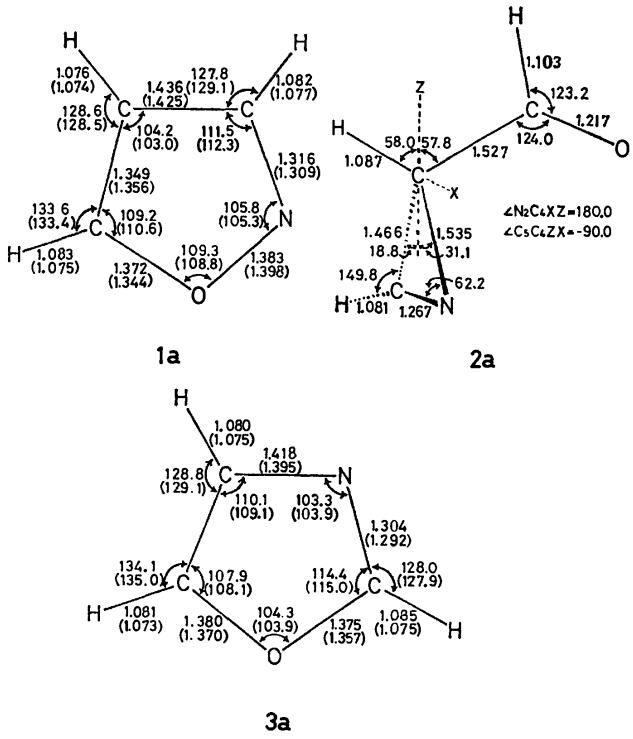


Fig. 2. Optimized ground-state geometries of **1a**, **2a**, and **3a**. **1a** and **3a** have a C_s symmetry. Values in parentheses are those determined by the experiments, see Ref. 7. Units are shown in Å and degree.

(1), (2), and (3) (see Fig. 1), it is of interest to examine the relation between the geometrical deformations and the state energy variation in the low-lying states of **1a** and **2a**. Several geometrical parameters are varied independently from the ground-state geometry. In **1a**, it is found that all of three geometrical variations, the C_5–C_4–C_3–N_2 torsional angle θ (by which the N_2 atom rises from the molecular plane and the O_1–N_2 bond is weakened), the C_3–C_4–C_5–O_1 torsional angle η (by which the O_1 atom stands up from the molecular plane and the O_1–N_2 bond is weakened), and the rotational angle with respect to the perpendicular

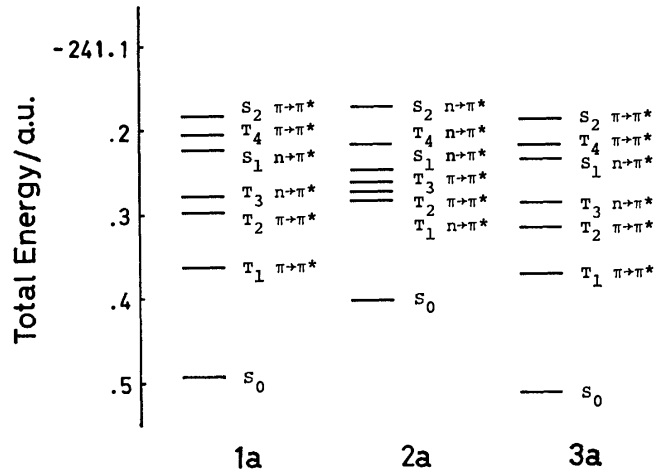

Fig. 3. State energies of the ground(S_0) and some low-lying excited states calculated by vertical excitation approximation.

bisector of the C_3–N_2 bond γ (by which the O_1–N_2 and the C_3–C_4 bonds are weakened simultaneously), give the rather flat potential curves in every excited states (see Figs. 4(a)—4(c)). The results of the independent geometrical variations show that the minima in the potential curves of the S_1 state appear at θ= 12.3° (depth is *ca.* 1.0 kcal mol^{-1}), η=17.2° (*ca.* 2.3 kcal mol^{-1}), and γ=9.9° (*ca.* 0.7 kcal mol^{-1}).

Excited States of ***2a***. T_1 and S_1 states of this intermediate are (n→π^*) states of the carbonyl chromophore and the T_4 and S_2 states are (n→π^*) states of the ketimine chromophore. Since the C_5=O_1 and the C_3=N_2 parts are perpendicular to each other, the excited states related these parts do not mix.

There are two ways of the reaction in the excited azirine intermediate. One is the N_2–C_4 bond break and the O_1–N_2 bond formation (reaction (2)), and the other is the C_3–C_4 bond break and the O_1–C_3 bond formation (reaction (3)). The former is described by the change of the N_2–C_3–C_4 bond angle δ (which causes the N_2–C_4 bond scission) and the out-of-plane torsional angle of the azirine ring (the C_4–

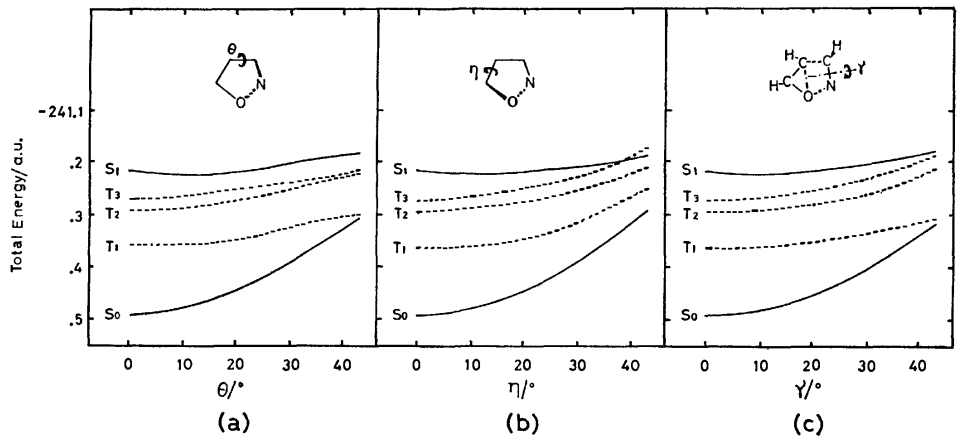

Fig. 4. State energy variations of **1a** by the deformations of (a) the C_5–C_4–C_3–N_2 torsional angle θ, (b) the C_3–C_4–C_5–O_1 torsional angle η, and (c) the rotational angle with respect to the perpendicular bisector of the N_2–C_3 bond γ relative to the ground-state geometry.

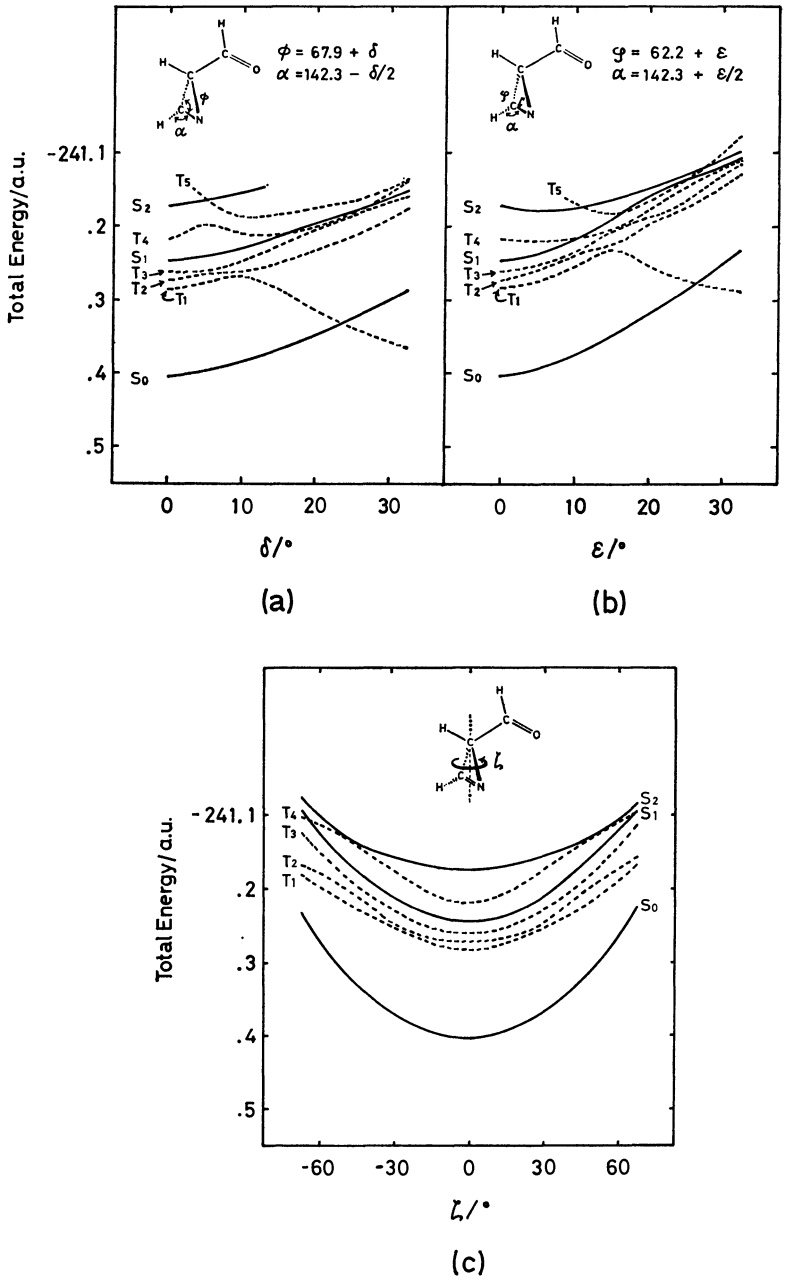

Fig. 5. State energy variations of **2a** by the deformations of (a) the N_2–C_3–C_4 bond angle δ, (b) the C_3–N_2–C_4 bond angle ε, and (c) the out-of-plane torsional angle of azirine ring (the C_4–N_2–C_3 plane) ζ relative to the ground-state geometry.

N_2–C_3 plane) ζ. The latter is described by the change of the C_3–N_2–C_4 bond angle ε (which causes the C_3–C_4 bond scission) and the geometrical parameter ζ. These three geometrical parameters are varied independently from the ground-state geometry. The results for some low-lying states are given in Fig. 5. Other geometrical parameters are also varied, but such geometrical deformations destabilize considerably any state. Therefore, only the geometrical parameters δ and ε can contribute to the initial stage in the reactions (2) and (3). In other words, the character of the reaction coordinate is varied from δ or ε to ζ gradually as the reaction proceeds.

While the S_1 state does not mix with the S_2 state at $\delta=\varepsilon=0$, the geometrical deformations cause the mixing of excited states each other. Let us consider the mechanism of the N_2–C_4 bond scission due to the geometrical deformation δ. As Fig. 5(a) shows, the T_1 state becomes more stable at large δ. Therefore, this state promotes the N_2–C_4 bond scission. Since both the S_1 and T_1 states are ($n\rightarrow\pi^*$) states of the carbonyl chromophore, and their energy separation is rather small, the intersystem crossing (ISC) between these states may rapidly occur. Thus, the excitation to the S_1 state leads to the N_2–C_4 bond scission *via* ISC to the T_1 state.

On the other hand, the geometrical deformation ε makes both the T_1 and S_1 states unstable, while it makes the S_2 state stable (see Fig. 5(b)). But the T_1 state becomes much stable at large ε. Therefore,

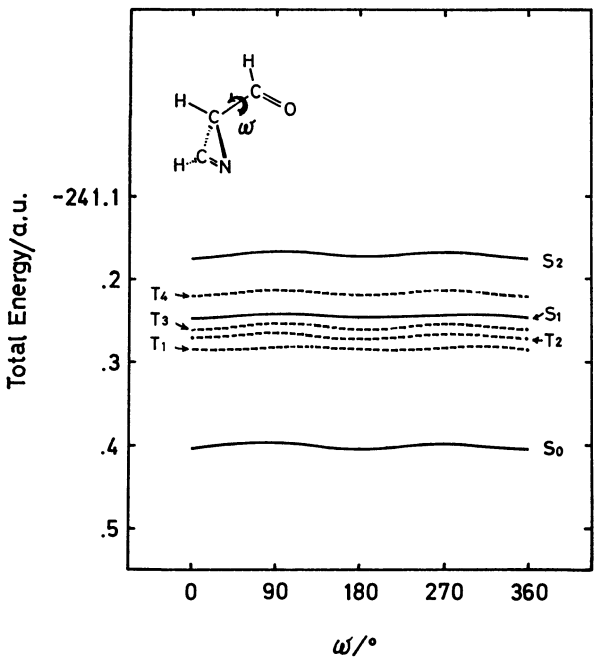

Fig. 6. State energy variation of **2a** by the rotation of CHO group ω. When $\omega=0°$ or 360°, **2a** is *s-trans* form. When $\omega=180°$, it is *s-cis* form.

the C_3–C_4 bond scission occurs *via* ISC from the S_2 to T_1 states.

In the ground state, the *s-trans* form of **2a** is slightly stable than the *s-cis* form (*ca.* 0.5 kcal mol^{-1}). However, the *s-cis* form is of advantage to initiate the reactions. Energy variation with the rotation of the CHO group in the low-lying states is given in Fig. 6. The rotational barriers are calculated to be *ca.* 5.2 kcal mol^{-1}, *ca.* 2.6 kcal mol^{-1}, and *ca.* 5.1 kcal mol^{-1} for the S_0, S_1, and S_2 states of **2a**, respectively. These energy barriers are rather small and, therefore, might obstruct the initiation of reaction.

Reaction (1): ***1a*→*2a***. In order to estimate the reaction path and the height of the barrier roughly, the geometies in the excited states are partly optimized (only several geometrical parameters are chosen) along the reaction paths which are infered from the results of independent variations of geometrical parameters given in Figs. 4 and 5.

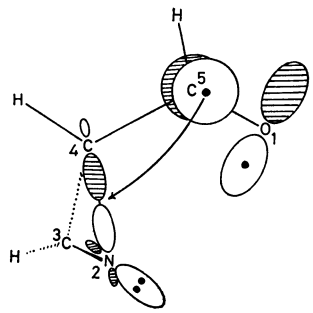
It is well known that the bond break and creation cannot be described correctly in terms of singly excited configurations only. Thus, all valence singly excited configurations and the doubly and triply excited configurations from three highest occupied (HO) MO's to three lowest unoccupied (LU) MO's ((S+D+T)-ECI) are included in the present optimization procedure. As a result of partial optimization, the energy in S_1 state of **1a** descents along the reaction path. On the other hand, the T_1 state has an energy hill (the roughly estimated height is about 40 kcal mol^{-1}, see Fig. 8), so that this reaction would proceed hardly in the triplet state. These results are in good agreement with the experimental results that the reaction (1) could not be sensitized with benzophenone, acetophenone, or acetone.[4]

As Fig. 4 shows, the O_1–N_2 bond of **1a** becomes loose in the excited states. This is in accordance with the experiments that the compounds containing the O and N atoms adjacently such as isoxazoline derivatives are easily cleft at the O–N bond under the influence of UV-visible light.[8]

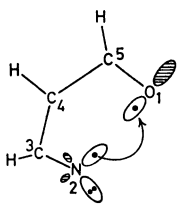
Let us consider this reaction in terms of the concept of orbital interaction.[9] The σ-type LUMO in **1a** is the *anti*-bonding orbital located at the O_1–N_2 bond. When a planar molecule such as isoxazole distorts with the out-of-plane motion, the σ-type LUMO becomes to mix with the occupied π MO's. In addition, since both O and N atoms have negative net charges and lone pair electrons, they repel each other by the electrostatic force. Thus, this force may be helpful for the twisting out-of-plane motion at the O_1–N_2 bond. This is the same as in the case of peroxides and hydrazines in which O–O and N–N bonds are broken very easily. In the excited states, the orbital mixing easily occurs because the σ-type LUMO is close energetically to π^* orbital and the out-of-plane distortion easily occurs, so that the O_1–N_2 bond break is promoted.

At the S_1 state of **1a**, the O_1–N_2 bond is cleft and a biradical might be formed at the N_2–C_3–C_4 part. Subsequently, the internal conversion (IC) into the ground state leads to the ring closure at the N_2 and C_4 atoms. Consequently, one can expect that the O_1–N_2 bond scission and the N_2–C_4 bond formation occur with nearly concerted manner.

Reaction(2): ***2a*→*1a***. As Fig. 5(a) shows, this reaction is favor to start from the S_1 or T_1 states which are (n→π^*) states localized at the C_5=O_1 chromophore. Therefore, in these excited states, electron charge density accumulates on the C_5 atom. The negative charge populated on the C_5 atom might delocalize into the σ-type LUMO of the three-membered ring which is the *anti*-bonding orbital (σ^*_{C-N}) of the N_2–

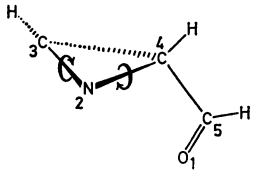


C_4 bond. Thus, this type of orbital interaction and also the strain of the three-membered ring promote the N_2–C_4 bond scission. Since σ^*_{C-C} orbital of the azirine ring lies much higher than σ^*_{C-N} orbital, it does not mix with π^*_{C-O} orbital so efficiently as σ^*_{C-N} orbital. The reaction does not experience nitrene be-

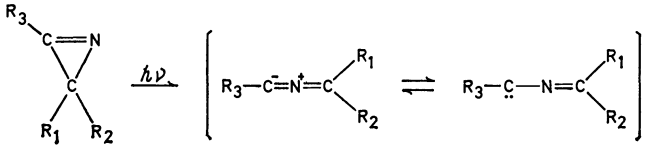


cause one of unpaired electrons is on the O_1 atom. That is, this reaction proceeds by above mentioned manner.

Reaction (3): ***2a→3a.*** As Fig. 5(b) shows, ($n\rightarrow\pi^*$) states of the $C_3{=}N_2$ chromophore, S_2 and T_4 states, become stable with the increase in the C_3–N_2–C_4 bond angle, because the hybridization on the N atom is varied from sp^2 to sp due to the removal of an electron from the lone-pair orbital of N atom (Walsh's rule).[10] Bigot *et al.* have shown that the ring opening of 2*H*-azirine occurs *via* ISC from $^1(n\rightarrow\pi^*)$ to $^3(n\rightarrow\pi^*)$ states.[11] The present results accord with theirs. But this ring opening would not occur with retaining the plane of azirine ring. The fol lowing motion would be also helpful for the ring opening. In fact, the present calculation shows that this conrotatory motion gives the descending potential curve in the T_1 state and leads to the O_1–C_3 bond formation.

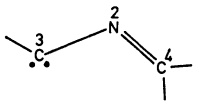


Padwa *et al.*[12] and Schmid *et al.*[13] have reported that 2*H*-azirines undergo the irreversible ring opening at the C–C bond to give nitrile ylides as the reactive intermediates. These intermediates can be intercepted



with dipolarophiles to form five-membered heterocyclic rings or other type of isomers.[14] With this analogy, Ullman and Singh have proposed nitrile ylide intermediates as the precursor of oxazole in the reaction (3).[4b,15] In order to examine whether the reaction (3) proceeds *via* this intermediate or not, the state energy variation due to the deformation of the C_3–N_2–C_4 bond angle of the nitrile ylide intermediate χ is calculated. The result is shown in Fig. 7. The decrease of χ in the ground state indicates the slow energy ascent. One can expect that the nitrile ylide intermediate in the ground state transforms to an oxazole with relative low activation energy.

However, the ground-state nitrile ylide has a linear structure at the C_3–N_2–C_4 part, while the lowest excited state nitrile ylide is carbenic and has a bent structure such as



The ring opened form of **2a** in the triplet state seems to be biradical. If the ground-state nitrile ylide is formed during the reaction, the bond formation between O_1 and C_3 atoms requires too much motion of nuclei, which contravenes the principle of least

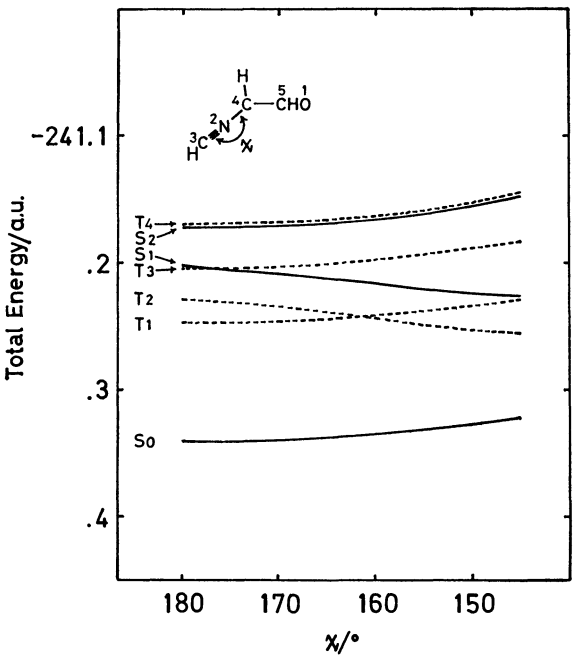


Fig. 7. State energy variation of nitrile ylide intermediate by the decrease of the C_3–N_2–C_4 bond angle χ.

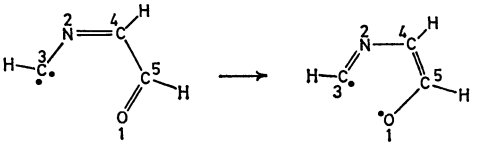

motion.[16] Therefore, it might be concluded that **3a** is formed without any intermediacy, that is, with almost one-step reaction.

Concluding Remarks

As Figs. 4 and 5 show, any geometrical deformation greatly destabilizes the ground states of both **1a** and **2a**, which suggests that these reactions hardly occur thermally.

As mentioned above, the azirine intermediate has different two reactive states, S_1 and S_2 states. These states are almost localized at the C=O and C=N chromophores, respectively, and lead to different reaction products each other *via* different reaction paths. This is the reason why the azirine intermediate has the wavelength dependent photochemistry.

From the calculated results, the mechanism of the photoisomerization of isoxazole can be summarized as follows;

Reaction (1): Isoxazole in the lowest $^1(n\rightarrow\pi^*)$ state interconverts to azirine intermediate in the ground state through the N_2–C_3–C_4–C_5 torsional deformation which leads to the O_1–N_2 bond scission and the N_2–C_4 bond formation simultaneously.

Reaction (2): The S_1 state of azirine intermediate is an ($n\rightarrow\pi^*$) state of the carbonyl chromophore. The deformation of the N_2–C_3–C_4 bond angle in the T_1 state produced through the ISC from the S_1 state causes the N_2–C_4 bond rupture. Subsequently, odd electrons on the O_1 and N_2 atoms combine to form the O_1–N_2 bond, leading to the formation of isoxazole.

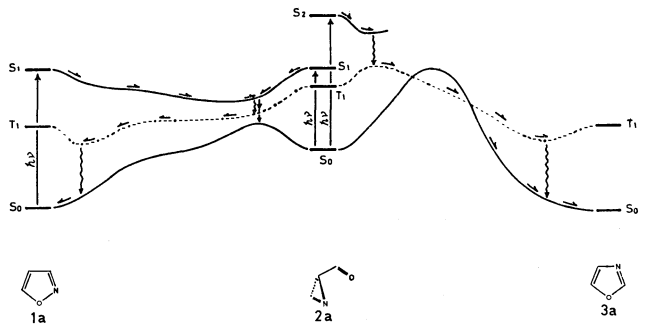

Fig. 8. The possible mechanism of the photoisomerization of isoxazole to oxazole infered from the present (S+D+T)ECI calculation.

This reaction does not experience nitrene.

Reaction (3): Azirine intermediate in S_2 state which is an ($n\rightarrow\pi^*$) state of the ketimine chromophore causes the C_3–C_4 bond rupture by the deformation of the C_3–N_2–C_4 bond angle. It is possible to follow the conrotatory motion in such a ring opening process. The transformation to oxazole proceeds *via* ISC from the S_2 to T_1 states. The doubly and triply excited configurations have an effect of small modification in this reaction.[5] This reaction does not experience any intermediacy.

The possible reaction path of photoisomerization reaction of isoxazoles to oxazoles through azirine intermediates can be shown pictorially in Fig. 8.

The authers would like to express their gratitude to the Computer Center of Institute for Molecular Science and to the Data Processing Center of Kyoto University, for the use of the HITAC M-180 and FACOM M-200 computers. They also thank Dr. Shinichi Yamabe, Nara University of Education, for the use of the GAUSSIAN 70 program.

ESR and ENDOR Studies of Azulenophane Anion Radicals

Masamoto Iwaizumi,* Yoshimasa Fukazawa,† Nobuo Kato,† and Shô Itô†

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

†*Department of Chemistry, Faculty of Science, Tohoku University, Aramaki Aoba, Sendai 980*

(Received August 4, 1980)

The anion radicals of *syn*- and *anti*-[2.2](2,6)azulenophane, (**1**) and (**2**), [2.2](1,3)azulenophane, (**3**), and [2](1,3)-azuleno[2]paracyclophane, (**4**), all produced by alkali metal reduction in various solvents, have been investigated by ESR and ENDOR spectroscopy. They exist in the ion pair with cations in the solutions, except for $\mathbf{4}^{\cdot-}$ which exists in 1,2-dimethoxyethane with Na^+. Their ion pairing tendency is appreciably higher than that of the naphthalenophane anion radicals. The unpaired electron in these ion pairs localizes mostly on an azulene ring (in $\mathbf{1}^{\cdot-}$, $\mathbf{2}^{\cdot-}$, and $\mathbf{3}^{\cdot-}$, close to a cation). The polarization effects due to the pairing with the cations are much larger than those in the naphthalenophane anion radicals, and increase in the order $\mathbf{1}^{\cdot-} \leq \mathbf{2}^{\cdot-} \leq \mathbf{3}^{\cdot-}$, indicating that the smaller the inter-layer orbital overlap, the larger the polarizability. The unpaired electron of $\mathbf{4}^{\cdot-}$ localizes mostly on the azulene ring even in the free anion.

Extensive studies have been carried out during the past decade on the distribution of unpaired electron in the anion radicals of paracyclophanes, because of the general interest in the transannular interaction in these layered compounds.[1-9] However, the compounds studied so far contain only alternant hydrocarbons with a few exceptions. In this paper, we describe the result of ESR and ENDOR spectroscopic studies on the anion radicals of *syn*- and *anti*-[2.2]-(2,6)azulenophanes (**1** and **2**), [2.2](1,3)azulenophane (**3**) and [2](1,3)azuleno[2]paracyclophane (**4**), all containing azulene rings. Investigation of these compounds seems significant, since they contain, as aromatic moieties, azulene which is a typical non-alternant hydrocarbon known to have unique physicochemical properties different from alternant hydrocarbons. We were interested in the evaluation of the difference in the unpaired electron delocalization found for $\mathbf{1}^{\cdot-}$ and $\mathbf{2}^{\cdot-}$ with opposite orientation of the azulene ring.

Experimental

Compounds **1**, **2**, **3**, and **4** were synthesized by the method reported.[10] In order to prepare the anion radicals of the compounds, reduction with sodium or potassium in 1,2-dimethoxyethane (DME), tetrahydrofuran (THF), 2-methyltetrahydrofuran (MTHF), and mixture of the former two was carried out. ESR and ENDOR spectra of the anion radicals were measured with Varian E112 ESR and E1700 ENDOR spectrometers. However, no radicals $\mathbf{1}^{\cdot-}$, $\mathbf{2}^{\cdot-}$, and $\mathbf{3}^{\cdot-}$ could be detected in DME because of their instability at *ca.* −85 °C, the freezing point of the solution.

Results and Discussion

ESR Spectra. All the ESR spectra of anion radicals produced from **1**—**4** at temperatures below −90 °C in various solvents are well defined (Figs. 1—4). However, in mixed DME–THF with concentration of DME higher than 3:1 (volume), radical

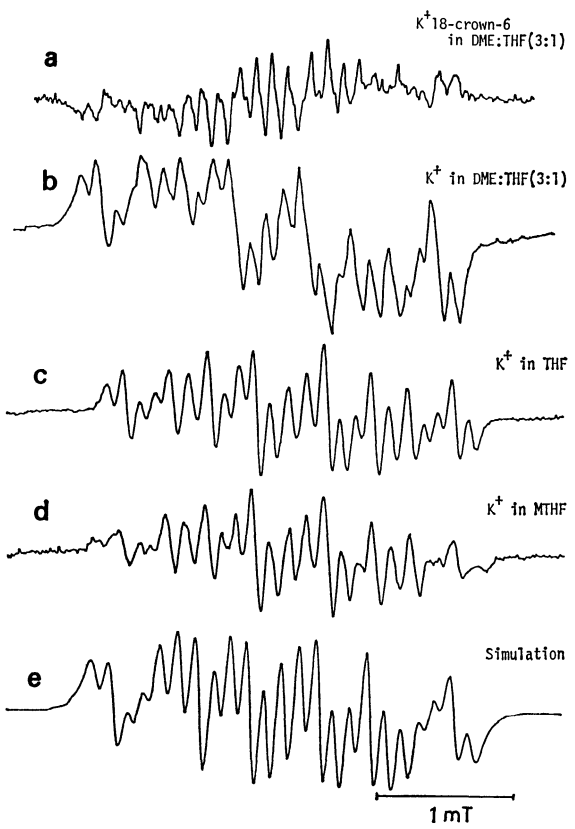

Fig. 3. ESR spectra of $\mathbf{3}^{\cdot-}$ observed at −95 °C in a) K^+ 18-crown-6 in DME:THF (3:1), b) K^+ in DME:THF (3:1), c) K^+ in THF, d) K^+ in MTHF, and e) simulated spectrum for d) using the hf coupling constants in Table 3.

species produced from **1** displayed different hf structure and smaller total spread (2.7 mT) than the spectra shown in Fig. 1. Furthermore, on reduction with sodium, **1** and **2** exhibit spectra due to two different radical species, one showing a very broad pattern with no hf splitting and the other a sharp one with many hf lines. In all cases, no reliable analysis was possible and no radical species could be identified.

From Figs. 1—4 we see that the spectra of $\mathbf{1}^{\cdot-}$ and $\mathbf{3}^{\cdot-}$ are hardly affected at all by solvents, the spectrum of $\mathbf{2}^{\cdot-}$ changing slightly, while that of $\mathbf{4}^{\cdot-}$, which is similar to that of $\mathbf{3}^{\cdot-}$, changes a great deal with solvent. The spectrum of $\mathbf{4}^{\cdot-}$ also changes with temperature. The hf pattern produced with potassium in DME at −50——60 °C is very similar to that in THF or MTHF, but on cooling to *ca.* −85 °C, the pattern becomes similar to that in DME with sodium ion.

ENDOR Spectra. Measurements of ENDOR spectra of $\mathbf{1}^{\cdot-}$—$\mathbf{4}^{\cdot-}$ were undertaken, but except for $\mathbf{4}^{\cdot-}$ no spectra could be obtained because of insufficient radical concentration. A typical spectrum observed for $\mathbf{4}^{\cdot-}$ is shown in Fig. 5.

Analysis of the ESR Spectra. The ESR spectra of $\mathbf{1}^{\cdot-}$ can be interpreted in terms of six sets of triplet splittings, those of $\mathbf{2}^{\cdot-}$ by four sets of triplets and those of $\mathbf{3}^{\cdot-}$ and $\mathbf{4}^{\cdot-}$ by two sets each of triplets and doublets. This indicates that the unpaired electrons in $\mathbf{1}^{\cdot-}$, $\mathbf{2}^{\cdot-}$, and $\mathbf{3}^{\cdot-}$ are distributed unequally on the two azulene rings in the molecules since the quintet splittings would be observed if the unpaired electrons are distributed equally on the two azulene rings. The observed distribution suggests that the anion radicals interact with the counter ion in the solutions. $\mathbf{4}^{\cdot-}$ is also considered to have interaction with the counter ion. The coupling constants were determined from the ESR and ENDOR (for $\mathbf{4}^{\cdot-}$) spectra and assigned to the respective protons on the basis of MO calculation (*vide infra*), referring to the hf interaction in the azulene anion radical ($\mathbf{5}^{\cdot-}$), since the relative ratio of the spin densities in the azulene should not change so much by the transannular interaction or ion pairing. No calculation was carried out for $\mathbf{3}^{\cdot-}$, but the assignment was easily made by comparison with that of $\mathbf{4}^{\cdot-}$, which gives very similar ESR spectra.

MO Calculation for the Hf Coupling Constants. The unpaired electron distribution and the hf coupling constants of the anion radicals in the ion pair form were calculated by the method reported.[9] The geometry of the anion radicals was estimated from the X-ray data for the neutral molecules,[10] the exchange integrals being assumed to be proportional to the overlap integrals, and the proportional constant for the exchange integrals between the layers one and half times the constant within the layers. Only the sets of atomic orbitals which gave larger overlap in-

tegrals than 0.02 were taken into account for the interlayer exchange integrals.

The potential energy maps for the cation placed at a distance of 0.38 nm above the nearest azulene ring were calculated for ion pairs of $\mathbf{1}^{\cdot-}$, $\mathbf{2}^{\cdot-}$, and $\mathbf{4}^{\cdot-}$. The results are shown in Fig. 6, together with a similar map for $\mathbf{5}^{\cdot-}$. Another model of $\mathbf{4}^{\cdot-}$ examined in which the cation was placed above the benzene ring gave less stable potential energies. The results show that the most stable position of cation in $\mathbf{1}^{\cdot-}$ is above the center of the five-membered ring. The position shifts toward the seven-membered ring on going from $\mathbf{1}^{\cdot-}$ to $\mathbf{2}^{\cdot-}$ and then to $\mathbf{4}^{\cdot-}$.

The spin density distribution and the hf coupling constants were calculated[11] as a function of the distance between the cation and the anion radicals by

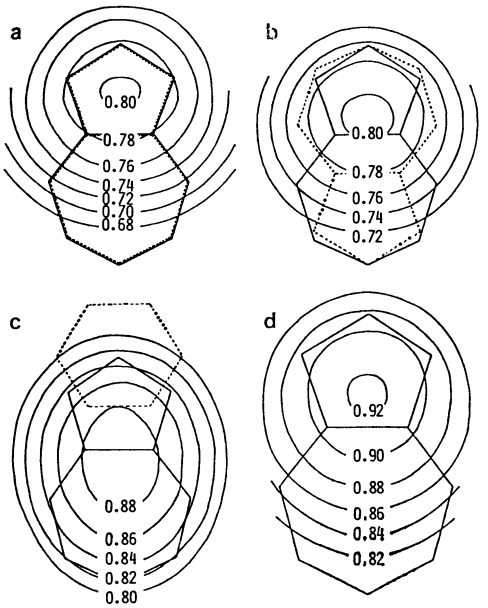

Fig. 6. Electrostatic interaction energies between a cation and anion radicals, a) $\mathbf{1}^{\cdot-}$, b) $\mathbf{2}^{\cdot-}$, c) $\mathbf{4}^{\cdot-}$, and d) $\mathbf{5}^{\cdot-}$ (in unit of β). The cation is placed at the distance of 0.38 nm from the nearest aromatic plane (drawn by solid lines).

placing the former above the potential minimum points. The potential minimum position of the cation has been shown to change slightly with distance which may cause some effect on the hf constants.[12] However, such an effect was ignored because it would not be so large as to give a wrong assignment of the hf coupling constants.

Spin Distribution in $\mathbf{1}^{\cdot-}$ and $\mathbf{2}^{\cdot-}$. The observed proton hf coupling constants could reasonably be assigned to the protons (Tables 1 and 2) of the anion radicals in the ion pair form on the basis of the above calculation. The MO calculation showed that the hf coupling constants change drastically with the distances between the cation and the anion radicals. The calculated coupling constants are for the distance 0.35 nm which give the best fit with the experimental values.

In order to observe the ESR spectra of $\mathbf{1}^{\cdot-}$ and $\mathbf{2}^{\cdot-}$ in the free anion state, generation of the anion radicals

in the presence of 18-crown-6 was examined. However, the ESR spectrum observed for $2^{\cdot-}$ was still due to the ion pair, and that attributable to $1^{\cdot-}$ was not observed under these conditions.

It is apparent from the hf coupling constants obtained that the unpaired electron largely localized on the azulene ring at the cation side. By comparison with the hf coupling constants of the azulene anion radical ($a_{1,3}^H=0.0274$ mT, $a_2^H=0.3948$ mT, $a_{4,8}^H=0.6219$ mT, $a_{5,7}^H=0.1338$ mT, $a_6^H=0.8829$ mT),[13] the unpaired electron densities on the azulene ring at the cation side were estimated to be *ca.* 87—91% for $1^{\cdot-}$ and 89—93% for $2^{\cdot-}$. The [2.2](1,4)naphthalenophane anion radical also shows a similar large polarization in the spin distribution by the formation of ion pairs.[5b] In the ion pair of the *syn* isomer($6^{\cdot-}$), the unpaired electron densities on the naphthalene ring close to a cation can be estimated as *ca.* 72—77% by comparison of its hf coupling constants with those of naphthalene anion radical.[14] The polarization in the azulenophane anion radicals is appreciably larger than that in the naphthalenophane anion radical.

The hf coupling constants of 11 position in $1^{\cdot-}$ is larger than that for the corresponding position in $2^{\cdot-}$, while that of 2 position in $1^{\cdot-}$ is smaller than that for the same position in $2^{\cdot-}$, indicating that the unpaired electron distribution in $1^{\cdot-}$ is polarized more from the head position (3 position) to the tail (7 position) than in $2^{\cdot-}$.

Spin Distribution in $3^{\cdot-}$. The observed hf coupling constants (Table 3) apparently show that the unpaired electrons are mostly distributed on one of the azulene ring. The situation did not change with the presence of 18-crown-6. As in $1^{\cdot-}$ and $2^{\cdot-}$, the observed polarization in the spin distribution can be attributed to the ion pairing of the anion radical. From a comparison with the hf coupling constants of the azulene anion radical, the unpaired electron densities on the azulene ring at the cation side are estimated to be *ca.* 94—95%; larger polarization than that in $1^{\cdot-}$ and $2^{\cdot-}$.

Spin Distribution in $4^{\cdot-}$. The ESR spectrum at −50—−60 °C of $4^{\cdot-}$ in DME with potassium ion is similar to spectra observed for $4^{\cdot-}$ in THF or MTHF, becoming similar to that observed in DME with sodium ion with lowering in temperature. This suggests that $4^{\cdot-}$ in DME with sodium ion exists mostly as a free anion; it is associated with the cation in THF and MTHF, and $4^{\cdot-}$ in DME with potassium ion is in an equilibrium between these two forms. The equilibrium shifts toward the free anion state by lowering in temperature. The hf coupling constants obtained for $4^{\cdot-}$ both in the free anion and in the ion pair are given in Table 4.

We see that the unpaired electrons are distributed mostly on the azulene ring even when the anion radical is in a free anion state. By ion pairing the spin density is polarized more from the benzene ring to the azulene ring. This indicates that the cation is associated with $4^{\cdot-}$ at the azulene ring side, in line with the result of calculation of the cation-anion interaction energies. The unpaired electron densities on the azulene ring are *ca.* 91—95% in the free anion state and *ca.* 98—99% in the ion pair form.

In contrast to the increase of spin density of the azulene ring as a whole, the density of carbon 10 is reduced by the interaction with the counter ion. Such polarization effect by ion pairing can be shown by MO calculation using the ion-pair model in which the cation is placed above the potential minimum point. The calculation using the other ion pair model does not reproduce the observed effect (Table 4).

Polarization of Unpaired Electron Distribution and the Interlayer Interaction. The unpaired electron in $1^{\cdot-}$, $2^{\cdot-}$, and $3^{\cdot-}$ is localized in one of the azulene rings. The unpaired electrons in the anion radical of [2.2]-

a) The difference between the hf coupling constants of the free anion state and the ion pair form. b) The distance between the cation and the anion radical was taken to be 0.35 nm. c) In models I, II, and III, the cation is placed above the center of the five-membered ring, the potential minimum point and the center of the seven-membered ring, respectively. d) The empirical hf coupling constants were tentatively assigned to the proton positions. The hf interactions were not observed in the ESR spectra and the coupling constants were obtained from the ENDOR specta.

paracyclophanes with the identical aromatic rings are distributed equally on both rings unless there is interaction with a counter ion.[1-7] The observed localization (polarization) might arise from such an interaction. The results indicate that polarization due to a cation increases in the order $\mathbf{1}^{\cdot-} \leq \mathbf{2}^{\cdot-} < \mathbf{3}^{\cdot-}$. Since the geometry of these molecules indicates the decreasing order $\mathbf{1}^{\cdot-} > \mathbf{2}^{\cdot-} > \mathbf{3}^{\cdot-}$ in the interlayer π-π interaction,[10] the observed order of the polarization shows that smaller interlayer π-π interaction gives larger polarization in the electron spin distribution.

The unpaired electron in $\mathbf{1}^{\cdot-}$ and $\mathbf{2}^{\cdot-}$ is polarized to a greater extent than in $\mathbf{6}^{\cdot-}$. Such a difference may be attributed to the nature of the two aromatic ring systems.

Tendency to Ion Pairing. While $\mathbf{6}^{\cdot-}$ exists as a free anion in THF with potassium ion,[5b] $\mathbf{1}^{\cdot-}$ and $\mathbf{2}^{\cdot-}$ exist in the ion pair form under the same conditions. This indicates that $\mathbf{1}^{\cdot-}$ and $\mathbf{2}^{\cdot-}$ have higher tendency of ion pairing than $\mathbf{6}^{\cdot-}$. It seems of interest to compare the ion pairing tendencies of the azulenophane anion radicals with those of other relating anion radicals. By taking into account the fact that anion radicals tend to associate more at higher temperature with the alkali metal cations in various solvents in the order $Li^+ < Na^+ < K^+$, and DME < THF < MTHF, the following order for ion pairing tendency is estimated: $\mathbf{6}^{\cdot-}$ < *anti*-[2.2](1,4)naphthalenophane$^{\cdot-}$ ($\mathbf{7}^{\cdot-}$) < $\mathbf{1}^{\cdot-}$, $\mathbf{2}^{\cdot-}$, $\mathbf{3}^{\cdot-}$, $\mathbf{4}^{\cdot-} \leq$ naphthalene$^{\cdot-}$ ($\mathbf{8}^{\cdot-}$) < $\mathbf{5}^{\cdot-}$.[15] Thus, the anion radicals corresponding azulene rings have higher tendency of ion pairing than the naphthalene counterparts. Such a pronounced tendency of ion pairing of azulenophane anion radicals may be mainly attributed to the nature of the azulene ring which tends to accumulate a high negative charge on its five-membered ring. The estimated order for the ion pairing agrees with the order in the electrostatic interaction energies calculated for the most stable ion pair structures for the anion radicals: $\mathbf{6}^{\cdot-}$(0.752) < $\mathbf{7}^{\cdot-}$(0.787) < $\mathbf{1}^{\cdot-}$(0.802) ≤ $\mathbf{2}^{\cdot-}$(0.806) < $\mathbf{4}^{\cdot-}$(0.893) < $\mathbf{8}^{\cdot-}$(0.895) < $\mathbf{5}^{\cdot-}$(0.920).[16]

Spin Distribution in $\mathbf{1}^{\cdot-}$ and $\mathbf{2}^{\cdot-}$ in the Free Anion State. The spin density distributions in $\mathbf{1}^{\cdot-}$ and $\mathbf{2}^{\cdot-}$ in the free anion state were not clarified experimentally in the present work. However, the electron spin distribution (Table 5) predicted by MO calculation shows that the unpaired electron in $\mathbf{2}^{\cdot-}$ is localized more on the seven-membered ring than in $\mathbf{1}^{\cdot-}$, in view of the finding that in ion pairs the unpaired electron in $\mathbf{2}^{\cdot-}$ is localized more on the five-membered ring than in $\mathbf{1}^{\cdot-}$.

A Sandwich Photocell Using Chlorophyll Electrodes

Fujio TAKAHASHI* and Tetuo KOMORI

Faculty of Engineering, Utsunomiya University, Utsunomiya 321

(Received August 22, 1980)

A sandwich-type photocell was made by placing an electrolyte between two electrodes. A transparent electrode, a glass plate coated with In_2O_3, was used for one electrode. A mixture of chlorophyll and 2-(*cis*-10-heptadecenyl)-6-methoxy-*p*-benzoquinone was spread onto this transparent electrode. A Pt plate covered by chlorophyll or a mixture of chlorophyll and riboflavin tetrabutyrate was used as the other electrode. The electrolyte contained flavin mononucleotide in a phosphate buffer. The potential difference between the two electrodes was 314 mV and the maximum photovoltage under illumination was 176 mV. The photocell is compact and can produce a photocurrent for more than 90 h.

Recently there have been many papers concerning the energy conversion from light to electricity by photocells using a chlorophyll-coated electrode.[1,2] We reported already that the photovoltage and the photocurrent were obtainable by light irradiation on a system of a chlorophyll-quinone electrode immersed into an electrolyte.[3] This system consisted of two chambers separated by a porcelain diaphragm; each chamber contained a different electrolyte. The composition of electrolyte in each chamber was changed when the photoelectrolytic reaction was carried out. It was thought that such a photocell had to be made of two electrodes immersed into one electrolyte.

A sandwich-type photocell in which chlorophyll was placed between two different species of metals was found to generate a photovoltage caused by the difference of contact potential barrier on the two interfaces of chlorophyll and metal.[4] If we modeled on this system, a photocell using the electrolyte could be made in a compact shape.

This paper will present the results concerning a sandwich type photocell in which the electrolyte was placed between two different chlorophyll electrodes. This should be more compact than the two-chamber-type photocell, and could be expected to keep the composition of electrolyte constant during a cycle in which the redox compound in the electrolyte was reduced at the cathode and in turn the equivalent amount of reduced compound was oxidized at the anode to recover the original form.

Experimental

Materials. Chlorophyll and 2-(*cis*-10-heptadecenyl)-6-methoxy-*p*-benzoquinone (IQ) were obtained as described in the previous paper.[5] Riboflavin tetrabutyrate (RTB) was made by Wakamoto Pharmaceutical Co. Glutathione (abbreviated GSH or GSSG as the reduced or the oxidized form), flavin mononucleotide (FMN) and the other chemicals were of reagent grade or the best commercially available.

Photocell. A glass plate coated by In_2O_3 containing 5% SnO_2, or a silver or platinum plate (2 cm × 4 cm each) was used as the electrode. One electrode was prepared by covering a layer of a mixture of chlorophyll and IQ (molar ratio 1:5). The layer contained 0.03 μmol/cm² of chlorophyll. The other electrode was covered by chlorophyll alone or by a mixture of chlorophyll and RTB. A sheet of parafilm (American Can Co.; 2 cm × 2 cm × 0.013 cm) hollowed out in one part (1 cm × 1 cm) was placed on the electrode and the hollow was filled by the electrolyte. Then another electrode was placed on top of it to set up a sandwich-type photocell.

Measurements. The potential was measured by a Kikusui Denshi volt-ammeter model 116 connected to a recorder. A projector lamp (100 V, 150 W) was used for the source of light. The light of shorter wavelength than 460 nm was cut off by a color filter, V-Y46, and the heat wave band was cut off by a water filter.

Results and Discussion

Various Combination of Electrodes. It was observed that the photovoltage was generated by photocells made up by various combinations of two electrodes under illumination. The electrolyte used was composed of 0.1 M KCl solution containing 1 mM GSH and 1/2 mM GSSG. Glutathione was used because it gave the highest photovoltage among several redox compounds in the electrolyte as reported in the previous paper.[5] The results are summarized in Table 1.

In the case that two In_2O_3 electrodes were used for the photocell, the potential of the chlorophyll electrode was found to shift to a positive state with respect to the chlorophyll-IQ electrode when the light was turned on. This is in accord with the result in the previous paper.[5] The In_2O_3 electrode acted as an anode in the system of In_2O_3 and Ag electrodes, but as a cathode in the system of In_2O_3 and Pt electrodes. On the system of Ag|Chl|electrolyte|Chl, IQ|In_2O_3, and the system of In_2O_3|Chl|electrolyte|Chl,IQ|Pt, the potential differences between two electrodes became lower after the light was turned on, because the photopotential of chlorophyll electrode against chlorophyll-IQ electrode was always positive.

Table 1. The potentials of the photocells of

$$M_1|Chl\left|\begin{matrix}1\text{ mM GSH}\\0.5\text{ mM GSSG}\\0.1\text{ M KCl}\end{matrix}\right|Chl,\ IQ\ (1:5)|M_2$$

M_1	M_2	Potential (mV *vs.* M_2)		
		Dark (d)	Light (l)	Photovoltage (l) − (d)
In_2O_3	In_2O_3	15	84	69
In_2O_3	Ag	134	225	91
Ag	In_2O_3	−172	−149	23
In_2O_3	Pt	−98	−88	10
Pt	In_2O_3	175	228	53

3×10^4 lx, 20—24 °C.

The highest photovoltage was obtained with the system of In_2O_3|Chl|electrolyte|Chl,IQ|Ag. However this system was unstable. The photovoltage reduced with the lapse of time. Therefore the system of Pt|Chl|electrolyte|Chl,IQ|In_2O_3 was chosen for this work. This system produced a 0.05 $\mu A/cm^2$ photocurrent. It was thought that same other redox compound should be used instead of glutathione in order to obtain higher photovoltage and higher photocurrent.

The Photocells with FMN in Electrolyte. It is known that FMN can photoexcite and oxidize NADH, EDTA, or catecholamine easily.[6,7] Therefore, FMN rather than GSSG in the electrolyte might take the electron away from the chlorophyll electrode under illumination. The photoresponse-time curves of the photocell using FMN in the electrolyte were obtained and are shown in Fig. 1. Chlorophyll was coated on the In_2O_3 electrode. Another In_2O_3 electrode without coating was used as a counter electrode. The electrolyte contained 0.1 M KCl and 5 mM FMN in all cases.

The potential-time curve at the top in Fig. 1 shows that the potential shifted to a positive state at the beginning of light irradiation. Then the potential turned over into a negative state. It was assumed that photoexcited FMN might decompose to produce some substance whose isoalloxazine ring was reduced to form a hydroquinone type.[8] If so, the potential of the system containing EDTA, which reduced FMN under illumination,[6] should shift to a negative state more rapidly. It seems that the second curve in Fig. 1 sustains the above assumption. In order to keep the potential positive, the decomposition of FMN had to be avoided. Tryptophan is known to be effective for the suppression of FMN decomposition.[6] As seen at the bottom in Fig. 1, the potential of the system containing an equimolar mixture of FMN and tryptophan remained in the positive state during light irradiation.

A plate of Ag, Pt, or In_2O_3 covered by chlorophyll was used for one electrode. The other one was lined with a mixture of chlorophyll and IQ on In_2O_3 electrode. The electrolyte contained FMN and tryptophan. The results are summarized in Table 2. The potential difference between Ag and In_2O_3 electrodes was 40 mV under illumination. This value was the smallest. The potential difference of the Pt–In_2O_3 system was twice as great as that of the In_2O_3–In_2O_3 system.

It was found that the magnitude of the photovoltage was influenced by the pH of electrolyte. The pH-photovoltage curves obtained from the system of Pt|Chl|electrolyte|Chl,IQ|In_2O_3 are shown in Fig. 2. The maximum photovoltage appeared around pH 7 for the FMN-tryptophan electrolyte. The glutathione result is also shown in Fig. 2.

For the promotion of electron transfer at the surface of the chlorophyll electrode, RTB was mixed with chlorophyll on a Pt electrode. RTB was expected to relay the electron from chlorophyll on the electrode to FMN in the electrolyte. The photovoltages on the system of Pt|Chl,RTB|FMN,Trp|Chl,IQ|In_2O_3 are shown in Fig. 3. The results show 176 mV as the maximum photovoltage and 314 mV as the potential difference between the two electrodes.

At the optimum condition of the above photocell, the current shown in Fig. 4 was produced. The current began to reduce gradually with the lapse of time and finally reached an almost constant value.

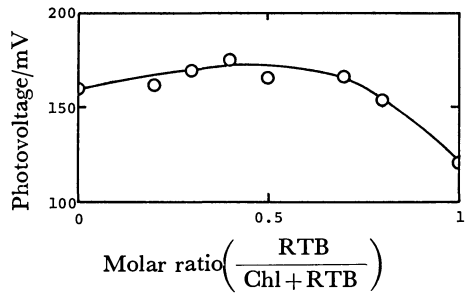

Fig. 3. The influence of molar ratio to the photovoltage.
Pt|Chl, RTB|5 mM FMN, 5 mM Trp (pH 6.7)|Chl, IQ|In_2O_3. Chl: 0.03 μmol/cm², Chl:IQ=1:5, 25—31 °C, 3×10^4 lx.

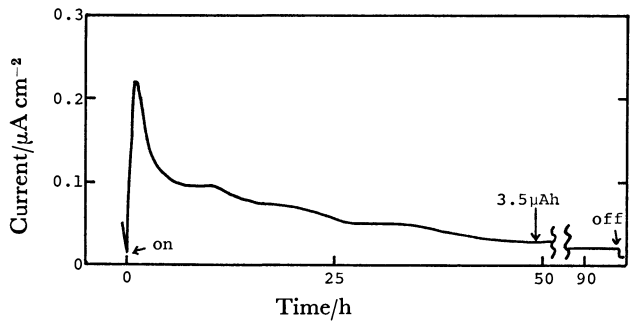

Fig. 4. The photocurrent.
Pt|Chl, RTB|5 mM FMN, 5 mM Trp (pH 6.7)|Chl, IQ|In_2O_3. Chl: 0.03 μmol/cm², Chl:RTB=1:1, Chl:IQ=1:5, 31—32 °C, 3×10^4 lx.

A steady state was found to exist after the current which had been passed reached the theoretical amount for the reduction of FMN in the electrolyte (3.5 μA h).

It is plausible from Fig. 1 that FMN in the electrolyte is reduced at the chlorophyll-RTB electrode and the photopotential shifts to a negative state, and thus the photocurrent becomes smaller. The reduced FMN, which is a strong reducing agent,[9] is susceptible to being oxidized to reproduce FMN at the chlorophyll-IQ electrode. Therefore it is very possible that a steady state was obtained during the photoelectrochemical reaction.

As a conclusion, the electron transfer process of the photocell may be the following:

Heterogeneous Reactions of Nitrogen Monoxide on Titanium Dioxide Photocatalysts in Solutions

Hiroshi Yoneyama,* Hisashi Shiota, and Hideo Tamura
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565
(Received August 28, 1980)

Heterogeneous reactions of nitrogen monoxide on illuminated TiO_2 catalysts in 1 mol dm^{-3} $HClO_4$ were studied by electrochemical analysis. Nitrogen monoxide was reduced to ammonia and hydrazine. The main reaction was found to be a chemical reaction of hydroxylamine as a reaction intermediate with nitrogen monoxide to give molecular nitrogen. Nitrate was detected as an oxidation product formed by the counterpart reaction of the reduction of nitrogen monoxide.

Heterogeneous reactions on semiconductor photocatalysts in solutions are of interest in view of solar energy utilization. Fundamental mechanisms of the photocatalysts have been elucidated,[1–6] and several reaction systems in line with the established view have recently been reported.[7–14]

According to Guth and Schrauzer,[15] the reduction of molecular nitrogen to ammonia and hydrazine takes place on illuminated moist TiO_2 powders with simultaneous evolution of oxygen. However, the yield was poor. Causes for this might be: (1) the reaction terminates in the gas phase, when adsorbed active water is consumed, and (2) the reaction requires large positive Gibbs energy changes.

$$1/2N_2 + 3/2H_2O \longrightarrow NH_3 + 3/4O_2 \quad (1)$$
$$\Delta G^0_{298} = 382.5 \text{ kJ/mol}$$
$$N_2 + 2H_2O \longrightarrow N_2H_4 + O_2 \quad (2)$$
$$\Delta G^0_{298} = 625.7 \text{ kJ/mol}$$

In view of thermodynamics, the reduction of nitrogen monoxide to ammonia and hydrazine should take place more easily.

$$NO + 3/2H_2O \longrightarrow NH_3 + 5/2O_2 \quad (3)$$
$$\Delta G^0_{298} = 292.6 \text{ kJ/mol}$$
$$2NO + 2H_2O \longrightarrow N_2H_4 + 2O_2 \quad (4)$$
$$\Delta G^0_{298} = 448.1 \text{ kJ/mol}$$

The present study was undertaken to investigate reactions of NO on illuminated TiO_2 photocatalysts in solution.

Experimental

A tank NO gas (99.9% purity) was passed through 5 mol dm^{-3} KOH and then through 5 mol dm^{-3} H_2SO_4 to remove N_2O and NO_2.

TiO_2 powder of the rutile modification (Fuji Titanium Co.) was used in a commercially available form and a partially reduced one. The powder was soaked in a dilute HCl solution overnight, washed with twice distilled water several times, and then dried in a drying oven. Partial reduction was carried out under a stream of H_2 at 700 °C for 30 min. Platinization of the powder was carried out by means of photodeposition.[16] The powder was suspended in a HCl solution containing H_2PtCl_6. Illumination with a 500 W xenon lamp was carried out under N_2 atmosphere until the yellow color of the solution completely faded. The amount of platinum deposited on the powder surface was 21.8 mg/g of TiO_2, its specific surface area being 14.2 m^2/g as determined by the BET method. The amount of deposited Pt was comparable to that required for a monolayer coverage of the powder when the surface exposed to solution is the (001) face.

A TiO_2 single crystal, reduced in a stream of H_2 at 600 °C for 30 min, was used as an electrode as well as a photocatalyst. The (001) face was chosen as the electrode surface. Platinization of the electrode surface was carried out by means of electrodeposition.[17] The amount of deposited platinum was estimated by measuring the charge passed during the course of deposition, and converted into equivalent monolayers.[17]

Polarization measurements were carried out in the usual beaker type cell or in a H type cell with a potentiostat (Hokuto Denko, model HA 101). Experiments of the heterogeneous reaction were carried out in a beaker cell of *ca.* 10 ml capacity equipped with a gas inlet in the side wall near the bottom and with a gas outlet in the top of the cell. Illumination was made with focusing light from a 500 W xenon lamp. The powder catalyst was agitated with a magnetic stirrer during the course of illumination, NO gas being continuously bubbled into the solution.

Quantitative analysis of NH_3, N_2H_4, NH_2OH, NO_3^-, and NO_2^- was carried out by colorimetry. Solutions in the heterogeneous reaction vessel were transferred to a volumetric flask and diluted to 25 ml. In the case of powder photocatalysts, the solution was separated from the catalyst by filtration, and then diluted to the same volume. The diluted solutions were used as the sample solutions. The amount of NH_3 was determined by the method of Kruse and Mellon.[18] 10 ml of the sample solution was subjected to distillation in a micro-Kjeldahl apparatus. The ammonia in the distillate was collected in 0.01 mol dm^{-3} H_2SO_4, and determined. N_2H_4 was determined in 10 ml of the sample solution with *p*-dimethylamminobenzaldehyde.[19] For the determination of NH_2OH,[20] 5 ml of the sample solution was mixed with 1 ml of 10% NaOH, and then with 0.25 ml ethyl acetate. After the color of the ester had faded the solution was acidified with 25% HNO_3 making the volume of solution 25 ml. 1 ml of a 8% $FeCl_3$ solution was then added and the absorbance was measured at 505 nm. NO_3^- was determined by the nitration of sodium salicylate in the presence of H_2SO_4.[21] In order to eliminate interference from NO_2^-, 1 ml of the sample solution was diluted to 10 ml, and 1 ml of a sulfanilamide solution (1 g of sulfanilamide/100 ml of 1% HCl) was added to it. After standing for 15 min, 1 ml of a *N*-(naphthyl)ethylenediamine solution (0.1 g of *N*-(naphthyl)ethylenediamine/100 ml of water) was added, and the absorbance was measured at 530 nm after shaking for 20 min.[22]

N_2 originated from NO was determined by gas chromatography with the use of a helium carrier and a 70 cm length

molecular sieve 5 A column. In order to eliminate any error introduced by N_2 in air, experiments for collection of gases were carried out under Ar atmosphere. Since the chromatograms of N_2 and NO_2 overlapped at room temperature, the column was cooled down to −76 °C by dipping in a mixture of dry ice and acetone, the sample gas being then injected. After the chromatogram of Ar appeared, the coolant was removed to warm up the column to room temperature. During this time, N_2, NO, and NO_2 appeared successively in the chromatograms.[23,24]

Results and Discussion

Electrochemical Reactions of NO on TiO_2 Electrodes. According to the results obtained by Dutta and Landoldt on Pt electrodes in 4 mol dm^{-3} H_2SO_4,[25] the electrochemical reduction of NO occurs with two waves. The first wave starting at 0.6 V *vs.* SCE was postulated to be due to the formation of an intermediate having an oxidation state identical with that of N_2O such as $H_2N_2O_2$ or NO^-, and the second one to further reduction of the intermediate to NH_3OH^+. If the intermediate is assumed to be $H_2N_2O_2$, then the reactions are represented by

$$2NO + 2H^+ + 2e^- = H_2N_2O_2, \quad (5)$$

$$E^0 = 0.71 \text{ V } vs. \text{ SHE}^{26}$$

$$H_2N_2O_2 + 6H^+ + 4e^- = 2NH_3OH^+. \quad (6)$$

$$E^0 = 0.39 \text{ V } vs. \text{ SHE}^{23}$$

Figure 1 shows cyclic voltammograms for the reduction of NO in 1 mol dm^{-3} $HClO_4$ at a Pt electrode. Two waves appear by cathodic polarization up to 0.1 V *vs.* SCE. The formation of NH_3OH^+ is conceivable at potentials equal to or more negative than 0.1 V *vs.* SCE. The overall reaction for the reduction of NO is then represented by

$$NO + 4H^+ + 3e^- = NH_3OH^+. \quad (7)$$

Steady state current-potential curves obtained at the TiO_2 single crystal electrode are shown in Fig. 2, and those at a platinized electrode in Fig. 3. Measurements were carried out under both NO and N_2 atmosphere. The cathodic curves were obtained in the dark, while anodic ones under illumination. The cathodic current is enhanced by introduction of NO into the electrolyte, suggesting that the cathodic reaction is mainly due to the reduction of NO when it is present in the solution. The enhancement of the cathodic current is great when the electrode is platinized. On the other hand, a slight suppression of the anodic photocurrent is observed by introduction of NO. This seems to be due to the absorption of near-ultraviolet light in the electrolyte, causing a decrease in light quanta incident on the electrode. As shown in Fig. 4, NO-saturated 1 mol dm^{-3} $HClO_4$ shows relatively high absorption in wavelengths 340—400 nm which are effective for excitation of TiO_2.

In order to study the anodic photocurrents, constant

potential electrolysis at 0.5 V *vs.* SCE was carried out in 1 mol dm^{-3} $HClO_4$ in the presence and absence of NO, and the volume of gases evolved from the anodic compartment of an H type cell was compared with those predicted theoretically from the following equation on the basis of the consumed electrolytic charge.

$$2H_2O + 4p^+ \longrightarrow O_2 + 4H^+, \quad (8)$$

where p^+ denotes a photo-generated positive hole. The results are given in Table 1. When NO was dissolved in the electrolyte, gas evolution was appreciably suppressed, resulting in a low current efficiency for the oxygen evolution reaction. Not only water but also NO should participate in the photoanodic processes.

Reduction of NO gives rise to hydroxylamine.[25,26] However, by constant potential electrolysis of TiO_2 electrodes in the dark in NO-saturated solutions under various polarization conditions, ammonia and hydrazine, but not hydroxylamine, were produced regardless of whether or not the platinization of the electrode was made. The results are given in Table 2, in which the results obtained at Pt electrodes are also given. No formation of hydroxylamine was formed even by use of Pt electrode. If we assume that both ammonia and hydrazine are produced by the electrochemical reduction of hydroxylamine, then the reactions would be represented by Eqs. 9 and 10. We see from the

$$NH_3OH^+ + 2H^+ + 2e^- = NH_4^+ + H_2O, \quad (9)$$
$$E^0 = 1.35 \text{ V } vs. \text{ SHE}^{28)}$$

$$2NH_3OH^+ + H^+ + 2e^- = N_2H_5^+ + 2H_2O. \quad (10)$$
$$E^0 = 1.41 \text{ V } vs. \text{ SHE}^{28)}$$

results (Table 2) the following. (1) The ammonia production increases with a cathodic shift of the electrode potential. At the extreme of the shift of 0.5 V *vs.* SCE, however, hydrogen evolution seems to occur competitively, as judged from the onset potential of the cathodic current in alkaline solutions.[17] Even at 0.25 V *vs.* SCE, the same would be true for the platinized electrode, though the competition would occur to a much smaller extent. Adsorbed hydrogen on the electrode surface is essential for the production of ammonia and hydrazine in appreciable amounts. Theoretically, the reactions given by Eqs. 9 and 10 should occur easily, since the standard electrode potentials are positive. However, the actual rates of the reactions are so low[27] that a large overpotential is needed for the reactions to occur with appreciable rates. (2) The platinized TiO_2 is the most active for the conversion of NO to ammonia and hydrazine. Physical and chemical nature of the deposited platinum on TiO_2 has not so far been characterized. A high capability of sorbing hydrogen might be related to the observed high activity, since electrodeposited platinum has a high activity for the hydrogen electrode reaction.

Judging from electrochemical analysis on the reduction of NO on Pt electrodes,[25,26] there is no doubt as to the formation of hydroxylamine. However, this is not the case in electrolyte solutions. The current efficiency for the production of ammonia and hydrazine, determined on the basis of Eqs. 7, 9, and 10,

Table 1. Current efficiency for the evolution of oxygen at illuminated TiO_2 electrode in 1 mol dm^{-3} $HClO_4$ with and without dissolved NO

Atmosphere	Volume of gas / ml	Consumed charge / C	Current efficiency / %
N_2	0.82	14.1	100
NO	0.52	15.0	60.1

Table 2. Electrolytic reduction of NO at TiO_2 electrodes in the dark in 1 mol dm^{-3} $HClO_4$

Run No.	Electrode	Potential *vs.* SCE / V	Consumed charge / C	Produced substance			Total current[a] efficiency / %
				NH_3 / μmol	N_2H_4 / μmol	N_2 / μmol	
1	Pt	0.00	50.0	0.93	n.d.[b]	n.d.	0.90
2	Pt	−0.50	12.5	2.1	0.66	n.d.	12.2
3	TiO_2	−0.25	12.4	0.60	0.12	n.d.	3.08
4	TiO_2	−0.50	12.5	2.8	0.11	n.d.	11.5
5	$Pt(\theta=100)/TiO_2$[c]	−0.25	12.7	0.76	1.87	n.d.	14.3
6	$Pt(\theta=100)/TiO_2$	−0.50	12.5	5.13	1.87	n.d.	31.4
7	TiO_2	−0.20	12.7	0.55	0.08	34.1	80.3

a) Calculated on the basis of the determined substance. b) Not determined. c) TiO_2 electrode covered with deposited Pt the amount of which roughly corresponds to 100 monolayers coverage.

was found to be low, suggesting that a large fraction of the produced hydroxylamine is consumed in another reaction.

Gas bubbles stick to the electrode surface during the course of electrolysis even at potentials at which no hydrogen evolution is conceivable. The formation of N_2 was postulated as a principal reduction reaction. For the sake of confirmation determination of N_2 originating from NO was attempted. Electrolysis was carried out in a sealed cell with atmosphere of NO, the cell being kept in Ar during the course of electrolysis. After electrolysis at -0.2 V *vs.* SCE for 30 h, where the evolution of hydrogen is thermodynamically impossible, N_2 in the sealed cell was determined. As expected, N_2 was produced by electrolysis (Table 2). The reaction schemes for the formation of N_2 can be given by either one or both of the following equations.

$$NH_3OH^+ + 2NO = N_2 + HNO_2 + H_3O^+, \quad (11)$$
$$\Delta G^0 = -407.6 \text{ kJ/mol}$$
$$4/3NH_3OH^+ + 2/3NO + 2/3H^+ = N_2 + 2H_3O^+. \quad (12)$$
$$\Delta G^0 = -214.6 \text{ kJ/mol}$$

If the N_2 production is due to the reduction given by Eqs. 7 and 11, then the total current efficiency for the formation of ammonia, hydrazine and N_2 amounts to 80.3%. If Eqs. 7 and 12 are used, the value is 106%.

Table 3 shows the decrease in the amount of NH_3OH^+ by bubbling NO into the solution. The results show that even ammonia and hydrazine, when produced, are consumed to evolve N_2, causing a decrease in current efficiency for the formation of these substances. NO_2^- is formed by bubbling NO into 1 mol dm^{-3} $HClO_4$, possibly by the equation,

$$2NO + H_2O = NOH + HNO_2. \quad (13)$$

Heterogeneous Reactions on TiO_2 Single Crystal Photocatalysts. In heterogeneous reactions on n-type semiconductor photocatalysts, reduction process and photosensitized oxidation process proceed mainly on the non-illuminated and illuminated surfaces, respectively.[28,29] Electrochemical prediction of occurring heterogeneous reactions can be made by means of the current-potential curves of semiconductor photocatalysts in the photocatalytic reaction systems,[3,4] (Figs. 2 and 3). The current-potential curve due to the reduction of NO intersects with photoanodic curves,

Table 3. Decrease of NH_2OH, NH_3 and N_2H_4 by chemical reactions with NO

Substance[a]	Amount[b] Initial (μmol)	Final (μmol)	Decrease (μmol)	Produced NO_2^- (μmol)
NH_3	27.6	13.4	13.6	70.7
N_2H_4	112.0	0.7	111.3	59.9
NH_2OH	150.0	65.3	84.7	83.9
